Similarly, Taylor series expansion around any point (x, u) is given as below:

$$f(x^*,u^*) = f(x,u) + \left.\frac{\partial f}{\partial x}\right|_{x,u} (x^* - x) + \frac{1}{2!}\left.\frac{\partial f^2}{\partial^2 x}\right|_{x,u} (x^* - x)^2 \tag{7}$$

Equation 6 and equation 7 are the Taylor series expansions at two points (x^* and x), given by Taylor series extension to second order. Rearranging equation 7, we get;

$$f(x,u) = f(x^*,u^*) + \left.\frac{\partial f}{\partial x}\right|_{x,u} (x^* - x) + \frac{1}{2!}\left.\frac{\partial f^2}{\partial^2 x}\right|_{x,u} (x^* - x)^2 \tag{8}$$

Adding equation 6 and equation 8 (while higher order terms are canceled, assuming $\frac{1}{2!}\left.\frac{\partial f^2}{\partial^2 x}\right|_{x,u} = \frac{1}{2!}\left.\frac{\partial f^2}{\partial^2 x}\right|_{x^*,u^*}$), we get;

$$f(x,u) = f(x^*,u^*) + \frac{1}{2}\left[\left.\frac{\partial f}{\partial x}\right|_{x^*,u^*} + \left.\frac{\partial f}{\partial x}\right|_{x,u}\right](x - x^*) \tag{9}$$

Equation 9 is the approximation of $f(x, u)$ using higher order terms. There are two Jacobian evaluations involved in this approach, an approximation using knowledge at steady-state (x^*) and approximation using current state (x) knowledge. The block structure representation of this approximation is shown in figure 7.

3. REDUCED ORDER HAMMERSTEIN STRUCTURE

Approximation block structure shown in figure 7 is full state model. Since it is a prerequisite for the approximation block structure, to be valid within certain operating domain.

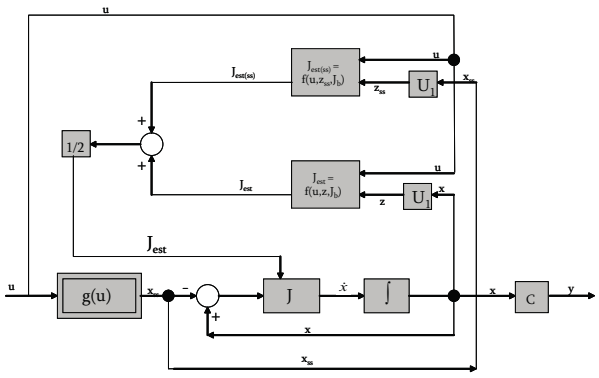

Fig. 7. Approximation model (I/S Hammerstein); Higher order approximation)

3.1 Operating domain/Input Design

Within defined domain, inputs are designed with the purpose to define an input trajectory that travels through complete domain. The process is known as '*input design*'. As the name indicates, it is the process of designing inputs based on constraints on input or output (depending upon a process). In summary, the operating domain is a region, where the approximated model is supposed to be valid, once identified (based on data from the physical process) and input design is the procedure, which defines the boundaries of this operating domain.

The steady-state and dynamic state data is obtained by taking snapshots over the operating domain. Similarly, Jacobian data is collected by taking the snapshots of Jacobians over the operating domain. Jacobian basis J_b are computed by SVD analysis of Jacobian data.

The I/S Hammerstein block structure gives scope to get the reduced order structure by;

i. Reduction in state size.
ii. Reduction in Jacobian size.

i. Reduction in state size.
The singular value analysis on data of states indicates that there is a low dimensional space, such that low order state (z) can represent the whole operating domain. The state reduction is performed by transformation matrix. The transformation matrix U_1 (to obtain reduced state 'z') is obtained by SVD analysis of data over the operating domain. Reduced states are back-transformed to full state by back transformation matrix $\hat{U}_1$. The block structure of the reduced approximation model is shown in figure 8. The Jacobian reduction takes place online (in the block $U_1 * J * U_1^T$).

ii. Reduction in Jacobian size.
The scheme in figure 7 shows that Jacobian estimation takes place using Jacobian basis J_b, state z and input u information. The estimated Jacobian J_{est} is full order Jacobian. There is possibility to obtain reduced size Jacobian, by using reduced order Jacobian basis ($J_{b_{red}}$) and reduced state (z). With reduced basis $J_{b_{red}}$ and reduced states z, estimated Jacobians are also reduced sized and the block structure is a reduced order I/S

Hammersteins approximation model. The block structure is shown in figure 9.

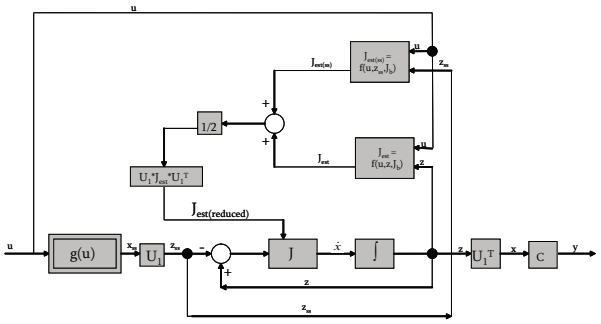

Fig. 8. Reduced order approximation model (I/S Hammerstein); Higher order approximation

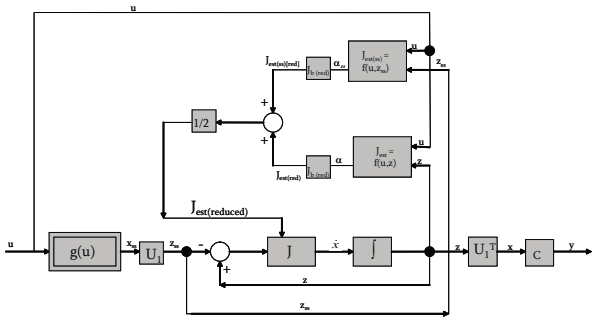

Fig. 9. Approximation block structure with reduced Jacobian and state size

4. APPLICATION TO HIGH PURITY DISTILLATION COLUMN

The approximation block structure and reduced block structure model has been applied to the benchmark. A benchmark is high purity distillation column, and its properties will be discussed in subsequent sections. But before the methodology is implemented on benchmark, a prerequisite for the methodology is to define the operating domain, within which the approximation/reduced model is valid. Input design, discussed in section 3.1 is designed for distillation column; the operating domain has been finalized by constraint in output purity. A set of input variables (reflux (L) and vapour boilup (V)) is chosen, for which output variables are observed. The product purity for output variables sets the boundary for operating domain.

High purity distillation column

A high purity distillation column is used as test case, on which the approximated and reduced model estimation is applied. The distillation column has following properties; The column has 72 trays, a total condenser and partial reboiler. It is a nonlinear system. The thermodynamics of the column are governed by constant relative volatility. The relative volatility for this specific system is 1.33. Pressure is assumed to be constant. Vapour holdups are considered negligible and liquid holdups are considered

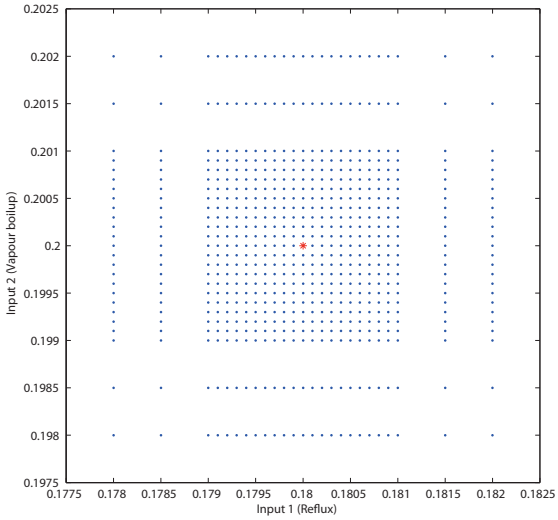

Fig. 10. Figure of operating domain '*input design*'

to be constant. Moreover, the column is assumed to be working with equimolal flow (which results in eliminating energy balances). The distillation benchmark model has been explained in detail by Lévine and Rouchon (1991).

The benchmark is modelled in gPROMS while the approximation model is modelled in MATLAB and SIMULINK. The approximation technique is implemented on the benchmark. The operating domain is finalized (input design) shown in figure 10. The static part consists of lookup table which interpolates the steady-states. The steady-states are fed into the dynamic part. The difference between current state and steady-state is fed to Jacobian block, which is estimated based on state and steady-state data. This represents the linear block as bilinear system.

Two types of changes

There are two types of input signals tested for the validation of approximated (and reduced) model.

a) 'Separation index' (SI) is change in distillation, when both the input variables (reflux rate (L) and vapour boilup (V)) are given *same* steps at the same time, or the rate of flow of distillate D and bottom B does not change.
b) 'Effective Cut Point' (ECP) is change in distillation, when one input variable (reflux rate (L) or vapour boilup (V)) is kept constant and step change is given to the other input variable. This change is known to be highly non-linear for high purity distillation column (in process industry).

Figure 11 show the step in both inputs at the same time (separation index). The approximation model structure (in full state) and reduced order model structure approximate the behavior very well. The mismatch between the approximations and original is cause by offset form lookup table (NL block of approximated model).

Figure 12 show the result comparison of original, full order approximated model and reduced order model, when step in vapour boilup (V) input (effective cut point) is

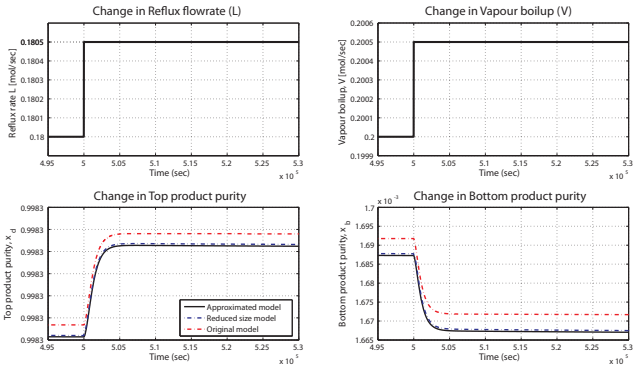

Fig. 11. Results for comparison of SI change between original, approximation '*full*' and '*reduced*' model

applied. The approximation model structure (in full state) and reduced order structure approximates the behavior satisfactorily. There is a very small mismatch in dynamics between the approximation model and original. The offset is acceptable (and sufficiently accurate) for this application.

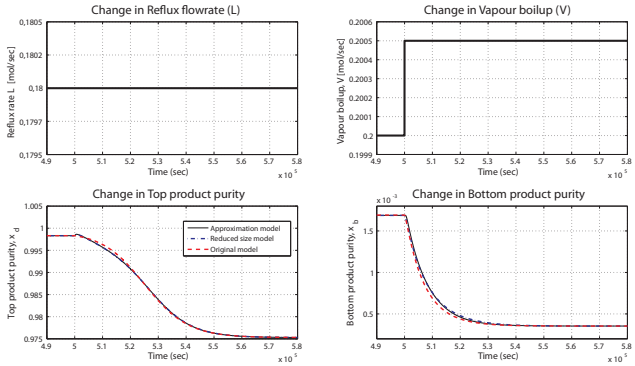

Fig. 12. Results for comparison of ECP change between original approximation '*full*' and '*reduced*' model

5. CONCLUSIONS & FUTURE WORK

In this paper, it is shown that Input-State Hammerstein structure can be derived from a Taylor expansion. The approximation model's accuracy can be improved by including higher order terms. The approximation results were shown for a high purity distillation benchmark are acceptable for the kind of application. Order reduction of 70% is possible using the methodology with satisfactory results (high accuracy).

Work on the following tasks is done presently or is to be considered in future:

i) The computational load reduction for the benchmark example (high purity distillation column) is to be investigated. The computational load and simulation time reduction has to be compared with original NL model.

ii) It is planned to extend the methodology to industrial case. The industrial models make use of dynamic link library (dll) files (as foreign process) to compute different task (such as thermodynamic properties). Such foreign processes buildup overhead costs,resulting in increased computational load. It is anticipated, that transformation of large DAE model to ODE structure will reduce the computational effort (and simulation time), since the algebraic computations are vanished in ODE structure, replaced by NL mapping.

Abstract: The dynamic behaviour of a coal slurry gasifier in an Integrated Gasification Combined Cycle is modelled by means of mass, energy and momentum conservation equations as well as reaction kinetics descriptions. The main phenomena taken into consideration are (i) slurry drying and devolatilisation, (ii) char and volatile gas combustion, char gasification and water-gas shift reaction, and (iii) syngas cooling. The proposed 0-dimensional description is sufficient to capture process dynamics and it is a useful starting point for control design and verification. In particular, basic control strategies are discussed. Both model and control implementation is carried out in the Matlab-Simulink environment. Simulation results are shown to support model reliability and control effectiveness.

Keywords: Process modelling, Process automation, Process control, Process simulators, Power generation, Coal gasification.

1. INTRODUCTION

As it is well known, nowadays the scenario in electric energy production is characterised by a constant increase in demand, a decrease in fossil fuel reserves, more and more demanding restrictions on pollutant levels. Feasible solutions can be increasing efficiency and reducing pollutant emissions in thermoelectric power plants, and contributing to the development of the so called "green energy". Coal can play a major role, especially because of the important amount of its proven reserves worldwide; a main challenge for research is then to develop high-efficiency coal-based energy production systems with near zero emissions. In this paper, reference is made to a 70 MWe coal-fed Integrated Gasification Combined Cycle (IGCC) pilot plant (Fantini et al., 2007), allowing flexible production of electric energy and hydrogen. For the design, work is in progress to build up a simulator of the whole process, in order to obtain reliable predictions of its dynamic behaviour in different operating conditions and to study the operating manoeuvres. Dynamical models of the shift reactor and of the Pressure Swing Adsorption (PSA) unit have already been studied ((Bittanti et al., 2008), (Canevese et al., 2007)). Here, we focus on the gasifier, working out a first-principle model useful for control design.

In Section 2 of this paper, the gasification process is analysed, and its main phases are represented by a dynamical model, based on a thermo-fluid-dynamical and a kinetic-chemical description; such model has been developed in full detail starting from the basic conservation equations and the constitutive equations (including the kinetic equation of char gasification); here, of course, we will present only a partial outline of this model. Section 3 deals with control problems. Section 4 reports some simulation results highlighting control effectiveness. Finally, Section 5 reports some conclusions and hints to future work.

2. PROCESS ANALYSIS

The gasifier under study is an entrained-flow gasifier working at about 65 bar and 1650-1700 K. It is formed essentially by two coaxial cylinders: in the inner one, the gasification process occurs, while the outer one is employed for a first syngas cooling. As illustrated in Fig. 1, the reactor is fed with slurry (pulverized coal mixed with water which can be handled like a liquid fuel) and highly pure oxygen and it produces a gaseous mixture whose main components are CO, CO_2, H_2, N_2, H_2O, and pollutants (COS, H_2S, and dusts). We sketch the overall process of gasification and cooling as composed of the following phases (Smoot and Smith, 1985):

- *drying and devolatilisation*:

slurry can be described as coal powder where each particle is coated with a water film; when it is pumped into the inner cylinder, the high temperature that it meets makes water evaporate, thus yielding dry char, and then makes volatile gases (such as N_2, H_2S, H_2O and several kinds of hydrocarbons, among which CH_4) leave char;

- *oxidation and gasification*:

oxygen burns both the volatile gases and the char, according to the reactions

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O \quad (volatile\ combustion), \tag{1}$$

$$C + \left(1/\phi\right)O_2 \rightarrow 2\left(1 - 1/\phi\right)CO + \left(2/\phi - 1\right)CO_2, \quad 1 \le \phi \le 2 \quad (char\ combustion) \tag{2}$$

(the mechanism factor ϕ indicating whether CO or CO_2 is transported from the particle surface is calculated according to (Wen and Dutta, 1979), (van der Looij, 1988)). The related temperature increase sustains the drying and volatile emission process and the endothermic reactions

$$C + H_2O \rightarrow CO + H_2 \quad (gasification)\,, \tag{3}$$

$$C + CO_2 \rightarrow 2CO \quad (char - CO_2\ reduction)\,, \tag{4}$$

$$CO + H_2O \rightleftarrows CO_2 + H_2 \quad (water - gas\ shift)\,; \tag{5}$$

- *cooling*:

the thus obtained hot syngas (its temperature is around 1760 K) is sent to the bottom of the reactor, where contact with relatively cold liquid water causes a thermal shock which decreases the gas temperature abruptly and stops all reactions still going on; besides, unburned char residuals and char ashes solidify, fall down and are extracted as slag. After bubbling into water, the syngas is pushed by pressure difference (65 bar Vs 62 bar in the considered case) to the outer cylinder, where it is further cooled by a counter-current water spray. Spray temperature and flow rate can be used to control the outlet fluid mixture temperature and humidity. ■

Actually, the first two phases occur in the same region (gasification region). A detailed 3-D description of the phenomena taking place here is suggested, e.g., in (Chen, et al., 2000). Simpler models can be worked out by assuming that both temperature and pressure are uniform in the whole region (0-D assumption). This assumption, motivated by the intense recirculation of gases and adopted also in (Schoen, 1993) for a different type of gasifier, is adopted herein. The proposed model is able to capture the process fundamental dynamics with a low complexity degree, thus ensuring both clear physical insight and short simulation times, in view of the study of control strategies.

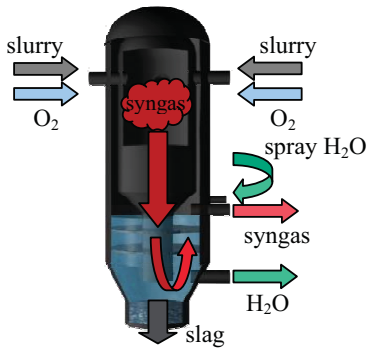

Fig. 1. The GE-Texaco gasifier: schematic view.

The following subsections report the conservation equations employed to model each phase and a reaction kinetic description for the second phase. Table 1 collects the main symbols employed.

Table 1. Nomenclature

Symbol	Description	Unit
c	Specific heat	kJ/(kg·K)
e	Relative energy	kJ/kg
f	Mass fraction	-
h	Relative enthalpy	kJ/kg
$j_k^{(r)}$	Component k stoichiometric coefficient in reaction r=1,..,5	-
p	Pressure	bar
w	Mass flow rate	kg/s
$\tilde{w}$	Molar flow rate	kmol/s
x	Molar fraction	-
A	Area	m^2
L	Length	m
M	Mass	kg
PM_k	Component k molecular weight	kg/kmol
Q	Thermal power	W
S_{ch}	Char active surface	m^2
T	Temperature	K
V	Volume	m^3
β	Mass exchange coefficient	kg/(N·s)
γ	Convective energy exchange coefficient	W/(K·m^2)
ρ	Density	kg/m^3
Ω	Equivalent perimeter	m
Subscripts		
c	Cooling region	
ch	Char	
d/u	Volume under/above the cooling liquid surface	
ev/vol	Resulting from evaporation/devolatilisation	
g/l	Gas/liquid phase	
$g\text{-}l$	Exchange between gas and liquid phases	
in/out	At the inlet/outlet of the region under study	
int/ext	Internal/external chamber	
sat	Saturation	
sh	Shift reaction	
sl	Slurry	
$surf$	Char surface	

2.1 Drying and Devolatilisation

The coal slurry injected into the gasifier forms a jet of length L_{ev} where the water evaporates heated by the hot gases. Then, after water evaporation, the volatile release takes place, due to further heating of the mass of dried coal.

The mass conservation equations for the liquid water and the dry char are respectively

$$\rho_{H_2O}\overline{A}_{H_2O}\dot{L}_{ev} = w_{sl}f_{H_2O,in} - w_{ev}\,, \tag{6}$$

$$\dot{M}_{dry} \equiv \frac{d(\rho_{dry}\overline{A}_{dry}L_{ev})}{dt} = w_{sl}(1 - f_{H_2O,in}) + \\ - M_{dry}u_j/L_{ev} + \rho_{dry}\overline{A}_{dry}\dot{L}_{ev}, \tag{7}$$

where $\overline{A}_{H_2O}$ is the evaporation average equivalent area for water and $\overline{A}_{dry}$ is the equivalent area for char,

$$w_{ev} = \beta_{g-l} L_{ev} \Omega_{ev} (p_{sat}(T_{ev}) - p_{H_2O,g}), \quad (8)$$

$L_{ev}\Omega_{ev}$ is the average evaporation surface and u_j is the particle average velocity in the drying region.

As to energy conservation, a unique average temperature T_{ev} can be adopted for the overall particle (water and char), so

$$\begin{aligned}(\rho_{H_2O}\overline{A}_{H_2O}c_{H_2O} + \rho_{dry}\overline{A}_{dry}c_{dry})[(T_{ev} - T_{sl})\dot{L}_{ev} + \\ +L_{ev}\dot{T}_{ev}] = Q_{ev} - w_{ev}\cdot(h_{g,sat}(T_{ev}) - h_{H_2O}(T_{sl})),\end{aligned} \quad (9)$$

$$Q_{ev} = \gamma_{g-l} L_{ev} \Omega_{ev} \cdot (T_g - T_{ev}). \quad (10)$$

Volatile emission is assumed to occur almost instantaneously after drying, since its dynamics are of the order of few tens of ms ((Thambimuthu and Whaley, 1987), (Kobayashi et al., 1977)); therefore, such dynamics, together with the related heating process, are neglected here. Evaporation is very fast as well, with dynamics of the order of a second at most (Thambimuthu and Whaley, 1987), so it is neglected in the simulations reported in Section 4.

2.2 Oxidation and Gasification

The mass conservation equation for the *k*-th gaseous component in the gasification volume can be written as

$$\begin{aligned}\dot{M}_k = w_{k,in} - w_{g,out} f_{k,out} + \sum_{r=2,3,4} \tilde{w}_{ch}^{(r)} PM_k j_k^{(r)} + \\ +\tilde{w}_{sh} PM_k j_k^{(5)} + \tilde{w}_{CH_4,vol} PM_k j_k^{(1)},\end{aligned} \quad (11)$$

where the component inlet flow rate is

$$w_{k,in} = \begin{cases} w_{ev}, & \text{for } k = H_2O \\ w_{k,vol}, & \text{for } k = CO_2, H_2S \\ 0, & \text{for } k = CO, H_2 \\ w_{N_2,vol} + w_{air} f_{N_2,air}, & \text{for } k = N_2 \end{cases} \quad (12)$$

and $w_{g,out}\, f_{k,out}$ its outlet flow rate. O_2 can be assumed to be completely consumed, and with extremely fast dynamics, by the combustion reactions (1) and (2) (Cotone, 2003); therefore, it is not necessary to write a mass conservation equation for it. For char, which is in the solid phase, we write

$$\dot{M}_{ch} = w_{dry} - \eta_g \frac{w_{g,out} M_{ch}}{\rho_g V_g} + \sum_{r=2,3,4} \tilde{w}_{ch}^{(r)} PM_{ch} j_{ch}^{(r)}, \quad (13)$$

where η_g <<1 is a shape factor (De Marco, et al., 1991) which accounts for the reaction spatial development and which can be identified from experimental results,

$$\tilde{w}_{ch}^{(r)} = \frac{K_r M_{ch} M_r}{V_{\text{int}}}, r = 3,4, M_3 = M_{H_2O}, M_4 = M_{CO_2}, \quad (14)$$

$$\tilde{w}_{ch}^{(2)} = \phi \tilde{w}_{O_2}. \quad (15)$$

$\tilde{w}_{O_2}$ is the difference between the O_2 inlet molar flow rate and the O_2 molar flow rate consumed by reaction (1). We remark that (14) is taken from the unreacted-core-shrinking model described in (Wen and Chaung, 1979); K_r accounts both for reaction kinetics, by means of an Arrhenius-type term, and for component diffusion between the gaseous bulk and the char reacting surface. The reversible shift reaction (5) kinetics is assumed to be at equilibrium on the char surface, so that the gaseous components surface diffusion is the limiting phenomenon, except for H_2, whose diffusion coefficient can be assumed as ideally infinite.

The energy conservation equations, for the gaseous mixture in the gasification volume and for solid char, read as

$$M_g c_g \dot{T}_g = Q_{g,in} - \tilde{w}_{sh}\Delta H_{sh} + w_{vol}\Delta H_{vol} + Q_{ch-g} - Q_{ev}, \quad (16)$$

$$M_{ch} c_{ch} \dot{T}_{ch} = -Q_{ch,in} + Q^{(2)} - Q^{(3)} - Q^{(4)} - Q_{ch-g}, \quad (17)$$

where

$$\begin{aligned}Q_{g,in} = w_{ev}\cdot(h_{H_2O}(T_{ev}) - h_g(T_g)) + w_{O_2}\cdot(h_{O_2}(T_{ev}) + \\ -h_g(T_g)) + w_{ev}\cdot(h_{ev}(T_{ev}) - h_g(T_g)) + w_{dry,out,vol}\cdot \\ \cdot(e_{ch}(T_{ev}) - h_g(T_g)),\end{aligned} \quad (18)$$

$$Q_{ch-g} = \gamma_{ch-g} S_{ch} \cdot (T_{ch} - T_g), \quad (19)$$

$$\begin{aligned}Q_{ch,in} = w_{dry,out,vol}(e_{ch}(T_{ch}) - e_{ch}(T_{ev})) + w_{O_2}\cdot \\ \cdot(e_{ch}(T_{ch}) - h_{O_2}(T_{ev})) + w_{ev}(e_{ch}(T_{ch}) - h_{H_2O}(T_{ev})) + \\ +w_{vol}\cdot(e_{ch}(T_{ch}) - h_{vol}(T_{ev})),\end{aligned} \quad (20)$$

$$Q^{(r)} = \tilde{w}_{ch}^{(r)} PM_{ch} \Delta H^{(r)}, r = 2,3,4 \quad (21)$$

and $\Delta H^{(2)}$ is a function of ϕ, since CO and CO_2 have different heating values.

Finally, as to pressure, the perfect gas law yields

$$p_g = \frac{R T_g}{V_g} \sum_k \frac{M_k}{PM_k}, k = H_2O, H_2, CO, CO_2, N_2, H_2S. \quad (22)$$

2.3 Cooling

The cooling volume is composed of two regions, separated by the liquid water surface: a lower "pool" region, where gas bubbles into water, and an upper spray region, where water droplets further cool humid gas leaving the pool region. Mass and energy conservation equations will be written separately for the gas mixture and for liquid water in each region.

As to the overall gas and to its water part under the surface, first of all, one can write mass conservation as

$$\dot{M}_{gd} = w_b - w_{bout} - w_{g-l}, \quad (23)$$

$$\dot{M}_{H_2O,gd} = w_b f_{H_2O,in} - w_{bout} f_{H_2O,out} - w_{g-l}, \quad (24)$$

where w_b is the gasification outlet flow rate, w_{bout} the flow rate leaving the liquid surface and w_{g-l} the exchanged (usually condensating, anyway) water flow rate inside the gas phase.

Adopting a steady-state model for the gas phase under the free liquid surface, from (23) and (24) we can write

$$w_{bout} = w_{g,out}\,(1 - f_{H_2O,in})\big/(1 - f_{H_2O,out}) \quad (25)$$

$$w_{g-l} = w_b\,(f_{H_2O,out} - f_{H_2O,in})\big/(1 - f_{H_2O,out}), \quad (26)$$

and, adopting an equilibrium model,

$$f_{H_2O,out} = \frac{PM_{H_2O} p_{sat}(T_{ld})}{\overline{PM_{gd}}\,[p_c - p_{sat}(T_{ld})] + PM_{H_2O} p_{sat}(T_{ld})}, \quad (27)$$

where $\overline{PM_{gd}}$ is the average molecular weight of the "dry" gas, i.e. without considering its water contents.

As to energy conservation, we have

$$M_g c_g \dot{T}_{gd} = Q_{g,ex} - Q_{gl} - w_b(h(p_g, T_{in}, f_{gd}) + -h(p_c, T_{gd,out}, f_{gd,out})), \quad (28)$$

$$Q_{g,ex} = w_{g-l}(h_{g,sat}(T_{ld}) - h_g(T_{gd})), \quad (29)$$

$$Q_{gl} = \gamma_{g-l} S_{g-l}(T_{gd} - T_{ld}). \quad (30)$$

In (28), the last product term in the right-hand member describes the heat lost to decrease the inlet gas temperature; p_c is the upper cooling region pressure.

As to the liquid water mass M_{ld} under the surface, one has

$$\dot{M}_{ld} = w_{H_2O\_down} + w_{g-l} - w_{ld,out}, \quad (31)$$

where the three terms on the right-hand member are due to water falling down from the cooling upper region into the pool because of gravity, to the condensating water and to the outlet water respectively. In particular,

$$w_{H_2O\_down} = M_{w\_spr} / \tau_{down}, \quad (32)$$

where the average delay factor τ_{down} (Lydersen, 1983) models the residence time (typically of the order of a few seconds) of spray water (whose mass is M_{w_spr}) in the spray region. $w_{ld,out}$ is a control variable which can be employed for level regulation, by means of a suitable valve.

For the liquid water temperature T_{ld} under the surface, one can write

$$M_l c_l \dot{T}_{ld} = -Q_{H_2O\_down} + Q_{l,ex} + Q_{gl}, \quad (33)$$

$$Q_{H_2O\_down} = w_{H_2O\_down}(h_{H_2O}(T_{lu}) - h_{H_2O}(T_{ld})), \quad (34)$$

$$Q_{l,ex} = w_{g-l}(h_{g,sat}(T_{ld}) - h_l(T_{ld})). \quad (35)$$

For gas mass conservation above the free surface, one has

$$\dot{M}_{gu} = w_{bout} - w_{gas,mix} - w_{cnd}, \quad (36)$$

where $w_{gas,mix}$ is the overall gasifier outlet syngas flow rate, which is assumed, for simplicity, to be regulated by a critical valve, and

$$w_{cnd} = \frac{6 M_{lu} \beta_{g-l,u}}{\rho_{lu} d_{drop}} \cdot \left(\frac{M_{steam} R T_{gu}}{P M_{H_2O} V_{spr}} - p_{sat}\left(\frac{T_{lu} + T_{w\_spr}}{2} \right) \right) \quad (37)$$

is due to humid gas condensation. T_{w_spr} is the spray inlet temperature, d_{drop} the average spray drop diameter (water drops are assumed as spherical), V_{spr} the spray region volume. M_{steam} can be derived from the conservation equation

$$\dot{M}_{steam} = w_{bout} f_{H_2O,out} - w_{cnd} - w_{gas,mix} M_{steam} / M_{gu}. \quad (38)$$

For gas energy conservation above the free surface, one has

$$M_g c_g \dot{T}_{gu} = -Q_{g,sc} - Q_{exch} + w_{bout}(h(T_{gd}, p_c) - h(T_{gu}, p_c)), \quad (39)$$

$$Q_{g,sc} = w_{cnd}(H_{g,sat}(T_{lu}) - h(T_{gu})), \quad (40)$$

$$Q_{exch} = \gamma_{g-l,u} S_{g-l,u}(T_{gu} - T_{lu}). \quad (41)$$

For the liquid water mass M_{lu} and temperature T_{lu} above the surface, respectively, one can write

$$\dot{M}_{lu} = -w_{H_2O,down} + w_{cnd} + w_{spr}, \quad (42)$$

$$M_l c_l \dot{T}_{lu} = Q_{l,sc} + Q_{exch} + w_{spr}(h(T_{w\_spr}) - h(T_{lu})), \quad (43)$$

where w_{spr} is the inlet spray water flow rate and

$$Q_{l,sc} = w_{cnd}(H_{g,sat}(T_{lu}) - h_l(T_{lu})). \quad (44)$$

Again, pressure in the cooling chamber can be derived from the ideal gas law:

$$p_c = R T_{gu} M_{gu} / (V_{spr} \overline{PM_{gu}}). \quad (45)$$

2.4 Model Verification

As for the coal composition and steady-state nominal conditions, we have made reference to the data published in (Cotone, 2003). The main model parameters, especially for the correlations, have been drawn from the literature as well. In particular, the K_r's in (14) have been taken from (Wen and Chaung, 1979). This way, our model has been fully specified. For its verification, the molar fractions supplied by the model have been compared with the molar fractions in the literature. In Table 2 such comparison is carried out by referring to the situation occurring after the thermal shock at T=1077 K.

Table 2. Comparison between literature data (Cotone, 2003) and simulation results at nominal steady state

	Reference data	Simulation results	Relative Error
x_{CO}	34%	38%	12%
x_{H_2O}	14.9%	13%	13%
x_{CO_2}	16%	15.9%	1%
x_{H_2}	33%	30.6%	7%
x_{N_2}	1.8%	2%	11%

3. CONTROL ISSUES FOR THE GASIFICATION PLANT

In this work, attention is focused on problems related to fulfilling the electrical network's needs, such as supplying the requested power variations, in normal operation (load following) or in emergency conditions, taking part in primary frequency control, or even contributing to secondary frequency control. In particular, the problem of coordinate control is dealt with here: the gasifier load and the global plant operating conditions are mastered so as to satisfy power requests from the electrical network, while preserving plant integrity and correct operation, of course. A simplified plant scheme is shown in Fig. 2. It is composed of three main parts: (i) the gasification island; (ii) a lower pressure system for the syngas treatment, together with thermal energy recovery; (iii) a conventional gas turbine, with its own fuel feed system

controlled by valve v_3. A valve, v_2 (or an expansor for power recovery), connects part (i) and part (ii). The symbol θ is adopted for actuator command signals.

We now focus on the problem of supplying fast and relatively large power variations, in order to fulfil the network's requests. For this purpose, the control scheme of Fig. 3 can be considered. Fast power variations are obtained by acting on valve v_3, regulating the turbine inlet flow rate (as in conventional power plants). By means of two feed-forward actions (FFW in Fig. 3), such variation results in corresponding changes in command signals θ_1 and θ_2. Signal θ_1 controls the slurry flow rate as well as the oxygen flow rate. θ_2 determines the flow rate of the outlet syngas. The two feed-forward actions have to be designed so as to keep constant pressure p_1, at the gasifier outlet, pressure p_2, at the turbine inlet, and temperature T_g inside the gasifier. To this purpose, in Fig. 3 a decentralized control scheme is proposed, where control signals θ_1 and θ_2 are adopted for the regulation of p_1 and p_2 (dashed rectangle of Fig. 3). Alternatively, one can resort to a centralized controller, here omitted for reasons of conciseness. As for T_g, the control action is manually operated and indicated in Fig. 3 by a dash-dotted rectangle.

Note that, for the overall control system, variations of θ_3 can be seen as main (measurable) disturbances.

We now conclude with some observations about the regulation problems.

Variable θ_1 acts simultaneously on the slurry and O_2 flow rates. Here the main objective is to keep constant the ratio between the two flow rates. However, these cannot be varied simultaneously, in order to avoid excessive over- or under-elongations in the gasification temperature. More precisely, when there is a load variation, the corresponding variation of the O_2 flow rate must take place with some delay after the variation of the slurry flow rate. The reason is that the oxygen reacts extremely fast, so that the temperature variation occurs abruptly. Such delay is represented in Fig. 3 as well (lag).

Let us finally consider the 2x2 MIMO system where θ_1 and θ_2 are the input signals, and p_1 and p_2 the output signals.

Conventional power plant operating experience would suggest regulating independently p_1 by the gasifier load and p_2 by valve v_2, as shown at the top of Fig. 3. However, the variables under study are rather interacting with each other: for instance, increasing the gasifier inlet load implies an increase in pressure p_1, which makes valve v_2 flow rate increase and therefore pressure p_2 increase as well. The degree of coupling is *quantitatively* captured by the relative gain matrix RGA, whose elements are not far from 0.5. Therefore, a centralized control solution, carried out by a forward decoupling technique, has been also analysed. The open-loop SISO transfer functions employed for controllers tuning have been identified from the system step responses around the chosen steady-state nominal point (see Section 2.4). Summing up, both centralized and decentralized controllers have been designed and simulated. Simulation results are reported in the subsequent section.

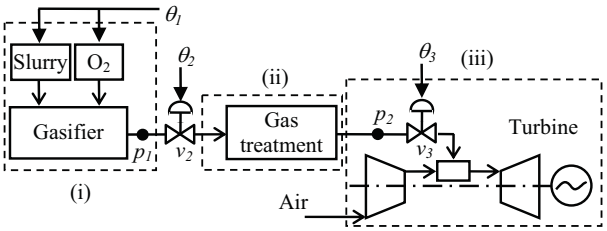

Fig. 2. The controlled simplified plant scheme.

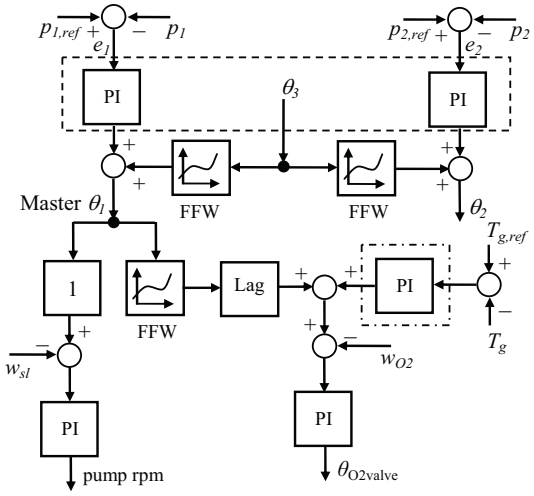

Fig. 3. A controller structure for the plant.

4. SIMULATION RESULTS

The simplified plant depicted in Fig. 2 has been simulated in the Matlab-Simulink environment, with the gasifier model, in particular, implemented by means of an S-function written in the C++ language. Simulations have been carried out both in open loop and in closed loop by considering both the centralized and the decentralized schemes. Integration has been executed in the continuous-time domain, by resorting to the standard Matlab algorithms.

Some of the results of a dynamical simulation with the centralized controller are now reported. Starting from the steady-state nominal conditions, a positive 10% step on the turbine valve position is given, at time t = 1500 s; this simulates a variation of power request from the network, so that the turbogas control system requires more inlet fuel flow rate. The top of Fig. 4 shows the responses of pressure p_1 and temperature T_g: as expected, their steady-state values are unaffected by the disturbance, and elongations around such values are very small. In Fig. 4 - bottom the control variables slurry and oxygen flow rates are depicted: they both increase in a rather slow manner, so as to preserve the integrity of the gasifier itself and of the other devices (with their dynamic operating constraints). Finally, it turns out that also the opening of valve v_2 exhibits a smooth behaviour.

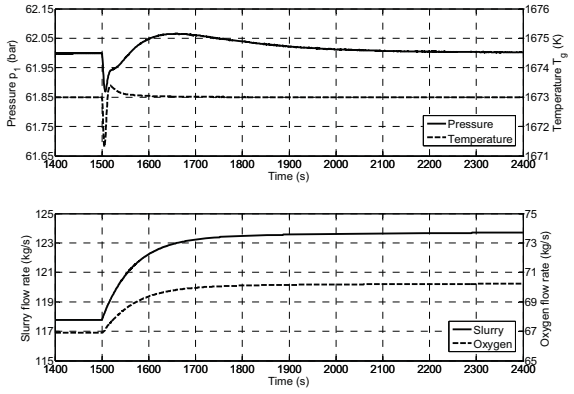

Fig. 4. Simulation results with centralized control.

5. CONCLUSIONS

A control-oriented first-principle dynamical model for a coal slurry gasifier has been proposed. Model parameters have been identified from literature data. Classical control schemes have been proposed for the 2x2 problem of controlling gasifier pressure and turbine inlet pressure by the gasifier inlet slurry and O_2 flow rates and by the gasifier outlet syngas flow rate. Simulations have shown satisfactory performance for disturbance rejection. Also the set-point tracking (not presented in this paper, for brevity) leads to good results. Future activities include model validation in transient conditions and integration of this model and models of other plant devices (see Section 1) into an overall IGCC plant simulator. Then, control strategies will be studied concerning the interaction between the gasifier and the other devices, in normal operating conditions and during startups/shutdowns; such strategies will be implemented both by standard techniques, based on SISO PID controllers, and by more involved MIMO techniques.

ACKNOWLEDGEMENTS

We are grateful to P. D'Adamo and P. De Francesco, formerly students at Politecnico di Milano, for their collaboration in the phase of parameter tuning.

This work has been financed by the Research Fund for the Italian Electrical system under the Contract Agreement between CESI RICERCA and the Ministry of Economic Development - General Directorate for Energy and Mining Resources stipulated on June 21, 2007 in compliance with the Decree n. 73 of June 18, 2007. Research has also been supported by the Italian National Research Project "New Techniques of Identification and Adaptive Control for Industrial Systems" and partially by CNR-IEIIT.

Abstract: In this work, a dynamic model of a catalytic fixed bed reactor (FBR) based on partial differential equations (PDE) is introduced and used for the identification of reaction mechanisms which take place during the oxidation of sulfur dioxide over a vanadium pentoxid catalyst. The measured data is collected from a pilot plant, which uses commercial sized catalyst particles. In order to reduce the experimental effort, a developed framework based on the methods of nonlinear optimal experimental design is applied using a steady state FBR model. The systematic procedure is improved using a dynamic reactor model. This makes the time dependent measurement data valuable for the identification procedure.

Keywords: Catalytic fixed bed reactor (FBR), reaction mechanisms, partial differential equations (PDE), parameter identification, optimal experimental design.

1. INTRODUCTION

Catalytic gas phase reactions have a high relevance in chemical engineering. The majority of chemical processes will not be profitable and in some cases not even viable without the usage of catalysts. An important application represents the utilization of FBR for waste gas treatment processes. In this work, the oxidation of sulfur dioxide to sulfur trioxide is considered, which is converted with water to sulphuric acid. It should be noted that huge effort is made in the development of new catalysts with a higher activity. Commonly, new catalysts are designed and tested at micro scale, i.e. a pulverized catalyst. However, the catalyst used in industrial plants are much larger and the previously identified mechanisms and kinetic parameters can not be transferred without further investigations in a scale up procedure w.r.t. the reactor layout. Thus, measurements with commercial catalyst particles are inevitable implying a high experimental effort. The sized particles require a larger reactor diameter, and thus, high gas flow rates are necessary in order to hold the operation conditions close to the industrial scale reactor. Moreover, corresponding requirements for process automation and safety engineering have to be met. Consequently, in order to reduce the experimental effort while reaching a desired model quality, methods of nonlinear optimal experimental design can be applied. In addition, due to the fact that a good deal of data enhances the mechanism and parameter identification, the proposed framework can still be improved when using a model, which describes the pilot plant dynamic behavior. In this work, a homogeneous and a two-phase FBR model are presented. The latter can be used for dynamic simulations. Both are compared to each other based on a set of measured data taken from an identification campaign. The experiments were performed in a pilot plant (Fig. 1) using a commercially available vanadium pentoxid catalyst.

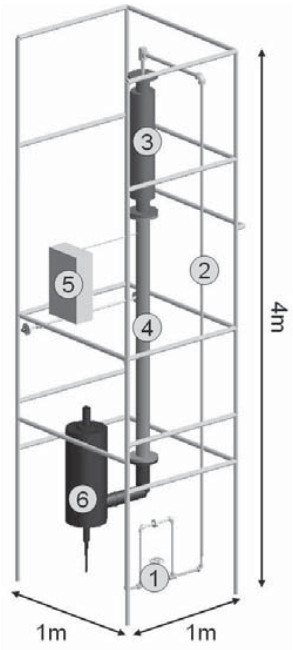

Fig. 1. Pilot plant set-up: (1) Quality measurement, (2) Heating section, (3) Reactor, (4) Tube bundle cooler, (5) Quality measurement, (6) Bubble column.

2. PILOT PLANT DESCRIPTION

The core of the pilot plant is the tubular reactor which has a diameter of $D_R = 0.1$ m and a length of $L_R = 1$ m.

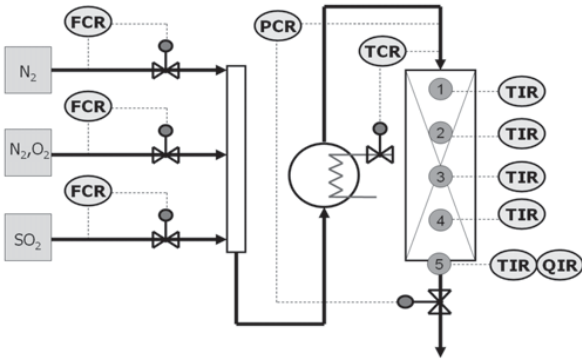

Fig. 2. Control structure: (FCR) Flow control and measurement, (TCR) Temperature control and measurement, (PCR) Pressure control and measurement, (TIR) Temperature measurement, (QIR) Quality measurement.

The diameter results from the size of the catalyst particle, which is about $D_P = 0.005$ m for the examined catalyst. It represents the minimum diameter required in order to get a uniform particle distribution. The reactor consists of five beds of catalyst packing, where each is $H_B = 0.1$ m high. The additional length is used to reduce in and outlet effects. The reactor is operated nearly adiabatic using an electric heated isolation. The majority of the available space is occupied by the secondary units such as the heating, cooling and gas scrubbing. The last two steps are combined in a bubble column. Fig. 1 gives an idea of the pilot plant set-up. The pilot plant is automated using ABB Freelance. Beside the implemented safety engineering procedures, the reactor inlet variables are controlled using the structure given in Fig. 2. The gas flow rate $\dot{V}$ can be varied between 200 and 400 norm liter per minute at inlet temperatures up to $T_{in} = 500$°C.

3. REACTOR MODELS

Two reactor models are presented, which describe the FBR behavior, namely the *homogeneous model* and the *two-phase model*. The chemical reaction is modeled with six different reaction mechanisms for which several steps of parameter identification and model discrimination are performed in order to find the best suitable mechanism. Besides the kinetic parameters in the reaction rate equations, the reactor models contain several parameters. Some of them can be obtained from the particles geometry e.g. the packing porosity ϵ, the relative particle diameter D_P, the specific surface area a, and the catalyst density ρ_C, other parameters are derived from property functions such as the component heat capacities $c_{P,i}$ and $c_{V,i}$, the heat of reaction Δh_R, and the thermodynamic equilibrium constant, K_P. The heat loss can be determined from experimental runs without reactions and is then calculated with the estimated heat transfer coefficient, k_W, and the measured wall temperature, T_W. Four components are considered in the model with the indices as given in Tab. 1.

Table 1. Component indices

Index	1	2	3	4
Component	**SO_2**	**O_2**	**SO_3**	**N_2**

3.1 Homogeneous Model

The model equations composed of mass balances, (1), energy balance, (2), and momentum balance, (3), imply the assumption of a plug flow profile in the reactor and an instant heat and mass transfer between the gas and the solid phase. This means that the temperature of the catalyst particle is the same as the gas phase bulk temperature. Due to this issue the model can not be used for the description of the dynamic behavior, since the heat capacities of gas and solid differ a lot. A detailed description and derivation of the homogeneous model can be found in Arellano-Garcia et al. (2007).

$$\frac{dF_i}{dz} = \nu_i \dot{r} \cdot \rho_C (1-\epsilon) \frac{\pi}{4} D_R^2 \tag{1}$$

$$\frac{dT}{dz} = \frac{-\dot{r} \Delta h_R(T) \rho_C (1-\epsilon) \frac{\pi}{4} D_R^2 - k_W \pi \; D_R \, (T - T_W)}{\sum F_i c_{P,i}} \tag{2}$$

$$\frac{dP}{dz} = -\frac{\sum F_i M_i}{\rho \frac{\pi}{4} D_R^2 D_P} \left(\frac{1-\epsilon}{\epsilon^3}\right) \cdot \left[\frac{150(1-\epsilon)\eta}{D_P} + 1.75 \frac{\sum F_i M_i}{\frac{\pi}{4} D_R^2}\right] \tag{3}$$

In the model equations, F_i denotes the component flow rates, ν_i the stoichiometric coefficient, and M_i, the molar mass. T stands for the gas and the catalyst temperature, P for the gas phase pressure. The viscosity η is calculated assuming an ideal mixing.

Following the simulation results based on this model, the pressure drop can be neglected for the given reactor set-up and is not considered anymore in the two-phase model.

3.2 Two-Phase Model

The key idea of developing a two-phase model is to perform dynamic simulations of the reactor behavior in order to include time variant measurement data in the parameter estimation procedure. Due to the varieties in the resulting time constants in the energy balances, which are mainly influenced by the heat capacity and density in its corresponding phase, a split modeling of the gas and solid phase becomes inevitable. The resulting equation system comprises mass and energy balances for the two phases,(4)- (7), which are coupled via mass and heat transfer correlations,(8)-(10). Instead of the component flow rates (see (1)), the concentrations in the gas phase $c_{G,i}$ and the solid phase $c_{C,i}$ are used here as state variables.

$$\frac{dc_{G,i}}{dt} = D_{ax_i} \frac{\partial^2 c_{G,i}}{\partial z^2} - \frac{\dot{V}}{\epsilon \frac{\pi}{4} D_R^2} \frac{\partial c_{G,i}}{\partial z} - a \frac{1-\epsilon}{\epsilon} \beta (c_{G,i} - c_{C,i}) \tag{4}$$

$$\frac{dc_{C,i}}{dt} = \nu_i \dot{r} \rho_k + a \, \beta (c_{G,i} - c_{C,i}) \tag{5}$$

$$\sum_{i=1}^{4} c_{G,i} c_{V_i} \frac{dT_G}{dt} = a \frac{1-\epsilon}{\epsilon} \alpha (T_C - T_G) - \frac{\dot{V}}{\epsilon \frac{\pi}{4} D_R^2} \cdot \sum_{i=1}^{4} c_{G,i} c_{P_i} \frac{\partial T_G}{\partial z} - k_W \frac{4}{\epsilon \; D_R} (T_G - T_W) \tag{6}$$

$$\frac{dT_C}{dt} = \frac{a\alpha}{\rho_C c_{P,C}} (T_G - T_C) - \frac{\Delta h_R \dot{r}}{c_{P,C}} \tag{7}$$

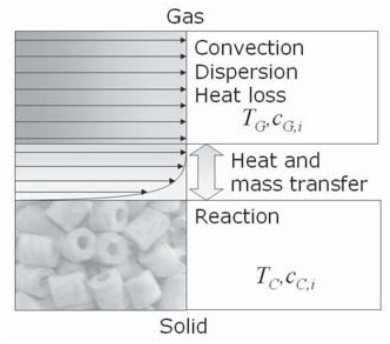

Fig. 3. Control volume of the two-phase model.

The control volume and the considered state variables of the two phases are shown in Fig. 3. The transfer coefficients (α, β, D_{ax}) are calculated with dimensionless numbers (Nusselt number Nu, Sherwood number Sh, axial Peclet number Pe_{ax}) and correlations taken from literature, see e.g. Fogler (2006). Here, $D_{ab,i}$ stands for the diffusion coefficient of the component i in nitrogen and $\bar{\lambda}$ for the mixtures heat conductivity.

$$D_{ax} = \frac{\dot{V} D_P}{Pe_{ax} \epsilon \frac{\pi}{4} D_R^2} \tag{8}$$

$$\beta_i = \frac{Sh_{\epsilon,i}\, D_{ab_i}}{D_P} \tag{9}$$

$$\alpha = \frac{\bar{\lambda} Nu}{D_P} \tag{10}$$

On the one hand, a dynamic simulation becomes possible with the inclusion of the solid phase, but on the other hand, new unknown or not well-known parameters are introduced. Three parameters are used in the transport correlations, one for each equation. In addition, two parameters depend on the catalyst particle properties, namely, the catalyst heat capacity, $c_{P,C}$, and the specific surface area, a. These additional parameters are to be determined from the measurement data, but they are strong correlated with the reaction rate, and thus, with the kinetic parameters of the reaction mechanisms. This problem can be overcome by running experiments without a reaction, i.e. with pure nitrogen or air. By this means the parameter in the heat transfer correlation, and the catalyst properties can be determined independently.

3.3 Reaction Mechanisms

In the open literature, plenty of different reaction mechanisms have been published for the oxidation of sulfur dioxide over vanadium pentoxid, we refer to Mezaki and Kadlec (1972) for an overview. In this work, the five of the most promising rate laws are selected. Additionally, a generic power law mechanism is also considered. All the rate equations describe the reaction stated in equation (11). They are functions of the components partial pressures, P_i, and the temperature, T, which affects the calculation of the velocity constant k, and the equilibrium constants K_P, and K.

$$\mathbf{SO_2} + \frac{\mathbf{1}}{\mathbf{2}}\,\mathbf{O_2} \rightleftharpoons \mathbf{SO_3} \tag{11}$$

Power Law: In the rate equation for the power law mechanism (12), the component exponents a, b, and c are treated as model parameters and have to be determined from the measurements. The temperature dependent velocity constant k is calculated with equation (13), in which the kinetic parameters p_1 and p_2 have to be identified.

Rate 1:

$$\dot{r} = k \left(P_{SO_2}^a P_{O_2}^b P_{SO_3}^c - \frac{P_{SO_2}^{(a-2)} P_{O_2}^{(b-1)} P_{SO_3}^{(c+2)}}{K_P} \right) \tag{12}$$

$$k = exp\left(\frac{p_1}{T} + 0.5\ ln(T) + p_2\right) \tag{13}$$

Mechanistic Rate Equations: The rate equations (14) to (18) can be derived assuming a liquid metal phase on the catalyst particle formed by vanadium, in which the supplied oxygen is dissolved. This is a widely accepted assumption for the oxidation over vanadium pentoxid. The differences in the reaction rates result from different mechanisms of the catalyst activation with oxygen.

Rate 2:

$$\dot{r} = \frac{k K P_{SO_2} P_{O_2}^{1/2}}{\left[P_{SO_3}^{1/2} + (K P_{SO_2})^{1/2}\right]^2} \left(1 - \frac{P_{SO_3}}{K_P P_{SO_2} P_{O_2}^{1/2}}\right) \tag{14}$$

Rate 3:

$$\dot{r} = \frac{k K P_{SO_2} P_{O_2}}{\left[P_{SO_3}^{1/2} + (K P_{SO_2})^{1/2}\right]^2} \left(1 - \frac{P_{SO_3}^2}{K_P^2 P_{SO_2}^2 P_{O_2}}\right) \tag{15}$$

Rate 4:

$$\dot{r} = \frac{k K P_{SO_2} P_{O_2}^{1/2}}{\left[P_{SO_3}^{1/2} + (K P_{SO_2})^{1/2}\right] P_{SO_3}^{1/2}} \left(1 - \frac{P_{SO_3}}{K_P P_{SO_2} P_{O_2}^{1/2}}\right) \tag{16}$$

Rate 5:

$$\dot{r} = \frac{k\,(K P_{SO_2})^{1/2} P_{O_2}}{\left[P_{SO_3}^{1/2} + (K P_{SO_2})^{1/2}\right]} \left(1 - \frac{P_{SO_3}^2}{K_P^2 P_{SO_2}^2 P_{O_2}}\right) \tag{17}$$

Rate 6:

$$\dot{r} = \frac{k K P_{SO_2} P_{O_2}}{\left[P_{SO_3}^{1/2} + (K P_{SO_2})^{1/2}\right] P_{SO_3}^{1/2}} \left(1 - \frac{P_{SO_3}^2}{K_P^2 P_{SO_2}^2 P_{O_2}}\right) \tag{18}$$

All these rate equations utilize the same approach for the velocity constant k, and the equilibrium of the vacant sites K, which are given in the equations (19) and (20).

$$k = exp\left(p_1 - \frac{p_2}{T}\right) \tag{19}$$

$$K = exp\left(p_3 - \frac{p_4}{T}\right) \tag{20}$$

3.4 Numerical Solution

In order to keep the computational effort low, both reactor models were discretized using the orthogonal collocation (OC), see Schöneberger et al. (2009). In the case of the homogeneous model this leads to an algebraic equation system (AE) and in the case of the two-phase model to a system of ordinary differential equations (ODE). The

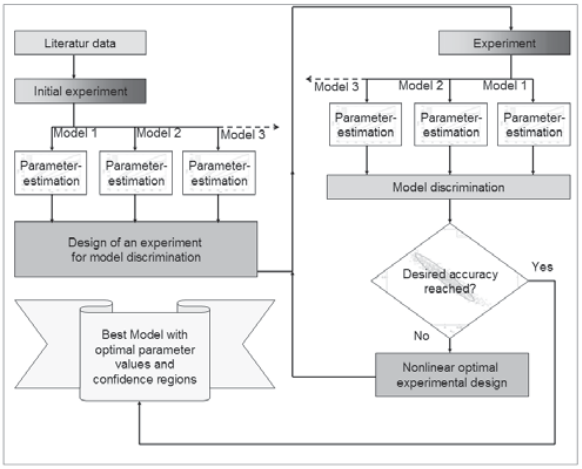

Fig. 4. Model identification framework.

AE is solved with a Newton-Raphson step and the ODE is integrated with an OC based Runge-Kutta algorithm. The use of the numerical solution in an optimization framework requires a very robust solution algorithm, in particular, when the free variables are positioned in exponential terms such as in the case of kinetic parameter estimation. Therefore, specialized initial value generation algorithms and step size control algorithms are required, see Schöneberger et al. (2007). Anyhow, the solution of the homogeneous model is more robust. Consequently, the first parameter estimation is performed with this model in order to get good initial parameter values for the two-phase model.

4. MECHANISM IDENTIFICATION FRAMEWORK

The proposed framework in Fig. 4 is based on the methods of nonlinear experimental design. It is similar to the model building framework proposed by Franceschini and Macchietto (2008), but with some improvements regarding the specific problem. There is only one experiment designed for model discrimination, and this is performed in the beginning of the identification procedure. Further experiments are exclusively designed in order to improve the parameter accuracy until the parameter spreading is in an acceptable region. Please note that all six reaction rates are considered in the steps 'Parameter estimation' and 'Model discrimination' of the loop in Fig. 4, but the 'Nonlinear optimal experimental design' is only performed for the actually best rate model.

4.1 Parameter Estimation Problem

The objective of the parameter estimation procedure is to find the parameter values which set the numerical solution of the model equations (e.g. (1), (2), and (3) for the homogeneous model) as close as possible to the measured data. For this purpose, the problem (21), here stated for the homogeneous model, has to be solved. In this work, a weighted least square functional is used as objective function and it's final value is named LSQ. High values are related to a high lack of fit.

$$\min_{p_1,p_2,a,b,c} \mathsf{LSQ} = \sum_{j=1}^{NM} \frac{\left(T_{ns,j} - T_{md,j}\right)^2}{\sigma^2_{T_j,T_j}} \tag{21}$$

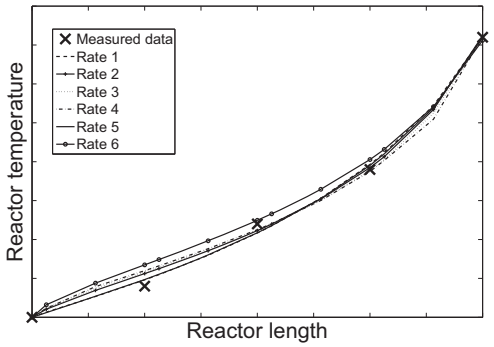

Fig. 5. Initial experiment.

In equation (21) the subscripts ns and md denote numerical solution and measured data, respectively, NM is the number of measured data points, and $\sigma^2_{T_j,T_j}$ is the standard deviation of the measured quantity (here the temperature T) at the measured point j. The calculated temperature profiles for the different rate laws after the parameter estimation are compared to the measured temperature data in Fig. 5. In Tab. 2, the LSQ values for the different rate models are given. All models are able to describe the measured data. This is not surprising, because 4 parameters (5 for rate 1) are fitted to only 5 measured points. Anyhow, the structure of the rate equations does not allow the same good fit for all rates. The best fit is reached with rate 5.
The parameter estimation problem becomes more difficult when more data points are available. The model equations have to be solved separately for each new experiment, making the parameter estimation the most expensive step regarding the computational effort.

Table 2. LSQ values for different rate models.

Rate	1	2	3	4	5	6
LSQ	0.488	0.688	0.821	0.916	0.461	1.901

4.2 Model Discrimination Problem

It is difficult to choose the best suitable rate model from Fig. 5. The discrimination step normally is performed taking the model with the lowest LSQ value. But, after only one experiment the models LSQ values are still close together, see Tab. 2. Thus, in a second step an experiment is designed that drift apart from the calculated temperature profiles for the estimated set of parameters. To do this, the optimization problem given in equation (22) is solved. By this means, the obtained inlet conditions are optimal for the discrimination step. Due to the fact that only one measured variable is considered, here a simpler formulation is chosen as proposed by Akaike (1974) and other authors.

$$\min_{\dot{V},c_{SO_2,in},c_{O_2,in},T_{in}} \Phi_{\text{Disc.}} \text{ , with}$$
$$\Phi_{\text{Disc.}} = \sum_{m=2}^{6} \sum_{i=m}^{6} \sum_{j=1}^{5} \left(T_{ns,Mod=m,j} - T_{ns,Mod=i,j}\right)^2 \tag{22}$$

The temperature profiles calculated with the solution of (22) are plotted in Fig. 6. After the experiment is per-

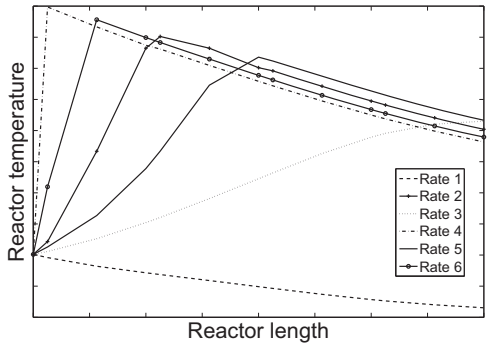

Fig. 6. Model discrimination experiment.

formed and the new parameters for each model are found, the profiles are not separated anymore. However, the experiment forces the rate models parameter values to move, and thus, the models flexibility and arbitrariness is reduced considerably.

Only one experiment is designed for a better model discrimination. After the discrimination experiment the rates 1, 2, and 3 are the most promising candidates. The other rates are still considered in the calculations but not plotted anymore in this paper. Further designs for discrimination are not performed because the focus on the parameter accuracy forces also an increasing difference in the models LSQ values. This means that after the convergence of the loop in Fig. 4 a good distinguishability between the rates is reached in addition.

4.3 Nonlinear Optimal Experimental Design Problem

In this work, the A-Criterion is used in order to increase the parameter accuracy, leading to the objective function given in equation (23). A detailed description of the nonlinear optimal experimental design and the different criteria so as a reason for the selection of the A-Criterion can be found in Schöneberger et al. (2008).

$$\min_{\dot{V},c_{SO_2,in},c_{O_2,in},T_{in}} \Phi_{\mathrm{A}}, \text{ with}$$
$$\Phi_{\mathrm{A}} = \frac{\mathrm{trace}\,(\mathbf{C})}{\dim\,(\mathbf{C})} \tag{23}$$

The covariance matrix of the model parameters $\mathbf{C}$ is approximated with the inverse of the Fisher information matrix $\mathbf{F}$ which can be calculated with equation (24), see Bard (1974). The rate model parameters are summarized in the parameter vector $\mathbf{P}$.

$$\mathbf{C} \geq \mathbf{F}^{-1} = \left[\sum_{j=1}^{NM} \left(\left(\frac{\partial T_{ns,j}}{\partial \mathbf{p}} \right) \frac{1}{\sigma^2_{T_j,T_j}} \left(\frac{\partial T_{ns,j}}{\partial \mathbf{p}} \right)^{\mathbf{T}} \right) \right]^{-1} \tag{24}$$

The parameter's standard deviations $\sigma_{p_n,p_n} = \sqrt{\mathbf{C}(n,n))}$ can be calculated with the diagonal elements of the covariance matrix. The framework is stopped, when a maximal standard deviation of $\sigma_{p_n,p_n,max} \leq 0.02$ is reached. This was accomplished after 8 experiments. The development of the A-Criterion and the maximal parameter standard deviation w.r.t. the experiments is shown in Fig. 7. The development of the LSQ values for the first three rate models

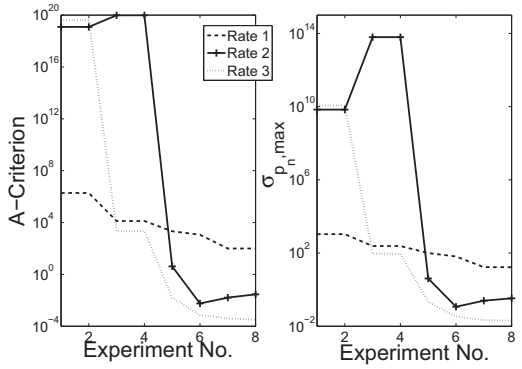

Fig. 7. Development of the parameter accuracy.

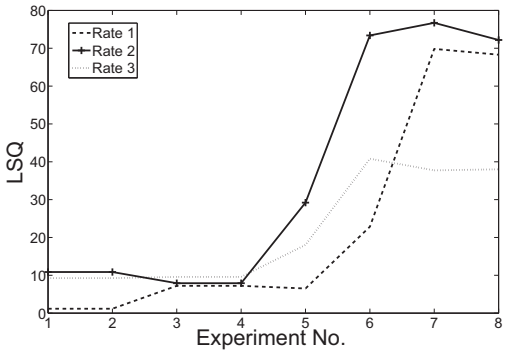

Fig. 8. Development of the lack of fit.

are depicted in Fig. 8. The experiments 1 and 2 and so 3 and 4 are repeated experiments used for the determination of the measured variables standard deviation σ_{T_j,T_j}.

5. RESULTS

In this section, the measured dynamic reactor behavior and the results obtained with the two-phase model are presented.

5.1 Catalyst Properties and Heat Transfer

The specific heat capacity of the catalyst phase $c_{P,k}$ is a model specific property, which has to be determined from experimental data. It should be noted that it is not equal to the heat capacity of the catalysts bulk material since the modeled catalyst phase contains also the particle pores. It can be estimated together with the parameter in the heat transfer correlation from experiments without reaction. This saves reactant gases and reduces the experimental effort because no off-gas treatment is necessary. The transient temperature profiles during the reactor heat up procedure can be used for this issue. They allow the independent estimation of the two parameters because they contain also the initial steady state, when the reactor inlet temperature is reached. These steady state profiles are independent of the catalyst phase heat capacity, but a function of the heat transfer coefficient. In Fig. 9 the numerical solution (surface) is fitted to the measured temperature data (black lines) based on the procedure described in section 4.1.

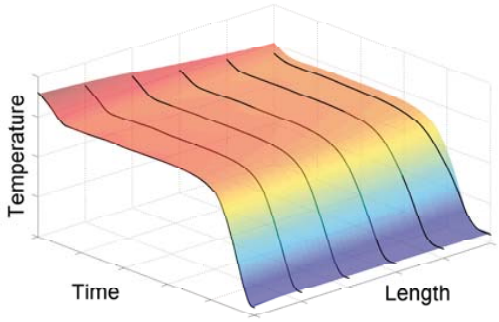

Fig. 9. Time-space surface without reaction.

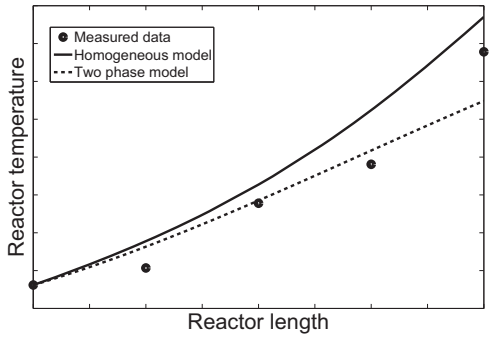

Fig. 10. Steady state comparison of the reactor models.

5.2 Parameter Transfer

Under the assumption of an instantaneous heat and mass transfer and a neglecting of axial dispersion, the model equations of the two-phase model can be rearranged to the form of the homogeneous model in the case of steady state. To show this, the profiles of a solution with the homogeneous model are compared to the steady state solution of the two-phase model in Fig. 10. The differences arise from the stated assumptions, which are not completely fulfilled. However, a steady state examination of a catalyst would not justify the use of the more complex two-phase model.

5.3 Dynamic Reactor Behavior

In Fig. 11, the transient temperature data is plotted. The temperatures after the first and the second bed show a strong overshooting. This behavior can be explained with the two-phase model. The coupled balances for gas and solid phase lead to a PT2 behavior when linearized. This second order element has the potential to produce a swinging solution. The effect is reduced in relation to the distance from the reactor inlet. The last two profiles show inflexion points instead. This can be explained with the increasing reactor wall temperature, which is also disturbing the system as well.

6. CONCLUSIONS

First calculation results show that the two-phase model is able to describe the dynamic reactor behavior. It has been demonstrated that for steady state experiments with a FBR the more complex two-phase model is not required. However, the information content of the transient profiles is much higher than the one from the steady state profiles. The effect on the parameter accuracy still has to be examined, in particular, because of the inclusion of the additional parameters. The knowledge of the dynamic reactor behavior enables the design of optimal transient experiments and their implementation in the proposed identification framework.

Modeling and Simulation of the Polymeric Nanocapsule Formation Process

Luciane S. Ferreira and Jorge O. Trierweiler

GIMSCOP – Chemical Engineering Department – UFRGS. Rua Luis Englert, s/n. Porto Alegre. RS. Brasil.
(e-mail: {luciane,jorge}@enq.ufrgs.br)

Abstract: In this work the modelling and simulation of nanoparticle formation according to the technique of nanoprecipitation was done. In this method, the particle is formed due to the further diffusion of solvent into the water, resulting in the aggregation of the associated polymer chains. In order to predict the characteristics of the nanoparticle and also to improve the process, it was developed a mathematical model that considers: (a) the type of polymer; (b) interaction between solvent and polymer; and, (c) dynamics of solvent diffusion. The diffusivity between polymer-solvent was modelled by means of the Vrentas & Duda Free Volume Theory, including the Sanchez-Lacombe equation-of-state. The model was written in terms of Partial Differential Equation, and solved with MAPLE for a given initial size distribution. Additionally, it is a moving boundary problem because the diffusion of the solvent out of the droplet leads to its size reduction. Based on a given initial droplet size distribution, the transient behaviour and the final droplet size distribution can be evaluated. The dynamic simulation shows both the evolution of the solvent inside the droplet and the variation of size in time. Additionally, the comparison between experimental and simulated results showed a very good agreement.

Keywords: nanoprecipitation, modeling, simulation, diffusion, moving boundary, droplet size distribution.

1. INTRODUCTION

Polymeric nanoparticles are of especial interest from the pharmaceutical point of view. First, they are more stable in the gastrointestinal tract than other colloidal carriers and can protect encapsulated drugs from gastrointestinal environment. Second, the use of various polymeric materials enable the modulation of physicochemical characteristics (e.g. hydrophobicity, zeta potential), drug release properties, and biological behavior (e.g. targeting, bioadhesion, improved cellular uptake) of nanoparticles. Finally, their submicron size and large specific surface area favor their absorption compared to larger carriers (Des Rieux *et al.*, 2006). For instance, nanoparticles encapsulating proteins and vaccines (Des Rieux *et al.*, 2006) and chemotherapeutic agents (Jabr-Milane *et al.*, 2008) have been investigated in the last years.

One of the methods applied to produce nanoparticles is the so-called Nanoprecipitation. This method, first presented in 1989 (Fessi *et al.*, 1989), was largely applied by other authors in the subsequent years (Guterres *et al.*, 1995, Thioune *et al.*, 1997, Govender *et al.*, 1999, Chorny *et al.*, 2002, Galindo-Rodriguez *et al.*, 2004, Bilati *et al.*, 2005, Galindo-Rodriguez *et al.*, 2005). It consists of a simple procedure for the preparation of nanocapsules (NC) by interfacial deposition of a preformed, well-defined, and biodegradable polymer following displacement of a semi-polar solvent miscible with water from a lipophilic solution. The method of preparation yielded spherical vesicular nanocapsules, which consisted of an oily cavity – where the drug is dissolved - surrounded by a thin wall formed by interfacial deposition of the polymer. When organic and aqueous phases are in contact, it is assumed that solvent diffuses from the organic phase into the water and carries with it some polymer chains, which are still in solution. Then, as the solvent diffuses further into the water, the associated polymer chains aggregate forming NC. Therefore, this method involves the equilibrium among a polymer, its solvent and a non-solvent.

In order to predict the characteristics of the nanoparticle and also to improve the process, it was developed a mathematical model that takes in account: (a) the type of polymer; (b) interaction between solvent and polymer; and, (c) solvent diffusion process. After the description of the nanocapsules preparation, the mathematical model is explained. Then, the numerical simulation and its results are discussed. Finally, in the appendix the Free Volume model, applied to calculate the diffusivity polymer/solvent, is explained.

2. NANOCAPSULES PREPARATION

As mentioned in the previous section, the nanocapsules are prepared according to the method of nanoprecipitation. This method is based on the spontaneous emulsification of the organic internal phase, in which the polymer is dissolved, into the external aqueous phase. In this work nanocapsules of poly(ε-caprolactone) (PCL) containing 3-benzophenon (solar protection factor) were prepared according to the following procedure (Fessi *et al.*, 1989): 100 mg of PCL, 76.6 mg of sorbitan monostearate, 333 mg of Mygliol 810 (caprylic/capric triglyceride) and 30mg of Benzophenon-3 are first dissolved in acetone (27 ml). The resulting organic solution is poured in 53 ml of water containing 76.6 mg of polysorbate 80. The aqueous phase immediately turns milky with bluish opalescence as a result of the formation of nanocapsules, the wall of which is mainly constituted by PCL, and the oily core by the benzophenon-mygliol solution. The size of the nanoparticles is then analyzed by *Dynamic Light Scattering* (Zetasizer Nano, Malvern).

3. MATHEMATICAL MODELLING

It was considered that the nanoprecipitation produces perfect spherical particles and also that each nanoparticle is originated from one droplet formed immediately after the mixing of organic phase and aqueous phases. The major model assumptions are: (a) there is a negligible relative velocity between the droplet and the water; therefore, the external mass transfer is approximated by diffusion. This assumption can be done based on the order of the Stokes number, which is related to the particle velocity and is defined as (Crowe, 2005, Rielly and Marquis, 2001):

$$St \equiv \frac{\tau_v}{\tau_F} = \frac{d_p^{\,2}\rho_p V}{18\mu L} \quad [1] \tag{1}$$

For small Stokes numbers, the particles follow the fluid motion; but for large *St*, the particles follow different trajectories from the fluid elements. The Stokes number (Figure 1) was calculated for fluid velocities between $1x10^{-3}$ and 1 $m.s^{-1}$ (based on CFD simulations for a stirred tank that are not showed here), and particle diameters from 100 to 4000 nm. As the Stoke number is in all cases less than 10^{-5}, the assumption of negligible relative velocity between the droplets and the external phase can be considered valid.

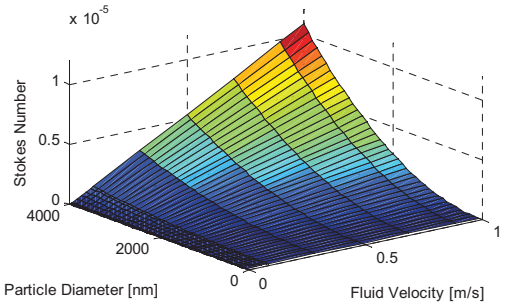

Fig. 1. Stokes Number.

(b) the diffusion is one-dimensional along the radial direction; and, (c) the diffusivity varies with time and concentration only.

Based on these assumptions, the mass balance equation for the solvent, written in spherical coordinates is:

$$\frac{\partial c_1(r,t)}{\partial t} = \frac{D}{r^2}\left(\frac{\partial}{\partial r}\left(r^2\left(\frac{\partial c_1(r,t)}{\partial r}\right)\right)\right)^{2} \tag{2}$$

This is a moving boundary problem, since the size of the droplet reduces because of the diffusion.

As the dimensions of dependent and independent variables are not the same, a variable normalization was be done including new variables τ, rh, and c_{1h} defined as,

$$t_0 = \frac{r_0^2}{D} \tag{3}$$

$$\left\{r = rh \cdot r_0,\ t = \tau \cdot t_0,\ c_1(r,t) = c_{1h}(rh,\tau)\cdot \rho_1\right\}^{3} \tag{4}$$

After the normalization, (2) is then rewritten as:

$$\frac{1}{t_0}\cdot\frac{\partial c_{1h}(rh,\tau)}{\partial \tau} = \frac{D}{r_0^{\,2}\cdot rh^2}\left(\frac{\partial}{\partial rh}\left(rh^2\left(\frac{\partial c_{1h}(rh,\tau)}{\partial rh}\right)\right)\right). \tag{5}$$

3.1 Initial and Boundary Conditions

It is assumed that the solution is well mixed and therefore, the concentration inside the droplet is uniform. Thus the initial condition is,

$$c_{1h}(rh,0) = c_{1h0} \qquad 0 \le rh \le r0\,. \tag{6}$$

Where c_{1h0} is evaluated according to the experimental conditions.

The boundary condition at the center of the droplet (rh=0) arises from the symmetry,

$$\left.\frac{dc_{1h}}{drh}\right|_{rh=0} = 0 \qquad t \ge 0\,. \tag{7}$$

Additionally, the boundary condition at the interface was calculated based on the mass balance and can be written as

$$\left.\frac{dc_{1h}}{dt}\right|_{\text{rh=R}} = \frac{D_{S-W}}{4\pi R^2}\left(c_{1h}(R) - c_{1h}(\infty)\right)^{4} \tag{8}$$

3.2 Boundary Movement

The boundary movement is calculated based on the assumption that both the mass of polymer, oil and drug remain constant during the diffusion process. The volume of the droplet is considered to be

$$V_D = V_2 + V_1 + V_{oil} + V_{drug} \equiv \frac{4}{3}\pi R^{3\,5} \tag{9}$$

Per definition the volume of polymer and solvent inside the droplet are

$$V_2 = m_2/\rho_2 \qquad V_1 = (c_1/\rho_1)V_D^{\,6} \tag{10}$$

Substituting (10) in (9) and isolating for *R*, then the radius can be calculated as

$$R(t) = \sqrt[3]{\left[3\cdot\left(\frac{m_2}{\rho_2} + V_{oil} + V_{drug}\right)\cdot\left(1 - \frac{c_1(t)}{\rho_1}\right)^{-1}\right]\Big/ 4\pi}\,. \tag{11}$$

3.3 Model Parameters

The two main parameters of this model are the diffusivity solvent/polymer and the diffusivity solvent/water.

The experimental data presented by Wild (2003) was adjusted as a polynomial curve to describe the diffusivity of acetone in water.

$$D_{S\text{-}W} = -4.737 w_S + 15.92\, w_S - 14.71\, w_S + 4.738 \tag{12}$$

where w_s is the molar fraction of water in the external phase.

The diffusivity between polymer and solvent was modelled according to the Free Volume Theory (Vrentas and Duda, 1976, Vrentas and Duda, 1977a, Vrentas and Duda, 1977b, Vrentas and Duda, 1979). Those authors applied the Flory–Huggins thermodynamic model in their free volume diffusion theory to describe the polymer solvent enthalpic and entropic

[1] τ_F - characteristic time of the flow field; τ_v - particle relaxation time; d_p - particle diameter; ρ_p - particle density; V - fluid velocity, μ - fluid viscosity; L - characteristic dimension of the obstacle.

[2] c_1 - concentration of solvent; r - particle radius; D - diffusivity; t - time.

[3] r_0 - initial droplet radius; D - diffusivity; ρ_1 - solvent density.

[4] R - actual radius of the droplet; $D_{S\text{-}W}$ - diffusivity of the solvent in the external phase; $c_{1h}(R)$ - concentration of solvent at the interface; $c_{1h}(\infty)$ - bulk concentration.

[5] V_D - volume of the droplet; V_1, V_2, V_{oil}, V_{drug} - volume of solvent, polymer, oil, and drug, respectively.

[6] m_2 - mass of polymer; ρ_2 - polymer density.

interactions. For the estimation of solvent diffusion coefficient in polymer solution systems, free-volume parameters for the both polymer and solvent must be available. The free volume (FV) diffusion model developed by Vrentas & Duda describes the solvent self-diffusion coefficient (D_1) and the polymer/solvent binary mutual diffusion coefficient (D) as given by (13) and (14), respectively.

$$D_1 = D_0 \exp\left(\frac{-E}{RT}\right)\cdot\exp\left(\frac{-\left(w_1\hat{V}_1^* + w_2\xi\hat{V}_2^*\right)}{w_1\left(\frac{K_{11}}{\gamma}\right)\left(K_{21}-T_{g1}+T\right)+w_2\left(\frac{K_{12}}{\gamma}\right)\left(K_{22}-T_{g2}+T\right)}\right) \quad (13)$$

$$D = D_1\left(1-\phi_1\right)^2\left(1-2\chi\phi_1\right) \quad (14)$$

In (13) the first exponential term can be considered as the energy factor, and the second exponential term is the free-volume factor. Eq. (14) contains the following implicit assumptions (Zielinski and Duda, 1992): (a) the mutual-diffusion coefficient is related theoretically to the solvent and polymer self-diffusion coefficients through an expression developed by Bearman (1961); (b) the contribution of the polymer self-diffusion coefficient to the mutual-diffusion is negligible; and, (c) the Flory-Huggins (Flory, 1970) model accurately describes the polymer activity. In addition, the specific free volumes of the polymer and solvent are presumed to be additive (without a volume change on mixing), and thermal expansion coefficients are approximated by average values over the temperature intervals of interest (Frick *et al.*, 1990, Lodge *et al.*, 1990). There are 13 independent parameters to be evaluated in (14). Some of them can be grouped reducing this number to the following variables: K_{11}/γ, $K_{21}-T_{g1}$, K_{12}/γ, $K_{22}-T_{g2}$, $\hat{V}_1^*$, $\hat{V}_2^*$, D_0, E, , ξ, and χ, that must be determined to estimate mutual diffusivities. All of these parameters have physical significance, and therefore one must be able to evaluate every parameter from sources other than diffusion studies. The guidelines to calculate them, clarified by Zielinski and Duda (1992), were used in this work. Additionally the modification proposed by Wang *et al.* (2007), according to the Sanchez-Lacombe equation-of-state (SL EOS), was also taken in account and is explained in Appendix A. The process was considered to be isotermic and isobaric (T=298K, P=1bar and E=0). All the parameters are listed in Table 1 and more details can be found in Appendix A.

Table 1: Model Parameters.

$\hat{V}_1^*$	0.9695 cm^3/mol	(K_{11}/γ)	0.983 x 10^{-3}
$\hat{V}_2^*$	0.8181 cm^3/mol	ρ^*	1.1427 g/cm^3
δ_1	18.29 J$^{1/2}$/cm$^{3/2}$	T^*	668 K
δ_2	20.85 J$^{1/2}$/cm$^{3/2}$	P^*	4035 bar
D_0 x 10^4	14.3 cm^2/s	T_{g2}	213 K
K_{21}-T_{g1}	-12.12		

The numerical values of number- and volume-average (size and standard deviation) – measured with ZetaSizer Nano® from samples all prepared according to the same methodology – are described in Table 2.

4. NUMERICAL SIMULATION

Experimentally the mean diameter is measured by *Dynamic Light Scattering* (ZetaSizer Nano® – Malvern). Typical number and volume density distributions, measured, can be seen in Fig. 2.

According to Table 2 and Fig. 2, it is observed that: (a) The number-average size is always smaller than the volume-average, as the contribution of a spherical particle grows proportionally with D^3; (b) The standard deviation is about 32 – 41% of the averaged value; and, (c) The size distribution does not follow a normal distribution.

Table 2: Number and Volume average sizes.

	Number-average particle diameter	Volume-average particle diameter
Sample 1	222.12 ± 71.25	303.76 ± 103.68
Sample 2	199.23 ± 67.83	285.13 ± 103.97
Sample 3	200.81 ± 73.60	300.90 ± 117.73
Sample 4	200.57 ± 72.48	303.66 ± 126.88

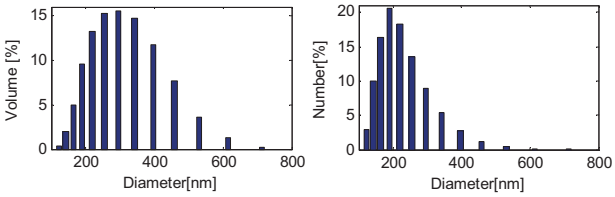

Fig. 2: Measured Number and Volume density distribution.

If it is assumed that the number of droplets/particles remains constant during all the process, the initial distribution can be calculated through the mass balance and based on the experimentally volume density distribution at final time, as explained by Fig. 3.

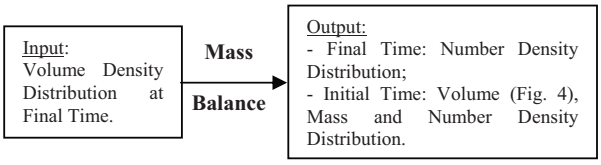

Fig. 3: Measured number and volume size distribution.

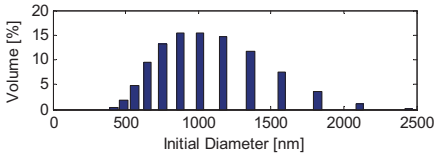

Fig. 4: Calculated Initial Size Distribution.

The calculated number density at final time was compared to the measured one, as can be seen in Fig. 5. The good agreement between both assures that the methodology used in this work is correctly applied.

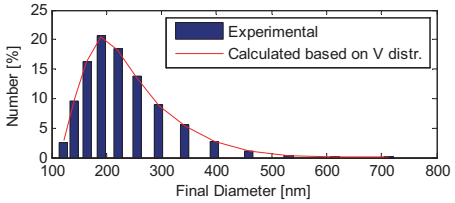

Fig. 5: Comparison between the Experimental and Calculated Number Density Size Distribution.

As the initial size distribution is now available, the diffusion

model can be simulated. It was done in Maple, which is capable of finding solutions for higher order PDE or PDE systems.

Based on the initial size distribution, (5) is solved for each class of particle size. After that, the new radius can be thus calculated. If the relative difference (*ΔDiam*) between the new and old radius is less than $1x10^{-5}$, the process ends; if not, the iteration process goes on as illustrated in Fig. 6.

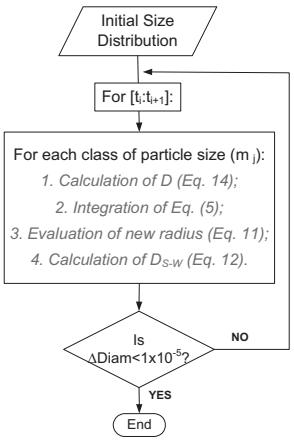

Fig. 6: Scheme of solution implemented in MAPLE.

5. RESULTS AND DISCUSSION

The model predicts that in about 12 ms all the particles reach the final diameter. This result is in qualitative agreement with what is observed experimentally, that is, as the organic phase is mixed in the aqueous phase, the suspension becomes *immediately* (at least for the human eyes) opaque, as a result of the nanoparticle formation.

Throughout the diffusion process, gradients of oil, acetone and polymer arise into the droplet leading to the reduction in size and the formation of the nanoparticle, as can be seen in Fig. 7. Each line represents one class of particle that forms the distribution.

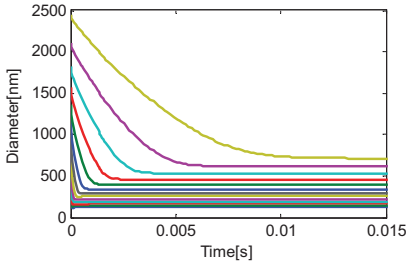

Fig. 7: Evolution of Particle Size in time.

For the smallest particles, it is observed that the diameter reduction is very fast, which is a consequence of the fast diffusion of acetone to the external medium, as can be seen in Fig. 8.

The order of magnitude of the diffusion time is in agreement with that found by Moinard-Chécot *et al.* (2008). They tried to measure the duration of the solvent diffusion step with a stopped-flow apparatus. In this experiment, only the signal corresponding to the final state could be observed, i.e., the diffusion step is less than 20 ms (the acquisition time of the apparatus).

Meanwhile the biggest particles presented a slower diffusion profile. Because of their initial big size, it takes longer for the solvent to reach the interface and consequently, to be transferred to the external medium. As more solvent diffuses out of the droplet, the concentration of polymer inside the droplet increases and consequently, the diffusivity polymer/solvent also grows up. At intermediate steps, the slow reduction in size showed by the largest particles leads almost to a bimodal volume and mass density distribution, as can be seen in Fig. 9.

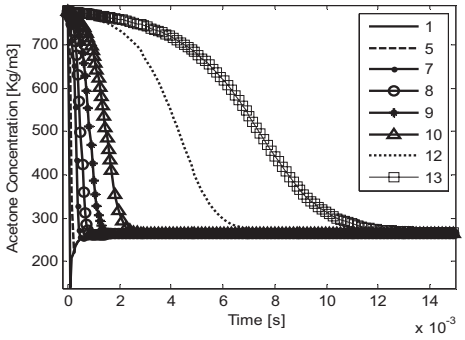

Fig. 8: Acetone concentration at the interface.

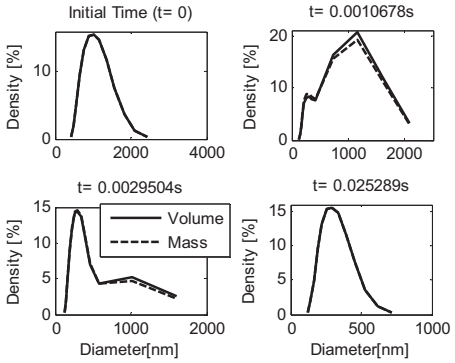

Fig. 9: Volume and Mass Distribution at the initial and final time, and 2 instants of time in-between.

The comparison between the experimental and calculated final volume density distribution (Fig. 10) shows a very good agreement, confirming that the assumptions done in sections 2 and 3 are suitable for modelling the system.

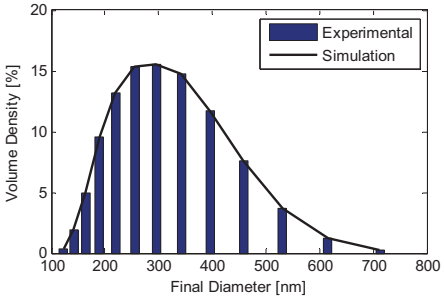

Fig. 10: Comparison between the experimental and simulated volume density distribution.

In order to generalize the model, a probability density

distribution can be employed to describe the initial size of the droplets. Applying the gamma distribution it is possible then to compare the experimental and simulation results, as show in Fig. 11. Analyzing both results and considering the standard deviation of the measurement, it is possible to confirm that the model and the methodology presented in this work are suitable to simulate the nanoprecipitation.

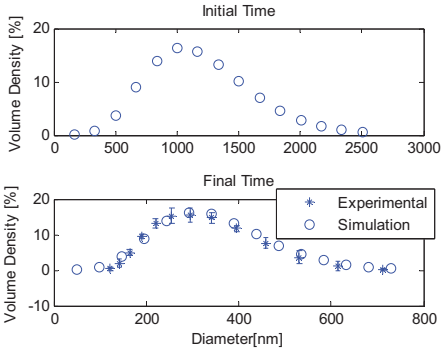

Fig. 11: Results obtained when using a gamma distribution to describe the droplets initial size. (a) Initial size distribution, (b) Final size distribution.

6. CONCLUSIONS

This work shows that it is possible to obtain satisfactory results using a simplified PDE model for the nanoprecipitation. The adopted approach considers several variables that have influence on diffusion, like type of polymer, solvent and non-solvent; affinity among them; and, polymer solubility. As a result, it is then possible to evaluate the particle size distribution during the nanoprecipitation. The comparison between the simulated and measured sizes showed a quite good agreement, suggesting that the employed methodology can describe correctly the nanoprecipitation.

The proposed model can be combined with CFD simulator in order to improve the predictions. From the simulation, one could try to evaluate more accurately the initial droplet distribution. This methodology could thus be applied to study the influence of several kinds and sizes of reactors and mixers in the final properties of the nanoparticles.

Appendix A. FREE VOLUME THEORY PARAMETERS

$\hat{V}_1^*$ *and* $\hat{V}_2^*$ – The two critical volumes were approximated as the specific volumes of solvent and polymer at absolute zero temperature. The molar volumes at 0K were estimated using a group contribution method (Sugden, 1927).

χ – The interaction parameter in terms of solubility parameters can be calculated through the following equation (Van Dijk and Wakker, 1997):

$$\chi = \frac{V_m}{RT}\left(\delta_1 - \delta_2\right)^2 \tag{15}$$

where V_m is the molar volume, R is the ideal gas constant and δ_1 and δ_2 are the solvent and polymer solubility parameters respectively.

A widely used solubility parameter approach for predicting polymer solubility is proposed by Hansen (2000). The basis of the so-called Hansen Solubility Parameters (HSP) is that the total energy of vaporization of a liquid consists of several individual parts. These arise from (atomic) dispersion forces (E_D), (molecular) permanent dipole-permanent dipole forces (E_P) and (molecular) hydrogen bonding (electron exchange) (E_H). The basic equation which governs the assignment of Hansen parameters is that the total cohesion energy, E, must be the sum of the individual energies which make it up

$$E = E_D + E_P + E_H \tag{16}$$

Dividing each one by the molar volume gives the square of the total solubility parameter.

$$\begin{aligned} E/V &= E_D/V + E_P/V + E_H/V \\ \delta^2 &= \delta_D^2 + \delta_P^2 + \delta_H^2 \end{aligned} \tag{17}$$

The solubility parameter components were predicted from group contribution method, using the following equations (Van Krevelen, 1990).

$$\delta_d = \sum F_{di} \Big/ V \qquad \delta_p = \sqrt{\sum F_{pi}^2} \Big/ V \qquad \delta_h = \sqrt{\sum E_{hi} \Big/ V} \tag{18}$$

D_0, K_{21}-T_{g1}, (K_{11}/γ) – These are solvent parameters (acetone) and the values previously collected by Zielinski and Duda (1992) were used here.

$(K_{12}/\gamma)(K_{22}$-T_{g2}+$T)$*(Wang et al., 2007)* – According to the Vrentas-Duda model (Zielinski and Duda, 1992), the hole free volume of a polymer $\hat{V}_{FH2}$ in its rubbery state can be expressed as

$$\frac{\hat{V}_{FH2}}{\gamma} = \left(K_{12}/\gamma\right)\left(K_{22} - T_{g2} + T\right) \tag{19}$$

Assuming that the hole free volume is equal to the volume defined by the WLF (Williams, Landel and Ferry) theory, at the atmospheric pressure, (19) becomes

$$\frac{\hat{V}_{FH2}}{\gamma} = V\left\{0.025 + \int_{T_{g2}}^{T}\left[\left(1+\frac{\tilde{P}}{\tilde{\rho}^2}\right)\Big/\left(T\left[\frac{\tilde{T}}{1-\tilde{\rho}} - 2\right]\right)\right]_{P0} dT\right\} \tag{20}$$

where $V(=1/\rho)$ is the volume of polymer per gram at temperature T, which can be estimated by the SL EOS according to the equation,

$$\tilde{\rho} = 1 - \exp\left[-\left(\tilde{\rho}^2 + \tilde{P}\right)/\tilde{T} - \tilde{\rho}\right] \tag{21}$$

with the definition

$$\tilde{\rho} = \rho/\rho^*, \qquad \tilde{T} = T/T^*, \qquad \tilde{P} = P/P^* \tag{22}$$

where ρ^*, T^* and P^* are characteristics parameters of mass density, temperature and pressure, respectively. These parameters are listed by Rodgers (1993) and those for PCL used in this work are listed in Table 1. This method eliminates the need to use polymer viscoelastic data for determining the polymer free volume parameters. Additionally, its scope is also extended to include not only temperature and concentration but also pressure influence on solvent diffusivities. The only new parameters introduced by this model (ρ^*, T^* and P^*) are three parameters of the SL EOS (Wang et al., 2007).

Predictive Modeling of Key Process Variables in Granulation Processes based on Dynamic Partial Least Squares

Abstract: Granulation is a multivariable process characterized by several physical attributes that are essential for product performance, such as granule size and size distribution. An optimally operated granulation process will yield, in a reproducible manner, product with tightly controlled performance attributes. In this paper predictive models of the dynamics of these key variables are developed using a dynamic partial least squares approach. The method, demonstrated here on process simulation as well as on an industrial mixer-granulator process, result in accurate predictions. These models motivate the development of model predictive controllers for these processes.

Keywords: Granulation, Process control, Dynamic modeling, Partial least squares

1. INTRODUCTION

Granulation is a complex process in which many input variables influence many product properties. As Iveson et al. describe in a review paper (2001), the understanding of the fundamental processes that control granulation behavior and product properties have increased in recent years. This knowledge can be used during process design, in choosing the right formulation and operating conditions, and it can also be used to improve process control. Although many variables are set constant during process design, variations during production in input variables occur due to the variable nature of the powder feed. Even if all granule properties, except for size, are ignored for process control, a one dimensional granule size distribution can be constructed by multiple discrete output variables, in order to represent the shape of the distribution (these can be mean sizes (with coefficients of variation), percentile sizes, moments or size bins). Model Predictive Control (MPC) is an effective method to control such multiple input, multiple output processes (García, et al., 1989). The majority of MPC applications in the chemical process industries utilize empirical models that are constructed from plant data. In this work, we explore the use of dynamic partial least squares to construct these empirical models.

2. METHODS

2.1 Partial Least Squares

Partial Least Squares (PLS) methods have been demonstrated as a useful tool for analysis of data and modeling of the systems from which the data are collected (Kaspar and Ray, 1993). Unlike related methods, such as Principal Component Analysis (PCA), which finds factors that capture the greatest amount of variance in the predictor (X) only, the PLS method attempts to find factors which both capture variance and achieve correlation. PLS handles this by projecting the information in high dimensional spaces (X,Y) down to low dimensional spaces defined by a small number of latent vectors (t_1,t_2…t_a). These new latent vectors summarize all the important information contained in the original data sets, by representing the scaled and mean-centered values of X and Y matrices as:

$$X = \sum_{i=1}^{a} t_i p_i^T + E$$
$$Y = \sum_{i=1}^{a} u_i q_i^T + F \qquad (1)$$

where the t_i are latent (score) vectors calculated sequentially for each dimension i=1,2,…a.

In the PLS method, the covariance between the linear combinations of X and the output measurement matrix Y is maximized at each iteration, using the vectors p_i and q_i which are the loading vectors whose elements express the contribution of each variable in X and Y toward defining the new latent vectors t_i and u_i. E and F are residual matrices for X and Y blocks, respectively. The optimal number of latent vectors retained in the model is often determined by cross-validation (Dayal et al. 1994).

In an industrial environment, it is more often the case that many of the predictor variables (X) are highly correlated with one another and their covariance matrix is nearly singular,

which renders classical regression methods intractable. Reduced space methods such as PLS and PCA can overcome this problem (MacGregor and Kourti, 1995). PLS is also robust to measurement noise in the data and can be used in cases where there are random missing data and when the number of input variables is greater than the number of observations (Dayal et al. 1994). Various examples of the implementation of PLS analysis to industrial process modeling and control can be found in the literature (for example, Dayal et al., 1994, MacGregor and Kourti, 1995, and others).

Process dynamics can be incorporated into the PLS model by including columns of lagged outputs and/or inputs into the predictor block (*X*) (Dayal et al., 1994, Kaspar and Ray, 1993, Juricek et al. 2001). The resulting PLS model is actually an ARX type input-output model of the form:

$$A(q^{-1})y_i(k) = \sum_{j=1}^{mu} B_j(q^{-1})u_j(k - nk_j) \tag{2}$$

$$A(q) = 1 + a_1 q^{-1} + a_2 q^{-2} + ... + a_m q^{-m} \tag{3}$$

$$B_j(q) = b_{j,1} q^{-1} + b_{j,2} q^{-2} + ... + b_{j,m} q^{-m} \tag{4}$$

where y denotes the output variable (e.g., median particle size, d_{50}), and u denotes the manipulated variable (e.g., binder flow). The terms A and B contain the autoregressive and exogenous terms of the model, respectively. The autoregressive term captures dynamics through lagged terms of the output, and the exogenous term captures dynamics through lagged terms in the input.

Once the models have been calculated from the plant data, it is useful to evaluate their properties using several key statistical measures. Some of the useful statistics that are associated with reduced space models (Wise et al. 2006) are outlined below:

Q residual – is simply the sum of squares of each row of E (from eq. 1), i.e. for the ith sample in X, x_i:

$$Q_i = e_i e_i^T \tag{5}$$

where e_i is the ith row of E. The Q statistics is a measure of the difference between a sample and its projection into the a principal components retained in the model.

Hotelling T^2 is a measure of the variation in each sample within the model. Its value is the sum of normalized squared scores, defined by:

$$T_i^2 = t_i \lambda^{-1} t_i^T \tag{6}$$

where t_i are the score vectors (eq. 1) and λ is a diagonal matrix containing the eigenvalues corresponding to a eigenvectors (principal components) retained in the model.

Together, the T^2 and Q residual statistics are useful in evaluating the fitness of a PLS model to specific data. It is possible to calculate statistically meaningful confidence limits for both cases.

2.2 Simulation studies

In our previous work, a nonlinear one dimensional population balance model (1D-PBM) was successfully used to model a laboratory continuous drum granulation process with fine particle recycle (Glaser et al., 2008). The same model is used here as a base for a process simulation (Figure 1) for a preliminary evaluation and sensitivity test of the applicability of the dynamic PLS modeling technique for granulation.

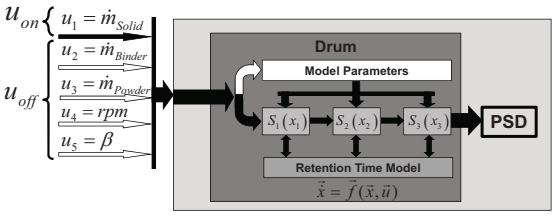

Fig. 1. Simulator structure: five inputs are included in the simulator: binder spray rate, fine powder feed-rate, drum rotation-rate and the drum inclination angle. The model is divided into three well mixed drum compartments, each described by an individual set of ODEs, a retention time model and a set of global parameters that influence the model behavior (taken from Glaser 2008).

Both particle median size (d_{50}) and, separately, particle size distribution width (d_{84}/d_{16}) were used as output variables for this study. The predictor (X) was constructed from 4 manipulated variables (solid feed flow rate, binder feed flow rate, drum rotation speed, recycle rate) and the computed recycle flow as an additional input variable. Process dynamics were incorporated into the X block by including columns of lagged output variables. The lag time was estimated using an autocorrelation function. Delay times of each of the input variables were estimated using cross correlation function, and the predictor matrix was adjusted according to the obtained delay vector. During the simulation, the 4 manipulated variables were randomly perturbed around their nominal values at steady state sequentially, i.e. input variables were perturbed one after the other in fixed time gaps. The resulting PLS-based ARX model's short horizon predictive ability was tested by cross validation with a set of separately calculated simulation sequences with different excitation regimes. For each of these cross validation sequences, the root mean square error of the model based prediction (RMSEP), relative to the simulated plant measurements was calculated for a given short horizon period. In order to make a more representative quantification of the predicting ability of the model, the short horizon start point was moved along the time axis of the data one time step after another thus creating a set of RMSEP measures out of which an average and maximum RMSEP could be calculated. All variables were mean centered and scaled to unit variance prior to processing.

Based on this technique a sensitivity test was performed in order to estimate the required size of the data set needed for reliable process modeling. Figure 2 shows the convergence of RMSEP related to the length of data set used for the PLS model training. This plot is based on averaging 100 multiple simulations and modeling runs for each training length. Sample rate was set to 2 minutes and the simulated process step response time (τ) was set to 4.5 minutes. The prediction horizon was set to 8 samples (i.e., 16 minutes). From this figure one can note that most of the dynamic features are captured by the model in the first 200 minutes of training data, as the mean RMSEP converges to low values. However using training data of up to 600 minutes would improve the model predictions. Notice that these results are not so sensitive to the excitations rate used in the modeling data set (i.e., time between two successive input variable perturbations), as long as this time is in the order of magnitude of the expected variations in process variables. Figure 3 depicts the response of the process model obtained with 520 minutes of training data to the process simulation for a step response in one of the input variables.

All of these models use one lagged output variable (granules median size) in the predictor block and 2 latent variables in the PLS model, which are linear combinations of the time-lagged values of the output variable and the delayed values of the five process variables. Figure 4 shows the prediction abilities of three PLS models obtained using different lengths of data sets for training (120, 220 and 520 minutes long) from a single simulation data, with input variable excitation every 15 minutes. In this example, the predictions of these models are cross-validated using data from a separate simulation run with randomly timed excitations of the inputs. Considering that PLS models captures covariance in X and Y, it is possible to calculated the percentage of variance captured by each of their latent variables by dividing the variance predicted by the latent variables to the total variance in the original data. The percentage of variance captured by the abovementioned 3 PLS models (from the training data) is detailed in Table 1. It is noticeable that the longer the training set used, more fine details of the process dynamics are captured by the models, confirming Figure 2 results. Notice that high values of explained variance do not guarantee good prediction of validation data by these models. The robustness of the PLS based models to measurement noise is demonstrated in Figure 5 and Table 2, where the simulated process was subject to 5% white noise on the output and input variable measurements.

3. DYNAMIC PLS MODELLING OF AN INDUSTRIAL PROCESS PLANT

3.1 Process plant description

In this section, we report on some preliminary studies on granulation model identification for a Procter & Gamble (P&G) industrial granulation process using normalized process data.

A complex industrial granulation process, such as the flowsheet shown in Fig. 6, was subjected to a series of (designed) random perturbations in a number of input parameters. This plant is equipped with an on-line granule size measurement system that measures particle size based on image analysis of 2-D camera images. The analysis constructed size distributions on the basis of the measured cross sectional area of the 2-D images. Granule size data along with all other plant variables were then sent to the UCSB team for modeling.

There are notable distinctions between the P&G study and the one reported in Section 2.2. The P&G process study is not meant to be used as a direct comparison (or validation) for the process simulation studies in Section 2.2. Rather, we present both as separate case studies to demonstrate the feasibility of using PLS methodology as an empirical modeling tool for granulation process control.

The low-shear drum-granulation pilot plant that was used to design the simulator in Section 2.2 produced particles with d_{50}'s of several mm; on the other hand, the medium-high shear mixer-granulation process shown in Fig 6 typically produced particles with d_{50}'s less than 1 mm. While the underlying physical mechanisms of growth and consolidation may be similar, the flow and shear fields are very different for the two processes (the drum granulator is relatively low shear, compared to the medium-high shear mixer-granulation process), the process layouts and control handles are different, as are the material properties. As such, the choices of process variables (manipulated and measured) are unique for each process.

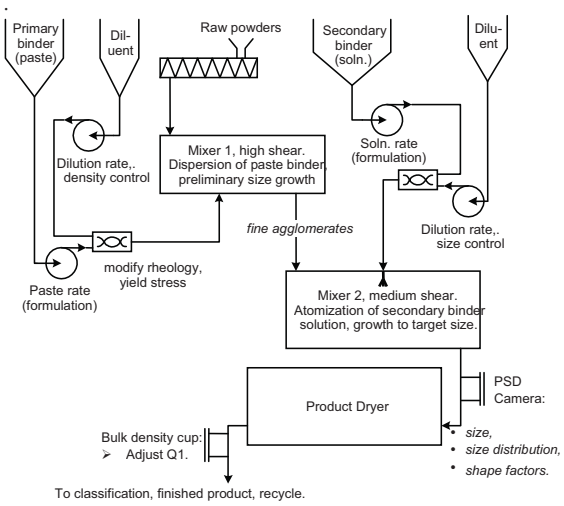

Figure 6. Representative P&G process flow diagram for mixer-granulator (Mort et al. 2001). For simplicity, this diagram omits the usual operations for classification and recycle.

3.2 PLS modeling of real plant data- Case I

Figure 7 describe the dynamic PLS model fitting obtained for the granules median size. The data set obtained from the plant originally contained 147 sampling points, each consist of 81 process variables, together with granules size measurements. Sampling time was 0.4 times the process characteristic time τ. During this time period 4 manipulating variables were subjected to random perturbations around their nominal values at steady states (Fig. 8) in a similar way to the simulation work described earlier (adjusted to the process τ), while other adjustments were continuously made to other plant variables (i.e. normal plant operations). Granules median size (d_{50}) was selected as the output variable. Nine out of the 81 process variables were chosen as predictor variables for the PLS model, based on engineering judgment, GA based variable selection (PLS Toolbox 5.0 by Eigenvector research incorporated), and trial and error. The

output lag time and process variables delay times were evaluated using the auto and cross correlation functions, respectively, as described in section 2.2. The process model uses two latent variables, which are linear combinations of the time-lagged values of the output variable and the delayed values of the nine process measurements. For an independent cross validation of the model, the above data was divided to two sections – the first half was used to train the PLS model, and the second used to test model predictions, yielding RMSEP value of 0.26. These results, as shown in Fig. 9. and Table 3, are very similar to the fitting obtained for the simulation data of the same training length to τ ratio (Fig. 2 and Fig 4. upper plot).

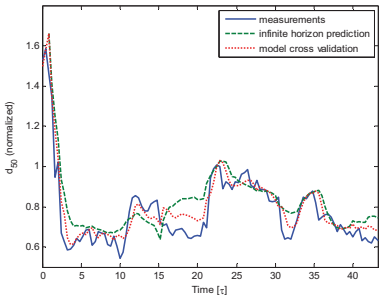

Fig. 7. Dynamic PLS model fitting to plant d_{50} data.

Table 3: Percent variance captured by PLS model, plants' d50 data.

Training set length	LVs	X Block		Y Block	
		LVi	Total	LVi	Total
60τ	1	24.97	24.97	79.34	79.34
	2	25.09	50.06	9.04	88.38
36τ	1	39.46	39.46	72.13	72.13
	2	23.31	62.77	16.8	88.92

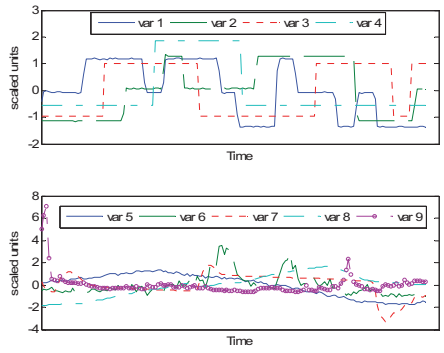

Fig. 8. Values of the 9 predictor variables used in Case I PLS model – 4 manipulated variables (top) and 5 additional process variables (bottom)

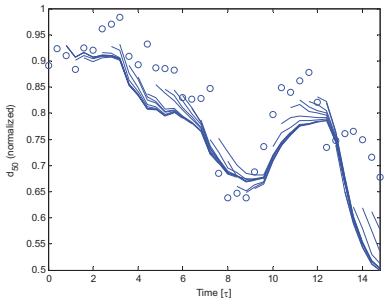

Fig. 9. Cross validation of the dynamic PLS model for plant d_{50} data. Circles represents measurements, lines represent 8 point horizon prediction.

3.3 PLS modeling of real plant data- Case II

In a separate test, the granules distribution width as a function of selected process variables was modeled. This analysis was performed on two limited sets of data, each from a different operating day. A series of step tests were performed on one of the manipulating variables. As in the previous case, other adjustments were continuously made to other plant variables to maintain normal plant operation. The standard deviation of the granules measured area was used as the output variable to be modeled. A dynamic PLS model was built using 3 input variables and one lagged output variable, based on the first data set, and then validated using the second data set, resulting in an excellent fit (Figure 10). In this case, as well, the process model uses two latent variables.

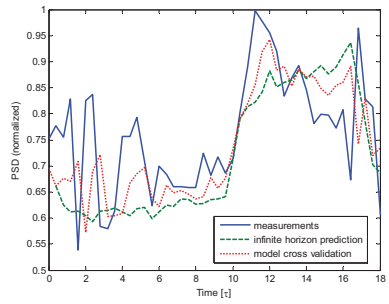

Fig. 10. Actual process data (granules area standard deviation): Cross validation of model based on first data set, tested on second data set

On the scores plot (Figure 11) it is clear, however, that these two sets represent different and distinct operating conditions. If one further examines the contribution of each variable for these two sets (Figures 12) we can see that the main difference is that on the validation set, much lower values of variable 2 were used, compared to the modeling set. It is also interesting to note that the only outlier of the modeling set also exhibits the same low value on variable 2.

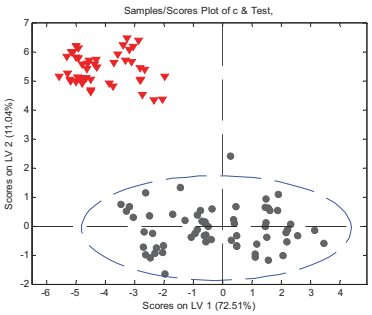

Fig. 11. Score Plots for the PSD width model. Circles are samples from the modeling set; Triangles are samples from the validation set. The ellipse marks the 95% confidence limit for the model.

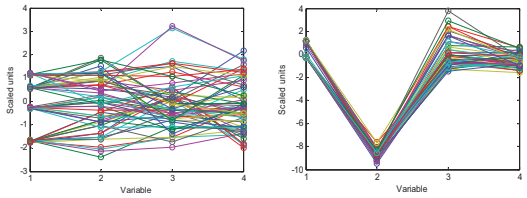

Figure 12: Values of input variables used in the modeling set (left) and in the validation set (right).

Although these results looks promising with respect to the ability to analyze and predict the granulation process variables, a quick look at the high values of Q residuals and Hotelling T^2 (Figure 13) indicates that this model is far from describing the whole complexity of the process, and many more measurements should be done in order to characterize the different operating regimes of this process.

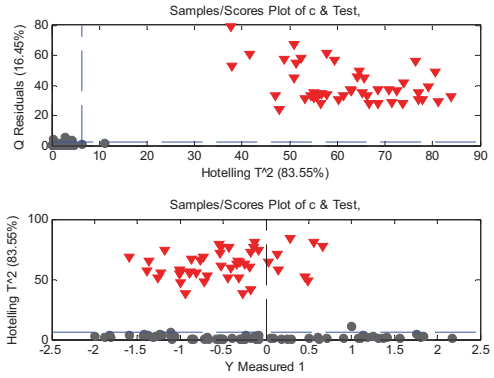

Figure 13: Q Residuals and Hotelling T^2 Values for the PSD width model

4. CONCLUSIONS

Dynamic PLS modeling was proven to be an effective tool in modeling key process variables in an industrial granulation process. Our future work will explore methods to capture the additional dynamics that remain in the plant data. We are also planning longer plant runs with larger input variable excitation to improve the model identification. Longer term goals are to develop a model-based controller for plant testing.

Funding for this work from IFPRI (International Fine Particle Research Institute) is gratefully acknowledged.

Abstract: The problem of designing the estimation structure to perform a specific (entire profile, single/two-effluent, and so son) concentration estimation task in a binary distillation column with two temperature measurements is addressed within a geometric estimation (GE) framework. The structure design involves the choices of: (i) the measurement locations, (i) the complete or truncated estimation model, and (iii) the innovated-noninnovated state partition of the model. First, a structural analysis is performed on the basis of detectability measures in the light of the column characteristics, yielding candidate structures for a specific estimation task. Then, the behavior of the structures is assessed with estimator functioning and dimension considerations, yielding conclusive structural results. The proposed methodology is applied to a representative case example with experimental data.

Keywords: Nonlinear estimator, geometric estimator, nonlinear system realization, distillation column estimation.

1. INTRODUCTION

The study of the concentration estimation problem for distillation columns is motivated by the development of advanced monitoring and control schemes. The estimator design involves decisions on: (i) the structure (sensor number and locations), and (ii) the kind of (EKF, Luenberger, Geometric, etc) algorithm. In the distillation column estimation field: (i) the EKF has been, by far, the most widely employed and accepted algorithm, (ii) the sensor structure has been decided with heuristics (Oisiovici and Cruz, 2000) or observability measures (van der Berg et al. 2000; Singh and Hahn, 2005), (ii) only in a few studies (Alonso et al, 2004; Bian and Henson 2006; Venkateswarlu and Kumar, 2006; Kadu et al, 2008) the measure-based sensor location results have been tested with estimator functioning and is not clear to what extent the results depend on tuning. In principle, the resolution of this drawback requires a unified framework to address the algorithm, sensor location, and tuning aspects.

Recently (Alvarez and Fernandez, 2009), the general-purpose nonlinear geometric estimator (GE) (Alvarez and Lopez, 1999; Alvarez 2000) has been redesigned with: (i) an implementation in terms of model Jacobian matrices (and not of the cumbersome or intractable Lie derivation-based gain of the nonlinear Luenberger observer), (ii) the structure (sensors, complete/truncated model, innovation scheme) as a key design degree of freedom, and (iii) a simple tuning procedure based on a robust convergence criterion, regardless of the structure, and (iv) testing with an experimental binary distillation column. This adjustable-structure GE methodology and the associated nonlinear detectability measures (Lopez and Alvarez, 2004) constitute the methodological points of departure for the present study.

In this work, the problem of designing the best estimation structure (in terms of reconstruction speed, robustness, and algorithm simplicity) to perform a specific (entire profile or two-effluent) concentration estimation task in a binary distillation column with two temperature measurements is addressed, with structure meaning the choices of: (i) the *measurement locations*, (i) the (complete or truncated) *estimation model*, and (iii) the innovated-noninnovated model *state partition*. The proposed methodology is applied to a representative case example with experimental data.

2. ESTIMATION PROBLEM

2.1 Column system and model

Consider an N-stage binary distillation column, with molar feed flow F in tray n_f at (light-component) mole fraction c_F, and bottoms (or distillate) flow B (or D) at composition c_B (or c_D), and a total condenser. Under standard (constant pressure, stage equilibrium, fast holdup dynamics with perfect mixing, evaporator level control, constant molar flow, saturated feed, and adiabatic system) assumptions the *N-composition column model* is given by (Luyben, 1990)

$$\dot{c}_1 = \{(R + F)(c_2 - c_1) - V[\varepsilon(c_1) - c_1]\}/M_1 := f_1, \qquad c_B = c_1$$

$$\dot{c}_i = \{(R + F)(c_{i+1} - c_i) - V[\varepsilon(c_i) - \varepsilon(c_{i-1})]\}/\eta^{-1}(R + F) := f_i,$$
$$1 \le i \le n_f - 1, \qquad \eta(M) = a_\eta(M - M_o)^{b_\eta}$$

$$\dot{c}_{nf} = \{(R + F)(c_{nf+1} - c_{nf}) - V[\varepsilon(c_{nf}) - \varepsilon(c_{nf-1})] + F(c_F - c_{nf})\}/\eta^{-1}(R + F) := f_{nf}$$

$$\dot{c}_i = \{R(c_{i+1} - c_i) - V[\varepsilon(c_i) - \varepsilon(c_{i-1})]\}/\eta^{-1}(R) := f_i, \quad n_f + 1 \le i \le n-1$$

$$\dot{c}_N = \{R[\varepsilon(c_N) - c_N] - V[\varepsilon(c_N) - \varepsilon(c_{N-1})]\}/\eta^{-1}(R) := f_N, \; c_D = \varepsilon(c_N)$$
$$y_1 = T_1 = \beta(c_{l1}), \qquad y_2 = T_2 = \beta(c_{l2})$$

c_i is the i-th stage mol fraction of light component, V (or R) is the vapor (or reflux) flow, M_i is the i-th stage molar holdup, and T_i is the temperature measurement at the l_1-th stage, ε, β, and η are the liquid-vapor, bubble point, and (Francis weir equation) hydraulics functions, respectively. Assuming the feed composition is fixed at $\bar{c}_e$, the *preceding N-composition column model* is written by

$$\dot{c} = f_c(c, u), \quad c(0) = c_o, \quad y = h(c) := [\beta(c_{l_1}), \beta(c_{l_2})] \qquad (1)$$
$$c = (c_1,\ldots, c_N)', \quad u = (F, R, V)', \quad \dim (c, y, u) = (N, m, 3, 1)$$

In virtue of the afore stated modeling assumptions, the *actual column dynamics* are given by

$$\dot{c} = f_c(c, u) + \tilde{f}_c(c, \xi, d), c(t_o) = c_o, \ y = h(c) + \tilde{h}_c(c, \xi) + e_y \quad (2a)$$
$$\dot{\xi} = f_\xi(c, \xi, d, \dot{d}), \qquad \xi(t_o) = \xi_o, \ d = (u, e_u, d_e), \dim \xi = n_\xi \quad (2b)$$

with concentration (or unmodeled) state x (or ξ), actuator error e_u, and unmodeled exogenous input d_e. The unmodeled dynamics (2b) have slow and fast components due to the modeling-measurement errors, including holdup and enthalpy QSS assumptions. Thus, the N-composition model (1) is the actual system (2) with the modeling assumption $(\tilde{f}_c, \tilde{h}_c, e_y) = 0$.

2.2 *Adjustable*-structure estimation model

Following a previous binary distillation column GE (Alvarez and Fernandez, 2009) study with the estimation model regarded as design degree of freedom, rewrite the actual column dynamics (1) in terms of $n \le N$ modeled compositions (x):

$$\dot{x} = f(x,u) + \tilde{f}(x, \chi, d, u), x(t_o) = x_o, \ y = h(x) + \tilde{h}(x, \chi) + e_y \quad (3a)$$
$$\dot{\chi} = f_\chi(x, \chi, d, \dot{d}), \ \chi(t_o) = \chi_o, \ (x, x_\varnothing) = I_c c, \ \chi = (x_\varnothing, \xi) \qquad (3b)$$

where $x_\varnothing$ are the unmodeled concentrations and χ is the augmented unmodeled state. The vector f depends only on the modeled concentrations x, due to a key modeling assumption made for estimator decentralization purposes (Alvarez and Fernandez, 2009): (i) f is the part of f_c that describes x, and is calculated with the unmodeled state at an average constant value ($\bar{x}_\varnothing$), as the related error can be effectively compensated by the GE integral action when the estimation structure is adequately chosen. In terms of κ_1 (or κ_2) *innovated sates* x_1 (or x_2) and (n - κ) *noninnovated states* (x_ι), the *actual dynamics* (2) are given by

$$\dot{x}_1 = f_1(x_1, u) + \tilde{f}_1(x, \chi, d, u), y_1 = h_1(x_1) + \tilde{h}_1(x, \chi) + e_1 \quad (4a)$$
$$\dot{x}_2 = f_2(x_2, u) + \tilde{f}_2(x, \chi, d, u), y_2 = h_2(x_2) + \tilde{h}_2(x, \chi) + e_2 \quad (4b)$$
$$\dot{x}_v = f_v(x_v, x_1, x_2, u) + \tilde{f}_v(x, \chi, d, u), \quad x_v(t_o) = x_{vo} \quad (4c)$$
$$\dot{\chi} = \tilde{f}_\chi(x, \chi, d, \dot{d}), \ \chi(t_o) = \chi_o, \ x_1(t_o) = x_{1o}, \ x_2(t_o) = x_{2o} \quad (4d)$$

where $(x_1, x_2, x_v, x_\varnothing) = I_c c$, $\dim (x_1, x_2, x_v) = (\kappa_1, \kappa_2, \kappa_v)$
$\kappa_1 + \kappa_2 = \kappa_\iota$, $\kappa_1 + \kappa_2 + \kappa_v = n \le N$, $(x_1, x_2) = x_\iota$, $\dim (x_\iota) = \kappa_\iota$

f_1 (or f_2) corresponds to x_1 (or x_2), and is calculated with some (average) constant value [$\bar{x}_1$(or $\bar{x}_2$), $\bar{x}_v$]. From the specialization of the general-purpose definition of model structure [Alvarez and Fernandez, 2009] to the binary column case, the definition of *column model structure* follows

$$\sigma = (\kappa, x_\iota\text{-}x_v), \ \kappa = (\kappa_1, \kappa_2), \ \kappa_1 + \kappa_2 = \kappa_\iota \le n, \ x_\iota = (x_1', x_2')' \quad (5)$$

where κ is the *estimation order* vector, x_ι-x_v is the innovated-noninnovated state partition, and x_1 (x_2) are κ_1 (or κ_2) adjacent concentrations associated with the measurement y_1 (or y_2). Thus, from the enforcement of the modeling assumption

$$(\tilde{f}_1, \tilde{f}_2, \tilde{f}_v) = 0, \qquad (\tilde{h}_1, \tilde{h}_2) = 0, \qquad (e_1, e_2) = 0 \qquad (6)$$

upon the actual subsystem (4a-c), the *estimation model*, with estimation structure σ (5), follows:

$$\dot{x}_1 = f_1(x_1, u), \qquad x_1(t_o) = x_{1o}, \qquad y_1 = h_1(x_1) \qquad (7a)$$
$$\dot{x}_2 = f_2(x_2, u), \qquad x_2(t_o) = x_{2o}, \qquad y_2 = h_2(x_2) \qquad (7b)$$
$$\dot{x}_v = f_v(x_v, x_1, x_2, u), \quad x_v(t_o) = x_{vo} \qquad (7c)$$

2.3 Adjustable-structure geometric estimator (GE)

In virtue of the σ-detectability property of the N-composition staged model (7), the (possibly truncated) model state (x) can be on-line robustly estimated by the *geometric estimator (GE) with structure* σ:

$$\dot{\hat{x}}_1 = f_1(\hat{x}_1, u) + O_1^{-1}(\hat{x}_1, u)\{\pi_1\hat{\iota}_1 + k_1(\zeta_1, \omega_1)[y_1 - h_1(\hat{x}_1)]\},$$
$$\hat{x}_1(t_o) = \hat{x}_{1o}; \qquad \dot{\hat{\iota}}_1 = \omega_1^{\kappa 1+1}[y_1 - h_1(\hat{x}_1)]\}, \quad \hat{\iota}_1(0) = \hat{\iota}_{1o} \qquad (8a)$$
$$\dot{\hat{x}}_2 = f_2(\hat{x}_2, u) + O_2^{-1}(\hat{x}_2, u)\{\pi_2\hat{\iota}_2 + k_2(\zeta_2, \omega_2)[y_2 - h_2(\hat{x}_2)]\},$$
$$\hat{x}_2(t_o) = \hat{x}_{2o}; \qquad \dot{\hat{\iota}}_2 = \omega_2^{\kappa 2+1}[y_2 - h_2(\hat{x}_2)], \quad \hat{\iota}_2(0) = \hat{\iota}_{2o} \qquad (8b)$$
$$\dot{\hat{x}}_v = f_v(\hat{x}_\iota, \hat{x}_1, \hat{x}_2, u) \qquad \hat{x}_v(t_o) = \hat{x}_{vo} \qquad (8c)$$

where: $k_i(\zeta_i, \omega_i) = [a_1^i(\zeta_i)\omega_i, \ldots, a_{\kappa i}^i(\zeta_i)\omega_i^{\kappa i}]'$ (9c)
$O_i'(x_i, u) = [\beta'(c_{l_i})e_i[I, A_i(x_i, u),\ldots,A_i^{\kappa i+1}(x_i, u)], \ i = 1, 2$ (9a)
$A_i(x, u) = \partial_x f(x_i, u), \ \pi_i = (0, \ldots, 0, 1)', \ \dim \pi_i = \kappa_i$ (9b)
$|\beta'(c_{l_1})| \ge \varepsilon_T, \quad |\beta'(c_{l_2})| \ge \varepsilon_T$ (10a-b)

ζ_i (or ω_i) is the damping factor (or characteristic frequency) of the prescribed linear, noninteractive, pole assignable (*LNPA*) output error dynamics

$$\tilde{y}_i^{(\kappa i+1)} + a_1^i(\zeta_i)\omega_i\tilde{y}_i^{(\kappa i)} + \ldots + a_1^i(\zeta_i)\omega_i\tilde{y}_i^{(1)} + \omega_i^{\kappa i+1}\tilde{y}_i = 0, \ i = 1, 2 \quad (11)$$

with coefficient sets $\{a_1,\ldots, a_{\kappa_1}\}_i$ determined by pole placement (Lopez and Alvarez, 1999). The invertibility of O_1 and O_2 is ensured by the tridiagonal state dependency of f_c and the sensor location condition (10) which amounts placing each sensor at a tray with temperature gradient larger than a minimum value (say, two degrees). For any model structure σ (5) (Alvarez and Fernandez, 2009): (i) the afore stated nonlocal robustness convergence feature holds with respect to the N-composition model (1) with decentralization,

truncation, and actuator-measurement errors, and (ii) the rather simple GE tuning scheme applies to any structure. Thus, the adjustable structure-algorithm GE methodological framework offers the means to fairly compare the behavior of different structures, in the sense that the behavior differences are due to the structures itself and not to the tuning.

2.4 Estimation structure design problem

In view of the preceding adjustable-structure column GE approach, *our present problem* consists in, given a specific estimation objective, determining the two-measurement structure, which yields the best estimator behavior in terms of reconstruction speed, robustness and dimensionality. Technically speaking, the problem amounts to choosing the (complete or truncated) estimation model (7) and its σ-detectability structure (5), or equivalently: (i) the location l_1 (or l_2) of the temperature measurement y_1 (or y_2), (ii) the corresponding innovated concentrations x_1 (or x_2), and (iii) the noninnovated state (x_v).

2.5 Structure search methodology

From the perspective of a general-purpose mixed-integer optimization approach, in our 12-stage distillation column example, the N-composition model offers 527, 345 structural possibilities with 4,095 observable (or passive) ones structures, and the number of possibilities grows even more when model truncation is considered. Leaving aside the implementation complexity and difficulties of an optimization-based search method, in the spirit of the constructive control (Sepulchre, 1997) and GE (Alvarez and Fernandez, 2009) approaches, here the structural search will performed by exploiting the column staged feature in the light of the easy to compute version (Alvarez and Fernandez, 2009) of the GE detectability measures (Lopez and Alvarez, 2004), in two steps: (i) first, detectability measures will be used to draw candidate structures for a given estimation objective, and (ii) then, conclusive structural results will be obtained in terms of GE functioning.

2.6 Experimental case example

The proposed methodology will be illustrated and tested with experimental case example employed before to illustrate and test the theoretically drawn features and capabilities of the general-purpose GE approach (Alvarez and Fernandez, 2009): a methanol-water mixture feed F = 40 ml/min, at light component composition c_e = 0.2 and temperature 57°C. Initially, the column was at a steady-state with low reflux ratio (R/D = 0.2) and poor separation ($c_B \approx 0.0$, $c_D \approx 0.57$). Then, at time t = 0, a feed concentration step increase (c_e: 0.2 → 0.4) was introduced, yielding: (i) an overall composition response that settled (≈ 40 min) at an intermediate separation steady-state ($c_B \approx 0.01$, $c_D \approx 0.79$), and (ii) a distillate (or bottoms) composition settling time of ≈ 15 (or 40) min. Finally, at t = 40 min, a reflux step increase (R/D: 0.2 → 1.5) was introduced, yielding: (i) an overall response that settled (≈ 60 min.) at a high-separation steady-state ($c_B \approx 0.15$, $c_D \approx 0.98$), and (ii) a distillate (or bottoms) composition settling time of ≈ 20 (or 50) min. The experimental data can be seen in (Alvarez and Fernandez, 2007 and 2009).

3. STRUCTURAL ANALYSIS

In this section, the dependency of the GE detectability measures (Lopez and Alvarez, 2004; Alvarez and Fernandez, 2007) over sensor location and innovated state dimension are analyzed to draw candidate structures for complete profile and two-effluent estimation purposes.

3.1 Detectability measures

To account for the effect of the decentralization-truncation performed in the passage from the complete N-composition (1) to the truncated-decentralized n-composition estimation model (7) with structure σ (5), the detectability measures (12) for the next N-composition model (13) with innovated-noninnovated state partition will be employed (Alvarez and Fernandez, 2009):

$$s_\iota = 1/\mathrm{msv}(O), \quad c_\iota = \mathrm{cn}(O) \qquad (12a\text{-}b)$$

$$s_v = \mathrm{msv}(F), \quad c_v = \mathrm{cn}(F); \quad \lambda_v = \tfrac{1}{2}\,\mathrm{lev}(F + F') < 0 \qquad (12c\text{-}d)$$

$$\dot{x}_\iota = f_\iota(x_\iota, x_v, u), \quad x(0) = x_{\iota o}, \; y = h(x_\iota), \; \dim(x_\iota) = N \qquad (13a)$$

$$\dot{x}_v = f_v(x_\iota, x_v, u), \quad x_v(t_o) = x_{vo}, \quad \dim(x_v) = N\text{-}n \qquad (13b)$$

where $O(x, u) = \mathrm{bd}(E_1^\dagger, E_2^\dagger)'(x, u)$, $A_i(x_i, u) = \partial_{x_\iota} f_\iota(x, u)$

$F(x, u) = [\partial_{x_v} f_v + \partial_{x_\iota} f_v O^{-1} D](x, u)$, $A_v(x, u) = \partial_{x_v} f_v(x, u)$

$E_i^\dagger(x, u) = \beta'(c_{l_i}) e_i(I, A_i, \ldots, A_i^{\kappa i-1})(x, u)$, $i = 1, 2$

$D'(x, u) = \beta'(c_{l_i}) e_i(I, A_v, \ldots, A_v^{\kappa i-1})(x, u)$, $(x_1^\dagger, x_2^\dagger)' = x_\iota$

s_ι (or s_v) is the singularity measure equal to the inverse of the minimum singular value (msv) of the matrix O (or F), c_ι (or c_v) is the illconditioning measure equal to condition number (cn) of the matrix O (or F), and λ_v is the dominant frequency of the noninnovated dynamics, or equivalently, the negative of the smallest eigenvalue (lev) of the matrix (F + F')/2, O is the estimation matrix of the σ-structure model (13), and F is the Jacobian matrix of the noninnovated dynamics (13b). The illconditioning value c_ι (or c_v) measures the overshoot response of the innovated (or noninnovated) state estimation error to an initial estimate error, and the singularity value s_ι (or s_v) measures the asymptotic offset of the innovated (or noninnovated) state error due to persistent modeling errors, and the number λ_v measures the convergence rate of the noninnovated state error dynamics. In general, these measures can be taken over a column motion x(t) (Lopez and Alvarez, 2004). In our column case, the detectability measures will be computed at the intermidiate steady state (reached after ≈ 40 min).

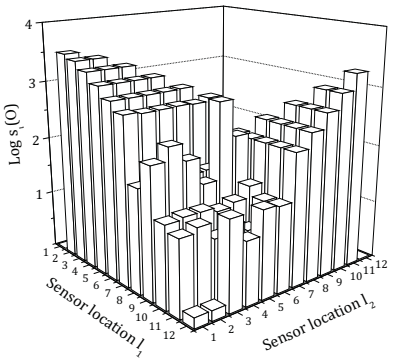
3.2 Measurement locations

In Figure 1 are presented the singularity (s_ι) and ill conditioning (c_ι) measures (12) of the estimation matrix O (9a) as function of the sensor location pair (l_1, l_2), for a completely observable structure σ (5) with estimation order pair $\kappa = (\kappa_1, \kappa_2) = (6, 6)$ and $\kappa_\iota = \kappa_1 + \kappa_2 = 12 = n = N$ (i.e., complete model with observable structure), showing that: (i) the largest singularity and illconditioning values are obtained with the sensor stage location pair (l_1, l_2) ≈ (1 to 2, 12), (ii) the smallest singularity and illconditioning values are

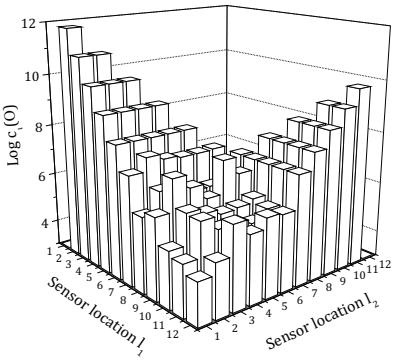
obtained with the sensor location $(l_1, l_2) \approx (1, 2)$ [or (11, 12)] with two adjacent sensors in the bottom (or top) of the column, followed by the sensor location $(l_1, l_2) \approx (5, 6)$ with two adjacent sensors above or below the feed tray (5). These consideration lead to the *following conclusions*: (i) the two sensors should not be in the same section, and (ii) the best location pair for complete profile estimation is given by

$$(l_1, l_2) = (2, 12) := (l_s, l_e) \tag{14}$$

meaning one sensor in stage $l_s = 2$ (tray one) [or $l_e = 12$ tray 10] of the stripping (or enriching section), precisely in the stage with the largest temperature and concentration stage-to-stage gradient.



a)



b)

Fig. 1: Dependency of the singularity s_t and ill conditioning c_t of the estimation matrix O on the sensor location pair (l_1, l_2), for comple observable structure σ (5) estimation order pair $\kappa = (\kappa_1, \kappa_2)$ and $\kappa_1 + \kappa_2 = 12$.

These location results are in agreement with location criteria employed in: (i) two-point temperature PI control of distillation columns (Tolliver, 1980; Castellanos-Sahagun et al., 2005), and (ii) previous distillation column studies with EKF (Baratti et al., 1995; Oisiovici and Cruz, 2000).

3.3 Innovated state dimension pair

Next, the sensor pair location (14) determined in the last section for the complete model (1), with observable structure κ (5), is kept fixed, and the dependency of the illconditioning c_t (12a) and the speed parameter λ_v (12c) of the noninnovated dynamics upon the innovated state dimension (or equivalently, estimation order) pair $\kappa = (\kappa_s, \kappa_e)$ is examined, with κ_s (or κ_e) being the number of adjacent innovated states x_s (or x_e) associated with the measurement y_s (or y_e) of the stripping (or enriching) section. The resulting measure c_t (or λ_v) is presented in Figure 2a (or 2b), showing that the illconditioning measure c_t remains within a reasonable bound $(1 \le c_t \le 100)$ for all the estimation order pairs with at most three innovated states per measurement $[(\kappa_s, \kappa_e) \le (3, 3)]$. As expected (Lopez and Alvarez, 2004): (i) the passive structure $(\kappa_s, \kappa_e) = (1, 1)$ yields the smallest possible value $c_t = 1$, and (ii) the speed parameter λ_v of the noninnovated dynamics is minimum ($\lambda_v = 0$) when the structure is observable with $(\kappa_s, \kappa_e) = (6, 6)$. These results are consistent with the general-purpose GE approach (Alvarez y Fernandez, 2009): (i) as the number of innovated states grows, the reconstruction speed grows and the robustness decreases, and (ii) the maximum robustness is obtained with the passive structure $(\kappa_s, \kappa_e) = (1, 1)$, and (iii) the maximum reconstruction speed is obtained with the observable structures $(\kappa_s, \kappa_e) = (6, 6)$.

3.4 Candidate structures

From the preceding structural analysis the next results follow. For *complete profile estimation*, the candidate models are decentralized versions of the N-concentration model (1) with structure σ (5):

$$\dot{c}_s = f_s(c_s, u), \qquad \dot{c}_e = f_e(c_e, u), \quad y = h(c) \tag{15a}$$
$$(\kappa_s, \kappa_e) \le (3, 3), \quad (l_s, l_e) = (2, 12) \tag{15b}$$

For *two-effluent estimation*, the candidate model is the truncated-decentralized model with passive structure σ (5):

$$\dot{c}_1 = \{(R + F)(c_2 - c_1) - V[\varepsilon(c_1) - c_1]\}/M_1, \tag{16a}$$
$$\dot{c}_2 = \{(R + F)(\bar{c}_3 - c_2) - V[\varepsilon(c_2) - \varepsilon(c_1)]\}/\eta^{-1}(R + F), \; y_s = \beta(c_2)$$
$$\dot{c}_{12} = \{R[\varepsilon(c_{12}) - c_{12}] - V[\varepsilon(c_{12}) - \varepsilon(\bar{c}_{11})]\}/\eta^{-1}(R), \quad y_e = \beta(c_{12})$$
$$(\kappa_s, \kappa_e) = (1, 1), \qquad (l_s, l_e) = (2, 12) \tag{16b}$$

4. STRUCTURAL RESULTS

Having as point of departure the suggestive structural results (15, 16) of the last section, in the present section conclusive results are obtained by assessing the candidate structures in terms of reconstruction speed and robustness.

4.1 Estimator tuning and convergence

The column (or holdup) dominant (or fastest) frequency ω_c (or ω_η) was determined from the experimental data and the detailed model (1), the estimator frequency ω is written as n_ω times ω_n, and the adjustable constants (20) are listed next:

$$(\omega_c, \omega_\eta) \approx (1/15, 1)\ \text{min}^{-1};\ \zeta_s, \zeta_e, \omega_s = \omega_e = \omega = n_\omega \omega_c \tag{17-18}$$

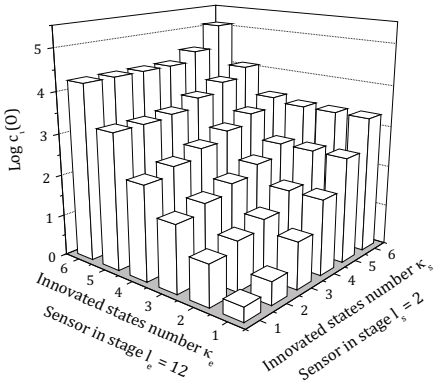
Thus: (i) there are three adjustable gains (ζ_s, ζ_e, n_ω), and (ii) the limit upper ω^+ is related to ω_η. From the specialization to

the column case of Lemma and Proposition 1 in (Alvarez and Fernandez, 2009): (i) the GE error dynamics is robustly stable if the stabilizing term λ_s dominates the potentially destabilizing one λ_d (λ_s and λ_d defined in Alvarez and Fernandez, 2009), according to inequality (19), or equivalently, if: (i) the related threshold equation (20) has two strictly positive and sufficiently separated roots (ω^- and ω^+) for ω, and (ii) the gain frequency ω (18) of the prescribed LNPA output error dynamics (11) is chosen so that the low-high gain conditions (21) are met:

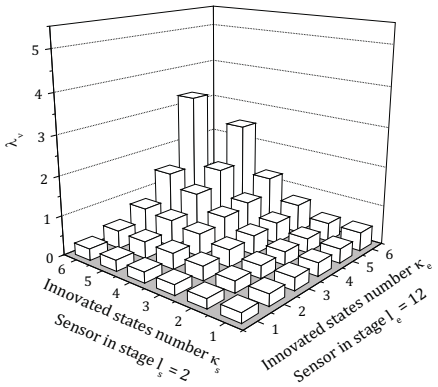
$$\lambda_s(\omega, \zeta, \sigma) - \lambda_d(\omega, \zeta, \sigma) := \lambda(\omega, \zeta, \sigma) > 0, \quad \zeta = (\zeta_s, \zeta_e) \qquad (19)$$

$$\lambda(\omega, \zeta, \sigma) = 0 \quad \Rightarrow \quad \exists \quad \omega = \omega^-(\zeta, \sigma), \quad \omega^+(\zeta, \sigma) \qquad (20)$$

$$0 < \omega^-(\zeta, \sigma) < \omega < \omega^+(\zeta, \sigma) \qquad (21)$$



a)



b)

Fig. 2: Dependency of the singularity (or noninnovated-dynamics speed parameter) s_t (or c_t) of the estimation matrix O (or Jacobian matrix F) on the dimension $\kappa = (\kappa_s, \kappa_e)$ of the innovated state pair x_s-x_e, for the sensor location $(l_s, l_e) = (2, 12)$

The meaning of these conditions and their dependency on κ_t ($= \kappa_1, \kappa_2, \kappa_3$ with $\kappa_1 < \kappa_2 < \kappa_3$) are depicted in the Figure 1b of Alvarez and Fernandez (2009): (i) the fulfilment ($\kappa_t = \kappa_1$) or violation ($\kappa_t = \kappa_2, \kappa_3$) of the conditions, and (ii) as the estimation order κ_t grows, the convergence gain (ω^+, ω^-) decreases, and eventually vanishes. In our column problem, we shall be interested in the interplay between structure, behavior, and tuning (ζ_s, ζ_e, ω, ω^-, ω^+, $\Delta\omega$).

4.2 Entire profile estimation

First, the GE estimator (8) was run with the candidate structures $(\kappa_s, \kappa_e) = (1, 1), \ldots (6, 6)$, finding that the best behavior was attained with $(\kappa_s, \kappa_e) = (3, 3)$, followed by (2, 2). In Figure 3 are presented the results for $(\kappa_s, \kappa_e) = (1, 1)$, (3, 3), and (6, 6), and the corresponding gain tuning limit results are listed in Table 1. The structure with three innovated states per measurement yields the best speed versus robustness behavior, with a reasonable gain interval (ω^+, ω^-). In agreement with the convergence-tuning theoretical derivations (Alvarez and Fernandez, 2009): (i) the passive (or observable) structure yields the slowest (or fastest) reconstruction rate with the largest (smallest) robustness, or equivalently, the largest (or smallest) gain interval $\Delta\omega$, and (iii) to avoid oscillatory response, the damping factor $\zeta_{s/e} = 2^{1/2}$ (or 1.5) is used for observable (or passive) innovation (Alvarez and Lopez, 1999).

4.3 Two-effluent estimation

In this case, the three-state model with two decoupled subsystems and passive innovation candidate structure (15) was implemented as well as several other neighbouring structures, finding that, the candidate structure yielded the best behavior with the least number of states, followed closely by some neighboring structures. The corresponding tuning and behavior are listed in Table 2 and Figure 4, respectively. As it can be seen in the Figure 4, for effluent estimation purposes, the truncated model outperforms the complete one, and this verifies the effectiveness of setting the model dimension as design degree of freedom. Comparing with the complete model-based estimation cases, the truncated model with single-stage innovation per measurement yields faster and more robust effluent estimates.

Table 1. Tuning for entire profile estimation.

y	κ	ζ	ω^-	ω	ω^+	$\Delta\omega$	n_ω
T_2, T_{12}	6, 6	$2^{1/2}$	1/15	2/5	8/15	7/15	6
T_2, T_{12}	3, 3	1	1/15	2/3	4/5	11/15	10
T_2, T_{12}	1, 1	3/2	1/15	4/5	14/15	13/15	12

Table 2. Tuning for two-effluent estimation.

n	κ	ζ	ω^-	ω	ω^+	$\Delta\omega$	n_ω
12	1, 1	3/2	1/15	4/5	14/15	13/15	12
3	1, 1	3/2	1/15	14/15	1	14/15	14

5. CONCLUSIONS

The problem of drawing the structure for best estimator behavior with respect to a specific concentration estimation task has been resolved for a binary distillation column with two temperature measurements and experimental data. It was found that: (i) the (12-concentration) profile must be estimated with the complete model, six innovated concentrations (three per measurement), and a 6-concentration open-loop observer module, and (ii) the two-effluent concentration must be estimated with a three-stage truncated model, two innovated concentrations, (one per

measurement), and one noninnovated module. In the complete (or two-effluent) estimation case, the GE consists of 5 (or 14) ODE's, which are considerably less than the 72 ODEs required by an EKF implementation.

The proposed approach: (i) resolves the structure-algorithm estimation design problem in a way that is more effective and simpler than the ones of previous studies, and (ii) is a point of departure to address the multi-component case.

Abstract: A distributed predictive control framework based on a state-space model with constraints on the output and control-input is proposed. By a benchmark process, the performance of this framework is analyzed and compared with centralized control strategies in a regulation problem of a distillation column.

Keywords: Model predictive control, distributed optimization, distillation column, convex optimization, interior-point method.

1. INTRODUCTION

Advanced techniques for multivariable control like model predictive control (MPC) have become widespread in the industry, but they are still complex, time-consuming to set-up, and consequently expensive. Further, the centralized approach may not be suitable to the operation of large dynamic networks, either by the communication difficulty between sensors and the central unit, or by the computational limitation to solve optimization problems. Some petrochemical plants are examples of large systems composed by distributed, however coupled subsystems.

An alternative is distributed predictive control (Camponogara et al., 2002), which breaks the static optimization problem into smaller sub-problems to be solved by a network of control/optimization agents. It aims to solve the sub-problems in the most simple form while the final performance is preserved or even improved.

Many studies about distributed formulations are being developed. Mercangöz and Doyle III (2007) propose a distributed formulation that ensures self-sufficient state estimation in each node. Motee and Jadbabaie (2006) present a study of receding horizon control applied to physically decoupled systems with input and state constraints, where the couplings appear through the finite horizon cost function. Li et al. (2005) and Giovanini and Balderud (2006) propose MPC strategies based on Nash optimality to decoupled sub-systems.

Besides this, many algorithms to ensure convergence of distributed problems are being proposed. Dunbar (2007) presents distributed algorithms for dynamically coupled nonlinear systems subject to decoupled input constraints. An iterative procedure based on cooperation that ensures convergence to the global optimum for linear systems with constraints on the local controls is presented by Venkat et al. (2008). Camponogara and Talukdar (2007) present synchronous and asynchronous solutions of optimization problems, proposing a high level optimization framework and safety margins for meeting constraints. Recently, distributed predictive control was specialized to linear dynamic networks and applied to traffic light control, in which the dynamics of the sub-systems are coupled and the constraints are on the local controls (Camponogara and de Oliveira, 2009).

This paper proposes a problem decomposition and distributed algorithm for predictive control of linear networks with dynamic couplings and restrictions on output and control-input signals. Further, it reports on a comparison with existing approaches for the control of a distillation column.

The end result of this research is a distributed predictive control technique for programming control agents which can be deployed to perform regulatory control of linear dynamic networks. Each agent would be responsible for solving a problem of control action, exchanging its local sensor data and control actions with the other agents. The resulting control action is obtained after resolving conflicts with neighboring agents.

Because the algorithms embedded in the agents are much simpler than the centralized one, the distributed approach makes it simpler to modify and reconfigure the plant. Instead of modifying the complex centralized algorithm, it would suffice to add new agents and update only the nearby agents with whom the new agents would have relation. Further, maintenance would be facilitated since the distributed agents are much simpler.

2. DYNAMIC MODEL AND CONTROL PROBLEM

A linear dynamic network is obtained by interconnecting decoupled sub-systems that have local dynamics and controls. The couplings arise from the dynamic interconnections and the constraints on the network's output equations. $\mathscr{M} = \{1, \ldots, M\}$ denotes the set of sub-systems. Each sub-system m is governed by the following discrete-time linear dynamic equation:

$$\mathbf{x}_m(k+1) = A_m \mathbf{x}_m(k) + B_m \mathbf{u}_m(k) \quad (1)$$

⋆ This research has been funded in part by Agência Nacional do Petróleo, Gás Natural e Biocombustíveis (ANP) under grant PRH-34/aciPG/ANP and by Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) under grant 473841/2007-0.

where $\mathbf{x}_m \in \mathbb{R}^{n_m}$ is the state, $\mathbf{u}_m \in \mathbb{R}^{p_m}$ is the control input, and A_m and B_m are matrices of appropriate dimensions. The output from sub-system m depends on the state of the sub-systems in set $I(m) \subseteq \mathscr{M}$ such that $m \in I(m)$:

$$\mathbf{y}_m(k) = \sum_{i \in I(m)} C_{m,i}\mathbf{x}_i(k) \tag{2}$$

and is subject to the output constraints:

$$\mathbf{y}_m^{\min} \leq \mathbf{y}_m(k) \leq \mathbf{y}_m^{\max} \tag{3}$$

with $C_{m,i}$ being matrices of suitable dimensions.

The regulation problem for the overall system subject to output and control-input constraints is:

$$\min \frac{1}{2}\sum_{m=1}^{M}\sum_{k=0}^{\infty}\left[\mathbf{y}_m(k+1)'Q_m\mathbf{y}_m(k+1) + \mathbf{u}_m(k)'R_m\mathbf{u}_m(k)\right] \tag{4a}$$

$$\text{S.to : For } m = 1,\ldots,M,\ k = 0,\ldots,\infty:$$

$$\mathbf{x}_m(k+1) = A_m\mathbf{x}_m(k) + B_m\mathbf{u}_m(k) \tag{4b}$$

$$\mathbf{y}_m(k+1) = \sum_{i \in I(m)} C_{m,i}\mathbf{x}_i(k+1) \tag{4c}$$

$$\mathbf{u}_m^{\min} \leq \mathbf{u}_m(k) \leq \mathbf{u}_m^{\max} \tag{4d}$$

$$\mathbf{y}_m^{\min} \leq \mathbf{y}_m(k+1) \leq \mathbf{y}_m^{\max} \tag{4e}$$

where Q_m are symmetric positive semi-definite and R_m are symmetric positive definite matrices.

Model predictive control solves an optimization problem that approximates the regulation problem for a finite-time horizon. Given the state $\mathbf{x}(k) = (\mathbf{x}_1,\ldots,\mathbf{x}_M)(k)$ of the system at time k, the MPC regulation problem is defined as:

$$P: \min f = \frac{1}{2}\sum_{m=1}^{M}\sum_{j=0}^{T-1}\left[\hat{\mathbf{y}}_m(k+j+1|k)'Q_m\hat{\mathbf{y}}_m(k+j+1|k) + \hat{\mathbf{u}}_m(k+j|k)'R_m\hat{\mathbf{u}}_m(k+j|k)\right] \tag{5a}$$

$$\text{S.to : For } m = 1,\ldots,M,\ j = 0,\ldots,T-1:$$

$$\hat{\mathbf{x}}_m(k+j+1|k) = A_m\hat{\mathbf{x}}_m(k+j|k) + B_m\hat{\mathbf{u}}_m(k+j|k) \tag{5b}$$

$$\hat{\mathbf{y}}_m(k+j+1|k) = \sum_{i \in I(m)} C_{m,i}\hat{\mathbf{x}}_i(k+j+1|k) \tag{5c}$$

$$\mathbf{u}_m^{\min} \leq \hat{\mathbf{u}}_m(k+j|k) \leq \mathbf{u}_m^{\max} \tag{5d}$$

$$\mathbf{y}_m^{\min} \leq \hat{\mathbf{y}}_m(k+j+1|k) \leq \mathbf{y}_m^{\max} \tag{5e}$$

$$\hat{\mathbf{x}}_m(k|k) = \mathbf{x}_m(k) \tag{5f}$$

where $\hat{\mathbf{u}}_m(k+j|k)$ is the prediction for the control input to sub-system m at time $(k+j)$ as predicted at time k, and similarly $\hat{\mathbf{y}}_m$ and $\hat{\mathbf{x}}_m$ are output and state predictions respectively. The variable T is the length of the prediction and control horizons, that have the same length to make the developments simpler.

The term "$|k$" is dropped from all variables for the sake of simplification. Before continuing with the MPC formulation, some terminology will be introduced to simplify the representation. First, it is possible to obtain the state of sub-system m at time $(k+t)$ by using the initial state and the past controls. The future states and outputs are represented as:

$$\hat{\mathbf{x}}_m(k+t) = A_m^t\mathbf{x}_m(k) + \sum_{j=1}^{t} A_m^{j-1}B_m\hat{\mathbf{u}}_m(k+t-j)$$

$$\hat{\mathbf{y}}_m(k+t) = \sum_{i \in I(m)} C_{m,i}\left(A_i^t\mathbf{x}_i(k) + \sum_{j=1}^{t} A_i^{j-1}B_i\hat{\mathbf{u}}_i(k+t-j)\right)$$

By defining the vectors $\hat{\mathbf{x}}_m$, $\hat{\mathbf{u}}_m$, and $\hat{\mathbf{y}}_m$ to represent the predictions over the entire horizon of the states, controls, and outputs, respectively, and the matrices $\overline{CA}_{m,i}$ and $\overline{CB}_{m,i}$ for the dynamics:

$$\hat{\mathbf{x}}_m = \begin{bmatrix}\hat{\mathbf{x}}_m(k+1)\\ \vdots \\ \hat{\mathbf{x}}_m(k+T)\end{bmatrix}, \quad \hat{\mathbf{u}}_m = \begin{bmatrix}\hat{\mathbf{u}}_m(k)\\ \vdots \\ \hat{\mathbf{u}}_m(k+T-1)\end{bmatrix}$$

$$\hat{\mathbf{y}}_m = \begin{bmatrix}\hat{\mathbf{y}}_m(k+1)\\ \vdots \\ \hat{\mathbf{y}}_m(k+T)\end{bmatrix}, \quad \overline{CA}_{m,i} = \begin{bmatrix}C_{m,i}A_i\\ C_{m,i}A_i^2\\ \vdots \\ C_{m,i}A_i^T\end{bmatrix}$$

$$\overline{CB}_{m,i} = \begin{bmatrix} C_{m,i}B_i & 0 & \cdots & 0 \\ C_{m,i}A_iB_i & C_{m,i}B_i & \cdots & 0 \\ \vdots & \vdots & \ddots & 0 \\ C_{m,i}A_i^{T-1}B_i & C_{m,i}A_i^{T-2}B_i & \cdots & C_{m,i}B_i \end{bmatrix}$$

the prediction of the outputs over the entire horizon is written in a compact form as:

$$\hat{\mathbf{y}}_m = \sum_{i \in I(m)}\left(\overline{CA}_{m,i}\mathbf{x}_i(k) + \overline{CB}_{m,i}\hat{\mathbf{u}}_i\right) \tag{6}$$

Defining the matrices $\bar{Q}_m$ and $\bar{R}_m$ with proper dimensions:

$$\bar{Q}_m = \begin{bmatrix} Q_m & 0 & \cdots & 0 \\ 0 & Q_m & \cdots & 0 \\ \vdots & \vdots & \ddots & 0 \\ 0 & 0 & 0 & Q_m \end{bmatrix}, \quad \bar{R}_m = \begin{bmatrix} R_m & 0 & \cdots & 0 \\ 0 & R_m & \cdots & 0 \\ \vdots & \vdots & \ddots & 0 \\ 0 & 0 & 0 & R_m \end{bmatrix}$$

and the vectors $\hat{\mathbf{u}}_m^{\min}$, $\hat{\mathbf{u}}_m^{\max}$, $\hat{\mathbf{y}}_m^{\min}$, and $\hat{\mathbf{y}}_m^{\max}$:

$$\hat{\mathbf{u}}_m^{\min} = \begin{bmatrix}\mathbf{u}_m^{\min}\\ \vdots \\ \mathbf{u}_m^{\min}\end{bmatrix}, \quad \hat{\mathbf{u}}_m^{\max} = \begin{bmatrix}\mathbf{u}_m^{\max}\\ \vdots \\ \mathbf{u}_m^{\max}\end{bmatrix}$$

$$\hat{\mathbf{y}}_m^{\min} = \begin{bmatrix}\mathbf{y}_m^{\min}\\ \vdots \\ \mathbf{y}_m^{\min}\end{bmatrix}, \quad \hat{\mathbf{y}}_m^{\max} = \begin{bmatrix}\mathbf{y}_m^{\max}\\ \vdots \\ \mathbf{y}_m^{\max}\end{bmatrix}$$

problem P is expressed as:

$$P: \min \frac{1}{2}\sum_{m=1}^{M}\left(\hat{\mathbf{y}}_m'\bar{Q}_m\hat{\mathbf{y}}_m + \hat{\mathbf{u}}_m'\bar{R}_m\hat{\mathbf{u}}_m\right) \tag{7a}$$

$$\text{S.to : For } m = 1,\ldots,M:$$

$$\hat{\mathbf{y}}_m = \sum_{i \in I(m)}\left(\overline{CA}_{m,i}\mathbf{x}_i(k) + \overline{CB}_{m,i}\hat{\mathbf{u}}_i\right) \tag{7b}$$

$$\hat{\mathbf{u}}_m^{\min} \leq \hat{\mathbf{u}}_m \leq \hat{\mathbf{u}}_m^{\max} \tag{7c}$$

$$\hat{\mathbf{y}}_m^{\min} \leq \hat{\mathbf{y}}_m \leq \hat{\mathbf{y}}_m^{\max} \tag{7d}$$

The next step is to represent problem P using only the current state and the control predictions. First, let us define f_m as the portion of problem P for a specific m and replace (6) in the objective function:

$$
\begin{aligned}
f_m =& \frac{1}{2}\left(\sum_{i\in I(m)}\left(\overline{CA}_{m,i}\mathbf{x}_i(k)+\overline{CB}_{m,i}\hat{\mathbf{u}}_i\right)\right)'\bar{Q}_m \\
&\cdot\left(\sum_{i\in I(m)}\left(\overline{CA}_{m,i}\mathbf{x}_i(k)+\overline{CB}_{m,i}\hat{\mathbf{u}}_i\right)\right)+\frac{1}{2}\hat{\mathbf{u}}_m'\bar{R}_m\hat{\mathbf{u}}_m \\
=& \frac{1}{2}\left(\sum_{i\in I(m)}\overline{CA}_{m,i}\mathbf{x}_i(k)\right)'\bar{Q}_m\left(\sum_{i\in I(m)}\overline{CA}_{m,i}\mathbf{x}_i(k)\right) \\
&+\left(\sum_{i\in I(m)}\overline{CA}_{m,i}\mathbf{x}_i(k)\right)'\bar{Q}_m\left(\sum_{i\in I(m)}\overline{CB}_{m,i}\hat{\mathbf{u}}_i\right) \\
&+\frac{1}{2}\left(\sum_{i\in I(m)}\overline{CB}_{m,i}\hat{\mathbf{u}}_i\right)'\bar{Q}_m\left(\sum_{i\in I(m)}\overline{CB}_{m,i}\hat{\mathbf{u}}_i\right) \\
&+\frac{1}{2}\hat{\mathbf{u}}_m'\bar{R}_m\hat{\mathbf{u}}_m
\end{aligned}
\tag{8}
$$

Defining vectors $\mathbf{g}_{m,i,j}$, matrices $H_{m,i,j}$, and a constant c_m to represent the terms of f_m:

$$\mathbf{g}_{m,i,j} = \overline{CB}_{m,i}'\bar{Q}_m\overline{CA}_{m,j}\mathbf{x}_j(k) \text{ for } i,j\in I(m) \tag{9a}$$

$$H_{m,m,m} = \overline{CB}_{m,m}'\bar{Q}_m\overline{CB}_{m,m}+\bar{R}_m \tag{9b}$$

$$H_{m,i,j} = \overline{CB}_{m,i}'\bar{Q}_m\overline{CB}_{m,j} \quad \text{for } i,j\in I(m), i\neq m \text{ or } j\neq m \tag{9c}$$

$$c_m = \frac{1}{2}\sum_{i\in I(m)}\sum_{j\in I(m)}\mathbf{x}_i(k)'\overline{CA}_{m,i}'\bar{Q}_m\overline{CA}_{m,j}\mathbf{x}_j(k) \tag{9d}$$

it is possible to redefine problem P as:

$$P: \min\frac{1}{2}\sum_{m=1}^{M}\sum_{i\in I(m)}\sum_{j\in I(m)}\left[\hat{\mathbf{u}}_i'H_{m,i,j}\hat{\mathbf{u}}_j+\mathbf{g}_{m,i,j}'\hat{\mathbf{u}}_i\right]+\sum_{m=1}^{M}c_m \tag{10a}$$

$$\text{S.to}: \text{For } m=1,\ldots,M:$$

$$\hat{\mathbf{u}}_m^{\min}\leq\hat{\mathbf{u}}_m\leq\hat{\mathbf{u}}_m^{\max} \tag{10b}$$

$$\hat{\mathbf{y}}_m^{\min}\leq\sum_{i\in I(m)}\left(\overline{CA}_{m,i}\mathbf{x}_i(k)+\overline{CB}_{m,i}\hat{\mathbf{u}}_i\right)\leq\hat{\mathbf{y}}_m^{\max} \tag{10c}$$

This quadratic programming formulation will be used to solve the problem of control calculation in the centralized approach.

2.1 Logarithmic Barrier Method

The logarithmic barrier method is an *interior-point* method for solving convex optimization problems with inequality constraints (Boyd and Vandenberghe, 2004),

$$\text{minimize } f(\mathbf{x}) \tag{11a}$$

$$\text{subject to } A\mathbf{x}\leq\mathbf{b}, \tag{11b}$$

It is assumed that the problem is solvable, *i.e.*, an optimal solution $\mathbf{x}^\star$ exists, and the constraints delimit a closed set. A *barrier function* is any function $B(\mathbf{x}):\Re^n\to\Re$ that satisfies

- $B(\mathbf{x})\geq 0$ for all $\mathbf{x}$ that satisfy $A\mathbf{x}<\mathbf{b}$, and
- $B(\mathbf{x})\to\infty$ as $\mathbf{x}$ approaches the boundary of $\{\mathbf{x}|A\mathbf{x}\leq\mathbf{b}\}$

Being $\mathbf{a}_i'$ the i-th row of A, the idea of the method is to treat the constraints using a logarithmic barrier function as follows:

$$\phi(\mathbf{x}) = -\sum_{i=1}^{m}\log\left(b_i-\mathbf{a}_i'\mathbf{x}\right) \tag{12}$$

where the domain of ϕ is $\mathbf{dom}\ \phi=\{\mathbf{x}|A\mathbf{x}<\mathbf{b}\}$.

With (12), problem (11) can be approximated by:

$$P(\varepsilon):\ \min\ g(\mathbf{x}) = f(\mathbf{x})+\varepsilon\phi(\mathbf{x}) \tag{13}$$

where $\varepsilon>0$ is a parameter that sets the accuracy of the approximation. As ε decreases, more accurate the approximation $P(\varepsilon)$ becomes, whose optimal solution is $\mathbf{x}(\varepsilon)$. The optimal solution is reached by solving (13) for a decreasing sequence of $\varepsilon\to 0^+$, *i.e.*, $\lim_{\varepsilon\to 0^+}\mathbf{x}(\varepsilon)=\mathbf{x}^\star$. The pseudo-code of the barrier method for solving problem (11) appears in Algorithm 1.

Newton's method can be used to compute the optimal solution to $P(\varepsilon)$ using the gradient and the Hessian of $\phi(\mathbf{x})$ and $f(\mathbf{x})$. Algorithm 2 shows how to use Newton's method with a backtracking line search to choose the step size of each iteration. The gradient and the Hessian of the logarithmic barrier function ϕ are given by:

$$\nabla\phi(\mathbf{x}) = \sum_{i=1}^{M}\frac{1}{(b_i-\mathbf{a}_i'\mathbf{x})}\mathbf{a}_i,\ \nabla^2\phi(\mathbf{x}) = \sum_{i=1}^{M}\frac{1}{(b_i-\mathbf{a}_i'\mathbf{x})^2}\mathbf{a}_i\mathbf{a}_i'$$

Algorithm 1: Barrier method

given: strictly feasible $\mathbf{x}$, $\varepsilon:=\varepsilon^0$, $0<\mu<1$, tolerance $e>0$
repeat
  compute $\mathbf{x}(\varepsilon)$ by minimizing $g(\mathbf{x})$, starting at $\mathbf{x}$;
  update $\mathbf{x}:=\mathbf{x}(\varepsilon)$; $\varepsilon:=\mu\varepsilon$;
until $\varepsilon\leq e$;

Algorithm 2: Newton's method

given: a starting point $\mathbf{x}\in\mathbf{dom}\ g$, tolerance $e>0$
repeat
  compute the Newton step: $\Delta\mathbf{x}_{nt}:=-\nabla^2 g(\mathbf{x})^{-1}\nabla g(\mathbf{x})$;
  choose step size
    given: a descent direction $\Delta\mathbf{x}_{nt}$, $\alpha\in(0,0.5)$, $\beta\in(0,1)$
    $t:=1$;
    while $g(\mathbf{x}+t\Delta\mathbf{x}_{nt})>g(\mathbf{x})+\alpha t\nabla g(\mathbf{x})'\Delta\mathbf{x}_{nt}$ **do**
      $t:=\beta t$;
  end
  update: $\mathbf{x}:=\mathbf{x}+t\Delta\mathbf{x}_{nt}$;
  compute the decrement: $\lambda^2:=\nabla g(\mathbf{x})'\nabla^2 g(\mathbf{x})^{-1}\nabla g(\mathbf{x})$;
until $\lambda^2/2\leq e$;

By approximating problem P given in (10) to the equivalent unconstrained form $P(\varepsilon)$, where the constraints on outputs and controls are put together in $\phi(\hat{\mathbf{u}})$, unconstrained minimization algorithms like those described in this section can be used to solve the problem.

3. DISTRIBUTED OPTIMIZATION AND CONTROL

This paper focuses now on the distributed solution of P, discussing how to perform a decomposition of the problem into a network of coupled sub-problems P_m that will be solved by a network of distributed agents (Camponogara and Talukdar, 2005, 2007), and the use of a distributed iterative algorithm to solve these sub-problems.

Each agent will compute a control vector $\hat{\mathbf{u}}_m$. So, for a perfect decomposition, each agent m must have all the information on problem P that depends on $\hat{\mathbf{u}}_m$. Before giving the decomposition, let us define some special sets:

- $O(m)=\{i: m\in I(i), i\neq m\}$ to represent the set of *output neighbors* of m;

- $C(m) = \{(i,j) \in I(m) \times I(m) : i = m \text{ or } j = m\}$ for the sub-system pairs of quadratic terms in the cost function of sub-system m that depend on $\hat{\mathbf{u}}_m$;
- $O(m,k) = \{(i,j) \in I(k) \times I(k) : i = m \text{ or } j = m\}$ for the pairs of quadratic terms in the cost function of sub-system k, $k \in O(m)$, that depend on $\hat{\mathbf{u}}_m$;
- $N(m) = (I(m) \cup O(m) \cup \{i : (i,j) \in O(m,k), k \in O(m)\}) - \{m\}$, which defines the *neighborhood* of agent m, including input and output *neighbors*;
- $\hat{\omega}_m = (\hat{\mathbf{u}}_i : i \in N(m))$, for the set of control signals of the neighbors of agent m;
- $\hat{\mathbf{z}}_m = (\hat{\mathbf{u}}_i : i \in \mathscr{M} - N(m) \cup \{m\})$, for the set of all control signals that are not in $\hat{\omega}_m$ and $\hat{\mathbf{u}}_m$.

The problem P from the view of agent m is defined as:

$$\begin{aligned} P_m: \ \min \ & \frac{1}{2} \sum_{(i,j) \in C(m)} \hat{\mathbf{u}}_i' H_{mij} \hat{\mathbf{u}}_j + \sum_{i \in I(m)} \mathbf{g}_{mmi} \hat{\mathbf{u}}_m + c_m \\ & + \frac{1}{2} \sum_{k \in O(m)} \sum_{(i,j) \in O(m,k)} \hat{\mathbf{u}}_i' H_{kij} \hat{\mathbf{u}}_j \qquad (14a) \\ & + \sum_{k \in O(m)} \sum_{(m,j) \in O(m,k)} \mathbf{g}_{kmj} \hat{\mathbf{u}}_m \\ \text{S.to}: \ & \hat{\mathbf{u}}_m^{\min} \le \hat{\mathbf{u}}_m \le \hat{\mathbf{u}}_m^{\max} \qquad (14b) \\ & \hat{\mathbf{y}}_i^{\min} \le \sum_{j \in I(i)} \left(\overline{CA}_{i,j} \mathbf{x}_j(k) + \overline{CB}_{i,j} \hat{\mathbf{u}}_j \right) \le \hat{\mathbf{y}}_i^{\max}, \qquad (14c) \\ & \quad \text{for all } i \in O(m) \cup \{m\} \end{aligned}$$

It is possible to simplify the representation of problem P_m by grouping some terms as follows:

$$H_m = H_{mmm} + \sum_{k \in O(m)} H_{kmm} \qquad (15a)$$

$$\begin{aligned} \mathbf{g}_m = \ & \frac{1}{2} \sum_{(i,m) \in C(m): i \ne m} \left(H'_{mim} + H_{mmi} \right) \hat{\mathbf{u}}_i + \sum_{i \in I(m)} \mathbf{g}_{mmi} \\ & + \frac{1}{2} \sum_{k \in O(m)} \sum_{(i,m) \in O(m,k): i \ne m} \left(H'_{kim} + H_{kmi} \right) \hat{\mathbf{u}}_i \qquad (15b) \\ & + \sum_{k \in O(m)} \sum_{(m,j) \in O(m,k)} \mathbf{g}_{kmj} \hat{\mathbf{u}}_m \end{aligned}$$

Using the terms defined above, problem P_m is represented as:

$$\begin{aligned} P_m(\hat{\omega}_m): \ \min f_m(\hat{\mathbf{u}}_m) \ &= \frac{1}{2} \hat{\mathbf{u}}_m' H_m \hat{\mathbf{u}}_m + \mathbf{g}_m' \hat{\mathbf{u}}_m + c_m \qquad (16a) \\ \text{S.to}: \ & \hat{\mathbf{u}}_m^{\min} \le \hat{\mathbf{u}}_m \le \hat{\mathbf{u}}_m^{\max} \qquad (16b) \\ & \hat{\mathbf{y}}_i^{\min} \le \sum_{j \in I(i)} \left(\overline{CA}_{i,j} \mathbf{x}_j(k) + \overline{CB}_{i,j} \hat{\mathbf{u}}_j \right) \le \hat{\mathbf{y}}_i^{\max}, \qquad (16c) \\ & \quad \text{for all } i \in O(m) \cup \{m\} \end{aligned}$$

This quadratic form will be used by each agent m to compute the control signal $\hat{\mathbf{u}}_m$ in the distributed approach.

Some properties about the decomposition are:

- $P_m(\hat{\omega}_m)$ consists of problem P with all the objective terms and constraints that depend on $\hat{\mathbf{u}}_m$;
- each sub-problem $P_m(\hat{\omega}_m)$ is convex.

3.1 Distributed Algorithm

This section describes briefly the distributed algorithm for the agent network to reach a solution. Let $P_m(\varepsilon)$ be the centering problem for $P_m(\hat{\omega}_m)$ with a given ε:

$$P_m(\varepsilon): \ \min \ f_m(\hat{\mathbf{u}}_m) + \varepsilon \phi_m(\hat{\mathbf{u}}_m) \qquad (17)$$

where $\phi_m(\hat{\mathbf{u}}_m)$ is the logarithmic barrier function of the constraints given in (16). It is important to note that the problem to be solved by each agent is much simpler than the one used in the centralized formulation. So, the distributed solution must encompass a sequence of steps before the optimal control sequence is reached (de Oliveira and Camponogara, 2008).

First, define the vector $\hat{\mathbf{u}}^k = \left(\hat{\mathbf{u}}_1^k, \ldots, \hat{\mathbf{u}}_M^k\right)$ with the set of all control variables of P at iteration k. For a given ε, all agents have to *negotiate* to find a solution for each $P_m(\varepsilon)$ in the network. And this process is repeated for a decreasing sequence of $\varepsilon \to 0^+$. The convergence to a stationary solution is ensured by respecting two assumptions:

(1) *Synchronous Work:* if agent m revises its decisions at iteration k, then:
   (a) agent m uses $\hat{\omega}_m^k$ to produce an approximate solution of $P_m(\varepsilon)$;
   (b) all the neighbors of agent m keep their decisions at iteration k: $\hat{\mathbf{u}}_i^{k+1} = \hat{\mathbf{u}}_i^k$ for all $i \in N(m)$.

(2) *Continuous Work:* if $\hat{\mathbf{u}}^k$ is not a stationary point for problems $P_i(\varepsilon)$, $i \in \mathscr{M}$, then at least one agent m for which $\hat{\mathbf{u}}_m^k$ is not a stationary point for $P_m(\varepsilon)$ produces a new iterate $\hat{\mathbf{u}}_m^{k+1}$.

Condition (a) of Assumption 1 and Assumption 2 hold by arranging the agents to iterate repeatedly in a sequence $\langle S_1, \ldots, S_r \rangle$, where $S_i \subseteq \mathscr{M}$, $\cup_{i=1}^r S_i = \mathscr{M}$, and all distinct pairs $m, n \in S_i$ are non-neighbors for all i. The pseudo-code of the distributed barrier method for solving the problem network $\{P_m(\varepsilon)\}$ is given in Algorithm 3.

Algorithm 3: Distributed barrier method

given: strictly feasible $\hat{\mathbf{u}}^0 = (\hat{\mathbf{u}}_1^0, \ldots, \hat{\mathbf{u}}_M^0)$, $\varepsilon = \varepsilon^0 > 0$, $0 < \mu < 1$, tolerance $e > 0$, and a sequence $\langle S_1, \ldots, S_r \rangle$

repeat
- Define the initial group of decoupled agents, $i := 1$;
- Define a flag for the stationary test, $\delta := false$;
- **repeat**
  - each agent $m \in S_i$ receives $\hat{\omega}_m^k$ and computes $\hat{\mathbf{u}}_m^{k+1}$ by solving $P_m(\varepsilon)$ starting at $\hat{\mathbf{u}}_m^k$;
  - each agent j computes $\hat{\mathbf{u}}_j^{k+1} = \hat{\mathbf{u}}_j^k$ for $j \notin S_i$;
  - $\hat{\mathbf{u}}^{k+1} := (\hat{\mathbf{u}}_1^{k+1}, \ldots, \hat{\mathbf{u}}_M^{k+1})$;
  - **if** $\hat{\mathbf{u}}^{k+1}$ *is a stationary point for* $P_i(\varepsilon)$, $\forall i \in \mathscr{M}$ **then**
    - $\delta := true$;
  - **else**
    - $k := k + 1$;
    - $i := (i \mod r) + 1$;
- **until** $\delta = true$;
- $\varepsilon := \mu \varepsilon$;

until $\varepsilon < e$;

4. COMPUTATIONAL ANALYSIS

4.1 Distillation Column

This section presents the application of model predictive control to a benchmark problem, comparing the performance of the centralized and distributed approaches. The model of the heavy oil fractionator utilized is referred in the literature as the Shell Oil's heavy oil fractionator (Prett and Morari, 1987; Camacho and Bordons, 2004). It relates the controlled variables y_1, y_2, and y_3 that correspond to the top endpoint composition, side end composition, and bottom reflux temperature, respectively, with the manipulated variables u_1, u_2, and u_3, corresponding to top draw, side draw, and bottom reflux duties. The discrete model is obtained with a sampling time of 4 minutes, and it is possible to obtain a state space representation in the form:

$$\begin{bmatrix} \mathbf{x}_{11}(k+1) \\ \mathbf{x}_{21}(k+1) \\ \mathbf{x}_{31}(k+1) \\ \mathbf{x}_{12}(k+1) \\ \vdots \\ \mathbf{x}_{33}(k+1) \end{bmatrix} = \begin{bmatrix} A_{11} & & & \\ & A_{21} & \emptyset & \\ & & \ddots & \\ & \emptyset & & A_{33} \end{bmatrix} \begin{bmatrix} \mathbf{x}_{11}(k) \\ \mathbf{x}_{21}(k) \\ \vdots \\ \mathbf{x}_{33}(k) \end{bmatrix} + \begin{bmatrix} B_{11} & 0 & 0 \\ B_{21} & \vdots & \vdots \\ B_{31} & 0 & \\ 0 & B_{12} & 0 \\ \vdots & \vdots & \vdots \\ 0 & 0 & B_{33} \end{bmatrix} \begin{bmatrix} u_1(k) \\ u_2(k) \\ u_3(k) \end{bmatrix}$$

$$\begin{bmatrix} y_1(k+1) \\ y_2(k+1) \\ y_3(k+1) \end{bmatrix} = \begin{bmatrix} C_{11} & 0 & 0 & C_{12} & \cdots & 0 \\ 0 & C_{21} & 0 & 0 & \ddots & \vdots \\ 0 & 0 & C_{31} & 0 & \cdots & C_{33} \end{bmatrix} \begin{bmatrix} \mathbf{x}_{11}(k) \\ \mathbf{x}_{21}(k) \\ \vdots \\ \mathbf{x}_{33}(k) \end{bmatrix}$$

where each group $\mathbf{x}_{ij}$, A_{ij}, B_{ij}, and C_{ij} represents the couplings among the outputs and controls of the transfer function located in line i and column j of the transfer function matrix (Camacho and Bordons, 2004).

This formulation makes the distillation column a special case of the theory developed in the previous sections. For this special case, because the column is fully coupled, the set $I(m)$ is equal to $\{1,2,3\}$ for any m, and the *neighborhood* is equal to the *output* for each agent m. Other sets are given in Table 1.

Table 1. Sets used in the problem decomposition

m	$O(m)$	$C(m)$	$O(m,k)$
1	{2,3}	{(1,1),(1,2),(2,1),(1,3),(3,1)}	$O(1,2) = O(1,3) = C(1)$
2	{1,3}	{(1,2),(2,1),(2,2),(2,3),(3,2)}	$O(2,1) = O(2,3) = C(2)$
3	{1,2}	{(1,3),(3,1),(2,3),(3,2),(3,3)}	$O(3,1) = O(3,2) = C(3)$

Three different algorithms were used to solve the problem for the purpose of comparison:

- *Centralized Quadratic Programming* (cent_{QP}): the solution of P is obtained using a specific solver in Matlab® for problems in the quadratic form with constraints;
- *Centralized Barrier* (cent_{Br}): the solution of P is reached using the logarithmic barrier method and the centralized formulation;

Table 2. Numerical results

	dist_{Br}		cent_{Br}		cent_{QP}	
T	time	objective	time	objective	time	objective
1	0.0332	5.6188	0.0133	5.6188	0.0099	5.6188
2	0.0386	11.5680	0.0200	11.5680	0.0096	11.5680
5	0.0553	40.5596	0.0243	40.5596	0.0096	40.5596
10	0.0857	73.1869	0.0423	73.1868	0.0109	73.1868
15	0.1417	85.9801	0.0670	85.9797	0.0157	85.9797
20	0.2527	91.2292	0.1211	91.2284	0.0197	91.2284
25	0.3880	93.7129	0.2004	93.7115	0.0361	93.7115
30	0.6258	95.0680	0.2657	95.0660	0.0302	95.0660

- *Distributed Barrier* (dist_{Br}): each problem P_m is solved by a different agent and the constraints are treated with the logarithmic barrier method.

The criteria of convergence in Newton's method, which is used in cent_{Br} and dist_{Br} to solve centering problems, is $\lambda^2/2 \leq 10^{-5}$. The convergence criterion for the logarithmic barrier method is $\varepsilon \leq 10^{-4}$, while the stationary test is satisfied with $e \leq 10^{-4}$. The weights on control action and output deviation were set equal because their adjustment is not the focus of this work, but it is clear that the choice of weights affects directly the compromise between performance and robustness.

Ten different feasible start points were chosen at random in the experiments and the initial ε was defined as 10^3. The previous solution was not used as an initial approximation for reoptimization to induce worst-case scenarios. The analyses considered each type of algorithm, different lengths of prediction horizon (T), and rate of decrease $\mu \in \{0.05,\ 0.1,\ 0.3,\ 0.5\}$ for the interior-point methods.

4.2 Numerical Results

The objective function given in (7) is used for comparison as the cost of the computational experiments. Table 2 has the results of the accumulated cost obtained with the ten start points and the four different values for μ. The cost difference between dist_{Br} and the centralized approach is less than 3×10^{-3}, proving that solving the set of distributed problems, $\{P_m\}$, and solving the centralized problem, P, is equivalent. The gap in cost is due to the acceptance range of the convergence criteria.

Table 2 also contains the results about the time spent in the experiments, comparing cent_{QP}, cent_{Br} and dist_{Br}. A computer with an AMD Turion™ 64x2 1.60 GHz processor and 2048 MB of memory was used to perform the experiments. Time is given in seconds and represents the mean time spent to compute the control actions of forty different experiments with each algorithm. As expected, the greater the value of T, more time is necessary to reach the solution, but the time used was always less than one second, which is a very good result, considering real applications.

The iterations between agents to exchange information were also counted. Fig. 1 depicts the average number of iterations for the experiments with varying prediction horizon and decrease rate of the barrier method.

The convergence criterion can be relaxed to minimize the number of iterations between agents. In this case, due to the strong couplings among the variables, the information exchange is considerable. More scattered models will be used in future experiments, which are more suitable for a distributed approach.

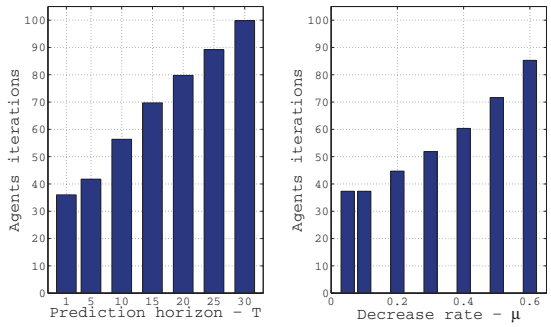

Fig. 1. Algorithm iterations varying T and μ, respectively.

Ending the analyses, it can be said that a network of distributed agents can solve the set of sub-problems $\{P_m\}$, rather than having a single agent solve P in centralized MPC, without incurring great loss of performance. Other adjustments can be made in the algorithm, such as the limit on the number of iterations, to guarantee the fulfillment of the deadlines, but all modifications have a compromise between speed and quality.

5. CONCLUSION

This work presented a distributed MPC framework with constraints on output and control-input signals. The methodology of problem decomposition was outlined and the barrier method was used to deal with the constraints, replacing the constrained minimization problem by a sequence of unconstrained minimization problems. Centralized MPC algorithms and the distributed MPC algorithm were applied to solve a regulation problem in a distillation column model.

The performance of distributed MPC in the distillation column scenario was comparable to the performance obtained with centralized MPC. The computational cost necessary to solve each agent problem was less than the centralized case. This advantage might allow the use of the distributed algorithm in machines with less computational resources.

It is worth emphasizing that distributed predictive control is more appropriate for multivariable problems where the couplings are scattered, which does not happen with the model of the distillation column.

Future works will focus on the implementation of reference tracking and state observers. As well as the whole study of how to introduce these extensions in a distributed algorithm. Another goal is to look into other scenarios that can be more appropriate for the application of distributed algorithms.

Abstract: In this paper we present a high-gain observer implemented in its discrete and continuous-discrete versions in order to compare the performance of both algorithms. The comparison is made considering the sampling time used to perform the observer's correction stage in order to establish that the continuous-discrete observer is the best option when a low sampling time is used. Under this condition the continuous discrete observer can process data performing a reliable on-line estimation of the system (a slow dynamics of the process is required). We apply both algorithms to a distillation column that uses the Ethanol-Water binary mixture.

Keywords: High-gain observer, discrete, continuous-discrete, distillation columns.

1. INTRODUCTION

The knowledge of state variables is often required in order to apply the advanced concepts of control and fault diagnosis to practical applications, specially in the chemical process industry. A method to obtain such variables, consists of combining a priori knowledge about physical systems with experimental data to provide an on-line estimator (observer).

The main control problems of distillation columns are caused due to tight interactions between the process variables, nonlinearities of the process, process and measurement delays and the large number of variables involved (see Murray-Gunther (2003)). For these reasons, a significant amount of effort has been devoted to develop algorithms that provide accurate parameter identification and state estimation (state observers) to reconstruct the product composition dynamics by secondary measurements (e.g., temperatures and flows) (see Quintero-Mármol et al. (1991), Deza et al. (1991)), and most recently in Bahar et al. (2006)Jana et al. (2006). The proposed observers are used to estimate unmeasured state variables from on-line and/or off-line measurements, see e.g. Bakir et al. (2005), Hammouri et al. (2006), Yildiz et al. (2005), Astorga et al. (2002) and Nadri et al. (2004).

Estimators are generally dynamic systems obtained from a nominal model by adding a correction term which is proportional to some output deviation. In other words, given a nominal model:

$$\begin{cases} \dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t)) \\ \mathbf{y}(\mathbf{t}) = \mathbf{h}(x(t)) \end{cases} \tag{1}$$

The state $x(t)$ belongs to an open subset $\mathbf{V}$ of $\mathbb{R}^n$, the input u(t) belongs to a Borelian subset $\mathbf{U}$ of $\mathbb{R}^m$ and the output $y(t) \in \mathbb{R}^p$. An observer for the system represented by Eq. (1) is generally a dynamic system of the form:

$$\begin{cases} \dot{\hat{x}}(t) = \mathbf{f}(\hat{\mathbf{x}}(t), \mathbf{u}(t)) + \mathbf{k}(\mathbf{t})[h(\hat{\mathbf{x}}(\mathbf{t})) - \mathbf{y}(\mathbf{t})] \\ \dot{\mathbf{r}} = \mathbf{F}(\mathbf{r}(\mathbf{t}), \mathbf{u}(\mathbf{t}), \mathbf{y}(\mathbf{t}), \hat{\mathbf{x}}(\mathbf{t})) \\ \mathbf{k}(\mathbf{t}) = \varphi(\mathbf{r}(\mathbf{t})) \end{cases} \tag{2}$$

$r(t)$ and $k(t)$ are called indifferently the gain of the observer (see Hammouri et al. (2002)). An interesting class of nonlinear systems consists of those systems which are observable for every input, called *uniformly observable systems*. For this class of nonlinear systems, we can design an observer whose gain does not depend on the inputs (see Bornard and Hammouri (1991) and Gauthier et al. (1992)). For such systems a canonical (called triangular) form is designed in order to develop an observer. To ensure mathematical convergence, a particular high-gain is required (see Hammouri et al. (2002)).

However, using a high-gain observer may generate the so-called peak phenomena (overshoot problem); moreover, the estimator becomes noise sensitive. Due to nonlinearity of the system, the choice of the gain which gives the best compromise between fast convergence, the noise rejection and the attenuation of the peak phenomena becomes a difficult task, and only simulations allow to determine a possible gain. This paper aims to present a high-gain observer status in its discrete and continuous-discrete versions. We apply this algorithms to a binary distillation column that uses the binary mixture Ethanol-Water.

2. THE BINARY DISTILLATION COLUMN MODEL

The binary distillation column model is derived from the binary distillation column scheme shown in Fig. 1. There are three principal stages considered for a distillation column (condenser, tray and boiler); for every stage, the balances of energy and material should be formulated as well as the equilibrium conditions of the mixture.

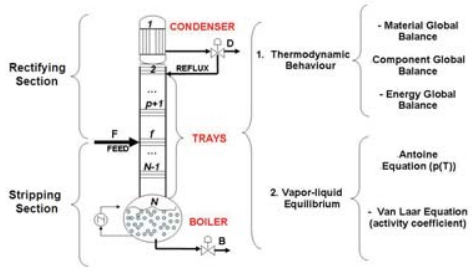

Fig. 1. Distillation column

2.1 General Aspects

The scheme of a typical distillation column is shown in Fig. 1. The binary feeding mixture (molar flow rate F) is introduced toward the middle of the column (the feeding tray). The distilled product (molar flow rate D), which mainly contains the light component, is removed from the top of the column. The bottom product (molar flow rate B), which contains the heavy component in greater concentration, is removed from the bottom of the column. Part of the overhead product is returned into the column to improve purity. Column stages are labeled with an ascendent numeration from the condenser to the boiler: $i = 1, ..., N$. The sections of the column are: the condenser, tray $i = 1$; the rectifying section, trays $i = 2, ..., f - 1$; the feeding tray, tray $i = f$; the stripping section, trays $i = f + 1, ..., N - 1$; the boiler, tray $i = N$.

2.2 Physic Behaviour

Due to its physical structure, a distillation column can be modeled as a set of interconnected stages using the mass balance and vapor-liquid equilibrium relation at every stage. The algebraic and differential equations of the model are formulated to calculate the light component composition of the mixture. The liquid phase and the vapor phase of the light component are designated by x and y, respectively.

Assumptions: The following assumptions, taken from Luyben (1992) and Halvorsen and Skogestad (2000) are considered in the model formulation:(**A1**) Constant pressure; (**A2**) Ideal Liquid-Vapor Equilibrium; (**A3**) Liquid-properties behave as a non-ideal mixture; (**A4**) Negligible molar vapor holdup compared to the molar liquid holdup; (**A5**) Boiler as a theoretical tray; (**A6**) Total condenser; (**A7**) Constant liquid volumetric hold up.

Vapor-liquid equilibrium: If a vapor and a liquid are in intimate contact for a long period of time, equilibrium is attained between the two phases. This concept of vapor-liquid equilibrium is fundamental to model distillation columns. If the vapor-liquid equilibrium exists, then the vapor composition y_i and the liquid composition x_i can be computed by means of correlating equations of the form $(y_i^{eq}, x_i^{eq}) = K_i(T_i, P_T)$, where T_i is the temperature, P_T is the total pressure, y_i^{eq} and x_i^{eq} are the vapor and liquid composition at the equilibrium phase respectively. The equilibrium constant K_i depends on the thermodynamical properties of the mixture.

The non-ideality of a binary mixture is due to different causes, the most frequent is the non-ideality of the liquid phase. In consequence, specially designed models are used to represent these non-idealities. For low pressure systems, the equation that represents the vapor composition is:

$$y_{i,j} P_T = P_{i,j}^{sat} x_{i,j} \gamma_{i,j} \tag{3}$$

where $j = 1$ if the component is ethanol and $j = 2$ if the component is water; $\gamma_{i,j}$ is the activity coefficient for every stage, it is a correction factor highly dependent on the concentration. In this work the vapor composition is calculated as a function of the light component. One method to determine this coefficient in every component of the mixture uses the Van Laar equation (see Perry (1999)).

Mass transfer effects: In order to deal with the mass transfer effects, the Murphree's efficiencies are introduced. The Murphree stage efficiency E_i is the ratio between the current change in vapor composition between two stages and the change that will occur if the vapor is in equilibrium with the liquid leaving the stage (see Murray-Gunther (2003)).

The molar flow rates: In the rectifying section the vapor molar flow V_R and the liquid molar flow L_R are :

$$\begin{cases} V_R = V_S + (1 - q_F)F, & i = 1, ..., f \\ L_R = (1 - R)V_R, & i = 1, ..., f - 1 \end{cases} \tag{4}$$

where

$$q_F = 1 + \frac{C_p(T_b - T_F)}{\lambda} \tag{5}$$

q_F describes the feeding condition. C_{p_j} is the specific heat, T_b is the boiling temperature, T_F is the feeding temperature and λ is the vaporization enthalpy for ethanol and water respectively.

F is the molar flow of the feeding stream:

$$F = F_V[\rho_1 w_1 + \rho_2(1 - w_1)] \left(\frac{x_f}{M_{W_1}} + \frac{1 - x_f}{M_{W_2}} \right) \tag{6}$$

where F_V is the volumetric flow of the feeding stream, ρ_j is the density of the component j, M_{W_j} is the molecular weight, w_1 is the weight fraction of the light component given by:

$$w_1 = \frac{x_f \rho_1}{x_f \rho_1 + (1 - x_f)\rho_2} \tag{7}$$

and x_f is the molar composition of the feeding stream given by:

$$x_f = \left(\frac{V_1 \rho_1 / M_{W_1}}{V_1 \rho_1 / M_{W_1} + V_2 \rho_2 / M_{W_2}} \right) \tag{8}$$

where V_j is the initial volume of the component j on the feeding container.

The distilled product flow rate, $D = 0$ if the three-way ON-OFF reflux valve shown in 1) is totally closed ($r_v = 0$) and $D = V_R$ if this valve is totally open ($r_v = 1$)

In the stripping section (subindex $[\cdot]_S$ is used), the vapor molar flow V_S and the liquid molar flow L_S are, respectively

$$\begin{array}{rcll} V_S & = & \dfrac{Q_b}{\Delta H_1^{vap} x_{1,N} + \Delta H_2^{vap}(1 - x_{1,N})}, & i = f+1, ..., N \\ L_S & = & L_R + q_F F, & i = f, ..., N \end{array} \tag{9}$$

where Q_b is the heating power on the boiler. Finally, the molar flow rate of the bottom product is:

$$B = (L_S - V_S) b_v$$

b_v is a binary variable representing the bottom-valve opening, *i.e.*: $b_v = 0$ if a batch distillation is performed and $b_v = 1$ if the bottom product is totally withdrawn from the boiler.

Molar hold-up: The molar hold-up for every stage must be determined from the distillation plant features and properties of the mixture. This quantity can be approximated as:

$$M_i = v_i \frac{1}{\dfrac{x_1 M_{W_1}}{\rho_1} + \dfrac{(1 - x_2) M_{W_2}}{\rho_2}} \tag{10}$$

2.3 The dynamic model

Tray and distilled product compositions are estimated by using the dynamic model based on material, component and energy balances. Taking into account the assumptions (**A1**) to (**A7**), a set of differential equations can be derived for the light component material balance as follows:

$$\begin{cases} \frac{dM_1}{dt} = V_2 - L_1 - D \\ \frac{dM_i}{dt} = V_{i+1} - L_i - V_i + L_{i-1} + \delta(i) F \\ \frac{dM_N}{dt} = L_{N-1} - V_N - B \end{cases} \tag{11}$$

for $i = 2, 3, ..., N-1$. M_i is the molar holdup of the boiler. The component balances for every stage are given by:

$$\begin{cases} \frac{d(M_1 x_1)}{dt} & = V_2 y_2 - L_1 x_1 - D x_1 \\ \frac{d(M_i x_i)}{dt} & = V_{i+1} y_{i+1} - L_i x_i - V_i y_i + L_{i-1} x_{i-1} + \delta(i) F x_F \\ \frac{d(M_N x_N)}{dt} & = L_{N-1} x_{N-1} - V_N y_N - B x_N \end{cases} \tag{12}$$

where $\delta(i) = 1$ if $i = f$ and $\delta(i) = 0$ if $i \neq f$

The enthalpies of the process are considered constants, therefore the energy balance is not taken into account to develop this model. The state model presented in the following section is based on this dynamic model for the distillation column.

2.4 The state model

The distillation column is a process that belongs to a class of multi-variable nonlinear systems. The process inputs are the heating power applied on the boiler, and the opening period of the reflux valve, this is $\mathbf{u}(t) = [Q_b(t)\ r_v(t)]^T$. F y x_F are considered perturbations in the system, this is $\mathbf{d} = [F, x_F, b_v]$. A state representation can be obtained from Eqs. (11) and (12). Additionally, the nonlinear model has the following triangular form:

$$\begin{cases} \dot{\zeta}_1 = f_1(\zeta_1, \zeta_2, \mathbf{u}) \\ \dot{\zeta}_i = f_i(\zeta_1, ..., \zeta_i, \zeta_{i+1}, \mathbf{u}); \quad (i = 2, ..., f-2) \\ \dot{\zeta}_{f-1} = f_{f-1}(\zeta_1, ..., \zeta_{f-1}, \zeta_f, \mathbf{u}) \\ \dot{\zeta}_f = f_f(\zeta_{f-1}, ..., \zeta_N, \mathbf{u}, \mathbf{d}) \\ \dot{\zeta}_i = f_i(\zeta_{i-1}, ..., \zeta_N, \mathbf{u}, \mathbf{d}); \quad (i = f+1, ..., N-1) \\ \dot{\zeta}_N = f_N(\zeta_{N-1}, \zeta_N, \mathbf{u}, \mathbf{d}) \end{cases} \tag{13}$$

where, ζ represent the states of the process (the liquid compositions of the light component). Subindex f represents the feeding tray number in Eqs. (11) and (12). The model allows to calculate the flows B, D, V_i, L_i and T_i, x_i from inputs Q_b, r_v, b_v, F_V, x_F.

3. OBSERVER DESIGN FOR A CLASS OF NONLINEAR TRIANGULAR SYSTEMS

A special class of nonlinear systems consists of those which are observable for every input, called uniformly observable systems (see Hammouri et al. (2002)). For this class of nonlinear systems, an observer whose gain does not depend on the inputs can be designed. For such systems a canonical (triangular) form is used in order to design an observer. Due to the nonlinearity of the system, it is important to select the gain which gives the best compromise between fast convergence and accuracy. Consider the follow triangular system that can be rewritten in a compact form:

$$\begin{cases} \dot{\zeta}^1 = \mathbf{f^1}(\boldsymbol{\zeta}(t), \mathbf{u}(t)) \\ \dot{\zeta}^2 = \mathbf{f}^2(\boldsymbol{\zeta}(t), \mathbf{u}(t), \mathbf{d}(t), \varepsilon(t)) \\ \boldsymbol{\varrho(t)} = (\varrho_1(t), \varrho_2(t))^T = (\mathbf{C}_{n_1} \boldsymbol{\zeta^1}(t), \mathbf{C}_{n_2} \boldsymbol{\zeta^2}(t))^T \end{cases} \tag{14}$$

where the states $\boldsymbol{\zeta}(t) = \left[\boldsymbol{\zeta}^1(t), \boldsymbol{\zeta}^2(t)\right]^T \in \mathbb{R}^n$ and $n = n_1 + n_2$; $\zeta^j = \left[\zeta_1^j, \zeta_2^j, \ldots, \zeta_{n_j}^j\right]^T \in \mathbb{R}^{n_j}$ for $j = 1, 2$; $y_j = \mathbf{C}_{n_j} \zeta^j = \zeta_1^j$ the first component of ζ^j; $\mathbf{C}_{n_j} = [1, 0, \ldots, 0]$; the input $\mathbf{u} \in \mathbb{R}^m$, and $\varepsilon(t)$ is an unknown and bounded function. The following assumptions are considered in order to design the observer:

- (**A8**) $\mathbf{f}^j$ is globally Lipschitz *w.r.t.* ζ.
- (**A9**) The state variables $\boldsymbol{\zeta}(t)$ are bounded

Considering the following notations:

i) $\mathbf{C}_{n_j} = [1, \ldots, 0] \in \mathbb{R}^{n_j}$ where n_j is the size for every state vector ζ^j.
ii)

$$\mathbf{A}_{n_j}(t) = \begin{bmatrix} 0 & a_1(t) & 0 & 0 \\ \vdots & & a_2(t) & 0 \\ & & & \ddots \\ 0 & & \ddots & a_{n_j-1}(t) \\ 0 & \ldots & 0 & 0 \end{bmatrix},$$

where $a_k(t)$, $k = 1, \ldots, n_{j-1}$ are bounded and unknown functions satisfying the following assumption:

- (**A10**) There are two finite real numbers α, β with $\alpha > 0$, $\beta > 0$ such that $\alpha \leq a_k(t) \leq \beta$.

Lemma 1 *Under assumptions (**A8**) and (**A10**) exist a symmetric positive definite (S.P.D.) matrix $\mathbf{S}_{n_j}$ and a constant $\mu > 0$ s.t.:*

$$\forall t, \mathbf{S}_{n_j}\mathbf{A}_{n_j}(t) + \mathbf{A}_{n_j}^T(t)\mathbf{S}_{n_j} \leq -\mu\mathbf{I}_d \tag{15}$$

where $\mathbf{I}_d$ is the identity matrix.

Then,

$$\mathbf{S}_{n_j} = \begin{bmatrix} s_{11} & s_{12} & 0 & & & 0 \\ & & \ddots & & & \vdots \\ s_{12} & s_{22} & & & & \\ 0 & \ddots & & \ddots & & 0 \\ \vdots & & & \ddots & & s_{(n_j-1)n_j} \\ 0 & \ldots & 0 & s_{(n_j-1)n_j} & & s_{n_j n_j} \end{bmatrix},$$

Assume that the system given in Eq. (14) satisfies hypothesis (**A8**) to (**A10**). Then the observer:

$$\begin{cases} \dot{\hat{\boldsymbol{\zeta}}}^1 = \mathbf{f}^1(\hat{\boldsymbol{\zeta}}, \mathbf{u}) - r_1\boldsymbol{\Delta}_{\theta^{\delta_1}}\mathbf{S}_{n_1}^{-1}\mathbf{C}_{n_1}^T(\mathbf{C}_{n_1}\hat{\boldsymbol{\zeta}}^1 - \varrho_1) \\ \dot{\hat{\boldsymbol{\zeta}}}^2 = \mathbf{f}^2(\hat{\boldsymbol{\zeta}}, \mathbf{u}, \mathbf{d}) - r_2\boldsymbol{\Delta}_{\theta^{\delta_2}}\mathbf{S}_{n_2}^{-1}\mathbf{C}_{n_2}^T(\mathbf{C}_{n_2}\hat{\boldsymbol{\zeta}}^2 - \varrho_2) \end{cases} \tag{16}$$

is an estimator for the system given in Eq. (14), where $r_1 > 0$, $r_2 > 0$; $\theta > 0$; $\boldsymbol{\Delta}_{\theta^{\delta_j}} = diag(\theta^{\delta_j}, \theta^{2\delta_j}, ..., \theta^{n_j\delta_j})$; $\delta_1 > 0$, $\delta_2 > 0$; $\mathbf{S}_{n_1}$ is given by **Lemma 1**.

The following theorem is given:

Theorem 1: *Denote by ε the upper bound of $|\varepsilon(t)|$ i.e. $\varepsilon = \sup_{t>0}|\varepsilon(t)|$, then for $r_1 > 0$, $r_2 > 0$, $\theta > 0$ sufficiently large and $\forall\delta_1 > 0$, $\delta_2 > 0$ s.t.*

$$\frac{2n_1 - 1}{2n_2 + 1}\delta_1 < \delta_2 < \frac{2n_1 + 1}{2n_2 - 1}\delta_1; \tag{17}$$

$$|\hat{\zeta}(t) - \zeta(t)\| \leq \lambda e^{-\mu t} + \lambda'\varepsilon; \tag{18}$$

for some constants $\lambda > 0$, $\mu > 0$ and $\lambda' > 0$. Moreover, $\mu \to +\infty$ as $\theta \to 0$.

Remark 1. *If $\varepsilon = 0$, the system given in Eq. (16) becomes an exponential observer for the system given in Eq. (14). A proof of this result is given in Hammouri et al. (2002).*

3.1 Application of the designed observer to a distillation column

In the previous sections Eqs. (14) to (16) describe the high-gain observer designed for a distillation column, as well as the appropriate model in which this observed is based. In this section, an observer synthesis to the following class of nonlinear systems is developed, which contains the model of binary distillation columns, considering the following notations:

$$\begin{cases} \zeta_i = \zeta_i^1; \ \ 1 \leq i \leq f - 1 \\ \zeta_{N-i+1} = \zeta_i^2; \ \ 1 \leq i \leq N - f + 1 \\ \zeta_F = \zeta_{N-f+2}^2 \end{cases} \tag{19}$$

then, the system given in Eq. (13) can be represented in the following compact form:

$$\begin{cases} \dot{\zeta}^1(t) = \mathbf{f}^1(\boldsymbol{\zeta}(t), \mathbf{u}(t), D(t)) \\ \dot{\zeta}^2(t) = \mathbf{f}^2(\boldsymbol{\zeta}(t), \mathbf{u}(t), \mathbf{d}(t), \varepsilon(t), B(t)) \\ \boldsymbol{\varrho}(t) = (\zeta_1^1, \zeta_1^2)^T = (\zeta_1, \zeta_N)^T \end{cases} \tag{20}$$

where $\varepsilon(t)$ is a bounded and unknown function *s.t.* $\dot{\zeta}_F = \varepsilon(t)$. The liquid flow rates in the stripping section and vapor flow rates in the rectifying section are not known variables. The holdup in the condenser, the boiler and trays (where it is assumed to be constant) is calculated . The weighted error between the estimated and the measured compositions is feed back to the model equation in order to correct the liquid flow rates in the stripping section and the vapor flow rates in the rectifying section (see Halvorsen and Skogestad (2000)).

The hypothesis (**A9**) and (**A10**) must be verified:

- (**A9**) is fulfilled since the flow rates are physically bounded.
- (**A10**) is satisfied because the liquid compositions $x_i \in [0, 1]$

Applying **Theorem 1**, the high-gain observer for the distillation column is:

$$\begin{cases} \dot{\hat{\boldsymbol{\zeta}}}^1 = \mathbf{f}^1(\hat{\boldsymbol{\zeta}}, \mathbf{u}, D(t)) - \mathbf{Q}_{1\theta}(\mathbf{C}_{n_1}\hat{\boldsymbol{\zeta}}^1 - \varrho_1) \\ \dot{\hat{\boldsymbol{\zeta}}}^2 = \mathbf{f}^2(\hat{\boldsymbol{\zeta}}, \mathbf{u}, B(t), \mathbf{d}, \varepsilon(t)) - \mathbf{Q}_{2\theta}(\mathbf{C}_{n_2}\hat{\boldsymbol{\zeta}}^2 - \varrho_2) \end{cases} \tag{21}$$

where $\mathbf{Q}_{j\theta} = r_j\boldsymbol{\Delta}_{\theta^{\delta_j}}\mathbf{S}_{n_j}^{-1}\mathbf{C}_{n_j}^T$, for $j = 1, 2$. The constant parameters are the same described in Eq. (16).

4. EXTENSION OF THE HIGH-GAIN OBSERVER TO THE CONTINUO-DISCRETE CASE

There are processes where the measurement of their variables are performed using long sampling times due to their slow dynamics. In Bahar et al. (2006) it is demonstrated that certain restrictions in the dimension of the sampling period used by a purely discrete observer exist. An alternative of solution for this problem is the use of continuous-discrete observers (see Hammouri et al. (2002)).

Consider a non-linear uniformly observable systems of the form:

$$\begin{cases} \dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t)) \\ \mathbf{y}(\mathbf{t}) = \mathbf{h}(x(t)) \end{cases} \tag{22}$$

where $x(t) \in \mathbb{R}^n$, $u = (u_1, ..., u_n) \in \mathbb{R}^m$, are measurable inputs and $y \in \mathbb{R}$ is a measurable output. Using the model of the system with $u(t), y(t)$ as known measurements it is possible to estimate the state line in $x(t)$ of the system represented by Ec. 22, this task is performed by a recursive algorithm with the following structure:

i. A prediction period in the time interval $t \in [t_k, t_{k+1}]$:

$$\dot{\hat{x}}_k(t) = \mathbf{f}(\hat{\mathbf{x}}(t), \mathbf{u}(t)) \tag{23}$$

ii. A correction period in the time $t = t_{k+1}$:

$$\dot{\hat{x}}_{k+1}(t) = \hat{\mathbf{x}}_{\mathbf{k+1}}(-) - r\Delta_\theta S_\theta^{-1}C^T(C\hat{x}_{k+1}(-) - y_{k+1}) \tag{24}$$

To make the extension of the high-gain observer to continuous-discrete case, it is assumed that the observations are made at the time $k\triangle t$, where $\triangle t$ is the time between measurements and k is the instant in which the sample is taken. In this case, it is not considered a coordinates change because the triangular structure of the model studied in section 3 is used.

As the observer gain is constant, it is true that:

$$\forall t > 0, \mathbf{A}_k^T(t)\mathbf{S}_k + \mathbf{S}_k\mathbf{A}_k(t) - \rho\mathbf{C}_k^T\mathbf{C}_k \leq\leq -\mu\mathbf{I}_k \quad (25)$$

where S_k is a symmetric positive definite matrix with the following structure:

$$\mathbf{S}_k = \begin{bmatrix} s_{11} & s_{12} & 0 & & 0 \\ & \ddots & & & \vdots \\ s_{12} & s_{22} & \ddots & & \\ & \ddots & & \ddots & 0 \\ \vdots & & & \ddots & s_{(k-1)k} \\ 0 & \dots & 0 & s_{(k-1)k} & s_{kk} \end{bmatrix},$$

C_k is denoted as a vector of k elements:

$$\mathbf{C}_{n_j} = [1, \dots, 0] \quad (26)$$

and A_k is given by:

$$\mathbf{A}_k(t) = \begin{bmatrix} 0 & a_1(t) & 0 & 0 \\ \vdots & & a_2(t) & 0 \\ & & \ddots & \\ 0 & & & a_{k-1}(t) \\ 0 & \dots & 0 & 0 \end{bmatrix},$$

where the terms a_k may be unknown and satisfy the hypothesis **A9**.

5. EXPERIMENTAL VALIDATION OF THE OBSERVER

The distillation pilot plant, located at the Process Control Laboratory of the National Center of Technological Research and Development (CENIDET) in Cuernavaca, Morelos, México, was used to carry out the required experiments. It has twelve trays, where temperature measurements are available through 8 RTD's Pt-100 located at trays 1, 2, 4, 6, 7, 9, 11 and 12. Using these measurements and considering the equilibrium relation (see Section 2.2.2), the respective liquid compositions can be obtained.

The mixture used in these experiments was Ethanol(EtOH)-Water(H_2O) which is considered as a non-ideal mixture. The experimental validation of the observers is done considering: EtOH volume of 2000 ml, H_2O volume of 2000 ml and process total pressure of 105.86 kPa. The specifications of every component of the mixture can be found in Perry (1999). The experiment lasts 82 minutes, once it has reached the stable state. In minute 27 the system goes from total reflux to partial reflux. In minute 54, a change in the input Q_b is applied.

In the discrete observer the sampling time is used to estimate and correct. In the continuous-discrete observer the prediction and correction times can be different in order to use less data, therefore less processing time, performing a reliable online estimation. The observer estimates the liquid composition of the light component (EtOH) for every stage by having the temperature measurements on stage 1 (condenser) and stage 12 (boiler) only.

The high-gain observer is obtained by fixing $r_1 = r_2 = 25$; $\theta = 0.09$ and satisfying (16) with $\delta_1 = 1.2$, $\delta_2 = \frac{1}{2}\left[1 + \left(\frac{2n_1+1}{2n_2-1}\right)^2\right]\delta_1 = 0.0983$(where $n_1 = f - 1 = 6, n_2 = n - f + 2 = 6$). Finally Lemma 1 gives:

$$\mathbf{S}_{n_1} = \mathbf{S}_{n_2} = \begin{bmatrix} 1 & -1 & 0 & 0 & 0 & 0 \\ -1 & 2 & -1.5 & 0 & 0 & 0 \\ 0 & -1.5 & 4 & -2 & 0 & 0 \\ 0 & 0 & -2 & 8 & -3 & 0 \\ 0 & 0 & 0 & -3 & 10.5 & -4 \\ 0 & 0 & 0 & 0 & -4 & 15.5 \end{bmatrix}$$

Fig. 2 shows a comparison between the experimental dat and the estimation performed by the discrete observer in plate 12 (boiler) using a sampling time of $3s$. If the sampling time is slightly increased to $5.4s$ the discrete observer can not perform an adequate estimation, as can be seen in Fig. 3.

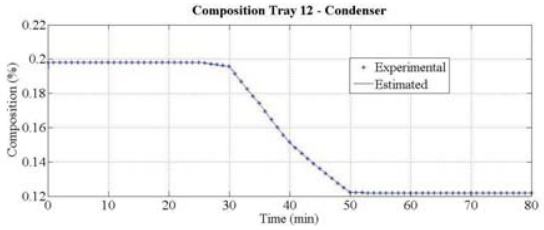

Fig. 2. Composition estimation of tray 12 by the discrete observer using a sampling time of 3 sec

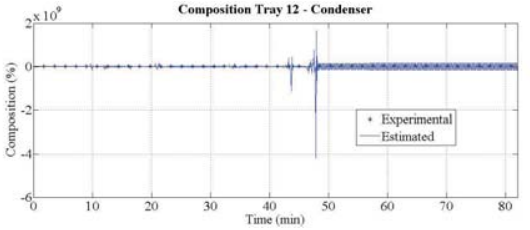

Fig. 3. Composition estimation of tray 12 by the discrete observer using a sampling time of 5.4 sec

In the continuous-discrete observer, a fixed prediction time of $3s$ is used, but different correction times are used in order to validate its performance. Figs. 4 to 6 show the experimental and estimated data when the correction time is 15 seconds, 30 seconds and 1 minute, respectively. In these figures it can be seen the good tracking and quickly convergence of the observer to the experimental data. The observer estimates the compositions of the plant adequately, under different conditions of correction time, having a maximum error of 0.03 and a minimum error 0.0001 between the estimated and the experimental data (the Euclidiean norm was used to estimate the error).

6. CONCLUSIONS

In order to validate the performance of the high-gain observer versions: discrete and continuous-discrete, some experiments were conducted under similar conditions. First,

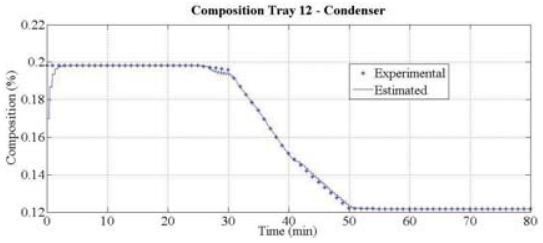

Fig. 4. Composition estimation of tray 12 by the continuous-discrete observer using a correction time of 15 sec

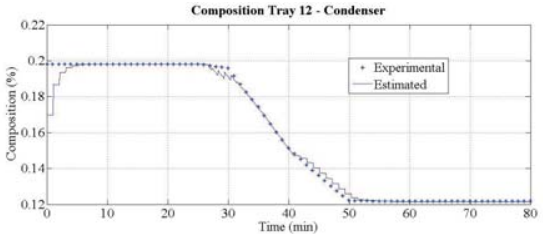

Fig. 5. Composition estimation of tray 12 by the continuous-discrete observer using a correction time of 30 sec

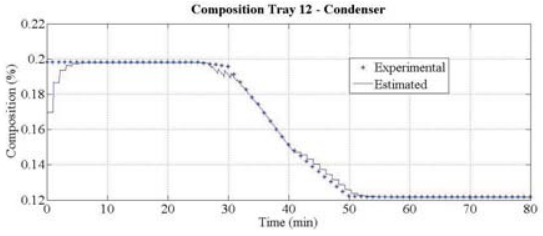

Fig. 6. Composition estimation of tray 12 by the continuous-discrete observer using a correction time of 60 sec

the purely discrete observer was validated, in order to perform, later, an adequate comparison with the continuous-discrete observer and analyze their response. Both validation use the same component specifications and same experimental inputs.

As can be seen in the presented figures the continuous-discrete observer presents a good tracking and quickly convergence to the experimental data, in spite of the sampling time used in the correction stage unlike the purely discrete observer, where the sampling time affects considerably its performance. Therefore, it can be assumed that the continuous-discrete observer is a suitable option to estimate the desired variables when the measurements of the system are performed using a long sampling time due to the slow dynamics of the process, which is the case of a distillation column where the compositions of the light component in a binary mixture of Ethanol-Water are estimated accurately.

Abstract: The problem of jointly designing the estimation structure and algorithm to infer all or some composition in a six-component distillation column with temperature measurements is addressed. The structure design involves the choices of: (i) modeled and unmodeled compositions, (ii) the number of measurements and their location, and (iii) the innovated-noninnovated state partition. The algorithm is the dynamic data processor that performs the estimation task. The application of the geometric estimation approach (GE), in the light of the column characteristics, yields a tractable procedure to draw the solution of the estimation structure-algorithm design problem, with an estimation scheme that is considerably simpler than previous ones with extended Kalman Filter (EKF). The proposed methodology is applied to a representative six-component case example through simulations, finding that the estimation task can be performed with a three-component reduced model.

Keywords: Distillation column, nonlinear, estimators, geometric estimators, multicomponent.

1. INTRODUCTION

Distillation is an important energy-intensive industrial operation where many substances are separated and purified. The development of estimation schemes with temperature measurements for multicomponent distillation columns is motivated by: (i) the need of developing monitoring systems and (supervisory, advisory, and feedback) controllers with applicability-oriented requirements on reliability, tractability and maintenance cost, and (ii) the availability of reasonable and reliable multicomponent distillation models, including commercial packages.

The extended Kalman Filter (EKF) (Jazwinsky (1970)) has been by far the most widely used estimation technique in chemical process systems engineering in general, and in multicomponent distillation columns in particular, with successful simulations and experimental implementations for continuous and batch column operations, mostly for binary (Baratti et al. (1995); Yang and Lee (1997)) and ternary systems (Baratti et al. (1998)), and up to four-component systems (Venkateswarlu and Kumar (2006)). Even though adequate multicomponent column models are available, the related EKF construction and implementation for multicomponent systems still rises reliability, complexity, and development-maintenance cost concerns among industrial practitioners, because: (i) the dimensionality of the EKF grows rapidly with the number of stages and components ($\frac{n(n+1)}{2}+n$), (ii) the tuning of the covariance gains of the Riccati equation is a rather complex task, and (iii) due to the lack of formal connections between estimator tuning and functioning, the implementation of the EKF requires extensive testing.

Recently, the geometric estimation (GE) approach (Alvarez (2000)), which does not require the on-line integration of Riccati equations, has been redesigned with the following features (Alvarez and Fernandez (2008)): (i) the obstacle of high order Lie derivations has been removed and replaced by Jacobian model-based gain computations, enabling the consideration of staged systems, (ii) the equivalence between the GE and the EKF has been identified, (iii) the estimation model, its (innovation-noninnovation) detectability structure, and the sensor locations are regarded as structural design degrees of freedom, and (iv) a simple tuning scheme is coupled with a robust convergence criterion. The general-purpose GE approach has been successfully tested with experimental binary columns with complete (Tronci et al. (2005); Fernandez and Alvarez (2007)) or reduced models (Alvarez and Fernandez (2008)), and ternary columns (Pulis et al. (2006)), yielding estimation schemes which are considerably simpler than the EKF-based ones. These considerations motivate the present study on the six-component distillation column problem.

In this work, the problem of simultaneously designing the estimation structure and algorithm to infer all or some composition in a six-component distillation column with temperature measurements is addressed. By structure design we mean the choices of: (i) modeled and unmodeled compositions, (ii) the number of measurements and their locations, and (iii) the innovated-noninnovated composi-

tion state partition which, in conjunction with the model-sensor choice, determines the data assimilation versus error propagation mechanism. By algorithm it is meant the dynamic data processor that performs the estimation task, according to the estimation structure and a suitable gain tuning scheme. The application of afore discussed GE approach, in the light of the six-component column characteristics, yields a tractable procedure to solve the structure-algorithm problem, with an estimation scheme that is considerably simpler than previous EKF-based ones. The proposed methodology is applied to a representative six-component case example through simulations, finding that the estimation task can be performed with a three-component reduced model, a single-stage innovation with passive structure, and without the need of online integrating Riccati equations. The study can be seen as an inductive step towards the consideration of columns with more than six components.

2. ESTIMATION PROBLEM

2.1 Six-component distillation column

Consider a continuous multicomponent column with N stages and C components. Under standard assumptions (energy balance neglected on each tray, constant vapor and liquid flows, holdup dynamics neglected, tight reboiler and condenser level control, and stage liquid-vapor equilibrium), the column dynamics are described by the following set of nonlinear differential equations (Skogestad (1997); Baratti et al. (1998)):

Reboiler ($i = 1$, $j = 1, \ldots, C-1$)

$$\dot{c}_1^j = \frac{(R+F)c_2^j - V\epsilon_j(c_1, P_1) - Bc_1^j}{M_1} = f_1^j(c_1, c_2^j) \quad (1a)$$

Stripping section ($2 \le i \le N_F - 1$, $j = 1, \ldots, C-1$)

$$\dot{c}_i^j = \frac{(R+F)(c_{i+1}^j - c_i^j) - V(\epsilon_j(c_i, P_i) - \epsilon_j(c_{i-1}, P_{i-1}))}{M_i} \quad (1b)$$
$$= f_i^j(c_{i-1}, c_i, c_{i+1}^j)$$

Feed tray ($i = N_F$, $j = 1, \ldots, C-1$)

$$\dot{c}_{N_F}^j = \frac{R(c_{N_F+1}^j - c_{N_F}^j) + F(c_F^j - c_{N_F}^j)}{M_{N_F}} - \frac{V(\epsilon_j(c_{N_F}, P_{N_F}) - \epsilon_j(c_{N_F-1}, P_{N_F-1}))}{M_{N_F}} \quad (1c)$$
$$= f_{N_F}^j(c_{N_F-1}, c_{N_F}, c_{N_F+1}^j, c_F)$$

Enriching section ($N_F + 1 \le i \le N - 1$, $j = 1, \ldots, C-1$)

$$\dot{c}_i^j = \frac{R(c_{i+1}^j - c_i^j) - V(\epsilon_j(c_i, P_i) - \epsilon_j(c_{i-1}, P_{i-1}))}{M_i} \quad (1d)$$
$$= f_i^j(c_{i-1}, c_i, c_{i+1}^j)$$

Condenser ($i = N$, $j = 1, \ldots, C-1$)

$$\dot{c}_N^j = \frac{V\epsilon_j(c_{N-1}, P_{N-1}) - Rc_N^j - Dc_N^j}{M_N} = f_N^j(c_{N-1}, c_N^j) \quad (1e)$$

Temperature measurements ($i = 1, \ldots, m$)

$$T_{s_i} = \beta(c_{s_i}, P_{s_i}) \quad (1f)$$

where m is the number of sensors along the column and s_i is the location of the i-th sensor, c_i^j is the composition of the component j at i-th stage, $c_i = [c_i^1 \ \ldots \ c_i^{C-1}]^T$ is the composition vector at i-th stage, T_{s_i} and P_{s_i} are respectively the temperature and the pressure at s_i-th stage, F is the feed flow rate with composition $c_F = [c_F^1 \ \ldots \ c_F^{C-1}]^T$, D, B, R, and V are respectively the distillate, bottom, reflux and vapor flow rate (V is proportional to reboiler duty Q through the heat of vaporization λ), M_i is the holdup at i-th stage, ϵ_j is the liquid-vapor equilibrium function that determines the vapor composition of the component j, and β is the bubble-point implicit function that sets the temperature. The components c_i^C are determined by the (mass conservation) condition $\sum_{j=1}^{C} c_i^j = 1$, where $i = 1, \ldots, N$. Henceforth, column system (1), will be referred to as the *complete six-component column system*, which in compact vector notation is written as follows:

$$\dot{x}_P = f_P(x_P, u_P, d_P) \qquad y_P = h_P(x_P) \quad (2)$$

where $x_P = [{c_1}^T \ldots {c_N}^T]^T$, $c_i = [c_i^{C2}\, c_i^{C3}\, c_i^{IC4}\, c_i^{NC4}\, c_i^{IC5}]^T$, $u_P = [R\, V]^T$, $d_P = [F\, {c_F}^T]^T$, and $y_P = [T_{s_1} \ \ldots \ T_{s_m}]^T$ are respectively the states, the inputs, the disturbances, and the outputs. The disturbances d_P are assumed to be constant and known.

2.2 Estimation problem

The estimation problem consists in jointly designing the estimation structure (i.e. estimator model, sensor location, innovated states and data assimilation mechanism), and the estimation algorithm (i.e., the dynamic data processor), to infer some of or all the effluent compositions of the six-component distillation column (2) on the basis of a reduced model (to be designed) in conjunction with temperature measurements, according to a specific estimation objective. In virtue of the general-purpose GE approach (Alvarez and Fernandez (2008)) and its applications to binary (Fernandez and Alvarez (2007); Alvarez and Fernandez (2008)) and ternary columns (Pulis et al. (2006)), in the present six-component column estimation study, the emphasis will be placed on: (i) the design of a reduced-component model for estimation, (ii) the employment of a robustness-oriented single-stage innovation scheme with passive structure (Pulis (2007)), (iii) the corresponding decision on the innovated components, meaning the components of the measurement stage with information and error injection, and (iv) the estimation of the effluent (distillate and bottom) impurity compositions as estimation objective.

2.3 Case example

As a representative industrial case example, consider the T110 distillation column located at SARAS refinery (Sarroch, Italy) with $N = 37$ stages and $C = 6$ components: a C3-C4 (propane-butane) splitter fed with propane (C3), iso-butane (IC4), and n-butane (NC4), as well as ethane (C2), iso-pentane (IC5), and n-pentane (NC5) as secondary components (with compositions less than 1%).

The column has a kettle reboiler (1-st stage), a total condenser (37-th stage), 35 nutter float valve trays, the feed is introduced at 19-th stage, the tray spacing is 61 cm, the column diameter is 2 m, and the pressure changes linearly along the column, with the top and bottom pressure being 16.3 Kg·cm^{-2} and 16.6 Kg·cm^{-2}, respectively. This case example represents a sufficiently important class of industrial columns, where two or three main components to be split are present, together with other secondary components in a much smaller amount.

The behavior of the "actual" six-component system (2) was numerically simulated with MATLAB, in the understanding that the same task can be performed with commercial packages (say ASPEN). The thermodynamics was simulated with ideal equilibrium (Reid et al. (1998)). The feed flow and compositions, as well as the reflux flow, and reboiler duty are given in Table 1. In all simulations, the initial conditions for the complete column system correspond to the steady-state determined by the data listed in Table 1.

Table 1. Input values for feed flow and compositions, reflux flow and reboiler duty

F (m^3·h^{-1})	82.9	C2 molar fraction	0.0036
R (m^3·h^{-1})	69.7	C3 molar fraction	0.281
Q (BTU)	19819000	IC4 molar fraction	0.236
		NC4 molar fraction	0.4746
		IC5 molar fraction	0.004
		NC5 molar fraction	0.0008

3. STRUCTURAL ANALYSIS

Motivated by the GE detectability measure-based sensor location criterion employed in previous binary (Tronci et al. (2005); Fernandez and Alvarez (2007); Alvarez and Fernandez (2008)) and ternary columns (Pulis et al. (2006)) as well as by their interpretation in terms of thermodynamic diagrams (Pulis et al. (2006)), in this section the sensor location and innovated composition structure is analyzed on the basis of stage-to-stage temperature gradients and their component-wise contributions.

3.1 Model reduction

The stage-to-stage temperature gradient about a certain operation condition is approximated as follows:

$$\Delta T_i = T_{i+1} - T_i \approx \sum_{j=1}^{C} \frac{\partial T_i}{\partial c_i^j}\bigg|_{c_i} \Delta c_i^j = \sum_{j=1}^{C} \Delta T_{c_i^j} \qquad (3)$$

where $\Delta c_i^j = c_{i+1}^j - c_i^j$, ΔT_i is the temperature gradient at the i-th stage, and $\Delta T_{c_i^j}$ is the contribution of the i-th gradient due to the component j. The idea which underlies the model reduction criterion is to set a data assimilation scheme with a favorable compromise between data assimilation and error propagation: (i) the stages with large temperature gradients are candidates for robustness-oriented single-stage (i.e. passive) innovation, and (ii) the compositions with large contributions to the overall gradient are candidates for being both modeled states and innovated states.

Table 2. Feed compositions for the reduced model

C3 molar fraction	0.2838
IC4 molar fraction	0.2388
NC4 molar fraction	0.4774

On the basis of the steady-state solution of the complete system (2) in conjunction with the total and per-component temperature gradient formula (3), the diagram presented in Figure 1 was obtained, showing that: (i) with respect to stage-to-stage temperature change, the most sensitive zone is the enriching section around the 32-nd stage, (ii) in general, the temperature gradients are due to C3, IC4 and NC4 composition changes, (iii) the IC5, and NC5 components have a rather small contribution to the temperature gradient, and (iv) at the top of the column (around the condenser stage) the C2 has a rather important influence on temperature.

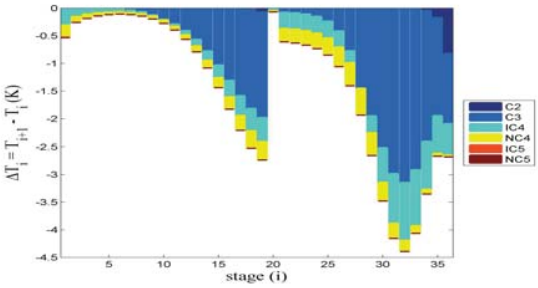

Fig. 1. Complete model-based temperature gradient and its per-component contributions

From the examination of the stage-to-stage temperature gradient and the per-component contributions to such gradient, the following structural conclusions are reached: the reduced model is obtained by retaining the C3, IC4, and NC4 components with appreciable manifestation in the temperature gradient, and discarding the three other ones (C2, IC5, and NC5) with comparatively small manifestation. Thus the reduced model is given by (1) with $C = 3$. In vector notation, the *reduced model* is written as follows:

$$\dot{x} = f(x, u, d) \qquad y = h(x) \qquad (4)$$

where $x = [c_1^{C3} c_1^{IC4} \dots c_N^{C3} c_N^{IC4}]^T$, $u = [R\,V]^T$, $d = [F c_F^{C3} c_F^{IC4}]^T$, and $y = [T_{s_1} \dots T_{s_m}]^T$ are respectively the states, the inputs, the disturbances, and the outputs. The reduced model (4) was set with the feed compositions presented in Table 2.

The behaviors of the reduced three-component model (4) and complete six-component system (2) are presented in Figure 2, showing that the model reduction error has an appreciable (or negligible) manifestation in the distillate (or bottoms) concentrations, and the same is true for the enriching (or stripping) section. This signifies that: (i) the bottom composition can be adequately estimated, without measurement injection, by means of a reduced model-based open-loop observer, and (ii) the distillate compositions can be estimated with a reduced model-based estimator with one temperature measurement, as

the temperature measurement before the top of the column basically reflects C3 and IC4 changes.

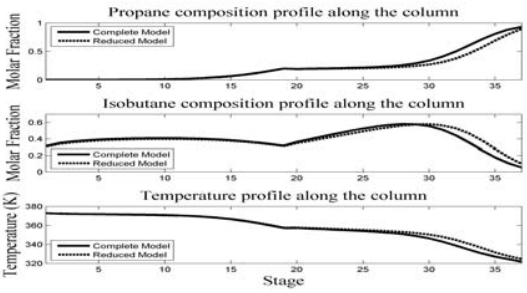

Fig. 2. C3 and IC4 composition and temperature profiles along the column with (six-component) complete and (three-component) reduced models

3.2 Sensor location and innovated states

On the basis of the steady-state solution of the reduced model (4) in conjunction with the total and per-component temperature gradient formula (3), the diagram presented in Figure 3 was obtained, showing that: (i) in the stripping (or enriching) section, the largest temperature gradient, or equivalently, the richest-in-information zone, is located below the feed (or top) tray, and (ii) in the stripping (or enriching) section, the smallest temperature gradient, or equivalently, the poorest-in-information zone, is located above the reboiler (or feed) tray.

From the preceding comments and the findings of Subsection 3.1, the next conclusions on sensor location follow: (i) one temperature measurement should be placed in the stripping section, located at the richest-in-information region (between 29-th and 33-rd stages) with the largest temperature gradient, and (ii) no temperature measurement is needed in the stripping section, as the bottom compositions can be adequately estimated using just the reduced model (without measurements). According to Figure 3, the C3 component has the largest contribution to the temperature gradient in the richest-in-information zone, meaning that the C3 component is an innovated state candidate for a robustness-oriented GE with passive structure (Pulis et al. (2006)).

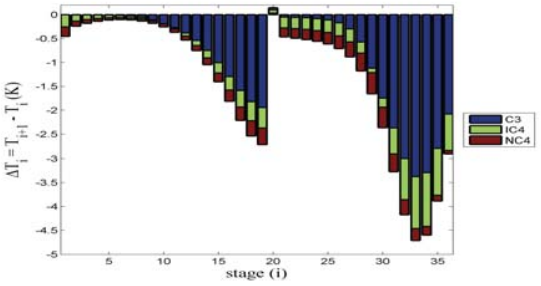

Fig. 3. Reduced model-based temperature gradient and its per-component contributions

3.3 Candidate estimation structures

According to the preceding developments, the two-effluent composition estimation task for the six-component system (2) can be performed using the reduced three-component model with one temperature sensor located between 25-th and 33-rd stages, with the C3 component as innovated state in a robustness-oriented GE with passive structure (Pulis et al. (2006)). To preclude unduly bottom-to-top model and measurement error propagation, no measurement in the stripping section is placed. To have a favorable balance between data assimilation and model-measurement error propagation from the measurement to distillate effluent composition estimate, a measurement should be located in the tray interval between stages 29 and 33, and not in any of the two top trays (stages 35 and 36) as shown in Figure 1. Thus, the preceding considerations lead to the following candidate estimation structure: (i) no sensor in the stripping section, (ii) one sensor in the enriching section between 29-th and 33-rd trays, and (iii) the C3 composition as innovated state. These structural conclusions are suggestive in the sense that: (i) candidate sensor location and innovated C3 compositions around the afore concluded candidates must be examined, and (ii) the conclusive structural assessment will be performed in the next section, on the basis of GE functioning. In order to verify the estimator performance, some different choices for the set of innovated states have been selected by following the considerations above: these innovated state sets will be illustrated and compared in Section 4.

4. STRUCTURE ASSESSMENT WITH ESTIMATOR FUNCTIONING

Having as point of departure the candidate structures identified in the preceding section, in this section the estimation structure for effluent composition estimation aims is assessed on the basis of the structure behavior with a robustness-oriented GE with passive structure (Pulis et al. (2006)). The role of the actual process will be played by the six-component system (2), and the GE will be implemented with the reduced three-component model (4).

4.1 Geometric estimator with passive innovation

Let us recall the adjustable-structure proportional-integral (PI) GE with passive structure (Alvarez and López (1999); Alvarez and Fernandez (2008)):

$$\begin{aligned} \dot{\hat{x}}_I &= f_I(\hat{x},\hat{u}) + \Phi_{x_I}^{-1} P(K_P(y_P - \hat{y}) + z) \\ \dot{\hat{x}}_{II} &= f_{II}(\hat{x},\hat{u}) \qquad \dot{z} = K_I(y_P - \hat{y}) \qquad \hat{y} = h(\hat{x}) \end{aligned} \tag{5}$$

where $\hat{x}$, $\hat{u}$, and $\hat{y}$ are the estimates of x, u, and y, $x_I \in \mathbb{R}^{n_I}$ is the set of the innovated states, $x_{II} \in \mathbb{R}^{n-n_I}$ is the set of the non-innovated states, K_P and K_I are respectively the proportional and integral gain matrices. For this kind of estimator structures, if $x_I = [c_{s_1}^{l_1} \ \dots \ c_{s_1}^{l_1^{n_1}} \ \dots \ c_{s_m}^{l_m^1} \ \dots \ c_{s_m}^{l_m^{n_m}}]^T$, then K_P, K_I, Φ_{x_I}, and P assume the following form:

$$K_P = \begin{bmatrix} K_{P,s_1} & & \\ & \ddots & \\ & & K_{P,s_m} \end{bmatrix} \qquad K_I = \begin{bmatrix} K_{I,s_1} & & \\ & \ddots & \\ & & K_{I,s_m} \end{bmatrix}$$

$$\Phi_{x_I} = \left[\left. \frac{\partial \hat{T}_{s_1}}{\partial \hat{c}_{s_1}^{l_1^1}} \right|_{\hat{c}_{s_1}} \cdots \left. \frac{\partial \hat{T}_{s_1}}{\partial \hat{c}_{s_1}^{l_1^{n_1}}} \right|_{\hat{c}_{s_1}} \cdots \left. \frac{\partial \hat{T}_{s_m}}{\partial \hat{c}_{s_m}^{l_m^1}} \right|_{\hat{c}_{s_m}} \cdots \left. \frac{\partial \hat{T}_{s_m}}{\partial \hat{c}_{s_m}^{l_m^{n_m}}} \right|_{\hat{c}_{s_m}} \right] \cdot \begin{bmatrix} 1 & & \\ & \ddots & \\ & & 1 \end{bmatrix} \qquad P = \begin{bmatrix} 1 \ldots 1 & & \\ & \ddots & \\ & & 1 \ldots 1 \end{bmatrix}^T$$

Note that: (i) the generic composition $c_{s_i}^{l_i^j}$ is innovated only by using temperature at s_i-th stage; (ii) n_i represents the number of innovated components at s_i-th stage and the condition $\sum_{i=1}^{m} n_i = n_I$ holds; (iii) $[x_I \, x_{II} \, z]^T \in \mathbb{R}^{n+m}$; (iv) P is a matrix of 1s and 0s, where for every column $i \in \{1, \ldots, m\}$ there are n_i 1s as shown above. When the integral action state is eliminated, the proportional (P) GE is obtained.

The robust convergence aspects and its connection with the tuning of gains can be seen in Alvarez and Fernandez (2008), and here it suffices to mention that: (i) the convergence criterion is coupled with rather easy-to-apply tuning guidelines, and (ii) the tuning scheme and guidelines apply over all structures. In this way, one has the certainty that the estimator functioning results are due to the structure and not to the tuning scheme.

Next the GE tuning guidelines for the GE PI estimator with passive structure are recalled. Consider an innovated state $c_{s_i}^{l_i^j}$: then, the corresponding temperature used in order to estimate this composition is T_{s_i} and the tuning parameters are:

$$K_{P,s_i} = 2\xi_{s_i}\omega_{s_i} \qquad K_{I,s_i} = {\omega_{s_i}}^2 \tag{6}$$

where ω_{s_i} and ξ_{s_i} are respectively the characteristic frequency and the damping factor of the estimator at s_i-th stage. The characteristic frequency ω_{s_i} must be chosen between 5 and 10 times faster than ω_{o,s_i} (where ω_{o,s_i} is the natural characteristic frequency of composition at s_i-th stage). Following conventional-like filter and control behavior assessments, the estimator functioning will be measured with the IAE index and the steady-state error.

As mentioned before, the estimation task is to infer the effluent impurity compositions (i.e., C3 in the bottom and IC4 in the top). Since the C3 in the reboiler is adequately described by the model without measurement, only the results of the IC4 distillate composition estimates will be presented. Several simulations have been performed, but for sakes of brevity only one of them is reported here. To test the estimator over different structures, a column transient has been induced by some step changes at the reboiler duty ($\Delta Q = +3\%$ at $t = 2$ hrs and $\Delta Q = 0$ at $t = 8$ hrs, with respect to Q value of Table 1)

Two different measures have been employed: (i) the steady-state error (7a), and (ii) the IAE index (7b)

$$e_{i,SS1}^j \quad \text{if} \quad \Delta Q = 0 \quad \text{and} \quad e_{i,SS2}^j \quad \text{if} \quad \Delta Q = +3\% \tag{7a}$$

$$IAE(e_i^j) = \int |e_i^j| dt \tag{7b}$$

where e_i^j is the composition error for the component j at i-th stage. There are two steady-state errors, since two different steady-state conditions are present, as can be seen from Figures 4, 5, and 6. For all the structures considered, the estimator has been tuned with the tuning guidelines sketched in (6), with $\omega_{s_i} = 10\omega_{o,s_i}$ and $\xi_{s_i} = 3$ for $i = 1, \ldots, m$.

4.2 Estimation with one innovated state

On the basis of the structural analysis performed in Section 3, two single-innovated state cases have been considered: $x_I = [c_{29}^{C3}]$ and $x_I = [c_{33}^{C3}]$.

The corresponding GE behavior results are presented in Figure 4 and Table 3, showing that: (i) comparing with the reduced model behavior, in both cases the estimate error undergoes a considerable reduction by measurement injection, and (ii) the case with c_{33}^{C3}-innovation yields a slightly better behavior than with c_{29}^{C3}-innovation. This result is consistent with the conclusion reached in Section 3, as 33-th stage has the largest stage-to-stage gradient and is close to the top stage.

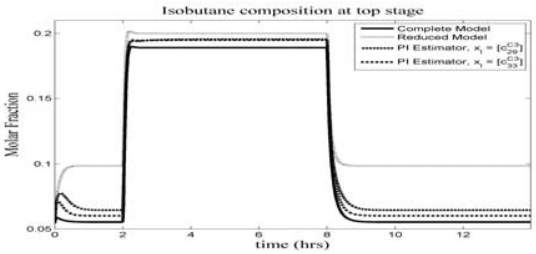

Fig. 4. IC4 distillate composition estimate with one innovated state

4.3 Estimation with two innovated states

Now, let us find out whether the joint consideration of the two previous cases leads to some estimator behavior improvement, this is $x_I = [c_{29}^{C3} \, c_{33}^{C3}]^T$.

The corresponding GE behavior results are presented in Figure 5 and Table 3, showing that there is not an appreciable improvement over the estimation structures with one innovated state discussed in the last subsection (see Figure 4).

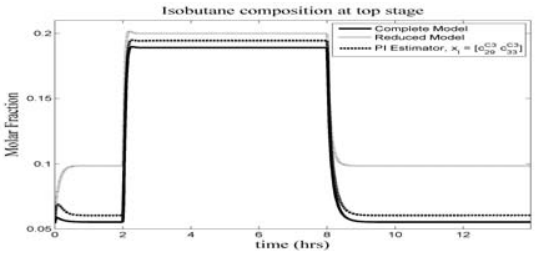

Fig. 5. IC4 distillate composition estimate with two innovated states

4.4 Estimation with three innovated states

Finally, let us investigate if the effluent estimation behavior can be improved by adding one innovated state to the two-innovated state structure presented in Subsection 4.3,

this is $x_I = [c_{29}^{C3}\ c_{31}^{C3}\ c_{33}^{C3}]^T$, with the incorporation of the innovated state c_{31}^{C3} being motivated by the fact that 29-th and 33-rd stages bracket the rich-in-information zone of the enriching section. The corresponding GE behavior results are presented in Figure 6 and Table 3, showing that there is an appreciable improvement over the two-innovated state estimation structure discussed in the last subsection (see Figure 5).

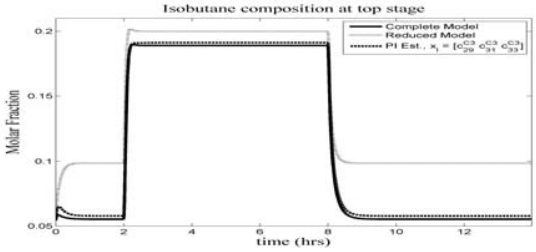

Fig. 6. IC4 distillate composition with three innovated states

Table 3. IAE values and steady-state errors (the subscript T refers to the top stage)

	$e_{T,SS1}^{IC4}$	$e_{T,SS2}^{IC4}$	$IAE(e_T^{IC4})$
Reduced model	−0.0433	−0.0109	20.1124
$x_I = [c_{29}^{C3}]$	−0.0092	−0.0064	5.9306
$x_I = [c_{33}^{C3}]$	−0.0049	−0.0058	3.8622
$x_I = [c_{29}^{C3}\ c_{33}^{C3}]^T$	−0.0052	−0.0054	3.8077
$x_I = [c_{29}^{C3}\ c_{31}^{C3}\ c_{33}^{C3}]^T$	−0.0025	−0.0022	1.7871

4.5 Concluding remarks

The behavior measures of the four estimation structures considered in this section are summarized in Table 3, showing that: the best GE estimator behavior is obtained with the three-innovated state structure, followed by the two-innovated state structure, and by the two single-innovated state structures. It must be pointed out that the steady-state estimation error is smaller than 1% and therefore comparable with typical measurement errors. These results are in agreement with the a priori structural assessments drawn in Section 3. The IC4 distillate composition estimation task can be effectively performed using: (i) a three-component reduced model, (ii) one or more sensors located between stages 29 and 33 in the enriching section, and (iii) passive innovation for component C3.

5. CONCLUSIONS

The problem of jointly designing the estimation structure and algorithm to infer an effluent composition for a six-component distillation column with temperature measurement option has been resolved in a tractable manner within a GE design framework in the light of the staged column system characteristics. The design focused on structural aspects: model reduction, sensor location, and innovation mechanism. The methodology consisted of: (i) one structural analysis step that yielded a few candidate structures and (ii) a step with conclusive structural results on the basis of estimator behavior assessment. The resulting GE (with 75 to 77 nonlinear ordinary differential equations (ODEs), depending on the structure) was considerably simpler than its EKF counterpart (with 2812 ODEs) and of tuning procedure (trial-and-error or optimization for the EKF and well defined for the GE).

Currently, work is underway to apply the proposed approach to estimate the pollutant contents in the outlet streams of an actual industrial column.

Temperature Inferential Dynamic Matrix Control of Reactive Distillation Systems

Deeptanshu Dwivedi and Nitin Kaistha *
Department of Chemical Engineering
Indian Institute of Technology Kanpur India 208016

Abstract: Two-temperature inferential control of the ideal and the methyl acetate double feed reactive distillation (RD) systems operated neat is evaluated using constrained dynamic matrix control (CDMC) and traditional decentralized control. For the ideal RD system, significant improvement in the stripping tray temperature control and the transient deviation in the bottoms purity is observed using CDMC. For the methyl acetate system, CDMC results in significant improvement in the control of the two tray temperatures as well as transient deviations in both the distillate and bottoms purity. Results also show that the magnitude of the maximum through-put change for which the control system fails is noticeably higher using CDMC.

Keywords: Reactive distillation control, dynamic matrix control, temperature inferential control

1. INTRODUCTION

Reactive distillation (RD) is now an established process intensification technology combining reaction and separation in a single column with potentially significant economic savings when the reaction kinetics and component relative volatilities are favorable (Siirola, 1995). When compared to conventional "reactor-separator" processes, the high non-linearity due to direct interaction between reaction and separation combined with fewer control degrees-of-freedom makes the design of an effective control system crucial to the successful implementation of RD technology.

In probably the first paper on RD control, Roat et al (1986) demonstrated that seemingly appropriate control structures succumb to a steady state transition for a moderately large through-put change suggesting the presence of high-non-linearity. Several later articles highlighted the presence of steady state multiplicity in various RD systems (see eg Mohl et al, 1999; Taylor and Krishna, 2000). The presence of steady state multiplicity can result in non-linear dynamic phenomena under open and closed loop operation. Sneesby et al (1997) considered the implications of steady state multiplicity on the operation and control of etherification columns. Kumar and Kaistha (2008a) demonstrated the occurrence of 'wrong' control action and closed loop steady state transition for the hypothetical quaternary ideal RD column studied by Al-Arfaj and Luyben (2000).

Given the high non-linearity in RD systems, the application of non-linear control techniques has been recommended in the literature. Among the prominent non-linear RD control works, Kumar and Daoutiditis (1999) implemented a non-linear inversion based control scheme for an ethylene glycol RD column. Model based gain scheduling has been applied to an ETBE RD column. Gruner et al (2003) report the non-linear control of an industrial RD column operated by Bayer. More recently, Kawathekar and Riggs (2007) have applied a non-linear model predictive control scheme to an ethyl acetate column.

Even as non-linear model based control is widely accepted in the academic community, industrial practice remains strongly biased towards the traditional decentralized PI control and where justifiable, linear model predictive control techniques such as DMC. This is probably due to the difficulty in developing a high fidelity non-linear process model and identifying the model parameters in an industrial setting.

A careful examination of the RD control literature reveals that the control of two-reactant double-feed RD columns operated neat (no excess of a reactant) such as the quaternary ideal RD system and the methyl acetate RD system, is particularly challenging due to the need for stoichiometric balancing of the two fresh feeds. Adjusting one of the fresh feeds to maintain an appropriate tray composition has been shown to be an effective means of maintaining this balance. The use of temperature measurements instead of composition, the former being much more rugged, reliable, cheap and with fast measurement dynamics, however causes the control system to succumb to non-linear dynamic phenomena such as 'wrong' control action in the methyl acetate RD system or a closed loop steady state transition in the quaternary ideal RD system (Kumar and Kaistha, 2008a). Application of linear MPC techniques, which have found industrial acceptance, may significantly improve the performance of a temperature inferential control system for such 'difficult to regulate' processes. This work addresses the same for the quaternary ideal and the methyl acetate RD systems.

2. BASE-CASE COLUMN DESIGN

Figure 1 shows a schematic of the double feed RD columns studied in this work. The reaction $A + B \leftrightarrow C + D$ occurs in the reactive zone. For the methyl acetate system, the components A, B, C and D correspond to methanol, acetic acid, methyl acetate and water respectively. For the ideal RD

system, the component relative volatilities are in the order $\alpha_C > \alpha_A > \alpha_B > \alpha_D$ so that the reactants are intermediate boiling. The reaction kinetics and thermodynamic property models for the methyl acetate and the ideal RD system are taken from Singh et al (2005) and Al-Arfaj and Luyben (2000), respectively. The base-case design and operating conditions for the ideal RD system are taken from Kaymak and Luyben (2006). The internally heat integrated design of the methyl acetate RD system reported in Kumar and Kaistha (2008 b) is studied here. The salient design and operating conditions for the two systems are reported in Table 1.

$$A + B \leftrightarrow C + D$$

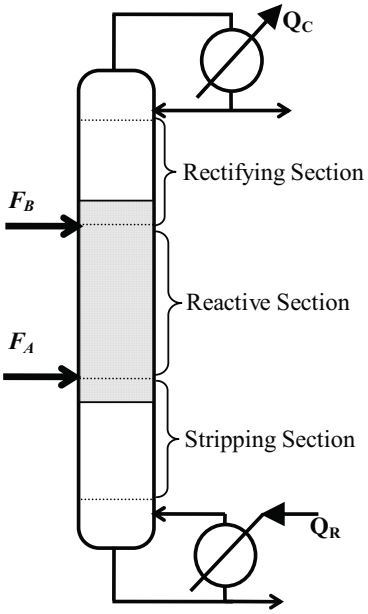

Figure 1. Schematic of a double feed reactive distillation column

Table 1: Design Parameters of Ideal RD system and Methyl Acetate system

	Ideal RD Column	Methyl Acetate RD column
Flow rate of feeds	$F_A = F_B$ = 12.6 mol/s	$F_{HAc}=F_{MeOH}$ =300 kmol/hr
$N_E/N_{RX}/N_S$ design	5/10/5	7/18/10
Feed tray locations	n_{FA} = 9; n_{FB} = 12	n_{FMeOH} =16; n_{FHAc} =28
Catalyst loading per reactive tray	0.7 kmol	300 kg
Pressure	8.5 bar	1.013 bar
Reflux ratio	2.6927	1.4877
Distillate rate	12.6 mol/s	308.63 kmol/h
Reboiler duty	0.8516 MW	3.66387 MW
Product purities	X_C,D = X_D,B = 0.95	X_{MeOAc},D=0.95 X_{H2O},B=0.96

3. TEMPERATURE INFERENTIAL CONTROL

3.1 Control Structures

Figure 2 & 3 plot the tray temperature sensitivities with respect to the two fresh feeds and the reboiler duty at constant reflux ratio for the ideal and methyl acetate columns. The sensitivity plots, suggest two candidate control structures, labeled as CS1 and CS2 for convenience. In CS1, F_A controls a sensitive stripping tray temperature while F_B controls a sensitive reactive tray temperature. The reboiler duty (Q_R) acts as the through- put manipulator. CS2 differs from CS1 in that the Q_R, instead of F_B is used to control a sensitive reactive tray temperature with F_B being the through-put manipulator. The two control structures are schematically depicted in Figure 4. Using bottom-up tray numbering, the temperature of Tray 2 (T_2), a stripping tray, and Tray 12 (T_{12}), a reactive tray, is controlled in the ideal RD column. In the methyl acetate column, the control tray temperature locations are Tray 2 (T_2) and Tray 13 (T_{13}). Note that in the ideal RD system, even as a rectifying tray temperature exhibits higher sensitivity than a reactive tray with respect to F_B (see Figure 2), it is not controlled due an inverse response with respect to F_B (Kaymak and Luyben, 2006) and severe input multiplicity resulting in a steady state transition for moderately large through-put changes (Kumar and Kaistha, 2008a).

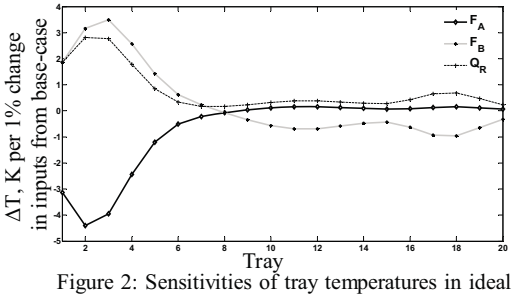

Figure 2: Sensitivities of tray temperatures in ideal RD system with respect to fresh feeds (F_A & F_B) and reboiler (Q_R) duty at fixed reflux ratio

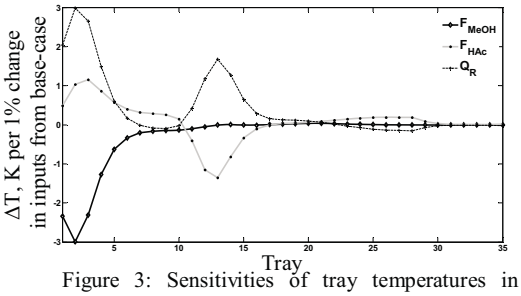

Figure 3: Sensitivities of tray temperatures in methyl acetate system with respect to Methanol feed (F_{MeOH}) and Reboiler Duty (Q_R) at fixed reflux

3.2 Dynamic Simulation and Temperature Controller Details

An in-house dynamic simulator is used to generate the open and closed loop dynamic simulation results for the two RD columns. With the two level controllers and perfect pressure control in place, a 2x2 temperature control system as in structures CS1 and CS2 is implemented. A 1 min lag is applied to the temperature measurements. The performance

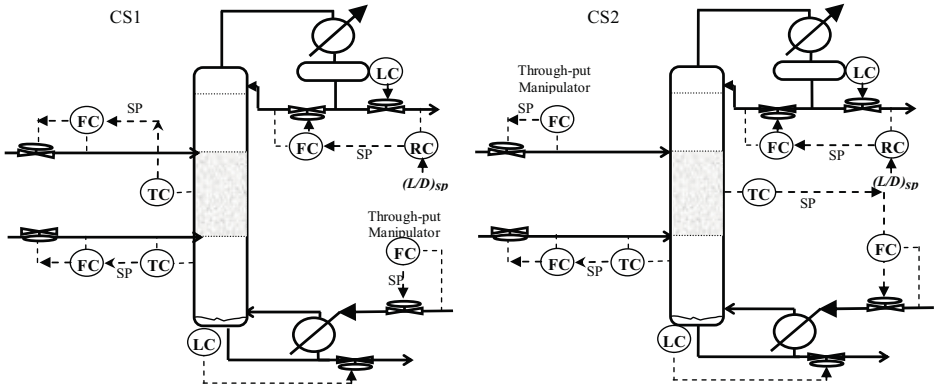

Figure 4. Schematic of used two point temperature inferential control structures

Table 2: CS1 & CS2 controller parameters for the ideal and methyl acetate RD column

Tuning parameters used in CDMC in the two systems						
System	MV	γ	CV	λ	P min	C min
Ideal RD Column with CS1	F_A	1	T_3	5	90	50
	F_B	40	T_{12}	10		
Ideal RD Column with CS2	F_A	1	T_3	5	90	50
	Q_R	4	T_{12}	10		
Methyl Acetate Column with CS1	F_{MeOH}	3	T_2	20	250	125
	F_{HAc}	4	T_{13}	25		
Methyl Acetate Column with CS2	F_{MeOH}	1	T_2	20	250	125
	Q_R	4	T_{13}	25		
Span of temperature measurements = 50K; All valves are 50% open at their design steady state. Slew rate constraints used in CDMC limits the rate of change of manipulated variable from zero to the base-case design value in no less than 2 minutes.						

of a 2x2 decentralized controller is to be compared with that of a 2x2 multivariable constrained dynamic matrix control (DMC) controller. For tuning the two decentralized PI temperature controllers, the relay feedback test is performed to obtain the ultimate gain and ultimate period of the temperature loops. The Tyreus-Luyben controller settings are then applied with appropriate de-tuning, if necessary. In the ideal RD column, both the temperature loops are tuned independently. In the methyl acetate column, sequential tuning is applied where the stripping loop is first tuned. For the DMC controller, appropriate valve saturation and slew rate constraints are applied. The slew rate constraint corresponds to the maximum rate of change of the DMC controller causing the output to saturate in two minutes. The sampling rate of the DMC controller is 0.5 minutes for the ideal RD column and 0.625 minutes for the methyl acetate RD column. The DMC step coefficient matrix is obtained using a +1% step change in the appropriate input. The tuning parameters used for CDMC are shown in Table 2.

4. RESULTS

A through-put change is considered as the primary disturbance to be rejected by the control system. The closed loop performance of the multivariable DMC and decentralized controller is now evaluated for the ideal and the methyl acetate RD columns.

Figure 5 plots the ideal RD column closed loop response to a ±20% through-put change using CS1 as the control structure. The response completion time is about 4 hours for both the controllers. Significantly tighter stripping tray temperature control (T_2) is achieved by the DMC controller while the reactive tray temperature control is comparable. This translates to tighter bottoms purity (x_D,B) control and no appreciable benefit in the distillate purity (x_C,B) control using the DMC controller.

Figure 6 plots the closed loop response to a ±20% through-put change in ideal RD column for CS2 using a decentralized and DMC 2x2 temperature controller. Significantly tighter T_2 and T_{12} temperature control is achieved by the DMC controller.

The closed loop response of the methyl acetate column to a ±20% through-put change is plotted shown in Figure 7. The CDMC temperature controller is far superior to the decentralized controller. The transient deviation in reactive T_{13} control is much smaller for the DMC controller. The tightness of the T_2 control is also better. The tighter temperature control translates to lower transient deviations in both the distillate (x_{MeOAC},D) and bottoms product purity (x_{H2O},B). Notice that with the DMC controller, the two fresh feeds move in tandem for a better stoichiometric feed balance during the transient with consequent improvement in the control performance. Figure 8 plots the closed loop response of CS2 to a ±20% through-put change for the methyl acetate RD column. For this structure also, the DMC achieves much tighter control of the stripping and reactive tray temperatures.

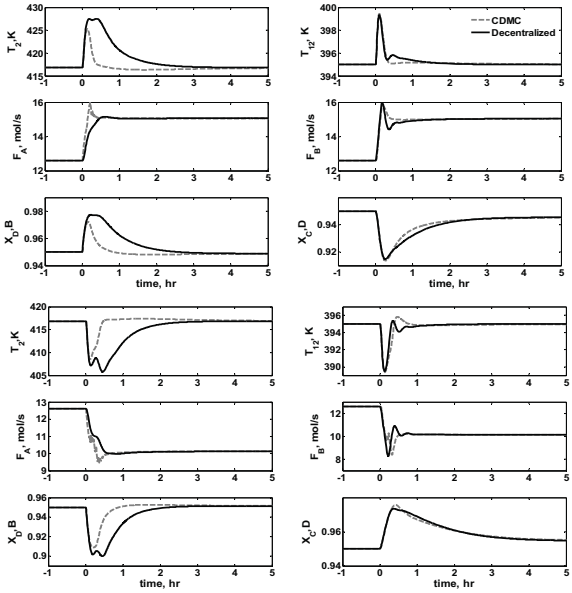

Figure 5. Closed Loop response in Ideal RD system with CS1structure for +20% (Fig A) and -20% (Fig B) change in throughput using CDMC & Traditional decentralized temperature controllers

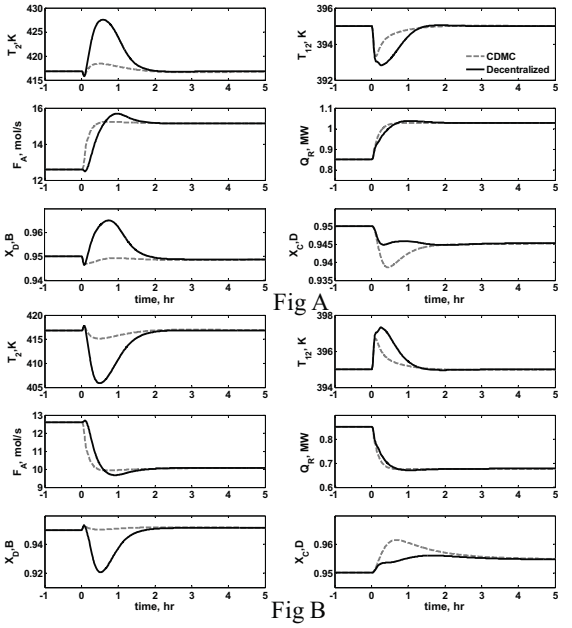

Fig A

Fig B

Figure 6. Closed Loop response in Ideal RD system with CS2 structure for +20% (Fig A) and -20% (Fig B) change in throughput using CDMC & Traditional decentralized temperature controllers

To gain a better perspective on the performance of the controller algorithms and structures, the maximum through-put change that can be handled was studied. In both the ideal and the methyl acetate RD columns, a through-put decrease turns out to be the more severe disturbance with both CS1 and CS2 For the ideal RD column, CS1 using DMC fails for value for the decentralized controller is -45%. CS2 on the a

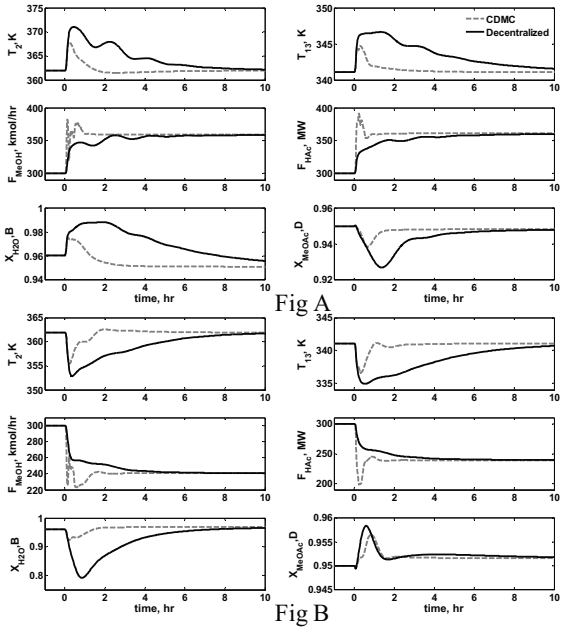

Fig A

Fig B

Figure 8. Closed Loop response in Methyl Acetate RD system with CS2 structure for +20% (Fig A) and -20% (Fig B) change in throughput using CDMC & Traditional decentralized temperature controllers

-70% step change in the through-put. The corresponding other hand fails for -65% and -55% through-put changes using respectively the DMC and decentralized control algorithms. For the methyl acetate system, CS2 with a DMC controller exhibits no improvement in the magnitude of the

maximum through-put decrease handled. Column operation using CS1 with a DMC controller allows for a 60% through-put decrease to be handled where CS1 with decentralized control fails for a 45% through-put decrease.

5 DISCUSSION

The Integral Abslolute Error (IAE) of product purity is plotted in Figure 9 & 10 as the magnitude of the through-put change is increased. Regardless of the control structure and the RD system, the 2x2 DMC control provides tighter product purity controller for large through-put changes.

We have considered a through-put change to be the primary disturbance for the double feed ideal RD systems operated neat. In some situations, variation in the fresh feed composition may also constitute a principal disturbance into the column. To test for the closed loop control performance of the temperature inferential control systems under consideration, we consider a 5 mol% step change in the purity of either feed as a disturbance. For the ideal RD system, component B in F_A and component A in F_B are the feed impurities. For the methyl acetate RD system, water is taken as the impurity in the fresh feeds. Table 3 reports the IAE of the two controlled tray temperatures and the distillate and bottoms purity for the two RD systems using CS1 and CS2. In both the RD systems, the reactive tray temperature control is poorer while the stripping loop temperature is better than decentralized controller. The inferior reactive temperature control is possibly due to the change in the step response coefficients for the altered feed conditions. Inspite of the poorer reactive temperature control, the data in the Table 3 suggests that the deviations in the distillate and bottoms purity for the DMC and decentralized controller are comparable. The DMC controller can thus withstand a feed composition disturbance.

Table 3: Comparison of Controllers for Regulatory Performance with impure fresh feed as disturbance with Integral Absolute Error (IEA's) key control variables

	Disturbance	Control Variable	CS1		CS2	
			CDMC	Decentralized	CDMC	Decentralized
Ideal RD Column	Pure F_A & Impure F_B with Z_B=0.95, Z_A=0.05	T_{12}	72.85	29.285	43.70	46.504
		T_2	334.83	433.47	266.01	695.89
		Top Purity	0.46	0.63	0.703	0.76
		Bottom Purity	0.59	0.88	0.56	1.27
	Pure F_B & Impure F_A with Z_A=0.95, Z_B=0.05	T_{12}	96.28	45.78	35.50	48.65
		T_2	296.61	202.32	143.31	347.67
		Top Purity	1.33	1.09	0.88	0.581
		Bottom Purity	0.612	0.58	0.47	0.35
Methyl Acetate RD Column	Pure F_{H2O} & Impure F_{HAc} with 5 % water	T_{13}	67.26	58.26	68.86	28.94
		T_2	126.38	460.02	120.77	425.32
		Top Purity	0.047	0.046	0.06	0.036
		Bottom Purity	0.429	1.40	0.41	1.20
	Pure F_{HAc} & Impure F_{H2O} with 5 % water	T_{13}	41.19	167.94	52.65	82.71
		T_2	125.61	535.69	137.49	371.41
		Top Purity	0.49	0.51	0.516	0.51
		Bottom Purity	0.45	2.68	0.350	1.62

The asymmetry in the closed loop results (see e.g. Figure 5) suggests the presence of non-linear effects. To investigate this, Figure 11 & 12 plots the variation in the two tray temperatures with respect to the fresh feeds and the reboiler duty at constant reflux ratio. In the ideal RD system, input multiplicity in the stripping tray temperature (T_2) for excess F_B and lower F_A is evident. The reactive tray temperature (T_{12}) exhibits input multiplicity as F_A and F_B are decreased. For the methyl acetate RD system, even as a crossover with respect to base-case steady state does not occur for the range of variation in the column inputs shown, the reactive tray temperature exhibits gain sign reversal with respect to the fresh acetic acid feed. Also, notice the severe directionality in the steady state reactive tray temperature response with respect to the fresh methanol feed with a very small decrease in temperature as the feed rate is increased and very large increase as it is decreased. This extreme directionality, at least partially, explains the asymmetry. The input-output (IO) relations (Figure 11 & 12) can also be used to understand the control system failure mode to large through-put changes. For example, for CS1 with a decentralized controller, for a -50% through-put change, the F_B valve ends up shutting down in slightly under an hour with F_A maintaining T_2 at its set-point. The control system failure mode likely corresponds to 'wrong' control action due to input multiplicity.

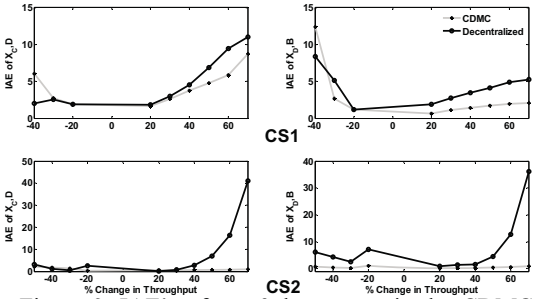

Figure 9: IAE's of top & bottom purity by CDMC and decentralized control using CS1 & CS2 in Ideal RD column for large throughtput changes

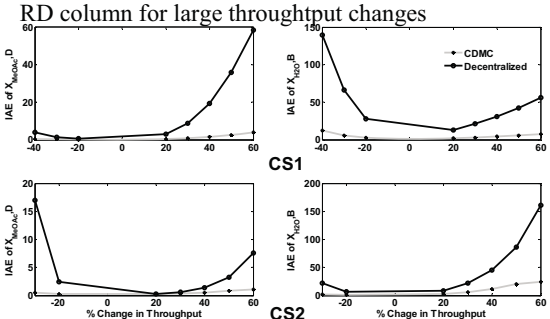

Figure 10: IAE's of top & bottom purity by CDMC and decentralized control by CS1 & CS2 in Methyl Acetate RD column for large throughtput changes

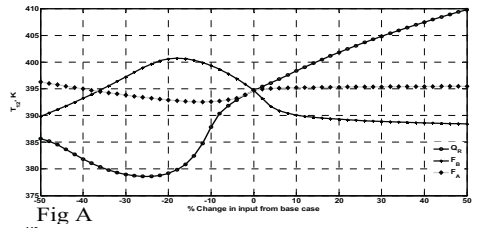

Fig A

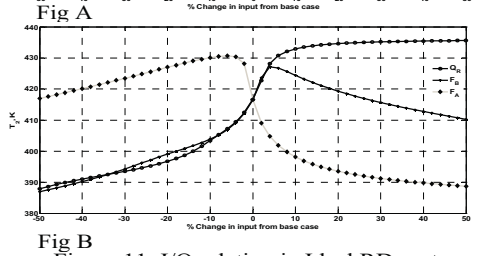

Fig B

Figure 11: I/O relation in Ideal RD system

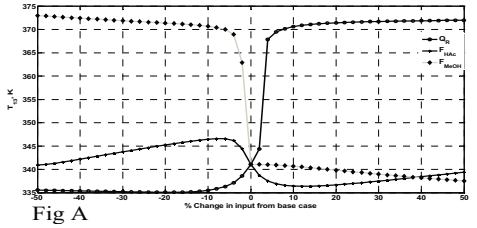

Fig A

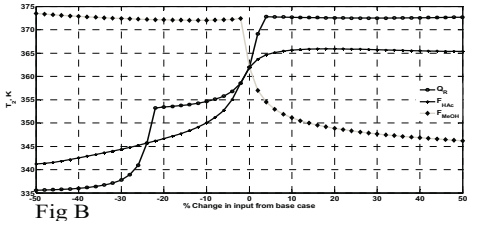

Fig B

Figure 12: I/O relation in Methyl acetate column

It is comforting to note that in spite of the highly non-linear IO relations, a linear control system (decentralized or DMC) effectively rejects such a severe disturbance without succumbing to non-linear dynamic phenomena.

6. CONCLUSIONS

In conclusion, this work demonstrates that the application of constrained dynamic matrix control for two-point temperature inferential control of double feed RD columns operated neat improves the control system performance in terms of the maximum through-put handled and/or the tightness of product purity control achieved. Specifically, in the ideal RD column, significantly tighter bottoms purity control is achieved In the methyl acetate column, tighter control of both the distillate and bottoms purity is achieved using the DMC controller for both the structures. The maximum through-put decrease handled is noticeably higher in CS1 while no such benefit was observed for CS2. These results suggest an overall incentive for the application of linear model predictive control algorithms over conventional decentralized of the highly non-linear RD systems.

A General Quadratic Performance Approach to Binary Distillation Control

Ansgar Rehm *

* *University of Applied Sciences Osnabrück,D-49076 Osnabrück, Germany (Tel: ++49-541-9692156; e-mail: a.rehm@fh-osnabrueck.de).*

Abstract: High purity distillation control of a binary mixture in a tray column is considered in the paper at hand. The approach is based on an inferential control idea: dynamics within the column may be described as movements of concentration waves; the position of the wave front on the one hand side can be inferred from few temperature measurements, on the other hand the position implies the product concentrations. Dynamics of wave propagation is derived by simplification of a first principles model of the column. The resulting descriptor model is the basis for a recent LMI based controller design scheme that provides general quadratic performance for descriptor systems.

Keywords: Quadratic performance; descriptor system; binary distillation; inferential Control.

1. INTRODUCTION

Distillation is one of the most common separation processes in the chemical industries and it is also one of the most energy consuming ones. Therefore the control of this kind of processes has been a focus of process control for many years. Most approaches toward control of distillation columns are based on linear models which are based on identification techniques (e.g. Skogestad et al. [1988], Allgöwer and Raisch [1992]). The disadvantage of identified models is the missing physical interpretation. First principle models on the other hand are rather complex and typically not suitable for a direct model based controller computation.

In the paper at hand a reduced model for a distillation column is derived in descriptor form. The control problem is captured as a generalized quadratic performance problem. A solution to this problem is briefly reviewed (see Rehm and Allgöwer [2002] for details) and applied to the problem at hand.

The resulting controller is tested by means of a high order nonlinear model of the distillation process.

2. DESCRIPTOR MODEL

Separation of a binary mixture in a 40 tray distillation column with one feed stream is considered. A schematic representation of the process is given in the left part of Fig. 1. Exemplary the separation of two alcohols (Methanol,n-Propanol) is taken into account. The mixture is fed in the column with the feed flow rate F. Feed flow rate F and feed composition x_F (molar fraction) are determined by upstream processes.

The stationary feed flow rate and feed composition are corrupted by disturbances. The feed stream separates the column into rectifying- (upper part of the column) and stripping section (lower part of the column). Separation is achieved due to intensive heat and mass transfer between liquid flow and countercurrently rising vapor flow.

At the bottom of the column the liquid flow splits up into a liquid product stream which is removed with flow rate B from the column and a stream which is, after being heated in the reboiler, recirculated back to the column as vapor flow with flow rate V.

At the top of the column the vapor flow with the accumulated more volatile product is completely condensed in the condenser. The condensate is partly pumped back in the column with a flow rate L (reflux stream) and is partly removed as the distillate product with a flow rate D (Deshpande [1985]).

We consider the distillation column in "LV" configuration, that is: liquid flow rate L and vapor flow rate V are considered to be control inputs. Measured variables are the concentrations on trays 14 and 28.

2.1 Control Objectives

The main control objective is to stabilize the product concentrations at the top and bottom of the column at their stationary values. Additionally the deviations from the stationary values due to disturbances in the feed flow should be small.

Table 1. Notation for model variables

x_i	... liquid concentration of the more volatile component on the i^{th} tray
y_i	... vapor concentration of the more volatile component on the i^{th} tray
n_i	... liquid holdup of the i^{th} tray
$(\cdot)_{B,M,D}$	... corresponding quantities of reboiler feed tray, and condensor

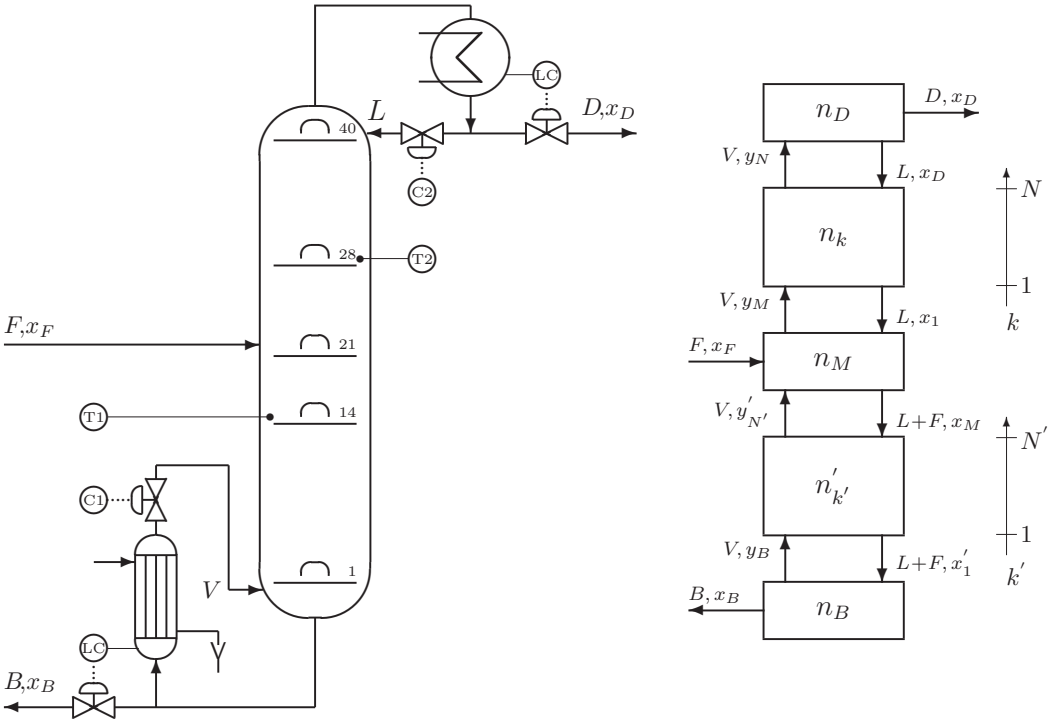

Fig. 1. Scheme of considered 40 tray distillation column (left) and subsystem structure for reduced modelling (right).

2.2 Reference Dynamics

A relatively detailed nonlinear model (CMO model without pressure losses, energy balances, and hydrodynamics (Deshpande [1985])) is used for simulation studies. The modelling equations describe the liquid concentrations of the more volatile component and are derived from the mass balance for every tray and for reboiler and condensor.

$$y_i = \frac{\alpha x_i}{1 + (\alpha - 1)x_i}, \quad \alpha = const. \tag{1}$$

The most important source of nonlinearity in the model are the equations (1) describing the vapor-liquid equilibrium (constant relative volatility α). The resulting model consists of 42 first order differential equations (40 equations from the intermediate trays plus two equations from reboiler and condensor).

2.3 Reduced Dynamics (Descriptor Model)

Starting point for the development of a reduced model in descriptor form of the distillation column is the fact (Retzbach [1986]) that qualitatively the behaviour of the column towards changes in the input values (V, L, F, x_F) can be regarded as motion and distortion of the stationary concentration profile (concentration versus tray number).

Instead of having detailed mass balances for rectifying and stripping section, the idea for a reduced model is thus to capture dynamics just by one position variable for a suitable concentration profile in every column section Due to (1) it is sufficient to consider a moving concentration profile only for the lighter component (measured in molar fractions, denoted by x in the following). Therefore the reduced model will contain two positions (s_r for the rectifying section and s_s in the stripping section) and three

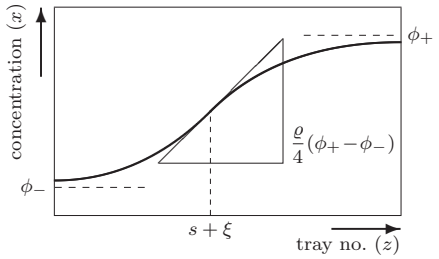

Fig. 2. Illustration of the shape parameters in function (2)

concentrations (concentration x_B in the reboiler, x_M for the feed tray, and x_D in the condenser) as state variables.

Here, only a sketch of the derivation of the reduced model in descriptor form is given, details can be found in Rehm [2004]. Furthermore we restrict ourselves to the presentation of the procedure for one column section, the deviation for the other section is completely analogous. The trays in this section are numbered by $z = 1, \ldots, N$ (see right side of Fig. 1). The concentration profile is modeled with the (continuous) function $x(z)$ (eq. (2), Fig. 2) which is well suited to describe the stationary profile in long packed columns (Kienle [1998]):

$$x(z) = \phi_- + \frac{\phi_+ - \phi_-}{1 + e^{-\varrho(z-s-\xi)}}. \tag{2}$$

With the least squares method the shape parameters ϕ_-, ϕ_+, ϱ, and ξ (see Fig. 2) are calculated such that $x(z)$ matches the stationary concentration profile ($s = 0$, i.e. s denotes the displacement relative to the stationary case) of the tray column for the discrete values $z = 1, \ldots, N$ in a least squares sense.

$$\begin{bmatrix} AY_1+Y_1^{\mathrm{T}}A^{\mathrm{T}}+ & * & * & * \\ B_2\hat{C}_K+(B_2\hat{C}_K)^{\mathrm{T}} & & & \\ (A+B_2\hat{D}_KC_2)^{\mathrm{T}}+\hat{A}_K & X_1^{\mathrm{T}}A+\hat{B}_KC_2+ & * & * \\ & (X_1^{\mathrm{T}}A+\hat{B}_KC_2)^{\mathrm{T}} & & \\ B_1^{\mathrm{T}}+D_{21}^{\mathrm{T}}\hat{D}_K^{\mathrm{T}}B_2^{\mathrm{T}}+ & B_1^{\mathrm{T}}X_1+D_{21}^{\mathrm{T}}\hat{B}_K^{\mathrm{T}}+ & (D_{11}+D_{12}\hat{D}_KD_{21})^{\mathrm{T}}W_P+ & * \\ W_P^{\mathrm{T}}(C_1Y_1+D_{12}\hat{C}_K) & W_P^{\mathrm{T}}(C_1+D_{12}\hat{D}_KC_2) & W_P^{\mathrm{T}}(D_{11}+D_{12}\hat{D}_KD_{21})+V_P & \\ Q_P^{\mathrm{T}}(C_1Y_1+D_{12}\hat{C}_K) & Q_P^{\mathrm{T}}(C_1+D_{12}\hat{D}_KC_2) & Q_P^{\mathrm{T}}(D_{11}+D_{12}\hat{D}_KD_{21}) & -\Sigma_P \end{bmatrix} < 0. \tag{3}$$

$$\begin{aligned} Y_1 &:= RE^{\mathrm{T}}+E^{\mathrm{T}\perp}W_Y,\ R>0, \qquad \begin{bmatrix} R & E^+ \\ E^{\mathrm{T}+} & S \end{bmatrix} > 0 \\ X_1 &:= SE+E^{\perp}W_X, \quad S>0, \end{aligned} \tag{4}$$

$$\begin{pmatrix} * & 0 & 0 & 0 & 0 \\ * & * & * & 0 & 0 \\ 0 & 0 & * & 0 & 0 \\ 0 & 0 & * & * & * \\ 0 & 0 & 0 & 0 & * \end{pmatrix} \begin{pmatrix} \frac{d\Delta x_B}{dt} \\ \frac{d\Delta s_r}{dt} \\ \frac{d\Delta x_M}{dt} \\ \frac{d\Delta s_s}{dt} \\ \frac{d\Delta x_D}{dt} \end{pmatrix} = \begin{pmatrix} * & * & * & 0 & 0 \\ * & * & * & 0 & 0 \\ * & * & * & * & * \\ 0 & 0 & * & * & * \\ 0 & 0 & * & * & * \end{pmatrix} \begin{pmatrix} \Delta x_B \\ \Delta s_r \\ \Delta x_M \\ \Delta s_s \\ \Delta x_D \end{pmatrix} + \begin{pmatrix} 0 & * \\ 0 & * \\ * & * \\ 0 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \Delta x_F \\ \Delta F \end{pmatrix} + \begin{pmatrix} * & * \\ * & * \\ * & * \\ * & * \\ 0 & * \end{pmatrix} \begin{pmatrix} \Delta L \\ \Delta V \end{pmatrix}$$

$$\begin{pmatrix} \Delta x_{14} \\ \Delta x_{28} \end{pmatrix} = \begin{pmatrix} * & * & * & 0 & 0 \\ 0 & 0 & * & * & * \end{pmatrix} (\Delta x_B, \Delta s_r, \Delta x_M, \Delta s_s, \Delta x_D)^{\mathrm{T}} \tag{5}$$

However, while ϱ and ξ are kept constant, ϕ_- and ϕ_+ are used as adaptation parameters since concentration profiles not only move but also are distorted. Adaptation of these parameters is based on the requirement that (2) should also match the concentrations for the neighbouring systems when evaluated for $z = 0$ and $z = N + 1$. This adaptation rule implies that the time derivatives of x_B, x_M, and x_D influence the dynamics of wave propagation. The linearisation of the overall reduced descriptor model of the distillation column is given in (5). Here "Δ" implies deviations from the stationary value while "$*$" denotes numerical entries. A detailed derivation of the model and numerical values are given in Rehm [2004].

3. CONTROLLER COMPUTATION

3.1 Synthesis for Generalized Quadratic Performance for Descriptor Systems

The idea of generalized quadratic performance (GQP) control is to impose a general quadratic constraint of the type

$$\int_0^T \begin{bmatrix} \boldsymbol{z}(t) \\ \boldsymbol{w}(t) \end{bmatrix}^{\mathrm{T}} \begin{bmatrix} U_P & W_P \\ W_P^{\mathrm{T}} & V_P \end{bmatrix} \begin{bmatrix} \boldsymbol{z}(t) \\ \boldsymbol{w}(t) \end{bmatrix} dt \ll 0, \tag{6}$$

on the external input/output chanel $\boldsymbol{w} \to \boldsymbol{z}$ of a generalized plant description G_{cl}. Here the notation "$\ll 0$" means that $\int_0^T Q(\boldsymbol{w}(t), \boldsymbol{z}(t))\, dt \le -\epsilon \int_0^T \boldsymbol{w}^{\mathrm{T}}(t)\boldsymbol{w}(t))\, dt$ holds for all $\boldsymbol{w}(\cdot) \in L_2$ and some fixed $\epsilon > 0$.

The rather general GQP problem contains some important control problems as a special case if the objective parameters $U_P \ge 0$, $V_P = V_P^{\mathrm{T}}$, and W_P are chosen accordingly (Scherer et al. [1997]). For example

- the H_∞ constraint $\|G_{cl}\|_\infty < \gamma$, if U_P, V_P, and W_P are specified as $U_P = \frac{1}{\gamma}I$, $V_P = -\gamma I$, $W_P = 0$;
- the strict passivity constraint $G_{cl}(j\omega)+G_{cl}(j\omega)^* > 0$ for all $\omega \in \mathbb{R} \cup \{\infty\}$, when U_P, V_P, W_P are chosen as $U_P = 0$, $V_P = 0$, $W_P = -I$;
- sector constraints of the form

$$\int_0^T (\boldsymbol{z}(t)-\alpha\boldsymbol{w}(t))^{\mathrm{T}} (\boldsymbol{z}(t)-\beta\boldsymbol{w}(t))\ dt \ll 0 \tag{7}$$

for $U_P = I$, $V_P = -\alpha\beta I$, $W_P = -\frac{1}{2}(\alpha+\beta)I$.

We consider a generalized plant description Σ in descriptor form

$$\Sigma: \quad \begin{aligned} E\dot{\boldsymbol{x}}(t) &= A\boldsymbol{x}(t) + B_1\boldsymbol{w}(t) + B_2\boldsymbol{u}(t) \\ \boldsymbol{z}(t) &= C_1\boldsymbol{x}(t) + D_{11}\boldsymbol{w}(t) + D_{12}\boldsymbol{u}(t) \\ \boldsymbol{y}(t) &= C_2\boldsymbol{x}(t) + D_{21}\boldsymbol{w}(t) \end{aligned} \tag{8}$$

with $\boldsymbol{x}(t) \in \mathbb{R}^{n_x}$, $\boldsymbol{w}(t) \in \mathbb{R}^{n_w}$, $\boldsymbol{u}(t) \in \mathbb{R}^{n_u}$, $\boldsymbol{z}(t) \in \mathbb{R}^{n_z}$, and $\boldsymbol{y}(t) \in \mathbb{R}^{n_y}$ denoting the generalized state variables, the external input variables, the control input variables, the external output variables, and the measurement variables, respectively. E and A are square constant matrices where, explicitly, E is allowed to be singular, i.e. $\mathrm{rank}(E) =: r \le n_x$. The remaining matrices are constant matrices of appropriate dimension.

The control problem is, for given matices $U_P \ge 0$, $U_P \in \mathbb{R}^{n_z \times n_z}$, $V_P = V_P^{\mathrm{T}} \in \mathbb{R}^{n_w \times n_w}$, and $W_P \in \mathbb{R}^{n_z \times n_w}$, to find a linear output feedback controller such that the undisturbed closed loop ($\boldsymbol{w} \equiv \boldsymbol{0}$) is an admissible system and such that the transfer matrix from the external input $\boldsymbol{w}$ to the external output $\boldsymbol{z}$ suffices a general quadratic performace bound (6).

The actual design problem therefore consists in the selection of matrices U_P, V_P, W_P such that the transfer matrix from $\boldsymbol{w}$ to $\boldsymbol{z}$ reflects the performance requirements (e.g. robustness, energy dissipation, ...). Since we aim at an admissible close loop, we assume in the following the corresponding necessary stabilizability/detectability properties for descriptor systems, namely stabilizability/detectability at infinity (see also Dai [1989]).

With a controller K_E,

$$K_E: \quad \begin{array}{l} E\dot{\boldsymbol{\zeta}}(t)=A_K\boldsymbol{\zeta}(t)+B_K\boldsymbol{y}(t) \\ \boldsymbol{u}(t)=C_K\boldsymbol{\zeta}(t)+D_K\boldsymbol{y}(t),\ \boldsymbol{\zeta}(t)\in\mathbb{R}^{n_x} \end{array} \tag{9}$$

parametrized by A_K, B_K, C_K, D_K the closed loop system is given by

$$\begin{aligned} E_{cl}\dot{\boldsymbol{\xi}}(t) &= A_{cl}\boldsymbol{\xi}(t)+B_{cl}\boldsymbol{w}(t) \\ \boldsymbol{z}(t) &= C_{cl}\boldsymbol{\xi}(t)+D_{cl}\boldsymbol{w}(t), \qquad \boldsymbol{\xi}(t)\in\mathbb{R}^{2n_x}, \end{aligned} \tag{10}$$

$$\begin{aligned} E_{cl} &= \begin{bmatrix} E & 0 \\ 0 & E \end{bmatrix}, \qquad A_{cl} = \begin{bmatrix} A+B_2D_KC_2 & B_2C_K \\ B_KC_2 & A_K \end{bmatrix}, \\ B_{cl} &= \begin{bmatrix} B_1+B_2D_KD_{21} \\ B_KD_{21} \end{bmatrix}, \quad C_{cl}^{\mathrm{T}} = \begin{bmatrix} C_1^{\mathrm{T}}+C_2^{\mathrm{T}}D_K^{\mathrm{T}}D_{12}^{\mathrm{T}} \\ C_K^{\mathrm{T}}D_{12}^{\mathrm{T}} \end{bmatrix}, \\ D_{cl} &= (D_{11}+D_{12}D_KD_{21}) \end{aligned} \tag{11}$$

Then a sufficient condition for a controller K_E solving the GQP control problem for DAE systems is given by the following theorem:

Theorem 1. Consider a plant (8) and a controller (9). There exists a controller parameterization A_K, B_K, C_K, D_K such that the undisturbed (i.e. $\boldsymbol{w}\equiv 0$) closed loop system (10) is admissible with general quadratic performance if the LMIs (3), (4) [1] admit a solution $\{R, S, W_Y, W_X, \hat{A}_K, \hat{B}_K, \hat{C}_K, \hat{D}_K\}$.

Remark. The preceding theorem constitutes also a necessary condition for the existence of a controller with GQP in the cases, where the corresponding analysis result is necessary for general quadratic performance, i.e. especially in the case of the H_∞ control problem. Therefore the results of Masubuchi et al. [1997] are included in Theorem 1 as a special case.

Theorem 1 is constructive: controller computation consists of three steps:

- Solution of the LMIs (3), (4). This is possible via effective numerical tools tailored for LMI problems arising from control theoretic problem setups (e.g. Gahinet et al. [1994], El Ghaoui et al. [1995]).
- Computation of non-singular matrices X_3, Y_3 such that

$$X_1Y_1+X_2Y_3 = I \tag{12}$$
$$X_3Y_1+X_4Y_3 = 0 \tag{13}$$

  hold together with the coupling condition $E^{\mathrm{T}}X_2 = X_3^{\mathrm{T}}E$. This is a essentially a factorization problem on the range of E which is always solvable provided (3), (4) have a solution.
- Solution of the linear equations

$$\begin{aligned} \hat{D}_K &:= D_K \\ \hat{C}_K &:= C_KY_3+D_KC_2Y_1 \\ \hat{B}_K &:= X_3^{\mathrm{T}}B_K+X_1^{\mathrm{T}}B_2D_K \\ \hat{A}_K &:= X_1^{\mathrm{T}}(A+B_2D_KC_2)Y_1+X_3^{\mathrm{T}}A_KY_3+ \\ &\quad +X_3^{\mathrm{T}}B_KC_2Y_1+X_1^{\mathrm{T}}B_2C_KY_3 \end{aligned} \tag{14}$$

  for the controller matrices D_K, C_K B_K, A_K.

[1] Here E^+ denotes any generalized inverse with the property $EE^+E = E$ and "$*$" is used in order to indicate the symmetric expansion of a block matrix.

3.2 Distillation Control Problem as S/KS Mixed Sensitivity Problem

As a special case of generalized quadratic performance, the H_∞ control problem for the distillation problem is solved. The control objectives are translated into a mixed sensitivity set-up depicted in Fig. 4. with G representing the plant (reduced model in descriptor form), K the controller, and W_1, W_2, V frequency dependent weighting matrices. Controller design by "loop shaping" requires a selection of the weighting matrices such that the solution of the H_∞ control problem

$$\left\| \begin{array}{c} W_1(I+GK)^{-1}V \\ -W_2K(I+GK)^{-1}V \end{array} \right\|_\infty \overset{!}{<} \gamma \tag{15}$$

results in a well behaved closed loop system. In this

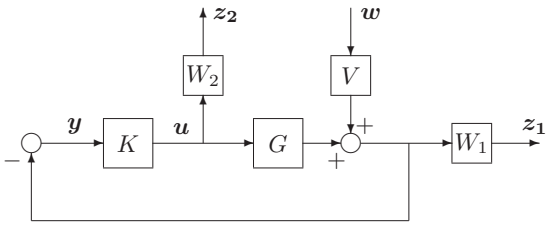

Fig. 4. Mixed sensitivity configuration

setup V can be interpreted as a filter which models the disturbance considered to be relevant for the problem at hand. With $S(s) := (I+GK)^{-1}$ being the sensitivity matrix of the closed loop the expression (15) with $\gamma = 1$ suggests to choose W_1 to be approximately the inverse of the wanted behavior for $S(s)$ and analogously W_2 to be the inverse of $K \cdot S$. General indications on selecting these weighting matrices can be found in Skogestad and Postlewaite [1996].

In case of the distillation control problem at hand an indirect approach is taken: with stabilizing the measured concentrations x_{14}, x_{28} also the stationary profiles are fixed and thus approximately also the product concentrations. In order to realize this idea the descriptor S/KS H_∞ control problem depicted in Figure 4 (with G being the descriptor model (5)) is solved by the outlined descriptor GQP synthesis procedure with specification of W, Q, and Σ as for the H_∞ set-up. The synthesis LMIs are jointly optimized with respect to γ. A final value of $\gamma = 1.01$ shows that the control objectives are approximately met.

The resulting controller has a dynamical order of 9, i.e. equal to the order of the generalized plant description. After removing the fastest two eigen-modes of the controller in order to avoid numerical problems due to stiffness, the controller is tested in simulation studies with the nonlinear CMO model of the distillation column.

4. RESULTS

In Figure 5 the stationary concentration profiles for various severe persistent disturbances for the closed loop are shown. It can be seen that the controller is able to stabilize the profile position although the disturbances result in a distortion of the stationary profile in the vicinity of the feed tray.

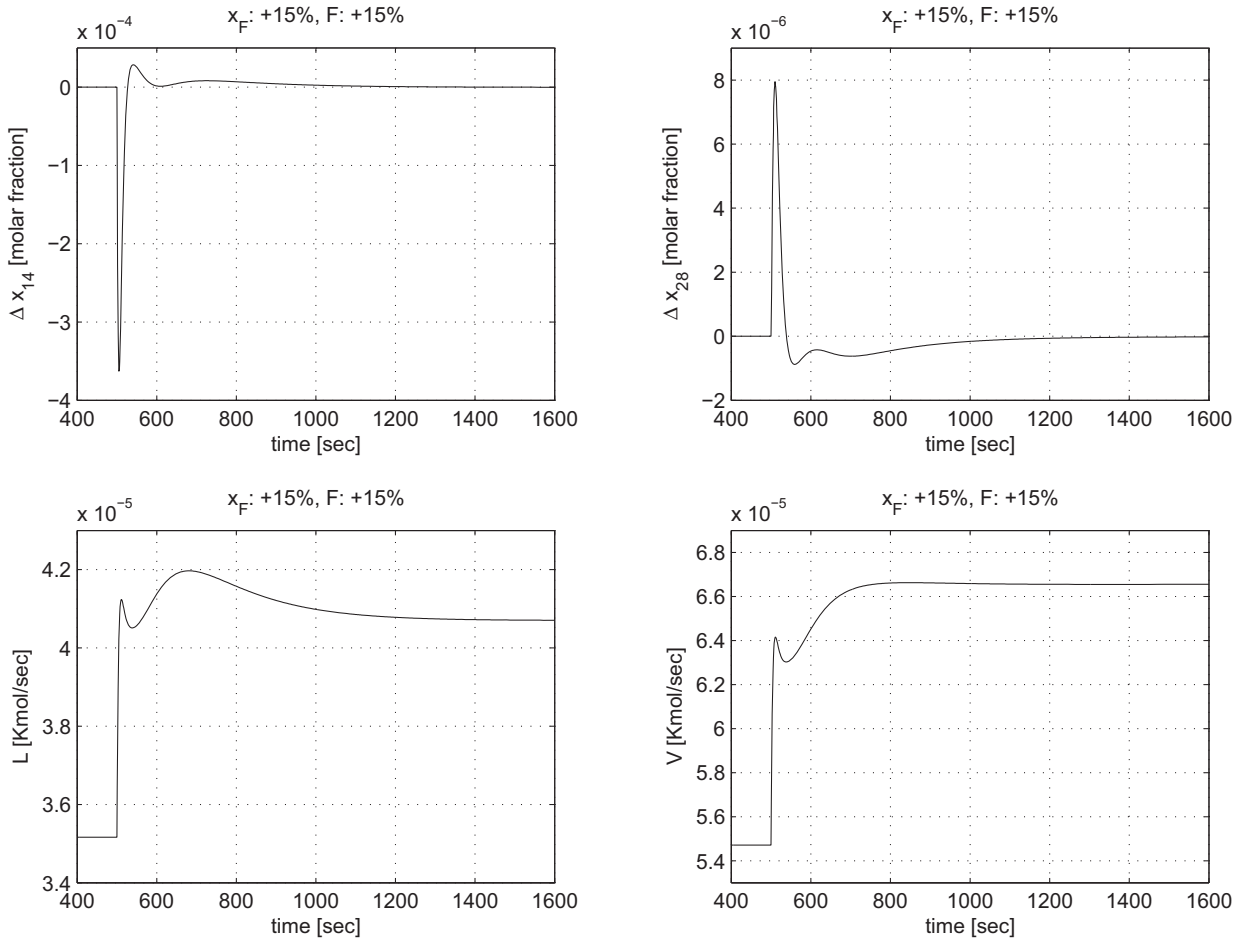

Fig. 3. Step responses for the controlled distillation column (+15% increase in feed flow rate F and +15% increase in feed concentration x_F with respect to stationary values at $t = 500sec$). Top: deviations from the steady state for the controlled variables x_{14} and x_{28}. Bottom: control variables, i.e. liquid flow rate L and vapor flow rate V.

In Figure 3 a detailed view on the control variables and the error in the controlled variables is given for a mutual step in the feed flow rate and feed composition. The plots show a fast transient behavior and small deviations. Furthermore no excessive action in the control variables is needed.

5. CONCLUSION

The generalized quadratic performance control problem for descriptor systems is solved for a reduced model of a distillation control problem. The resulting controller shows rather good results for a nonlinear reference model. The descriptor problem formulation is a direct result of reduced modeling. Furthermore, also standard approaches to build generalized plant descriptions easily fit into the descriptor system set-up. This was demonstrated by means of a S/KS - control problem formulation that directly leads to a descriptor model.

Advances in Identification

Oral Session

Identification of low-order unstable process model from closed-loop step test

Tao Liu, Furong Gao*

*Department of Chemical and Biomolecular Engineering, Hong Kong University of Science & Technology, Kowloon, Hong Kong (Tel: +852-2358-7139; e-mail address: kefgao@ust.hk)

Abstract: Based on a closed-loop step response test, control-oriented low-order model identification algorithms are proposed for unstable processes. By using a damping factor to the closed-loop step response for realization of the Laplace transform, an algorithm for estimating the process frequency response is developed in terms of the closed-loop control structure used for identification. Correspondingly, two model identification algorithms are derived analytically for obtaining the widely used low-order process models of first-order-plus-dead-time (FOPDT) and second-order-plus-dead-time (SOPDT), respectively. Illustrative examples from the recent literature are used to demonstrate the effectiveness and merits of the proposed identification algorithms.

1. INTRODUCTION

As model-based control strategies have demonstrated apparently improved set-point tracking and load disturbance rejection for open-loop unstable processes, control-oriented identification of low-order process model, e.g., first-order-plus-dead-time (FOPDT) or second-order-plus-dead-time (SOPDT), has been increasingly explored in the process control community (Seborg, Edgar, and Mellichamp, 2003; Liu and Gao, 2008a and 2008b). For safety and economic reasons, unstable processes are usually not allowed to be operated in an open-loop manner. Closed-loop identification methods have been therefore studied in the literature. One of the mostly used identification tests is the close-loop step response test, owing to its implemental simplicity. Based on closed-loop step test in terms of the internal model control (IMC) structure, Häggblom K. E. (1996) demonstrated that closed-loop identification facilitates better representation of the process dynamic response characteristics for closed-loop operation. Using a conventional proportional (P) or proportional-integral-derivative (PID) controller for closed-loop stabilization, recent closed-loop step identification methods can be seen in the references (Paraskevopoulos, Pasgianos and Arvanitis, 2004; Sree and Chidambaram, 2006; Cheres, 2006). Using relay feedback to yield sustained oscillation within an admissible fluctuation of the process output, identification methods based on the resulting limit cycle data have been developed in the papers (Shiu, Hwang and Li, 1998; Marchetti, Scali and Lewin, 2001; Vivek and Chidambaram, 2005; Liu and Gao, 2008a). It was, however, pointed out that the conventional relay feedback structure cannot guarantee periodic oscillation for unstable processes with large time delay (Tan, Wang and Lee, 1998; Thyagarajan and Yu; 2003). Some limiting conditions to form the limit cycle from relay feedback for an unstable process have been disclosed by Liu and Gao (2008b). Besides, using the pseudo-random binary sequence (PRBS) as excitation signal to the set-point, closed-loop identification methods for application of model predictive control (MPC) have been reported in the references (Sung et al, 2001; Saffer and Doyle, 2002; Bindlish, Rawlings and Young, 2003).

In this paper, identification algorithms based on a closed-loop step test are proposed for obtaining low-order models of FOPDT and SOPDT for tuning unstable processes. By using a damping factor to the closed-loop step response for realization of the Laplace transform, an algorithm is first given to estimate the closed-loop frequency response in terms of using a conventional P, PI or PID controller for closed-loop stabilization. Accordingly, the process frequency response can be analytically derived from the closed-loop frequency response with the knowledge of the controller. Then, two identification algorithms are analytically developed for obtaining FOPDT and SOPDT models, respectively. Both the algorithms can give good accuracy if the model structure matches the process. Measurement noise tests are also performed to demonstrate identification robustness of the proposed algorithms.

2. FREQUENCY RESPONSE ESTIMATION

It is commonly known that the Fourier transform of a step response does not exist due to $\Delta y(t) \neq 0$ for $t \to \infty$, where $\Delta y(t) = y(t) - y(t_0)$ and $y(t_0)$ denotes the initial steady output. However, by substituting $s = \alpha + j\omega$ into the Laplace transform to the step response,

$$\Delta Y(s) = \int_0^\infty \Delta y(t) e^{-st} dt \tag{1}$$

we can formulate

$$\Delta Y(\alpha + j\omega) = \int_0^\infty [\Delta y(t) e^{-\alpha t}] e^{-j\omega t} dt \tag{2}$$

Note that if $\alpha > 0$, there exists $\Delta y(t) e^{-\alpha t} = 0$ for $t > t_N$, where t_N may be numerically determined using the condition of $\Delta y(t_N) e^{-\alpha t_N} \approx 0$, since $\Delta y(t)$ reaches a steady value after

the closed-loop transient response to a step change of the set-point. Therefore, by regarding α as a damping factor to the closed-loop step response for Laplace transform, we may compute $\Delta Y(\alpha + j\omega)$ from the N points of step response data as

$$\Delta Y(\alpha + j\omega) = \int_0^{t_N} [y(t)e^{-\alpha t}]e^{-j\omega t}dt \tag{3}$$

For a closed-loop step test with initial steady state, i.e., $y(t) = r(t) = c$ for $t \le t_0$, where $r(t)$ denotes the set-point value, c is a constant and t_0 is the time for step test, we may formulate the step change of the set-point by using a time shift of t_0 (i.e., letting $t_0 = 0$) as

$$\Delta r(t) = \begin{cases} 0, & t \le 0; \\ h, & t > 0. \end{cases} \tag{4}$$

where h is the magnitude of the step change. Its Laplace transform for $s = \alpha + j\omega$ with $\alpha > 0$ can be explicitly derived as

$$\Delta R(\alpha + j\omega) = \int_0^{\infty} he^{-(\alpha + j\omega)t}dt = \frac{h}{\alpha + j\omega} \tag{5}$$

Hence, the closed-loop frequency response can be derived using (3) and (5) as

$$T(\alpha + j\omega) = \frac{\alpha + j\omega}{h}\Delta Y(\alpha + j\omega), \ \alpha > 0 \tag{6}$$

Note that $T(\alpha + j\omega) \to 0$ as $\alpha \to \infty$. On the contrary, $\alpha \to 0$ will cause t_N much larger for computation of (6). A proper choice of α is therefore required for implementation. Considering that all the closed-loop transient response data to a step change of the set-point should be used to procure good estimation of the closed-loop frequency response, the following constraint is suggested to choose α,

$$\Delta y(t_{\text{set}})e^{-\alpha t_{\text{set}}} > \delta \tag{7}$$

where $\Delta y(t_{\text{set}})$ denotes the steady-state output deviation to the step change in terms of the settling time (t_{set}), and δ is a threshold of the computational precision that may be practically taken smaller than 1×10^{-6}. It follows from (7) that

$$\alpha < \frac{1}{t_{\text{set}}}\ln\frac{\Delta y(t_{\text{set}})}{\delta} \tag{8}$$

To ensure computational efficiency with respect to the complex variable, $s = \alpha + j\omega$, for frequency response estimation, the lower bound of α may be simply taken as δ, if there exists no limit on the time length of the step test.

Once α is chosen in terms of the above guideline, the time length, t_N, may be determined from a numerical constraint for computation of (3), i.e.,

$$\Delta y(t_N)e^{-\alpha t_N} < \delta \tag{9}$$

which can be solved as

$$t_N > \frac{1}{\alpha}\ln\frac{\Delta y(t_N)}{\delta} \tag{10}$$

Note that there exists the following Laplace transform with initial steady closed-loop state of $y(0) = r(0) = c$, where c is a constant,

$$L[\int_0^t \Delta y(t)dt] = \frac{\Delta Y(s)}{s} \tag{11}$$

To guarantee identification robustness against measurement noise, we may compute the frequency response by

$$T(\alpha + j\omega) = \frac{\dfrac{\Delta Y(\alpha + j\omega)}{\alpha + j\omega}}{\dfrac{\Delta R(\alpha + j\omega)}{\alpha + j\omega}} = \frac{(\alpha + j\omega)^2}{h}\int_0^{t_N}[\int_0^t \Delta y(\tau)d\tau]e^{-\alpha t}e^{-j\omega t}dt \tag{12}$$

It can be seen from (12) that, rather than use individual output data measured from the step test, a time integral for each measurement point is used to compute the outer-layer integral for obtaining the frequency response estimation. This facilitates reducing measurement errors according to the statistic averaging principle.

Denote the n-th order derivative for a complex function of $F(s)$ with respect to s as

$$F^{(n)}(s) = \frac{d^{(n)}}{ds^n}F(s), \ n \ge 1. \tag{13}$$

It follows from (3) and (6) that

$$T^{(1)}(s) = \frac{1}{h}\int_0^{\infty}(1 - st)\Delta y(t)e^{-st}dt \tag{14}$$

$$T^{(2)}(s) = \frac{1}{h}\int_0^{\infty} t(st - 2)\Delta y(t)e^{-st}dt \tag{15}$$

Hence, by letting $s = \alpha$ and choosing α as well as that for computation of (3), the single integral in (14) and (15) can be computed numerically. The corresponding time lengths of t_N can be respectively determined using the numerical constraints,

$$(1 - \alpha t_N)\Delta y(t_N)e^{-\alpha t_N} < \delta \tag{16}$$

$$t_N(\alpha t_N - 2)\Delta y(t_N)e^{-\alpha t_N} < \delta \tag{17}$$

For a conventional PID controller used in the closed-loop structure to stabilize an unstable process for step test,

$$C(s) = k_C(1 + \frac{1}{\tau_I s} + \frac{\tau_D s}{0.1\tau_D s + 1}) \tag{18}$$

where k_C denotes the controller gain, τ_I the integral constant and τ_D the derivative constant, it can be derived that

$$C^{(1)}(s) = k_C[-\frac{1}{\tau_I s^2} + \frac{\tau_D}{(0.1\tau_D s + 1)^2}] \tag{19}$$

$$C^{(2)}(s) = 2k_C[\frac{1}{\tau_I s^3} - \frac{0.1\tau_D^2}{(0.1\tau_D s + 1)^3}] \tag{20}$$

Note that the closed-loop transfer function can be derived as

$$T(s) = \frac{G(s)C(s)}{1 + G(s)C(s)} \tag{21}$$

It follows from (21) that

$$G(s) = \frac{T(s)}{C(s)[1 - T(s)]} \tag{22}$$

Its first and second derivatives can be derived accordingly as

$$G^{(1)} = \frac{T^{(1)}C + C^{(1)}T(T - 1)}{C^2(1 - T)^2} \tag{23}$$

$$G^{(2)} = \frac{CT^{(2)} + 2C^{(1)}T^{(1)}T + C^{(2)}T(T - 1)}{C^2(1 - T)^2}$$

$$-\frac{2[CT^{(1)}+C^{(1)}T(T-1)][CC^{(1)}(1-T)-C^2T^{(1)}(1-T)]}{C^3(1-T)^3} \quad (24)$$

Therefore, by substituting $s=\alpha+j\omega_k$ ($k=1,2,\ldots,M.$), where M is the number of representative frequency response points in a user specified frequency range, the process frequency response can be numerically estimated for model fitting.

3. MODEL IDENTIFICATION ALGORITHMS

Low-order unstable process models of FOPDT and SOPDT are respectively in the form of

$$G_1(s)=\frac{k_p e^{-\theta s}}{\tau_p s-1} \quad (25)$$

$$G_2(s)=\frac{k_p e^{-\theta s}}{(\tau_1 s-1)(\tau_2 s+1)} \quad (26)$$

where k_p denotes the process gain, θ the process time delay and τ_p (or τ_1 and τ_2) the process time constant(s).

By regarding $s\in\mathbb{R}$ and taking the natural logarithm for both sides of (25) in terms of $0<s<\tau_p$, we obtain

$$\ln[-G_1(s)]=\ln(k_p)-\ln(1-\tau_p s)-\theta s \quad (27)$$

Subsequently, taking the first and second derivatives for both sides of (27) with respect to s yields

$$\frac{1}{G_1(s)}\frac{d}{ds}[G_1(s)]=\frac{\tau_p}{1-\tau_p s}-\theta \quad (28)$$

$$Q_2(s)=\frac{\tau_p^2}{(1-\tau_p s)^2} \quad (29)$$

where $Q_2(s)=d[Q_1(s)]/ds$ and $Q_1(s)$ is the left side of (28).

Substituting $s=\alpha$ into (29), it can be derived that

$$\tau_p=\begin{cases}\dfrac{\sqrt{Q_2}}{\alpha\sqrt{Q_2}-1} \text{ or } \dfrac{\sqrt{Q_2}}{\alpha\sqrt{Q_2}+1}, & \text{if } Q_2>\dfrac{1}{\alpha^2};\\ \dfrac{\sqrt{Q_2}}{\alpha\sqrt{Q_2}+1}, & \text{if } Q_2\le\dfrac{1}{\alpha^2}.\end{cases} \quad (30)$$

Note that for $Q_2\ge 1/\alpha^2$, we may determine a suitable solution based on model fitting accuracy for the closed-loop step response.

It should be noted that the above parameter estimation is without loss of generality since there exists $\alpha<\tau_p$ in general, which may be verified from the guideline for choosing α as given in the earlier section.

Consequently, the other two model parameters can be derived from (28) and (25) using $s=\alpha$ as

$$\theta=-Q_1(\alpha)+\frac{\tau_p}{1-\tau_p\alpha} \quad (31)$$

$$k_p=(\tau_p\alpha-1)G_1(\alpha)e^{\alpha\theta} \quad (32)$$

Hence, the above algorithm named **Algorithm-I** for obtaining a FOPDT model for an unstable process can be summarized as:

(i) Choose $s=\alpha$ and t_N to compute $T(\alpha)$, $T^{(1)}(\alpha)$ and $T^{(2)}(\alpha)$ in terms of (6) (or (12)), (14) and (15);
(ii) Compute $C(\alpha)$, $C^{(1)}(\alpha)$ and $C^{(2)}(\alpha)$ in terms of (18), (19) and (20);
(iii) Compute $G_1(\alpha)$, $G_1^{(1)}(\alpha)$ and $G_1^{(2)}(\alpha)$ in terms of (22), (23) and (24);
(iv) Compute $Q_1(\alpha)$ and $Q_2(\alpha)$ in terms of (28) and (29);
(v) Compute the process time constant, τ_p, from (30);
(vi) Compute the process time delay, θ, from (31);
(vii) Compute the process gain, k_p, from (32).

Following a similar procedure as above, taking the natural logarithm for both sides of (26) in terms of $0<s<\tau_1$, yields

$$\ln[-G_2(s)]=\ln(k_p)-\ln(1-\tau_1 s)-\ln(\tau_2 s+1)-\theta s \quad (33)$$

Accordingly, the first and second order derivatives for both sides of (33) with respect to s can be derived respectively as

$$\frac{1}{G_2(s)}\frac{d}{ds}[G_2(s)]=\frac{\tau_1}{1-\tau_1 s}-\frac{\tau_2}{\tau_2 s+1}-\theta \quad (34)$$

$$Q_2(s)=\frac{\tau_1^2}{(1-\tau_1 s)^2}+\frac{\tau_2^2}{(\tau_2 s+1)^2} \quad (35)$$

where $Q_2(s)=d[Q_1(s)]/ds$ and $Q_1(s)$ is the left side of (34).

Substituting $s=\alpha$ into (35) yields

$$Q_2(\alpha)=[2\alpha^2-\alpha^4Q_2(\alpha)]\tau_1^2\tau_2^2+[2\alpha-2\alpha^3Q_2(\alpha)](\tau_1^2\tau_2-\tau_1\tau_2^2)$$
$$+4\alpha^2Q_2(\alpha)\tau_1\tau_2+[1-\alpha^2Q_2(\alpha)](\tau_1^2+\tau_2^2)+2\alpha Q_2(\alpha)(\tau_1-\tau_2) \quad (36)$$

To solve τ_1 and τ_2 from (36), we reformulate (36) in the LS form of

$$\psi(\alpha)=\phi(\alpha)^T\gamma \quad (37)$$

where

$$\begin{cases}\psi(\alpha)=Q_2(\alpha),\\ \phi(\alpha)=[2\alpha^2-\alpha^4Q_2(\alpha),\ 2\alpha-2\alpha^3Q_2(\alpha),\ -\alpha^2Q_2(\alpha),\ 1,\ 2\alpha Q_2(\alpha)]^T,\\ \gamma=[\tau_1^2\tau_2^2,\ \tau_1^2\tau_2-\tau_1\tau_2^2,\ \tau_1^2+\tau_2^2-4\tau_1\tau_2,\ \tau_1^2+\tau_2^2,\ \tau_1-\tau_2]^T.\end{cases} \quad (38)$$

By choosing 5 different values of α in terms of the guideline given in (8) and denoting $\Psi=[\psi(\alpha_1),\ \psi(\alpha_2),\ldots,\ \psi(\alpha_5)]^T$ and $\Phi=[\phi(\alpha_1),\ \phi(\alpha_2),\ldots,\ \phi(\alpha_5)]^T$, an LS solution can be derived from the linear regression,

$$\gamma=(\Phi^T\Phi)^{-1}\Phi^T\Psi \quad (39)$$

It is obvious that all the columns of Φ are linearly independent with each other, such that Φ is guaranteed non-singular for computation of (39). Accordingly, there exists a unique solution of γ for parameter estimation.

Then, the model parameters can be retrieved from γ as

$$\begin{cases}\tau_1=\dfrac{\gamma(5)}{2}+\dfrac{1}{2}\sqrt{\gamma^2(5)+4\dfrac{\gamma(2)}{\gamma(5)}}\\ \tau_2=\tau_1-\gamma(5)\end{cases} \quad (40)$$

Note that there exist three redundant fitting conditions in the parameter estimation of γ, which can be surely satisfied if the model structure matches the process to be identified. To procure fitting accuracy for a high-order process, we may use $\gamma(1)$, $\gamma(3)$ and $\gamma(4)$ together with $\gamma(2)$ and $\gamma(5)$ to derive

an LS fitting solution for parameter estimation in terms of using the natural logarithm, i.e.,

$$\begin{bmatrix} 2 & 2 \\ 1 & 1 \\ 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \ln \tau_1 \\ \ln \tau_2 \end{bmatrix} = \begin{bmatrix} \ln \gamma(1) \\ \ln[\dfrac{\gamma(4)-\gamma(3)}{4}] \\ \ln[\dfrac{\gamma(5)}{2}+\dfrac{1}{2}\sqrt{\gamma^2(5)+4\dfrac{\gamma(2)}{\gamma(5)}}] \\ \ln[\dfrac{\gamma(5)}{2}+\dfrac{1}{2}\sqrt{\gamma^2(5)+4\dfrac{\gamma(2)}{\gamma(5)}}-\gamma(5)] \end{bmatrix} \tag{41}$$

Consequently, the other two model parameters can be derived from (34) and (26) as

$$\theta = -Q_1(\alpha) + \frac{\tau_1}{1-\tau_1\alpha} - \frac{\tau_2}{\tau_2\alpha+1} \tag{42}$$

$$k_{\mathrm{p}} = (\tau_1\alpha-1)(\tau_2\alpha+1)G_2(\alpha)e^{\alpha\theta} \tag{43}$$

Hence, the above algorithm named **Algorithm-II** for obtaining an SOPDT model for an unstable process can be summarized as:

(i) Choose $s=\alpha$ and t_N to compute $T(\alpha)$, $T^{(1)}(\alpha)$ and $T^{(2)}(\alpha)$ in terms of (6) (or (12)), (14) and (15);
(ii) Compute $C(\alpha)$, $C^{(1)}(\alpha)$ and $C^{(2)}(\alpha)$ in terms of (18), (19) and (20);
(iii) Compute $G_2(\alpha)$, $G_2^{(1)}(\alpha)$ and $G_2^{(2)}(\alpha)$ in terms of (22), (23) and (24);
(iv) Compute $Q_1(\alpha)$ and $Q_2(\alpha)$ in terms of (34) and (35);
(v) Compute the time constants, τ_1 and τ_2, from (40) (or (41));
(vi) Compute the process time delay, θ, from (42);
(vii) Compute the process gain, k_{p}, from (43).

4. ILLUSTRATION

Example 1. Consider the FOPDT unstable process studied in the recent literature (Padhy and Majhi, 2006),

$$G(s) = \frac{1}{s-1}e^{-0.8s}$$

Based on relay feedback test with two P controllers, Padhy and Majhi (2006) derived a FOPDT model, $G_{\mathrm{m}} = 1.0e^{-0.8033s}/(1.0007s-1)$. For illustration, the unity feedback control structure with a proportional controller of $k_{\mathrm{c}}=1.2$, which is equivalent to that of Padhy and Majhi (2006), is used for closed-loop step test. By adding a step change with a magnitude of $h=0.05$ to the set-point, the closed-loop step response is shown in Fig.1. According to the guidelines given in (8) and (10), $\alpha=0.1$ and $t_N=150$ (s) are chosen to use the proposed Algorithm-I, resulting in a FOPDT model listed in Table 1, which indicates high accuracy. The fitting error is given in terms of the closed-loop transient response in the time interval [0, 50]s.

To demonstrate identification robustness against measurement noise, assume that a random noise of $N(0,\sigma_N^2=0.035\%)$, causing the noise-to-signal ratio (NSR) to 5%, is added to the output measurement which is then used for feedback control. By performing 100 Monte-Carlo tests in terms of varying the 'seed' of the noise generator from 1 to 100, the identified results are listed in Table 1, where the model parameters are respectively the mean of 100 Monte-Carlo tests, and the values in the adjacent parentheses are the sample standard deviation. The results for the noise levels of NSR=10% and 20% are also listed in Table 1 to show the achievable identification accuracy and robustness.

Example 2. Consider the SOPDT unstable process studied by Cheres (2006) and Sree and Chidambaram (2006),

$$G(s) = \frac{1}{(2s-1)(0.5s+1)}e^{-0.5s}$$

Based on a closed-loop step test in terms of a PID controller ($k_{\mathrm{c}}=2.71$, $\tau_{\mathrm{I}}=4.43$ and $\tau_{\mathrm{D}}=0.319$) and a unity step change to the set-point, Cheres (2006) derived only a referential FOPDT model for controller tuning, and so was done in Sree and Chidambaram (2006). By performing the same closed-loop step test, the proposed Algorithm-II based on the choice of $\alpha=0.1, 0.15, 0.2, 0.25, 0.3$ and $t_N=300$ (s) gives a SOPDT model listed in Table 1, again demonstrating good accuracy. The fitting error is given in terms of the closed-loop transient response in the time interval [0, 30]s.

To demonstrate identification robustness against measurement noise, 100 Monte Carlo tests are performed in terms of NSR=5%, 10% and 20%, respectively. The identified results are listed in Table 1 for comparison, which indicate again that good identification accuracy and robustness is therefore obtained.

5. CONCLUSIONS

Low-order model identification methods have been increasingly appealed for improving control system design to operate unstable processes. By applying a damping factor to the closed-loop step response for realization of the Laplace transform, a frequency response estimation algorithm has been proposed for model fitting. Based on the process frequency response estimated from the closed-loop step response with the knowledge of the controller, two model identification algorithms have been analytically developed for obtaining the widely used low-order process models of FOPDT and SOPDT for practical applications. Two illustrative examples from the recent literature have been performed to demonstrate the achievable accuracy of the proposed algorithms. The results under Monte Carlo noise tests have also demonstrated good identification robustness of the proposed algorithms.

Multivariable System Identification for Integral Controllability – Computational Issues

Mark L. Darby, Michael Nikolaou

Chemical & Biomolecular Engineering Department, University of Houston, Houston, TX 77204-4004 USA
(darbymark@sbcglobal.net, nikolaou@uh.edu)

Abstract: A process model satisfies the integral controllability (IC) condition if the model can be used in a model-based controller that can be arbitrarily detuned without jeopardizing closed-loop stability. For decoupling multivariable control this requirement is equivalent to the inequality $\mathrm{Re}\left[\lambda\left(\mathbf{G}\hat{\mathbf{G}}^{-1}\right)\right]>0$ for the actual and estimated process steady-state gain matrices $\mathbf{G}$ and $\hat{\mathbf{G}}$. This necessitates experiments for identification of $\hat{\mathbf{G}}$ that satisfies the IC inequality. In this work we explore, via computer simulations, computational issues related to the design of such experiments for an FCC process. The proposed approach is based on a general mathematical optimization framework we presented in prior work.

Keywords: Identification, Integral controllability, multivariable systems

1. INTRODUCTION

A process model satisfies the integral controllability (IC) condition if the model can be used in a model-based controller that can be arbitrarily detuned without jeopardizing closed-loop stability. For decoupling multivariable control this requirement is equivalent to the inequality

$$\mathrm{Re}\left[\lambda\left(\mathbf{G}\hat{\mathbf{G}}^{-1}\right)\right]>0 \tag{1}$$

for the actual and estimated process steady-state gain matrices $\mathbf{G}$ and $\hat{\mathbf{G}}$ (Garcia and Morari 1985). The problem is acute for ill-conditioned processes. This necessitates experiments for identification of a model $\hat{\mathbf{G}}$ that satisfies the IC inequality. "The main weakness of the eigenvalue conditions [eqn. (1)] is that they consist of a coupling between the plant model and the true plant which is highly cumbersome for use in robust control analysis and design." (Featherstone and Braatz 1998b). A number of attempts have been made to address this weakness. Featherstone and Braatz (1998a) showed that for processes with constant rotation matrices in the singular-value decomposition (svd) of their transfer matrix the problem reduces to D-optimal design of experiments. Using insightful geometric reasoning to ensure IC for general linear 2×2 systems, Koung and MacGregor (1993) introduced experiment designs in terms of rotated PRBS input vectors, with power of each component of the rotated input vector reciprocally proportional to the corresponding singular value of $\hat{\mathbf{G}}$. Koung & MacGregor (1994) heuristically extended these design rules to $n\times n$ multivariable systems. The same rules were also used by Bruwer & MacGregor (2006) for the design of identification experiments subject to input and output bounds in the time domain. Darby and Nikolaou (2008) showed that the design rules proposed by Koung and MacGregor (1993; 1994) accept the same deep theoretical justification for both 2×2 and $n\times n$ systems in a number of cases. However, Darby and Nikolaou (2008) also showed that these design rules are not optimal for a number of typical cases, such as when outputs and/or inputs are constrained or when input rather than output variance alone must be maintained at a minimum. Furthermore, the same authors provided rigorous design rules for optimal inputs in a number of such cases. These design rules from solution of corresponding optimization problems. The purpose of this article is to explore the nature of the optimal input designs produced by the mathematical framework introduced by Darby and Nikolaou (2008) when applied to a realistic system, such as a 5×5 fluid catalytic cracking (FCC) unit.

2. BACKGROUND: EXPERIMENT DESIGN FOR IC

Consider a stable, linear, time-invariant, multivariable system with steady-state input-output relationship

$$\mathbf{y}=\mathbf{G}\mathbf{m} \tag{2}$$

where $\mathbf{y},\mathbf{m}\in\mathbb{R}^n$, $\mathbf{G}$ and $\hat{\mathbf{G}}\triangleq[\hat{\mathbf{g}}_1,...,\hat{\mathbf{g}}_n]^T\in\mathbb{R}^{n\times n}$. Because the IC condition, eqn. (1), involves the real process $\mathbf{G}$ and identified model $\hat{\mathbf{G}}$, it cannot directly guide input design for an $n\times n$ system. The following results (Darby and Nikolaou 2008) avoid that difficulty and can be used directly to design experiments pursuing IC.

Theorem 1. Experiment design for IC. Let the model uncertainty matrix $\mathbf{D} = \mathbf{G} - \hat{\mathbf{G}} \in \mathbb{R}^{n\times n}$ *belong to the ellipsoidal uncertainty set*

$$D \triangleq \left\{ [\mathbf{d}_1 ... \mathbf{d}_n]^T \in \mathbb{R}^{n\times n} \middle| \mathbf{d}_k^T \mathbf{M}^T \mathbf{M} \mathbf{d}_k \le c^2, 1 \le k \le n \right\}. \quad (3)$$

Then, an experiment design guarantees IC if the resulting information matrix $\mathbf{M}^T\mathbf{M}$ *and identified model* $\hat{\mathbf{G}}$ *satisfy the inequality*

$$\sum_{k=1}^{n} a_k \sqrt{\hat{\mathbf{v}}_k^T \left(\mathbf{M}^T\mathbf{M}\right)^{-1} \hat{\mathbf{v}}_k} < 1. \quad (4)$$

where

$$a_k \triangleq c \left\| \hat{\mathbf{u}}_k \right\|_1 / \hat{\sigma}_k, \quad k = 1,...,n \quad (5)$$

and $\hat{\sigma}_1 \ge \cdots \ge \hat{\sigma}_n$, $\hat{\mathbf{u}}_k$, $\hat{\mathbf{v}}_k$ *are defined through the svd*

$$\hat{\mathbf{G}} = \hat{\mathbf{U}}\hat{\Sigma}\hat{\mathbf{V}}^T = \sum_{k=1}^{n} \hat{\sigma}_k \hat{\mathbf{u}}_k \hat{\mathbf{v}}_k^T. \quad (6)$$

Eqn. (4) clearly suggests that IC can be satisfied if the information matrix $\mathbf{M}^T\mathbf{M}$ is "large enough". Given bounds on the input vector $\mathbf{m}$, a large enough $\mathbf{M}^T\mathbf{M}$ can be achieved if (a) the identification experiment is run long enough, or (b) $\mathbf{m}$ is shaped appropriately. While the first alternative is straightforward, it is far less desirable than the second one. Therefore, the essence of experiment design for IC is how to *shape process inputs that satisfy eqn. (4) subject to relevant constraints*. Darby and Nikolaou (2008) showed that numerical or analytical solutions can be developed for a number of cases. While for some of these cases the resulting designs are similar to designs that have appeared in literature, for others the resulting designs are entirely different.

2.1. Analytical solutions

Suppose that the quantity $\sum_{k=1}^{n} a_k [\hat{\mathbf{v}}_k^T (\mathbf{M}^T\mathbf{M})^{-1} \hat{\mathbf{v}}_k]^{1/2}$ in eqn. (4) is to be minimized with respect to the zero-mean random input $\mathbf{m}$, subject to the total weighted variance inequality

$$x \operatorname{var}(\mathbf{y}) + (1-x) \operatorname{var}(\mathbf{m}) \le W^2 \quad (7)$$

where $0 \le x \le 1$ and $0 < a_1 < ... < a_n$. Then it can be shown that the optimal input vector $\mathbf{m}$ is

$$\mathbf{m} = \hat{\mathbf{V}}\boldsymbol{\xi}, \quad (8)$$

where $\boldsymbol{\xi}$ is a zero-mean multivariable PRBS with

$$E\left[\xi_k^2\right] = \left(\frac{a_k}{b_k^2}\right)^{2/3} \frac{W^2}{\left[\sum_{j=1}^{n} \left(a_j b_j\right)^{2/3}\right]^2}, \quad k = 1,...,n \quad (9)$$

$$b_k^2 \triangleq x\sigma_k^2 + 1 - x, \quad k = 1,...,n. \quad (10)$$

and $b_1 \ge ... \ge b_n > 0$. Reversing the role of the above objectives and constraints, the minimum of the cost function $x \operatorname{var}(\mathbf{y}) + (1-x) \operatorname{var}(\mathbf{m})$ subject to eqn. (4) can be shown to be attained at an optimal $\mathbf{m}$ satisfying eqn. (8) with

$$E\left[\xi_k^2\right] > \left(\frac{a_k}{b_k^2}\right)^{2/3} \left[\sum_{j=1}^{n} \left(a_j b_j\right)^{2/3}\right]^2, \quad k = 1,...,n. \quad (11)$$

Note that for $x = 1$ (all cost on output variance, as is desirable in early stages of an identification experiment) both eqns. (9) and (11) result in the well known design rule

$$r_{kj} \triangleq \sqrt{\frac{E\left[\xi_k^2\right]}{E\left[\xi_j^2\right]}} = s_{kj} \frac{\hat{\sigma}_j}{\hat{\sigma}_k} \approx \frac{\hat{\sigma}_j}{\hat{\sigma}_k}. \quad (12)$$

where $s_{kj} \triangleq (\| \hat{\mathbf{u}}_k \|_1 / \| \hat{\mathbf{u}}_j \|_1)^{1/3} \approx 1$ for most cases of practical interest, and $1/n^{1/6} \le s_{kj} \le n^{1/6}$ when $\hat{\mathbf{u}}_k$, $\hat{\mathbf{u}}_j$ are any orthonormal vectors in $\mathbb{R}^n$. However, for $x = 0$ (all cost on input variance) we get the new input design

$$r_{kj} \triangleq \sqrt{\frac{E\left[\xi_k^2\right]}{E\left[\xi_j^2\right]}} = s_{kj} \left(\frac{\hat{\sigma}_j}{\hat{\sigma}_k}\right)^{1/3} \approx \left(\frac{\hat{\sigma}_j}{\hat{\sigma}_k}\right)^{1/3}. \quad (13)$$

The above design would keep inputs small to avoid inadvertent loss of IC by failure to excite the process by inputs along directions corresponding to small singular values.

Finally, a D-optimal design subject to eqns. (4) and (7) can be shown to be attained, if feasible, at an optimal $\mathbf{m}$ as in eqn. (8) with

$$E\left[\xi_k^2\right] = W^2 / \left(n b_k^2\right), \quad k = 1,...,n, \quad (14)$$

if eqn. (4) is satisfied by the above ξ_k, or each $E\left[\xi_k^2\right]$ equal to the unique positive solution of the equation

$$\frac{\rho}{t-1}\left(\frac{a_k}{\sqrt{(t-1)E\left[\xi_k^2\right]}} - \frac{1}{n}\right) = b_k^2 E\left[\xi_k^2\right] - \frac{W^2}{n} \quad (15)$$

for a value of $\rho > 0$ such that eqn. (4) is satisfied. It has been shown that eqn. (15) guarantees that $E\left[\xi_{k+1}^2\right] > E\left[\xi_k^2\right]$ and that D-optimality is compatible with IC by Cauchy's inequality (Darby and Nikolaou 2008). Note that as $t \to \infty$ eqns. (14) and (15) coincide asymptotically.

2.2. Numerical solutions

The preceding section 2.1 summarized analytical solutions for simple cases, offering insight into the nature of corresponding solutions. However, in many practical situations individual constraints on m_i and y_i may be present, such as

$$\sum_{\tau=1}^{t} m_{i,\tau}{}^2 = [\mathbf{M}^T\mathbf{M}]_{ii} \le (t-1) M_i^2 \quad (16)$$

$$\sum_{\tau=1}^{t} y_{i,\tau}{}^2 = [\mathbf{Y}^T\mathbf{Y}]_{ii} = [\hat{\mathbf{G}}\mathbf{M}^T\mathbf{M}\hat{\mathbf{G}}^T]_{ii} \le (t-1)Y_i^2 \quad (17)$$

corresponding to bounds on the variance of individual inputs m_k or outputs y_k. In such cases a numerical solution is required. To obtain a numerical solution, assume a zero-mean input vector $\mathbf{m}$, approximate the information matrix as $\mathbf{M}^T\mathbf{M} \approx (t-1)\mathbf{C}_m$, parametrize the input covariance matrix $\mathbf{C}_m$ in terms of the triangular matrix $\mathbf{Q}$ through the Cholesky factorization $\mathbf{C}_m = \mathbf{Q}\mathbf{Q}^T$, and substitute $\mathbf{M}^T\mathbf{M}$ into eqn. (4), to get

$$\frac{c}{\sqrt{t-1}} \underbrace{\sum_{i=1}^{n} \frac{\|\hat{\mathbf{u}}_k\|_1}{\hat{\sigma}_k} \sqrt{\hat{\mathbf{v}}_k^T \left(\mathbf{Q}\mathbf{Q}^T\right)^{-1} \hat{\mathbf{v}}_k}}_{\beta} \triangleq \frac{c}{\sqrt{t-1}} \beta < 1. \quad (18)$$

(Other parametrizations of a symmetric matrix in terms of corresponding basis matrices could be used. This is subject of ongoing investigation.) We can then design experiments for IC using eqn. (18) as a constraint or by minimizing β with respect to $\mathbf{Q}$ subject to input and output constraints such as in eqns. (16) and (17). Then, the corresponding optimal input $\mathbf{m}$ is

$$\mathbf{m} = \mathbf{Q}_{\text{opt}}\mathbf{z} \quad (19)$$

where $\mathbf{z}$ is a zero-mean PRBS with $\text{cov}(\mathbf{z}) = \mathbf{I}$. Even though β is not convex, resulting design problems are not prohibitively large for realistic systems, as demonstrated in section 4. It should be stressed that minimizing β may result to neither uncorrelated rotated inputs $\boldsymbol{\xi}$, nor magnitudes of rotated input components reciprocally proportional to corresponding singular values of the steady-state gain matrix, eqn. (12). In fact, the advantage of the above numerical formulation is that no such underlying assumptions on the nature of optimal inputs are necessary. Rather, the numerical optimization determines the nature of optimal input designs.

3. SUMMARY OF PROPOSED APPROACH

a. Establish constraints commensurate with time t available for identification experiments.

b. Obtain preliminary estimates of $\hat{\mathbf{G}}$ and c^2.

c. Compute the svd of $\hat{\mathbf{G}}$ to get $\hat{\mathbf{U}}$, $\hat{\boldsymbol{\Sigma}}$, $\hat{\mathbf{V}}^T$, eqn. (6).

Case I

d. Compute $\lambda_{k,\text{opt}}$ via eqns. (9) or similar

e. Design $\mathbf{m} = \hat{\mathbf{V}}\boldsymbol{\xi}$ with $\boldsymbol{\xi}$ zero-mean PRBS and $\text{cov}(\boldsymbol{\xi}) = \text{diag}(\lambda_{\ell_1,\text{opt}}^2, ..., \lambda_{\ell_n,\text{opt}}^2)/(t-1)$

Case II

d. Compute $\mathbf{Q}_{\text{opt}} = \arg\min \beta$ subject to constraints.

e. Design $\mathbf{m} = \mathbf{Q}_{\text{opt}}\mathbf{z}$ with $\mathbf{z}$ zero-mean PRBS and $\text{cov}(\mathbf{z}) = \mathbf{I}$ (eqn. (19)).

f. Implement $\mathbf{m}$ and collect data, to update $\hat{\mathbf{G}}$ and c^2.

g. If $\hat{\mathbf{G}}$ is adequate, stop. Otherwise go to step c.

4. CASE STUDY

A steady-state gain matrix is obtained from a linear empirical dynamic model of an industrial reactor-regenerator from a FCC unit, identified from plant testing (Harmse 2007). Note that the specific inputs and outputs are not indicated. Scaling is performed according to the inverse of the typical operating ranges of the inputs and outputs. The resulting gain matrix is

$$\mathbf{G} = \begin{bmatrix} 0.3866 & 0.0 & 0.1192 & 0.0 & 0.0630 \\ 0.0 & -0.6935 & 1.5463 & -0.1311 & -0.2462 \\ 0.0 & 0.0 & 0.5225 & -0.1298 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.1058 & 0.0 \\ 0.0 & -0.5803 & -0.3669 & -0.2057 & -0.4435 \end{bmatrix} \quad (20)$$

We tested the designs shown in Table 1. The constraints shown in Table 2 were considered.

Table 1. Summary of experimental designs tested

Design	Objective	Constraints
ICmin	$\min_{\mathbf{Q}} \beta$	$\mathbf{Q}$ triangular
KM	(Koung and MacGregor 1994)	
PRBSmax	$\min_{\mathbf{C}_m} -\log(\det \mathbf{C}_m)$	$\mathbf{C}_m \triangleq \text{diag}(v_i) \succ \mathbf{0}$

Table 2. Constraints considered for experiment design

Design case	Bounds	
A	$\text{var}(m_i) \le \infty$	$\text{var}(y_1) \le 0.50$
	$i = 1, ..., 5$	$\text{var}(y_2) \le 0.47$
		$\text{var}(y_3) \le 0.44$
		$\text{var}(y_4) \le 0.41$
		$\text{var}(y_5) \le 0.38$
B	$\text{var}(m_i) \le 0.5$	$\text{var}(y_i) \le 0.5$
	$i = 1, ..., 5$	

In all simulations, parameter estimation is initiated at time step 5 and is performed at each subsequent time step. The IC condition, eqn. (1), is calculated based on the true gain matrix and the inverse of the gain estimate at each time step. For simulations of case A, independent Gaussian noise of zero-mean and unit variance is added to all outputs.

Realizations of the inputs and outputs for each design are shown in Figure 1. We see that due to the high noise levels, the actual output variances are significantly higher than the optimal output variances (which are based on the model without noise). Note that the relatively low signal-to-noise ratio allows us to observe the evolution of gains over a longer period of time.

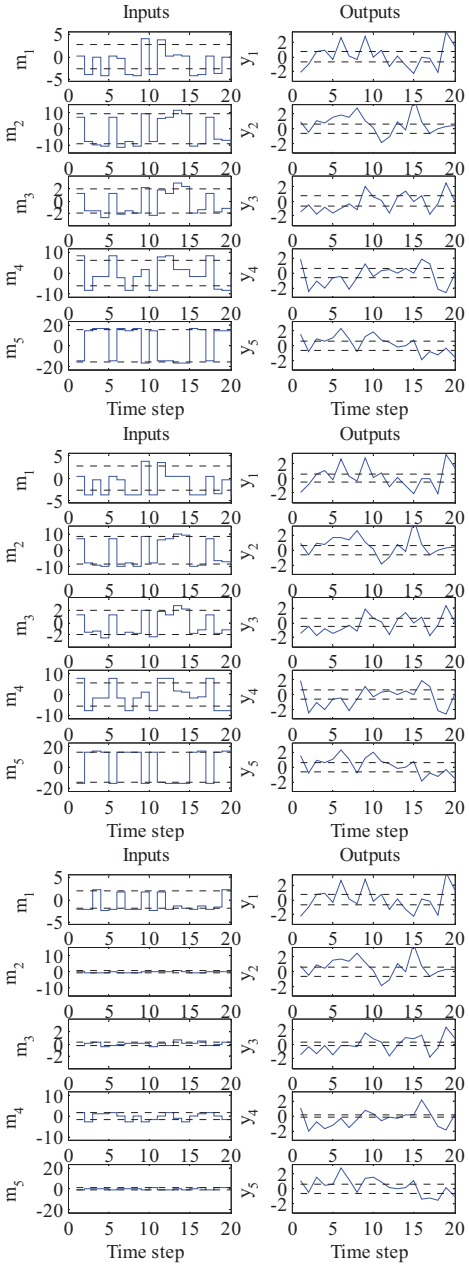

Figure 1 – Example realization of reactor regenerator for the three designs of case A (Table 1). The dotted lines represent $\pm(\mathrm{var}(m_i)^{\mathrm{opt}})^{1/2}$ and $\pm(\mathrm{var}(y_i)^{\mathrm{opt}})^{1/2}$ values.

Trends of the gain errors and an indicator of the IC condition are shown in Figure 2 For this realization, we see that IC is achieved first by ICmin at time step 7, followed by KM at time step 8, and finally PRBSopt at time step 13. The evolution of the gain errors is similar for ICmin and KM, whereas the PRBSopt results show higher gain errors and slower error reduction over time, consistent with the lower value of det(cov(**m**)) for PRBSopt.

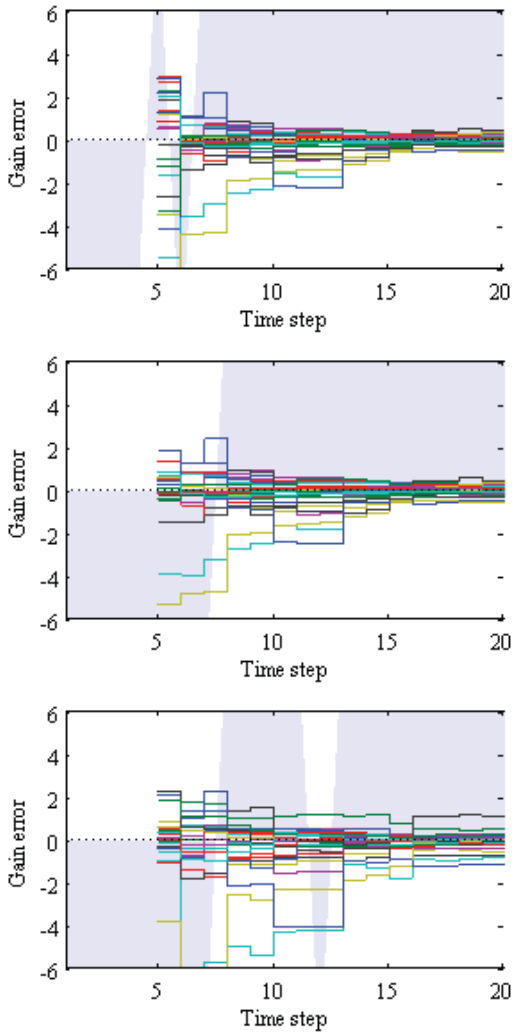

Figure 2 – Gain errors and IC condition for example realization of design case A (Table 1). Satisfaction or violation of the IC condition corresponds to shading above or below 0, respectively.

For the simulations of case B, independent, Gaussian noise of zero mean and variance (0.15^2) is added to all outputs. Realizations of the inputs and outputs for each design are shown in Figure 3. Note that the smaller signals for the KM design, compared to the other two designs, are due to the

fact that inputs must satisfy all inequality constraints, as well as equality constraints on rotated input ratios. The latter are clearly not optimal for case B.

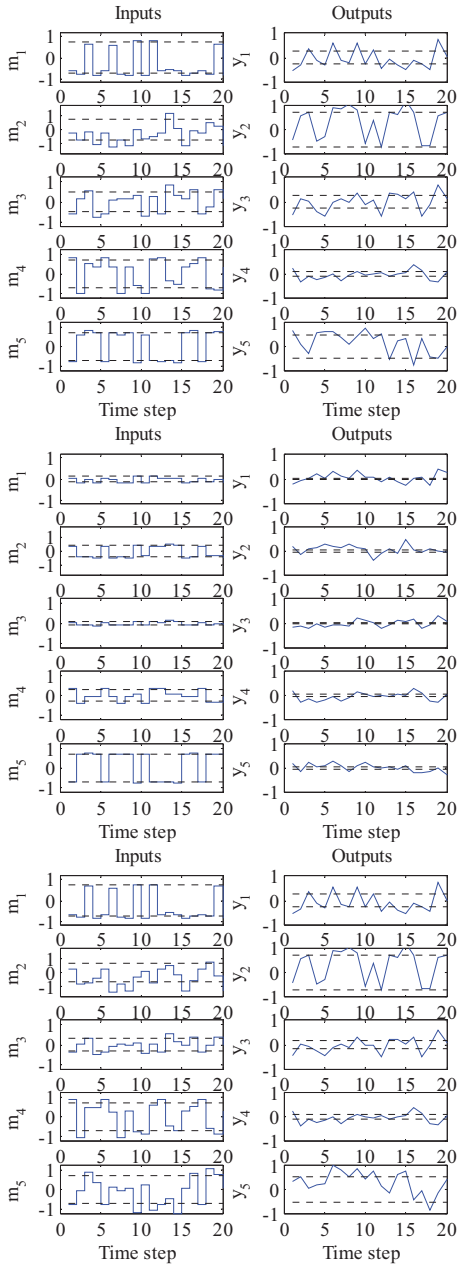

Figure 3 – Example realization of reactor regenerator case B (Table 1). The dotted lines represent $\pm\sqrt{\text{var}(m_i)^{\text{opt}}}$ and $\pm\sqrt{\text{var}(y_i)^{\text{opt}}}$ values.

Trends of the gain errors and an indicator of the IC condition are shown in Figure 4. We see that the parameters estimates for the KM design are significantly inferior to the ICmin and PRBSopt designs, reflecting the much smaller value of det(cov(**m**)) for KM. Further, while IC is achieved by ICmin at time step 6 and by PRBSopt at time step 5, the KM design does not satisfy the IC condition by time step 20 (it is actually achieved at time step 22 – not shown – more then 3 times longer than required for either ICmin or PRBSopt).

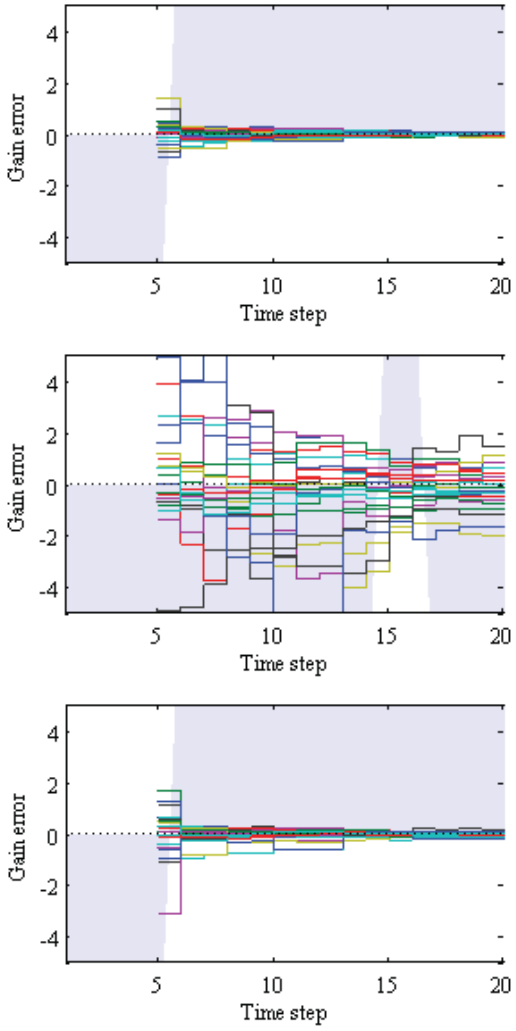

Figure 4 – Gain errors and IC condition for example realization of design case B (Table 1). Satisfaction or violation of the IC condition corresponds to shading above or below 0, respectively.

To develop these designs we used the Matlab routine fmincon with multiple starting points, to reduce the possibility of missing a global optimum for non-convex optimization problems. Run time for all simulations was, on the average, of the order of 0.25 seconds when using the Yalmip interface, and of the order of 0.1 seconds without it.

5. CONCLUSIONS

The purpose of this paper was to explore numerical aspects of a numerical optimization approach proposed in prior work for the design of experiments targeting IC. Given that analytical solutions for this approach are available only for some cases, it is natural to ask how well numerical optimization can work, given that the proposed problems are non-convex. In this work, we develop what appear to be useful designs for a 5×5 multivariable FCC unit. Convergence time appeared not to be an issue. These results suggest that the proposed approach can work reasonably well for problems of that size. Clearly, other optimization methods (either deterministic or probabilistic) can be explored.

Abstract: This work is concerned with the model re-identification of processes controlled by MPC systems. The MPC system considered here has a two-layer structure, where in the upper layer a steady-state optimization algorithm determines a set of optimal targets for the process inputs and passes this set to the MPC controller that determines the best way to drive the process to such targets. This is the case of several commercial MPC packages applied in industry. In this paper, it is proposed two internal excitation approaches aiming to obtain closed-loop data sufficiently rich for process identifiability. Here, the term internal is used to indicate that the excitation test signal is applied within the MPC control structure. In the first excitation approach, the test signal is introduced as a weighting factor in the objective function of the target calculation layer. In the second approach, the test signal is injected as a dither signal in the objective function of the dynamic controller layer. These two approaches are compared to the usual method where the excitation signal is added to the controller output. The application of the methodologies is illustrated through numerical simulations carried out on a depropanizer column of the oil industry. The results show the effectiveness of the proposed approaches and their good potential to be applied in practice.

1. INTRODUCTION

Model identification has become a bottleneck of MPC technology. It is the most expensive, difficult and time-consuming step of the MPC project. Although industrial processes present nonlinear dynamic characteristics, typically, empirical linear and time-invariant (LTI) models based on process input-output data obtained in open-loop operation are used in MPC implementation (Qin & Badgwell, 2003). While this approach is only acceptable at operating conditions around the operating point where the model was obtained, the control system with this model works satisfactorily in most applications.

However, after some operation time (2-3 years), MPC is seldom performing as when it was commissioned. The main cause of this problem is related to the model deterioration resulting from changes in the dynamics of the plant or persistent unmeasured disturbances that force the plant to a different operating point (Conner & Seborg, 2005). Changes in the dynamics of the plant may result from fatigue conditions, fouling, debottlenecking, etc, or changes in the operating conditions or product specifications. In general, the above listed problems intensify with time and tend to accentuate the plant/model mismatch, leading to poor output prediction and, therefore, degradation of the control system performance. In order to keep the performance of the MPC at an acceptable level, it is essential to carry out the MPC re-commissioning in a periodic basis, which means to re-identify the process model and, if necessary, to retune the MPC considering the new model (Gugaliya et al., 2005). However, due to production goals and safety aspects, model re-identification means, in most cases, to develop a new model based on plant data obtained in closed-loop conditions.

Closed-loop identification is a research subject with growing interest in the last decade (Van den Hof, 1998; Forssell & Ljung, 1999; Hjalmarsson, 2005). Important aspects on model identification have been studied and several identification strategies have been proposed, which can be categorized as variants of the following three approaches (Forssell & Ljung, 1999): direct, indirect and joint input-output methods. Both indirect and joint input-output methods require prior knowledge of the controller or assume that it has a certain LTI structure. Obviously, these methods are not suitable for MPC applications, because MPC presents nonlinear and time-variant features, especially when operating under constraints. For this sort of control strategy, the direct method is the recommended choice for closed-loop identification. See for example Rivera & Flores (1999).

In closed-loop identification, the use of routine operating data would be an ideal goal. But, the inherent reduction in the excitation resulting from the presence of the controller may result in a poor signal-to-noise ratio. In this case, and in order to achieve the necessary and sufficient conditions for process identifiability, an external persistently exciting (PE) test signal is required. External excitation is a dither signal that may be introduced on the controlled variable set-point and/or on the manipulated variable (added to the controller output).

However, adding such a signal is often undesirable or too expensive, and there is no guarantee that the process constraints and product specifications will be attended during the execution of the excitation procedure. On the other hand, an insufficient excitation may compromise the identification requirements.

The main goal of this paper is to compare internal excitation approaches that exploit the two-layer structure of MPC packages. Motivation for this work is due primarily to commercial needs and as an attempt to overcome the significant gap between practical applications and theory in closed-loop identification with MPC. In the proposed methodologies an external PE test signal is applied within the MPC control structure: (a) the test signal is introduced in the objective function of the target calculation layer, and (b) the test signal is injected in the objective function of the dynamic MPC control layer. These approaches does not modify the optimization code and they allows the adequate excitation of the process coupled with the continuous operation of the system as the process constraints and product specification can be satisfied during the test. Results from the proposed excitation methodologies are also compared with the one provided by a conventional external excitation procedure in the closed-loop identification of an industrial depropanizer column.

2. THE TWO-LAYER MPC STRUCTURE

In modern processing plants, MPC control systems are usually implemented in a two-layer scheme (Ying & Joseph, 1999; Qin & Badgwell, 2003; Nikandrov & Swartz, 2009). The two-layer MPC considered here is shown in Figure 1. The upper layer usually corresponds to a simplified steady-state target optimization and the lower layer stands for a constrained dynamic optimization in which the outputs are controlled in specified zones or ranges instead of fixed references. It is at the dynamic layer where the main control objectives (setpoint tracking, disturbance rejection) are pursued. All commercial MPC packages offer the option of zone control. In the target calculation layer, one searches for the optimum steady-state values to the system (input targets), by usually solving a linear or quadratic objective function subject to bound constraints in the inputs and outputs. The outputs at the optimal steady-state are computed through a static model, consistent with the dynamic MPC model, and the available steady-state output prediction computed at the previous time step in the MPC algorithm. The optimal input targets are sent to the dynamic layer, where the control cost is extended with a term that penalizes the distance between the present value of the input and the optimal target. Both layers are executed with the same sampling period.

In this paper, the target calculation layer solves a LP (linear programming) problem where the objective may be to maximize production by forcing one or more inputs to their bounds, while keeping the outputs inside the bounds:

$$\min_{\Delta u_s, \delta_y} W_1^T \Delta u_s + \left| W_2^T \delta_y \right| \tag{1}$$

subject to:

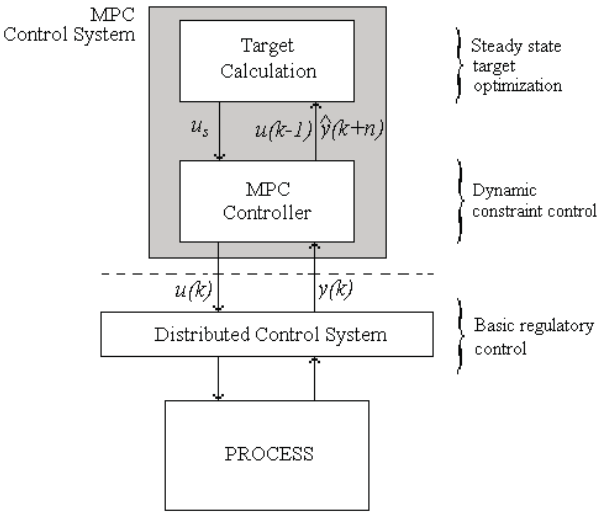

Fig. 1. Two-layer MPC structure

$$\begin{aligned} &\Delta u_s = u_s - u(k-1) \\ &y_s = G_0 \Delta u_s + \hat{y}(k+n) \\ &u_{\min} \le u_s \le u_{\max} \\ &y_{\min} \le y_s + \delta_y \le y_{\max} \end{aligned} \tag{2}$$

where $u(k-1)$ is the last implemented control action, k is the present time, u_s is the vector of steady-state targets for the manipulated inputs, y_s is the vector of predicted output at steady-state, $\hat{y}(k+n)$ is the prediction of the controlled output at time instant $k+n$ (n is the model horizon or settling time of the process in open-loop) computed at time k, δ_y is the vector of slack variables for the controlled outputs, G_0 is the steady state gain matrix model, W_1 and W_2 are weight vector of appropriate dimensions, $u_{\min}$ and $u_{\max}$ are the bounds of the manipulated inputs, $y_{\min}$ and $y_{\max}$ are the bounds of the controlled outputs.

As a result of the solution to the problem formulated in (1) and (2), it is obtained the input target u_s that is passed to the dynamic layer, which typically solves the following QP (quadratic programming) problem:

$$\begin{aligned} \min_{\Delta u} &\sum_{i=1}^{p} \left\| Q\left(\hat{y}(k+i) - y_{sp}\right) \right\|_2^2 + \sum_{j=1}^{m} \left\| R\Delta u(k+j-1) \right\|_2^2 + \\ &\sum_{j=1}^{m} \left\| R_u \left(u(k+j-1) - u_s \right) \right\|_2^2 \end{aligned} \tag{3}$$

subject to:

$$\begin{aligned} &-\Delta u_{\max} \le \Delta u(k+j-1) \le \Delta u_{\max}, \quad j = 1, \cdots, m \\ &u_{\min} \le u(k+j-1) \le u_{\max}, \qquad j = 1, \cdots, m \end{aligned} \tag{4}$$

with $u(k+j-1) = u(k-1) + \sum_{i=1}^{j} \Delta u(k+i-1)$

where $\hat{y}(k+i)$ is the output prediction at time $k+i$, y_{sp} is the setpoint to the system output, $\Delta u = \left[\Delta u(k)^T \quad \Delta u(k+1)^T \quad \cdots \quad \Delta u(k+m-1)^T \right]^T$ is the vector of control moves, $\Delta u_{\max}$ is the upper limit to the control moves, m is the control horizon, p is the prediction horizon, and Q, R and R_u are diagonal weighting matrices of appropriate dimensions. Note that only the first element of the computed input sequence Δu is implemented in the plant, i.e. $u(k) = \Delta u(k) + u(k-1)$.

In this controller, the zone control strategy is implemented as follows: if the prediction of a given output is inside its reference zone or range, the error in this output is considered to be equal to zero and the output is not included in the controller optimization problem. When the output prediction lies outside the corresponding reference range, depending on whether the prediction is above or below the max or min values of this range, one of these bounds is adopted as the output reference. In general, the zone control strategy is used as an attempt to release some degrees of freedom to allow the inputs to approach their optimal targets (constraints pushing) and to smooth out the system response. For more details see Sotomayor et al. (2009).

The two-layer MPC algorithm as described above is similar to the structure of several MPC packages widely applied to control the refining and petrochemical processes. For instance, this MPC algorithm, with slight modifications, is supported by the advanced control package SICON@, which is the standard process control software in the oil refineries of PETROBRAS in Brazil.

3. INTERNAL EXCITATION APPROACHES

To solve the problem of lack of excitation during normal operation of MPC systems, some authors have proposed a new class of excitation methods for MPC that can be considered as internal excitation methods. Genceli & Nikolaou (1996) use the MPCI framework (model predictive control and identification) where the PE characteristic of the inputs is imposed as a constraint in the optimization problem related to the MPC. The drawback of this method is that the additional constraint is non-convex, resulting in a non-convex optimization problem. Since solving non-convex problems is significantly more involved than solving convex problems, the additional non-convex constraints are undesirable and the method cannot be directly applied to existing commercial MPC packages, without extensive modifications of the controller code, which limits its practical application.

On the other hand, a reasonable consideration of the layered MPC is that when the model is biased, the target calculation layer will change the input target to the dynamic layer quite often, and so, the input target could be viewed as a possible test signal. However, to assume that these natural moves on the input targets will be PE is a questionable matter. Here, taking advantage of the layered structure of MPC, and in order to guarantee the necessary excitation of the input targets, an external PE test signal, namely a binary signal of magnitude ± 1, is applied within the MPC control structure according to the following approaches:

Method 1. Introducing the test signal into the LP layer

Given that the weight vector W_1 in the objective function of the target calculation layer is usually available to be set on-line by the user of the MPC package, the external test signal can be introduced in the MPC system as a variable that multiplies W_1. Thus, Equation (1) is re-written as follows:

$$\min_{\Delta u_s, \delta_y} \left(W_{exc} \otimes W_1 \right)^T \Delta u_s + \left| W_2^T \delta_y \right| \tag{5}$$

subject to (2)

where W_{exc} is a vector whose elements are the components of the binary test signal and operator $\otimes$ denotes the Schur (or element-by-element) product. Then, if the product $W_{exc,i} W_{1,i}$ is positive (negative), the solution to the LP problem will tend to reduce (increase) input u_i until it reaches its lower (upper) bound or the output predictions lies outside the control zones. Note that if W_{exc} is set equal to a vector of ones, then the excitation procedure will end and the original objective function (1) is recovered. This method is described with details in Sotomayor et al. (2009).

Method 2. Introducing the test signal into the dynamic layer

In this case, the external test signal, conveniently scaled, is injected as a dither signal in the input target u_s that enters the MPC layer. This is similar to writing the objective function (3) as follows:

$$\min_{\Delta u} \sum_{i=1}^{p} \left\| Q\left(\hat{y}(k+i) - y_{sp} \right) \right\|_2^2 + \sum_{j=1}^{m} \left\| R \Delta u(k+j-1) \right\|_2^2 + \sum_{j=1}^{m} \left\| R_u \left(u(k+j-1) - (u_s + u_{s,dith}) \right) \right\|_2^2 \tag{6}$$

with $u_{s,dith} = \lambda W_{exc}$, subject to (4), where W_{exc} is the excitation vector as defined in Section 3.1 and λ is a scaling factor. Then, the achievement of excitation of the system will largely depend on the value of tuning parameter R_u, which will define if the MPC layer will implement the input target faster than the main process dynamics. Observe that if λ is set equal to zero, the excitation procedure is ended and the original cost function (3) is obtained.

Particularly, Method 1 can be easily implemented in existing MPC packages with a structure similar to the one detailed in Section 2, as the excitation signal is introduced through a tuning parameter of the controller. In both methods the MPC problem is still solved through a QP, and the problem is reduced to design the binary sequence for W_{exc} such that the on-line solution of the problems (5)-(2) and (6)-(4) produces persistent excited inputs, which is the primary requirement for the process identifiability (Ljung, 1999).

As it will be shown in the application section, with the approaches proposed here, the inputs can be adequately excited and if the outputs are controlled within zones, the feedback effect on the test data may be minimized. Also, the approaches attend the process safety requirements and the product specifications can be satisfied adequately.

In the next section it is illustrated the application of the proposed excitation procedures to the closed-loop identification of a depropanizer column. The identification procedure follows same steps as the usual identification methodology applied to industrial processes (Ljung, 1999): design of the test signal and generation of dataset, model structure selection, computation of the model parameters and model validation.

4. APPLICATION: DEPROPANIZER COLUMN

Figure 2 presents the process considered in this work. It is an industrial depropanizer column of the FCC unit at the PETROBRAS Refinery of Cubatão (RPBC), Brazil.

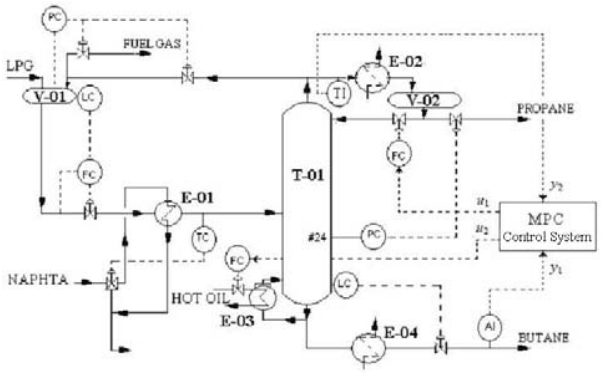

Fig. 2. Schematic diagram of the depropanizer column

In the depropanizer column, the C3 stream (propane and propene) is separated from a C4 stream (butane and butene). The operation of this process is controlled by a commercial MPC system as detailed in Section 2. Basically, it is a 2x2 control system, where the output variables y_1 and y_2 are the molar concentration (%) of C3 in the bottom stream and the temperature (°C) at the first stage of the top section of the column, respectively. The input variables u_1 and u_2 are the reflux flowrate to the top of the column (m^3/d) and the flowrate of hot oil to the reboiler (m^3/d), respectively. Transfer function models of order 2 corresponding to points FD and 1 from Porfirio et al. (2003) are used to simulate the "true" process and to represent the nominal process model (as it is used by the MPC system), respectively. MPC tuning parameters are here omitted but they can be found in Sotomayor et al. (2009).

PE test signal and generation of the dataset

Based on the guidelines provided by Zhu (2001) and a priori knowledge of the process (already existing model in the MPC), two independent GBN (generalized binary noise) (Tulleken, 1990) signals of magnitude ± 1 are designed. These test signals are applied directly to the LP layer of the MPC system if Method 1 is used or they are firstly scaled using $\lambda_1 = 0.065u_{s,1}$ and $\lambda_2 = 0.07u_{s,2}$, respectively, and applied to the MPC dynamic layer if excitation Method 2 is employed. In addition to the these excitation approaches, the system is also perturbed using a conventional external excitation as in MacArthur &. Zhan (2007). For this purpose, the MPC controller first calculates the normal movement for each controller output. New projected outputs are computed by superimposing a dither signal on the moves proposed by the controller. The projected outputs are then compared to the controller's high and low limits (constraints). Projected moves are then modified to ensure that all constraints are honored. In the present case, the dither signals are the GBN test signals scaled to ± 0.0034 and ± 0.0043, respectively. In all the cases, the duration of the excitation test is 4500 min. The data were collected with a sampling time of 1 min, resulting 4500 samples of input-output data.

For better identification results, the dataset is normalized, de-trended and filtered. Next, the dataset is divided into two subsets, where the first one containing 3000 data points is used to identify the model while the second one containing the remaining points is used to cross-validate the model. The PE characteristic of the inputs for the three cases is tested for order $\eta = 4$, which means that 2nd-order transfer functions can be satisfactory identified (Söderström & Stoica, 1989).

Model structure selection

In the present paper, it is considered that the model structure is defined by a continuous-time multi-input and single-output (MISO) output-error (OE) transfer function model, with the stochastic model parameterized as unitary:

$$\hat{y}_j(t,\rho_j) = \sum_{i=1}^{n_u} \hat{G}_{j,i}(s,\rho_{j,i})u_i(t) + \varepsilon_j(t), \quad j = 1,\cdots,n_y \quad (7)$$

where $\hat{G}_{j,i}(s,\rho_{j,i})$ is the (j,i)th transfer function defined as:

$$\hat{G}_{j,i}(s,\rho_{j,i}) = \frac{\hat{B}_{j,i}(s)}{\hat{A}_{j,i}(s)} = \frac{\sum_{k=0}^{m_{j,i}} \hat{b}_{j,i,k}s^k}{\sum_{k=0}^{n_{j,i}} \hat{a}_{j,i,k}s^k} e^{-s\hat{\theta}_{j,i}}$$

with $\hat{a}_{j,i,n_{j,i}} = 1$, $n_{j,i} \geq m_{j,i}$, where $u(t)$ is the input vector, $\hat{y}(t,\rho)$ is the model output, $\hat{\theta}_{j,i}$ is the estimated time-delay between the i_{th} input and the j_{th} output, $\varepsilon(t)$ is the residual or total model error (bias plus variance), n_u and n_y are the number of inputs and outputs, respectively, and $\rho_{j,i} = \left[\hat{b}_{j,i,m_{j,i}} \cdots \hat{b}_{j,i,0}\ \hat{a}_{j,i,(n_{j,i}-1)} \cdots \hat{a}_{j,i,0}\ \hat{\theta}_{j,i}\right]^T \in \mathbb{R}^{q_{j,i}}$, with $q_{j,i} = n_{j,i} + m_{j,i} + 2$, where $n_{j,i}$ and $m_{j,i}$ denotes the denominator and numerator orders of $\hat{G}_{j,i}(s,\rho_{j,i})$, respectively.

Computation of the model parameters

The goal is to build a model as defined in eq. (7) based on closed-loop sampled data, focusing on the parameters of each transfer function $\hat{G}_{j,i}(s,\rho_{j,i})$ rather than on the model error. Thus, the task of the identification procedure is to compute the vector of model parameters:

$$\rho_j = \left[\rho_{j,1}^T \cdots \rho_{j,nu}^T\right]^T \in \mathbb{R}^{q_j \times 1}, \quad q_j = \sum_{i=1}^{n_u} q_{j,i} \tag{8}$$

Here it is used the CONTSID toolbox (Garnier et al., 2008) to find the vector ρ_j for each closed-loop sampled dataset from the depropanizer column, assuming $n_u = n_y = 2$, $n_{j,i} = 2$ and $m_{j,i} = 1$. The identification is carried out off-line considering the values of the parameters of the existing (old) process model as the initial solution to the identification problem.

Three new models are obtained and they are evaluated based on the following performance criteria:

$$FIT = 100 \times \left(1 - \frac{norm(y_j - \hat{y}_j)}{norm(y_j - mean(y_j))}\right)$$

$$R_T^2 = 1 - \frac{\mathrm{var}\left(y_j - \hat{y}_j\right)}{\mathrm{var}\left(y_j\right)}$$

where y is the true system output and $\hat{y}$ the model output. Coefficient FIT indicates the percentage of the output variation that can be associated to the model, while coefficient R_T^2 measures how well the model output explains the behavior of the system output, and this parameter will be close to 1 in low noise conditions.

Model validation

Figure 3 shows the step response comparison between the old model and the new models obtained with the three excitation methods considered here. Observing the responses of the old model used in the controller and the new models obtained with the re-identification procedure, one may conclude that the re-identification of the process model is quite justified not only because of the difference between the gains of the old and new models, but also because of the different dynamics. Also, observing the responses of the re-identified models, one can confirm that the model obtained with excitation method 3 is, in general, inferior to the models obtained with the two other excitation methods, showing a significant bias on the gain of $\hat{G}_{2,1}$. Moreover, from a practical point of view, one may conclude that the internal excitation methods 1 and 2 can be considered equivalent in terms of the model that is obtained, particularly if the step response of the process is to be used as in several MPCs. This result is in concordance with the performance indicators obtained from the cross-validation procedure of the three new models (not presented here).

5. CONCLUSIONS

Three closed-loop excitation methods for systems being controlled by MPCs with a two layer structure were studied here. These excitation methods allow the closed-loop model re-identification that should be used for periodic MPC monitoring and maintenance and for the design of an explicit adaptive MPC. The first two methods are based on the introduction of a persistently exciting signal within the MPC structure. The third method corresponds to the traditional approach of adding the excitation signal to the controller output. The three methods showed equivalence in terms of producing a data set that is adequate for model identification. The main difference between the excitation methods lies in the implementation of the approach in practice. Method 1 introduces the excitation signal in the coefficients of the objective function of the target calculation layer which are usually available as tuning parameters of the controller. So, there is no need of any modification in the controller code and the method does not require any particular attention of the operator while the process excitation is performed. Thus, this method seems to be the most adequate in practical terms. Method 2 adds the excitation signal to the input target of the dynamic layer of the controller. Besides, some new tuning parameters this method requires a slight modification in the controller code and, consequently, can only be implemented if the source code is available. The third or conventional method, that adds the excitation signal to the output of the controller, requires more care in the design stage and more attention of the operator because the control action really injected in the process will not satisfy the process constraints.

Abstract: In this paper we propose a novel procedure for obtaining a low order non-linear model of a large scale multi-phase, non-linear, reactive fluid flow systems. Our approach is based on the combinations of the methods of Proper Orthogonal Decomposition (*POD*), and non-linear System Identification (*SID*) techniques. The problem of non-linear model reduction is formulated as parameter estimation problem. In the first step POD is used to separate the spatial and temporal patterns and in the second step a model structure and it's parameters of linear and of non-linear polynomial type are identified to approximate the temporal patterns obtained by the POD in the first step. The proposed model structure treats POD modal coefficients as states rather than outputs of the identified model. The state space matrices which happens to be the parameters of a black-box to be identified, comes linearly in parameter estimation process. For the same reason, Ordinary Least Square (*OLS*) method is used to estimate the model parameters. The simplicity and reliability of the proposed method gives computationally very efficient linear and non-linear low order models for extremely large scale processes. The method is of generic nature. The efficiency of proposed approach is illustrated on a very large scale benchmark problem depicting Industrial Glass Manufacturing Process (*IGMP*). The results show good performance of the proposed method.

1. INTRODUCTION

Industrial processes involving fluid flows are usually modeled by Navier-Stoke's equations which are solved by some kind of spatial discretization. Due to this modeling approach they are referred to as Distributed Parameter Systems (DPS). Spatial discretization of DPS is done by means of Finite Volume or Finite Element methods and Galerkin or Petro-Galerkin projection techniques and they are simulated in a Computational Fluid Dynamic (CFD) software environment. Although such discretizations approximate the dynamic process behavior reasonably well, it leads to very large order process model. It takes huge computational efforts (time, CPU requirement) to simulate such models and therefore such process models can not be used for online plant optimization and control purposes. Model Order Reduction (MOR) is therefore an important step before proceeding to control design, see e.g. Shvartsman and Kevrekidis [1998]. The method of Proper Orthogonal Decomposition (POD) or Principle Component Analysis (PCA) is widely used for deriving lower dimensional models from the First Principle Model (FPM). The POD method searches for dominant patterns in the given process and defines an optimal, data-dependent basis, that is subsequently used as a projection space to infer reduced order models through Galerkin type of projections, see Astrid [2004] and the references therein. POD methods are empirical (data dependent) in nature and therefore these methods are susceptible to changes in process inputs and process parameters. The reduced model obtained by POD techniques with Galerkin projections are usually very dense and one loses the original sparse model structure. Such a dense model does not always give computational advantage over original full scale CFD model. This motivates one to look for other possible approaches which can give computationally efficient, reliable models which can be used for the online control and optimization purpose. Other motivations for the method proposed in this paper are that in many commercial CFD packages sometimes it becomes impossible to get access to the Partial Differential Equations (PDE) used to implement full scale model and even with access to the PDEs the reduced order modeling efforts can also be very expensive and laborious. In such situations one needs to explore the other possible ways to get a low order model by some identification method. One of such methods is explained in Wattamwar et al. [2008], which uses POD and system identification tools like N4SID algorithms, as explained in e.g. Overschee and Moor [1996], Favoreel et al. [2000]. But the method proposed there results in linear models which are not sufficient for approximating the non-linearities of large scale applications like IGMP. Moreover in the method proposed there, the states of the linear reduced order model have no physical meaning. These problems have motivated us to investigate another model reduction strategy which can approximate process non-linearity. The identification based approach proposed in this paper can be very useful, because it allows to use the available large-scale first principle based detailed non-linear process model in the form of commercial package, not just for the purpose of computationally extremely efficient dynamic

process analysis but also for the purpose of design of the process controller and optimization. Therefore the method proposed here helps in minimizing the dependence on the expensive testing of the plant required for the controller design.

This paper is organized as follows. The overall methodology involving necessary tools from system theory like POD, a black-box type of system identification for linear and non-linear polynomial system is explained in section 2. The application/motivation is IGMP and is explained in the section 3. Some results of the proposed method on the motivation problem are presented in the section 4 which is followed by future work and references.

2. THEORY BACKGROUND AND METHODOLOGY

One of the most promising and successful techniques for an efficient reduction of large-scale nonlinear systems in fluid dynamics is the method of Proper Orthogonal Decompositions (POD) also known as the Karhunen-Loève method Holmes et al. [1996]. The method is based on the observation that flow characteristics reveal coherent structures or *patterns* in many processes in fluid dynamics. This has led to the idea that the solutions of model equations may be approximated by considering a small number of dominant coherent structures (called *modes* or *basis*) that are inferred in an *empirical* manner from measurements or simulated data. Given an ensemble of K measurements $\mathbf{T}^k(\cdot), k = 1, \ldots, K$ with each measurement defined on some spatial domain Ω, the POD method amounts to assuming that each observation $\mathbf{T}^k$ belongs to a Hilbert space $\mathcal{H}$ of functions defined on Ω. With the inner product defined on $\mathcal{H}$, it then makes sense to call a collection $\{\varphi_j\}_{j=1}^{\infty}$ an *orthonormal basis* of $\mathcal{H}$ if any element, say $\mathbf{T} \in \mathcal{H}$, admits a representation

$$\mathbf{T}(z) = \sum_{j=1}^{\infty} a_j \varphi_j(z), \quad z \in \Omega \tag{1}$$

Here, the a_j's are referred to as the *modal coefficients*(MC) and the φ_j's are the *modes* or *basis* of the expansion. The truncated expansion

$$\mathbf{T}_n(z) = \sum_{j=1}^{n} a_j \varphi_j(z), \quad z \in \Omega \tag{2}$$

causes an approximation error $\|\mathbf{T} - \mathbf{T}_n\|$ in the norm of the Hilbert space. We will call $\{\varphi_j\}_{j=1}^{\infty}$ a *POD basis* of $\mathcal{H}$ whenever it is an orthonormal basis of $\mathcal{H}$ for which the *total approximation error* in some norm over the complete ensemble is

$$\sum_{k=1}^{K} \|\mathbf{T}^k - \mathbf{T}_n^k\| \tag{3}$$

is minimal for all truncation levels n. This is an *empirical basis* in the sense that every POD basis depends on the data ensemble. Using variational calculus, the solution to this optimization problem amounts to finding the normalized eigenfunctions $\varphi_j \in \mathcal{H}$ of a positive semi-definite operator $R : \mathcal{H} \to \mathcal{H}$ that is defined as

$$\langle \psi_1, R\psi_2 \rangle := \frac{1}{K} \sum_{k=1}^{K} \langle \psi_1, \mathbf{T}^k \rangle \cdot \langle \psi_2, \mathbf{T}^k \rangle \tag{4}$$

with $\psi_1, \psi_2 \in \mathcal{H}$. R is well defined in this manner and corresponds to a positive semi-definite matrix whenever $\mathcal{H}$ is finite dimensional. In that case, a POD basis is obtained from the normalized eigenvectors of R, see e.g. Astrid [2004].

The POD modal coefficients 'a_j' are then obtained by the projection of the ensemble on the span of dominant POD modal coefficients as given by:

$$a_j(k) = \langle \varphi_j(z), \mathbf{T}_n(k, z) \rangle \tag{5}$$

Subsequently, a Galerkin projection is used to obtain the reduced order model as follows. Suppose that the system is governed by a PDE of the form

$$\frac{\partial T_n}{\partial t} = \mathcal{A}(T_n) + \mathcal{B}(u) + \mathcal{F}(T_n, u, d) \tag{6}$$

and let $\mathcal{H}_n$ denote an n dimensional subspace of $\mathcal{H}$ and let $P_n : \mathcal{H} \to \mathcal{H}_n$ and $I_n : \mathcal{H}_n \to \mathcal{H}$ denote the canonical projection and canonical injection maps or operators respectively. The injection map reconstruct the full scale model from reduced space. The reduced model is then given by

$$P_n \frac{\partial T_n}{\partial t} = P_n \mathcal{A}(T_n) + P_n \mathcal{B}(u) + P_n \mathcal{F}(T_n, u, d) \tag{7}$$

where observation $T_n(\cdot, k) = \mathbf{T}_n(k) \in \mathcal{H}_n = P_n \mathcal{H} \quad \forall k$, $\mathcal{A}$ is the spatial operator for convection and diffusion, and is of linear nature $\mathcal{B}$ defines input matrix and $\mathcal{F}$ is nonlinear source term. In the specific case of a POD basis, the finite dimensional subspace $P_n = \text{span}\{\varphi_j\}$, $j = 1, \ldots, n$ where the φ_j's denote POD basis functions. In that case eq. (6) becomes an *ordinary differential equation* in the coefficients $a_j(k)$ in the expansion of T_n as eq. (8) and eq. (9)

$$\frac{\partial \langle P_n, \mathbf{T}_n \rangle}{\partial t} = \mathcal{A}\langle P_n, \mathbf{T}_n \rangle + \mathcal{B}\langle P_n, u \rangle + P_n \mathcal{F}(T_n, u, d) \tag{8}$$

or equivalently,

$$\frac{da_n}{dt} = \mathcal{A}_n a_n + \mathcal{B}_n u + P_n \mathcal{F}(P_n^{-1} a_n, u, d) \tag{9}$$

Eq. (9) is reduced order model (ROM) and the POD modal coefficients 'a_j' are the states of the ROM. Therefore the POD MC can also be viewed as *dominant temporal patterns/dynamics* along which system evolves. The optimization problem to obtain POD basis as mentioned above in eq. (4) equivalently can also be solved for the ensemble $\mathbf{T}_n$ as a 'Singular Value Decomposition' *SVD* which then gives POD basis function (*spatial patterns*) in the form of left singular vectors and POD modal coefficients (*temporal patterns* as singular values multiplied by the right singular vectors. From the property of SVD these patterns are arranged as per their importance, i.e. the first POD basis corresponds to the direction of maximum energy. Usually a tolerance criterion based on amount of energy captured in the reduced model is used to decide the order or the reduced model, i.e. the span of POD basis as defined above in $\mathcal{H}_n$. The criterion is usually called projection energy and is given as below:

$$P_{tol} = \frac{\sum_{k=1}^{r} \lambda_k}{\sum_{k=1}^{n} \lambda_k} \tag{10}$$

where λ_k is the 'k^{th}' eigenvalue of the correlation operator as defined in eq. (4), 'r' is order of ROM and 'n' is order of finite dimensional full scale model. The first two terms of

eq. (9) on RHS are linear and the third non-linear term do not appear for the systems defined by linear PDEs. For the system governed by linear PDEs the differential equation eq. (9) can be transformed in equivalent discrete time form as:

$$a_n(k+1) = A_d a_n(k) + B_d u(k) \tag{11}$$

At this point one can observe that given the ensemble $\mathbf{T}_n$ one can obtain POD basis and corresponding MC, and from this knowledge of MC and system inputs 'u' the system parameters 'A_d' and 'B_d' can be easily estimated by ordinary least square (OLS) estimation techniques. If one now think of the possible approach to identify the system parameters when the governing equations are non-linear like the one in eq. (9), one needs then some approximation for non-linear terms. There are many possible ways to approximate the non-linearities like black-box, neural net, fuzzy logic, grey box, e.g. see Romijn et al. [2008] and many other input-output based fit of Weiner-Hammerstein type. It is also well known that Taylor series expansion of a nonlinear function can be a good approximation of a non-linear function. The use of Taylor Series is not considered in usual input-output identification methods due to the lack of state information. But as explained earlier in the case of model reduction, the states of ROM are accessible and therefore one can make use of Taylor series to approximate the non-linear terms. If one is interested in approximating the original full scale non-linear model then one need to include the Jacobian terms of the Taylor series in ROM. But if the approximation by linear system is not sufficient enough then one must consider the Hessian and other higher terms from the Taylor series. Note that the inclusion of the Hessian terms results into polynomial form of the identified ROM. Replacing the non-linear part by a polynomial system for multi-variable system is cumbersome due to the involvement of the tensor algebra (*Hessian computation*). For this reason we will briefly explain what does a Taylor series expansion for a scalar valued function means and then we will explain it for the vector valued function, and its implementation for the computation purpose. Another interesting feature of he polynomial systems is that they are promising candidates and have structure better suited for analytical analysis and for extension of the notions from linear system theory, e.g. see Ebenbauer et al. [2005]. For a scalar valued function,

$$\dot{x} = f(x)\,, \text{ where } f : \mathcal{R} \to \mathcal{R} \;\; \& f(x^*) = 0 \tag{12}$$

Taylor series expansion in x as a nominal variable and $\tilde{x}$ as a deviation variable, $\tilde{x} = x - x^*$

$$\dot{\tilde{x}} = f(x^*) + f^{'}(x^*)\,\tilde{x} + (1/2!)\,f^{''}(x^*)\,\tilde{x}^2 + ... \tag{13}$$

where, $f^{'}(x) = \mathcal{J}(x) : \mathcal{R} \to \mathcal{R}$, system jacobian operator
$f^{''}(x) = H(x) \; : \mathcal{R} \to \mathcal{R}$, system Hessian operator.
For a vector valued function $f : \mathcal{R}^n \to \mathcal{R}^n$,

the first derivative is defined as a map: $f^{'} : \mathcal{R}^n \to \mathcal{L}(\mathcal{R}^n, \mathcal{R}^n)$, and when the first derivative is evaluated at $x^* \in \mathcal{R}^n$ then $f^{'}(x^*) \in \mathcal{L}(\mathcal{R}^n, \mathcal{R}^n)$, i.e. $f^{'}(x^*)$ is a linear operator, and when it acts on the 'n' dimensional vector 'x' then its image is $\in \mathcal{R}^n$, i.e. $f'(x^*)(x) \in \mathcal{R}^n$. This lets us to understand first derivative as a map, $f' : \mathcal{R}^n * \mathcal{R}^n \to \mathcal{R}^n$. As $f'(x^*)$ is constant term (fixed operator), we better write it as $[f'(x^*)](x) \in \mathcal{R}^n$.

We usually refer the above operator as system Jacobian matrix as, $[f'(x^*)] := \mathcal{J}(x^*)$.

The operator defined in the last expression can be written in terms of partial derivatives as,

$$[f'(x^*)]\,(x) = \begin{bmatrix} \dfrac{\partial f_1}{\partial x_1}(x^*) \ldots \dfrac{\partial f_1}{\partial x_n}(x^*) \\ . \\ \dfrac{\partial f_n}{\partial x_1}(x^*) \ldots \dfrac{\partial f_n}{\partial x_n}(x^*) \end{bmatrix} \begin{bmatrix} x_1 \\ . \\ . \\ . \\ x_n \end{bmatrix} \tag{14}$$

equivalently,

$$[f^{'}(x^*)](x) = \begin{bmatrix} \displaystyle\sum_{k=1}^{n} \frac{\partial f_1(x^*)}{\partial x_k} x_k \\ . \\ \displaystyle\sum_{k=1}^{n} \frac{\partial f_n(x^*)}{\partial x_k} x_k \end{bmatrix} \tag{15}$$

The same procedure is repeated for computing the second derivative of the function,

$f'' : \mathcal{R}^n * \mathcal{R}^n * \mathcal{R}^n \to \mathcal{R}^n$, i.e.
$f'' : \mathcal{R}^n \to \mathcal{L}(\mathcal{R}^n, \mathcal{L}(\mathcal{R}^n, \mathcal{R}^n))$, i.e.
$f''(x^*) \in \mathcal{L}(\mathcal{R}^n, \mathcal{L}(\mathcal{R}^n, \mathcal{R}^n))$, i.e.
$f''(x^*)(x) \in \mathcal{L}(\mathcal{R}^n, \mathcal{R}^n)$, i.e.
$f''(x^*)(x)(x) \in \mathcal{R}^n$, i.e. $[f''(x^*)](x, x) \in \mathcal{R}^n$
$[f''(x^*)] := H(x^*)$, system Hessian operator.

It is clear from the above discussions that the Hessian operator is a tensor with argument from two domains while its codomain remains the same that of the Jacobian operator. The linearity of Hessian operator allows us to compute it like the Jacobian operator as in (15), but now with one more argument as:

$$[f^{''}(x^*)](x, x) = \begin{bmatrix} \displaystyle\sum_{k=1}^{n}\sum_{j=1}^{n} \frac{\partial^2 f_1(x^*)}{\partial x_k \partial x_j} x_k x_j \\ . \\ \displaystyle\sum_{k=1}^{n}\sum_{j=1}^{n} \frac{\partial^2 f_n(x^*)}{\partial x_k \partial x_j} x_k x_j \end{bmatrix} \tag{16}$$

the above expression can be written as:

$$[f^{''}(x^*)](x, x) = A_1(x \otimes x) \tag{17}$$

where, $(x \otimes x)$ is the Kroneckar product.

The complete simplification procedure mentioned above is aimed to express, $f'' : \mathcal{R}^n \to \mathcal{L}(\mathcal{R}^n, \mathcal{L}(\mathcal{R}^n, \mathcal{R}^n))$ as, $f'' : \mathcal{R}^n \to \mathcal{L}(\mathcal{R}^{n^2}, \mathcal{R}^n)$. This is possible due to the notion of the linearity of the tensor operator.

From the discussion above, a nonlinear equation of the form $\dot{x} = f(x, u)$ can be expanded in Taylor series as in (13) which can be approximated by a polynomial of the form,

$$\begin{aligned} \dot{x} =& Ax(t) + Bu(t) + A_1(x(t) \otimes x(t)) \\ &+ B_1(u(t) \otimes u(t)) + Q(x(t) \otimes u(t)) \end{aligned} \tag{18}$$

Where, A_1, B_1, Q are equivalent Hessian operators and $x \in \mathcal{R}^n$, $u \in \mathcal{R}^l$, $A \in \mathcal{R}^{n*n}$, $B \in \mathcal{R}^{n*l}$, $A_1 \in \mathcal{R}^{(n*n)*n}$, $B_1 \in \mathcal{R}^{(l*l)*n}$, $Q \in \mathcal{R}^{(l*n)*n}$ and $\otimes$ is the Kronecker products.

These methodological developments are based on CFD software as plant model, so for the moment we are not considering the output equations here.

Equivalent discrete form of Eq. (18) can be written as:

$$x(k+1) = A_d x(k) + B_d u(k) + A_{1d}(x(k) \otimes x(k)) + B_{1d}(u(k) \otimes u(t)) + Q_d(x(k) \otimes u(k)) \quad (19)$$

As we are considering the discrete identification problem here, for the convenience in remaining part of the paper we have dropped the superscript 'd' from eq. (19).

Please note that the polynomial equation (19) is non-linear in states and inputs but it is linear in all the system parameters (equivalent Jacobian and Hessian terms). This is a big advantage. Because if the states and inputs are known then by fixing the above polynomial model structure we can estimate the system parameters by Least Square parameter Estimation (LSE) techniques.

Coming back to the problem of the reduced model identification, the states in the (18) can be seen as POD modal coefficients (MC) and then linear and non-linear part in (9) can be written as (18).

Another interesting feature of the proposed framework is that for a large scale parameter varying systems, given the knowledge of the variation of the time varying parameter, similar approach as proposed above can be used. But the uncertain parameter should then be treated like process inputs and therefore the corresponding process snapshots due to the parameter excitation need to be included while computing the POD basis functions and MCs. As per the knowledge of the author, this approach of model reduction for very large scale process under process parameter uncertainty is never studied in past.

Once the MC and POD basis are obtained from the full scale CFD model as mentioned earlier, then by using the tensors decomposition as in eq.(16) for eq.(18), the problem of polynomial model parameter estimation is an ordinary least square estimation(*OLS*) problem and if we define,

$$\xi_k := col\,(x(k), u(k), (x(k) \otimes x(k)), (x(k) \otimes u(k)), (u(k) \otimes u(k))) \quad (20)$$

then from (19), $x_{k+1} \simeq \Theta\,\xi_k$ Where, $\Theta = [A\,B\,A_1\,B_1\,Q]$ and define the parameter estimation error at each time instance as

$$e_{k+1} = x_{k+1} - \Theta\,\xi_k \quad (21)$$

similarly the estimation error that is minimized by LSE method over the complete simulation horizon 'N' is

$$E := [x_1 \dots x_N] - \Theta[\xi_0 \dots \xi_{N-1}] \quad (22)$$

equivalently, $E := X - \Theta\Xi$
where, N is the number of samples and , $X \in \mathcal{R}^{n*(N-1)}$, $\Xi \in \mathcal{R}^{(n+l+n*n+l*l+n*l)*(N-1)}$ and $\Theta \in \mathcal{R}^{n*(n+l+n*n+l*l+n*l)}$

The least square solution will be

$$\Theta = X\,\Xi^T\,(\Xi\,\Xi^T)^{-1} \quad (23)$$

Please make a note here that the system parameter vector Θ is rank deficient due to the involved Kronecker product. Nevertheless, there are some simple ways to estimate the parameters for rank deficient problem as well. We simply used *Matlab* routines for our case.

The complete CFD spatio-temporal information can be reconstructed by projecting back the solution of reduced model (19) on the span of dominant POD basis P_n. The reconstructed CFD state space will be:

$$\tilde{\mathcal{I}}_n(k) = I_n\,a_n(k) = P_n^{-1}\,a_n(k), \text{or equivalently} \quad (24)$$

$$\tilde{\mathcal{I}}_n(k) = \sum_{j=1}^{r} \phi_j^{-1}\,a_j(k) \quad (25)$$

As this study is based on software simulations, the outputs can be chosen as per the user choice. In our study we have decided them close to the real life situation. The constructed output equations can be approximated as:

$$\tilde{y}(k) = C\,\tilde{\mathcal{I}}_n(k) \quad (26)$$

Note that the original Navier-Stokes equation (*non-linear PDEs*) modeled in CFD software are continuous in time and in the approach presented above we have proposed to approximate them by using discrete time linear or polynomial type non-linear equations.
The error involved here will be the sum of projection error and the statistical fit in the identification step to the few selected POD modal coefficients corresponding to the maximum energy content as per eq. (10).

One of the serious drawbacks of this approach is that the OLS estimation method for as described earlier can easily lead to an unstable system, although the original system could be a stable one. Notion of stability is discussed here as divergence of simulation results. We think one of the possible explanation could be the small data set, another could be that the POD MC obtained from SVD are right singular vectors and they are orthonormal vectors. These Orthonormal basis functions (MC) are considered as signals while they are being fitted by using a polynomial model. The orthogonality of vectors is equivalent to the property of uncorrelatedness of signals. Or, orthogonality of MC in terms of the inner product is

$$< a_i,\, a_j > \begin{cases} = 1, & i = j \\ = 0, & i \neq j \end{cases} \quad (27)$$

To overcome this drawback of spurious instability one might like to try some other parameter estimation method or to impose the stability in the proposed polynomial model by using some regularization trick. But usually regularization leads to bad performance of the identified model. Moreover regularization if not carried out smartly can lead to completely different dynamics of the identified model. Typically in subspace state space linear model identification techniques, regularization is imposed in the form of forcing the eigenvalues of the identified model to lie in the unit circle, e.g. see Gestel et al. [2000].
In this paper we have not solved the stability issue as the research in polynomial systems is still relatively new and imposing the stability in identification procedure will need considerable amount of further efforts.

3. MOTIVATION: GLASS MANUFACTURING

This section describes the motivating example of Industrial Glass Manufacturing Process, *IGMP*. IGMP is usually carried out in large furnaces which are very well designed in order to have a desired laminar flow pattern of the glass. A 2D view of a typical furnace is shown in figure 1. The flow pattern of glass determines the residence time of the glass in the melting furnace which in turn determines the quality of the glass produced. The process is an example of very large scale integrated systems. Most of the process variables like temperature, velocity, pressure, viscosity are

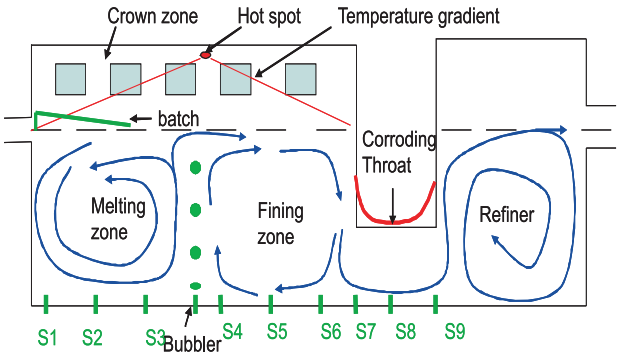

Fig. 1. Glass Manufacturing Furnace

interacting with each other. Due to this interacting nature the control of the furnace has to be done carefully. Usually pull rate (production rate), heat input and pressure valve positions are some of the control variables. Whereas variables of interest are temperature distribution and velocity profiles in the furnace. The product quality is determined by these two factors. The temperature maintained inside the furnace varies between $1400 - 1650\ ^0$C. The glass raw material enters from the left side (inlet) in the form of a batch blanket, it is melted by applying heat from the top. After circulating through the glass furnace for many hours glass passes through the throat and then leaves via the outlet. Based on the process operation there are roughly three regimes - glass melting, fining to remove high concentration of dissolved gases from the molten glass and refining to remove all remaining undissolved gases from the glass. The IGMP shows large variation in the time constants, from minutes to days. The transport of physical quantities in IGMP can be approximated with reasonable accuracy by modeling it by a set of nonlinear Navier-Stokes equations, see Huisman [2005]. There are many different types of glass furnaces and many different ways to manufacture glass depending on the type of glass required. Most of the glass manufacturing process dynamics are series combination of Continuous Stirrer Tank Reactor (CSTR) and Plug Flow Reactor (PFR). Some more details about mathematical modeling of glass can be found in Huisman [2005], Patankar [1980], Post [1988].

Due to very high process temperature and due to the viscous nature of glass, the glass furnace is a hostile environment for sensor systems. Sensors are largely limited to temperature measurements in the bottom refractory of the melting furnace. As 3 dimensional glass furnace model easily consist of $10^4 - 10^6$ finite elements, simulating its steady and/or dynamic behavior takes days for a normal configured PC and therefore it becomes very difficult to generate and process sufficient data that can be used to develop a model reduction method. For this reason we are using an approximate $2D$ glass furnace which mimics the vertical cross section along the length of $3D$ glass furnace and has only 2 grids cells in width direction.

Currently, apart from modeling the process non-linearity in the reduced order model, we are also trying to model the very slow geometric changes that take place in real $3D$ furnace in the form of throat or dam wall corrosion, see figure 1. This corrosion results into back-flow of molten glass from the refining zone to the fining zone. Such back-flow behavior causes undesired changes in the temperature distribution in the furnace which ultimately leads to economic losses. In this paper we are not addressing the corrosion problem but interested readers can refer Wattamwar et al. [2008] and a Linear Parameter Varying (LPV) system approximation in Wattamwar et al. [2009].

4. RESULTS AND DISCUSSION

In this paper a $2D$ benchmark CFD model of the original process is considered. The full scale CFD model has 3000 cells. It has many variables like temperature, velocity, concentration, pressure, etc. in each grid cell. Although most of the variables are interconnected, for the study here we have considered only temperature as variable of the interest. Therefore the order of the full scale model is 3000. From the method explained in the section 2 we have obtained a fourth order linear and non-linear polynomial model. The choice of fourth order approximation is decided based on the stability issue of polynomial model. Approximation order larger than four leads to an unstable ROM. For the linear model as well, there is not much improvement in the parameter fit above fourth order. This means that for the linear reduced model larger than fourth order there is no way to improve its performance merely by increasing its order, and there is need for non-linear reduced order model. The four POD modal coefficients corresponding to the order approximately capture 80% of the total projection energy. Usually it is desired to capture approximately 99% of the energy of the full model. But due to the stability limitation we can not satisfy this requirement.

The input considered for the identification purpose is pull-rate(feed) in terms of tons/day, which varies 5% around the nominal value in the form of +/- steps superimposed by PRBS signal. This is done to excite the slow and fast dynamics. The simulation horizon is 120 hrs and sampling time is 16 mins, therefore we have 450 snapshots. Like most of the POD related methods, this identification process is very sensitive to the type of input excitation signal. For such complex process it is also very important to know what non-linearity the identification input signal excites. If one excites soft non-linearities for such a complex process then one can expect to get a better and stable polynomial model which would fit more POD MC.

Figure 2 shows the identification result for both linear and polynomial models as proposed in this paper. Figure 3 shows zoomed version of the faster dynamics from the figure 2. Plot shows the result for four outputs which are temperature at the bottom of the four main zones of the glass, viz. Melting, Fining, Throat and Refining section. The sensors are assumed to be placed at the bottom of the tank. This is close to the real life situation. The readers can refer to the figure 1 for sensor locations. $S1$ to $S9$ are the sensors in the figure. Plot shows that the both the models approximates the overall trend very well, but the linear model fails to capture the PRBS signal dynamics precisely compared to the polynomial model.

Figure 4 shows the performance of the two models for the validation signal, which is a step input on the raw-material feed rate. Plot shows that both models follows the trend very well, but both models do not match the time constant and the final gain exactly. This is due to the two reasons. First, this is a distributed system and the

excitation signal used for the identification was designed based on the average time constant of the whole glass tank and it was not designed based on only the four location shown in the figure. Reason for the mismatch of the final gain is that these ROM could not capture 99% of the projection energy of the full scale model. One can expect smaller offset if the approximation order of the reduced model is higher. Unfortunately, as explained earlier in 2, approximation order can not be increased more than 4^{th} for the polynomial form of ROM. Nevertheless, for the size and involved complexity in GMP, even the current results seems to be very interesting.

5. CONCLUSION AND FUTURE RESEARCH

In this paper we have proposed a new model reduction method and its application on large scale industrial application. The proposed method is promising and suited especially for the very large scale processes where complexity reduction by using merely physical insight is not possible. The proposed method is also well formulated in technical aspects and with further improvements in imposing the stability in the identification of polynomial system could make this method of great potential.

We want to explore following topics in near future which has never/rarely been explored in literature like:
1. To investigate the possibility of imposing the stability in the identification process for the polynomial systems.
2. It is also possible to identify multiple linear/polynomial ROM at different working points by the method explained in this paper and construct a non-linear LPV ROM like the one described in Wattamwar et al. [2009].
3. Observer and controller design for polynomial ROM.

Identification of Nonlinear State-Space Models: The Case of Unknown Model Structure

R.Bhushan Gopaluni *

* *Department of Chemical and Biological Engineering, University of British Columbia, Vancouver, BC, Canada V6T 1Z4, Email: gopaluni@chml.ubc.ca.*

Abstract: This article presents an algorithm for identification of nonlinear state-space models when the "true" model structure of a process is unknown. In order to estimate the parameters in a state-space model, one needs to know the model structure and have an estimate of states. An approximation of the model structure is obtained using radial basis functions centered around a *maximum a posteriori* estimate of the state trajectory. A particle filter approximation of smoothed states is then used in conjunction with expectation maximization algorithm for estimating the parameters. The proposed approach is illustrated through an example.

Keywords: Nonlinear Systems, Maximum Likelihood Parameter Estimation, Expectation Maximization, Particle Filters.

1. INTRODUCTION

Nonlinear models are commonly used to describe the behavior of many chemical processes. Process variables, typically, can be divided into latent variables (that are not measured) and measured variables. A combination of latent and measured variables can be elegantly used to represent the dynamic behavior of a nonlinear process in the following form,

$$\begin{aligned} x_{t+1} &= f(x_t, u_t, \theta) + w_t \\ y_t &= g(x_t, u_t, \theta) + v_t \end{aligned} \tag{1}$$

where $x_t \in \mathbf{R}^n$ is the n-dimensional state vector, $u_t \in \mathbf{R}^s$ is the s-dimensional input vector, $y_t \in \mathbf{R}^m$ is the m-dimensional output or measurement vector, and w_t, v_t are independent and identically distributed Gaussian noise sequences of appropriate dimension and variances Q and R respectively, $\theta \in \mathbf{R}^p$ is a p-dimensional parameter vector and $f(.)$, $g(.)$ are some nonlinear functions that describe the dynamics of the process. The nonlinear functions $f(.)$ and $g(.)$ are typically obtained using physical laws such as energy and mass balance expressions for the process. However, often, due to the complexity of chemical processes, it is difficult to develop accurate and reliable nonlinear functions. This article provides an algorithm for approximation and estimation of $f(.)$ and $g(.)$ using a combination of radial basis functions and Expectation Maximization (EM) algorithm Shumway and Stoffer (2000).

The complexity of the parameter estimation problem considered in this article arises due to unknown nonlinearities, and presence of unmeasured latent variables. If the latent variables are measured, then the model parameters can be estimated using a straightforward nonlinear least squares method Ljung (1999). If the process dynamic functions are linear, then any sub-space approach can be used Van Overschee and Moor (1996). On the other hand, if the process dynamic functions are nonlinear and latent variables are not measured, then approximate maximum likelihood approaches such as the one based on local linearization in Goodwin and Agüero (2005) and the one based on particle filter approximation in Gopaluni (2008) can be used.

The algorithm presented in this article extends the one in author's previous work on parameter estimation for known model structure Gopaluni (2008). The central idea is to find the parameter vector, θ, that maximizes the likelihood function of the observations, y_t. Due to the presence of latent variables, x_t, it is difficult to develop this likelihood function. On the other hand, due to Markov property of latent variables, it is rather straightforward to develop a joint likelihood function of the the latent and measured variables. Hence, expectation maximization, a maximum likelihood approach, that iteratively maximizes the likelihood of the observations by maximizing the joint likelihood function in each iteration, is used. EM algorithm is implemented by iteratively finding the expected value of the joint likelihood function in the first step and maximizing it in the second step Dempster et al. (1977).

This approach using EM algorithm for parameter estimation poses two problems. A structure of the process model (or in other words, the functions $f(.)$ and $g(.)$), and the distribution of noise sequence is needed to develop the joint likelihood function required in EM algorithm. Moreover, since the process is nonlinear, the distribution of latent variables, x_t, and measurements is not Gaussian even if Gaussian noise is assumed. As a result, the expected value of the joint likelihood function required in EM algorithm can not be analytically calculated. In this article, an approach that uses radial basis functions to approximate the process dynamics and particle filters to approximate the expected value of the joint likelihood function is presented.

The rest of this paper is divided into following sections: The problem is mathematically defined in section 2, a summary of expectation maximization algorithm is presented in section 3, the proposed algorithm is presented in section 4, and an example is presented in section 5.

2. PROBLEM DEFINITION AND NOTATION

As explained in the previous section, it is assumed that the process dynamics are unknown and therefore an approximation of the dynamics is needed to apply EM algorithm. It is well-known that any function can be approximated to an arbitrary degree of accuracy using basis functions such as radial basis functions. Hence, the model in (1) is approximated using radial basis functions as follows:

$$x_{t+1} = \sum_{i=1}^{I_x} h_i \rho_i(x_t, u_t, c_i, \Sigma_x) + Ax_t + Bu_t + w_t$$

$$y_t = \sum_{i=1}^{I_y} g_i \gamma_i(x_t, u_t, d_i, \Sigma_y) + Cx_t + Du_t + v_t$$

where $\rho_i(.,.)$ and $\gamma_i(.,.)$ are the radial basis functions centered around c_i and d_i with variance Σ_x and Σ_y respectively, A, B, C, D are appropriate matrices that are used to capture any linear dynamics in the model. w_t, and v_t are identically and independently distributed Gaussian noise sequences with zero mean and covariances Q and R respectively. h_i and g_i are constant vectors of appropriate dimensions. I_x and I_y are the number of basis functions used in the state and observation equations. Theoretically, even linear dynamics in the process can be approximated if sufficiently large number of radial basis functions are used. In order to reduce the total number of parameters, and capture linear dynamics, linear terms involving the matrices A, B, C, and D are added. In this article, radial Guassian basis functions of the following form are used:

$$\rho_i(x_t, u_t, c_i, \Sigma_x) = e^{\left[-(\bar{x}_t - c_i)^T \Sigma_x^{-1} (\bar{x}_t - c_i)\right]}$$

$$\gamma_i(x_t, u_t, d_i, \Sigma_y) = e^{\left[-(\bar{x}_t - d_i)^T \Sigma_y^{-1} (\bar{x}_t - d_i)\right]}$$

where $\bar{x}_t$ is the concatenated vector of states and inputs. The input-output data from the nonlinear model in (1) are denoted by $\{y_{1:T}, u_{1:T}\}$, where $y_{1:T}$ are the observations from time, $t = 1$, to $t = T$, and $u_{1:T}$ are corresponding inputs during that time period. The parameter vector θ includes all the constant parameters in the above model that describe the process behavior, and is defined as $\theta = (\theta_l, \theta_{nl})$, where θ_l consists of all "linear" parameters, h_i, g_i, Q and R, and θ_{nl} consists of all "nonlinear" parameters, c_i, d_i, Σ_x, Σ_y.

The expectation maximization algorithm plays a central role in the method developed in this article, and hence a summary of EM algorithm is presented below. It is an elegant optimization algorithm that constructs a complete likelihood function including the latent states and observations, and maximizes the likelihood function of observed data through iterations. A brief description of the EM algorithm is presented in this section to facilitate the development of the proposed algorithm in later sections.

For the state-space model described in this article, let $p(y_{1:T}|\theta)$ denote the likelihood function of the observed data. The maximum likelihood estimate of the parameter vector is obtained by maximizing this observed data likelihood function. For certain classes of state-space models, such as linear systems, it is possible to derive an explicit expression for this joint density. However, for the model considered in this paper, it is difficult to develop such an expression due to the presence of latent states. Instead, using the Markov property of the states it is straightforward to develop an expression for the complete (including states and observations) likelihood function, $p(x_{1:T}, y_{1:T}|\theta)$. In light of this feature of the Markovian states, the joint probability density function of the states and observations is iteratively maximized to obtain a maximizing θ for $p(y_{1:T}|\theta)$.

This maximization approach is called EM algorithm and can be summarized in four steps:

(1) Choose an initial guess of the parameter vector, say θ_0.
(2) Estimate the states given the parameter vector and the observations and evaluate

$$Q(\theta_i, \theta) = \int \log[p(x_{1:T}, y_{1:T}|y_{1:T}, \theta)] p(x_{1:T}|y_{1:T}, \theta_i) dx_{1:T} \quad (2)$$

where $p(x_{1:T}|y_{1:T})$ is the joint conditional density function of the states given the observations, and θ_i is an estimate of the parameter vector from a previous iteration.
(3) Maximize $Q(\theta_i, \theta)$ with respect to θ. Call the maximizing value θ_{i+1}.
(4) Repeat the above two steps until the change in parameter vector is within a specified tolerance level.

The second step in the above algorithm is called E-step and the third step is called M-step. The likelihood function, $p(y_{1:T}|\theta)$, increases monotonically through these iterations. Due to the nonlinear nature of the dynamics it is not possible to analytically evaluate the Q-function in (2). In the next section, an approximation of the Q-function and an approach to maximize it are presented.

3. MAIN ALGORITHM

3.1 Approximation of Q function

A number of approximations of EM algorithm, involving different approximations of Q function have been proposed in the literature. They either involve approximating the nonlinearities Goodwin and Agüero (2005) or approximating expected value of the joint likelihood function using particle filters and other simulation based approaches Schön et al. (2006); Gopaluni (2008). Methods involving approximation of nonlinearities will fail if the nonlinearities are prominent and on the other hand, methods involving approximation of expected value are usually computationally intensive. In this article, the Q function is approximated using a combination of particle filters and smoothers. The complete details of this approximation and its extension to handle missing data are presented in the author's work in Gopaluni (2008). For continuity a summary of this approach is presented in this section.

The Q function, using Markov property of states, can be expanded to

$$\begin{aligned}
&Q(\theta_i, \theta) \\
&= \int \log[p(x_1|y_{1:T}, \theta)] p(x_1|y_{1:T}, \theta_i) dx_1 \\
&\quad + \sum_{t=2}^{T} \int \log[p(x_t|x_{t-1}, \theta)] p(x_{t-1:t}|y_{1:T}, \theta_i) dx_{t-1:t} \\
&\quad + \sum_{t=1}^{T} \int \log[p(y_t|x_t, \theta)] p(x_t|y_{1:T}, \theta_i) dx_t. \qquad (3)
\end{aligned}$$

From the above expression, it is easy to notice that in order to obtain an approximation of the Q function, the following density functions are needed:

(1) $p(x_1|y_{1:T}, \theta_i)$,
(2) $p(x_{t-1:t}|y_{1:T}, \theta_i)$, and
(3) $p(x_t|y_{1:T}, \theta_i)$.

It is possible to obtain the following particle approximations of the above density functions (please see Gopaluni (2008) for details)

$$\begin{aligned}
p(x_1|y_{1:T}, \theta_i) &= \sum_{i=1}^{N} w_{1|1}^{(i)} \delta(x_1 - x_1^{(i)}) \\
p(x_t|y_{1:T}, \theta_i) &= \sum_{i=1}^{N} w_{t|T}^{(i)} \delta(x_t - x_t^{(i)}) \\
p(x_{t-1}, x_t|y_{1:T}, \theta_i) &= \sum_{i=1}^{N} w_{t-1,t}^{(i)} \delta(x_{t-1} - x_{t-1}^{(i)}) \delta(x_t - x_t^{(i)})
\end{aligned}$$

where $w_{1|1}^{(i)}$, $w_{t|T}^{(i)}$ and $w_{t-1,t}^{(i)}$ are appropriate weights calculated using Bayes rule and importance sampling Klaas et al. (2006), $\delta(.)$ is the Kronecker delta function, and $x_t^{(i)}$ are N samples of states obtained through simulations. Using the above approximations of the density functions in the Q function, one can write the following expression,

$$\begin{aligned}
Q(\theta_i, \theta) \approx &\sum_{i=1}^{N} w_{1|1}^{(i)} \log[p(x_1^{(i)}|y_{1:T}, \theta)] + \sum_{t=2}^{T} \sum_{i=1}^{N} w_{t-1,t}^{(i)} \\
&\log[p(x_t^{(i)}|x_{t-1}^{(i)}, y_{1:T}, \theta)] + \sum_{t=1}^{T} \sum_{i=1}^{N} w_{t|T}^{(i)} \log[p(y_t|x_t^{(i)}, \theta)]
\end{aligned} \qquad (4)$$

In the above approximation, since the noise sequences are assumed to be Gaussian, the density functions, $p(x_t^{(i)}|x_{t-1}^{(i)}, y_{1:T}, \theta)$, and $p(y_t|x_t^{(i)}, \theta)$ can be written in terms of Gaussian density functions and hence,

$$\begin{aligned}
&\log[p(x_t^{(i)}|x_{t-1}^{(i)}, y_{1:T}, \theta)] = \\
&-\frac{1}{2}\log(2\pi) - \frac{1}{2}\log(\det(Q)) - \frac{1}{2}(x_t^{(i)} - \hat{x}_{t-1}^{(i)})^T Q^{-1} \\
&(x_t^{(i)} - \hat{x}_{t-1}^{(i)})
\end{aligned}$$

$$\begin{aligned}
&\log[p(y_t|x_t^{(i)}, \theta)] = \\
&-\frac{1}{2}\log(2\pi) - \frac{1}{2}\log(\det(R)) - \frac{1}{2}(y_t^{(i)} - \hat{\hat{x}}_{t-1}^{(i)})^T R^{-1} \\
&(y_t^{(i)} - \hat{\hat{x}}_{t-1}^{(i)})
\end{aligned}$$

where $\hat{x}_t^{(i)} = \sum_{i=1}^{I_x} h_i \rho_i(x_t^{(i)}, u_t, c_i, \Sigma_x) + Ax_t^{(i)} + Bu_t$, and $\hat{\hat{x}}_t^{(i)} = \sum_{i=1}^{I_y} g_i \gamma_i(x_t^{(i)}, u_t, d_i, \Sigma_y) + Cx_t^{(i)} + Du_t$.

3.2 Maximization of Q function

The maximization of Q function is performed in two steps using separable least squares. It is easy to notice that the parameters in θ_l enter the model linearly, while those in θ_{nl} enter the model nonlinearly. Hence, a two step procedure (called separable least squares) where the linear parameters are estimated in the first step using linear least squares, and the nonlinear parameters are estimated in the second step through nonlinear least squares. The procedure is explained below.

Step 1 Starting with an initial guess for the nonlinear parameter vector, θ_{nl}, the Q function is maximized with respect to θ_l. This maximization can be achieved through linear least squares. Before providing the maximizing value of the linear parameter vector, define the following matrices,

$$\begin{aligned}
\Omega_x &= [h_1 \; h_2 \; \cdots h_{I_x} \; A \; B] \\
s_t &= [I_1 \rho_1(x_t, u_t, c_1, \Sigma_x) \; I_1 \rho_2(x_t, u_t, c_2, \Sigma_x) \cdots \\
&\qquad I_1 \rho_{I_x}(x_t, u_t, c_{I_x}, \Sigma_x) \; x_t \; u_t]
\end{aligned}$$

where I_1 is a vector of ones of appropriate dimensions. Noting that the Q function is quadratic in Ω_x, through straightforward calculations, it can be shown that

$$\Omega_x = \left[\sum_{t=1}^{T} < x_t s_t^T >_{xx}\right] \left[\sum_{t=1}^{T} < s_t s_t^T >_{xx}\right]^{-1} \qquad (5)$$

where $< . >_{xx}$ is used to denote integration with respect to the density function $p(x_{t-1:t}|y_{1:T}, \theta)$. This integration can be approximated using the particle approximation of $p(x_{t-1:t}|y_{1:T}, \theta)$. The state co-variance can be shown to be

$$Q = \frac{1}{T} \sum_{t=1}^{T} \left\langle (x_{t+1} - \Omega_x s_t) x_{t+1}^T \right\rangle_{xx}.$$

Similarly, defining the matrices,

$$\begin{aligned}
\Omega_y &= [g_1 \; g_2 \; \cdots g_{I_y} \; C \; D] \\
r_t &= [I_1 \gamma_1(x_t, u_t, d_1, \Sigma_y) \; I_1 \gamma_2(x_t, u_t, d_2, \Sigma_y) \cdots \\
&\qquad I_1 \gamma_{I_y}(x_t, u_t, d_{I_x}, \Sigma_y) \; x_t \; u_t]
\end{aligned}$$

and noticing that the Q function is quadratic in Ω_y, it can be shown that,

$$\Omega_y = \left[\sum_{t=1}^{T} < y_t r_t^T >_x\right] \left[\sum_{t=1}^{T} < r_t r_t^T >_{yx}\right]^{-1} \qquad (6)$$

where $< . >_x$ denotes integration with respect to the density function $p(x_t|y_{1:T}, \theta)$ and $< . >_{yx}$ denotes integration with respect to the density function $p(y_t|x_t, \theta)$. The measurement noise co-variance can be shown to be,

$$R = \frac{1}{T}\sum_{t=1}^{T} \left\langle (y_t - \Omega_y r_t) y_t^T \right\rangle_x .$$

The parameters in the matrices Ω_x, Ω_y, Q, and R constitute the linear parameter vector, θ_l.

Step 2 : In step one, it is assumed that the centers and widths of the radial basis functions are known. However, in practice, it is difficult estimate them. In this step an approach to estimate centers and radii is presented. The idea is to obtain a *maximum a posteriori* (MAP) estimate of the state trajectory and fix centers and radii that provide the best possible predictions of MAP state estimate and the observations. The MAP estimate of the state is obtained using a modified Viterbi algorithm as described in Godsill et al. (2001). For the sake of completeness, Viterbi algorithm is described below [1] .

Viterbi Algorithm

1. *Initialization*: For $1 \leq i \leq N$, $\delta_1(i) = \log(p(x_1^{(i)}) + \log(p(y_1|x_1^{(i)}))$.
2. *Recursion*: For $2 \leq t \leq T$, and $1 \leq j \leq N$,
$$\delta_t(j) = \log(p(y_t|x_t^{(j)})) + \max_i \left[\delta_{t-1}(i) + \log(p(x_t^{(j)}|x_{t-1}^{(i)}))\right]$$
$$\psi_t(j) = \arg\max_i \left[\delta_{t-1}(i) + \log(p(x_t^{(j)}|x_{t-1}^{(i)}))\right]$$
3. *Termination*: $i_T = \arg\max_i \delta_T(i)$ and $x_{MAP}(T) = x_T^{(i_T)}$.
4. *Backtracking*: For $t = T-1, T-2, \cdots, 1$, $i_t = \psi_{t+1}(i_{t+1})$, and $x_{MAP}(t) = x_t(i_t)$.

An estimate of θ_{nl} is now obtained from the data $\{x_{MAP}(1:T), y_{1:T}, u_{1:T}\}$ by fixing θ_l to its estimated value from step 1 and using nonlinear least-squares. Step 1 and Step 2 are iterated until changes in θ_l and θ_{nl} between iterations are less than a specified tolerance level.

3.3 Proposed Algorithm

The complete proposed identification algorithm is summarized below:

0. **Initialization**: Initialize the parameter vector to θ_0.
1. **Expectation**: Approximate the expected value of the complete log-likelihood function (E-step) using particle filters.
2 **Maximum a Posteriori Estimate**: Obtain a maximum *a posteriori* estimate of the state trajectory using Viterbi algorithm. Using this MAP estimate of the state trajectory, fix the centers and variances of the radial basis functions. In other words, estimate $(\theta_{nl})_{i+1}$, where i denotes the number of EM algorithm iterations performed so far.
3. **Maximization**: Maximize the Q function with respect to θ_l and call the maximizing parameter, $(\theta_l)_{i+1}$. Then set $\theta_{i+1} = [(\theta_l)_{i+1} \;\; (\theta_{nl})_{i+1}]$.
4. **Iterate**: Repeat steps 1, 2, and 3 until the change in parameter vector is within a specified tolerance level.

[1] for notational clarity, the parameter dependence is not shown in the density functions below

4. ILLUSTRATIVE EXAMPLES

The proposed approach is tried on data collected from a real continuous stirred tank reactor. The governing

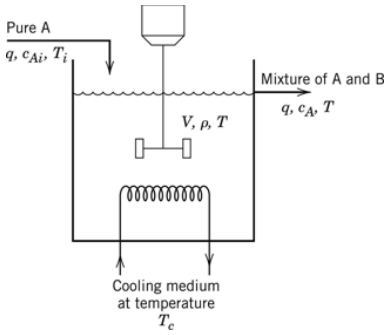

Fig. 1. Continuous Stirred Tank Reactor - Picture taken from Seborg et al. (2004).

equations of this popular CSTR, shown in figure 1, are given below (Morningred et al. (1992); Chen (2004))

$$\frac{dC_A}{dt} = \frac{q}{V}(C_{Ai} - C_A) - k_0 C_A e^{-E_A/T}$$
$$\frac{dT}{dt} = \frac{q}{V}(T_i - T) - \frac{\Delta H}{\rho C_p} k_0 C_A e^{-E_A/T} - \frac{\rho_c C_{pc}}{\rho C_p V} q_c (1 - e^{-\frac{hA}{q_c \rho_c C_{pc}}})(T - T_c)$$

where C_A is the concentration of the reactant in the reactor, T is the temperature in the reactor, q is the flow rate, V is the volume of the reactor, C_{Ai} and T_i are inflow concentration and temperature, $k_0 C_A e^{-E_A/T}$ is the reaction rate, ΔH is the reaction heat, ρ and ρ_c are the densities of the reactant and the cooling fluid respectively, C_p and C_{pc} are the corresponding specific heats, h and A are the effective heat transfer coefficient and area respectively, T_c and q_c are the temperature and flow rate of the cooling fluid. Finite difference discretization of the above continuous time differential equations results in the following model,

$$f(x_t, u_t, \theta) = x_{t-1} + \Delta t \begin{bmatrix} \frac{q}{V}(C_{Ai} - x_{t-1}(1)) - \theta_1 x_{t-1}(1) e^{-E_A/x_{t-1}(2)} \\ \frac{q}{V}(T_i - x_{t-1}(2)) - \theta_2 x_{t-1}(1) e^{-E_A/x_{t-1}(2)} \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{\rho_c C_{pc}}{\rho C_p V} u_{t-1} \left[1 - e^{-\theta_3 A/(u_{t-1}\rho_c C_{pc})}\right](T_c - x_{t-1}(2)) \end{bmatrix}$$

where the state vector is $x_t = [x_t(1) \;\; x_t(2)] = [C_A(t) \;\; T(t)]$, $\theta_1 = k_0$, $\theta_2 = (k_0 \Delta H)/(\rho C_p)$, $\theta_3 = hA$, $u_t = q_c$, $g(x_t, u_t, \theta) = x_t$ and Δt is the discretization sample time. C_{Ai} and q_c are input variables. Real data [2] collected from this reactor is shown in figures 2 and 3. Our goal is to fit a state-space model to this data assuming that the energy and mass balance expressions provided above are unknown.

[2] Please note that this data is available at http://homes.esat.kuleuven.be/ smc/daisy/

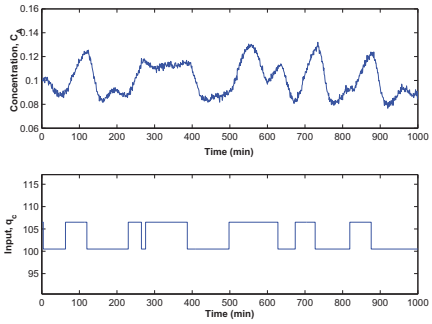

Fig. 2. The concentration, C_A, measurements.

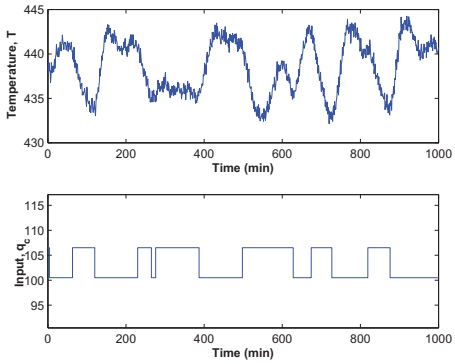

Fig. 3. The temperature, T, measurements.

The proposed algorithm is applied on this data, with a single radial basis function to describe the nonlinearities in the state and observation equations *i.e.,* with $I_x = 1$, $I_y = 1$. The accuracy of the model can definitely be increased by increasing the number of radial basis functions used. The predictions of concentration from this model for different prediction horizons are shown in figure 4. The %-fit, at these prediction horizons, calculated with the estimated model is comparable to that of input-output Hammerstein-Weiner (HW) models built using Matlab system identification toolbox. However, it should be noted that while there is no realistic and fair way to compare the complexities of HW and state space models, an attempt is made to compare the "best" trial and error based HW model with the state-space model estimated using the proposed approach.

The main advantage of the proposed method, over other nonlinear input-output identification methods, is in its ability to handle missing data - both in states and observations. In this article, missing observations are not considered. However, as shown in Gopaluni (2008), it is possible to derive particle approximations of density functions, required to approximate the Q function, even if there are some missing observations. Hence, extension of this approach to handle missing observations is rather straightforward.

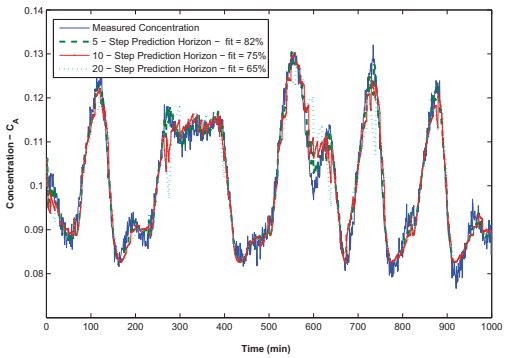

Fig. 4. True and predicted concentration profiles.

5. CONCLUSIONS

An approach to identify stochastic nonlinear systems using a combination of expectation maximization algorithm and particle filters is presented. In the proposed approach it is assumed that the model structure is unknown, and is approximated using radial basis functions. The expectation step in the algorithm is approximated using particle approximations of certain density functions. The maximization step is performed by separable least squares, where linear parameters are estimated using linear least squares, and the nonlinear parameters are estimated by using nonlinear least squares on a sequence of maximum *a posteriori* states and observations. The developed algorithm is applied to a real continuous stirred tank reactor. The proposed approach is easily extendable to handle missing observations.

Subspace closed loop identification using the integration of MOESP and N4SID methods

Santos Miranda, Claudio Garcia

Polytechnic School of the University of São Paulo.
e-mail: santos.borjas@poli.usp.br, clgarcia@lac.usp.br

Abstract: Linear identification of time invariant systems operating in closed loop is of special interest for a large number of engineering applications. There are different techniques and methods to carry out this type of identification. For example, modifying the N4SID method, one can derive a closed loop subspace identification method. The same can be done using the MOESP method. Based on them, the MON4SID method is introduced, which estimates the extended observability matrix and the state sequence directly from a LQ decomposition, using a combination of the techniques contained in both, MOESP and N4SID. This new method uses an algorithm to identify state space model of a plant in a closed loop system, in the same way as in MOESP method. The advantage of the proposed algorithm is that it does not require any knowledge about the controller, whereas such information is essential for other methods (e.g. N4SID). The disadvantage of this algorithm is that it needs a great amount of data to obtain better estimates. A simulated process to show the performance of this algorithm is presented.

Keywords: Subspace identification; closed loop identification; state space models.

1. INTRODUCTION

Great part of the literature referring to system identification deals with how to find polynomial models as Prediction Error Method (PEM). In case of complex systems, there is a parameterization problem in the PEM model, so the state space model appears as an alternative to PEM, such as Multivariable Output-Error State sPace (MOESP) (Verhaegen, 1994), Canonical Variate Analysis (CVA) (Larimore, 1990) and Numerical algorithms for Subspace State Space System Identification (N4SID) (Van Overschee; De Moor, 1996). Statistical properties such as consistency and efficiency of these algorithms were studied by (Bauer, 2003; Bauer; Ljung, 2002; Chiuso; Picci, 2005). One of the main assumptions of theses methods is that the process and the measurement noises are independent of the plant input. This assumption is violated when the system is working in closed loop. The closed loop identification is of special interest for a large number of engineering applications (Ljung, 1999), since closed loop experiments are necessary if the open loop plant is unstable, or the feedback is an inherent mechanism of the system (Forssell; Ljung, 1999; Van den Hof, 1997). Several closed loop identification methods have been suggested in the last years and can be broadly classified into three main groups: direct, indirect and joint input output identification methods (Forssell; Ljung, 1999). The results of any of the N4SID, MOESP and CVA methods cited above are asymptotically biased when closed loop identification is applied. To solve this problem, the MOESP method (Verhaegen, 1993) proposed a closed loop subspace identification method through the identification of an overall open loop state space. Based on it, the plant and the controller models are estimated. To do so, it is necessary to know the order of the controller. In the N4SID case (Van Overschee; De Moor, 1997) it is necessary to know a limited number of impulse response samples of the controller and, via direct identification, the plant model is estimated. There are other possible solutions to the closed loop identification problem; the reader can consult (Huang *et al*., 2005; Katayama, 2005; Katayama *et al.*, 2002; Katayama *et al.*, 2005; Ljung; McKelvey, 1996; Qin *et al.*, 2005).

Combining the MOESP and N4SID methods, we obtain the MON4SID algorithm, which estimates the extended observability matrix in the same way it occurs in the MOESP method, the state sequence is computed through the oblique projection, as it is done in the N4SID method. From this sequence, the past and future states are obtained, and finally a consistent estimate of the system matrices is obtained, applying the least squares method. In this paper, it is proposed an algorithm to identify the state space model of a plant in a closed loop system, in the same way as it was proposed in the MOESP method, that first computes a global model from which is extracted the plant model. **T**his method does not need any knowledge about the controller.

1.1 Open Loop Subspace identification

Consider a time discrete linear time invariant dynamic system described by the state space models in the innovation form:

$$\begin{aligned} x_{k+1} &= Ax_k + Bu_k + Ke_k \\ y_k &= Cx_k + Du_k + e_k \end{aligned} \tag{1}$$

where $u_k \in R^m$ and $y_k \in R^l$ denote the input and output signals, respectively and $x_k \in R^n$ is the vector of states. $e_k \in R^l$ is zero-mean Gaussian white noise and independent of past input and output data. *A*, *B*, *C*, *D* and *K* are matrices with appropriate dimensions.

1.2 Open Loop Subspace identification problem

The subspace identification problem is: given $u = [u_1,..,u_{nd}]$ and $y = [y_1,..,y_{nd}]$ a set of input-output measurements, determine the order *n* of the unknown system, the system matrices (*A*, *B*, *C*, *D*) up to within a similarity transformation and Kalman filter gain *K* (Van Overschee; De Moor, 1996).

1.3 Subspace matrix equation

Making successive iterations in equation (1), one can derive the following matrix equation:

$$Y_f = \Gamma_i X_f + H_i^d U_f + H_i^s E_f \tag{2}$$

where subscript f stands for the "future" and p for the "past". For the definition of the matrices H_i^d and H_i^s given in (2), see (Van Overschee; De Moor, 1996). The past and future input block-Hankel matrices are defined as:

$$\left(\frac{U_p}{U_f}\right) = \left(\begin{array}{cccc} u_0 & u_1 & \cdots & u_{j-1} \\ u_1 & u_2 & \cdots & u_j \\ \cdots & \cdots & \cdots & \cdots \\ u_{i-1} & u_i & \cdots & u_{i+j-2} \\ \hline u_i & u_{i+1} & \cdots & u_{i+j-1} \\ u_{i+1} & u_{i+2} & \cdots & u_{i+j} \\ \cdots & \cdots & \cdots & \cdots \\ u_{2i-1} & u_{2i} & \cdots & u_{2i+j-2} \end{array}\right) \tag{3}$$

where $U_p, U_f \in R^{mixN}$. The output and noise innovation block-Hankel matrices $Y_p, Y_f \in R^{lixN}$ and $E_p, E_f \in R^{mixN}$, respectively, are defined in a similar way to (3).

The states are defined as:

$$X_p = X_0 = \lfloor x_0,..,x_{j-1} \rfloor \tag{4}$$

$$X_f = X_i = \lfloor x_i,..,x_{i+j-1} \rfloor \tag{5}$$

The extended observability matrix Γ_i is given by:

$$\Gamma_i = \begin{pmatrix} C \\ CA \\ \cdots \\ CA^{i-1} \end{pmatrix} \tag{6}$$

The orthogonal projection of the row space of A_x into the row space of B_x is:

$$A_x / B_x = A_x B_x^T (B_x B_x^T)^* B_x \tag{7}$$

where $(\bullet)^*$ denotes the Moore-Penrose pseudo-inverse of the matrix $(\bullet)$.

The projection of the row space of A_x into the orthogonal complement of the row space of B_x is:

$$A_x / B_x^\perp = A_x - A_x / B_x \tag{8}$$

The oblique projection of the row space of *G* along the row space *H* into the row space of *J* is:

$$G /_H J = (G / H^\perp) \cdot (J / H^\perp)^* \cdot J \tag{9}$$

Properties of the orthogonal and oblique projections:

$$A_x / A_x^\perp = 0 \tag{10}$$

$$A_x /_{A_x} C_x = 0 \tag{11}$$

For a proof, see (Van Overschee; De Moor, 1996).

2. PROPOSED IDENTIFICATION METHOD

2.1 MON4SID identification method

In this subsection, the MON4SID method is presented. To solve the problem in section 1.2, it is used the POMOESP method to calculate the extended observability matrix Γ_i and the N4SID method is employed to calculate the matrices *A*, *B*, *C*, *D* through the least squares method. Therefore, it is necessary to eliminate the last two terms in the right side of equation (2). That is done in two steps: first, eliminating the term $H_i^d U_f$ in (2), performing an orthogonal projection of equation (2) into the row space of $U_f^\perp$, which yields:

$$Y_f / U_f^\perp = \Gamma_i X_f / U_f^\perp + H_i^d U_f / U_f^\perp + H_i^s E_f / U_f^\perp \tag{12}$$

And by the property (10), equation (12) can be simplified to:

$$Y_f / U_f^\perp = \Gamma_i X_f / U_f^\perp + H_i^s E_f / U_f^\perp \tag{13}$$

Second, to eliminate the noises in (13), an instrumental variable $Z = (U_p^T Y_p^T)^T$ is defined. Multiplication of (13) by *Z* yields:

$$Y_f / U_f^\perp Z = \Gamma_i X_f / U_f^\perp Z + H_i^s E_f / U_f^\perp Z \tag{14}$$

As it is assumed that the noise is uncorrelated with input and output past data (Verhaegen; Dewilde, 1992), which means that $E_f / U_f^\perp Z = 0$. Therefore, (14) is written as:

$$Y_f / U_f^\perp Z = \Gamma_i \hat{X}_f \tag{15}$$

In equation (15), $X_f / U_f^\perp Z = \hat{X}_f$ is the estimate of the Kalman filter state. Equation (15) indicates that the column space of Γ_i can be calculated by the SVD decomposition of $Y_f / U_f^\perp Z$. For further details, see (Verhaegen; Dewilde, 1992). Γ_i, given in (15), can be derived from a simple LQ factorization of a matrix constructed from the block-Hankel matrices U_f, U_p and Y_f, Y_p, in the form:

$$\begin{pmatrix} U_f \\ Z_p \\ Y_f \end{pmatrix} = \begin{pmatrix} L_{11} & 0 & 0 \\ L_{21} & L_{22} & 0 \\ L_{31} & L_{32} & L_{33} \end{pmatrix} \begin{pmatrix} Q_1 \\ Q_2 \\ Q_3 \end{pmatrix} \tag{16}$$

and the orthogonal projection in the left side of (15) can be computed by matrix L_{32} (Verhaegen; Dewilde, 1992). The SVD of L_{32} can be given as:

$$L_{32} = (U_1\ U_2)\begin{pmatrix} S_n & 0 \\ 0 & S_2 \end{pmatrix}\begin{pmatrix} V_1^T \\ V_2^T \end{pmatrix} = USV^T \tag{17}$$

The order *n* of the system is equal to the number of non-zero singular values in S. The column space of U_1 approximates that of Γ_i in a consistent way (Verhaegen; Dewilde, 1992), that is:

$$\Gamma_i = U_1 \tag{18}$$

The system (1) can be written as:

$$\begin{pmatrix} \widetilde{X}_{i+1} \\ Y_{i|i} \end{pmatrix} = \begin{pmatrix} A & B \\ C & D \end{pmatrix}\begin{pmatrix} \widetilde{X}_i \\ U_{i|i} \end{pmatrix} + \begin{pmatrix} r_i \\ r_2 \end{pmatrix} \tag{19}$$

In equation (19), suppose (ideally) that $\widetilde{X}_{i+1}$ and $\widetilde{X}_i$ are given, then the system matrices (*A*, *B*, *C*, *D*) could be computed through the least squares method. Therefore, the problem now is to find the state sequences.

$\Theta_i = Y_f /_{U_f} Z_p$ is the oblique projection (Van Overschee; De Moor, 1996), which is achieved by performing an oblique projection of equation (2), along the row space U_f onto the row space of Z_p, that is:

$$Y_f /_{U_f} Z_p = \Gamma_i X_f /_{U_f} Z_p + H_i^d U_f /_{U_f} Z_p + \\ + H_i^s E_f /_{U_f} Z_p \tag{20}$$

It is easy to see that the last two terms of equation (20) are zero, by the property of the oblique projection, equation (11); and by the assumption that the noise is uncorrelated with input and output past data (Van Overschee; De Moor, 1996). Thus, equation (20) can be simplified to:

$$Y_f /_{U_f} Z_p = \Gamma_i \widetilde{X}_i \tag{21}$$

where $\widetilde{X}_i = X_f /_{U_f} Z_p$. Then equation (21) is written as:

$$\Theta_i = \Gamma_i \widetilde{X}_i \tag{22}$$

The oblique projection Θ_i given in equation (22) can be computed from (16) by:

$$\Theta_i = Y_f / U_f W_p = L_{32}(L_{22})^{-1}(L_{21}\ L_{22})\begin{pmatrix} Q_1 \\ Q_2 \end{pmatrix}. \tag{23}$$

An estimate of the state sequence X is given by:

$$X = (\Gamma_i)^* L_{32}(L_{22})^{-1} Z_p. \tag{24}$$

The following matrices are defined: $\widetilde{X}_i = X(:,1:N-1)$, $\widetilde{X}_{i+1} = X(:,2:N)$. Thus, the system matrices can be estimated from equation (19). To estimate *K* see (Van Overschee; De Moor, 1996) or (Verhaegen; Dewilde, 1992).

2.2 Closed loop identification method

Figure 1 shows a typical standard closed loop system, where *P* and *C* denote respectively the plant and the controller, r_k is the exogenous input, u_k the input control, y_k the plant output, w_k the plant disturbance and v_k the plant noise.

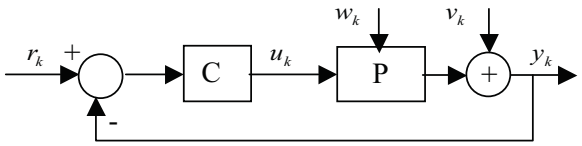

Figure1. Standard closed loop system.

P is given by equation (1) and *C* can be described by the following state equation:

$$\begin{aligned} s_{k+1} &= A_c s_k + B_c(r_k - y_k) \\ u_k &= C_c x_k + D_c(r_k - y_k) \end{aligned} \tag{25}$$

where A_c, B_c, C_c and D_c are matrices with appropriate dimensions.

2.3 Closed loop subspace identification problem

Given (r_k, u_k, y_k), a set of input output measurements finite data, of a well posed problem (Katayama, 2005), one considers the problem of identifying the deterministic part of the plant, that is, one determines the order *n* of the unknown system, the system matrices (*A*, *B*, *C*, *D*) up to within a similarity transformation.

2.3 Identification by joint input output approach

The objective of this paper is to obtain a state space model of the deterministic part of the plant *P*, based on finite measurement data (r_k, u_k, y_k). The present problem is practically the same as it was exposed in Verhaegen (1993), but the approach is quite different, as it is not necessary to know any information about the controller.

Using equations (1) and (25), it is possible to obtain a global state space model (Verhaegen, 1993):

$$\begin{aligned} \Psi_{k+1} &= \widetilde{A}\Psi_k + \widetilde{B}r_k + \Xi_k \\ \Phi_k &= \widetilde{C}\Psi_k + \widetilde{D}r_k + \Lambda_k \end{aligned} \tag{26}$$

where $\Psi_k = [x_k^T\ s_k^T]^T$, $\Phi_k = [u_k^T\ y_k^T]^T$. Ξ_k, Λ_k are noises and $\widetilde{A}, \widetilde{B}, \widetilde{C}, \widetilde{D}$ are matrices with appropriate dimensions.

The method MON4SID is applied to find an estimate of the matrices $\widetilde{A}, \widetilde{B}, \widetilde{C}, \widetilde{D}$, and based on them, to estimate Φ_k. Once Φ_k is known, it is easy to compute the matrices of the plant. To do so, the method POMOESP (Verhaegen, 1994) is used.

3. SIMULATION

In this section, we provide a simulation example to evaluate the performance of the MON4SID algorithm and to compare it with other existing identification algorithms PEM, N4SIDC and ARXS. N4SIDC here denotes the algorithm of Van Overschee and De Moor (1997) and ARXS the algorithm of Ljung and MacKelvey (1996). This example was used by (Huang *et al.*, 2004; Katayama, 2005; Overschee; De Moor, 1997 and Verhaegen, 1993). It is important to stress that the algorithm N4SIDC has three versions (Overschee; De Moor, 1997): two of them are unbiased and one is biased. The version implemented in this paper is the biased one, based on

states. In this version, it is used two different initial conditions, one for past states and the other for future states, what causes the bias. For further details see (Overschee; De Moor, 1997).

The plant is a discrete time model of a laboratory plant setup of two circular plates rotated by an electrical servo motor with flexible shafts. For further details, see (Hakvoort, 1990). The model of the plant is given by equation (1), where:

$$A = \begin{bmatrix} 4.4 & 1 & 0 & 0 & 0 \\ -8.09 & 0 & 1 & 0 & 0 \\ 7.83 & 0 & 0 & 1 & 0 \\ -4 & 0 & 0 & 0 & 1 \\ 0.86 & 0 & 0 & 0 & 0 \end{bmatrix}, \quad B = 10^{-3} \begin{bmatrix} 0.98 \\ 12.99 \\ 18.59 \\ 3.3 \\ -0.02 \end{bmatrix}, \quad C^T = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

$$K = \begin{bmatrix} 2.3 \\ -6.64 \\ 7.515 \\ -4.0146 \\ 0.86336 \end{bmatrix} \text{ and } D = 0$$

e_k is the white noise, which generates the disturbance on the plant, with standard deviation equal to 0 (for the case of deterministic system), 0.001 (to denote a system of little noise) and 0.01 (to denote a system of high noise). The controller has a state space description as in the equation (25), where:

$$A_c = \begin{bmatrix} 2.65 & -3.11 & 1.75 & -0.39 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{bmatrix}, \quad B_c = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

$$C_C^T = \begin{bmatrix} -0.4135 \\ 0.8629 \\ -0.7625 \\ 0.2521 \end{bmatrix} \text{ and } D_c = 0.61$$

PRBS was used as an exogenous input signal, that is, persistently exciting of any finite order. There were collected 3000 samples and the number of block rows $i = 20$.

The simulation results for a closed loop deterministic identification without noise is shown in figure 2, where the order of the plant is n = 5. From figure 2, one can observe that all the algorithms had a good performance, apart from the algorithm N4SIDC, which had am improvement using n =7, as it is shown in figure 4. Figure 3 shows the poles of the original open loop plant and the estimated systems, where • denotes the original poles of the plant. One can see that all the algorithms had a good performance in relation to the estimation of the poles, which are on the unit circle.

To see an advantage of the proposed algorithm, a white noise is added to the plant, first with measurement noise variance 0.001 and then with 0.01. The comparison results are shown in figures 5 and 7 respectively.

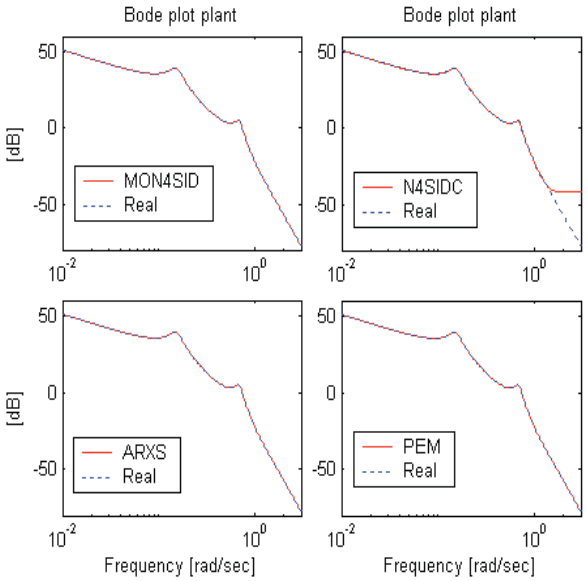

Fig.2. Bode plots of the plant P, to n=5 and no noise.

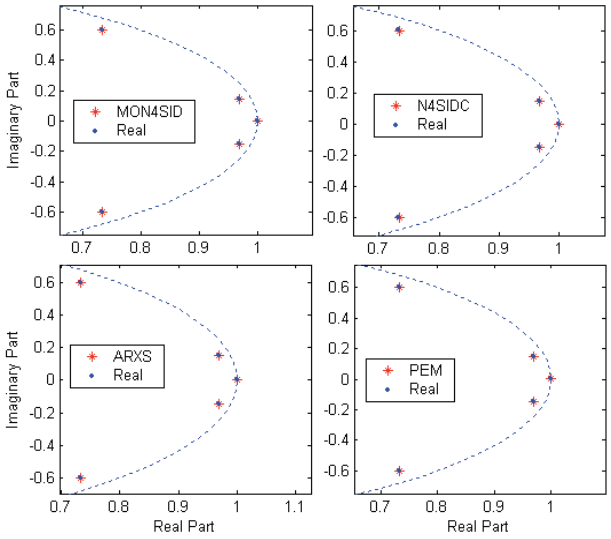

Fig. 3 Poles of the eigenvalues of the estimated A matrix.

From figures 5 and 7 one can see that the algorithm MON4SID performs better in the presence of noise. The order for identification of the plant is $n = 7$. Figures 6 and 8 show the pole estimates and the true poles of the plant. From figure 5 one can see that the algorithm ARXS does not have a good performance.

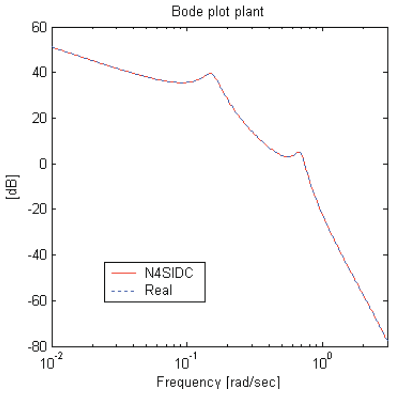

Fig.4. Bode plots of the plant P, to n=7 and no noise.

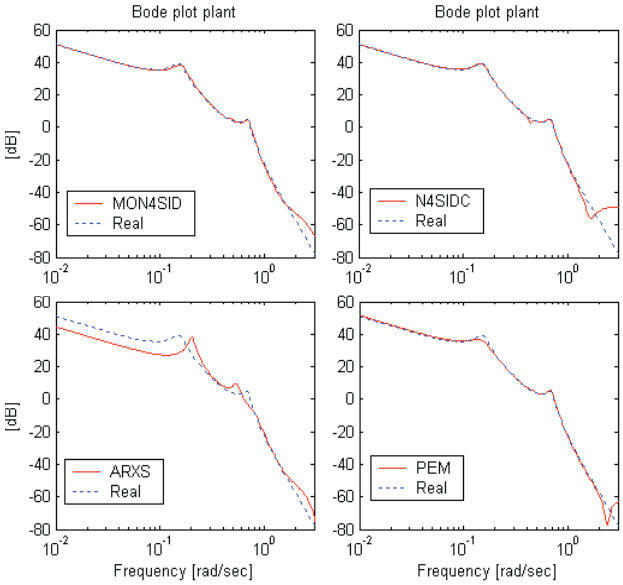

Fig.5. Bode plots of the plant P, to n=7 and little noise.

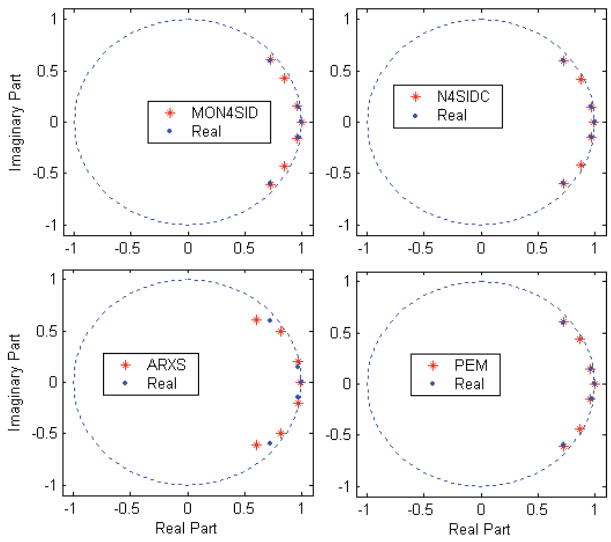

Fig.6 Poles of the eigenvalues of the estimated A matrix.

As can be noticed in figure 6 for the ARXS model, there is a difference between the estimated and real poles, what causes the difference between the real and estimated plots in figure 5.

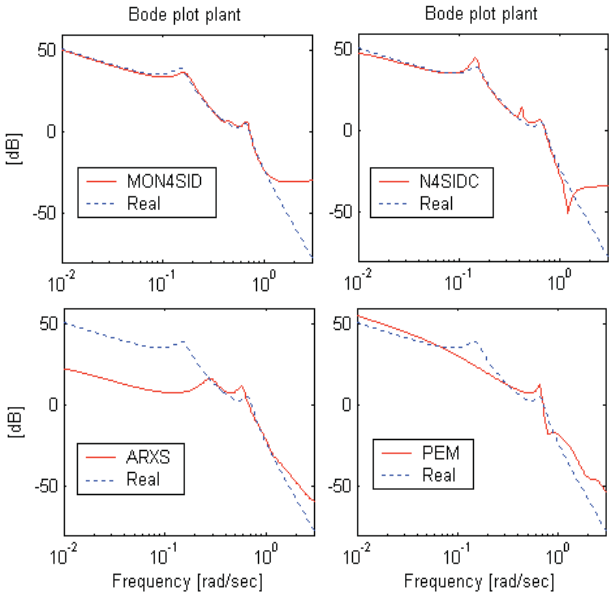

Fig.7. Bode plots of the plant P, to n=7 and high noise.

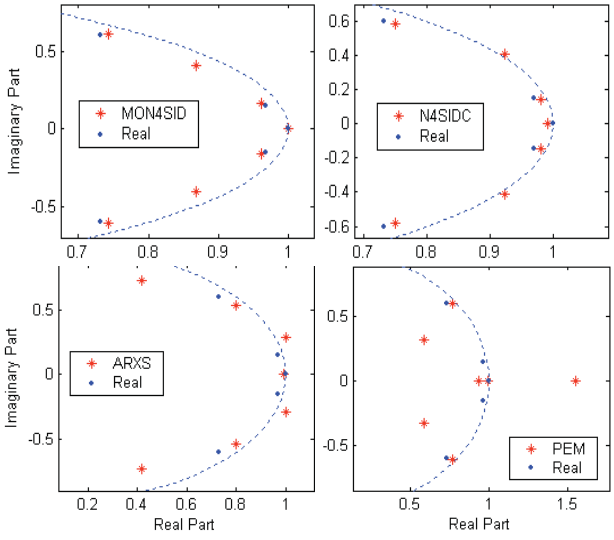

Fig.8 Poles of the eigenvalues of the estimated A matrix.

From figure 8 it can be seen that the MON4SID method provides a better estimation of the most crucial pole and all the poles are inside the unit circle. This does not happen for the other methods. Based on figure 8 one can say that direct identification models do not have a good performance for closed loop identification in the presence of high noises.

6. CONCLUSIONS

In this work, the MON4SID algorithm is presented, which uses LQ factorization in the same way as the MOESP method, which is used to compute the oblique and orthogonal

projections; these projections are used to compute the state sequence and the extended observability matrix, respectively. The past and future state sequences are computed from the state sequences, which have only one initial state. It does not happen in the N4SID method, because for each oblique projection (Θ_i and Θ_{i+1}) different state sequences ($\widetilde{X}_1$ and $\widetilde{X}_{i+1}$) are computed, generating a problem of bias in the estimates.

This algorithm was compared with three identification algorithms (PEM, N4SIDC, ARXS), when applied to a simulated example, which was used in (Van Overschee; De Moor, 1997) to identify a plant model in discrete time state space. Their results were compared by means of Bode plot and the comparison of the estimated poles with the true poles. The algorithm MON4SID presented good performance in all the cases. This algorithm has an advantage over the N4SIDC algorithm in the sense that it does not need any knowledge about the controller.

Abstract: Performance monitoring of model predictive control systems (MPC) has received a great interest from both academia and industry. In recent years some novel approaches for multivariate control performance monitoring have been developed without the requirement of process models or interactor matrices. Among them the prediction error approach has been shown to be a promising one, but it is k-step prediction based and may not be fully comparable with the MPC objective that is multi-step prediction based. This paper develops a multi-step prediction error approach for performance monitoring of model predictive control systems, and demonstrates its application in an industrial MPC performance monitoring and diagnosis problem.

Keywords: Multivariable control systems, Model predictive control, Performance evaluation, Performance monitoring, Prediction error methods.

1. INTRODUCTION

Since early work of Harris (1989), research on control performance assessment (CPA) has achieved a great progress and continues to be an active area. There is a great demand from industry for this research to produce practical solutions, particularly for MPC monitoring. Many algorithms in CPA including commercial software have been developed. There are several interesting reviews addressing related research achievements in different stages (Harris et al., 1999; Huang et al., 1999; Jelali , 2006; Qin , 2007).

Even with great achievements, multivariable CPA still has a number of stumbling blocks in practical applications. Recently some progress has been made towards this direction (Jelali , 2006; Huang et al., 2006). In particular, performance assessment of model predictive control (MPC) has been an interest since MPC is the most effective and widely used advanced multivariate control strategies in modern industries. With the existence of the constraints and economic optimization, the existing CPA is not directly applicable to its performance assessment (Xu et al., 2007).

For multivariable CPA to be practical, it must reduce *a priori* knowledge requirement. Traditional approaches for the multivariable CPA with minimum variance control as the benchmark need to estimate the interactor matrices, which is equivalent to knowing the process model (Huang et al., 1999) or at least the first few Markov parameter matrices. Recently, some new methods have been developed to address the multivariable CPA problems with only the input/output data (Jelali , 2006; Huang et al., 2006).

What simple index may be considered as a measure or one of the most important MPC performance measures? Consider that, if a closed-loop output is highly predictable, one should be able to do better, i.e. to compensate the predictable content by a well designed controller. This is the principle of predictive control. Should a better controller be implemented, the closed-loop output would have been less predictable. Therefore, high predictability of a closed-loop output implies high potential to improve its performance by controller re-tuning and/or re-design, or in other words, the existing controller may not have been satisfactory in terms of exploring its potential.

However, the CPA approach based on the prediction error has an equivalence to minimum variance based performance measure (Huang et al., 2008). Thus it may not be fully comparable with the MPC objective. Motivated by the prediction-error approach of (Huang et al., 2006; Zhao et al., 2008) and multi-step identification of Shook et al. (1992), this paper further develops closed-loop prediction-error measures based on multi-step prediction that is more relevant to model predictive control. Furthermore, applications of the proposed performance measures for an industrial model predictive control system are reported in this paper.

The remainder of this paper is organized as follows: Section 2 revisits the concept of prediction-error and closed-loop potentials for CPA. Section 3 introduces the

multi-step prediction error. Based on it, new potential measures are defined for the MPC controller performance assessment in Section 4. This is followed by an industrial case study in Section 5 to illustrate the utility of the new performance measures. Finally the conclusion is drawn in Section 6.

2. REVISIT OF CLOSED-LOOP POTENTIAL FOR MULTIVARIATE CPA

In this section, we shall revisit the concepts of prediction error and closed-loop potentials as defined in Huang et al. (2006).

For a multivariable process, the closed-loop output driven by white noise can be described by a time series model:

$$Y_t = G_{cl} a_t \tag{1}$$

where G_{cl} is the time series model and a_t is white noise with mean zero and covariance Σ_a.

Transfer the above time series model to a moving average (MA) form:

$$Y_t = \sum_{k=0}^{\infty} F_k a(t-k) = F_0 a_t + F_1 a_{t-1} + \cdots + F_{i-1} a_{t-(i-1)} + F_i a_{(t-i)} + \cdots \tag{2}$$

Note that this time series model can be estimated without any a priori knowledge about the process.

With the MA model, one can obtain the optimal ith step prediction:

$$Y_{t|t-i} = F_i a_{(t-i)} + F_{i+1} a_{(t-i-1)} + \cdots \tag{3}$$

and the prediction error:

$$e_{t|t-i} = Y_t - Y_{t|t-i} = F_0 a_t + F_1 a_{t-1} + \cdots + F_{i-1} a_{t-(i-1)} \tag{4}$$

where $F_0 = I$. The covariance of the prediction error can be calculated as

$$cov(e_{t|t-i}) = F_0 \Sigma_a F_0^T + F_1 \Sigma_a F_1^T + \cdots + F_{i-1} \Sigma_a F_{i-1}^T \tag{5}$$

Define its scalar measure:

$$s_i = tr(cov(e_{t|t-i})) = tr(F_0 \Sigma_a F_0^T + \cdots + F_{i-1} \Sigma_a F_{i-1}^T) \tag{6}$$

s_i is monotonically increasing with i, as $i \to \infty$, $e_{t|t-i} \to Y_t$, and $s_\infty = tr(cov(Y_t))$. If we plot s_i versus i, the plot reflects how the prediction error increases with the prediction horizon.

A closed-loop potential is defined in Huang et al. (2006) as:

$$p_i = \frac{s_\infty - s_i}{s_\infty} \tag{7}$$

The closed-loop potential can be interpreted as following (Huang et al., 2006): If a deadbeat control action can be applied from time i, then the sum of squared error (SSE) can be reduced by $100 \times p_i$ percent. From stochastic view point, if i is greater than the interactor order d, it is possible that the variance of the multivariate output can be reduced by $100 \times p_i$ percent of the current variance. Since the order of the actual interactor matrix may not be known, one can check the trajectory of the closed-loop potential versus a range of possible time lag d. As s_i is monotonically increasing with i, p_i is monotonically decreasing. When $i \to 0$, $s_0 = tr(cov(Y_t - Y_{t|t})) = 0$, $p_0 = 1$. Therefore, the index p_i starts from 1 at $i = 0$ and monotonically decreases to 0 at $i \to \infty$. Larger the closed-loop potential is, more potential the control performance can be improved.

From the potential plot we can draw the conclusion whether or how much the present closed-loop has potential to improve. Furthermore, with the plot, we can compare performance of a controller between different tuning parameters.

3. CLOSED-LOOP POTENTIAL MEASURES BASED ON MULTI-STEP PREDICTION

3.1 Multi-step optimal prediction and its scalar measure

It is well-known that minimum variance control is an aggressive control and not all controllers are designed towards minimum variance performance. Therefore, in addition to the measure of the optimal i-step prediction error s_i, which is associated with minimum variance performance, we consider a control that achieves optimal prediction performance over multi-steps, i.e. over a window from N_1 to N_2, where N_1 typically equals time delay d. In this way, we consider an optimum that is not based on a single prediction point but based on multiple prediction points.

For the multi-step optimal prediction problem, the minimization of the following multi-step prediction error is of interest (Shook et al., 1992; Huang et al., 2003):

$$s_{N_1,N_2} = \frac{1}{N_p} \sum_{j=N_1}^{N_2} E[Y_{t+j} - Y_{t+j|t}]^T [Y_{t+j} - Y_{t+j|t}] \tag{8}$$

where $Y_{t+j|t}$ is an optimal j-step ahead prediction, N_1 and N_2 are the minimum and maximum prediction step, $N_p = N_2 - N_1 + 1$, and s_{N_1,N_2} is defined as the scalar measure of the optimal multi-step prediction error (from N_1 to N_2). MPC attempts to minimize the error of multi-step predictions, i.e. from the first N_1 step to the N_2 step prediction. Thus the objective function (8) is MPC relevant.

It has been shown in Huang et al. (2003) that the objective function of multi-step prediction error is equivalent to the variance of filtered one-step prediction error:

$$\begin{aligned} s_{N_1,N_2} &= \frac{1}{N_2 - N_1 + 1} \sum_{n=N_1}^{N_2} E||[Y_{t+n} - Y_{t+n|t}]||^2 \\ &= E||[F_{N_1,N_2}(z^{-1})(Y_t - Y_{t|t-1})]||^2 \end{aligned} \tag{9}$$

where the filter $F_{N_1,N_2}(z^{-1})$ is the spectral factor of the following spectrum (Huang et al., 2003):

$$L_{N_1,N_2} = \frac{1}{N_2 - N_1 + 1} \sum_{n=N_1}^{N_2} ||F_n(e^{-nj\omega})||^2 \tag{10}$$

where

$$F_n(z^{-1}) = \sum_{i=0}^{n-1} F_n z^{-i}$$

If $N_1 = 1$ and $N_2 = k$, it is easy to show that $F_{1,k}(z^{-1})$ has the following form:

$$F_{1,k}(z^{-1}) = \tilde{F}_0 + \tilde{F}_1 z^{-1} + \cdots + \tilde{F}_{k-1} z^{-k+1} \tag{11}$$

where $\tilde{F}_i$ is to be determined next.

According to Eqn. 4, the optimal one step prediction error $Y_t - Y_{t|t-1} = a_t$, i.e. white noise. Thus

$$\begin{aligned} s_{1,k} = & \quad E[F_{1,k}(z^{-1})a_t]^T[F_{1,k}(z^{-1})a_t] \\ & = tr\{[(\tilde{F}_0 + \tilde{F}_1 z^{-1} + \cdots + \tilde{F}_{k-1}z^{-k+1})a_t]^T \\ & \quad [(\tilde{F}_0 + \tilde{F}_1 z^{-1} + \cdots + \tilde{F}_{k-1}z^{-k+1})a_t]\} \end{aligned}$$

which can be further written as

$$s_{1,k} = tr(\tilde{F}_0\Sigma_a\tilde{F}_0^T + \tilde{F}_1\Sigma_a\tilde{F}_1^T + \cdots + \tilde{F}_{k-1}\Sigma_a\tilde{F}_{k-1}^T) \quad (12)$$

In the next two sections we will derive univariate and multivariate expressions of the optimal multi-step prediction error, respectively.

3.2 The Univariate Process

For the univariate process, the terms F_i and $\tilde{F}_i$ are both scalars (hence we use f_i and $\tilde{f}_i$ to stand for the scalar values), so the scalar prediction error measures can be simplified to the following forms:

$$s_k = (f_0^2 + f_1^2 + \cdots + f_{k-1}^2)\sigma_a^2 \quad (13)$$

$$s_{1,k} = (\tilde{f}_0^2 + \tilde{f}_1^2 + \cdots + \tilde{f}_{m-1}^2)\sigma_a^2 \quad (14)$$

When $k = 1$, by definition, $s_{1,1}$ is the variance of one step prediction error; thus

$$s_1 = s_{1,1}$$

When $k = 2$, the following result could be obtained:

$$s_{1,2} = (\tilde{f}_0^2 + \tilde{f}_1^2)\sigma_a^2 = \frac{1}{2}(2f_0^2 + f_1^2)\sigma_a^2 = \frac{1}{2}(s_1 + s_2)$$

Similarly, when $N_1 = 1, N_2 = k$, we have

$$\begin{aligned} s_{1,k} &= \frac{\sigma_a^2}{k}\{kf_0^2 + (k-1)f_1^2 + \cdots + f_{k-1}^2\} \\ &= \frac{1}{k}\sum_{i=1}^{k} s_i \end{aligned} \quad (15)$$

Thus

$$\begin{aligned} s_{k,m} = & \frac{1}{m-k+1}[(m-k+1)(f_0^2 + f_1^2 + \cdots + f_{k-1}^2) \\ & + (m-k)f_k^2 + \cdots + f_{m-1}^2]\sigma_a^2 \end{aligned}$$

Proposition 1. For a univariate control loop, the measure of optimal multi-step prediction error from k to m ($s_{k,m}$) is no smaller than that of the optimal k-step prediction error (s_k), and the two measures are asymptotically equal, namely

$$s_{k,m} - s_k \geq 0 \quad (16)$$

$$\lim_{k\to\infty}\{s_{k,m} - s_k\} = 0 \quad (17)$$

Proof.

Recall that the measures of the optimal k-step prediction error and optimal multi-step prediction error are respectively:

$$s_k = (f_0^2 + f_1^2 + \cdots + f_{k-1}^2)\sigma_a^2 \quad (18)$$

and

$$\begin{aligned} s_{k,m} = & \frac{1}{m-k+1}[(m-k+1)(f_0^2 + f_1^2 + \cdots + f_{k-1}^2) \\ & + (m-k)f_k^2 + \cdots + f_{m-1}^2]\sigma_a^2 \end{aligned} \quad (19)$$

Thus

$$\begin{aligned} & s_{k,m} - s_k = \frac{1}{m-k+1}[(m-k+1)(f_0^2 + f_1^2 + \cdots + f_{k-1}^2) \\ & + (m-k)f_k^2 + \cdots + f_{m-1}^2]\sigma_a^2 - (f_0^2 + f_1^2 + \cdots + f_{k-1}^2)\sigma_a^2 \\ & \triangleq \frac{1}{N_p}[(N_p-1)f_k^2 + (N_p-2)f_{k+1}^2 + \cdots + f_{m-1}^2]\sigma_a^2 \quad (20) \\ & \geq 0 \end{aligned}$$

where $N_p = m - k + 1$.

Consider a stable closed-loop response:

$$\begin{aligned} y_t = G_{cl}(z^{-1};\theta)e_t &= \frac{B(z^{-1})}{A(z^{-1})}e_t \\ &= \frac{b_0 + b_1 z^{-1} + \cdots + b_m z^{-m}}{a_0 + a_1 z^{-1} + \cdots + a_n z^{-n}}e_t \end{aligned} \quad (21)$$

Write the above transfer function in the zero-pole form

$$y_t = \frac{b_0(1-\beta_1 z^{-1})(1-\beta_2 z^{-1})\cdots(1-\beta_m z^{-1})}{(1-\alpha_1 z^{-1})(1-\alpha_2 z^{-1})\cdots(1-\alpha_n z^{-1})}e_t \quad (22)$$

where $|\alpha_i| < 1$.

Partial fraction expansion of Eqn. (22) yields

$$\begin{aligned} y_t &= (\frac{c_1}{1-\alpha_1 z^{-1}} + \frac{c_2}{1-\alpha_2 z^{-1}} + \cdots + \frac{c_n}{1-\alpha_n z^{-1}})e_t \\ &= \sum_{p=1}^{n} c_p(1 + \alpha_p z^{-1} + \alpha_p^2 z^{-1} + \cdots)e_t \\ &\triangleq (f_0 + f_1 z^{-1} + \cdots + f_i z^{-i}\cdots)e_t \end{aligned} \quad (23)$$

where

$$f_i = \sum_{p=1}^{n} c_p \alpha_p^i \quad (24)$$

So, the *ith* term of Eqn. (18) can be calculated as

$$\begin{aligned} f_i^2 &= (\sum_{p=1}^{n} c_p\alpha_p^i)^2 \\ &= \sum_{p=1}^{n} c_p^2\alpha_p^{2i} + 2\sum_{p=1}^{n-1}\sum_{q=p+1}^{n} c_p c_q(\alpha_p\alpha_q)^i \end{aligned} \quad (25)$$

According to Eqn. (20)

$$s_{k,m} - s_k = \frac{1}{N_p}\sum_{i=k}^{m-1}(m-i)f_i^2\sigma_a^2 \quad (26)$$

Substituting Eqn. (25) in Eqn. (26), we obtain that

$$\begin{aligned} & s_{k,m} - s_k \\ = & \frac{\sigma_a^2}{N_p}\sum_{i=k}^{m-1}(m-i)(\sum_{p=1}^{n} c_p^2\alpha_p^{2i} + 2\sum_{p=1}^{n-1}\sum_{q=p+1}^{n} c_p c_q(\alpha_p\alpha_q)^i) \\ = & \frac{\sigma_a^2}{N_p}(m\sum_{p=1}^{n} c_p^2\sum_{i=k}^{m-1}\alpha_p^{2i} - \sum_{p=1}^{n} c_p^2\sum_{i=k}^{m-1} i\alpha_p^{2i} \\ & + \sum_{p=1}^{n-1}\sum_{q=p+1}^{n} 2mc_p c_q\sum_{i=k}^{m-1}(\alpha_p\alpha_q)^i \\ & - \sum_{p=1}^{n-1}\sum_{q=p+1}^{n} 2c_p c_q\sum_{i=k}^{m-1} i(\alpha_p\alpha_q)^i) \end{aligned} \quad (27)$$

where the terms $\sum_{i=k}^{m-1}\alpha_p^{2i}$, $\sum_{i=k}^{m-1} i\alpha_p^{2i}$, $\sum_{i=k}^{m-1}(\alpha_p\alpha_q)^i$ and $\sum_{i=k}^{m-1} i(\alpha_p\alpha_q)^i$ can be determined respectively as

$$\sum_{i=k}^{m-1}\alpha_p^{2i}=\frac{\alpha_p^{2k}(1-\alpha_p^{2(m-k)})}{1-\alpha_p^2} \tag{28}$$

$$\sum_{i=k}^{m-1} i\alpha_p^{2i}=\frac{\alpha_p^{2k}(1-\alpha_p^{2(m-k)})}{(1-\alpha_p^2)^2}+\frac{(k-1)\alpha_p^{2k}-(m-1)\alpha_p^{2m}}{(1-\alpha_p^2)} \tag{29}$$

$$\sum_{i=k}^{m-1}(\alpha_p\alpha_q)^i=\frac{(\alpha_p\alpha_q)^k(1-(\alpha_p\alpha_q)^{m-k})}{1-\alpha_p\alpha_q} \tag{30}$$

$$\sum_{i=k}^{m-1} i(\alpha_p\alpha_q)^i=\frac{(\alpha_p\alpha_q)^k(1-(\alpha_p\alpha_q)^{m-k})}{(1-\alpha_p\alpha_q)^2}+\frac{(k-1)(\alpha_p\alpha_q)^k-(m-1)(\alpha_p\alpha_q)^m}{(1-\alpha_p\alpha_q)} \tag{31}$$

Substituting the above four equations in Eqn. (27) yields

$$\begin{aligned}&s_{k,m}-s_k\\ =&\frac{\sigma_a^2}{N_p}\Big(\sum_{p=1}^{n}c_p^2\Big(-\frac{\alpha_p^{2k}(1-\alpha_p^{2(m-k)})}{(1-\alpha_p^2)^2}+\frac{N_k\alpha_p^{2k}-\alpha_m^2}{1-\alpha_p^2}\Big)\\ &+\sum_{p=1}^{n-1}\sum_{q=p+1}^{n}2c_pc_q\Big(-\frac{(\alpha_p\alpha_q)^k(1-(\alpha_p\alpha_q)^{m-k})}{(1-\alpha_p\alpha_q)^2}\\ &+\frac{N_k(\alpha_p\alpha_q)^k-(\alpha_p\alpha_q)^m}{1-\alpha_p\alpha_q}\Big)\Big)\\ \triangleq&\sum_{p=1}^{n}c_p^2\times Sum1+\sum_{p=1}^{n-1}\sum_{q=p+1}^{n}(2c_pc_q)\times Sum2\end{aligned} \tag{32}$$

where

$$Sum1=\frac{\sigma_a^2}{N_p}\Big[-\frac{\alpha_p^{2k}(1-\alpha_p^{2(m-k)})}{(1-\alpha_p^2)^2}+\frac{N_p\alpha_p^{2k}-\alpha_m^2}{1-\alpha_p^2}\Big]$$

$$Sum2=\frac{\sigma_a^2}{N_p}\Big[-\frac{(\alpha_p\alpha_q)^k(1-(\alpha_p\alpha_q)^{m-k})}{(1-\alpha_p\alpha_q)^2}+\frac{N_p(\alpha_p\alpha_q)^k-(\alpha_p\alpha_q)^m}{1-\alpha_p\alpha_q}\Big]$$

When $k\to\infty$, $m\to\infty$ since $m\geq k$. Let $m-k=P\geq 0$. Consequently, $N_p=m-k+1=P+1$. The limits of $Sum1$ and $Sum2$ can be obtained:

$$\begin{aligned}\lim_{k\to\infty}Sum1=&\lim_{k\to\infty}\Big[-\frac{\alpha_p^{2k}(1-\alpha_p^{2(m-k)})}{N_p(1-\alpha_p^2)^2}+\frac{N_p\alpha_p^{2k}-\alpha_p^{2m}}{N_p(1-\alpha_p^2)}\Big]\sigma_a^2\\ =&0\end{aligned} \tag{33}$$

As $|\alpha_i|<1$, obviously $|\alpha_p\alpha_q|<1$. Similarly,

$$\begin{aligned}&\lim_{k\to\infty}Sum2\\ =&\lim_{k\to\infty}\Big(-\frac{(\alpha_p\alpha_q)^k(1-(\alpha_p\alpha_q)^{m-k})}{N_p(1-\alpha_p\alpha_q)^2}+\frac{N_p(\alpha_p\alpha_q)^k-(\alpha_p\alpha_q)^m}{N_p(1-\alpha_p\alpha_q)}\Big)\\ =&0\end{aligned} \tag{34}$$

Consequently,

$$\begin{aligned}&\lim_{k\to\infty}\{s_{k,m}-s_k\}\\ =&\sum_{p=1}^{n}c_p^2\times Sum1+\sum_{p=1}^{n-1}\sum_{q=p+1}^{n}(2c_pc_q)\times Sum2\\ =&0\end{aligned} \tag{35}$$

3.3 The multivariate process

Following a similar procedure as that for the univariate process, the following measure of optimal multi-step prediction error can be derived:

$$\begin{aligned}s_{k,m}=&tr(\tilde{F}_0\Sigma_a\tilde{F}_0^T+\tilde{F}_1\Sigma_a\tilde{F}_1^T+\cdots+\tilde{F}_{m-1}\Sigma_a\tilde{F}_{m-1}^T)\\ =&\sum_{p=0}^{k-1}\sum_{j=1}^{N}\sum_{i=1}^{N}f_{ijp}^2\sigma_j^2+\sum_{p=k}^{m-1}\frac{m-p}{m-k+1}\sum_{j=1}^{N}\sum_{i=1}^{N}f_{ijp}^2\sigma_j^2\end{aligned} \tag{36}$$

A same proposition as in the univariate case can be proved, but is omitted in this shorter version due to space limit.

4. CLOSED-LOOP POTENTIALS BASED ON THE MULTI-STEP PREDICTION

Based on the multi-step prediction error derived in the above section, the following closed-loop potential measure is defined for performance assessment of MPC:

$$p_{k,m}=\frac{s_{\infty,\infty+N_p}-s_{k,m}}{s_{\infty,\infty+N_p}} \tag{37}$$

where $N_p=P+1$ and P represents the prediction horizon. It can be shown that $s_{\infty,\infty+N_p}=s_\infty=trace\{cov(Y_t)\}$.

Here we use the multi-step prediction error scalar measure $s_{k,m}$ instead of the k-step prediction error scalar measure s_k of Huang et al. (2006) to derive closed-loop potential. As has been proven in the last section, with a fixed prediction horizon P, i.e. $m-k=P=N_p-1$, the scalar measure $s_{k,m}$ is monotonically increasing with k. So $p_{k,m}$ is monotonically decreasing. When $k=0$, $s_{k,m}\geq=s_0=0$, so $p_{0,N_p}\leq 1$. Besides, as $s_{\infty,\infty+N_p}\geq s_{k,m}$, consequently, $0\leq p_{k,m}\leq 1$. According to its definition we can see that the $p_{k,m}$ is dimensionless and in addition, the potential measure is more relevant to the MPC control strategy as it is multi-step prediction based. The actual process time delay (that corresponds to k) may not be known in practice. So the trajectory of the potential measure with a range of k will be more useful to assess the performance of the controller.

It is also desirable to know details about the performance of each output. So, the individual scalar potential measure is required. By replacing the operator $tr(\cdot)$ in Eqn. (36) with $diag(\cdot)$, the individual scalar measure is defined as:

$$s_{k,m}^{ind}=diag(\tilde{F}_0\Sigma_a\tilde{F}_0^T+\tilde{F}_1\Sigma_a\tilde{F}_1^T+\cdots+\tilde{F}_{m-1}\Sigma_a\tilde{F}_{m-1}^T)$$

where $s_{k,m}^{ind}\in\mathbb{R}^{N\times 1}$ and N represents the number of controlled variables.

The ith component of $s_{k,m}^{ind}$ can be obtained:

$$s_{k,m}^{ind}(i)=\sum_{p=0}^{k-1}\sum_{j=1}^{N}f_{jip}^2\sigma_i^2+\sum_{p=k}^{m-1}\frac{m-p}{m-k+1}\sum_{j=1}^{N}f_{jip}^2\sigma_i^2 \tag{38}$$

As a result, the individual potential measure can be defined as:

$$p_{k,m}^{ind}(i)=\frac{s_{\infty,\infty+N_p}^{ind}(i)-s_{k,m}^{ind}(i)}{s_{\infty,\infty+N_p}^{ind}(i)} \tag{39}$$

where $s_{\infty,\infty+N_p}^{ind}=diag(s_{\infty,\infty+N_p})=diag(cov(Y_t))$ and $1\leq i\leq N$.

5. INDUSTRIAL APPLICATION

In this section the proposed multi-step closed-loop potential measures will be applied to evaluate the performance of an industrial control system.

5.1 Process description

This is a control performance assessment and diagnosis problem for a MPC control system in a delayed coking refinery unit. Fig. 1 is a simplified process flow chart.

The control system consists of three manipulated variables (MVs), three controlled variables (CVs) and one disturbance variable (DV), the temperature of the feedstocks. A description of process variables and their corresponding tag names and the parameters for the MPC design is shown in Table 1.

Two different closed-loop operation data sets are collected with 1 min sampling interval under different MPC controller tunings as shown in Fig. 2. All the data is selected without the drum events to avoid unusual upset. The first part of the data from 1 to 1900 is selected before the controller tuning and the rest part is selected after the controller tuning.

5.2 Performance assessment

By using the proposed approach, the scalar potential measure trajectories for each data set are generated and

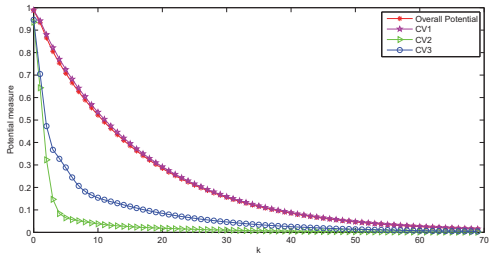

Fig. 3. Scalar potential measures of the system before controller tuning.

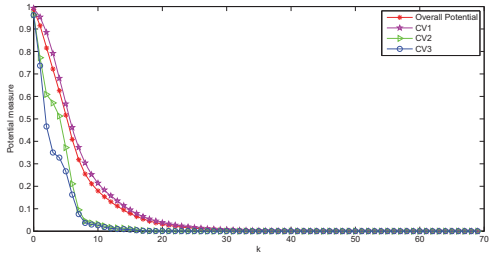

Fig. 4. Scalar potential measures of the system after controller tuning.

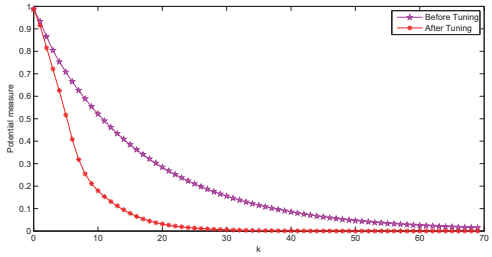

Fig. 5. Overall scalar potential measures of the system under different controller tunings.

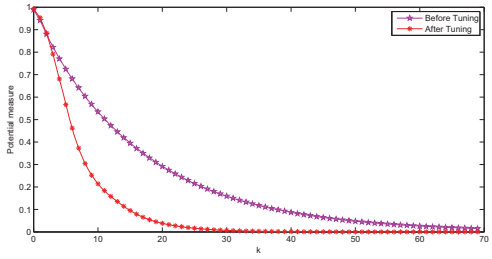

Fig. 6. Individual scalar potential measures of the system under different controller tunings of CV1.

shown in Fig. 3 and 4, respectively. The comparisons of the overall potential and individual potential for each CV are displayed from Fig. 5 to Fig. 8.

With these figures, the following performance analysis conclusions can be obtained:

Table 1. List of process variables and their corresponding tag names and parameters for MPC design.

No.	Tag	Weight	Horizon	Operation Range
CV1	Temperature of diesel	10	20	275-295
CV2	Temperature in the intermediate	1	20	285-295
CV3	Temperature of light coker gas oil	1	20	360-380
MV1	Valve opening of diesel	0.1	3	0-100
MV2	Valve opening of intermediate reflux	0.1	3	0-100
MV3	Valve opening of light coker gas oil reflux	0.1	3	0-100

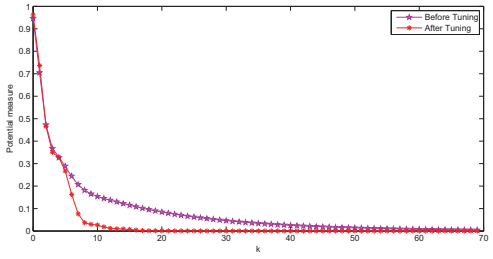

Fig. 7. Individual scalar potential measures of the system under different controller tunings of CV2.

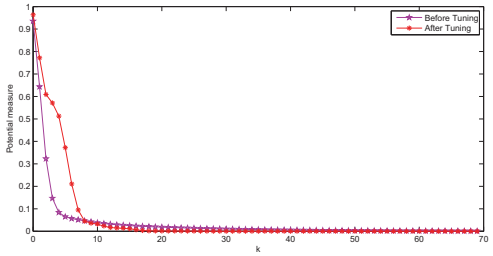

Fig. 8. Individual scalar potential measures of the system under different controller tunings of CV3.

- According to Fig 3, before the controller tuning, the overall scalar potential measure trajectory converges slowly and CV1 contributes the more potential to the overall potential than the other two CVs.
- According to Fig 4, after the controller tuning, the overall scalar potential measure trajectory converges fast and the three individual trajectories come close to each other, although the trajectory of CV1 still lies above the other two.
- According to Fig 5, there is significant improvement of the system's performance after the tuning as there is less potential after the controller tuning than that before tuning.
- According to Fig 6, 7 and 8, performance of both CV1 and CV2 is improved after the controller tuning; however, performance of CV3 is degraded after the tuning.
- The above results indicate that the improvement of the overall performance comes from the improvement of CV1 and CV2 but at some cost of CV3. As CV1 is the most important quality variable (the weight of CV1 is larger than those of the other two in Table 1.), it is worth to improve its performance by slightly deteriorating the performance of CV3.

In summary, after the controller tuning, there is significant improvement of the system's performance.

6. CONCLUSION

The closed-loop potentials are promising measures of model predictive control performance. However, they have certain limitations as they are originally defined. In this paper, new closed-loop potentials are proposed. The proposed performance potentials are multi-step prediction based and thus MPC relevant. Regardless of the dimension of the plant, the closed-loop potentials can be easily calculated, which facilitates the implementation, visualization, and interpretation. Industrial application demonstrates powerfulness of the the proposed performance measures.

Abstract: Friction in control valves and inadequate controller tuning are two of the major sources of control loop performance degradation. As friction models are needed to diagnose abnormal valve operation or to compensate such undesirable effects, process models play an essential role in controller design. This paper extends existing optimization-based methods that jointly identify the process and friction model parameters, so that a nonlinear process model structure is considered. The procedure is based on data generated from closed-loop experiments with an external test signal. A simulation example indicates that the method accurately quantifies the valve friction, the process dynamics and the nonlinear steady state characteristics, even when the system is subjected to different level of disturbances.

Keywords: Control valves; Nonlinear models; Identification algorithms; Friction.

1. INTRODUCTION

Among several process variability sources (e.g., inadequate controller structure/ tuning, equipment malfunction, poor design, lack of maintenance) valve friction is supposed to be one of the most prevalent (Desborough and Miller, 2001). For this reason, friction quantification methods are highly desirable, since they can be applied in the development of model-based compensators or to diagnose valves that need repair. Moreover, quantification methods based only on controller output (*op*) and process output (*pv*) measurements from closed-loop experiments, are preferable for practical reasons.

Choudhury et al. (2004) dealt with friction quantification by means of the *pv*-*op* plot, but the results produced by this technique depend on the controller tuning. In a method proposed by Srinivasan et al. (2005), an optimization approach is used to jointly estimate the process dynamics and the friction model parameters. This method can be seen as a Hammerstein model identification, since the valve friction is treated as a nonlinear static block ($\mathcal{N}$) followed by a linear dynamic block ($\mathcal{L}$) that represents the process. As the process dynamics is also estimated, the joint procedure previously mentioned can be used for controller retuning. However, in that work, an inappropriate friction model structure that is unable to reproduce important sticky valve characteristics is employed. In a recent work (Choudhury et al., 2008), this drawback was eliminated through the adoption of another friction model structure.

An additional extension to the method originally proposed by Srinivasan et al. (2005) is to model the process with a Wiener structure (Figure 1), built up with a linear dynamic block connected to a nonlinear static function ($\mathcal{L} \rightarrow \mathcal{N}$). In this approach the Hammerstein structure is

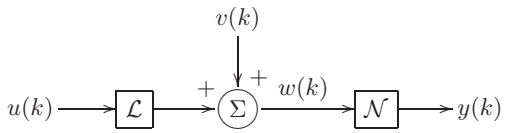

Fig. 1. Wiener model structure with nonlinear disturbance.

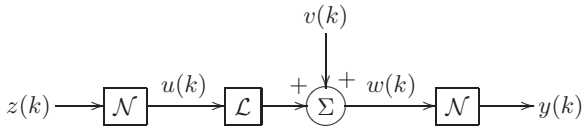

Fig. 2. Hammerstein-Wiener model structure with nonlinear disturbance.

extended to a Hammerstein-Wiener one ($\mathcal{N} \rightarrow \mathcal{L} \rightarrow \mathcal{N}$), i.e., the valve friction is associated with the first nonlinear block, while the remainder blocks represent the process. The Hammerstein-Wiener structure is shown in Figure 2.

This extension intends to provide some features: (*i*) to avoid that process nonlinearities be erroneously incorporated in the friction model, (*ii*) to prevent bias problems in the process model identification and (*iii*) to turn the estimation method suitable to wider operating ranges.

This work proposes a procedure to jointly estimate nonlinear process dynamics and friction model parameters from closed-loop experiments. Actually, it is an extension from previous works (Choudhury et al., 2008; Srinivasan et al., 2005). The paper is organized as follows: the structure that models the valve friction is described in section 2. The parameterization of the nonlinear process, as well as an estimation algorithm suitable for closed-loop data are treated in section 3. The friction and process model joint estimation procedure is presented in section 4. This

procedure is tested through a simulated example in section 5. At last, the conclusions are drawn.

2. VALVE FRICTION MODEL

Several friction models were evaluated using ISA standard tests in Garcia (2008). The best trade-off between accuracy and simplicity was achieved by the data-driven model proposed by Kano et al. (2004). This is a modified version of the model employed in the friction quantification algorithm proposed in Choudhury et al. (2008) and it is characterized by two parameters: S that represents the cummulative input signal $z(k)$ amplitude change necessary to revert the valve movement direction and J that is the size of the stem slip, also referred as slip-jump, observed when the valve starts to move.

Besides the parameters S and J, the friction model uses three auxiliar variables: stp that indicates if the valve is moving ($stp = 0$) or if it is stuck ($stp = 1$), z_s that is updated with $z(k)$ every time the valve sticks and $d = \pm 1$ that denotes the direction of the friction force.

The relationship between the command signal $z(k)$ and the valve stem position $u(k)$ is described in the flowchart shown in Figure 3. After testing whether the valve stopped, so that z_s and stp are eventually updated, a new value is assigned to $u(k)$ if: (i) the valve is moving ($stp = 0$), (ii) the valve changes its direction and overcomes S or (iii) the valve moves in the same direction and overcomes J. On the contrary, the position remains the same.

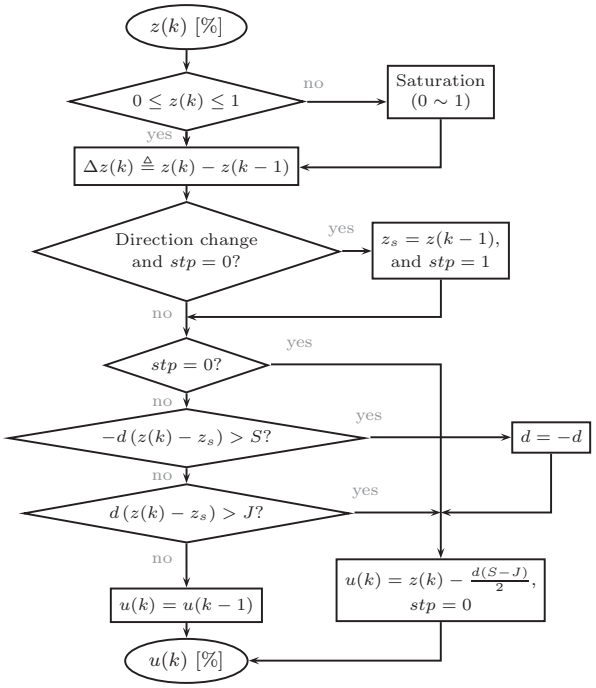

Fig. 3. Flowchart of the data-driven model parameterized by S and J (Kano et al., 2004).

3. NONLINEAR PROCESS MODEL

3.1 Model parameterization

Consider the Wiener model depicted in Figure 1, where the input signal is denoted by $u(k)$, the output signal by $y(k)$ and $v(k)$ represents the process disturbances. Notice that $v(k)$ is applied before the nonlinear block. In this case, the disturbances are also subject to the process nonlinearity. This scheme, proposed by Zhu (1999), is more realistic from a process operation point of view.

The linear dynamic block can be represented by a rational transfer function of order n:

$$G(q) = \frac{b_1 q^{-1} + \ldots + b_n q^{-n}}{1 + a_1 q^{-1} + \ldots + a_n q^{-n}} = \frac{B(q)}{A(q)} \tag{1}$$

where q^{-1} is the backward operator.

When prior knowledge about the process nonlinearity is not available, piecewise polynomials of third degree (cubic spline) provide advantages in respect of polynomials and piecewise linear functions to model the nonlinear block. For a set of m different knots:

$$w_{\min} = w_1 < w_2 < \ldots < w_{m-1} < w_m = w_{\max} \tag{2}$$

A cubic spline can be expressed by (Lancaster and Šalkauskas, 1986):

$$\begin{aligned} y(k) &= f\left(w(k)\right) \\ &= \sum_{i=2}^{m-1} \xi_i \left|w(k) - w_i\right|^3 + \xi_m + \xi_{m+1} w(k) \end{aligned} \tag{3}$$

where $\Xi \triangleq \left(\xi_2, \ldots, \xi_{m+1}\right)^T$ is the cubic spline parameter vector and $w(k)$ denotes the Wiener model intermediate signal.

3.2 Wiener model parameter estimation

In the closed-loop identification of Wiener models, the prediction error approach yields unbiased estimates, provided the process and the disturbance models are built simultaneously and the process model contains at least a delay of one sampling period (Forssell, 1999). To satisfy this condition, the disturbance term is modeled using an Auto Regressive Moving Average (ARMA) structure:

$$\begin{aligned} v(k) &= H(q)e(k) = \frac{C(q)}{D(q)} e(k) \\ &= \frac{1 + c_1 q^{-1} + \ldots + c_{n_c} q^{-nc}}{1 + d_1 q^{-1} + \ldots + d_{n_d} q^{-nd}} e(k) \end{aligned} \tag{4}$$

where $e(k)$ is white noise with zero mean and variance σ^2.

Suppose that the function which describes the process nonlinearity is monotonic and invertible. Hence, analogously to (3), the inverse of the process nonlinearity $f^{-1}(\cdot)$ can be denoted by:

$$w(k) = \sum_{i=2}^{p-1} \gamma_i \left|y(k) - y_i\right|^3 + \gamma_p + \gamma_{p+1} y(k) \tag{5}$$

Furthermore, as the intermediate signal $w(k)$ is unmeasurable, the gain of the Wiener model can be arbitrarily distributed between the dynamic and the static block. For this reason, the constraint $\gamma_{p+1} = 1$ is introduced in (5), so that the parameters can be uniquely determined.

The Wiener model parameters can be obtained from the minimization of the prediction error criterion:

$$V = \sum_k \left(H^{-1}(q)\left(w(k) - G(q)u(k)\right)\right)^2 \tag{6}$$

In order to estimate the Wiener and disturbance model parameters, besides the assumption that the process nonlinearity is invertible, the algorithm considers that the process is open loop stable. Both assumptions are commonly found in many practical situations, e.g., CSTRs, distillation columns and pH neutralization processes. Hence, $G(q)$ can be approximated by a finite impulse response (FIR) model, so that the intermediate signal is expressed by:

$$w(k) = \beta_1 u(k-1) + \ldots + \beta_r u(k-r) + v(k) \tag{7}$$

For more compact notation, consider the regression $\psi(k)$ and the parameter θ vectors:

$$\psi(k) \triangleq \Big(-|y(k) - y_2|^3, \ldots, -|y(k) - y_{p-1}|^3, -1, u(k-1), \ldots, u(k-r)\Big)^T \tag{8}$$

$$\theta \triangleq (\gamma_2, \ldots, \gamma_{p-1}, \gamma_p, \beta_1, \ldots, \beta_r)^T \tag{9}$$

Considering (8) and (9), (6) can be rewritten as:

$$V = \sum_k \left(H^{-1}(q)\left(y(k) - \psi^T(k)\theta\right)\right)^2 \tag{10}$$

Since the criterion (10) is a nonlinear least-squares problem, the following algorithm is employed to calculate $G(q)$, $f(\cdot)$ and $H(q)$:

***Algorithm** 1.* Wiener and ARMA disturbance model parameter estimate.

i. Initialize the disturbance model $H(q)$ with:

$$\hat{C}(q) = \hat{D}(q) = 1 \tag{11}$$

ii. Calculate filtered version of the output and the regression vectors:

$$y_f(k) = \frac{D(q)}{C(q)} y(k)$$

$$\psi_f(k) = \frac{D(q)}{C(q)} \psi(k)$$

iii. Estimate the parameter vector θ from:

$$\hat{\theta} = \left(\sum_k \psi_f(k)\psi_f^T(k)\right)^{-1} \left(\sum_k \psi_f(k) y_f(k)\right) \tag{12}$$

iv. Calculate the residuals $\zeta(k)$ of the Wiener model obtained from the previous step:

$$\zeta(k) = y(k) - \psi^T(k)\hat{\theta} \tag{13}$$

v. Estimate an ARMA model for $\zeta(k)$, i.e., a filter to uncorrelate the residuals:

$$\hat{D}(q)\zeta(k) = \hat{C}(q)e(k) \tag{14}$$

vi. While convergence of $\hat{H}(q)$ does not occur, go to step (ii). Otherwise, go to the next step.

vii. The parameters of $A(q)$ and $B(q)$, defined in (1), are estimated by minimizing the error between the outputs of the FIR model and the transfer function $G(q)$:

$$V_{red} = \sum_k \left(\sum_{i=1}^{r} \hat{\beta}_i u(k-i) - \frac{B(q)}{A(q)} u(k)\right)^2 \tag{15}$$

viii. The nonlinear block parameter vector Ξ estimate is given by:

$$\hat{\Xi} = \arg\min_{\Xi} \sum_k \left(y(k) - \phi^T(k)\Xi\right)^2 \tag{16}$$

where:

$$\phi(k) \triangleq \left(|\hat{w}(k) - w_2|^3, \ldots, |\hat{w}(k) - w_{m-1}|^3, 1, \hat{w}(k)\right)^T$$

$$\hat{w}(k) \triangleq \hat{f}^{-1}(y(k))$$

Correspondingly to the iterative calculation of θ, the linear model reduction (15) and the nonlinear function determination (16) are formulated as linear least squares problems. For this reason, the procedure is considered to be numerically simple and suitable for practical situations.

4. FRICTION AND PROCESS MODEL JOINT IDENTIFICATION ALGORITHM

Consider the process control loop depicted in Figure 4. Since in most of the practical situations only the controller output and the process output are known, the problem to be treated is to identify the friction and process model by means of $z(k)$ and $y(k)$.

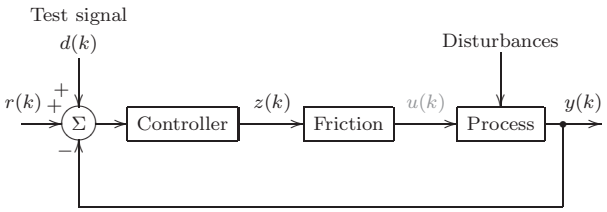

Fig. 4. Process control loop subject to valve friction.

In this work, the friction block is represented by the data-driven model of section 2, while the process dynamics is modeled by a Wiener structure. These parameterizations originate the control loop model shown in Figure 5.

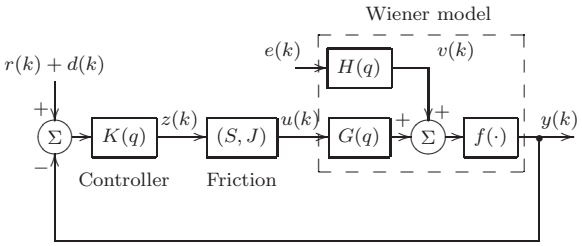

Fig. 5. Control loop where the valve friction and the process are modeled by a Hammerstein-Wiener structure.

In a first moment, suppose that the friction model parameters S and J are known. With this in mind, as the

controller output $z(k)$ is considered to be measurable, it is possible to estimate $u(k)$ with:

$$\hat{u}(k) = \mathcal{F}\left(z(k), \hat{u}(k-1), S, J\right) \tag{17}$$

where $\mathcal{F}(\cdot)$ is the nonlinear transformation described in the flowchart of Figure 3. Hence, the Wiener model parameters can be estimated, using the measured output $y(k)$ and $\hat{u}(k)$ instead of $u(k)$, by means of the algorithm presented in section 3. However, S and J are unknown. To deal with this fact, the following algorithm is proposed:

***Algorithm** 2.* Algorithm that simultaneously estimate the parameters of the friction and nonlinear process model.

i. Generate a set of candidate values for the pair (S, J). Two aspects are considered in order to restrict the set of candidate values: (a) the behavior of most real valves is reproduced by the data-driven model with $\max(J) \leq S$; (b) it is obvious that without stem movement, to estimate the valve friction is an impossible task. If an appropriate excitation $d(k)$ is employed, it is reasonable to consider that the stem velocity reversions are produced by the test signal. Therefore, the controller output imposes an upper bound for S:

$$\max(S) < \max(z(k)) - \min(z(k)) \tag{18}$$

Such constraints yield the geometric locus shown in Figure 6.

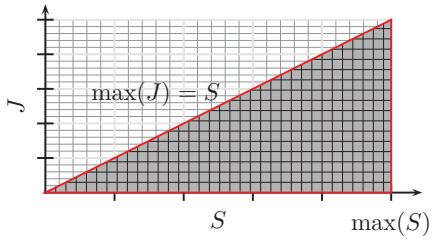

Fig. 6. Geometric locus of the friction model parameter candidate values.

ii. Choose a pair (S_i, J_j) from the set described in the previous step.

iii. Calculate the sequence of values $\hat{u}(k)$ from (17).

iv. Estimate the process model parameters using algorithm *1*, described in section 3.

v. Compute the prediction error of the intermediate signal $w(k)$ through the criterion:

$$\mathcal{C} = \sum_{k} \left(\hat{H}^{-1}(q) \left(\hat{f}^{-1}(y(k)) - \hat{G}(q)\, \hat{u}(k) \right) \right)^2 \tag{19}$$

vi. Until all the candidate values have been tested, back to step (ii). Otherwise, the values of S, J, $G(q)$ and $f(\cdot)$ are supposed to be the ones for which $\mathcal{C}$ is minimum.

Furthermore, note in Figure 4 that a test signal $d(k)$ is introduced into the set-point. Although external interferences are highly undesirable, the test signal guarantees sufficiently informative experiments. A well-known result from the closed-loop identification literature (Ljung, 1999) is that prediction error approach is not consistent if the data have been collected exclusively under feedback. In fact, the variance on the parameter estimate increases with disturbances and decreases the higher $d(k)$ is.

5. SIMULATIONS

To verify the applicability of the friction and process joint identification algorithm, the process loop in Figure 4 is simulated with a PI controller $C(q)$, a process dynamics reproduced by a continuous linear dynamic model $G(s)$ followed by a nonlinear block $f(w(k))$ and a disturbance $v(k)$ given by:

$$C(q) = \frac{0.5\left(1 - 0.5q^{-1}\right)}{\left(1 - q^{-1}\right)}$$

$$G(s) = \frac{5}{(0.5s+1)(s+1)(10s+1)}$$

$$y(k) = f\left(w(k)\right) = \frac{w(k)}{\sqrt{0.1 + 0.9w^2(k)}}$$

$$v(k) = \frac{\rho}{1 - 2.65q^{-1} + 2.335q^{-2} - 0.684q^{-3}} e(k)$$

The simulated friction model parameters are $S = 10\%$ and $J = 2\%$. The algorithm is tested in two distinct situations: low and high disturbances. In the first case, ρ is adjusted so that the disturbance level in $y(k)$ is 1.44% (in variance), while in the high disturbance scenario $v(k)$ provides a ratio of 12.5%.

A randomly switched multi-level signal, GMN (see Zhu, 2001), with average switch time of 25 sampling intervals and amplitude uniformly distributed between $[-0.15, 0.15]$ is applied in $d(k)$. The set-point $r(k)$ is fixed in 0.75. The input-output data of the high disturbance situation, as well as the excitation signal are shown in Figure 7.

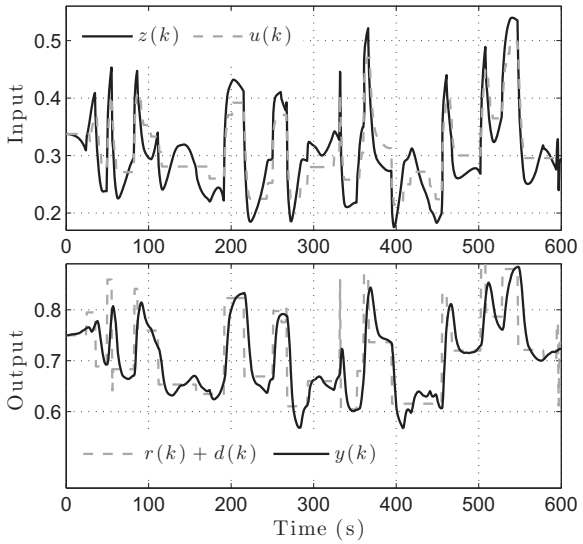

Fig. 7. Input-output data and external test signal of the high disturbance simulation.

The friction and process model parameters are estimated using 600 samples and a 1s sampling period. From (18) one has $\max(S) = 35\%$. A set of candidate values of the pair (S,J) is generated with a resolution of 1% and the process model was estimated using: $m = p = 3$, $r = 35$, $n_c = 0$, $n_d = 6$ and $l = 3$.

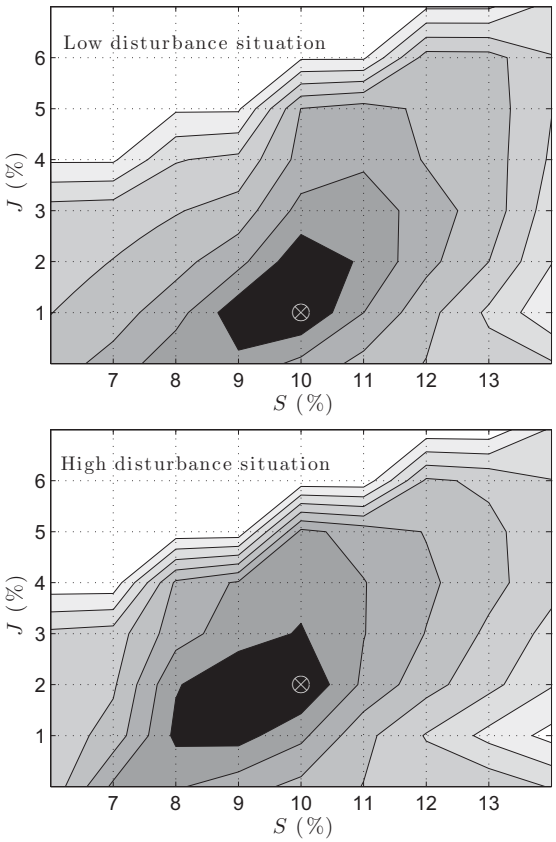

Fig. 8. Level curves of the prediction error $\mathcal{C}$.

The behavior of the prediction error $\mathcal{C}$, in both disturbance situations, is shown in Figure 8. Darker locations indicate lower prediction errors and the symbol "$\otimes$" indicates the minimum. In both disturbance situations, the parameter S is exactly estimated.

On the other hand, $\hat{J} = 1\%$ and 2% for the low and high disturbance scenarios, respectively. The slight misfit obtained in lower disturbance situation has two reasons: (1) the influence of the parameter S is prominent if compared to J and (2) the occurences of slip-jumps in the low disturbance simulation is minor (21 slip-jumps against 26 provided by the major disturbance simulation).

The Nyquist plot of linear block estimate from both disturbances scenarios are compared to the actual one in order to check if the process dynamics were incorporated. From Figure 9 it can be seen that the estimation from the low disturbance dataset provided better results. Therefore, it is clear that the disturbances degrade the accuracy of the identified linear dynamic block.

To get a better insight about frequency domain errors, the Bode plot of the estimates is depicted in Figure 10. Although the Nyquist curves suggest that the dynamic block estimate from the high disturbance simulation data presents a larger misfit, one can see that the errors related to the actual frequency response are acceptable for practical purposes.

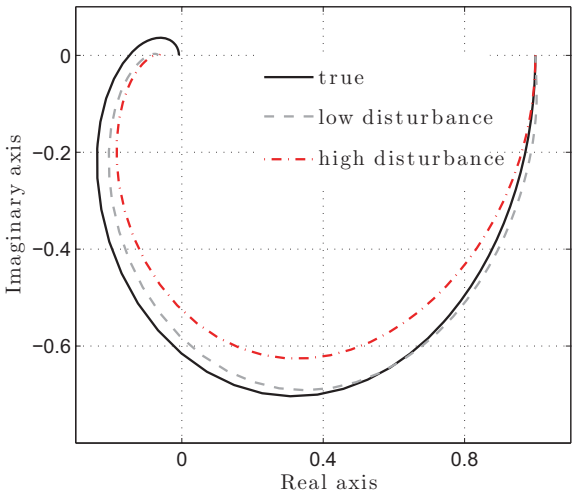

Fig. 9. Nyquist plot of $\hat{G}(q)$ obtained from both disturbance scenarios.

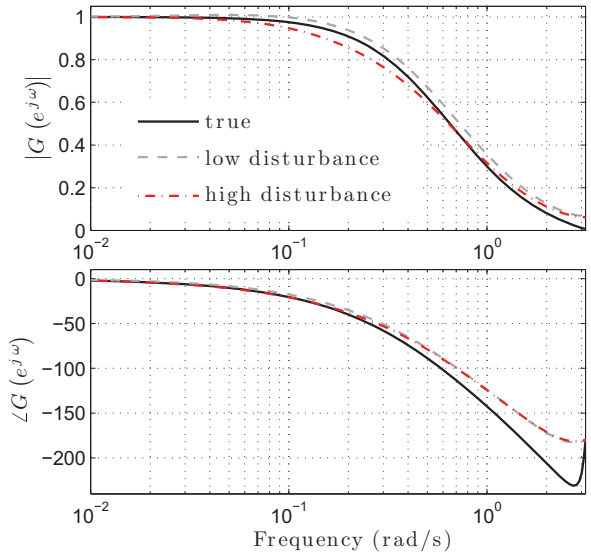

Fig. 10. Bode plot of the estimated dynamic models.

Finally, the nonlinear block fit is investigated. The true process nonlinearity and the estimates from low and high disturbance scenarios, denoted as $\hat{f}_{(low)}(\cdot)$ and $\hat{f}_{(high)}(\cdot)$, are presented in Figure 11. Despite adopting a parameterization different from the cubic splines during the simulations, the process nonlinearity is accurately estimated in both disturbance conditions.

Comparing the results achieved in each of the disturbance situations, one can see that the process steady state curve fit is better when the disturbance level is lower. Nevertheless, the estimation performance deterioration is slight, in spite of the substantial increase (almost 10 times higher) in the disturbance level.

6. CONCLUSIONS

The results provided by the simulated example suggests that the proposed procedure that jontly identifies the

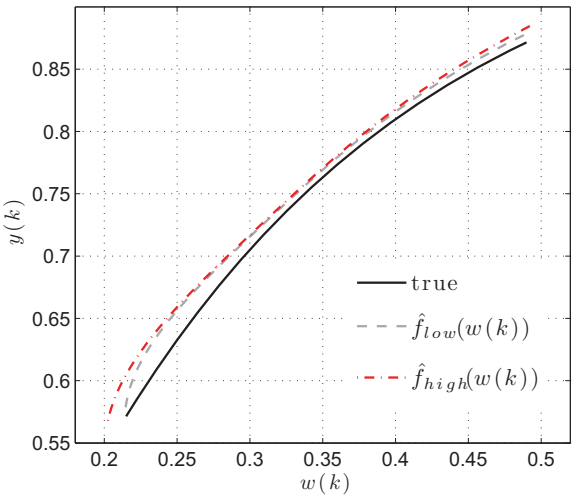

Fig. 11. Actual and estimated process nonlinearity.

friction and the nonlinear process model parameters is promising.

Moreover, the estimation results indicate that the GMN test signal is suitable for the process model identification. On the other hand, this excitation can not be adjusted in order to control the ocurrences of slip jumps. Thus, the GMN is insufficient to guarantee accurate estimates of the parameter J. An alternative to deal with this drawback is to combine a multi-level randon noise with a staircase excitation.

Another aspect that shoud be emphasized is that, when the process nonlinearity is severe, the Wiener model can be used to develop nonlinear controllers, such as gain schedule strategies.

Results of the procedure proposed here applied to industrial data is under development.

Abstract: The predictability of a control-loop behavior beyond its control horizon is an unambiguous indication of loop malfunctioning. Based on the dynamic complexity of the error residual time series the permutation entropy is proposed to define a sensitive index for performance monitoring using data from close-loop operation. A generic framework to understand and quantify the distinctive increase in predictability of the controller error resulting from ill-tuning, sensor errors and actuator faults using a entropy-like index is presented. The dynamic complexity of a well-performing control loop should correspond to the maximum entropy. As loop performance degrades the entropy of its residual time series decreases and any loss of dynamic complexity in the control system gives rise to an increase of the predictability of the control error time series. Results obtained using the proposed performance index along with its confidence interval for industrial data sets are presented to discuss the influence of the sample size, control horizon, and variance estimation in the assessment of close-loop performance.

Keywords: Control-loop performance; Monitoring; Permutation entropy; Fault detection and diagnosis; Error predictability; Ordinal patterns; Time-series analysis.

1. INTRODUCTION

Control loops implementing a hierarchy of functions for process regulation and optimization are the cornerstone of safety and economy in process plants (Thornhill et al., 1999). Many loops are just PID controllers whilst other may be more advanced ones, such as inferential loops, MPCs and real-time optimizers working on top of the regulation layer. It is well known that in most industrial environments the behavior of control loops deteriorate with time due to a number of reasons, e.g. plant-wide perturbations, fouling, utility constraints and raw material variability. Accordingly, process dynamic characteristics change over time and, if not properly maintained, most control loops will perform poorly after some time, which can lead to degraded process operation. In particular, ill-functioning of the regulation layer can easily cancel the benefits of advanced control systems and real-time optimization (Jelali, 2006; AlGhazzawi and Lennox, 2009). With the increasing complexity of control structures and the sheer number of controllers in modern process plants, the automation of performance monitoring tasks is mandatory.

Systematic assessment of SISO control loops can be traced back to the seminal work of Harris (1989) who related the performance of a single-loop control system to the controller errors of a minimum variance controller. The latter, even though it is rather impractical to be implemented, serves as a performance benchmark to provide a lower bound for the variance of the controlled variable. On this basis, the well-known Harris index is defined as the ratio of the variance achievable using minimum variance controller to the variance measured under the current control law (Desborough and Harris, 1992, 1993). As the value of this statistic is reduced then so too does the measured performance of the control system. The key advantage of the Harris approach to control loop monitoring is that only routine close-loop operating data are required to determine the performance of the control system. This fact has made the approach very attractive to industry and it is now applied as a matter of routine by many companies. However, a disadvantage of the Harris index is that it is based on a rather extreme (in terms of cost and energy involved) behaviour and no hints are provided for characterizing the behaviour a well-performing realistic controller based on the control task for which it was designed. Also, it is difficult to pinpoint an informative threshold for the Harris index to differentiate between normal and faulty operation of a control loop.

Based on the insightful concept of control horizon, Thornhill *et al.* (1999) proposed the predictability of the error time series to characterize the performance of a SISO controller. The predictability of a control-loop behaviour beyond its control horizon is an unambiguous indication of loop malfunctioning in biological systems (Li, Ouyang and Richards, 2007). Along this research avenue, Ghraizi *et al*. (2007), proposed a practical index for performance monitoring of a control loop based on the analysis of the predictability of the error time series and emphasizes proper

selection of the control horizon using engineering judgment and the amplitude and frequency of disturbances to which the loop is designed for. To develop ideas further, Martínez and de Prada (2007) resort to ordinal analysis methods of the error time series to define a performance index for performance monitoring based on the permutation entropy.

In this work, the interplay between predictability of controller behaviour and its dynamic complexity for performance monitoring is highlighted by resorting to the residual error time series, which is obtained using a regression model. A generic framework to understand and quantify the distinctive increase in predictability of the controller error resulting from ill-tuning, sensor errors and actuator faults using an entropy-like index is proposed. A well-performing controller should behave so that the sequence of residuals in the error series looks like one generated using *i.i.d.* samples from a random walk and the corresponding dynamic complexity is thus maximum. Accordingly, ordinal patterns in the error residuals will all be equally probable and the corresponding permutation entropy will be then the highest possible.

2. MONITORING METHODOLOGY

2.1 *Predictability analysis*

The performance-monitoring concept revolves around the idea of predictability of controller behaviour beyond a chosen horizon *b*. If a control loop exhibits "good" performance, it should be able to cancel any disturbance entering the loop up to present time *t*, or follow a set point change correctly, after some sensible time interval *b* (expressed in terms of sampling periods). Then, it can be argue that, as from time *t+b* onwards, the error time series cannot be distinguished from a random walk stochastic process so that it cannot be predicted at all using information up to time instant *t* (see Fig. 1 for details). Nevertheless, over the control horizon *b*, the controller behaviour is fully predictable since it corresponds to its own control policy built-in by design. By contrast, error time series of a control loop exhibiting "poor" performance, will show patterns of behaviour (oscillations, steady-state errors, etc.) which can be predicted after time instant *t+b* using present and past measurements.

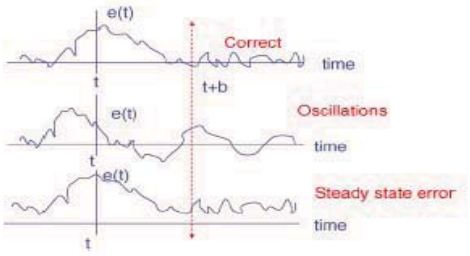

Fig. 1. Error patterns and their predictability

The most sensitive approach to detect patterns of predictability in the time series is analyzing the time series of error residuals $r(t)$ which are obtained using an inductive model to predict future errors.

Let's denote by $e(t)$ the controller error defined as

$$e(t) = \omega(t) - y(t) \tag{1}$$

Where $\omega(t)$ stands for the desired set-point at any time t, and $\hat{e}(t)$ stands for the prediction of such error based on past values of the controller error. The difference between the actual and predicted controller errors is the residue *r(t)* whose time series has a dynamic complexity closely related to the predictability patterns in the controller error time series

$$r(t) = e(t) - \hat{e}(t) \tag{2}$$

The error prediction $\hat{e}(t)$ can be obtained in different ways, but the easiest alternative is using the regression model

$$\begin{aligned}\hat{e}(t+b) = e_o + e_1(t) + e_2(t-2) + e_3(t-3)....\\ + e_m(t-m+1)\end{aligned} \tag{3}$$

Where time indices refer to sampling periods, *m* is the model order and a_i is the unknown parameters, which are fitted using a dataset of size *n* by means of the least-square regression:

$$[a_0, a_1, ..., a_m]^T = (X^T X)^{-1} X^T Y \tag{4}$$

Where

$$X = \begin{bmatrix} 1 & e(1) & e(2) & \cdots & e(m) \\ 1 & e(2) & e(3) & \dots & e(m+1) \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & e(n-b-m+1) & \cdots & \cdots & e(n-b) \end{bmatrix} \tag{5}$$

And

$$Y = \left[e(m+b)\ e(m+b+1) \cdots e(n)\right]^T \tag{6}$$

It is worth noting that for a well-performing controller in a given time interval the sequence of error residuals is a chaotic, completely random, and non-stationary stochastic process exhibiting maximum dynamic complexity. The reader is referred to the work of Peng et al. (2009) for an interesting discussion on the meaning of regularity and dynamic complexity in physiologic time series from highly controlled biological systems. To quantify the dynamic complexity of residuals there are several options.

In a previous work, the authors, Ghraizi *et al*. (2007), used a performance index based on the ratio between the variance of the residuals and the variance of the errors:

$$PI = \frac{\sigma_r^2}{\sigma_e^2} \tag{7}$$

Assuming that in a perfectly predictable loop the variance of

the residual would be zero, while non-predictable random walk would give a variance similar to the loop error, this expression would provide an index ranging from zero to one that will measure the performance of the controller. In order to obtain a confidence interval of the index the following analysis can be performed:
It is known that the following ratio

$$\frac{(n-1)\hat{\sigma}^2}{\sigma^2} \tag{8}$$

between the estimated and real variance for an stochastic process must follow a χ^2 distribution with n-1 degrees of freedom. Applying this line of reasoning to the residuals and the controller errors and dividing them, we can obtain:

$$\frac{\sigma_r^2\hat{\sigma}_e^2}{\sigma_e^2\hat{\sigma}_r^2} \tag{9}$$

Which will follow a F-distribution with n-1,n-1 degrees of freedom. Hence:

$$\begin{aligned} &P(F_{1-0.5\alpha,n-1} \le \frac{\hat{\sigma}_e^2\sigma_r^2}{\sigma_e^2\hat{\sigma}_r^2} \le F_{0.5\alpha,n-1}) = 1-\alpha \\ &P(\frac{\hat{\sigma}_r^2}{\hat{\sigma}_e^2}F_{0.5\alpha,n-1}^{-1} \le \frac{\sigma_r^2}{\sigma_e^2} \le \frac{\hat{\sigma}_r^2}{\hat{\sigma}_e^2}F_{0.5\alpha,n-1}) = 1-\alpha \end{aligned} \tag{10}$$

Will can be used to compute the 100(1-α) % interval of confidence for the *PI* index defined in (7).

In practice, when this index is computed, large confidence interval appears sometimes, mainly when loop performance degrades, which reduces the interest in the above method. An alternative not based on statistical assumptions, which are always difficult to verify, would be desirable. In this regard, an appealing and sound choice is resorting to an entropy-like index based on ordinal patterns of the residual time series.

2.2 *Residual order patterns*

The complexity of a residual time series can be quantified by means of its symbolic dynamics. A new permutation method was proposed by (Bandt and Pompe, 2002; Bandt, 2005) to map a continuous time series onto a symbolic sequence; the statistics descriptive of the dynamic complexity of the symbolic time series is called permutation entropy. Given a data set for the scalar residual time series $r(t), t = 1,....,n$, the local order of the series can be characterized by patterns in vectors $\Re(t)$ ensembled as follows

$$\Re(t) = [r(t), r(t+\ell),...r(t+(\kappa-1)\ell))] \tag{11}$$

where κ is the embedded dimension parameter and ℓ is the lag parameter (here $\ell = 1$). Then entries in each $\Re(t)$ are arranged in increasing order which allows assigning to it one out of the possible order patterns. For κ different numbers, there will be $\kappa!$ possible order patterns π, which are also called permutations. In Fig. 2 the six order patterns for $\kappa = 3$ are shown. Let $f(\pi)$ denote the frequency of permutation π in the data set whereas $\rho(\pi) = f(\pi)/(n-(\kappa-1)\ell)$ is the relative frequency. For a perfectly working controller the relative frequencies should all be close to $1/\kappa!$

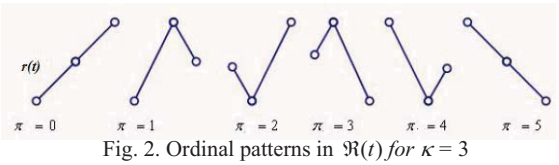

Fig. 2. Ordinal patterns in $\Re(t)$ *for* $\kappa = 3$

2.3 *Permutation entropy and performance monitoring*

The local permutation entropy of order κ for the error residual time series is defined as

$$H_\kappa = -\sum_{\pi=1}^{\kappa!}\rho(\pi)\ln\rho(\pi) \tag{12}$$

The largest possible value for the permutation entropy will correspond to the perfectly working controller where all $\kappa!$ permutations are equally probable which coincides with a residual time series of maximum complexity where the permutation entropy is ln $\kappa!$

Permutation entropy depends on the selection of κ. When κ is too small a value (say less than 3), the scheme will not work, since there are only very few distinct states for characterizing the control system behavior. For too large values of κ (greater than 6), the number $\kappa!$ of permutations which can appear in the time series can result in computer memory problems, due to the large number of data points that need to be examined. In the present work, only values of $\kappa = 3$, 4 or 5 will be used.

For loop monitoring, the permutation entropy of the residual time series is obtained from a sample where the total number of patterns counted is n and the tally number for the *ith* pattern in the sample is denoted by f_i

$$\hat{H}_\kappa^n = -\sum_{i=1}^{\kappa!}\left(\frac{f_i}{n}\ln\frac{f_i}{n}\right) \tag{13}$$

The corresponding variance for this sample estimation of the permutation entropy is (see Moddemeijer, 1989, for details)

$$Var\left(\hat{H}_\kappa^n\right) = \frac{1}{n}\left(\sum_{i=1}^{\kappa!}\frac{f_i}{n}\ln^2\frac{f_i}{n} - \left(\frac{f_i}{n}\ln\frac{f_i}{n}\right)^2\right) \tag{14}$$

Based on equations (13) and (14) and a sample of size n, the following performance index is proposed

$$PI = \frac{\hat{H}_\kappa^n}{\ln\kappa!}, \kappa = 3,4,... \tag{15}$$

Since ln$\kappa!$ is a constant, the variance for the sample estimation of the performance index can be written as

$$Var(PI) = \frac{Var\left(\hat{H}_\kappa^n\right)}{\ln\kappa!}, \kappa = 3,4,... \tag{16}$$

The highest value of *PI* is one, which means the error residual time series is complete random and is its dynamics is very complex; the smallest possible value of *PI* is zero, which

means the error residual time series is highly regular.

Eq. (14) is very important for the following reasons: it is possible to make a very reliable characterization of the variance of a sample-based estimation of the performance index *PI* in Eq. (15). For a well-performing control loop, since the probability for ordinal patterns are all the same, after elementary algebra steps in Eq. (14) an *exact* measure of the variance for the performance index is obtained

$$\frac{\left[\ln\left(\frac{1}{\kappa!}\right)\right]^2(\kappa!-1)}{\ln\kappa!\; n\;\kappa!} \qquad (17)$$

As can be readily calculated, this variance for a properly working loop is very small even for small sample sizes. For example, for n=1000 and κ=3, the variance of *PI* is ≅0.00149 for a perfectly working controller. For a much smaller sample size such n=100 is still rather small (≅0.0149).

To compute a 100(1-α) % confidence interval for the *PI* index estimated through Eq. (15), the Student's *t*-distribution is assumed so that the sample variance in Eq. (16) is used to define upper/lower limits in the usual way as follows

$$\pm t_{1-\alpha/2,n-1}\sqrt{\frac{Var(PI)}{n}} \qquad (18)$$

where α defines the chosen level of confidence.

3. RESULTS

In order to show the applicability of the proposed method, several data sets from an industrial site have been considered. They correspond to routine plant data of a set of typical control loops for pressure, flow, etc. The first one is displayed in Fig.3 and contains 9000 samples of the controlled and manipulated variables as well as the set point of a pressure control loop.

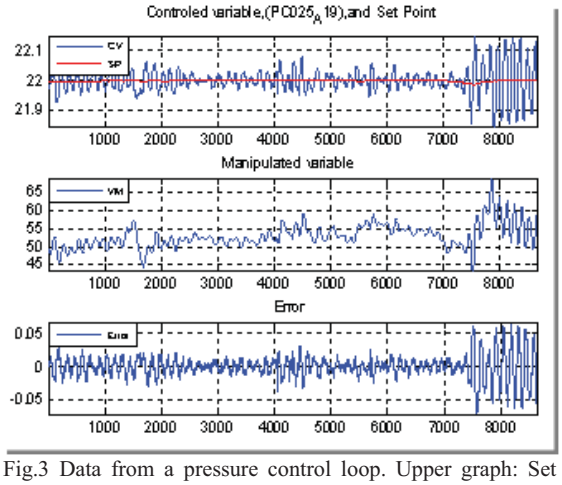

Fig.3 Data from a pressure control loop. Upper graph: Set point (in red) and gauge pressure. Middle graph: control valve signal. Bottom graph: error between set point and pressure readings.

Despite the fact that pressure readings stand close to the set point, the loop experiments an oscillatory behavior, likely as result of a too tight tuning. This can be better observed in a close-up to the data, as the one shown in Fig.4.

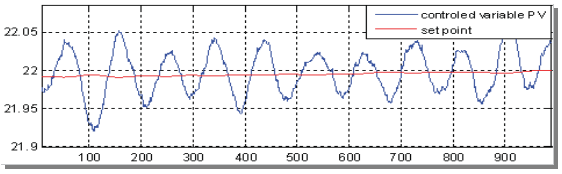

Fig.4. A detailed view of the first 1000 data of the time evolution of pressure and its set point for the example data set shown in Fig.3.

Results obtained from the application of the proposed method to pressure loop are discussed next. Fig.5. displays the actual error and its predictions computed from the expression (3). As can be seen, predictatility is significantly high, as one could expect in a badly tuned control loop whereas residuals are small. The residual time series is displayed in the upper part of Fig. 6, exhibiting a certain regularity, whereas in the bottom part the values of the proposed performance index (15) computed at regular time intervals every 120 data are shown for the case κ = 3 and b = 12.

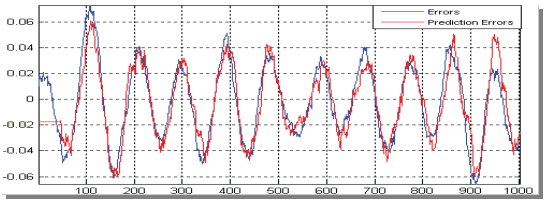

Fig.5. A detailed view of the errors and its predictions (in red) for the first 1000 data using prediction formula (3).

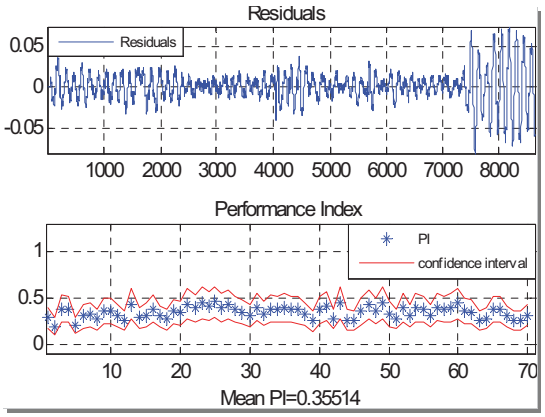

Fig.6. Upper graph: Residuals of the predictions computed with expression (2) for the example of Fig.3. Lower graph: Performance index computed from (16).

As can be seen, in this example, sample estimation the performance index have an average value of 0.35, which is an indication of poor performance of the pressure loop. For the sake of comparison, the *PI* computed from (7) is displayed in Fig.7. Even though consistent results are obtained, but the

confident limits rise up to 1 which creates a great deal of uncertainty in the estimation of this performance index.

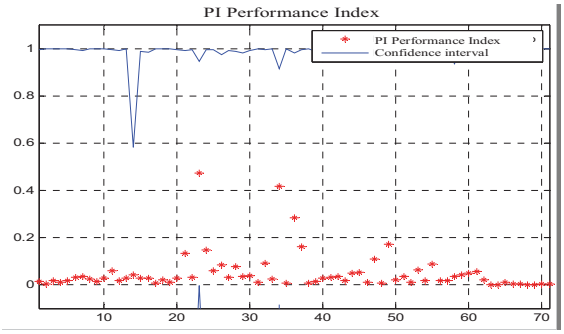

Fig.7. Performance index (in red) computing with expression (7) for the example of Fig.3. Blue line gives the upper confidence limit based on Eqs. (9) and (10).

Data from a second case study are given in Fig. 8. This time data correspond to a flow control loop that is the slave in a cascade configuration. 16,000 data poins are collected and, as can be seen, the loop behaviour is quite good, with fine set point tracking and moderate control signal changes, except in the range for data poins from 12,000 to 13,000, where extreme values of the set point from the master loop lead to saturation of the manipulated variable.

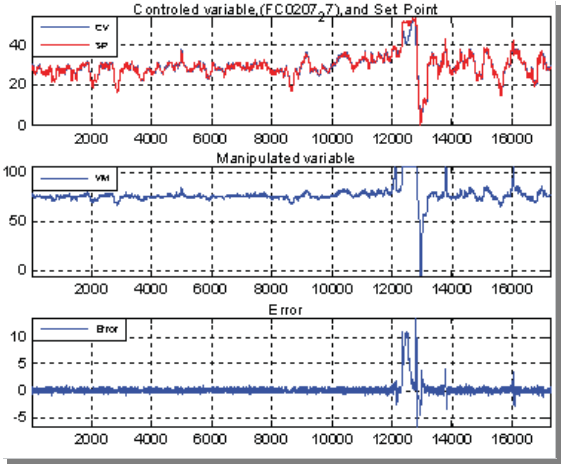

Fig.8. Data from a slave flow control loop. Upper graph: Set point (in red) and flow readins. Middle graph: control valve signal. Bottom graph: error between set point and actual flow.

As can be seen in the close-up displayed in Fig.9, there is a good following of the set point and the predictions of the errors computed with the expression (3) differ from the actual errors, so that the residuals (2), displayed in Fig.10, approach to a random walk, as expected in a loop with good behaviour.

The performance index (15) has been computed using the values $\kappa = 3$ and $b = 12$, at regular time intervals that include 120 data points. The numerical values displayed on the bottom of Fig.10 give regular values around 0.82 that is a reasonable value for this entropy-like index when all patterns are almost equiprobable.

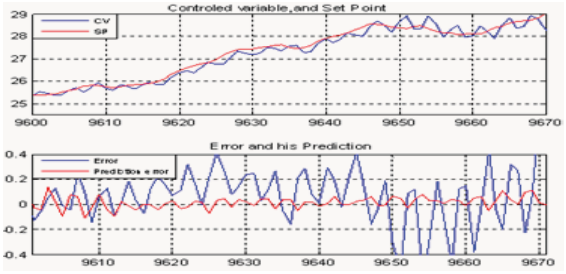

Fig.9. Upper graph: A close-up of data of the time evolution of flow and its set point (in red) for the example of Fig.8. Lower graph: A detailed view of the errors and its predictions (in red) for this range of data using prediction formula (3).

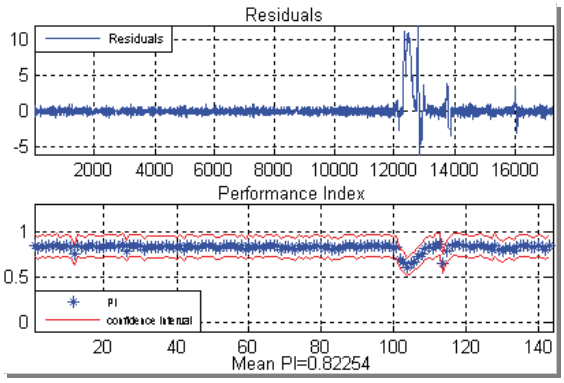

Fig.10. Upper graph: Residuals of the predictions computed with expression (2) for the example of Fig.8. Lower graph: Performance index computed from (16).

Nevertheless, in a set of intervals from data 12,000 on, where the manipulated variable is saturated, the predictions of the errors can be made very well, as can be observed in Fig.11, where the errors and its predictions computed with formula (3) are given.

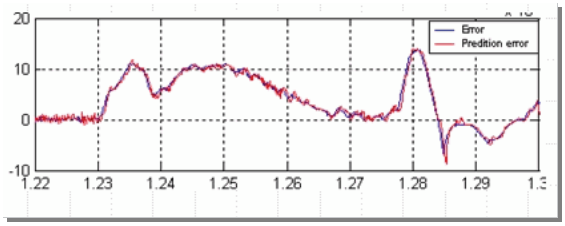

Fig.11. A detailed view of the errors and its predictions (in red) for a range of data above sample 12,000 of the example of Fig.8, using prediction formula (3).

In this case, the residuals are small and do not follow a random walk stochastic process, as can be seen in the corresponding range of variation shown in Fig.10. Accordingly, the *PI* decreases, indicating performance degradation of the loop in this portion of the data set.

For comparison, the *PI* computed with expression (7) and blocks of about 1000 data is given in Fig.12. As we can see, the index is between 0.75 and 0.9 giving consistent indications about the goodness of the loop behaviour, but at

the time intervals where the saturation occurs it drops to 0.1, 0.3 as expected. Nevertheless, the confidence bands increases at this precise times, decreasing the certitude of the diagnosis.

A final test was made to compare previous results with the ones provided by the Harris index for this case study, which are displayed in Fig.13. The values for the Harris index range from 0.3 to 0.5 for most samples, indicating that a margin for improvement exists in relation to the best possible linear controller -the minimum variance one- but it is worth noting that this index does not provide a direct measurement of the loop performance. Notice also that the index drops to 0 and 0.1 in the critical range when the saturation of the manipulated variable occurs.

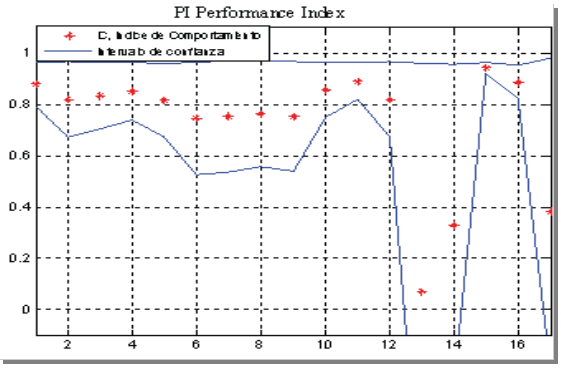

Fig. 12. Performance index (in red) computed with expression (7) for the example of Fig.8. Blue line gives the upper confidence limit.

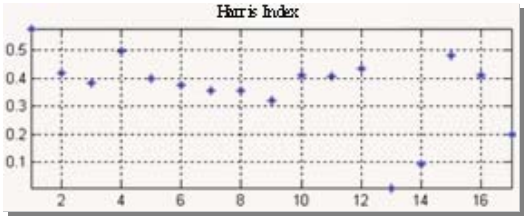

Fig. 13. Sample estimation of the Harris index for the example in Fig. 8 computed from batches of 1,000 data points.

4. CONCLUSIONS

A new index for performance assessment of control loops using normal operating plant data has been proposed. It combines the idea of predictability of the controller error at a point in time beyond the desired settling time of the loop, with an analysis of the corresponding sequence of prediction residuals based on ordinal methods along with the concept of local permutation entropy. The main advantage of the Performance Index defined in this way is the fact that no statistical assumptions are made on the residuals, which allows for a crisp interpretation of sample estimation of the performance index. Moreover, the entropy-like index is easy to compute and can be applied to single isolated loops as well as to cascades or other control configurations including model predictive controllers. For industrial data sets, the proposed *PI* has provides consistent results.

To highlight several advantages some comparisons were made with other indices such the Harris index and a previous *PI* based on the error predictability idea. The proposed method based on the permutation entropy can be applied in real time with minimum computational costs which opens the possibility of automatic supervision of hundreds of control loops of a typical process plant. Also, linking information content with predictability of error residuals is a novel idea for loop monitoring using dynamic complexity.

Abstract: Minimum variance (MV) benchmark is useful for identifying variance reduction opportunities in industrial control systems. During the past two decades, MV benchmarks for single-input single-output (SISO) and multi-input multi-output (MIMO) systems have been proposed. These MV benchmarks do not account for the structure of the decentralized or multi-loop controllers, which are used almost exclusively for regulation purposes in process industries. Due to this drawback, the available MV benchmarks can lead to incorrect conclusions regarding the performance of decentralized controllers. This paper aims to fill this gap. For performance assessment of decentralized controllers on a loop-by-loop basis, we present a simple modification of the available MV benchmark for SISO systems. For simultaneous performance assessment of all loops, we present a method for computing a tight lower bound on the achievable output variance. In the latter approach, the non-convexity of the resulting optimization problem is handled using sums of squares programming. The usefulness of the proposed benchmarks is evaluated using examples drawn from the literature.

1. INTRODUCTION

The performance of a well-designed control system can degrade over time due to changes in operating conditions and disturbance dynamics. Controller performance assessment is useful for identifying the opportunities for performance improvement of industrial controllers. Among the various available methods (Qin, 1998; Jelali, 2006), minimum variance (MV) benchmarking is one of the most promising methods for controller performance assessment. In this approach, the controller is deemed to provide satisfactory performance, if MV benchmark (ratio of least achievable and observed output variances) is close to 1. On the other hand, reduction in output variance is considered to be feasible through controller retuning, when the MV benchmark is significantly lower than 1.

The origin of MV benchmark can be traced back to Åström (1970), who demonstrated that the achievable output variance for a single-input single-output (SISO) process under feedback control depends on the first few impulse response coefficients of the disturbance model. Harris (1989) showed that with *a priori* knowledge of time delay, MV benchmark can be estimated using closed loop operating data and established it as a tool for performance assessment of SISO systems. Using the concept of interactor matrices, Harris et al. (1996) and Huang et al. (1997) proposed MV benchmark for multi-input multi-output (MIMO) systems.

This paper focusses on performance assessment of decentralized or multi-loop controllers, which are used almost exclusively for regulation purposes in process industries. Though useful, the available MV benchmarks for SISO and MIMO processes show limitations, when applied to processes under decentralized control. The conventional approaches for performance assessment of decentralized controllers include (see *e.g.* (Harris et al., 1996) and (Huang et al., 1997) for examples):

(1) *Loop by loop analysis*: The performance of individual loops is assessed independent of each other using MV benchmark for SISO processes.
(2) *Simultaneous analysis*: The performance of all loops is assessed simultaneously using MV benchmark for MIMO processes.

The MV benchmark for SISO processes assumes that the loop under consideration is being operated in isolation from the rest of the process and thus inherently views the process as being diagonal; see Figure 1. Due to this assumption, it may be possible to improve the performance of the existing controller further than indicated by the MV benchmark; see Section 3 for details. On the other hand, MV benchmark for MIMO processes ignores the diagonal structure of the decentralized controller and thus has more degrees of freedom for variance minimization than are available in the actual controller. Using a simple 2×2 process, we demonstrate in Section 4 that the least output variance that can be achieved using a diagonal controller can be four times higher than that can be achieved using a full multivariable controller. In summary, ignoring the controller structure can lead to incorrect conclusions regarding performance assessment of decentralized controllers.

The derivation of an approach for MV benchmarking of decentralized controllers requires characterization of the

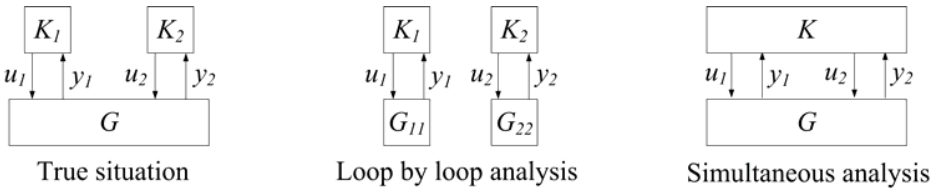

Fig. 1. Insufficiency of available MV benchmarks for performance assessment of decentralized controllers

least achievable output variance and its subsequent estimation from closed-loop data. This paper mainly focusses on the first issue. We first propose an MV benchmark for loop-by-loop analysis, where the presence of other loops is accounted for. The proposed result requires a small modification of the existing MV benchmark for SISO processes. It is further shown that the modified MV benchmark for loop-by-loop analysis can be directly estimated from closed-loop data with *a priori* knowledge of the delays of the different elements of the process model. An interesting insight is that for processes under decentralized control, the pre-whitening of output data using algorithms such as filtering and correlation (FCOR) algorithm (Huang and Shah, 1999) does not necessarily provide the first few impulse response coefficients of the disturbance model, as is traditionally believed.

The derivation of MV benchmark for simultaneous analysis of decentralized controller is more challenging. This happens as the optimization problem involving minimization of output variance becomes non-convex, once the diagonal structure is imposed on the controller (Sourlas and Manousiouthakis, 1995; Rotkowitz and Lall, 2006). With this difficulty, one may alternately look for tight upper and lower bounds on the least achievable output variance using decentralized controllers. Clearly, any suboptimal tuning strategy for the decentralized controller provides an upper bound on the least achievable output variance. Some approaches for finding upper bounds on least achievable output variance have been reported using non-convex optimization (Ko and Edgar, 1998; Jain and Lakshminarayanan, 2007) or by utilizing the structure of the optimization problem (Yuz and Goodwin, 2003; Kariwala et al., 2005). Recently, Kariwala (2007) addressed the more difficult problem involving derivation of a tight lower bound on the least achievable output variance, where an explicit bound is proposed by considering those impulse response coefficients of the closed-loop transfer function between disturbances and outputs, which depend linearly on the controller parameters. In general, however, the lower bound proposed in (Kariwala, 2007) can be conservative due to the neglected impulse response coefficients.

In this paper, we show that though nonlinear, the impulse response coefficients of the closed-loop transfer function between disturbances and outputs can be represented as polynomials in unknown controller parameters. Subsequently, the non-convex optimization problem related to the minimization of output variance is solved using sums of squares (SOS) programming (Parillo, 2000). This result is further extended to find a lower bound on the least achievable output variance, when the individual subcontrollers of the decentralized controller are restricted to be of proportional-integral-derivative (PID) type. The estimation of these lower bounds is difficult from closed-loop data only and the knowledge of process model is required. Nevertheless, the derivation of lower bound on the least achievable output variance can itself be seen as a major step towards systematic performance assessment of decentralized controllers.

2. PROBLEM FORMULATION

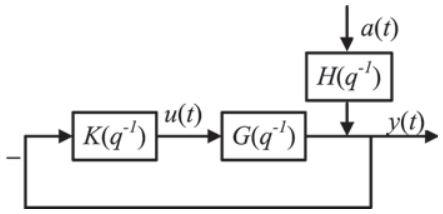

Fig. 2. Block diagram of closed-loop system

We consider the closed-loop system shown in Figure 2. For this system, we denote $G(q^{-1})$ and $H(q^{-1})$ as the process and disturbance models, respectively, such that

$$y(t) = G(q^{-1})\,u(t) + H(q^{-1})\,a(t) \tag{1}$$

Here, $y(t), u(t)$ and $a(t)$ are controlled outputs, manipulated variables and disturbances, respectively. We make the following simplifying assumptions:

(1) $G(q^{-1})$ and $H(q^{-1})$ are stable, causal transfer matrices, contain no zeros on or outside the unit circle except at infinity (due to time delays), and are square having dimensions $n_y \times n_y$.
(2) $a(t)$ is a random noise sequence with unit variance.

When $H(q^{-1})$ contains zeros outside the unit circle, these zeros can be factored through an all pass factor without affecting the noise spectrum (Huang and Shah, 1999). Further, there is no loss of generality in assuming that the system is affected by noise having unit variance, as the disturbance model can always be scaled to satisfy this assumption. For notational simplicity, we drop the arguments q^{-1} and t in the subsequent discussion.

Our objective is to find the least achievable value of $\mathrm{Var}(y)$ with respect to the controller K, *i.e.*

$$J_{\mathrm{decen}} = \min_{K} \mathrm{Var}(y) = \min_{K} E[\mathrm{tr}(y\,y^T)] \tag{2}$$

where K is assumed to have a diagonal structure, *i.e.* $K = \mathrm{diag}(K_1, K_2, \cdots, K_{n_y})$. In (2), $E(\cdot)$ and $\mathrm{tr}(\cdot)$ denote the expectation and trace operators, respectively. The pairings are considered to be selected on the diagonal elements of G.

Based on (2), the MV benchmark for decentralized controller can be defined as

$$\eta_{\text{decen}} = \frac{J_{\text{decen}}}{E[\text{tr}(y\,y^T)]} \tag{3}$$

where $E[\text{tr}(y\,y^T)]$ is the observed output variance.

A related problem involves finding the least achievable variance of the ith output, *i.e.*

$$J_{i,\text{decen}} = \min_{K_i} E[\text{tr}(y_i\,y_i^T)] \tag{4}$$

Similar to (3), the MV benchmark for the ith output can be defined as

$$\eta_{i,\text{decen}} = \frac{J_{i,\text{decen}}}{E[\text{tr}(y_i\,y_i^T)]} \tag{5}$$

where $E[\text{tr}(y_i\,y_i^T)]$ is the observed variance of the ith output.

3. LOOP-BY-LOOP ANALYSIS

We first consider performance assessment of the decentralized controller on a loop-by-loop basis. For clarity of presentation, we limit the discussion to 2×2 systems. The result can be generalized to $n_y \times n_y$ systems using block-partitioning of G and H. We have

$$y_1 = G_{11}\,u_1 + G_{12}\,u_2 + H_1\,a \tag{6}$$

$$y_2 = G_{21}\,u_1 + G_{22}\,u_2 + H_2\,a \tag{7}$$

The time delay associated with G_{ij} is denoted as d_{ij}, *i.e.*

$$G_{ij} = q^{-d_{ij}}\bar{G}_{ij} \tag{8}$$

where $\bar{G}_{ij}$ denotes the invertible part of G_{ij}. Without loss of generality, we consider that the objective is to characterize the least achievable variance of y_1.

3.1 Conventional approach

The traditional approach for loop-by-loop analysis involves using the MV benchmark for SISO systems. Here, H_1 is decomposed using Diophantine identity as

$$H_1 = F_1 + q^{-d_{11}}R_1 \tag{9}$$

Then, the least achievable variance of y_1 is taken as (Åström, 1970; Harris, 1989)

$$J_1 = \min_{K_1} E[\text{tr}(y_1\,y_1^T)] = \|F_1\|_2^2 \tag{10}$$

where $\|\cdot\|_2$ denotes the $\mathcal{H}_2$-norm. The MV benchmark for individual outputs is defined similar to (5). An inherent assumption in the derivation of (10) is that $u_2 = 0$ at all times or in other words, the first loop is being operated in isolation from the rest of the process. We next demonstrate that when the presence of other loops is accounted for, the first d_{11} elements of H_1 are not necessarily feedback invariant and thus the least achievable variance of y_1 can be lower than J_1 in (10).

3.2 Modified MV benchmark

Consider that the second loop is closed with $u_2 = -K_2 y_2$. Under partially closed loop conditions, we have (Skogestad and Postlethwaite, 2005)

$$y_1 = P_{11}\,u_1 + P_{d1}\,a \tag{11}$$

where

$$P_{11} = G_{11} - \frac{G_{12}K_2G_{21}}{1+G_{22}K_2},\; P_{d1} = H_1 - \frac{G_{12}K_2H_2}{1+G_{22}K_2} \tag{12}$$

Since $1/(1+G_{22}K_2)$ and K_2 are rational and invertible, it follows that the delay associated with P_{11} or the effective delay of the first loop is

$$d_1^{'} = \min(d_{11}, d_{12}+d_{21}) \tag{13}$$

Now, let P_{d1} be decomposed using Diophantine identity as

$$P_{d1} = F_1^{'} + q^{-d_1^{'}}R_1^{'} \tag{14}$$

Using (11) and (14), it follows that

$$y_1 = F_1^{'}\,a + q^{-d_1^{'}}(\bar{P}_{11}\,u_1 + R_1^{'}\,a) \tag{15}$$

where $P_{11} = q^{-d_1^{'}}\bar{P}_{11}$ and $\bar{P}_{11}$ denotes the invertible part of P_{11}. Since the first term in (15) cannot be affected by u_1 (invariant of K_1), it follows that

$$J_{1,\text{decen}} = \min_{K_1} E[\text{tr}(y_1\,y_1^T)] = \|F_1^{'}\|_2^2 \tag{16}$$

Note that $\|F_1^{'}\|_2^2$ represents the least achievable variance of y_1, when the presence of second loop is accounted for and can be used readily for performance assessment of decentralized controllers on a loop-by-loop basis.

Remark 1. In general, $J_{1,\text{decen}}$ may depend on K_2. This dependance, however, has no bearing on the loop-by-loop performance assessment, where the objective is to find the least achievable variance of y_i through tuning of K_i. If both controllers are allowed to be tuned simultaneously, using similar analysis as used in this section earlier, it can be shown that the first $d_1^{''} = \min(d_{11}, d_{12})$ impulse response coefficients of H_1 are feedback invariant and thus

$$\min_{K_1,K_2} E[\text{tr}(y_1\,y_1^T)] = \|F_1^{''}\|_2^2 \tag{17}$$

where $H_1 = F_1^{''} + q^{-d_1^{''}}R_1^{''}$. Note that the bound in (17) is independent of controller type (full multivariable or decentralized).

Though the result in (16) may seem entirely mathematical, a physical reasoning with this result can be associated by considering the block diagram of a 2×2 system shown in Figure 3. Here, u_1 can affect y_1 directly through G_{11}, but also through a parallel path involving G_{12} and G_{21} (shown with thick line in Figure 3). Thus, $d_1^{'} = \min(d_{11}, d_{12}+d_{21})$ represents the delay of the fastest path through which u_1 can affect y_1. In this sense, loop interaction can sometimes be beneficial for reducing output variance.

Example 2. To illustrate the findings of this section, we use the case study of a binary distillation column (Wood and Berry, 1973). The continuous-time model is discretized with a sampling time of 1 minute to get

$$G = \begin{bmatrix} \dfrac{0.744q^{-2}}{1-0.942q^{-1}} & \dfrac{-0.879q^{-4}}{1-0.954q^{-1}} \\ \dfrac{0.579q^{-8}}{1-0.912q^{-1}} & \dfrac{-1.302q^{-4}}{1-0.933q^{-1}} \end{bmatrix} \tag{18}$$

$$H = \begin{bmatrix} \dfrac{0.247q^{-9}}{1-0.935q^{-1}} \\ \dfrac{0.358q^{-4}}{1-0.927q^{-1}} \end{bmatrix} \tag{19}$$

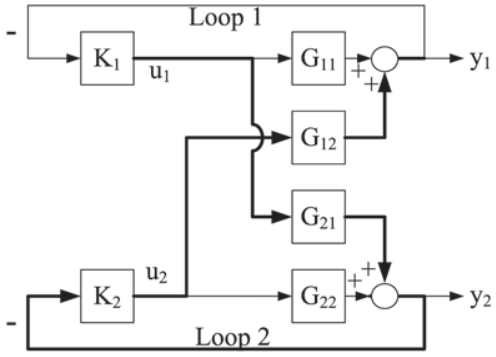

Fig. 3. Presence of parallel path (shown with thick line) from u_1 to y_1 for 2×2 systems

For diagonal pairings, the following decentralized PI controller is tuned using internal model control (IMC) method (Skogestad, 2003)

$$K = \text{diag}\left(\frac{0.652 - 0.571q^{-1}}{1 - q^{-1}}, \frac{-0.124 + 0.115q^{-1}}{1 - q^{-1}}\right) \quad (20)$$

which provides $\text{Var}(y_1) = 0.122$ and $\text{Var}(y_2) = 0.759$. After factoring the time delay of H, the least achievable variances of y_1 and y_2 according to the conventional approach discussed in Section 3.1 are $J_1 = 0.114$ and $J_2 = 0.413$, respectively. Thus, the conventional MV benchmarks for loops 1 and 2 are $\eta_1 = 0.932$ and $\eta_2 = 0.544$, respectively, which indicate that the variance of y_2 can be reduced significantly by re-tuning K_2, but tuning K_1 will not reduce variance of y_1 significantly. Using the modified MV benchmark, we next show that this conclusion is not entirely correct.

We have $d_{11} = 2$, $d_{12} = 4$, $d_{21} = 8$ and $d_{22} = 4$. Thus, $d_1^{'} = \min(d_{11}, d_{12} + d_{21}) = 2$ and $d_2^{'} = \min(d_{22}, d_{12} + d_{21}) = 4$. Since the first $d_2^{'} = d_{22}$ impulse response coefficients of P_{d2} and H_2 are the same, we find that $J_{2,\text{decen}} = J_2 = 0.413$ and $\eta_{2,\text{decen}} = \eta_2 = 0.544$. The first $d_1^{'} = d_{11}$ impulse response coefficients of P_{d1}, however, are different from the corresponding impulse response coefficients of H_1 and we find that $J_{1,\text{decen}} = 0.031$ and $\eta_{1,\text{decen}} = 0.251$. Thus, the modified MV benchmark identifies that the variance of y_1 can be reduced by approximately 4 times through tuning of K_1.

We point out that for this process, the first $d_1^{'}$ impulse response coefficients of P_{d1} and thus $J_{1,\text{decen}}$ depend on K_2. For example, when the gain of K_2 is decreased by a factor of 0.75, $J_{1,\text{decen}}$ increases to 0.037. With this controller tuning the variance of y_1 is 0.126. Thus, we have $\eta_{1,\text{decen}} = 0.293$, which indicates that the variance of y_1 can still be reduced by approximately 3 times.

Remark 3. Although for Example 2, the effective delays for both loops are the same as open-loop delays, *i.e.* $d_1^{'} = d_{11}$ and $d_2^{'} = d_{22}$, this is not true in general. For example, when pairings are chosen on the off-diagonal elements of G in (18), the effective delay for loop 1 is $d_1^{'} = \min(d_{12}, d_{11} + d_{22}) = 6$, which is different from open-loop delay, $d_{12} = 8$.

Remark 4. Based on (11), under closed loop conditions

$$y_1 = \frac{P_{d1}}{1 + P_{11}K_1} a \quad (21)$$

Let $K_1 = M_1/(1 - P_{11}M_1)$, where M_1 is a stable transfer function (Youla parameterization). Then,

$$y_1 = (1 - P_{11}M_1)P_{d1}\, a \quad (22)$$

$$= F_1^{'} a - q^{-d_1^{'}}(\bar{P}_{11}M_1P_{d1} - R_1^{'})a \quad (23)$$

Thus, $F_1^{'}$ and thus $\eta_{i,\text{decen}}$ can be estimated using closed loop data, *e.g.* using the FCOR algorithm (Huang and Shah, 1999), with *a priori* knowledge of the delays of G_{ij}. It is also interesting to note that the use of FCOR algorithm for loop-by-loop analysis of decentralized controllers leads to estimation of the first few impulse response coefficients of P_{d1} and not H_1, as is traditionally believed.

4. SIMULTANEOUS ANALYSIS

The variance of other outputs can increase, when the variance reduction of ith output is attempted through tuning of K_i. This effect is not taken into account by loop-by-loop analysis. To overcome this drawback, we derive an MV benchmark for simultaneous performance assessment of all loops in this section.

4.1 Conventional approach

A multivariable process can be represented as

$$G = D^{-1}\bar{G} \quad (24)$$

such that $\bar{G}$ and D^{-1} contain the invertible and non-invertible parts of G, respectively. We consider that $D(q)$ is a unitary interactor matrix, *i.e.* $D^T(q^{-1})\, D(q) = I$ (Huang and Shah, 1999). Let

$$q^{-d}DH = F + q^{-d}R \quad (25)$$

where d denotes the order of the interactor matrix. Then (Harris et al., 1996; Huang et al., 1997),

$$J_{\text{full}} = \min_K E[\text{tr}(y\, y^T)] = \|F\|_2^2 \quad (26)$$

The MV benchmark for simultaneous analysis is defined similar to (3). The bound on achievable output variance in (26), however, does not take the diagonal structure of the controller into account and thus may classify well-performing decentralized controllers as poorly performing. In the subsequent discussion, we present a lower bound on the achievable output variance for systems under decentralized control.

4.2 MV benchmark for Decentralized controllers

For regulatory control, we have $u = -K\, y$. Thus, the closed loop transfer function between a and y can be written as

$$y = S\, a; \quad S = (I + G\, K)^{-1}\, H \quad (27)$$

Since $E[a(t)a^T(t)] = I$,

$$J_{\text{decen}} = \min_K E[\text{tr}(y\, y^T)] = \min_K \|S\|_2^2 \quad (28)$$

When diagonal structure is imposed on K, the optimization problem in (28) becomes non-convex. A key observation to overcome this difficulty is that

$$\|S\|_2^2 = \sum_{i=0}^{\infty} \mathrm{tr}\,(S_i^T\, S_i) \geq \sum_{i=0}^{n} \mathrm{tr}\,(S_i^T\, S_i) \tag{29}$$

for any finite n. Thus, a lower bound on J_{decen} can be found by minimizing $\sum_{i=0}^{n} \mathrm{tr}\,(S_i^T\, S_i)$. Here, S_i represents the ith impulse response coefficient of S.

When the closed-loop system is stable, (27) can be expanded using Taylor Series expansion to get

$$S = \left[\sum_{i=0}^{\infty} (-1)^i (G\,K)^i\right] H \tag{30}$$

For given n, we define the following $nn_y \times nn_y$-dimensional Hankel matrices

$$G_H = \begin{bmatrix} G_0 & 0 & \cdots & 0 \\ G_1 & G_0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ G_{n-1} & \cdots & G_1 & G_0 \end{bmatrix} \tag{31}$$

$$K_H = \begin{bmatrix} K_0 & 0 & \cdots & 0 \\ K_1 & K_0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ K_{n-1} & \cdots & K_1 & K_0 \end{bmatrix} \tag{32}$$

and the following $nn_y \times nn_d$-dimensional matrices

$$H_v = \begin{bmatrix} H_0^T & H_1^T & \cdots & H_{n-1}^T \end{bmatrix}^T \tag{33}$$

$$S_v = \begin{bmatrix} S_0^T & S_1^T & \cdots & S_{n-1}^T \end{bmatrix}^T \tag{34}$$

Based on (32)-(34), S_v can be compactly written as

$$S_v = \left[\sum_{i=0}^{n} (-1)^i (G_H\, K_H)^i\right] H_v \tag{35}$$

Now, a lower bound on J_{decen} can be found by solving

$$J_{\mathrm{decen}} = \min_K \sum_{i=0}^{\infty} \mathrm{tr}\,(S_i^T\, S_i) \geq \min_K \mathrm{tr}\,(S_v^T\, S_v) \tag{36}$$

for any finite n. Based on (35), we note that S_v and thus $\mathrm{tr}\,(S_v^T S_v)$ depend polynomially on the controller parameters. Thus, the optimization problem in (36) can be seen as finding the global minimal value of a polynomial. For this purpose, we use sums of squares (SOS) programming (Parillo, 2000) in this paper. SOS programming transforms the polynomial minimization problem to a semi-definite program, which is solved using Sedumi (Sturm, 1999) interfaced with Matlab through Yalmip (Löfberg, 2004) in this paper.

SOS programming does not necessarily provide the minimum value of the polynomial, but guarantees a global lower bound (Parillo, 2000). For any controller K, however, since

$$\sum_{i=0}^{n+1} \mathrm{tr}\,(S_i^T\, S_i) \geq \sum_{i=0}^{n} \mathrm{tr}\,(S_i^T\, S_i) \tag{37}$$

tight lower bound on J_{decen} can be found by increasing n sequentially until convergence. In comparison with Kariwala (2007), where only the first $(2d-1)$ impulse response coefficients of S are used to find a lower bound on J_{decen}, the use of SOS programming provides a tighter lower bound, whenever $n > (2d-1)$. A similar approach involving SOS programming has been used earlier by Sendjaja and Kariwala (2009) to characterize the achievable output variance of SISO systems under PID control.

Example 5. We consider the following 2×2 process, where

$$G = \begin{bmatrix} \dfrac{-0.1q^{-2}}{(1-0.1q^{-1})\,(1-0.2q^{-1})} & \dfrac{-0.25q^{-1}\,(1-0.3q^{-1})}{(1-0.1q^{-1})\,(1-0.2q^{-1})} \\ \dfrac{0.5q^{-1}\,(1+0.9q^{-1})}{(1-0.1q^{-1})\,(1-0.2q^{-1})} & \dfrac{-0.1q^{-2}}{(1-0.1q^{-1})\,(1-0.2q^{-1})} \end{bmatrix} \tag{38}$$

and $H = 1/(1-q^{-1})\,I$ (Kariwala, 2007). Then, $D = q\,I$, $F = I$ and $J_{\mathrm{full}} = \|F\|_2^2 = 2$.

By considering the contribution of first $(2d-1)$ impulse response coefficients of S towards $\|S\|_2^2$, Kariwala (2007) found $J_{\mathrm{decen}} \geq 4$. Using the SOS programming approach, however, we find $J_{\mathrm{decen}} \geq 8.023$. Using non-convex optimization with multiple randomized initial guesses, Kariwala (2007) showed that the exact value of J_{decen} is approximately 8.16. This example amply demonstrates the usefulness of the SOS programming approach for finding tight lower bound on least achievable value of output variance for systems under decentralized control. The reader should also note that for this process, the MV benchmark found using conventional approach will be approximately 4 times lower than the MV benchmark found by accounting for the controller structure. Thus, the conventional approach for performance assessment of decentralized controllers may incorrectly classify well-performing controllers as poorly performing.

Remark 6. Unlike loop-by-loop analysis (see Remark 4), it is difficult to estimate η_{decen} directly from closed-loop data. When G is known (or has been identified using open or closed-loop identification experiments), H can be estimated by pre-whitening the pseudo-signal $(y - Gu)$. Then, SOS programming can be used to identify a lower bound on J_{decen} and η_{decen} based on identified model. We point out that the knowledge of G is also required by other available approaches for performance assessment of decentralized controllers (Ko and Edgar, 1998; Jain and Lakshminarayanan, 2007). In practice, the task of identifying G should be undertaken, only when J_{full} differs significantly from the observed output variance.

4.3 MV benchmark for Decentralized PID Controllers

In industrial practice, the individual sub-controllers of the decentralized controller are often fixed to be of PID-type. Clearly, the presence of additional controller structure can further limit the least achievable variance of outputs. Next, we show that the SOS programming approach can be easily extended to derive a tight lower bound on J_{decen} for decentralized PID controllers.

We note that the decentralized PID controller can be expressed as

$$K_{PID} = \frac{1}{\Delta} \sum_{i=0}^{2} C_i\, q^{-1} \tag{39}$$

where C_i has diagonal structure and $\Delta = 1 - q^{-1}$ is the integrator. For

$$\hat{G} = \frac{1}{\Delta} G \tag{40}$$

let us define the Hankel matrices $\hat{G}_H$ and C_H, which have the same structure as G_H and K_H defined in (32). Using similar approach, as used in Section 4.2, it can be shown that for any finite n

$$S_v = \left[\sum_{i=0}^{n} (-1)^i (\hat{G}_H\, C_H)^i\right] H_v \tag{41}$$

Thus, a lower bound on J_{decen} for decentralized PID controller can be found by minimizing $\text{tr}\,(S_v^T\, S_v)$ using SOS programming as before.

Example 7. We revisit Example 5. When individual sub-controllers are restricted to be of PI-type, the lower bound on J_{decen} increases to 9.980 (approximately 25% higher than unrestricted decentralized controller). The following sub-optimal controller is designed using trial and error

$$K_{\text{PI}} = \text{diag}\left(\frac{-0.629 + 0.474\, q^{-1}}{\Delta}, \frac{-2.844 + 1.862\, q^{-1}}{\Delta}\right) \tag{42}$$

which provides $E[\text{tr}(y\, y^T)] = 10.087$. When PID controllers are used, the lower bound on J_{decen} is 9.250 (approximately 15% higher than unrestricted decentralized controller). The following sub-optimal controller

$$K_{\text{PID}} = \text{diag}\left(\frac{-0.884 + 0.924\, q^{-1} - 0.205\, q^{-2}}{\Delta}, \frac{-3.210 + 2.764\, q^{-1} - 0.869\, q^{-2}}{\Delta}\right) \tag{43}$$

provides $E[\text{tr}(y\, y^T)] = 9.421$. For both cases (PI and PID control), the lower bounds are close to the upper bounds, which demonstrates that SOS programming technique can be used to find tight bounds on J_{decen} for decentralized PID controllers efficiently and reliably.

5. CONCLUSIONS AND OPEN ISSUES

The use of decentralized or multi-loop controllers is common in process industries. In this paper, we have shown that the use of existing MV benchmarks for SISO and MIMO systems for performance assessment of decentralized controllers may lead to incorrect conclusions regarding the opportunities for variance reduction through controller retuning. We proposed modified MV benchmarks for loop-by-loop analysis of the decentralized controller, which can be directly estimated from closed-loop data. An MV benchmark for simultaneous analysis of the decentralized controller is also proposed through the novel use of SOS programming, which guarantees a lower bound on the least achievable output variance. In summary, this paper takes a major step towards systematic performance assessment of decentralized controllers.

A limitation of the use of SOS programming approach is that the knowledge of process model is required. Furthermore, SOS programming requires solving large semi-definite programs, whose size and solution time increase rapidly with process dimensions. We are currently exploring the use of alternate approaches to handle the computational complexity of the SOS programming approach.

Abstract: Control performance assessment or CPA is a useful tool to establish the quality of industrial feedback control loops, but this requires establishing the minimum variance lower bound. While reliable algorithms have been developed for linear systems, common nonlinearities such as valve stiction require modifications to the basic strategy.
If the valve gets stuck due to stiction, for stable plants the output will reach steady state until the valve again moves. During this time the nonlinearity due to stiction is essentially removed from the system, and it is possible to compute performance assessment indices in the standard manner.
This paper describes an automated strategy to reliably identify these linear steady-state periods and subsequently compute the minimum variance lower bounds. The results of a simulation example illustrate that the proposed methodology is efficient and accurate enough for the classes of systems and nonlinearities considered to provide statistics for control performance assessment for linear systems with nonlinearities caused by valves.

Keywords: Control performance assessment, Valve stiction, Steady state.

1. INTRODUCTION

It is perhaps not surprising that instrument and control engineers are overwhelmed by the sheer number of loops that need attention on any typical industrial processing plant. Many loops are mis-tuned, if tuned at all, as noted by Bialkowski (1998) and other practitioners, and many control valves are only maintained when something catastrophic occurs. However the economic benefits from improving the performance of control loops, even those operating at a cursory glance acceptably, is often grossly under estimated.

In this paper, we present a strategy to compute the minimum variance lower bound, which is arguably the difficult step in quantifying the performance improvement of a typical control loop that suffers from the specific nonlinear phenomena of valve stiction being a very common cause for poor control performance.

Control performance assessment, or CPA, is a technology to diagnose and maintain operational efficiency of control systems. CPA is routinely applied in the refining, petrochemicals, pulp and paper and the mineral processing industry as noted by Qin (1998), Harris (1999), Huang and Shah (1999), Jelali (2006), although these, and many other publications, are mainly restricted to linear systems.

In the case of nonlinear systems, Harris and Yu (2007) superimposes the nonlinear dynamic model to an additive linear or partially nonlinear disturbance. It is shown that a minimum variance feedback invariant exists and the minimum variance performance can be estimated from routine operating data. Continuing this idea, a semi-parametric method was proposed in Yu et al. (2008) to find the minimum variance lower bound for linear systems with valve stiction. In that work a local smoothing spline approximated the stiction nonlinearity, but given the complexity of the nonlinearity, and the heuristic approach, it must be expected that this strategy will fail for some cases.

In this paper, we will extend CPA to a important practical nonlinear problem, that of control valve stiction. The performance degradation due to stiction prompted Horch (1999), Choudhury et al. (2005, 2006), Thornhill and Horch (2007) to investigate ways to diagnose the issue, while Jelali (2008) and the references therein, attempt the estimation of parametric stiction models, but few have continued the analysis to quantify the performance loss. Consequently, rather than attempt to approximate the nonlinearity, the approach taken here is to develop an automated strategy that extracts the steady state periods resultant once the valve is stuck fast. Based

⋆ Sponsor and financial support from the Industrial Information and Control Centre, AUT University and The University of Auckland, New Zealand.

on readily available input/output data collected during these periods, the minimum variance lower performance bound is computed in the standard manner. This gives an indication of how the control loop, even one suffering from stiction, would perform if it was serviced. Of course this presupposes that one is not allowed the luxury of setting the valve under consideration in manual, or one is charged with assessing many hundreds of operating loops.

The incentive to compute this control performance index is that it delivers a benchmark giving the engineer an idea of the improvement potential if the valve was to be serviced. For example, it could well be that of the hundreds of valves on site that required maintenance, the expected performance improvement, even if the stiction was entirely removed, would not be worth the time and effort.

The layout of the paper is as follows. In Section 2, the problem statement and model including valve stiction is introduced. Section 3 describes the methodology proposed in this paper to first extract, then check the validity of the steady-state linear periods. Section 4 illustrates by way of simulation the performance of the proposed methodology. This is followed by a discussion and conclusions highlighting both the limitations and potential of the method.

2. PROCESS DESCRIPTION

We assume the plant can be adequately modelled by

$$y_t = \frac{B(q^{-1})}{A(q^{-1})} q^{-b} u_t + d_t \tag{1}$$

where $A(q^{-1})$ and $B(q^{-1})$ are polynomials in the backshift operator q^{-1}, and b is the time delay of the system. The disturbance d_t is modelled as the output of a linear Autoregressive-Integrated-Moving-Average (ARIMA) filter driven by white noise a_t of zero mean and variance σ_a^2 of the form

$$d_t = \frac{\theta(q^{-1})}{\phi(q^{-1})\nabla^d} a_t = \psi(q^{-1}) a_t \tag{2}$$

where $\nabla \stackrel{\text{def}}{=} (1 - q^{-1})$ is the difference operator and d is a non-negative integer, typically less than 2. The polynomials $\theta(q^{-1})$ and $\phi(q^{-1})$ are monic and stable.

A common process nonlinearity afflicting control valves is known as 'stiction' which exhibits a range of of nonlinear behaviour including hysteresis, backslash and deadzones, both dynamic and static, and is summarised in de Wit et al. (1995), Lampaert et al. (2004).

Fig. 1 illustrates the typical sawtooth characteristic behaviour of a poorly maintained valve suffering from stick/slip friction using the stiction model developed in Choudhury et al. (2004). It is important to note that under normal industrial operations, the manipulated variable (MV) signal injected into the plant, here denoted as u^v, is unobservable.

We include the nonlinear stiction function $f(\cdot)$ (which represents the relationship between the manipulated variable and the actual valve output), into Eqn. 1 giving

$$y_t = \frac{B(q^{-1})}{A(q^{-1})} q^{-b} f(u_t) + d_t \tag{3}$$

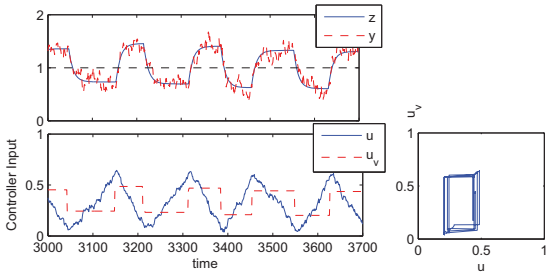

Fig. 1. The output of the controller, u, and the subsequent output of the control valve, u^v, suffering from slip/stick stiction.

Fig. 2 summarises the system considered in this paper. The intended controller output, u, (sometimes referred to as OP), is typically different from the actual valve position, u^v, due to the stiction. In the ideal case however, we can simply assume $u_t^v = f(u_t) = u_t$.

3. MINIMUM VARIANCE PERFORMANCE BOUNDS: VALVE STICTION CASES

The basis for minimum variance performance bounds was developed by Harris (1989) where it was was shown that the minimum variance performance bound for linear systems could be estimated from routine closed-loop data provided the process delay is known in advance. For the system described by Eqn. 1, the minimum variance performance lower bound is simply

$$\sigma_{MV}^2 = (1 + \varphi_1^2 + \cdots + \varphi_{b-1}^2)\sigma_a^2 \tag{4}$$

where the φ weights are the first $b-1$ impulse coefficients of the disturbance transfer function in Eqn. 2.

The minimum variance performance bounds for a class of nonlinear systems described by Eqn. 3 have been reported in Harris and Yu (2007) which used a nonlinear polynomial-AR or polynomial-ARX model to estimate the b-step ahead prediction. The drawback for this application is that it is difficult to find a general function to adequately approximate the valve stiction. Notwithstanding, the non-parametric spline method to approximate the nonlinearity proposed in Yu et al. (2008) partially overcomes the issue of modelling valve stiction/friction, but it too will fail for some cases.

In this paper, we propose a method to find the minimum variance performance bounds for valve stiction cases. Rather than trying to find a parametric or non-parametric function to approximate the nonlinear function as suggested in Yu et al. (2008), we will focus solely on the periods when we know, or at least suspect, that the system is operating in a linear regime. That way, we can simply ignore the now non-existent nonlinearity, and compute the minimum variance lower bound in the standard manner. The success of this strategy depends on how well we can establish that the system is behaving essentially as a linear system.

We can potentially ignore the effects of the nonlinearity by exploiting a unique characteristic of valve stiction. Due to the stick/slip friction, the times that the valve is stuck gives the system a chance to reach steady state and during these periods, we can use linear ARMA techniques to estimate the lower performance bound.

The key problem is how to identify the steady state periods from the closed loop output data. Our approach includes two parts. First we use a heuristic pattern method to select the periods of steady state in the observable time series y, and we validate this by employing a linearity test. Second, given possibly multiple segments of a linear time series, not necessarily contiguous, we can now fit a linear ARMA model and subsequently compute the minimum variance performance bound. The details of the methodology are discussed in the following sections.

3.1 Identifying steady-state periods

The presence of valve stiction induces a limit cycle with a characteristic triangular shape in the controller output as is shown in Fig. 1. This cycling is exacerbated by the integral component of the controller which eventually increases to such an extent that the stuck valve again moves. Unfortunately the valve moves too far, and the cycle begins again as demonstrated in Fig. 3.

Since the information of the actual valve output position, u^v, is not available for most industrial implementations, (if it was, we could simply use this series for the computation), the steady state periods must be identified from the data consisting solely of the process output y and controller output u.

Under the cycling conditions due to stiction, the scaled difference between u and y will describe a sawtooth trend as given in Fig. 4. The discontinuous turning points of the triangle wave indicate when the valve actually moves and it is these instances, (depicted as the vertical dashed and dotted lines) that we need to identify.

Given that most industrial plants have a stable low-pass frequency response that attenuates high frequency noise, and that the plant measurement is disturbed by d, it may be necessary to weight the subtraction to better highlight the trend. Fig. 4 actually trends $cu - y$ where the scale factor c is in this case 10.

After the periods of steady state are identified, an initial segment in each period will be discarded so that the previous input effects will be removed. Then subsequently

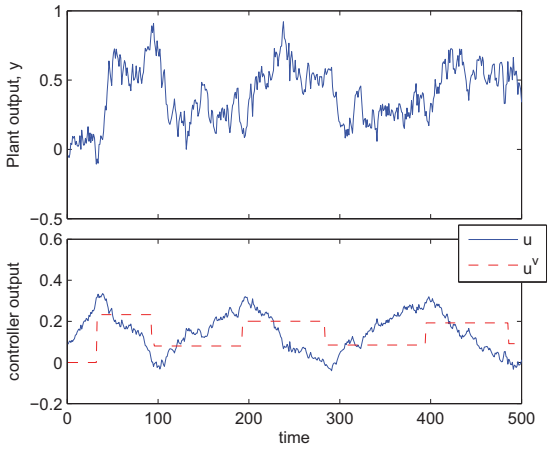

Fig. 3. The plant output, y, the controller output u, and the output of the valve suffering from stiction, u^v.

we can derive a minimum variance controller performance lower bound using these periods of data.

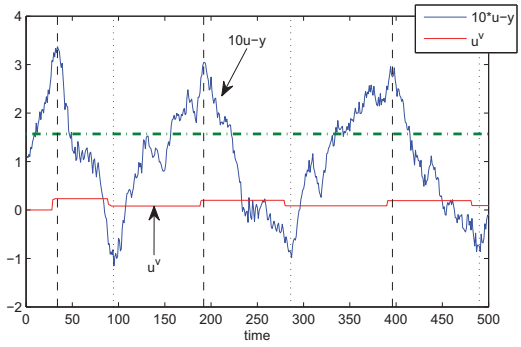

Fig. 4. Establishing the steady-state periods by computing $cu - y$.

An automated procedure to establish the stuck periods relies on reliably identifying the maxima and minima of the sawtooth shaped $cu - y$ trend in Fig. 4. First the times of the zero-crossings and their directions (falling, or raising edges) are established. Then, between each crossing instance, a search is made for the corresponding maximum or minimum.

Of course using such a heuristic approach, this simple algorithm is suspectable to false positives and correspondingly derives estimates of the steady-state periods shorter than the actual period. In cases of excessive suspected false crossings, standard techniques such as data smoothing or a Fourier identification of the dominant period could be applied to the noisy data series. However since these erroneous short periods will not be used for the minimum variance calculation anyway, they do not overly deteriorate the quality of the computed result. They do however, lower the efficiency of the data use.

3.2 Ensuring the removal of any nonlinearities

Notwithstanding the expectation that the valve stiction nonlinearity exhibits little memory, we need to be assured

that the selected period is in fact linear. One way is to do this is to apply a statistical test of linearity proposed by Subba and Gabar (1980), Hinich (1982) and previously used in this context by Choudhury et al. (2004) and Yu et al. (2008). This test, known as the Hinich test, is both nonparametric and reasonably robust.

In the simulations subsequently presented in section 4 it was obvious that the periods were linear so the nonlinear test was not actually employed. However if one is still in doubt, Yu et al. (2008) illustrates how such a validation could be performed.

3.3 Establishing the limit cycle

The proposed strategy works best when the valve is stuck for relatively long periods allowing the system to reach steady state. That is, periods larger than about 10 dominant time constants since we discard the first 3–4 to allow the system to reach steady-state, and then use the remaining data for the ARMAX model identification. Consequently we desire that the period of oscillation due to the valve nonlinearity is long compared to the settling time of the compensated loop and therefore we need to *a priori* establish reasonable conditions when that is likely to occur.

From the literature, and our simulation experience detailed further in section 4, it is found that there are three main factors which will affect the period of oscillation, namely the tuning of the PI controller, the magnitude of the disturbance, and the valve characteristics of the valve stiction.

4. SIMULATION EXPERIMENTS

The purpose of this section is to demonstrate the proposed method for the minimum variance performance assessment for valve stiction cases. A second order single-input, single-output (SISO) system with time constants 10 and 2, and steady-state gain of 3 is sampled at $T_s = 1$ to give

$$G_p = \frac{B}{A} = \frac{0.04338 + 0.03755q^{-1}}{1 - 1.621q^{-1} + 0.6483q^{-2}} \tag{5}$$

with time delay $b = 4$ under feedback control with controller

$$G_c = \frac{0.11 - 0.1q^{-1}}{1 - q^{-1}} \tag{6}$$

was used for generating simulated data. An additive disturbance of

$$d_t = \frac{0.2a_t}{1 - 0.8q^{-1}} \tag{7}$$

where a_t is a sequence of independent and identically distributed Gaussian random variables with zero mean and nominal variance $\sigma_a^2 = 0.1$.

A data-driven model for valve stiction proposed by Choudhury et al. (2004) is used to simulate the valve stiction. The model is characterised by two parameters, s for the valve stickiness and j for the magnitude of the valve jump. The closed loop behaviour with various combinations of s and j are plotted in Fig. 5. Pure deadband occurs when $j = 0$, (b) represents the undershoot case of a sticky valve, $s < j$, (c) illustrates the pure stick-slip situation, $s = j$ and (d) shows the valve output overshooting case, $s < j$. Note that the oscillation period decreases while the j value increases.

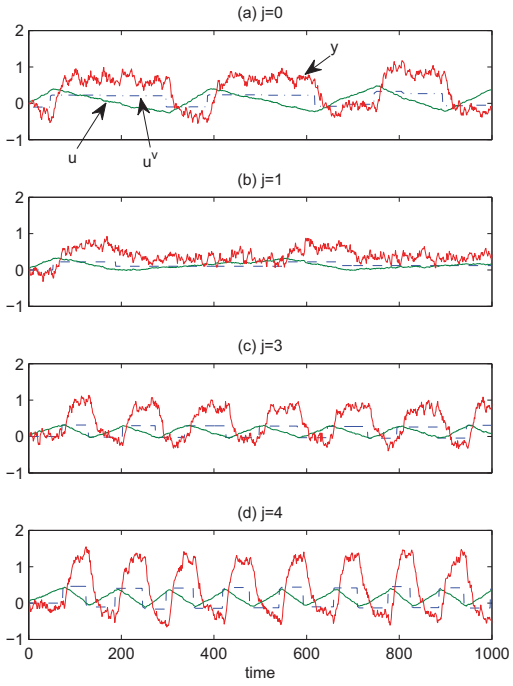

Fig. 5. The closed-loop behavior for $s = 3$ and with various values of j: (a) $j = 0$ (b) $j = 1$ (c) $j = 3$ (d) $j = 4$.

As noted in the pervious section, this strategy is reliant on relatively long periods when the valve is stuck. Given a fixed PI controller, we can vary the magnitude of the disturbance and the stiction jump/slip parameters, j, s and use a Monte-Carlo simulation to establish the largest period on average of the oscillation for each (σ_a^2, s, j) triplet. The resultant contour plots of periods are shown in Fig. 6.

In all cases we are most interested in the 'islands' of high periods apparent in all three examples given in Fig. 6.

Areas with periods less than about 100 are not interesting and are not plotted in Fig. 6. This is because since the plant in Fig. 6 has a dominant time constant of 10 sampled at 1, ten dominant time constants correspond to about 100 samples. We discard 30 to 40 samples to allow time for the system to reach steady-state, leaving a minimum of 60 samples in which to do the ARMA model identification. This data series length is about at the minimum recommended by Ljung (1987).

As expected the 'islands' of large periods occur when both the noise, σ_a^2, and jump parameters are not too big. This makes sense because if both s and j are zero, there is no stiction, and there is no self sustained oscillation due to the nonlinearity. Also for a given stiction, as the noise variance increases beyond the deadband limit, the valve will continually move, lowering, or completely eliminating, the potential steady-state periods.

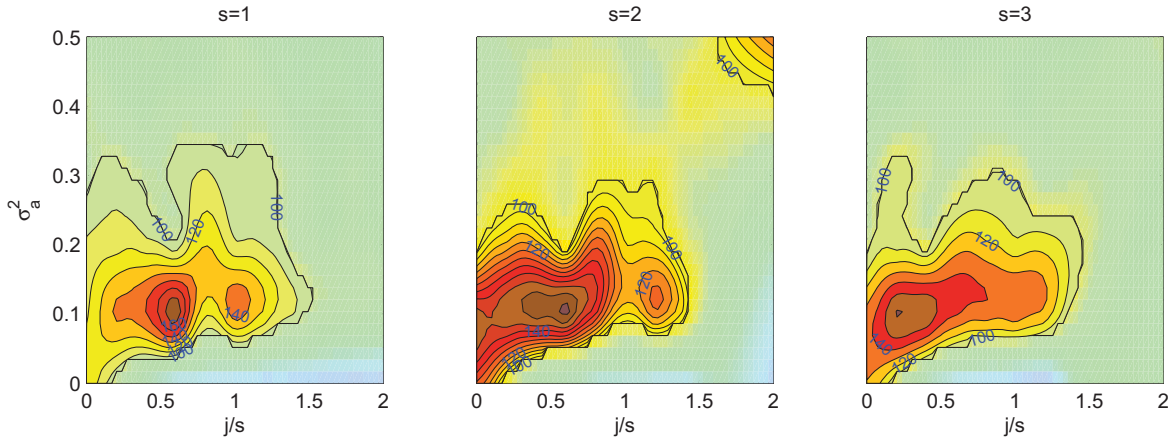

Fig. 6. The period of oscillation as a function stiction jump parameter j, and noise disturbance variance σ_a^2, at differing levels of stiction slip parameter s. Areas where the period is less than about 100 samples are not interesting for t his specific application because they are too short to perform a meaningful identification.

Due to the intractable nature of the nonlinearity, a Monte Carlo method is used to estimate the performance of the proposed strategy to estimate the minimum variance, σ_{MV}^2. 1000 observations generated from the valve stiction simulation are passed to the automated steady-state period identifier described in section 3.1 from which suitable periods are extracted. An ARMA model is fitted to the longest period from which σ_{MV}^2 is directly computed from the parametric model. This procedure is repeated 500 times.

The estimates of σ_{MV}^2 and associated uncertainties for different valve slip/jump conditions are shown in the comparative box plot in Fig. 7 again as in Fig. 5 for the case where $s = 3$ and various values for j. The true value of the minimum performance lower bound for this example is $\sigma_{MV}^2 = 9.2 \times 10^{-3}$.

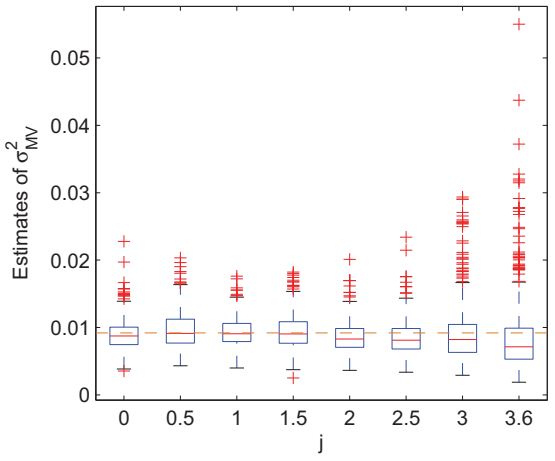

Fig. 7. Comparative box plots of the quality estimates of σ_{MV}^2 for $s = 3$ and for different j models. The horizontal dashed line is the true value of $\sigma_{MV}^2 = 9.2 \cdot 10^{-3}$.

5. DISCUSSION

The results from the numerical experiments to establish the minimum variance performance lower bound from normal operating data given in Fig. 7 show that the proposed strategy does reconstruct the correct σ_{MV}^2. Furthermore it is interesting to note that the quality of the estimate is best for the jump parameter $j \approx 1$, while for values smaller, and particularly larger, it begins to deteriorate. This is consistent with the results presented in Fig. 6 reinforcing the requirement to have reasonably long periods of steady-state to extract statistically significant results.

In the cases where the jump parameter j is larger than the slip s, we experience short periods of the stuck valve coupled with a comparatively large nonlinearity that contributes to the obvious deterioration in the confidence of the estimated minimum variance lower bound.

Similarly, if the zero-crossings are too frequent (and therefore the period available for steady-state consideration is too short compared to the anticipated dominant time constant), then we suggest that the strategy proposed in Yu et al. (2008) which uses smoothing splines to remove the nonlinearity might be more appropriate.

The proposed strategy has some limitations. First of all, as developed, we assume that the plant is stable, and reasonably well-damped. For type 1 plants with integrators, it is of course possible to differentiate the output. Furthermore, we assume that the dominant time constant is approximately known in order to discard the appropriate amount of data while waiting for steady-state. This is unlikely to be an overly onerous requirement for any processing plant. Finally we restrict our attention to those cases with moderate extent of stiction, since of course excessive stiction *must* be addressed, and minimal stiction would probably not be noticed anyway.

6. CONCLUSIONS

Valve stiction is a debilitating feature of many control loops that cannot, nor should not, be corrected by con-

troller tuning. However given the time and energy required to service the valve, it may be prudent for the instrument engineer to first establish what the best controlled performance would be if the valve was serviced.

The strategy proposed in this paper establishes the minimum performance lower bound in the case of excessive valve stiction using only observable signals and estimates of the plant dominant time constants and plant delay. In the case of rapid oscillation in the limit cycle, it is possible to stitch the short periods together to build up enough input/output data to make a reasonable identification.

While the examples considered only nonlinearities introduced by valve stiction, this strategy will work for any system which reaches steady states and stays there for a while.

Abstract: Valve stiction is a well known villain in process industry. Quantifying this valve damage is essential to ensure plant stability and profitability. The scope of this work is to propose a new method to compute valve stiction parameters, using a two parameter model, using only routine operating data. The proposed method uses global optimization to evaluate loop and plant parameters. Combining the proposed procedure with an efficient global optimization algorithm, the mean computation time for each valve was about 5 minutes. The method was applied in both simulation and industrial valves, providing reliable results, with relative errors smaller than 3% in all parameters.

Keywords: Performance Monitoring, Valve, Static Friction, Hysteresis, Global Optimization.

1 INTRODUCTION

In the last two decades, control loop performance monitoring has been a fruitful research field, providing automatic tools for process industry, which has great interest in evaluating loop performance in real time. Inside this scope, one topic that has been in focus is valve stiction, whose frequency in control loops is about 30% (Bialkowski, 1993). The effects of stiction are one explanation for these developments: it can cause plant-wide oscillations and increase the variability of the process and products.

Evaluating loop stiction is not a new issue. First studies were dated from 60's (Brown, 1958). However, in the last years, a big effort has been made to diagnose and solve this valve illness. A first group of works aimed at diagnosing stiction automatically, using only process variable (PV) and controller output (OP) (He *et al.*, 2007, Horch, 1999, Rossi and Scali, 2005, Ruel, 2000, Scali and Ghelardoni, 2008, Singhal and Salsbury, 2005, Stenman *et al.*, 2003, Yamashita, 2006). Some works have proposed specific stiction models for diaphragm type valves (Chen *et al.*, 2008, Choudhury *et al.*, 2005). A good survey about stiction models was recently written by Garcia (2008).

Also, some authors have proposed to compute stiction parameters in real time. Choudhury et al. (2006) proposed two methods to quantify stiction parameters, based on ellipse fitting and *c-clustering*, using a 1 parameter empirical model. Subsequently, some authors have proposed to quantify stiction parameters using a more reliable model, with two parameters. Choudhury *et al.* (2008) have proposed a method based on optimization and grid search.

Recently, Jelali (2008) has introduced one methodology to compute both stiction models, based on least-squares and global search algorithms. This method has two drawbacks: it is dependent of initial guess and it is computationally expensive. The scope of this work is to propose an alternative method based on global optimization to compute stiction parameters and linear plant model.

The main difference between our and Jelali's method is the optimization procedure, which is made in a single step, using global optimization. Both plant models and stiction parameters are computed in each optimization step. Combining the proposed procedure with an efficient global optimization algorithm, the computation time for each valve was less than 5 minutes.

The proposed methodology was applied in a set of 1000 simulation valves, with a relative error smaller than 3% in all cases, for all parameters. Then, the proposed method was applied in a group of industrial valves, showing reliable results.

The paper has been organized as follows: in section 2, the stiction definition, model and methodologies to evaluate valve stiction will be briefly discussed. Then, in section 3, the proposed methodology will be detailed. Several simulated and industrial case studies are shown in section 4, to corroborate the applicability of the proposed methodology. The paper ends with the concluding remarks.

2 STICTION: MODEL AND COMPUTATION

Stiction, or high static friction, can be defined as the valve damage that keeps the stem from moving, because the static friction exceeds the dynamic. As a consequence, the force to move the steam is generally larger than the desired new stem value, and the movement is jumpy (Ruel, 2000).

2.1 Stiction: model

A valve "suffering from stiction" has in the phase plot MV versus OP, shown in Fig. 1, four components: deadband (*DB*), stickband (*SB*), slip jump (*J*) and moving phase (*MP*). The method assumes that the process and controller have

linear behaviour, while the sticky valve inserts in the loop nonlinear behaviour.

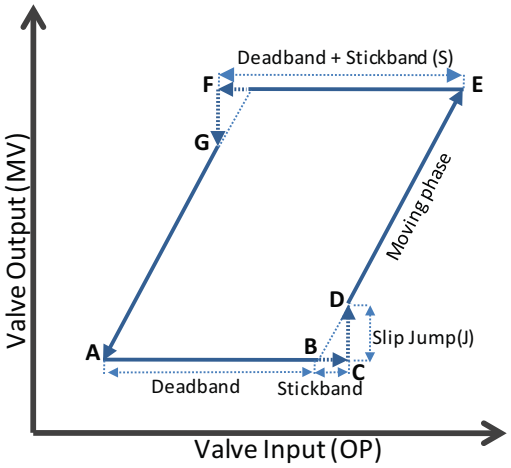

Fig. 1. Relation between controller output (OP) and valve position (MV) for a sticky valve.

When the valve changes the direction (A), the valve becomes sticky. The controller should overcome the deadband (AB) plus stickband (BC), and then the valve jumps to a new position (D). The stiction model consists of these two parameters: *S* (deadband+stickband) and *J* (jump).

Next, the valve starts moving, until its direction changes again or the valve comes to rest, between D and E.

The deadband and stickband represent the behaviour of the valve when it is not moving, although the input of the valve keeps changing. Slip jump represents the abrupt release of potential energy stored in the actuator chambers due to high static friction in the form of kinetic energy as the valve starts to move. The magnitude of the slip jump is crucial to determine the limit cycle amplitude and frequency.

The stiction model used in this work is proposed by Kano (2004), which is an extension of Choudhury's method, where stiction is modeled using two parameters. Their main advantage is that it can deal with both stochastic and deterministic signals. Kano's model flowchart representation is shown in Fig. 2.

The first two branches check the valve bounds. In the Kano's model, two valve states are distinguished: moving (*stp=0*) or resting (*stp=1*). When the valve changes its direction, its actual position state (us) is kept, until the static force is overcome. The friction force direction is denoted by $\pm d$.

2.2 Stiction: computation

In the literature, two methods to compute stiction parameters, using only normal operating data are proposed.

In the method proposed by Jelali (2008), a two step procedure is described. In the first step the stiction parameters are quantified using pattern search methods or genetic algorithms (GA). Next, the low-order linear plant model is identified, using a least-squares estimator. Both simulation and industrial valves are analyzed, and the errors between predicted and actual values for stiction parameters are less than 10%.

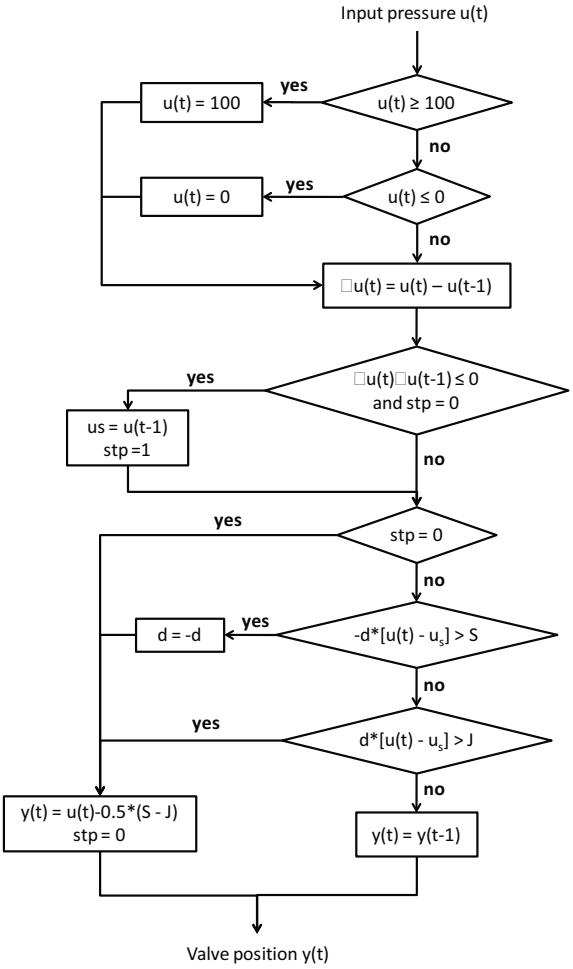

Fig. 2. Flowchart for Kano model.

a second method proposed by Choudhury *et al.* (2008) describes a method based on a grid search. Initially, a grid using several different values of *J* and *S* is built and then based on the process output, the plant model is identified. Based on the mean square error (MSE) between predicted process output and actual output in each grid point, the stiction parameters are estimated.

3 STICTION QUANTIFICATION

This section describes a new method to compute both stiction parameters and plant model, using only normal operating data. Data from process variable (PV) and controller output (OP) are required. Here, only first order with time delay models (FOPTD) will be used. However, the methodology is adequate for second orders, integrating process, among others.

Our approach uses the following assumptions, which are quite similar to the other methods available in the literature:

- The plant model is (locally) linear;
- The loop nonlinearity is caused by the valve;
- The stiction model can be considered a Hammerstein model;

The proposed method computes both plant stiction parameters in a single step, using a global optimization algorithm. This is the first difference between this work and the work proposed by Jelali (2008), where a two step procedure is proposed.

3.1 Optimization problem

The optimization problem to be solved is a non-linear programming type, where the objective function is the mean square error (MSE) of the difference of model output (PV_P) and plant output (PV).

$$MSE = \sum_{i=1}^{n} \frac{\left(PV_i - PV_{P_i}\right)^2}{n}$$

Where *n* is the length of PV.

In this class of problems, the function inside the search space is non-smooth and has some flat areas, where the gradient is zero, or close to this values. Fig 3 illustrates this behavior, using a FOPTD model and a sticky valve. The MSE was computed, varying *J* and *S*. In the process output, white noise is added, with signal-noise ratio equal to 1.

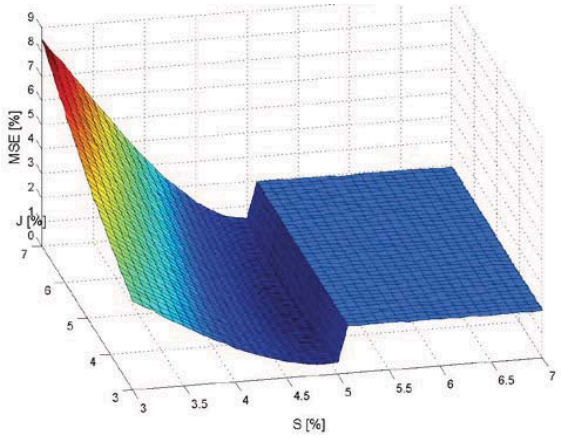

Fig 3: Objective function shape for variable S and J

Fig. 3 clearly shows that this class of function pattern requires global search algorithms; otherwise probably it will stick, depending on the initial guess. One possibility is to use stochastic algorithms, as proposed by Jelali (2008). A second possibility is to use global optimization deterministic algorithms, where the convergence is guaranteed, as proposed in this work.

The optimization problem for a FOPTD model to be solved is:

$$\min_{J,S,K,\tau} (MSE)$$

Where K and τ are the static gain and process time constant, respectively. The time delay is assumed to be known. Several methodologies available in the literature can be used to estimate this loop parameter (Elnaggar *et al.*, 1991, Ahmed *et al.*, 2006, Liang *et al.*, 2003).

The proposed technique can be easily extended to higher order or integrating processes. In this case, the plant model is replaced by an integrating transfer function $\left(\frac{K}{As}\right)$. In this case, the *K* and *A* are estimated by the optimization algorithm.

To allow the industrial application of the proposed method, the computational time should be reasonable. Thus, an efficient global optimization algorithm should be selected. Several optimization methods have been evaluated, and the best obtained by the authors is DIRECT (Finkel and Kelley, 2006). All algorithms are deterministic and deal with bounded decision variables.

4 CASE STUDIES

This section illustrates the applicability of the proposed methodology. Over a thousand simulation systems and a dozen of industrial sticky valves were analyzed and the proposed methodology has shown reliable results, what corroborates its industrial usefulness. Some of these systems will be shown here.

All computations were performed in an Intel Pentium D, 2GHz with 1 GB Ram.

4.1 Simulation case-studies

The objective of this section is to show the applicability of the proposed method in a set of simulation studies. All simulations use a PI controller and a first order plus time delay transfer function. Tab. 1 shows the models used in this work.

Tab. 1: Process and controller models used in the simulation case studies

Parameter	Model
Plant	$G(s) = \frac{1}{\tau s + 1} e^{-3s}$
Controller (PI)	$C(s) = 2\frac{\tau s + 1}{\tau s}$

Here, only twelve cases are shown, where a closed loop system is investigated with variable stiction parameters (*S* and *J*) and different plant time constant. The remaining parameters are maintained constant. Kano's model was used in all cases. The stiction parameters are specified as percentage of input and process variable span (%). Tab. 2 provides the summary of the results obtained by the application of the proposed methodology, where the true plant and valve stiction parameters (τ, *S*, and *J*) were compared with their values obtained by the proposed methodology. (τ_p, S_p, and J_p). The computation time (CPU_t) is also shown. All default settings in the DIRECT algorithm were used, except the maximum number of evaluations of objective functions, which was increased by 1000.

Tab. 2 corroborates the applicability of the proposed method, where the model parameters have deviation less than 3% of

the actual values. These values are comparable with Jelali's simulation cases, where the errors are less than 10%. If the maximum number of evaluations of objective function is increased by 3000, then the deviation reduces by less than 1%, however the CPU time increases to 12 min each.

Tab. 2: Results for process simulations

Case	J (%)	J_p (%)	Error (%)	S (%)	S_p (%)	Error (%)	τ (min)	τ_p (min)	Error (%)	CPU_t (min)
1	2,3	2,3	0,1%	3,0	3,0	0,1%	30,0	30,0	0,0%	4.3
2	2,3	2,3	0,1%	3,0	3,0	0,1%	10,0	10,0	0,0%	4.3
3	3,0	3,0	0,1%	3,0	3,0	0,1%	30,0	30,0	0,0%	4.3
4	3,0	3,0	0,0%	3,0	3,0	0,1%	10,0	10,0	0,0%	4.3
5	3,8	3,8	0,1%	3,0	3,0	0,1%	30,0	30,0	0,0%	4.2
6	3,8	3,7	-1,2%	3,0	3,0	0,0%	10,0	9,9	-1,0%	4.2
7	0,8	0,8	0,6%	1,0	1,0	1,1%	30,0	30,0	0,1%	4.4
8	0,8	0,8	2,9%	1,0	1,0	3,1%	10,0	10,1	1,3%	4.4
9	1,0	1,0	0,0%	1,0	1,0	0,1%	30,0	30,0	0,0%	4.0
10	1,0	1,0	-1,7%	1,0	1,0	-1,2%	10,0	10,0	-0,1%	4.1
11	1,3	1,3	1,3%	1,0	1,0	0,4%	30,0	30,1	0,2%	4.0
12	1,3	1,2	-1,6%	1,0	1,0	-0,9%	10,0	10,0	0,0%	4.3

The second factor also analyzed in this work, was the impact of white noise. Using the same case study of Tab. 1 with $\tau = 20, J = 5$, and $S = 5$, and different level of added white noise to the process variable several optimizations have been performed and the results are summarized in Tab. 3 where SNR is the relationship between Signal-Noise Ratio and the predicted stiction parameters, expressed in percentage of actual value.

Tab 3. White noise impact over the predicted stiction parameters – % change in each parameter

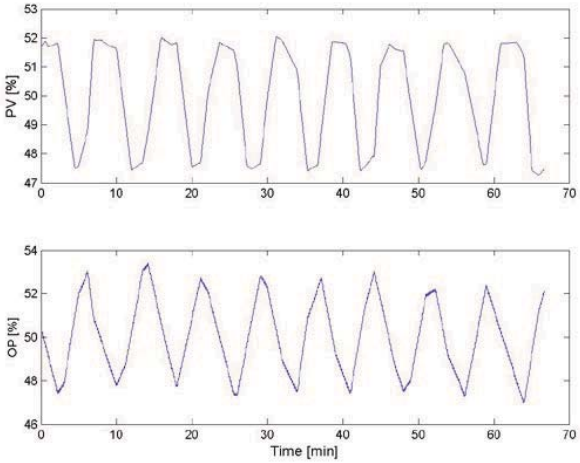
SNR	% S	% J
100	0.09%	-0.23%
50	0.29%	0.87%
5	0.50%	1.23%
0.5	5.9%	25%

As shown in Tab 3, the methodology is not very sensitive to white noise impact. Only when the noise is significant (i.e. SNR = 0.5) the results have been corrupted.

4.2 Industrial case-studies

This section shows some of the industrial application where the proposed methodology was applied. One flow control (case 1) and one pressure control (case 2) with sticky valves, from a Brazilian refinery, are analyzed.

Fig. 4 illustrates the PV and OP for industrial case study 1, where the presence of stiction can be easily seen. The application of the procedure proposed in this work leads to the estimates of $J = 2.6$, $S = 4.0$, and $\tau = 80$ sec. The comparison between the measured and predicted curves is shown in Fig. 5. This comparison shows that the estimated curve is in good agreement with the measured process variable.



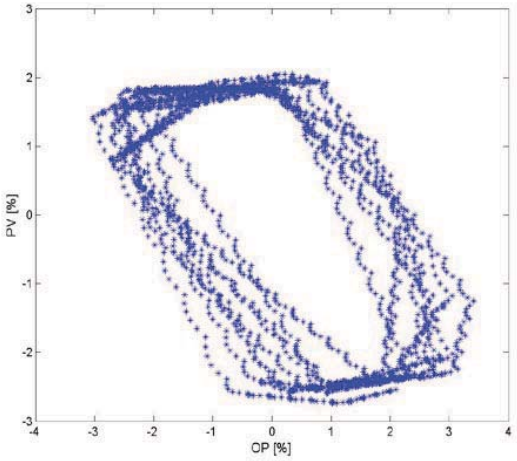


Fig. 4: Data trend for industrial case study 1 – flow control.

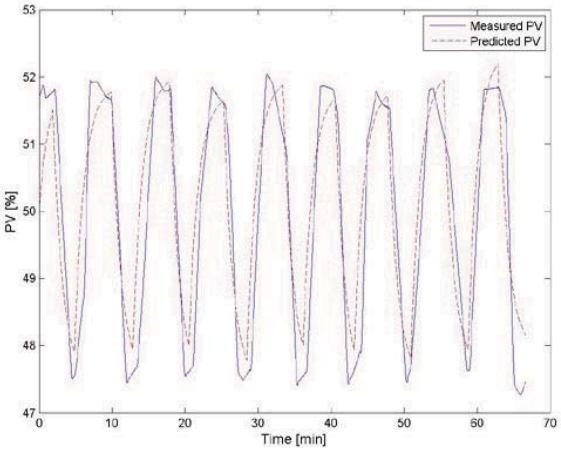

Fig 5: Comparison between measured and predicted PV for industrial case study 1 – flow control.

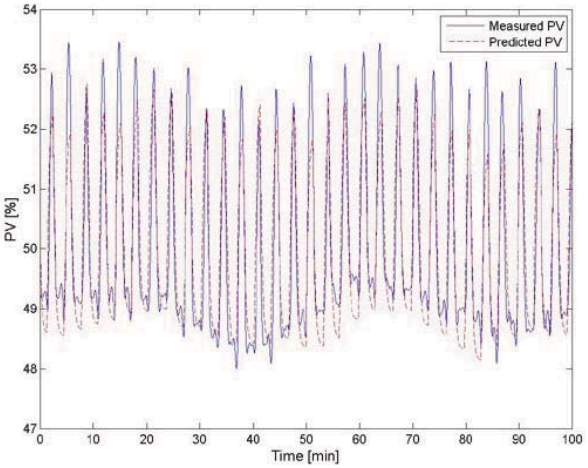

Fig 7 Comparison between measured and predicted PV for industrial case study 2 – pressure control.

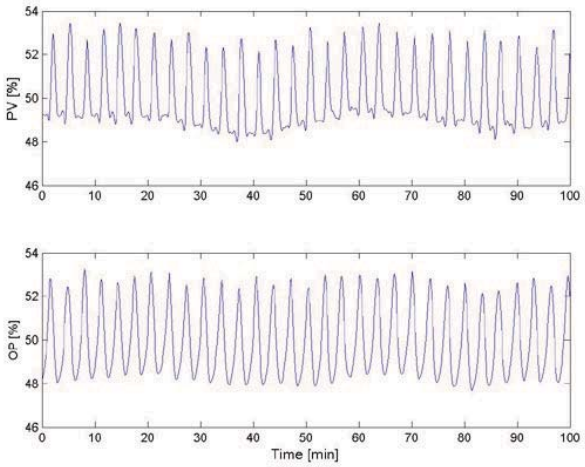

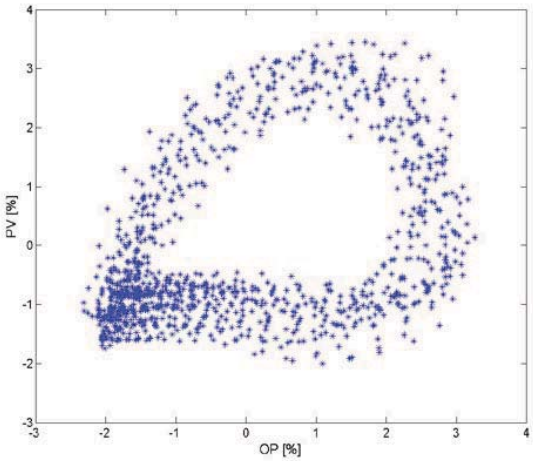

Fig. 6: Data trend for industrial case study 2 – pressure control.

The PV and OP signals for the second industrial sticky valve are shown in Fig. 6. Again, the stiction can be detected by visual inspection of PV versus OP plot, where a parallelogram shape is seen. The proposed estimation algorithm leads to the parameters estimates: $J = 1.6$, $S = 2.9$, and τ=18 sec. The comparison between the measured and predicted curves is shown in Fig. 7.

5 CONCLUSIONS

This work proposes a new method for quantifying valve stiction based on global optimization, using a one-step procedure, where both stiction parameters and plant model are simultaneously quantified, using only process variable (PV) and controller output (OP). The objective function minimized the mean square error between the measured and predicted process output and the optimization algorithm used for this class of problem is called DIRECT (Finkel and Kelley, 2006).

The validity of the method is successfully demonstrated by comparing simulation results, where valves with known stiction parameters were evaluated. Industrial valves were also evaluated, providing very good results. Comparing the actual procedure with the available in the literature, the CPU time is considerably smaller – in this case lower than 5 min against 20 to 30 min – and the quality of the results is comparable – an error lower than 3% against 10%. The industrial applicability of the proposed method has been corroborated by two industrial applications, where reliable results have been obtained.

Abstract: A novel method based on the generalized gradient and nonsmooth optimization techniques called bundle methods is introduced to optimize the performance of a class of dynamic systems whose governing equations change depending on the values of the parameters, controls and the current state of the system.

Keywords: Nonsmooth Optimization, Generalized Gradient, Bundle Methods, Dynamic Optimization

1. INTRODUCTION

This paper describes a novel method to determine the optimal controls and parameters for a large class of engineering systems with varying structure which have the following characteristics:

(1) The systems evolve according to different ordinary differential equations depending on the values of the states, controls and parameters.
(2) The vector field is unique and continuous.
(3) The values of the continuous states, controls and parameters solely determine the vector field.

Example 1. The liquid level dynamics of a tank with a weir with multiple inlet and outlet flows is

$$\dot{h}(t,\mathbf{p}) = \sum_{i=1}^{n} F_i(t)/A - F_W(h(t,\mathbf{p}),\mathbf{p}) \tag{1}$$

$$F_W(h(t,\mathbf{p}),\mathbf{p}) = \begin{cases} 0 & \text{if } h(t,\mathbf{p}) \le \bar{h} \\ k(h(t,\mathbf{p}) - \bar{h}) & \text{if } h(t,\mathbf{p}) \ge \bar{h} \end{cases}$$

$$\mathbf{p} = (\bar{h}, k, A)^{\mathrm{T}}$$

where h is the liquid level; A is the cross-sectional area of the tank; F_i are volumetric flows; $\bar{h}$ is the weir height; k is an equivalent valve constant for the weir. The governing ordinary differential equations are determined by h and $\bar{h}$. At $h = \bar{h}$, two ordinary differential equations are applicable but the vector field is unique and continuous.

These systems can be expressed in the form,

$$\dot{\mathbf{x}}(t,\mathbf{p}) = \mathbf{f}(\mathbf{x}(t,\mathbf{p}),\mathbf{u}(t),\mathbf{p})$$

where $\mathbf{x}$ represents the continuous-valued states, $\mathbf{p}$ is a finite set of continuous-valued parameters, $\mathbf{u}(t)$ are the bounded controls with possible discontinuities at finitely many points in time. $\mathbf{f}$ is continuous on its domain. The domain of $\mathbf{f}$ is partitioned into finitely many sets, D_k, such that if $(\mathbf{x}(t,\mathbf{p}),\mathbf{u}(t),\mathbf{p}) \in D_k$ then $\mathbf{f}(\mathbf{x}(t,\mathbf{p}),\mathbf{u}(t),\mathbf{p}) = \mathbf{f}_k(\mathbf{x}(t,\mathbf{p}),\mathbf{u}(t),\mathbf{p})$ where $\mathbf{f}_k$ are continuously differentiable with respect to their arguments. As a result of this particular structure $\mathbf{f}$ is piecewise continuously differentiable with respect to its arguments.

In order to formulate a finite dimensional optimization problem, the controls are reformulated as piecewise constant functions of parameters and time with finitely many discontinuities at $t_i,\ i = 1,\ldots,n$ with $t_i < t_{i+1}$, $t_1 = 0$ and $t_n < \infty$. As a result of this reformulation, the dynamics can be represented by a set of equations $\dot{\mathbf{x}}(t,\mathbf{p}) = \mathbf{f}^i(\mathbf{x}(t,\mathbf{p}),\mathbf{p})$ if $t \in (t_i, t_{i+1}]$. Note that each $\mathbf{f}^i$ has a partitioned domain with finitely many partitions, $\{D_k^i,\ k = 1,\ldots,n_i\}$, and corresponding continuously differentiable vector fields $\{\mathbf{f}_k^i\}$.

The mathematical program to be solved is

$$\min_{\mathbf{p}} J(\mathbf{p}) = \sum_{i=1}^{n-1} \int_{t_i}^{t_{i+1}} h(\mathbf{x}(t,\mathbf{p}),\mathbf{p})dt + H(\mathbf{x}(t_n,\mathbf{p}),\mathbf{p}) \tag{2}$$

$$\text{s.t} \sum_{i=1}^{n-1} \int_{t_i}^{t_{i+1}} \mathbf{g}(\mathbf{x}(t,\mathbf{p}),\mathbf{p})dt + \mathbf{G}(\mathbf{x}(t_n,\mathbf{p}),\mathbf{p}) \le \mathbf{0}$$

$$\dot{\mathbf{x}}(t,\mathbf{p}) = \mathbf{f}^i(\mathbf{x}(t,\mathbf{p}),\mathbf{p}),\ \forall t \in (t_i, t_{i+1}], \tag{3}$$

$$\mathbf{x}(0,\mathbf{p}) = \mathbf{f}^0(\mathbf{p}),\ i = 1,\ldots,n-1$$

where H, h, $\mathbf{G}$, $\mathbf{g}$, $\mathbf{f}^0$ are continuously differentiable functions of their arguments that are used to compute values of the objective, values of the constraints and the initial conditions.

Standard numerical methods of dynamic optimization (Betts, 1998) are not applicable to solve (2) because the $\mathbf{f}^i$ are not continuously differentiable. Sensitivity results (Galán et al., 1999) are also not applicable because given $t \in (t_i, t_{i+1}]$, it is not a priori known which $\mathbf{f}_k^i$ govern the dynamics of the system. Furthermore, at $t \in (t_i, t_{i+1}]$ the governing $\mathbf{f}_k^i$ depends on the value of $\mathbf{p}$. The solution of (2) not only determines an optimal $\mathbf{p}$ but prescribes a sequence of $\mathbf{f}_k^i$ in time. This implicit selection complicates the solution process.

The *mixed-integer* (Avraam et al., 1998; Bemporad and Morari, 1999) and the *differential variational inequalities, DVI* (Schumacher, 2004; Pang and Stewart, 2008; Raghunathan et al., 2004) approaches make this selection explicit using transcription. Given $[t_i, t_{i+1}]$, a mesh of time points $\{\tau_j : \ j = 1, 2, \ldots n_i, \ \tau_1 = t_i \ \tau_{n_i} = t_{i+1}\}$ is determined a priori. For each τ_j, a variable, $\mathbf{x}_j$, representing the continuous state is created. In order to make the selection of $\mathbf{f}_k^i$ explicit, (3) needs to be replaced with suitable algebraic relationships and additional constraints. The governing dynamics need to be determined in the intervals $[\tau_j, \tau_{j+1}]$. Both approaches replace (3) with a discretization such as the forward Euler method. Both methods introduce additional variables, μ_j^k, at each τ_j for each $\mathbf{f}_k^i$ and approximate the dynamics between time points using the function; $\sum_k \mu_j^k \mathbf{f}_k^i(\mathbf{x}_j, \mathbf{p})$. For example, if the forward Euler discretization is used, an algebraic relationship replacing (3) is $\mathbf{x}_{j+1} - \mathbf{x}_j = (\tau_{j+1} - \tau_j) \sum_{k=1}^{n_i} \mu_j^k \mathbf{f}_k^i(\mathbf{x}_j, \mathbf{p}), \ j = 1, \ldots, n_i - 1$. Both approaches replace the integral terms in (2) by appropriate quadratures.

The approaches differ in the way the values of μ_j^k are determined. In the mixed-integer approach, μ_j^k are binary variables. Additional constraints enforce that a single μ_j^k is non-zero at a given τ_j and that this is consistent with parameter, $\mathbf{p}$, and state values, $\mathbf{x}_j$ at τ_j. The final formulation is a mixed-integer nonlinear program. In the DVI approach, μ_j^k are part of the solution of an embedded mathematical program of the states and parameters at each τ_j. These programs are replaced with their equivalent KKT conditions.

Both approaches result in large optimization problems as a result of transcription. Only linear and quadratic formulations of the mixed-integer approach can be solved practically. This restricts the underlying ODEs to be linear and the sets D_k to be polyhedral. The DVI approach requires that the embedded programs are convex to guarantee that the KKT conditions are sufficient to determine an optimal solution. Complementarity constraints in the KKT conditions necessitate special solvers because complementarity conditions violate constraint qualifications which are necessary for ordinary nonlinear programming, NLP, algorithms to work. The required special solvers are not as efficient as usual NLP solvers.

This paper describes a method where the selection of dynamics is not handled explicitly. The method is based on *single-shooting*. In single shooting, the dynamics in (3) are solved by an initial value solver, IVP. In the differentiable case, the IVP solver is also used to solve an auxiliary set of equations to obtain parametric sensitivities. These sensitivities are used to calculate gradient information for numerical optimization methods. There are no additional variables or constraints. The resultant optimization problems do not grow with the number of time points in the mesh nor the size of the possible set of ODEs. In addition, the convexity constraints on the dynamics as in the mixed-integer and DVI approaches can be relaxed.

In order to use single-shooting on (2), which is a nonsmooth program, derivative-like information needs to be obtained. Nonsmoothness also prevents the application of standard nonlinear programming solvers. In order to handle these complications, *Clarke's generalized Jacobian* (Clarke, 1990) is employed in conjunction with a class of nonsmooth optimization methods called *bundle methods* (Kiwiel, 1985; Mäkelä, 2001) to solve (2).

In the remainder, the necessary mathematical background is summarized. The method is then described. The paper ends with an illustrative example and directions of further research.

2. MATHEMATICAL BACKGROUND

$\mathbf{F} : \mathbb{R}^n \to \mathbb{R}^m$ is *locally Lipschitz continuous* at $\mathbf{x}$ if there exists a neighborhood, $N_\epsilon(\mathbf{x})$ and a finite positive constant, K, such that $\|\mathbf{F}(\mathbf{y}) - \mathbf{F}(\mathbf{z})\| \leq K\|\mathbf{y} - \mathbf{z}\| \ \forall \mathbf{z}, \mathbf{y} \in N_\epsilon(\mathbf{x})$. Rademacher's theorem states that locally Lipschitz continuous functions are almost everywhere differentiable on their domain (Rockafellar and Wets, 1998). The locally Lipschitz continuous property is preserved under addition and composition of functions.

Let $\mathbf{F} : \mathbb{R}^n \to \mathbb{R}^m$ be locally Lipschitz continuous at $\mathbf{x}$, then the *generalized Jacobian* (Clarke, 1990) at $\mathbf{x}$ is

$$\partial \mathbf{F}(\mathbf{x}) = \text{co}\{ \lim_{\mathbf{x}_i \to \mathbf{x}} J\mathbf{F}(\mathbf{x}_i) : \ \mathbf{x}_i \notin S \cup T\} \quad (4)$$

where co is the convex hull, $J\mathbf{F}$ denotes the Jacobian of $\mathbf{F}$ where it exists; S is the set of measure zero nondifferentiable points and T is an arbitrary set of measure zero. In words, the generalized Jacobian at $\mathbf{x}$ is the convex hull of all the limits of convergent Jacobian sequences with the Jacobians evaluated at points converging to $\mathbf{x}$. In finite dimensional Euclidean spaces, the *generalized gradient* is the generalized Jacobian when $m = 1$ and the elements of the generalized Jacobian are transposed.

Example 2. $\dot{h}(t, \mathbf{p})$ in (1) is locally Lipschitz continuous with respect to $\bar{h}$ and the generalized gradient is:

$$\partial_{\bar{h}} \dot{h}(t, \mathbf{p}) = \begin{cases} 0 & \text{if } h(t, \mathbf{p}) < \bar{h} \\ \text{co}[0, k] & \text{if } h(t, \mathbf{p}) = \bar{h} \\ k & \text{if } h(t, \mathbf{p}) > \bar{h}. \end{cases}$$

Chain rules can be derived for generalized gradients and Jacobians. Implicit function theorems can be formulated. Necessary conditions of optimality for mathematical programs with locally Lipschitz continuous functions can be defined in terms of generalized gradients. For numerical methods, if the generalized gradient at a point is known, a direction of descent can be obtained by using the element of minimum norm.

In general, it is not possible to calculate all the elements of the generalized gradient at a point to determine directions of descent. *Bundle Methods* (Kiwiel, 1985; Mäkelä, 2001) use an approximation to the generalized gradient to solve

$$\min_{\mathbf{z} \in Z} f(\mathbf{z}) \text{ s.t: } g_m(\mathbf{z}) \leq 0, \ m = 1, \ldots, M$$

where f and g_m are locally Lipschitz continuous functions. Bundle methods require that only an element of $\partial f(\mathbf{z})$ and of each $\partial g_m(\mathbf{z})$ are available. The generalized gradient at an iterate is approximated by the convex

hull of a set of generalized gradients of nearby points called the *bundle*. The element of minimum norm of the approximation is used as the descent direction. Using a specialized line search procedure, either the next iterate is determined or another element is added to the bundle to change the direction of descent.

Bundle methods converge to stationary points satisfying KKT type conditions under a *semismoothness* (Mifflin, 1977; Qi, 1993) assumption on f and g_m. Semismoothness guarantees that the iterative line search algorithm in bundle methods terminates after finite number of iterations. Similar to local Lipschitz continuity, semismoothness is conserved under addition, multiplication and composition. Piecewise continuously differentiable functions, finite convex functions and continuously differentiable functions are all examples of functions that are semismooth and locally Lipschitz continuous.

3. METHOD DESCRIPTION

In this section, the theoretical discussion focuses on the dynamic systems,

$$\begin{aligned}&\dot{\mathbf{x}}(t,\mathbf{p}) = \mathbf{f}^i(\mathbf{x}(t,\mathbf{p}),\mathbf{p}),\ \forall t \in (t_i, t_{i+1}] \\ &\mathbf{x}(t_1,\mathbf{p}) = \mathbf{f}^0(\mathbf{p}),\ \mathbf{p} \in P,\ i = 1 \dots n-1\end{aligned} \tag{5}$$

where $\mathbf{f}^i : \mathbb{R}^{n_x} \times \mathbb{R}^{n_p} \to \mathbb{R}^{n_x}$ are piecewise continuously differentiable with respect to their arguments, $\mathbf{f}^0 : \mathbb{R}^{n_p} \to \mathbb{R}^{n_x}$ is continuously differentiable and P is a compact set with non-empty interior. In order to develop a numerical method, the following assumptions are made:

Assumption 1. Equation (5) has a solution on $[t_i, t_{i+1}]$, $i = 1, \dots, n-1$ for each $\mathbf{p} \in P$.

Assumption 2. The domain of each $\mathbf{f}^i$ is partitioned into a finite set of subdomains with nonempty interior, $\{D^i_k,\ k = 1, \dots, n_i\}$ and $D^i_k = \{(\mathbf{v},\mathbf{p}) : d^i_{k,j}(\mathbf{v},\mathbf{p}) \leq 0,\ j = 1, \dots, n_{i,k}\}$ where $d^i_{k,j}$ are continuously differentiable. In other words, the partitions have boundaries that can be expressed using continuously differentiable functions and $d^i_{k,j}(\mathbf{v},\mathbf{p}) = 0$ represent continuously differentiable manifolds of dimension $n_x \times n_p - 1$. There exists a corresponding set of $\{\mathbf{f}^i_k\}$ such that $\mathbf{f}^i(\mathbf{x}(t,\mathbf{p}),\mathbf{p}) = \mathbf{f}^i_k(\mathbf{x}(t,\mathbf{p}),\mathbf{p})$ if $(\mathbf{x}(t,\mathbf{p}),\mathbf{p}) \in D^i_k$ and $\mathbf{f}^i_k$ are continuously differentiable with respect to their arguments.

$\mathbf{x}(t,\mathbf{p})$ is a locally Lipschitz continuous (Coddington and Levinson, 1955) and semismooth function of $\mathbf{p}$ (Pang and Stewart, 2009) as a result of continuity and piecewise continuous differentiability of $\mathbf{f}^i$. The constraints and objective of (2) are composite functions of semismooth and locally Lipschitz functions and $\mathbf{x}(t,\mathbf{p})$. As a result, the constraints and objective of (2) are locally Lipschitz and semismooth functions.

In order to calculate the necessary generalized gradient information for optimization, an element of the generalized gradient of the states with respect to $\mathbf{p}$, $\partial_{\mathbf{p}}\mathbf{x}(t,\mathbf{p})$, is required. The next theorem provides a sufficient condition to detect points where an element can be calculated. It can be deduced from Theorem 7.4.1 in Clarke (1990) using appropriate chain rules and the definition of the Jacobian.

Theorem 1. Let $\mathbf{x}(t,\bar{\mathbf{p}})$ be a solution of (5). If the set-valued mapping, $\partial_{(\mathbf{x},\mathbf{p})}\mathbf{f}^i_{\mathbf{p}}(\mathbf{x}(t,\bar{\mathbf{p}}),\bar{\mathbf{p}})$ is a singleton for almost all $t \in (t_1, t_n]$, then for each $i = 1, \dots, n-1$, there exist unique solutions to the matrix differential inclusions:

$$\begin{aligned}&\dot{Y}_{\mathbf{p}}(t) \in \partial\mathbf{f}^i_{\mathbf{x}}(\mathbf{x}(t,\bar{\mathbf{p}}),\bar{\mathbf{p}})Y_{\mathbf{p}}(t) + \partial\mathbf{f}^i_{\mathbf{p}}(\mathbf{x}(t,\bar{\mathbf{p}}),\bar{\mathbf{p}}), \\ &\qquad\qquad \forall t \in (t_i, t_{i+1}] \\ &\dot{Y}_{\mathbf{x}}(t) \in \partial\mathbf{f}^i_{\mathbf{x}}(\mathbf{x}(t,\bar{\mathbf{p}}),\bar{\mathbf{p}})Y_{\mathbf{x}}(t), \forall t \in (t_i, t_{i+1}] \\ &Y_{\mathbf{p}}(t_1) = 0,\ Y_{\mathbf{x}}(t_1) = I.\end{aligned}$$

The following relations hold for all $t \in (t_i, t_{i+1}]$ except on set of measure zero,

$$\dot{Y}_{\mathbf{p}}(t) = J\mathbf{f}^i_{\mathbf{x}}(\mathbf{x}(t,\bar{\mathbf{p}}),\bar{\mathbf{p}})Y_{\mathbf{p}}(t) + J\mathbf{f}^i_{\mathbf{p}}(\mathbf{x}(t,\bar{\mathbf{p}}),\bar{\mathbf{p}}) \tag{6}$$

$$\dot{Y}_{\mathbf{x}}(t) = J\mathbf{f}^i_{\mathbf{x}}(\mathbf{x}(t,\bar{\mathbf{p}}),\bar{\mathbf{p}})Y_{\mathbf{x}}(t) \tag{7}$$

where $J\mathbf{f}^i_{\mathbf{x}}$ and $J\mathbf{f}^i_{\mathbf{p}}$ are the partial derivatives of $\mathbf{f}^i$ with respect to $\mathbf{x}$ and $\mathbf{p}$ respectively.

Finally, $\partial_{\mathbf{p}}\mathbf{x}(t_n,\bar{\mathbf{p}}) = Y_{\mathbf{x}}(t_n)J\mathbf{f}_0(\bar{\mathbf{p}}) + Y_{\mathbf{p}}(t_n)$.

Definition 1. A trajectory, $\mathbf{x}(t,\mathbf{p})$, is called *singleton* if $\partial\mathbf{f}^i_{(\mathbf{x},\mathbf{p})}(\mathbf{x}(t,\mathbf{p}),\mathbf{p})$ is a singleton for almost all $t \in [t_i, t_{i+1}]$. Otherwise, it is called *non-singleton*.

Note that due to assumption (2) and the piecewise continuous differentiable nature of $\mathbf{f}^i$, the points where $\partial\mathbf{f}^i_{(\mathbf{x},\mathbf{p})}(\mathbf{x}(t,\mathbf{p}),\mathbf{p})$ may not be a singleton are where $d^i_{k,j}(\mathbf{x}(t,\mathbf{p}),\mathbf{p}) = 0$ holds for some k and j. Trajectories that are not singleton have arcs that lie on the surfaces defined by $d^i_{k,j}(\mathbf{x}(t,\mathbf{p}),\mathbf{p}) = 0$.

The next theorem is a result on the occurrence of non-singleton trajectories for autonomous systems with piecewise continuously differentiable vector fields.

Theorem 2. Consider the dynamic system

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t)),\ t \in (0, t_f],\ \mathbf{x}(0) = \mathbf{x}_0,\ \mathbf{x}_0 \in X_0 \subset D \tag{8}$$

where X_0 is an open set in $\mathbb{R}^{n_x}$, D is the bounded domain where all solutions with initial conditions in X_0 remain for $t \in (0, t_f]$. Let $\mathbf{f} : \mathbb{R}^{n_x} \to \mathbb{R}^{n_x}$ be piecewise continuously differentiable on D. Let assumptions (2) hold where all $d^i_{k,j}$ are continuously differentiable functions of $\mathbf{x}$. Then the set of initial conditions producing non-singleton trajectories is a measure zero subset of X_0.

Proof. Since $\mathbf{f}$ is locally Lipschitz continuous on D, the set of points where it is not differentiable is a set of measure zero in D. In addition, due to piecewise continuous differentiability, the generalized Jacobian is a singleton where $\mathbf{f}$ is differentiable. The only points where the generalized Jacobian is not a singleton are on the boundaries of the subdomains which constitute a set of measure zero in D. The solutions of (8) are unique due to the Lipschitz continuous property of $\mathbf{f}$ on D. Due to the autonomous nature of the dynamics, no two solutions intersect for any $t \in (0, t_f]$. Now consider trajectories that pass through boundary points. Since points on the boundaries are a set of measure zero in D, the set of initial conditions producing these trajectories are a set of measure zero in D. Since the set of initial conditions that produce non-singleton trajectories is a subset of the set of initial conditions that produce trajectories passing through boundary points, the set of initial conditions producing non-singleton trajectories is a set of measure

zero in D. Finally the intersection of X_0 which is open in $\mathbb{R}^{n_x}$ with this set of initial conditions is a set of measure zero.

If the initial conditions of (8) are functions of a set of parameters, then the result of the previous theorem may not hold. It is possible that the functions always map the parameters to initial conditions resulting in non-singleton trajectories. Sufficient conditions to determine functions that map parameters to sets of initial conditions for which theorem (2) holds is under investigation.

In the remainder of the paper, the following statement is assumed to hold.

Assumption 3. Let $\tilde{P}$ the set of parameters such that $\mathbf{x}(t, \mathbf{p})$ with $\mathbf{p} \in \tilde{P}$ is not a singleton trajectory. The set $\tilde{P}$ has measure zero in P.

The equations (5), (6) and (7) have to be solved numerically. The solution of (5) poses no problems and can be accomplished with an ordinary IVP solver because $\mathbf{f}^i$ are Lipschitz continuous vector field on their domains. On the other hand, solutions of (6) and (7) require further discussion. Since $\mathbf{f}^i$ are only piecewise continuously differentiable, $J_{\mathbf{p}}\mathbf{f}^i$ and $J_{\mathbf{x}}\mathbf{f}^i$ are not continuous on the domain of $\mathbf{f}^i$. As a result (6) and (7) are differential equations with discontinuities in time. These discontinuities need to be detected for an efficient and correct solution. By virtue of assumption (2), the points where $\mathbf{f}^i$ are not differentiable are on the boundaries of the partitions and satisfy $d^i_{k,j}(\mathbf{x}(t, \mathbf{p}), \mathbf{p}) = 0$ for some values of k and j. Event detection algorithms (Park and Barton, 1996) are used to determine t^* such that $d^i_{k,j}(\mathbf{x}(t^*, \mathbf{p}), \mathbf{p}) = 0$. The event detection algorithm tracks the signs of $d^i_{k,j}(\mathbf{x}(t, \mathbf{p}), \mathbf{p})$ for each i and j. A sign change implies that the state trajectory, $\mathbf{x}(t^*, \mathbf{p})$ crossed a boundary of discontinuity. The event detection algorithm finds the earliest time when the boundary crossing occurred. The integration of (6) and (7) are restarted at t^*.

Event detection algorithms are also used to detect trajectories that are non-singleton. Once t^* is detected where $d^i_{k,j}(\mathbf{x}(t^*, \mathbf{p}), \mathbf{p}) = 0$ for some k and j, $\dot{d}^i_{k,j}(\mathbf{x}(t^*, \mathbf{p}), \mathbf{p})$ is checked. If $\dot{d}^i_{k,j}(\mathbf{x}(t^*, \mathbf{p}), \mathbf{p}) = 0$ for some k and j, this implies that the state trajectory may not leave the surface defined by $d^i_{k,j}(\mathbf{x}(t^*, \mathbf{p}), \mathbf{p}) = 0$ resulting in a trajectory that is possibly non-singleton. Integration is continued until $t + \delta t$ where δt is a small quantity. If there exists any k and j such that $d^i_{k,j}(\mathbf{x}(t^*, \mathbf{p}), \mathbf{p}) = 0$ and $d^i_{k,j}(\mathbf{x}(t^* + \delta t, \mathbf{p}), \mathbf{p}) = 0$, the trajectory is considered to be not a singleton trajectory.

In case $\bar{\mathbf{p}}$ does not correspond to a singleton trajectory, the definition of the generalized Jacobian (4) can be used to approximate an element of the generalized Jacobian. Random parameter values in an ϵ neighborhood, $N_\epsilon(\bar{\mathbf{p}})$, can be used to find a nearby singleton trajectory and calculate an approximate generalized Jacobian.

The necessary generalized gradient information for the objective and constraint functions of (2) is obtained by applying the chain rules for generalized gradients once an element or an approximation of $\partial_{\mathbf{p}}\mathbf{x}(t, \mathbf{p})$ is calculated. The calculated generalized gradient information is used in conjunction with a bundle method to obtain a stationary point of (2).

4. ILLUSTRATIVE EXAMPLE

In this section, a modified version of the cell cycle specific chemotherapy model introduced in Pannetta and Adam (1995) is used to determine an optimal chemotherapy drug schedule. The dynamics,

$$\alpha = a - m - n$$

$$\dot{P} = \alpha P + bQ - F_A(v_A, P) \tag{9}$$

$$F_A(v_A, P) = \begin{cases} 0 & \text{if } v_A - \bar{v}_A \leq 0 \\ k_A(v_A - \bar{v}_A)P & \text{if } v_A - \bar{v}_A \geq 0 \end{cases}$$

$$\dot{Q} = mP - bQ - F_B(v_B, Q) \tag{10}$$

$$F_B(v_B, Q) = \begin{cases} 0 & \text{if } v_B - \bar{v}_B \leq 0 \\ k_B(v_B - \bar{v}_B)Q & \text{if } v_B - \bar{v}_B \geq 0 \end{cases}$$

$$\dot{Y} = \sigma Y(1 - Y/K) - k_A v_A Y - k_B v_B Y \tag{11}$$

$$\dot{v}_A = u_A - \gamma_A v_A \tag{12}$$

$$\dot{v}_B = u_B - \gamma_B v_B \tag{13}$$

represents the behavior of tumor cells and healthy cells in human tissue under chemotherapy. The tissue comprises healthy cells, Y, proliferating tumor cells, P, and quiescent tumor cells, Q. Chemotherapy comprises two drugs; A and B. u_A and u_B are the chemotherapy drug schedules. v_A and v_B are the exponentially decaying drug concentrations in the tissue. Tumor cells develop resistance to drugs. As a result, drugs are effective against the tumor cells only if their concentrations in the tissue are above $\bar{v}_A$ and $\bar{v}_B$. A fraction, n, of proliferating cells die of natural causes and and a fraction, m, of proliferating cells become quiescent cells. The increase in proliferating cell population by cell division is represented as another fraction, a, of the proliferating cell population. In addition, a fraction, b of quiescent cells become proliferating cells. The tumor cell dynamics are in (9) and (10).

A logistic equation (11) governs the healthy cell population to ensure that the number of healthy cells does not exceed the carrying capacity, K. Numerical values for the various parameters are displayed in Table 1. Most of the values are obtained from (Dua et al., 2008) where cell cycle specific chemotherapy with a single drug and without drug resistance is considered. Note that $[D]$ is a unit of drug concentration. The program,

$$\min_{\mathbf{u}_A, \mathbf{u}_B} P(t_f, \mathbf{u}_A, \mathbf{u}_B) + Q(t_f, \mathbf{u}_A, \mathbf{u}_B) \tag{14}$$

$$\text{s.t: } Y(t_f, \mathbf{u}_A, \mathbf{u}_B) \geq Y_{\min} \tag{15}$$

$$u_{\min} \leq u_{A,j} \leq u_{\max},\ j = 1, \ldots, n_f,$$

$$u_{\min} \leq u_{B,j} \leq u_{\max},\ j = 1, \ldots, n_f,$$

$$P(1, \mathbf{u}_A, \mathbf{u}_B) = P_0,\ Q(1, \mathbf{u}_A, \mathbf{u}_B) = Q_0,$$

$$Y(1, \mathbf{u}_A, \mathbf{u}_B) = Y_0,\ v_A(1, \mathbf{u}_A, \mathbf{u}_B) = 0,$$

$$v_B(1, \mathbf{u}_A, \mathbf{u}_B) = 0$$

where $\mathbf{u}_A = \{u_{A,j}\}$ and $\mathbf{u}_B = \{u_{B,j}\}$ are the set of daily drug doses for an n_f-day treatment, is solved to minimize the tumor cell population without totally destroying the healthy cell population. The numerical values used are in Table 2.

DSL48SE is the IVP solver (Tolsma, 2001; Tolsma and Barton, 2002; Feehery et al., 1997) used to integrate the dynamics and the corresponding auxiliary equations to obtain an element of the generalized Jacobian. The event detection algorithm of DSL48SE (Park and Barton, 1996) is used to detect non-singleton trajectories. The necessary Jacobians for the auxiliary system of equations are obtained using automatic differentiation algorithms implemented in DAEPACK (Tolsma and Barton, 2000). The differential equations are integrated with an absolute tolerance of 1×10^{-7} and a relative tolerance of 1×10^{-9}.

A modified proximal bundle method based on the algorithm in (Lukšan and Vlček, 2001) is used to solve (14). A penalty approach to handle (15) is used because the algorithm in (Lukšan and Vlček, 2001) is handles only linear constraints on the decision variables. The objective of (14) is augmented with (15) to obtain

$$J(\mathbf{u}_A, \mathbf{u}_B) = P(t_f, \mathbf{u}_A, \mathbf{u}_B) + Q(t_f, \mathbf{u}_A, \mathbf{u}_B) + \mu_k \max(Y_{\min} - Y(t_f, \mathbf{u}_A, \mathbf{u}_B), 0)$$

where μ_k is the penalty parameter. The modified program is successively solved three times with increasing penalty parameter to an optimality tolerance of 1×10^{-5}. The solution of the preceding programs are used as the initial guesses for the following programs. For the first program, the drug schedules are assigned random values between 0.0 and 5.0. The penalty parameter values are 5000, 25000 and 125000.

The cell population numbers at the beginning and end of the treatment are in Table 3. The tumor cell population is reduced to one percent of its initial size. The drug schedules are shown in Figure 1 and Figure 2. The preference to use drug B is clearly seen. The effects of the drugs are proportional to the corresponding cell populations. Therefore using drug B results in more effective treatment as the population of quiescent cells is greater than that of proliferating cells. In addition, the ratio of tumor cells killed to the ratio of healthy cells killed per unit drug concentration is larger for drug B.

The drug B schedule has four distinctive phases. The initial four-day treatment reverses the increase in the tumor cell population by using drug B as much as possible. In the next week, the drug B concentration is allowed to decay to a tolerable level for the patient. The treatment until the last three days keeps the drug B concentration at that tolerable level. In the last days of the treatment, the drug dose is increased to kill the maximum number of tumor cells. This spike in the drug concentration shows its effect on the healthy cell population after the treatment is over and does not affect (15) significantly.

5. CONCLUSION

In this document, a novel method to optimize the performance of a class of systems with varying structure has been introduced. The theoretical basis and an initial implementation has been described. An illustrative numerical example has been presented.

The implementation of the optimization method will be streamlined in the future. There are different variants of

Table 1. Parameters of equations (9)-(13)

a	$0.500\ \text{day}^{-1}$	$\bar{v}_A$	10.000 [D]
m	$0.218\ \text{day}^{-1}$	$\bar{v}_B$	10.000 [D]
n	$0.477\ \text{day}^{-1}$	k_A	$8.400 \times 10^{-3}\ \text{day}^{-1}[D]^{-1}$
b	$0.100\ \text{day}^{-1}$	k_B	$8.400 \times 10^{-3}\ \text{day}^{-1}[D]^{-1}$
σ	$0.100\ \text{day}^{-1}$	K	$10000M$ cells

bundle methods available (Mäkelä, 2001). These variants will be investigated in addition to different methods to handle nonlinear constraints. In this paper, a penalty approach is described. Improvements to this approach will be considered and the improvement function approach will be investigated (Mäkelä, 2001).

The performance of the proposed algorithm will be compared to the performance of the available transcription-based algorithms. It is expected that the method introduced in this document can be advantageous in problems with a large number states and candidate dynamics.

Abstract: For good performance in practice, real-time optimization schemes need to be able to deal with the inevitable plant-model mismatch problem. Unlike the two-step schemes combining parameter estimation and optimization, the modifier-adaptation approach uses experimental gradient information and does not require the model parameters to be estimated on-line. The dual modifier-adaptation approach presented in this paper drives the process towards optimality, while paying attention to the accuracy of the estimated gradients. The gradients are estimated from successive operating points generated by the optimization algorithm. The novelty lies in the development of an upper bound on the norm of the gradient errors, which is used as a constraint when determining the next operating point. The proposed approach is demonstrated in simulation via the real-time optimization of a continuous reactor.

Keywords: Real-time optimization, estimation of experimental gradients, modifier adaptation.

1. INTRODUCTION

Real-time optimization (RTO) of continuous plants aims at improving some steady-state performance index (Marlin and Hrymak [1997]). Since the majority of RTO schemes uses a model of the plant, reaching optimal performance in the presence of plant-model mismatch is a difficult task, which necessitates adaptation based on measured information. Chachuat et al. [2009] proposed a three-way classification of RTO schemes. One class includes the so-called modifier-adaptation approach (Marchetti et al. [2009]), whereby appropriate terms are added to the optimization problem and identified so that the KKT conditions of the model match those of the plant. In this context, the modifier-adaptation approach requires to be able to estimate on-line the experimental gradients, i.e., the derivatives of the plant outputs with respect to the inputs. This paper investigates the estimation of experimental gradients and their use in modifier-adaptation schemes.

A comparison of different approaches for on-line gradient estimation is given in Mansour and Ellis [2003]. Finite-difference techniques can be used to estimate the gradients experimentally. The most straightforward approach consists in perturbating each input individually around the current operating point to get an estimate of the corresponding gradient elements. This is the case, e.g., when forward finite differencing (FFD) is applied at each RTO iteration. An alternative approach, which was introduced in the ISOPE (Integrated System Optimization and Parameter Estimation) literature under the name *dual ISOPE*, is to estimate the gradients based on the current and past operating points (Brdyś and Tatjewski [1994, 2005]). The key issue therein is the ability to estimate the experimental gradients reliably while updating the operating point. Indeed, there are two conflicting objectives: the "primal objective" consists in solving the optimization problem, while the "dual objective" aims at estimating accurate gradients. These conflicting tasks can be accommodated by adding a constraint in the optimization problem so as to ensure sufficiently rich information in the measurements and guarantee gradient accuracy. Brdyś and Tatjewski [1994, 2005] proposed a constraint that prevents ill-conditioning in gradient computation. The present paper goes further and investigates the two main sources of errors, namely the error introduced by numerical approximation of a derivative (truncation error) and measurement noise. A constraint that enforces an upper bound on the gradient error norm is proposed. Since the constraint for ensuring sufficient information might compromise optimality in the vicinity of the optimum, Gao and Engell [2005] suggested using the ill-conditioning measure not to constrain the optimization problem but rather to determine whether an additional input perturbation is needed. Note that such a scheme could also be used in the context of the dual-modifier approach proposed here.

The paper is organized as follows. Section 2 formulates the optimization problem. The modifier-adaptation scheme is reviewed in Section 3. Analysis of the errors in the gradient estimates obtained from past operating points is carried out in Section 4. Based on this analysis, Section 5 proposes a norm-based constraint, which is incorporated into the dual modifier-adaptation algorithm presented in Section 6. The approach is illustrated via the reactor of the Williams-Otto plant in Section 7, and Section 8 concludes the paper and presents directions for future work.

2. PROBLEM FORMULATION

For the sake of simplicity, an unconstrained optimization problem is considered throughout. This way, only the

gradient of the objective function needs to be estimated, while in the constrained case, the constraint gradients would need to be evaluated as well. A possible way of tackling constrained optimization problems will be sketched in the conclusion section.

The unconstrained optimization problem reads:

$$\min_{\mathbf{u}} \quad \Phi_p(\mathbf{u}) := \phi(\mathbf{u}, \mathbf{y}_p(\mathbf{u})) \tag{1}$$

where $\mathbf{u} \in \mathbb{R}^{n_u}$ are the decision (or input) variables, $\mathbf{y}_p \in \mathbb{R}^{n_y}$ are the measured (or output) variables, and $\phi : \mathbb{R}^{n_u} \times \mathbb{R}^{n_y} \to \mathbb{R}$ is the scalar cost function to be minimized. The notation $(\cdot)_p$ will be used for the variables that are associated with the plant. Also, it is assumed that $\phi(\mathbf{u}, \mathbf{y}_p)$ is a known function of $\mathbf{u}$ and $\mathbf{y}_p$. On the other hand, the steady-state input-output mapping of the plant, $\mathbf{y}_p(\mathbf{u})$, is typically unknown, and only the approximate model $f(\mathbf{u}, \mathbf{y}, \boldsymbol{\theta}) = \mathbf{0}$ is available, where $\boldsymbol{\theta} \in \mathbb{R}^{n_\theta}$ is the set of model parameters. Assuming that the model outputs $\mathbf{y}$ can be expressed explicitly as functions of $\mathbf{u}$ and $\boldsymbol{\theta}$, the cost function predicted by the model becomes $\Phi(\mathbf{u}, \boldsymbol{\theta}) := \phi(\mathbf{u}, \mathbf{y}(\mathbf{u}, \boldsymbol{\theta}))$.

It is furthermore assumed that the decision variables $\mathbf{u}$ are of the same order of magnitude, which can be achieved via scaling. For example, if the decision variable u_i remains within the interval $[u_{i,\mathrm{a}}, u_{i,\mathrm{b}}]$, it can be scaled as $u_i^{\mathrm{scaled}} = (u_i - u_{i,\mathrm{a}})/(u_{i,\mathrm{b}} - u_{i,\mathrm{a}})$. For notional simplicity, the superscript indicating a scaled variable will be omitted in the sequel.

3. MODIFIER-ADAPTATION SCHEME

In the modifier-adaptation scheme, a gradient-correction term is added to the cost function of the model-based optimization problem (Marchetti et al. [2009]). At the kth iteration, the next input $\mathbf{u}_{k+1}$ is obtained as:

$$\mathbf{u}_{k+1} = \arg\min_{\mathbf{u}} \Phi_m(\mathbf{u}, \boldsymbol{\theta}) := \Phi(\mathbf{u}, \boldsymbol{\theta}) + \boldsymbol{\lambda}_k^{\mathsf{T}} \mathbf{u} \tag{2}$$

where $\boldsymbol{\lambda}_k$ is the cost-gradient modifier at the kth iteration. This modifier is adapted at each iteration based on the difference between the gradient of the plant and that predicted by the model. For example, upon implementation of a first-order exponential filter, the gradient modifier is calculated as:

$$\boldsymbol{\lambda}_k^{\mathsf{T}} = (1-d)\boldsymbol{\lambda}_{k-1}^{\mathsf{T}} + d\left[\frac{\partial \Phi_p}{\partial \mathbf{u}}(\mathbf{u}_k) - \frac{\partial \Phi}{\partial \mathbf{u}}(\mathbf{u}_k, \boldsymbol{\theta})\right] \tag{3}$$

with the filter gain $d \in (0,\ 1]$. Computation of the modifier $\boldsymbol{\lambda}_k$ requires the knowledge of the plant gradient $\frac{\partial \Phi_p}{\partial \mathbf{u}}(\mathbf{u}_k)$.

An appealing property of the modifier-adaptation scheme is that, upon convergence and in the absence of noise, the optimum $\mathbf{u}_\infty$ for the modified model-based optimization problem (2) satisfies the first-order necessary conditions of optimality of the optimization problem (1) (Marchetti et al. [2009]). Note that this is the case despite plant-model mismatch. Note also that the need to match the plant outputs $\mathbf{y}_p(\mathbf{u})$ by means of a parameter estimation problem, as this is the case for the ISOPE modifier (Roberts [1979]), is removed. However, the downside of modifier adaptation lies in the need to estimate the experimental gradient $\frac{\partial \Phi_p}{\partial \mathbf{u}}$.

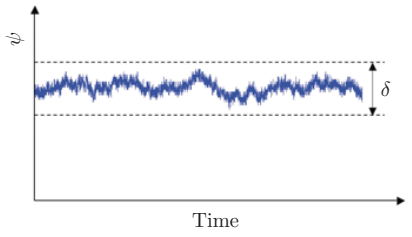

Fig. 1. Noisy cost function at steady state.

4. EXPERIMENTAL GRADIENT COMPUTED FROM PAST OPERATING POINTS

It is assumed that the cost function can be evaluated from the noisy output measurements as follows:

$$\psi(\mathbf{u}) = \phi(\mathbf{u}, \mathbf{y}_p(\mathbf{u}) + \boldsymbol{\nu}) = \Phi_p(\mathbf{u}) + v \tag{4}$$

where $\boldsymbol{\nu}$ is the measurement noise on the outputs and v the induced noise in the cost estimates. Note that, even if $\boldsymbol{\nu}$ is zero mean, v might have a nonzero mean if the function $\phi(\mathbf{u}, \mathbf{y})$ is nonlinear in $\mathbf{y}$.

The forthcoming analysis is conducted assuming that the cost estimates remain within the interval δ at steady-state operation, as illustrated in Figure 1. Based on a statistical description of v, δ could be selected by considering a desired confidence interval. Values that fall outside the selected confidence interval can simply be discarded.

Consider the kth iteration and the n_u past operating points, $\mathbf{u}_{k-j},\ j = 0, \ldots, n_u - 1$, and let us evaluate the cost as a function of the next operating point, which will generically be labeled $\mathbf{u}$. Using a first-order approximation of $\Phi_p(\mathbf{u}_{k-j})$ in the neighborhood of $\mathbf{u}$, the value of ψ at the past operating points is given by:

$$\begin{aligned}\psi(\mathbf{u}_{k-j}) = \Phi_p(\mathbf{u}_{k-j}) + v_{k-j} = (\psi(\mathbf{u}) - v) \\ + \frac{\partial \Phi_p}{\partial \mathbf{u}}(\mathbf{u})[\mathbf{u}_{k-j} - \mathbf{u}] + O\left(\|\mathbf{u}_{k-j} - \mathbf{u}\|^2\right) + v_{k-j}\end{aligned} \tag{5}$$

and, by neglecting the higher-order and noise terms:

$$\psi(\mathbf{u}_{k-j}) = \psi(\mathbf{u}) + \hat{\boldsymbol{\beta}}(\mathbf{u})[\mathbf{u}_{k-j} - \mathbf{u}], \tag{6}$$

where $\hat{\boldsymbol{\beta}}(\mathbf{u})$ is an estimate of the experimental cost gradient $\frac{\partial \Phi_p}{\partial \mathbf{u}}(\mathbf{u})$. $\hat{\boldsymbol{\beta}}(\mathbf{u})$ can be computed from the n_u past operating points $\mathbf{u}_k, \ldots, \mathbf{u}_{k-n_u+1}$ and the corresponding noisy cost values $\psi(\mathbf{u}_k), \ldots, \psi(\mathbf{u}_{k-n_u+1})$ by writing (6) in the following matrix form (Brdyś and Tatjewski [2005]):

$$\hat{\boldsymbol{\beta}}(\mathbf{u}) = \mathcal{Y}(\mathbf{u})\, \mathcal{U}^{-1}(\mathbf{u}) \tag{7}$$

with

$$\mathcal{U}(\mathbf{u}) := [\, \mathbf{u} - \mathbf{u}_k \ \ldots\ \mathbf{u} - \mathbf{u}_{k-n_u+1} \,] \in \mathbb{R}^{n_u \times n_u} \tag{8}$$

$$\mathcal{Y}(\mathbf{u}) := [\, \psi(\mathbf{u}) - \psi(\mathbf{u}_k) \ \ldots\ \psi(\mathbf{u}) - \psi(\mathbf{u}_{k-n_u+1}) \,] \tag{9}$$

The gradient error is defined as $\boldsymbol{\epsilon}(\mathbf{u}) := \hat{\boldsymbol{\beta}}(\mathbf{u}) - \frac{\partial \Phi_p}{\partial \mathbf{u}}(\mathbf{u})$, which, from (7) together with (4), can be split as $\boldsymbol{\epsilon}(\mathbf{u}) = \boldsymbol{\epsilon}^t(\mathbf{u}) + \boldsymbol{\epsilon}^n(\mathbf{u})$, with:

$$\begin{aligned}\boldsymbol{\epsilon}^t(\mathbf{u}) = [\, \Phi_p(\mathbf{u}) - \Phi_p(\mathbf{u}_k) \quad \ldots \\ \ldots \quad \Phi_p(\mathbf{u}) - \Phi_p(\mathbf{u}_{k-n_u+1}) \,]\, \mathcal{U}^{-1}(\mathbf{u}) - \frac{\partial \Phi_p}{\partial \mathbf{u}}(\mathbf{u})\end{aligned} \tag{10}$$

$$\boldsymbol{\epsilon}^n(\mathbf{u}) = [\, v - v_k \quad \ldots \quad v - v_{k-n_u+1} \,]\, \mathcal{U}^{-1}(\mathbf{u}) \tag{11}$$

where $\boldsymbol{\epsilon}^t$ and $\boldsymbol{\epsilon}^n$ represent the errors due to truncation and noise, respectively. Next, we investigate these two components of the gradient error.

Gradient Error due to Truncation. An upper bound on the norm of this error is given in the next proposition.

Proposition 1. Let $\Phi_p(\mathbf{u})$ be twice continuously differentiable with respect to $\mathbf{u}$. Then, given the n_u past operating points $\mathbf{u}_k, \ldots, \mathbf{u}_{k-n_u+1}$, an upper bound on $\|\boldsymbol{\epsilon}^t(\mathbf{u})\|$ is given by

$$\|\boldsymbol{\epsilon}^t(\mathbf{u})\| \leq \mathcal{E}^t(\mathbf{u}), \tag{12}$$

with

$$\mathcal{E}^t(\mathbf{u}) := \frac{\mathsf{d}_2}{2}\Big\| \big[\ (\mathbf{u}-\mathbf{u}_k)^\mathsf{T}(\mathbf{u}-\mathbf{u}_k)\ \ldots \tag{13}$$
$$\ldots\ (\mathbf{u}-\mathbf{u}_{k-n_u+1})^\mathsf{T}(\mathbf{u}-\mathbf{u}_{k-n_u+1})\ \big]\ \mathcal{U}^{-1}(\mathbf{u})\Big\|$$

where d_2 is the largest absolute eigenvalue of the Hessian of $\Phi_p(\cdot)$.

Proof. By Taylor series expansion of $\Phi_p(\mathbf{u}_{k-j})$ at $\mathbf{u}$ and upper bounding of the norm of the Hessian of Φ_p [Marchetti, 2009]. □

Note that d_2 represents an upper bound on the curvature of $\Phi_p(\cdot)$.

Gradient Error due to Measurement Noise. For relating the error norm $\|\boldsymbol{\epsilon}^n(\mathbf{u})\|$ to the location of the new operating point, the concepts of affine subspaces and distance between complement affine subspaces will be used (see Appendix A for a brief review of these concepts).

The largest possible value of $\|\boldsymbol{\epsilon}^n(\mathbf{u})\|$, noted $\|\boldsymbol{\epsilon}^n(\mathbf{u})\|_{\max}$, is computed in the next proposition.

Proposition 2. Given the n_u past operating points $\mathbf{u}_k, \ldots, \mathbf{u}_{k-n_u+1}$ and the interval δ for the noisy function $\psi(\cdot)$, the largest possible value of $\|\boldsymbol{\epsilon}^n(\mathbf{u})\|$ is

$$\|\boldsymbol{\epsilon}^n(\mathbf{u})\|_{\max} = \delta / l_{\min}(\mathbf{u}) \tag{14}$$

where $l_{\min}(\mathbf{u})$ is the shortest distance between all possible pairs of complement affine subspaces that can be generated from $\mathcal{S} = \{\mathbf{u}, \mathbf{u}_k, \ldots, \mathbf{u}_{k-n_u+1}\}$.

Proof. The proof proceeds in two parts: (i) the largest error occurs when the error v is either $\delta/2$ for some of the operating points and $-\delta/2$ for the other points, with each set of points defining an affine subspace; and (ii) the error vector $\boldsymbol{\epsilon}^n(\mathbf{u})$ is normal to both affine subspaces, which results in the largest possible error norm given by (14) [Marchetti, 2009]. □

5. UPPER BOUND ON GRADIENT ERROR

A bound on the condition number of the matrix $\mathcal{U}(\mathbf{u})$ was proposed in Brdyś and Tatjewski [1994, 2005]. This bound ensures that the new operating point does not introduce large errors in the gradient estimates due to ill-conditioning of $\mathcal{U}(\mathbf{u})$. However, the bound is not directly related to the errors resulting from truncation and measurement noise. This section introduces a consistent, although possibly conservative, upper bound on the gradient error norm.

Consider the desired upper bound $\mathcal{E}^U$ on the gradient error norm:

$$\|\boldsymbol{\epsilon}(\mathbf{u})\| \leq \|\boldsymbol{\epsilon}^t(\mathbf{u})\| + \|\boldsymbol{\epsilon}^n(\mathbf{u})\| \leq \mathcal{E}^U \tag{15}$$

Given the n_u past operating points $\mathbf{u}_k, \ldots, \mathbf{u}_{k-n_u+1}$, the following theorem provides a sufficient condition for the location of $\mathbf{u}$ so as to satisfy (15).

Theorem 1. (Sufficient condition for gradient accuracy). The gradient error norm $\|\boldsymbol{\epsilon}(\mathbf{u})\|$ does not exceed the desired upper bound $\mathcal{E}^U$ by choosing $\mathbf{u}$ that satisfies

$$\mathcal{E}(\mathbf{u}) := \mathcal{E}^t(\mathbf{u}) + \|\boldsymbol{\epsilon}^n(\mathbf{u})\|_{\max} \leq \mathcal{E}^U, \tag{16}$$

with $\mathcal{E}^t(\mathbf{u})$ and $\|\boldsymbol{\epsilon}^n(\mathbf{u})\|_{\max}$ given by (13) and (14), respectively.

Proof. The proof follows from (15), inequality (12) and the fact that $\|\boldsymbol{\epsilon}^n(\mathbf{u})\| \leq \delta / l_{\min}(\mathbf{u})$ from (14). □

For given values of δ and d_2, there is a minimal value that $\mathcal{E}(\mathbf{u})$ can take. Hence, $\mathcal{E}^U$ should be selected larger than this minimal value for the constraint (16) to be feasible.

Example 1. Consider the two-dimensional case ($n_u = 2$) with $\delta = 0.2$, $\mathsf{d}_2 = 2$ and the past operating points $\mathbf{u}_k = [0\ \ -0.5]^\mathsf{T}$ and $\mathbf{u}_{k-1} = [0\ \ 0.5]^\mathsf{T}$. The upper bounds $\mathcal{E}^t(\mathbf{u})$ and $\|\boldsymbol{\epsilon}^n(\mathbf{u})\|_{max}$ can be evaluated in terms of the location of the new operating point $\mathbf{u} = [u_1\ \ u_2]^\mathsf{T}$. Figures 2a-c show the contours of the error norms $\mathcal{E}^t(\mathbf{u})$, $\|\boldsymbol{\epsilon}^n(\mathbf{u})\|_{max}$ and $\mathcal{E}(\mathbf{u})$. It is seen that (i) both $\mathcal{E}^t(\mathbf{u})$ and $\|\boldsymbol{\epsilon}^n(\mathbf{u})\|_{max}$ increase as $\mathcal{U}(\mathbf{u})$ becomes more ill-conditioned ($\mathbf{u}$ aligned with $\mathbf{u}_k$ and $\mathbf{u}_{k-1}$), and (ii) the two regions generated by the constraint (16) *are nonconvex.*

Convex Constraint. The objective being to use the constraint (16) in the optimization problem (2), the fact that this constraint is nonconvex creates the possibility of multiple local solutions. Next, we introduce a tight relaxation that makes the constraint convex.

It can be seen that, for a given error level c, the expression $\mathcal{E}^t(\mathbf{u}) = c$ generates two $(n_u - 1)$-dimensional spheres of radius $r = \frac{c}{\mathsf{d}_2}$. The centers of these spheres are located symmetrically on each side of the hyperplane $\mathbf{n}_k^\mathsf{T}\mathbf{u} = b_k$ generated by the n_u past operating points $\mathbf{u}_k, \ldots, \mathbf{u}_{k-n_u+1}$. Considering the new operating point $\mathbf{u}$ located on the sphere, the center point is given by

$$\mathbf{u}_c^\mathsf{T}(\mathbf{u}) = \frac{1}{2}\Big[\ \mathbf{u}^\mathsf{T}\mathbf{u} - \mathbf{u}_k^\mathsf{T}\mathbf{u}_k\ \cdots \tag{17}$$
$$\mathbf{u}^\mathsf{T}\mathbf{u} - \mathbf{u}_{k-n_u+1}^\mathsf{T}\mathbf{u}_{k-n_u+1}\ \Big]\ \mathcal{U}^{-1}(\mathbf{u}).$$

It can be shown that $\|\boldsymbol{\epsilon}^n(\mathbf{u})\|_{\max}$ is convex on each side of the hyperplane $\mathbf{n}_k^\mathsf{T}\mathbf{u} = b_k$ (see also Figure 2b). Hence, non-convexity of the constraint (16) is due to the part of the aforementioned spheres that crosses the hyperplane $\mathbf{n}_k^\mathsf{T}\mathbf{u} = b_k$. The distance (positive or negative) from the center point $\mathbf{u}_c(\mathbf{u})$ to the hyperplane $\mathbf{n}_k^\mathsf{T}\mathbf{u} = b_k$ is given by:

$$l_C(\mathbf{u}) = \frac{b_k - \mathbf{n}_k^\mathsf{T}\mathbf{u}_c(\mathbf{u})}{\|\mathbf{n}_k\|}. \tag{18}$$

Given the n_u operating points $\mathbf{u}_k, \ldots, \mathbf{u}_{k-n_u+1}$, the point $\mathbf{u}_{\mathrm{m},k}$ can be obtained by projecting the center point $\mathbf{u}_c(\mathbf{u})$ on the hyperplane $\mathbf{n}_k^\mathsf{T}\mathbf{u} = b_k$:

$$\mathbf{u}_{\mathrm{m},k} = \mathbf{u}_c(\mathbf{u}) + \frac{l_C(\mathbf{u})}{\|\mathbf{n}_k\|}\mathbf{n}_k \tag{19}$$

It appears that $\mathbf{u}_{\mathrm{m},k}$ is independent of $\mathbf{u}$. For a given upper bound $\mathcal{E}^U$, it is then possible to define convex feasible

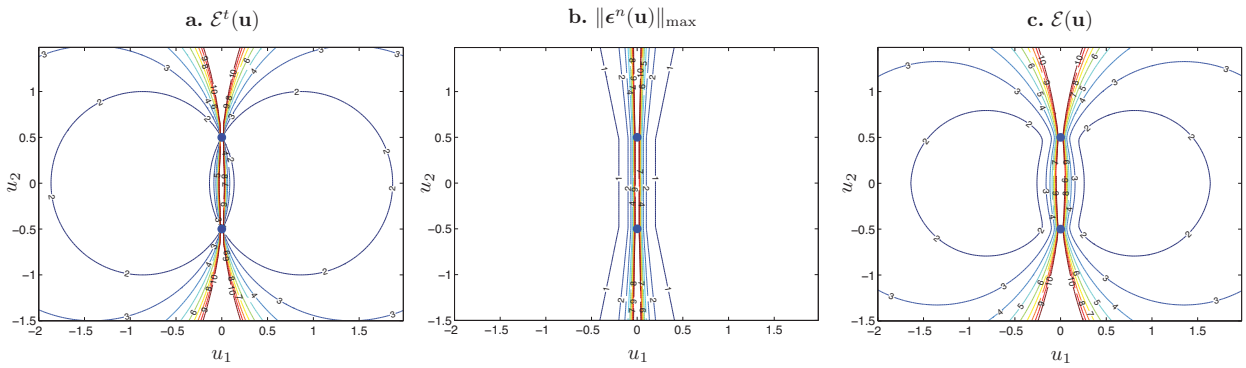

Fig. 2. Contour maps for the norm of the gradient error due to (**a**) truncation error, (**b**) measurement noise, and (**c**) total error.

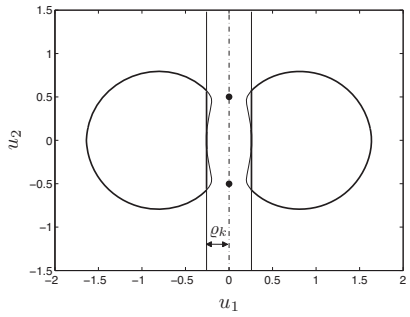

Fig. 3. Convex regions (in bold) corresponding to the constraint $\mathcal{E}(\mathbf{u}) \leq 2$.

regions by adding constraints expressing the minimal distance between the new operating point $\mathbf{u}$ and the hyperplane, which eliminates the non-convex part of the regions generated by (16), as illustrated in Figure 3. The minimal point-to-hyperplane distance ϱ_k can be determined numerically by finding the smallest absolute value solution of the following equation:

$$\mathcal{E}\left(\mathbf{u}_{\mathrm{m},k} + \frac{\varrho_k}{\|\mathbf{n}_k\|}\mathbf{n}_k\right) = \mathcal{E}^U$$

6. DUAL MODIFIER-ADAPTATION SCHEME

The dual modifier-adaptation scheme proposed in this section uses the upper bound on the gradient error defined in Section 5 as a constraint in the optimization problem (2). On each side of the hyperplane $\mathbf{n}_k^\mathsf{T}\mathbf{u} = b_k$ generated by the n_u past operating points, a modified model-based optimization problem is solved. The optimization problem corresponding to the half space $\mathbf{n}_k^\mathsf{T}\mathbf{u} > b_k$ reads:

$$\mathbf{u}_{k+1}^+ = \arg\min_{\mathbf{u}} \Phi_m(\mathbf{u},\boldsymbol{\theta}) = \Phi(\mathbf{u},\boldsymbol{\theta}) + \boldsymbol{\lambda}_k^\mathsf{T}\mathbf{u} \qquad (20)$$
$$\text{s.t.} \quad \mathcal{E}(\mathbf{u}) \leq \mathcal{E}^U, \qquad \mathbf{n}_k^\mathsf{T}\mathbf{u} > b_k + \varrho_k\|\mathbf{n}_k\|$$

while, for the half space $\mathbf{n}_k^\mathsf{T}\mathbf{u} < b_k$, one has:

$$\mathbf{u}_{k+1}^- = \arg\min_{\mathbf{u}} \Phi_m(\mathbf{u},\boldsymbol{\theta}) = \Phi(\mathbf{u},\boldsymbol{\theta}) + \boldsymbol{\lambda}_k^\mathsf{T}\mathbf{u} \qquad (21)$$
$$\text{s.t.} \quad \mathcal{E}(\mathbf{u}) \leq \mathcal{E}^U, \qquad \mathbf{n}_k^\mathsf{T}\mathbf{u} < b_k - \varrho_k\|\mathbf{n}_k\|$$

The modifiers $\boldsymbol{\lambda}_k^\mathsf{T}$ are adapted as in (3). The next operating point is chosen as the value of $\{\mathbf{u}_{k+1}^+, \mathbf{u}_{k+1}^-\}$ that minimizes the augmented cost function $\Phi_m(\mathbf{u},\boldsymbol{\theta})$.

7. OPTIMIZATION OF REACTOR OPERATION

The reactor in the Williams-Otto plant (Williams and Otto [1960]), as modified by Roberts [1979], is used to illustrate the dual modifier-adaptation scheme. This reactor example has also been used to illustrate model adequacy and RTO performance (Forbes et al. [1994], Zhang and Forbes [2000]). It consists of an ideal CSTR in which the following reactions occur:

$$\begin{array}{ll} A + B \longrightarrow C & \bar{k}_1 = 1.660 \times 10^6 e^{-6666.7/(T_R+273.15)} \\ C + B \longrightarrow P + E & \bar{k}_2 = 7.212 \times 10^8 e^{-8333.3/(T_R+273.15)} \\ C + P \longrightarrow G & \bar{k}_3 = 2.675 \times 10^{12} e^{-11111/(T_R+273.15)} \end{array}$$

where the reactants A and B are fed with the mass flowrates F_A and F_B, respectively. The desired products are P and E. C is an intermediate product and G is an undesired product. The product stream has the mass flowrate $F = F_A + F_B$. Operation is isothermal at the temperature T_R. The reactor mass holdup is 2105 kg.

The objective is to maximize profit, which is expressed as the cost difference between the products and the reactants:

$$\phi(\mathbf{u},\mathbf{y}) = 1143.38X_P F + 25.92X_E F - 76.23F_A - 114.34F_B$$

The flowrate of reactant A is fixed at 1.8275 kg/s. The flowrate of reactant B and the reactor temperature are the decision variables, thus $\mathbf{u} = [F_B \; T_R]^\mathsf{T}$.

In this example, the aforementioned reaction scheme corresponds to the simulated reality. However, since it is assumed that the reaction scheme is not well understood, the following two reactions have been proposed to model the system (Forbes et al. [1994]):

$$\begin{array}{ll} A + 2B \longrightarrow P + E & k_1 = 2.189 \times 10^8 e^{-8077.6/(T_R+273.15)} \\ A + B + P \longrightarrow G & k_2 = 4.310 \times 10^{13} e^{-12438/(T_R+273.15)} \end{array}$$

The material balance equations for the plant and the approximate model can be found in Zhang and Forbes [2000].

The inputs are scaled using the intervals $[3, 6]$ for F_B, and $[70, 100]$ for T_R. In this range, the maximal value of d_2 obtained with the scaled inputs is $\mathsf{d}_2 = 1030$ for the model, whereas the (unknown) plant value is $\mathsf{d}_2 = 1221$. The simulations are carried out assuming that the noise v has a Gaussian distribution with standard deviation $\sigma_\phi = 0.5$. The noise interval $\delta = 3$ is chosen. The exponential filter (3) is implemented with $d = 0.5$.

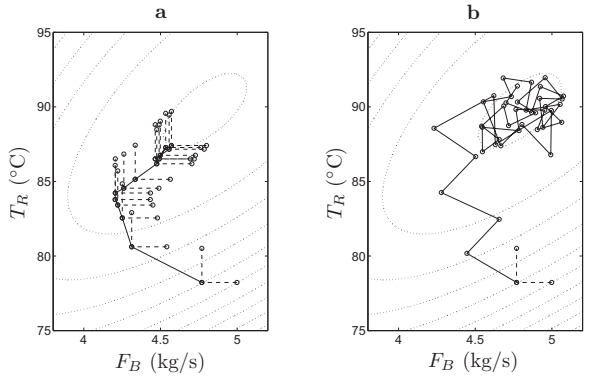

Fig. 4. Input trajectories for 45 operating points. The dotted lines represent the contours of the plant cost function. (**a**) Modifier adaptation using FFD. (**b**) Dual modifier adaptation with bound on gradient error.

Modifier Adaptation using FFD. First, modifier adaptation is applied using the FFD approach, which consists in perturbing the inputs one at the time from the current operating point with the fixed step size h. The gradient error norm, which is a function of h, is found to be minimal for $h^\star = 0.0763$ (scaled value). The corresponding gradient error norm $\mathcal{E}^t(h^\star) + \|\boldsymbol{\epsilon}^n(h^\star)\|_{\max}$ is 111.2 (Marchetti [2009]). Figure 4a shows a resulting input trajectory. The observed offset with respect to the plant optimum results mainly from the gradient error due to truncation.

Dual Modifier Adaptation with Bound on Gradient Error. Dual modifier adaptation is applied with $\mathcal{E}^U = 111.2$ (same value as above). The algorithm is initialized using FFD. Figure 4b shows a resulting input trajectory. Compared with modifier adaptation using FFD, significantly fewer operating points are required to approach the optimum.

Figure 5a shows the evolution of the plant profit and the gradient error norm for 20 noise realizations. At iteration 20, the flowrate F_A is increased from 1.8275 kg/s to 2.2 kg/s. Modifier adaptation tracks the change in the plant optimum. It can be seen in the upper plot of Figure 5a that the neighborhood of the new optimal profit is reached within 6 iterations for all 20 realizations. Also, the lower plot of Figure 5a shows that the gradient error norm is kept below $\mathcal{E}^U$. The observed peak in gradient error occurring at iterations 21 and 22 is due to the fact that, at these points, the gradient is inconsistent in that it is estimated using operating points with different values of F_A.

Dual Modifier Adaptation with Bound on Condition Number. For the sake of comparison, dual modifier adaptation is also applied with a lower bound on the inverse condition number of $\mathcal{U}(\mathbf{u})$, as proposed in Brdyś and Tatjewski [1994, 2005]. The results are shown in Figure 5b. A lower bound of 0.4 gives an adaptation that is similar to that using the gradient error bound in the first iterations. However, as soon as the neighborhood of the plant optimum is reached, the distance between the operating points decreases, and the gradient estimates become much less accurate. Furthermore, the feasible regions given by the condition number constraint decrease proportionally

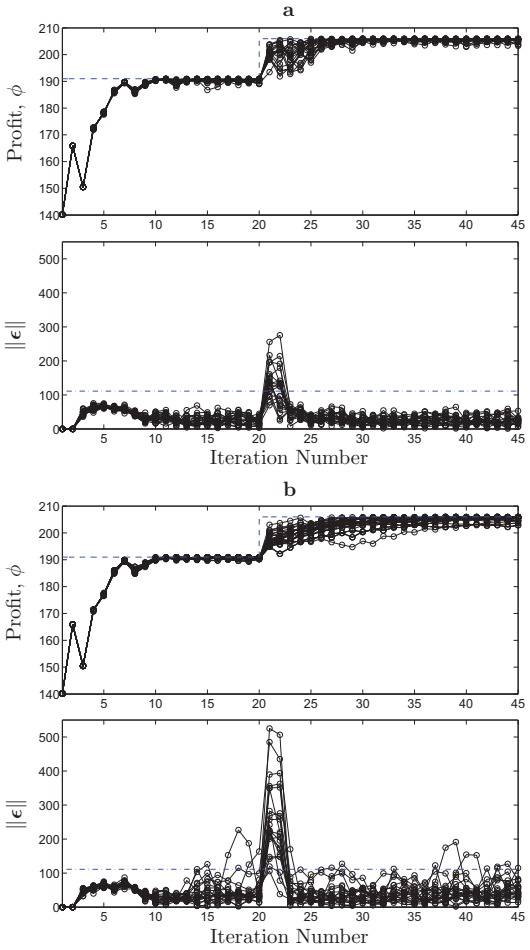

Fig. 5. Optimization for 20 noise realizations; there is a flowrate change at iteration 20. (**a**) Dual modifier adaptation with bound on gradient error norm. (**b**) Dual modifier adaptation with bound on the condition number. Dashed line: Optimal profit for the plant. Dash-dotted line: $\mathcal{E}^U = 111.2$.

to the distance between points. This appropriately prevents taking large steps in the wrong direction, but it also appears less suitable for tracking a changing optimum.

8. CONCLUSIONS

This study has demonstrated the potential of dual modifier adaptation, which pays attention to the accuracy with which the gradients are estimated. The results of the case study indicate that this approach, wherein the gradient error norm is bounded, produces more accurate gradient estimates than with simply bounding the condition number of $\mathcal{U}(\mathbf{u})$, i.e. a measure of the relative position of the successive inputs. In addition, the proposed scheme seems more capable of tracking a changing optimum. The performance depends on the amount of plant-model mismatch, the noise level, the estimated curvature of the cost function d_2, and the filter parameter d.

Future work will consider the extension of this approach to constrained optimization problems. In this case, mod-

ifier adaptation will require an estimate of the cost and constraint gradients of the plant to be available at each iteration. In order to be able to use the upper bound on the gradient error developed in this paper, a possible way is to associate the parameters δ and d_2 to a Lagrangian function, which represents a linear combination of the cost and constraint functions.

Appendix A. AFFINE SUBSPACES

In a n_u-dimensional space, a point is an affine subspace of dimension 0, a line is an affine subspace of dimension 1, and a plane is an affine subspace of dimension 2. An affine subspace of dimension $(n_u - 1)$ is called an hyperplane.

Hyperplane. An hyperplane in n_u-dimensional space is given by

$$n_1 u_1 + n_2 u_2 + \cdots + n_{n_u} u_{n_u} = b, \quad \text{or:} \quad \mathbf{n}^\mathsf{T}\mathbf{u} = b \quad \text{(A.1)}$$

and divides the space into two half-spaces: $\mathbf{n}^\mathsf{T}\mathbf{u} > b$, and $\mathbf{n}^\mathsf{T}\mathbf{u} < b$.

Complement affine subspaces. Given a set of $(n_u + 1)$ points in a n_u-dimensional space, $\mathcal{S} := \{\mathbf{u}_1, \ldots, \mathbf{u}_{n_u+1}\}$, a proper subset $\mathcal{S}^A$, i.e. $\mathcal{S}^A \subsetneq \mathcal{S}$, of $n_u^A \in \{1, \ldots, n_u\}$ points generates an affine subspace of dimension $(n_u^A - 1)$:

$$\mathbf{u} = \mathbf{u}_1 + \lambda_{1,2}\frac{\mathbf{u}_1 - \mathbf{u}_2}{\|\mathbf{u}_1 - \mathbf{u}_2\|} + \cdots + \lambda_{1,n_u^A}\frac{\mathbf{u}_1 - \mathbf{u}_{n_u^A}}{\|\mathbf{u}_1 - \mathbf{u}_{n_u^A}\|} \quad \text{(A.2)}$$

where the parameters $\lambda_{1,2}, \ldots, \lambda_{1,n_u^A}$ represent distances from the point $\mathbf{u}_1$ in the directions $\mathbf{u}_1 - \mathbf{u}_2, \ldots, \mathbf{u}_1 - \mathbf{u}_{n_u^A}$, respectively. The complement subset $\mathcal{S}^C := \mathcal{S} \setminus \mathcal{S}^A$ of $(n_u + 1 - n_u^A)$ points, generates the complement affine subspace of dimension $(n_u - n_u^A)$:

$$\mathbf{u} = \mathbf{u}_{n_u^A+1} + \lambda_{n_u^A+1,n_u^A+2}\frac{\mathbf{u}_{n_u^A+1} - \mathbf{u}_{n_u^A+2}}{\|\mathbf{u}_{n_u^A+1} - \mathbf{u}_{n_u^A+2}\|} + \ldots \quad \text{(A.3)}$$
$$\cdots + \lambda_{n_u^A+1,n+1}\frac{\mathbf{u}_{n_u^A+1} - \mathbf{u}_{n_u+1}}{\|\mathbf{u}_{n_u^A+1} - \mathbf{u}_{n_u+1}\|}$$

Distance between complement affine subspaces.

Definition 1. (Distance between complement affine subspaces). Given a set of (n_u+1) points in a n_u-dimensional space, $\mathcal{S} := \{\mathbf{u}_1, \ldots, \mathbf{u}_{n_u+1}\}$, a proper subset of $\mathcal{S}$, $\mathcal{S}^A \subsetneq \mathcal{S}$ of $n_u^A \in \{1, \ldots, n_u\}$ points, and its complement $\mathcal{S}^C := \mathcal{S} \setminus \mathcal{S}^A$ of $(n_u + 1 - n_u^A)$ points, the distance between complement affine subspaces is defined as the (orthogonal) distance between the affine subspace of dimension $(n_u^A - 1)$ generated by all the points in $\mathcal{S}^A$, and the affine subspace of dimension $(n_u - n_u^A)$ generated by all the points in $\mathcal{S}^C$.

The total number of possible pairs of complement affine subspaces that can be generated from $\mathcal{S}$ is $n_b = 1 + \sum_{s=1}^{n_u-1} 2^s$.

Definition 2. (Nearest complement affine subspaces). The shortest distance between complement affine subspaces is given by $l_{\min} := \min\{l_1, l_2, \ldots, l_{n_b}\}$, where $l_1, l_2, \ldots, l_{n_b}$ are the distances between all possible pairs of complement affine subspaces that can be generated from $\mathcal{S}$.

In the 2-dimensional case ($n_u = 2$), the number of distances to evaluate is $n_b = 3$, which corresponds to the 3 point-to-line distances. In the 3-dimensional case, there are $n_b = 7$ distances to evaluate, which correspond to 4 point-to-plane distances, and 3 line-to-line distances.

In order to compute the distance between the complement affine subspaces (A.2) and (A.3), a vector $\mathbf{n}$ that is normal to both subspaces is required:

$$[\ \mathbf{u}_1 - \mathbf{u}_2\ \ldots\ \mathbf{u}_1 - \mathbf{u}_{n_u^A}\ \ \mathbf{u}_{n_u^A+1} - \mathbf{u}_{n_u^A+2}\ \cdots \quad \text{(A.4)}$$
$$\mathbf{u}_{n_u^A+1} - \mathbf{u}_{n_u+1}\ ]^\mathsf{T}\mathbf{n} = \mathbf{0}, \qquad \text{or,} \qquad \mathsf{U}\mathbf{n} = \mathbf{0}.$$

The matrix $\mathsf{U} \in \mathbb{R}^{(n_u-1)\times n_u}$ is of rank $(n_u - 1)$. The vector $\mathbf{n}$ can be obtained by singular-value decomposition of U.

Given a point $\mathbf{u}^a$ that belongs to the affine subspace (A.2), a point $\mathbf{u}^b$ that belongs to the complement affine subspace (A.3), and a vector $\mathbf{n}$ that is normal to both complement affine subspaces, the distance l_{AC} between the two complement affine subspaces is:

$$l_{AC} = \frac{|\mathbf{n}^\mathsf{T}(\mathbf{u}^b - \mathbf{u}^a)|}{\|\mathbf{n}\|} \quad \text{(A.5)}$$

Optimally Invariant Variable Combinations for Nonlinear Systems

Abstract: In this article we present an "explicit RTO" approach for achieving optimal steady state operation without requiring expensive online calculations. After identifying regions of constant active constraints, it is shown that there exist some optimally invariant variable combination for each region. If the unknown variables can be eliminated by measurements and system equations, the invariant combinations can be used for control. Moreover, we show that the measurement invariants can be used for detecting changes in the active set and for finding the right region to switch to. This explicit RTO approach is applied to a CSTR described by a set of rational equations. We show how the invariant variable combinations are derived, and use polynomial reduction to eliminate the unknown variables to obtain the measurement invariants which are used for control.

Keywords: Optimizing control, Polynomial systems, Real-time optimization, Explicit RTO, Self-optimizing control, Optimally invariant measurement combinations, Changing active sets

1. INTRODUCTION

Optimal operation of chemical processes becomes increasingly important in order to be able to compete in the international markets and to minimize environmental impact. A well established tool to achieve this goal is real-time optimization (RTO), where the optimal set-points are computed on-line, based on measurements taken at given sample times. This involves setting up and maintaining a real-time computation system, which can be very expensive and time consuming.

An alternative approach is to use off-line calculations and analysis to minimize or avoid complex on-line computations for example by finding optimally invariant measurement combinations ('self-optimizing' variable combinations, (Narasimhan and Skogestad (2007)). Controlling these combinations to their setpoints guarantees to operate the process optimal or close to optimal, with a certain acceptable loss (Skogestad (2000)). The combinations can be controlled by a simple control structure based on PI controllers. The conventional real-time optimization problem can either be replaced completely or partially by controlling invariant variable combinations. In practice, many processes are operated by something similar to this alternative approach, although not always consciously. That is, the optimization problem is not formulated explicitly and the control variables are chosen from experience and engineering intuition.

This publication presents two main results. The first one is extending the idea of self-optimizing control from unconstrained linear problems to constrained nonlinear problems. To the authors knowledge, optimally invariant variable combinations have been considered systematically only for linear plants with quadratic performance index (see e.g. Alstad et al. (2009)). A second contribution is the proof that using controlled variable to identify new sets of active constraints will always identify the correct active set. Although measurement invariants have been used before for active set identification (Manum et al. (2007)), it has not been proved that this holds for nonlinear problems, too.

2. GENERAL PROCEDURE

We consider a plant at steady state and assume the plant performance can be modelled as an optimization problem with a performance index J together with equality and inequality constraints, $g(\mathbf{u}, \mathbf{x}, \mathbf{d})$ and $h(\mathbf{u}, \mathbf{x}, \mathbf{d})$:

$$\min_{\mathbf{u},\mathbf{x}} J \quad \text{s.t} \quad \begin{cases} g(\mathbf{u}, \mathbf{x}, \mathbf{d}) = 0 \\ h(\mathbf{u}, \mathbf{x}, \mathbf{d}) \leq 0 \end{cases} \tag{1}$$

The variables $\mathbf{u}$, $\mathbf{x}$, $\mathbf{d}$ denote the manipulated input variables, the internal states, and the disturbance variables, respectively. In addition, we assume that there are measurements $\mathbf{y}(\mathbf{x}, \mathbf{u}, \mathbf{d})$, which provide information about the internal states and the disturbances of the process.

In order to obtain optimal operation we do not optimize the model on-line at given sample times. Instead, we use the structure of the problem to find optimally invariant variable combinations for the system. Since the available number of degrees of freedom changes when an inequality constraint becomes active, we have to find a new set of invariant measurement combinations for each set of constraints that becomes active during operation of the plant. This makes it necessary to define separate control structures for each region. Therefore, the first step is to partition the operating space into regions defined by the set of active constraints, i.e. the system is optimized for all possible disturbances $\mathbf{d}$ and the active constraints in each region are identified.

In the second step, we determine (nonlinear) variable combinations which yield optimal operation when kept at their constant setpoint. The variables resulting from this step cannot be used for control directly, because they contain unknown disturbance variables and internal states which are not known. To be able to control the system, we attempt to "model" the variable invariants by expressions which only contain known variables. These can then be used for control in feedback loops.

The last step in this procedure is to define rules for detecting and switching regions when the active constraints change. In many cases this can be done by monitoring the controlled variables of the neighbouring region and switching when the controlled variable of the neighbouring region reaches its optimal value.

3. DETERMINING INVARIANT VARIABLE COMBINATIONS

3.1 Invariants for systems with quadratic objective and linear inequality constraints and linear measurements

To illustrate the idea of finding invariant variable combinations we first consider a problem with a quadratic objective and linear constraints. After having identified n_r regions of active constraints, we can define an equality constrained optimization problem for each region.

Given $\mathbf{z} \in \mathbb{R}^{n_z \times 1}$ and $\mathbf{d} \in \mathbb{R}^{n_d \times 1}$, consider the constrained optimization problem:

$$\min_{\mathbf{z}} J = \min_{\mathbf{z}} [\mathbf{z^T}\, \mathbf{d^T}] \begin{bmatrix} \mathbf{J_{zz}} & \mathbf{J_{zd}} \\ \mathbf{J_{zd}}^{\mathbf{T}} & \mathbf{J_{dd}} \end{bmatrix} \begin{bmatrix} \mathbf{z} \\ \mathbf{d} \end{bmatrix} \tag{2}$$

subject to

$$\mathbf{A}_z \mathbf{z} + \mathbf{A}_d \mathbf{d} = \tilde{\mathbf{A}} \begin{bmatrix} \mathbf{z} \\ \mathbf{d} \end{bmatrix} = 0 \tag{3}$$

where we have $\mathbf{A}_z \in \mathbb{R}^{n_c \times n_z}$ has rank n_c, $\mathbf{A}_d \in \mathbb{R}^{n_c \times n_d}$, $\tilde{\mathbf{A}} = [\mathbf{A}_z\, \mathbf{A}_d]$, and $\mathbf{J_{zz}} > 0$.

Eq. (3) may include the model equations as well as active (equality) constraints. Instead of using (3) to eliminate n_c internal states to obtain an unconstrained problem, we keep the constraints explicit in the formulation as this more general formulation will be used later when presenting the nonlinear case (where the internal states are not easily substituted). The Karush-Kuhn-Tucker first order optimality conditions give

$$\nabla_z L = \nabla_z J + \mathbf{A_z^T} \lambda = \tilde{J} \begin{bmatrix} \mathbf{z} \\ \mathbf{d} \end{bmatrix} + \mathbf{A_z^T} \lambda = 0, \tag{4}$$

where $\tilde{J} = [\mathbf{J_{uu}}\, \mathbf{J_{ud}}]$, and λ is the vector of Lagrangian multipliers. Therefore, from (4) we have that

$$\mathbf{A_z^T} \lambda = -\tilde{J} \begin{bmatrix} \mathbf{z} \\ \mathbf{d} \end{bmatrix}. \tag{5}$$

$\mathbf{A}_z$ is not full column rank, so let $\mathbf{N}_z$ be a basis for the null space of $\mathbf{A}_z$ with dimension $n_{DOF} = n_z - n_c$. Then $\mathbf{N_z^T A_z^T} = 0$, and at the optimum we must have

$$\mathbf{c}^v(\mathbf{z}, \mathbf{d}) \triangleq \mathbf{N_z^T} \tilde{J} \begin{bmatrix} \mathbf{z} \\ \mathbf{d} \end{bmatrix} = 0 \tag{6}$$

for the system (5) to be uniquely solvable for λ. Keeping $\mathbf{c}^v(\mathbf{z}, \mathbf{d})$ at zero (in addition to the active constraints), is always optimal. However, it cannot be used for control directly, as it contains unknown (unmeasured) variables. For control, we need a function of measurements $\mathbf{c}(\mathbf{y})$, such that the difference between the invariant and the measurement combination is minimal. Here, we want to "model" $\mathbf{c}^v(\mathbf{z}, \mathbf{d})$ perfectly, such that

$$\mathbf{c}(\mathbf{y}) = \mathbf{c}^v(\mathbf{z}, \mathbf{d}). \tag{7}$$

Then controlling $\mathbf{c}(\mathbf{y}) = 0$ yields optimal operation. If we have $n_z + n_d$ independent linear measurements

$$y = \mathbf{G}^y \begin{bmatrix} \mathbf{z} \\ \mathbf{d} \end{bmatrix}, \tag{8}$$

where $\mathbf{G}^y$ is invertible, we can use them with (6) to give

$$\mathbf{c}(\mathbf{y}) = \mathbf{N^T} \tilde{J} [\mathbf{G}^y]^{-1} \mathbf{y}. \tag{9}$$

However, note that we actually only need $n_z - n_c + n_d = n_{DOF} + n_d$ measurements, since the model equations (3) can be used to eliminate the constrained degrees of freedom (internal states). This is shown in Appendix A.

Remark 1. In the unconstrained case, the optimal invariant variable combination is simply the gradient, such that we have $\mathbf{c}(\mathbf{y}) = \mathbf{H}\mathbf{y} = \nabla_u J$, and $\mathbf{H} = \tilde{J}[\tilde{\mathbf{G}}^y]^{-1}$.

3.2 Invariants for polynomial and rational systems

An analog approach may be taken for obtaining invariant variable combinations for more general systems described by polynomials. Since rational equations can be transformed into polynomials by multiplying with the common denominator, the method is applicable to rational systems, too.

Initially, all regions defined by constant active constraints are determined. For each region we then have:

Theorem 1. (Nonlinear invariants). Given $\mathbf{z}, \mathbf{d}$ as in section 3.1, consider the nonlinear optimization problem

$$\min_{\mathbf{z}} J(\mathbf{z}, \mathbf{d}) \quad \text{s.t} \quad g_i(\mathbf{z}, \mathbf{d}) = 0, \quad i = 1 \dots n_g, \tag{10}$$

and implicit measurement relations

$$m_j(\mathbf{y}, \mathbf{z}, \mathbf{d}) = 0 \quad j = 1 \dots n_y, \tag{11}$$

where $\mathbf{y}$ is the measured variable. If the Jacobian $\mathbf{A}_z(\mathbf{z}, \mathbf{d}) = [\nabla_z g]$ has full rank n_g at the optimum throughout the region, following holds:

(1) There exist $n_{DOF} = n_z - n_g$ independent invariant variable combinations $\mathbf{c}^v$ with

$$\mathbf{c}^v = [\mathbf{N}_z(\mathbf{z}, \mathbf{d})]^{\mathbf{T}} \nabla_z J(\mathbf{z}, \mathbf{d}), \tag{12}$$

where $\mathbf{N}_z(\mathbf{z}, \mathbf{d})$ denotes the null space of the Jacobian of the active constraints $g(\mathbf{z}, \mathbf{d})$.

(2) If there exist polynomials $\alpha_i(\mathbf{z}, \mathbf{d})$ and $\beta_j(\mathbf{z}, \mathbf{d})$, such that element of $\mathbf{c}^v$ can be expressed by

$$c^v = \sum_{i,j} (\alpha_i(\mathbf{z}, \mathbf{d}) g_i(\mathbf{z}, \mathbf{d}) + \beta_j(\mathbf{z}, \mathbf{d}) m_j(\mathbf{y}, \mathbf{z}, \mathbf{d})) + c(\mathbf{y}), \tag{13}$$

then the term $c(\mathbf{y})$ is the desired self-optimizing variable which when controlled to zero yields optimal operation.

Proof. Calculate the Jacobian of the constraints:

$$\mathbf{A}_z(\mathbf{z}, \mathbf{d}) = \left[[\nabla_z g_1(\mathbf{z}, \mathbf{d})]^{\mathbf{T}}, \cdots, [\nabla_z g_{n_g}(\mathbf{z}, \mathbf{d})]^{\mathbf{T}} \right]^{\mathbf{T}} \tag{14}$$

Since $\mathbf{A}_z(\mathbf{z},\mathbf{d})$ has full rank, the null space has a constant dimension and there exist a unique vector λ which satisfies the KKT conditions (Nocedal and Wright (2006)):

$$\begin{aligned} \nabla_z J(\mathbf{z},\mathbf{d}) + [\mathbf{A}_z(\mathbf{z},\mathbf{d})]^{\mathbf{T}} \lambda = 0 \\ g_i(\mathbf{z},\mathbf{d}) = 0, \quad i = 1 \dots n_g \end{aligned} \tag{15}$$

For the existence and uniqueness of λ, we always must have, that

$$[\mathbf{N}_z(\mathbf{z},\mathbf{d})]^{\mathbf{T}} \nabla_z J = -[\mathbf{N}_z(\mathbf{z},\mathbf{d})]^{\mathbf{T}} [\mathbf{A}(\mathbf{z},\mathbf{d})]^{\mathbf{T}} \lambda, \tag{16}$$

where $\mathbf{N}_z(\mathbf{z},\mathbf{d})$ is chosen as a basis for the $n_z - n_g$-dimensional null space of $\mathbf{A}_z(\mathbf{z},\mathbf{d})$. The optimal invariant variable combination to be kept at $\mathbf{c}^v = 0$ is then given by:

$$\mathbf{c}^v = [\mathbf{N}_z(\mathbf{z},\mathbf{d})]^{\mathbf{T}} \nabla_z J(\mathbf{z},\mathbf{d}) \tag{17}$$

The second statement follows from the implicit relations $g_i(\mathbf{z},\mathbf{d}) = 0$ and $m_j(\mathbf{y},\mathbf{z},\mathbf{d}) = 0$. □

Remark 2. This variable combination (17) is not unique in the sense that it can be premultiplied by any nonsingular matrix while still yielding optimal operation. However, since the variable combination is derived from the KKT conditions, it is unique in the sense that for a convex optimization problem $\mathbf{c}^v = 0$ if the system is operated optimally, because the stationary point is unique.

Remark 3. The full rank assumption for $\mathbf{A}_z(\mathbf{z},\mathbf{d})$ at the optimum is valid in most practical cases, as rank deficiency at the optimum implies that the degrees of freedom in the problem change.

Remark 4. The functions α and β can be found using Gröbner theory (Cox et al. (1992)), and the condition for the existence of polynomial functions α_i and β_i is that every variable to be eliminated must appear in the initial ideal generated by all g_i and m_j in lower or equal degree than in $\mathbf{c}^v$.

To illustrate the concept, we present a toy example.

Example 1. (Nonlinear invariants). We consider a cost function $J(z_1, z_2, d) = z_1^2 + z_2^2$ subject to the constraint

$$g = (z_1 - 1)^2 + (z_2 - d)^2 - 5. \tag{18}$$

In addition to the known z_1, z_2, the system has one measurement y with the measurement relation

$$m = z_1 z_2 + z_1 d - y = 0. \tag{19}$$

First we calculate the Jacobian of (18) with respect to z

$$\mathbf{A}(z_1, z_2, d) = [\, 2(z_1 - 1) \;\; 2(z_2 - d) \,], \tag{20}$$

and the basis of its null space:

$$\mathbf{N}(z_1, z_2, d) = [\, -(z_2 - d) \;\; (z_1 - 1) \,]^{\mathbf{T}}. \tag{21}$$

After computing the gradient of the cost function J

$$\nabla J = [\, 2z_1 \;\; 2z_2 \,]^{\mathbf{T}}, \tag{22}$$

we obtain the invariant variable combination as in (17):

$$c^v = \underbrace{[\, -(z_2 - d) \;\; (z_1 - 1) \,]}_{[\mathbf{N}(\mathbf{z},\mathbf{d})]^{\mathbf{T}}} \underbrace{\begin{bmatrix} 2z_1 \\ 2z_2 \end{bmatrix}}_{\nabla J} = 2(z_1 d - z_2) \tag{23}$$

However, c^v contains the unmeasured disturbance d, so it cannot be used for control. Using the measurement relation (19) and equation (13) we see by inspection that $\alpha = 0$ and $\beta = 2$ yield a $c(y)$ which satisfies (7):

$$\begin{aligned} c^v = \underbrace{2(z_1 d - z_2)}_{c^v} = \underbrace{0}_{\alpha} g + \underbrace{2}_{\beta} \underbrace{(z_1 z_2 + z_1 d - y)}_{m} \\ + \underbrace{2y - 2z_2 - 2z_1 z_2}_{\mathbf{c}(\mathbf{y})}. \end{aligned} \tag{24}$$

Since $m = 0$, we have that $c^v = c(y)$. In more complex cases, α and β have to be determined by computing a Gröbner basis for the constraint and measurement relations and by reducing c^v modulo the Gröbner basis.

4. SWITCHING OPERATING REGIONS

After the controlled variables for all regions are identified, the remaining issue is to determine how to switch between operating regions. Under certain assumptions, the switching points can be found using the already defined invariant variable combinations.

Theorem 2. (Switching regions). Assume the system (10) convex and at the optimum $\nabla_z J(\mathbf{z},\mathbf{d}) \neq 0$ wherever a constraint is active. If a disturbance moves the system continuously from one region of active constraints to another, (i.e. the system does not jump over regions) the exact switching points can be detected by monitoring the controlled variables and the constraints of the neighbouring regions.

Proof. We consider to type of changes, denoted type I and II. In changes of type I, a constraint is replaced or added to the current active set. This change is easily detected by monitoring the active constraints of the neighbouring regions. As the system is operated optimally and the disturbance moves the system gradually to the new region, the region boundary is reached, when the constraint is hit.

In changes of type II, a constraint becomes inactive and the released degree of freedom is controlled using a measurement invariant. Detecting a type II change is done by monitoring the invariant variable combinations of the neighbouring regions. If if an invariant variable combination hits the zero value, the region is switched. The invariant variable combinations assume the value zero only at the switching points. This can be seen by contradiction. Consider two regions with c_1^v and c_2^v. Let the system be operated optimally at $(\mathbf{z}_0, \mathbf{d}_0)$ in the constrained region 1 ($c_1^v(\mathbf{z}_0, \mathbf{d}_0) = 0$), and let $c_2^v(\mathbf{z}_0, \mathbf{d}_0) = 0$. The Jacobians of the set of constraints $g^1(\mathbf{z},\mathbf{d})$ and $g^2(\mathbf{z},\mathbf{d})$ are denoted as $\mathbf{A}^1(\mathbf{z},\mathbf{d})$ and $\mathbf{A}^2(\mathbf{z},\mathbf{d})$.

Since $c_1^v(\mathbf{z}_0, \mathbf{d}_0) = c_2^v(\mathbf{z}_0, \mathbf{d}_0) = 0$ we have

$$\underbrace{\left[\mathbf{N}^1(\mathbf{z}_0, \mathbf{d}_0)\right]^{\mathbf{T}} \nabla_z J(\mathbf{z}_0, \mathbf{d}_0)}_{=0} = \underbrace{\left[\mathbf{N}^2(\mathbf{z}_0, \mathbf{d}_0)\right]^{\mathbf{T}} \nabla_z J(\mathbf{z}_0, \mathbf{d}_0)}_{=0}. \tag{25}$$

Since $\nabla_z J(\mathbf{z},\mathbf{d}) \neq 0$, this implies that $\mathbf{A}^1$ and $\mathbf{A}^2$ are row equivalent and the null spaces of $\mathbf{A}^1(\mathbf{z}_0, \mathbf{d}_0)$ and $\mathbf{A}^2(\mathbf{z}_0, \mathbf{d}_0)$ have the same basis. However, this is not possible, because by assumption, $\mathbf{A}^1$ and $\mathbf{A}^2$ have different ranks. Therefore the invariant variable combination of a "less constrained" region cannot become zero in a region which is "more constrained". Thus, the active constraints and the measurement combinations can be used for determining when to switch region. □

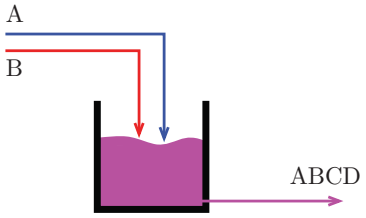

Fig. 1. CSTR with two reactions

Table 1. Variables relevant for control

Measurements $\mathbf{y}$	F, c_B, q
Manipulated variables $\mathbf{u}$	F_A, F_B
Unknown disturbance $\mathbf{d}$	Rate constant k_1
Internal states $\mathbf{z}_{unknown}$	c_A, c_C

5. APPLICATION

We consider an isothermal CSTR with two parallel reactions, Fig. 1, from Srinivasan et al. (2008). Two feed streams F_A and F_B with the concentrations c_A and c_B react in a tank to the desired product C and the undesired side product D. The tank is equipped with one outflow in which all components are present. In order to enable isothermal reaction conditions a temperature loop is closed such that the correct amount of heat is removed from the system. The temperature control is assumed to be perfect. The products C and D are formed by the reactions:

$$\begin{aligned} \mathrm{A} + \mathrm{B} &\xrightarrow{k_1} \mathrm{C} \\ 2\,\mathrm{B} &\xrightarrow{k_2} \mathrm{D} \end{aligned} \tag{26}$$

The optimization objective is to maximize the desired product $(F_A + F_B)c_C$ weighted by a yield factor $(F_A + F_B)c_C/(F_A c_{A,in})$. The amount of heat to remove and the maximum flow rate are limited. This lets us formulate the optimization problem of the system as follows:

$$\max_{F_A, F_B} \frac{(F_A + F_B)c_C}{F_A c_{A_{in}}}(F_A + F_B)c_C \tag{27}$$

subject to

$$\begin{aligned} F_A c_{A_{in}} - (F_A + F_B)c_A - k_1 c_A c_B V &= 0 \\ F_B c_{B_{in}} - (F_A + F_B)c_B - k_1 c_A c_B V - 2k_2 c_B^2 V &= 0 \\ -(F_A + F_B)c_C + k_1 c_A c_B V &= 0 \\ F_A + F_B - F &= 0 \\ k_1 c_A c_B V(-\Delta H_1) + 2k_2 c_B V(-\Delta H_2) - q &= 0 \\ q - q_{max} &\leq 0 \\ F - F_{max} &\leq 0 \end{aligned} \tag{28}$$

The variables k_1 and k_2 are the rate constants for the two reactions, $(-\Delta H_1)$ and $(-\Delta H_2)$ are the corresponding reaction enthalpies, q the heat produced by the reactions, V the reactor volume, and F the total flow rate. The measured variables ($\mathbf{y}$), the manipulated variables ($\mathbf{u}$), the disturbance variables ($\mathbf{d}$), and the internal states are listed in table 1, and the parameter values of the system are given in table 2. The combined vector of states and manipulated variables is

$$\mathbf{z} = [\, c_A,\ c_B,\ c_C,\ F_A,\ F_B \,]^{\mathbf{T}}. \tag{29}$$

5.1 Identifying operational regions

The first step of the procedure, optimizing the system offline for all possible values shows that the system operation

Table 2. Parameters

$(-\Delta H_2)$	j/mol	5×10^4
$c_{A,in}$	mol/l	2
$c_{B,in}$	mol/l	1.5
V	l	500
$F_{\max}$	l	22
q_{max}	kJ/h	1000

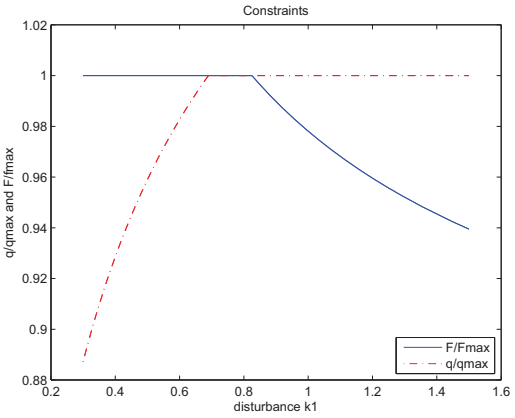

Fig. 2. Optimal values of the constrained variables

space can be partitioned into three regions defined by the set of active constraints. In region 1, for values of k_1 below about $k_1 = 0.65$ only the flow constraint is active (Fig. 2). In region 2 for values between $k_1 = 0.65$ and $k_1 = 0.8$ both constraints are active, and in region 3 above $k_1 = 0.8$ only the heat constraint is active.

After satisfying the active constraints in the regions we are left with $N_{\mathrm{DOF},1} = 1$ for region 1, $N_{\mathrm{DOF},2} = 0$ for region 2, and $N_{\mathrm{DOF},1} = 1$ for region 3.

In region 1, one of the manipulated variables (flow rates) is used to control the active constraint (maximum flow) and the other manipulated variable is used to control the invariant measurement combination of the region. In region 2 we simply control the active constraints, keeping q at $q_{\max}$ and F at $F_{\max}$. In region 3, again one of the manipulated variables is used to control the active constraint (maximum heat removal) and the other one is used to control the invariant measurement combination of region 3.

5.2 Determining the invariant variable combinations

Using the information from the previous section, we determine the invariant variable combinations in each region. First, we calculate the null space of Jacobian of the active set $\mathbf{N}_z^{\mathbf{T}}$ and multiply it with the gradient of the objective function $\nabla_z J(\mathbf{z}, \mathbf{d})$, as in (17) to obtain the invariant variable combination. Generally this is a fractional expression, but since we are controlling it to zero, it is sufficient to consider only the numerator of $\mathbf{N}_z^{\mathbf{T}} \nabla_z J$. For *region 1* we obtain the invariant

$$\begin{aligned}\mathbf{c}_1^v(\mathbf{z},\mathbf{d}) = &-(F_A+F_B)^2c_C\left[-3c_CF_B^2F_A-3c_CF_A^2F_B\right.\\&-4c_Cc_BF_A^2k_2V-4c_Ck_2V^2k_1c_B^2F_A-c_CF_A^3\\&-c_CF_B^3-4c_Ck_2V^2k_1c_B^2F_B-c_Cc_BF_A^2k_1V\\&-4c_Cc_BF_B^2k_2V-c_Cc_BF_B^2k_1V-c_CF_A^2c_Ak_1V\\&-c_CF_B^2c_Ak_1V-8c_CF_Ac_BF_Bk_2V\\&-2c_CF_Ac_BF_Bk_1V-2c_CF_AF_Bc_Ak_1V\\&+8F_Ak_1V^2c_{A,in}k_2c_B^2+2F_A^2k_1Vc_Bc_{A,in}\\&+2F_Ak_1VF_Bc_Bc_{A,in}-2F_A^2k_1Vc_{B,in}c_A\\&\left.-2F_Ak_1VF_Bc_{B,in}c_A\right]\end{aligned} \tag{30}$$

which should be controlled to zero. This invariant can be simplified somewhat further, since we know that $(F_A + F_B)^2c_C \neq 0$. It is therefore sufficient to control the second term in the square brackets in (30) to zero.

As mentioned above, *region 2* does not have any unconstrained degree of freedom, so satisfying all active constraints yields optimal operation. In *region 3* we obtain an expression similar to (30) for $\mathbf{c}_3^v(\mathbf{z},\mathbf{d})$.

5.3 Eliminating unknown variables

The invariant variable combination $\mathbf{c}_1^v(\mathbf{z},\mathbf{d})$ and $\mathbf{c}_3^v(\mathbf{z},\mathbf{d})$ still contain the unknown and internal variables k_1, c_a and c_C, so they cannot be used for feedback control directly. In the next step the unknown variables have to be replaced by expressions in the measured variables, so that this invariant can be used for control. Depending on the type of the system equations, different methods may be applied in this step. The general idea is that we use the measurements together with the equations that are satisfied in the active set to express the invariant. As all equations in this case study are polynomial (rational expressions equal to zero can transformed to polynomials by multiplication with the denominator), we attempt to reduce the invariants modulo the active set with a variable ordering that eliminates the unknowns. To simplify the elimination procedure, k_1 is eliminated by solving the third equality constraint for k_1.

$$k_1 = (F_A + F_B)c_C/(c_Ac_BV) \tag{31}$$

and inserting it into (30). The other unknown variables c_A and c_C are eliminated using polynomial reduction and the resulting measurement invariant in *region 1* becomes:

$$\begin{aligned}c_1(\mathbf{y}) = &-F_{max}(F_{max}c_B+2c_B^2k_2V-F_Bc_{B,in})^2\\&(4c_B^4k_2^2V^2+4F_{max}c_B^3k_2V-6k_2Vc_B^2F_Bc_{A,in}\\&-4k_2VF_{max}c_{B,in}c_B^2+6k_2Vc_B^2F_{max}c_{A,in}\\&+F_{max}^2c_B^2-2F_{max}^2c_{B,in}c_B+2c_BF_{max}^2c_{A,in}\\&-2c_BF_{max}F_Bc_{A,in}-F_B^2c_{B,in}^2+3F_{max}F_Bc_{A,in}c_{B,in}\\&-F_B^2c_{A,in}c_{B,in}+2F_{max}F_Bc_{B,in}^2-2F_{max}^2c_{A,in}c_{B,in})\end{aligned} \tag{32}$$

This expression depends only on known variables and parameters. The measurement invariant for *region 3* is found in the same way:

$$\begin{aligned}c_3(\mathbf{y}) = &-(F_Ac_B+c_BF_B+2c_B^2k_2V-c_{B,in}F_B)^2\\&(-3F_B^2q_{max}c_{B,in}c_B+8c_B^4q_{max}k_2^2V^2\\&+F_B^2q_{max}c_{B,in}^2+2c_B^2F_B^2q_{max}+2F_A^2q_{max}c_B^2\\&+4c_B^4F_Bk_2^2c_{B,in}V^2\Delta H_2+8c_B^3F_Bq_{max}k_2V\\&+2c_B^3F_B^2k_2c_{B,in}V\Delta H_2-6c_B^2F_Bq_{max}k_2c_{B,in}V\\&-2c_B^2F_B^2k_2c_{B,in}^2V\Delta H_2-F_A^2q_{max}c_{B,in}c_B\\&+4F_Ac_B^2F_Bq_{max}+F_AF_Bq_{max}c_{B,in}^2+2F_A^2c_Bq_{max}c_{A,in}\\&+6F_A^2k_2c_{B,in}V\Delta H_2c_B^3+12F_Ak_2^2c_{B,in}V^2\Delta H_2c_B^4\\&+8F_Ac_B^3F_Bk_2c_{B,in}V\Delta H_2+8F_Ac_B^3q_{max}k_2V\\&-2F_Ac_B^2q_{max}k_2c_{B,in}V-6F_Ac_B^2F_Bk_2c_{B,in}^2V\Delta H_2\\&-4F_AF_Bq_{max}c_{B,in}c_B+2F_A^2c_B^2k_2c_{A,in}c_{B,in}V\Delta H_2\\&-F_A^2q_{max}c_{A,in}c_{B,in}+4F_A^2c_B^3k_2c_{A,in}V\Delta H_2\\&+4F_Ac_B^3F_Bk_2c_{A,in}V\Delta H_2-2F_Ac_B^2F_Bk_2c_{A,in}c_{B,in}V\Delta H_2\\&+4F_Ac_B^2q_{max}k_2c_{A,in}V+2F_Ac_BF_Bq_{max}c_{A,in}\\&-F_AF_Bq_{max}c_{A,in}c_{B,in})\end{aligned} \tag{33}$$

Although these expressions seem complicated, they contain only known variables and can therefore be easily evaluated and controlled to their setpoint using a PI controller. In both invariants, the term in the first bracket is never zero (to see this, compare it with the second equality constraint in (28)), so it is sufficient to control the term in the second bracket to zero.

The values of these polynomials vary over order of magnitudes, so they are scaled to avoid numerical problems. The invariant of region 1 was scaled by 10^5 and the invariant of region 3 was scaled by 10^6.

5.4 Using measurement invariants for control and region identification

We use the controlled variables of the neighbouring regions for determining when to switch. Starting in region 1 optimal operation is achieved by using the two inputs F_A and F_B to control $c_1(\mathbf{y}) = 0$ and $F_A + F_B = F_{max}$. If k_1 increases, the amount of heat to be removed (the controlled variable of region 2) increases until it reaches the maximum possible value, q_{max} (Fig 3). When this value is reached, the control structure has to be changed to region 2. Now the inputs are used to control $q = q_{max}$ and $F_A + F_B = F_{max}$. While operating in region 2 the controlled variables of the neighbouring regions, $c_1(\mathbf{y})$ and $c_3(\mathbf{y})$ are monitored. If k_1 increases further, $c_3(\mathbf{y})$ approaches its optimal setpoint for region 3 and we switch region when the optimal value is reached. Switching back from the different regions is done in an analog manner.

6. DISCUSSION

The invariant variable combinations above are obtained by a two-step method, in which first the Lagrangian multipliers are eliminated, and subsequently the unknown variables (disturbances and internal states) are replaced by measurement relations. However, for systems which can be described by rational functions, as the CSTR example, there exists possibilities to eliminate both, the Lagrangian multipliers and the unknown variables simultaneously.

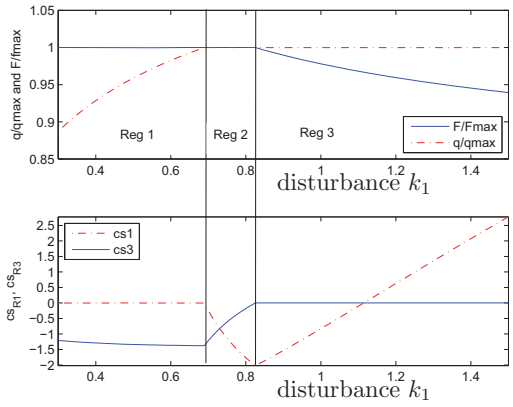

Fig. 3. Optimal values of controlled variables

This is done by defining an ideal which is generated by the polynomials describing the Karush-Kuhn-Tucker conditions and choosing an appropriate term order to eliminate the unknown disturbance and state variables (Cox et al. (1992)) Applying the chosen order to generate the elimination ideal gives a set of equations which are fulfilled at all times when the KKT conditions hold, but which do not contain any of the unknown variables.

Choosing a polynomial from this set which is not a (polynomial) combination of the equality constraints (i.e. which is not in the ideal generated by the equality constraints), gives a candidate for the measurement invariant. However, presently there are two challenges with the simultaneous method. First, the system with the chosen invariant measurement combinations may have (many) more roots than the KKT system. If we use them for control, we might control to "solutions" which do not satisfy the first order optimality conditions. Second, it is generally difficult to determine a term ordering a priori which eliminates the unknown variables and, at the same time ensures that the equations in the elimination ideal are not polynomial combinations of the equality constraints. If this is the case, the chosen variable combination is in the ideal generated by the equality constraints and the invariant will always be zero when the equality constraints are satisfied. This leads to an infinite number of solutions for the system. So far we are not aware of a method to handle these challenges in a systematic way, but we have found invariants in the elimination ideals which yield optimal operation in for the CSTR case study shown above.

The two step method presented in this work fundamentally shows the existence of invariant variable combinations for nonlinear systems and gives an easy way to compute and to use them. Additionally, in contrast to the elimination ideal method, the two-step method is principally not restricted to polynomial or rational models, provided that the unknowns can be eliminated.

7. CONCLUSION

The procedure presented in this paper is applicable to nonlinear steady state optimization problems and consists of four steps. First, regions of constant active constraints are defined. Second, optimally invariant nonlinear variable combinations are determined for each of the regions. Third, the unknown internal variables and disturbances are eliminated from the invariants to obtain variable combinations containing only known variables (measurements). It is proven that these variables can be used to uniquely identify a new active set. This makes the method applicable over a wide disturbance range with changing active sets. Finally, we have applied the method to a case study with a four component isothermal CSTR.

Although designing a self-optimizing control structure may require more work in advance, its implementation and maintenance is easy in practice. After the control structure is designed, optimal operation can achieved by simple PI controllers and there is no need to invest in expensive real-time equipment to operate the process optimally.

Appendix A. ELIMINATING INTERNAL STATES

We define the combined input and internal state vector as

$$\mathbf{z} = \begin{bmatrix} \mathbf{x^T} & \mathbf{u^T} \end{bmatrix}^{\mathbf{T}}. \tag{A.1}$$

It is assumed that we have $n_u + n_d$ independent measurements for system 3.

$$\mathbf{y} = \tilde{\mathbf{G}}^y \begin{bmatrix} \mathbf{u^T} & \mathbf{d^T} \end{bmatrix} \tag{A.2}$$

with $\tilde{\mathbf{G}}^y$ invertible. Then

$$\begin{bmatrix} \mathbf{z} \\ \mathbf{d} \end{bmatrix} = \begin{bmatrix} \mathbf{x} \\ \mathbf{u} \\ \mathbf{d} \end{bmatrix} = \begin{bmatrix} -\mathbf{A}_x^{-1}\mathbf{A}_u & -\mathbf{A}_x^{-1}\mathbf{A}_s \\ \mathbf{I} & 0 \\ 0 & \mathbf{I} \end{bmatrix} \underbrace{\begin{bmatrix} \mathbf{u} \\ \mathbf{d} \end{bmatrix}}_{=[\tilde{\mathbf{G}}^y]^{-1}\mathbf{y}}, \tag{A.3}$$

and we derive the optimal measurement combination which satisfies (7) as

$$\mathbf{c}(\mathbf{y}) = \mathbf{H}\mathbf{y} \tag{A.4}$$

with

$$\mathbf{H} = \mathbf{N}_z^{\mathbf{T}} \tilde{J} \begin{bmatrix} -\mathbf{A}_x^{-1}\mathbf{A}_u & -\mathbf{A}_x^{-1}\mathbf{A}_s \\ \mathbf{I} & 0 \\ 0 & \mathbf{I} \end{bmatrix} \left[\tilde{\mathbf{G}}^y\right]^{-1}. \tag{A.5}$$

Influence of Differences in System Dynamics in the context of Multi-unit Optimization

François Reney, Michel Perrier, Bala Srinivasan.

Chemical Engineering Department, École Polytechnique, Montreal, Quebec, Canada (e-mail: bala.srinivasan@polymtl.ca).

Abstract: Extremum-seeking methods are unconstrained real-time optimization techniques that control the gradient to zero. The crucial difference between them lies in the gradient estimation method used. Multi-unit optimization technique proposes the use of a multiple units operated with an offset between them and the estimation of the gradient is by finite difference. Though this method gives fast convergence, the major bottleneck is that it assumes the units to be identical. This paper addresses the case where the static curves are indeed identical, while the dynamics are not so. It is shown that if all the units are stable, despite the difference in dynamics, the method would indeed converge to the true optimum. Also, it is shown that the difference in dynamics does not affect stability in the neighborhood of the optimum. In addition, this paper presents a possibility of replacing real units by static models in the calculation of the gradient. Experimental results are presented from a mixing system where an optimal temperature is sought.

Keywords: Real time optimization and control, multi-units optimization.

1. INTRODUCTION

Process optimization is a tool of choice to find the best operating point that balances conflicting objectives such as productivity, selectivity, and operating cost for continuous chemical process. To perform this optimization numerically, it is necessary to have a model of its operation. Though most processes are dynamic in nature, often a steady state model suffices since typically, for continuous process, one is interested in finding the best steady state operation point. However, due to process changes, the optimal operating point varies with time, and to reap the benefits, it is indeed crucial to track these changes.

Without being exhaustive, two main classes of techniques have been employed in the real-time optimization of continuous processes. The first class comprises of the repeated optimization techniques (Marlin & Hrymak, 2000) that alternate between the identification of a steady state model using measurements and numerical computation of the optimal input using the updated model. On the other hand, extremum-seeking methods (Ariyur & Krstic, 2003, Guay et al., 2004) treat the optimization problem as one of controlling the gradient to zero.

In the extremum-seeking framework, various methods have been used for the gradient determination. The perturbation method (Ariyur & Krstic, 2003) deduces the gradient by adding perturbation signal that is very slow compared to the process dynamics. The correlation between the input and output is used to estimate the gradient. In adaptive extremum seeking techniques (Guay et al., 2004), parameters of a dynamic model are adapted and the gradient is computed from the adapted model. All the above mentioned techniques have to respect time-scale separations between gradient estimation and the process dynamics, thereby leading to slow convergence.

The multi-unit optimization technique (Srinivasan, 2007) is an attempt to find another gradient method that would converge faster. The basic method uses two identical units operated with an offset between them and uses finite difference to estimate the gradient. However, the main drawback of this technique is that it needs multiple identical processes working in parallel, which is impossible to get in practice. It has been shown that, if the units are not identical, the stability of the scheme and the convergence toward the true optimum are not guaranteed (Woodward et al., 2009).

Further research (Woodward et al., 2009) has revealed a way to compensate the difference in the curves that represent the steady-state relationship between the input and the objective function. It uses translation in both the input direction and direction of the objective function so as to evaluate correctly the gradient and converge toward the true optimum.

The key advantage of multi-unit optimization technique is that a reliable gradient is available during the transient, and one need not have to wait for the steady state. This advantage arises from the fact that if the process dynamics are the same, the difference of the objective functions is rendered insensitive to the process dynamics. However, if the processes' dynamics are different, even if the static curves are identical, the gradient would be falsified. The stability and convergence to the true optimum are a priori not assured.

In this paper, the case of non-identical dynamics is considered. It is however assumed that the static curves are the same. Such a case occurs when the optimization objective is only a function of the system output whose dynamics is controlled by a controller with integrator. Results from

stability analysis and the equilibrium point are presented. It is shown that the difference in dynamics does not change the equilibrium point but it indeed affects stability and the way it converges. The theoretical results are experimentally verified and the data are also presented in this paper.

This paper also analyses the possibility of replacing a physical unit by a mathematical model. This way, the multi-unit optimization runs with one physical system and one mathematical model. Here, experimental results with a physical dynamic system and a static mathematical model are presented to show that this option is indeed viable.

The rest of this paper is organized as follows. Section 2 of this paper presents briefly the standard multi-unit optimization technique. Section 3 presents the results of the analysis for stability and convergence when the units' dynamic are different. Section 4 presents the methodology and the results for the experimental trials.

2. MULTI-UNIT OPTIMIZATION

2.1 Problem formulation

Mathematically, a standard real time optimization problem is written as follows:

$$\begin{aligned} &\min_{u} \quad J = g(x,u) \\ &\dot{x} = f(x,u) = 0 \end{aligned} \tag{1}$$

J is a twice-differentiable function that is minimized and f represents the dynamics of a stable process. The states of the system are represented by the vector *x* and the inputs by the vector *u*. For the easing of presentation, inequality constraints are ignored.

In order to find the optimal input, it is easier to use the equality constraints to find an expression of x = h(u) and then substitute the same. This transforms the original problem into a unconstrained optimization problem, i.e. min J = p(u). Then, the necessary condition of optimality is then given by:

$$\partial p/\partial u \,|_{u^*} = 0 \tag{2}$$

If it is assumed that the unconstrained optimization problem is convex, then the necessary condition indeed leads to the only minimum. Equation (2) is used in extremum-seeking methods to find the optimal point by gradient control.

2.2 Multi-unit optimization scheme

A schematic representation of a simplified version of the multi-unit optimization framework is shown in Fig. 1 (Srinivasan, 2007). The term "unit" is used to represent a real continuous chemical process, and here they are labeled "0" and "1". A difference of Δ between the inputs "u_0" and "u_1" is necessary to estimate the gradient by a first order finite difference equation $\partial J/\partial u = (J_1 - J_0)/\Delta$. Then, the method uses an integral controller with an appropriate value of gain to push the gradient towards 0. The gain K can be tuned to as a compromise between convergence speed and stability.

$$\dot{u}_0 = \dot{u}_1 = \frac{K}{\Delta}\left(J_1 - J_0\right) \tag{3a}$$

$$u_0 = u - \frac{\Delta}{2} \text{ and } u_1 = u + \frac{\Delta}{2} \tag{3b}$$

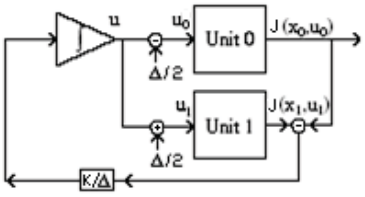

Fig. 1. Standard multi-unit optimization control loop.

In the case of multi-unit optimization, it is necessary to precise the dynamics of each of the units. The two units can be written mathematically as follows:

$$\begin{aligned} \dot{x}_0 &= f_0(x_0,u_0) \\ \dot{x}_1 &= f_1(x_1,u_1) \\ J_0 &= g_0(x_0,u_0) \\ J_1 &= g_1(x_1,u_1) \end{aligned} \tag{4}$$

The steady state for each unit can be described by:

$$\begin{aligned} x_0 &= h_0(u_0) \\ x_1 &= h_1(u_1) \end{aligned} \tag{5}$$

And the objective functions of each of the units at steady-state given by:

$$\begin{aligned} J_0 &= g_0(h_0(u_0),u_0) = p_0(u_0) \\ J_1 &= g_1(h_1(u_1),u_1) = p_1(u_1) \end{aligned} \tag{6}$$

3. MULTI-UNIT OPTIMIZATION WITH DIFFERENT DYNAMICS

In this section, the results of the analyses for stability and convergence are presented for the case when the units' dynamic are different but the static curve for each unit are identical. These analyses are made assuming that the technique is applied without any modification to compensate for the difference in dynamics.

3.1 Analysis for the equilibrium point

Here it is shown that if the scheme is stable, the system will converge toward the true optimum as long as the static curves between the units are identical. The difference between the dynamics does not bias the equilibrium point.

Theorem 1: If (i) the scheme converges, (ii) the static curves of the two units are identical, then despite the difference in the dynamics, the steady state of the multi-units optimization control loop represents the real optimum as Δ tends to zero.

Proof: From (3a), it can be seen that at steady state:

$$\dot{u}_0 = \dot{u}_1 = 0 = \frac{K}{\Delta}\left(J_1 - J_0\right) = \frac{K}{\Delta}\left(p_1(u_1) - p_0(u_0)\right) \tag{7}$$

So, the equilibrium point is determined by:

$$p_0(u_0) = p_1(u_1) \quad (8)$$

As the static curves of two units are considered identical,

$$p_0(u) = p_1(u) = p(u) \quad (9)$$

Let $\bar{u}$ be the value of u at steady state. Then,

$$p\left(\bar{u} + \Delta/2\right) = p\left(\bar{u} - \Delta/2\right) \quad (11)$$

A second order Taylor expansion of the function p is considered:

$$p(\bar{u}) + p'(\bar{u})\frac{\Delta}{2} + p''(\bar{u})\frac{\Delta^2}{4} - p(\bar{u}) + p'(\bar{u})\frac{\Delta}{2} - p''(\bar{u})\frac{\Delta^2}{4} + O(\Delta^3) = 0 \quad (12)$$

$$p'(\bar{u}) = O(\Delta^2) \quad (13)$$

$$\lim_{\Delta \to 0} p'(\bar{u}) = \lim_{\Delta \to 0} O(\Delta^2) = 0 \quad (14)$$

Calculating the limit as Δ tends to zero, it is observed that the derivative becomes zero, indicating that the two units arrive at optimal point. ■

3.2 Analysis for the stability of the scheme.

To analyze the stability of the above scheme, the units are linearized around the current operating point. The transfer function representation is used and normalized transfer function that has a unit steady state gain is derived. Then, the characteristic equation of the loop is obtained and analyzed if the roots of this equation are in the left half of the complex plane.

Theorem 2: If an integral controller with gain K can stabilize the average of the two normalized dynamics, then for a small enough value of Δ, the scheme is locally asymptotically stable around the optimum.

Proof: In order to analyze locally the stability, it is necessary to linearize the dynamics of both units. With the linearization, it is possible to represent directly the relationship between u and J by a transfer function T(s). It is useful to rewrite T(s) as a combination of a dynamic term with a static gain of 1, labeled as N(s), and a static term which represents the steady state gain:

$$T_0(s) = N_0(s)p'(u_0) \text{ and } T_1(s) = N_1(s)p'(u_1) \quad (15)$$

Note that the static gain of the different units is given by the gradient (linearization) of the static curve p(u) at their respective operating points. The above decomposition separates the static behavior of the units from its dynamics. The condition on the characteristic equation for this loop to be stable is given by:

$$Z = 1 + \frac{K}{s\Delta}\left(T_1(s) - T_0(s)\right) = 0 \quad (16)$$

Considering a Taylor expansion approximation of p gives:

$$p'(u_0) = b - \frac{\Delta}{2}M \text{ and } p'(u_1) = b + \frac{\Delta}{2}M \quad (17)$$

where b = p'(u) and M = p''(u). Distributing and rearranging the terms in (16), one gets,

$$s + \frac{KM}{2}\left(N_1 + N_0\right) + \frac{Kb}{\Delta}\left(N_1 - N_0\right) = 0 \quad (18)$$

At the equilibrium point (which has been shown to be the optimum in Theorem 1), as Δ tends to zero, (b/Δ) goes to zero. Then, the third term of the characteristic equation disappears. So, around the optimum, the stability is no more influenced by the value of Δ, nor by the error in the dynamics. The stability of the system around the optimum is then determined by whether or not the integral controller with the given gain stabilizes the average dynamics. ■

Note that the difference in the dynamics would not affect the stability around the optimum. However, the difference in dynamics can affect the characteristic equation considerably when the system is far from the optimum. The characteristic equation (18) is a rich source of information from which two conclusions can be drawn:

Effect of gain K: The value of the gain is crucial to stability in all cases. If the normalized average dynamics is stable and minimum phase, then for small values of gain, the overall scheme would be stable. Moreover, if the value of K is small, it can be seen from (18) that the influence of the difference in dynamics is negligible. In other words, with a small gain, the inputs variations are slow compared to the dynamics, and the two units operate at their respective pseudo-steady states.

Evolution far from the optimum: When the starting point is far from optimum ("b" is not zero), it can be seen from (18) that the dynamic behavior is influenced by the sign of the ratio (b/Δ), rather than the sign of the individual components.

Without loss of generality, suppose unit 0 is faster than unit 1. A negative Δ and a negative b mean that the faster unit is closer to the optimum. The same situation occurs for a positive Δ and a positive b. These two cases would have similar adaptation characteristics, and are shown in Figure 3 with the red dot representing the faster unit 0 and the green representing the slower unit 1.

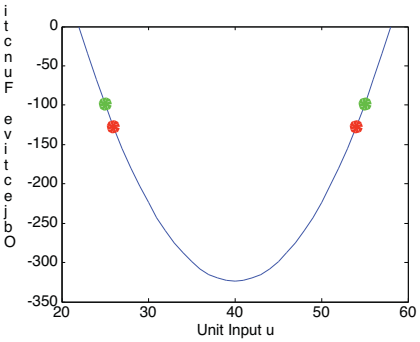

Fig. 3. Analysis of configurations with respect to dynamic behavior. Red faster than green leads to oscillations. Green faster than red leads to slow convergence.

In this configuration, since the system with a rapid dynamics is closer to the optimum, the difference between the outputs will be larger during the transients (for the same change in u). This will overestimate the gradient which, in the best case, will cause the system to converge with oscillations.

A negative Δ and positive b means that the slower unit is closer to the optimum. The same situation occurs for a positive Δ and a negative b. These two cases would have

similar dynamics, and are shown in Figure 3 with the green dot representing the faster unit 0 and the red representing the slower unit 1.

In this configuration, since the system with a slower dynamics is closer to the optimum, the difference between the outputs will be smaller during the transients (for the same change in u). This will underestimate the gradient which will cause the system to converge slowly.

The interesting point is that even if there is an overestimation of the gradient (faster unit closer to the optimum), the system would not in general become unstable. This is due to the fact that once both the units overshoot the optimum, the situation is reversed, i.e., the slower unit is closed to the optimum. So, an under estimation of the gradient occurs, where the return back would be slow and sure.

4. EXPERIMENTAL RESULTS

4.1 Problem Formulation

In order to prove the theoretical results shown in the previous section, an experimental setup has been designed. The setup is composed of two tanks (units) whose temperature is controlled in order to minimize the criterion mentioned below.

$$\min_{F_c} \quad J = (T_{out} - T_c)(T_{out} - T_h)$$
$$\dot{T}_{out} = \frac{F_h}{V}(T_h - T_{out}) + \frac{F_c}{V}(T_c - T_{out}) = 0 \tag{19}$$

Each unit is supplied with water by two pumps: a hot water pump and cold water pump. Hot water at temperature T_h and cold water at temperature T_c are added to these tanks with flow rates F_h and F_c respectively. The hot water pump is fixed with two heads in order to feed the same flow for both units. However, each unit has its own cold water pump (F_{c0} and F_{c1} being the decision variable). The temperatures in the units T_{out0} and T_{out1}, in the hot water tank and in the cold water tank are measured using thermistors. V is the volume of each of the units. The answer to this problem is:

$$T_{out} = \frac{T_h + T_c}{2}; \quad F_c = F_h \tag{20}$$

Also, in order to control the dynamics of each unit independently, cascade control has been implemented. Essentially, the multi-unit scheme sends a temperature set point u to each temperature control loop, which is controlled using a PI controller. This way that the static curves are identical (steady state error is zero). However, by tuning the temperature controllers differently, the two units will have different dynamics.

4.2 Experiments conditions tested

Four experiments are performed for all cases. In Experiment 1, the system is initialized to a value higher than the optimum with a positive value of Δ. Experiment 2 starts with an initial condition that is less than the optimum. Experiment 3 and Experiment 4 start from the initial conditions of Experiment 1 and 2 respectively, but with negative Δ.

It is always arranged that Unit 1 is slower than Unit 0. So, in Experiments 1 and 4, the optimum is closer to the faster unit, while the optimum is closer to the slower unit in the other two experiments. Experiments 1 and 4 show a configuration that overestimates the gradient, while experiments 2 and 3 present a configuration that underestimates the gradient. The gain K is the same for all experiment and is chosen so that the scheme is always stable.

Exp.	Start Temp	Temp Unit 0 (fast)	Temp Unit 1 (slow)
1	47 C	+1 C	-1 C
2	33 C	+1 C	-1 C
3	47 C	-1 C	+1 C
4	33 C	-1 C	+1 C

Table 1: Experimental plan for all experiments

4.3 Experiments with two real units.

In this set of experiments, the controller of "unit 1" has been tuned so that the internal loop (dynamics between the temperature output and temperature set point) is two times slower than its counterpart "unit 0". The results are presented in Figures 5-8.

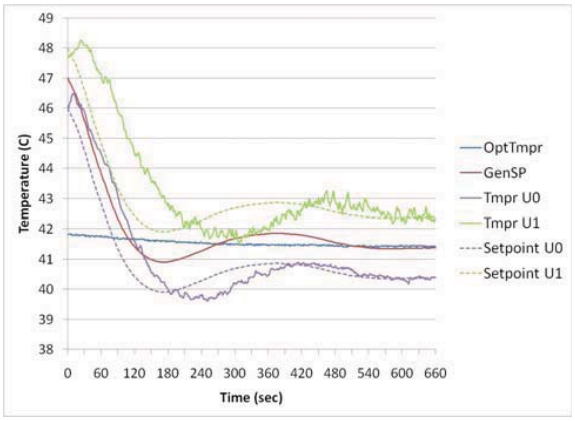

Fig. 5. Evolution for Experiment 1 with real units.

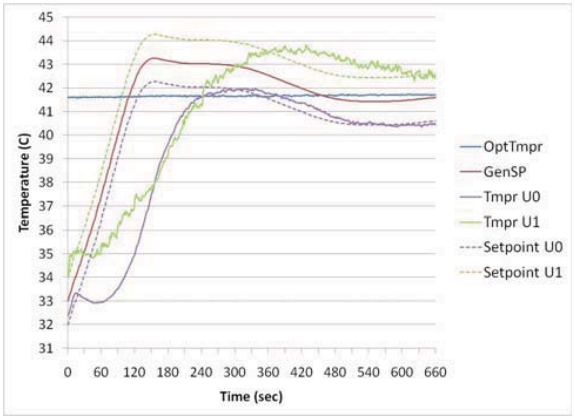

Fig. 6. Evolution for Experiment 2 with real units.

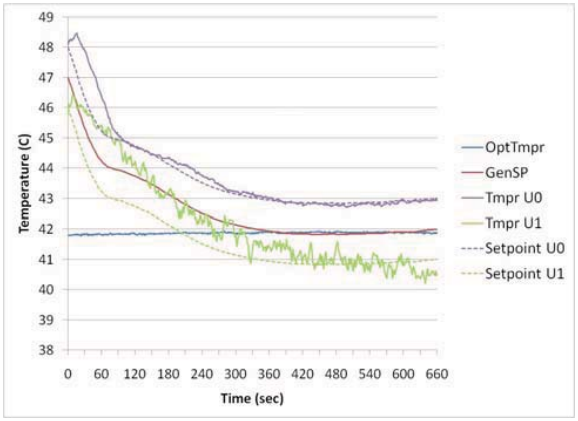

Fig. 7. Evolution of the system for Exp. 3 with real units.

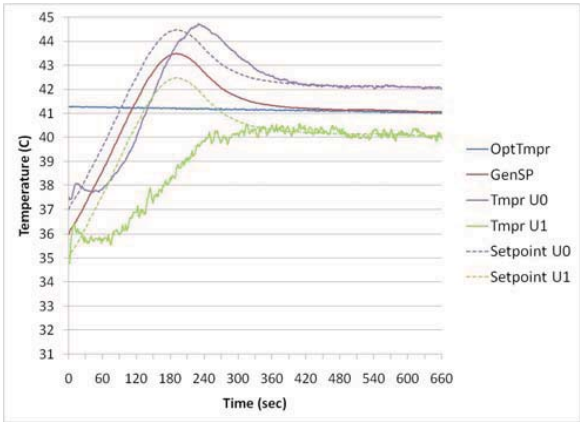

Fig. 8. Evolution of the system for Exp. 4 with real units.

The influence of the sign of Δ can be seen by comparing Fig 5 (Exp1) and Fig 7 (Exp3). The positive value of Δ brings the faster unit closer to the optimum in Exp1 and farther from the optimum in Exp3. Note that in both these experiments, there is a larger difference between the set point and the measured temperature in Unit 1 compared to that of Unit 0. The effect of the transients is more marked when the system is far from the optimum where the set point changes rapidly.

In the case of Exp 1, because of the difference in speed of the respective responses, the gradient is overestimated. This causes the scheme to converge with oscillations. On the contrary, in the case of Exp 3, the gradient is underestimated due the above mentioned speed difference. This underestimation causes the scheme to converge slowly but surely.

The above conclusion can be generalized for the ratio (b/Δ). Comparing Fig 5 (Exp1) and Fig 8 (Exp4), it can be seen that in both these experiments, the faster unit is closer to the optimum ($b/\Delta > 0$). The gradient is overestimated, resulting in an oscillatory response toward the optimum. In contrast, Fig 6 (Exp2) and Fig 7 (Exp3) show slower convergence since the faster unit is farther from the optimum ($b/\Delta < 0$).

Comparing Exp 1 and Exp3, it can be noted that the response for Exp3 is not as smooth as expected. Taking into account that a linear controller was used to control a nonlinear system, such a behavior is expected, The controller parameters are clearly not tuned for all points of operation. The controller settings used favored higher temperatures as can be seen from Figure 3.

4.3 Experiments with a real unit and a virtual unit

The purpose of next series of tests is to check the viability of replacing one of the real units by a mathematical model. This removes one of the major constraints of the scheme, i.e., the availability of two physical identical units in operation. There are two kinds of model that one can use: (i) a first principles/black box dynamic model (ii) a black box static model. Though the dynamic models were tested experimentally, the more interesting and extreme case, i.e., the use of the static model, is presented here.

In this set of experiments, “unit 0” is a static mathematical model whose dynamics is by definition instantaneous and so faster compared to the real unit (unit 1). In practice, it is done by setting the output equal to the set point of the control loop.

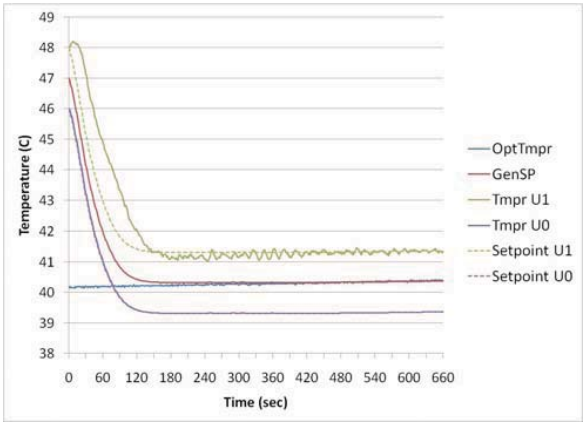

Fig. 9. Evolution for Exp. 1v with real and virtual units.

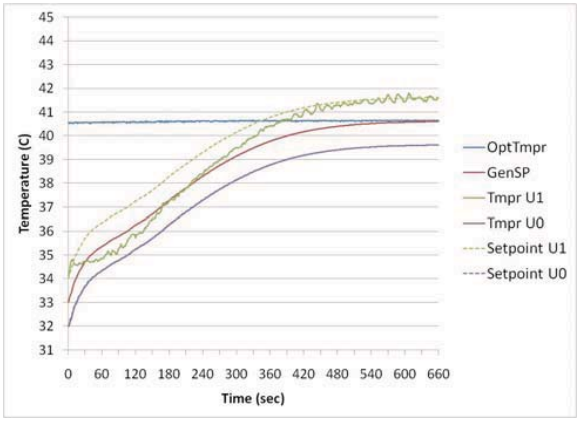

Fig. 10. Evolution for Exp. 2v with real and virtual units.

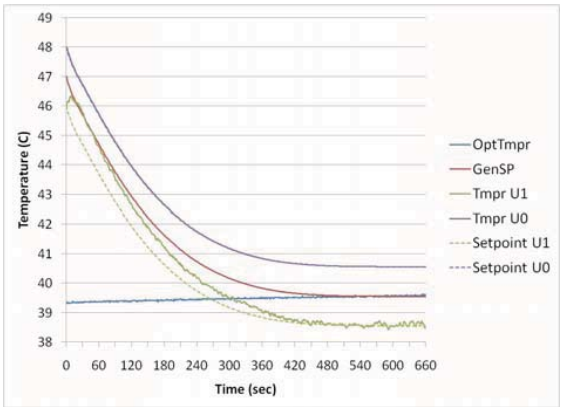

Fig. 11. Evolution for Exp. 3v with real and virtual units.

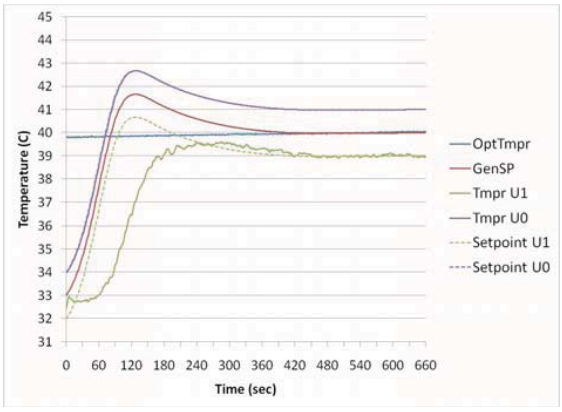

Fig. 12. Evolution for Exp. 4v with real and virtual units.

The results obtained using a system with a real unit and a virtual unit are similar to those obtained with two real units under the same testing conditions. The conditions on stability and convergence remain the same for this series of experiments. Indeed, the comparison of Fig 9 (Exp1v) and Fig 11 (Exp3v) yields the same general conclusion as the comparison of Exp1 and Exp3. It is also true for the comparison of Fig 9 (Exp1v) and Fig 12 (Exp4v) with Exp1 and Exp4 and the comparison of Fig 10 (Exp2v) and Fig 11 (Exp3v) with Exp2 and Exp3. However, for the last comparison, it is easier now to see that the smaller difference between the unit temperatures results in an underestimation of the gradient, thereby leading to slow convergence.

Note that while replacing the real unit by a model, it was assumed that the static characteristics are matched. The only difference between the real and virtual units is at the dynamics level. In this particular example, since the objective function is only dependant on the unit temperature, this assumption of matching the static behavior is easily verified. However, if the objective function is a function of both the output and input (T_{out} and F_c) of the dynamic part, it then becomes mandatory to have a good model of the physical system in order to match the static characteristics.

The conclusion here is that if the static characteristics are matched, then multi-unit optimization can be performed even when the dynamics are not necessarily identical. In extension, a real unit can be replaced by a virtual static model, which has the same static characteristics as the real unit. However, in order to converge to the true optimum, where the static characteristics are different, parameter adaptations are indeed necessary so as to compensate for these differences. In short, the differences in the dynamics can be tolerated, while differences in the static behavior needs to be quantified and compensated.

5. CONCLUSIONS

In this paper, it is shown that it possible to use the multi-unit scheme with differences in dynamics without affect its performance considerably. If the static curves are the same, the equilibrium point and the stability around the optimum are not affected. However, far from the optimum, the choice of the offset plays an important role; it can either make the system converge slowly or make it oscillatory.

Experimentally, it is shown that replacing a real dynamic unit by a simple static mathematical model is indeed viable. This means that the major constraint of having real multiple identical units can be circumvented. A good, not necessarily perfect, approximation of the process is sufficient to this effect.

Abstract: The new methodology presented provides a way to optimize the operation of a variety of batch processes (chemical, pharmaceutical, food processing, etc.) especially when at least one time-varying operating decision function needs to be selected. This methodology calculates the optimal operation without the use of an *a priori* model that describes in some accuracy the internal process characteristics. The approach generalizes the classical and widely used Design of Experiments (DoE), which is limited in its consideration of decision variables that are constant with time. The new approach, called the Design of Dynamic Experiments (DoDE), systematically designs experiments that explore a considerable number of dynamic signatures in the time variation of the unknown decision function(s). Constrained optimization of the interpolated response surface model, calculated from the performance of the experiments, leads to the selection of the optimal operating conditions. Two examples demonstrate the powerful utility of the method. The first examines a simple reversible reaction in a batch reactor, where the time-dependant reactor temperature is the decision function. The second example examines the optimization of a penicillin fermentation process, where the feeding profile of the substrate is the decision variable. In both cases, a finite number of experiments (4 or 16, respectively) lead to the very quick and efficient optimization of the process.

1. INTRODUCTION

Batch processes are often related to small production rates resulting in processes that are not understood enough to enable the development of an accurate mathematical model describing their inner workings. To accommodate such a lack of detailed understanding, our research group introduced the concept of Tendency Modelling (Fotopoulos, Georgakis, & Stenger, 1996, 1998) which has been applied to several processes with significant success. See for example (Cabassud et al., 2005; Martinez, 2005). On the other hand, François et al. (François, Srinivasan, & Bonvin, 2005) have also introduced a methodology in which the feedback control concept is used to evolve from an initial batch operation to operations that are incrementally better and, after several cycles, arrive at an optimum operation. In the case that a model is available, several model-based optimization techniques can be utilized (Biegler, 2007). We will refer to this model-based approach as the *Classical Approach*.

2. THE CLASSICAL MODEL-BASED APPROACH

The classical approach in optimizing a batch process assumes we have a first-principles model describing our fundamental understanding of the process. Assuming that all important idiosyncrasies of the process are known to make the model quite comprehensive and accurate, one needs only to account for the model's parameters whose values are not well known. Based on the number of unknown parameters, a set of experiments is designed using the classical Design of Experiments (DoE) approach (Box & Draper, 2007; Montgomery, 2005), or any other systematic or not so systematic approach. Once the experimental data are collected, the model parameters can be calculated using a parameter estimation method and related algorithms (van den Bos, 2007). Such a model will often have the form of a set of nonlinear ordinary differential equations (ODEs), as in eq. 1.

$$\frac{d\mathbf{x}}{dt} = \mathbf{f}(\mathbf{x},\mathbf{p},\mathbf{u},t), \quad \mathbf{y}(t) = \mathbf{g}(\mathbf{x}); \quad \text{with } \mathbf{x}(0)=\mathbf{x}_0 \quad \text{and} \quad \mathbf{u}_{\min} \le \mathbf{u}(t) \le \mathbf{u}_{\max} \tag{1}$$

Here, **x** and **y** represent the states and output variables of the system, respectively; **p** the parameters of the model fitted to the experiments; and **u**(t) the decision variable with which we wish to maximize (or minimize) the system's performance index *J*. The performance index is assumed to be only a function of the final values of the state variable at the end of the batch at $t=t_B$:

$$J^* = \max_{\mathbf{u}(t)} J(\mathbf{x}(t_B)) \tag{2}$$

With such a model at hand, one can calculate the optimum value of the decision variable **u**(t) that will yield the optimum value J^* of the performance index *J*. There are

several ways such a calculation can be performed, but here we will follow the method strongly advocated by Professor Biegler's group (Biegler, 2007; Kameswaran & Biegler, 2006, 2008). In such an approach, the interval (0, t_B) is divided into a number of finite elements and inside each element, the method of orthogonal collocations (Biegler, 1984) is used to convert the set of ODEs into a set of algebraic equations. Then, an optimization algorithm, such as sequential quadratic programming, calculates the optimum.

In summary, the Classical Model-based Optimization (CMO) approach involves the following steps: i) Postulation of model, ii) Experiments, iii) Parameter Estimation, and iv) Optimization.

3. THE NEW APPROACH: DESIGN OF DYNAMIC EXPERIMENTS

3.1. The Main Idea

To facilitate the discussion that follows, let us define a dimensionless time τ equal to t/t_B. The decision variable $\mathbf{u}(\tau)$ is considered to be a member of the Hilbert space $\mathcal{L}_2(0,1)$ of square-integrable vector functions. Let us denote with $\{\varphi_i(\tau); i = 1, 2, 3, \ldots\}$ a convenient set of basis-functions in that space. The unknown function $\mathbf{u}(\tau)$ can be written as follows.

$$\mathbf{u}(\tau) = \mathbf{u}_0 + \Delta\mathbf{U}\left(\sum_{i=1}^{\infty}\mathbf{a}_i\phi_i(\tau)\right) \simeq \mathbf{u}_0 + \Delta\mathbf{U}\left(\sum_{i=1}^{N}\mathbf{a}_i\phi_i(\tau)\right)$$
$$\mathbf{u}_0 = (\mathbf{u}^{\max} + \mathbf{u}^{\min})/2, \quad \Delta\mathbf{U} = diag\left((u_i^{\max} - u_i^{\min})/2\right) \tag{3}$$

The summation is truncated to a finite number of *N* terms and the unknowns are the expansion coefficients $\mathbf{a}_i$. If we now expand the performance index $J(\mathbf{x}(\tau=1))$ in terms of the $\mathbf{a}_i$ constants, of the $\mathbf{u}(\tau)$ function can be written as:

$$J(u) = b_0 + \sum_{i=1}^{N} b_i a_i + \sum_{j=i}^{N}\sum_{i=1}^{N} b_{ij} a_i a_j + \sum_{k=j}^{N}\sum_{j=i}^{N}\sum_{i=1}^{N} b_{ijk} a_i a_j a_k + \ldots \tag{4}$$

This will be called the Response Surface Model (RSM). For simplicity's sake, we have assumed in eq. (4) that there is only one decision function u(τ) and that each of the a_i constants is a scalar rather than a vector. The main model parameters are now the constants b_i, b_{ij}, b_{ijk} etc., relating the performance index *J* and the different choices of the decision variable u(τ). In the rare case that the knowledge-based process model is known *a priori*, the constants *b* can be explicitly calculated. Once the *b* constants are known, an optimization can be performed to calculate the optimal values of the parameters a_i (i=1, 2…n) that describe the estimate of the unknown optimal profile $u^*(\tau)$. *Of interest here is the circumstance in which* ***no model*** *for the batch process is available a priori.* In such a case, the novel approach introduced by the present paper consists of the following five steps:

a. Select a functional basis $\varphi_i(\tau)$ to parameterize the input function u(τ).
b. Design a set of time-varied experiments characterized by a properly selected set of constants a_i.
c. Perform the experiments.
d. Estimate the values of the *b* parameters in the RSM (eq. 4), using the values of *J* that correspond to each of the performed experiments.
e. Calculate the values of a_i that optimize *J*. Perform the optimal experiment and compare the results with the response surface model predictions.

The proposed approach is called Model-Free for two reasons. First, the RSM is a rather simple easy-to-develop interpolative model that contains no fundamental information about the process. Second, the process can be still substantially optimized my simply choosing the best of the initial dynamic experiments.

3.2. The Algorithmic Steps

We provide here some additional details of the four steps described before.

1. Define a dimensionless variable $w(\tau)$, referred as coded variable, that varies between -1 and +1 and which characterizes the time dependent process variable, or dynamic factor. For example, if the dynamic factor is the reactor temperature and it is allowed to vary between T_{max} and T_{min}, then the coded variable w(τ) is defined by:

$$w(\tau) = [2T(\tau) - (T_{\max} + T_{\min})]/(T_{\max} - T_{\min}) \tag{5}$$

   In the case that we have more than one decision variable u(τ), we define the coded variable by

$$\mathbf{w}(\tau) = \Delta\mathbf{U}^{-1}\left(\mathbf{u}(\tau) - \mathbf{u}_0\right) \tag{6}$$

2. Select an appropriate functional basis $\{\varphi_i(\tau)|\ i=1, 2,\ldots\}$ defined in the interval [0, 1]. These functions must be a linearly independent set that is complete and thus can serve as a functional basis. This functional basis could be either an orthogonal or a non-orthogonal one. The selection of this basis should be influenced by the expected character of the problem's solution in order to reduce the number of needed expansion terms and thus the number of experiments.

3. The unknown value of the dynamic factors $\mathbf{u}(\tau)$ that maximizes a certain performance index of the process $J(\mathbf{u})$ is denoted by, $\mathbf{u}^*(\tau)$:

$$J(\mathbf{u}^*) = \max_{\mathbf{u}(\tau)} J(\mathbf{u}) \tag{7}$$

   The unknown vector function $\mathbf{u}^*(\tau)$ is expanded in terms of a linear combination of the basis functions $\varphi_i(\tau)$, given in eq. (3).

4. Substitute the optimization with respect to $\mathbf{u}(\tau)$ with an optimization with respect to the constants $\boldsymbol{a}_i$. For each component function $u_q(\tau)$ of $\mathbf{u}(t)$, the corresponding constants $a^q{}_i$ are called the sub-factors that characterize the unknown dynamic factor $u_q(\tau)$. The infinitely dimensional search for the optimal function $\mathbf{u}^*(\tau)$ is then substituted by a finite dimensional search of the *pN* constants *a*, where *p* is the dimensionality of $\mathbf{u}(\tau)$.

5. Design experiments motivated by the classical Design of Experiments (DoE) methodology for the selection of the appropriate values of the sub-factors a^q_i. Each set of values of the sub-factors correspond to a specific time-dependent function $u_j(\tau)$ or $w_j(\tau)$. However, one needs to take into account certain constraints that $u_j(\tau)$ or $w_j(\tau)$ will have to satisfy.
6. Develop an appropriate interpolating response surface model relating J to the values of the a^q_i in the form of eq. (4). The unknown parameters of the model are the coefficients b_j, b_{ij}, b_{ijk} etc. and a linear regression algorithm can be used for their estimation. An analysis of variance (ANOVA) is performed to reveal which of the terms are the most significant based on the accuracy of the experimental measurements.
7. Calculate the optimal values of the a^{q*}_i coefficients that optimize J. This is a constrained optimization task since each of the coefficients a_i is constrained by an upper and lower value (usually $-1 \le a_i \le +1$). The optimal values of the a_j determine the optimal function $u(\tau)$.

The methodology described above substitutes the unknown function $u(\tau)$ by its coefficients a_i. By selecting the appropriate values of the a_i, one designs dynamic experiments with several choices of the input function $u(\tau)$. Each of the experiments results in a value of the performance index J. The set of such values enables the calculation of the response surface model (RSM) of equation (4), which is used to optimize the process with respect to the decision variable(s) $u(\tau)$. The proposed methodology generalizes the classical design of experiments (DoE) (Montgomery, 2005) methodology with respect to dynamically varying processes. For this reason, the term Design of Dynamic Experiments (DoDE) was coined to describe it (Georgakis, 2008).

4. DESIGN OF THE DYNAMIC EXPERIMENTS

Here we present some example designs of the DoDE experiments. We select the (shifted) Legendre polynomial as the basis in the Hilbert space $\mathcal{L}_2(0,1)$. The first three Legendre polynomials are

$$\phi_1(\tau) = P_0(\tau) = 1, \quad \phi_2(\tau) = P_1(\tau) = 1 - 2\tau, \\ \phi_3(\tau) = P_2(\tau) = 1 - 6\tau + 6\tau^2, \ \ldots \tag{8}$$

We will use these orthogonal polynomials to define the dynamic experiments in all the examples discussed here.

4.1. Simple Example of the DoDE Design Approach

The simplest set of DoDE experiments is obtained by selecting the smallest value of N in eq. (3), equal to two. This implies that the dynamic profile of $u(\tau)$, or the coded variable $w(\tau)$, is a linear combination of the first two Legendre polynomials $P_0(\tau)$ and $P_1(\tau)$. This limits our consideration among constant or linear time dependencies. In deciding the values of the a_1 and a_2 sub-factors we can follow the classical DoE approach. If we do level-2 experiments for each sub-factor, we will design the following 2^2=4 experiments:

$$\begin{pmatrix} a_1 \\ a_2 \end{pmatrix} = \left[\begin{pmatrix} +1 \\ +1 \end{pmatrix}, \begin{pmatrix} +1 \\ -1 \end{pmatrix}, \begin{pmatrix} -1 \\ +1 \end{pmatrix}, \begin{pmatrix} -1 \\ -1 \end{pmatrix} \right] \tag{9}$$

Translating, for example, the second experiment to the corresponding dynamic coded variable $w(\tau)$ we have $w(\tau) = P_0(\tau) - P_1(\tau) = 2\tau$. We realize that this profile does not meet its constraints $-1 \le w(\tau) \le +1$. This is easily remedied by imposing the following constraints on the a_1 and a_2 constants: $-1 \le a_1 + a_2 \le +1$ and $-1 \le a_1 - a_2 \le +1$ reducing the values of a_1 and a_2, without changing their relative magnitude so the that the constraints on $w(\tau)$ are met. This leads to the following design of experiments

$$\begin{pmatrix} a_1 \\ a_2 \end{pmatrix} = \left[\begin{pmatrix} +0.5 \\ +0.5 \end{pmatrix}, \begin{pmatrix} +0.5 \\ -0.5 \end{pmatrix}, \begin{pmatrix} -0.5 \\ +0.5 \end{pmatrix}, \begin{pmatrix} -0.5 \\ -0.5 \end{pmatrix} \right] \tag{10}$$

In this case, the four time-variations in $w(\tau)$ are shown in Figure 1.

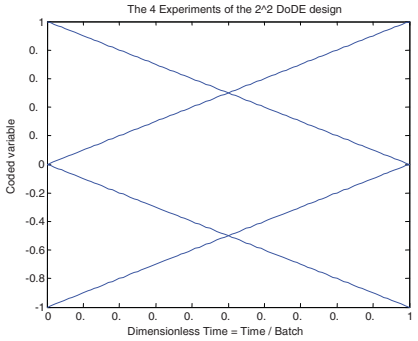

***Figure 1**: The 2^2=4 DoDE experiments*

4.2. Other DoDE Examples

For N=3, we are considering the first three Legendre polynomials, and if we consider only low and high values, we need to perform 2^3= 8 experiments. Here we are considering quadratic dependence on time along with the constant and linear sub-factors considered before. If we add cubic dependence by letting N=4 we need 2^4= 16 experiments and the use of the next Legendre polynomial: $P_3(\tau) = -20\tau^3 + 30\tau^2 - 12\tau + 1$. For N=5 we involve the first five shifted Legendre polynomials. This includes the four polynomials mentioned above along with the fifth one: $P_4(\tau) = 70\tau^4 - 140\tau^3 + 90\tau^2 - 20\tau + 1$. Here we need 2^5= 32 experiments. In the case we design level-3 full factorial experiments we need 3^2= 9 experiments for N=2, and 3^3= 27 experiments for N=3.

We should note that the way the dynamic experiments are designed involves two steps that are similar to the ones presented in section 4.1 for the simplest of the DoDE designs. In the first step, the sub-factors related to the values of the coefficients a_i are treated as independent from each other and are assigned initial values of (-1 , +1) in the level 2 designs and values (-1, 0, +1) in the lever 3 designs. In the second

Table 1: *Details of the Batch Reactor Optimization using the DoDE Methodology*

Dynamic Sub-factors	Levels	Case Number and Number of Experiments	Best Conversion from Initial 2^n or 3^n Experiments	Best Profile from the Initial 2^n or 3^n Experiments: $T(\tau)=308+15u(\tau)$ ^oK with $u(\tau)=a_1P_0+a_2P_1+a_3P_3+\ldots$	RSM-Optimum Conversion of A	Defining Parameters of the Calculated RSM-Optimum Profile $w(\tau)$

2	2	DA2 : 2^2= 4	73.46%	(a_1, a_2) = (-0.5, 0.5)	76.57%	(a_1, a_2) = (0, 1)
3	2	DA3: 2^3= 8	74.61%	(a_1, a_2, a_3) = (-0.3, 0.3, -0.3)	77.77%	(a_1, a_2, a_3) = (0, 1, 0)
4	2	DA4: 2^4=16	74.82%	(a_1, a_2, a_3, a_4) = (-0.3, 0.3, -0.3, 0.3)	78.10%	(a_1, a_2, a_3, a_4) = (0, 1, 0,- 0.04)
5	2	DA5: 2^5=32	74.43%	(a_1, a_2, a_3, a_4, a_5) = (-0.3, 0.3, -0.3, 0.3, .3)	78.43%	(a_1, a_2, a_3, a_4, a_5) = (0, 0.9, 0,- 0.08, -0.2)
Level 3 FULL Factorial Designs						
1	3	DA6 3^1= 3	73.91%	a_1 = 0	73.92%	a_1 = -0.03
2	3	DA7 3^2= 9	77.35%	(a_1, a_2) = (0, 1)	77.57%	(a_1, a_2) = (0.1, 0.9)
3	3	DA8 3^3=27	77.35%	(a_1, a_2, a_3) = (0, 1, 0)	77.66%	(a_1, a_2, a_3) = (0.05, 0.9, 0.06)

step, all of the a_i values related to a single experiment are scaled up or, in most cases, down by a common factor, so that the coded dynamic variable w(τ) attains values that are inside the [-1, +1] interval. Making the maximum (or minimum) of each profile touch the maximum (or minimum) values of $w(\tau)$ also ensures that the set of DoDE experiments covers all areas on the [-1, +1] x [0, 1] rectangle.

5. BATCH REACTOR WITH REVERSIBLE REACTION

Here we consider the optimization of the operation of a batch reactor in which a reversible reaction between reactant A and product B takes place with the following characteristics:

$$A \underset{k_2}{\overset{k_1}{\rightleftarrows}} B; \quad r = k_1C_A - k_2C_B \quad with$$

$$k_1 = k_{10}\exp(-E_1/RT)\ [1/hr]; \quad k_2 = k_{20}\exp(-E_2/RT)\ [1/hr]$$

$$k_{10}=1.32\text{x}10^7; \quad k_{20}=5.24\text{x}10^{13}; \quad E_1=10,000; \quad E_2=20,000$$

We select the activation energy of the reverse reaction to be larger than that for the forward reaction. This leads to the expectation that the optimum temperature profile is a decreasing one (Rippin, 1983). One needs to note here, that for the development of the fundamental model above, we need to *assume* that the first order kinetic rate is correct. We then perform *at least* 4 experiments to estimate the values of k_{10}, k_{20}, E_1, and E_2.

With such a model at hand, one can optimize the reactor temperature profile to maximize the conversion of reactant A. This is achieved by converting the ODEs into algebraic equations via Radau collocation on finite elements (Biegler, 2007). The reactor temperature is constrained between 20 ^{0}C and 50 ^{0}C and the optimization is achieved by use of the IPOPT algorithm (Wächter & Biegler, 2006).

The optimum profile calculated is constant at the upper temperature constraint for almost 0.4 hrs and then decreases to the minimum constraint at the end of the batch. We select here to fix the batch time to 2.5 hrs and the maximum conversion of the reactant A is calculated to be 77.68%. In Table 1, the results of the different DoDE experiments are presented. They involve up to 5 dynamic sub-factors and include level-2 (low-high) and level-3 (low-medium-high) experiments. In the fourth column the best conversion value of the initial runs is given. In the second to last column, the expected best batch performance, as calculated by the optimization of the response surface model (RSM), is given. In the last column the characteristics of this RSM-optimal profile is given in terms of the coded variable: $w(\tau) = a_1P_0(\tau) + a_2P_1(\tau) + \ldots$ The temperature profile can then be calculated by eq. 5. We observe that in the case denoted as DA2 in Table 1 *only* four experiments described in Figure 1 yield an RSM-optimum with a conversion of 76.57% which is just 1.43% away from the true optimum of 77.68%. We also observe that a larger number of experiments, such as those of cases DA4, DA5, DA7 and DA8, predict a higher conversion, even closer to the true optimum. However, as the number of experiments performed increases, the changes in the predicted optimum conversion becomes smaller and smaller per additional experiment, implying that the true optimum has been reached.

6. PENICILLIN FERMENTATION

Here we simulate the penicillin fermentation model of Bajpai and Reuss (Bajpai & Reuss, 1980) which has been the center of attention in several model-based optimizations (Riascos & Pinto, 2004). The model used to simulate the experiment consists of the equations in the Appendix. To focus on the main idea of calculating the optimum *time-varying* profile, we fix the batch time to t_b=130 hrs and the growth phase of the biomass to t_f=30 hrs. Here we want to demonstrate the application of the DoDE approach to this challenging optimization problem to demonstrate its power in optimizing complex processes. For this reason, we are *not* designing experiments that vary the t_f and t_b values, since they are not time-varying decision variables or factors.

We choose to design 16 experiments with $4=2^2$ variations for the substrate flow in growth phase $0\le t\le t_f$ *(or* $0\le\tau\le\gamma$; $\gamma=t_f/t_b$*)*

and $4=2^2$ additional variations for the production phase $t_f \le t \le t_b$ *(or* $\gamma \le \tau \le 1$*)*, the profiles are depicted in Figure 2. In the growth phase, the average value of the substrate flow is 30 gr/hr, with an allowed change up and down of 20 *gr/hr*. In the production phase, the average flow considered is 7 *gr/hr* and it varies by 3 *gr/hr*, up or down. Each of the four feeding profiles in the first phase is combined with each of the four feeding profiles of the second phase.

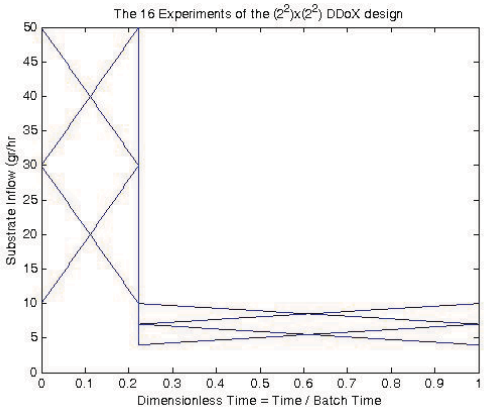

Figure 2: *The $2^2x2^2=14$ DoDE Experiments for Penicillin Fermentation (Total Volume Unconstrained)*

Some of these designs result in an increase in the bioreactor volume by more than 4 lt. from the initial value of 7*lt*. For example, one such profile is the one identified with the following sub-factor coefficients $(a_{11}, a_{12}, a_{21}, a_{22}) = (0.5, 0.5, 0.5, 0.5)$. To meet the final volume constraint of 11*lt*, we impose the following total volume constraint:

$$(u_{1m} + \Delta u_1 * a_{11})t_f + (u_{2m} + \Delta u_2 * a_{21})(t_b - t_f) \le (V_T - V_0)s_f$$

with

$$u_{1m} = 30gr/hr,\ u_{2m} = 7gr/hr,\ \Delta u_1 = 20gr/hr,\ \Delta u_2 = 3gr/hr$$

$$t_b = 130hr,\ t_f = 30hr,\ V_0 = 7lt \text{ and } V_T = 11lt$$

This profile is modified to the (0.44, 0.5, 0.44, 0.5) one (DB16). Three additional profiles need such modification. The resulting time dependencies on the overall feeding profiles are defined in Table 2. The resulting final bioreactor volume and total amount of penicillin produced (i.e. the performance index *J*) are also given in Table 2.

The time evolution of the simulated process during experiments DB9 is given in Figure 3. Using all the data of Table 2, a response surface model is estimated and constrained optimization, $V(t_b)<11$, yields an optimum of the penicillin process with the production of $J=102.30$ grams of product. The calculated optimum feeding profile is characterized by the following values of the 2+2 sub-factor coefficients: $(a_{11}, a_{12}, a_{21}, a_{22}) = (0.19, 0, 0.95, 1.0)$. Simulation of this operation yields 104.17 grams of product, a bit more than predicted.

Here we used a level 2 experimental design which necessitates that the response surface model has only linear and interaction terms. No quadratic terms are allowed. A more accurate response surface model can be constructed if one uses a level 3 DoDE design. In such a case, the response surface model includes quadratic terms.

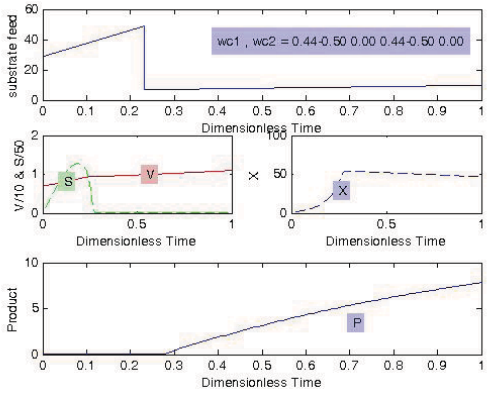

Figure 3: *The time evolution of the state and input variables of the $2^2x2^2=16$ DoDE experiments for penicillin fermentation (total volume constrained)*

We observe that the RSM-optimal run yields a performance index that is 20.82% better than any of the initial 16 experiments. This is very significant but this is not the major result of this investigation. The major result is that the process is significantly optimized with just the 16 initial

systematically designed DoDE experiments. This is a much smaller effort than what is needed to develop a fundamental model describing the process, necessary for the classical approach in process optimization.

7. CONCLUSIONS

We presented a new approach to optimize batch processes with respect to one or more time-varying decision variables. The method, called Design of Dynamic Experiments (DoDE), defines a set of experiments in which time-varying patterns of the decision variable is used. A response surface model, built from the performance index values of each experiment, is used to optimize the process. Two examples, a batch reaction and penicillin fermentation, are used to demonstrate the powerful characteristics of the new methodology. Due to space limitations, we have not presented the related ANOVA analysis. The effect of measurement error (1%-5%) was investigated and it has been convincingly shown that its effect on the process optimization is not at all detrimental to the proposed approach.

The author wishes to acknowledge the assistance of Victor Zavala and Larry Biegler in the selection of the AMPL and IPOPT software environment for calculation of the Model-based Optimum of the first example process. Alex Marvin, a ChBE senior undergraduate student at Tufts University calculated the simulation data used in Table 1.

10. APPENDIX

In this Appendix we present the penicillin model used:

$$x_1 = V: \quad \frac{dV}{dt} = u / s_f$$

$$x_2 = x: \quad \frac{dx}{dt} = \mu x - \frac{x}{s_f V} \qquad \mu = \mu_{\max} \frac{s}{k_x x + s}$$

$$x_3 = s: \quad \frac{ds}{dt} = -\frac{\mu x}{Y_{x/s}} - \rho \frac{x}{Y_{p/s}} - \frac{m_s s}{k_m + s} x + \left(1 - \frac{s}{s_f}\right) \frac{u}{V}$$

$$x_4 = p: \quad \frac{dp}{dt} = \rho x - kd - \frac{p}{s_f V} \mathrm{u} \qquad \rho = \rho \max \left(\frac{s}{k_p + s + s^2 / k_{in}} \right)$$

The model parameters used are the ones reported in (Riascos & Pinto, 2004)

Controller Tuning

Oral Session

An Internal Model Control Approach to Mid-Ranging Control

Sandira Gayadeen*, William Heath*

*Control Systems Centre, School of Electrical and Electronic Engineering, The University of Manchester, PO Box 88, Sackville Street, Manchester M60 1QD UK (e-mail:sandira_vg@hotmail.com, William.Heath@manchester.ac.uk)

Existing tuning rules for mid-ranging control can be improved. In this paper a novel strategy for mid-ranging control based on Internal Model Control (IMC) principles is presented. The design reformulates mid-ranging control specifications in terms of classical bandwidth and sensitivity requirements. The performance of this design is demonstrated through simulation studies. The overall benefits of the IMC design are that it provides transparent and flexible tuning, and that it offers a natural framework for anti-windup. Both classical IMC and modified IMC structures are considered for anti-windup. Their performance during saturation is demonstrated through simulation studies, where minimal degradation is observed.

Keywords: control system analysis, control system design, controller, constraints, saturation

1. INTRODUCTION

The term mid-ranging control typically refers to the class of control problems where two control inputs i.e. actuators are manipulated to control one output. Furthermore there is the condition that one input should return to its midpoint or some setpoint. The inputs usually differ in their dynamic effect on the output and in the relative cost of manipulating each one with the faster input normally being more costly to use than the slower input (Henson et al., 1995). Therefore mid-ranging control schemes seek to manipulate both inputs upon an upset but then gradually reset or mid-range the fast input to its desired setpoint (Allison and Ogawa, 2003).

Mid-ranging control is commonly implemented using the architecture shown in Fig. 1 where u_1 is the fast input and u_2 is the slow input. This structure is referred to as Valve Position Control (VPC) and C_1 is usually chosen as a PI controller and C_2 as an I-only controller. The VPC method for mid-ranging has been found to be sub-optimal (Allison and Isaksson, 1998, Allison and Ogawa, 2003). As such, improvements to the approach of mid-ranging control problems are suggested by many authors. Model predictive control (MPC) has also been suggested by Allison and Isaksson (1998) as an advantageous approach to mid-ranging given that it is inherently a multi-variable control problem. Henson et al. (1995) also propose MPC as well as a Direct Synthesis approach for the design of habituating controllers. The habituating control described by Henson et al. (1995) is essentially a mid-ranging control problem. Allison and Ogawa (2003) put forward a Modified Valve Position Control (MVPC) scheme which combines the simplicity of conventional VPC with the systematic tuning of Direct Synthesis. Allison and Ogawa (2003) compare the performance of MVPC with that of both conventional VPC and Direct Synthesis.

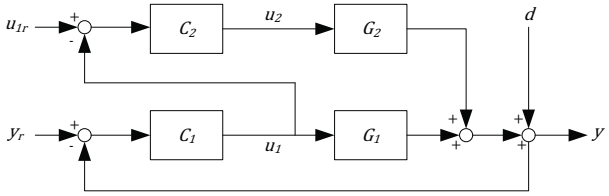

Fig. 1 Block diagram of VPC strategy (Allison and Ogawa, 2003)

For many applications MVPC works fine and has the advantage that it can be implemented using the standard VPC structure in Fig. 1 with PID control blocks. However, MVPC is not optimal; Henson et al. (1995) show that better performance (and implicitly better robustness) can be obtained by using a more general structure which includes both feedforward and feedback elements. This is acknowledged by Allison and Ogawa (2003). The Direct Synthesis design, unlike MVPC, also allows enhanced performance such as decoupling between u_{1_r} and y. MVPC does not achieve this decoupled response though u_1 tracks changes in u_{1_r} correctly.

The mid-ranging design proposed by Henson et al. (1995) uses both feedback and pre-filters. The design criteria are focused on:

- obtaining a desired response from y_r to y
- obtaining a desired response from u_{1_r} to u_1
- obtaining a decoupled response from u_{1_r} to y.

In this paper, a similar general structure is utilised where the decoupling can be achieved through the use of pre-filters.

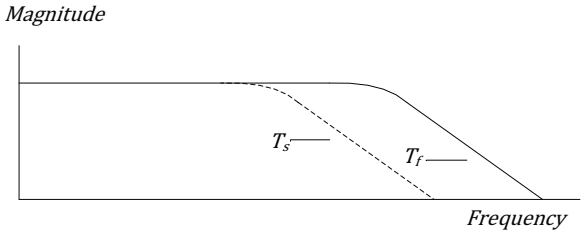

Fig. 2 Desired frequency response of complementary sensitivities

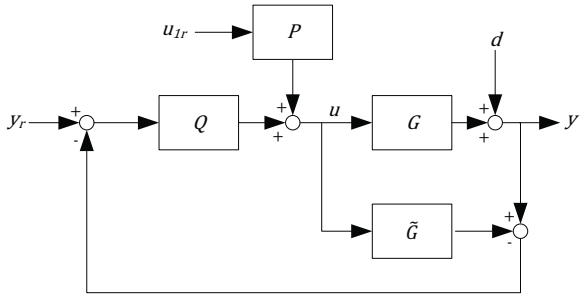

Fig. 3 IMC mid-ranging structure

The mid-ranging design proposed in this paper focuses on the respective disturbance responses of y, u_1 and u_2 and exploits both the structure and tuning methodology of internal model control (IMC). This makes the design trade-offs transparent.

Allison and Ogawa (2003) do not discuss anti-windup for MVPC. However Haugwitz et al. (2005) have shown that for some applications an additional feedback block can significantly improve the anti-windup performance of MVPC. The IMC structure provides a natural framework for both anti-windup (discussed in this paper) and robustness analysis (see Morari and Zafiriou, 1989, for the general case).

In Sections 2 to 5 the IMC tuning method for mid-ranging is presented followed by simulation studies in Section 6 that demonstrate the performance of IMC compared to Direct Synthesis. Anti-windup in IMC mid-ranging is discussed in Section 7 with an example that shows how the classical IMC structure presented in the previous sections and a modified IMC structure perform during saturation of the inputs.

2. MID-RANGING CONTROL OBJECTIVES

The plant model is (see Fig. 1),

$$y = G_1 u_1 + G_2 u_2 + d$$

where u_1 is the fast input and u_2 is the slow input. The objective is to use the both inputs to control y and mid-range u_1 i.e. to return u_1 to its setpoint, u_{1_r}.

The transfer function between y_r and y can be defined as the fast complementary sensitivity, T_f. The response from y_r to y when u_1 is set to zero can be defined as the slow complementary sensitivity, T_s (corresponding to the control action with the slow actuator alone). These are chosen to produce desired responses to setpoint changes such that the frequency response looks like Fig. 2. The proposed IMC mid-ranging design is to specify not only T_f but also T_s. With two degrees of freedom, the rest follows as illustrated in Sections 3 and 4.

3. IMC STRUCTURE FOR MID-RANGING

Firstly the general IMC structure shown in Fig. 3 is considered. Assuming that the model is perfect ($G = \tilde{G}$), y and u can be derived as:

$$y = Gu + d \quad (1)$$

$$u = Q(y_r - y + Gu) + Pu_{1_r} \quad (2)$$

Equations (1) and (2) can expressed as:

$$u = Qy_r - Qd + Pu_{1_r} \quad (3)$$

$$y = GQy_r + (I - GQ)d + GPu_{1_r} \quad (4)$$

For classical feedback control,

$$u = C(y_r - y) + \hat{P}u_{1_r}$$

where C is the equivalent feedback controller and $\hat{P}$ is the equivalent pre-filter.

C can be found by expressing (2) as:

$$u = (I - QG)^{-1}Q(y_r - y) + (I - QG)^{-1}Pu_{1_r} \quad (5)$$

This gives:

$$C = (I - QG)^{-1}Q$$
$$= Q(I - GQ)^{-1} \quad (6)$$

For mid-ranging the following are defined as:

$$u = \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}, G = [G_1 \quad G_2], Q = \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} \text{ and } P = \begin{bmatrix} P_1 \\ P_2 \end{bmatrix}$$

4. IMC MID-RANGING DESIGN

From (4), T_f and T_s can be expressed in terms of Q_1 and Q_2. This gives the conditions for the controller design:

Controller Design Conditions:

$$T_f = GQ = G_1Q_1 + G_2Q_2$$

$$T_s = G_2Q_2$$

The sensitivity, S_f is defined as $S_f = 1 - T_f$ such that (4) can be expressed as,

$$y = T_f y_r + S_f d + GPu_{1_r}$$

To achieve the control objectives,

$$T_f|_{ss} = G_1Q_1 + G_2Q_2|_{ss} = 1$$

$$Q_1|_{ss} = 0$$

This means that $T_s|_{ss} = G_2Q_2|_{ss} = 1$.

The decoupling between u_{1_r} and y is achieved through the use of pre-filters. From (4), to obtain a decoupled response between u_{1_r} and y, the following condition must be satisfied:

Pre-filters Design Conditions:

$GP = G_1P_1 + G_2P_2 = 0$

The design algorithm is then as follows:

1. Choose T_s
2. Q_2 is then designed such that $Q_2 = \frac{T_s}{G_2}$
3. Choose T_f
4. Q_1 is then designed such that $Q_1 = \frac{(T_f - T_s)}{G_1}$
5. To design pre-filters, $GP = 0$ must be satisfied. There are different ways to achieve this:
   a. Let $P_1 = 1$ and $P_2 = -G_1/G_2$
   b. Let $P_1 = G_2/G_2|_{ss}$ and $P_2 = -G_1/G_2|_{ss}$
   c. Let $G_2 = {G_2}^-{G_2}^+$ where ${G_2}^+$ is minimum phase and ${G_2}^-$ is non-minimum phase, then let $P_1 = H{G_2}^-$ where $H{G_2}^-|_{ss} = 1$ and $P_2 = -H\,G_1/{G_2}^+$

G_1 and G_2 can be either minimum phase or non-minimum phase. This design above can be extended for non-minimum phase systems as follows:

1. Choose T_s such that $T_s = {T_s}^-\tilde{T}_s$ where ${T_s}^-$ includes the non-minimum phase components (including delays) of both G_1 and G_2 i.e. so that T_s/G_1 and T_s/G_2 are both casual and stable.
2. Q_2 is then designed such that $Q_2 = \frac{T_s}{G_2}$
3. Choose $T_f = {T_f}^-\tilde{T}_f$ where ${T_f}^-$ includes the non-minimum phase component (including delay) of G_1 i.e. so that T_f/G_1 is casual and stable.
4. $Q_1$is then chosen as $Q_1 = \frac{(T_f - T_s)}{G_1}$.
5. P_1 and P_2 are chosen as before.

The IMC approach concentrates on the disturbance responses i.e. the third column of the sensitivities matrices (17) and (28) in Henson et al. (1995) where nine sensitivities are discussed. Equation (7) shows the sensitivities for the IMC design.

$$\begin{bmatrix} y \\ u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} GQ & GP & (I - GQ) \\ Q_1 & P_1 & -Q_1 \\ Q_2 & P_2 & -Q_2 \end{bmatrix} \begin{bmatrix} y_r \\ u_{1_r} \\ d \end{bmatrix} \quad (7)$$

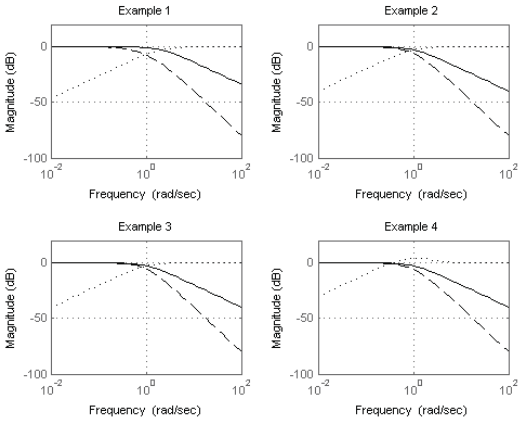

Fig. 4 Complementary sensitivities T_f (solid) and T_s (dashed) and sensitivity, S_f (dotted) for all examples.

From a classical point of view, the disturbance responses correspond to the sensitivity S_f and two control sensitivities, Q_1 and Q_2. For the mid-ranging problem, it is required that the slow actuator should have a control sensitivity that is low bandwidth only; meanwhile the fast actuator should have a control sensitivity that is mid-frequency only and goes to zero at steady state, giving mid-ranging. IMC is advantageous because it gives the control sensitivities of the fast and slow actuators directly as Q_1 and Q_2.

5. IMPLEMENTATION IN VPC STRUCTURE

The IMC mid-ranging design described in Section 4 can be extended for implementation using the VPC structure. This structure is similar to Fig. 1 but includes the pre-filters P_1 and P_2. Without the pre-filters this design does not achieve the decoupled response between u_{1_r} and y; it can only track u_1 to $u_1 = u_{1_r}$.

For the VPC structure in Fig. 1,

$$\begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} C_1 \\ -C_2C_1 \end{bmatrix} (y_r - y)$$

From (6),

$$\begin{bmatrix} C_1 \\ -C_2C_1 \end{bmatrix} = \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} \left[I - \begin{bmatrix} G_1 & G_2 \end{bmatrix} \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} \right]^{-1}$$

Therefore,

$$\begin{bmatrix} C_1 \\ -C_2C_1 \end{bmatrix} = \begin{bmatrix} Q_1/(I - G_1Q_1 - G_2Q_2) \\ Q_2/(I - G_1Q_1 - G_2Q_2) \end{bmatrix}$$

This gives,

$$C_1 = \frac{Q_1}{(I - G_1Q_1 - G_2Q_2)}$$

$$C_2 = -\frac{Q_2}{Q_1}$$

6. SIMULATION STUDIES

The performance of the IMC design in the previous sections is demonstrated via simulation of four examples. The examples are all linear, stable systems. Examples 1, 2 and 3 are taken from Henson et al., (1995) to compare the performance of IMC controllers to the Direct Synthesis controllers. Therefore T_f and T_s for examples 1 to 3 are chosen to correspond to g_{y_d} and g_{u_d} given in Henson et al. (1995). In example 1, both G_1 and G_2 are minimum phase systems. For examples 2 and 3, G_1 is minimum phase whereas G_2 has a right half plane zero and a time delay respectively. Example 4 is an original example where both G_1 and G_2 are non-minimum phase. Additional first order setpoint filters are included in both control schemes according to Henson et al. (1995).

The process model transfer functions for the examples are given below.

Example 1: $y = \frac{1}{2s+1}u_1(s) + \frac{1}{5s+1}u_2(s) + \frac{1}{s+1}d(s)$

Example 2: $y = \frac{1}{2s+1}u_1(s) + \frac{-2s+1}{(2s+1)^2}u_2(s) + \frac{1}{s+1}d(s)$

Example 3: $y = \frac{1}{2s+1}u_1(s) + \frac{e^{-2s}}{2s+1}u_2(s) + \frac{1}{s+1}d(s)$

Example 4: $y = \frac{-s+1}{(2s+1)^2}u_1(s) + \frac{-2s+1}{(2s+1)^2}u_2(s) + \frac{1}{s+1}d(s)$

T_f and T_s are as follows:

Example 1: $T_f = \frac{1}{0.5s+1}$ and $T_s = \frac{2}{(2s+1)(s+2)}$

Example 2: $T_f = \frac{1}{s+1}$ and $T_s = \frac{-2s+1}{(2s+1)(s+1)^2}$

Example 3: $T_f = \frac{1}{s+1}$ and $T_s = \frac{e^{-2s}}{(s+1)^2}$

Example 4: $T_f = \frac{-s+1}{(s+1)^2}$ and $T_s = \frac{(-s+1)(-2s+1)}{(2s+1)(s+1)^3}$

The frequency response of sensitivity, S_f and the complementary sensitivities, T_f and T_s for the examples are shown in Fig. 4. T_f is chosen to determine the closed-loop bandwidth and T_s to determine the relative work done by u_1 and u_2.

Figs. 5 to 8 show setpoint and disturbance responses for the IMC controllers (solid line) and Direct Synthesis controllers, both parallel (dashed line) and series (dotted line).

It can be seen from Figs. 5 to 7 that identical output responses are obtained for Direct Synthesis and IMC schemes. This is expected since both pairs of controllers are tuned with the same time constants. The Direct Synthesis parallel architecture and IMC structure are identical when (6) is satisfied where C_1 and C_2 are the habituating controllers, $g_{c_{11}}$ and $g_{c_{21}}$ from Henson et al. (1995).

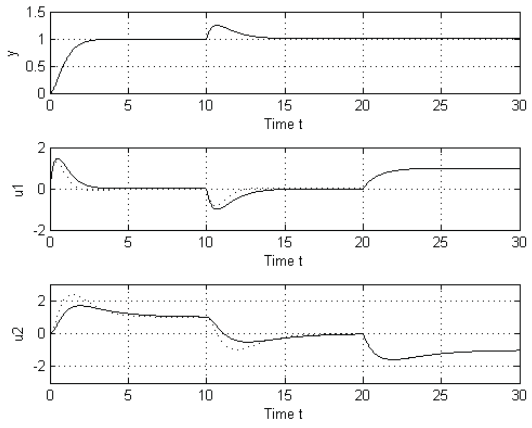

Fig. 5 Example 1: IMC (solid), Direct Synthesis parallel (dashed) and series (dotted) responses to unit changes in y_r at t=0, d at t=10 and u_{1_r} at t=20.

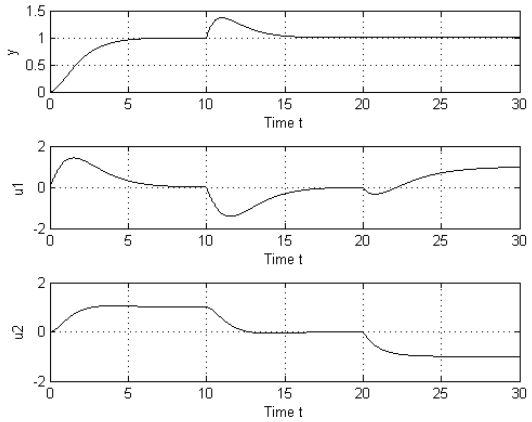

Fig. 6 Example 2: IMC (solid), Direct Synthesis parallel (dashed) and series (dotted) responses to unit changes in y_r at t=0, d at t=10 and u_{1_r} at t=20.

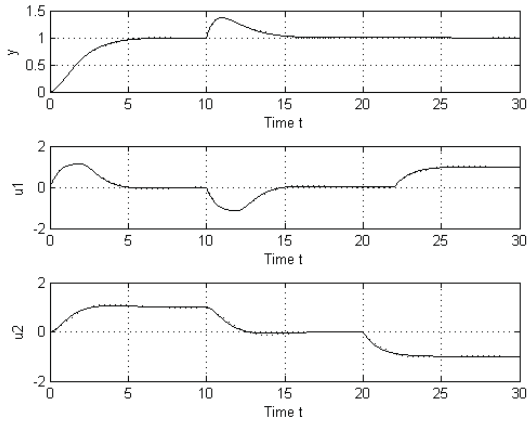

Fig. 7 Example 3: IMC (solid), Direct Synthesis parallel (dashed) and series (dotted) responses to unit changes in y_r at t=0, d at t=10 and u_{1_r} at t=20.

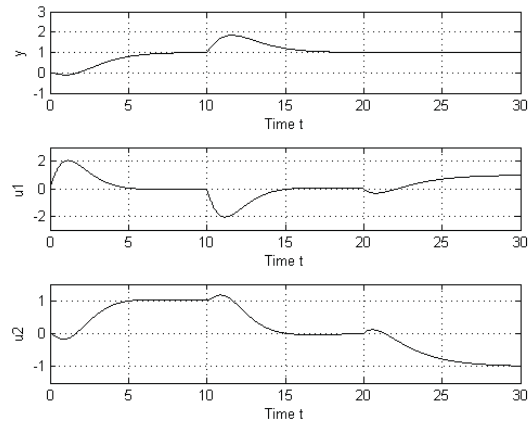

Fig. 8 Example 4: IMC (solid) response to unit changes in y_r at t=0, d at t=10 and u_{1_r} at t=20.

Direct Synthesis implemented in the series architecture responds differently from the IMC and the parallel architecture in example 1 because the relationship given by (11) in Henson et al. (1995) is not satisfied (because of the choice of g_{c21} in the design). For all examples, both methods produce completely decoupled response between u_{1_r} and y. However the IMC design gives more flexibility since H in Section 4 can be adjusted to tune the response to allow faster setpoint tracking of u_{1_r}.

From (7), Q_1 and Q_2 are directly related to the output setpoint and disturbance responses. Therefore it is simple to adjust these controllers because in the absence of model uncertainty, closed loop stability is automatically guaranteed as long as Q_1 and Q_2 are stable (Prett and Garcia, 1988). Henson et al. (1995) state that the controller g_{c21} can also be used to tune the responses of the two inputs to changes in y_r and d. The effect on closed loop performance of adjusting this tuning parameters is however not obvious. Neither is it obvious for what parameter values the closed loop system is stable.

7. ANTI-WINDUP IN MID-RANGING CONTROL

Haugwitz et al. (2005) propose anti-windup schemes for MVPC when u_1 saturates. Guidelines are given on how to tune mid-ranging controllers to maintain the same control action of u_2 in the saturated case as in the unsaturated case. Furthermore a modified anti-windup scheme is presented that achieves increased control action in u_2 to further reduce performance degradation. However, if the MVPC structure is to be modified, then significantly improved performance can be achieved for the saturated case by using the IMC approach in this paper.

In this section, the performance of the classical IMC structure used for mid-ranging (see Fig. 3) is considered when the inputs u_1 and u_2 saturate. This IMC structure works for most cases but as demonstrated by Zheng et al. (1994), sometimes IMC requires a modified structure. The modified IMC structure presented by Zheng et al. (1994) can be utilised for

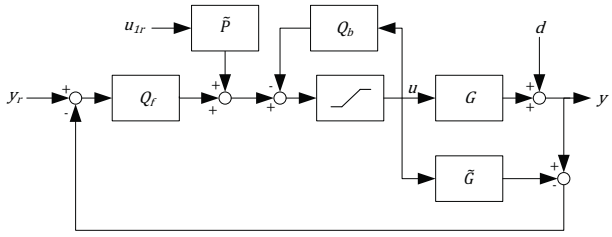

Fig. 9 Modified IMC mid-ranging structure for anti-windup

the proposed IMC mid-ranging design as shown in Fig. 9. The performance during saturation of this modified IMC structure (Fig. 9) is also considered in this section.

7.1 Anti-windup in IMC

As with the controller design, firstly the general case is considered. For the unsaturated case in Fig. 9,

$$u = (1 + Q_b)^{-1} Q_f (y_r - y + Gu) + (1 + Q_b)^{-1} \tilde{P} u_{1_r}$$

From (2),

$$u = Q(y_r - y + Gu) + P u_{1_r}$$

Therefore it is desired that,

$$Q = (1 + Q_b)^{-1} Q_f \tag{7}$$

$$P = (1 + Q_b)^{-1} \tilde{P}$$

For mid-ranging, u, G, Q and P are defined as in Section 3. Additionally, $\tilde{P}$, Q_f and Q_b are as follows:

$$\tilde{P} = \begin{bmatrix} \tilde{P}_1 \\ \tilde{P}_2 \end{bmatrix}, \; Q_f = \begin{bmatrix} Q_{f_1} \\ Q_{f_2} \end{bmatrix} \text{ and } Q_b = \begin{bmatrix} Q_{b_1} & 0 \\ 0 & Q_{b_2} \end{bmatrix}.$$

Extending the general case before for mid-ranging gives:

$$\begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \left(I + \begin{bmatrix} Q_{b_1} & 0 \\ 0 & Q_{b_2} \end{bmatrix} \right)^{-1} \begin{bmatrix} \bar{u}_1 \\ \bar{u}_2 \end{bmatrix}$$

$$\text{where } \begin{bmatrix} \bar{u}_1 \\ \bar{u}_2 \end{bmatrix} = \begin{bmatrix} \tilde{P}_1 \\ \tilde{P}_2 \end{bmatrix} u_{1_r} + \begin{bmatrix} Q_{f_1} \\ Q_{f_2} \end{bmatrix} \left(y_r - y + [G_1 \quad G_2] \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} \right)$$

Therefore,

$$\begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} \dfrac{Q_{f_1}}{1 + Q_{b_1}} \\ \dfrac{Q_{f_2}}{1 + Q_{b_2}} \end{bmatrix} (y_r - y + G_1 u_1 + G_2 u_2) + \begin{bmatrix} \dfrac{\tilde{P}_1}{1 + Q_{b_1}} \\ \dfrac{\tilde{P}_2}{1 + Q_{b_2}} \end{bmatrix} u_{1_r}$$

This means that

$$\begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} = \begin{bmatrix} \dfrac{Q_{f_1}}{1 + Q_{b_1}} \\ \dfrac{Q_{f_2}}{1 + Q_{b_2}} \end{bmatrix} \text{ and } \begin{bmatrix} P_1 \\ P_2 \end{bmatrix} = \begin{bmatrix} \dfrac{\tilde{P}_1}{1 + Q_{b_1}} \\ \dfrac{\tilde{P}_2}{1 + Q_{b_2}} \end{bmatrix}$$

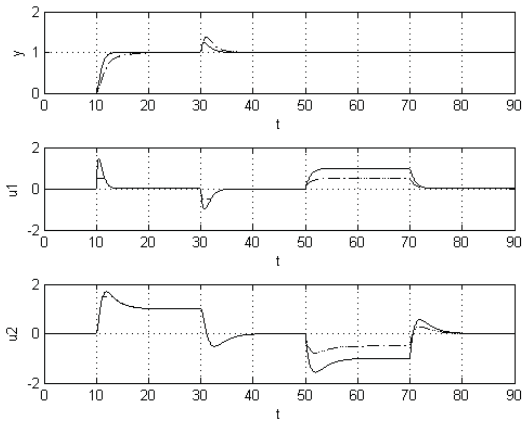

Fig. 10 Example 1: Response of IMC scheme with no saturation (solid), $\lambda = 0$ (dashed) and $\lambda = 1$ (dotted) for a unit changes in y_r at t=10, d at t=30, u_{1_r} at t=50 and t= 70.

From Zheng et al. (1994), Q_f can usually be chosen by the following relationship:

$$Q_f = \lambda Q(\infty) + (1 - \lambda)Q$$

- Condition 1: when $\lambda = 0$, then $Q_f = Q$ and from (7) $Q_b = 0$
- Condition 2: when $\lambda = 1$, then $Q_f = Q(\infty)$ and from (7) $Q_b = (Q(\infty) - Q)/Q$

The classical IMC structure as shown in Fig. 3 corresponds to the condition where $\lambda = 0$ and the modified IMC structure given by the block diagram in Fig. 9 corresponds to $\lambda = 1$. For condition 2 above, Q_{f_1} cannot be chosen to be $Q(\infty)$ because for the mid-ranging control problem it is required that $Q_{f_1}(0) = 0$. To ensure that $Q_{f_1}(0) = 0$, Q_f can be chosen such that,

$$Q_{f_1} = Q_1(\infty)\frac{s}{s + p_1}$$

where p_1 is a pole of Q_1.

Q_{f_2} can simply be chosen as $Q_{f_2} = Q_2(\infty)$. However, if Q_2 is strictly proper then Q_2 can be defined as:

$$Q_2 = Q_{2_b} \times Q_{2_s}$$

where Q_{2_b} is bi-proper and Q_{2_s} is strictly proper so that $Q_{f_2} = Q_{2_b}(\infty) \times Q_{2_s}$.

Fig. 10 shows the response of the system in example 1 defined in Section 6 when u_1 and u_2 saturate. Responses for both the classical IMC structure (Fig. 3) and the modified IMC structure (Fig. 9) are considered. For this example the response when $\lambda = 0$ and $\lambda = 1$ is similar because $Q_{f_1} = Q_1$.

When u_1 saturates, output tracking is still achieved by the slow actuator. The control action of u_2 is the same when u_1 saturates as in the unsaturated case. When u_2 saturates however, the fast actuator compromises between input and output tracking. Therefore the classical IMC structure offers acceptable performance during saturation. In some cases, the modified IMC structure offers even better performance with saturation of u_1 and u_2.

8. CONCLUSION

Many mid-ranging designs have been proposed and of them, MVPC and Direct Synthesis are most appropriate to address the ad hoc nature of conventional mid-ranging tuning procedures. MVPC works sufficiently especially when restricted to conventional mid-ranging structure and PID control. However, when not restricted, the Direct Synthesis (Henson et al., 1995) and IMC approaches give better performance. The IMC mid-ranging design presented in this paper gives the same improved performance over MVPC as Direct Synthesis. Moreover, this approach gives insight to the design trade-offs of MVPC and Direct Synthesis by emphasis on bandwidth considerations. An added benefit of the IMC approach is the ability to integrate anti-windup to mid-ranging control. Other mid-ranging approaches require additional control blocks and further modifications to achieve acceptable performance under saturation of the inputs. IMC mid-ranging is already a natural structure for anti-windup.

Abstract: Modern process plants are highly integrated and as a result, decentralized PID control loops are often strongly interactive. The currently used sequential tuning approach is not only time consuming, but does also not achieve optimal performance of the inherently multivariable control system. This paper describes a method and a software tool which allows a control engineer to calculate optimal PID controller settings for multiloop systems. It is based on the identification of a state space model of the multivariable system, and it uses constrained nonlinear optimization techniques to find the controller parameters. The solution is tailored to the specific control system and PID algorithm to be used. The methodology has been successfully applied in several industrial advanced control projects. The tuning results which have been achieved for interacting PID control loops in the stabilizing section of an industrial Gasoline Treatment Unit at SABIC Petrochemicals are presented.

Keywords: PID controller tuning, multi-loop control, decentralized control system design, nonlinear optimization, genetic algorithm, multivariable system identification.

1. INTRODUCTION

One of the most important challenges facing the process industry today is optimizing the operation of complex units, without compromising the safety and integrity of the process equipment. Process complexity has increased significantly over the past two decades due to increased level of heat integration and use of recycle streams. In addition, the need for increased process flexibility to deal with changing raw materials and alternate energy sources, as well as the need to adapt quickly to fluctuating throughput and quality targets, often means that the process dynamics will vary significantly over time and with operating point. The basic control layer of process plants almost always consists of a large number of decentralized SISO PID controllers, although this approach is intrinsically inadequate for multivariable processes. Due to the situation described above, the interactions between these controllers are becoming more important, and tuning these control loops for good performance and adequate robustness is a challenging task.

The industrial practice of PID controller tuning is still dominated by manual trial-and-error tuning. If tuning rules are used at all, it's the "classical" ones like Ziegler-Nichols or Chien-Hrones-Reswick which are based on simplified first order plus dead time (FOPDT) process models and do not consider stability robustness issues, therefore often being not adequate in modern process units with more complex dynamics and nonlinearity. In addition, many tuning rules assume that all PID controller equations work as described in the textbooks, when in fact there is substantial variation between the different vendors. In contrast, different PID controller structures result due to use of either the parallel or the serial form, using the control error or the PV by the Proportional (P) and Derivative (D) terms, and many other quirks like alternative implementations of the derivative filters. Tuning SISO PID controllers in a multivariable environment is usually done in a time-consuming sequential and iterative way, starting with the most important loops, and heuristic detuning in case the interactions are significant.

For a long time, vendors of automation systems such as Distributed Control Systems (DCS) and Programmable Logic Controllers (PLC) have been offering PID self-tuning functionality (tuning on demand). Unfortunately, they have only found limited application. This is also true for model based PID controller tuning software provided by the same or third-party vendors. Moreover, in most cases these tools are restricted to single loop tuning applications, and do not support multi-loop tuning (Li et al., 2006, Espinosa Oviedo et al., 2006 and Zhu, 2004).

The design of interacting PID controllers in a multivariable environment is not a new topic in the process control literature. At least three research directions can be identified: (1) reduction of controller interactions by proper MV-CV pairing, (2) design of decoupling networks and (3) consideration of MIMO interactions in decentralized controller tuning. In this paper, only the third direction is relevant. Several methods have been developed, Luyben's

BLT method being the most popular one (Monica et al., 1988). Here, the individual PI loops are first tuned by the Ziegler-Nichols rules independently. Then, a detuning factor is calculated which assures a certain stability margin for the controlled MIMO system. All individual controller gains are divided by this factor, and the reset times are multiplied by it. The price to be paid for the reduced interaction is a more sluggish behaviour of PI loops. Other methods include the sequential loop closing approach (Hovd and Skogestad, 1994), the independent design method (Hovd and Skogestad, 1993) and the multivariable generalization of the relay-feedback self-tuning method (Halevi et al. 1997). For a discussion of these methods the reader is referred to (Chen and Seborg, 2003).

This paper introduces a new method and a software tool "AptiTune™" for the calculation of optimum PID controller settings in a multivariable system (multivariable loop tuning). The method consists of several steps. First, a set of Finite Impulse Response (FIR) models of the open-loop MIMO plant is being identified and approximated by a reduced-order state space model. In a second step, optimal parameters for the decentralized PID controllers are calculated using constrained optimization. Finally, the setpoint tracking, disturbance rejection and noise attenuation behaviour of the controlled system is simulated.

It was the aim of the development to come up with a software tool which is based on recent identification and control developments, but which does not require in-depth knowledge of identification and control theory by the average user. Furthermore, the optimization solution is tailored to the specific target automation system, e.g. the particular DCS or PLC which is used for control purposes.

The remainder of the paper is organized as follows: In section 2, the identification and optimal tuning methods will be described together with the "AptiTune™" software tool. Section 3 presents some results of multiloop tuning in the stabilizer section of an industrial Gasoline Treatment Unit (GTU). The retuning of the PID controllers was one of the first steps of an advanced control project, which also included the design and commisioning of an MPC controller.

2. METHOD AND TOOL FOR MULTILOOP TUNING

2.1 Identification of the MIMO process model

The first step of model based multiloop tuning is to develop a dynamic model of the multivariable process with n inputs and n outputs, the outputs (u_i) and process variables (y_i) of the PID controllers shown in Fig. 1.

Our preferred approach is to switch all PID controllers to be tuned into manual mode whenever possible and to perform a series of output steps of different duration and amplitude. According to our experience, four to six steps with duration varying between 10% and 100% of the desired closed-loop settling time are usually sufficient. If a test signal generator is available, PRBS (pseudo-random binary sequence) or GBN

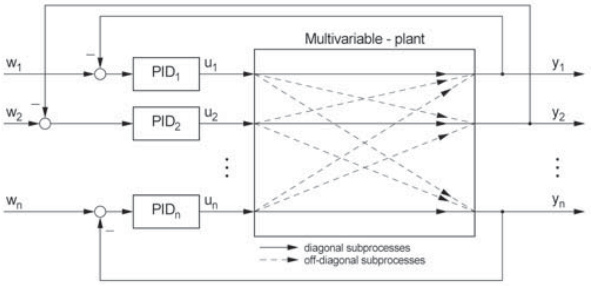

Fig. 1: Decentralized multiloop PID control system

(generalized binary noise), then an automated test may be used as an alternative. Both types of plant tests can be performed in sequential or in time-saving simultanous mode.

If one or more PID controllers cannot be switched to manual mode, then the loop can be kept in automatic mode and multiple setpoint steps can be made. The Projection Method described in (Forsell and Ljung, 2000) can then be used.

After pre-processing the raw test data (detection/rejection of outliers, filtering, decimation, cutting out periods of bad data etc.), the parameters of a MIMO FIR model

$$\vec{g}_{ij} = \left[g_{ij}(0), g_{ij}(1), g_{ij}(2), \ldots, g_{ij}(n_M) \right] \qquad i, j = 1...n \quad (1)$$

are estimated by least squares regression. The user should specify a-priori knowledge such as zero gain, known dead time or integrating behaviour of subprocesses. Although FIR models are estimated, the results are presented as Finite Step Response (FSR) models for easier visualization and understanding. The "AptiTune™" software tool also supports the import of FSR models created by identification tools from MPC packages, but also allows the user to specify a transfer function matrix.

In the next step, the MIMO FIR model is approximated by a linear state-space model of the form

$$\begin{aligned} \dot{x}(t) &= A\,x(t) + B\,u(t) \\ y(t) &= C\,x(t) \end{aligned} \qquad (2)$$

This approximation is not based on the raw or preprocessed plant test data, but on a model-to-model fit. To remove noise and cycles from the FIR model, it can first be smoothed using a central average filter. The state-space model is constructed using the singular value decomposition (SVD) model reduction technique (Maciejowski, 1989). While creating the state-space model, the diagonal model curves are given more preference than the off-diagonal models. As a result, diagonal models normally have higher order than the off-diagonal ones and consequently fit the original FIR model curves more accurately. The step responses calculated based on the stat-space models are graphically displayed.

If it is possible to do a closed-loop step test (or if historical data contain a clear SP step), a practical way of validating the process model is to simulate the closed loop behaviour of the control system with the actual PID controller parameters

currently entered on the DCS , and to compare the simulation results with plant data. If the observed responses are similar to the simulated responses, then we can conclude that the model is sufficiently accurate for loop tuning purposes.

2.2 Calculation of optimal PID controller parameters

The PID controller parameters (controller gains $K_{c,i}$, reset times $T_{r,i}$ and derivative time constants $T_{d,i}$) are calculated solving numerically the nonlinear constrained optimization problem

$$\min_{K_{Pi},T_{Ni},T_{Vi}} \quad J$$
$$g_j(K_{Pi},T_{Ni},T_{Vi}) \le 0 \quad i=1...n,\ j=1...m \tag{3}$$

where J denotes the objective function and g_j are constraints. The objective function J is a weighted sum of three terms $J = J_1 + \alpha J_2 + \beta J_3$ which assess different aspects of the control loop performance. The first part $J_1 = \int_0^{T_f} \left| y(t) - y_r(t) \right| dt$ refers to the Integrated Absolute Error (IAE) criterion for setpoint tracking. Here, the error is defined as the difference between the PV and a user-defined first order reference trajectory $y_r(t)$ connecting the actual PV and the setpoint. By specifying the time constant of the trajectory, the user can affect the speed of the response to setpoint changes. The second part $J_2 = \int_0^{T_f} \left| w(t) - y(t) \right| dt$ denotes the IAE for an input step disturbance. Finally, the third term $J_3 = \int_0^{T_f} \left| \Delta u(t) \right| (t)$ reflects the control effort. By setting the weighting coefficients α and β, the user can balance a compromise between the different performance objectives. Another design parameter allows the user to weight the performance of the n SISO control loops against the necessary degree of decoupling between them.

For each control loop, the user can specify one or more inequality constraints $g_j \le 0$ from the following list: maximum OP deviation after setpoint changes, maximum overshoot, minimum damping ratio, maximal noise amplification, process gain and deadtime margins, maximum/minimum limits of the controller parameters. For level buffering controllers, the maximum setpoint deviation and the minimum return time after a level disturbance can be specified. By careful specification of the constraints, the user can tailor the tuning to process-specific requirements.

For starting the numerical optimization, initial controller parameter values have to be selected. For this purpose, the user can choose to use the actual DCS values or values calculated by the Cohen-Coon tuning rule (for individual controller tuning assuming a SISO model). The degree of difficulty of the nonlinear constrained optimization problem depends on the number of controllers involved, the order of the process model, and the number and nature of the inequality constraints. In general, non-convexity and local minima can occur. Therefore, several search algorithms have been implemented, including a brute force global search in the entire parameter space, a genetic algorithm (both intended for initialization), and a generalized gradient algorithm (Vlachos et al., 2000).

In contrast to some PID controller tuning software available mainly for teaching and training purposes, the "AptiTune™" tool not only calculates "generic" PID controller parameters, but parameters for a specific realization of the PID controller equation for specific commercial control system hardware. The user can select between different control algorithms of widespread DCS systems such as Honeywell, Emerson DeltaV, Foxboro I/A, ABB and several others. For example, six different versions of the PID algorithms are available for the Emerson DCS, for which the optimization results may be quite different. Optimal controller parameters can of course also be calculated for P, I only and PI controllers.

After the optimizer has converged and optimal controller parameters have been found, the design process will be finished by simulation of the dynamic behaviour of the control system. It is useful to study different scenarios: setpoint tracking, input disturbance rejection, and noise attenuation. The "integrity" of the controlled MIMO system should be studied as well, i.e. the behaviour of the controlled system if one or more controllers are in manual mode, or if components like final actuators fail. Finally, the robustness against plant-model mismatch should be evaluated. For this purpose, robustness plots such as in Fig. 2 are helpful. It shows the purple stability limit in a process gain ratio/dead time graph, and the stability region for the minimum required combined gain and deadtime margins as the red polygon (left hand plot, lower left hand corner).

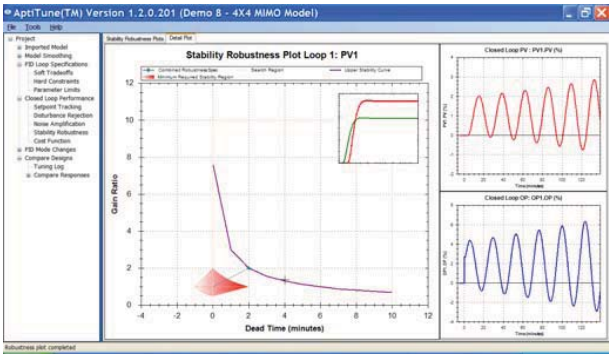

Fig. 2: Robustness plot

3. INDUSTRIAL EXAMPLE

The method and software tool described above have been used successfully in a number of advanced control projects. A good example is the stabilizing section of a GTU process, where improving the PID controller tuning was a prerequisite for successful MPC design and implementation.

The Process and Instrumentation Diagram for the GTU process is shown in Fig. 3. Although the overall system is (8x8), it was possible to decompose it into a (2x2) system on

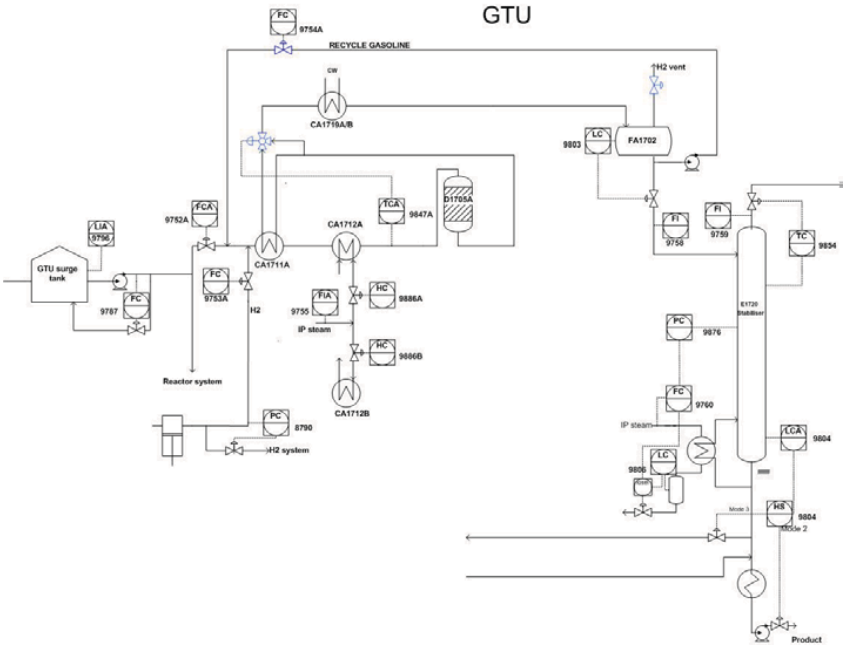

Fig. 3: P&I diagram of the GTU process

the E20 column and (6x6) for the rest of the unit. Due to limited space, the results for the (2x2) system are presented.

The objective of the E20 stabilizer column (on the right hand side of the P&ID) is to remove hydrogen and methane dissolved in the petrol (mostly C5) stream. The column is essentially a degassing drum with trays for improved separation. The current PID control scheme is somewhat unconventional in that the PID loop pairing is the "wrong" way round:

- A tray temperature close to the top of the column is controlled (even though the product specification is on the bottoms stream) by using the overhead vent valve for temperature control. There is no reflux drum, and feed comes in close to the top, providing the internal reflux stream.
- The column pressure controller cascades to the steam flow SP on the reboiler.

One reason for the unconventional PID loop pairing is that controlling pressure with the reboiler duty ensures that the pressure is less likely to go high and lift the safety valve. If the PID was paired the other way around, there is a chance for the pressure to go high if the overhead valve saturates before the column runs out of reboiler duty. Since the degree of interaction between the two loops is quite strong, the pressure loop will go unstable if either the feed drum LIC or the TIC approached unstable (even though there is nothing wrong with the tuning of the PIC). The drum level controller sets the valve position directly without the benefit of a cascaded flow controller. Any change in either upstream or downstream pressure affect the feed flow PV, which then affects the temperature and pressure in the E20 column. Due to the heavy coupling between the three loops, it is not really feasible to tune one loop without due consideration of the remaining two control loops.

Best results were obtained by step testing condensate flow setpoint and vent valve, fitting a 2x2 model and then calculating moderately fast but well damped tuning that takes the strong off-diagonal interaction into account. We tuned it for fast SP tracking but high robustness margins. The standard deviations of the two PVs are now substantially better than before and that both loops are tracking SP well.

The gain for the tray temperature vs. vent valve varies very substantially depending on operating point (from almost zero when the top of the column is perfectly pure, to almost infinite when the column goes rapidly off-spec). This value represents the best model we could identify by keeping the tray temperature in the correct range with the column pressure at the nominal operating point. The dynamic model is shown in Fig. 4.

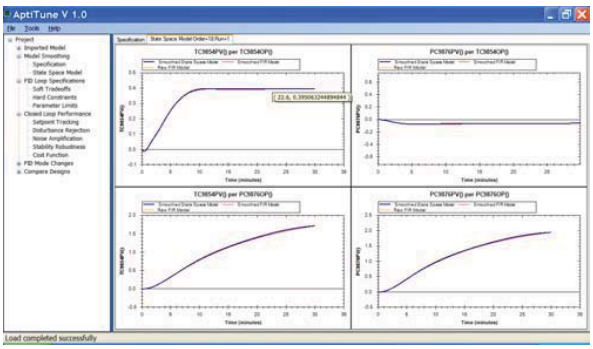

Fig. 4: Step responses of the dynamic model
(Legend: TC.PV=Tray 6 Temperature; PC=Column Pressure; TC.OP=Vent Valve; PC.OP=Steam Flow SP)

Note that the total state-space model order is 18. Fig. 5 shows the optimized PV responses for a step change in both SPs:

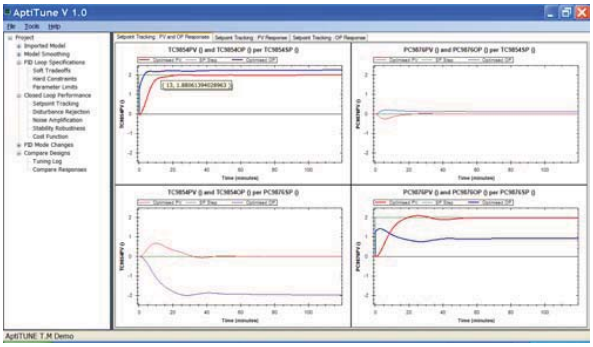

Fig. 5: Response of the 2x2 system to SP step changes
(Legend: PV is shown in red, OP in blue)

Note that PV overshoot is very low and that damping is exceptionally good. The OP value for the vent has a peak value that is almost the same as the steady state value, and the loop has about the same rise time in closed loop as compared to open loop (a speed-up factor of about 1x). The pressure loop is about 2x faster in closed loop compared to open loop. The load disturbance response is shown in Fig. 6:

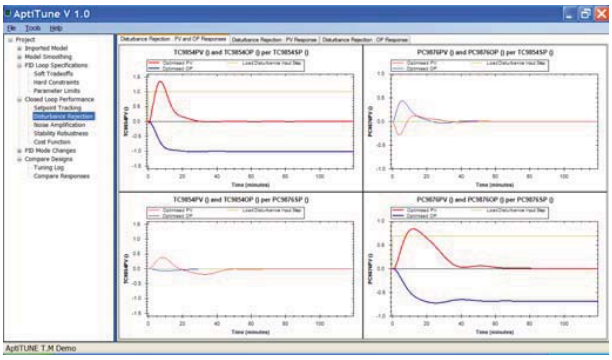

Fig. 6: Response of the 2x2 system to load disturbances

Note that the PV and OP responses have very good damping with peak OP values that are very similar to the steady state values. This will ensure exceptionally good damping on the actual process unit even when the process gain varies significantly. Gain and dead time (stability) margins are very good, see Fig. 7:

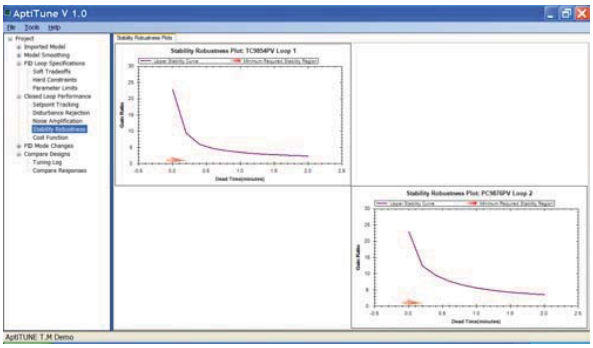

Fig. 7: Robustness plot (gain and deadtime stability margins)

A sensitivity analysis on the tray temperature loop shows that the gain of the process will have to increase by 3x AND the dead time will have to increase by another 12 seconds before the damping of the loops is unacceptable. Instability sets in at a process gain increase of more than 20x. A dead time error of more than 2 minutes is needed to reach instability, and there is no process mechanism for this to occur while the TIC is in the active range. These margins are exceptionally safe.

In order to compare the performance of the loops before and after retuning, we collected a week of normal operating data before we arrived on site, and one week of normal operating data after the re-tuning work was concluded. From these large data sets, we then calculated histograms to show the distribution of the control error (SP-PV). For process reasons, we wanted the loops to be robust and to be able to withstand changes in process dynamics. As a result, some loops were intentionally slowed down, and of course, their probability distributions will be wider than before. However, this compromise is all for a good cause as it will ensure that the loops remain operational for the years to come.

The performance of the pressure control loop PCA9876 is compared in Fig. 8:

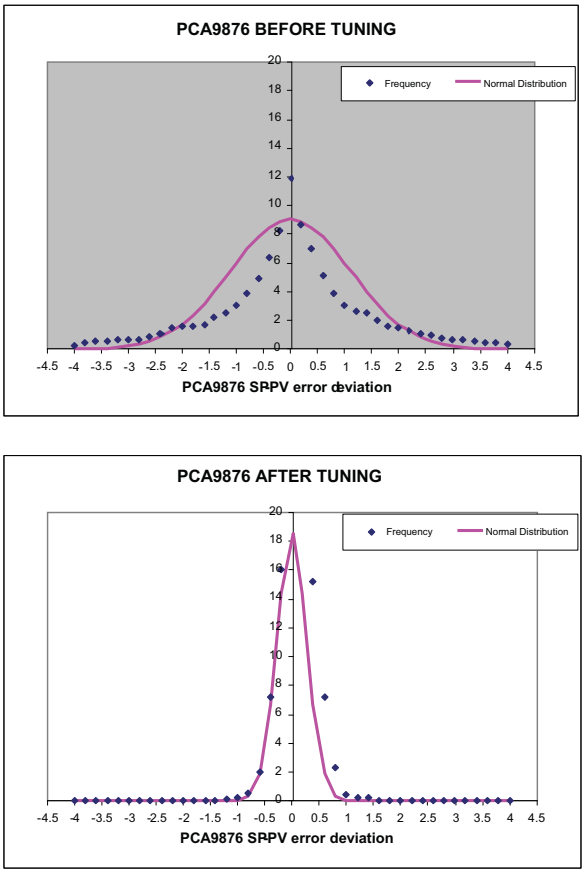

Fig. 8: Control error histograms for PCA9876 before and after retuning

It is clear from the two histograms shown above that the variability in the PV has reduced by about a factor of 4x. This is a big improvement in performance, yet this could be accomplished without compromising the robustness characteristics of the loop. The pink trace shows the best fit for a normal (Gaussian) distribution to the data, assuming a zero mean value. The estimated standard deviation σ reduced from 1.1 to 0.28.

The histograms for temperature loop TC9854 are compared in Fig. 9:

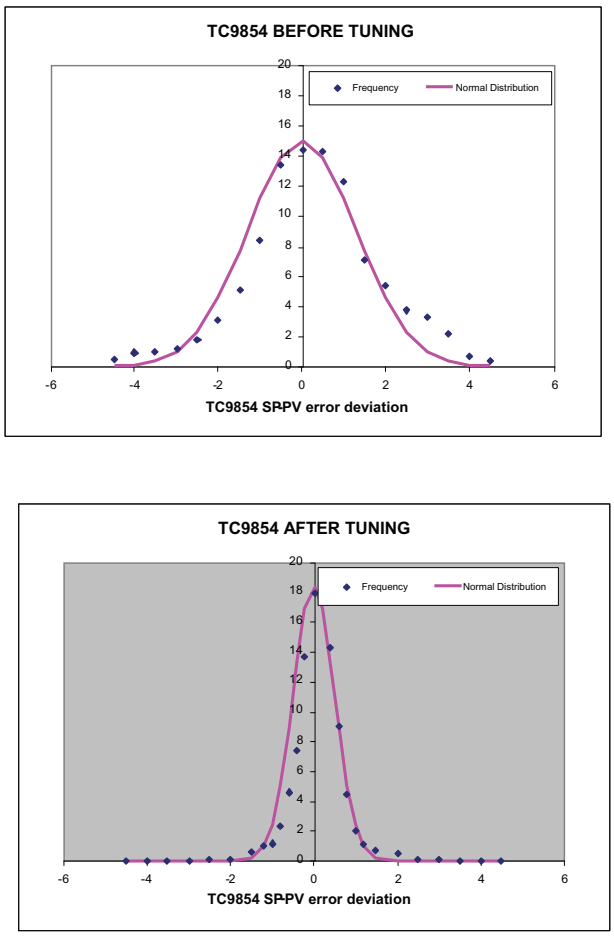

Fig. 9: Control error histograms for TC9854 before and after retuning

The standard deviation reduced from 1.3 down to 0.5, so by a factor of almost 3x. To be honest, these good results are partly due to the very slow initial tuning of some loops we found at the beginning of the project.

4. CONCLUSIONS

The following conclusions can be made. A MIMO model-based approach can be used to successfully tune multiple PID loops that interact strongly. If the open loop model is moderately accurate, then "one-shot" tuning is achievable and the simulated and observed OP and PV responses will be almost identical. The use of sufficiently large gain and dead time robustness margins ensures that the loop will remain stable and well damped even if the process is strongly nonlinear. This also helps to protect us against inaccurate model identification results. The ability to impose hard constraints on damping ratio, maximum PV overshoot, and the maximum OP value means we can ensure that the final design is safe from a process point of view. PID tuning rules cannot achieve this.

Abstract: This paper makes two key contributions. First there is a definition and implementation of a novel auto-tuned predictive controller. The key novelty is that the modelling is based on relatively crude but pragmatic plant information. Secondly, the paper tackles the issue of availability of predictive control for low level control loops. Hence the paper describes how the controller is embedded in an industrial Programmable Logic Controller (PLC) using the IEC 1131.1 programming standard. Laboratory experiment tests were carried out in two bench-scale laboratory systems to prove the effectiveness of the combined algorithm and hardware solution. For completeness, the results are compared with a commercial PID controller (also embedded in the PLC) using the most up to date auto-tuning rules.

Keywords: Predictive control, auto-tuning, programmable logic controller, IEC-1131.1.

1. INTRODUCTION

Control design methods based on the predictive control concept have found wide acceptance in industry and in academia, mainly because of the open formulation that allows the incorporation of different types of models of prediction and the capability of constraint handling in the signals of the system.

Model predictive control (MPC) has had a peculiar evolution. It was initially developed in industry where the need to operate systems at the limit to improve production requires controllers with capabilities beyond PID. Early predictive controllers were based in heuristic algorithms using simple models. Small improvements in performance led to large gains in profit. The research community has striven to give a theoretical support to the practical results achieved and thus the economic argument, predictive control has merited large expenditure on complex algorithms and the associated architecture and set up times. However, with the perhaps notable exception of Predictive Functional Control (PFC) (Richalet, 1993), there has been relatively little penetration into markets where PID strategies dominate, and this despite the fact that predictive control still has a lot to offer in the SISO domain because of its enhanced constraint handling abilities and the controller format being more flexible than PID. The major obstacles cost, complexity and the algorithm not being available in the off the shelf hardware most likely used for local loop control.

Some authors have improved the user-friendliness (complexity) of MPC software packages available for high level control purposes (Froisy, 2006; Zhu *et al.*, 2008). Nevertheless, they have the same implementation drawback in that the development platform is a stand-alone computer running under Windows® OS. Furthermore, these packages involve complex identification procedures which thus requires the control commissioning to be in the hands of a few skilled control engineers; ownership by non control experts is an impediment for more widespread utilization.

Some early industrial work (Richalet, 2007) has demonstrated that with the right promotion and support, technical staff are confident users of PFC where these are an alternative to PID on a standard PLC unit. Technical staff relate easily to the tuning parameters which are primarily the desired time constant and secondly a coincidence point which can be selected by a simple global search over horizons choices. Because PFC is based on a model, the controller structure can take systematic account of dead-times and other characteristics, which are not so straightforward with PID. Also constraint handling can be included to some extent by using predicted violations to trigger a temporary switch to a less aggressive strategy.

The vendors conjecture is that PFC was successfully adopted because of two key factors: first there is effective support in technician training programmes (get it on the syllabus) and second the algorithm is embedded in standard PLC hardware they encounter on the job, thus making it easily accessible (and cheap). However, despite its obvious success academia has shied away from the PFC algorithm because its mathematical foundations are not as systematic or rigorous as other approaches; the performance/stability analysis is primarily an a *posteriori* approach as opposed to the a *priori* one more popular in modern literature. So there is a challenge for the academic community to propose more rigorous but nevertheless intuitive and simple algorithms which could equally be embedded in cheap control units.

On the other hand, in recent specialized conferences authors are often focussing on the level of rigor required in the modelling and tuning procedure for different cases (Morari *et al.*, 2008). However, accessibility and useability

in such a mass market may require different assumptions from those typically adopted in the literature; specifically much less rigor and more automation in the modelling will be essential.

Hence, the first objective of this paper is to develop an auto-tuned MPC controller based on minimal plant information which would be available from staff at technician level only who may be responsible for maintaining and tuning local loops. Secondly, the paper aims to demonstrate how an MPC algorithm, using this model information, can be embedded in a commercial PLC (Valencia-Palomo and Rossiter, 2008); this paper gives some extensions to that developments in (Valencia-Palomo *et al.*, 2008) and of particular interest to readers will be the incorporation of systematic constraint handling within the PLC unit. A final objective is to contrast the auto-tuned MPC with a commercial PID controller in order to show that the MPC is a practical (available and same cost) alternative to PID for local loops.

The paper is organized as follows: Section 2 outlines the controllers and the auto-tuning rules, Section 3 describes the implementation of the controllers in the target hardware, Section 4 presents the simulation results on real hardware and finally in Section 5 are the conclusions and future work.

2. THE CONTROLLERS

This section outlines the auto-tuning rules and modelling assumptions for the MPC and PID strategies adopted. We note that the auto-tuning rules are only applicable to stable systems so discussion of unstable systems is deferred for future work.

2.1 Modelling assumptions

If anything, this paper is more generous with the auto-tuned PID than the MPC because it allows the PID algorithm a large quantity of measurement data and the ability to dither the input substantially during tuning to extract the required information. Moreover, the complexity of this algorithm means that the modelling is done offline. This decision was taken to give a stiff test for the auto-modelled/tuned MPC algorithms.

For MPC we provide crude modelling information only, for instance as could be provided by a technician or plant operator but specifically avoiding the use of a rigorous least squares model estimator which could be expensive if required for large numbers of loops and impractical to put on the PLC unit. The technician should provide estimates of behaviour as compared to standard second order characteristics: rise-time, settling time, overshoot, steady-state gain and dead-time. From this data an approximate second order model with dead-time is determined [1].

2.2 Design point, auto-tuning and constraint handling for PID

A novel auto-tuned PID controller as described in (Clarke, 2006; Gyöngy and Clarke, 2006) is used. A schematic

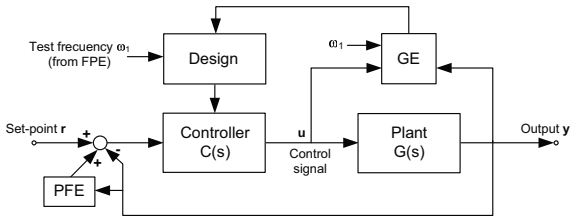

Fig. 1. Schematic diagram of the auto-tuning PID.

diagram of the system is shown in Fig. 1. The objective is to adapt the controller so as to achieve a carefully chosen design point on the Nyquist diagram.

The key components are phase/frequency and plant gain estimators (PFE, GE), described in detail in (Clarke, 2002). In essence a PFE injects a test sinewave into a system and continuously adapts its frequency ω_1 until its phase shift attains a desired value θ_d (in this case the design point). Also forming important part of the tuner, but not shown in Fig. 1, are variable band-pass filters (VBPF) at the inputs of the PFE and GE. These are second-order filters centered on the current value of the test frequency. They are used to isolate the probing signal from the other signals circulating on the loop (such as noise, set-point changes and load disturbances).

The algorithm is initialized using a first-order/dead-time (FODT) approximation $G_a(s)$ for the plant, obtained from a simple step test. The initialization involves the computation of suitable values for the parameters associated with the GE, PFE and the controller.

The controller is based on a design point in the Nyquist diagram. This design point is chosen to obtain the desired closed loop behavior, i.e. rise time, damping value, settling time. In this case, the desired damping value of 0.5 for all the systems is chosen. From this desired damping value, the variables for all the auto-tuning process are obtained as is shown in (Clarke, 2006; Gyöngy and Clarke, 2006).

The PID design does not take explicit account of constraints and thus ad hoc mechanisms are required. Typically input saturation with some form of anti-windup will be used but state constraints are not considered; this is a weakness.

2.3 Basic assumptions for MPC

For the purpose of this paper almost any conventional MPC algorithm can be deployed as the main distinguishing characteristic, **with sensible tuning**, is the model. Hence, assume that the MPC law can be reduced to minimising a GPC [2] cost function of the form:

$$J = \sum_{j=1}^{H_P} \|\hat{\mathbf{y}}(k+j|k) - \mathbf{w}(k+j|k)\|^2 + \sum_{j=1}^{H_C} \|\Delta\mathbf{u}(k+j|k)\|_\lambda^2 \tag{1}$$

where the second term in the eq. (1) is the control effort and λ is the weighting sequence factor. The reference trajectory $\mathbf{w}(k)$, is the desired output in closed loop of the system and is given by:

[1] We accept that for more complex dynamics a slightly more involved procedure may be required.

[2] To simplify some algebra compared to dual-mode approaches, e.g. (Rossiter *et al.*, 1998).

$$\mathbf{w}(k+i|k) = \mathbf{s}(k+i) - \alpha^i [\mathbf{s}(k) - \mathbf{y}(k)]; \ 1 \leq i \leq H_P \quad (2)$$

where $\mathbf{s}(k)$ is the set-point and α determines the smoothness of the approach from the output to $\mathbf{s}(k)$. The objective (1) can be expressed in more compact form in terms of the predicted output:

$$\min_{\Delta \mathbf{u}} \mathbf{J}(\Delta \mathbf{u}) = \frac{1}{2} \Delta \mathbf{u}^T \mathbf{H} \Delta \mathbf{u} + \mathbf{f}^T \Delta \mathbf{u} + \mathbf{b} \quad (3)$$

$$s.t. \qquad \mathbf{R} \Delta \mathbf{u} \leq \mathbf{c} \quad (4)$$

where $\Delta \mathbf{u}$ is the vector of future inputs increments and the other matrix details are omitted for brevity but available in standard references, e.g. (Maciejowski, 2002; Rossiter, 2003; Camacho and Bordons, 2004).

The tuning parameters are usually taken to be the horizons H_P, H_C and weights λ. However, more recent thinking suggests that H_P should be larger than the settling time, H_C is typically 2 or 3 (for practical reasons rather than optimality which requires higher values) and λ becomes the major tuning parameter, albeit some may argue a poor mechanism for tuning. The parameter α will also have a substantial impact but is rarely discussed except in PFC approaches.

2.4 Constraint handling for MPC

The systems considered in this paper are stable, therefore in the absence of output constraints, for a reachable set point the system will only violate the constraints in presence of disturbances or overshoots derived from set point changes. In practice, one may not be able to program a complete QP solver, so a sensible way of handling constraints is to interpolate two control laws (Rossiter and Grieder, 2005), one with good performance (e.g. $\Delta \mathbf{u}_{fast}$) and one with good feasibility (e.g. $\Delta \mathbf{u}_{slow}$) , using:

$$\Delta \mathbf{u} = (1-\beta) \Delta \mathbf{u}_{fast} + \beta \Delta \mathbf{u}_{slow}; \quad 0 \leq \beta \leq 1 \quad (5)$$

The variable β is used to form the mix of fast and slow according to the predicted situation (if feasible $\beta = 0$). Hence, the optimization procedure reduces to simple linear program in one variable that is a set of inequality checks of the form:

$$\min \beta \ \ s.t. \ \ R_i \beta - c_i \leq 0, \quad i = 1, ..., H_C \quad (6)$$

Remark 1. If $\beta = 1$ and the constraints are still being violated, the inputs are saturated. Essentially this means the state is outside the maximal admissible set for the unconstrained control law designed for good feasibility. Such scenarios need more complex strategies not covered in this paper.

2.5 Simple auto-tuning rules for MPC

There are many alternatives for auto-tuning, some with better properties then used here are possible, but the authors felt this paper should initiate discussion with an industrial standard. Thus, the predictive control design and tuning procedure is described next.

For the MPC the prediction horizon H_P is chosen equal to the settling time plus H_C, with $H_C \ll H_P$. Assuming normalisation of input/output signals, $0.1 \leq \lambda \leq 10$, a form of global search can be used to settle on the 'best' parameters against some criteria, however, if we take the criteria to be the cost J of eq. (1) with $\lambda = 1$, then this fixes λ and H_C is chosen to be as large as possible [3] . The design response speed α_{fast} (for $\Delta \mathbf{u}_{fast}$) will be taken as half the open-loop time constant α_0 so that the controller has to deliver some extra speed of response as well as stability and offset free tracking; and α_{slow} (for $\Delta \mathbf{u}_{slow}$) will be taken as 0.95 to have a smooth close loop response and avoid overshooting in set point changes. Thus, the auto-tuning is fixed precisely by the model parameters and the technician role is only to provide best estimates of these parameters (in practice some iteration should take place).

Fig. 2. Allen Bradley PLC – SCL500 processor family.

3. IMPLEMENTATION OF THE ALGORITHMS ON A PROGRAMABLE LOGIC CONTROLLER

This section briefly introduces the PLC and the corresponding implementation of the controllers described in the previous section.

3.1 Allen Bradley — Rockwell Automation Inc. PLC

PLCs are by far the most accepted computers in industry which offer a reliable, safe and robust system; we will not revisit the reasons here. Nevertheless, normally their use is only to implement control sequences in open loop and/or different structures of PID controllers. For the purposes of this paper, the implementation is based on the family of SLC500 processors belonging to the Allen Bradley PLC systems, e.g. see Fig. 2.

The Allen Bradley set of PLC includes the facilities to be programmed in 3 of 5 languages in agreement with the IEC 1131.3 standard using Control Logix 5000^{TM} software programming package. Each of these allows for any combination of programming languages to be used for a single project. These three languages are: (i) *Ladder Diagram*, (ii) *Function Block Diagram* and (iii) *Structured Text*.

3.2 PID

The Control Logix 5000^{TM} software programming package also includes a function block to implement a PID controller. The PID function block is a professional development from Rockwell Inc. used in industry (with a PLC) to control a variety range of processes.

[3] For sensible sample times, a choice of $H_C \geq 5$ implies that this is approximately equivalent in behaviour to a dual-mode approach.

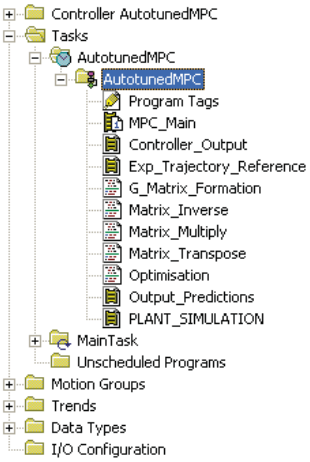

Fig. 3. Structure of the MPC algorithm in the target PLC.

The tuning of the PID is done off-line by the algorithm described in subsection 2.2. The obtained parameters are passed to the PID block before downloading the program to the PLC. As noted earlier, the PID has been unfairly favoured here in that this off-line procedure requires a certain amount and type of experimental data for the model identification of the process.

This controller is going to be used to compare the results obtained with the auto-tuned MPC.

3.3 MPC

For the implementation, is worth mentioning that it is advisable to use a a graphical language such as *ladder logic* or *function block* because technical staff are much more familiar with this than structured text; also it is easier to maintain and debug for the changing nature of bits, timers, counters etc. while being monitored. However, a significant barrier for MPC implementation is that operations between vectors and matrices are not defined in any of the supported IEC 1131.1 languages, thus, all of these operations have to be programmed from scratch.

The complete structure of the proposed MPC program (based on subsections 2.3–2.5) is shown in Fig. 3. The algorithm has been programmed in the High Priority Periodic Execution Group [4] called `AutotunedMPC` which contains the routines summarised in Table 1. The software design, matrix formations, sequence of execution and the computation of the calculated output is described in detail in (Valencia-Palomo and Rossiter, 2008); with the exception of the routine `Optimisation` which is new to this paper and developed to include constraint handling, as described in subsection 2.4.

It can be seen from the properties of the controller with the RSLogix programming tool (Fig. 4) that the programm uses 17% of the available storage of the PLC including memory requirements for I/O, running cache and other necessary subroutines.

Finally, the input parameters for the program are only those who are related with de model, i.e. dead time t_d,

[4] This periodicity is set up with the chosen sample time.

Table 1. Routines and programming languages.

	Routine name	Programming language

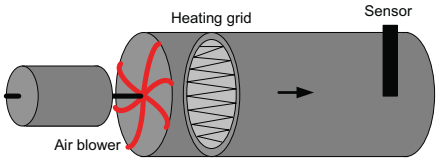

Fig. 5. Heating process.

rise time t_r, settling time t_s, overshoot M_P, gain K and sampling time Ts. The tuning is done online in the first scan of the program and is not repeated after, however, some mechanisms to update the model of the plant and tuning parameters can be embedded.

4. EXPERIMENTAL LABORATORY TESTS

This section shows the experimental results from applying the MPC law via a PLC on a first and a second order plant. For both processes the interest is tracking of step references, which is the most common situation in industry. The PID/MPC experiments ran under the same conditions, in so far as this can be guaranteed.

4.1 First order plant – Temperature control

The first experiment is a heating process consisting of a centrifugal blower, a heating grid, a tube and a temperature sensor, see Fig. 5. The objective is to control the temperature at the end of the tube by manipulating speed of the blower (the input voltage of the D.C. motor).

The model of the plant for the PID off-line tuning is done by a least square estimator assuming a first order plant.

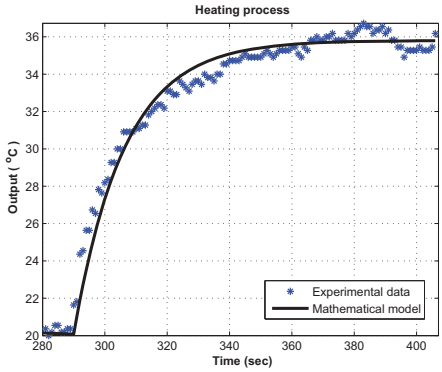

Fig. 6. Model validation of the heating process.

Table 2. Tuning parameters for the PID controller and input parameters for the auto-tuned MPC.

		Heating Proc.	**Speed Proc.**	
Cont.	Par.	Value	Value	Units
PID	P	1.590	0.325	–
	I	0.486	0.799	–
	D	0.0	0.0	–
MPC	Ts	10.0	0.50	Sec
	t_d	2.0	1.00	Samples
	t_r	38.0	4.90	Sec
	t_s	64.0	2.71	Sec
	K	16.0	190.0	–
	M_p	–	–	%

The resulting discrete model, with a sampling time of 10 sec. (which is also roughly the dead-time), is:

$$x(k+1) = 0.94x(k) + u(k)$$
$$y(k) = 0.94x(k)$$

The experimental validation of the mathematical model is shown in Fig. 6.

The tuning parameters for the PID controller and the input parameters for the Auto-tuned MPC are shown in Table 2. The second order approximate model for the predictions is built using standard analysis of the transient response of the plant i.e. nonparametric identification.

The simulation comparisons deploy a step change at $t = 50\,secs$ of the set point from 20 $°C$ to 30 $°C$; after the output reaches a new steady state, the process is disturbed at $t \approx 120\,secs$ by partially blocking the end of the tube. A new change in the set point to 20 $°C$ is required at $t = 180\,secs$ without taking out the disturbance.

It can be seen in Fig. 7 that the plant output is successfully tracking the reference signal for both controllers. Of course this is a simple first order model and thus good control is to be expected. MPC has clearly given better control of overshoot and settling.

4.2 A second order plant – Speed control

This process consists of a motor fitted with a speed sensor, the control objective is to regulate the speed of the motor by manipulation of the input voltage. The same procedure as in the first experiment is applied. The mathematical model of the system with a sampling time of 0.5 sec is:

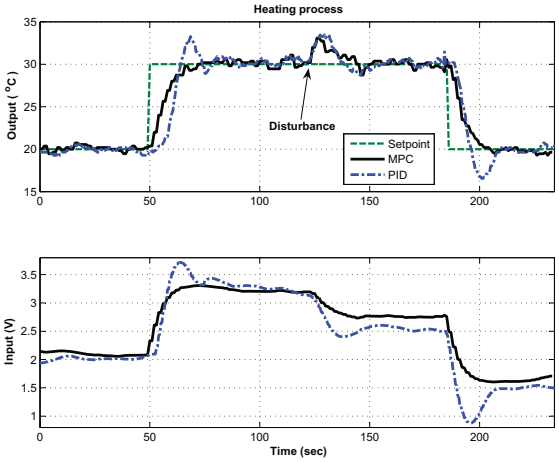

Fig. 7. Experimental test for the heating process.

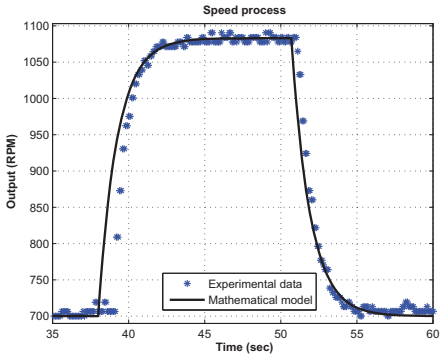

Fig. 8. Model validation of the speed process.

$$x(k+1) = \begin{bmatrix} 0.93 & -0.01 \\ 0.04752 & 0.9964 \end{bmatrix} x(k) + \begin{bmatrix} 1 \\ 0 \end{bmatrix} u(k)$$
$$y(k) = \begin{bmatrix} -0.01 & 3.71 \end{bmatrix} x(k)$$

The experimental validation is shown in Fig. 8 and the tuning parameters are in Table 2. Two set point step changes are demanded; once again, the results in Fig. 9 show that MPC and PID are tracking the set point accurately.

4.3 Performance indexes of the algorithms

The numerical performance indexes of the systems with the two different controller strategies are summarised in Table 3. Specifically the table shows the measures of performance are given by the cost function (J), the settling time (τ_s) and the overshoot (M_p). These numbers show that MPC performs similar to the standard PID controller but,in this case, with a much simpler auto-tuning procedure.

The constraint handling was not tested in a rigorous manner to let the PID controller act in the best possible scenario. Despite that, this simple control task finds its optimal value in saturation (Rojas and Goodwin, 2002).

To complete the analysis of the implemented program, the diagnostics tool from the hardware (shown in Fig. 10)

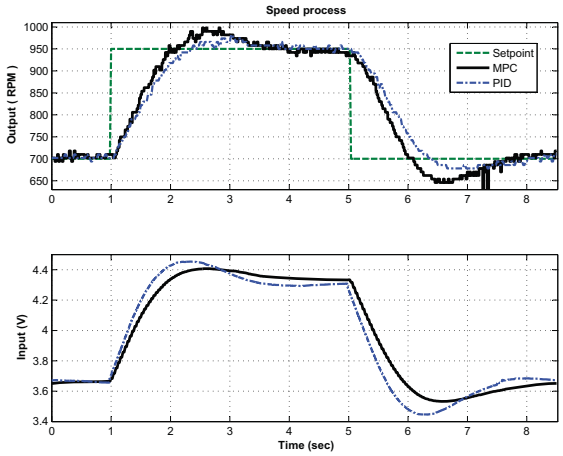

Fig. 9. Experimental test for the speed process.

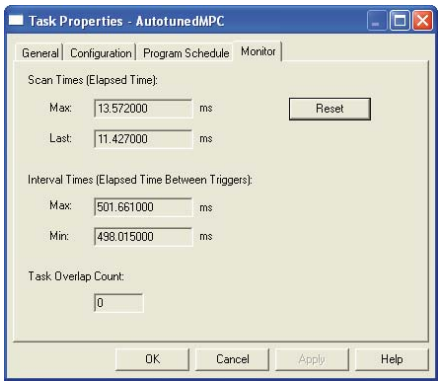

Fig. 10. Execution time and sampling jittering for the speed process.

Table 3. Performance indices for the systems.

	Heating process			Speed process		
	τ_s	M_p	J	τ_s	M_p	J
PI	31 sec	33.45 %	1645	3.3 s	16%	2,615
MPC	20 sec	0.0 %	1629	3.3 s	8%	2,816

displays that the time for scanning the program each sample time oscillates between 11.42 ms and 13.57 ms while the elapsed time between triggers (sampling instants) for the speed process oscillates between 498.01 ms and 501.66 ms. The significance of this is the potential to apply the algorithm on much faster processes.

5. CONCLUSIONS

This paper has made three contributions. First it has demonstrated that an MPC algorithm with systematic, albeit simplistic, constraint handling can be coded in an industrial standard PLC unit and with sample times of milliseconds. Secondly it has demonstrated that such an algorithm can make use of simplistic modelling information in conjunction with basic auto-tuning rules and still outperform an advanced auto-tuned PID whose design relied on far more information. Moreover the MPC includes constraint handling. Thus, thirdly the paper has demonstrated that MPC is a realistic industrial alternative to PID in loops primarily controlled with PLC units. This final contribution opens up the potential for much improved control of loops where PID may be a poor choice.

These results demonstrate the potential for implementing auto-tuned MPC within a PLC. Some issues the authors intend to pursue are: (i) demonstrate the algorithm in more challenging test rigs such as those with non-minimum phase behaviour and/or significant dead-times; (ii) consider extensions for unstable systems; and (iii) implement more advanced dual-mode type MPC algorithms and more advanced constraint handling facilities into the PLC.

Abstract: In this paper, two types of multiple-model adaptive controllers are practically evaluated on a laboratory-scale pH neutralization process. The first one is supervisory switching multiple-model adaptive controller (SMMAC) whose model bank is fixed and selected a priori, and another one is a controller based on multiple models, switching, and tuning strategy (MMST) which uses the possibility of model bank tuning. In addition to investigation of the effect of tuning, the advantage of a disturbance rejection supervisor is studied. Various experiments and exhaustive numerical analyses are provided to assess the abilities of the proposed algorithms.

Key Words: multiple models, adaptive control, pH control, switching control, pole-placement control

1. INTRODUCTION

Multiple-model adaptive control is a promising approach to control complex, nonlinear, and time-variant systems. On the grounds that a very complicated system is decomposed to simpler and smaller ones in this approach, and therefore, a large set of model uncertainty is converted to smaller sets, this approach results in a robust controller. It is, also, called an intelligent approach if intelligence is defined as rapid and appropriate response to large and sudden variations in a system (Narendra and Balakrishnan, 1997).

Multiple-model approaches are well-known not only in control but also in identification and estimation (Johansen and Murray-Smith, 1997). Multiple-modeling means that a set of models describes a dynamical system instead of one lone model. According to the type of contribution of members of this set to construct the global model of the process, switching or interacting multiple-model approaches are obtained. In switching multiple-model control strategies, at each instant, one model of the bank is selected as the global model, and the controller is designed according to the parameters of the model. This kind of control strategy has been evaluated in many subject areas such as robotics (Czlzz and Narendra, 1996), flight control (Boskovic and Mehra, 1999), aerospace applications (Karimi and Landau, 2000), and process control (Pishvaie and Shahrokhi, 2000; Gundala, Hoo, and Piovoso, 2000).

It is obvious that model bank significantly affects control performance. Thus, it is critical to have a model bank that considers all possible operating points. Since all possible operating points are not known a priori, increasing the number of model bank members may be a solution. However, in addition to intensifying computational burden, there is a chance of deteriorating performance owning to excessive competition of unnecessary members (Li and Bar-Shalom, 1996). Another solution is model bank tuning.

Model bank tuning means that beside each fixed models there is an adaptive model which starts to adjust itself from the location of the fixed model after the fixed model was chosen by the supervisor of the control system. Consequently, a quite new control strategy is introduced and called *multiple models, switching, and tuning* (MMST) (Narendra and Balakrishnan, 1997; Narendra and Xiang, 2000).

The main objective of this paper is to study how the possibility of tuning affects the effectiveness of a multiple-model adaptive controller. To accomplish the objective, we experiment two multiple-model controllers on a pH pilot-plant. The pilot-plant was designed and constructed by members of the research group at KNTU. Figure 1 shows this plant. The secondary objective is to investigate practically a disturbance rejection supervisor, introduced firstly in (Peymani et al, 2008). Since there is no buffer stream in the pilot-plant, the process keeps its high nonlinearity such that the static gain of the process can vary more than 70 times for the entire operating range.

The paper is organized as follows. After introduction, the principles of multiple-model adaptive controllers are reviewed. Two control strategies are presented: one has tuning possibility and the other does not. In the next section, section 3, a disturbance rejection supervisor is designed and its specifications are stated. Then, section 4 is allocated for the pH pilot plant description. Application results are, also, provided in this section. Finally, conclusions end the paper.

2. THE BASIS OF MULTIPLE MODELS ADAPTIVE CONTROLLERS

The control strategies utilized in this paper are based on supervisory switching multiple-model adaptive controllers. In these controllers, the whole nonlinear system is divided into several linear systems which can be represented more exactly by a set of simple linear models, called *model bank*.

Fig 1. pH pilot-plant at ACSL, K. N. Toosi University of Technology

That which model and when must be selected is the duty of the *supervisor*. The supervisor determines the appropriate model according to a *switching scheme*.

Let us presume that we have the simplest form of model bank which contains N fixed-parameter models. In fact, each model is a predictor anticipating the future output of the process in accordance with the last measured input and output. The difference between the output of the real plant and of each model is sent to the supervisor to calculate the identification performance index according to eq. (1):

$$J_s(t) = \alpha e_s^2(t) + \beta \sum_{k=1}^{M} \lambda^k e_s^2(t-k), \quad 0 < \lambda \le 1, \alpha, \beta, M > 0 \tag{1}$$

in which $e_s = y - \hat{y}_s$, and α, β, λ and M are the free-design parameters. Pole-placement control design method is utilized in this paper. It is a two-degree of freedom dynamical output feedback controller having the form of:

$$R(q)u(t) = T(q)u_r(t) - S(q)y(t) \tag{2}$$

where R, S, and T are calculated after the process model was selected. The process is viewed as a first order plus time delay model (FOPDT). To find the appropriate values for the controller parameters, it is necessary to define a model reference, a priori, regarding the control objective, and solve a polynomial Diophantine equation on-line. For more details about the controller design method see (Astrom and Wittenmark, 1995; Peymani et al, 2008).

The significance of model bank on the performance of the control system is beyond dispute. The more precise a model bank represents the plant, the better the control system performs. Difficulties arise from the problem of decomposing a plant into efficient smaller linear subsystems. Moreover, a real-world plant inevitably encounters variations which are able to make new operating conditions.

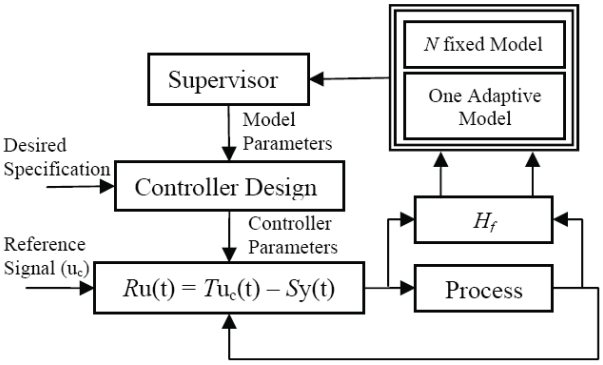

Fig 2. The block diagram of the multiple models, switching, and tuning adaptive controller

If an unpredicted one comes about, the control performance may become weak. To cover more states of the process, the number of members of the model bank should be increased. This solution is not suitable because a bank with too many members may deteriorate the performance in addition to excessive complexity burden (Li and Bar-Shalom, 1996).

Tuning of the current model is another solution to solve this problem. In this idea, after a fixed model is selected, an adaptive model starts to adjust itself to the process condition from the location of the fixed model. Thus, convergence of the adaptation algorithm may be reached soon, and the adaptive model may describe the process more precisely than the selected fixed model does. This model is called *re-initialized adaptive model*, and can be built by a recursive least-squares (RLS) identification method with exponentially forgetting factor (Astrom and Wittenmark, 1995). This control structure containing both fixed and adaptive models in the bank is also called *Multiple Models, Switching, and Tuning* (MMST) control strategy and firstly is introduced by Narendra et al. Thus, this adaptive control strategy possesses a two-stage identification unit: the switching stage to overcome sudden and large changes of the process and the tuning stage to track slow and gradual process variations. Figure 2 shows this control strategy.

Switching Scheme: Decision-making part in MMST is done by supervisor as follows. At each sampling time, performance indexes of N fixed models and one re-initialized adaptive model are updated. Then, in the switching stage, the best fixed model whose index is smaller than the product of other indexes by h_S is selected. The factor h_S is the hysteresis constant for the switching stage. After each change of the best fixed model, the adaptive model is reinitialized by the parameters of the fixed model unless the identification performance of the adaptive model is better than the best fixed model. The decision can be made by comparing their performance indexes.

After the switching stage, the tuning stage triggers. In this stage, the supervisor orchestrates which of the adaptive or the best fixed model is appropriate for control. This stage owns another hysteresis constant, represented by h_T. If the index of

the adaptive model is smaller than the multiplication of the index of the best fixed model by h_T, the adaptive model is used to design the controller. At this time, the process is controlled by an *adaptive pole-placement controller* (APPC). With the same logic, the supervisor determines whether it is appropriate to use the fixed model for control. As mentioned, SMMC is simpler than MMST control strategy and dose not have tuning stage and adaptive model, so switching stage is simpler.

3. DISTURBANCE REJECTION SUPERVISOR

All adaptive controllers need the process information to adapt itself to the current condition. The process has to be excited very well in order to collect appropriate information. In process control, the set-point rarely changes. Nonetheless, disturbances occur occasionally. Hence, disturbances can be considered as the staple source of excitation.

When a disturbance happens, at first the process output deviates from the reference input. Then, the controller reacts against this action. Consequently, it is possible to divide the process output into two parts. The first part is the duration which the disturbance, as an unmeasured input, affects the process output, and the second is the one that the control signal derives the system in spite of disturbance. Excitation resulted from the first part is adverse for identification, but excitation caused by the second part which the control signal dominantly affects the system is proper for process identification.

Then, discarding irrelevant data is vital to enhance on-line system identification. This aim is achieved if the time when a disturbance occurs is detected; that is, the identification stage is interrupted in the first part of excitation caused by a disturbance. An idea to discover disturbance occurrence is proposed in (Hagglund and Astrom, 2000) and is shown in Fig. 3, in which y_f and u_f are high-pass filtered process output and input, respectively. According to this idea which is proposed for positive-gain systems, when filtered process input and output are larger than predefined thresholds and have opposite signs, a disturbance has occurred. The time when the control action is appropriate for identification can be estimated based on the maximum value of the filtered process output.

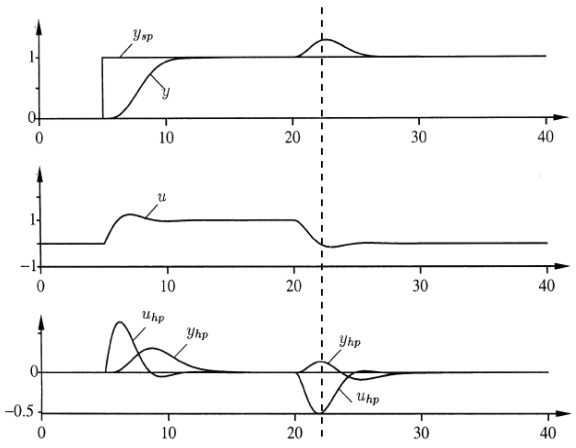

Fig 3. Response of a linear system in close-loop feedback on condition that a disturbance occurs (Hägglund and Astrom, 2000).

According to the extension of this supervisory function for multiple-model controllers, which is proposed by the authors in (Peymani et al, 2008), when a disturbance discovered, both switching and tuning stages are not allowed to work, and the controller is designed based on the best fixed model. After the first part of excitation, the tuning and switching parts are permitted again. In MMST strategy, it is possible to re-initialize the adaptive model to converge rapidly after negative excitation of disturbance.

4. APPLICATION RESULTS

The aim of this paper is to study the effect of tuning in the model bank of multiple-model adaptive control strategies by evaluating two multiple-model based controllers on a pH pilot-plant. After pH pilot plant description, application results are provided.

4.1 pH pilot-plant Description

This plant was designed and constructed in K. N. Toosi University of Technology (Fig. 1). In this process, as shown in Fig. 4, there are four streams: acid, base, water, and effluent. The acid stream is the process stream; its concentration and flow rate are presumably constant. The base stream is the titrating stream whose concentration is constant but flow rate is calculated by the controller to regulate pH of the effluent stream. The effluent stream has a constant flow rate. Moreover, this plant is composed of a continuous stirred tank reactor (CSTR) where chemical components are mixed, a pH sensor, a level sensor, and three dosing pumps which inject water, base, and acid with precise flow rate. To keep the level of the tank constant, a classical PI controller is designed which uses water stream flow rate as the control signal. Figure 5 displays the block diagram of this control system.

It is valuable to mention that aquatic solution of acid acetic (a weak acid) and sodium hydroxide (a strong base) are used as process stream and titrating reagent, respectively. However, there is no buffer stream in this pilot-plant. This feature makes this process highly nonlinear. Figure 6 depicts the titration curve of the process with typical concentrations. As it can be seen, it has a steep and large increase in its derivative. This curve is calculated for a batch process because calculating the titration curve of a continuous process is very difficult owning to inherent nonlinearity and various external disturbances. Figure 7 reveals that the static gain can vary more than 70 times for pH in the range of 5 to 10. It is worth mentioning that the measurement noise of the process varies with pH. It is about 5e-5 outside the range of [7, 8.2], whereas it is about 1e-3 inside the range.

4.2 Experimental Evaluation

In this section, two multiple models adaptive controllers, proposed earlier, are considered and their parameters are presented specifically. To have comparable situations, the parameters of both controllers are chosen the same. Indeed, the only difference between them is that MMST based controller has the possibility of model bank tuning, while supervisory switching multiple models adaptive controllers (SMMC) has a fixed-parameter model bank. Anyway, to construct a fixed model bank, the process is controlled by a classical adaptive pole-placement controller in varying pH values.

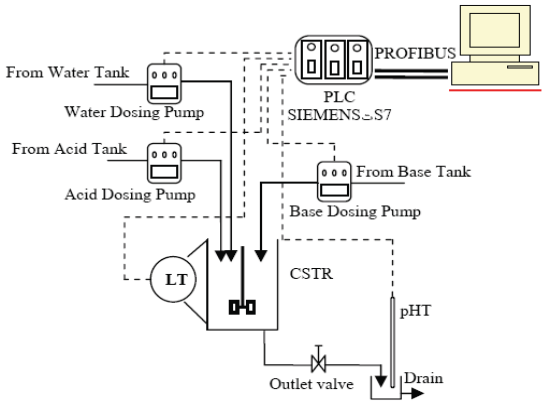

Fig 4. Schematic diagram of pH pilot-plant

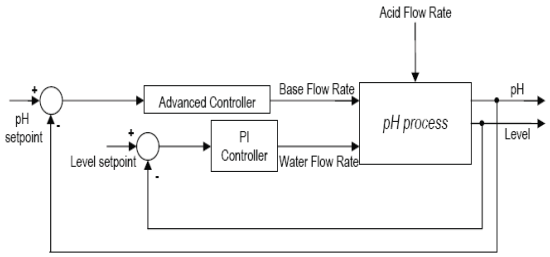

Fig 5. Block diagram of the control system

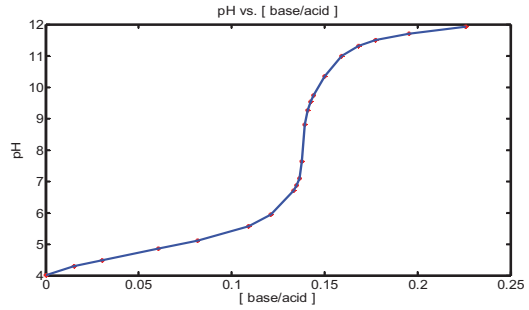

Fig 6. Titration curve of the process stream in the batch form.

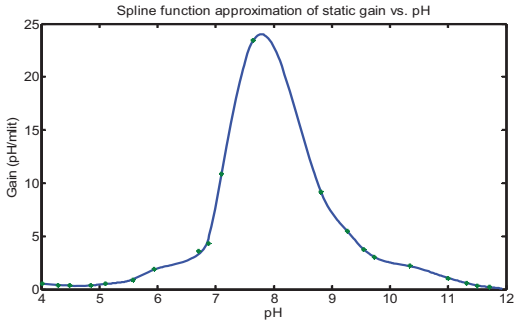

Fig 7. Variations of static gain of pH pilot-plant versus pH

After convergence of the adaptive model, the model is saved as the model of current operating condition. Table I collects models of various operating points. Before identifying, data are passed through a band-pass filter to discard bias and attenuate the adverse effect of noise. Hence, as shown in Fig. 2, filter H_f is located at the beginning of the identification loop, which is:

$$H_f(q) = \frac{(q-1)}{(q-\alpha)^2}(1-\alpha)^2 \tag{3}$$

The parameter α is 0.9652. Then, the model reference for pole-placement control design method is:

$$G_m(q) = \frac{0.0012}{(q-0.9652)^2} q^{-8} \tag{4}$$

The parameters of performance index are selected as $M = 50$, $a = 320$, $b = 100$, $\lambda = 0.985$. Hysteresis factor for SMMAC equals to 0.80, and switching and tuning hysteresis factors in MMST are chosen 0.85 and 0.75, respectively.

We consider a sequence for step-like set-point changes containing three kinds of variations: 1) small changes which means set-point varies from 5 to 10 one by one (Fig. 8.a); 2) medium changes which means set-pint changes from 6 to 8 and to 10, and then returns to 6 in the same manner (Fig. 8.b). These variations are known as the most difficult ones in this process; 3) large changes that contain some variations larger than two units in pH (Fig 8.c). Moreover, the acid feed rate is considered as a measured disturbance. Its nominal value is 30% of maximum power of the corresponding pump. The sequence of 30% → 18% → 42% → 30% is considered as disturbance sequence.

A criterion is defined in order to compare the results numerically, so we choose a two-part measure. Each part is calculated individually for each change in set-point or each disturbance. It is:

$$\begin{aligned} C &= \sum MSWE + 10 \sum O.C. \\ MSWE &= \frac{100}{n-1} \sum \left((y(t) - y_r(t))^2 e^{0.005\,t} \right) \\ O.C. &= 1 - \left| \frac{\sum (y_f)}{\sum |y_f|} \right| \end{aligned} \tag{5}$$

in which *O.C.* is a measure of oscillation. Mean square weighted error (*MSWE*) shows how much the process output is similar to y_r, the model reference output or desired output. It weights the errors exponentially in time.

At first, our aim is to regulate pH of effluent process at different values. Thus, we use the same set-point sequence with various changes to assess how much each controller is able to drive the process similar to the desired output. Fig. 8 shows the results, and table II gathers numerical analysis.

The second test is to evaluate the ability of the controllers to reject external disturbances. Figures 9 to 11 show the results of this test. The effect of disturbance rejection supervisor is demonstrated in Fig. 10 and Fig. 11. Table III compares the disturbance rejection abilities numerically.

4.3 Discussion

This section is allocated for application results. According to Fig. 8, the presence of tuning in the model bank of a multiple-model adaptive control can improve transient response. In this figure, MMST control algorithm has a smoother response, especially for pH around 7.5. Changing from 6 to 8 (and vice versa) is the most difficult change in this plant because the control system has to drive the process from a low-gain operating point to the highest one. The same result can be derived from disturbance rejection part. Hence, it is evident that MMST strategy has a better performance than the other strategy without tuning possibility does.

Figures 9, 10, and 11, and table III demonstrate that the disturbance rejection supervisor can help the supervisor to make a better decision, so this additional supervisory function is satisfactory. Generally, according to Fig. 11, the disturbance rejection supervisor is the reason to a faster rejection.

Table 1 Local models of the process, time delay neglected to be shown equals to 9 sampling times (45 seconds).

Model no.	1	2	3	4
Local Model	$\frac{0.0070}{z-0.985}$	$\frac{0.0166}{z-0.990}$	$\frac{0.0044}{z-0.970}$	$\frac{0.001}{z-0.970}$

5. CONCLUSION

The proposed MMST control strategy is modified slightly from the original version and the switching stage is transparently separated from the tuning phase. Moreover, to constrain the speed of switching, hysteresis constants are used. The presence of tuning in multiple-model adaptive controllers has positive effect in performance. The application results, which are provided for both tracking and disturbance rejection problems by implementation two multiple-model controllers on a pH pilot-plant, prove that the response of MMST is smoother and more similar to desired output. Also, they uncover that the possibility of tuning in identification loop prevents the model bank to be specified to a certain process. In fact, tuning tries to generalize the model bank. Furthermore, the application results reveal that the presence of the disturbance rejection supervisor can augment the effectiveness of multiple-model adaptive controllers to face load disturbances without imposing significant computational burden. The disturbance rejection supervisor is designed for positive-gain systems.

It can be claimed on condition that the model bank has a severe deficiency to describe the process, SMMC may result in instability, while MMST can stabilize the process because of the presence of tuning.

Table 2 Comparison between SMMC and MMST in tracking

	Small	Medium	Large	Overall

Abstract: In this paper we propose different Sliding Mode Control (SMC) strategies to control slug-flow oscillations in submarine oil-risers. The main idea is to design a switching control law that induces a sliding bifurcation on the system, changing its dynamics and, in this way, controlling the amplitude of a limit cycle. Simulation results were obtained using OLGA Scandpower software in order to compare the different SMC strategies.*Copyright©2009 IFAC*

1. INTRODUCTION

Transportation of multiphase fluid (oil, gas and water) is an important task in the oil industry. Nowadays, there is a trend to increase the number of satellite wells and the length of risers between clusters of wells and off-shore production systems. Besides, the increasing depths of oil wells produces several new multiphase transport problems, see Storkaas and Skogestad (2004), Storkaas (2005). In this scenario a common problem is the phenomena so called slug-flow characterized by the intermittent axial distribution of gas and liquid. The pressure and flow rate oscillations induced by the slug-flow can provoke several undesired effects on the surface equipments. These types of disturbances can cause serious problems in the input of the multiphase flow separator, deteriorating the separation quality and causing level overflow (Godhavn et al. (2005)). In short, the slug-flow phenomena in submarine risers cause several problems to the oil off-shore industry. The suppression of this type of oscillations by means of feedback automatic control methods can be applied to stabilize the flow in risers and, consequently, minimize the problems on the separator. At the same time, two other benefits can be obtained: (i) in cases where the oil is pumped from sea bottom, energy consumption is minimized; (ii) in cases of risers connected to wells with natural or artificial lift flows, higher production is obtained by minimizing the pressure in front of the well perforated zones.

A schematic diagram of a riser used in an oil production off-shore system is shown in Fig. 1 with parameters shown in Table 1. This system was simulated in OLGA [1] .

In Fig. 1, bottom and top riser pressures P_1 and P_2, respectively, are measured in [Pa] units and the control action is applied on the production choke. Modelling this system is quit complex since it involves partial differential equations. A simplified third order dynamical model developed in ordinary differential equations can be found in Storkaas and Skogestad (2004), Storkaas (2005). The bifurcation diagram considering the

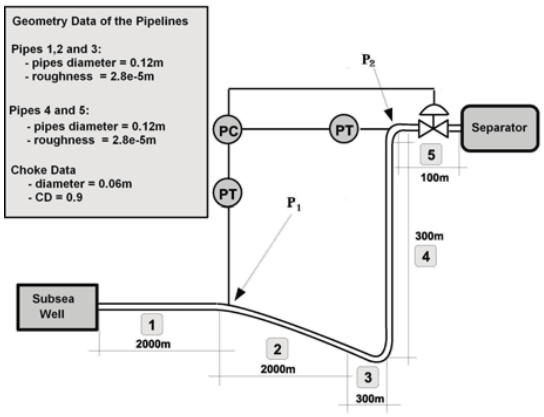

Fig. 1. Oil-riser system set-up simulated in OLGA.

Table 1. Parameter values of the riser setup.

Parameter	value	unit
Mass flow rate entering the riser	5	$Kg.s^{-1}$
Separator pressure	5.10^6	Pa
Gas void fraction	5	%
Temperature in the riser output	22	^oC
Temperatura in the well	62	^oC

choke opening as a bifurcation parameter (see Fig. 2), was obtained based on OLGA data simulations for a mass flow rate entering the riser equal to $5Kg.s^{-1}$ and a pressure separator of $5.10^6 Pa$. The bifurcation diagram of Fig. 2 is qualitatively similar to the diagram shown in Storkaas and Skogestad (2004). The stable and unstable equilibria manifold are depicted in Fig. 3. In this figure we show also the curves corresponding to maximal and minimum values of the limit cycle. A projection

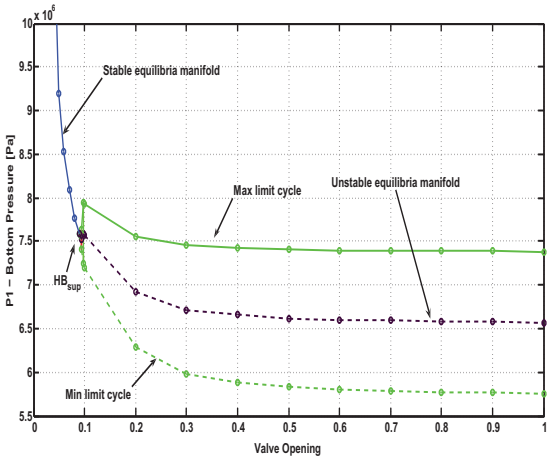

Fig. 3. Bifurcation diagram in $(u(t), P_1)$ plane.

of the limit cycles for different choke openings in the (P_1, P_2)-plane is shown in Fig. 4. As we can observe in this picture, the relation between P_1 and P_2 pressures on the stable (unstable) equilibria manifold can be approximated by a straight line. As can be seen in Figs. 2-4, a supercritical Hopf Bifurcation takes place, at the point HB_{sup} in the diagram, giving rise to a stable limit cycle. Thus, without active feedback control it is necessary to operate the system with choke opening below 10% in order to avoid output system oscillations. The pressure drop around the choke rises for low choke opening and this pressure drop is added to riser's bottom. High pressure for the same mass flow rate means higher energy consumption for sea floor pump applications. On the other hand, risers connected to natural or artificial lift wells may affect the pressure in front of the perforated zones leading to less oil production flow rate. Whatever the case it is desirable to have a steady flow with minimum pressure drop in the surface choke.

Several linear control laws to prevent slug-flow oscillations in submarine oil-risers have been proposed in different works, see

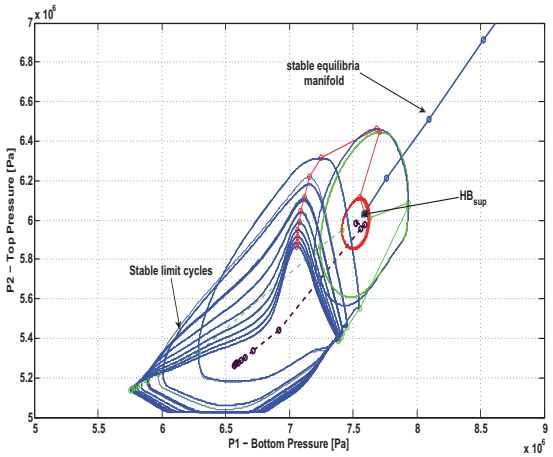

Fig. 4. Bifurcation diagram in (P_1, P_2) plane.

for instance Storkaas (2005), Godhavn et al. (2005). Linear controllers are only local solutions for this complex non-linear control problem. In this paper, as an alternative solution, we propose different non-linear control systems based on the Sliding Mode Control (SMC) theory.

The paper is organized as follows. In Section 2, the Proportional-Integral (PI) control law is revisited showing that it is not robust under disturbances in the input riser flow rate. In Sections 3 and 4, we propose different SMC strategies to control slug-flow oscillations. Our slug SMC washout strategy is presented in Section 5. Finally we discuss some of the limitations of these switching strategies and propose future improvements.

2. REVISITING THE PI CONTROL STRATEGY TO SUPPRESS SLUG-FLOW

In this Section we show by means of simulation results that the PI control law is not robust to disturbances in the input riser flow rate. A simulation test was made to evaluate the efficiency of the PI control. The PI control law is given by

$$u(t) = k_c[e(t) + \frac{1}{T_i}\int_0^t e(\tau)d\tau],$$

where $k_c = -7.92 \cdot 10^{-6} Pa^{-1}$, $T_i = 49.5s$, $e(t)$ is the error and the process variable is the pressure P_1. The PI discrete form implemented is given by

$$u(k) = u(k-1) + s_0 e(k) + s_1 e(k-1)$$

where $s_0 = k_c(1 + \frac{T_s}{T_i})$, $s_1 = -k_c$, $T_s = 1s$ is the sampling time and T_i is the integral time. PI control tuning was made using simple rules of adjusting since no mathematical model of reduced order for control design was available. The simulation setup was defined as:

(1) the choke opening is fixed at 20% and the corresponding operating point calculated from the equilibria manifold curve is $(P_1^*, P_2^*) = (6.93 \cdot 10^6[Pa], 5.56 \cdot 10^6[Pa])$;
(2) at $5000s$ the control is switched ON;
(3) a disturbance in the input riser flow rate is applied at $15000s$;
(4) the control is switched OFF at $25000s$.

Two flow rate disturbances were defined (i) from $5Kg.s^{-1}$ to $3.5Kg.s^{-1}$ and (ii) from $5Kg.s^{-1}$ to $3Kg.s^{-1}$. We use the

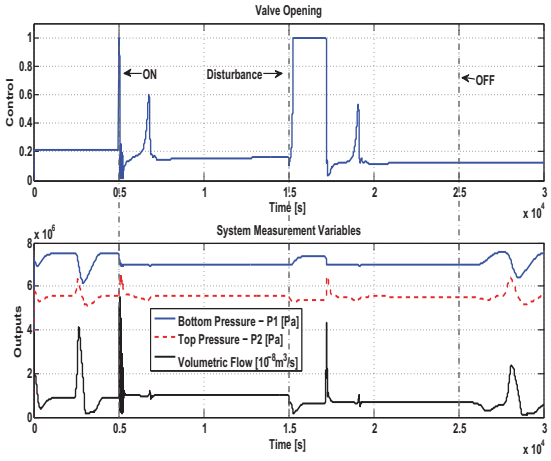

Fig. 5. System time response under *PI* control for a flow rate disturbance from $5Kg.s^{-1}$ to $3.5Kg.s^{-1}$.

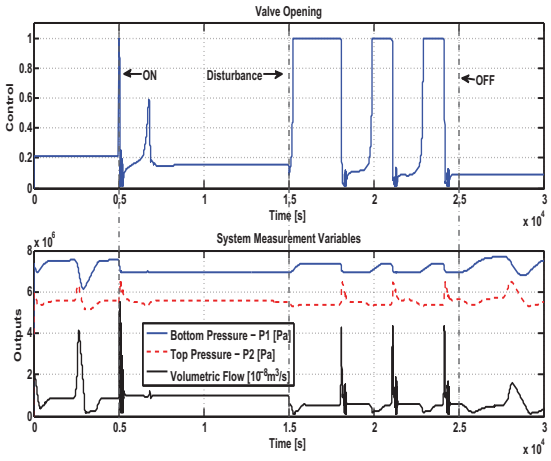

Fig. 6. System time response under *PI* control for a flow rate disturbance from $5Kg.s^{-1}$ to $3Kg.s^{-1}$.

previous simulation setup in order to obtain comparative results between the different slug control strategies.

Simulation results using the PI control are shown in Fig.5 for the first disturbance and in Fig.6 corresponding to the second disturbance. As can be seen, the PI control reject the first perturbation but it is not robust for the second disturbance.

In order to tackle this problem for large flow rate disturbances, three different Sliding Mode Control (SMC) strategies are proposed in the following Sections.

3. SLUG SMC STRATEGY

The main idea is to design a Sliding Mode Control (SMC) law (switching system) that induces a grazing-sliding bifurcation (see Angulo et al. (2005a)) on the system, changing its dynamics and, in this way, the amplitude of the target limit cycle is controlled. This type of non-smooth bifurcation introduces partial sliding motion along a sliding surface, reducing or suppressing the amplitude of the undesired limit cycle. In order to explain these ideas, consider a general system defined by

$$\dot{x} = F(x, u(x)) \tag{1}$$

where $x \in \mathbb{R}^n$ is the state vector of dimension n, and $u(x) \in \mathbb{R}$ is the control signal. The function $F(x) = (F_1, F_2, ..., F_n) : \mathbb{R}^n \rightarrow \mathbb{R}^n$, represents a non-smooth continuous system. We also assume that as a result of a Hopf bifurcation (continuous or not, see di Bernardo et al. (2008)), the system exhibits a steady state oscillatory behavior, where a stable limit cycle is the solution from (1).

The grazing-sliding bifurcation to suppress a limit cycle occurs when the limit cycle is crossed by a sliding surface that generates a grazing-sliding non-smooth transition where part of the trajectory of the limit cycle stands on the sliding surface as shown in Fig. 7.

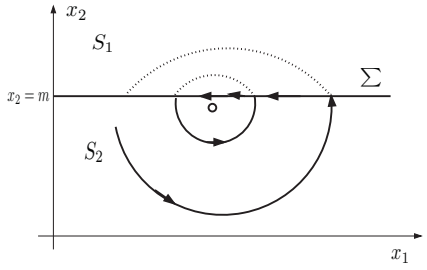

Fig. 7. Grazing-sliding bifurcation induced in the system.

For example, on a system with dimension 2, we consider a region S_1 of the form

$$S_1 := \{x = (x_1, x_2) : x_2 > m\}$$

for arbitrary m, being

$$\Sigma := \sigma(x) = \{x = (x_1, x_2) : x_2 = m\}$$

and

$$S_2 := \{x = (x_1, x_2) : x_2 < m\}.$$

With the variation of m, a grazing-sliding bifurcation occurs and the amplitude of the limit cycle is reduced or even eliminated.

Thus, the sliding mode control suggested is

$$u = u_0 + \Delta u \ \text{sgn}(\sigma(x)) \tag{2}$$

where $\sigma(x) = 0$ is the sliding surface, a function of the system's states that allow the changing of its dynamics; u_0 is the value of the control variable at the operating point and Δu is the maximum value that the control variable can assume from u_0.

The function $sgn(\cdot)$ can be defined as

$$\text{sgn}(\sigma(x)) = \begin{cases} -1, & \text{if } \sigma(x) < 0; \\ 1, & \text{if } \sigma(x) > 0. \end{cases} \tag{3}$$

or

$$\text{sgn}(\sigma(x)) = \begin{cases} 0, & \text{if } \sigma(x) < 0; \\ 1, & \text{if } \sigma(x) > 0. \end{cases} \tag{4}$$

Applying the above equations, we propose the following control law given by

$$u = u_0 + \Delta u \ \text{sgn}(\sigma), \tag{5}$$

$$\sigma(P_1, P_2) = P_2 - P_1 + \beta, \tag{6}$$

where $\beta = P_1^* - P_2^*$; $\Delta u = u_0 - u_{min}$; u_0 is the desired choke opening and u_{min} is the control value at the Hopf Bifurcation point. The switching surface is defined as $P_2 = P_1 - \beta$ and we define the $sgn(\cdot)$ to close the choke whenever $\sigma > 0$. The choke opening bias u_0 is defined at the riser desired operating point. At this point P_1^*, P_2^* are defined on the equilibria manifold curve, for a given mass flow rate of the riser input, as shown in Fig. 3. Choosing the surface choke opening bias u_o has to consider two factors. For one the value should be high enough in order to ensure a minimum pressure drop around the choke. On the other hand the bias should not be too far from values which can cause high pressure drops in order to answer quickly to disturbances. Choke opening close to 100% cause minimum pressure drop but depending on the choke characteristics a significant choke pressure drop can only be obtained for values smaller than 10%.

The control strategy can be interpreted as a mechanism to force an hypothetical steady flow rate which would be obtained without the slug flow behavior. For a constant input gas and liquid mass flow rate the pressure P_1 could be expressed as $P_1 = P_2 + \beta$ where β would take into account the gravity and friction terms of a pseudo stable flow. For instance, the simplest model is the homogeneous model given by

$$P_1 - P_2 = \frac{m_{gr} + m_{lr}}{A} g + \frac{f \bar{\rho} \bar{v}^2}{2 d_r} h, \qquad (7)$$

where A is the section of the pipe; m_{gr} and m_{lr} are the mass of gas and mass of liquid in the riser; $\bar{\rho}$ is the mean density of the flow; $\bar{v}$ is the mean velocity of the flow in the riser; h is the height of the riser; f is the friction function; d_r is the diameter of the pipeline. In (7), first term corresponds to the gravity term and the second is the friction term.

Anytime the relationship is violated action is taken in the choke opening to force the desired P_1, P_2 relationship. Obviously this is done in a way that provides a desired choke opening which minimizes P_1 and consequently the energy used to lift the gas and liquid flow-rates entering the riser.

Time open-loop system responses are shown in Fig. 8. At $t = 5000s$ the proposed control system is turned on. At $t = 15000s$, a disturbance in the flow rate (from $5Kg.s^{-1}$ to $3.5Kg.s^{-1}$) was applied. It can be observed in Fig. 8 and Fig. 9 where the amplitude of the oscillations are decreased around the operating point when the control is switched on. As can be seen in Fig. 8, after the control is switched off, at $t = 250000s$, the oscillations back to the system. State space diagram, in (P_1, P_2)-plane, is depicted in Fig. 9.

The proposed SMC works well for small input riser flow rate disturbances but the control action switches permanently to maintain the equilibrium at the operating point.

4. A MODIFIED SLUG SMC STRATEGY

The SMC strategy development in Section 3 is not efficient to suppress pressure or flow oscillations in the riser since the control action switches permanently to maintain the equilibrium at the operating point. This would be very detrimental to the choke integrity. Another desired control characteristic is to be able to suppress the oscillations while keeping the choke nearly 100% opened. This represents significant less power needed to pump the multiphase fluid to the surface. In this Section, we propose a change in the control algorithm to minimize the switching in the control signal. The idea is to combine two control laws (i)

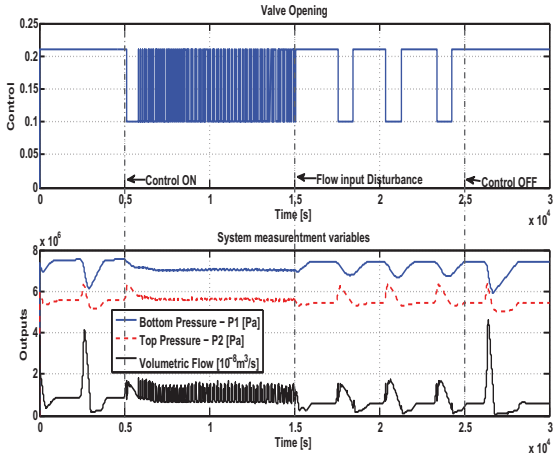

Fig. 8. Time system response (open-loop and with feedback control) with the SMC control strategy. a) choke opening; b) states of the system.

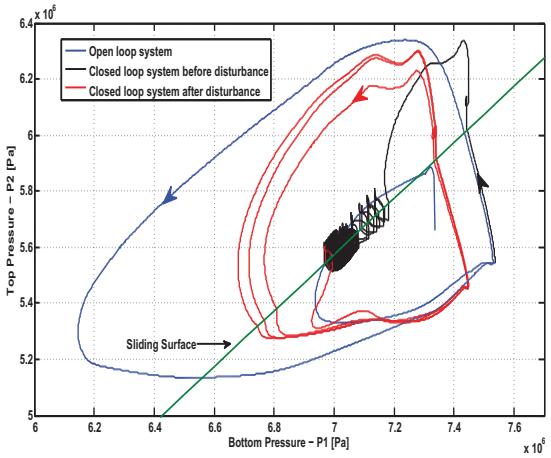

Fig. 9. State space diagram in (P_1, P_2)-plane

the control used in Section 3 and (ii) a discrete form of the PI control law as used in Section 2 by means of a convex function as

$$u(t) = \mu \; u_{SMC} + (1 - \mu) \; u_{PI}, \qquad (8)$$

$$u_{SMC} = u_0 + \Delta u \; sgn(\sigma), \qquad (9)$$

where

$$\sigma = P_2 - P_1 + \beta.$$

$$u_{PI}(k) = u_{PI}(k-1) + s_0 \; e(k) + s_1 \; e(k-1), \qquad (10)$$

where u_{SMC} is the switching control law given by (9) and u_{PI} is the PI control (10), with $e(k) = P_1^*(k) - P_1(k)$.

The parameter $\mu = \mu(P_1, P_2)$ provides a smooth transition between the two control laws in such a way that if the trajectories are far away the equilibrium point then μ is close 1; otherwise μ is close to 0. It is defined as

$$\mu = \frac{1}{1 + e^{\gamma(\lambda - \delta)}}$$

$$\lambda(P_1, P_2) = \left(\frac{P_1}{P_1^*} - 1\right)^2 + \left(\frac{P_2}{P_2^*} - 1\right)^2 \qquad (11)$$

where P_1^* is the operating point for bottom pressure and P_2^* is the desired value for the input choke pressure. Parameter values of (9), (10) and (11) are given in Table 2. Parameter

Table 2. Control law parameters.

Parameter	value	unit
u_0	0.2	
Δu	0.12	
s_0	$-8.08 \cdot 10^{-6}$	Pa^{-1}
s_1	$7.92 \cdot 10^{-6}$	$Pa{-}1$
γ	$8/\delta$	
δ	0.008	

β is defined as $\beta = P_1^* - P_2^*$. The system response with the proposed control law to a disturbance of the well mass flow rate is shown in Fig. 10 and the space state diagram is depicted in Fig. 11. The sample time was chosen as $T_a = 1s$. At

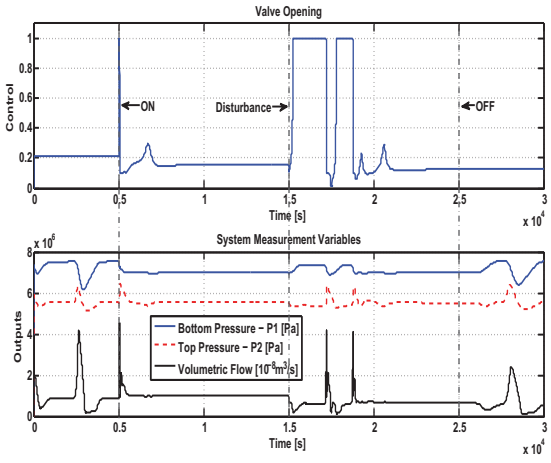

Fig. 10. Control and output system responses with the modified control law (8) for a disturbance input.

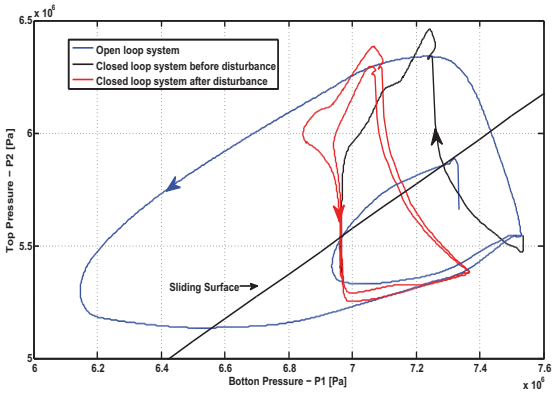

Fig. 11. State-space diagram of the system with the modified control law (8).

$t = 15000s$, the mass flow rate coming from the well is reduced from $5kg/s$ to $3.5kg/s$. This disturbance changes the operating process conditions. The proposed SMC control strategy control the system reduce the amplitude of the oscillations.

At $t = 25000s$, the control is turned off and the system starts to exhibit pressure and flow signal oscillations again. As can be seen the oscillations are back since the choke opening value is now in the instability region.

A disadvantage using the SMC algorithm discussed in this Section is that it is not possible to stabilize the system for large flow rate disturbances.

5. SLUG WASHOUT SMC CONTROL

All approaches presented so far for the slug control have used set-points to derive the control law. These strategies have a problem when there are changes in the fluid mass flow rate entering the riser. Even a stabilized flow rate will exhibit a different value both for P_1 and P_2 since higher mass flow rate will result in higher gravity and friction terms on the riser pressure drop as well as higher pressure drop in the surface choke. For the sliding mode control keeping the set-points for changes in the input mass flow rate means to request the system to operate in a limit cycle not sufficiently collapsed or to ask for an infeasible stabilized flow.

Since the practical objetive is to stabilize the flow keeping the surface choke with a minimum pressure drop, the idea of pressure set-point looses significance. One could say that the control problem is well solved if the pressures and flow rates do not oscillate while the surface choke is kept opened well above the opening which characterizes the beginning of the limit cycle. The idea is to develop a control strategy which supres the oscillation while keeping the choke opening operating around a desired opening value. If the oscillations are suppressed the resultant pressures will be a consequence of the input mass flow rate, fluid characteristics and the system geometry.

In order to attend the former constraints, we propose, in this Section, a new SMC strategy to reject mass flow rate input riser perturbations based on washout filters. Washout filters are intensively used to control chaotic systems by means of techniques based on bifurcation theory Wang and Abed (1995) and in flight control systems Lee and Abed (1991). Recently, washout filters were applied to power electronic converters in conjunction with SMC controllers in order to reject load disturbances Cunha and Pagano (2002). A washout filter is a high-pass linear filter that washes out steady-state inputs while passing transient inputs. The use of washout filters ensures that all the equilibrium points of the original system are preserved in the controlled system, i.e., their location remains unchanged.

The transfer function of a typical washout filter is given by

$$G_F(s) = \frac{s}{s+w} = 1 - \frac{w}{s+w},$$

where w denotes the reciprocal of the filter time constant which is positive for stable filter. We assume that it is possible to filter the inductor current x to achieve a new signal x_F and define an auxiliary variable z so that it is satisfied the output equation

$$x_F = x - z.$$

Then the effect of the washout filter can be represented by means of an additional differential equation, namely

$$\frac{dz}{dt} = w(x - z). \tag{12}$$

In our problem, we use two washout filters in order to filter the signals P_1 and P_2 in such a way that

$$\dot{z}_1 = w_1(P_1 - z) = w_1\tilde{p}_1$$

$$\dot{z}_2 = w_2(P_2 - z) = w_2\tilde{P}_2$$

where $\tilde{p}_1$, $\tilde{p}_2$ are the bottom and top filtered pressures, $w_1 = \frac{2\pi}{5} f_1$ and $w_2 = \frac{2\pi}{5} f_2$ are washout filter constants designed from the oscillatory frequencies f_1, f_2 measurement from the OLGA data simulation.

$$u_{WSMC} = u_0 + \Delta u \ sgn(\sigma), \tag{13}$$

where

$$\sigma(\tilde{P}_1, \tilde{P}_2) = \tilde{P}_2 - \tilde{P}_1. \tag{14}$$

Note that (14) is similar to (6) but now the parameter β is equal to zero. The sliding surface is now defined as $\tilde{P}_2 = -\tilde{P}_1$ and it does not depend on the operating point.

At $t = 10000s$ automatic control is turned on and at $30000s$ a well flow rate is reduced from $5kg/s$ to $3kg/s$.

At $50000s$ the control is again turned off and the system back to the oscillatory behavior. Simulation results are shown in Fig. 12. The state-space diagram in $(P_1 - P_2)$-plane is shown in Fig.

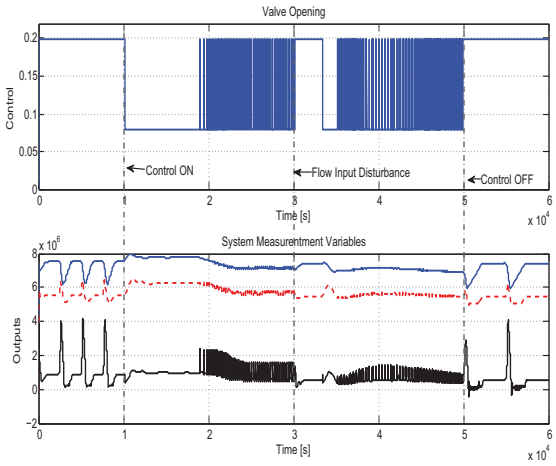

Fig. 12. Control and output system responses with slug washout SMC for a disturbance in the input riser flow rate.

13. As can be seen, the propose control law stabilize the process and at the same time allow to work over the full choke range. A disadvantage to use this propose control law is the resulting

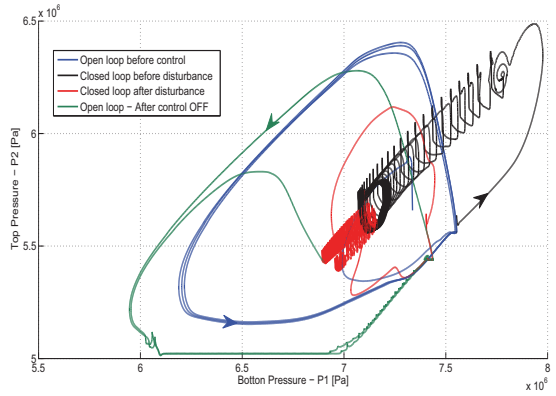

Fig. 13. State-space diagram of the system with slug washout SMC.

chattering produced by the control action signal on the choke. An alternative to overcome the high frequency chattering from the dynamics of the standard sliding mode control presented in the this Section is to design a Higher Order Sliding Mode (HOSM) control.

6. CONCLUSIONS

The lack of robustness to control slug-flow oscillations in submarine oil-risers using classical PI linear control system was tackled in this paper applying SMC techniques. Three different SMC controllers to suppress slug-flow control oscillations were proposed. Simulation results were obtained using OLGA software in order to compare the different SMC strategies subject to mass flow input riser disturbances from $5Kg.s^{-1}$ to $3Kg.s^{-1}$. The SMC technique reveal itself as a robust way of suppressing limit cycles when the mathematical model of the process is not available in practice. The dynamical of the slug system with unknown operating point was treated in this work using washout filters. This situation is manifested in the presence of mass flow rate input riser disturbances.

An existing practical obstacle to apply the standard SMC in the field is the high frequency chattering of the generated control signal. This problem leads to a premature wear down of the choke actuator and could be tackled in future works using High Order Sliding Mode - HOSM controllers.

Abstract: A suitable design of state estimators requires a representative model for capturing the plant behavior and knowledge about the noise statistics, which are generally not known in practical applications. While the measurement noise covariance can be directly derived from the measurement device reproducibility, the choice of the process noise covariance is much less straightforward. Further, processes such as continuous process with grade transitions and batch or semi-batch process are characterized by time-varying structural uncertainties which are, in many cases, partially and indirectly reflected in the uncertainty of the model parameters. It has been shown that the robust performance of state estimators significantly enhances with a time-varying and non-diagonal process noise covariance matrix, which explicitly takes parameter uncertainty into account. For this case, the parameter uncertainty is quantified through the parameter covariance matrix. This paper presents a direct and a sensitivity method for the parameter covariance matrix computation. In the direct method, the parameter covariance matrix is found during the parameter estimation step of the SELEST algorithm, while in the sensitivity method, the parameter covariance matrix is obtained through a time-varying sensitivity matrix. The results have shown the efficacy of these methods in improving the performance of an extended Kalman filter (EKF) for a semi-batch reactor process.

Keywords: state estimator design, noise statistics, parameter estimation, sensitivity analyses.

1. INTRODUCTION

Since usually not all states of a nonlinear dynamic model are measured, they need to be estimated to be used in any control and optimization strategy. State estimators are used to estimate the unmeasured states and to filter the measured ones. Therefore, they are essential for any advanced control and optimization application. Besides an accurate plant model, an appropriate choice of process and measurement noise covariances is crucial in applying state estimators. The measurement error covariance matrix is usually known from the error statistics of the measurement device and is readily available. However, in actual problems, the process-noise statistics are often unknown, do not satisfy the assumptions of normal distribution and are mostly due to the uncertainties in the model that can be either parametric or structural.

Adaptive filtering techniques estimate noise covariances from data and have been used for nonlinear systems (Mehra, 1972; Odelson et al. 2006). The methods in this field can be divided into four general categories (Mehra, 1972): Bayesian, maximum likelihood, covariance matching, and correlation techniques. Bayesian and maximum likelihood methods have fallen out of favor because of their sometimes excessive computation times. Covariance matching is the computation of the covariances from the residuals of the state estimation problem, but has been shown to give biased estimates of the true covariances. The fourth category is correlation techniques, which is the most popular for determining these covariances (Odelson et al. 2006). However, these methods assume constant noise characteristics and the availability of data required to obtain a true representation of noise statistics. For continuous or batch processes with time-varying process dynamics and operating within a wide range of process conditions, these noise statistics are time varying. The use of a fixed value of noise statistics can lead to poor filter performance and even result in filter divergence (Vallapil & Georgakis 1999, 2000, Leu & Baratti, 2000).

Valappil & Georgakis (1999, 2000) introduced two systematic approaches to be used for the calculation of a time-varying and non-diagonal process noise covariance matrix, which explicitly takes parameter uncertainty into account. The first, called linearized approach, is based on a Taylor series expansion of the nonlinear equations around the nominal parameter values, while the second, called Monte Carlo approach, accounts for the nonlinear dependence of the system on the fitted parameters by Monte Carlo simulations that can easily be performed on-line. Both approaches have been compared favorably with the traditional methods of trial-and-error tuning of EKF. For the linearized approach, the process noise covariance matrix for the filter is obtained by a procedure using the known parameter covariance matrix. The main advantage of the linearized approach is that it involves very simple algebraic calculations and can easily be executed on-line. Afterwards this approach was employed successfully in EKF-based NMPC algorithms for batch

processes (Valappil & Georgakis, 2001, 2002; Nagy and Braatz, 2003).

In this work, a new process noise covariance matrix tuning algorithm is proposed. It is an extension of the linearized approach proposed by Valappil and Georgakis (1999, 2000) with two methods for the parameter covariance matrix computation. In the direct method, the parameter covariance matrix is found during the parameter estimation step using SELEST (Secchi et al., 2006), an algorithm for automatic selection of model parameters based on an extension of the identifiability measure of Li et al. (2004). In the sensitivity method, the parameter covariance matrix is obtained through a time-varying sensitivity matrix. Both methods can be successfully applied for state estimator design.

2. PROBLEM FORMULATION AND SOLUTION STRATEGIES

2.1 Hybrid Extended Kalman Filter (H-EKF)

Consider the following nonlinear dynamic system to be used in the state estimator

$$\begin{aligned} \dot{x} &= f(x,u,t,p)+\omega(t) \\ y_k &= h_k(x_k,t_k)+v_k \\ \omega(t) &\sim (0,Q) \\ v_k &\sim (0,R_k) \end{aligned} \tag{1}$$

where u denotes the deterministic inputs, x denotes the states, and y denotes the measurements. The process-noise vector, ω(t), and the measurement-noise vector, v_k, are assumed to be a white Gaussian random process with zero mean and covariance Q and R_k, respectively. The H-EKF formulation uses a continuous and nonlinear model for state estimation, linearized models of the nonlinear system for state covariance estimation, and discrete measurements (Simon, 2006). This is often referred to as continuous-discrete extended Kalman filter (Jazwinski, 1970). Here, the system is linearized at each time step to obtain the local state-space matrices as below:

$$F(t)=\left(\frac{\partial f}{\partial x}\right)_{x,u,t,p_{nom}}, \qquad H(t)=\left(\frac{\partial h}{\partial x}\right)_{x,u,t,p_{nom}} \tag{2}$$

The equations that compose the different steps in the H-EKF are given below.

State transition equation:

$$\hat{x}_{k|k-1}=\hat{x}_{k-1|k-1}+\int_{k-1}^{k} f(\hat{x},u,\tau,p)\,d\tau \tag{3}$$

State covariance transition equation

$$P_{k|k-1}=P_{k-1|k-1}+\int_{k-1}^{k}\left[F(\tau)P(\tau)+P(\tau)F(\tau)^{T}+Q\right]d\tau \tag{4}$$

Kalman gain equation:

$$K_k=P_{k|k-1}H_k^{T}\left[H_kP_{k|k-1}H_k^{T}+R_k\right]^{-1} \tag{5}$$

State update equation:

$$\hat{x}_{k|k}=\hat{x}_{k|k-1}+K_k\left[y_k-h\left(\hat{x}_{k|k-1},t_k\right)\right] \tag{6}$$

State covariance update equation:

$$P_{k|k}=\left[I_n-K_kH_k\right]P_{k|k-1}\left[I_n-K_kH_k\right]^{T}+K_kR_kK_k^{T} \tag{7}$$

2.2 Linearized Approach to Calculate the ω(t) Statistics

As introduced by Valappil & Georgakis (1999, 2000), the linearized approach to calculate the ω(t) statistics of (1) consists in assuming that the process noise vector ω(t) mostly represents the effects of parametric uncertainty. As $\dot{x}(t)$ and $\dot{x}_{nom}(t)$ are desired to be the same, ω(t) can be defined by

$$\omega(t)=f(x,u,t,p)-f(x_{nom},u,t,p_{nom}) \tag{8}$$

Performing a first-order Taylor's series expansion of the right-hand side of (8) around the nominal state trajectory (x_{nom}) and the nominal parameters (p_{nom}), neglecting the higher-order terms, results in following approximation

$$\begin{aligned} \omega(t)=&\left(\frac{\partial f}{\partial x}\right)_{x_{nom},u,t,p_{nom}}\left[x(t)-x_{nom}(t)\right] \\ &+\left(\frac{\partial f}{\partial p}\right)_{x_{nom},u,t,p_{nom}}\left[p-p_{nom}\right] \end{aligned} \tag{9}$$

Assuming that $\left[x(t)-x_{nom}(t)\right]=\left[\hat{x}(t)-x_{nom}(t)\right]\approx 0$, the process noise is calculated from

$$\omega(t)=F_{p_{nom}}(t)\left[p-p_{nom}\right] \tag{10}$$

where $F_{p_{nom}}(t)=\left(\frac{\partial f}{\partial p}\right)_{\bar{x},u,t,p_{nom}}$. Calculating the expected value of both sides of (10) yields

$$\bar{\omega}(t)=F_{p_{nom}}(t)(p_{nom}-p_{nom})=0 \tag{11}$$

indicating that the noise sequence ω(t) has zero mean if the employed linearization in the parameters was accurate. Then the desired computation of the covariance Q(t) of ω(t) is given by

$$Q(t)=F_{p_{nom}}(t)C_pF_{p_{nom}}^{T}(t) \tag{12}$$

where $C_p\in\Re^{n_p\times n_p}$ is the parameter covariance matrix. In this work, we propose two methods to calculate C_p, which are presented in the next subsection.

2.3 Proposed Methods to Calculate the C_p Matrix

Consider the general process model.

$$\dot{x}=f(x,u,t,p_{nom}) \tag{13}$$

Differentiating (13) with respect to the nominal parameter vector, p_{nom}, gives

$$\dot{S}=\left(\frac{\partial f}{\partial x}\right)S+\left(\frac{\partial f}{\partial p_{nom}}\right)=F(t)S+F_{p_{nom}}(t) \tag{14}$$

where S is the sensitivity matrix $(\partial x/\partial p_{nom})$ determined by numerical integration of (14) along with the model of (13).

2.3.1 Direct Method: Parameter Covariance Matrix via Parameter Estimation

In this method, C_p is constant and directly obtained from the parameter estimation procedure. For this purpose, we have selected the SELEST algorithm proposed by Secchi et al. (2006). This algorithm uses a sensitivity matrix, S, based on calculation of the parameters effects on the measured outputs and of a linear-independence metric, as proposed by Li et al. (2004). A predictability degradation index and a parameter correlation degradation index are used as stopping criterion. The definitions of these indexes as well as the SELEST algorithm are presented in Secchi et al. (2006).

2.3.2 Sensitivity Method: Parameter Covariance Matrix via Sensitivity Matrix

As pointed out by Sharma & Arora (1993), the sensitivity matrix, S, can play a role in quantifying how good the estimate of the parameters is. For uncorrelated and normally distributed measurement errors and for nonlinear least-squares problems, a parameter covariance matrix C_p can be estimated from

$$C_p \approx s^2 \left(S^T S\right)^{-1} \tag{15}$$

where s^2 accounts for the accuracy of the data used to fit the parameters ($\hat{Y}$) and is usually represented by the residual mean square

$$s^2 = \frac{\sum \left(\hat{Y}\text{-}Y_p\right)^T \left(\hat{Y}\text{-}Y_p\right)}{n\text{-}np} \tag{16}$$

where Y_p is the estimated data, n is the number of samples and np is the number of estimated parameters. The residual mean square s^2 is also obtained from the parameter estimation using SELEST algorithm. Since the sensitivity matrix, S, is time-varying, C_p is also time-varying, which represents an advantage of this method.

3. MATRIX Q TUNING ALGORITHM

This section presents an algorithm for tuning of the process noise covariance matrix. As mentioned earlier, this algorithm is an extension of the linearized approach proposed by Valappil and Georgakis (1999, 2000) with two methods for the parameter covariance matrix computation.

Since any model is an abstraction of reality, both the structural and parametric uncertainties are present to some degree in most real situations. The structural uncertainties is often captured by uncertainty in the model parameters only. The proposed algorithm requires knowledge about which parameters can be considered time-varying. Afterwards, SELEST algorithm estimates the best possible subset of parameters within a full set of model parameters assumed time-varying.

Parameter estimation is a key ingredient to quantify the parametric model uncertainty. However, most contributions on parameter estimation in process control assume that all model states are measured, which is not true in practical applications. In order to carry out proper parameter estimation, the EKF is used in a previous stage with the nominal parameters to estimate the unmeasured states and to filter the measured ones. Afterwards, the state estimation is carried out a posteriori with the estimated parameters, p_{est}, and a time-varying and non-diagonal matrix Q obtained from the procedure described above. The required covariance matrix C_p is calculated by one of the two methods proposed in this work. The structure of the algorithm for process noise covariance matrix Q tuning is shown in Fig. 1.

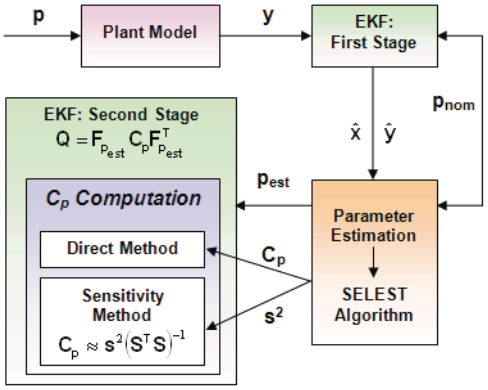

Fig. 1: Process noise covariance matrix Q tuning algorithm.

Note that the matrix Q in our algorithm takes into account the estimated parameters, p_{est}, rather than the nominal parameters, p_{nom}, as introduced by Vallapil and Georgakis (1999, 2000) in (12).

4. CASE STUDY: WILLIAMS-OTTO SEMI-BATCH REACTOR

A description of the Williams-Otto semi-batch reactor, as introduced by Forbes (1994), is provided in this section. The following reactions take place in the reactor:

$$A + B \xrightarrow{k_1} C$$
$$C + B \xrightarrow{k_2} P + E$$
$$P + C \xrightarrow{k_3} G$$

Reactant A is already present in the reactor, whereas reactant B is fed continuously to the reactor. During the exothermic reactions the products P and E as well the side-product G are formed. The heat generated through the exothermic reaction is removed by a cooling jacket, which is controlled by manipulating the cooling water temperature. The manipulated control variables of this process are the inlet flow rate of reactant B (F_B) and the cooling water temperature (T_w), whose values have been kept constant in our study. The model equations are given below and the model parameters are reported in Table 1:

$$\frac{dm_A}{dt} = -\frac{M_A}{M_A} r_1 V \tag{17}$$

$$\frac{dm_B}{dt} = F_B - \frac{M_B}{M_A} r_1 V + \frac{M_B}{M_B} r_2 V \tag{18}$$

$$\frac{dm_C}{dt} = \frac{M_C}{M_A} r_1 V - \frac{M_C}{M_B} r_2 V - \frac{M_C}{M_C} r_3 V \tag{19}$$

$$\frac{dm_P}{dt} = \frac{M_P}{M_B} r_2 V - \frac{M_P}{M_C} r_3 V \quad (20)$$

$$\frac{dm_E}{dt} = \frac{M_E}{M_B} r_2 V \quad (21)$$

$$\frac{dm_G}{dt} = \frac{M_G}{M_C} r_3 V \quad (22)$$

$$\frac{dV}{dt} = \frac{F_B}{\rho} \quad (23)$$

$$\frac{dT_r}{dt} = \frac{H - F_B c_p T_r}{V \rho c_p} \quad (24)$$

where

$$V = \frac{m_A + m_B + m_C + m_P + m_E + m_G}{\rho} \quad (25)$$

$$r_1 = k_1 \frac{m_A m_B}{V^2}; \quad r_2 = k_2 \frac{m_B m_C}{V^2}; \quad r_3 = k_3 \frac{m_C m_P}{V^2} \quad (26)$$

$$k_i = A_i e^{\frac{-E_i}{(T_r + T_{ref})}}; \quad i = 1,2,3 \quad (27)$$

$$H = F_B c_p T_{in} - \Delta H_1 \frac{M_A}{M_A} r_1 V - \Delta H_2 \frac{M_B}{M_B} r_2 V - \Delta H_3 \frac{M_C}{M_C} r_3 V - V \frac{A_0}{V_0} U(T_r - T_w) \quad (28)$$

Table 1. Model Parameters

M_A	100 kg.kmol^{-1}	ΔH_1	-263.8 kJ.kg^{-1}
M_B	200 kg.kmol^{-1}	ΔH_2	-158.3 kJ.kg^{-1}

t_f	1000 s		

In order to illustrate the application of the Q tuning algorithm, the kinetic parameters E_1, E_2, and E_3 were chosen as uncertain parameters. A parametric uncertainty of ±5% is assumed. The correct parameter values ("plant parameters"), p, and the nominal parameters, p_{nom}, are reported in Table 2.

Table 2. Uncertain Parameters

	E_1	E_2	E_3
p	6333.4	7916.3	11666.6
p_{nom}	6666.7	8333.3	11111.1

The application of Q tuning algorithm to the Williams-Otto semi-batch reactor is shown below.

4.1 First Iteration of Q Tuning Algorithm.

4.1.1 Results of State Estimation: First Stage

A first state estimation with nominal parameters is performed to provide information on unmeasured states to be used in the subsequent parameter estimation step. The states and measurements of the Williams-Otto semi-batch reactor are

$$x = [m_A \quad m_B \quad m_C \quad m_P \quad m_E \quad m_G \quad V \quad T_r] \quad (29)$$

$$y = [m_B \quad m_E \quad m_G \quad V] \quad (30)$$

The measurements are obtained from a simulation of the plant model with the plant parameters p. The initial condition and the parameters of the state estimation are

$$x_0 = [2000 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0 \quad 2 \quad 65] \quad (31)$$

$$P_0 = 0.0001^2 I_{8x8} \quad (32)$$

$$\Delta t = t_k - t_{k-1} = 31.25 \quad (33)$$

$$R = \mathrm{diag}(0.1^2 \quad 0.1^2 \quad 0.01^2 \quad 0.01^2) \quad (34)$$

$$Q = \mathrm{diag}(0.1^2 \quad 0.01^2 \quad 0.1^2 \quad 0.01^2 \quad 0.01^2 \quad 0.1^2 \quad 0.1^2 \quad 0.01^2) \quad (35)$$

The state estimation results using the EKF with nominal parameters and a constant-value and diagonal matrix Q are shown in Fig. 2. As expected, in the presence of a constant parametric model mismatch, the estimated states show a bias (cf. Fig. 2b).

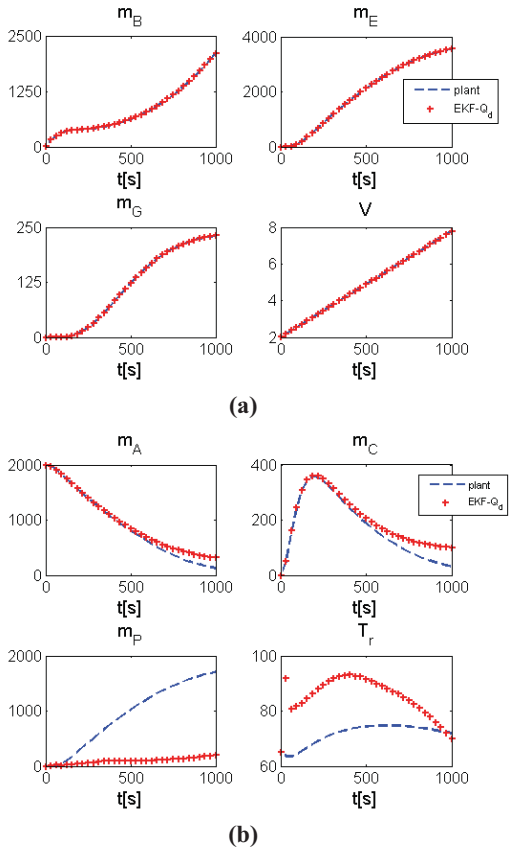

Fig. 2: EKF with nominal parameters (p_{nom}) and a constant-value and diagonal matrix Q (Q_d): (a) filtered measured states and (b) estimated states.

4.1.2 Results of Parameter Estimation Step

Using the SELEST algorithm, the parameter estimation step is based on the nominal parameters, p_{nom}. The data used to fit the parameters are composed of the estimated states and the filtered measured states provided by the first state estimation stage. As a result of the parameter estimation step, the SELEST algorithm provides the estimated parameters, p_{est}, the parameter covariance matrix, C_p, and the residual mean square, s^2

$$p_{est} = \begin{bmatrix} 6333.8 & 7957.9 & 11223.5 \end{bmatrix}$$

$$C_p = \begin{bmatrix} 3.2469E-5 & -8.6175E-6 & -4.2417E-5 \\ -8.6175E-6 & 3.8060E-5 & 8.2221E-6 \\ -4.2417E-5 & 8.2221E-6 & 3.8060E-5 \end{bmatrix}$$

$$s^2 = \frac{\sum\left(\hat{Y}-Y_p\right)^T\left(\hat{Y}-Y_p\right)}{\left(\frac{t_f}{\Delta t}+1\right)-np} = \frac{\sum\left(\hat{Y}-Y_p\right)^T\left(\hat{Y}-Y_p\right)}{\left(\frac{1000}{31.25}+1\right)-3} = 1.66E2$$

where $\hat{Y}$ is composed of the estimated and the filtered measured states resulting from the first state estimation stage and Y_p is calculated by the SELEST algorithm.

4.1.3 Results of State Estimation: Second Stage

At this point, state estimation is carried out with the estimated parameters and the time-varying and non-diagonal Q obtained by C_p. The performance of the EKF with the following choices for calculating Q is compared and the results are shown in Fig. 3.

Direct method: Q is time-varying and non-diagonal, with p_{est} and C_p estimated by means of the SELEST algorithm.

Sensitivity method: Q is time-varying and non-diagonal, with p_{est} and s^2 estimated by means the SELEST algorithm and C_p obtained via sensitivity integration.

Random Variation: Proposed by Valappil and Georgakis (1999, 2000). The parameters in the plant are assumed to vary with time, taking values at each sample interval from a nominal distribution. The mean value of the varying plant parameter is assumed to be different from the nominal value of the model parameter by a fixed amount σ. The parameter covariance matrix used in the filter is given by $C_p = \sigma^2$.

Monte Carlo Approach: Proposed by Valappil and Georgakis (1999, 2000). This approach accounts for the nonlinear dependence of the system on the fitted parameters by Monte Carlo simulations. For the case study, 500 Monte Carlo simulations of different parameter values were used, resulting in 500 evaluations of the process noise.

The initial conditions (31) and the parameters of the state estimation algorithm (32 to 35) remain the same in this stage. According to Fig. 3, the EKF with a time-varying and non-diagonal matrix Q obtained by random variation in the plant parameters presents the worst performance. The sensitivity method performs better compared to the direct method. As mentioned before, an advantage of this method is that the parameter covariance matrix, C_p, is time-varying due to the time-varying sensitivity matrix S. In spite of accounting the nonlinear dependence of the system on the fitted parameters, the Monte Carlo shows a performance slightly inferior to the that of the sensitivity method for estimated states (Fig. 3b) and a performance quite inferior to that of the sensitivity and direct methods for measured states (Fig. 3a), not to mention the high computational effort.

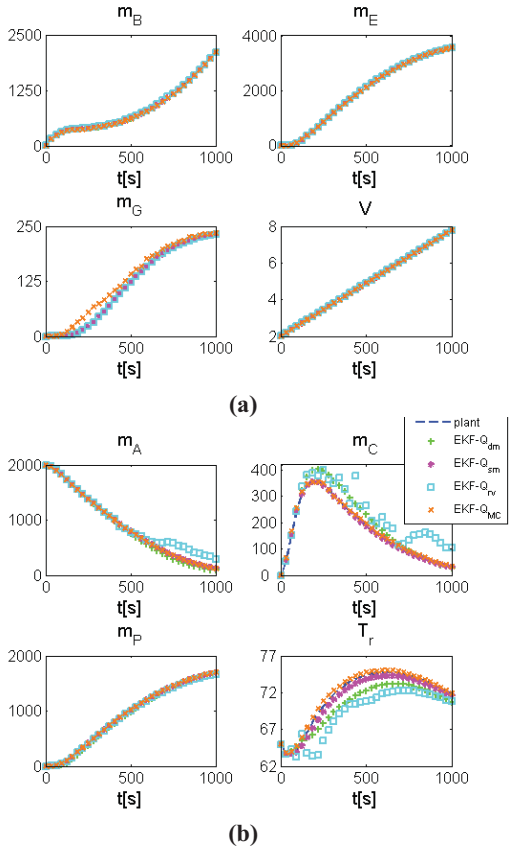

Fig. 3: EKF with estimated parameters (p_{est}) and a time-varying and non-diagonal Q matrix obtained by the proposed methods: direct (Q_{dm}) and the sensitivity (Q_{sm}); and by the literature methods: random variation (Q_{rv}) and Monte Carlo (Q_{MC}): (a) filtered measured states and (b) estimated states.

4.2 Second Iteration of Matrix Q Tuning Algorithm

Since the unmeasured states are unknown in practical applications, the state estimation accuracy shall be quantified. The matrix Q tuning algorithm is hence performed iteratively with the proposed methods for the parameter covariance matrix computation until the state estimation accuracy could not be significantly improved.

The parameter estimation is now taking place with the estimated parameters, p_{est}, and the estimated states and filtered measurements from the first iteration of the proposed algorithm. The parameter estimation results for both methods are given in Table 3.

Table 3. Uncertain Parameters

Method	p_{est}			s^2
	E_1	E_2	E_3	
Direct	6328.1	7952.7	11668.9	7.0880
Sensitivity	6333.9	7921.3	11666.3	0.7785

Disregarding numerical round off, the matrix C_p is the same for both methods, i.e.

$$C_p = \begin{bmatrix} 4.9337E-5 & -4.6902E-6 & 4.3956E-6 \\ -4.6902E-5 & 7.7390E-5 & 4.7829E-6 \\ 4.3956E-5 & 4.7829E-6 & 5.0158E-5 \end{bmatrix}$$

As expected, the residual mean square s^2 is smaller for the sensitivity method which performs better than direct method in an a-posteriori state estimation stage, as shown in Fig. 4.

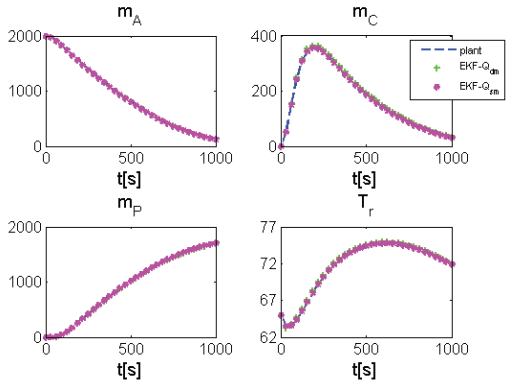

Fig. 4: Estimated states for the EKF with estimated parameters (p_{est}) and a time-varying and non-diagonal Q matrix obtained by the direct (Q_{dm}) and the sensitivity (Q_{sm}) methods.

For this example, a third iteration of the algorithm has not improved significantly the state estimation accuracy.

5. CONCLUSIONS

A new process noise covariance matrix tuning algorithm is presented which incorporates the linearized approach proposed by Valappil and Georgakis (1999, 2000) with two methods for the parameter covariance matrix computation. As pointed out by Valappil and Georgakis (1999, 2000), the investment in a nondiagonal time-varying matrix Q is justified because (a) parametric uncertainties cause significant cross-correlations between the process noises for different states (b) for continuous or batch processes with time-varying process dynamics and operating on wide range of process conditions, the noise statistics are time varying.

The Q tuning algorithm consists of two state estimation steps and a parameter estimation step in between. A first state estimation step with nominal parameters is performed to provide information on unmeasured states to be used in the subsequent parameter estimation step. Afterwards, the state estimation is carried out with the estimated parameters and a time-varying and non-diagonal tuning of matrix Q obtained from the parameter covariance matrix C_p, evaluated by the direct and sensitivity methods. In the direct method, C_p is assumed to be constant and directly obtained from the parameter estimation step using the SELEST algorithm (Secchi et al., 2006). In the sensitivity method, C_p is obtained from the computation of the time-varying sensitivity matrix. Although the EKF with a time-varying and non-diagonal matrix Q obtained from the sensitivity method performs better compared to the direct method, both methods can be successfully applied for state estimator design. Moreover, these methods improve considerably the EKF performance when compared to a) the case of a constant-value and diagonal matrix Q in the presence of constant parametric uncertainty and to b) the methods of prior publications. Successive iterations of the Q tuning algorithm shall improve the state estimation accuracy. For the Williams-Otto semi-batch reactor, only two iterations were necessary to improve the state estimation accuracy, significantly.

The main advantage of the algorithm presented in this work is that it is feasible for practical applications. Besides, of an online EKF tuning, the process model is updated online due to the integration of the state and the parameter estimation steps. Further, the algorithm eliminates an offline, exhaustive, and inexact tuning of EKF by trial and error.

Abstract: Classical observers are constructed on the basis of the nature of the measurement signals, namely, a continuous observer requires continuous output measurements. In this work, a novel observer which estimates continuous states when continuous and discrete measurements are available is presented. By resetting the initial condition of the observer at each sample instant, the convergence of the continuous states is guaranteed. The application to the the estimation of substrate and biomass concentrations in an anaerobic wastewater treatment process in which continuous and discrete measurements usually appear, shows the feasibility of the proposed scheme.

Keywords: jump observer, anaerobic digestion, discrete measurements

1. INTRODUCTION

Because of the increasing complexity and necessity for safety of industrial processes, efficient monitoring, decision and control systems are becoming more an more important. This is particularly true in the case of bioprocesses where the state of the live organisms of the system must be closely monitored. Extensive surveys have been published on this topic (Dochain, 2008). Furthermore, the last two decades have seen an increasing interest in improving the operation of bioprocesses by applying advanced control schemes. In particular, biological waste treatment process, more efficient that the traditional physicochemical methods but at the same time more complex, call for a consistent good performance,which leads to a needing for more efficient instrumentation, control and automation.

To apply any control strategy it is necessary to measure the process main variables, this can be performed placing sensors (**?**), however, although in many cases continuous measurements are easily available, for example the temperature or pH, due to economical reasons or consuming time techniques, other key variables can be only measured intermittently, or even not measured at all. For this reason the non measurable state variables should be estimated from available measurements (Meleiro and Filho, 2000). To deal with these problems, many solutions have been proposed in the past such as the well known classical Kalman filters and Luenberger observers (Ray, 1980) in both, continuous and discrete approaches. On of the reasons for the popularity of these estimators is that they are easy to implement since the algorithm can be derived directly from the state space model. However, these state observers can not be easily implemented when both continuous and discrete information must be considered. In this direction Scali et al. (1997) have proposed an extended Kalman filter which update some observer parameters each time that the sampled date is available. Using Lyapunov functions , Liu et al. (2008) and Muñoz de la Peña and Christofides (2008) have designed controllers that involve continuous and discrete retarded measurements. Nguang and Shi (2003) also use discrete measurements to design continuous fuzzy control algorithms. Based on this idea in this work it is proposed a continuous observer to be continuously updated from the continuous measurements and also retune the states at each instant when the discrete measurement are available.

This work is organized as follows. A review of jump observers is presented in section 2, then in section 3 the observational problem is formulated, while the proposed solution is developed in section 4. In section 5 we analyze the dynamic behavior through numerical simulations for an anaerobic digestion system. Finally we close the paper with some concluding remarks.

2. BASIC FACTS OF JUMP OBSERVERS

Consider the linear system

$$\dot{x}(t) = Ax(t) + Bu(t) \qquad \forall t \in [0, \infty) \tag{1}$$

$$y(k\delta) = Cx(k\delta) \qquad k = 1, 2, 3, \ldots, \tag{2}$$

where $x \in \mathbb{R}^n$, $u \in \mathbb{R}^m$, and $y \in \mathbb{R}^q$ are the state, input and output vectors, respectively. In this case the outputs are obtained at each sampling time δ.

The usual way to estimate the unknown states of system (1) from output (2) consists in discretizing the system

⋆ Partially Supported by PROMEP under proyect 103.5/08/2919 and CONACYT under grant 43658.

and design a discrete observer. However, the observer thus obtained provides only information at each sampling period. Additionally, to obtain a discrete version of (1) it is necessary to have a well defined input in order to place the appropriate holder (for example a zero holder or a exponential holder), hence unexpected input variations during intersampling periods may produce discrete observer failures (García-Sandoval, 2006). For this reason, an interesting problem would be to construct an observer given by

$$\dot{z}(t) = Az(t) + Bu(t) \qquad \forall t \neq k\delta \tag{3}$$

$$z\left(k\delta^{+}\right) = z(k\delta) - G\left[y(k\delta) - Cz(k\delta)\right] \quad t = k\delta \tag{4}$$

where $z \in \mathbb{R}^n$ are the observer states and $z\left(k\delta^{+}\right)$ denotes the updated observer states at each sampling instant. This is a continuous observer which updates its states at each sampling instant. The next lemma establishes conditions for the existence of such observer.

Lemma 1. Consider system (1)-(2) and suppose the pair $\left(e^{A\delta}, C\right)$ is observable, then an observer of the form (3)-(4) with the matrix gain G such that matrix $(I + GC)\, e^{A\delta}$ is Schur, guaranteeing that $\lim_{t\to\infty}\left[x(t) - z(t)\right] = 0$.

Proof. See Appendix.

Remark 2. The main feature of observer (3)-(4) remains in the fact that the intersampling state information is available at any time and it is not necessary to have a pre-established dynamic behavior for the input. Equation (3) can be seen as a continuous open loop observer in the intersampling period and whose states, according to (4), are reseted each sampling period.

3. PROBLEM FORMULATION

Consider the dynamic system

$$\dot{x}(t) = f\left(x(t), u(t)\right) \quad \forall t \in [0, \infty) \tag{5a}$$

$$y_1(t) = C_1 x(t) \qquad \forall t \in [0, \infty) \tag{5b}$$

$$y_2(k\delta) = C_2 x(k\delta) \qquad k = 1, 2, 3, \ldots \tag{5c}$$

where $x \in \mathbb{R}^n$, $u \in \mathbb{R}^m$ and $y_1 \in \mathbb{R}^{q_1}$, $y_2 \in \mathbb{R}^{q_2}$ are the state, input and output vectors for the dynamic system, respectively. The outputs are divided into continuous (y_1), and discrete (y_2) with sampling time δ. For this system it is desirable to design a continuous observer which uses both discrete and continuous measurements, in order to have continuous information about the full vector state. The following assumption is instrumental for the observer design.

Assumption 3. Defining

$$A = \left.\frac{\partial f}{\partial x}\right|_{x=0,u=0} \quad \text{and} \quad B = \left.\frac{\partial f}{\partial u}\right|_{x=0,u=0}$$

as the linear matrices for system (5), it is assumed that the pair (A, C), with

$$C = \begin{pmatrix} C_1 \\ C_2 \end{pmatrix}$$

is observable but, the pairs (A, C_1) and (A, C_2) related with continuous and discrete measurements, are not necessarily completely observable. That is, the observability matrix of these pairs may not have full rank.

In the following section it is presented a continuous observer for system (5), which is the main result of this work.

4. OBSERVER DESIGN

Assume that there is a transformation $T \in \mathbb{R}^{n\times n}$, such that the linear approximation of system (5a)-(5b) becomes

$$\begin{aligned} \dot{z} &= \bar{A}z(t) + \bar{B}u(t) \\ y_1 &= \bar{C}_1 z(t) \end{aligned} \tag{6}$$

where

$$z = Tx = \begin{pmatrix} z_1 \\ z_2 \end{pmatrix}, \quad \bar{A} = TAT^{-1} = \begin{pmatrix} A_{11} & 0 \\ A_{21} & A_{22} \end{pmatrix}$$

$$\bar{B} = TB = \begin{pmatrix} B_1 \\ B_2 \end{pmatrix}, \quad \bar{C}_1 = C_1 T^{-1} = (C_{11}\ 0)$$

$z_1 \in \mathbb{R}^{n_1}$, $z_2 \in \mathbb{R}^{n_2}$, and the pair (A_{11}, C_{11}) is completely observable. In this case a partial observer for z_1 can be designed in such way that given a matrix G_{11}, $(A_{11} - G_{11}C_{11})$ is Hurwitz. Applying the inverse transformation, the proposed observer is,

$$\dot{\zeta}(t) = f\left(\zeta(t), u(t)\right) - G_1\left(C_1\zeta(t) - y_1(t)\right)$$

where

$$G_1 = T^{-1}\begin{pmatrix} G_{11} \\ 0 \end{pmatrix}.$$

This is a partial observer which only make use of continuous measurements (5b), however, using discrete measurements it is possible to design a jump observer as described in section 2, which include both continuous and discrete measurement. The following theorem states this result.

Theorem 4. Consider the system (5), which has a set of continuous measurements (5b) and a set of discrete measurements (5c) with sampling time δ. Furthermore consider that there is a transformation $T \in \mathbb{R}^{n\times n}$ which transforms the linear approximation of system (5a)-(5b) to its observable canonical form (6), while the matrix $G_1 = T^{-1}\left(G_{11}^T\ 0\right)^T$, is calculated in such a way that $(A_{11} - G_{11}C_{11})$ is Hurwitz and the matrix G_2 is such that $(I + G_2C)\, A_d$ is Schur, with $A_d = e^{(A - G_1C_1)\delta}$. Then, an observer for system (5), which takes continuous measurements and is also updated each sampling period is given by

$$\begin{aligned} \dot{\zeta}(t) &= f\left(\zeta(t), u(t)\right) && \forall t \neq k\delta \\ &\quad -G_1\left(C_1\zeta(t) - y_1(t)\right), \end{aligned} \tag{7a}$$

$$\begin{aligned} \zeta\left(k\delta^{+}\right) &= \zeta(k\delta) && t = k\delta, \\ &\quad +G_2\left(C\zeta(k\delta) - y(k\delta)\right), && k = 1, 2, 3, \ldots \end{aligned} \tag{7b}$$

where $\zeta \in \mathbb{R}^n$ are the observer states and $\zeta\left(k\delta^{+}\right)$ are its updated values at each sampling time and

$$y(k\delta) = \begin{pmatrix} y_1(k\delta) \\ y_2(k\delta) \end{pmatrix}.$$

This observer guarantees that, in a neighborhood of the origin, the error between the system and the observer states tends asymptotically to zero, i.e. $\lim_{t\to\infty}[x(t) - \zeta(t)] = 0$.

Proof. First, consider the linear approximations of both, system (5a) and observer (7a)

$$\dot{x}(t) = Ax(t) + Bu(t) \quad \forall t \in [0, \infty) \tag{8}$$

$$\dot{\zeta}(t) = (A - G_1 C_1)\zeta(t) + Bu(t) + G_1 y_1(t) \tag{9}$$

additionally, consider that there is a matrix T that transforms the system (8) and its output (5b) to its observable canonical form (6), i.e.

$$z = Tx = \mathrm{col}(z_1, z_2),$$
$$\xi = T\zeta = \mathrm{col}(\xi_1, \xi_2),$$

where z_1 and ξ_1 are the observable modes of x and ζ. Then for the observable subsystems of z and ξ defining the error $e_1(t) = z_1(t) - \xi_1(t)$, whose dynamic is

$$e_1(t) = (A_{11} - G_{11}C_{11})e_1(t).$$

Since G_{11} is such that $(A_{11} - G_{11}C_{11})$ is Hurwitz, $e_1(t)$ tends asymptotically to zero. On the other hand, using discrete measurements, $y(k\delta)$, a jump observer (7) which allows the updating of the continuous dynamic observer states in every sampling period it is designed, taking advantage of the discrete information. Defining now the error

$$\eta(t) = x(t) - \zeta(t)$$
$$\eta(k\delta^+) = x(k\delta) - \eta(k\delta^+)$$

its linear dynamic approximation around $\eta = 0$ is

$$\dot{\eta}(t) = (A - G_1 C_1)\eta(t) \qquad \forall t \neq k\delta$$
$$\eta(k\delta^+) = (I + G_2 C)\eta(k\delta) \qquad t = k\delta, \quad k = 1, 2, 3, \ldots$$

As described in Lemma 1, these dynamics are stable if the pair (A_d, C) with $A_d = e^{(A - G_1 C_1)\delta}$ is observable and the gain G_2 is such that the matrix $(I + G_2 C)A_d$ is Schur, thereby ensuring that $\lim_{k\to\infty}[x(k\delta) - \zeta(k\delta)] = 0$ and thus $\lim_{t\to\infty}[x(t) - \zeta(t)] = 0$, which proves the theorem.

Observer (7) can be seen as a hybrid observer since incorporates continuous dynamics (7a) and a discrete event (7b) which modifies the continuous part. It should be also noted that the calculation of the observer part for continuous measurements is independent of the discrete observer part, however, the total discrete observer depends on the gain G_1.

5. STUDY CASE

Last years, the environmental laws have been tightened and it has became mandatory treating wastewater from industries as well households (**?**Huntington, 1998). Because of this, the wastewater treatment control processes have received great importance, especially anaerobic processes are being widely considered as an alternative for the treatment of wastewater because it produces smaller quantities of organic matter and also yields a high-energy gas (Méndez-Acosta et al., 2008). To achieve the control of these processes, state observers are frequently used, however for economical reasons some key variables can just be measured using long sampling times, while others may be measured more often. For this reason, a jump observer is proposed as presented in theorem 4.

There exists many dynamic models to describe anaerobic process (**?**Batstone et al., 2002; Bernard et al., 2006). However, to apply the proposed observer, a macroscopic model of the anaerobic process developed and validated by Bernard et al. (2001) it is considered,

$$\dot{X}_1 = (\mu_1(S_1) - \alpha D)X_1 \tag{10a}$$

$$\dot{S}_1 = -k_1\mu_1(S_1)X_1 + (S_{1in} - S_1)D \tag{10b}$$

$$\dot{X}_2 = (\mu_2(S_2) - \alpha D)X_2 \tag{10c}$$

$$\dot{S}_2 = -k_3\mu_2(S_2)X_2 + k_2\mu_1(S_1)X_1 + (S_{2in} - S_2)D \tag{10d}$$

where X_1, X_2, S_1, S_2, are respectively the concentrations of acidogenic bacteria, methanogenic bacteria, Chemical Oxygen Demand (COD) and Volatile Fatty Acids (VFA), D is the dilution rate, defined by the ratio $D = Q/V$, where Q is the feeding flow and V the digester volume, S_{1in} and S_{2in} are respectively the concentrations of influent organic substrate and of influent VFA. The $k_i s$ are pseudo-stoichiometric coefficients associated to the bioreactions. Parameter $\alpha \in (0, 1]$ represents the fraction of the biomass which is not retained in the digester (Hess and Bernard, 2008). The bacterial growth rates $\mu_1(S_1)$ and $\mu_2(S_2)$, are nonlinear functions given respectively by the Monod and Haldane kinetics (Henze and Harremoes, 1983)

$$\mu_1(S_1) = \mu_{\max 1}\frac{S_1}{S_1 + K_{S1}}$$
$$\mu_2(S_2) = \mu_{\max 2}\frac{S_2}{S_2 + K_{S2} + (S_2/K_{I2})^2}$$

where $\mu_{1\max}$, K_{S1}, $\mu_{2\max}$, K_{S2} and K_{I2} are the maximum bacterial growth rate and the half-saturation constant associated to the substrate S_1, the maximum bacterial growth rate in the absence of inhibition, and the saturation and inhibition constants associated to substrate S_2, respectively. The values of parameters and the input concentrations used for simulations are listed in Tables 1 and 2.

If we consider that VFA concentration (S_2) is a continuous measurement while the COD concentration (S_1) can just be periodically acquired (in fact in real operations, VFA concentration can be obtained up to every hour or less (Méndez-Acosta et al., 2008), hence it can be considered continuous compared with the resident time and the COD concentration that could be measured even just once a

Table 1. Model Parameters (Alcaraz-González et al., 2003)

day), the jump observer developed in the previous section can be then applied to the dynamic system (10) writing it in the form

$$\dot{x}(t) = \begin{pmatrix} \mu_1(S_1)X_1 \\ -k_1\mu_1(S_1)X_1 \\ \mu_2(S_2)X_2 \\ -k_3\mu_2(S_2)X_2 + k_2\mu_1(S_1)X_1 \end{pmatrix} + \begin{pmatrix} -\alpha X_1 \\ S_{1in} - S_1 \\ -\alpha X_2 \\ S_{2in} - S_2 \end{pmatrix} u(t) \tag{11}$$

$$y_1(t) = (\,0\;0\;0\;1\,)\,x(t)$$
$$y_2(k\delta) = (\,0\;1\;0\;0\,)\,x(k\delta)$$

where

$$x(t) = \begin{pmatrix} X_1 \\ S_1 \\ X_2 \\ S_2 \end{pmatrix}, \quad C = \begin{pmatrix} C_1 \\ C_2 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \end{pmatrix},$$

and $u\,(t) = D\,(t)$. System (11) can be represented as

$$\dot{x}(t) = f(x) + g(x)u(t). \tag{12}$$

To calculate the jump observer (7) is necessary to linearize the system (12) around a neighborhood of equilibrium points (Hess and Bernard, 2008; Méndez-Acosta et al., 2008) so the system has the form

$$\dot{x}(t) = Ax(t) + Bu(t) + \hat{f}(x,u)$$

where

$$A = \left[\frac{\partial f}{\partial x} + \frac{\partial g}{\partial x}u\right]_{x=0,u=0}, \quad B = g\,(x)|_{x=0}$$

are the linear approximation matrices around the steady state [see (Hess and Bernard, 2008) for a detailed steady state analysis]. In this case, the observability matrices for pairs (A, C_1), (A, C_2) and (A, C) have ranks 4, 2 and 4, respectively, i.e. using S_2 it is possible to estimate the four states, while using S_1 it is just possible to estimate the acidogenic part of the system. This is obvious since system (10) has a cascade dynamic form between acidogenic and methanogenic dynamics.

Considering a sampling time (δ) equal to 1 and parameters listed in Tables 1 and 2, it is easy to verify that A, B and A_d take the values

$$A = \begin{pmatrix} 0 & 0.7900 & 0 & 0 \\ -1.8756 & -5.7825 & 0 & 0 \\ 0 & 0 & 0 & 0.0015 \\ 2.2166 & 6.1622 & -173.6936 & -1.4701 \end{pmatrix},$$

$$B = \begin{pmatrix} -2.7976 \\ 18.4640 \\ -0.1413 \\ 90.0000 \end{pmatrix},$$

$$A_d = \begin{pmatrix} 0.8033 & 0.1145 & 0 & 0 \\ -0.2719 & -0.0349 & 0 & 0 \\ 0.0003 & 0.0008 & 0.9186 & 0.0007 \\ 0.1556 & 0.3069 & -87.2825 & 0.1798 \end{pmatrix},$$

Using LQR techniques to calculate observer gains, observer (7) is designed in order to fulfill theorem 4, obtaining

Table 3. Initial conditions for simulations runs.

5.1 Simulation Results

In order to illustrate the performance of observer (7), some numerical simulations were carried out. Initial conditions and input concentrations for these simulations are listed in Table 3 and 2, while dilution rate was considered as a time varying sinusoidal signal around the nominal value. To verify if the incorporation of the discrete measurement to the continuous observer reduces convergence time, hybrid observer (7) was compared with a continuous observer identical to (7a) without the use of (7b) (or equivalently, for this observer G_2 was settled equal to zero). Figure 1 shows the dynamic behavior of hybrid observer, the discrete actualization is clearly visible in Figure 1a where at time $t = 1$ d there is a jump on the acidogenic biomass estimation. As can be seen, observer states converges after approximately tree days. In contrast, the continuous observer (see Figure 2) converges in approximately twelve days, i.e. four times slower than the hybrid observer. Comparing both observers it easy to see that the hybrid observer obtained a faster convergence rate.

6. CONCLUSIONS

An nonlinear observer which updates the states using continuous and discrete measurements was presented. Despite this is a local observer, since observer gain matrices were calculated using the linear approximation of the original nonlinear system, its application to an anaerobic digestion model presents an excellent performance and stability, obtaining an improvement in convergence rate in comparison with an observer which only uses the continuous information. As future work, the authors are considering to extend this theory to the case where there exists parametric variations in the original plant, as well as the use of these observers to the control of systems with continuous and discrete measurements.

Appendix A. APPENDIX

Proof. [Lemma 1] Let us define

$$\xi(t) = x(t) - z(t), \quad \text{and } \xi\left(k\delta^+\right) = x(k\delta) - z\left(k\delta^+\right),$$

where $\xi(t)$ represents the continuous error and $\xi\left(k\delta^+\right)$ is the updated error for each sampling period. Note that $x\left(k\delta^+\right) = x(k\delta)$ since system (1) is continuous. Now

$$\dot{\xi}(t) = A\xi(t) \qquad \forall t \neq k\delta \tag{A.1}$$

$$\xi\left(k\delta^+\right) = (I + GC)\,\xi(k\delta) \qquad t = k\delta. \tag{A.2}$$

Solving (A.1) for $t \in \left[k\delta^+, (k+1)\,\delta\right]$, it follows that

$$\xi(k+1) = A_d \xi\left(k\delta^+\right), \tag{A.3}$$

where $A_d = e^{A\delta}$. From (A.2) and (A.3) it is obtained

$$\begin{aligned}\xi\left((k+1)\,\delta^+\right) &= (I + GC)\,\xi(k+1)\\ &= (I + GC)\,A_d \xi\left(k\delta^+\right),\end{aligned}$$

and thus, if the pair (A_d, CA_d) is observable, then a matrix G can be calculated such that $A_d + GCA_d$ is Schur and the error $\xi\left(k\delta^+\right)$ will converge to zero, hence $\lim_{k\to\infty}\left[x(k\delta) - z\left(k\delta^+\right)\right] = 0$; then for $k\delta < t \leq (k+1)\,\delta$ the solution $z(t)$ converges to $x(t)$, that is $\lim\limits_{t\to\infty}\left[x(t) - z(t)\right] = 0$. On the other hand, to prove that the pair (A_d, CA_d) is observable if the pair (A_d, C) is observable, consider its observability matrix

$$\mathcal{O} = \begin{pmatrix} CA_d \\ CA_d^2 \\ \vdots \\ CA_d^n \end{pmatrix},$$

where $A_d \in \mathbb{R}^{n\times n}$, then using the Hamilton-Cailey theorem (Kailath, 1980)

$$A_d^n = a_0 I + a_1 A_d + \cdots + a_{n-1} A_d^{n-1},$$

the observability matrix becomes

$$\mathcal{O} = \begin{pmatrix} CA_d \\ CA_d^2 \\ \vdots \\ a_0 C + a_1 CA_d + \cdots + a_{n-1} CA_d^{n-1} \end{pmatrix}.$$

Since A_d is obtained through a discretization of matrix A then $a_0 \neq 0$ and $\mathcal{O}$ has full rank if the pair (A_d, C) is observable.

Soft sensing for two-phase flow using an ensemble Kalman filter

Abstract: A new approach for real-time monitoring of horizontal wells, which is based on data assimilation concepts, is presented. Such methodology can be used when the direct measurement of multiphase flow rates is unfeasible or even unavailable. The real-time estimator proposed is an ensemble Kalman filter employing a dynamic model of the pipe flow and information from several downhole pressure sensors with a single measurement of the flow velocity and composition. By means of simulation examples it is shown that the proposed algorithm operates quite accurately both for noisy synthetic measurements and artificial data generated by the OLGA simulator.

Keywords: Distributed state estimation, Ensemble Kalman filter, Two-phase flow, Inverse dynamic problem

1. INTRODUCTION

The growing demand for hydrocarbon production has resulted into improved oilfield management with various monitoring and optimization strategies (Glandt, 2003, Jansen *et al.*, 2008). These strategies in turn strongly rely on the efficiency of downhole equipment which is used to obtain real-time oil and gas production rates with sufficient spatial and temporal resolution. In particular, multiphase flowmeters installed downhole can improve the production of long horizontal wells by allocating the zones of oil, gas and water inflow. However, existing multiphase meters are expensive, inaccurate or accurate only within a limited operating range and therefore such monitoring is unrealistic.

To overcome these problems one can use so-called multiphase soft-sensors, i.e. to estimate flow rates from conventional meters, such as downhole pressure gauges, in combination with a dynamic multiphase flow model. Despite the variety of soft-sensing techniques (which are also referred to as data assimilation methods), one can note two principal approaches. Variational data assimilation, which is based on the minimization of a cost function within a certain time interval, and sequential methods or filtering when the state of the system is updated every time instant data becomes available. One way to solve these sequential data assimilation problems is to use Kalman filtering (Kalman, 1960). This method, which was originally developed for linear models, has got numerous extensions (Jazwinski, 1970, Evensen, 1994 and Julier *et al.*, 2000) to deal with non-linearity, which is the case for most industrial processes.

Although there are numerous applications of soft-sensing techniques in oil and gas industry, they mainly deal with the estimation of reservoir properties (Naevdal *et al.*, 2003, Evensen *et al.*, 2007). The range of wellbore flow application includes gas-lift wells (Bloemen *et al.*, 2004) and underbalanced drilling (Lorentzen *et al.*, 2001). Also, the Kalman filter has been used for tuning the parameters of two phase flow models (Lorentzen *et al.*, 2003). Leskens *et al.* (2008) considered the simultaneous estimation of downhole oil, water and gas flow rates from downhole pressure and temperature measurements in a single well. This approach has been extended by de Kruif *et al.* (2008) to the multi-lateral well case both for the two-phase (oil and gas) and three-phase (oil, gas and water) cases.

Despite the variety of applications considered, little attention has been given to the inflow allocation problem. More specific, long horizontal wells with a continuous inflow profile from a reservoir to a wellbore require the use of soft-sensing techniques for the gas breakthrough prediction.

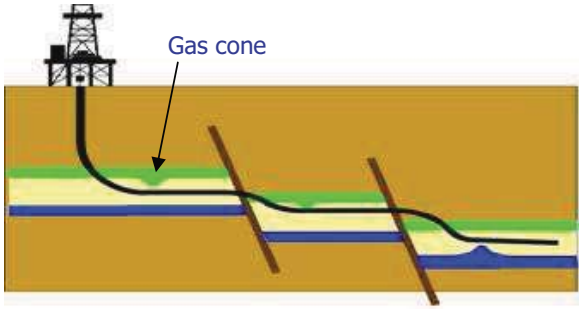

Fig. 1. Schematic view of a horizontal well.

Gas coning is a phenomenon where the gas-oil contact of a reservoir moves towards a producing well (see Figure 1). At a certain moment the gas-oil contact will reach the well and gas breakthrough can happen causing a large gas influx. Consequently, the gas phase may start to dominate production making the well uneconomical. In order to handle or prevent this, several strategies are available. However, the most convenient countermeasure is to isolate gas producing

zones of a wellbore by means of inflow control valves. The purpose of a soft-sensor is to provide the inflow control valves with information of the downhole flow rate distribution.

This study discusses the feasibility of such multiphase soft-sensors. In particular, the required and sufficient set of measurements is defined. Furthermore, the influence of model error and measurement noise on the quality of estimates is studied.

This paper is organized as follows. First, the pipe flow model and the computational setup for soft-sensing are given. Next, the description of the used soft-sensing algorithm is presented. Finally, the simulations results are given.

2. DYNAMIC FLOW MODEL

A model describing one-dimensional two-phase flow in pipes consists of non-linear partial differential equations describing mass and momentum conservation for each phase. This model is obtained from cross-sectional averaging of the Navier-Stokes equations and replacing diffusion terms by empirical correlations. Since the main purpose of this work is the application of estimation techniques, no detailed flow description is required. Therefore, it was assumed that the gas and liquid are travelling with the same velocity u (Vicente, *et al.*, 2001).

The simplified mass conservation equations are

$$\frac{\partial}{\partial t}(\rho_l H) + \frac{\partial}{\partial s}(\rho_l H u) = \Phi_l \tag{1}$$

$$\frac{\partial}{\partial t}(\rho_g (1-H)) + \frac{\partial}{\partial s}(\rho_g (1-H) u) = \Phi_g \tag{2}$$

Where H is the liquid volume fraction, ρ_g is the gas density, ρ_l is the liquid density, t denotes time and s denotes the coordinate along the length of the pipe. Φ_l and Φ_g are the mass sources representing the inflow from a reservoir to the pipe. These sources are normally time dependent.

Although the continuity equations have been written for each phase it is common to write the momentum equation for the mixture.

$$\frac{\partial}{\partial t}(\rho_m u) + \frac{\partial}{\partial s}(\rho_m u^2) = -\frac{\partial p}{\partial s} - S_{fr} \tag{3}$$

Where ρ_m is the mixture density defined by

$$\rho_m = \rho_g (1-H) + \rho_l H \tag{4}$$

A frequently used model for frictional losses in the momentum equation has the form

$$S_{fr} = \frac{\lambda}{2d} \rho_m u^2 \tag{5}$$

Here d is the pipe diameter and λ is the friction factor, which is a function of the Reynolds number and pipe roughness k. In this study the Techo formula is used:

$$\lambda = \left[-0.8685 \ln\left(\frac{1.964 \ln(\mathrm{Re}) - 3.8215}{\mathrm{Re}} + \frac{k}{d \cdot 3.71} \right) \right]^{-2} \tag{6}$$

Here Re is the Reynolds number defined as

$$\mathrm{Re} = u d \rho_m / \mu_m \tag{7}$$

with the mixture viscosity μ_m calculated in terms of liquid volume fraction and gas μ_g and liquid μ_l viscosities

$$\mu_m = \mu_g (1-H) + \mu_l H \tag{8}$$

The gas is treated as a compressible phase with a corresponding equation of state given in the form

$$\rho_g = f(p) \tag{9}$$

The closure of the problem is given by the following boundary conditions.

$$p(s=L,t) = p_{out}, \; p(s,t=0) = p_{out} \tag{10}$$

$$u(s=0,t) = u_{\inf}, \; u(s,t=0) = u_{\inf} \tag{11}$$

$$H(s=0,t) = H_{\inf}, \; H(s,t=0) = H_{\inf} \tag{12}$$

Here the subscripts *inf* and *out* refer to inflow and outflow cross-section of the pipe respectively. L denotes the length of the pipe.

3. DATA ASSIMILATION

3.1 State-space form of the model equations

Due to the nonlinearity of the given equation system (1)-(12) the numerical solution is needed in order to solve it for the dependent variables. For the discretization of the simulation domain a staggered grid approach has been used, meaning that the different grids are used for the continuity and momentum equation. Afterwards, the governing equations are integrated over different control volumes. Any solution procedure can be applied for solving the non-linear system of algebraic equations. Finally, the model can be written in the following state-space notation (Crassidis, 2004):

$$x_k = f(x_{k-1}, u_{k-1}) \tag{13}$$

Here u_{k-1} is the model input representing the inflow from reservoir to wellbore. x_{k-1} is the state vector evaluated on the previous time step. Using the primitive set of variables, the state vector can be written as

$$x = [\, p \; u \; H \,]^T \tag{14}$$

Here p, u and H are the vectors, representing pressure, velocity and liquid volume fraction related to the spatial grid.

3.2 Formulation of the inverse problem

The computational setup for the inverse problem is shown in Figure 2. It should be noted here, that only the horizontal part of the well is being modelled, and the outflow measurements are assumed to be available directly at the outflow cross-section of the horizontal part.

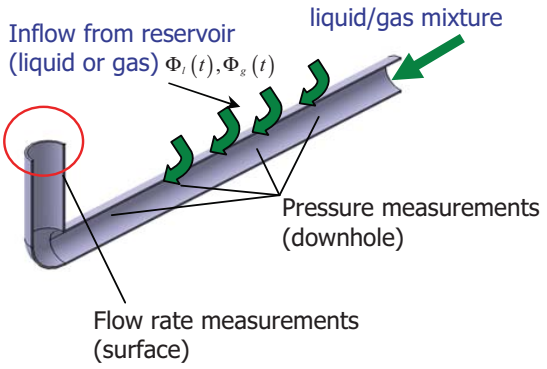

Fig. 2. Scheme of the computational setup for soft-sensing.

For the soft sensing purposes the augmented state vector is introduced:

$$X = \left[p_i \; u_i \; H_i \left| \Phi_{g\,i} \; \Phi_{l\,i} \right. \right]^T \tag{15}$$

Here i indicates the number of the cell defined by the numerical discretization.

It is assumed that several downhole pressure measurements are available. Moreover, outflow information about flow rates is also known, giving the following measurement vector:

$$y = \left[p_i \; u_{out} \; H_{out} \right]^T \tag{16}$$

Finally, the data assimilation problem can be formulated as follows: with the measurements (16) and the flow model (1)-(12) available the components of the augmented state vector should be estimated.

Due to a lack of experimental data, a set of synthetic measurements has been used as a source for soft-sensing. First, a twin experiment concept has been implemented. Here the same mathematical model was used both for generating measurements with predefined inflow distribution and the inverse modelling, when missing dynamic variables are estimated by means of the soft-sensing algorithm. In order to mimic the situation of testing the soft-sensor with "real-life" data, simulation results from the commercially available flow simulator OLGA were used in the second test case.

3.3 Ensemble Kalman filtering

One way to solve estimation problems via the sequential data assimilation algorithm is by using the Kalman filter equations. The Kalman filter is a stochastic recursive estimator, which estimates the values of model states and unknown input by integrating measured data in a mathematical model in real-time. Due to its straightforward numerical implementation and recursive nature, the Kalman filter algorithm is very well adapted to online model calibration.

Kalman filtering was initially developed for linear dynamic systems. Although several extensions of the Kalman filter exist for non-linear system, here the ensemble Kalman filter (EnKF) is used (Evensen, 1994). In this approach, the approximation of the error covariance matrix is calculated using an ensemble of possible model realizations, which are propagated according to the full dynamics of the system.

In order to initialize the filter the initial ensemble is generated. Here a mean value of the initial augmented state vector $\overline{X}_0^a$ and a corresponding covariance matrix Q_o is required. The mean value of the initial ensemble should be a good estimate of the true initial state. The members of the ensemble are generated randomly according to a Gaussian distribution. The j'th member of the ensemble is defined as

$$X_{0,j}^a = \overline{X}_0^a + w_{0,j} \tag{17}$$

With an EnKF the augmented state vector, which also contains the inflow input, is estimated in a recursive manner through the following two steps:

1) The forecast step, which consists in running the flow model one time step forward for each member of the ensemble. This leads to

$$X_{k,j}^f = f\left(X_{k-1,j}^a \right) + w_{k,j} \tag{18}$$

Here $w_{k,j}$ is a Gaussian zero mean white noise with the corresponding covariance matrix Q_k representing the model error. This noise is only added to components of the state vector, which produce the most uncertainty in a simulation. These are in this case the inflow sources Φ_l and Φ_g.

Using the calculated forecast of ensemble states, the error covariance matrix can be calculated using the covariance matrix of the ensemble. The mean value of the ensemble is given by

$$\overline{X}_k^f = \frac{1}{N} \sum_{j=1}^{N} X_{k,j}^f \tag{19}$$

And the error covariance matrix is then calculated as

$$P_k^f = L_k^f (L_k^f)^T \tag{20}$$

With

$$L_k^f = \frac{1}{\sqrt{N-1}} [(X_{k,1}^f - \overline{X}_k^f) \; (X_{k,2}^f - \overline{X}_k^f) ... (X_{k,N}^f - \overline{X}_k^f)] \tag{21}$$

where N is the number of members in the ensemble.

2) The analysis step, which takes into account measurements. The errors in the measurements are assumed to be statistically independent with known variances. This leads to a diagonal covariance matrix for the measurement errors. As it has been pointed out in Burgers *et al.* (1998), it is necessary to define new measurements for the proper error propagation. Therefore, a new observation vector is introduced for each member of the ensemble

$$y_{k,j} = M_k \cdot X_{k,j} + v_{k,j} \tag{22}$$

Here M_k is the measurement matrix and $v_{k,j}$ is the measurement noise generated from a normal distribution with zero mean and covariance matrix R_k.

The Kalman gain is then calculated as follows

$$K_k = P_k^f M_k^T (M_k P_k^f M_k^T + R_k)^{-1} \quad (23)$$

The analyzed state for each member of the ensemble is given by

$$X_{k,j}^a = X_{k,j}^f + K_k (y_{k,j} - M_k X_{k,j}^f) \quad (24)$$

The mean value of the analyzed ensemble is

$$\overline{X}_k^a = \frac{1}{N} \sum_{j=1}^{N} X_{k,j}^a \quad (25)$$

The unknown inflow sources are updated at each time step measurements are available and extracted from the augmented state vector. The analyzed error covariance matrix, from which the estimation error of the inflow parameters can be defined, is then approximated by

$$P_k^a = (I - K_k M_k) P_k^f \quad (26)$$

An important issue with the use of the EnKF is the size of the ensemble. Based on the experience of data assimilation for large-scale atmospheric models (Houtekamer and Mitchell, 1998), 100 ensemble members have been chosen for the ensemble Kalman filtering. The optimal size of the ensemble is, however, not known and it is a subject for future research.

4. RESULTS AND DISCUSSIONS

4.1 Soft sensing under measurement error

A first test case considered uses a twin experiment concept. Here the same mathematical model is used for generating the measurements with predefined inflow distribution. This study deals with two-phase liquid/gas flow and the details of the initial data are given in Table 1. The sketch of the simulation domain is given in Figure 3. The inflow profiles are given only as a reference since they are unknown and have to be estimated via the proposed data assimilation procedure.

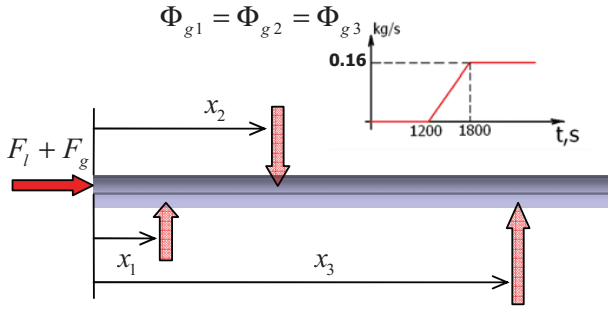

Fig. 3. Computational setup for soft-sensing.

Initially the well produces a mixture of liquid and gas with a total flow rate of 10 kg/s. After 20 minutes of production, gas is injected in three locations of the wellbore. The amount of gas injected increases linearly up to 0.5 kg/s during next 30 minutes and afterwards kept constant for the last 10 minutes of simulation.

The soft-sensor has been tested using the following measurement layout. The number of pressure measurements was taken equal to number of grid nodes obtained from the discretization. The velocity and liquid volume fraction measurements are located at the last grid block of the simulation domain.

Table 1. Initial data for the numerical experiments

Quantity	Value
Pipe diameter, m	0.05
Pipe length, m	100
Liquid density, kg/m^3	1000
Liquid viscosity, Pa·s	0.001
Gas reference density, kg/m^3	118.9
Gas viscosity, Pa·s	$1.82 \cdot 10^{-5}$
Time step, s	60
Inflow liquid rate F_l, kg/s	9.5
Inflow gas rate F_g, kg/s	0.5
x_1, m	15
x_2, m	45
x_3, m	75
Absolute roughness, m	0
Number of grid nodes	12

The Kalman filter initialization is based here on the outflow values of velocity and liquid volume fraction, which are assumed to be known from a flow meter. Since all the pressure measurements are available, pressure is initialized from the current pressure distribution. The synthetic measurements representing downhole pressure and liquid outflow flow rate are generated using equations (1)-(12). A zero mean white Gaussian noise is then added to mimic the uncertainty in measurements.

Table 2. Measurement noise used in simulations

Uncertainty in pressure measurements	0.5%
Uncertainty in outflow velocity measurements	1%
Uncertainty in liquid volume fraction measurements	1%

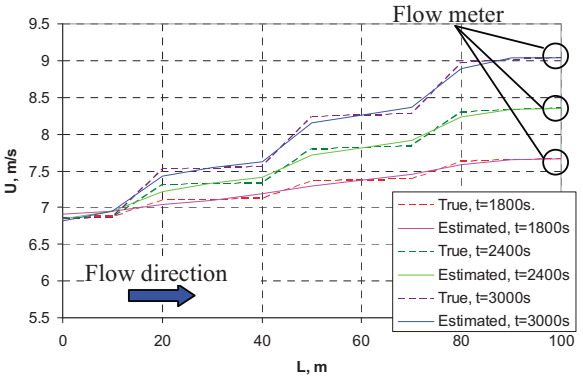

Fig. 4. Comparison of estimated and true flow velocity.

The results of the simulation are given in Figures 4-5. Figure 4 shows the comparison between the estimated and true velocity distributions along the pipe length. Flow velocity is used to allocate the zones where a fluid is entering or leaving the wellbore. In order to identify the type of fluid, the distribution of the estimated liquid volume fraction is required. It is depicted in Figure 5. The results are given for three time instants 30 minutes, 40 minutes and 50 minutes. Since the pressure is available continuously from the measurements it is not depicted as a soft-sensing result.

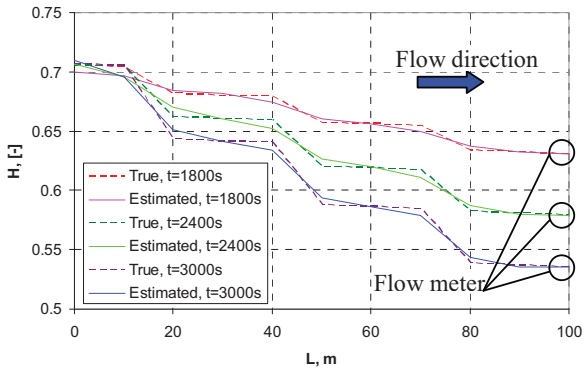

Fig. 5. Comparison of estimated and true liquid fraction.

The results show that the proposed soft-sensor, for the given simplified setup, is very well capable of reproducing the flow rate and liquid volume fraction distributions along the considered well part, even when measured data contains a certain measurement error. Therefore, it is capable to detect multiple fluid sources as it is depicted in the figures.

4.2 Soft sensing under model error

The second study provides an assessment of the influence of the model error on the soft-sensing estimation results. A similar soft-sensing setup was used as depicted in Figure 2 for case study 1. An important difference, however, was that the "true" well was not the same as the model used in the soft-sensor. The true wellbore measurements were obtained from the commercially available simulator OLGA. This was done to assess the inevitable effect of the model error on the soft-sensing estimation results. Here both transient gas and liquid sources are present in a computational setup. Liquid is injected in the first part of the pipe, while a gas source is present close to its outflow cross-section. This situation is a rough approximation of the gas breakthrough scenario. The scheme of the simulation domain is given in Figure 6.

Due to differences between the flow model used in OLGA simulator and the soft-sensor developed, one can point at the following sources of the model error:

- Friction factor correlation

- Fluid properties

- Simulation grid

- Mathematical model

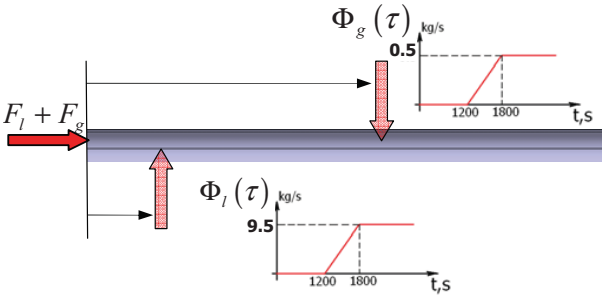

Fig. 6. Computational setup for soft-sensing. Test case 2.

A particularly important modelling assumption for performing OLGA simulations was to keep a dispersed bubble flow regime, since the model used for soft-sensing is valid only for that type of multiphase flow. This was possible using the same set of input parameters, as for the test case 1. The OLGA simulations were performed with 10 grid nodes, where the source term for liquid has been defined in the third grid block, and for gas in the eighth grid block. This consequently led to a soft-sensing setup with 10 available pressure measurements.

Figures 7 and 8 represent the estimated flow velocity and liquid volume fraction.

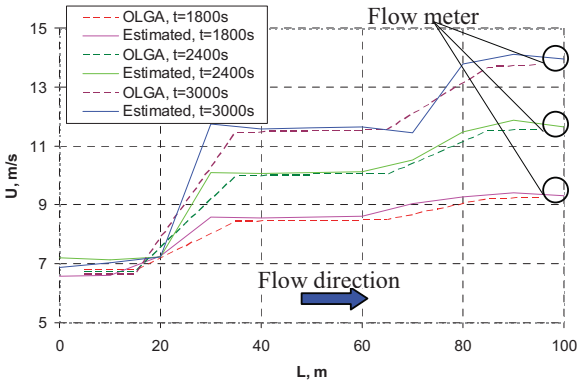

Fig. 7. Estimated velocity profile for the OLGA data.

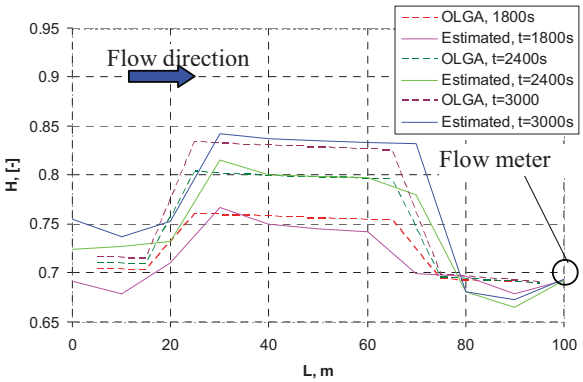

Fig. 8. Estimated liquid fraction profile for the OLGA data.

The results obtained under model error are not as accurate as for the twin-experiment. However, it is still possible to allocate easily zones of liquid or gas inflow. A displacement of the estimated profiles with respect to the true ones is observed. This can be explained by the use of a different grid in the OLGA simulator and different interpolation of the flow variables between grid nodes and edges.

5. SUMMARY AND CONCLUSIONS

By means of two case studies, some limitations and possibilities of soft-sensor multiphase flow meters have been studied. The proposed soft-sensor is based on the ensemble Kalman filter approach and requires as the input the dynamic model of the pipe flow together with pressure measurements available downhole and one composition and velocity measurement at the outflow.

It has been shown, that for a two-phase flow formulation it is possible to reconstruct the distributions of the flow velocity and liquid volume fraction along a pipe and to allocate the inflow of certain fluids in a specific location along it.

The results indicate that the proposed method is quite stable for a certain range of wellbore operational conditions, and capable of taking into account measurement and model error.

6. ACKNOWLEDGEMENTS

This work has been supported by ISAPP knowledge center, which is a joint research project of Shell, TNO and Delft University of Technology. The authors would also like to thank Wouter Schiferli (TNO Science and Industry) for performing the OLGA runs.

Abstract: In this paper, a moving horizon state and parameter estimation (MHE) scheme for the Varicol process is presented. The Varicol process is an extension of the Simulated Moving Bed (SMB) process that realizes non-integer column distributions over the separation zones by an asynchronous switching of the inlet and outlet ports (the ports are shifted individually). These additional degrees of freedom can be used to yield an improvement in economical performance compared to SMB operation. The proposed estimation scheme is based on a rigorous SMB model that incorporates rigorous chromatographic columns and port switching. The absence of model simplifications allows the extension of the estimation scheme to the more complex Varicol process. The goal of the estimation scheme is to reconstruct the full state of the system, i.e. the concentration profiles along all columns, and to identify critical model parameters in the presence of noisy measurements. The estimation is based on measurements of the concentrations of the components at the two outlet ports (which are asynchronously switched from one column to the next) and at one fixed location between two columns. The state estimation scheme utilizes a deterministic model within the prediction horizon. State noise is only considered in the state and in the parameters up to the beginning of the horizon. By applying a multiple-shooting method and a real-time iteration scheme for solving the resulting optimization problem, the computation times are reduced and the scheme can be applied online. A numerical simulation for an enantiomer separation system with nonlinear adsorption isotherm is presented.

Keywords: Varicol, Simulated Moving Bed chromatography, moving horizon estimation, state estimation, model identification, real-time application, real-time iteration

1. INTRODUCTION

The Simulated Moving Bed (SMB) process is an efficient chromatographic separation technology that is increasingly applied in the food, fine chemicals, and pharmaceutical industries. Industrial applications have been reported especially for the separation of temperature sensitive components and for the separation of species with similar thermodynamic properties. A SMB process is realized by connecting several chromatographic columns in a closed loop as illustrated by Figure 1. The Varicol process switches the ports indvidually and thereby realizes non-integer column distributions over the zones **?**), see Figure 2.

SMB processes and their variants are characterized by mixed discrete and continuous dynamics, spatially distributed state variables with steep slopes, and slow and strongly nonlinear responses of the concentrations profiles to changes of the operating parameters, therefore, they are difficult to control and to observe. In the literature, relatively few contributions that deal with state estimation of SMB processes can be found. The published work is based upon the approximation of the concentration profiles by a set of truncated exponential functions Alamir and Corriou (2003), or by using the equivalent True Moving Bed (TMB) model Mangold et al. (1994), Kloppenburg and Gilles (1999), or deals with the engineering of tailored estimation schemes Küpper and Engell (2006), Kleinert and Lunze (2005). Recently, a rigorous moving horizon estimation approach for SMB processes was proposed by Küpper et al. (2009). In this formulation of the MHE, a deterministic behaviour of the process on the estimation horizon and Gaussian independent identically distributed measurement noise are assumed. The initial state at the beginning of the horizon and its covariance are computed by an Extended Kalman Filter (EKF). The state noise covariance and the initial error covariance of this EKF are the only tuning parameters of this scheme. A fast online solution of the underlying constrained least-squares optimization problem is obtained by using the direct multiple shooting method Bock (1981, 1987). A full rigorous process

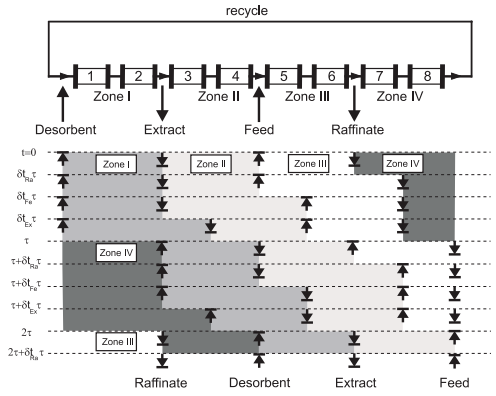

Fig. 2. Asynchronous switching in the Varicol process

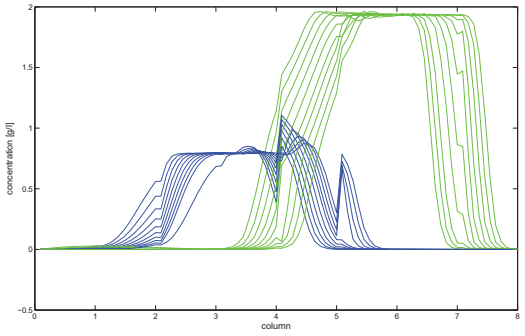

Fig. 3. Concentration profiles of the Varicol process during one period with $\delta\tau_{Ra} = 0.3$, $\delta\tau_{Fe} = 0.6$, $\delta\tau_{Ex} = 0.9$, $\delta\tau_{De} = 1.0$, $\delta\tau_{Re} = 1.0$

model is applied and therefore no assumption that the plant is close to the periodic steady state is needed. Along with the states, key adsorption parameters are estimated online. Simulations demonstrate that the states and critical model parameters can be reconstructed successfully. The scheme also works during transition periods including the start-up phase. The computation times are such that the estimator can be applied online. Since a rigorous full scale SMB model is used, the MHE approach can be extended to more complex variants of the SMB process. In this contribution, the moving horizon state and parameter estimation scheme is applied to the Varicol operation.

2. THE VARICOL SMB PROCESS

Chromatographic separation is based on the different adsorption affinities of the molecules in the liquid to an adsorbent which is packed in a chromatographic solid bed. The SMB process realizes a counter-current movement between the liquid and the adsorbent by switching the ports in the direction of the liquid flow periodically, as illustrated by Figure 1. In the Varicol process, the individual ports i (Eluent, Extract, Feed, Raffinate) are switched individually at the subperiod times δt_i, as illustrated by Figure 2. The individual port switching reduces the impurities by early switching of the Raffinate port and delayed switching of the Extract port. Since the Varicol process offers a larger number of degrees of freedom, it can be operated with better process economics than the SMB process, see Toumi et al. (2002), Toumi et al. (2003).

In the estimation scheme, the counter-current flow of the solid and of the liquid phases is modelled in the same way as it is achieved in the real plant by asynchronously switching the inlet and outlet ports in the direction of the liquid flow after subperiod n with subperiod length $(\delta t_n - \delta t_{n-1})\tau$ has passed. The state variables represent the concentrations in the physical columns and do not exhibit jumps. Only the input flow rates and the inflow concentrations change discontinuously. The dynamic simulation of the Varicol process is achieved by integrating the differential equation over the subperiods n

$$\dot{\mathbf{x}} = f(\mathbf{x}, Q_n, \mathbf{p}) \qquad (1)$$
$$t \in [(m-1)\tau + \delta t_{n-1}\tau,\ (m-1)\tau + \delta t_n \tau]$$
$$\mathbf{x}(t_0) = \mathbf{x}_{m,0} \qquad (2)$$

followed by the switching of the flows $Q_{n,j,\delta t_j}$:

$$Q_{n+1,j,\delta t_j} = M_Q Q_{n,j,\delta t_j} \quad j = \mathrm{De}, \mathrm{Ex}, \mathrm{Fe}, \mathrm{Ra}, \mathrm{Re}, \qquad (3)$$

with differential states $\mathbf{x}(t) \in \mathbb{R}^{n_x}$ and parameters $\mathbf{p} \in \mathbb{R}^{n_p}$. The vector $Q_{n,j,\delta t_j}$ defines the inlet/outlet flow of port j (desorbent, extract, feed, raffinate) and the recycle stream at the individual switching time δt_j in period m (m denotes the full period count). The components of $Q_{n,j}$ represent the flows of the ports j to the columns. M_Q is a permutation matrix that shifts the flow ports after the asynchronous switching time δt_j of port j has passed (with individual period counter n). The recycle flow that defines the total flow rate in the zone in front of the desorbent port is switched with the last port. The zone flow rates result from the port flows and the recycle flow. The concentration profiles during one switching period are illustrated by Figure 3. The asynchronous switching of the feed port and of the extract port can be clearly seen in the profiles. In this paper, three positions where the concentrations of the two substances of the mixture are measured are assumed. The measurements are installed behind the extract port, behind the raffinate port, and behind one column in the process where physically the closing of the loop is realized (six measurements total). The extract and raffinate concentration measurements

move together with the ports. More measurements are not available in production plants.

2.1 Rigorous Dynamic Modelling

From mass balances of the components around the inlet and the outlet ports, the internal flow rates and the inlet concentrations can be calculated according to:

$$\text{Desorbent node: } Q_{\mathrm{IV}} + Q_{\mathrm{De}} = Q_{\mathrm{I}} \tag{4}$$

$$c_{i,\mathrm{out,IV}} Q_{\mathrm{IV}} = c_{i,\mathrm{in,I}} Q_{\mathrm{I}} \quad i = \mathrm{A}, \mathrm{B} \tag{5}$$

$$\text{Extract node: } Q_{\mathrm{I}} - Q_{\mathrm{Ex}} = Q_{\mathrm{II}} \tag{6}$$

$$\text{Feed node: } Q_{\mathrm{II}} + Q_{\mathrm{Fe}} = Q_{\mathrm{III}} \quad i = \mathrm{A}, \mathrm{B} \tag{7}$$

$$c_{i,\mathrm{out,II}} Q_{\mathrm{II}} + C_{i,\mathrm{Fe}} Q_{\mathrm{Fe}} = c_{i,\mathrm{in,III}} Q_{\mathrm{III}} \tag{8}$$

$$\text{Raffinate node: } Q_{\mathrm{Ra}} + Q_{\mathrm{IV}} = Q_{\mathrm{III}}, \tag{9}$$

where $Q_{\mathrm{I-IV}}$ are the flow rates in the corresponding zones, Q_{De}, Q_{Ex}, Q_{Fe}, and Q_{Ra} denote the external flow rates and $c_{i,\mathrm{in}}$ and $c_{i,\mathrm{out}}$ denote the concentrations of the component i in the streams leaving and entering the respective zone. The initial distribution of the columns over the four separation zones is 2/2/2/2 and the individual switching times are $\delta\tau_{Ra} = 0.3$, $\delta\tau_{Fe} = 0.6$, $\delta\tau_{Ex} = 0.9$, $\delta\tau_{De} = 1.0$, $\delta\tau_{Re} = 1.0$ from which the non-integer column distribution 2.1/2.3/2.3/1.3 results.

The chromatographic columns are modelled by the General Rate Model. It is assumed that there are no radial gradients in the column and that the particles of the solid phase are uniform, spherical, porous (with a constant particle porosity ϵ_{p}), and that the mass transfer between the particle and the surrounding layer of the bulk is in local equilibrium. The concentration of component i is denoted by c_i in the liquid phase and by q_i in the solid phase. D_{ax} is the axial dispersion coefficient, u the interstitial velocity, ϵ_{b} the void fraction of the bulk phase, $k_{\mathrm{l},i}$ the film mass transfer resistance, and D_{p} the diffusion coefficient within the particle pores. The concentration within the pores is denoted by $c_{\mathrm{p},i}$. The following partial differential equations of a column can be derived from a mass balance around an infinitely small cross section area of the column assuming a constant radial distribution of the interstitial velocity u and the concentration c_i.

$$\frac{\partial c_i}{\partial t} + \frac{(1-\epsilon_{\mathrm{b}}) 3 k_{\mathrm{l},i}}{\epsilon_{\mathrm{b}} r_{\mathrm{p}}} \left(c_i - c_{\mathrm{p},i}|_{r=r_{\mathrm{p}}}\right) = D_{\mathrm{ax}} \frac{\partial^2 c_i}{\partial x^2} - u \frac{\partial c_i}{\partial x} \tag{10}$$

$$(1-\epsilon_{\mathrm{p}}) \frac{\partial q_i}{\partial t} + \epsilon_{\mathrm{p}} \frac{\partial c_{\mathrm{p},i}}{\partial t} - \epsilon_{\mathrm{p}} D_{\mathrm{p}} \left[\frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial c_{\mathrm{p},i}}{\partial r}\right)\right] = 0, \tag{11}$$

with appropriate initial and boundary conditions. It is assumed that the concentration q_i is in thermodynamic equilibrium with the liquid concentrations in the particle and their relationship can be described by an extended Langmuir adsorption isotherm

$$q_i = H_i^1 c_{\mathrm{p},i} + \frac{H_i^2 c_{\mathrm{p},i}}{1 + k_{\mathrm{A}} c_{\mathrm{p,A}} + k_{\mathrm{B}} c_{\mathrm{p,B}}} \quad i = \mathrm{A}, \mathrm{B}, \tag{12}$$

with H_i^j and k_i as isotherm constants. The resulting system of coupled differential equations can be efficiently solved by the numerical approach proposed in Gu (1995) where a Galerkin finite element discretization of the bulk phase is combined with orthogonal collocation for the solid phase. This numerical method was first applied to SMB processes in Dünnebier and Klatt (2000). The bulk phase is divided into n_{fe} finite elements and the solid phase is discretized by n_{c} internal collocation points. As a result, the set of initial values, boundary values, and partial differential equations (PDE) is transformed into a set of initial values and a system of ordinary differential equations (ODE)

$$\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{u}, \mathbf{p}), \tag{13}$$

where the flows Q are summarized in the input vector $\mathbf{u}(t) \in \mathbb{R}^{n_u}$. The system output is defined as

$$y = h(\mathbf{x}(\mathbf{u}, \mathbf{p})), \tag{14}$$

with $y \in \mathbb{R}^{n_y}$. For $n_{\mathrm{fe}} = 5$, $n_{\mathrm{c}} = 1$, number of components $n_{\mathrm{sp}} = 2$, and number of columns $n_{\mathrm{col}} = 8$ a system order of the SMB process of

$$n_x = n_{\mathrm{col}} * n_{\mathrm{sp}} * (n_{\mathrm{c}} + 1) * (2 * n_{\mathrm{fe}} + 1) = 352 \tag{15}$$

results. The ODE-system is stiff due to large differences in the speeds of the interacting dynamics.

3. ESTIMATION IN THE VARICOL PROCESS

3.1 Moving Horizon Estimation

For the simultaneous estimation of the states and the parameters of SMB processes, we employ the Moving Horizon Estimation scheme introduced by Diehl et al. (2006); Kühl et al. (2008), which is modified in order to handle the shift of the inputs and of the measurements of the SMB process. The Moving Horizon Estimator estimates the states and the parameters based on the past measurements at specific time points that are located in the horizon $T_N = t_K - t_L$. t_K represents the current time and t_L is the time at the beginning of the horizon. A least-squares minimization is performed that minimizes the deviations of the real measurements η_k from the simulated measurements $h(\mathbf{x}(t_k; \mathbf{u}, \mathbf{p}))$ at times t_k. The expression $||.||^2_{V^{-\frac{1}{2}}}$ denotes $||\mathbf{x}||^2_{V^{-\frac{1}{2}}} = \mathbf{x}^T V^{-1} \mathbf{x}$, where the matrix V is the positive semidefinite noise covariance matrix of the variables $\mathbf{x}$. $V^{-\frac{1}{2}}$ can be interpreted as weighting matrix of $\mathbf{x}$. The measurement information prior to the moving horizon is considered in the estimation problem by an arrival cost term that is computed from the expected value of the state and the parameters and the estimation error covariance before the horizon. The optimization problem of the MHE results as:

$$\min_{\mathbf{x}(t_L), p} \left\{ \left\| \begin{matrix} \mathbf{x}(t_L) - \overline{\mathbf{x}}_L \\ \mathbf{p} - \overline{\mathbf{p}}_L \end{matrix} \right\|^2_{P_L^{-\frac{1}{2}}} + \sum_{k=L}^{K} \|\eta_k - h(\mathbf{x}(t_k; \mathbf{u}, \mathbf{p}))\|^2_{V_k^{-\frac{1}{2}}} \right\} \tag{16}$$

$$s.t. \quad \dot{\mathbf{x}}(t) = f(\mathbf{x}(t), \mathbf{u}(t), \mathbf{p}) \tag{17}$$

$$\mathbf{x}_{min} \leq \mathbf{x}(t) \leq \mathbf{x}_{max} \tag{18}$$

$$\mathbf{p}_{min} \leq \mathbf{p} \leq \mathbf{p}_{max} \tag{19}$$

$$t \in [t_L, t_K]\,. \tag{20}$$

The second term represents the prediction errors within the horizon and the first term represents the arrival cost (the penalization of a change of the estimates of the initial values of the states and of the parameters), where $(\overline{\mathbf{x}}_L, \overline{\mathbf{p}}_L)$ are the expected values and $P_L \in \mathbb{R}^{(n_x+n_p)\times(n_x+n_p)}$ is the joint covariance matrix of $\mathbf{x}(t_L)$ and $\mathbf{p}_L$. Note that only the initial values of the states and the parameters are free parameters of the optimization problem because no state

noise is assumed within the horizon. The absence of state noise on the horizon is compensated by the simultaneous estimation of key model parameters which is an appropriate assumption since uncertainties are mostly due to model errors and not to disturbances. Furthermore, the inclusion of state noise at each point within the horizon would lead to a large number of degrees of freedom of the estimation and result in a considerably larger optimisation problem with additional $n_x \times (K - L)$ variables that, taking the system dimension into account, would be hard to solve online reliably. From the solution $\mathbf{x}(t_L)$ and $\mathbf{p}$ of the optimization problem, the deterministic model is simulated forward to obtain the current estimated state $\mathbf{x}_K$. The MHE takes upper and lower bounds on the states and on the parameters into account. The expected value and the covariance of $\mathbf{x}(t_L)$ and $\mathbf{p}_L$ in the arrival cost are determined by an Extended Kalman Filter. The smoothed Extended Kalman Filter Robertson et al. (1996) is employed where the recent state estimation $x_{L+1|K}$ and linearizations of the dynamics $G_{L+1|K}$ and the output matrix $C_{L+1|K}$ are utilized. In order to guarantee positive definite matrices in the presence of numerical errors, the smoothed Extended Kalman update is reformulated by two QR-decompositions yielding the equivalent smoothed Extended Kalman Filtering update in square-root formulation Diehl (2002); Kühl et al. (2008).

$$\begin{pmatrix} \overline{\mathbf{x}}_{L+1} \\ \overline{\mathbf{p}}_{L+1} \end{pmatrix} = \begin{pmatrix} \mathbf{x}(t_{L+1}; t_L, \mathbf{x}_{L|K}, \mathbf{u}_L, \mathbf{p}_{L|K}) \\ \mathbf{p}_{L|K} \end{pmatrix} + G_{L|K} R^{-1} Q^T \begin{pmatrix} P_{L|L-1}^{-\frac{1}{2}} \begin{pmatrix} \mathbf{x}_{L|L} - \mathbf{x}_{L|K} \\ \mathbf{p}_{L|L} - \mathbf{p}_{L|K} \end{pmatrix} \\ V_L^{-\frac{1}{2}} (\eta_L - h(\mathbf{x}_{L|K})) \end{pmatrix} \tag{21}$$

$$P_{L+1|L}^{-\frac{1}{2}} = \overline{Q}^T \begin{pmatrix} 0 \\ W^{-\frac{1}{2}} \end{pmatrix} \tag{22}$$

with the linearizations of the dynamics

$$G_{L|K} = \begin{pmatrix} X_{x,L|K} & X_{p,L|K} \\ 0 & I_{n_p} \end{pmatrix} \tag{23}$$

$$X_{x,L|K} = \left. \frac{d\mathbf{x}(t_{L+1}; \mathbf{x}_{L|K}, \mathbf{p}_{L|K})}{d\mathbf{x}} \right|_{L|K} \tag{24}$$

$$X_{p,L|K} = \left. \frac{d\mathbf{x}(t_{L+1}; \mathbf{x}_{L|K}, \mathbf{p}_{L|K})}{d\mathbf{p}} \right|_{L|K}, \tag{25}$$

the linearization of the output

$$H_{L|K} = \begin{pmatrix} H_{x,L|K} & H_{p,L|K} \end{pmatrix} \tag{26}$$

$$H_{x,L|K} = \left. \frac{dh(\mathbf{x}(t_{L+1}; \mathbf{x}_{L|K}, \mathbf{p}_{L|K}))}{d\mathbf{x}} \right|_{L|K} \tag{27}$$

$$H_{p,L|K} = \left. \frac{dh(\mathbf{x}(t_{L+1}; \mathbf{x}_{L|K}, \mathbf{p}_{L|K}))}{d\mathbf{p}} \right|_{L|K}, \tag{28}$$

the QR-decompositions

$$\begin{pmatrix} P_{L|L-1}^{-\frac{1}{2}} \\ V_L^{-\frac{1}{2}} H_{L|K} \end{pmatrix} = (Q|\breve{Q}) \begin{pmatrix} R \\ 0 \end{pmatrix} \tag{29}$$

$$\begin{pmatrix} R \\ -W^{-\frac{1}{2}} G_{L|K} \end{pmatrix} = (\overline{Q}|\widetilde{Q}) \begin{pmatrix} \overline{R} \\ 0 \end{pmatrix}, \tag{30}$$

and the state noise covariance matrix of the states and of the parameters

$$W = \begin{pmatrix} W_x & 0 \\ 0 & W_p \end{pmatrix}. \tag{31}$$

$\mathbf{x}(t_{L+2}; t_{L+1}, \mathbf{x}_{L+1|K}, \mathbf{u}_{L+1}, \mathbf{p}_{L+1|K})$ denotes the prediction of the system based on the recent estimate at $_{L+1|K}$ while $\mathbf{x}_{L+2|L+1}$ is the smoothed prediction.

The MHE has to cope with jumps in the extract and raffinate measurements that are caused by the port switching. In order to obtain a smooth calculation of the gradients with respect to the simulated measurements which exhibit jumps due to the periodic movement of the ports, virtual measurements at constant positions at the outlet of each chromatographic column are included in the mapping h. In order to account for the actual existence of real measurements at the considered point of time k, the corresponding components on the diagonal of the measurement weight V_k^{-1} are set to $\frac{1}{\sigma_v^2}$ while nonexisting measurements cause zero entries on the diagonal of V_k^{-1}. A zero weight can be interpreted as infinite measurement noise. Thus, the correction terms of nonexisting measurements in the smoothed Extended Kalman Filtering update and in the moving horizon are zero. The switching of the measurement weights at the respective extract and raffinate switching times $\delta t_j \tau$ in period m is realized according to the movement of the extract and raffinate port:

$$\overline{V}_{m,j} = M_V \overline{V}_{m,j} \quad j = Ex, Ra \tag{32}$$

$$\overline{V}_m = \overline{V}_{m,Ex} + \overline{V}_{m,Ra} \tag{33}$$

$$V_m = \mathrm{diag}(\overline{V}_{m+1}(1, \ldots, (n_{\mathrm{col}} - 1) * 2), \sigma_v^2, \sigma_v^2). \tag{34}$$

The permutation matrix M_V for shifting the extract and raffinate measurements around the plant for a new period $m+1$ is similar to the permutation matrix M_Q for shifting the port flows. The last two entries of V_k are the variances of the measurements at the internal measurement position (recycle) which are not shifted.

3.2 Multiple-Shooting Real-Time Iteration Scheme for MHE

The moving horizon optimization problem is solved by the multiple shooting method for parameter estimation Bock (1981, 1987). The basic idea of multiple shooting is to subdivide the time horizon into subintervals and to formulate autonomous initial value problems on each individual subinterval which are coupled by continuity conditions. The computational requirements are largely reduced by applying the *real-time iteration* scheme for the multiple shooting method introduced in Diehl et al. (2002, 2004); Diehl (2002) that updates the sensitivity matrices that are necessary to solve the optimization problem before the most recent measurement η_K is available. Another important feature is that the next optimization problem is initialized well at the current solution such that the number of iterations can be reduced to one.

4. RESULTS

For the demonstration of the performance of the moving horizon estimator, the separation of the enantiomer mixture EMD-53986 is considered which is described by a nonlinear adsorption isotherm of extended Langmuir type (12). Enantiomers are chemical molecules that are mirror images of each other, much as one's left and right hands.

The separation of the enantiomers of EMD-53986 was studied experimentally in a joint project by *Merck* (Germany) and Universität Dortmund in 2001. From this work, an accurate simulation model is available. The parameters of the SMB model were taken from Jupke et al. (2002). More details on the process and the model parameters can be found in Jupke (2004). In order to demonstrate the performance of the MHE estimator, a simulation study is presented in which step changes of the Henry coefficients H_A^2, H_B^2 of the nonlinear adsorption isotherm are assumed. The performance of the moving horizon estimator is illustrated by the evolution of the parameters and of the overall state reconstruction error which is defined as

$$J = \sum_{j=1}^{352} (\mathbf{x}(j) - z(j))^2, \tag{35}$$

where z is the true state. The measurements are corrupted by noise with a standard deviation of 0.025 g/l as observed in Jupke et al. (2002). No cross-correlations between the state noises and between the state noises and the parameters were assumed. Since the concentration profiles move around the simulated plant together with the ports, the same noise variances were assumed for each state. The tuning of the moving horizon estimator was performed by varying the covariances of the state variables and of the free parameters. The weighting matrix W incorporates a standard deviation of 0.00433 g/l for the state noise and a parameter standard deviation of 0.0316 for H_{A}^2 and 0.0265 for H_{B}^2: $W^{\frac{1}{2}} = \mathrm{diag}(0.00433, \ldots, 0.00433, 0.0361, 0.0265)$. The initial weight P_0 is set to $0.005 \times W$. The chosen state and parameter noises represent a compromise between the smooth estimation of the states and a quick adaptation of the parameters. The state and parameter bounds are chosen as -0.25 g/l $\leq x \leq 5$ g/l and $0 \leq H_i^2 \leq 50$ to prevent grossly wrong values. The lower bound on the states is chosen such that it remains inactive in the presence of large measurement noise. The sampling time of the estimator is 1/10 of the period length. The moving horizon length is five sampling intervals (half a period).

In the simulation scenario, H_{A}^2 is increased by 10.6% from 19.90 to 22.00 at $t = 14.58$ min while H_{B}^2 is increased by 10.3% from 5.85 to 6.45 at $t = 68.04$ min. It can be seen from figures 4 to 8, that the state is reconstructed correctly in the presence of the parameter variations and that the parameters are also estimated well. The Henry coefficient H_B^2 is estimated faster than H_A^2 due to the stronger excitation of the raffinate dynamics by the parameter perturbation. The axial concentration profiles are reconstructed correctly by the MHE (not show here due to limited space). The MHE is more robust against measurement noise and wrong initializations of the states and parameters than an EKF, see Küpper et al. (2009). The MHE estimator can be applied online, as can be seen from Figure 8. The CPU times are below the sampling rate at all sampling points. The CPU times of the MHE are around 23 s on a standard PC [1], the maximum and minimum values being 28.0 s and 18.5 s. The CPU times for the estimator varies periodically. It was observed that the estimation problem requires a longer computation time when a shift of one of the inlet/outlet ports occurs within the moving horizon.

AbstractMany relevant process states in wastewater treatment are not measurable, or their measurements are subject to considerable uncertainty. This poses a serious problem for process monitoring and control. Model-based state estimation can provide estimates of the unknown states and increase the reliability of measurements. In this paper, an integrated approach is presented for the estimation problem employing unconventional, but technically feasible sensor networks. Using the ASM1 model in the reference scenario BSM1, the estimators EKF and MHE are evaluated. Very good estimation results for the system comprising of 78 states are found.

Keywords: state estimation, MHE, EKF, wastewater treatment, ASM, BSM1

1. INTRODUCTION

One of the key challenges in the operation of activated sludge wastewater treatment plants (WWTP) is the uncertainty about relevant process state values. E. g. the concentrations of active biomass and of soluble substrate are not measurable online, but they considerably influence process behavior. Some states such as the concentration of total suspended solids are measurable, but their measurements involve significant measurement errors. Reliable estimates of these states are of great value for different operational tasks such as process monitoring, online simulation, and advanced multi-variable control. They are a necessity for model-based control approaches based on dynamic process models (e. g. Busch et al., 2007). Model-based state estimation is one alternative to obtain such estimates. For a given process model, its success depends on the choice of a suitable hardware sensor network and of an appropriate estimation method.

The intention of this paper is to present sophisticated solutions to the state estimation problem for large-scale WWTP and to investigate two distinct state estimation approaches from the practitioner's point of view. First, an optimization-based approach determines the cheapest hardware sensor network that is required for the state estimation task. Second, Extended Kalman Filtering (EKF) and Moving Horizon Estimation (MHE) are employed to estimate the unknown model states of the large-scale WWTP model ASM1 employed in the BSM1 reference scenario (Copp, 2002). Large measurement errors, plant/model-mismatch, and unknown inflow concentrations are considered.

State estimation aims at statistically optimal estimates of measurable and unmeasurable process states. Dochain (2003) provides an overview of state and parameter estimation for chemical and biochemical processes focusing on small models. Lubenova et al. (2003) use an adaptive observer for a bioprocess models with 5 states. Goffaux and Vande Wouwer (2005) compare an asymptotic observer, an EKF, and a particle filter (PF) for a bioprocess model with 4 states. A model with approximately 40 states based on the ASM1 successor ASM3 is considered by Chai et al. (2007), who evaluate a KF, an EKF, and an unscented KF (UKF). No rigorous MHE implementation for WWTP has been reported.

Generally speaking, observers prove to be efficient for small-scale models with maybe up to 10 states. For larger models, observer design becomes challenging. An exception are asymptotic observers, which exhibit slow convergence of the estimates to the true values, but which do not require kinetic models. The EKF is the standard choice for large-scale models. It is easy to implement and much experience is available concerning its design and tuning. It is not clear whether the related UKF and PF can significantly outperform the EKF in practical implementations. The MHE is a promising option, but it is not clear whether its increased implementation effort is justified by better estimation results in WWTP applications. Large-scale simulation case studies are rare, and real-life case studies are not available. Also, while the properties of the hardware sensor network are decisive for the success of any state estimation approach, this aspect has not been treated much with respect to WWTP applications.

Ideally, the choice of a sensor network, of a process model, and of the estimator should be considered as an integrated problem. This is beyond our possibilities today. The sensor networks used in this study are obtained by a simple optimization-based sensor network design approach. An observable system for a given large-scale plant model

involving 78 differential states is obtained. An EKF and an MHE are then employed as state estimators.

2. PROCESS AND PROCESS MODEL

The simulation study is based on the BSM1 (Copp, 2002), which has been developed as a benchmark scenario for the evaluation and comparison of different control approaches for WWTP. The plant layout is depicted in Fig. 1. Q_i and $\mathbf{Z}_i$ refer to the flow rate and vector of concentrations for stream i. The inflow is mixed with two recycle streams before entering the plant. Two denitrification basins (each $1000\,\mathrm{m}^3$) are followed by three aerated nitrification basins (each $1333\,\mathrm{m}^3$). The first recycle a is withdrawn from the last nitrification basin. The settler used in the BSM1 is replaced by a membrane filtration unit, which is located in a separate $250\,\mathrm{m}^3$ basin and which is modeled as an ideal splitter. The product stream e as well as a second recycle r and a waste stream w leave the membrane basin. All basins are assumed to be well-mixed.

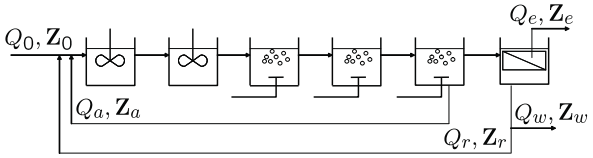

Figure 1. Modified BSM1 plant layout.

The degradation processes in the five biological basins are described by the ASM1 (Henze et al., 1987) with parameters taken from Copp (2002). The ASM1 describes 8 reactions and the component concentrations of inert soluble matter S_I, soluble substrate S_S, inert particulate matter X_I, particulate substrate X_S, heterotrophic biomass $X_{B,H}$, autotrophic biomass $X_{B,A}$, particulate inert metabolism products X_P, dissolved oxygen (DO) S_O, nitrate S_{NO}, ammonia S_{NH}, soluble organic nitrogen S_{ND}, particulate organic nitrogen X_{ND}, and the alkalinity S_{ALK}. The resulting model comprising mass balances and the kinetic model contains 78 differential states. It is formulated as a semi-explicit differential-algebraic model according to

$$\dot{\mathbf{x}} = \mathbf{f}\left(\mathbf{x}, \mathbf{z}, \mathbf{u}, \mathbf{p}\right) \ , \tag{1}$$

$$0 = \mathbf{g}\left(\mathbf{x}, \mathbf{z}, \mathbf{u}, \mathbf{p}\right) \ , \tag{2}$$

$$\mathbf{y} = \mathbf{M} \cdot \mathbf{x} \ . \tag{3}$$

$\mathbf{x}$ are differential and $\mathbf{z}$ are algebraic states, $\mathbf{u}$ are the manipulated variables, and $\mathbf{p}$ are the parameters. $\mathbf{y}$ are the measurable outputs and $\mathbf{M}$ is the measurement matrix. Note that for the BSM1 scenario, $\mathbf{g}(\cdot)$ represents defining equations that can explicitly be solved for $\mathbf{z}$. Generally $\mathbf{g}(\cdot)$ suffices to be of index 1.

The BSM1 benchmark describes a dry weather scenario for a period of 100 days with constant manipulated variables, inflow rates, and inflow concentrations to reach a steady state. This is followed by a period of 14 days with dynamic inflow conditions. One of the three different dynamic scenarios, the *storm scenario*, is used in this paper. It is characterized by dry weather inflow superposed by storm events on days 9 and 11. Exemplarily, the corresponding inflow rate and ammonia inflow concentration are depicted in Fig. 2.

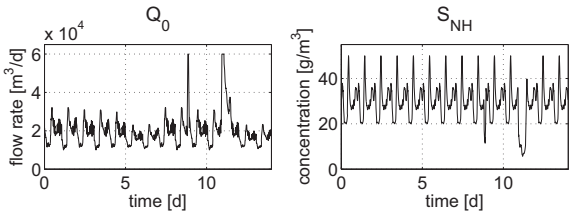

Figure 2. Inflow rate Q_0 and ammonia inflow concentration $Z_{0,S_{NH}}$.

3. SENSOR NETWORK DESIGN

The success of a state estimation approach depends on the process model, on the state estimation algorithm, and on the sensor network which supplies the measurements. Optimal sensor network design aims at the sensor network which leads to optimal state estimates at limited cost, or similarly, reliable state estimates at minimum cost (Singh and Hahn, 2005). So far, systematic approaches to this important aspect of state estimation have been neglected in the literature on WWTP applications. Rather, the sensor network is chosen based on experience and intuition.

The approach to obtain the sensor networks as used in this study is outlined in the following, details are presented in Busch et al. (2009). A sensor network is fully defined by the measurement matrix $\mathbf{M}$ (Eq. (3)), which relates process states $\mathbf{x}$ to measurements $\mathbf{y}$. By assigning prices to the measurement hardware, a cost function $\phi = \phi\left(\mathbf{M}\right)$ is obtained, which describes the cost of the sensor network. The relevant constraint for the sensor network is that it needs to yield an observable system. Hence, the nonlinear process model is linearized at many instances along a typical process trajectory, and observability is checked for each of these instances by a suitable criterium. Finally, a genetic optimization algorithm is employed to find the sensor network with the minimum cost $\phi\left(\mathbf{M}\right)$ which still fulfills the observability constraints (Heyen and Gerkens, 2002). The approach is applied to the simulation scenario described in Section 2. Considering 8 technically feasible measurements in 6 basins gives a total of $2^{6\cdot 8} \approx 2.8 \cdot 10^{14}$ measurement configurations.

The following sensor network is found to give observability at minimum cost: $COD_1, S_{ALK,1}, S_{O,2}, X_{TS,5}$, where the numeric index refers to the basin number. COD is the chemical oxygen demand. This result is quite surprising, as it implies that only four hardware sensors suffice to estimate all 78 model states. Some standard hardware sensors, which are commonly available at WWTP, are added to the sensor network. These are DO sensors in the aerated basins as well as nitrate, ammonia, alkalinity, and COD measurements in the effluent.

4. STATE ESTIMATORS

State estimation refers to retrieving all states of a dynamic system in real-time by utilizing available measurements, possibly in combination with a process model. While the state estimation problem is largely solved for *linear systems*, e. g. , by the Kalman Filter, the problem becomes significantly more difficult for non-linear systems. Most methods are extensions of linear state estimators, such

as the extended Kalman Filter (EKF), described e. g. in Becerra et al. (2001). A *non-linear* version of MHE is presented in Rao et al. (2003). A comparison of EKF and non-linear MHE applied to the BSM1 scenario is presented in Section 5. In the following, main principles and implementation details are reviewed.

4.1 Extended Kalman Filter

The Kalman Filter is a recursive method for state estimation. It consists of a prediction step (time update) and a measurement update. Past data is summarized and carried on by means of suitable statistics. For a non-linear system in discrete-time with measurement noise $\boldsymbol{\upsilon}_k \sim \mathcal{N}(0, \tilde{\mathbf{V}})$ and process noise $\boldsymbol{\mu}_k \sim \mathcal{N}(0, \tilde{\mathbf{W}})$

$$\mathbf{x}_k = \mathbf{f}_k\left(\mathbf{x}_{k-1}, \mathbf{z}_{k-1}, \mathbf{u}_{k-1}, \mathbf{p}_{k-1}\right) + \boldsymbol{\mu}_k \,, \tag{4}$$

$$\mathbf{0} = \mathbf{g}_k\left(\mathbf{x}_{k-1}, \mathbf{z}_{k-1}, \mathbf{u}_{k-1}, \mathbf{p}_{k-1}\right), \tag{5}$$

$$\mathbf{y}_k = \mathbf{M} \cdot \mathbf{x}_k + \boldsymbol{\upsilon}_k \,, \tag{6}$$

where k denotes the sampling instant, the respective filter equations in their most common form are:

Time update:

$$\hat{\mathbf{x}}_k^- = \mathbf{f}_k\left(\hat{\mathbf{x}}_{k-1}, \mathbf{z}_{k-1}, \mathbf{u}_{k-1}, \mathbf{p}_{k-1}\right), \tag{7a}$$

$$\mathbf{P}_k^- = \left.\frac{\partial \mathbf{f}_k}{\partial \mathbf{x}_{k-1}}\right|_{\hat{\mathbf{x}}_{k-1}} \cdot \mathbf{P}_{k-1} \cdot \left.\frac{\partial \mathbf{f}_k}{\partial \mathbf{x}_{k-1}}\right|_{\hat{\mathbf{x}}_{k-1}}^{\mathrm{T}} + \mathbf{W} \,, \tag{7b}$$

Measurement update:

$$\mathbf{K}_k = \mathbf{P}_k^- \cdot \mathbf{M}_d^{\mathrm{T}} \cdot \left(\mathbf{M}_d \cdot \mathbf{P}_k^- \cdot \mathbf{M}_d^{\mathrm{T}} + \mathbf{V}\right)^{-1} , \tag{8a}$$

$$\mathbf{P}_k = \left(\mathbb{I} - \mathbf{K}_k \cdot \mathbf{M}_d\right) \cdot \mathbf{P}_k^- \,, \tag{8b}$$

$$\hat{\mathbf{x}}_k = \hat{\mathbf{x}}_k^- + \mathbf{K}_k \cdot \left(\mathbf{y}_k - \mathbf{M}_d \cdot \hat{\mathbf{x}}_k^-\right), \tag{8c}$$

$$\mathbf{0} = \mathbf{g}_k\left(\hat{\mathbf{x}}_k, \hat{\mathbf{z}}_k, \mathbf{u}_k, \mathbf{p}_k\right). \tag{8d}$$

$\mathbf{f}_k$ typically represents a numerical integration of the continuous system Eq. (1) from time t_{k-1} to t_k with initial values $\mathbf{x}_{k-1}$. The matrix $\mathbf{P}_k$ is the covariance matrix associated with the state estimates $\hat{\mathbf{x}}_k$ at sampling time k. It reflects the confidence one can have in this estimate. The matrices $\mathbf{V}$ and $\mathbf{W}$ describe the assumed covariances of measurement noise and process noise, respectively. The Kalman Filter gain $\mathbf{K}_k$ then reflects the trade-off between the measurements and the process model.

4.2 Moving Horizon Estimation

A drawback of most estimation methods is that they cannot deal with known constraints on the estimated states. In the MHE scheme, such constraints are naturally incorporated in the optimization problem. The formulation also allows to additionally estimate process parameters without reformulating them as dummy states.

Unlike the EKF, the MHE uses more than just the most recent measurements: At a certain time t_j a number of $M+1$ measurements $(\mathbf{y}_{j-M}, \ldots, \mathbf{y}_j)$ associated with past time instants $t_{j-M} < \ldots < t_j$ are explicitly used for estimation. The length L of the time horizon $[t_j, \ldots, t_{j-M}]$ is defined as $L := j - M$. It is assumed that measurement and process noise are normally distributed with zero mean and covariance matrices $\mathbf{V}$ and $\mathbf{W}$. Additionally, a Gaussian distribution is assumed for $\mathbf{x}(t_L)$ and $\mathbf{p}$ at the beginning of the horizon, with expectation value $(\bar{\mathbf{x}}_L, \bar{\mathbf{p}}_L)$ and a block-diagonal covariance matrix $\boldsymbol{\Pi}_L$ with block elements $\boldsymbol{\Pi}_{\bar{x},L}$ and $\boldsymbol{\Pi}_{\bar{p},L}$.

The state estimation problem to be solved at time t_k – given the measurements $\mathbf{y}_j$ for $j = L, L+1, \ldots, k$, the known input $\mathbf{u}(t)$ for $t \in [t_L, t_k]$ and given $(\bar{\mathbf{x}}_L, \bar{\mathbf{p}}_L)$ and $\mathbf{P}_L$ – has the following form:

$$\min_{\mathbf{x}(\cdot),\mathbf{p}} \Big(\|\mathbf{x}(t_L) - \bar{\mathbf{x}}_L\|^2_{\boldsymbol{\Pi}_{\bar{x},L}} + \|\mathbf{p} - \bar{\mathbf{p}}_L\|^2_{\boldsymbol{\Pi}_{\bar{p},L}} + \sum_{j=L}^{k} \|\mathbf{y}_j - \mathbf{M} \cdot \mathbf{x}(t_j)\|^2_{\mathbf{V}} \Big) \tag{9}$$

$$\text{s.t.} \quad \dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{z}(t), \mathbf{u}(t), \mathbf{p}), \quad t \in [t_L, t_k], \tag{10a}$$

$$\mathbf{0} = \mathbf{g}(\mathbf{x}(t), \mathbf{z}(t), \mathbf{u}(t), \mathbf{p}), \tag{10b}$$

$$\mathbf{x}_{\min} \le \mathbf{x}(t) \le \mathbf{x}_{\max}, \tag{10c}$$

$$\mathbf{p}_{\min} \le \mathbf{p} \le \mathbf{p}_{\max}, \tag{10d}$$

where the applied norm is defined as $\|\mathbf{x}\|^2_{\mathbf{V}} := \mathbf{x}^{\mathrm{T}}\mathbf{V}^{-1}\mathbf{x}$.

At each new sampling time t_k, one new measurement vector $\mathbf{y}_k$ enters the set of measurements, while the last one $\mathbf{y}_L$ becomes $\mathbf{y}_{L-1}$ and drops out of the horizon.

The initial weight terms $\|\mathbf{x}(t_L) - \bar{\mathbf{x}}_L\|^2_{\boldsymbol{\Pi}_{\bar{x},L}}$ and $\|\mathbf{p} - \bar{\mathbf{p}}_L\|^2_{\boldsymbol{\Pi}_{\bar{p},L}}$ (often called "arrival costs") summarize information in the MHE problem prior to the horizon beginning at time t_L and also reflect a cumulated effect of process noise on the process. A typical approach is to compute the arrival costs by Kalman Filter updates of $\bar{\mathbf{x}}_L$ and $\bar{\mathbf{p}}_L$. As for the optimal length of the estimation horizon, no general results are available, yet. Horizon length and the weighting matrices $\mathbf{V}^{-1}$, $\boldsymbol{\Pi}^{-1}$ are the tuning parameters. Note that an extended MHE formulation exists that explicitly incorporates process noise (Rao et al., 2003; Diehl et al., 2006).

A necessity for the MHE scheme to work is a fast and reliable numerical scheme for the constrained non-linear dynamic optimization problem (9). The implementation in this work makes use of MUSCOD-II (Leineweber et al., 2003), which is based on a direct multiple shooting approach, see, e. g. , (Bock et al., 2007). For real-time feasibility, the least-squares problem at each time instant t_k is not solved to convergence. Instead, only one Gauss-Newton iteration is performed, combined with a meaningful shift of the problem variables. More information on this so-called *real-time iteration approach* along with other implementational details can be found in Diehl et al. (2006).

5. CASE STUDY

EKF and MHE are applied to the process model and scenario described in Section 2 and the sensor network calculated in Section 3. The estimation task was made increasingly difficult to evaluate the estimation performance under nominal and more realistic conditions.

Only little effort has been devoted to the fine-tuning of the estimators. This is intentional, since the aim of the study is to investigate the practical applicability and general performance of the two estimation methods. The tuning matrices $\mathbf{W}$ and $\mathbf{V}$ for the EKF and the MHE reflect covariances based on an assumed standard deviation of 5% of the initial values $\mathbf{x}_0$ and "initial measurements" $\mathbf{M} \cdot \mathbf{x}_0$. The MHE uses an estimation horizon of 5 measurement samples.

The initial guess for $\hat{\mathbf{x}}_0$ is deliberately set to $1.3 \cdot \mathbf{x}_0$ to introduce a strong initial offset. The measurements are corrupted by white noise $\boldsymbol{\upsilon}$ with a standard deviation of 5% of the initial measurements: $\mathbf{y}_k = \mathbf{M} \cdot \mathbf{x}_k + \boldsymbol{\upsilon}_k$. The sampling interval is set to 15 minutes. In the following, the quality of the estimation results will be illustrated by the estimates of the third basin, which is the one with the least measurements (only DO concentration). The DO concentration is not visualized as the estimates always closely follow the true values.

5.1 Nominal process

In the first scenario, no process noise is added and perfect knowledge of the inflow rate and concentrations is assumed. The estimated state values quickly converge from their initial offset to the true values (not shown). Only the concentration of X_P shows some occasional offset. The root of the cumulated squared relative error (RCSE) averaged over all J samplings is used in the following as a measure to compare the overall estimation performance:

$$\mathrm{RCSE} = \frac{1}{J} \sum_{k=1}^{J} \sqrt{\sum_{i=1}^{N} \left(\frac{\hat{x}_{i,k} - x_{i,k}}{x_{i,k}} \right)^2} , \qquad (11)$$

where J is the number of samples $x_{i,k}$ and $\hat{x}_{i,k}$ and N is the number of states. The RCSE values for the different simulation case studies are stated in Table 1. For the EKF and the MHE with known inputs and no process noise, RCSE of 0.3 and 0.4 are obtained, respectively.

Table 1. RCSE for the estimated states of different simulation scenarios and estimators.

Estimator	Known inputs, no process noise	Known inputs, process noise	Unknown inputs, process noise
EKF	0.3	0.7	1.8
MHE	0.4	0.8	1.6

5.2 Process noise

Process noise is added to introduce plant/model-mismatch to the problem. The process noise $\boldsymbol{\mu}$ has zero mean and a standard deviation of 5% of the initial states and enters the discrete time simulation model according to

$$\mathbf{x}_{k+1} = \mathbf{f}\left(\mathbf{x}_k, \mathbf{z}_k, \mathbf{u}_k, \mathbf{p}_k\right) + \boldsymbol{\mu}_k \, , \qquad (12a)$$

$$\mathbf{0} = \mathbf{g}\left(\mathbf{x}_k, \mathbf{z}_k, \mathbf{u}_k, \mathbf{p}_k\right) . \qquad (12b)$$

Noise-induced negative states representing concentrations are set to zero to ensure that the equations remain physically feasible. The estimation results are similar for the EKF and the MHE. Exemplarily, Fig. 3 shows the results for the third basin using the MHE. Deviations from the true trajectories are observed, but the estimation result averaged over all samples remains satisfactory for both estimators. The RCSE of the EKF and the MHE changes from 0.3 to 0.7 and from 0.4 to 0.8, respectively (Table 1). This result is not surprising, as the process noise now deviates the measured outputs, complicated even further by the process nonlinearities which are not fully captured by the estimators.

5.3 Unknown inflow concentrations

Up to now it has been assumed that the inflow rate and concentrations are perfectly known. This assumption is not realistic. While the inflow rate is indeed well-known, at least part of the inflow concentrations are not. Typically historic data is employed to obtain daily, weekly, and yearly trends and patterns of e. g. the concentrations or the composition of the COD. However, a substantial bias between these predictions and the real inflow concentrations must be expected. A worst case situation is considered in the following: The inflow concentrations of soluble inert matter S_I, soluble substrate S_S, particulate inert matter X_I, particulate substrate X_S, heterotrophic biomass $X_{B,H}$, as well as soluble S_{ND} and particulate organic nitrogen X_{ND} are treated as unknown model inputs. The inflow concentrations of DO S_O, autotrophic biomass $X_{B,A}$, metabolism products X_P, and nitrate X_{NH} are set to zero, and the alkalinity S_{ALK} is set to 7, which corresponds to typical inflow characteristics as well as to the BSM1. The inflow rate Q_0 and the inflow ammonia concentration S_{NH} are measurable. The unknown inputs need to be estimated together with the unknown states.

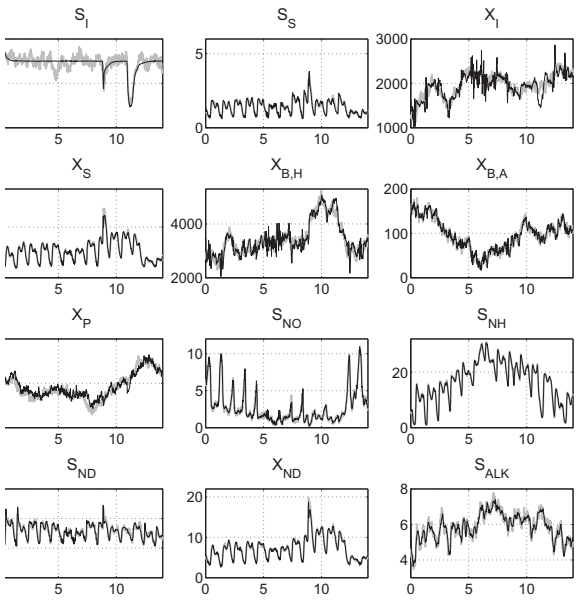

Figure 3. MHE with 5% process noise, third basin. The x-axis shows the time in days, and the y-axis shows the concentrations in [g/m^3]. The alkalinity S_{ALK} is dimensionless. The graphs show the true process state values (light grey) and the estimates (black).

First, a new sensor network is determined by applying the optimization procedure outlined in Section 3 to an extended model, which considers the unknown inflow concentrations as additional model states (Busch et al., 2009). The resulting sensor network is more complex than the network used for the estimation of the nominal process, but still technically and economically feasible:

$$X_{TS,1}, S_{ALK,1}, BOD_2, BOD_3, S_{O,3}, S_{ALK,3} \, , \\ S_{ALK,4}, COD_5, COD_6 \, ,$$

where BOD is the biological oxygen demand. The same standard measurements as discussed in Section 3 are added to the sensor network.

The estimation of the model parameters such as input concentrations is an integrated part of the MHE implementation and thus can be pursued very easily (see Section 4). For the EKF, the effort is slightly higher. Here, to additionally estimate process parameters, these have to be formulated as additional differential states $\mathbf{x}_p$ obeying the trivial differential equation $\dot{\mathbf{x}}_p = \mathbf{0}$ with initial values $\mathbf{x}_p(0) = \mathbf{p}$. The EKF then estimates the augmented state vector $(\mathbf{x}^{\mathrm{T}}\,\mathbf{x}_p^{\mathrm{T}})^{\mathrm{T}}$. Note that the covariance matrix $\mathbf{W}$ has to be adapted to the new state vector. The expected process noise standard deviation of the unknown parameters is specified as 5% of their nominal values. The initial guess for the inflow concentrations is also disturbed by +30%. Fig. 4 depicts the estimated states for the third basin. The estimation performance is again satisfactorily except for two states. The estimation of inert particulate matter X_I shows considerable offset from the true values. This is, however, not severe, as inert matter does not affect the reaction kinetics and is hence irrelevant for process prediction. The second state to exhibit a significant offset is the concentration of heterotrophic biomass $X_{B,H}$. This is more serious as heterotrophic biomass is responsible for the degradation of substrate and nitrate. Whether the offset is critical, e. g. in model-based control approaches, needs to be evaluated in future research. Fine-tuning of the estimator might further minimize the deviation. The overall RCSE is 1.8 for the states (Table 1) and 2.0 for the parameters.

Fig. 5 shows the estimation results for the states in the third basin as obtained by the MHE. The results do not differ much from those of the EKF. Again, the two states inert particulate matter X_I and heterotrophic biomass $X_{B,H}$ show the largest deviations. From visual inspection, the first seems to stay closer to the true value but then exhibits a sudden and sharp drop which is not present in the real trend. The overall RCSE for this case is 1.6 (Table 1) and hence slightly better than for the EKF. The estimated parameters achieve an RCSE of 2.1.

The estimated inflow concentrations are depicted exemplarily for the EKF in Fig. 6. All estimates exhibit high-frequent oscillations, which could probably also be improved by fine-tuning of the estimators. The estimation of the concentration of heterotrophic biomass $X_{B,H}$ again shows a stronger offset during days 11 to 13 following the second storm event but returns to the true value eventually. The graphs of inert particulate matter X_I and particulate organic nitrogen X_{ND} show that the estimates are not able to follow sudden concentration peaks (day 9).

The main trends in the inflow data are captured well, but it is not clear especially with respect to the concentrations of inert particulate matter X_I and heterotrophic biomass $X_{B,H}$ whether these parameter are actually observable. To clarify the issue, additional scenarios have been calculated which show that the parameters are indeed observable, but that their influence on the noisy process and process measurements is small, so that it is not possible to resolve higher frequent variations Busch et al. (2009).

5.4 Computation times

A general belief that can often be found is that optimization-based estimation methods such as MHE are impractical

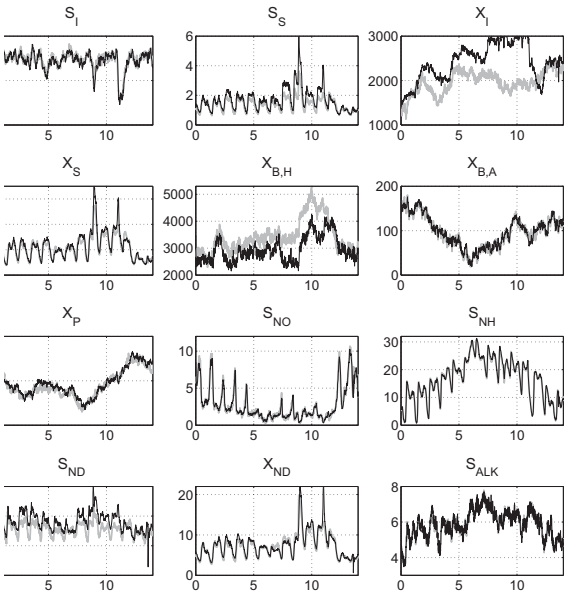

Figure 4. EKF with unknown inflow concentrations and 5% process noise, third basin. The x-axis shows the time in days, and the y-axis shows the concentrations in [g/m^3]. The alkalinity S_{ALK} is dimensionless. The graphs show the true process state values (light grey) and the estimates (black).

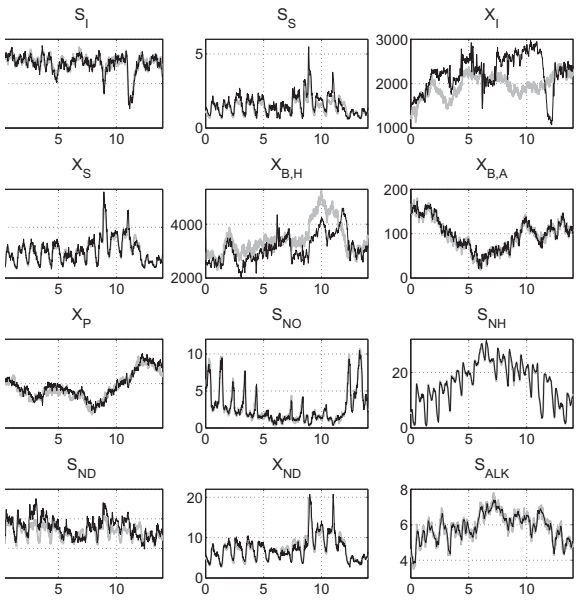

Figure 5. MHE with unknown inflow concentrations and 5% process noise, third basin. The x-axis shows the time in days, and the y-axis shows the concentrations in [g/m^3]. The alkalinity S_{ALK} is dimensionless. The graphs show the true process state values (light grey) and the estimates (black).

because of the excessive computation times to be expected. Indeed the time required to solve a constrained optimization problem to full convergence will necessarily be larger than recursively solving the corresponding unconstrained problem. However, the numerical approach sketched in Section 4 can significantly reduce the computation times. In the case studies described, the average computation time for the MHE was in the range of a few seconds with a maximum lower than 10 seconds on a Pentium 4 machine with 2.8 GHz, 1024 kB L2 cache, 1 GB RAM under Suse Linux 9.3. This is by far fast enough for the estimation tasks for WWTP.

6. CONCLUSIONS

In this paper inflow and state estimation approaches for large-scale wastewater treatment plants are presented. The process is based on the reference scenario BSM1 and employs the dynamic, non-linear process model ASM1. The two prominent state estimators EKF and MHE are evaluated. Large process and measurement disturbances as well as unknown influent conditions have been considered.

The results show that it is possible to yield a fully observable system with an unconventional sensor network of moderate complexity. Both the EKF and the MHE show good estimation performance even in difficult conditions. The EKF shows a marginally better performance for the scenarios with known inflow concentrations. For unknown inflow concentrations, the MHE delivers slightly better state estimates. These do not fully justify the higher implementational effort for the MHE. However, its simple and straightforward handling of unknown inflow conditions and parameters is an advantage over the EKF. The computation times presented here show that the EKF as well as the MHE are real-time feasible for WWTP.

Abstract: This paper demonstrates how feedforward control can assist in stabilizing unstable systems. Feedback control is necessary for stabilization, but feedforward can be used to avoid input constraints which would otherwise cause the system to go unstable. Thus, if disturbances can be measured, feedforward from disturbances can be a simple and low cost way of avoiding loss of stability due to input constraints.

Keywords: Feedforward, input constraints, stabilization

1. INTRODUCTION

Fundamental limitations in achievable control performance have received a lot of attention in the control literature. A number of important results in this area is covered in Skogestad and Postlethwaite (2005). One such fundamental limitation for unstable systems is that the range of actuation for the inputs must be sufficiently large to avoid saturation. If the inputs saturate, feedback is broken, and hence the stabilizing effect of the controller is lost. Ensuring that the inputs do not saturate is therefore important in order to guarantee closed loop stability, although an unstable system may remain stable despite the inputs being saturated for a limited period, as shown in Favez et al. (2006). If input saturation is avoided, local (linear) stability of the closed loop system is sufficient for stability.

Feedforward is normally used to improve control performance at high frequencies, beyond the achievable bandwidth for stable closed loop control. In this paper, feedforward is instead used to reduce the magnitude of the plant input moves, and therefore to avoid instability due to input constraints.

2. BACKGROUND

Consider a controlled system such as the one illustrated in Fig. 1. For the linear, unconstrained case with only feedback control ($K_f = 0$), we get

$$u = KSr - KSG_d d \tag{1}$$

where $S = (I + GK)^{-1}$. The dependence on the Laplace variable s is suppressed for notational convenience, whenever it is not needed for clarity.

Glover (1986) has shown that for unstable systems, the minimal achievable H_∞ norm of KS is given by

$$\|KS\|_\infty \geq 1/\underline{\sigma}_H(\mathcal{U}(G)^*) \tag{2}$$

where $\underline{\sigma}_H$ denotes the smallest Hankel singular value, and $\mathcal{U}(G)^*)$ denotes the anti-stable part of the plant G, with its unstable pole(s) mirrored into the left half plane.

Observe that for relationships like (2) to have any relevance for evaluating the likelihood of input saturation - with subsequent loss of stabilizing feedback - the plant model G needs to be appropriately scaled. Skogestad and Postlethwaite (2005) recommend scaling plant inputs such that $|u| < 1$ corresponds to inputs within the range of actuation, and scaling outputs such that $|y| < 1$ means that the control offset is acceptable. Similarly, the inputs of the disturbance model G_d should be scaled to get $|d| < 1$ for the expected range of disturbances, and outputs scaled in the same way as for G. In scaled variables, the references are then scaled to give $|r| < R(\omega)$ for the expected range of reference changes. Such scaling is implicitly assumed throughout this paper, and consequently the input saturation limits are assumed to be at ± 1.

Thus, with variables appropriately scaled, sinusoidal reference changes will not cause input saturation provided

$$\|KS\|_\infty < 1/R(\omega) \forall \omega \tag{3}$$

Although reference signals may contain more than a single frequency, and input saturation due to reference changes may therefore occur even if this relationship is fulfilled, this relationship is nevertheless useful in assessing whether

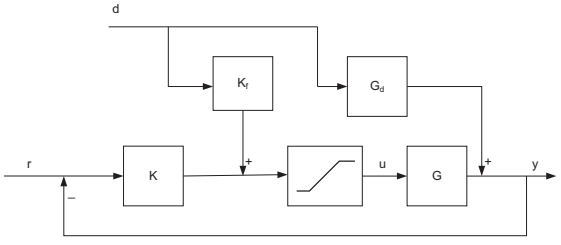

Fig. 1. Feedback and feedforward control, with limited input actuation range.

input saturation is a problem. However, it is also clear from the above that input saturation due to reference changes is not a fundamental problem - one may simply reduce the magnitude of the reference changes to avoid saturation.

On the other hand, it is typically not possible to control the magnitude of external disturbances d. Karivala et al. (2005) extended Glover's result to find that when using feedback only

$$\|KSG_d\|_\infty \geq 1/\underline{\sigma}_H(\mathcal{U}(G_{d,ms}^{-1}G)^*) \tag{4}$$

where $G_{d,ms}$ is the minimum phase and stable version of G_d, i.e., with both RHP poles and RHP zeros mirrored into the left half plane.

Accounting for the feedforward term K_f (but still assuming the saturation element to be inactive), we get

$$u = KSr + S_I(K_f - KG_d)d \tag{5}$$

where $S_I = (I + KG)^{-1}$. Note that $S = S_I$ for SISO systems, but this need not be the case for multivariable systems. From (5) we observe that introducing feedforward gives a new degree of freedom for minimizing input usage in the face of disturbances. Below, we will investigate in what situations this allows for a significant reduction of input usage, thus enabling closed loop stability.

3. STABLE DISTURBANCE MODELS

Consider the case where the plant is unstable from input to output, and hence requires feedback control for stabilization, but the unstable mode is not excited by the disturbances. This is motivated by the following example from Skogestad and Postlethwaite (2005):

Example:

$$G(s) = \frac{5}{(10s+1)(s-1)} \tag{6}$$

$$G_d(s) = \frac{k_d}{(s+1)(0.2s+1)} \tag{7}$$

The transfer functions are assumed to be appropriately scaled, as described above. From (4), we find that for $k_d > 0.54$, $\|KSG_d\|_\infty \geq 1$ for any feedback controller, and hence sinusoidal disturbances can drive the inputs to saturation. This is further illustrated in Skogestad and Postlethwaite (2005), where a stabilizing feedback controller is designed, but where saturation occurs for a step disturbance of magnitude 1 with $k_d = 0.5$. We seem to be in the paradoxical situation where control is not needed to counter the effect of disturbances (since a control offset of 1 is acceptable), but the controller needed to stabilize the system saturates due to the presence of the disturbance. Clearly, it would be better to do nothing to counteract the disturbance, but only manipulate the input to provide stabilization. However, a standard feedback controller does not distinguish the control offset caused by the (stable) disturbance from the offset caused by the unstable mode.

Equation (4) does not distinguish between stable and unstable disturbance models. For stable disturbance models, the feedforward controller K_f can be used to counter the effect of the disturbance on the input. That is, in stead of the conventional (ideal) feedforward

$$K_f = -G^{-1}G_d \tag{8}$$

which cancels the effect of the disturbance on the output [1], the ideal feedforward can from (5) be seen to be

$$K_f = KG_d \tag{9}$$

which cancels the effect of the disturbance on the input.

With this in mind, we revisit the example above, for the case with $k_d = 1$, meaning that feedback alone will not be able to maintain stability in the face of disturbances. The controller

$$K(s) = \frac{(10s+1)^2}{s(0.01s+1)} \tag{10}$$

will stabilize the unconstrained system. However, in Fig 2 we see that a unit step in the disturbance (applied at time $t = 1s$) will drive the input to saturation. Figure 3 shows that the system goes unstable as a result of the saturation. This is exactly as expected. The feedback controller $K(s)$ in (10) contains an integrator, and hence direct application of the ideal feedforward in (9) will mean that K_f will contain an integrator that is not stabilized by feedback. To avoid this problem, the controller is implemented as illustrated in Fig. 4, with the integrator in the block K_2. The corresponding feedforward is $K_f = K_1G_d$, with the overall feedback controller given by $K = K_2K_1$.

With this slight modification, we obtain the results in Figs. 5 and 6. The solid lines represents the 'ideal' feedforward control according to (9), whereas the dash-dot line is conventional feedforward according to (8). Clearly, the conventional feedforward does not avoid the input saturation. On the other hand, the modified feedforward according to (9) simply does nothing to counter the effect of the disturbance. Even though the control offset is acceptable according to the scaling used, most people would probably prefer the responses represented by the dashed line. This is obtained by augmenting the feedforward in (9) with a high pass filter, and results in offset-free control at steady state. Clearly, the pass band of the high pass filter should include frequencies significantly lower than that corresponding to the RHP pole(s).

4. UNSTABLE DISTURBANCE MODELS

It was shown above that it is simple to use feedforward from the disturbance to avoid input saturation and hence loss of stabilizing feedback, when the plant is unstable but the disturbance transfer function is stable. If the disturbance transfer function is unstable, the issue becomes more complicated.

Note, that for stabilization of the unstable disturbance transfer function to make sense, the unstable mode(s) must also be a part of the plant transfer function. That is, it must be possible to reformulate the plant and disturbance transfer functions as indicated in Fig. 7, with $G_3(s)$ a

[1] Neglecting for the moment the effects of possibly unknown initial conditions for the disturbance dynamics.

stable transfer function. In this case, the disturbance will obviously excite the unstable mode, and it therefore does not make sense to avoid the use of the manipulated input when a disturbance occurs.

Furthermore, the direct application of the 'ideal' feedforward in (9) would mean using an unstable feedforward element K_f, which would lead to an internally unstable control system. Instead, we would like to find the *stable* feedforward element K_f which minimizes the term $(K_f - KG_d)$ in (5). The term KG_d can be split into a stable and an anti-stable part. The stable part can be used directly in K_f, whereas we need a *stable approximation to the anti-stable part of* KG_d.

Approximation of an anti-stable transfer function by a stable transfer function (or *vice versa*) is known as a Nehari extension problem. That is, we want to find the optimal stable $Q(s)$ such that $\|Q(s)+R(s)\|_\infty$ is minimized, where $R(s)$ is ant-stable. A solution to this problem can be found in Glover (1984). In Glover (1984), it is also shown that the optimal error is given by $\|R^*\|_H$, where $\|\cdot\|_H$ denotes the Hankel norm, and R^* is the 'stable version of R', with the unstable poles mirrored into the left half plane. Thus, we would like to design a feedback controller K that not only stabilizes the plant, but also makes the Hankel norm of the unstable part of KG_d small. However, with

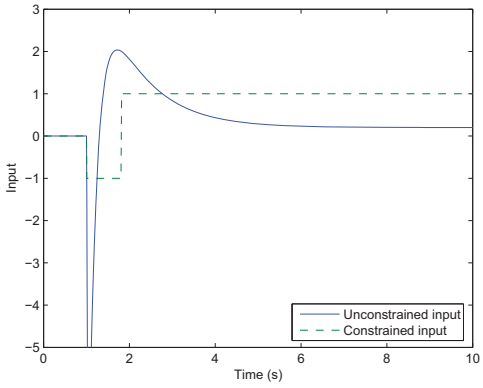

Fig. 2. Response in the input to a unit step in the disturbance as time $t = 1s$, using only feedback control.

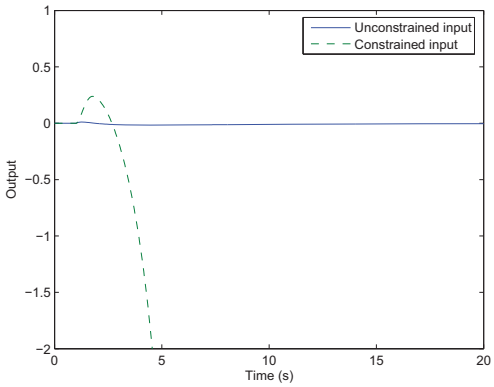

Fig. 3. Response in the output to a unit step in the disturbance as time $t = 1s$, using only feedback control.

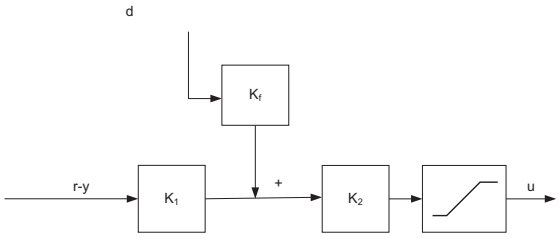

Fig. 4. Implementation of overall feedback/feedforward controller, with the integrator in the block K_2.

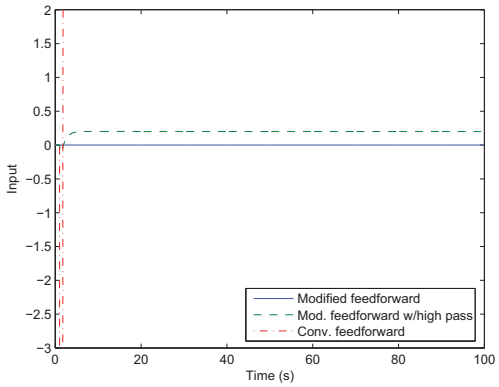

Fig. 5. Response in the input to a unit step in the disturbance as time $t = 1s$, using combined feedback and feedforward control.

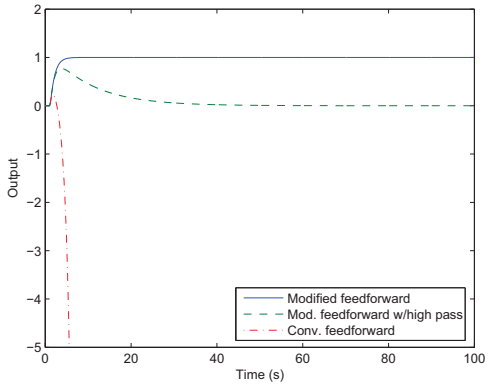

Fig. 6. Response in the output to a unit step in the disturbance as time $t = 1s$, using combined feedback and feedforward control.

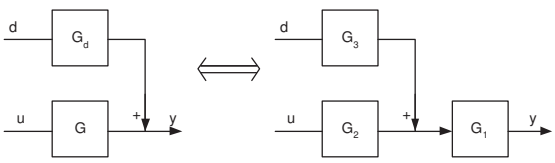

Fig. 7. Reformulation of plant and disturbance transfer functions.

a simple reformulation of the feedforward arrangement, this complication is easily avoided. This rearrangement is illustrated in Fig. 8, and may be regarded more as a 'reference governor' approach than feedforward in the ordinary sense.

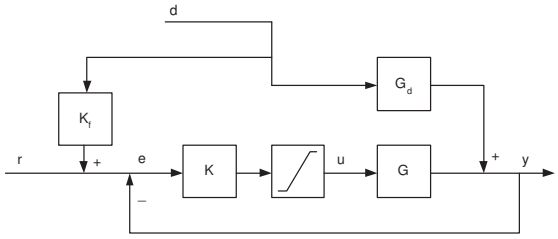

Fig. 8. 'Feedforward' arrangement for an unstable disturbance transfer function.

With the rearranged 'feedforward', the transfer function from the disturbance d to e, the input to the feedback controller K (assuming the saturation element is inactive), is given by

$$e = S(K_f - G_d)d \tag{11}$$

where $S = (I+GK)^{-1}$. Thus, for a given controller K, the controller input (and therefore also the controller output) will be small if the term $(K_f - G_d)$ is small. Next, the validity of the bound (4) and the design of the feedforward controller will be illustrated for two different cases:

- A disturbance transfer function G_d whose only non-minimum phase term is an unstable pole.
- A disturbance transfer function G_d with non-minimum phase terms in addition to the unstable pole.

The benefit of feedforward will be found to be different in these two cases. However, first the H_∞ problem formulation will be briefly explained. For the case with a stable disturbance transfer function, this was not needed, since the design of the feedforward controller was done separately from the design of the feedback controller.

4.1 H_∞ problem formulation

Using feedforward in combination with feedback means that we are using a controller with two degrees of freedom (2-DOF controller)). We wish to investigate the benefit of using a 2-DOF controller for stabilizing the system while minimizing the use of inputs in the face of measured disturbances. However, the resulting H_∞ control synthesis problem violates the standard assumptions. Assumptions A2 and A4 of Zhou et al. (1996), p. 450 are violated.

A small measurement noise n is therefore added, and the magnitude of that measurement noise is reduced until further reduction does not significantly affect the H_∞ norm achieved. The block diagram corresponding to the resulting controller synthesis problem is shown in 9.

4.2 The unstable pole as the only non-minimum phase term in G_d

The same plant transfer function as in (6) is used, whereas the disturbance transfer function is modified to

$$G_d(s) = \frac{k_d}{(s-1)(0.2s+1)} \tag{12}$$

The parameter value $k_d = 1$ is still used. First, a realization of $[G_d \quad G]$ with only one unstable mode is found. Then a 2-DOF controller is designed according to Fig. 9, and compared to a 1-DOF controller (feedback only) designed to minimize KSG_d. For both cases, a H_∞ norm of 1.83 is achieved. This also corresponds to the bound in (4). In this case, there is thus no advantage derived from using a 2-DOF controller with feedforward from disturbances[2].

However, if the feedback controller is designed for some other criterion than minimising $\|KSG_d\|_\infty$, there may be a possible advantage in designing the feedforward using the idea of approximating G_d with a stable transfer function. To illustrate, we first design a feedback controller for minimizing $\|KS\|_\infty$, achieving a H_∞ norm of 4.40 - which agrees with the bound in (2). Using this controller, we would also get $\|KSG_d\|_\infty = 4.40$. Instead, we augment the controller with feedforward as illustrated in Fig. 8. The transfer function G_d can be split into stable and unstable parts, giving

$$G_{d,stable} = \frac{-5k_d}{6(s+5)}$$
$$G_{d,unstable} = \frac{5k_d}{6(s-1)}$$

The task is this to find a stable approximation to $G_{d,unstable}$. The formulae in Glover (1984) for doing so are not directly applicable, since $G_{d,unstable}$ has only one state. However, it is easily verified that a stable approximation which achieves the minimum bound on the approximation error is given by

$$\tilde{G}_{d,unstable} = -\frac{5k_d}{12} \tag{13}$$

With the feedforward $K_f = G_{d,stable} + \tilde{G}_{d,unstable}$ used as illustrated in Fig. 8, and the feedback controller K which minimizes $\|KS\|_\infty$, we achieve an H_∞ norm of 1.83 from disturbance d to input u, while maintaining closed loop stability.

4.3 G_d with non-minimum phase terms in addition to the unstable pole

Consider next the case when the unstable disturbance transfer function is augmented with an all-pass term, giving

[2] And, in order to achieve $|u| < 1$ we would need $k_d < 0.54$, as in the original example in Skogestad and Postlethwaite (2005).

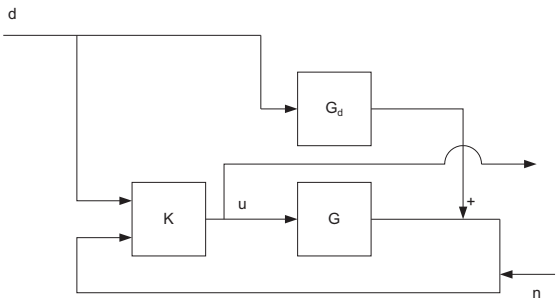

Fig. 9. H_∞ controller synthesis setup for 2-DOF controller.

$$G_d(s) = \frac{k_d(-10s+1)}{(s-1)(0.2s+1)(10s+1)} \quad (14)$$

The all-pass part of G_d cancels in the calculation of the bound in (4), and thus the minimum that can be achieved with feedback control alone is still $\|KSG_d\|_\infty = 1.83$. On the other hand, with a 2-DOF controller we achieve an H_∞ norm from d to u of 1.50. The same is achieved when designing a 1-DOF H_∞ controller minimizing $\|KS\|_\infty$ and subsequently adding feedforward to this controller in a manner similar to the preceding section.

Looking at the unstable part of $G_d(s)$ in (14), the reason for the improvement in input usage when adding the feedforward becomes apparent. One now finds that

$$G_{d,unstable} = \frac{-5k_d}{6(s-1)}\frac{9}{11}$$

The reduction in the unstable part of the disturbance transfer function by the factor 9/11 is a direct result of the all-pass term $(-10s+1)/(10s+1)$, since it modifies the residue at $s = 1$ by that same factor in the partial factor expansion of $G_d(s)$. Note that the improvement in H_∞ norm due to the introduction of feedforward also corresponds to the factor 9/11.

Stable all-pass terms will always reduce all residues in the RHP, and hence always reduce the size of the anti-stable part of $G_d(s)$ if there is a single unstable pole or a single pair of unstable complex conjugate poles. This covers a large fraction of the unstable system dynamics met in engineering practice. However, in general the unstable part of $G_d(s)$ may consist of several terms. The effect of all-pass terms will be different for the different unstable terms in $G_d(s)$, and it may therefore be possible for the unstable part of $G_d(s)$ to increase due to the presence of all-pass terms in the disturbance transfer function.

5. CONCLUSIONS

This paper illustrates how feedforward may be applied to reduce the input usage necessary for stabilizing unstable plants. If the disturbance transfer function is stable, one can thus easily remove the problem that disturbances may cause input saturation - with resulting loss of stabilizing feedback.

For the case of an unstable disturbance transfer function, it is clearly necessary to assume that the unstable mode is shared with the plant transfer function - otherwise it cannot be stabilized by feedback around the plant.

If the unstable pole is the only non-minimum phase term in the disturbance transfer function, feedforward has not been shown to improve on the optimal H_∞ norm achievable by feedback only. The bound on the H_∞ norm from d to u was found to apply for both 1-DOF and 2-DOF controllers in the example studied. However, if the 1-DOF controller is designed according to some other criterion than that of minimizing $\|KSG_d\|_\infty$, feedforward may be used to reduce the usage of inputs.

It is also found in an example that if the disturbance transfer function includes other non-minimum phase terms than the unstable pole, a 2-DOF controller can improve upon the optimal H_∞ norm achievable with feedback only. Feedforward may also in this case be added to a previously designed 1-DOF controller to reduce the usage of inputs.

Further work is necessary to quantify the optimal H_∞ norm from disturbance to plant input that is achievable when using a 2-DOF controller. Also, to simplify the analysis, the factor S has been ignored in (11), focusing instead on keeping $(K_f - G_d)$ small. Accounting for the factor S would lead to a *frequency weighted* Nehari extension problem. The possible benefit in accounting for this frequency weighting is not clear. In the examples studied, the optimal H_∞ norm for the 2-DOF problem has been achieved by appending feedforward (designed without accounting for the frequency weighting) to a 1-DOF controller design.

For the practising engineer, this paper points to the use of feedforward from disturbances to reduce input usage for stabilization. This may be an attractive alternative compared to alternative plant modifications in order to avoid input saturation (leading to loss of stabilizing feedback) in the face of disturbances.

Abstract: We discuss in this paper a novel and efficient implementation of distributed Model Predictive Control (MPC) systems for large-scale systems. The method is based on Partial Enumeration (PE), an approach that allows to compute the (sub)optimal solution of the Quadratic Program associated to the MPC problem by using a solution table that stores only a few most recently optimal active sets. This method is applied to the each local MPC system with significant improvements in terms of computational efficiency, and the original PE algorithm is modified to guarantee robust stability of the overall closed-loop system. We also discuss how input constraints that involve different units, e.g. on the summation of common utility consumption, can be appropriately handled. We illustrate the benefits of proposed method by means a simulated example comprising three units.

Keywords: Distributed MPC, Partial Enumeration, Explicit MPC, QP, Plant-wide Control

1. INTRODUCTION AND MOTIVATIONS

Model predictive control (MPC) is the most successful advanced control technique applied in the process industries (Qin and Badgwell, 2003), which nowadays tend to implement MPC systems in more and more plant units. Since units are often interconnected, it is clear that in some extent different MPCs may interfere, and depending on the steady-state and dynamic coupling of the units, these interactions may limit the overall achievable performance. From a pure theoretical point of view, the desire for optimality should push practitioners to implement a smaller number of (larger) MPC systems that encompass several units. From a practical point of view, however, the use of larger number of (smaller) MPC units may be preferred due to increased flexibility of the overall plant-wide control system, e.g. when one unit requires maintenance. Furthermore, depending on the size of the overall plant, a global centralized MPC system may simply be too large and too demanding in terms of computational resources. For these reasons, researchers are investigating so-called distributed MPC strategies, which aim to interconnect different MPC units with a minimal overhead structure and without increasing the complexity of the online problem solved by each MPC unit (Venkat et al., 2007; Dunbar, 2007; Rawlings and Stewart, 2008; Aske et al., 2008).

In the design of distributed MPC systems, several different "flavors" can be considered. The first one is the fully decentralized structure: each MPC unit optimizes its own objective function and no information regarding the computed input is exchanged among the MPC units. The second one is the so-called "non-cooperative" distributed MPC: the different units exchange their optimal input sequence, i.e. each MPC unit considers the other unit's planned input sequences in its optimal control problem. Both these approaches have no proven stability properties in closed-loop. In decentralized MPC the potential for instability comes first of all by the inherent model error induced by neglecting the interactions between different units. Furthermore in both decentralized and "non-cooperative" MPC structures, instability may arise because the different MPC systems optimize over different and competing objectives. When the closed-loop system is stable, "non-cooperative" MPC leads to a so-called Nash equilibrium point, which may be arbitrarily far away from the centralized optimum, also known as Pareto equilibrium point.

These issues are extensively discussed by Venkat et al. (2006a, 2007), who proposed the so-called "cooperative" distributed MPC architecture. In this distributed MPC system, each local controller optimizes, over its inputs, a common (overall) objective function and shares the computed optimal input sequence with all other controllers. As discussed by Venkat et al. (2006a,b), this scheme guarantees nominal stability, constraint satisfaction, and convergence towards the optimal centralized MPC solution, provided that no constraint involves coupling of inputs from different units.

In a recent paper (Pannocchia et al., 2007), we proposed for large-scale centralized MPC systems a novel online solution method called Partial Enumeration (PE) that allows fast evaluation of (a sub-) optimal solution of the MPC problem. Such method shares some ideas with Explicit MPC (Bemporad et al., 2002; Alessio and Bemporad, 2008; Baotic et al., 2008), which however is applicable only to small dimensional systems. In this paper, we investigate the use of PE for the solution of the local MPC problems with the aim of increasing the size and

⋆ This work was supported by National Science Foundation (Grant CTS-0456694)

complexity of problems that can be addressed efficiently by distributed MPC systems. A second objective of the present paper is to address the issue of coupled input constraints, which may limit the achievable performance of distributed MPC systems (Rawlings and Stewart, 2008).

2. COOPERATIVE MODEL PREDICTIVE CONTROL

2.1 Overall system, input constraints and local subsystems

We consider an overall time-invariant system (plant) in the discrete-time form:

$$x^+ = Ax + Bu, \qquad y = Cx\,, \tag{1}$$

in which $x \in \mathbb{R}^n$ and $x^+ \in \mathbb{R}^n$ are the state at a given time and at the successive time, respectively; $u \in \mathbb{R}^m$ is the input and $y \in \mathbb{R}^p$ is the output. Inputs are assumed to be constrained:

$$Du \le d\,, \tag{2}$$

in which the $d \in \mathbb{R}^q$ has non-negative components.

We assume that the plant is divided into $\mathcal{M}$ sub-systems (units), and each unit i has p_i outputs which are affected, in general, by *all* plant inputs. The objective is to design for each unit a Model Predictive Controller (MPC) that optimizes over a subset of inputs denoted with $u_i \in \mathbb{R}^{m_i}$, $i = 1, \ldots, \mathcal{M}$. The complementary input vector is denoted by $\bar{u}_i \in \mathbb{R}^{m-m_i}$. The subvectors u_i are *not* assumed to be disjoint. We define the selection matrices $T_i \in \mathbb{R}^{m_i \times m}$ and $\bar{T}_i \in \mathbb{R}^{(m-m_i)\times m}$ to be row submatrices of the identity, such that

$$u_i = T_i u, \qquad \bar{u}_i = \bar{T}_i u,$$

and thus

$$u = T_i' u_i + \bar{T}_i' \bar{u}_i\,.$$

Then, the dynamic evolution of each unit $i = 1, \ldots, \mathcal{M}$ can then described in the following form:

$$x_i^+ = A_i x_i + B_i u_i + \bar{B}_i \bar{u}_i, \qquad y_i = C_i x_i\,,$$

in which we distinguish the contribution of the inputs that belong to the $i-$th unit from the contribution of the other inputs. The subset of constraints in (2) that involve only u_i can be written as

$$D_i u_i \le d_i\,, \tag{3}$$

with D_i equal to the non-zero rows of (DT_i') and with d_i the corresponding elements of d. Similarly, the subset of constraints in (2) that involve $\bar{u}_i$ can be written as $\bar{D}_i \bar{u}_i \le \bar{d}_i$ with $\bar{D}_i$ equal to the non-zero rows of $(D\bar{T}_i')$ and with $\bar{d}_i$ the corresponding elements of d.

We consider the following assumptions.

Assumption 1. (Properties of subsystems). For each subsystem $i = 1, \ldots, \mathcal{M}$, the pair (A_i, C_i) is detectable, the pair (A_i, B_i) is stabilizable, and the inequality (3) represents *all* and *only* the constraints that involve elements of input vector u_i. The system from the input $\bar{u}_i$ to y_i is stable.

Remark 2. (Shared inputs). Notice that Assumption 1 admits the possibility that some inputs belong to more than one subsystem. It does require that all constraints involving any element of u_i can be written as constraints that do not involve elements of $\bar{u}_i$. Furthermore it assumes that inputs not belonging to unit i, $\bar{u}_i$, do not excite any unstable mode of A_i.

To clarify this point we present the following example.

Example 3. (Coupled constraints). Consider an overall system with four inputs and the following input constraint matrix and right-hand-side vector:

$$D = \left[\begin{array}{cc|cc} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \\ \hline 0 & 1 & 1 & 0 \end{array}\right], \qquad d = \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ \hline 1 \end{bmatrix}.$$

The first eight rows define upper and lower bound on each input whereas the last row defines an upper bound on the sum of second and third input. Suppose that we want to design two MPCs, one of which optimizes over (u_1, u_2) whereas the other one optimizes over (u_3, u_4). Since the last constraint involve both u_2 and u_3 that, in principle, belong to different units, in order to satisfy Assumption 1, we need to include u_3 in the set of inputs for Unit 1 and u_2 in the set of inputs of Unit 2. Thus, for Unit 1 we will consider (u_1, u_2, u_3) as inputs, and for Unit 2, we will consider (u_2, u_3, u_4) as inputs.

2.2 Centralized MPC problem

To simplify the notation and given the time invariance of the system, we consider that the current decision time to be $k = 0$. Let input, state and output targets be given, and satisfy:

$$x^s = Ax^s + Bu^s, \qquad y^s = Cx^s\,.$$

Notice that such targets can be either computed by a plant-wide steady-state optimizer or as the combination of $\mathcal{M}$ local steady-state optimizers. For convenience of notation we define:

$$w = x - x^s, \qquad v = u - u^s\,.$$

We consider a finite-horizon sequence of deviation inputs $\mathbf{v} = (v(0), v(1), \ldots, v(N-1))$ and define the overall cost:

$$V(w(0), \mathbf{v}) = \frac{1}{2}\sum_{k=0}^{N-1} w(k)'Qw(k) + v(k)'Rv(k) + \frac{1}{2}w(N)'Pw(N), \qquad \text{s.t. } w^+ = Aw + Bv\,,$$

Before defining the centralized MPC optimal problem, we make the following assumptions.

Assumption 4. (Properties of overall system). The matrices Q and R are positive definite. The matrix P is the given by $P = S_s'\Pi S_s$ with Π solution to the Lyapunov equation:

$$\Pi = A_s'\Pi A_s + S_s'QS_s\,,$$

where (A_s, S_s) come from the real Schur decomposition of A:

$$A = [S_s \;\; S_u]\begin{bmatrix} A_s & A_{su} \\ 0 & A_u \end{bmatrix}\begin{bmatrix} S_s' \\ S_u' \end{bmatrix}\,,$$

and A_s contains all stable eigenvalues of A.

The centralized MPC controller solves the following problem:

$$\mathbb{P}: \qquad \min_{\mathbf{v}} V(w(0), \mathbf{v}) \qquad \text{s.t.}$$
$$Dv \le d - Du^s, \quad S_u'w(N) = 0\,. \tag{4}$$

Remark 5. The constraint $Dv \le d - Du^s$ is equivalent to $Du \le d$. The terminal constraint $S_u'w(N) = 0$ is present only if the system is open-loop unstable (or integrating) and is needed to zero the unstable modes at the end of the horizon N. Furthermore, the cost function term $\frac{1}{2}w(N)'Pw(N)$ represents the infinite horizon cost-to-go when $v(k) = 0$ for $k \ge N$.

2.3 Distributed cooperative MPC subproblems

Let $\bar{\mathbf{v}}_i$ be a known sequence (in deviation variables) of the inputs that do not belong to Unit i, and define the control problem solved by the $i-$th MPC controller as follows:

$$\mathbb{P}_i: \quad \min_{\mathbf{v}} V(w(0),\mathbf{v}) \qquad \text{s.t.}$$
$$Dv \le d - Du^s, \quad S_u' w(N) = 0, \quad \bar{\mathbf{T}}_i \mathbf{v} = \bar{\mathbf{v}}_i\,, \quad (5)$$

in which $\bar{\mathbf{T}}_i \in \mathbb{R}^{(m-m_i)N \times mN}$ is the block diagonal matrix formed with $\bar{T}_i$, $i = 1,\dots,\mathcal{M}$. Similarly, later we use $\mathbf{T}_i \in \mathbb{R}^{m_i N \times mN}$ to denote the block diagonal matrix formed with blocks equal to T_i. We denote with $\tilde{\mathbf{v}}_i$ the solution to (5).

Remark 6. The last equality constraint enforces the inputs that do not belong to Unit i to be equal to the known value $\bar{\mathbf{v}}_i$.

The problem $\mathbb{P}_i$ (5) contains a large number of decision variables that are fixed, namely, all inputs of the other units. We can eliminate these inputs and reformulate this problem as follows. Let the deviation input sequence $\mathbf{v}$ be expressed as

$$\mathbf{v} = \mathbf{T}_i' \mathbf{v}_i + \bar{\mathbf{T}}_i' \bar{\mathbf{v}}_i\,, \quad (6)$$

in which $\mathbf{v}_i = \mathbf{T}_i \mathbf{v}$ is the sequence of inputs that belong to Unit i, and $\bar{\mathbf{v}}_i = \bar{\mathbf{T}}_i \mathbf{v}$ is the sequence of complementary inputs. We can now write the local control problem as:

$$\mathbb{P}_i: \quad \min_{\mathbf{v}_i} V(w(0),\mathbf{v}) \qquad \text{s.t. (6) and}$$
$$D_i v_i \le d_i - D_i u_i^s, \quad S_u' w(N) = 0\,. \quad (7)$$

Remark 7. We note that in (7) we consider only constraints for the inputs of Unit i, and constraints for the other inputs are assumed to be satisfied, i.e. $\bar{D}_i \bar{v}_i \le \bar{d}_i - \bar{D}_i \bar{u}_i^s$. Moreover, the terminal state constraint may contain equations that are not affected by $\mathbf{v}_i$, and such constraints can be eliminated.

2.4 Algorithm and properties

In distributed MPC, each local MPC unit optimizes and communicates its solution with other MPC units, forming a convex combination of the all $\mathcal{M}$ unit solutions to obtain an overall solution. If decision time permits, this procedure is repeated iteratively until convergence or until a specified maximum number of iterations is reached. The distributed MPC algorithm is initiated with an overall input sequence computed at the previous decision time, as follows:

$$\mathbf{v}^0 = (u^*(1) - u^s, \dots, u^*(N-1) - u^s, 0)\,, \quad (8)$$

in which we emphasize that the terms $u^*(\cdot)$ are the components of the (sub)optimal sequence computed at the previous decision time, whereas u^s is the input target at the current decision time.

Remark 8. Such initial sequence is feasible with respect to the input constraint $Dv \le d - Du^s$, and it is also feasible for the terminal constraint $S_u' w(N) = 0$ if it exists, provided the target has not changed from the previous decision time.

We now describe the distributed cooperative MPC algorithm.

Algorithm 1. (Distributed Cooperative MPC). Data: current target (u^s, x^s), deviation state $w(0) = x - x^s$, an overall initial sequence $\mathbf{v}^0$ as in (8). Relative tolerance parameter ρ, maximum number of iterations $l_{\max}$.

(1) (Local MPC problems) Set $l = 1$ and for each MPC unit i repeat the following steps:
   (a) Define $\bar{\mathbf{v}}_i = \bar{\mathbf{T}}_i \mathbf{v}^{l-1}$, solve problem $\mathbb{P}_i$. Let $\mathbf{v}_i$ be the optimal solution to $\mathbb{P}_i$.
   (b) Construct the "complete" solution obtained by Unit i: $\tilde{\mathbf{v}}_i = \mathbf{T}_i' \mathbf{v}_i + \bar{\mathbf{T}}_i' \bar{\mathbf{v}}_i$.

(2) (Convex Step) Define the "overall" solution as combination of the local solutions $\mathbf{v}^l = \sum_{i=1}^{\mathcal{M}} \lambda_i \tilde{\mathbf{v}}_i$, with $\lambda_i > 0$ and $\sum_{i=1}^{\mathcal{M}} \lambda_i = 1$.

(3) (Convergence Test) If $\frac{\|\mathbf{v}^l - \mathbf{v}^{l-1}\|}{1+\|\mathbf{v}^{l-1}\|} < \rho$ or $l = l_{\max}$, set $\mathbf{v}^* = \mathbf{v}^l$ and stop. Otherwise, increase $l \leftarrow l + 1$ and go to 1.

It is possible to show that such cooperative MPC algorithm converges to the optimal centralized solution in the limit of infinite iterations. Furthermore, we can establish closed-loop stability for any finite number of iterations l.

3. PARTIAL ENUMERATION

3.1 Introduction

Both the centralized problem $\mathbb{P}$ and each problem $\mathbb{P}_i$ can be written as convex Quadratic Programs, and for small to medium scale systems, the solution can be computed efficiently using either Active Set Method (ASM) or Interior Point Method (IPM) solvers (Rao et al., 1998; Bartlett et al., 2002; Milman and Davison, 2003). However, as the system dimension increases, online solvers cannot provide a solution within an acceptable decision time. In order to compute a (suboptimal) solution for large-scale systems that are currently out of the range of QP solvers, we recently proposed an approach called Partial Enumeration (Pannocchia et al., 2007). In Partial Enumeration (PE) we use a solution table that stores a (small) number of optimal active sets and the associated piecewise linear solution (Bemporad et al., 2002). This approach was applied to large-scale centralized MPC problems in (Pannocchia et al., 2007) with average speed-up factors of 80-200 times compared to conventional QP solvers, and with small closed-loop suboptimality. We review PE here and make appropriate modifications for applying it to the distributed MPC problem $\mathbb{P}_i$.

3.2 PE algorithm and properties

We first consider the centralized MPC problem $\mathbb{P}$ and write it as a parametric QP as follows:

$$\min_{\mathbf{v}} \frac{1}{2}\mathbf{v}'\mathbf{H}\mathbf{v} + \mathbf{v}'\mathbf{G}w(0) + \frac{1}{2}w(0)'\mathbf{P}w(0) \qquad \text{s.t.} \quad (9a)$$
$$\mathbf{D}\mathbf{v} + \mathbf{C}u^s \le \mathbf{d}, \quad \mathbf{E}\mathbf{v} + \mathbf{F}w(0) = 0. \quad (9b)$$

Note that $z = [w(0)', \ u^{s\prime}]'$ is the parameter that changes at each decision time point, while all other terms are constant and omitted in the sake of space.

Given a point $\mathbf{v}^*$, we denote by $(\mathbf{D}_a, \mathbf{C}_a, \mathbf{d}_a)$ the stacked rows of $(\mathbf{D}, \mathbf{C}, \mathbf{d})$ such that $\mathbf{D}_a\mathbf{v}^* + \mathbf{C}_a u^s = \mathbf{d}_a$ (i.e. the active constraints). We also denote with $(\bar{\mathbf{D}}_a, \bar{\mathbf{C}}_a, \bar{\mathbf{d}}_a)$ the complementary stacked rows, i.e. such that $\bar{\mathbf{D}}_a\mathbf{v}^* + \bar{\mathbf{C}}_a u^s < \bar{\mathbf{d}}_a$ (i.e. the inactive constraints). Next, we define:

$$\mathcal{G} = [\mathbf{G} \ 0]\,, \quad \mathcal{A} = \begin{bmatrix}\mathbf{D}_a \\ \mathbf{E}\end{bmatrix}, \quad \mathcal{B} = \begin{bmatrix}0 & \mathbf{C}_a \\ \mathbf{F} & 0\end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix}\mathbf{d}_a \\ 0\end{bmatrix}.$$

In order for $\mathbf{v}^*$ to be optimal for (9), the following first-order optimality KKT conditions must hold:

$$\mathbf{H}\mathbf{v}^* + \mathcal{G}z + \mathcal{A}'\lambda^* = 0, \quad (10a)$$
$$\mathcal{A}\mathbf{v}^* + \mathcal{B}z = \mathbf{b}, \quad (10b)$$
$$\lambda_j^* \ge 0, \qquad j \in \{\text{indices of active inequalities}\}, \quad (10c)$$
$$\bar{\mathbf{D}}_a\mathbf{v}^* + [0 \ \bar{\mathbf{C}}_i]z \le \bar{\mathbf{d}}_a. \quad (10d)$$

We now solve the system (10) to derive $\mathbf{v}^*$ as a linear function of the parameter z and we derive the conditions on z for which the considered active set is optimal. To this aim, several

approaches can be followed, and in this paper we use the so-called Null-Space method.

Let $\mathcal{Z}$ be a full rank matrix such $\mathcal{A}\mathcal{Z} = 0$, and consider the point $\mathbf{v}_0 = \mathcal{A}^+(\mathbf{b} - \mathcal{B}z)$, which $\mathcal{A}^+$ is the pseudo-inverse of $\mathcal{A}$. We can express any point that is feasible for (10b) as $\mathbf{v} = \mathbf{v}_0 + \mathcal{Z}p$ and thus rewrite (10a) as follows:

$$\mathbf{H}\mathcal{Z}p + \mathbf{H}\mathbf{v}_0 + \mathcal{G}z + \mathcal{A}'\lambda^* = 0\,.$$

Next, we multiply (on the left) by $\mathcal{Z}'$ (to eliminate the term $\mathcal{Z}'\mathcal{A}'\lambda^*$) and solve for p to obtain

$$\begin{aligned} p &= \left(\mathcal{H}^{-1}(\mathcal{Z}'\mathbf{H}\mathcal{A}^+\mathcal{B} - \mathcal{Z}'\mathcal{G})\right) z - \mathcal{H}^{-1}(\mathcal{Z}'\mathbf{H}\mathcal{A}^+)\mathbf{b} \\ &= \mathbf{\Gamma}_p z + \gamma_p\,, \end{aligned}$$

with $\mathcal{H} = \mathcal{Z}'\mathbf{H}\mathcal{Z}$. Finally, we compute $\mathbf{v}^*$ as follows:

$$\begin{aligned} \mathbf{v}^* &= \mathbf{v}_0 + \mathcal{Z}p = \mathcal{A}^+(\mathbf{b} - \mathcal{B}z) + \mathcal{Z}(\mathbf{\Gamma}_p z + \gamma_p) \\ &= \mathbf{\Gamma} z + \gamma\,. \end{aligned} \tag{11}$$

Now (10a) can be solved for λ^* as follows:

$$\lambda^* = -(\mathcal{A}')^+(\mathbf{H}\mathbf{v}^* + \mathcal{G}z) = -(\mathcal{A}')^+(\mathbf{H}\mathbf{\Gamma} + \mathcal{G})z - (\mathcal{A}')^+\mathbf{H}\gamma.$$

Finally, we write the Primal and Dual inequalities (10c) and (10d) as follows:

$$\begin{bmatrix} \bar{\mathbf{D}}_a\mathbf{\Gamma} + [0\ \bar{\mathbf{C}}_a] \\ [I\ 0]\,(\mathcal{A}')^+(\mathbf{H}\mathbf{\Gamma} + \mathcal{G}) \end{bmatrix} z \le \begin{bmatrix} \bar{\mathbf{d}}_a - \bar{\mathbf{D}}_a\gamma \\ -[I\ 0]\,(\mathcal{A}')^+\mathbf{H}\gamma \end{bmatrix},$$

or more concisely as

$$\begin{bmatrix} \mathbf{\Psi}_P \\ \mathbf{\Psi}_D \end{bmatrix} z \le \begin{bmatrix} \psi_P \\ \psi_D \end{bmatrix}. \tag{12}$$

Furthermore, by inserting the solution (11) into the objective function of (9), we can write the optimal cost for the current active set as: $V^*(z) = \frac{1}{2}z'V_2z + V_1z + V_0$.

In Partial Enumeration we store $(\mathbf{\Psi}_P, \mathbf{\Psi}_D, \mathbf{\Gamma})$, (ψ_P, ψ_D, γ), and also (V_0, V_1, V_2), for a fixed number of active sets that were optimal in the most recent decision time points. Online we scan the table to check if, for the given parameter z, optimality conditions (12) are satisfied, and in such case compute the optimal solution from (11). However, given the fact that not all possible optimal active sets are stored, it is possible that no entry in the table is optimal. In such cases it is necessary to compute a suboptimal solution for closed-loop control. Nonetheless, a QP solver is called afterwards to compute the optimal solution $\mathbf{v}^*$, and thus derive the matrices/vectors $(\mathbf{\Psi}_P, \mathbf{\Psi}_D, \mathbf{\Gamma})$, (ψ_P, ψ_D, γ), (V_0, V_1, V_2) for the corresponding optimal active sets. Whenever this table entry becomes available, it is inserted into the table. When the table exceeds its maximum size (defined by the user), we delete the entry that was optimal least recently. Thus, the table size is fixed and hence the table lookup process is fast, but the table entries are updated to keep track of new operating conditions for the plant.

In order to compute a suboptimal input sequence when the table does include the optimal active set for the current parameter z several options can be considered. It is important to ensure that the given suboptimal solution guarantees, at least, nominal closed-loop stability, and this can be obtained if we ensure a cost decrease from the previous decision time point. Here, we propose a procedure that allows us to prove robust stability of the closed-loop under PE MPC. The procedure requires two points, the first one which needs to be feasible and its computation is discussed later in Algorithm 2. The second point, instead, is a particular minimizer of (9a) subject to the equality constraint (if present) and all the input inequalities that are active at the target point. More specifically, given the input target u^s, let $(\bar{\mathbf{D}}, \bar{\mathbf{d}})$ denote the subset of rows of $(\mathbf{D}, \mathbf{d})$ such that $\bar{\mathbf{C}}u^s = \bar{\mathbf{d}}$. We define $\hat{\mathbf{v}}$ as the solution to:

$$\min_{\mathbf{v}} V(w(0), \mathbf{v}) \text{ s.t. } \bar{\mathbf{D}}\mathbf{v} = 0,\ \mathbf{E}\mathbf{v} + \mathbf{F}w(0) = 0\,. \tag{13}$$

We can show that $\hat{\mathbf{v}} = \hat{\mathbf{\Gamma}}(u^s)w(0)$, where the dependence of the matrix $\hat{\mathbf{\Gamma}}$ on u^s comes from the fact that u^s defines $(\bar{D}, \bar{d})$.

In the following, we denote by $\mathbf{v}^0 = (u^*(1) - u^s, \ldots, u^*(N-1) - u^s, 0)$ the previous shifted optimal sequence, where the inputs $(u(1)^*, \ldots, u^*(N-1))$ were computed at the previous decision time, while u^s is the current input target.

Algorithm 2. (Partial Enumeration). Data: table with M entries, each comprising the terms $(\mathbf{\Psi}_P, \mathbf{\Psi}_D, \mathbf{\Gamma})$, (ψ_P, ψ_D, γ), (V_0, V_1, V_2); current parameter $z = [w(0)',\ u^{s\prime}]'$; candidate sequence $\mathbf{v}^0$ and its cost V^0 if feasible (otherwise $V^0 = \infty$); maximum table size $M_{\max}$. Output: Input sequence $\mathbf{v}^*$ and updated table. Set $j = 0$, $\tilde{V} = V^0$, $\tilde{\mathbf{v}} = \mathbf{v}^0$.

(1) (Table scanning.) Set $j \leftarrow j+1$. If $j > M$ and $\tilde{\mathbf{v}}$ is feasible go to 4. If $j > M$ and $\tilde{\mathbf{v}}$ is infeasible go to 3. Otherwise, perform the following steps for the $j-$th entry:
   (a) If $\mathbf{\Psi}_P z \le \psi_P$ does not hold, go to 1. Otherwise,
   (b) If $\mathbf{\Psi}_D z \le \psi_D$ holds go to 2. Otherwise,
   (c) Compute the cost V. If $V < \tilde{V}$, set $\tilde{\mathbf{v}} = \mathbf{\Gamma}_u(\mathbf{d}_a - \mathbf{C}_a u^s) + \mathbf{\Gamma}_w w(0)$. Go to 1.

(2) (Optimal solution found.) Compute the optimal solution $\mathbf{v}^*$. Inject the optimal input. Put this entry in first position of the table. Stop.

(3) (Feasibility recovery; arrive at this step only if $\tilde{\mathbf{v}}$ is not feasible.) Solve the LP

$$\min_{\mathbf{q},\mathbf{s}} \mathbf{1}'(\mathbf{q} + \mathbf{s}) \qquad \text{s.t. } \mathbf{D}(\mathbf{q} - \mathbf{s}) \le \mathbf{r}_1,$$
$$\mathbf{E}(\mathbf{q} - \mathbf{s}) = \mathbf{r}_2, \quad \mathbf{q} \ge 0, \quad \mathbf{s} \ge 0$$

where $\mathbf{r}_1 = \mathbf{d} - \mathbf{C}u^s - \mathbf{D}\tilde{\mathbf{v}}$, $\mathbf{r}_2 = -\mathbf{F}w(0) - \mathbf{E}\tilde{\mathbf{v}}$, and $\mathbf{1}$ is the vector of ones. Redefine $\tilde{\mathbf{v}} \leftarrow \tilde{\mathbf{v}} + \mathbf{q} - \mathbf{s}$ and compute its cost $\tilde{V}$.

(4) (Solution improvement; $\tilde{\mathbf{v}}$ is feasible at this point.) Evaluate $\hat{\mathbf{v}}$, and compute the largest $t \in [0, 1]$ such that $\mathbf{D}(\hat{\mathbf{v}} - \tilde{\mathbf{v}})t \le \mathbf{d} - \mathbf{C}u^s - \mathbf{D}\tilde{\mathbf{v}}$. Set $\mathbf{v}^* = \tilde{\mathbf{v}}(1-t) + t\hat{\mathbf{v}}$.

(5) (Table update, performed in parallel.) Solve the QP (9), and find the terms $(\mathbf{\Psi}_P, \mathbf{\Psi}_D, \mathbf{\Gamma})$, (ψ_P, ψ_D, γ), (V_0, V_1, V_2) for the optimal active set. Insert this entry in first position of the table, set $M \leftarrow M+1$. If $M = M_{\max}+1$, delete the entry that was optimal least recently, and set $M = M_{\max}$.

Remark 9. The "feasibility recovery" step 3 is required *only if* the system is open-loop unstable *and* either the target changed from the previous decision time or a disturbance occurred. In the nominal case without target change, such step is not performed because $\mathbf{v}^0$ is always feasible. Step 3 is the only "expensive" computation in Algorithm 2 and is justified by closed-loop stability reasons of an open-loop unstable plant. For input bound constraints (i.e., $u_{\min} \le u \le u_{\max}$) further simplifications that allow increased speedup and lower sub optimality can be considered.

It can be shown that PE MPC is nominally stabilizing and robustly stabilizing for sufficiently small measurement noise and additive disturbances (Pannocchia et al., 2009).

3.3 Application of Partial Enumeration to cooperative MPC

Each $\mathbb{P}_i$ in (7) can be written as the following parametric QP:

Table 1. Outputs and inputs of the three units, according to two design schemes: Design A (existing), Design B (optimal).

	Outputs	Inputs	
		Design A	Design B
Unit 1	(y_1, y_2, y_3)	(u_1, u_2, u_3)	$(u_1, u_2, u_3, u_4, u_8)$
Unit 2	(y_4, y_5, y_6)	(u_4, u_5, u_6)	$(u_3, u_4, u_5, u_6, u_8)$
Unit 3	(y_7, y_8)	(u_7, u_8)	(u_3, u_4, u_7, u_8)

$$\min_{\mathbf{v}_i} \frac{1}{2}\mathbf{v}_i'\mathbf{H}_i\mathbf{v}_i + \mathbf{v}_i'\mathcal{G}_i z_i + \frac{1}{2} z_i \mathbf{P}_i z_i \qquad \text{s.t.} \qquad (14a)$$

$$\mathbf{D}_i\mathbf{v}_i + \mathbf{C}_i z_i \leq \mathbf{d}, \quad \mathbf{E}_i\mathbf{v}_i + \mathbf{F}_i z_i = 0\,, \qquad (14b)$$

in which $z_i = [z',\ \bar{\mathbf{v}}_i']'$ is the parameter augmented with the sequence of inputs that do not belong to Unit i, and $\mathbf{H}_i = \mathbf{T}_i\mathbf{H}\mathbf{T}_i'$, $\mathcal{G}_i = \begin{bmatrix}\mathcal{G} & \mathbf{T}_i\mathbf{H}\bar{\mathbf{T}}_i'\end{bmatrix}$, $\mathbf{P}_i = \begin{bmatrix}\mathbf{P} & 0 \\ 0 & 0 & \mathcal{G}'\bar{\mathbf{T}}_i' \\ \bar{\mathbf{T}}_i\mathcal{G} & \bar{\mathbf{T}}_i\mathbf{H}\bar{\mathbf{T}}_i'\end{bmatrix}$, $\mathbf{D}_i = \mathbf{D}\mathbf{T}_i'$, $\mathbf{C}_i = \begin{bmatrix}0 & \mathbf{C} & \mathbf{D}\bar{\mathbf{T}}_i'\end{bmatrix}$, $\mathbf{E}_i = \mathbf{E}\mathbf{T}_i'$, $\mathbf{F}_i = \begin{bmatrix}\mathbf{F} & 0 & \mathbf{E}\bar{\mathbf{T}}_i'\end{bmatrix}$. Notice that several rows of $\mathbf{D}_i$ and $\mathbf{E}_i$ are zero and can be deleted along with the corresponding rows of $\mathbf{C}_i$ and $\mathbf{F}_i$.

We notice that the QP (14) is in the same form of (9), with the main difference that the parameter z is augmented with the known sequence of inputs not belonging to Unit i. Given this increase in dimensionality, a full explicit MPC is impractical even for small systems. On the other hand, PE Algorithm 2 can be readily applied to solve (14). Since PE does not guarantee that each $\mathbb{P}_i$ is solved exactly, no convergence to the optimal centralized solution can be proved. Nonetheless, we can show closed-loop nominal stability and robust stability for sufficiently small disturbances.

4. APPLICATION EXAMPLE

4.1 Overall system and units definition

As an example, we consider a stable system with 8 inputs, 8 outputs and 48 states, whose details are omitted in the sake of space. Each input of the system is constrained in $[-1, 1]$, and the following coupled constraint holds:

$$[0\ 0\ 0\ 1\ 1\ 0\ 0\ 1]\, u \leq 1\,. \qquad (15)$$

In the MPC design we use: $Q = I$, $R = I$, and $N = 30$.

We consider that this overall plant is divided in three units. Outputs and inputs of each unit are reported in Table 1, where we emphasize two different design schemes. In Design A, which can be regarded as the existing scheme for this plant, no inputs belong to more than one unit at a time. However, because of the coupled constraint (15), such input partition scheme does not satisfy Assumption 1. Therefore, for such scheme convergence to the optimal centralized solution cannot be guaranteed. For this reason, we consider an alternative input partition scheme (Design B) in which the inputs (u_3, u_4, u_8) belong to all three units.

4.2 Effect of coupled constraints

First of all we investigate about the different convergence properties for the two distributed MPC architectures. We consider that at decision time 10, the input target changes from 0 to $u^s = (0, 0, 0.5, 0.2, 0, 0, 0, 0.3)'$, thus making the coupled constraint active. We report in Figure 1 the closed-loop response of $u_3 + u_4 + u_8$ obtained by three controllers: CMPC is the centralized controller, DMPC-A is the distributed control structure with $l = 1$ iteration based on Design A, DMPC-B is the distributed control structure with $l = 1$ iteration based on Design B. For this study, we solve the optimal control problems exactly, i.e. we do not use Partial Enumeration. We report in Table 2, the suboptimality of DMPC-A and DMPC-B as the number of iterations l increases, defined by the index:

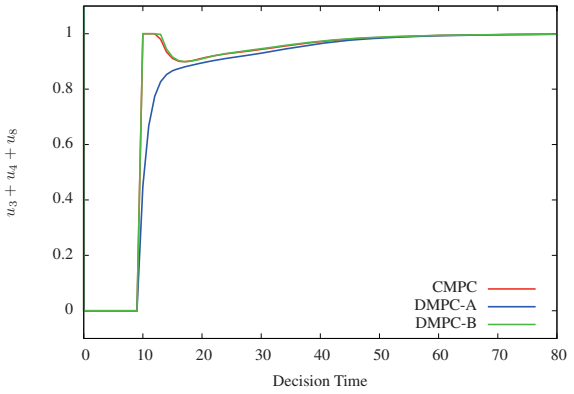

Fig. 1. Effect of coupled input constraints: closed-loop response of $u_3+u_4+u_8$ for centralized MPC (CMPC), distributed cooperative MPC based on Design A (DMPC-A), distributed cooperative MPC based on Design B (DMPC-B). Both DMPC-A and DMPC-B make $l = 1$ iteration.

Table 2. Suboptimality of DMPC-A and DMPC-B for different number of iterations l.

Dec. MPC	S_I			
	$l = 1$	$l = 5$	$l = 10$	$l = 50$
DMPC-A	22.9	0.885	0.682	0.673
DMPC-B	2.29	$4.86 \cdot 10^{-2}$	$5.43 \cdot 10^{-4}$	$1.53 \cdot 10^{-8}$

$$S_I = 100\frac{V_{CL} - V_{CL}^*}{V_{CL}}\,,$$

in which V_{CL} is the closed-loop cost for the considered (distributed) controller and V_{CL}^* is the closed-loop cost for the optimal centralized controller. As expected DMPC-B handles the coupled constraint much better than DMPC-A, and as the number of iterations increases, DMPC-B converges to the optimal centralized MPC solution, whereas the suboptimality index for DMPC-A does not go to zero.

4.3 Comparison of PE-based and QP-based distributed MPC

We now present the results for several decentralized controllers that solve the local MPC problems $\mathbb{P}_i$ either via PE or via an exact (active set) QP solver. We are interested in assessing the suboptimality of each scheme, as well as the computational efficiency quantified by the two indices [1] :

- Average Speed Factor: $A_{SF} = \frac{T_{\text{aver}}^*}{T_{\text{aver}}}$ where T_{aver}^* is the average CPU time required to solve the centralized problem $\mathbb{P}$ via QP solver, and T_{aver} is the average CPU time required to compute the solution using Algorithm 1 (either via PE or via exact QP solver).
- Worst Case Speed Factor: $W_{SF} = \frac{T_{\max}^*}{T_{\max}}$, where $T_{\max}^*$ and $T_{\max}$ are the maximum CPU times for the centralized (QP based) problem $\mathbb{P}$ and for the distributed Algorithm 1 (PE or QP based), respectively.

[1] All computations are performed using GNU Octave on a Pentium-M (1.86 GHz, 1 GB RAM) running Linux.

Table 3. Comparison of suboptimality and computational efficiency for several DMPC-B, based on PE or exact QP solver

	QP based			PE based		
Iter.	S_I	A_{SF}	W_{SF}	S_I	A_{SF}	W_{SF}
$l = 1$	14.7	5.24	12.1	14.8	93.5	285
$l = 5$	0.604	1.25	4.66	0.612	22.0	66.7
$l = 10$	0.0408	0.797	2.37	0.0490	13.9	34.4

We consider a closed-loop simulation of 5000 decision time points, in the presence of random output noise, affecting the state estimate and the target at each decision time, and 14 large target changes. When PE is used, each MPC unit deploys an initially empty table of maximum dimension $M_{\max} = 10$. The results are summarized in Table 3. We can observe, first of all, that as number of iterations l increases, DMPC-B converges to the centralized optimum performance, as indicated by the negligible suboptimality index S_I. Next, we can see that for a given number of iterations l, the suboptimality index obtained by solving the local problems with the QP solver is essentially equal to that obtained with the PE solver. However, the computational requirements using QP and PE solvers are remarkably different. If we compare the distributed controllers using the same number of iterations, DMPC-B based on local PE solvers can compute the solution 17–18 times faster (on average), 14–24 times faster (worst case) than the corresponding DMPC-B based on local QP solvers. In practice, since the time allowed for computation of local solutions and iterations among the distributed controllers may be regarded as fixed, the goal of using local PE solvers is that we can allow more iterations and thus (almost) achieve the centralized optimal performance. If compared with the centralized MPC, most of the computational benefits of using DMPC-B based on PE solvers are achieved with a limited number of iterations, e.g. $l = 5$, which allows one to obtain a suboptimality less than 1% with an average speedup factor of 22 and a worst case speedup factor of 67.

A final remark can be made regarding the possible (apparent) overlap of applicability and scope of Partial Enumeration and distributed MPC, i.e. as alternative means for solving MPC problems in large-scale systems. We want to stress that the main motivation for distributed MPC is organizational rather than computational and, in fact, if the number of iterations l is increased the distributed MPC architecture (based on QP solvers) may be even more time consuming than a centralized MPC architecture (notice the average "speedup" factor less than 1 for DMPC-B based on QP with $l = 10$ iterations). Therefore, distributed MPC should not be considered as a possible competitor of Partial Enumeration centralized MPC which, on the other hand, is motivated by computational issues.

5. CONCLUSIONS

We proposed in this paper an efficient implementation for distributed cooperative Model Predictive Control. The approach is based on Partial Enumeration, that solves the Quadratic Program associated to the MPC problem by means of a small solution table, which includes the most recently optimal active sets. If the optimal solution is not found in the table, a quick suboptimal solution is computed for closed-loop control. In parallel, the optimal active set is evaluated and inserted into the table, possibly deleting the least recently optimal active set. In this way the size of the table is kept small, thus limiting the required time for scanning it. We applied such approach for the solution of "local" MPC problems that are solved in each unit of a distributed MPC system. We also revised the cooperative distributed MPC architecture to optimally handle the case of coupled input constraints. Finally, we presented a simulation example of an 8 input 8 output plant comprising three units in which we achieved relevant speedup factors and negligible suboptimality compared to QP-based MPC.

Optimality of Process Networks. ⋆

Michael R. Wartmann * **B. Erik Ydstie** *

* *Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh, USA (e-mail: wartmann@cmu.edu, ydstie@cmu.edu).*

Abstract: In this paper we show that conservation laws for extensive quantities and the second law of thermodynamics lead to conditions for stability and optimality of a process network. Interconnections among nodes are represented through connectivity matrices and network graphs. A generalized version of Tellegen's theorem from electrical circuit theory plays a central role in deriving the objective function of the regarded dynamic process networks. The application of irreversible thermodynamics lead to stability and optimality results based on the co-content and content of the regarded process networks. The principle is illustrated in a pipeflow example.

Keywords: dissipation, network theory, irreversible thermodynamics, distributed control, passivity theory.

1. INTRODUCTION

The complexity of process systems arises from the variety of how simple subunits are connected (Hangos et al. (1999)). A crucial component in modeling process systems is therefore to understand how connections between the subunits lead to complex system behavior. Ydstie and Alonso (1997) developed a theoretical framework providing a link between passivity theory and physics using the second law of thermodynamics. They discussed the need to develop passivity based control techniques which focus on input-output properties of the systems. An understanding for complex behavior can then be derived from macroscopic thermodynamic constraints instead of microscopic equations and the complexity that results from using very detailed models can be reduced. Jillson and Ydstie (2007) developed a topological result similar to Tellegen's theorem of electrical circuit theory and passivity theory to derive sufficient conditions under which a network is stabilized using decentralized feedback. The theory shows that it is possible to control very complex networks of process systems without actually modeling the thermodynamics and kinetics explicitly. This is due to inherent passivity properties that follow from the second law of thermodynamics. The conditions for passivity can be checked in a distributed manner. In this work, we will explore if similar ideas can be applied for optimization.

We extend the approaches in Ydstie and Alonso (1997); Jillson and Ydstie (2007) to provide an organizational framework for treating complex process systems concerning optimality using ideas from network theory. The formalism of network theory has been particularly successful for modeling and control of dynamic systems in electrical engineering applications. Classically, electrical circuit theory is not considered an application of non-equilibrium thermodynamics. Nevertheless, electrical circuits are typical irreversible thermodynamic systems. The formalism developed in electrical circuit theory was extended to general thermodynamic systems by Oster et al. (1971); Peusner (1986). In particular the application to complex biological systems has been carried out successfully by Oster and Desoer (1971); Mickulecky (2001). In this paper, we apply the formalism of network theory to describe connected process systems. Network theory brings thermodynamics a degree of mathematical rigor and allows to unify ideas from non-equilibrium thermodynamics, dynamic system theory and control. In the context of dissipativity of process systems, network theory facilitates the extension of irreversible thermodynamics by the system's topological description which is an important part of the dynamic behavior. Looking at mathematical models of many dynamic physical systems, we can identify a certain inherent structure. We can separate the network model into a kinematic structure which addresses the topology of the system and a dynamical structure (Oster and Desoer (1971)). The connectivity properties of the system describe the physical processes where the dynamical structure defines the relationships between the state variables. The paper is organized as follows: In Section 2, we define the type of process systems and describe the connection to network theory, in Section 3, we describe fundamental topological properties of the regarded process networks. In Section 4 and 5, we elaborate the concepts of stability and optimality for the regarded systems and present a pipeflow example to illustrate our findings in Section 6.

2. PROCESS NETWORKS

Process networks are written as a collection of interconnected sub-systems

$$\dot{x}_i = F(x_i) + \sum_{j=0, j\neq i}^{n} G(u_i, x_i, x_j), \quad i = 0, ..., n \tag{1}$$

$$y_i = H(x_i) \tag{2}$$

x_i is the state of subsystem i and $x_i(0)$ is the initial condition. The function F describes the unforced motion of the system, the function G describes how the system is

connected with other sub-systems, and the output function H relates the state of the system to the measurement functions y_i. The functions u_i represent the manipulated variables. The functions F, G, H are all differentiable at least once. The state of the entire network is given by the vector $x = (x_0^T, x_1^T, ..., x_n^T)^T$.

Subscript zero refers to the reference (exo-) system. Often we are not interested in the dynamics of the exo-system, or more likely, it is too complex to model. The process system is modeled as the reduced system without the reference sub-system. Its state is given by the vector $x = (x_1^T, ..., x_n^T)^T$. The interactions with the exo-system are then established through the boundary conditions.

The network form, as illustrated in Figure 1 is convenient when we model systems with a graph structure. In such systems the interactions between the sub-systems depend on the state of the sub-system itself and the state of its immediate neighbors. Not all dynamical systems can be decomposed in this fashion. However, many large scale systems have sparse interconnections and they can be modeled compactly as networks of sub-systems with interconnections. It is also easy to see that many physical systems, especially those that satisfy the principle of local action, can be decomposed in the manner shown in (1).

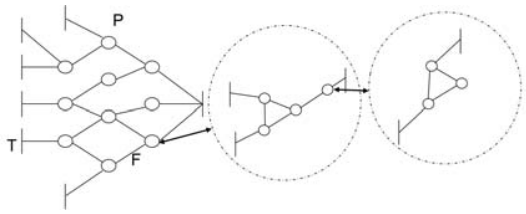

Fig. 1. Graphical network representation: Topological structure of a network consisting of nodes, terminals, and flows. Nodes can contain subgraphs and give rise to a hierarchical, multiscale structure.

We define the inventory Z of a sub-system or a group of systems to be a non-negative, additive function of the state of the corresponding sub-system(s). By additivity we mean that if Z_1 is the inventory of sub-system 1 and Z_2 is the inventory of sub-system 2, then $Z_1 + Z_2$ is the total inventory. Hence for any i, j

$$Z\begin{pmatrix} x_i \\ x_j \end{pmatrix} = Z(x_i) + Z(x_j)$$

By non-negativity we mean that the inventory cannot be less than zero. Examples of physical inventories include mass, energy and charge. More generally, an inventory is any property which is related to an amount.

By referring to (1) and using continuity we derive the conservation law

$$\frac{dZ_i}{dt} = p_i(x_i) + \sum_{j=1, j\neq i}^{n} f_{ij}(u) \tag{3}$$

The *drift* $p_i(x_i) = \frac{\partial Z(x_i)}{\partial x_i} F(x_i)$ measures the rate of production and the function $f_{ij}(u) = \frac{\partial Z(x_i)}{\partial x_i} G(u, x_i, x_j)$ measures the supply of Z between sub-systems j and i. We have the symmetry condition

$$f_{ij}(u) = f_{ji}(u)$$

The term

$$\phi(u, z, d) = \sum_{j=1, j\neq i}^{n} -f_{ij}(u)$$

therefore measures the net rate of supply to sub-system i from all other sub-systems. It is called the *action* on sub-system i.

Definition: Let X_0 be a subset of state-space. An inventory defined by (3) is said to have the

(1) *Clausius-Planck property* if $p(x) > 0$ for x not in X_0
(2) *Conservation property* if $p(x) = 0$ for all x not in X_0
(3) *Dissipation inequality* if $p(x) < 0$ for x not in X_0

The set X_0 associated with the dissipative action ϕ is called the set of *passive states*.

By a graph $\mathbf{G}$ we mean a finite set $\upsilon(\mathbf{G}) = (\upsilon_1, .., \upsilon_{n_P})$, whose elements are called **nodes**, together with the set $\epsilon(\mathbf{G}) \subset \upsilon \times \upsilon$, whose elements are called **branches**. A branch is therefore an ordered pair of distinct nodes.

- If, for all $(\upsilon_i, \upsilon_j) \in \epsilon(\mathbf{G})$, the branch $(\upsilon_j, \upsilon_i) \in \epsilon(\mathbf{G})$ then the graph is said to be **undirected**. Otherwise, it is called a **directed graph**.
- A branch (υ_i, υ_j) is said to be **incoming with respect to** υ_j and **outgoing with respect to** υ_i and can be represented as an arrow with node υ_i as its tail and node υ_j as its head.

Definition 1. A network of nodes $P_i, i = 1, ..., n_p, n_p + 1, ..., n_v$ consisting of nodes and terminals interconnected through branches $E_i, i = 1, ..., n_f$ with topology defined by the graph

$$\mathbf{G} = (\mathbf{E}, \mathbf{P})$$

is called a *process network* if its interconnection structure is described by a directed graph and we have

(1) **First law:** There exists an inventory E (the energy) which satisfies the conservation property
(2) **Second law:** There exists an inventory S (the entropy) which satisfies the Clausius-Planck property

We now develop a compact description of the topology of the network by introducing the incidence matrix.

Definition 2. The $n_t \times n_f$ matrix $\mathbf{A_a}$ is called incidence matrix for the matrix elements a_{ij} being

$$a_{ij} = \begin{cases} 1, & \text{if flow } j \text{ leaves node } i \\ -1, & \text{if flow } j \text{ enters node } i \\ 0, & \text{if flow } j \text{ is not incident with node } i \end{cases}$$

One node of the network is set as reference or datum node P_0 representing the exo-system. The $(n_t - 1) \times n_f$ matrix $\mathbf{A}$, where the row that contains the elements a_{0j} of the reference node P_0 is eliminated, is called reduced incidence matrix.

The connections between nodes through branches can be uniquely defined using the incident matrix $\mathbf{A}$. The conservation laws (3) can now be written

$$\mathbf{AF} = \mathbf{0} \tag{4}$$

for the node-to-branch incident matrix $\mathbf{A}$, where $\mathbf{F^T} = [\frac{dZ_1}{dt}, \frac{dZ_2}{dt}, .., \frac{dZ_t}{dt}, f_{12}, f_{13}..f_{n_{t-1}, n_t}, p_1, .., p_t]$. The flows f_{ij} represent connections between two nodes i.e. f_{ij} connects node i to node j, p_i denotes sources or sinks. The direction of the flows are defined according to the directionality

established in the graph. We now define a vector $\mathbf{W}$ so that

$$\mathbf{W} = \mathbf{A^T w} \tag{5}$$

where $\mathbf{W}$ are the potential differences across flow connections. The variables w are conjugate to Z if they are related via the Legendre transform of a convex potential like the entropy.

A dual structural representation can be derived using mesh analysis (the analysis developed above, which is based on the conservation laws, is called node analysis). Mesh analysis is counter-intuitive in process control applications but frequently used for electrical circuit analysis. When introducing stability and optimality concepts in this work, we will focus on describing the primal problem and its implications but refer to the dual mesh-based problem as proving the equivalent dual case.

2.1 Constitutive Relations

Constitutive equations relate efforts and flows (resistive), flows and displacements (capacitive), and efforts and fluxes (inductive). The constitutive equations describe energy dissipating, irreversible processes (resistive) or energy storing, reversible processes. The constitutive equations define the type of energetic transaction inside the process system or between the process system and the environment. The three main types can be described as

- Capacitive constitutive equation: storage of potential energy, $W = f_C(Z)$
- Inductive constitutive equation: storage of kinetic energy, $p = f_L(W)$
- Resistive constitutive equation: dissipation of energy, $F = f_R(W)$

In the context of process networks, storage of energy usually occurs through capacitive elements. In this work, inductive constitutive equations are neglected due to the fact that we focus on chemical processes or chemical process plants in which inertial effects in mass flow and thus accumulation of kinetic energy are not a significant contributor to the energy balance.

3. TOPOLOGICAL RESULTS, CONTENT AND CO-CONTENT

Consider two networks (a) and (b) with the same topology (identical incidence matrix) but not necessarily the same state. Denote the variables in network (a) with the superscript a and denote variables in the other network with superscript b. Using the conservation laws (4) we can then write $\mathbf{W^{a}}^T\mathbf{F^b} = (\mathbf{A}^T\mathbf{w^a})^T\mathbf{F^b} = \mathbf{w^a}^T\mathbf{A}\mathbf{F^b} = 0$. The equality

$$\mathbf{W^{a}}^T\mathbf{F^b} = 0$$

is often called *Tellegen's theorem.*

Without the reference system Tellegen's theorem is written

$$\mathbf{w^b}^T\frac{d\mathbf{Z^a}}{dt} = -\mathbf{W_R^b}^T\mathbf{F_R^a} - \mathbf{w_T^b}^T\mathbf{F_T^a} - \mathbf{w^b}^T\mathbf{p^a} \tag{6}$$

The term of the left hand side is called the storage. The three terms on the right refer to power dissipation due to transportation, supply from the exo-system through the terminals, and dissipation by production respectively.

If we consider a single network ($a = b$), then we can drop the superscript and we get the common form $\mathbf{W}^T\mathbf{F} = 0$ which represents a powerbalance. If Z represents the energy then we get the classical energy balance for the network. The "balance of entropy dissipation" results if we let one inventory correspond to the thermodynamic entropy defined so that

$$S = k_B \ln \Omega(x)$$

It is important to note that the fundamental equation gives a definition of the classical entropy in terms of extensive and intensive variables through the Pfaffian

$$TdS = dU + PdV - \sum_{i=1}^{n_c} \mu_i dN_i$$

Tellegen's theorem applied to the primal (extensive variable) vector $Z = (U, V, N_1, .., N_n)$ and its Legendre dual (intensive variable) vector $w = (1, P, \mu_1, .., \mu_n)/T$ then gives

$$\dot{S} = \mathbf{W_R}^T\mathbf{F_R} + \mathbf{w_T}^T\mathbf{F_T} + \mathbf{w}^T\mathbf{p}$$

where we used the fundamental equation and (6). The term $p_S = \mathbf{F_R}^T\mathbf{W_R} + \mathbf{w^T p}$ is called the rate of entropy generation.

We define the content of the network as the integral

$$G_R = \int_0^{\mathbf{F_R}} \mathbf{W_R}^T d\mathbf{F_R} + \int_0^{\mathbf{p}} \mathbf{w}^T d\mathbf{p} \tag{7}$$

The co-content is given as

$$G_R^* = \int_0^{\mathbf{W_R}} \mathbf{F_R}^T d\mathbf{W} + \int_0^{\mathbf{w}} \mathbf{p}^T d\mathbf{w} \tag{8}$$

By integration by parts and proper choice of the constant p^* (the constant of integration) we see that

$$G_R + G_R^* = p_S \geq 0$$

The second law dictates that the inequality holds (positive entropy production).

4. STABILITY OF PROCESS NETWORKS

In this section we derive a stability result using a combination of Tellegen's theorem and the co-content as a line integral. First, we note that Tellegen's theorem shows that for each time t the vectors $\mathbf{W}$ and $\mathbf{F}$ lie in fixed and orthogonal spaces. The identity $\dot{\mathbf{W}}^T\mathbf{F} = 0$ is therefore valid for all t and by taking out the sub-system which represent the exo-system we can write as before

$$\dot{\mathbf{Z}}^T\dot{\mathbf{w}} = -\mathbf{F_R^T}\dot{\mathbf{W}}_\mathbf{R} - \mathbf{F_T^T}\dot{\mathbf{w}}_\mathbf{T} - \mathbf{p_T^T}\dot{\mathbf{w}} \tag{9}$$

Due to the concavity of the entropy function we know that there exists a matrix $\mathbf{M} \geq 0$ so that $d\mathbf{w} = \mathbf{M}d\mathbf{Z}$, hence

$$\dot{\mathbf{Z}}^T\dot{\mathbf{w}} = \dot{\mathbf{Z}}^T M\dot{\mathbf{Z}} \geq 0$$

We can also write the co-content as a line integral

$$G_R^* = \int^t (\mathbf{F_R}^T\dot{\mathbf{W}}_\mathbf{R} + \mathbf{p}^T\dot{\mathbf{w}})dt \geq 0$$

Hence, by integrating (9) we get

$$\int_0^t \dot{\mathbf{Z}}^T M\dot{\mathbf{Z}}dt = -G_R^* - \mathbf{F_T^T}\dot{\mathbf{w}}_\mathbf{T}$$

The contribution due the terminal potentials vanish if $\dot{\mathbf{w}}_\mathbf{T} = 0$ and it follows that G^* is integrable and subject the condition of uniform continuity we conclude that G^* converges which implies that $\dot{\mathbf{w}}$ converges to zero.

5. OPTIMALITY OF PROCESS NETWORKS

Maxwell (1892) formulated the minimum heat theorem which states that for linear resistive electrical circuits driven by constant power sources, the flows distribute themselves in a way as to minimize the heat that is dissipated through the resistive elements. Prigogine (1947) observed that the theorem can be generalized to thermodynamic systems with the entropy production σ_S being minimized at steady state. Based on Tellegen's theorem and the content and co-content, we can propose an optimization problem that allows us to find the steady state and dynamic trajectory of a dynamic process network.

For a process network with a graph $\mathbf{G}$, we can define the extended content

$$G = \sum_{i=1}^{b} \int^{F_i} W_i dF_i = \int^{\mathbf{F}} \mathbf{W}^T d\mathbf{F} \tag{10}$$

and the extended co-content:

$$G^* = \sum_{i=1}^{b} \int^{W_i} F_i dW_i = \int^{\mathbf{W}} \mathbf{F}^T d\mathbf{W} \tag{11}$$

The extended content G and co-content G^* represent the sum of contents and co-contents for all branches i.e. reversible, irreversible, production and terminal flow connections of the network.

Lemma 3. For the network content G and the co-content G^*

$$G^*(\mathbf{W}) = \mathbf{W}^T\mathbf{F} - G(\mathbf{F}) \tag{12}$$

Equation (12) is a special form of Tellegen's theorem and can be used to do a variable change corresponding to a Legendre transformation.

Proof. The relation follows directly from integration by parts.

Lemma 4. For the sum of extended content $G = \int^{\mathbf{F}} \mathbf{W}^T d\mathbf{F}$ and extended co-content $G^* = \int^{\mathbf{W}} \mathbf{F}^T d\mathbf{W}$, the following relation holds:

$$G + G^* = 0$$

Proof. Using Tellegen's theorem and Lemma 3, the result follows immediately.

Definition 5. The following set of equations defines the process system:

$$\mathbf{AF} = \mathbf{0} \tag{13}$$
$$\mathbf{W} = \mathbf{A^T w} \tag{14}$$
$$\mathbf{F_R} = \Lambda(\mathbf{W_R}) \tag{15}$$
$$\mathbf{Z} = \mathbf{C w_C} \tag{16}$$
$$\mathbf{F_R} = \mathbf{F} - \mathbf{F_S} \tag{17}$$
$$\mathbf{W_R} = \mathbf{W} - \mathbf{W_S} \tag{18}$$
$$\mathbf{F_S} = \mathbf{F_T} \tag{19}$$
$$\mathbf{W_S} = \mathbf{W_T} \tag{20}$$
$$\mathbf{Z(0)} = \mathbf{Z_0} \tag{21}$$

The first two equations (13) and (14) are the Kirchhoff relations for process networks. Equations (15) are the resistive constitutive equations with Λ being a matrix function and (16) are the capacitive constitutive equations.

We introduced the variables $\mathbf{F_R}$ and $\mathbf{W_R}$ which facilitate writing the resistive constitutive equations in a compact way. The variables $\mathbf{F_R}$ and $\mathbf{W_R}$ allow us to include the terminals as sources or sinks through (19) and (20) for both, terminals where we have the function of the flows $\mathbf{F_T}$ or the potentials $\mathbf{W_T}$ given. For simplicity, we assume the terminal conditions as constant over time. The last equation (21) constitutes the initial conditions for the inventories $\mathbf{Z}$.

The set of equations can be transformed into a system of nonlinear differential algebraic equations (DAE) of the form

$$\frac{d\mathbf{Z}}{dt} = \mathbf{A}(\mathbf{Z}) + \mathbf{B_F^Z}(\mathbf{F_T^{input}}) + \mathbf{B_W^Z}(\mathbf{W_T^{input}}) \tag{22}$$
$$\mathbf{W_T^{output}} = \mathbf{C^W}(\mathbf{Z}) + \mathbf{D_F^W}(\mathbf{F_T^{input}}) + \mathbf{D_W^W}(\mathbf{W_T^{input}}) \tag{23}$$
$$\mathbf{F_T^{output}} = \mathbf{C^F}(\mathbf{Z}) + \mathbf{D_W^F}(\mathbf{W_T^{input}}) + \mathbf{D_F^F}(\mathbf{F_T^{input}}) \tag{24}$$

where nonlinearities are introduced through the constitutive equations. In this dynamic system, each terminal has an input and an output variable. The set of differential equations (22) determines the trajectories of $\mathbf{Z}$ and represent a state space system. The algebraic constraints (23) and (24) compute the output variables at the terminals from the input variables and the state $\mathbf{Z}$.

To find the stationary solutions of the system, we need to solve the set of equations

$$\mathbf{AF} = \mathbf{0} \tag{25}$$
$$\mathbf{W} = \mathbf{A^T w} \tag{26}$$
$$\mathbf{F} - \mathbf{F_T} = \Lambda(\mathbf{W} - \mathbf{W_T}) \tag{27}$$

with the three main sets of constraints: Conservations laws, uniqueness conditions, and the constitutive equations. The inventories and capacitive constitutive equations are only relevant for the dynamic case.

In the following theorem, we introduce the connection between content, co-content and the Kirchhoff laws, and present how duality of the free variables plays a crucial role for the optimization problem that is solved when a process network converges to a steady state solution. The constitutive equations are not directly involved as they are not relevant for the topological properties of the process network.

Theorem 6. For the optimization problem

$$\min_{\mathbf{w}} G^* = \int_0^W \mathbf{F}^T d\mathbf{W} \tag{28}$$
$$s.t. \quad \mathbf{W} = \mathbf{A^T w} \tag{29}$$
$$\mathbf{F} = \Lambda(\mathbf{W}) \tag{30}$$

with the cocontent G^* as objective function, the uniqueness conditions, and resistive constitutive equations as constraints, the solution exhibits a set of equations consisting of the uniqueness condition, the conservation laws, and the constitutive equations. The Langrange multipliers of the optimization problem are the network flow variables $\mathbf{F}$.

Proof. Starting with equations (28) - (30), we first substitute the constitutive equations (30) into the objective function (28) to eliminate the flow variables $\mathbf{F}$. The Lagrange function of the resulting optimization problem is

$$\min L(\mathbf{W}, \mathbf{w}, \lambda) = \int_0^W \Lambda(\mathbf{W})^T d\mathbf{W} + \lambda^T(\mathbf{A^T w} - \mathbf{W}) \quad (31)$$

First order conditions:

$$\frac{\partial L}{\partial \mathbf{W}} = \Lambda(\mathbf{W}) - \lambda = \mathbf{0} \quad (32)$$

$$\frac{\partial L}{\partial \mathbf{w}} = \mathbf{A}\lambda = \mathbf{0} \quad (33)$$

$$\frac{\partial L}{\partial \lambda} = \mathbf{A^T w} - \mathbf{W} = \mathbf{0} \quad (34)$$

comparing (32) and the constitutive equations (30), it follows that $\lambda = \mathbf{F}$. Using $\lambda = \mathbf{F}$ in (32) and (33), the result follows.

In principle, an optimization problem is solved where one set of Kirchhoff equations is omitted. Through the first order conditions, the missing set of equations is derived. The optimization problem with the Kirchhoff voltage law as constraints can be converted to an optimization problem with the Kirchhoff current law and vice versa.

We can now propose the main theorem which allows us to connect the steady state of a process network to the objective function that is simultaneously optimized i.e. we can find the natural optimization problem that a process network solves, when converging to a steady state. We explored the structure of the problem in the previous theorem, however, we need to be able to define boundary conditions and a solution for process networks connected to an exo-system.

Theorem 7. Consider a process network G with given resistive constitutive equations $\mathbf{F_R} = \Lambda(\mathbf{W_R})$ and boundary conditions for each terminal as well as one set of either the conservation laws or the uniqueness conditions. The stationary solution ($\frac{dZ_i}{dt} = 0$) for the network with conservation laws (13) and the uniqueness conditions (14)

$$\mathbf{AF} = \mathbf{0} \quad (35)$$

$$\mathbf{W} = \mathbf{A^T w} \quad (36)$$

$$\mathbf{F} - \mathbf{F_T} = \Lambda(\mathbf{W} - \mathbf{W_T}) \quad (37)$$

can be found by solving the following optimization problem

$$\min_{\mathbf{w}} \quad G^* = \int_0^W \mathbf{F}^T d\mathbf{W} \quad (38)$$

$$s.t. \quad \mathbf{W} = \mathbf{A^T w} \quad (39)$$

$$\mathbf{F_R} = \Lambda(\mathbf{W_R}) \quad (40)$$

$$\mathbf{F_T} = \text{const and/or } \mathbf{W_T} = \text{const} \quad (41)$$

or its equivalent dual optimization problem where (36) is replaced by (35).

Proof. Starting with (38) - (41), we substitute the boundary conditions (41) into the constitutive equations (40) and the constitutive equation into the objective function (38). We then form the Lagrange function using the flows $\mathbf{F}$ as Lagrange multipliers

$$L(\mathbf{W}, \mathbf{w}, \mathbf{F}) = \int_0^W (\Lambda(\mathbf{W} - \mathbf{W_T})^T d\mathbf{W} + \mathbf{W}^T \mathbf{F_T} \quad (42)$$

$$+ \mathbf{F}^T(\mathbf{A^T w} - \mathbf{W}) \quad (43)$$

First order conditions:

$$\frac{\partial L}{\partial \mathbf{W}} = \Lambda(\mathbf{W} - \mathbf{W_T}) + \mathbf{F_T} - \mathbf{F} = \mathbf{0} \quad (44)$$

$$\frac{\partial L}{\partial \mathbf{w}} = \mathbf{AF} = \mathbf{0} \quad (45)$$

$$\frac{\partial L}{\partial \mathbf{F}} = \mathbf{A^T w} - \mathbf{W} = \mathbf{0} \quad (46)$$

Comparing (25) - (27) to (44) - (46) shows the result. Concerning the second order conditions, we observe that convexity of the constraints is trivial for the linear Kirchhoff laws. Non-convexities of the optimization problem are due to non-linearities of the constitutive equations i.e. the constitutive equations are non-positive. For the second order conditions, it is apparent that the first derivative of the constitutive equations has to be analyzed and found positive definite for a global minimum, which corresponds exactly to the findings for passivity in Jillson and Ydstie (2007) for a unique network solution and convergence.

Generally, the objective function is a measure for dissipation of the storage variable over time. We conclude that the steady state of a passive network minimizes the dissipated power subject to the constraints imposed by the constitutive equations, topology, and boundary conditions, i.e. terminal connections.

6. PIPEFLOW NETWORK

A pipeline network example shows how optimization and dynamic simulation are connected. The network consists of two connected pipelines where each pipeline flows through a cylindrical storage tank with volume V_j open to the atmosphere, as shown in Fig. 2. A reference node is introduced representing the environment and connected to the terminals and dynamic nodes.

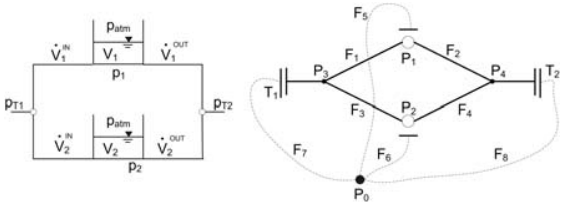

Fig. 2. Graphical network representations: Problem specific representation on the left, a generalized representation on the right including P_0 representing the exo-system.

Each pipeline's cross section is cylindrical with area A_i. The pipeline flow is given as a lumped parameter representation introducing pressure potentials p_j at the nodes and assuming laminar flow ($Re < 2300$). It is assumed that the fluid shows Newtonian behavior as well as being incompressible ($\rho = \text{const.}$). Therefore, the relation between

volumetric flow $\dot{V}_i$ and pressure drop $\Delta p_i = p_j - p_{j+1}$ can be modeled using Hagen-Poiseuille's law $\dot{V}_i = \frac{\pi r_i^4}{8\eta L_i}\Delta p_i$, where r_i is the radius of the pipeline's cross-section and L_i is the length of pipeline i. The potential at the bottom of the tank is given as $p_j = \rho g h_j + p_{atm}$ by hydrostatics. The fluid volume V_j in the tank is connected to the level h_j through $V_j = A_j h_j$ where A_j is the cross-section of the tank. We complete the model with the conservation laws for mass or, for constant density, the conservation of volume:

$$dV_1/dt = \dot{V}_1^{IN} - \dot{V}_1^{OUT} \quad (47)$$

$$dV_2/dt = \dot{V}_2^{IN} - \dot{V}_2^{OUT} \quad (48)$$

$$\dot{V}_{T1} = \dot{V}_2^{IN} + \dot{V}_2^{IN} \quad (49)$$

$$\dot{V}_{T2} = \dot{V}_2^{OUT} + \dot{V}_2^{OUT} \quad (50)$$

Initial conditions for the tank volumes $V_{0,i}$ have to be specified as well as boundary conditions at the terminals. The steady state of (47) - (50) can be found by integrating the differential equations.

The dynamic system given by the previous equations converges to the solution of the following optimization problem ($\frac{dV_1}{dt} = \frac{dV_2}{dt} = 0$):

$$\min \quad \sum_{i=1}^{4} \int_0^{\Delta p_i} \dot{V}_i d(\Delta p_i) \quad (51)$$

$$s.t. \quad (47) - (50) \quad (52)$$

$$\dot{V}_i = \frac{\pi r_i^4}{8\eta L_i}\Delta p_i \ , i = 1, .., 4 \quad (53)$$

$$\dot{V}_{T1} = const., p_{T2} = const. \quad (54)$$

Solving the optimization problem therefore corresponds to minimizing the power dissipated through viscous friction in the pipes subject to the conservation laws and boundary conditions. For each terminal, one boundary condition has to be specified which can be chosen freely ($\dot{V}_{T1} = 0.3$ m^3/s, $p_{T2} = 1.013$ bar). The parameters are given as $d = 0.5$ m and $L_1 = 2500$ m for the upper pipeline segments and $L_2 = 5000$ m for the lower segments. The tanks' cross-sectional diameter is chosen as $d_1 = d_1 = 2$ m. Fig. 3 shows the simulation results. We chose the initial conditions for $V_{0,1} = V_{0,2} = 25$ m ^{3}.

It is apparent that the value of the objective function as well as the flows of the dynamic simulation converge to the optimum determined through the optimization problem for arbitrary initial conditions. The constant inflow $\dot{V}_{T1}$ into the network divides itself into flows through the upper segments and lower segments choosing the path of least resistance.

7. CONCLUSIONS AND DISCUSSION

We introduced a new framework for analysis of optimality and stability of networked process systems in this work. We provide a systematic approach to define stability and optimality conditions for these systems. The objective function minimized by a process systems in its steady state is derived. Although for simplicity, we regard only the steady state in this example, the optimization problem

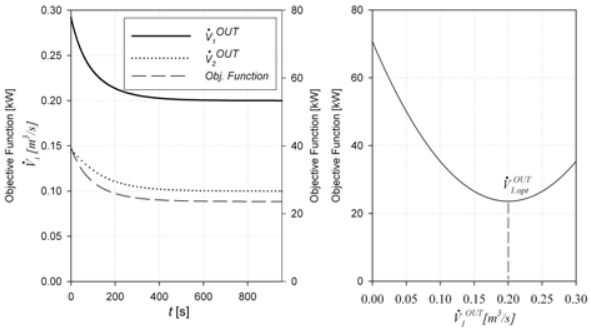

Fig. 3. Flows between tanks and outgoing terminal T_2 and the power dissipation (objective function) as a function of time on the left. Convergence of $\dot{V}_1^{OUT} =$ to 0.2 m^3/s and $\dot{V}_2^{OUT} =$ to 0.1 m^3/s. Objective function values of $\dot{V}_1^{OUT}$ on the right.

is also valid for transient conditions. The findings can explored to design decentralized control structures and hence shape the natural objective function of a process systems towards an economic objective.

Quasi-decentralized Scheduled Output Feedback Control of Process Systems Using Wireless Sensor Networks ⋆

Yulei Sun and Nael H. El-Farra *

* *Department of Chemical Engineering & Materials Science, University of California, Davis, CA 95616 USA (e-mail: nhelfarra@ucdavis.edu)*

Abstract: This paper presents a quasi-decentralized output feedback control structure for multi-unit plants with limited state measurements and distributed control systems that exchange information over a resource-constrained wireless sensor network (WSN). The networked control structure brings together model-based feedback control, state estimation and sensor scheduling to enforce closed-loop stability while simultaneously minimizing the rate of communication over the WSN. Initially, an observer-based output feedback controller is designed for each unit. To conserve the resources of the wireless devices, communication between the local control systems is suspended periodically for extended time periods during which each control system relies on models of the plant units to generate the necessary control action. Communication is then re-established at discrete time instances according to a certain schedule that determines the order and times at which the wireless sensor suites transmit the state estimates needed to update the states of the models embedded in the target units. By analyzing the combined discrete-continuous behavior of the scheduled closed-loop plant, we explicitly characterize the stability of the networked closed-loop system in terms of the communication rate, the sensor transmission schedule, the accuracy of the models, as well as the controller and observer design parameters. The results are illustrated using a chemical plant example where it is shown that by judicious management of the interplays between the control, communication and scheduling design parameters, it is possible to stabilize the plant while simultaneously enhancing the savings in WSN resources beyond what is possible with concurrent transmission configurations.

Keywords: Quasi-decentralized control, wireless sensor networks, model-based control, state estimation, scheduling algorithms, chemical plants.

1. INTRODUCTION

Chemical plants are large-scale dynamical systems that consist of a large number of distributed units which are tightly interconnected through mass and energy flows and recycle. Traditionally, the controller synthesis problem for such plants has been addressed within either the centralized or decentralized control frameworks. Both approaches have been the subject of numerous research studies aimed at understanding their advantages and limitations, as well as the development of strategies to overcome some of those limitations (e.g., see Siljak (1991); Lunze (1992); Sourlas and Manousiouthakis (1995); Katebi and Johnson (1997); Cui and Jacobsen (2002); Camponogara et al. (2002); Huang and Huang (2004); Skogestad (2004); Venkat et al. (2005); Goodwin et al. (2005); Kariwala (2007) and the references therein). Other notable contributions on this problem include the development of plant-wide control strategies based on passivity theory and concepts from thermodynamics (Hangos et al. (1999); Antelo et al. (2007)), the development of agent-based systems to control spatially-distributed reactor networks (Tetiker et al. (2008)), and the analysis and control of integrated process networks using time-scale decomposition and singular perturbations (Baldea et al. (2006)).

An approach that provides a compromise between the complexity of traditional centralized control schemes, on the one hand, and the performance limitations of decentralized control approaches, on the other, is quasi-decentralized control, which refers to a control strategy in which most signals used for control are collected and processed locally, while some signals are transferred between the local units and controllers to adequately account for the interactions and minimize the propagation of process upsets from one unit to another. A key consideration in the design and implementation of quasi-decentralized control systems is the selection of the communication medium over which the local control systems must communicate. While dedicated point-to-point links offer a reliable communication medium, the complexity and costs of installation and maintenance associated with this architecture, as well as the lack of flexibility for real-time reconfiguration, represent major drawbacks especially for large-scale plants with complex interconnections. An alternative solution is the use of wireless communication networks. The viability of this approach stems from the convergence of recent advances in actuator/sensor manufacturing, wireless communications and digital electronics,

⋆ Financial support by NSF CAREER Award, CBET-0747954, is gratefully acknowledged.

which has produced low-cost wireless sensors (e.g., Kumar (2001); Song et al. (2006)) that can be installed for a fraction of the cost of wired devices. Wireless sensor networks (WSNs) offer unprecedented flexibility ranging from high-density sensing capabilities to deployment in areas where wired devices may be difficult or impossible to deploy. Augmenting existing process control and monitoring systems with WSNs has the potential to expand the capabilities of the existing control technology beyond what is feasible with wired architectures alone. These are appealing goals that coincide with the recent calls for expanding the traditional process control and operations paradigm in the direction of smart plant operations (e.g., see Ydstie (2002); Christofides et al. (2007)).

One of the main challenges to be addressed when deploying a low-cost WSN for control is that of handling the inherent constraints on network resources, including the limitations on the computation, processing and communication capabilities. In an effort to address this problem, we developed in Sun and El-Farra (2008a) a quasi-decentralized model-based networked control architecture that enforces closed-loop stability with minimal cross communication between the constituent subsystems. The minimum allowable communication rate was characterized in terms of the plant-models' mismatch for the case when all sensors suites transmit their measurements concurrently and are given simultaneous access to the network. The networked control structure was subsequently generalized in Sun and El-Farra (2008b) to address the problem when only limited state measurements are available (for additional results and references on the design of networked control systems, the reader may refer to Walsh and Ye (2001); Montestruque and Antsaklis (2003); Munoz de la Pena and Christofides (2008) and the references therein).

In addition to transmitting the data at discrete time instances, another important way of conserving the WSN resources is to select and activate only a subset of the deployed sensor suites at any given time to communicate with the rest of the plant. Under this restriction, the stability and performance characteristics of each unit in the plant become dependent not only on the controller design but also on the selection of the scheduling strategy that, at any time, determines the order in which the sensor suites of the neighboring units transmit their data. Forcing the different subsystems to transmit their data at different times creates opportunities for providing a more targeted correction to the models' estimation errors, such that the models with the largest uncertainties can receive more timely updates than is feasible under the simultaneous transmissions configuration.

Motivated by these considerations, we present in this work an integrated approach for model-based control, state estimation and sensor scheduling in plants with limited state measurements and interconnected processing units that communicate over a resource-constrained WSN. The objective is to find a strategy for establishing and terminating communication between the sensors suites of the WSN and the local control systems in a way that minimizes the rate at which each node in the WSN broadcasts data to the rest of the plant without jeopardizing closed-loop stability. The rest of the paper is organized as follows. Following some preliminaries in Section 2, the networked control and scheduling problem is formulated. Section 3 then presents the quasi-decentralized output feedback control structure and describes its implementation over a WSN with the aid of appropriate local state observers, process models and sensor transmission scheduling. The closed-loop system is then formulated and analyzed in Section 4 where precise conditions for closed-loop stability are provided in terms of the communication rate over the WSN, the sensor scheduling strategy, as well as the accuracy of the models and the choice of controller and observer designs. We show how the stability criteria provide systematic tools that can guide the search for optimal transmission schedules that achieve the biggest savings in WSN resource utilization. Finally, the theoretical results are illustrated in Section 5 using a chemical plant example.

2. PRELIMINARIES

2.1 Plant description

We consider a large-scale distributed plant composed of n interconnected processing units, represented by the following state-space description:

$$\begin{aligned}
\dot{x}_1 &= A_1x_1 + B_1u_1 + \sum_{j=2}^{n} A_{1j}x_j, \qquad y_1 = C_1x_1 \\
\dot{x}_2 &= A_2x_2 + B_2u_2 + \sum_{j=1,j\neq 2}^{n} A_{2j}x_j, \; y_2 = C_2x_2 \\
&\vdots \qquad\qquad\qquad\qquad\qquad\qquad \vdots \\
\dot{x}_n &= A_nx_n + B_nu_n + \sum_{j=1}^{n-1} A_{nj}x_j, \qquad y_n = C_nx_n
\end{aligned} \tag{1}$$

where $x_i := [x_i^{(1)} \; x_i^{(2)} \; \cdots \; x_i^{(p_i)}]^T \in \mathbb{R}^{p_i}$ denotes the vector of process state variables associated with the i-th processing unit, p_i is the number of state variables in the i-th unit, $y_i := [y_i^{(1)} \; y_i^{(2)} \; \cdots \; y_i^{(q_i)}]^T \in \mathbb{R}^{q_i}$ and $u_i := [u_i^{(1)} \; u_i^{(2)} \; \cdots \; u_i^{(r_i)}]^T \in \mathbb{R}^{r_i}$ denote the vector of measured outputs and manipulated inputs associated with the i-th processing unit, respectively, x^T denotes the transpose of a column vector x; A_i, B_i, A_{ij} and C_i are constant matrices. The interconnection term $A_{ij}x_j$, where $i \neq j$, describes how the dynamics of the i-th unit are influenced by the j-th unit in the plant. Note from the summation notation in Eq.1 that each processing unit can in general be connected to all the other units in the plant.

2.2 Problem formulation and solution methodology

Referring to plant of Eq.1, we consider a quasi-decentralized control structure in which each unit in the plant has a local control system with its sensors and actuators connected to the local controller through a dedicated wired communication network. An additional suite of wireless sensors is deployed within each unit to transfer data from the local control system to the plant supervisor as well as to the other distributed control systems in the plant. The various sensor suites form a plant-wide WSN through which the plant units and their controllers communicate. The control objective is to stabilize all the plant units at the zero steady-state while simultaneously: (a) keeping the data dissemination and exchange over the WSN to a minimum, and (b) accounting for the lack of full-state measurements within each unit. To address the resource-constraints problem, we develop in the next section an

integrated model-based quasi-decentralized output feedback control and scheduling strategy that reduces the exchange of information between the plant units without loss of stability. This is accomplished by: (a) designing for each local control system an appropriate state observer that generate estimates of the local state variables from the measured outputs, (b) including models within each control system to estimate the interaction terms when measurements are not available through the WSN, and (c) limiting the number of WSN nodes that, at any given time, transmit their data to update the corresponding target models. The problem is to find an optimal scheduling strategy for establishing and terminating communication between the sensor suites and the target controllers. To illustrate the main ideas, we will consider as an example the configuration where only one wireless sensor suite is allowed to transmit its data to the appropriate units at any given time, while the other nodes remain dormant until the next suite is allowed to transmit its data.

3. QUASI-DECENTRALIZED STATE ESTIMATION AND CONTROL WITH SCHEDULED SENSOR TRANSMISSIONS

3.1 Synthesis of distributed output feedback controllers

Referring to the plant of Eq.1, we begin by synthesizing for each unit an output feedback controller of the form:

$$\begin{aligned} u_i &= K_i\bar{x}_i + \sum_{j=1,j\neq i}^{n} K_{ij}\bar{x}_j \\ \dot{\bar{x}}_i &= (A_i - L_iC_i)\bar{x}_i + \sum_{j=1,j\neq i}^{n} A_{ij}\bar{x}_j + B_iu_i + L_iy_i, \end{aligned} \tag{2}$$

where $\bar{x}_i$ is an estimate of the state of the i-th unit generated by an observer embedded within the local control system of the i-th unit, K_i is the local feedback gain responsible for stabilizing the i-th subsystem in the absence of interconnections, K_{ij} is a gain that compensates for the effect of the j-th neighboring subsystem on the dynamics of the i-th unit, and L_i is the observer gain (chosen such that $A_i - L_iC_i$ is Hurwitz). Note that, in addition to $\bar{x}_i$ which is supplied continuously by the local observer, the implementation of the controller of Eq.2 requires the availability of observer-generated state estimates from the other units in the plant, $\bar{x}_j$, which can be transmitted only through the WSN. A copy of the local observer must therefore be included within the wireless sensor suite of each unit in order to generate the state estimates which are then broadcast to the rest of the plant. This setup is possible given the computational capabilities of wireless sensors. An alternative approach, which avoids having the wireless sensors carry the computational load of the observer, is to have the WSN nodes transmit only the output measurements, but include within each control system an observer of the full plant instead (not just an observer of the local subsystem) which then generates the required state estimates of the full plant state. In addition to the complexity of designing a centralized observer for the entire plant, another difficulty with this approach is that the observer must be designed to have hybrid dynamics since the WSN data are transmitted only at discrete time instances while the local measurements are supplied continuously (or at least more frequently).

It should also be noted that the choice to use a Luenberger observer is made only to illustrate the design and implementation of the quasi-decentralized output feedback control architecture. This choice, however, is not unique and any other explicit observer design can be used instead. The only requirement is that the observer possess an explicit evolution equation that relates the dynamics of the state estimate explicitly to the plant matrices, the output and the observer design parameters. As we will see in the next section, this feature permits the derivation of explicit closed-loop stability conditions that depend in a transparent way on the observer design parameters.

3.2 Design of model-based networked control structure

To conserve battery power in the plant-wide WSN, we initially reduce the rate at which the information (i.e., $\bar{x}_j$) is transferred from the wireless sensor suite of each unit to the target control systems in the neighboring units as much as possible without sacrificing closed-loop stability. To this end, and following the idea presented in (Sun and El-Farra (2008b)), we embed in each unit (both in the local controller and in the wireless sensor suite) a set of dynamic models that provide estimates of the evolution of the states of the neighboring units when communication over the WSN is suspended. The model estimates are used to generate both the local state estimates and the local control action. The state of each model is then reset using the state estimate generated by the observer of the corresponding unit when the wireless sensor suite of the latter is allowed to transmit its data at discrete time instances. In mathematical terms, the local control and update laws for unit i are implemented as follows:

$$\begin{aligned} u_i(t) &= K_i\bar{x}_i(t) + \sum_{j=1,j\neq i}^{n} K_{ij}\widehat{x}_j^i(t),\ t\neq t_k^j,\ i=1,2,\cdots,n \\ \dot{\bar{x}}_i(t) &= (A_i - L_iC_i)\bar{x}_i(t) + \sum_{j=1,j\neq i}^{n} A_{ij}\widehat{x}_j^i(t) + B_iu_i(t) + L_iy_i(t) \\ \dot{\widehat{x}}_j^i(t) &= \widehat{A}_j\widehat{x}_j^i(t) + \widehat{B}_j\widehat{u}_j^i(t) + \widehat{A}_{ji}\bar{x}_i(t) + \sum_{l=1,l\neq i,l\neq j}^{n} \widehat{A}_{jl}\widehat{x}_l^i(t), t\neq t_k^j \\ \widehat{u}_j^i(t) &= K_j\widehat{x}_j^i(t) + K_{ji}\bar{x}_i(t) + \sum_{l=1,l\neq i,l\neq j}^{n} K_{jl}\widehat{x}_l^i(t),\ \ t\neq t_k^j \\ \widehat{x}_j^i(t_k^j) &= \bar{x}_j(t_k^j),\ \ j=1,\cdots,n, j\neq i,\ \ k=0,1,2,\cdots \end{aligned} \tag{3}$$

where $\widehat{x}_j^i$ is the estimate of x_j provided by a model of unit j embedded in unit i; $\widehat{A}_j$, $\widehat{B}_j$ and $\widehat{A}_{jl}$ are constant matrices; t_k^j indicates the k-th transmission time for the j-th sensor suite in the WSN. The fact that $\bar{x}_i$ appears directly in the model of the j-th unit follows from: (1) the structure of the plant and the way the i-th and j-th units are interconnected, and (2) the fact that the observer-generated estimates of x_i are assumed to be available continuously to the local control system of the i-th unit. Note that the models used by the i-th controller to recreate the behavior of the neighboring units do not necessarily match the actual dynamics of those processes, i.e., in general $\widehat{A}_j \neq A_j$, $\widehat{B}_j \neq B_j$, $\widehat{A}_{jl} \neq A_{jl}$.

3.3 Scheduling WSN transmissions and model updates

A key measure of the extent of WSN utilization is the update period for each sensor suite, $h^j := t_{k+1}^j - t_k^j$, which determines the frequency at which the j-th node sends observer estimates to the other units through the network to update the corresponding model states. A larger h implies

larger savings in WSN resource utilization. To simplify the analysis, we consider in what follows only the case when the update period is constant and the same for all the units, so that $t_{k+1}^j - t_k^j := h,\ j = 1, 2, \cdots, n$. To further reduce network utilization, we perform sensor scheduling whereby only one wireless sensor suite is allowed to transmit its observer estimates to the appropriate units at any one time, while the other suites remain dormant until the next suite is allowed to transmit its data (the analysis can be generalized to cases where multiple suites transmit at the same time). The transmission schedule is defined by: (1) the sequence (or order) of transmitting nodes: $\{s_j,\ j = 1, 2, \cdots, n\},\quad s_j \in \mathcal{N} := \{1, 2, \cdots, n\}$, where s_j is a discrete variable that denotes the j-th transmitting entity in the sequence, and (2) the time at which each node in the sequence transmits observer estimates. To characterize the transmission times, we introduce the variable: $\Delta t_j := t_k^{s_{j+1}} - t_k^{s_j},\ \ j = 1, 2, \cdots, n-1$, which is the time interval between the transmissions of two consecutive nodes in the sequence. Fig.1 is a schematic representation of how

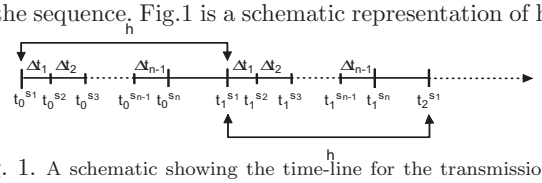

Fig. 1. A schematic showing the time-line for the transmission of each sensor suite in an h-periodic schedule.

sensor scheduling is performed. Note that the schedule is h-periodic in that the same sequence of transmitting nodes is executed repeatedly every h seconds (equivalently, each node transmits its data every h seconds). Note also from the definitions of both h and Δt_j that we always have the constraint $\sum_{j=1}^{n-1} \Delta t_j < h$. Since the update periods for all units are the same, the intervals between the transmission times of two specific units are constant, and within any single execution of the schedule (which lasts less than h seconds), each sensor suite can only transmit its observer estimates through the WSN and update its target models in the local control systems of its neighbors once. This can be represented mathematically by the condition: $s_i \neq s_j$ when $i \neq j$. By manipulating the time intervals Δt_j (i.e., the transmission times) and the order in which the nodes transmit, one can systematically search for the optimal sensor transmission schedule that leads to the largest update period (or smallest communication rate between each sensor suite and its target units).

4. NETWORKED CLOSED-LOOP STABILITY ANALYSIS

4.1 Characterizing the scheduled closed-loop response

In order to derive conditions for closed-loop stability, we need first to express the plant response as a function of the update period and the sensor transmission schedule. To this end, we define the model estimation errors by $e_j^i = \bar{x}_j - \widehat{x}_j^i$, for $j \neq i$, and $e_j^i = 0$, for $j = i$, where e_j^i represents the difference between the state of the observer of unit j (embedded in unit j) and the state of the model of unit j (embedded in unit i). Introducing the augmented vectors: $\mathbf{e}_j := [(e_j^1)^T\ (e_j^2)^T\ \cdots\ (e_j^n)^T]^T$, $\mathbf{e} := [\mathbf{e}_1^T\ \mathbf{e}_2^T\ \cdots\ \mathbf{e}_n^T]^T$, $\mathbf{x} := [x_1^T\ x_2^T\ \cdots\ x_n^T]^T$, $\bar{\mathbf{x}} := [\bar{x}_1^T\ \bar{x}_2^T\ \cdots\ \bar{x}_n^T]^T$, it can be shown that the overall closed-loop plant of Eq.1 and Eq.3 can be formulated as a combined discrete-continuous system of the form:

$$\begin{aligned}
\dot{\mathbf{x}}(t) &= \Lambda_{11}\mathbf{x}(t) + \Lambda_{12}\bar{\mathbf{x}}(t) + \Lambda_{13}\mathbf{e}(t)\\
\dot{\bar{\mathbf{x}}}(t) &= \Lambda_{21}\mathbf{x}(t) + \Lambda_{22}\bar{\mathbf{x}}(t) + \Lambda_{23}\mathbf{e}(t)\\
\dot{\mathbf{e}}(t) &= \Lambda_{31}\mathbf{x}(t) + \Lambda_{32}\bar{\mathbf{x}}(t) + \Lambda_{33}\mathbf{e}(t),\ \ t \neq t_k^j\\
\mathbf{e}_j(t_k^j) &= \mathbf{0},\ \ j = 1, 2, \cdots, n,\ \ k = 0, 1, 2, \cdots,
\end{aligned} \tag{4}$$

where Λ_{ij}'s are constant matrices whose explicit forms are omitted for brevity but can be obtained by substituting Eq.3 into Eq.1. Note that, unlike the case of simultaneous sensor transmissions (where no scheduling takes place) which was investigated in Sun and El-Farra (2008b), not all models within a given unit are updated (and hence not all estimation errors are re-set to zero) at each transmission time. Instead, only the model of the transmitting unit is updated using the observer-generated estimates provided by the wireless sensor suite of that particular unit. Defining the augmented state vector $\xi(t) := [\mathbf{x}^T(t)\ \bar{\mathbf{x}}^T(t)\ \mathbf{e}^T(t)]^T$, the dynamics of the overall closed-loop system can be cast in the following form:

$$\begin{aligned}
\dot{\xi}(t) &= \Lambda_o \xi(t),\ \ t \neq t_k^j\\
\xi(t_k^j) &= \left[\mathbf{x}^T(t_k^j)\ \ \bar{\mathbf{x}}^T(t_k^j)\ \ \mathbf{e}^T(t_k^j)\right]^T,\ k = 0, 1, 2, \cdots\\
\mathbf{e}^T(t_k^j) &= \left[\mathbf{e}_1^T(t_k^j)\ \cdots\ \mathbf{e}_{j-1}^T(t_k^j)\ \ \mathbf{0}\ \ \mathbf{e}_{j+1}^T(t_k^j)\ \cdots\ \mathbf{e}_n^T(t_k^j)\right]^T\\
\Lambda_o &= \begin{bmatrix} \Lambda_{11} & \Lambda_{12} & \Lambda_{13} \\ \Lambda_{21} & \Lambda_{22} & \Lambda_{23} \\ \Lambda_{31} & \Lambda_{32} & \Lambda_{33} \end{bmatrix}
\end{aligned} \tag{5}$$

The following proposition provides an explicit characterization of the scheduled closed-loop response in terms of the update period and the transmission schedule. The proof can be obtained by solving the system of Eq.5 within each sub-interval in Fig.1, and is omitted for brevity.

Proposition 1. Consider the closed-loop system described by Eq.5 with a transmission schedule $\{s_1, s_2, \cdots, s_n\}$ and the initial condition $\xi(t_0^{s_1}) = [\mathbf{x}^T(t_0^{s_1})\ \ \bar{\mathbf{x}}^T(t_0^{s_1})\ \ \mathbf{e}^T(t_0^{s_1})]^T = \xi_0$, with $\mathbf{e}_{s_1}(t_0^{s_1}) = \mathbf{0}$. Then, for $k = 0, 1, 2, \cdots$,

$$\xi(t) = \begin{cases} e^{\Lambda_o(t - t_k^{s_j})}\Gamma_j(\Delta t_j, I_o^{s_j}) M_o^k \xi_0,\ t \in [t_k^{s_j},\ t_k^{s_{j+1}}) \\ e^{\Lambda_o(t - t_k^{s_n})}\Gamma_n M_o^k \xi_0,\ t \in [t_k^{s_n},\ t_{k+1}^{s_1}) \end{cases} \tag{6}$$

where $j = 1, 2, \cdots, n-1$, and

$$\Gamma_j = \prod_{j-1-\mu=0}^{j-2} I_o^{s_{\mu+1}} e^{\Lambda_o \Delta t_\mu}, \text{for } j \geq 2, \text{and } \Gamma_j = I, \text{ for } j = 1 \tag{7}$$

$$M_o = I_o^{s_1} e^{\Lambda_o (h - \sum_{j=1}^{n-1} \Delta t_j)} \Gamma_n \tag{8}$$

$$I_o^{s_j} = \begin{bmatrix} I & O & \cdots & O \\ O & H_1 & \cdots & O \\ \vdots & \vdots & & \vdots \\ O & O & \cdots & H_n \end{bmatrix},\ H_i = \begin{cases} I, & i \neq s_j \\ O, & i = s_j \end{cases} \tag{9}$$

for $j = 1, 2, \cdots, n$, $t_{k+1}^{s_j} - t_k^{s_j} = h$ and $\Delta t_j = t_k^{s_{j+1}} - t_k^{s_j},\ j = 1, 2, \cdots, n-1$.

4.2 Characterizing the maximum allowable update period

Having expressed the overall closed-loop response in terms of the update period, the transmission times (which are determined by Δt_j) and the sequence of transmitting nodes (which determines the structure of $I_o^{s_j}$), we are in a position to state the main result of this section. The following theorem provides a necessary and sufficient condition for stability of the scheduled closed-loop plant under the quasi-decentralized networked output feedback control structure. The proof is omitted for brevity.

Theorem 2. Referring to the scheduled closed-loop system of Eq.5 whose solution is given by Eqs.6-9, the zero solution, $\xi = [\mathbf{x}^T\ \bar{\mathbf{x}}^T\ \mathbf{e}^T]^T = [\mathbf{0}\ \mathbf{0}\ \mathbf{0}]^T$, is globally exponentially stable if and only if the eigenvalues of the matrix in Eq.8 are strictly inside the unit circle.

By examining the structure of the test matrix M_o in Eq.8, it can be seen that its eigenvalues depend on the update period h, the closed-loop matrix Λ_o (which in turn depends on the plant-model mismatch as well as the controller and observer gains for all the units), the time intervals between sensor transmissions $\Delta t_1, \Delta t_2, \cdots, \Delta t_{n-1}$, as well as the sensor transmission sequence $\{s_1, s_2, \cdots, s_n\}$. The stability criteria in Theorem 2 can therefore be used to compare different schedules (by varying the transmission sequence as well as the transmission times) to determine the ones that require the least communication rate between the sensors and the target controllers and therefore produce the biggest savings in WSN battery power utilization. For a fixed schedule, the stability criteria can also be used to compare different models, as well as different controllers and state observers in terms of their robustness with respect to communication suspension (i.e., which ones require measurement updates less frequently than others). Note that choosing $\Delta t_1 = \Delta t_2 = \cdots = \Delta t_{n-1} = 0$ reduces the problem to one where all the nodes in the WSN transmit their observer estimates simultaneously. As expected, in this case stability of the networked closed-loop system depends only on Λ_o and h.

5. SIMULATION STUDY: APPLICATION TO CHEMICAL REACTORS WITH RECYCLE

We consider a plant composed of three non-isothermal continuous stirred-tank reactors (CSTRs) in a cascade. The reactant species A is consumed in each reactor by three parallel irreversible exothermic reactions. The output of the third CSTR is passed through a separator that removes the products and recycles unreacted A to the first CSTR. Under standard modeling assumptions, a plant model of the following form can be derived from conservation laws:

$$\begin{aligned}\frac{dT_j}{dt} &= \frac{F_j^0}{V_j}(T_j^0 - T_j) + \frac{F_{j-1}}{V_j}(T_{j-1} - T_j) \\ &\quad + \sum_{i=1}^{3}\frac{(-\Delta H_i)}{\rho c_p}R_i(C_{Aj}, T_j) + \frac{Q_j}{\rho c_p V_j} \\ \frac{dC_{Aj}}{dt} &= \frac{F_j^0}{V_j}(C_{Aj}^0 - C_{Aj}) + \frac{F_{j-1}}{V_j}(C_{A(j-1)} - C_{Aj}) \\ &\quad - \sum_{i=1}^{3}R_i(C_{Aj}, T_j),\ j = 1, 2, 3\end{aligned}$$

where T_j, C_{Aj}, Q_j, and V_j denote the temperature, the reactant concentration, the rate of heat input, and the volume of the j-th reactor, respectively, $R_i(C_{Aj}, T_j) = k_{i0}\exp\left(\frac{-E_i}{RT_j}\right)C_{Aj}$ is the rate of the i-th reaction, F_j^0 denotes the flow rate of a fresh feed stream associated with the j-th reactor, F_j is the flow rate of the outlet stream of the j-th reactor, with $F_0 = F_r, T_0 = T_3, C_{A0} = C_{A3}$ denoting the flow rate, temperature and reactant concentration of the recycle stream, ΔH_i, k_i, E_i, $i = 1, 2, 3$, denote the enthalpies, pre-exponential constants and activation energies of the three reactions, respectively, c_p and ρ denote the heat capacity and density of fluid in the reactor. Using typical values for the process parameters (see Sun and El-Farra (2008a)), the plant with $Q_j = 0$, $C_{Aj}^0 = C_{Aj}^{0s}$ and a recycle ratio of $r = 0.5$, has three steady-states (two locally asymptotically stable and one unstable). The control objective is to stabilize the plant at the (open-loop) unstable steady-state by manipulating Q_j and C_{Aj}^0, $j = 1, 2, 3$. Only the temperatures of the three reactors are assumed to be available as measurements. A plant-wide WSN composed of 3 wireless sensor suites is deployed. Each sensor suite collects estimates of the local process state variables provided by a state observer embedded within the unit and broadcasts it to the rest of the plant. It is desired to stabilize the plant with minimal data exchange over the WSN to conserve battery power for the wireless devices.

Linearizing the plant around the unstable steady-state yields a system of the form of Eq.1 to which the networked output feedback control and scheduling architecture described in the previous sections is applied. The synthesis details are omitted due to space limitations. In the remainder of this section, we will investigate the interplay between the communication rate and the sensor transmission schedule, and its impact on closed-loop stability. Since closed-loop stability requires all eigenvalues of M_o to lie within the unit circle, it is sufficient to consider only the maximum eigenvalue magnitude, denoted by $\lambda_{\max}(M_o)$.

Table 1. Sensor transmission schedules

Schedule	$s_1, s_2, s_3, s_1, s_2, s_3, \cdots$
1	$1, 2, 3, 1, 2, 3, \cdots$
2	$1, 3, 2, 1, 3, 2, \cdots$
3	$2, 1, 3, 2, 1, 3, \cdots$
4	$2, 3, 1, 2, 3, 1, \cdots$
5	$3, 1, 2, 3, 1, 2, \cdots$
6	$3, 2, 1, 3, 2, 1, \cdots$

We consider first the case when $\Delta t_1 = \Delta t_2 = \Delta t$. Fig.2(a) is a contour plot showing the dependence of $\lambda_{\max}(M_o)$ on both the interval between transmissions, Δt, and the update period, h, under the six possible sensor transmission schedules listed in Table 1 when imperfect models are embedded in the local control systems (each model has 10% parametric uncertainty in the heat of reaction). For each schedule, the area enclosed by the unit contour line is the stability region of the plant. It can be seen that, for sufficiently small Δt (below 0.03 hr), the maximum allowable update periods obtained under sequences 2 and 6 are larger than the one obtained when no scheduling takes place (i.e., with $\Delta t = 0$). As Δt is increased, however, the trend is reversed, indicating that the benefits of scheduling can be limited by a poor choice of the transmission times. For sequences 3 and 5, scheduling yields larger update periods (compared with the concurrent transmission configuration) only when the transmission times are chosen such that $\Delta t > 0.04$ hr. In general, allowing the different sensor suites to transmit their data and update their target models at different times (rather than simultaneously) can help provide a more targeted and timely (though only partial) correction to model estimation errors which in turn helps reduce the rate at which each node in the WSN must transmit its data. These predictions are further confirmed by the closed-loop state profile shown in Fig.2(b), which shows that the linearized plant is stable under sequence 6 but unstable under sequence 2, when $\Delta t = 0.02$ hr and

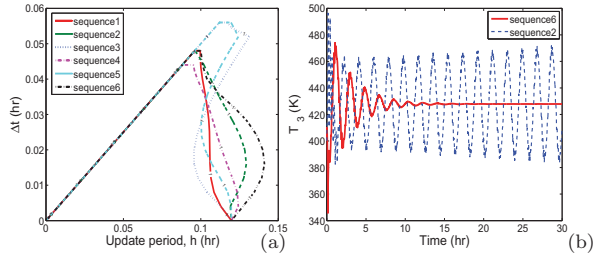

Fig. 2. (a) Dependence of $\lambda_{\max}(M_o)$ on Δt and h for different sensor transmission sequences under a model-based control scheme. (b) Closed-loop temperature profile for CSTR3 under the model-based quasi-decentralized output feedback control strategy using two different sensor transmission schedules with the same update period.

$h = 0.13$ hr (for brevity, only the temperature profile for CSTR 3 is shown; the state and input profiles for the other reactors exhibit similar behavior).

We consider next the more general case where $\Delta t_1 \neq \Delta t_2$. Fig.3(a) is a contour plot showing the dependence of $\lambda_{\max}(M_o)$ on Δt_1 and h for different values of Δt_2, when the WSN nodes transmit according to sequence 2 and an uncertain model is used (nominal value of the heat of reaction is 10% higher than the actual value). It can be seen that a larger update period (and hence larger reduction in WSN utilization) can be obtained by carefully choosing the transmission times for the sensor suites of different units than in the case when $\Delta t_1 = \Delta t_2$. For example, consider the case when $\Delta t_2 = 0.02$ hr and $h = 0.13$ hr. This point lies outside the stability region of schedule 2 when $\Delta t_2 = \Delta t_1 = 0.02$ hr (see Fig.2(a)). If we choose $\Delta t_1 = 0.08$ hr, however, the same update period becomes stabilizing under schedule 2 (the point now lies inside the stability region). These observations are further confirmed by the temperature profiles in Fig.3(b).

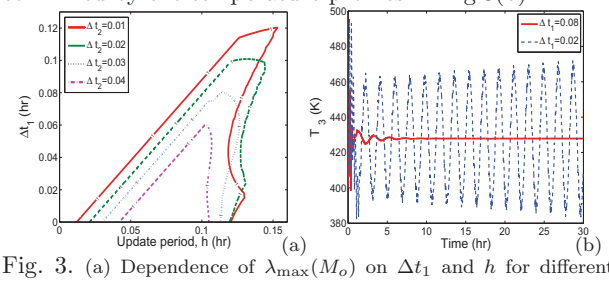

Fig. 3. (a) Dependence of $\lambda_{\max}(M_o)$ on Δt_1 and h for different values of Δt_2 under schedule 2 with a fixed model, and (b) Closed-loop temperature profile for CSTR 3 when $\Delta t_2 = 0.02$ hr and $h = 0.13$ hr for two different values of Δt_1.

Abstract: Controlled variable (CV) selection from available measurements through exhaustive search is computationally forbidding for large-scale problems. We have recently proposed novel bidirectional branch and bound (B^3) approaches for CV selection using the minimum singular value (MSV) rule and the local worst-case loss criterion in the framework of self-optimizing control. However, the MSV rule is approximate and worst-case scenario may not occur frequently in practice. In this work, the B^3 approach is extended to CV selection based on the recently developed local average loss metric, which represents the expected loss incurred over the long-term operation of the plant. Lower bounds on local average loss and fast pruning algorithms are derived for the efficient B^3 algorithm. Numerical tests and binary distillation column case study are used to demonstrate the computational efficiency of the proposed method.

Keywords: Branch and bound, Combinatorial optimization, Controlled variable, Self-optimizing control.

1. INTRODUCTION

The selection of controlled variables (CVs) from available measurements is an important task during the design of control systems for complex processes. Traditionally, CVs have been selected based on intuition and process knowledge. To systematically select CVs, Skogestad (2000) introduced the concept of self-optimizing control. In this approach, CVs are selected such that in presence of disturbances, the loss incurred in implementing the operational policy by holding the selected CVs at constant setpoints is minimal, as compared to the use of an online optimizer.

The choice of CVs based on the general non-linear formulation of self-optimizing control requires solving large-dimensional non-convex optimization problems (Skogestad, 2000). To quickly pre-screen alternatives, local methods have been proposed including the minimum singular value (MSV) rule (Skogestad and Postlethwaite, 1996) and exact local methods with worst-case (Halvorsen et al., 2003) and average loss minimization (Kariwala et al., 2008). Though the local methods simplify loss evaluation for a single alternative, every feasible alternative still needs to be evaluated to find the optimal solution. As the number of alternatives grows rapidly with process dimensions, such an exhaustive search is computationally intractable for large-scale processes. Thus, an efficient method is needed to find a subset of available measurements, which can be used as CVs (Problem 1).

Instead of selecting CVs as a subset of available measurements, it is possible to obtain lower losses using combinations of available measurements as CVs (Halvorsen et al., 2003). Recently, explicit solutions to the problem of finding locally optimal measurement combinations have been proposed (Kariwala, 2007; Kariwala et al., 2008; Alstad et al., 2009). It is possible, however, that the use of combinations of a few measurements as CVs may provide similar loss as the case where combinations of all available measurements are used (Kariwala, 2007; Kariwala et al., 2008; Alstad et al., 2009). Though the former approach results in control structures with lower complexity, it gives rise to another combinatorial optimization problem involving the identification of the set of measurements, whose combinations can be used as CVs (Problem 2).

Both Problems 1 and 2 can be seen as subset selection problems, for which only exhaustive search and branch and bound (BAB) method guarantee globally optimal solution. For minimization problems, a BAB approach divides the problem into several sub-problems (nodes) and calculates a lower bound of the selection criterion over all possible solutions of a node. If the lower bound is greater than an upper bound of the optimal solution, then the corresponding node is pruned (eliminated without further evaluation). In this way, the BAB method gains its efficiency in comparison with exhaustive search. The traditional BAB methods for subset selection use downwards approach, where pruning is performed on nodes with gradually decreasing subset size (Narendra and Fukunaga, 1977). Recently, a novel bidirectional BAB (B^3) approach (Cao and Kariwala, 2008) has been proposed for CV selection, where non-optimal nodes are pruned in downwards as well as upwards (gradually increasing subset size) directions simultaneously, which significantly reduces the solution time.

The bidirectional BAB (B^3) approach has been applied to solve Problem 1 with MSV rule (Cao and Kariwala, 2008) and local worst-case loss (Kariwala and Cao, 2009)

as selection criteria. A partially bidirectional BAB (PB^3) method has also been proposed to solve Problem 2 through minimization of local worst-case loss (Kariwala and Cao, 2009). The MSV rule, however, is approximate and can lead to non-optimal set of CVs (Hori and Skogestad, 2008). Selection of CVs based on local worst-case loss minimization can also be conservative, as the worst-case may not occur frequently in practice (Kariwala et al., 2008). Thus, CV selection through minimization of local average loss, which represents the expected loss incurred over the long-term operation of the plant, can be deemed as most reliable.

In this paper, lower bounds on local average loss and fast pruning algorithms are derived to develop an efficient B^3 method for CV selection using the exact local method with average loss minimization. A PB^3 method is also developed to find a subset of available measurements, whose combinations can be used as CVs to minimize local average loss. Numerical tests and binary distillation column case study are used to demonstrate the computational efficiency of the proposed method.

2. BAB METHODS FOR SUBSET SELECTION

Let $X_m = \{x_1, x_2, \cdots, x_m\}$ be an m-element set. The subset selection problem with selection criterion T involves finding an n-element subset $X_n \subset X_m$ such that

$$T(X_n^*) = \min_{X_n \subset X_m} T(X_n) \tag{1}$$

For a subset selection problem, the total number of candidates grows very quickly as m and n increase, which renders exhaustive search unviable. BAB approach can find the globally optimal subset without exhaustive search.

2.1 Unidirectional BAB approaches

Downwards. BAB search is traditionally conducted downwards (gradually decreasing subset size). A downwards solution tree for selecting 2 out of 6 elements is shown in Figure 1(a), where the root node is the same as X_m. Other nodes represent subsets obtained by eliminating one element from their parent sets. Labels at nodes denote the elements discarded there. To describe the pruning principle, let B be an upper bound of the globally optimal criterion, *i.e.* $B \geq T(X_n^*)$ and $\underline{T}_n(X_s)$ be a downwards lower bound over all n-element subsets of X_s, *i.e.* $\underline{T}_n(X_s) \leq T(X_n)\ \forall X_n \subseteq X_s$. Then,

$$T(X_n) > T(X_n^*)\,\forall X_n \subseteq X_s, \text{if } \underline{T}_n(X_s) > B \tag{2}$$

Hence, any n-element subset of X_s cannot be optimal and can be pruned without further evaluation, if $\underline{T}_n(X_s) > B$.

Upwards. Subset selection can also be performed upwards (gradually increasing subset size). An upwards solution tree for selecting 2 out of 6 elements is shown in Figure 1(b), where the root node is an empty set. Other nodes represent supersets obtained by adding one element to their parent sets. Labels at nodes denote the elements added there. To introduce the pruning principle, let the upwards lower bound of the selection criterion be defined as $\underline{T}_n(X_t) \leq T(X_n)\ \forall X_n \supseteq X_t$. Then,

$$T(X_n) > T(X_n^*)\,\forall X_n \supseteq X_t, \text{if } \underline{T}_n(X_t) > B \tag{3}$$

As downwards BAB, if $\underline{T}_n(X_t) > B$, any n-element superset of X_t cannot be optimal and hence can be pruned without further evaluation.

2.2 Bidirectional BAB approach

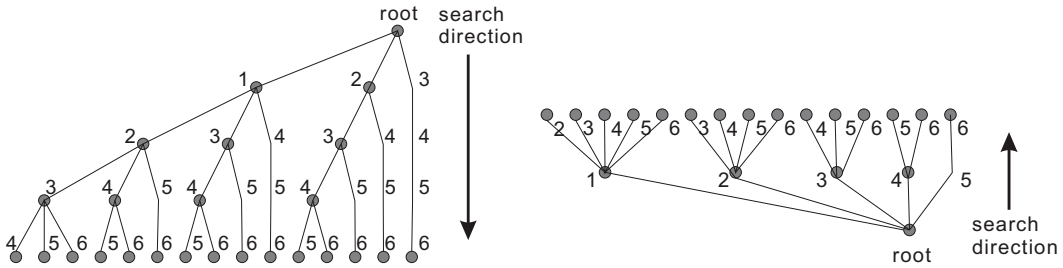
The upwards and downwards BAB approaches can be combined to form a more efficient bidirectional BAB (B^3) approach. This approach is applicable to any subset selection problem, for which both upwards and downwards lower bounds on the selection criterion are available (Cao and Kariwala, 2008).

Bidirectional pruning. In a B^3 approach, the whole subset selection problem is divided into several subproblems. A sub-problem is represented as the 2-tuple $\mathcal{S} = (F_f, C_c)$, where F_f is an f-element fixed set and C_c is a c-element candidate set. Here, $f \leq n$ and $n \leq f + c \leq m$. The elements of F_f are included in all n-element subsets that can be obtained by solving $\mathcal{S}$, while elements of C_c can be freely chosen to append F_f. In terms of fixed and candidate sets, downwards and upwards pruning can be performed if $\underline{T}_n(F_f \cup C_c) > B$ and $\underline{T}_n(F_f) > B$, respectively. In B^3 approach, these pruning conditions are used together (bidirectional pruning), where the subproblem $\mathcal{S}$ is pruned, if either downwards or upwards pruning condition is met.

The use of bidirectional pruning significantly improves the efficiency as non-optimal subproblems can be pruned at an early stage of the search. Further gain in efficiency is achieved by carrying out pruning on the sub-problems of $\mathcal{S}$, instead of on $\mathcal{S}$ directly. For $x_i \in C_c$, upward pruning is conducted by discarding x_i from C_c, if $\underline{T}_n(F_f \cup x_i) > B$. Similarly, if $\underline{T}(F_f \cup (C_c \backslash x_i)) > B$, then downward pruning is performed by moving x_i from C_c to F_f. Here, an advantage of performing pruning on sub-problems is that the bounds $\underline{T}_n(F_f \cup x_i)$ and $\underline{T}_n(F_f \cup (C_c \backslash x_i))$ can be computed from $\underline{T}_n(F_f)$ and $\underline{T}_n(F_f \cup C_c)$, respectively, for all $x_i \in C_c$ together, resulting in computational efficiency.

Bidirectional branching. In downwards and upwards BAB methods, branching is performed by removing elements from C_c and moving elements from C_c to F_f, respectively. These two branching approaches can be combined into an efficient bidirectional approach by selecting a decision element and deciding upon whether the decision element be eliminated from C_c or moved to F_f. In the B^3 algorithm, the decision element is selected as the one with the largest upwards or downwards upper bound for upward or downward search (best-first search), respectively.

The branching direction (upwards or downwards) is selected by comparing the number of terminal nodes (n-element subsets) of the resulting subproblems with alternate approaches such that the simpler branch is evaluated first, whilst the other branch is kept for possible pruning in future. For downwards branching, removing an element from C_c results in a subproblem with $\mathcal{C}_{c-1}^{n-f}$ terminal nodes, whilst for upwards branching, moving an element from C_c to F_f gives a subproblem with $\mathcal{C}_{c-1}^{n-f-1}$ terminal nodes. Therefore, if $2(n-f) > c$, downwards branching is performed, otherwise upwards branching is selected.



(a) downward search (b) upward search

Fig. 1. Solution trees for selecting 2 out of 6 elements.

3. SELF-OPTIMIZING CONTROL

To present the local method for self-optimizing control, consider that the economics of the plant is characterized by the scalar objective functional $J(\mathbf{u}, \mathbf{d})$, where $\mathbf{u} \in \mathbb{R}^{n_u}$ and $\mathbf{d} \in \mathbb{R}^{n_d}$ denote the degrees of freedom or inputs and disturbances, respectively. The linearized model of the process around the nominally optimal operating point is

$$\mathbf{y} = \mathbf{G}^y \mathbf{u} + \mathbf{G}_d^y \mathbf{W}_d \mathbf{d} + \mathbf{W}_e \mathbf{e} \tag{4}$$

where $\mathbf{y} \in \mathbb{R}^{n_y}$ denotes the process measurements and $\mathbf{e} \in \mathbb{R}^{n_y}$ represents the implementation error including measurement and control errors. Here, the diagonal matrices $\mathbf{W}_d$ and $\mathbf{W}_e$ contain the magnitudes of expected disturbances and implementation errors associated with the individual measurements, respectively. The CVs $\mathbf{c} \in \mathbb{R}^{n_u}$ are given as

$$\mathbf{c} = \mathbf{H}\mathbf{y} = \mathbf{G}\mathbf{u} + \mathbf{G}_d \mathbf{W}_d \mathbf{d} + \mathbf{H}\mathbf{W}_e \mathbf{e} \tag{5}$$

where $\mathbf{G}_d = \mathbf{H}\mathbf{G}_d^y$ and $\mathbf{G} = \mathbf{H}\mathbf{G}^y \in \mathbb{R}^{n_u \times n_u}$ is invertible, a necessary condition for integral control.

When $\mathbf{d}$ and $\mathbf{e}$ are constrained to satisfy

$$\left\| \begin{bmatrix} \mathbf{d}^T & \mathbf{e}^T \end{bmatrix} \right\|_2^T \leq 1 \tag{6}$$

Kariwala et al. (2008) have shown that the average loss over the set (6) is given as

$$L_{\text{average}}(\mathbf{H}) = \frac{1}{6(n_y + n_d)} \left\| (\mathbf{H}\tilde{\mathbf{G}})^{-1}\mathbf{H}\mathbf{Y} \right\|_F^2 \tag{7}$$

where $\tilde{\mathbf{G}} = \mathbf{G}^y \mathbf{J}_{uu}^{-1/2}$ and

$$\mathbf{Y} = \begin{bmatrix} (\mathbf{G}^y \mathbf{J}_{uu}^{-1} \mathbf{J}_{ud} - \mathbf{G}_d^y)\mathbf{W}_d & \mathbf{W}_e \end{bmatrix} \tag{8}$$

When individual measurements are selected as CVs, the elements of $\mathbf{H}$ are restricted to be 0 or 1 and $\mathbf{H}\mathbf{H}^T = \mathbf{I}$. Using index notation, this problem can be stated as

$$\min_{X_{n_u} \subset X_{n_y}} L_1(X_{n_u}) = \left\| \tilde{\mathbf{G}}_{X_{n_u}}^{-1} \mathbf{Y}_{X_{n_u}} \right\|_F^2 \tag{9}$$

Note that the scalar constant $1/(6(n_y+n_d))$ is neglected in (9), as it does not depend on the selected CVs. Instead of 2-norm, as used in (6), if a different norm is used to define the allowable set of $\mathbf{d}$ and $\mathbf{e}$, the resulting expressions for average losses only differ by scalar constants (Kariwala et al., 2008). Thus, the formulation of optimization problem in (9) is independent of the norm used to define the allowable set of $\mathbf{d}$ and $\mathbf{e}$.

Instead of using individual measurements, it is possible to use combinations of measurements as CVs. In this case, the integer constraint on $\mathbf{H} \in \mathbb{R}^{n_u \times n_y}$ is relaxed, but the condition $\text{rank}(\mathbf{H}) = n_u$ is still imposed to ensure invertibility of $\mathbf{H}\mathbf{G}^y$. The minimal average loss over the set (6) using measurements combinations as CVs is given as (Kariwala et al., 2008)

$$\min_{\mathbf{H}} L_{\text{average}} = \frac{1}{6\,(n_y + n_d)} \sum_{i=1}^{n_u} \lambda_i^{-1} \left(\tilde{\mathbf{G}}^T \left(\mathbf{Y}\,\mathbf{Y}^T \right)^{-1} \tilde{\mathbf{G}} \right) \tag{10}$$

Equation (10) can be used to calculate the minimum loss provided by the optimal combination of a given set of measurements. However, the use of all measurements is often unnecessary and similar losses may be obtained by combining only a few of the available measurements. Then, the combinatorial optimization problem involves finding the set of n among n_y measurements ($n_u \leq n \leq n_y$) that can provide the minimal loss for specified n. In index notation, the n measurements are selected by minimizing

$$\min_{X_n \subset X_{n_y}} L_2(X_n) = \sum_{i=1}^{n_u} \lambda_i^{-1} \left(\tilde{\mathbf{G}}_{X_n}^T (\mathbf{Y}_{X_n} \mathbf{Y}_{X_n}^T)^{-1} \tilde{\mathbf{G}}_{X_n} \right) \tag{11}$$

where the scalar constant has been omitted as (9).

4. BAB METHOD FOR CV SELECTION

As shown in Section 3, the selection of CVs using exact local method can be seen as subset selection problems. In this section, the BAB methods for solving these problems are presented. For simplicity of notation, we define the $p \times p$ matrix $\mathbf{M}(X_p)$ and the $n_u \times n_u$ matrix $\mathbf{N}(X_p)$ as

$$\mathbf{M}(X_p) = \mathbf{R}^{-T} \tilde{\mathbf{G}}_{X_p} \tilde{\mathbf{G}}_{X_p}^T \mathbf{R}^{-1} \tag{12}$$

$$\mathbf{N}(X_p) = \tilde{\mathbf{G}}_{X_p}^T (\mathbf{Y}_{X_p} \mathbf{Y}_{X_p}^T)^{-1} \tilde{\mathbf{G}}_{X_p} \tag{13}$$

where $\mathbf{R}$ is the Cholesky factor of $\mathbf{Y}_{X_p} \mathbf{Y}_{X_p}^T$.

4.1 Lower bounds

Individual measurements. L_1 in (9) requires inversion of $\mathbf{G}_{X_{n_u}}$ and thus $L_1(X_p)$ is well-defined only when $\mathbf{G}_{X_p}$ is a square matrix, *i.e.* $p = n_u$. On the other hand, BAB methods require evaluation of loss, when the number of selected measurements differs from n_u. Motivated by this drawback, two alternate representations of L_1 are derived as follows:

$$L_1(X_p) = \sum_{i=1}^{r} \lambda_i^{-1}\left(\mathbf{N}(X_p)\right) = \sum_{i=1}^{r} \lambda_i^{-1}\left(\mathbf{M}(X_p)\right) \quad (14)$$

where $r = \text{rank}(\tilde{\mathbf{G}}_{X_p})$. It is clear that for $r = p = n_u$, (14) is equivalent to (9). However, (14) generally holds for any number of measurements since $\mathbf{Y}_{X_p}\mathbf{Y}_{X_p}^T$ is invertible under the reasonable assumption that every measurement has a non-zero implementation error. Using the generalized expression for L_1 and interlacing properties of eigenvalues (Horn and Johnson, 1985), the downwards and upwards lower bounds required for the application of B^3 algorithm are derived as follows.

Proposition 1. (Lower bounds for L_1). Consider a node $\mathcal{S} = (F_f, C_c)$. For L_1 defined in (14),

$$L_1(F_f) \leq \min_{X_{n_u} \supset F_f} L_1(X_{n_u});\ f < n_u \quad (15)$$

$$L_1(F_f \cup C_c) \leq \min_{X_{n_u} \subset (F_f \cup C_c)} L_1(X_{n_u});\ f + c > n_u \quad (16)$$

To illustrate the implications of Proposition 1, let B represent the best available upper bound on $L_1(X^*_{n_u})$. Then (15) implies that, if $L_1(F_f) > B$, the optimal solution cannot be a superset of F_f and hence all supersets of F_f need not be evaluated. Similarly, if $L_1(F_f \cup C_c) > B$, (16) implies that the optimal solution cannot be a subset of $F_f \cup C_c$ and hence all subsets of $F_f \cup C_c$ need not be evaluated. Thus, upwards and downwards pruning can be conduced using (15) and (16) and the optimal solution can be found without complete enumeration.

Measurements combinations. The expression for L_2 in (11) is the same as the expression for L_1 in (14). Thus, similar to Proposition 1, it can be shown that

$$L_2(F_f \cup C_c) \leq \min_{X_n \subset (F_f \cup C_c)} L_2(X_n); \quad f + c > n \quad (17)$$

For selecting measurements, whose combinations can be used as CVs, the result in (17) is useful for downwards pruning. Equation (16), however, also implies that when $n_u \leq f < n$, $L_2(F_f)$ decreases as the subset size increases. Thus, unlike L_1, the expression for L_2 cannot be directly used for upwards pruning. In the following proposition, a lower bound on L_2 is derived, which can instead be used for upwards pruning, whenever $n - n_u < f < n$.

Proposition 2. (Upwards lower bound for L_2). For the node $\mathcal{S} = (F_f, C_c)$, let

$$\underline{L}_2(F_f) = \sum_{i=1}^{f+n_u-n} \lambda_i^{-1}\left(\mathbf{N}(F_f)\right) \quad (18)$$

where $f > n - n_u$. Then, $\underline{L}_2(F_f)$ represents a lower bound on the loss corresponding to combinations of any n measurements obtained by appending indices to F_f, *i.e.*

$$\underline{L}_2(F_f) \leq \min_{\substack{X_n \supset F_f \\ X_n \subset (F_f \cup C_c)}} L_2(X_n) \quad (19)$$

Proposition 2 implies that the lower bound of L_2 defined in (18) can be used for upwards pruning. In this case, upwards pruning can only be applied when the size of fixed set of the node under consideration is greater than $n - n_u$. Thus, the BAB algorithm based on $\underline{L}_2$ in (18) is referred to as partially bidirectional BAB (PB^3) algorithm. Development of fully bidirectional BAB algorithm for selection of measurement combination as CVs is an open problem.

4.2 Fast pruning and branching

Propositions 1 and 2 can be used to prune the non-optimal nodes quickly. Thus, the optimal solution can be found with evaluation of fewer nodes, but the solution time can still be large, as direct evaluation of L_1 in (14) and L_2 in (11) requires eigenvalue decomposition, which is computationally expensive.

Individual measurements. When $f < n_u$, $\mathbf{M}(F_f)$ in (12) is invertible. Similarly when $s = f + c > n_u$, $\mathbf{N}(S_s)$ in (13) for $S_s = F_f \cup C_c$ is invertible. Thus,

$$L_1(F_f) = \sum_{i=1}^{r} \lambda_i^{-1}(\mathbf{M}(F_f)) = \text{trace}(\mathbf{M}^{-1}(F_f)) \quad (20)$$

$$L_1(S_s) = \sum_{i=1}^{r} \lambda_i^{-1}(\mathbf{N}(S_s)) = \text{trace}(\mathbf{N}^{-1}(S_s)) \quad (21)$$

The use of (20) and (21) for evaluation of lower bounds on L_1 avoids computation of eigenvalues. The next two propositions relate the bounds of a node with the bounds of sub-nodes allowing pruning on sub-nodes directly and thus improving efficiency of the B^3 algorithm further.

Proposition 3. (Upwards pruning for L_1). Consider a node $\mathcal{S} = (F_f, C_c)$ and index $i \in C_c$. Then

$$L_1(F_f \cup i) = L_1(F_f) + \frac{\|\mathbf{z}_i^T\mathbf{Y}_{F_f} - \mathbf{Y}_i\|_2^2}{\eta_i} \quad (22)$$

where $\mathbf{z}_i = (\tilde{\mathbf{G}}_{F_f}\tilde{\mathbf{G}}_{F_f}^T)^{-1}\tilde{\mathbf{G}}_{F_f}\tilde{\mathbf{G}}_i^T$ and $\eta_i = \tilde{\mathbf{G}}_i(\mathbf{I} - \mathbf{G}_{F_f}^T(\tilde{\mathbf{G}}_{F_f}\tilde{\mathbf{G}}_{F_f}^T)^{-1}\tilde{\mathbf{G}}_{F_f})\tilde{\mathbf{G}}_i^T$.

Proposition 4. (Downward pruning for L_1). For a node $\mathcal{S} = (F_f, C_c)$, let $S_s = F_f \cup C_c$, where $s = f + c$. For $i \in C_c$,

$$L_1(S_s \setminus i) = L_1(S_s) + \frac{\|\mathbf{x}_i\mathbf{N}^{-1}(S_s)\|_2^2}{\zeta_i - \mathbf{x}_i\mathbf{N}^{-1}(S_s)\mathbf{x}_i^T} \quad (23)$$

where $\mathbf{x}_i = \mathbf{Y}_i\mathbf{Y}_{S_s\setminus i}^T(\mathbf{Y}_{S_s\setminus i}\mathbf{Y}_{S_s\setminus i}^T)^{-1}\mathbf{G}_{S_s\setminus i} - \mathbf{G}_i^T$ and $\zeta_i = \mathbf{Y}_i(\mathbf{I} - \mathbf{Y}_{S_s\setminus i}^T(\mathbf{Y}_{S_s\setminus i}\mathbf{Y}_{S_s\setminus i}^T)^{-1}\mathbf{Y}_{S_s\setminus i})\mathbf{Y}_i^T$.

In comparison with the direct calculation of L_1, the use of (22) and (23) is computationally less demanding. This happens as in (22), the inverse $(\tilde{\mathbf{G}}_{F_f}\tilde{\mathbf{G}}_{F_f}^T)^{-1}$ needs to be evaluated only once for all c sub-nodes, whilst in (23), two inverses $(\tilde{\mathbf{Y}}_{S_s\setminus i}\tilde{\mathbf{Y}}_{S_s\setminus i}^T)^{-1}$ and $N^{-1}(S_s)$ are evaluated only once for all c sub-nodes.

Measurements combinations. As the downwards pruning criteria for minimization of L_1 and L_2 are the same, Proposition 4 can be used for fast downwards pruning for selection of a subset of measurements, whose combinations can be used as CVs. The fast upwards pruning criteria for minimization of L_2 is presented in the next proposition.

Proposition 5. (Upwards pruning for L_2). Consider a node $\mathcal{S} = (F_f, C_c)$ and index $i \in C_c$. Then

$$\underline{L}_2(F_f \cup i) \geq \sum_{j=1}^{f+n_u-n+1} \frac{1}{\lambda_j(\mathbf{N}(F_f)) + t_j} \quad (24)$$

where $t = [t_1 \ \cdots \ t_{f+n_u-n+1}]^T$ is determined by solving the following linear equations:

$$t_j - t_{j+1} = \lambda_{j+1} - \lambda_j, \ j = 1, 2, \cdots, f + n_u - n \quad (25)$$

$$\sum_{j=1}^{f+n_u-n+1} t_j = \|\mathbf{s}_i\|_2^2/\beta_i \quad (26)$$

with $\mathbf{s}_i = \mathbf{Y}_i\mathbf{Y}_{F_f}^T(\mathbf{Y}_{F_f}\mathbf{Y}_{F_f}^T)^{-1}\mathbf{G}_{F_f} - \mathbf{G}_i^T$ and $\beta_i = \mathbf{Y}_i(\mathbf{I} - \mathbf{Y}_{F_f}^T(\mathbf{Y}_{F_f}\mathbf{Y}_{F_f}^T)^{-1}\mathbf{Y}_{F_f})\mathbf{Y}_i^T$.

Note that the relationship in (24) is an inequality, which can be conservative. As a BAB method spends most of its time in evaluating nodes that cannot lead to the optimal solution, we use the computationally cheaper albeit weaker pruning criteria in this paper.

5. NUMERICAL EXAMPLES

To examine the efficiency of the proposed BAB algorithms developed in this work and listed in Table 1, numerical tests are conducted using randomly generated matrices and binary distillation column case study. All tests are conducted on a Windows XP SP2 notebook with an Intel® Core™ Duo Processor T2500 (2.0 GHz, 2MB L2 Cache, 667 MHz FSB) using MATLAB® R2008a.

Table 1. BAB programs for comparison

program	description
UP	upwards pruning (22)
DOWN	downwards pruning (23)
B^3	bidirectional BAB by combining (22) and (23)
PB^3	partially B^3 by combining (23) and (24)

5.1 Random tests

To evaluate the efficiency of the different BAB algorithms developed in this work, we consider selection of n_u out of $n_y = 36$ variables, where n_u varies between 1 and 35 with $n_d = 5$. Six random matrices are generated: three full matrices, $\mathbf{G}^y \in \mathbb{R}^{n_y \times n_u}$, $\mathbf{G}_d^y \in \mathbb{R}^{n_y \times n_d}$ and $\mathbf{J}_{ud} \in \mathbb{R}^{n_u \times n_d}$, and three diagonal matrices, $\mathbf{W}_e \in \mathbb{R}^{n_y \times n_y}$, $\mathbf{W}_d \in \mathbb{R}^{n_d \times n_d}$ and $\mathbf{J}_{uu} \in \mathbb{R}^{n_u \times n_u}$. The average computation time and number of nodes evaluated over the 100 random cases are summarized in Figure 2.

From Figure 2, it can be seen that all the developed algorithms (UP, DOWN and B^3) show much superior performance than the currently used brute force method. As one may expect, upwards pruning based algorithm (UP) shows better efficiency for problems involving selection of a few variables from a large candidate set, whilst downwards pruning based algorithm (DOWN) is more efficient for problems, where a few among many candidate variables need to be discarded to find the optimal solution. The solution times for the B^3 algorithm is similar to the better of UP and DOWN algorithms, however, its efficiency is insensitive to the kind of selection problem. Within 1000 seconds, both UP and DOWN algorithms can only handle problems with $n_u < 9$ or $n_y - n_u < 9$. For all cases,

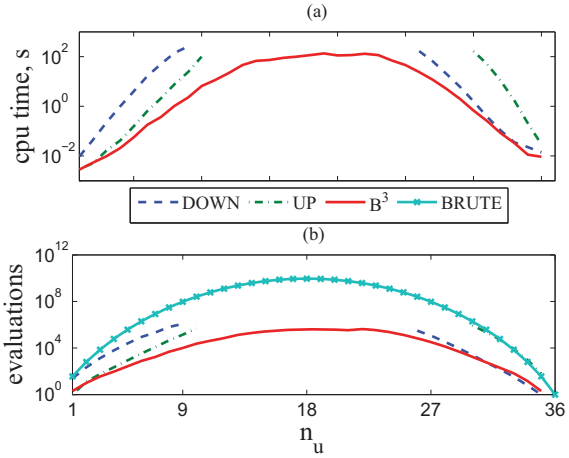


Fig. 2. Random test: (a) computation time and (b) number of nodes evaluated against n_u.

however, the B^3 algorithm exhibits superior efficiency and is able to solve the problem with $n_u = 18$ within 200 seconds.

5.2 Distillation column case study

To demonstrate the efficiency of the developed PB^3 algorithm, we consider self-optimizing control of a binary distillation column (Skogestad, 1997). The objective is to minimize the deviation of the distillate and bottoms composition from their nominal steady-state values in presence of disturbances in feed flow rate, feed composition and vapor fraction of feed. Two degrees of freedom (reflux and vapor boilup rates) are available and thus two CVs are required for implementation of self-optimizing control strategy. It is considered that the temperatures on 41 trays are measured with an accuracy of $\pm 0.5^o$ C. The combinatorial optimization problem involves selection of n out of 41 candidate measurements, whose combinations can be used as CVs. The reader is referred to Hori and Skogestad (2008) for further details of this case study.

The PB^3 algorithm is used to select the 10 best measurement combinations for $2 \leq n \leq 41$. The trade-off between the losses of the 10 best selections and n is shown in Figure 3(a). It can be seen that when $n \geq 14$, the loss is less than 0.075, which is close to the minimum loss (0.052) by using a combination of all 41 measurements. Furthermore, the reduction in loss is negligible, when combinations of more than 20 measurements are used.

Figures 3(b) and (c) show the computation time and number of node evaluations for PB^3 and DOWN algorithms. Overall, both algorithms are very efficient and are able to reduce the number of node evaluations by 5 to 6 orders of magnitude, as compared to the brute force search method. For example, to select 20 measurements from 41 candidates, evaluation of a single alternative requires about 0.15 ms on the specified notebook computer. Thus, a brute force search methods would take more than one year to evaluate all possible alternatives. However, both PB^3 and DOWN algorithms are able to solve this problem within 100 seconds. Hence, without algorithms developed here, it

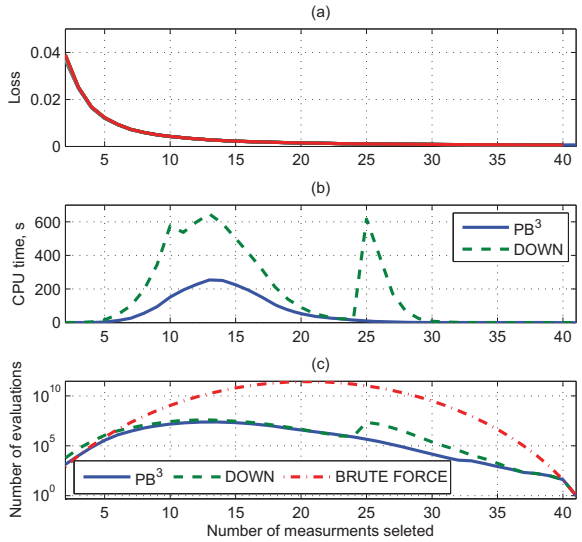

Fig. 3. (a) Average losses of 10-best measurement combinations against the number of measurements, (b) Comparison of computation time, and (c) Comparison of number of node evaluations

would be practically impossible to generate of the trade-off curve shown in Figure 3(a).

Due to the conservativeness of the pruning condition (24), the PB^3 algorithm is only able to reduce the number of node evaluations and hence computation time up to a factor of 2 for selection problems involving selection of a few measurements from a large candidate set. It is expected that a less conservative or fully upwards pruning rule would improve the efficiency, but the derivation of such a rule is currently an open problem.

6. CONCLUSIONS

In this paper, the concept of bidirectional branch and bound (BAB) proposed in Cao and Kariwala (2008) has been further developed for selection of controlled variables (CVs) using the local average loss minimization criterion for self-optimizing control (Kariwala et al., 2008). The numerical tests using randomly generated matrices and binary distillation column case study show that the number of evaluations for proposed algorithms is 4 to 5 orders of magnitude lower than the current practice of CV selection using brute force search.

The computational efficiency of the algorithms developed in this paper based on bidirectional pruning and branching principles and fast pruning algorithms is compatible to the BAB approach for CV selection based on minimum singular value (MSV) rule (Cao and Kariwala, 2008) and the local worst-case criterion (Kariwala and Cao, 2009). Despite the availability of the exact local criteria (the worst case and average loss), one of the apparent reasons for continued use of the approximate MSV rule is its computational efficiency. This work makes CV selection using the local average loss criterion computationally tractable so that it can be adopted as a standard tool for CV selection in the self-optimizing control framework.

While the algorithm for selection of individual measurements as CVs is fully bidirectional, the algorithm for selection of subset of measurements, whose combinations can be used as CVs, is only partially bidirectional. It is expected that the development of a fully bidirectional BAB algorithm for the latter problem would improve the computational efficiency further. Furthermore, the combination matrix H that minimizes average loss also minimizes worst-case loss (Kariwala et al., 2008). This super-optimality, however, only holds for a given subset of measurements and in general, different measurement subsets can be optimal for these two criteria. An extension of the bidirectional BAB algorithm to select CVs based on the bi-objective minimization of local worst-case and average losses for self-optimizing control is currently under consideration.

Plantwide control of fruit concentrate production

Mark van Dijk, Sander Dubbelman, Peter Bongers *

**Unilever Research Vlaardingen Netherlands, Process Systems Engineering.*
(E-mail: mark-van.dijk@unilever.com).

Abstract: Fruit concentrates are key ingredients in many fruit based Unilever products. We have designed a novel continuous fruit concentration process involving a decanter, an evaporator and a recombination process. In order to ensure best product quality and highest capacity a methodology for control structure design for complete processing plants (plantwide control) was applied. This included defining the control objectives, degrees of freedom analysis, definition of inventory and production rate control and the development of a non-linear dynamic model. Using the methodology, control alternatives were systematically analyzed and eliminated. The chosen control structure was successfully applied and implemented in a Unilever factory.

Keywords: Control structure design; Plantwide control; Dynamic control model; Decanter; Evaporator.

1. INTRODUCTION

Plantwide control is viewed as a strong methodology to design effective control structures in complex food plants.[1]

This paper presents the conceptual process control design of a novel fruit concentration method using a separation and recombination step. It involves the development of a dynamic control model of the system, the design of a suitable control strategy with the help of this model, the implementation of the control strategy in an actual factory process control system and evaluation of its performance.

1.1 Background

Traditionally fruit purees are produced by concentrating the fruit pulp in a forced recirculation evaporator, which are known to be detrimental to product quality because of their large residence time and high temperatures.

We have developed a novel fruit concentration process involving the use of a separation step to separate the fruit pulp into a cake fraction and a serum fraction. Because of the absence of fibres in the serum fraction, the serum fraction can be concentrated at lower temperatures, thus maintaining its freshness. Simultaneously, the fibres are not exposed to high shear and will therefore better maintain their water-binding properties.

A draw-back of the novel fruit concentration process is that the cake fraction and the concentrated serum fraction need to be recombined into a homogeneous fruit paste in a controlled way. At the same time, the Brix and viscosity of the resulting fruit concentrate need to be maintained within normal food standards. For this reason, a systematic approach is required in order to design an effective control strategy.

1.2 Approach

Plantwide control is a concept or methodology to systematically build control structures of large, continuous processes with complex interactions [1, 2, 3]. Process modelling and simulation form an important aspect of the method. It follows a series of logical steps which are easy to apply in practice:

1. Definition of Operational Control Objectives
2. Manipulated Variables and Degrees Of Freedom
3. Primary Controlled Variables
4. Production Rate
5. Regulatory Control Layer
6. Supervisory Control Layer
7. Optimization Layer
8. Validation

We applied most steps of this methodology in conjunction with a conceptual process design methodology [4] to ensure that the integration of process, equipment and control design is optimal. This paper will focus on the first five steps. In chapter 2 we will go systematically through steps 1 to 5 given above based on the process given in figure 2.1. Next, we will present the assumptions behind the underlying mathematical model that we used to determine the best control strategy. Finally we will present the results from the industrial process that we implemented in one of our factories.

2. PLANTWIDE CONTROL PROCEDURE

2.1 STEP 1: Overall control objective. Identify operational constraints.

The process control aims at producing high grade, constant quality fruit paste. Good quality paste has a nice red

[1] This is in contrast with plantwide automation which addresses the design and implementation of Industrial Process Control and Automation Systems (IPCAS).

colour, constant Brix (sugars) and Bostwick (viscosity) values and also good taste and flavour. In order to achieve this, it is necessary to control the product flow throughout the plant smoothly and to minimise the hold-up time of product in the system. The following process and control system requirements were considered:

Process Requirements

Maximization of assets. Maximization of plant output is a key objective since fruit concentration processes are mostly seasonal continuous operations. It is therefore important that the bottleneck is 100% utilised. In our case, the evaporator is the bottleneck of the process.

Process reliability. There are many factors in the process not directly related to the control system or strategy, which influence the control performance. A major factor is the overall factory reliability (equipment and utilities). The novel process is more complex and especially vulnerable for unplanned stoppages. Both factory reliability and the control system robustness towards unplanned stoppages are essential aspects to consider in the design process.

Equipment restrictions. It is industry practice to operate decanters with a constant in-flow in order to get a stable liquid/solid separation. It is recommended that feed flow variations are less than ±20%. It is also industry practise to operate forced recirculation evaporators with a constant steam supply (constant evaporation rate).

Fruit quality fluctuations. The fibre- and sugar content of raw fruit juice is known to vary up to ±20% on an hourly basis. The fibre- and sugar content vary independently.

Control system requirements

End-product variability Brix. The Brix boundaries should be less than 1.0 Brix from controller setpoint for commercial purposes.

End-product variability Bostwick. The Bostwick should be the same or lower as normal variations in standard paste (typically +/- 0.5 cm). This implies that there should not be *more* variation in the ratio of sugars to fibers in the puree as in the original fruit.

Simple control. The control strategy must be able to be implemented in the SIEMENS Control System and must be relatively easy to understand for the operators. For this reason, the control strategy is based on standard PID-controllers.

2.2 STEP 2: Manipulated variables and degrees of freedom.

According to the principles by Skogestad, we will identify dynamic and steady-state Degrees Of Freedom (DOF) based on the process given in figure 2.1 according to the equation below:

$$N_{ss} = N_m - (N_{0m} + N_{0y})$$

In which:

N_{ss}	Number of steady state DOFs
N_m	Number of dynamic (control) DOFs (valves, pumps)
N_{0m}	Number of manipulated input variables with no steady state effect
N_{0y}	Number of output variables with no steady state effect (product levels)

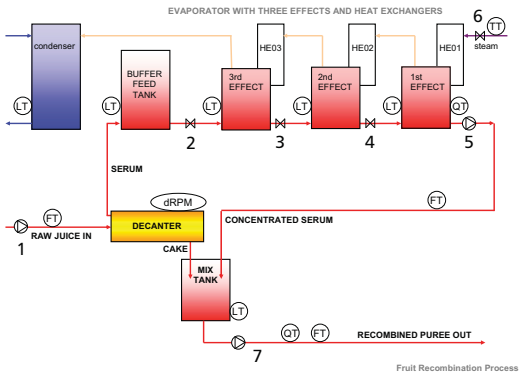

Figure 2.1: Process Flow Diagram of novel fruit concentration process with Degrees Of Freedom (DOFs).

As can be seen from figure 2.1, 7 dynamic DOFs (N_m) can be identified. Since the process consists of 5 tanks, there are 5 tank levels that need to be controlled (N_{0y}), but that do not contribute to the steady state mass- and composition balance. This means that there are two remaining DOFs (N_{ss}) to control the whole process. This is identical to an existing fruit concentrate process in which the two DOFs are used to control the Brix of the puree and the production rate. However we know that the dynamics of the novel process have changed, because we have combined a slow evaporation process with a fast separation process in one additional process step (the mix tank). Therefore a dynamic model is essential to evaluate the new process dynamics and possible process control structures.

2.3. STEP 3: Primary controlled variables.

Skogestad states that the primary variable to control is the active constraint. According to our control objectives, this is overall production rate as set by the evaporator. Another key primary controlled variable is the Brix of the resulting fruit puree. The Brix is given by the following equation:

$$\phi_{puree} \cdot Brix_{puree} = \phi_{cake} \cdot Brix_{cake} + \phi_{concentrated\ serum} \cdot Brix_{concentrated\ serum}$$

in which:

ϕ_{puree}	Flow of puree [kg/s]
$Brix_{puree}$	Brix of puree [Brix]
ϕ_{cake}	Flow of cake [kg/s]
$Brix_{cake}$	Brix of cake [Brix]
$\phi_{concentrated\ serum}$	Flow of concentrate serum [kg/s]
$Brix_{concentrated\ serum}$	Brix of concentrate serum [Brix]

The flow rate of cake is mainly driven by the amount of fibres in the fruit juice as well as the way the decanter is operated (level of drying of the cake), whereas the Brix of the cake is driven by the fruit variety, ripeness and other agronomical factors. Both Brix and flow rate of concentrated serum are highly dependent on the way that

the evaporator is operated and controlled. The chance of product that is out of specification is high since it is dependent on four variables.

2.4 STEP 4: Set of production rate.

The choice where to set the production rate determines the structure of the remaining inventory (level) control system. The production rate should be set at the (dynamic) bottleneck of the process as explained in section 2.3. For the traditional fruit concentrate process, the production rate is determined by the slow evaporator (dynamic bottle-neck). The evaporator is operated at a fixed steam pressure (constant evaporation rate). The up-stream and down-stream processes follow the evaporation rate. Since the end product Brix is controlled through manipulating the evaporator out-feed pump, this means the product flow through all unit operations is changing constantly dependent on the incoming Brix of the raw juice.

On the other hand, it is industry experience that decanters require a constant feed (within 20% of the main flow) to have the best performance. This requires controlling the flow towards the decanter and setting the production rate here, through a flow controller.

In order to control the level in the evaporator feed tank, therefore two options do exist:

A. **Control the level via manipulation of the steam supply** (thus via manipulation of the evaporation rate). No constant steam supply means that the evaporator cannot be operated at constant evaporation rate and temperatures. The potential negative impact should be evaluated and preferably minimized.

B. **Control the level via manipulation of the inflow to the decanter.** It is clear that in this scenario no constant inflow to the decanter can be guaranteed and that the potential negative impact on separation performance should be evaluated and minimized. It is noted that controlling the level through decanter serum outflow will disturb the separation process and therefore is not feasible.

Either scenario clearly forced us to deviate from the industry practice w.r.t equipment operation.

Already at this stage of the methodology we decided to develop a dynamic model based on the following arguments:

- The choice of setting the production rate highly influences the dynamics of the overall process
- There is a direct correlation between productivity and end-product composition in concentration processes
- The recombination process is highly vulnerable to variations
- We deviate from the industry standard w.r.t. equipment operation for either the decanter or the evaporator.
- The design of the control system will influence the process design, like the design of the recombination tank.

The model must involve the complete regulatory control layer in order to decide on the best control strategy. In section 2.5, we will provide the results from the model simulations and we will demonstrate how we used this to evaluate the various control strategies.

2.5. STEP 5, 6 and 8: Regulatory and Supervisory Control layers and Validation.

Section 2.4 showed that the production rate could not be defined because of the strong interactions between production rate, inventory control and product composition. It was also shown that there are two DOFs. With these two DOFs, a steady state analysis demonstrates that we can control the production rate and the Brix of the fruit puree in the following way:

1. Puree Brix control through manipulation of the concentrated serum Brix. Steady state mass- and composition balances show that an increase in concentrated serum Brix will increase the Brix of the resulting puree. Based on this, a cascade control loop can be designed. In this way, no extra DOF needs to be created and no additional equipment is required.

However, if the dynamics of this control structure prove to be unsuitable to control the Brix of the fruit puree, one additional DOF will be required in order to make the process controllable. This DOF should have sufficiently fast response time and a sufficient process gain. We have designed two alternative ways to create one extra DOF:

2. Puree Brix control through manipulation of decanter settings. By changing the differential speed of the screw inside the decanter [5] the amount of juice incorporated inside the cake can be controlled. Reducing the differential speed will send less water via the cake to the recombination tank and the Brix of the resulting puree will increase.

3. Puree Brix control through addition of juice to recombination tank. A third stream of juice can be added to the recombination tank to dilute a slightly over-concentrated puree to the specified composition.

All scenarios are summarized in table 2.1.

Table 2.1: Overview of control scenarios.

Production rate Brix control	Extra DOF created?	A. Control the level via steam supply	B. Control the level via inflow to the decanter.
1. Puree Brix control through manipulation of the concentrated serum Brix	No	A1	B1
2. Puree Brix control through manipulation of decanter settings.	Yes	A2	B2
3. Puree Brix control through addition of juice to recombination tank	Yes	A3	B3

Despite the fact that scenarios A1 and B1 are feasible based on steady state, an inverse response occurs initially: Upon increasing of the concentrated serum Brix (see figure 2.2 at t=10 hours), the outflow pump first slows down in order to increase the residence time in the first effect. The result is an inverse response of the puree Brix. This clearly demonstrates that in concentration processes, flow and concentration level are inversely proportional.

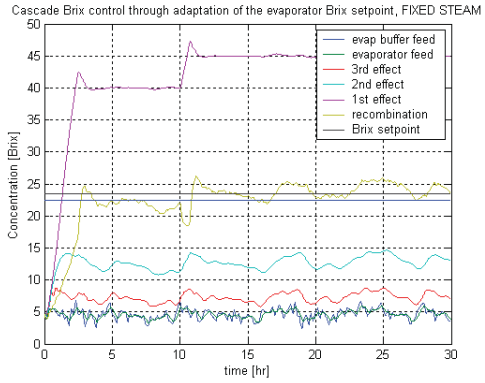

Figure 2.2: Dynamic model simulation of scenario A1. The inverse response in puree Brix (denoted in yellow-green as 'recombination') at t=10 hours is clearly visible.

The conclusion is that the additional DOF is required (Scenarios A2, B2, A3 and B3). In order to decide on the optimal control strategy, we will first evaluate the A2 and B2-strategies against the A3 and B3-strategies.

For strategies A2 and B2 the dynamic behaviour and operating window of the decanter needs to be known. Based on step response measurements on the serum exiting the decanter (see figure 2.3), we estimated that the response time of the cake fraction upon changes in differential speed is in the order of 300 seconds (three times the response time of the serum fraction).

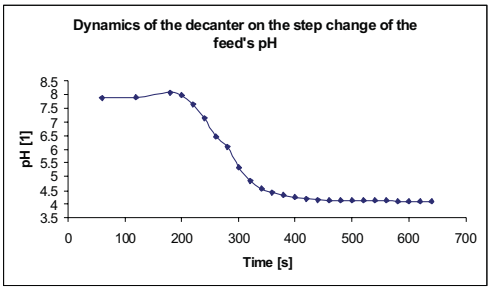

Figure 2.3: Response time of decanter serum exit on a step change in pH via citric acid addition (at 170 s).

Figure 2.4 shows the response behaviour of the solids concentration in the cake exiting the decanter as a function of changes in the differential speed (courtesy of GEA Westfalia). It can be seen that there is a strong response, but only in a small operating window. Also can be seen that the machine operation is highly non-linear.

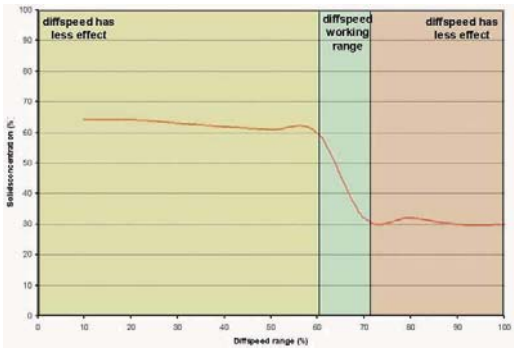

Figure 2.4: Response of solids concentration in the cake from a decanter. Courtesy of GEA Westfalia GmbH.

The results of the simulations with the above time delay and response behaviour are shown for scenario A2 in figure 2.5. As can be seen the fruit puree Brix cannot be kept within the desired range. Scenario B2 (not shown) behaved in a similar way. This means that the decanter is too slow to be used in a control loop, thus rendering strategies A2 and B2 ineffective.

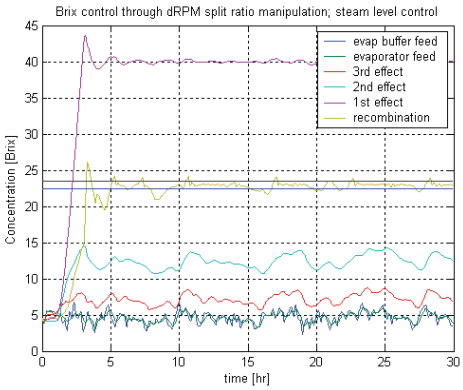

Figure 2.5: Dynamic model simulation of scenario A2. Fruit puree Brix control through manipulation of decanter settings. It can be seen that the Brix of the fruit puree (denoted in yellow-green as 'recombination') cannot be maintained within the desired range of ±1 Brix around setpoint.

We now need to decide between the scenarios A3 and B3. For a stable process, it is important that both concentrated serum and cake are recombined according to its natural ratio. This means that there cannot be an excess flow of either cake or concentrated serum in the mix tank. In this way no changes in hold-up volume of either the cake fraction or the serum fraction should occur. The only location where significant changes in hold-up volume can occur is the evaporator feed tank.

Figure 2.6 shows the level in the evaporator feed tank for scenarios A3 and B3. It can be seen that both control

strategies can control the level in this tank, but control strategy A3 requires a much longer time upon start-up to reach a stable level (> 5 hours). This means that this strategy is very slow due to the slow response of the evaporator upon changes in steam supply. For this reason, this control strategy is very vulnerable to disturbances and not recommended.

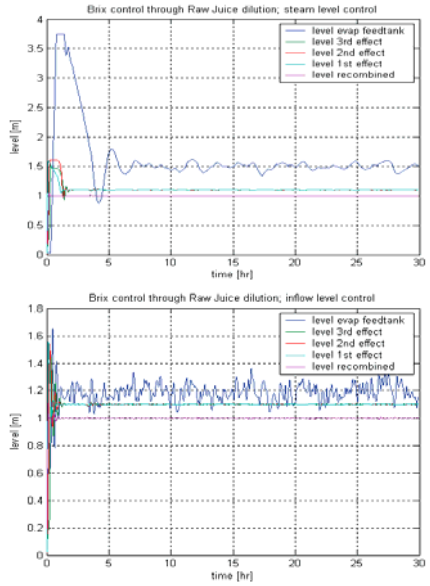

Figure 2.6: Dynamic model simulation of scenarios A3 (top) and B3 (bottom). It can be seen that the time delay to reach a setpoint of the evaporator feed tank is in the case of scenario A3 is in the order of 5 hours and in scenario B3 in the order of 1 hour.

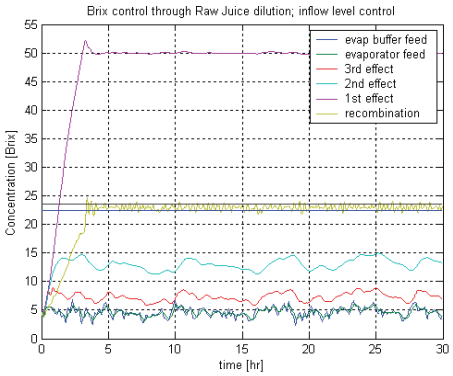
Scenario B3 gave the right dynamic behaviour to control the evaporator feed tank, allowing for a proper recombination of concentrated serum and cake. Figure 2.7 demonstrates that this strategy is also able to control the Brix of the fruit puree. Also, it can be seen that the variation of the ratio of sugars to fibers is within variations found in the raw material. Thus control strategy B3 is most suitable for this process.



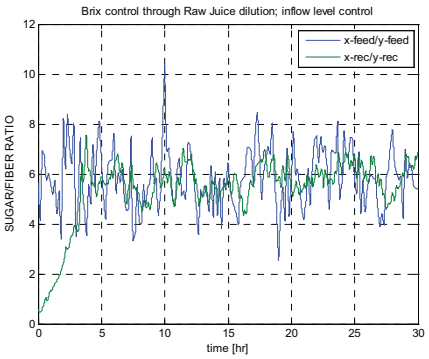


Figure 2.7: Dynamic model simulation of scenario of control strategy B3. It can be seen that the Brix of the fruit puree (denoted in yellow-green as 'recombination') can be maintained within the desired range of ±1 Brix around setpoint (left bottom). The ratio of sugars to fibers in the feed (x-feed/y-feed) and in the fruit puree (x-rec/y-rec) are shown above.

Proper tuning of the level control loop of the evaporator feed tank further contributes to the overall process stability. In order to minimize fast fluctuations in decanter inflow, it was decided to use a P-algorithm and to set the gain value relatively low. In this way, the evaporator feed tank can be used as a real buffer without impacting on the ratio of sugars to fibers. Also feed fluctuations to the decanter are minimised.

The resulting process flow diagram for strategy B3 with all sensors, actuators and control loops is given in figure 2.8.

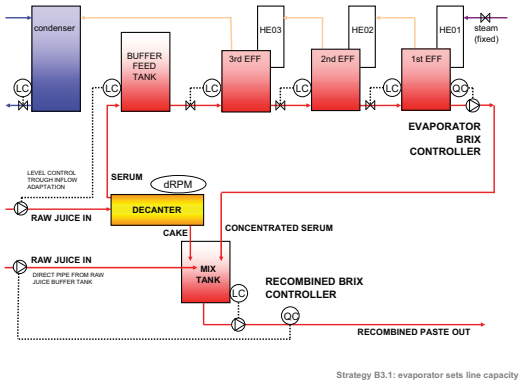

Figure 2.8: Process flow diagram with for strategy B3 with sensors, actuators and the final control structure.

3. DYNAMIC MODEL

We built a non-linear dynamic model in Matlab/Simulink [6] based on:

- Dynamic mass- and composition balance for all tanks
- Dynamic heat balance for all heat exchangers with the heat transfer coefficient estimated based on real-time factory data
- Steady state equations for the decanter with a first order transfer function with lag time
- Band-limited white noise in feed sugar and fibre levels of ±20% around the average
- PID-feedback control

4. IMPLEMENTATION INTO THE FACTORY

4.1 IPCAS implementation

The process and control strategy as defined before was implemented in a Unilever factory. To this purpose a "User Requirements Specification of the Industrial Process Control and Automation System (IPCAS)" was written. It specifies the Industrial Process Control System (PLC/SCADA process computer hardware and software), instrumentation and installation infrastructure.

4.2 Evaluation of control strategy B3 under factory conditions

The performance of the selected control strategy that was implemented in the SIEMENS PLC/SCADA system was evaluated during actual production.

Figure 4.1 shows that for the given day, the whole production was within specifications. During one whole season, the average Brix was 22.92 (with a setpoint of 23) with a standard deviation of only 0.3.

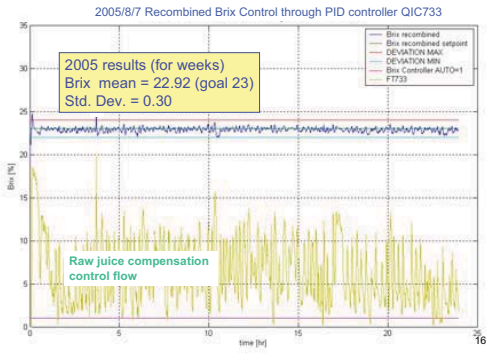

Figure 4.1: Factory data of fruit puree Brix (named QIC 733 in factory control system). Also the flow rate (named FT733 in the factory control system; raw juice compensation control flow) of the added juice is depicted. This flow rate should be multiplied by 100 and is expressed in kg/hour.

5. CONCLUSIONS

In this paper we presented a novel fruit concentrate production process involving a decanter, an evaporator and a recombination process. The choice for this process results in complex, non-linear, process dynamics. Such processes can be difficult to control and a systematic methodology was required.

We demonstrated that a strategy in which the Brix is controlled via addition of a third juice stream was the best choice for the given process. Evaluation of the control strategy under real factory conditions showed that the control strategy is very robust and that end-product specifications are met.

This case demonstrated to us that it is important to integrate control strategy design in an early stage with process and equipment design. Furthermore we required a non-linear dynamic model to understand the complex dynamics of the process and to design an appropriate control strategy.

Abstract: Multiagent systems provide a powerful framework for developing real-time process supervision and control systems for distributed and networked processes by automating adaptability and situation-dependent rearrangement of confidence to specific monitoring and diagnosis techniques. An agent-based framework for monitoring, analysis, diagnosis, and control with agent-based systems (MADCABS) is developed and tested by using detailed models of chemical reactor networks. MADCABS is composed of three main hierarchical layers, the physical communication layer, the supervision layer and the agent management layer. The supervision layer consists of agents and methods for data preprocessing, process monitoring, fault diagnosis, and control. The agent management layer conducts the assessment of agent performances to assign the priorities for selecting the most useful methods of process supervision for specific types of situations. The paper illustrates the operation of MADCABS for monitoring and fault detection.

Keywords: Multi-agent systems, process monitoring, fault detection, fault diagnosis, process supervision, process control, distributed systems, distributed artificial intelligence, autocatalytic reactions.

1. INTRODUCTION

Multi-layered and adaptive multiagent systems (MAS) provide a powerful framework for developing a new generation of real-time supervision and control systems for distributed and networked processes. The strategy, techniques and tools are being developed at IIT for monitoring, analysis, diagnosis, and control with agent-based systems (MADCABS) that automates knowledge extraction from data, analysis, and decision making. This distributed artificial intelligence framework is expected to enable the consideration of novel configurations for manufacturing such as distributed reactor networks to produce high-value-added specialty chemicals.

There are strong reasons for distributing the activities and intelligence in software for supervision of distributed process operations:

- The complex layout of a manufacturing process yields a problem that is physically distributed,
- The supervision problem is distributed and heterogeneous in functional terms,
- The complexity of the supervision problem dictates a local point of view that contributes to the development of system-wide decisions that may force reexamination of local decisions,
- The supervision system must be able to adapt to changes in the structure or environment of the supervised process or network.

Agents are capable of acting, communicating with other agents, perceiving their environment, and determining behavior to satisfy their objectives. They are endowed with autonomy and they possess resources. However, the MAS framework offers challenges as well: Agents have only partial information about their environments, they may act "selfishly" or initiate actions that may conflict with actions of other agents. This may lead to undesirable or harmful behavior in MADCABS or the supervised process, compromising its profitability and safety.

The nature of the supervision problem dictates the use of multiple layers of agents where lower-level agents perform local well-defined tasks such as information validation from sensors and higher-level agents perform more global tasks over wider regions of the supervised system. Several agents can be used to perform a specific task, each using different methods to enable not only decision by consensus-building but also to reduce the influence of the weaker methods over time. Intelligence and adaptation is provided both at agent and at system level.

MADCABS is composed of three main hierarchical layers, the *physical communication* layer, the *process supervision* layer and the *agent management* layer. The physical layer is where two-way information communication between the

⋆ This work is supported by the National Science Foundation CTS-0325378 of the ITR program.

process and MADCABS takes place. Process information, such as the flowchart of the process is mapped to MADCABS through the physical communication layer. The supervision layer consists of agents and methods for data preprocessing, process monitoring, fault diagnosis, and control. Data preprocessing agents filter the process data, check for outliers and missing data, and provide estimates for them. Monitoring agents detect deviations from normal operation and trigger the fault detection and diagnosis (FDD) agents. When abnormal process operation is validated, FDD is carried out using contribution plots, statistical methods, and process knowledge. Control agents range from simple local PI controllers to decentralized plant-wide grade transition agents. Some agents collaborate to help each other, while others work in a competing manner to satisfy a global objective. The performances of different agents and methods are evaluated in the topmost agent management layer. The agent management layer is responsible for selecting the best performing agents for process monitoring, fault detection and diagnosis, and process control for the current operating conditions. The assessment of agent performances guide the priorities assigned to select the most useful methods of process supervision for specific types of situations.

In this paper, MADCABS modules for monitoring and fault detection, and the information flow among them is discussed. The paper focuses on the architecture and functionality of MADCABS, the automated tools for assessing the success of its various functions, the redundancies in MADCABS, and the adaptation of MADCABS based on the current state of process operations. The communication and cooperation between different MADCABS modules is demonstrated with case studies using autocatalytic CSTR networks. The capabilities of MADCABS in detecting and diagnosing various types of faults are shown.

2. PROCESS MONITORING, FAULT DETECTION AND DIAGNOSIS

2.1 Statistical Process Monitoring Techniques

Multivariate statistical process monitoring (SPM) techniques are used in this study. Multivariate techniques that extract the correlation among variables based on principal component analysis (PCA) provide the basic tool for monitoring continuous processes (Kourti and MacGregor (1996); Cinar et al. (2007); Jackson (1980)). PCA is a multivariate projection method that extracts strong correlations among the variables in a data set, and based on that information defines a new orthogonal coordinate space where the coordinate axes are the highest variance directions. For chemical processes, where large highly-correlated process datasets need to be monitored, singularity problems may arise. PCA is well-suited for reducing the dimensionality of the data and capturing the essential information in the data.

For large processes that involve many processing units and many process variables with different correlation structures, a single PCA model for the whole process may not give sufficient explanation about the process behavior, may provide unreliable information based on many false and missed alarms, and may have difficulty localizing the source cause among so many variables when a fault is detected. Multiblock methods have been proposed in literature for large processes, where the process can be separated into meaningful process blocks, to increase the efficiency and interpretability of the statistical monitoring model. Algorithms to handle multiple data blocks include hierarchical PCA (HPCA) and consensus PCA(CPCA) (Qin et al. (2001); Wangen and Kowalski (1988); Westerhuis et al. (1998); Wold et al. (1996)). Multiblock algorithms enable monitoring of the process both locally and globally. The CPCA method is designed for comparing several blocks of descriptor variables measured on the same objects (Wold et al. (1996); Westerhuis et al. (1998)).

Dynamic PCA (DPCA) is an extension of conventional PCA to deal with multivariate process data that is correlated in time, using a time-lag shift method (Ku et al. (1995)). The flow of action, namely, monitoring, fault detection and diagnosis, is the same for all SPM methodologies independent of which monitoring algorithm is employed.

2.2 Fault Detection, Monitoring and Diagnosis Framework in MADCABS

MADCABS is written in Java, using Repast Simphony as the agent building platform (ROAD (2005)). Among the important features of Repast that MADCABS uses are its object oriented structure, scheduling tools and its built-in automated Monte Carlo simulation framework. Repast also allows users to change, add, delete agents in run time.

In Repast Simphony, a *context* is defined as a container where the agents reside. There are three contexts for monitoring, fault detection and diagnosis agents in MADCABS. The communications between different agents in these contexts are shown in Figure 1. Statistical models are built by the monitoring agents. The fault detection agents, which are the monitoring statistics, assign themselves to the fault detection organizer agents responsible for each subsystem that is monitored. A fault is flagged when a consensus is formed among different fault detection agents on the existence of a fault in the system. The fault flag triggers the diagnosis agent. Diagnosis agent uses information from the neighboring fault detection organizers, finds the most contributing process variables to the fault on the faulty subsystem, and investigates the potential reasons behind the fault.

Monitoring Agents. The monitoring agents are PCAStarter, DPCAStarter and MultiblockStarter agents and a monitoring organizer (Figure 2). After the system reaches steady state and a sufficient amount of normal operation data is available, monitoring starters are scheduled to form models. For all process units, a local statistical model is built using both PCA and DPCA. In the distributed framework, this is achieved by creating as many PCAStarters and DPCAStarters as the number of operating units. Each PCAStarter agent builds a separate PCA model since the data and the PC number that is used to build the models are different for each unit. DPCAStarters work identical to PCAStarters. There is only one MultiblockStarter for the whole process. In this case, the data blocks consist of data from each operating unit. The MultiblockStarter forms a single multiblock model, which

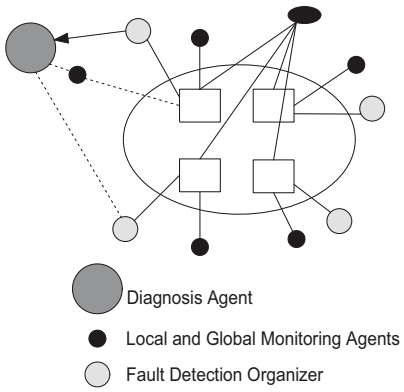

Fig. 1. Monitoring, fault detection and diagnosis agents in a four reactor network

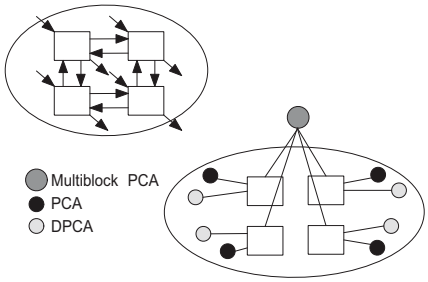

Fig. 2. Monitoring agents. The upper figure represents a four reactor network, which is simplified in the lower figure.

enables the monitoring of the process both locally and globally through block statistics and super statistics. Since there is only one model, the size retained in the model is the same for each block.

The starter agents are subclasses of MonitoringStarterParent class. Consequently, each of the starters extend some of the characteristics from the parent class and they also have class specific properties. The methods in each starter such as the buildModel and startProjection are common methods inherited from the parent, as well as the user-specified parameters. The number of principal components to be retained in the model is a superclass variable and it is overridden in each child class. Each model generates two monitoring statistics for each subsystem, a T^2 statistic and an SPE statistic. Three monitoring methods generate a total of six fault detection agents for each subsystem. The fault detection agents are contained in the fault detection context.

Fault Detection Agents. The fault detection agents, which are the T^2 and SPE statistics for each subsystem, assign themselves to the fault detection organizer of their subsystem (Figure 3). The fault detection organizer is responsible for keeping count of its fault detection agents, declaring consensus fault, keeping history of the performances of different fault detection agents under different fault scenarios, and in case of a consensus fault decision, triggering the diagnosis agent.

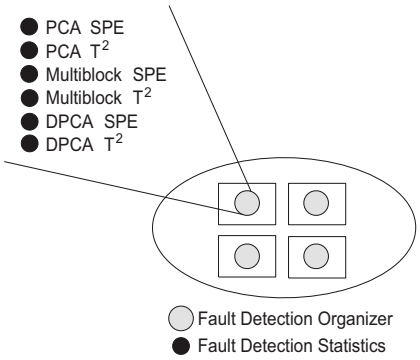

Fig. 3. Fault detection agents.

Statistics values and confidence limits are among the class variables for each fault detection agent. If the value of the statistic goes outside of the limits, the agent flags a fault. Fault detection organizer keeps track of all the fault flags given by its statistics. There are several criteria to form a consensus among different fault detection agents. The simplest would be to flag a fault, if the majority of the fault detection agents are flagging fault. This would require four of the six agents to flag a fault in order to declare that there is a fault in the unit. In the following, this strategy will be referred to as the "*number weighted*" consensus criteria.

Another criterion is based on the performances of fault detection agents over time, and based on their reliability, their decision is given more weight compared to less reliable fault detection agents. This is referred to as the "*reliability weighted*" consensus criteria. At each time point, when a new observation is available and new monitoring statistics are calculated, fault detection agents either detect a fault or not. Based on their decisions, they are given an instantaneous performance reward. The rewarding strategy is designed so that a missed alarm is penalized the most and the correct detection of fault is rewarded the most. A set of instantaneous performance rewards or penalties is given in Table 1, where the rows show the consensus and columns show the individual agent decisions. If the fault detection agent flags a fault but the consensus decision indicates otherwise, the agent is penalized for a false alarm. If the agent does not flag a fault, but the consensus flags a fault, then the agent is penalized for a missed alarm. A missed alarm is considered to be worse than a false alarm, and this is reflected in the instantaneous performance calculations. The instantaneous performances are summed in time for each detection agent, and makes up the accumulated performances. The reliability of an agent is determined by the accumulated performance values divided by the total accumulated performance value of all agents in that unit. The reliability weights are then considered in the consensus decision making.

Table 1. Instantaneous performance rewards

	Not faulty	Faulty
Not faulty	0.5	-0.5
Faulty	-1	1

The challenging problem of SPM methods is the missed and false alarm rates. For some cases, where the fault is

diffusing in the process and affecting the neighboring units and also with minor faults, the consensus flag may be oscillatory. This oscillation affects the performance mechanism in an undesired way such that an agent that has been flagging fault in the oscillatory period may not be reliable enough at that point to affect the consensus decision, and it will be penalized for flagging fault although the flag was right. Or an insensitive method could be rewarded if it did not flag the fault and again this would affect the consensus in an undesired way. In order to prevent these, the performances of agents are updated after fault episodes. A fault episode starts when a consensus fault is flagged. And the episode continues until no consensus fault is flagged for eight consecutive time points. At that point, looking back in history, the performances of agents are updated.

In order to design an automated fault detection framework, where the decisions of fault detection and diagnosis highly influence the succeeding tasks, reliability of the decisions is very important. Some of the monitoring methods may perform better than the others for various states of the process. Use of agent-based cooperation between different methods that are competing for the same task results in better overall performance than if these methods were used independently. Several monitoring agents have been implemented in MADCABS to provide diversity. The aim is to design an automated fault detection framework that can detect the faults on time, and that gives fewer false and missed alarms than if the monitoring methods were used independently. Comparison of different combinations of monitoring methods and the false and missed alarm rates of the corresponding monitoring statistics indicates that cooperation among agents improved the false and missed alarm rates.

Table 2. False and missed alarm summary of different fault detection agent combinations, using reliability weight condition

Agent	Missed Alarm	False Alarm
PCA	1.09	0.17
Multiblock PCA	20.98	0.01
DPCA	0.18	0.02
PCA-Multiblock PCA	1.21	0.06
DPCA-Multiblock PCA	0.75	0.07
PCA-DPCA	0	0.03
ALL	0	0.03

Diagnosis Agent. Diagnosis agent works in an event-driven way. It is activated when a consensus fault is flagged by a fault detection organizer. The responsibility of the diagnosis agent is to investigate the type and severity of the fault under consideration. Contribution plots are used as a diagnostic tool. The contributions of process variables to each fault detection statistic are calculated for different monitoring methods. The contribution plots do not indicate the source cause of the fault, but identify the variables that have contributed to the inflation in the SPM statistic. The diagnosis agent performs contribution plot analysis and determines the variables that inflated the SPM statistic that went out-of-control. At this point a sequence of events is activated. First, the most contributing variable to each statistic is chosen by checking if the variable contribution value is beyond the 3-*sigma* confidence limits and if it makes up a significant amount of the contributions. Each fault detection agent identifies their most contributing variables, and the common top most contributor to all is identified. That variable is then eliminated from the monitoring model data matrix and a new statistical model is built using the remaining variables. The aim is to detect if the fault is a sensor fault or a process fault. The assumption that is made here is, that a process fault usually has a fault signature and is realized in more than one variable. On the other hand, a sensor fault, especially a single sensor fault does not affect the other variables if it is not being used for control.

If the new observation, after the variable is eliminated, is in-control with the new model, it is declared as a potential sensor fault, however, the projection onto the new model continues in parallel to check if it will turn out to be a process fault later since some of the minor process faults can be misinterpreted as sensor faults in the beginning. If the new observation is not in-control with the new model, this means other variables have also been affected from the fault, and it is declared as a potential process fault. In addition to discriminating the types of faults, diagnosis agent estimates the severity of the fault by looking at how much the variable contributions have gone outside the confidence limits, how many of the neighboring fault detection organizer are signaling fault and how many of the fault detection statistics in the unit have identified the same fault signature.

3. MONITORING AND FAULT DETECTION OF A REACTOR NETWORK

3.1 Autocatalytic CSTR Network

Reactor networks hosting multiple species have a very complex behavior (Figure 2). As the number of steady states of the network increases, autocatalytic species are allowed to exist in the network that would otherwise not exist in a single CSTR. The cubic autocatalytic reaction for a single autocatalytic species is

$$R + 2P \rightarrow 3P \quad \text{and} \quad P \rightarrow D \tag{1}$$

R is the resource concentration, P is the species concentration, D is a dead species. The reaction rate for the first reaction, species growth rate constant, is k and k_d is the species death rate constant. The feed flow rates and interconnection flow rates are treated as manipulated variables. Each reactor has an inlet and outlet flow. The resource concentration in each reactor along with species concentrations is also available.

MADCABS is designed to work with process data from a real process plant or a process simulator. The data are stored in a database in MADCABS for use by MADCABS agents. For the case studies, the data are obtained from a simulator of the CSTR network, where multiple competing species coexist in the network and consume the same single resource. The ordinary differential equations modeling the operation of the reactors are written in C and connected to Repast Simphony through a Java Native Interface (JNI).

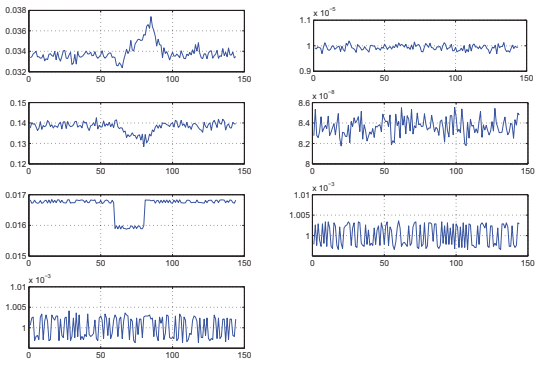

Fig. 4. A 5% process fault in the top right corner reactor 3.(a) Resource concentration in the reactor, (b) Species 1 concentration in the reactor, (c) Species 2 concentration in the reactor, (d) Species 3 concentration in the reactor (e) Feed flow rate into the reactor (Variable 5), (f) Outflowing interconnection to reactor 2 (g) Outflowing interconnection to reactor 7.

3.2 Monitoring and Fault Detection with MADCABS

The case studies use a four-by-five rectangular CSTR network, where three species coexist feeding from the same resource. Faults with different magnitudes and types are simulated to show the effectiveness of the agent-based monitoring, fault detection and diagnosis framework in MADCABS.

Fault Detection and Diagnosis. In Figure 4, a step decrease in the feed flow rate is introduced to reactor 3. The process fault affected the host species in the reactor since they start to die. The resource concentration in the reactor has increased after a delay after the dominant species start dying. From the figure, the variables that have been contributing to the fault are seen in the first three rows of the first column, the resource concentration in the reactor, dominant species concentration in the reactor and the feed flow rate to the reactor, which was reset to its original value after some time.

The contribution plots are given in Figure 5. For the five fault detection statistics that detected the existence of a fault in the system, PCA T^2, DPCA statistics and multiblock SPE showed that the main contributor to the fault is variable 5. PCA-SPE statistic had a smearing effect, where the signature of the fault could not be seen. Therefore, having multiple statistics improved diagnosis results as well. The fault has been detected on time by five fault detection agents.

Multiblock T^2 agent is insensitive to faults with magnitude less than 10%. A contribution chart that shows how many fault detection agents detected a contributing variable (Figure 6) indicates that variable 5, the feed flow rate to Reactor 3, is the common most contributor.

Table 2 provides a summary of 100 runs for each scenario. Multiblock PCA suffered from its insensitive T^2 agent, which had the highest missed alarm rate. The effect of the

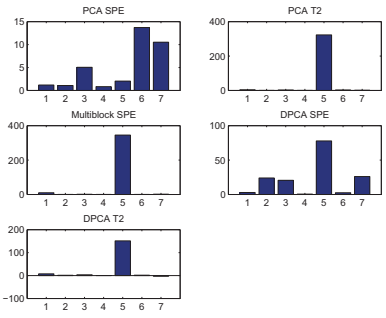

Fig. 5. Contribution plots for reactor 3 at the time of detection.

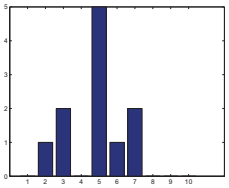

Fig. 6. Number of fault detection agents and common contributors for reactor 3.

insensitive statistic to the performance is realized in the performance of every combination with multiblock PCA. Combinations with DPCA improved the false and missed alarm rate. Especially PCA-DPCA performance is superior to any of the other less diverse combinations and seems to have a large impact on the combined performance when all three are used together. In summary, the results show that having multiple methods working together improves the effectiveness of the combined monitoring and fault detection.

Another type of fault in processes is sensor faults, where sensors might be defective and may provide false readings. A sensor fault should be identified in a timely manner since the measured variable can be used in computing the control actions and an erroneous reading may move the process to an undesired state, and may even destabilize the system. In general, correct and timely diagnosis and communication between control and diagnosis is required. A sensor fault in the form of a ramp decrease is given to the resource concentration sensor, variable 1 in reactor 6 (the figure is not provided because of space limitations). This sensor fault does not affect the other variables since it is not used for control.

The contribution plots show that the most contributing variable to the fault is variable 1. When this variable is taken out of the statistical model data, and a new model is built with one less variable, the new model reveals that the process is in-control. This indicates a potential sensor fault. The diagnosis results for reactor 6 are shared with control agents and also preprocessing agents in MADCABS so that preprocessing agents can provide reliable estimates instead of the faulty sensor, and control agents will continue to provide the necessary control actions to continue the desired operation level.

As another fault scenario, four consecutive faults are introduced to reactor 3. The fault is again introduced to the feed flow, and is of magnitude 1%. The fault introduction times and the detection times of the best performing combinations are given in Table 3. The reliability weight based consensus formation is shown to provide much earlier detection times than the majority based consensus criteria. Since the adapting reliability weight of the fault detection agents are taken into consideration, the first criteria provided earlier detection times, for consecutive faults. The results showed some kind of a learning pattern. However, this is going to be tested with different validation cases, where the training is followed by validation with different fault magnitudes. In Table 2, performance of DPCA-PCA combination was the same as the ALL combination, however, in Table 3, the detection times showed that when ALL of the monitoring agents are used in fault detection the fault is detected earlier than DPCA-PCA combination.

Table 3. Fault detection times (four consecutive process faults)

Agents	Fault#1	Fault#2	Fault#3	Fault#4
Actual Fault Times	220	250	290	330
PCA-DPCA (reliability)	221.9	250.9	290.4	330.8
ALL(reliability)	221.8	250.6	290.1	330.1
ALL(number)	223.1	254.4	294.0	333.6

The average number of agents that are flagging a fault when the consensus gives a fault flag is listed in Table 4 where two different consensus forming criteria are compared. When the agents' reliabilities increase with fault detection, less agents are required to declare a fault. When the presence of the majority of the fault detection agents is required to give a fault flag, the missed alarm rates increase and detection is delayed.

Table 4. Number of agents that flag fault at the time of detection (four consecutive process faults)

Agents	Fault#1	Fault#2	Fault#3	Fault#4
ALL(reliability)	4.06	3.46	3.48	3.25
ALL(number)	4.26	4.19	4.13	4.20

When the performances of different monitoring methods are compared the worst performing method is the multiblock PCA method because of the insensitive T^2 statistic. The overall performance of the PCA method is close to DPCA, but inferior because of the sensitive SPE statistic that gives many false alarms. The methods and the statistics are ranked and the results are provided in Table 5.

Table 5. Performances of the monitoring agents

Rank	Agent
1	DPCA SPE
2	Multiblock PCA SPE
3	PCA T^2
4	PCA SPE
5	DPCA T^2
6	Multiblock PCA T^2

4. SUMMARY AND CONCLUSIONS

PCA, DPCA and multiblock PCA methods are widely used multivariate SPM methods in process industries. However, all these methods are prone to false and missed alarms. The common practice in SPM is to test different monitoring tools form the literature, improve and tune the algorithms and find the best method that provides reliable monitoring. Considering the shortcomings of relying on a single SPM tool, consensus from several SPM tools is desirable. This is especially important for distributed and networked processes. Since there are multiple units, a monitoring system that is giving frequent false alarms on different operating units will be misleading and will not be relied on.

In order to improve the effectiveness of monitoring, several monitoring methods have been used together in the proposed framework. Some of the methods performed well on minor faults and disturbances, but had problems in contribution charts. Others gave good diagnostic results. Combining all these methods improved the effectiveness of the proposed overall monitoring, fault detection and diagnosis framework.

MADCABS provides an excellent environment to assess the performance of various SPM and fault detection methods for specific regions of process operation and adapt the reliance to different techniques based on prior experience and recursive assessment of performances. The agent management layer offers the tools and metrics to assess the performance of the monitoring, detection and diagnosis tools and dynamically update the confidence to specific techniques in a context-dependent way.

Abstract: Analysis and safety considerations of chemical and biological processes frequently require an outer approximation of the set of all feasible steady-states. Nonlinearities, uncertain parameters, and discrete variables complicate the calculation of guaranteed outer bounds. In this paper, the problem of outer-approximating the region of feasible steady-states, for processes described by uncertain nonlinear differential algebraic equations including discrete variables and discrete changes in the dynamics, is adressed.
The calculation of the outer bounding sets is based on a relaxed version of the corresponding feasibility problem. It uses the Lagrange dual problem to obtain certificates for regions in state space not containing steady-states. These infeasibility certificates can be computed efficiently by solving a semidefinite program, rendering the calculation of the outer bounding set computationally feasible. The derived method guarantees globally valid outer bounds for the steady-states of nonlinear processes described by differential equations. It allows to consider discrete variables, as well as switching system dynamics.
The method is exemplified by the analysis of a simple chemical reactor showing parametric uncertainties and large variability due to the appearance of bifurcations characterising the ignition and extinction of a reaction.

Keywords: Steady-states, nonlinear dynamical systems, discrete variables, hybrid dynamics, semidefinite programming, CSTR

1. INTRODUCTION

In the chemical and biochemical processing industry one frequently has to face large modelling uncertainties and process disturbances. Precise reaction mechanisms and kinetic parameters might be unknown and operating conditions, e.g. feed flowrate, or feed temperature, can be time dependent. Additionally, many of the substances handled in a chemical plant are potentially dangerous, e.g. inflammable or explosive. Reactions can lead to the disposal of large amounts of thermal energy, what makes safety considerations necessary. Stationary temperature and pressure have to stay below critical values and for instance in pharmaceutical processes the variability within the drug production has to be restricted. Hence, a detailed analysis of the process uncertainty is essential.

In this paper we address the problem of determining the set of all feasible steady-states of a process, for a class of uncertain hybrid nonlinear differential algebraic systems. Using the set of feasible steady-states the stationary process uncertainty can be upper bounded. Furthermore, it can be used to check whether for all possible disturbances, parameter variations, and operating conditions the process operates within previously defined constraints. One exemplary question to be asked is whether thermal runaway of a chemical reactor can be avoided under specific failure situations.

The physical processes taking place in chemical plants mostly behave in a continuous fashion. There are, however important discrete phenomena like changes in the physical system, e.g. phase transitions, imposed qualitative changes caused by limitation of the equipment, e.g. limited tank capacity, discontinuous input signals and process faults (Engell et al., 2000). To capture continuous as well as discrete phenomena, regime based approaches are used to model the process behavior (Seborg et al., 1989; Murray-Smith and Johansen, 1997; Lennartson et al., 1996). Frequently, one refers to this kind of models as hybrid models, because they contain both discrete and continuous dynamical components and an interface describing the interaction of them.

For most nonlinear systems an analytical calculation of the set of steady-states is impossible. Therefore, during the last decade several methods have been developed for approximating the set of feasible states, in the context of reachability analysis. Those methods are rather efficient if the considered system is linear time-invariant (Girard

and Guernic, 1996) and also for uncertain linear systems some results exist (Girard, 2005). However, if the systems under consideration are nonlinear, the approximation of the feasible set is more difficult. Asarin and coworkers developed an approach for two-dimensional systems based on piecewise linear approximation (Asarin et al., 2003) and Ramdani et al. (2008) proposed a method for high dimensional uncertain nonlinear systems using guaranteed set integration, which yields good results for cooperative systems. Nevertheless, the performance of these methods strongly depends on the particular structure of the nonlinear system and in many cases the results are very conservative.

Due to this drawback of set-based approaches, for the analysis of nonlinear systems, often simple Monte-Carlo type methods are employed (Robert and Casella, 2004). However, such approaches only provide the complete set of possible steady states in the limit of infinite many samples, i.e. important solutions might be left out, especially for highly nonlinear systems.

The method derived in this paper follows the idea presented in the work of Waldherr et al. (2008). There, recent advances in the field of semidefinite programming (SDP) (Parrilo, 2000; Chesi et al., 2003) are employed to compute certificates that a given set in state space cannot contain a steady-state for any feasible model parameterization. A very similar approach was earlier proposed by Kuepfer et al. (2007) for parameter estimation and later extended to dynamical systems by Borchers et al. (2009). However, all these methods are restricted to systems described by polynomial vector fields, which is rarely the case for chemical processes. Furthermore, discrete variables or parameters, as might occur in the analysis of chemical and biological processes, have not been considered.

In the following, an approach will be presented, which overcomes this shortcoming and allows the outer approximation of the set of all feasible steady-states of a process described by uncertain hybrid nonlinear differential algebraic equations with non-polynomial vector fields. Thus, systems combining continuous dynamics with logic or discrete components can be studied. Furthermore, a more elaborate algorithm is proposed to obtain a more precise approximation of the set of feasible steady-states, in cases the considered system has multiple steady-states.

The remainder of this paper is structured as follows: In Section 2 the problem of bounding the set of steady-states for processes described by non-polynomial hybrid differential algebraic equations is presented. Section 3 formalizes the problem statement. In Section 4 the resulting feasibility problem is relaxed to a semidefinite program which is used by the algorithm outlined in Section 5 to estimate the set of feasible steady-states. In Section 6 we provide as an example the analysis of a CSTR, before final conclusions are provided

Mathematical notation: The space of real symmetric $n \times n$ matrices is denoted as $\mathcal{S}^n$. N_a^b denotes the discrete set $\{1, \ldots, n_a^b\}$, where n_a^b is the number of considered variables. The positive semidefiniteness of a quadratic matrix $X \in \mathcal{S}^n$ is denoted $X \succeq 0$ and the trace of X by tr X. The transposed vector $(x^d)^T$ is written as x^{dT}.

2. PROBLEM STATEMENT

The processes under consideration are supposed to be described by hybrid differential algebraic systems which exhibit both continuous and discrete dynamical behavior. Such a process description is quite general. It covers for instance reaction networks which allow phase transitions, as well as discrete variables/inputs such as the opening of a valve or the on/off status of a heater. Mathematically, we assume that the process is described by

$$0 = F^d(\dot{x}^d, x^d, p^d, u^d), \qquad x^d(0) = x_0^d \tag{1}$$

Here $x^d \in \mathbb{R}^{n_x^d}$ is the state vector, $p^d \in \mathbb{R}^{n_p^d}$ the vector of parameters, $u \in \mathbb{R}^{n_u^d}$ the vector of inputs (externally manipulated variables), and $F^d : \mathbb{R}^{n_x^d} \times \mathbb{R}^{n_x^d} \times \mathbb{R}^{n_p^d} \times \mathbb{R}^{n_u^d} \to \mathbb{R}^{n_x^d}$ the mapping for a given discrete decision variable $d \in \mathbb{N}$. The decision variable d is assumed to be time dependent with $d(t) \in \mathcal{D}$.

To derive such hybrid differential algebraic descriptions in which each node captures the dynamics under certain operating conditions and to define switching surfaces is often easier than deriving ordinary differential equation models, holding for all process configurations.

In the following we are interested in the steady-state behavior of (1). The problem under consideration is to find all possible, or at least an outer bound of all, steady states of (1):

Problem 1. (Set of feasible steady states): Given the sets $\mathcal{D} \subset \mathbb{N}$, $\mathcal{P}^d \subset \mathbb{R}^{n_p^d}$ and $\mathcal{U}^d \subset \mathbb{R}^{n_u^d}$, compute the set $\mathcal{X}_s^*$ which contains all feasible steady-states of (1).

Note that the set of feasible steady-states for a given decision variable $d \in \mathcal{D}$ is defined by

$$0 = F^d(0, x^d, p^d, u^d). \tag{2}$$

Hence problem 1 can be split into n_d subproblems, where n_d is the cardinality of $\mathcal{D}$. For each subproblem one obtains a set of feasible steady states

$$\mathcal{X}_s^{d,*} = \{x^d \in \mathbb{R}^{n_x^d} \mid \exists\, p^d \in \mathcal{P}^d, u^d \in \mathcal{U}^d : f^d(x^d, p^d, u^d) = 0\}, \tag{3}$$

in which $f^d(x^d, p^d, u^d) = F^d(0, x^d, p^d, u^d)$. The whole set of feasible steady-states is given by the union of all steady-states

$$\mathcal{X}_s^* = \bigcup_{d \in \mathcal{D}} \mathcal{X}_s^{d,*}. \tag{4}$$

In the following the problem of computing an outer-approximation of $\mathcal{X}_s^*$ is considered. This was previously done by Waldherr et al. (2008) for differential equations with polynomial right hand sides. The main contribution of this paper is a generalization of these results to hybrid non-polynomial DAE systems.

3. BOUNDING BY PIECEWISE-POLYNOMIAL FUNCTIONS

The computational method we propose allows to handle uncertain systems that are described by polynomial equations. Therefore, (2) is transformed to a set of uncertain polynomial equations. In the case that f^d is rational, this can be trivially achieved by multiplying with the denominator. In cases in which the systems are non-rational, it is more difficult.

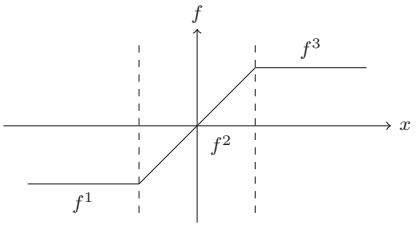

Fig. 1. Saturation function as example for the partitioning of piece-wise polynomial functions.

Savageau and Voit (1987) showed that any system with smooth non-polynomial nonlinearities can be converted to a polynomial system of larger state dimension, which is restricted via equality constraints to a manifold of the dimension of the original system. Unfortunately, in many cases the equality constraints are non-polynomial and so their method is not applicable for our approach. Instead, we apply a different method, which achieves a comparable result without enlarging the state space.

Piece-wise polynomial functions: In case that f^d is piece-wise polynomial, e.g. piece-wise linear, the state space can be partitioned into different intervals. This leads to an increase in the number of decision variables of the hybrid system and is illustrated in Figure 1 for the saturation function, which appears for instance if a process contains flow limiting valves. It has to be emphasized that in cases like this, the partitioning depends on the state. Thus, for a given region in state space $\mathcal{X}$ only a subset of decision variables $d \in \mathcal{D}$ is accessible.

General nonlinear functions: For functions which are not piece-wise polynomial, e.g. the exponential terms in the Arrhenius like rate constant, polynomial lower and upper bounds can be introduced as

$$\begin{aligned} g_1^d(x^d,p^d,u^d) \leq & f^d(x^d,p^d,u^d) \leq g_2^d(x^d,p^d,u^d) \\ & \forall x^d \in \mathcal{X}^d,\ p^d \in \mathcal{P}^d,\ u^d \in \mathcal{U}^d, \end{aligned} \tag{5}$$

in which $\mathcal{X}^d$ is the set in state space of interest. Using these bounds it can be shown that

$$\begin{aligned} \mathcal{X}_s^{d,*} \subseteq \{\, & x^d \in \mathbb{R}^{n_x^d} | \exists\, p^d \in \mathcal{P}^d, u^d \in \mathcal{U}^d, c \in [0,1] : \\ & c g_1^d(x^d,p^d,u^d) + (1-c) g_2^d(x^d,p^d,u^d) = 0 \} . \end{aligned} \tag{6}$$

Hence, the steady-state constraint $f^d(x^d,p^d,u^d) = 0$ can be substituted by the polynomial constraint

$$c g_1^d(x^d,p^d,u^d) + (1-c) g_2^d(x^d,p^d,u^d) = 0, \quad c \in [0,1], \tag{7}$$

where c has to be appended to p^d. This step corresponds to a constraint relaxation and $||f^d(x^d,p^d,u^d) - g_i^d(x^d,p^d,u^d)|| \ll 1$ should be enforced to keep the difference between $\mathcal{X}_s^{d,*}$ and the set of solutions of the relaxed problem small.

Combinations of the methods, e.g. rational, polynomial and nonlinear functions are possible, see Section 6.

4. BOUNDING STEADY STATES

In this section a method to compute an outer approximation of the state space region containing all steady-states is derived. For this purpose we define the feasibility problem,

$$(P): \begin{cases} \text{find} & d \in \mathcal{D},\ x^d \in \mathbb{R}^{n_x^d}, p^d \in \mathbb{R}^{n_p^d}, u^d \in \mathbb{R}^{n_u^d} \\ \text{subject to} & f^d(x^d,p^d,u^d) = 0 \\ & x^d \in \mathcal{X}^d,\ p^d \in \mathcal{P}^d,\ u^d \in \mathcal{U}^d, \end{cases}$$

which is in the following used for the classification of $\mathcal{X}^d$. If (P) is infeasible, $\mathcal{X}^d$ cannot contain any equilibrium points. (P) is called a mixed integer nonlinear program. Unfortunately, the feasibility problem (P) is in general non-convex and NP-hard.

Kuepfer et al. (2007) proposed a framework for relaxing a polynomial non-convex feasibility problem to a semidefinite program (SDP). Due to inherent convexity of SDPs, these problems can be solved computationally efficient, e.g. via primal-dual interior point methods. In the following, we present an approach which is based on the work of Kuepfer et al. (2007) and has been used for analysis of the set of feasible steady states in the case of biochemical reaction networks in Waldherr et al. (2008).

For the relaxation of (P) to a SDP, the original feasibility problem is at first rewritten as a quadratic feasibility problem (QP), for each d. Therefore, the vectors $\xi^d \in \mathbb{R}^{n_\xi^d}$ are introduced, which consists of the monomials of the model equation (1), i.e.

$$\xi^d = (1,\ x_i^d,\ p_j^d,\ u_k^d,\ x_i^d p_j^d,\ x_i^d u_k^d,\ p_i^d u_k^d, \ldots)^T \tag{8}$$

for all $i \in N_x^d$, $j \in N_p^d$, and $k \in N_u^d$. Using this monome vectors ξ^d, the equality constraints $f^d(x^d,p^d,u^d) = 0$ can be transformed to

$$0 = f_i^d(x^d,p^d,u^d) = \xi^{dT} Q_i^d \xi^d, \quad i \in N_x^d, \tag{9}$$

in which $Q_i \in \mathcal{S}^{n_\xi}$. Note that for higher order terms, additional constraints have to be introduced. For instance if ξ^d contains the second order term $x_1^d p_1^d$, the constraint $x_1^d p_1^d = x_1^d \cdot p_1^d$ must be introduced to express the dependency of the higer order monomial on the first order monomials. This leads to additional constraints of the form,

$$\xi^{dT} Q_i^d \xi^d = 0, \quad i \in N_c^d, \tag{10}$$

in which $Q_i \in \mathcal{S}^{n_\xi}$, $N_c^d = \{n_x^d + 1, \ldots, n_x^d + n_c^d\}$, and n_c^d is the number of dependencies. To simplify the notation we set $N_{xc}^d = N_x^d \cup N_c^d$.

To further simplify the notation we restrict $\mathcal{X}^d$, $\mathcal{P}^d$, and $\mathcal{U}^d$ to be generated by the intersection of half-spaces, e.g. $\mathcal{X}^d$, $\mathcal{P}^d$, and $\mathcal{U}^d$ can be convex polytopes. In this case, $x^d \in \mathcal{X}^d$, $p^d \in \mathcal{P}^d$, and $u^d \in \mathcal{U}^d$ can be written as

$$B^d \xi^d \geq 0, \tag{11}$$

in which $B^d \in \mathbb{R}^{n_b^d \times n_\xi^d}$, and n_b^d is the sum of constraints on x^d, p^d, and u^d.

The original feasibility problem (P) can then be restated as

$$(QP): \begin{cases} \text{find} & \xi^d \in \mathbb{R}^{n_\xi^d},\ d \in \mathcal{D} \\ \text{subject to} & \xi^{dT} Q_i^d \xi^d = 0,\ i \in N_{xc}^d \\ & B^d \xi^d \geq 0 \\ & \xi_1^d = 1. \end{cases}$$

Using the ideas suggested by Parrilo (2003), the (QP) is subsequently relaxed to a SDP, for each d, by introducing the matrices $X^d = \xi^d \xi^{dT}$ and dropping the appearing non-convex constraint $\text{rank}(X^d) = 1$. This leads to the relaxed feasibility problem

$$(RP): \begin{cases} \text{find} & X^d \in \mathcal{S}^{n_\xi^d},\ d \in \mathcal{D} \\ \text{subject to} & \operatorname{tr}(Q_i^d X^d) = 0,\ i \in N_{xc}^d \\ & B^d X^d e_1^d \geq 0 \\ & B^d X^d B^{dT} \geq 0 \\ & \operatorname{tr}(e_1^d e_1^{dT} X^d) = 1 \\ & X^d \succeq 0, \end{cases}$$

in which $e_1^d = (1, 0, \ldots, 0)^T \in \mathbb{R}^{n_\xi^d}$. Note that the relaxation may induce additional solutions. To reduce conservatism, the redundant constraint $B^d X B^{dT} \geq 0$ is added, which is fulfilled by every solution of the problem (QP) (Kuepfer et al., 2007).

From (RP) one can derive the Lagrange dual problem (DP_d) for each d,

$$(DP_d): \begin{cases} \text{maximize} & \nu_1^d \\ \text{subject to} & e_1^d \lambda_1^{dT} B^d + B^{dT} \lambda_1^d e_1^{dT} + B^{dT} \lambda_2^d B^d \\ & \quad + \lambda_3^d + \nu_1^d e_1^d e_1^{dT} + \sum_{i \in N_{xc}^d} \nu_{2,i}^d Q_i^d = 0 \\ & \lambda_1^d \geq 0,\ \lambda_2^d \geq 0,\ \lambda_3^d \succeq 0, \end{cases}$$

in which the Lagrange multipliers are $\lambda_1^d \in \mathbb{R}^{n_b^d}$, $\lambda_2^d \in \mathcal{S}^{n_b^d}$, $\lambda_3^d \in \mathcal{S}^{n_\xi^d}$, $\nu_1^d \in \mathbb{R}$ and $\nu_2^d \in \mathbb{R}^{n_x^d + n_c^d}$ (Waldherr et al., 2008). Using the dual problem, one can obtain an infeasibility certificate for the original problem.

Lemma 2. Let $\nu_1^{d,*}$ be the optimal cost of (DP_d). If

$$\inf \left\{ \nu_1^{d,*} \mid d \in \mathcal{D} \right\} = \infty, \tag{12}$$

then the original feasibility problem (P) is infeasible.

This follows directly from weak duality. Only if the Lagrange dual problem is unbounded from above for all $d \in \mathcal{D}$ the infeasibility of (P) can be guaranteed. The advantage of the formulation using the Lagrange duals is that all subproblems are convex and can be solved efficiently.

In case that $\operatorname{card}(\mathcal{D}) \gg 1$, checking all the distinct combinations of decision variables can become very costly. One possibility to reduce the problem size is to divide $\mathcal{D}$ into subsets $\mathcal{D}_i$. The subsets $\mathcal{D}_i$ can be merged to a common node and the analysis can be performed for all subsets instead of for all nodes. This approach can also be combined with a hierachical refinement of the subsets $\mathcal{D}_i$, which reduces the computational demand significantly.

5. ALGORITHM

Using the Lagrange dual problem (DP_d), certificates for the infeasibility of (4) can be computed. This allows to exploit (DP_d) to determine an outer approximation $\mathcal{X}_s$ of $\mathcal{X}_s^*$. In this work, this is done via simple a multi-dimensional bisection algorithm (Jaulin et al., 2001). Compared to the work by Waldherr et al. (2008) this allows a better approximation of $\mathcal{X}_s^*$ but is computationally more demanding. The basic implementation can be summarized as follows:

Algorithm: $\mathcal{X}_s = \text{Approximation-}\mathcal{X}_s^*(\mathcal{X}, \mathcal{P}, \mathcal{D})$

1. If volume$(\mathcal{X}) < \epsilon$, return $\mathcal{X}_s = \mathcal{X}$
2. Check feasibility of $DP_d(\mathcal{X}, \mathcal{P}, \mathcal{D})$, $\forall d \in \mathcal{D}$
3. If $\inf \left\{ \nu_1^{d,*} \mid d \in \mathcal{D} \right\} = \infty$, return $\mathcal{X}_s = \emptyset$
4. If $\inf \left\{ \nu_1^{d,*} \mid d \in \mathcal{D} \right\} \neq \infty$:

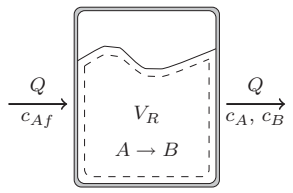

Fig. 2. Schematic of the considered simple CSTR.

4.1. Bisection of $\mathcal{X}$ in $\mathcal{X}_1$ and $\mathcal{X}_2$
4.2. $\mathcal{X}_{1,s} = \text{Approximation-}\mathcal{X}_s^*(\mathcal{X}_1, \mathcal{P}, \mathcal{D})$
4.3. $\mathcal{X}_{2,s} = \text{Approximation-}\mathcal{X}_s^*(\mathcal{X}_2, \mathcal{P}, \mathcal{D})$
4.4. Return $\mathcal{X}_s = \mathcal{X}_{1,s} \cup \mathcal{X}_{2,s}$

Remark 3. Note that for the application of this algorithm an initial set $\mathcal{X}_0$ must be chosen. If we want to guarantee that an outer approximation of $\mathcal{X}_s^*$ is found containing all feasible equilibrium points, $\mathcal{X}_s^* \subseteq \mathcal{X}_0$ must hold. This is not a restriction because a suitable $\mathcal{X}_0$ can often easily be determined from physical insight into the problem.

6. BOUNDING THE STEADY STATES OF A CSTR

In order to illustrate the proposed scheme the steady-state behavior of a CSTR is analyzed. The reactor considered is a simple tank filled with fluid stirred by an impeller, an inflow and an outflow, as depicted in Figure 2.

6.1 System description

Specifically we consider an adiabatic, constant volume CSTR in which the first-order, exothermal liquid-phase reaction

$$A \xrightarrow{k} B$$

takes place. The conversion rate is given by $R = k(T)c_A$, in which the reaction rate constant is modelled using Arrhenius' equation,

$$k(T) = k_\infty e^{-\frac{E}{RT}}. \tag{13}$$

Simple mass and energy balances lead to the following set of ordinary differential equations:

$$\begin{aligned} \frac{dc_A}{dt} &= \frac{1}{\theta}(c_{Af} - c_A) + k(T)c_A \\ \frac{dT}{dt} &= \frac{1}{\theta}(T_f - T) - \frac{\Delta H_R}{C_p \rho} k(T) c_A, \end{aligned} \tag{14}$$

which captures the dynamics of the CSTR (Rawlings and Ekerdt, 2002). The state variables are the concentration c_A of reactant A, and the reactor temperature T. The parameters are the mean residence time $\theta = V_R/Q$, the reactor volume V_R, the flowrate Q, the concentration of A in the feed stream c_{Af}, the feed stream temperature T_f, the reaction enthalpy ΔH_R, the heat capacity of the fluid C_p, and the fluid density ρ. The numerical values of the nominal parameters are provided in Table 1.

6.2 Analysis of the nominal CSTR

In case that all parameters are known, one can exactly predict how the reactor behaves in different operating conditions. Hereby, since the mean residence time θ is the easiest parameter to manipulate, the operating condition will be defined in terms of θ. The other parameters are assumed to be fixed.

Table 1. Parameter values.

Parameter	Value	Units	Uncertainty
T_f	298	K	3K
C_p	4.0	KJ/kg K	5%
c_{Af}	2.0	kmol/m^3	5%
k_∞	5.0×10^8	min^{-1}	5%
E/R	8.0×10^3	K	–
ρ	10^3	kg/m^3	–
ΔH_R	-3.0×10^5	kJ/kmol	5%

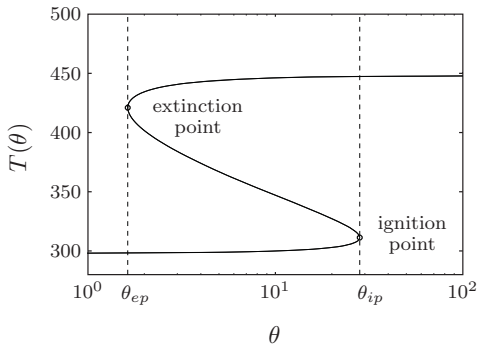

Fig. 3. Bifurcation diagram of CSTR without parameter uncertainties.

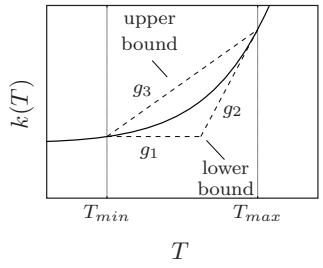

Fig. 4. Bounding of $(-)$ Arrenhius term with $(--)$ linear functions.

Using continuation methods it is possible to numerically compute the steady-state curve (bifuraction diagramm) for varying residence times (Dhooge et al., 2003), as shown in Figure 3. θ_{ep} and θ_{ip} denote the mean residence time at the extinction and the ignition point respectively.

6.3 Analysis of CSTR with parameter uncertainties

If one or more parameters are uncertain, which is in practice always the case, calculating the set of steady-state is significantly more challenging. Typically, sampling based techniques such as Monte-Carlo like methods are used. These allow the approximation of the union of all feasible equilibrium points $\mathcal{X}_s^*$. However, as for all Monte-Carlo like methods no bounds for the obtained sets can be provided. Our approach overcomes this problem and enables us to compute an outer approximation of the set of feasible equilibrium points of the uncertain system.

Approximation of the rate constant: Applying the proposed method requires in a first step to bound the Arrhenius-like rate constant from below and from above using polynomial functions. In this paper $k(T)$ is bounded via three linear functions,

$$\max(g_1, g_2) \leq k \leq g_3, \quad \forall T \in [T_{min}, T_{max}], \tag{15}$$

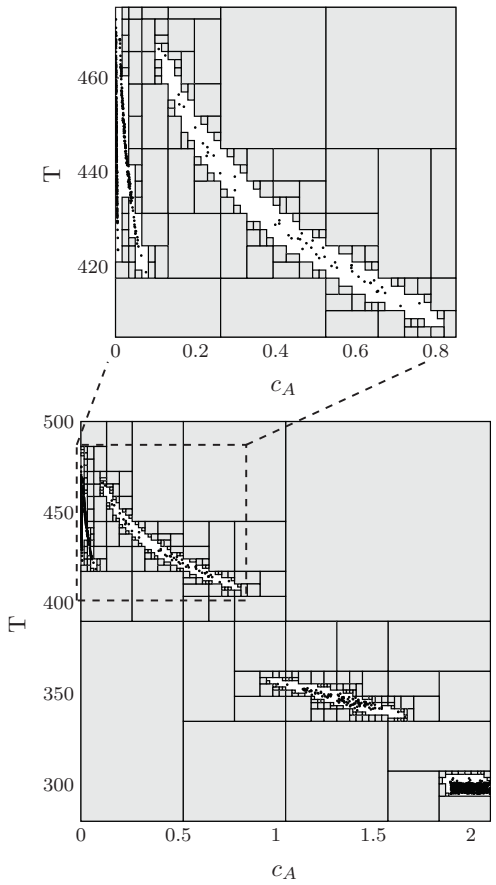

Fig. 5. Region in state space which cannot contain steady-states for given parameter uncertainties and $\theta \in \{1, 10, 100\}$ versus $(\cdot)$ steady-states computed using Monte-Carlo sampling.

as depicted in Figure 4. This approach is very simple and has the disadvantage that the approximation of $k(T)$ is less precise if the difference of T_{min} and T_{max} becomes large. Therefore, we don't use a static approximation but rather select g_1, g_2 and g_3 in each interation of the bisection algorithm dependent on the box $\mathcal{X}$ in state space currently under consideration. This allows to keep the overestimation of the set of feasible steady-states small as will be seen later.

One could of course choose other methods to bound $k(T)$, for instance based on high order polynomials and the Taylor series expansion, but in many cases the computational effort to solve the semidefinite program once will increase significantly and the presented simplistic approach will be more efficient.

Set of feasible steady-states: The above derived theory and the bounding of $k(T)$ allow to compute the set of feasible steady-states of the CSTR. As decision variable we consider besides the temperature interval also the mean residence time θ. Additionally, most parameters are uncertain. The amounts of uncertainty with respect to the nominal values are provided in Table 1.

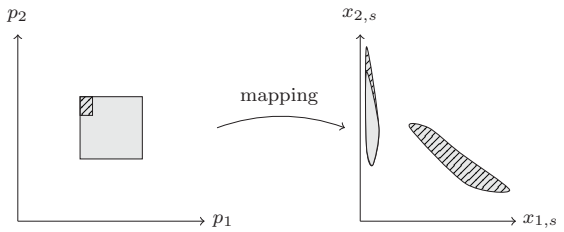

Fig. 6. Illustration of the nonlinear mapping from parameter to steady-states.

The algorithm outlined in Section 5 is in the following used to estimate the set of all feasible equilibrium points of (14) for the given parameter uncertainties and $\theta \in \{1, 10, 100\}$. The results are shown in Figure 5, where the part of the state space which is certified infeasible is marked light gray. To compare our results with classical approaches, five thousand equally distributed Monte-Carlo samples for the accessible parameter set were taken and the steady-states were determined.

Computation of the set of feasible steady-states: As one can see, the results match with each other. However, a closer look at the results reveals several disadvantages of the sampling based approach. First of all, the number of samples in some regions of the state space is small compared to other regions, where the sampling density is extremely high. This indicates that many parameters lead to steady-states in the region with high sampling density, but there are still some regions that cannot be explored unless even higher numbers of samples are used. This might represent a problem, whenever the set of all feasible steady-states has to be computed, since normally a homogeneous sampling rate is more desireable. However, the Monte-Carlo method is not able to guarantee under such a condition that the whole state space is explored, due to the highly nonlinear mapping between parameters and steady-states, illustrated in Figure 6. Therefore, the set of feasible equilibrium points is always underestimated, even for exhaustive Monte-Carlo sampling, while the proposed method guarantees that all equilibrium points are contained in the determined set.

7. CONCLUSION

In this work we studied the problem of outer bounding the region in state space containing all equilibrium points of uncertain hybrid differential algebraic systems. The proposed method is based on the formulation as a feasibility problem and a relaxation to a SDP. It is shown that guaranteed outer bounds of the feasible set of equilibrium points can be determined.

The advantage of the proposed methodology in comparison to Monte-Carlo based approaches is explained and shown considering a simple CSTR process. In particular, the developed method does not rely on sampling and can deal with strongly nonlinear and non-unique mappings from parameters to steady-states.

The computed set is guaranteed to contain all feasible steady-states, thus worst case scenarios can be analyzed. This is of certain interest to evaluate controller performance in fault situations.

Extremely Fast Catalyst Temperature Pulsing: Design of a Prototype Reactor

Jasper Stolte * **Ton Backx** * **Okko Bosgra** *

* *Eindhoven University of Technology, PO Box 513, 5600 MB Eindhoven, the Netherlands (e-mail: j.stolte@tue.nl).*

Abstract: This paper discusses a novel principle of advanced process control strategy: the extremely fast and local pulsing of temperature. This strategy leads to some interesting potential applications, but there are no devices implementing it available yet. One such device currently under construction by the authors is introduced in this paper. It operates by converting electrical energy into heat by forcing a very high current through a very thin resistive element, which also acts as the catalyst for heterogeneous reactions. A design procedure for the key parameters is developed and a simulation of heat distribution in the design under construction is presented. The simulation shows that it should be possible to get local temperature peaks of 500 K which exist for only about 20 μs.

Keywords: Process Control, Pulses, Heterogeneous Catalysis, Temperature Forcing, Periodic Control, Non-Steady State.

1. INTRODUCTION

For various reasons, chemical reaction engineers prefer to operate reactions in steady state. In modeling and design of chemical processes, reactors are almost always assumed to be ideally mixed. Control of such processes boils down to maintaining constant reaction conditions as best as possible. However, chemical reaction systems can be seen as systems of highly nonlinear partial differential equations, which are typically full of transient dynamics. If we know that these dynamics can be present, is it not possible to find cases where the dynamics can be exploited?

Attempting to exploit the dynamics demonstrated by chemical processes is not new. Horn and Lin (1967) already introduces periodic reactor operation, and it is shown there that there are reaction complexes for which periodic operation is fundamentally better than any steady state operation. This idea was picked up by researchers all over the world, and in the following decades there have been numerous studies showing there exist reaction complexes for which non steady state operation gives fundamental advantages, see Bailey (1973); Matsubara et al. (1973); Silveston et al. (1995); Silveston and Hudgins (2004) for excellent reviews of this research field.

Although there are plenty examples of academic (often theoretic) research, there are few known examples of practical applications in industry. One promising direction of research which has already shown significant improvements in a number of studies is microwave assisted chemistry, sometimes called microwave enhanced chemistry Wan et al. (1990); Wan (1993); Will et al. (2004). When some parts of a reactor subjected to microwave irradiation are more susceptible than others, they will heat up more and create gradients in temperature. Wan (1993) specifically considers heating the catalyst particles directly. Microwave assisted catalysis is not very accessible to most scientists, as powerful microwave equipment is expensive, it is difficult to model due to inhomogeneities, and measurements are difficult also. Still, microwave heating has shown to allow modes of operation that are impossible using steady state operation.

Silveston and Hudgins (2004) state that the field of temperature forcing is relatively underdeveloped compared to the periodic feed forcing, even though the reaction complexes show more strong non-linear behavior as a function of temperature. The reason given is that due to the large time constants and energy flows involved it is difficult to apply temperature forcing to large amounts of matter. That paper also indicates that the advance of micro-reactors may change allow for better heat transfer paving the way for new studies in the forced temperature direction.

The authors of this paper have started a project on dynamic operation of heterogeneous catalysis. A first theoretical result showed that very fast and local pulsing of temperature may in some cases fundamentally improve attainable results, see Stolte et al. (2008). Also, Wan et al. (1990) state that the fastest and most intense pulses of microwave energy shows the most interesting results for the important methane coupling reaction complex. Work has started on a setup that will create very fast and intense temperature pulses, of several hundred degrees Kelvin in tens of microseconds. To our knowledge this is orders of magnitudes faster than any setups reported in literature have realized.

This paper considers the considerations in designing a setup for heterogeneous catalysis capable of such temperature pulses, delivered directly at the catalyst. Section 2 describes the general reactor setup, as well as a design procedure to decide upon the critical design parameters. Section 3 considers a simulation of the heat distribution

within the reactor, which suggests that heating and cooling within such short timescales is possible. Section 4 discusses a few potential pitfalls that may be encountered when designing such a reactor.

2. REACTOR CONCEPT

The goal of this setup is to create a reactor which is capable of operating heterogeneous catalysis reactions where the catalyst is turned into an actuator which creates very fast and large pulses in temperature. Pulse shaped temperature profiles indicate that very fast heating as well as very fast cooling are required. A very schematic 2D-view of the reactor under construction is given in figure 1.

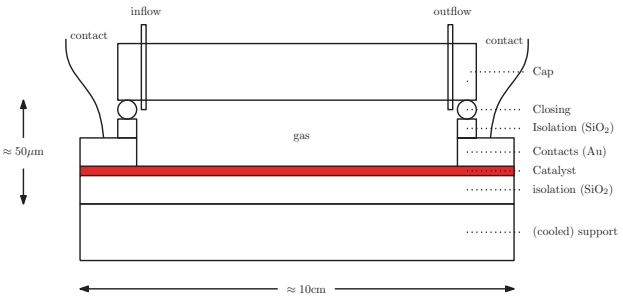

Fig. 1. Schematic view of the prototype reactor concept (not to scale). A channel is created where gas can flow through, with a floor consisting of a thin catalyst layer which is heated.

The concept is based upon a micro-flow-channel reactor, but it has a 'floor' consisting of a thin layer of catalyst through which an electrical current can be driven. Contacts are mounted at the sides to connect a source of electrical energy. For this general heterogeneous catalysis setup the catalyst is chosen to be platinum, which has excellent conductive properties. The reactor heating is supplied by the electrical source, but the cooling cannot be done actively. The heat simply has to flow to cooler areas to cool down the catalyst layer. The bulk of the energy in the catalytic layer will be conducted through the SiO_2 layer to the the cooled support which consists of pure silicon. To get a nice pulse like temperature profile it is desired to have the time constant for cooling approximately equal to the time constant for heating. If it is too small, the energy will flow away already while the pulse is still being applied, and if it is too large it will simply take a long time to cool down. The thickness of especially the catalyst layer and the SiO_2 layer supporting it are critical degrees of freedom to shape the time constant for cooling.

Reasons to choose for this design are:

- Energy is by definition directly added to the catalyst
- Fast creation of electrical currents is a well developed field
- Platinum resistance dependends on temperature almost linearly. By measuring voltage over and current through the catalyst layer an indication for its temperature can be found.
- By electrochemical deposition very thin layers of other catalyst can be deposited on the platinum, giving flexibility in using different catalysts.
- There are no fundamental reasons preventing this design from being scaled up for application in industry.

2.1 Basics of Electrical Heating

This subsection will summarize the basics of electrical heating as needed for this application. When voltage and current are used to heat a layer of resistive material and no heat is lost to the environment, all electrical energy is directly converted into temperature and the following relation holds:

$$\frac{dT}{dt} = \frac{P}{\rho c_p V} \tag{1}$$

where T is temperature [K], P is electrical power [W], ρ is material density [kg/m^3], c_p is specific heat [J/kg K] and V is volume [m^3]. Since the layer is rectangular in shape it can be described by a certain length l [m], height h [m] and width w [m], which together make up the layer volume as given in (2). Also there are the basic electrical relations for power and resistance given in (3) and (4):

$$V = lhw \tag{2}$$

$$P = \frac{U^2}{R} \tag{3}$$

$$R = \frac{l}{\sigma wh} \tag{4}$$

where R is the electrical resistance [Ω] and σ is the electrical conductivity [S/m]. Combining all the equations above, the following relation is found for the temperature gradient due to electrical heating:

$$\frac{dT}{dt} = \frac{\sigma}{\rho c_p}\frac{U^2}{l^2} \tag{5}$$

The relation as stated in (5) is used in the simulation of section 3. It can be seen from (5) that the heating is dependent on some material parameters, and on the applied voltage squared per unit length squared. This means that if a higher temperature gradient is desired for a given setup the voltage should be increased, or the length should be decreased.

The limiting factor is the electrical current. The voltage in the formulas above can only exist if the corresponding current runs through the material. The electrical current I [A] for a voltage applied to a layer of material is given by Ohms law:

$$I = \frac{U}{R} \tag{6}$$

From this relation it is evident that by increasing the voltage, the current increases also. Furthermore making the length smaller decreases the resistance according to (4) and therefore will also increase the current. Although there is no fundamental limit to the current, there is a practical limit in how quickly a large current can be created and switched.

2.2 Resonant Circuit for Energy Transfer

To create short bursts of energy, a resonant circuit is used. The basic resonant circuit is shown in figure 2, where R represents the resistance of the catalyst layer. This layer is connected to two external components, a capacitor C and an inductance L. The capacitor is charged to a certain

voltage separately, and then connected to the other two components resulting in the circuit of figure 2. Due to the charge in the capacitor, current will flow and through the inductance and the resistance dissipating energy which is released as heat.

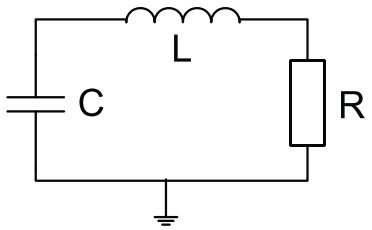

Fig. 2. Basic resonant circuit consisting of a capacitance, an inductance and a resistance. The resistance represents the catalytic layer.

From linear circuit theory, the circuit of figure 2 is governed by (7):

$$U_R = \frac{sRC}{s^2LC + sRC + 1} U_{C0} \tag{7}$$

where U_R is the voltage over the catalytic layer [V], U_{C0} is the initial voltage over the capacitor [V] and s is the Laplace operator. This equation shows second order dynamics in the numerator, which can be associated with a natural frequency ω_0 [rad/s] and a quality factor Q [-] as given in (8).

$$s^2/\omega_0^2 + s/\omega_0 Q + 1 = s^2LC + sRC + 1 \tag{8}$$

The natural frequency gives the frequency of the oscillation in the circuit, and the quality factor roughly indicates how many periods can be seen before the oscillation is gone and all the energy from the capacitor is dissipated in the resistance. From (8) the natural frequency and quality factor for a given circuit can be calculated:

$$\omega_0 = \frac{1}{\sqrt{LC}} \tag{9}$$

$$Q = \frac{1}{R}\sqrt{\frac{L}{C}} \tag{10}$$

In this application it is desired to release the energy stored in the capacitor as quickly as possible in the catalyst layer. A quality factor of 0.5 together with a high natural frequency is considered optimal.

2.3 Design Strategy

The question of how to choose values for R,L,C etcetera is an important one. This subsection proposes a strategy for consistent selection of most of the free parameters. The simulation introduced in section 3 is needed to verify the time constant for cooling and verifying validity of the thickness of the catalyst layer. The following design strategy is proposed:

(1) Fix resistance R and its dimensions: The value for the resistance should be the dominant resistance in the circuit. Wires and connections can easily account for up to 1 Ω, and the catalyst layer should have significantly more resistance. A value of 100 Ω is chosen. For this laboratory setup it is desired that the amount of energy needed to create a significant heat pulse is not too large, so volume should be kept small. At the same time it is desired that the width and length of the layer are much larger than the height, such that the energy loss to the sides can be neglected. Also the sizes should be chosen such that the device can be created using integrated circuit techniques. The layer should be very thin, a value of 100 nm is chosen for the height h. To make the resistance approximately 100 Ω, we choose w to be 0.5 mm and l to be 5 cm.

(2) The next step is to determine the pulse amplitude. Since we want to significantly influence kinetics for a very short time, the temperature pulse should be large. A value of 1000 K is chosen. Since the dimensions are already specified, the amount of energy needed to make the platinum layer temperature rise by this amount can easily be calculated. For the selected dimensions, this energy is 7.1 mJ. This value holds under the assumption that no energy is lost during the application of the pulse, which in practice will be the case. In the next section it is shown that for this design the simulation predicts an actual rise of 500 K which the authors find satisfactory.

(3) Determine the maximum available voltage. The voltage is limited mostly by the switching devices needed to open and close the current loop. In this design a MOSFET type device will be used for switching. Even high voltage MOSFETs can typically not deal with voltages greater than 1000 V. This will be the voltage used. For higher voltages spark gap switches can be applied if necessary. The voltage determines the size of the capacitance C needed by the basic relation of (11).

$$E = \frac{1}{2} C U_{C0}^2 \tag{11}$$

In this case the capacitance needed is 14 nF. Using this capacitance value, the corresponding inductance can be computed from (10) to get the proper quality factor for the resonance circuit. The natural frequency that corresponds to this network can be computed using (9), in this case it is 1.32 Mrad/s. That means the period length is approximately 4.75 μs, which is excellent for this application. If the natural frequency would have been too low, the applied voltage would have to be increased further.

Table 1. Design Parameters Chosen

Description	Parameter	Value	Unit
Resistance	R	106	[Ω]
Catalyst length	l	50	[mm]
Catalyst width	w	0.5	[mm]
Catalyst height	h	100	[nm]
Temperature rise	ΔT	1000 (500)	[K]
Pulse energy	E	7.1	[mJ]
Quality factor	Q	0.5	[−]
Capacitance	C	14	[nF]
Inductance	L	40	[μH]
Natural Frequency	ω_0	1.32	[Mrad/s]

Table 1 summarizes the choices made using this design procedure.

3. HEAT SIMULATION MODEL

The previous section introduced the design of a pulsed reactor, and in this section the heat distribution within that design is simulated. Since the design is developed in such a way that heat loss to the sides should be negligible in comparison to the heat loss to the support of the catalytic layer, only the vertical dimension is simulated. Figure 3 schematically shows the layers (not drawn to scale), with their respective sizes in one dimension which is named the x dimension.

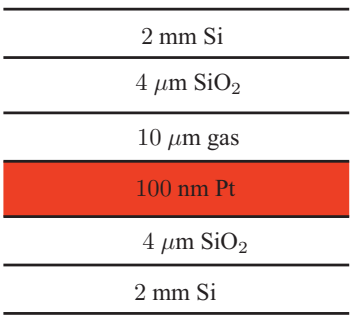

Fig. 3. Schematic view of the layers in the vertical dimension. In this dimension the heat distribution will be simulated. BC stands for boundary condition.

Heat distribution by conduction and diffusion in the model is simulated, as a lower limit to the cooling. The partial differential equation that is being solved is the standard heat diffusion equation given as (12), where κ is the local thermal conductivity [m^2/s].

$$\frac{dT}{dt} = \kappa(x)\frac{\partial^2 T}{\partial x^2} \tag{12}$$

Since this is a very straightforward geometry, the pseudo spectral method is used for collocation (Trefethen (2000); Weideman and Reddy (2000)) to get the benefit of spectral accuracy. Each of the layers is collocated separately, with energy preserving von Neumann boundary conditions at the layer boundaries. Only at the very top and bottom there are fixed temperatures (Dirichlet boundary conditions). Initially, all the layers have a temperature of 300 K. When heat enters the system in the catalytic layer, conduction will transport the heat through the other layers to the outer boundary where it is eventually lost to the surroundings.

After collocation, a system of ordinary differential equations which pose an initial value problem that is solved in Matlab using the built-in stiff ODE solvers.

3.1 Simulation Results

An RLC circuit is also simulated in parallel with the heating simulation. The RLC parameters are chosen identical to those find using the design procedure described in the previous section. The capacitor discharges via the inductance into the catalytic layer. The power that is released as heat into the catalytic layer is shown in figure 4. The peak power is about 5 kW which creates an enormous temperature gradient in the thin catalyst layer.

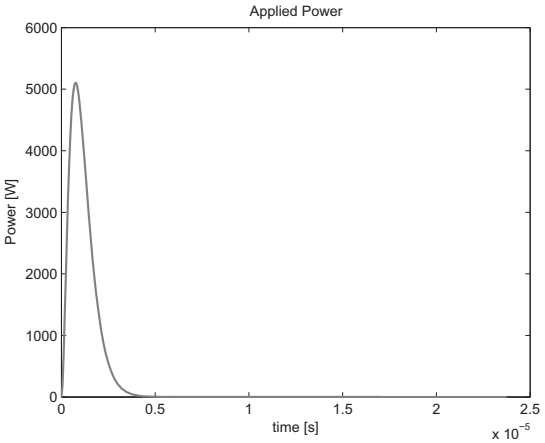

Fig. 4. Power supplied to the catalytic layer by the resonant circuit. The shape is very much like a pulse, with the peak power at about 5 kW.

This heat will result in a temperature rise of the catalytic layer, which will therefore have a temperature gradient with respect to the other layers. Transport of heat to the other layers will result. The temperature at the boundary between the catalytic layer and the gas layer is the surface temperature, which is critical for the catalytic reactions taking place. The simulated surface temperature resulting from the energy pulse is shown in figure 5. The surface temperature rises by about 500 K and not with the 1000 K for which this amount of energy (7.1 mJ) was computed in the previous section. This is due to the loss of energy to the other layers while the pulse is still in progress. About half the energy is lost to the other layers before the pulse is finished, so the heating and cooling time constants are approximately equal. If this is undesired, raising the voltage used in the design procedure will give a smaller capacitance and a faster resonance frequency. The applied energy pulse will then be shorter and higher. For the current laboratory application losing half of the 7.1 mJ is not a problem so the design is left as it is.

The heat will quickly spread into the gas layer and the SiO_2 (silica) layer supporting the catalyst. Figure 6 shows how the heat spreads through the silica supporting layer in time. The conduction within the metal layer that lies beneath the silica layer is so fast that, even though the Si layer is 2 mm thick, it does not allow for high internal temperature gradients. The whole Si layer remains at approximately 300 K and has a maximum at the boundary with the silica layer of only 301.5 K. The whole temperature gradient between the Si layer and the catalyst layer exists in the supporting silica layer, which very quickly builds up a linear temperature profile, due to the fact that the silica has a much lower thermal conductivity than the catalyst or Si layer.

The other side of the catalyst layer loses heat to the gas layer. Figure 7 shows the heat profile within the gas layer. The heat conductivity for gas is even lower than the one for the top silica layer and thus much lower than that of the metallic catalyst layer. Just like with the supporting silica layer at the bottom, the majority of the temperature gradient at the top side of the catalyst will be in the layer

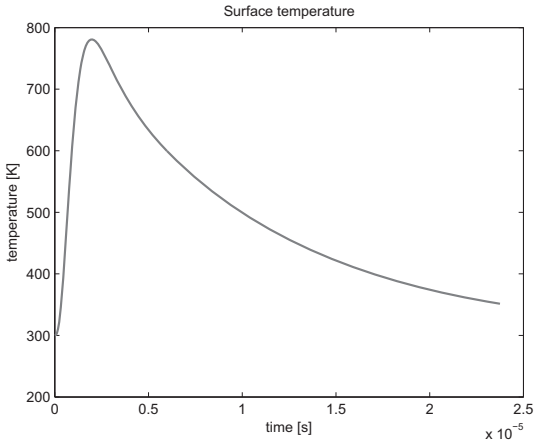

Fig. 5. Surface temperature when pulse is applied. The pulse causes the temperature to rise by about 500 K. The cooling time constant and the heating time constant are approximately equal for the parameters of table 1.

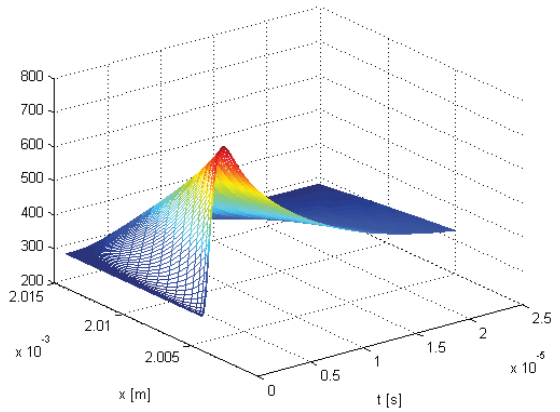

Fig. 7. The gas layer temperature profile over time. Like with the supporting SiO_2 layer a gradient leads to a linear profile, but the time taken for the linear profile to build up is longer.

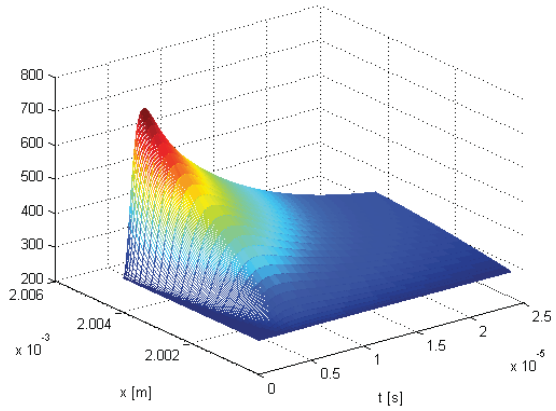

Fig. 6. Heat profile of the SiO_2 layer supporting the catalyst. A large temperature gradient over this layer quickly leads to a linear temperature profile.

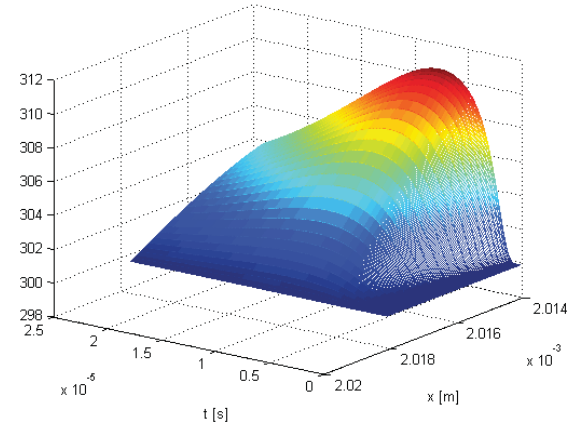

Fig. 8. Temperature profile within the top SiO_2 layer over time. The peak temperature is only about 10 K above the ambient temperature. Heat entering this layer from the gas layer is quickly transported to the top Si layer.

with the poorest heat conductivity which is the gas layer. Since the gas layer is thicker than the silica layer and even poorer in conducting heat, it takes a bit longer for the linear profile to build up. Due to the low conductivity of the gas, much less heat is lost to the gas than is lost through the supporting silica layer.

Figure 8 shows the top silica layer, which is heated through the gas layer. The maximum rise of temperature in the top silica layer is only 10 K even though the catalyst surface was heated by almost 500 K. The heat that ends up in the top silica layer is quickly lost to the top Si layer.

Just to confirm the results, the heat distribution within the platinum catalyst layer is shown in figure 9. From this figure it is clear that there exists almost no gradient within the catalyst layer, due to the superior heat conductivity of platinum.

The heating of the platinum layer is achieved through ohmic heating a resonant circuit with a high natural frequency and a low quality factor. By using higher voltages and adjusting the capacitance and inductance accordingly the heating can be made as fast as parasitic effects allow for. The cooling of the catalyst layer however cannot be forced, and the cooling time constant is created as an interplay between the different layers thicknesses and their values for thermal conductivity. By manipulating the thickness of the catalyst layer and the supporting silica layer the time constant for cooling can be shaped. A thickness of 100 nm for the catalyst layer and 4 µm for the supporting silica layer give a feasible time constant in this design.

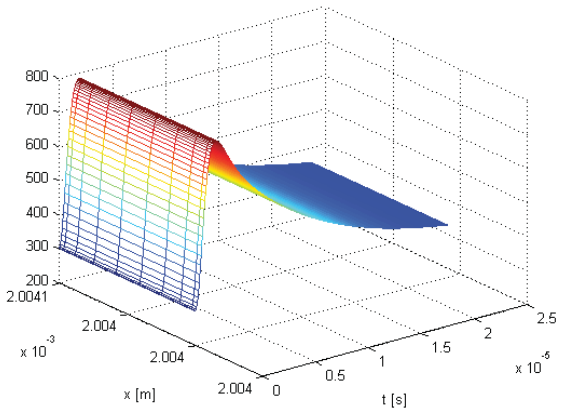

Fig. 9. The temperature profile within the catalytic layer. There exists almost no gradient within the catalyst layer, resulting in a flat profile.

4. POTENTIAL PITFALLS

Apart from the design variables already considered there are some miscellaneous design considerations that need to be included. This section mentions the most important ones.

4.1 Mechanical Strength

The heated metal layer will go up and down in temperature by hundreds of Kelvin. Metals normally expand when they become hot, and shrink when they cool down again. Unfortunately it is difficult to say whether this will physically break the layer or not. Since nobody ever tried this before there is no data on such high gradients in such thin supported metal layers. If mechanical strength is found to be a problem the pulses will need to be less intense.

4.2 Discharge Through SiO_2 Support

In the current design there is a 4 µm SiO_2 layer between the catalytic layer and the silicon support. The silicon support is electrically grounded for safety reasons. The catalytic layer is subjected to a high voltage. This voltage should not become so high that discharge occurs straight through the quartz layer because this will not only lead to pulse energy loss, but also break the device.

4.3 Electro Migration

When extremely high current densities are applied to any material, a phenomenon called electro migration will occur. The atoms of the metal start to physically move to one of the contacts, which in time will break the catalyst layer. To prevent this effect the current direction should be reversed between pulses.

4.4 Electromagnetic Interference

The high frequency currents are associated with a high frequency electromagnetic field. For any industrial application this field should be contained to such values that other electronic devices are not disturbed, and the radio spectrum is not polluted.

5. CONCLUSION

A new prototype reactor is presented to create extremely fast temperature pulses in heterogeneous catalysis. The authors intend to use this prototype to improve understanding of the effects of temperature pulsing on complex reaction schemes. The availability of such a reactor can help understanding the results of microwave enhanced catalysis as well. There appear to be no fundamental problems preventing a temperature pulse of 1000 K in less than 10^{-5} s, which is orders of magnitudes faster than what is known from literature.

Abstract: Experimental design is a fundamental problem in science and engineering. Traditional 'Design of Experiment' (DOE) approaches focus on minimization of variance. In this work, we propose a new "decision-oriented" DOE approach, which takes into account how the generated data, and subsequently the developed model, will be used in decision making. By doing so, the variance will be distributed in a manner such that its impact on the targeted decision making will be minimal. Our results show that the new decision-oriented experiment design approach significantly outperforms the standard D-optimal design approach. The new design method should be a valuable tool when experiments are conducted for the purpose of making R&D decisions.

Keywords: Decision making, optimal experiment design.

1. INTRODUCTION

Design of experiments (DOE) as a field has evolved over the period of last few decades. Its importance has grown significantly because of the increasing need to reduce the resource requirement for achieving the target. The targets historically perceived by the scientists in performing experiments have been driven towards understanding the underlying phenomenon or estimating the parameters. Consequently, the traditional DOE tools have been geared towards maximization of some measure of information or towards the minimization of the variance in the parameter estimates.

It is our opinion that this way of thinking over a long period of time has led the field to lose sight on the ultimate purpose of experiments in many applications. If one looks back into the history of the evolution of design of experiments one finds the answers in Bernardo (1979): "*Scientists typically does not have, nor can be normally expected to have, a clear idea of the utility of his results. An alternative is to design an experiment to maximize the expected information to be gained from it*". Bernardo (1979), further goes on proving that any *f* (function of the parameters, θ), in informational theoretical terms is '*garbling of θ*'. Hence follows the conclusion that maximization of information of θ is better than maximizing information on *f*.

This practice, while seeming logical, does not directly address the intended purpose of the experiments in many engineering applications. Today much of industrial research is driven by investment decisions, i.e., experiments are conducted with a specific objective in mind. For example, experiments can be conducted to aid decisions for the maximization of revenue function when investigating a new process or for the selection of a few processes among the large alternatives. In such scenarios, following the traditional route for design of experiments may be significantly suboptimal.

2. BACKGROUND

Traditionally there have been two major classes for the design of experiments (DOE) approaches: Classical approach and Bayesian approach. Historically, Classical DOE approaches like the factorial design have been more popular due to the computational complexities of the Bayesian approach. But recent developments in sampling techniques such as Markov Chain Monte Carlo (MCMC) (Kass (1998), Cowles (1996)) have rejuvenated the interest in the Bayesian approaches. In addition, the Bayesian approaches provide an added advantage of enabling the designer to incorporate the prior expert opinions. Hence, we will focus on the Bayesian approaches for design of experiments from here on.

To elaborate on the traditional Bayesian design strategies, we would follow Chaloner's (1995) approach, as it does justice to the inherent decision aspect hidden in the Bayesian approach. The idea of Bayesian DOE has evolved from information acquisition concepts in decision theory. Raiffa (1961) presented a decision theoretic approach for optimal information acquisition strategy using Expected Value of Information (EVOI) approach for investment decision problems. EVOI is defined as the expected difference between the expected posterior and prior utility, if one is to acquire information. Lindley (1956) introduced his seminal work on the use of Shannon information as a measure of information provided by an experiment. Following this, several authors (Stone (1959), DeGroot (1962) and Bernardo (1979)) presented a decision theoretic approach to experimental design, which was basically the maximization of EVOI with the utility function being replaced by Shannon information.

Consider a utility function (U), optimal decision (u) under posterior distribution, design matrix (η), parameters (θ) and observations (Y). Application of Lindley's EVOI maximization approach results in the maximization of expected pre-posterior utility as the expected value of the prior utility function is constant. The optimal expected pre-posterior utility is given in (1). Fig.1 demonstates how (1) can be solved numerically. Based on a given design (η) and the prior distribution of the parameters (θ_{prior}), potential observations (Y) are found via Monte Carlo simulation. For each of these potential realizations, posterior estimates (and covariances) for the parameters are obtained ($\theta_{Posterior}$) and corresponding to these posterior parameter estimates optimal decision variable (u) is estimated. Next step is to calculate the posterior expected utility(U) value corresponding to each of these potential realizations (Y). The average of the posterior utility values for each potential realization (Y) gives a utility of the design (η). The design that maximises this average utlity value is the optimal design.

$$U(\eta^*) = \max_{\eta} \int_{y} \max_{u} \int_{\Theta} U(\theta, \eta, Y, u) p(\theta \mid Y, \eta) p(Y \mid \eta) d\theta dY \quad (1)$$

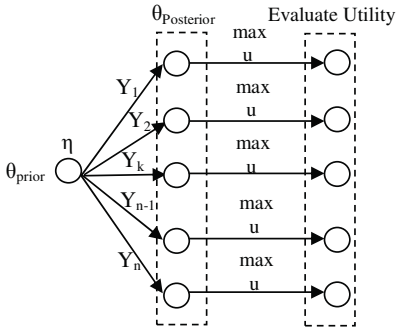

Fig. 1. Demonstrating the calculation of optimal design based on Lindley's EVOI concept.

Now, if one considers the Shannon information as the utility function, as suggested by Lindley, the above simplifies to (2). As both Fig. 2 and (2) show the calculations become much more tangible as the 'max' step drops out.

$$U(\eta^*) = \max_{\eta} \int_{y} \int_{\Theta} \log\{ p(\theta \mid Y, \eta) \} p(Y, \theta \mid \eta) d\theta dY \quad (2)$$

The rest of the Bayesian DOE methodologies, follow a similar line as (2) with some small changes to the utility function. In a broad sense, there exist three categories of Bayesian DOE approaches. First is the information maximization approach, which consists of maximizing the Kullback - Leibler distance between the prior and the posterior distribution. This approach consists of D-optimal and Ds-optimal designs. The second category is the set of designs, where the objective is to obtain a point estimate of the parameter values. This category consists of A-optimal and C-optimal designs. The third category is the minimax type of designs, where the objective is to minimize the maximum

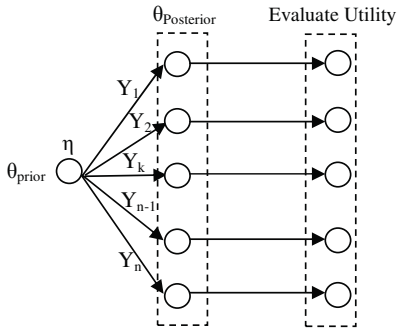

Fig. 2. Demonstrating the calculation of optimal design based on Shannon information criterion.

possible variance for all the linear combinations of the parameters under consideration. These various designs are further explained in details as follows:

D - Optimal: Maximize information gain for the parameters (Uses Kullback-Leibler distance between the prior and posterior distribution as a measure of gain in information).

Ds-optimality: Maximize gain in Shannon information of Ψ (= $S^T\theta$), where 'S' is a known constant vector.

A- Optimal: The objective of the experiment is to obtain a point estimate of the parameters. A design is chosen to maximize the following utility function:

$$U(\eta) = -\int \left(\theta - \hat{\theta}\right)^T A \left(\theta - \hat{\theta}\right) p(y, \theta \mid \eta) d\theta dy \quad (3)$$

Here 'A' is a symmetric nonnegative definite matrix. This design minimizes expected squared error of loss for estimating $C^T\theta$ or Minimizing square error of predicting at C, where C is not necessarily a fixed and a distribution is specified on it.

C- Optimal: Special case of A-optimality, where C is a constant.

E- Optimal: It is a minimax approach for variance. The maximum posterior variance of all possible normalized linear combinations of parameter estimates is minimized. An, E-optimal design minimizes:

$$\sup_{\|c\|=\omega} c^T \left(\eta^T \eta + R\right)^{-1} c = \omega^2 \lambda_{\max} \left[\left(\eta^T \eta + R\right)^{-1} \right] \quad (4)$$

G- Optimal: Closely related to E-optimal deign is G-optimal design, which minimizes $\sup_{x \in D} x^T \left(\eta^T \eta + R\right)^{-1} x$. An equivalence theorem [see Atkinson (1992)] states that continuous G-optimal designs are numerically identical to a corresponding continuous D-optimal design.

It is important to note that, among the above mentioned designs, D-, Ds- A- and C-optimal design have a utility function, which justifies its decision theoretic sense. On the other hand, E- and G-optimal designs though are considered

Bayesian design don't have any decision-theoretic sense, Chaloner (1995).

The rest of the document is structured as follows: Section 3 discusses in more detail the setup for the decision oriented design, section 4 presents the numerical results, and section 5 concludes the paper.

3. SELECTION/REJECTION DESIGN

As elaborated in the previous section the traditional design criterions either try to maximize the information gain or minimize the variance. Consider the case when the objective of the experimentation is to select/reject processes from a large set of potential processes. In this scenario traditional overall variance reduction design techniques may not be the optimal solution. For example, assume that the selection criterion is based on a cut-off value of operating profit margins, say \$10M/yr and processes that have operating profit margins equal or above the cut-off are worth pursuing. The question at this juncture may be: Should one be more focused towards reducing the overall parameter uncertainty or towards designing experiment strategies that directly target this objective?

In order to design experiments focused on this target, we propose to design experiments that maximize the expected operating profit margin. The premise here is that the designs that try to obtain the maximum operating profit margins would inherently be able to obtain values closer to the true optimal operating profit margin values. In order to obtain such a DOE we substitute the operating profit margin function in place of the utility function 'U' in (1).

3.1 Problem Formulation

Assume an initial model structure and prior estimates for the process models are available from the prior experimental results. The decision-maker wants to perform more experiments to select the few processes with the most potential.

Assume the yield (Y_1) of the process has a linear model, $Y_1 = \tilde{X}^T\tilde{\theta}_1 + \varepsilon$, where $\tilde{X}$ is the vector of the operating conditions to be optimized and ε is the Gaussian noise, $N(0,\sigma)$ with known variance(σ^2). We assume that the quality of the product also varies linearly, $Y_2 = \tilde{X}^T\tilde{\theta}_2 + \varepsilon$, with the operating conditions and the target quality is μ. We consider the operating profit margin function (*f*) in Eq. (5), which depends linearly on the yield value, has a quadratic penalty for the quality deviation, and a quadratic penalty (Q) for higher operating conditions.

$$f = \alpha * Y_1 - \beta * (Y_2 - \mu)^2 - \frac{1}{2}\tilde{X}^T * Q * \tilde{X} \qquad (5)$$

To obtain a DOE which maximizes the operating profit margins, we substitute *f*, operating profit margin function in place of the utility 'U' in (1) and follow the algorithm as explained in Fig.1 and section 2.

To evaluate the new design criterion, we consider $\tilde{X} = [x_1, x_2]^T$ to be a two dimensional vector and hence both the prior parameter estimates $\tilde{\theta}_1 = [\theta_{1,1}, \theta_{1,2}]^T$ & $\tilde{\theta}_2 = [\theta_{2,1}, \theta_{2,2}]^T$ are also two dimensional vectors. We consider the range of the operating conditions to be in the range of [1e-5, 10]. We consider the prior estimates of the parameters (θ_1 and θ_2) to be normal distributions with mean $\bar{\theta}_1 = [\bar{\theta}_{1,1}, \bar{\theta}_{1,2}]^T$, $\bar{\theta}_2 = [\bar{\theta}_{2,1}, \bar{\theta}_{2,2}]^T$ and covariance matrices $\Sigma_{\theta 1}$ and $\Sigma_{\theta 2}$ respectively.

In order to statistically evaluate the performance of our DOE approach against the traditional D-optimal DOE approach, we consider the following distributions for the parameter values:

$$\bar{\theta}_{1,1} \sim U[-100, 100] \qquad (6)$$

$$\bar{\theta}_{1,2} \sim U[\max(-100, -\bar{\theta}_{1,1}), 100] \qquad (7)$$

$$\bar{\theta}_{2,1} \sim U[-100, 100] \qquad (8)$$

$$\bar{\theta}_{2,2} \sim U[\max(-100, -\bar{\theta}_{2,1}), 100] \qquad (9)$$

$$\Sigma_{\theta 1} = [(0.1*\bar{\theta}_{1,1})^2 \;\; 0 \;;\; 0 \;\; (0.1*\bar{\theta}_{1,2})^2] \qquad (10)$$

$$\Sigma_{\theta 2} = [(0.1*\bar{\theta}_{2,1})^2 \;\; 0 \;;\; 0 \;\; (0.1*\bar{\theta}_{2,2})^2] \qquad (11)$$

$$\sigma = \sqrt{\min((0.1*\bar{\theta}_{1,1})^2, (0.1*\bar{\theta}_{1,2})^2)} \qquad (12)$$

$$\mu = U[0.5*1e\text{-}5*\min(\bar{\theta}_{2,1}, \bar{\theta}_{2,2}),\ 1.5*10*\max(\bar{\theta}_{2,1}, \bar{\theta}_{2,2})] \qquad (13)$$

The idea behind choosing the above parameter space is not only to have a sufficiently broad range of the parameter space but also to have some realistically sensible parameter values. The quadratic penalty matrix (14), Q, for higher operating conditions is chosen appropriately so that it is both positive definite and a practically reasonable value.

$$Q = [q_{11}\ q_{12};\ q_{21}\ q_{22}], \text{ where} \qquad (14)$$

$$q_{11} = U[1e^{-5}, \alpha * |(\bar{\theta}_{1,1} + \bar{\theta}_{1,2})/2|] \qquad (15)$$

$$q_{22} = U[1e^{-5}, \alpha * |(\bar{\theta}_{2,1} + \bar{\theta}_{2,2})/2|] \qquad (16)$$

$$q_{12} = U[1e^{-5}, \sqrt{(q_{11}*q_{22})}] \qquad (17)$$

$$q_{21} = U[1e^{-5}, \; q_{11}*q_{22}/q_{12}] \qquad (18)$$

Lastly the true parameter values, unknown to the decision-maker, are considered to be drawn randomly from the prior parameter distributions.

3.2 Solution Approach

To obtain the optimal design solution for the above mentioned problem, we need to solve (19). In (19) Y is the two dimensional vector $[Y_1, Y_2]^T$, each term corresponding to the yield and the quality value. And Θ is the vector of the corresponding parameters for the yield ($\tilde{\theta}_1 = \left[\theta_{1,1}, \theta_{1,2}\right]^T$) and quality ($\tilde{\theta}_2 = \left[\theta_{2,1}, \theta_{2,2}\right]^T$) respectively. Algorithm to calculate the optimal design via (19) is shown in Fig. (3).

$$U(\eta^*) = \max_{\eta} \int_y \max_u \int_\Theta f(\theta, \eta, Y, u)\, p(\theta \mid Y, \eta)\, p(Y \mid \eta)\, d\theta dY \quad (19)$$

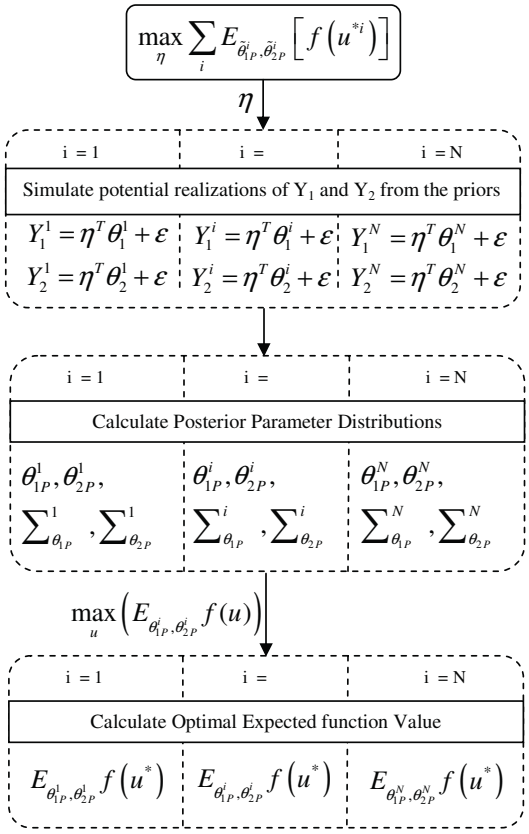

Fig. 3. Algorithm to calculate the optimal decision oriented design of experiment.

The calculation algorithm consists of two stages of optimization. The outer optimization is for selecting the optimal design and the inner optimization is for obtaining the optimal posterior operating conditions. The details for evaluating a given design 'η' are explained as follows:

Step 0: Assume an initial design 'η'

Step 1: Based on the given design and the prior distributions for the parameters $\tilde{\theta}_1 = \left[\theta_{1,1}, \theta_{1,2}\right]^T$ and $\tilde{\theta}_2 = \left[\theta_{2,1}, \theta_{2,2}\right]^T$ generate potential realizations of Y_1^i and Y_2^i for i = 1, 2,..., N (we consider N = 500).

Step 2: For each given realization estimate the posterior mean and covariance matrix for the parameters $\tilde{\theta}_1$ and $\tilde{\theta}_2$.

Step 3: For each posterior distribution estimate, obtain the optimal operating condition and hence the optimal function '*f*' value. Since the function '*f*' has nice structure in our case, the optimization has an analytical solution. But due to the constraints on the operating conditions, the optimal operating conditions are either at the boundary of the constraints or are given by the analytical solution.

Step 4: Calculate the expected value of the optimal function '*f*' value for each of the distributions.

Step 5: Calculate the average of all the optimal expected function values calculated in Step 4.

The value obtained in Step 5 is the value signifies potential of the given design ''. In order to obtain the optimal design, maximization is performed over the design space. This maximization is performed using the inbuilt function '*fmincon*' in MATLAB.

4. RESULTS

To compare the results given by our new design approach and the D-optimal design approach, we took 100,000 runs for different randomly sampled parameter values. To measure the performance of different designs, we measure the closeness of the predicted operating profit margin value to the true optimal operating profit margin value. The percentage of times the true value is closer to the predicted value by a design is reported as the 'Performance Index' of that design.

Table 1 Comparison of performance of new- and D-optimal designs for the 10% noise case.

Type of Prior Distribution	'Performance Index'	
	New Design	D Design
Strongly Informative	45.2290	25.9920
Informative	53.5120	22.8120
Mildly Informative	58.2250	21.1130
Un-Informative	63.5690	17.3060

In order to check if the kind of prior distribution has an effect on the performance of the new-design approach, we measure four levels of prior distributions. An '*Informative*' prior distribution is the one with square root of the diagonal elements of the prior covariance matrix being 10% of the prior mean of the respective parameter. This kind of prior distribution is the one we have shown in (10) and (11). A '*Strongly Informative*' prior distribution is the one with a small covariance and we depict it by replacing the 0.1 values

by 0.05 in (10) and (11). A '*Mildly Informative*' prior distribution is the one with a relatively high variance and is depicted by replacing 0.1 values by 0.15 in (10) and (11). A '*Un-Informative*' prior distribution is the one with a relatively high variance and is depicted by replacing 0.1 values by 0.30 in (10) and (11). The comparison of the performance measure for our decision-oriented and the D-optimal design is shown in Table 1. The above results clearly show ~20-35% improvement in the prediction power of the Decision-oriented design compared to the D-optimal design of experiments.

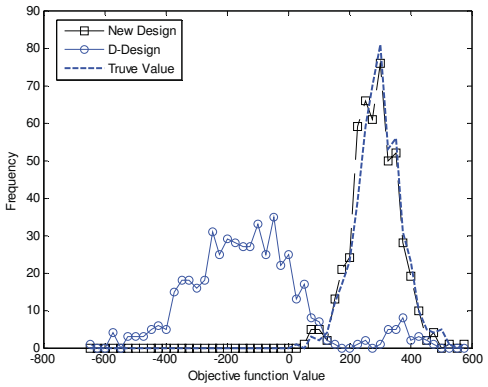

Fig. 4. Histogram comparing the prediction of the Decision oriented and D-optimal design to the true objective value for a '*Mildly Informative*' prior distribution.

Table 2 Comparison of performance of the Decision-oriented design and the D-optimal designs for the 5% noise case

Type of Prior Distribution	'Performance Index'	
	New Design	D Design
Strongly Informative	52.8330	23.3690
Informative	60.5130	18.2910
Mildly Informative	63.9620	16.4300
Un-Informative	67.3060	14.0870

To give more insight to the results we plot the histogram of the optimal operating margin values for the decision oriented and D-optimal design along with the optimal operating margin values (determined assuming that the 'true' parameter values are known), for a particular set of parameter values with 500 different 'true' parameter values being sampled from the prior distribution. To be precise, these are the operating margins for the 'true' plant (with 'true' parameter values) with the optimal operating conditions determined based on the parameter estimates resulting from the respective DOEs. Fig 4 shows the histogram for a '*Mildly Informative*' prior distribution, with 500 'true' parameter values sampled from the prior distribution.

Similarly Fig. 5, Fig. 6 and Fig. 7 show the histogram plots for the '*Informative'*, '*Strongly Informative*' and '*Un-Informative*' prior distributions respectively. Fig 4, 5, 6 & 7 clearly demonstrate the better performance of the decision-oriented DOE strategy compared to traditional D-optimal design strategy.

Table 3 Comparison of performance of the Decision-oriented design and the D-optimal designs for the 15% noise case

Type of Prior Distribution	'Performance Index'	
	New Design	D Design
Strongly Informative	39.5190	25.4060
Informative	49.3160	24.8090

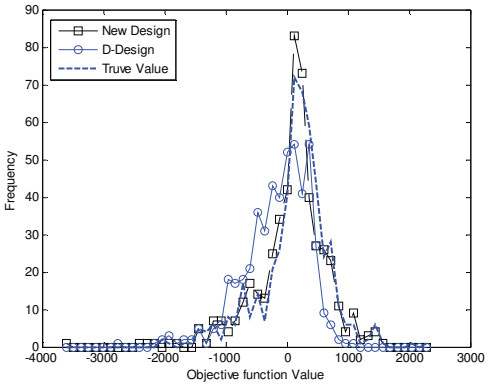

Fig. 6. Histogram comparing the prediction of the Decision oriented and D-optimal design to the true objective value for a '*Strongly Informative*' prior distribution.

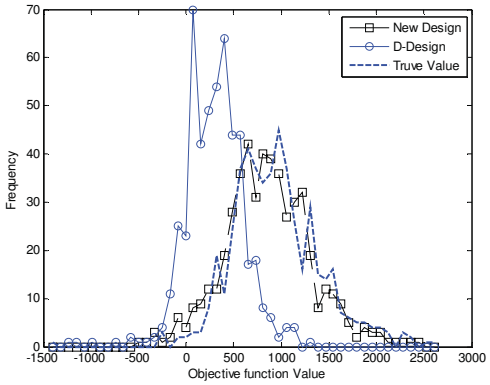

Fig. 7. Histogram comparing the prediction of the Decision oriented and D-optimal design to the true objective value for a '*Un-Informative*' prior distribution.

In order to check if noise has any significant impact on the performance of the decision-oriented designs, we vary the noise measured by the variance of the Gaussian noise in (12). In comparison to the initial noise of 10% as depicted by the value '0.1' in (12) we test two other levels of noise 5% and 15% , which correspond to changing '0.1 value in (12) to '0.05' and '0.15' respectively. The results for the 5% and the 15% noise cases are shown in the Table 2 and Table 3 respectively. The results clearly demonstrate that the decision-optimal design outperforms the D-optimal design regardless of the noise level.

5. CONCLUSIONS

We have introduced a new decision oriented design of experiment strategy, which significantly improves the prediction of a process's optimal objective function value compared to that of a D-optimal design of experiment strategy. These types of DOE strategies are expected to be of significant importance in improving the R&D decisions, especially in bio-fuel related research where one faces multiple process alternatives. Moreover, in addition to the design criterion considered in this work, one can consider alternative Acceptance/Rejection design criterion. For example, in the problem discussed in this work, we were mainly concerned with the mean value of '*f*', but an alternat-

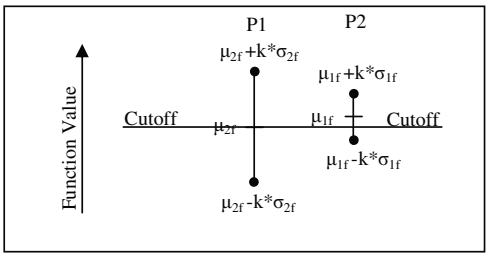

Fig. 8. An alternative Acceptance/Rejection criterion

-ive design criterion can be based on both the mean and the variance of '*f*' along with a cut-off value. Consider two processes P1 and P2, shown in Fig. 8. The selection criterion of the decision maker for these processes is that $\mu - k*\sigma$ be greater than the 'Cutoff' and the rejection criterion being that $\mu + k*\sigma$ be less than the 'Cutoff', where μ is the posterior mean and σ is the posterior standard deviation of the objective function '*f*'. To design experiments for selection/rejection of processes based on this type of criterion can be done by maximising $|\Sigma\delta_i|$, where δ_i is defined as follows:

$$\delta_i = \begin{Bmatrix} +1, if\ \mu_{fi} - k*\sigma_i > Cutoff \\ -1, if\ \mu_{fi} + k*\sigma_i < Cutoff \\ 0, Otherwise \end{Bmatrix}$$

The subscript 'i' represents the potential random samples with value ranging form i = 1, 2.., N, as explained earlier in section 3.2. Similarly various other design criterions can be created based on the decision maker's objective function. We will evaluate these and similar acceptance/rejection decision criterions in our future work.

Abstract: Although soft-sensors have been widely used for estimating product quality or other key variables, they do not always function well in practice due to changes in process characteristics. The Correlation-based Just-In-Time (CoJIT) modeling has been proposed to cope with changes in process characteristics. In the CoJIT modeling, the samples used for local modeling are selected on the basis of correlation together with distance, since changes in process characteristics are expressed as the difference of the correlation. In addition, the individuality of production devices should be considered when they are operated in parallel. However, the CoJIT modeling cannot cope with the individuality of production devices because it is only applicable to time-series data. In the present work, a new pattern recognition method, referred to as the Nearest Correlation (NC) method is proposed, and it selects samples whose correlations are similar to the query. In addition, the proposed NC method is integrated with the CoJIT modeling. The advantages of the proposed CoJIT modeling with the NC method are demonstrated through a case study of a parallelized CSTR process.

1. INTRODUCTION

A soft-sensor, or a virtual sensor, is a key technology for estimating product quality or other important variables when on-line analyzers are not available. Partial least squares (PLS) regression and artificial neural network (ANN) have been widely accepted as useful techniques for soft-sensor design (Kano and Nakagawa (2008), Mejdell and Skogestad (1991), Kresta et al. (1994), Kano et al. (2000), Kamohara et al. (2004) and Radhakrishnan and Mohamed (2000)). In addition, the application of subspace identification (SSID) to soft-sensor design has been reported in Amirthalingam and Lee (1999) and Kano et al. (2008) for achieving higher estimation performance.

Generally, building a high performance soft-sensor is very laborious, since input variables and samples for model construction have to be selected carefully and parameters have to be tuned appropriately. In addition, even if a good soft-sensor is developed successfully, its estimation performance deteriorates as process characteristics change. In chemical processes, for example, process characteristics are changed by catalyst deactivation or fouling. Such a situation may deteriorate product quality. Therefore, maintenance of soft-sensors is very important in practice to keep their estimation performance. Ogawa and Kano (2008) indicate that soft-sensors should be updated as the process characteristics change, and also manual, repeated construction of them should be avoided due to its heavy workload.

To update statistical models automatically when process characteristics change, recursive methods such as recursive PLS (Qin (1998)) were developed. These methods can adapt models to new operating conditions recursively. However, when a process is operated within a narrow range for a certain period of time, the model will adapt excessively and will not function in a sufficiently wide range of operating conditions. In addition, recursive methods cannot cope with abrupt changes in process characteristics.

On the other hand, the individuality of production devices should be taken into account. In semiconductor processes, for example, parallelized production devices are used, and they have different characteristics even if their catalog specifications are the same. Therefore, a soft-sensor developed for one device is not always applicable to another device, and it is very laborious to customize soft-sensors according to their individuality.

The Just-In-Time (JIT) modeling has been proposed to cope with process nonlinearity (Bontempi et al. (1999) and Atkeson et al. (1997)) and changes in process characteristics (Cheng and Chiu (2004)). In the JIT modeling, a local model is built from past data around the query only when an estimate is required. The JIT modeling is useful when global modeling does not function well. However, its estimation performance is not always high because the samples used for local modeling are selected on the basis of the distance from the query and the correlation among variables is not taken into account. How should we determine the samples used for local modeling to build

a highly accurate statistical model? Distance is not the most important. A good model cannot be developed when correlation among input-output variables is weak, even if the distance between samples is very small. Conversely, a very accurate model can be developed when the correlation is strong even if the distance is large.

Recently, a new JIT modeling method based on the correlation among variables, referred to as the correlation-based JIT (CoJIT) modeling, has been proposed by Fujiwara et al. (2008). In the CoJIT modeling, the samples used for local modeling are selected on the basis of correlation together with distance. The CoJIT modeling can cope with abrupt changes of process characteristics and also achieve high estimation performance. However, it is applicable to only time-series data because it uses moving windows to generate data sets for local modeling. In other words, the original CoJIT modeling cannot generate a data set consisting of such data that represent characteristics of a query sample and are obtained from various devices operated in parallel.

To make the CoJIT modeling applicable to soft-sensor design for parallelized production devices, samples obtained from various devices have to be discriminated on the basis of the correlation among variables. This discrimination problem is one of the unsupervised pattern recognition problems because the teacher signal is not used for sample classification.

The Nearest Neighbor (NN) method and k-means method are well-known conventional unsupervised pattern recognition algorithms. The NN method can detect samples that are similar to the query, and k-means method can cluster samples without the teacher signal. However, they are distance-based methods and do not take into account the correlation among variables. Self organizing map (SOM) also has been used as an unsupervised pattern recognition method (Kohonen (2001)). SOM is a machine learning process that imitates the brain ' s learning process, and it not only can classify samples but also can visualize high dimensional data. However, it requires high computational load, and the preprocessing data are complicated.

In the present work, to cope with the individuality of production devices as well as changes in process characteristics, a new unsupervised pattern recognition method based on the correlation among variables, referred to as the Nearest Correlation (NC) method, is proposed. The proposed NC method can detect samples that have correlation similar to the query on the basis of sample geometry. In addition, the proposed NC method is integrated with the CoJIT modeling. The usefulness of the integration is demonstrated through a case study of a parallelized CSTR process.

2. INDICES OF CORRELATION

In this section, several measures for quantifying correlation among variables are briefly explained.

2.1 Correlation coefficient

The correlation coefficient $C_{i,j}$ can be used as an index of the similarity between two vectors $\boldsymbol{x}_i$ and $\boldsymbol{x}_j \in \Re^M$.

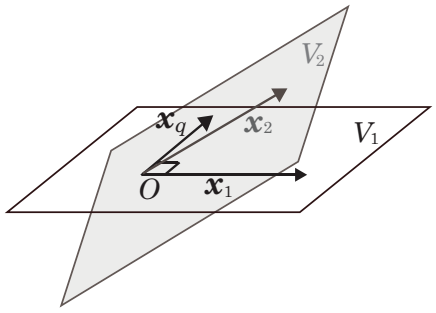

Fig. 1. An example of vector geometry in 3-dimensional space

$$C_{i,j} = \frac{\boldsymbol{x}_i^{\mathrm{T}} \boldsymbol{x}_j}{||\boldsymbol{x}_i|| ||\boldsymbol{x}_j||} = \cos\theta \tag{1}$$

where, θ is the angle between two vectors.

Suppose that the samples in the three-dimensional data consist of two classes K_1 and K_2, and samples belonging to classes K_1 and K_2 span the two-dimensional linear subspaces V_1 and V_2, respectively, as shown in Fig. 1.

Now, the query $\boldsymbol{x}_q$ is newly measured, and its class should be identified as K_1 or K_2. The correlation coefficients can be used as the index of sample discrimination. For example, $\boldsymbol{x}_1 \in K_1$ and $\boldsymbol{x}_2 \in K_2$ are selected from each class in a random manner, and the correlation coefficients between $\boldsymbol{x}_q$ and them are calculated respectively, and the class including the sample with the largest correlation coefficient can be identified as the class of $\boldsymbol{x}_q$.

In many cases, however, this method is inappropriate. In Fig. 1, the selected sample $\boldsymbol{x}_1$ and the query $\boldsymbol{x}_q$ are orthogonal to each other even though both vectors belong to K_1. In such a case, $\boldsymbol{x}_q$ is identified as an element of K_2 because the correlation coefficient between $\boldsymbol{x}_q$ and $\boldsymbol{x}_2$ is larger than the correlation coefficient between $\boldsymbol{x}_q$ and $\boldsymbol{x}_1$.

2.2 The Q statistic

In this work, the Q statistic is used as an index of sample discrimination.

The Q statistic is derived by principal component analysis (PCA), and it expresses the distance between the sample and the subspace spanned by principal components (Jackson and Mudholkar, 1979). The Q statistic is defined as

$$Q = \sum_{m=1}^{M} (x_m - \hat{x}_m)^2 \tag{2}$$

where x_m and $\hat{x}_m$ are the mth measurement and its estimate by the PCA model, respectively. The Q statistic is a measure of dissimilarity between the sample and the modeling data from the viewpoint of the correlation among variables.

In addition, to take into account the distance between the sample and the origin, Hotelling's T^2 statistic can be used. The T^2 statistic is defined as

$$T^2 = \sum_{r=1}^{R} \frac{t_r^2}{\sigma_{t_r}^2} \tag{3}$$

where σ_{t_r} denotes the standard deviation of the rth score t_r. The T^2 statistic expresses the normalized distance from the origin in the subspace spanned by principal components. The Q and T^2 statistics can be integrated into a single index for sample selection as proposed by Raich and Cinar (1994):

$$J = \lambda T^2 + (1 - \lambda)Q \tag{4}$$

where $0 \leq \lambda \leq 1$.

3. NEAREST CORRELATION METHOD

The NN method and the k-means method can discriminate or cluster samples on the basis of the distance without a teacher signal. However, they do not take into account the correlation among variables. In this section, a new unsupervised pattern recognition method based on the correlation among variables, referred to as the nearest correlation (NC) method, is proposed. In the proposed NC method, sample geometry is used for sample discrimination.

3.1 Concept of the NC method

Suppose that the hyper-plane P in Fig. 2 (left) expresses the correlation among variables and the samples on P have the same correlation. Although samples $\boldsymbol{x}_1$ to $\boldsymbol{x}_5$ have the same correlation and they are on P, samples $\boldsymbol{x}_6$ and $\boldsymbol{x}_7$ have different correlation from the others. The NC method aims to detect samples whose correlation is similar to the newly measured query $\boldsymbol{x}_q$. In this example, $\boldsymbol{x}_1$ to $\boldsymbol{x}_5$ on P should be detected.

At first, the whole space is translated so that the query becomes the origin. That is, $\boldsymbol{x}_q$ is subtracted from all samples $\boldsymbol{x}_i (i = 1, 2, \cdots, 7)$. Since the hyper-plane P is translated to the plane containing the origin, it becomes the linear subspace V.

Next, a line connecting each sample and the origin is drawn. Suppose another sample can be found on this line. In this case, $\boldsymbol{x}_1$-$\boldsymbol{x}_4$ and $\boldsymbol{x}_2$-$\boldsymbol{x}_3$ satisfy such a relationship as shown in Fig. 2 (right). The correlation coefficients of these pairs of samples must be 1 or -1. On the other hand, $\boldsymbol{x}_6$ and $\boldsymbol{x}_7$ that are not the elements of V cannot make such pairs. Therefore, the samples of the pairs whose correlation coefficients are ± 1 are thought to have the same correlation as $\boldsymbol{x}_q$.

However, $\boldsymbol{x}_5$ that does not make a pair cannot be detected by this method even though it is on V. To detect $\boldsymbol{x}_5$, a linear subspace is derived from the selected pairs by using PCA, and the derived linear subspace corresponds to V.

Finally, the Q statistics for all samples $\boldsymbol{x}_i$ $(i = 1, 2, \cdots, 7)$ are calculated by using the PCA model expressing V. The samples with small Q statistics are located close to the linear subspace V, and such samples have correlation similar to the query. Although $\boldsymbol{x}_5$ cannot be detected in the previous step, it can be detected in this step because its Q statistic is 0. On the other hand, $\boldsymbol{x}_6$ and $\boldsymbol{x}_7$ are not detected in this step since they have large Q statistics.

In addition, the T^2 statistic can be used to take into account the distance from the origin. In the present work,

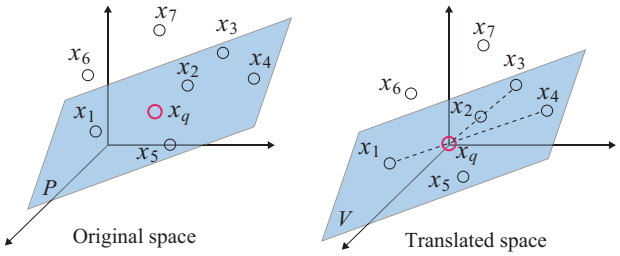

Fig. 2. An example of the procedure of the NC method

J in Eq. (4) is used as the index for sample selection. The samples with small J are selected as the samples similar to the query.

In the implementation of the above procedure, the threshold of the correlation coefficient γ $(1 \geq \gamma > 0)$ has to be used since there are no pairs whose correlation coefficient is strictly ± 1. That is, the pairs should be selected when the absolute values of their correlation coefficients are larger than γ.

3.2 Algorithm of the NC method

Assume that the samples stored in the database are $\boldsymbol{x}_n \in \Re^M$ $(n = 1, 2, \cdots, N)$ and the query is $\boldsymbol{x}_q \in P$ $(\dim(P) = R)$. The samples belonging to P should be detected in a manner similar to $\boldsymbol{x}_q$. The algorithm of the proposed NC method is as follows:

(1) Set R, $\gamma(1 \geq \gamma > 0)$, $\delta(\delta > 0)$ and K or $\bar{J}$.
(2) $\boldsymbol{x}'_n = \boldsymbol{x}_n - \boldsymbol{x}_q$ for $n = 1, 2, \cdots, N$.
(3) Calculate the correlation coefficients $C_{k,l}$ between all possible pairs of $\boldsymbol{x}'_k$ and $\boldsymbol{x}'_l$ $(k \neq l)$.
(4) Select the pairs satisfying $|C_{k,l}| \geq \gamma$, and set the number of the selected pairs S.
(5) If $S < R$, then $\gamma = \gamma - \delta$ $(\delta > 0)$ and return to step 4. If $S \geq R$, then go to the next step.
(6) Arrange the samples of the pairs selected in step 4 as the rows of the matrix $\boldsymbol{X}'$.
(7) Derive the linear subspace V from $\boldsymbol{X}'$ by using PCA. The number of principal components is R.
(8) Calculate the index J of $\boldsymbol{x}'_n$, and $J_n = J$ for $n = 1, 2, \cdots, N$.
(9) Detect the first K samples in ascending order of J_n or the samples whose J_n is smaller than $\bar{J}$ as samples similar to the query $\boldsymbol{x}_q$, where $\bar{J}$ is the threshold.

In step 5, when S is smaller than R, the threshold γ has to be relaxed to increase the number of selected pairs since the linear subspace V is not spanned by the samples of the selected pairs. R can be used as the tuning parameter.

3.3 Numerical example

The discrimination performance of the proposed NC method is compared with that of the NN method through a numerical example. In this example, data consist of three classes that have different correlations, and the samples belonging to the same class as the query should be detected. The discrimination rate is defined as

$$\text{Discrimination Rate [\%]} = \frac{L}{K} \times 100 \tag{5}$$

where K is the number of detected samples and L ($L \leq K$) is the number of samples that belong to the same class as the query among the detected samples. Samples in each of three classes are generated by using the following equation.

$$\boldsymbol{x}_i = \boldsymbol{A}_i \boldsymbol{s} + \boldsymbol{n} \ (i = 1, 2, 3) \tag{6}$$

$$\boldsymbol{s} = [s_1 \ s_2 \ s_3]^T \tag{7}$$

$$\boldsymbol{n} = [n_1 \ n_2 \ n_3]^T \tag{8}$$

where $\boldsymbol{A}_i$ is a coefficient matrix, $s_i \sim N(0, 10)$ and $n_i \sim N(0, 0.1)$. $N(m, \sigma)$ is the random number following the normal distribution whose mean is m and standard deviation is σ. The coefficient matrices are as follows:

$$\boldsymbol{A}_1 = \begin{bmatrix} 1 & 2 \\ 1 & 4 \\ 1 & 1 \\ 2 & 3 \\ 1 & 3 \end{bmatrix}, \ \boldsymbol{A}_2 = \begin{bmatrix} 3 & 3 \\ 2 & 1 \\ 3 & 1 \\ 3 & 2 \\ 2 & 0 \end{bmatrix}, \ \boldsymbol{A}_3 = \begin{bmatrix} 2 & 1 \\ 3 & 4 \\ 1 & 3 \\ 0 & 4 \\ 3 & 1 \end{bmatrix}. \tag{9}$$

100 samples are generated in each of three classes. In addition, a query belonging to each class is prepared. The number of detected samples K is fixed at 20.

In this example, the number of principal components is $R = 2$, the threshold is $\gamma = 1 - 10^{-4}$, the parameters are $\lambda = 0$ and $\delta = 0.9999$. Sample generation and sample detection by the NN method and the NC method are repeated 100 times and the average discrimination rates [%] and the average CPU time [ms] are calculated. The computer configuration used in this numerical example is as follows: OS: Windows Vista Business (64bit), CPU: Intel Core2 Duo 6300 (1.86GHz×2), RAM: 2G byte, and MATLAB® 7.5.0 (2008a).

Table 1 shows the discrimination results of the NN method and the NC method. The proposed NC method can achieve higher discrimination performance than the NN method. On the other hand, the computational load of the NC method is relatively heavy since singular value decomposition (SVD) is used for calculating the correlation among variables. In fact, the computation of SVD occupies most of the computation time of the NC method.

4. CORRELATION-BASED JUST-IN-TIME MODELING

The conventional JIT modeling uses the distance for sample selection when a temporary local model is constructed. However, its estimation performance is not always high since it does not take into account the correlation among variables. Recently, The Correlation-based JIT (CoJIT) modeling that selects samples for local modeling on the basis of the correlation among variables has been proposed by Fujiwara et al. (2008).

Figure 3 shows the difference of sample selection for local modeling between the JIT modeling and the CoJIT modeling. The samples are classified into two groups that have

Table 1. Discrimination performance of the NC method and the NN method

	Discrimination rate [%]			CPU time [ms]
	Class 1	Class 2	Class 3	
NC method	97.5	95.9	96.9	13.9
NN method	78.7	68.0	51.1	1.1

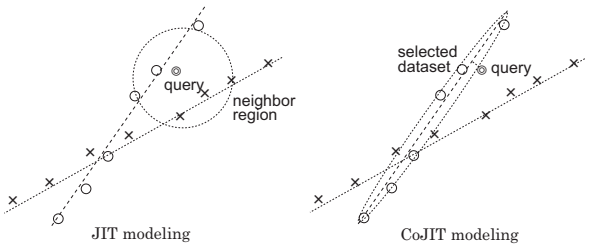

Fig. 3. Sample selection in the JIT modeling (left) and the CoJIT modeling (right)

different correlations. In conventional JIT modeling, samples are selected regardless of the difference of correlation as shown in Fig. 3 (left), since a neighbor region around the query point is defined only by distance. On the other hand, the CoJIT modeling can select samples whose correlation is best fit for the query as shown in Fig. 3 (right).

The procedure of the CoJIT modeling is as follows: 1) several data sets are generated from data stored in the database. 2) The index J is calculated from the query and each data set. 3) The data set whose J is the smallest is selected. 4) A temporary local model is constructed from the selected data set. In the above procedure, each data set is generated so that it consists of successive samples included in a certain period of time, because the correlation in such a data set is expected to be very similar (Fujiwara et al. (2008)).

However, the NC method can detect samples that have correlation similar to the query regardless of whether the objective data is time-series data or not. This is the motivation for integrating the proposed NC method with the CoJIT modeling.

Assume that the sampling interval of the output is longer than that of the input, and the output at time t, $\boldsymbol{y}_t$, should be estimated. Now, the input and the output measured at the same time are stored in the database, and the sth input-output sample $\boldsymbol{x}^{\{s\}} \in \Re^M$ $(s = 1, 2, \cdots, S)$ and $\boldsymbol{y}^{\{s\}} \in \Re^L$ are stored as matrices $\boldsymbol{X}_S \in \Re^{S \times M}$ and $\boldsymbol{Y}_S \in \Re^{S \times L}$, respectively. To cope with process dynamics, measurements at different sampling times can be included in $\boldsymbol{x}^{\{s\}}$. The algorithm of the proposed CoJIT modeling with the NC method is as follows:

(1) When the input at time t, $\boldsymbol{x}_t$, is measured, the index J is calculated from $\boldsymbol{x}_t$ and $\boldsymbol{X}_{t-1}$ that was used for building the previous local model f_{t-1}, and $J_I = J$.
(2) If $J_I \leq \bar{J}_I$, $f_t = f_{t-1}$, $\boldsymbol{X}_t = \boldsymbol{X}_{t-1}$, and f_t is used for estimating the output $\boldsymbol{y}_t$. Then, return to step 1. If $J_I > \bar{J}_I$, go to the next step. Here, $\bar{J}_I$ is the threshold.
(3) K input samples whose correlation is similar to the query are detected from $\boldsymbol{X}_S$ by the NC method, and they are arranged as the rows of $\boldsymbol{X}_t \in \Re^{K \times M}$. In addition, K output samples corresponding to the detected input samples are selected from $\boldsymbol{Y}_S$, and they are arranged as the rows of $\boldsymbol{Y}_t \in \Re^{K \times L}$, where K is the number of the detected samples.
(4) A new local model f_t whose input is $\boldsymbol{X}_t$ and output is $\boldsymbol{Y}_t$ is built.
(5) The output $\boldsymbol{y}_t$ is estimated by using f_t.

(6) The above steps 1 through 5 are repeated until the next output sample $\boldsymbol{y}_{S+1}$ is measured. When $\boldsymbol{y}_{S+1}$ is measured, $\boldsymbol{y}_{S+1}$ and its corresponding input $\boldsymbol{x}_{S+1}$ are stored in the database, and return to step 1.

In the above algorithm, any modeling method can be used for building a local model f. In the present work, partial least squares regression (PLS) is used to cope with the colinearity problem. In addition, steps 1 and 2 control the model update frequency. When the threshold $\bar{J}_I$ is large, the update frequency becomes low. The local model is updated every time when new input measurements are available in the case where $\bar{J}_I = 0$.

5. CASE STUDY

In this section, the estimation performance of the proposed CoJIT modeling with the NC method is compared with that of the conventional JIT modeling through their applications to product composition estimation for a parallelized CSTR process. The detailed CSTR model used in this case study is described in Johannesmeyer and Seborg (1999).

5.1 Problem setting

In this process, CSTR1 and CSTR2 are operated in parallel. Although these CSTRs have the same structure

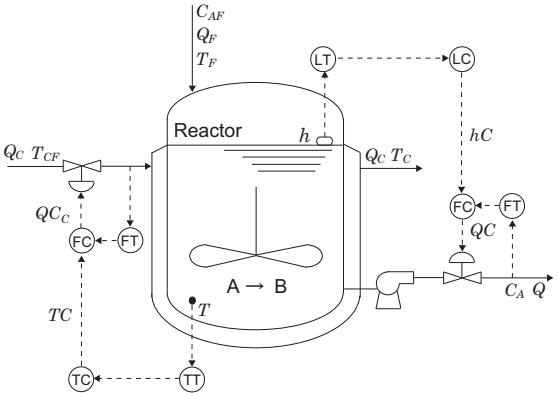

Fig. 4. Schematic diagram of CSTR with cascade control systems

Table 2. Process variables of the CSTR processes

Variable	Caption
C_A	Reactant concentration [mol/m^3]
T	Reactor temperature [K]
T_C	Coolant temperature [K]

QC_C	Colorant flow rate controller instruction
T_{set}	Reactor temperature set point [K]

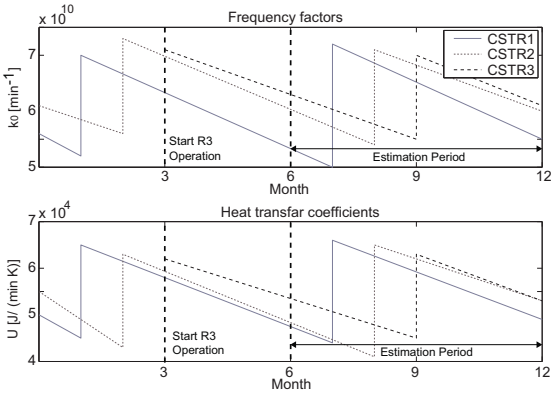

Fig. 5. Changes of overall heat transfer coefficients and frequency factors of the CSTRs

as shown in Fig. 4, they have different characteristics. In each CSTR, an irreversible reaction A $\longrightarrow$ B takes place. The set point of the reactor temperature $T^{[d]}(d = 1, 2)$ is independently changed between $\pm$2K every ten days. Although 15 process variables listed in Table 2 are calculated in the simulations, measurements of only five variables $T^{[d]}$, $h^{[d]}$, $Q^{[d]}$, $Q_C^{[d]}$, $Q_F^{[d]}$ are used for analysis, and their sampling interval is one minute. In addition, reactant concentration $C_A^{[d]}$ is measured in a laboratory once a day.

In this case study, to take into account catalyst deactivation and fouling as changes in process characteristics and individuality of each CSTR, the frequency factor $k_0^{[d]}$ and the heat transfer coefficient $UAc^{[d]}$ are assumed to decrease with time. In addition, each CSTR is maintained every half year (180 days). Figure 5 shows changes of the frequency factors $k_0^{[d]}$ and heat transfer coefficients $UAc^{[d]}$. The operation data of each CSTR for the half years (180 days) were stored in the database.

The soft-sensor for estimating reactant concentration of the newly developed CSTR3 is designed. The estimation of CSTR3 starts the 90th day after the start of its operation, and the soft-sensor is updated in the next half year. Although CSTR3 has only a small amount of data due to its short operation term, the soft-sensor is updated searching samples similar to the current operation of CSTR3 from the other CSTR operation data in the past.

5.2 Estimation result

The reactant concentration $C_A^{[3]}$ is estimated by the JIT modeling and the proposed CoJIT modeling with the NC method. To take into account process dynamics, the input data consist of the present sample and the sample measured one minute before.

In the JIT modeling, linear local models are built and Euclidean distance is used as the measure for selecting samples to build local models. The MATLAB Lazy Learning Toolbox developed by Bontempi et al. (1999) is used.

In the CoJIT modeling, samples for local modeling are selected by the NC method, and PLS is used for model building. The parameters of the NC method are deter-

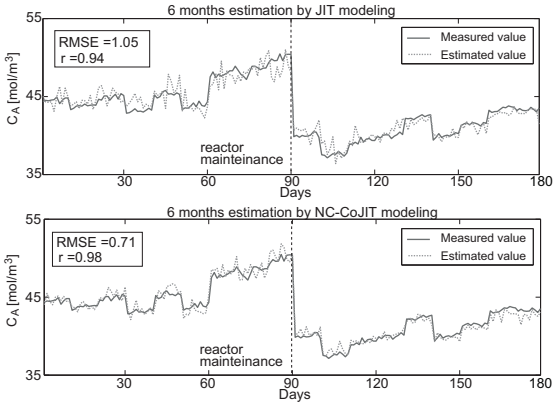

Fig. 6. Prediction result of $C_A^{\{3\}}$ by the JIT modeling (top) and the CoJIT modeling (bottom)

mined by trial and error, the threshold is $\gamma = 1 - 10^4$, the parameter is $\lambda = 0.01$, and the parameter for update frequency $\bar{J}_I = 0$.

The soft-sensor design results are shown in Fig. 6. Although $C_A^{[3]}$ is estimated every minute, only estimates corresponding to the measurements are plotted. In this figure, r denotes the correlation coefficient between measurements and estimates, and RMSE is the root-mean-squares error.

This result shows that the JIT modeling does not function well. On the other hand, the estimation performance of the proposed CoJIT modeling with the NC method is very high. With the proposed CoJIT modeling, RMSE is improved by about 35% in comparison with the JIT modeling. These results of this case study clearly show that the proposed CoJIT modeling can cope with not only abrupt changes in process characteristics but also the individuality of production devices. In addition, it can construct a high performance soft-sensor for a newly develop device, even if only a small amount of operation data is available.

6. CONCLUSION

A new unsupervised pattern recognition method that can detect samples whose correlation is similar to the query is proposed. In addition, the JIT modeling is integrated with the proposed the NC method. The proposed CoJIT modeling with the NC method can cope with not only changes in process characteristics but also the individuality of production devices and improve the estimation performance of a soft-sensor since it can select samples for local modeling by appropriately accounting for the correlation among variables. The proposed CoJIT modeling has the potential for realizing efficient maintenance of soft-sensors.

Process Monitoring

Oral Session

On-line statistical monitoring of batch processes using Gaussian mixture model

Abstract: The statistical monitoring of batch manufacturing processes is considered. It is known that conventional monitoring approaches, e.g. principal component analysis (PCA), are not applicable when the normal operating conditions of the process cannot be sufficiently represented by a Gaussian distribution. To address this issue, Gaussian mixture model (GMM) has been proposed to estimate the probability density function of the process nominal data, with improved monitoring results having been reported for continuous processes. This paper extends the application of GMM to on-line monitoring of batch processes, and the proposed method is demonstrated through its application to a batch semiconductor etch process.

Keywords: Batch processes, mixture model, principal component analysis, probability density estimation, multivariate statistical process monitoring.

1. INTRODUCTION

Batch processing is of great importance in many industrial applications due to its flexibility for the production of low-volume, high-value added products. With increasing commercial competition it is crucial to ensure consistent and high product quality, as well as process safety. These requirements have resulted in wide acceptance of the technique of multivariate statistical process monitoring (Martin et al., 1999; Qin, 2003). The basis of the monitoring schemes is historical data that has been collected when the process is running under normal operating conditions (NOC). This data is then used to establish confidence bounds for the monitoring statistics, e.g. Hotelling's T^2 and squared prediction error (SPE), to detect the onset of process deviations. The primary objective of process monitoring is to identify abnormal behavior as early as possible, in addition to keeping an acceptably low false alarm rate.

As a result of the multi-way characteristic of batch process data, special tools are required for the modelling and monitoring purposes, including multi-way principal component analysis (MPCA) (Nomikos and MacGregor, 1995b), hierarchical PCA (Rannar et al., 1998) and multi-way partial least squares (MPLS) (Nomikos and MacGregor, 1995a). The methods for on-line monitoring of batch process can be classified into two categories. The first does not require measurements on the entire batch duration to be available. Techniques that are within this class include hierarchical and two-dimensional dynamic PCA (Rannar et al., 1998; Lu et al., 2005). In the other category, the entire batch data is required for the calculation of the monitoring statistics, whilst the data from a new batch is available only up to the current time. Therefore the future data must be predicted in some way (Nomikos and MacGregor, 1995b). In this paper the latter of the two approaches is considered, and the details will be discussed subsequently in Section 2.

However, the afore reviewed conventional process monitoring methods are based on a restrictive assumption that the NOC can be represented by a multivariate Gaussian distribution. Specifically the confidence bounds for T^2 and SPE are calculated by assuming the PCA/PLS scores and prediction errors are Gaussian distributed. This assumption may be invalid when the process data is collected from a complex manufacturing process. To address this issue, Gaussian mixture model (GMM) (Chen et al., 2006; Choi et al., 2004; Thissen et al., 2005), which is capable of approximating any probability density function (*pdf*), has been proposed for the monitoring of continuous processes, as well as batch-wise monitoring of batch processes.

The major contribution of this paper is to extend the application of GMM to on-line monitoring of batch processes. As the first step MPCA is applied to the nominal batch data to extract the low-dimensional representation of the process. The challenge with on-line monitoring is that the scores and SPE must be predicted based on available process measurements up to the current time step. Clearly the predicted scores and SPE are not identical to the values that are calculated from the entire batch duration, and thus the predictions may not conform to the nominal distribution even if the process is running normally. We follow the approach of Nomikos and MacGregor (1995b) to pass the nominal batches through the monitoring procedure and collect the predicted scores and SPE at each time step. Then GMM is employed to estimate the joint *pdf* of these predicted scores and SPE from MPCA at each

time step, as opposed to the traditional T^2 and SPE where the process data is assumed to be Gaussian distributed.

The rest of this paper is organized as follows. Section 2 gives a summary of the PCA and GMM tools for process monitoring, followed by the discussion of the on-line monitoring strategy in Section 3. Section 4 demonstrates the application of the on-line monitoring techniques to a batch semiconductor manufacturing process. Finally Section 5 concludes this paper.

2. PCA AND GAUSSIAN MIXTURE MODEL FOR PROCESS MONITORING

This section presents a brief overview of the PCA and GMM techniques. A number of issues related to the application to process monitoring are discussed, including model selection and the construction of confidence bound.

2.1 PCA

Principal component analysis (PCA) (Jolliffe, 2002) is a general multivariate statistical projection technique for dimension reduction, where the original data is linearly projected onto low-dimensional space such that the variance is maximized. Formally the D-dimensional data $\mathbf{x}$ is represented by a linear combination of the Q-dimensional scores $\mathbf{t}$ plus a noise vector $\mathbf{e}$: $\mathbf{x} = \mathbf{W}\mathbf{t} + \mathbf{e}$, where $\mathbf{W}$ are the eigenvectors of the sample covariance matrix having the Q largest eigenvalues ($Q \leq D$). Consequently normal process behavior can be characterized by the first Q principal components, which capture the main source of data variability.

The proper number of principal components can be selected using a number of criteria, including variance ratio, cross-validation and the "broken-stick" rule (Jolliffe, 2002). This is essentially a model selection problem. The "broken-stick" rule is adopted in this paper due to its low computation and good results reported in the literature (Nomikos and MacGregor, 1995b). According to this rule, the q-th principal component should be retained if the percentage of variance explained by it exceeds the corresponding G value given by

$$G(q) = \frac{100}{C} \sum_{i=q}^{C} \frac{1}{i} \tag{1}$$

where $C = \min(D, N)$.

In statistical process monitoring, the next step is to define the monitoring statistics and the corresponding confidence bounds. Traditionally two metrics are used: $T^2 = \mathbf{t}^{\mathrm{T}}\mathbf{\Lambda}^{-1}\mathbf{t}$ and SPE as $r = \mathbf{e}^{\mathrm{T}}\mathbf{e}$, where $\mathbf{\Lambda}$ is a diagonal matrix comprising the Q largest eigenvalues.

As discussed previously, the first issue with T^2 and SPE is that the corresponding confidence bounds are calculated based on restrictive Gaussian distribution. Secondly two separate metrics are required for process monitoring. Practically the process is identified as deviating from normal operation if either T^2 or SPE moves outside the confidence bounds. This empirical solution could potentially increase the false alarm level [1]. The technique of GMM is suitable for addressing the two issues simultaneously. In our previous work (Chen et al., 2006) we have demonstrated that a unified monitoring statistic can be obtained by estimating the joint *pdf* of the PCA scores and log-SPE using GMM, i.e. the *pdf* of a $(Q+1)$-dimensional vector $\mathbf{z} = (\mathbf{t}^{\mathrm{T}}, \log r)^{\mathrm{T}}$. The logarithm operator is used to transform the non-negative SPE onto the whole real axis on which the GMM is defined.

In this paper the methodology in (Chen et al., 2006) is followed to establish the confidence bounds for process monitoring based on PCA and GMM techniques. GMM is described in detail in the next subsection.

2.2 Gaussian mixture model

As a general tool for *pdf* estimation, Gaussian mixture model (GMM) has been used in a wide variety of problems in applied statistics and pattern recognition. A GMM is a weighted sum of M component densities, each being a multivariate Gaussian with mean $\boldsymbol{\mu}_i$ and covariance matrix $\mathbf{\Sigma}_i$:

$$p(\mathbf{z}|\boldsymbol{\theta}) = \sum_{i=1}^{M} \alpha_i G(\mathbf{z};\, \boldsymbol{\mu}_i, \mathbf{\Sigma}_i) \tag{2}$$

where the weights satisfy the constraint: $\sum_{i=1}^{M} \alpha_i = 1$. A GMM is parameterized by the mean vectors, covariance matrices and mixture weights: $\boldsymbol{\theta} = \{\alpha_i, \boldsymbol{\mu}_i, \mathbf{\Sigma}_i; i = 1, \ldots, M\}$.

Given a set of training data $\{\mathbf{z}_n, n = 1, \ldots, N\}$, the parameters can be estimated by maximizing the likelihood function: $L(\boldsymbol{\theta}) = \prod_{n=1}^{N} p(\mathbf{z}_n|\boldsymbol{\theta})$. In the context of process monitoring, $\mathbf{z}_n$ is the $(Q+1)$-dimensional vector of PCA scores and log-SPE: $\mathbf{z}_n = (\mathbf{t}_n^{\mathrm{T}}, \log r_n)^{\mathrm{T}}$. The maximization is typically implemented iteratively using the expectation-maximization (EM) algorithm (Dempster et al., 1977).

The number of mixture components, M, must be selected prior to the training of a GMM. This is a model selection problem that can be addressed using a number of methods, including cross-validation and Bayesian information criterion (BIC) (Schwarz, 1978). BIC is widely applied in model selection problems for its effectiveness and low computational cost. According to BIC the model is selected such that $L - (H/2)\log N$ is the largest, where L is the log-likelihood of the data and H is the total number of parameters within the model. The motivation of BIC is that a good model should be able to sufficiently explain the data (the log-likelihood) with low model complexity (the number of parameters). In this study BIC is adopted for the selection of number of mixtures.

One of the advantages of the GMM for process monitoring is that it provides the likelihood value as the single statistic for the construction of confidence bounds, as opposed to the confidence bounds for two statistics (i.e. the T^2 and SPE) in conventional process monitoring techniques. In

[1] Suppose 95% confidence bound is used, and thus by definition the false alarm rate is 5% for both T^2 and SPE. The probability of either T^2's bound or SPE's bound being exceeded, when the process is runing normally, will be equal to or greater than 5%.

practice a single monitoring statistic simplifies the plant operators' decision effort, and it may be more sensitive to some subtle process faults (Chen et al., 2006).

On the basis of the *pdf* $p(\mathbf{z}|\boldsymbol{\theta})$ for the normal operating data, the $100\beta\%$ confidence bound is defined as a likelihood threshold h that satisfies the following integral (Chen et al., 2006):

$$\int_{\mathbf{z}:p(\mathbf{z}|\boldsymbol{\theta})>h} p(\mathbf{z}|\boldsymbol{\theta})d\mathbf{z} = \beta \tag{3}$$

To determine the confidence bound, we can calculate the likelihood of all the nominal data, and then find h that is less than the likelihood of $100\beta\%$ (e.g. 99%) of the nominal data (Thissen et al., 2005). This approach is applicable to most continuous processes where the number of nominal data points can be up to several thousand; however it may be unreliable when the nominal data is very limited as in batch process monitoring. The estimation of the confidence bound based on limited batches would be very sensitive to the data, and thus a small perturbation in the data would result in very different estimation of the h.

To address this issue, we resort to numerical Monte Carlo simulation to approximate the integral in Eq. (3) (Chen et al., 2006). Specifically we generate N_s random samples, $\{\mathbf{z}^j, j = 1, \ldots, N_s\}$, from $p(\mathbf{z}|\boldsymbol{\theta})$. These samples serve as the "pseudo data" (since the real data is not sufficient) to represent the normal process behavior. Thus the Monte Carlo samples, in conjunction with nominal process data, are used to calculate the confidence bound h. Then a new batch $\mathbf{z}$ is considered to be faulty if $p(\mathbf{z}|\boldsymbol{\theta}) < h$ (or equivalently $-p(\mathbf{z}|\boldsymbol{\theta}) > -h$). The number of Monte Carlo samples required (N_s) to approximate the confidence bounds is dependent on the dimension of $\mathbf{z}$, and it can be determined heuristically.

3. MONITORING OF BATCH PROCESSES

To analyze the three-way batch data ($N \times J \times K$) (N, J and K denote the number of batches, process variables at each time instance, and time steps, respectively), multiway analysis methods have been proposed to unfold the data array into a two-way matrix on which conventional PCA is then performed (Nomikos and MacGregor, 1995b). This study unfolds the data array into a large matrix ($N \times JK$) such that each batch is treated as a "data point". This two-way matrix is then pre-processed to zero mean and unit standard deviation on each column, prior to the application of PCA to extract the scores $\mathbf{t}_n$ and SPE r_n, $n = 1, \ldots, N$. Then a Gaussian mixture model is developed for the joint vector $\mathbf{z}_n = (\mathbf{t}_n^{\mathrm{T}}, \log r_n)^{\mathrm{T}}$, followed by the calculation of confidence bound using Monte Carlo simulation.

3.1 On-line monitoring

In the on-line monitoring stage, it is necessary to project the new batch onto the PCA space to obtain the scores and SPE, and then to calculate the likelihood value under the GMM to identify possible process anomaly. The issue is that, at time step t, the batch measurements are only available up to the current time. It is possible to develop multiple PCA and GMM models at each time step; however this strategy requires excessive computation and computer memory. A more reasonable and widely accepted method is to predict the scores and SPE using the available measurements.

More specifically, let $\bar{\mathbf{x}}_{1:t}$ be the vector of a new batch with available measurements from time step 1 to t. Note $\bar{\mathbf{x}}_{1:t}$ is a vector of order Jt. According to Nomikos and MacGregor (1995b), the least square prediction of the scores is:

$$\bar{\mathbf{t}}_{1:t} = \left(\mathbf{W}_{1:t}^{\mathrm{T}}\mathbf{W}_{1:t}\right)^{-1}\mathbf{W}_{1:t}^{\mathrm{T}}\bar{\mathbf{x}}_{1:t} \tag{4}$$

where $\mathbf{W}_{1:t}$ is the sub-matrix of $\mathbf{W}$ having the rows corresponding to time step 1 to t. In Eq. (4) the matrix to be inverted is well conditioned due to the orthogonality of the loading $\mathbf{W}$. Since the future measurements are not available, the prediction error can only be calculated up to time step t:

$$\bar{\mathbf{e}}_{1:t} = \bar{\mathbf{x}}_{1:t} - \mathbf{W}_{1:t}\bar{\mathbf{t}}_{1:t} \tag{5}$$

The SPE is then obtained as $\bar{\mathbf{e}}_{1:t}^{\mathrm{T}}\bar{\mathbf{e}}_{1:t}$. It was suggested to use the "instantaneous" SPE associated with the latest on-line measurements for process monitoring (Nomikos and MacGregor, 1995b), i.e. $\bar{\mathbf{e}}_t^{\mathrm{T}}\bar{\mathbf{e}}_t$, which is expected to increase the sensitivity of fault detection method. However the instantaneous SPE leads to an excessive number of false alarms in the case study of this paper (see details in Section 4). This phenomenon could be due to the non-Gaussian distribution of the process data. The SPE calculated from Eq. (5), which in a sense is a smoothed version of the instantaneous SPE, may be a more appropriate monitoring metric. We will discuss this issue through the application study in Section 4.

Clearly the predicted scores and SPE from Eqs. (4)(5), based on current available measurements, are not identical to the values that are calculated should the entire batch be available. As a result the predicted scores and SPE may not conform to the *pdf* developed based on the entire duration of nominal batches, even if the process being monitored is running normally. This is a serious issue particularly in the initial stage of a batch processing, when only a small number of measurements are available to calculate the scores and SPE. We follow the standard approach in on-line batch process monitoring (Nomikos and MacGregor, 1995b) to pass each of the nominal batches through the monitoring procedure to collect the predicted scores and SPE at each time step from Eqs. (4)(5), and then apply GMM to estimate the joint *pdf* of these predicted scores and log-SPE at each time step, and to establish the confidence bounds as presented in Section 2. Essentially we propose to replace the confidence bounds for T^2 and SPE in (Nomikos and MacGregor, 1995b), where the process data is assumed to be Gaussian distributed, with more powerful Gaussian mixture model. For on-line monitoring of a new batch, the scores and SPE are calculated from Eqs. (4)(5), and the likelihood value is calculated under the GMM for the current time step. If this likelihood value is lower than the confidence bound, the process under monitoring is considered to be in a faulty condition.

Table 1. Variables used for the monitoring of the semiconductor process.

1	Endpoint A detector	7	RF impedance
2	Chamber pressure	8	TCP tuner
3	RF tuner	9	TCP phase error
4	RF load	10	TCP reflected power
5	RF Phase error	11	TCP Load
6	RF power	12	Vat valve

4. CASE STUDY

The manufacture of semiconductors is introduced as an example of the on-line monitoring of batch processes. This study focuses specifically on an Al-stack etch process performed on the commercially available Lam 9600 plasma etch tool (Wise et al., 1999). Data from 12 process sensors, listed in Table 1, was collected during the wafer processing stage which run for 80 s. A sampling interval of 1 s was used in the analysis. Thus for each batch, the data is of the order (12×80). A series of three experiments, resulting in three distinct data groups, were performed where faults were intentionally introduced by changing specific manipulated variables (TCP power, RF power, pressure, plasma flow rate and Helium chunk pressure). There are 107 normal operating batches and 20 faulty batches. Twenty batches were randomly selected from the normal batches to investigate the effect of false alarms. The remaining 87 nominal batches were used to build the MPCA and GMM models.

4.1 Off-line analysis

According to MPCA, the three-way nominal data array $(N \times J \times K = 87 \times 12 \times 80)$ is unfolded into a large two-way matrix of the order (87×960), which is then mean-centered and scaled to unit standard deviation on each column. Then PCA is applied to the pre-processed data, where two principal components are retained according to the broken-stick rule (Jolliffe, 2002). Considering there are 960 columns in the unfolded matrix, it is not surprising to find that two principal components explain only 45.50% of the total variance (similar results can be found in the literature, e.g. (Nomikos and MacGregor, 1995b)).

Figure 1 gives the scatter plot of the PCA scores corresponding to the first two principal components. It is clear that the nominal data exhibits the characteristic of multiple groups, and it cannot be adequately approximated by a single multivariate Gaussian distribution. As a result, the 99% confidence bound does not capture the region of NOC accurately. In addition to the normal testing batches, 17 out of 20 faulty batches are within the confidence bound, resulting in 17 missing errors. Clearly more complex models are required to represent the nominal behavior of the process.

To develop a GMM for the PCA scores and log-SPE, the appropriate number of mixtures must be selected. According to the BIC, the GMM with three mixture components is utilized for the analysis of the semiconductor process. Once the GMM is developed, the 95% and 99% confidence bounds is calculated using Monte Carlo simulation presented in Section 2.2, where the number of random samples is heuristically determined to be 10,000. Despite the large sample size, the CPU time for the Monte Carlo simulation

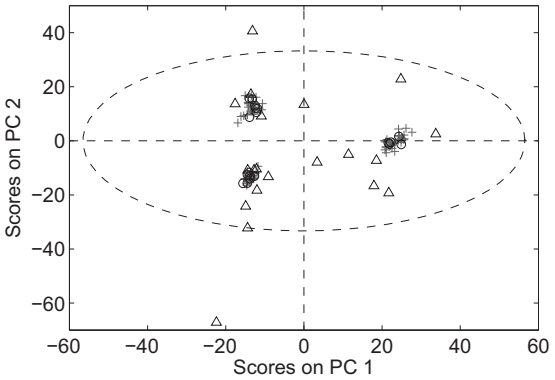

Fig. 1. Bivariate scores plot for principal components 1 and 2 with 99% confidence bound (− − −−): nominal (+), normal (○) and faulty (△).

Table 2. Off-line monitoring results.

	T^2	SPE	T^2 + SPE	GMM
False alarms	0	0	0	0
Missing errors	17	7	7	4

was only 0.03 s (Matlab implementation under Windows XP with Pentium 2.8 GHz CPU). In the literature the 95% is treated as "warning bound" and 99% "action bound". Throughout this section the process is classified as faulty if the 99% confidence bound is violated.

Table 2 summarizes the off-line batch-wise monitoring results for both conventional PCA and the GMM approach. Both methods incur no false alarms in this example. The large number of missing errors from T^2, as depicted in Figure 1, is the result of over-estimation of the confidence bound. It appears that SPE is more sensitive to the fault and it attains seven missing errors. By combining T^2 and SPE in the way that the process is identified as faulty if either metric is exceeded, the number of missing errors is still seven. Table 2 clearly indicates that GMM outperforms the conventional PCA in terms of smaller number of missing errors through the direct estimation of the joint *pdf* of the PCA scores and log-SPE.

4.2 On-line monitoring

The on-line monitoring results are given in Table 3. A normal testing batch is considered to be a false alarm if it is identified as faulty within the batch duration. A missing error means a faulty batch is not detected during the entire duration. Similar to the off-line monitoring, T^2 fails to detect most of the faulty batches because the scores do not conform to a multivariate Gaussian distribution. A comparison between Table 3 (a) and (b) suggests that the instantaneous SPE can detect more faulty batches than the smoothed SPE; however the increased sensitivity is at the cost of dramatically decreased robustness. The number of false alarms for instantaneous SPE is excessively large (13 out of total 20 batches), and thus the smoothed SPE is adopted for the rest of this paper. Table 3 indicates that the GMM approach gives better results than the conventional MPCA in terms of smaller number of false alarms and missing errors.

Table 3. On-line monitoring results. (a) SPE is calculated based on process measurements at current time step (instantaneous SPE); (b) SPE is calculated based on process measurements from batch beginning to current time step (smoothed SPE).

(a)

	T^2	SPE	T^2 + SPE	GMM
False alarms	0	13	13	8
Missing errors	17	2	2	0

(b)

	T^2	SPE	T^2 + SPE	GMM
False alarms	0	3	3	1
Missing errors	17	4	4	2

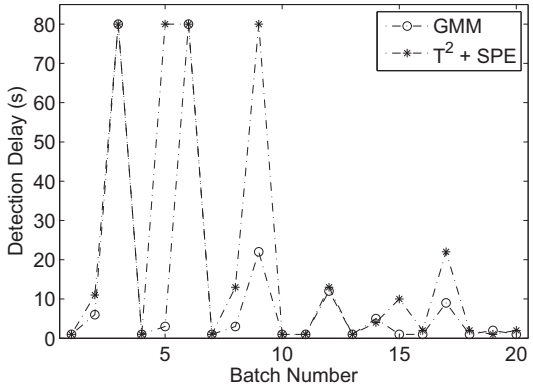

Fig. 2. Delay in the detection of the faulty batches.

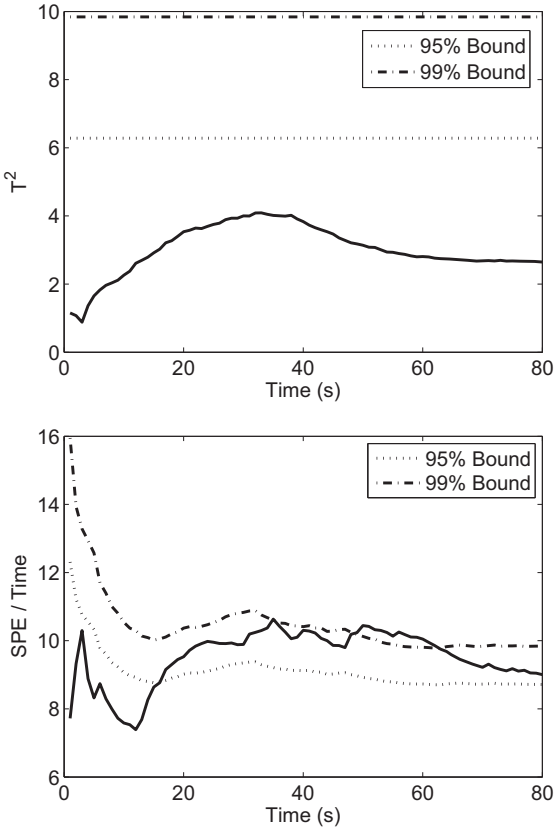

Fig. 3. On-line monitoring of a normal batch using T^2 and SPE.

It should be noted that the number of missing errors in on-line monitoring is not the only index to evaluate the monitoring performance. Of greater practical importance is the time delay between the occurrence and the detection of the fault. Figure 2 illustrates the detection delay of the 20 faulty batches using MPCA and GMM. To facilitate the calculation of average delay for comparison, the detection delay is artificially set to the batch duration (i.e. 80 s) if a faulty batch is not detected by the monitoring system. Essentially this is to assume that the abnormal behavior will be identified in some way (e.g. the presence of off-specified product) when the batch finishes. In practice plant operators are often not able to identify the fault until much later than the end of batch duration. On average, the detection delay for GMM is 11.6 s that is significantly shorter than 20.3 s obtained by the PCA method. Since the process is operating relatively fast, the reduction of delay in 9 s (equivalently 9 time steps) may not be sufficient for the operators to take appropriate actions in practice. Nevertheless if the proposed approach is applied to monitor a slow process, for example batch fermentation that takes several days to complete where data is sampled every half day, a shorter detection delay of 9 time steps would provide significant advantage in terms of reduced operational cost and improved process safety and product quality.

Figure 3 illustrates the on-line monitoring charts of a normal batch, which is false-alarmed by conventional PCA. Since the value of on-line SPE increases with time, we plot SPE divided by time for better illustration in the figure. The T^2 indicates that this batch is under normal operation; however T^2 is not a reliable index for the monitoring of this process as discussed previously. The SPE metric appears to be susceptible to process disturbance; it exceeds the 95% confidence bound from 17 s and is over the 99% bound between 50 s to 60 s, despite the fact that the process is running normally. Figure 4 shows the GMM based monitoring chart, where the negative likelihood value is plotted. The GMM approach correctly recognizes that this batch is within the region of NOC during the whole batch duration.

Figure 5 and 6 give the on-line monitoring charts of a faulty batch (batch 5 as in Figure 2), using conventional PCA and the GMM approach, respectively. Both T^2 and SPE fails to detect this fault. In contrast, the likelihood value from the GMM is becoming outside the 99% confidence bound since time 3 s.

5. CONCLUSIONS

This paper extends the GMM technique for the modelling and on-line performance monitoring of batch manufacturing processes. The handling of the unobserved future batch measurements is discussed for the purpose of on-line monitoring. The GMM provides a probabilistic approach to estimating the *pdf* of the nominal process data and therefore enables more accurate calculation of the

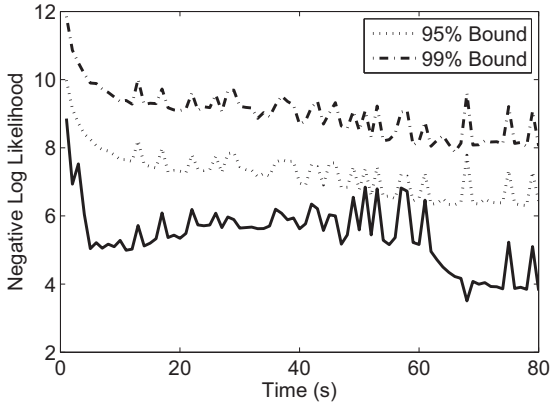

Fig. 4. On-line monitoring of a normal batch using GMM.

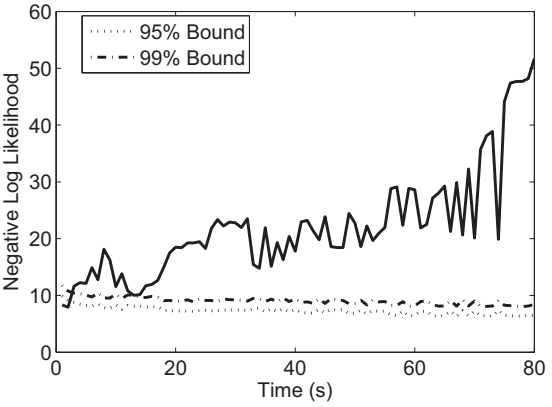

Fig. 6. On-line monitoring of a faulty batch using GMM.

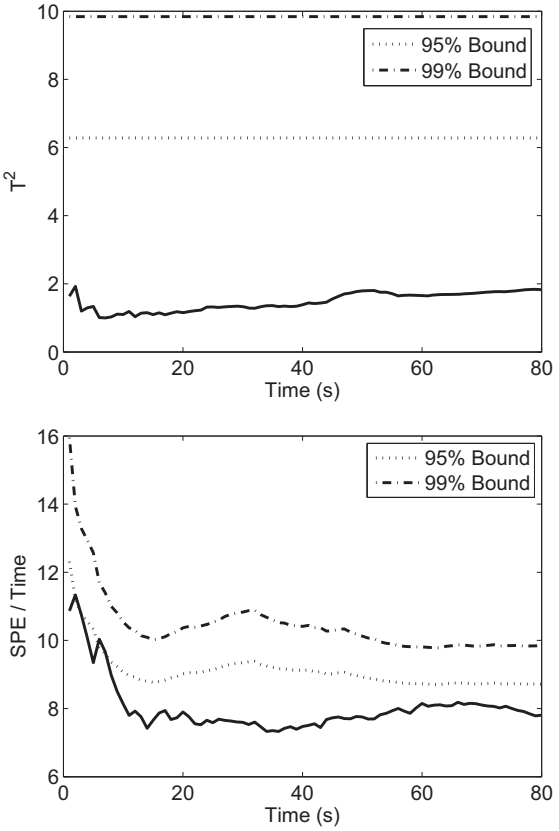

Fig. 5. On-line monitoring of a faulty batch using T^2 and SPE.

confidence bounds. The case study confirms that through accurate modelling of the process historical data collected from NOC, GMM is a promising approach to maintaining a low rate of both false alarms and missing errors in process performance monitoring.

Abstract: It is now common knowledge that as many as 40% of the control loops in most industrial processes have considerable potential for improving control performance by reducing variability. Because of the large number of control loops in an industrial plant, controller performance monitoring is indispensable, but equally important is how to prioritize their maintenance. It is well known that variance reduction in a loop occurs by transferring variability to other variables or loops. The focus of this study is to propose a methodology to prioritize loop maintenance based on the potential improvement of each loop and the variability transfer among them. The central point of this work is the Variability Matrix (VM), an array that shows the impact of performance improvement of a given loop on the whole plant. Based on the VM, a methodology to translate this array into a potential loop economic benefit metric is also introduced. The VM can be quantified in the ideal scenario where plant model and controller are available and also when they are not, thus allowing the application of these ideas in industry. The efficacy of proposed methodology is illustrated by successful application to two case studies.

1. INTRODUCTION

The main requirement for a control system is to ensure process stability and robustness. This is the key reason for the widespread industrial interest in performance assessment methodologies and tools. A typical plant has hundreds or thousands of controllers and most of them have potential for improvement (Bialkowski, 1993). Many good reviews on assessment of control loops are available in the literature (Huang and Shah, 1999, Jelali, 2006). A common problem in controller performance monitoring is how to prioritize loop maintenance. The answer should not only be based on the performance potential, but also on the economic benefits that can be realized in improving the performance of each loop.

The main motivation for improving the performance of the plant is simple: reduction in process variability allows achieving a more profitable operating point, closer to the constraints, as shown in Fig. 1. In scenario I, the process has large variability and therefore the setpoint or the target has to be significantly far away from the economically optimal operating point. If the variability is reduced, due to controller or process improvement (scenario II) the process operating point can be moved to a more profitable setpoint (scenario III).

The literature is relatively sparse in terms of quantification of economic benefits due to improvement of controller performance. Muske (2003) proposed the idea of potential reduction in control loop variability. The economic benefit is quantified based on the shift in the mean operation toward a product specification or process constraint. The variance reduction can be based on a fixed or user-specified benchmark, e.g. minimum variance benchmark or a desired

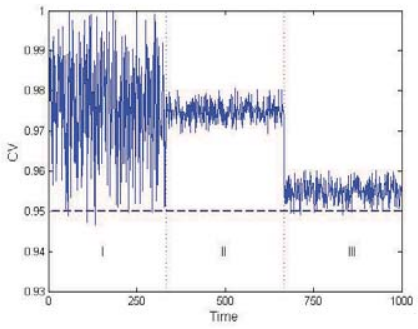

Fig. 1: Variability reduction impact: (I) normal operating variability (II) variability reduction and (III) operating point shift.

rise time or settling time benchmark. Craig and Henning (2000) proposed another methodology to quantify the economic benefit of Advanced Process Control (APC) projects. The authors mention that the whole part of the benefits come from the steady-state optimization. They assume that the variance of the products can be reduced by 35% to 50%. Mascio and Barton (2001) proposed a methodology to quantify the control quality in economic terms based on the Taguchi Framework.

All available methodologies agree that reduction in variability means shifting the operating point to a more profitable point. The main drawback is that they consider each loop as an isolated case, i.e. if performance of one loop is improved then the whole plant will not suffer its effect.

All modern industrial plants have significant interaction among loops due to tighter heat integration. Because of this,

one cannot assume that the variance reduction in one loop will occur without impacting other loops adversely. Typically, variability is transferred from loops where it should be reduced to loops that have the room or the buffer to accommodate large fluctuations (e.g. level loops). In many cases, if one variable has its variability reduced and its operating point shifted, then it is likely that other interacting or complementary loops will have their variability increased, shifting the operating point away from the constraints. This implies that "part of the profit" realized by variability reduction in a given loop "will be offset" by the loops where the variability increases. This is why a control loop should not be considered in isolation and the potential economic benefit should be computed by analyzing the whole plant and not only a specific loop. The common idea that the improvement of a given controller performance will increase the performance of the whole plant is not always true. Sometimes in an interacting system, the coupling between the channels can help or hinder overall performance. For example, decrease in the variability of a given controller can also reduce the variability in other loops in which case, one can say that the interaction helps. In other cases, the interaction may affect performance of associated loops adversely.

The main contribution of this work is the introduction of the notion of the Variability Matrix (VM). This array shows how the variability will transfer between the loops and the impact of one specific loop on the variances of all other interacting or complementary loops. The potential economic benefit of each loop can be quantified based on VM.

This paper is structured as follows: section 2 introduces the concept of Variability Matrix. In section 3, practical issues in computing the VM are discussed. The methodology to quantify the economic benefit of each control loop and prioritize loop maintenance is shown in section 4. The complete methodology is illustrated by successful application on two case studies (section 5). The paper ends with concluding remarks.

2. VARIABILITY MATRIX: CONCEPTS AND DEFINITION

2.1 Preliminary Definitions

To quantify the economic impact, it is interesting to consider the classification of control loops into the following two categories:

Main Loops: Loops that directly control the products specification. Their performance improvement affects the product variability, which can be directly translated into profitability.

Auxiliary Loops: Loops that do not directly control product quality, but can indirectly affect the product variability.

2.2 Variability Matrix Structure

The structure of the variability matrix consists of the following:

Rows: The rows show the influence of each loop on the same final product. The number of rows is the same as the products or the number of main loops.

Columns: Shows the influence of a specific loop on all other loops that may impact or influence the specification of the final product. The number of columns is the same as the number of control loops implemented in the plant. The first columns correspond to the main loops and the adjacent set of columns corresponds to the auxiliary loops as shown in Figure 2.

		Main Loops				Auxiliary Loops		
		Mn_1	Mn_2	…	Mn_m	Aux_1	⋯	Aux_{l-m}
Main	Mn_1	$VM_{1,1}$	$VM_{1,2}$	…	$VM_{1,m}$	$VM_{1,m+1}$	…	$VM_{1,l}$
	Mn_2	$VM_{2,1}$	$VM_{2,2}$	…	$VM_{2,m}$	$VM_{2,m+1}$	…	$VM_{2,l}$
	⋮	⋮	⋮	…	⋮	⋮	…	⋮
	Mn_m	$VM_{m,1}$	$VM_{m,2}$	…	$VM_{m,m}$	$VM_{m,m+1}$	…	$VM_{m,l}$

Fig. 2: Schematic representation of Variability Matrix

In Fig. 2 Mn_i is the main loop i and Aux_j is the auxiliary loop j. The total number of loops in the plant is l and it has m main loops. For example, column 1 (Mn_1) shows the impact of variability reduction in main controller 1 on all other main loops. Row 1 shows the impact on the variability of Mn_1 when the performance of all other loops is changed.

2.3 VM Computation

This section discusses the methodology for computing each element *VM(i,j)* of the Variability Matrix. In the first scenario, the following assumptions are taken: (I) the plant model (G) is available; (II) the controller model (C) is also available; and (III) the controlled variables (y) and control outputs (u) are available. For the sake of simplicity, we consider that the setpoint is fixed and set to zero.

Based on the previous assumptions, the procedure to quantify the VM is described below:

1. Read process data y_j ($j = 1…l$) and u_j ($j = 1…l$) with all loops closed (with actual performance);
2. Select main and auxiliary loops;
3. Compute the actual variance for each main loop ($\text{var}_{\text{act,i}}$, $i = 1…m$);
4. For each loop j ($j = 1…l$)
    1. Calculate the best performance achievable (see section 3.2) for loop j;
    2. Apply the controller;
    3. Calculate the new variance for each main loop i ($var_{best,i,j}$, $i = 1…m$)
    4. Compute the elements of VM j^{th} column using eq. 1.

$$VM(i,j) = \frac{\text{var}_{act,i} - \text{var}_{best,i,j}}{\text{var}_{act,i}} \quad (1)$$

This structure for VM elements was chosen because for two main reasons: 1) it provides a direct measure of the

variability improvement potential for each loop; and 2) it is dimensionless, a fact that allows the comparison of the impact of two or more loops in the plant. For example, consider the VM of:

$$\begin{bmatrix} 0.3 & 0 & -1.2 \\ -0.7 & 0.9 & -1.5 \end{bmatrix} \quad (2)$$

Initially, we can verify that this plant has 2 main loops and one auxiliary loop. From this VM, by examining column 1, we can conclude that: if the performance of main controller 1 is improved, its variance will decrease 30%; however, it has a negative and strong impact on another loop: its variance will increase by 70%. Is this healthy for the process? Clearly the answer to this question depends on the economic impact of each main loop. In column 2, the main loop 2 has potential reduction in variability of 90%. This controller has no influence on the main loop 1 variance; furthermore improving the performance of the auxiliary loop (3rd column) will lead to variability increase in both main loops.

In complement with the VM, the concept of the complementary VM arises (CVM). It is not necessary for all controllers to have fast performance, many loops have to play the role of accommodating or buffering disturbances. Based on this assumption, we define the Complementary Variability Matrix (*CVM*). The values are computed with actual loop variance ($var_{act,i}$) and the variance of the loop with the worst performance acceptable ($var_{wor,i,j}$). The structure is the same as shown before, and the elements are computed as follows:

$$CVM(i,j) = \frac{\text{var}_{act,i} - \text{var}_{wor,i,j}}{\text{var}_{act,i}} \quad (3)$$

The same procedure as considered earlier can be used to evaluate the Complementary Variability Matrix (*CVM*). Only step 4.1 is replaced by the slowest accepted performance (see Smith, 2002) and the worst accepted performance (var_{wor}) should be quantified.

The proposed computational steps may not be easily applicable in an industrial setting, because the required information (controller and process model) is generally unavailable. The algorithm to compute VM where the controller and plant model are not available is shown in section 3.

2.4 VM Dependence of the System Parameters

From a preliminary inspection, VM seems to be analogous to static the RGA (Skogestad and Postlethwaite, 2005), where only the process static gains have impact in the analysis. However, VM is not only a function of process gains, but also depends on process behavior (dynamics and time delays), disturbance patterns and correlation among the disturbances, controller structure (e.g. PI, PID, MPC, among others), closed loop performance, and best performance achievable. The VM values are specific for each process: even two systems where the models and controllers are the same can have a completely different VM, because of the disturbance pattern.

2.5 Some Peculiar Behaviour

Intuitively, the diagonal elements of the VM should have a positive sign and the off-diagonal elements negative sign, i.e.: improving the performance of a given controller will reduce its variability; and transfer variability to the other loops, increasing their variability. However, this may not always be the case:

Proposition 1*: Diagonal elements of VM can have negative sign, i.e. the performance improvement of a given controller can increase its variability.*

Proof: Consider a SISO system with linear PI type controller that is affected by an output disturbance (*d*). Suppose that the disturbance is a pure white-noise random signal. Considering that *d* is random, it is not possible to predict its future values based on the past values. In this case increasing loop gains will likely increase *y* variability. In this case, the diagonal VM element will have a negative sign.

Proposition 2*: Off-diagonal elements can have positive sign, i.e. the performance increase of a given controller can also decrease the variability in other interacting loops. Typically this happens when interactions help in accommodating disturbances.*

Proof: Consider the triangular system shown in Fig. 3.

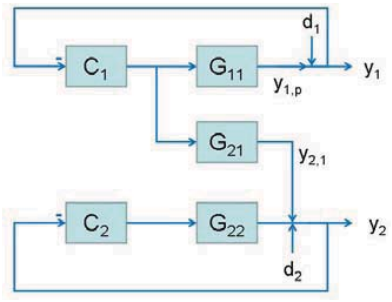

Fig. 3: Schematic representation of the triangular system

Consider the case when C_1 reduces the output variability when it is compared with the open loop case (i.e. $\sigma^2(d_1 + y_{1,p}) < \sigma^2(d_1)$), and upon improving C_1 performance, y_1 will also decrease its variability.

$$\sigma^2(d_1) > \sigma^2(d_1 + y_{1,p1}) > \sigma^2(d_1 + y_{1,p2}) \quad (4)$$

Where p_1 and p_2 are the controllers performance and $p_2 > p_1$ (i.e. closed loop performance in the second scenario (p_2) is faster than p_1). Considering the case when:

$$\begin{aligned} G_{11} &= G_{21} \\ d_1 &= d_2 \end{aligned} \quad (5)$$

Then $y_{1,p} = y_{2,1}$. From the loop 2 and $y_{2,1}$, it is clear that improving the performance of loop 1, will also have the effect of reducing the variability of y_2. This will occur as $y_{2,1}$ will help offset the effect of d_2 (in the same way as $y_{1,p}$ offsets d_1). Thus leads to:

$$\sigma^2(d_2) > \sigma^2(d_2 + y_{2,1,p1}) > \sigma^2(d_2 + y_{2,1,p2}). \quad (6)$$

3. PRACTICAL ISSUES IN COMPUTING VM

3.1 Computing the VM

This section presents the methodology to evaluate VM in industrial settings where process and/or controller models may not be available.

The first analyzed scenario is where a Model Predictive Controller is implemented. In this case, the controller model is not available, because most industrial MPCs are "closed box solutions". However, the plant model is available. In this case, setpoint variations in MPC controllers are quite common, because of the optimization layer. In this scenario, the controller model can be extracted (identified) using the *Asymptotic Method* (Zhu, 1998) or *Subspace Identification* (Overschee and Moor, 1996).

A second scenario contemplates the case where only low order controllers (PI and PID) are present and setpoint activity is available in all loops. For this case, the following steps are contemplated: (I) identify the controller order and parameters (*C*) using *structured target factor analysis* (STFA) (Fotopoulos et al., 1994); (II) estimate the time delay (Tuch et al., 1994); (III) identify the process model (*G*) using *Subspace Identification* (Overschee and Moor, 1996); (IV) identify the disturbance model (*d*) using *Subspace Identification*; (V) with *G*, *C*, and *d* available, the VM can be estimated applying the methodology shown in section 2.3.

Based on our limited experience, we can affirm that the VM is not extremely dependent on the accuracy of the plant and controller. Even for a visible mismatch in the plant model, the obtained results are fairly good, comparing with the case where accurate controller and plant models are available.

3.2 Best and Worst Controller Performances

A natural question that arises is: how can the best and worst performance be computed for a given system? The answer clearly depends on the controller that is implemented on the process.

For MPC controllers, the best achievable performance can be computed using the methodology proposed by Trierweiler and Farina (2003). If the desired performance is attainable, this methodology provides the tuning parameters for the chosen performance. Otherwise, if it's not achievable, the best achievable performance is quantified. In this work, we assume that the "best performance" is based on the open and closed loop rise time ratio, and a convenient value for this ratio is 3.

For low order (PI and PID) decentralized controllers, the best performance can be estimated using the methodology proposed by Faccin and Trierweiler (2004). The worst performance can be evaluated based on the methodology to tune buffer tank controllers (Smith, 2002).

4. QUANTIFYING THE ECONOMIC BENEFITS BASED ON VM

The economic benefits of improving control performance of each loop can be computed in two ways. The first method considers that the best performance can be achieved. In this case the VM can be used as follows. We represent the column *j* of the VM as VM_j. The economic benefit can be easily quantified using the relationship:

$$CLEB = D \cdot VM \quad (7)$$

where *CLEB* is the *Control Loop Economic Benefit* array. It has the same number of elements as the number of loops in the plant (*l*).

$$CLEB = \begin{bmatrix} D \cdot VM_1 & D \cdot VM_2 & \cdots & D \cdot VM_l \end{bmatrix} \quad (8)$$

Where *D* is the array that translates variability reduction into $ per unit time.

$$D = \begin{bmatrix} D_1 & D_2 & \cdots & D_m \end{bmatrix} \quad (9)$$

where *m* is the number of main loops in the plant. This array can be quantified as a function of plant throughput increase, utilities reduction, etc. This value can be provided by the commercial department of the plant or the optimization layer weights used in MPC design.

However, as previously mentioned, not all controllers need to have high or tight tuning and the economic benefit, considering the worst performance of each one, can also be quantified. This vector is defined as *Complementary Control Loop Economic Benefit:*

$$CCLEB = \begin{bmatrix} D \cdot CVM_1 & D \cdot CVM_2 & \cdots & D \cdot CVM_l \end{bmatrix} \quad (10)$$

For example, suppose a plant where the VM and D are:

$$VM = \begin{bmatrix} 0.7 & -0.6 \\ -0.3 & 0.8 \end{bmatrix} \quad (11)$$

$$D = [100 \quad 50] \quad (12)$$

the *CLEB* is then be computed as:

$$CLEB = \begin{bmatrix} 55 & -20 \end{bmatrix} \quad (13)$$

The CLEB indicates that improvement in loop 1 performance means increase the plant profitability. However, the opposite behavior is expected when loop 2 performance is improved.

5. CASE STUDIES

5.1 Wood and Berry Distillation Column Model

The pilot-scale distillation column proposed by Wood and Berry (1973) is the first case study. The plant model is given by:

$$\begin{bmatrix} x_D(s) \\ x_B(s) \end{bmatrix} = \begin{bmatrix} \frac{12.8}{16.7s+1}e^{-1s} & \frac{-18.9}{21s+1}e^{-3s} \\ \frac{6.6}{10.9s+1}e^{-7s} & \frac{-19.4}{14.4s+1}e^{-3s} \end{bmatrix} \begin{bmatrix} R(s) \\ S(s) \end{bmatrix} \quad (14)$$

where x_D and x_B are the overhead and bottom products composition, and R and S are the reflux and steam flow rates, respectively. The time constants and time delays are expressed in minutes.

Two decentralized PI type controllers were applied in this case study. The disturbance was generated by passing a random signal through a first order transfer function with unitary gain and 50 minute time constant. The VM analysis of this case study is presented next under 3 scenarios: 1) controller and plant models are assumed to be available; 2) only plant model is available; 3) neither the plant model nor controller models are available. However setpoint activity is assumed. This serves as good excitation for closed loop identification. For case 3), details of closed-loop based subspace identification method are not included here due to lack of space. The PI controllers were tuned to have a performance where the desired closed loop rise time is twice faster the open loop case. We consider here the best achievable performance when the rise time is 6 times faster than open loop.

The *D* vector for this case is hypothetically set as:

$$D = \begin{bmatrix} 100 & 30 \end{bmatrix} \tag{15}$$

In the first scenario, the controller and plant model were available. The VM was computed using the methodology shown in section 2.3.

$$VM = \begin{bmatrix} 0.57 & -0.17 \\ -0.18 & 0.41 \end{bmatrix} \tag{16}$$

The *CLEB* for this case is:

$$CLEB = \begin{bmatrix} 52 & -5 \end{bmatrix} \tag{17}$$

Based on *CLEB*, loop 1 should have its performance improved (top composition), increasing the plant profitability. Loop 2 shows the opposite behavior, improvement in its performance is likely to result in decreased plant profitability.

In the second scenario, the controller model is assumed to be unavailable. Initially, using a scenario where two setpoint variations in each variable are available, the controller model was identified (see section 3.1). In this scenario, the VM was estimated to be:

$$VM = \begin{bmatrix} 0.60 & -0.19 \\ -0.19 & 0.46 \end{bmatrix} \tag{18}$$

Notice that the estimated VM closely matches the true VM shown in (16). In the third scenario, both controller and plant model were identified using closed loop data. The estimated VM for this scenario is:

$$VM = \begin{bmatrix} 0.60 & -0.19 \\ -0.18 & 0.46 \end{bmatrix} \tag{19}$$

Even for this case, where controller and plant model were first identified using subspace identification, a good estimate of VM was obtained.

5.2 Shell Benchmark Process

The Shell Control Problem benchmark was proposed by Prett and Morari (1987). The system is characterized by the high interaction among channels and large time delays.

It involves one heavy oil fractionator. It has three product draws, three side circulating loops and a gaseous feed stream. The system consists of seven measured outputs, three manipulated inputs and two unmeasured disturbances. In this case study, we will reduce the problem to a 3 input and 3 output case. The three controlled variables are: top end point (*y1*); side endpoint (*y2*); bottom reflux temperature (*y3*). The manipulated variables are: top draw (*u1*); side draw (*u2*); bottom reflux duty (*u3*). The system has also two disturbances: upper reflux (*d1*); intermediate reflux (*d2*). The process output can be written as:

$$y = Gu + G_d d \tag{20}$$

Where G is the plant model

$$G = \begin{bmatrix} \frac{4.05}{50s+1}e^{-27s} & \frac{1.77}{60s+1}e^{-28s} & \frac{5.88}{50s+1}e^{-27s} \\ \frac{5.39}{50s+1}e^{-18s} & \frac{5.72}{60s+1}e^{-14s} & \frac{6.9}{50s+1}e^{-15s} \\ \frac{4.38}{33s+1}e^{-20s} & \frac{4.42}{44s+1}e^{-22s} & \frac{7.2}{19s+1} \end{bmatrix} \tag{21}$$

and G_d is the disturbance model:

$$Gd = \begin{bmatrix} \frac{1.2}{45s+1}e^{-27s} & \frac{1.44}{40s+1}e^{-27s} \\ \frac{1.52}{25s+1}e^{-15s} & \frac{1.83}{20s+1}e^{-15s} \\ \frac{1.14}{27s+1} & \frac{1.26}{32s+1} \end{bmatrix} \tag{22}$$

Where the time constant and time delays are reported in minutes. The MPC from Matlab® (MPC toolbox V. 2.2.2) was applied in this study. The analysis for this case is reported under two scenarios: (I) where controller and plant models are available and (II) when both are unavailable.

The *D* vector for this case is (hypothetically set):

$$D = \begin{bmatrix} 100 & 50 & 20 \end{bmatrix} \tag{23}$$

The actual performance in this case was computed based on closed loop rise time when it is set equal to the open loop case. The desired performance for each channel is three times faster than open loop. The VM for this scenario is:

$$VM = \begin{bmatrix} -0.39 & 0.10 & 0.26 \\ -0.12 & -0.16 & 0.28 \\ -0.24 & -0.60 & 0.32 \end{bmatrix} \tag{24}$$

The VM shows that improving the performance of controller 1 and 2 will result in an increase in the variance of all main loops. Retuning loop 1 means increase its variance by 39% and increase in the variances of loops 2 and 3 by 12% and 24% respectively. On the other hand, improvement of loop 3 performance means decrease in its variance by 32% and

corresponding reductions in variances in loop 1 and loop 2 by 26% and 28%, respectively. The *CLEB* for this case is:

$$CLEB = \begin{bmatrix} -50 & -10 & 46 \end{bmatrix} \quad (25)$$

The answer to improving plant profitability lies not only in VM but also the CVM, i.e. some controllers should not have their performance improved, but rather detuned. The CVM for this case is:

$$CVM = \begin{bmatrix} 0.15 & 0.13 & -0.12 \\ 0 & 0.28 & -0.13 \\ -0.30 & -0.29 & -0.44 \end{bmatrix} \quad (26)$$

The *CCLEB* for this case is:

$$CCLEB = \begin{bmatrix} 9 & 21 & -27 \end{bmatrix} \quad (27)$$

The maintenance list for this hypothetical case indicates that the most important controller to maintain or improve performance is loop 3. The second loop in the maintenance list should be loop 2 followed by loop 1.

In the second scenario, both controller and plant are assumed to be unavailable, only setpoint activity is assumed. In this case, the VM is estimated using the procedure shown in section 3.1. The estimated VM is:

$$VM = \begin{bmatrix} -0.42 & 0.06 & 0.26 \\ -0.15 & -0.27 & 0.28 \\ -0.32 & -0.74 & 0.32 \end{bmatrix} \quad (28)$$

Both plant model and controller are identified using subspace identification from Matlab® (system identification toolbox version 6.1.1, function n4sid). Both models have 9 states.

Eq. 28 shows that the estimated VM compared with the original (eq. 24) is fairly good. We attribute the success of this fairly accurate VM estimation to the direct closed loop subspace identification method under reasonable level of setpoint activity.

6. CONCLUDING REMARKS

The main conclusions of the proposed work can be summarized as:

- industrial plants have many loops with considerable potential for performance improvement and therefore a methodology to prioritize loop maintenance is required;
- the concept of Variability Matrix was introduced in this work and has been shown to highlight the potential improvement in each loop and its impact on the whole plant;
- the methodologies to compute VM where neither the controller nor plant model are available has also been presented; in this scenario Subspace Identification can be used; even for this case the methodology has been shown to yield very good results based on closed loop identification;
- the proposed methodology was applied to two case studies providing good results;
- the proposed scenarios where the VM can be computed allows the application of these ideas in an industrial setting.

ACKNOWLEDGMENT

The first two authors wish to thank CAPES, PETROBRAS and FINEP for supporting this work.

Abstract: Bias updating is a widespread adaptive procedure to allow inference models to pursue time variant features of a real world process. The aim of this work is to clarify the statistical consequences of bias updating to soft sensor estimates as well to point up the need of careful analysis of the effect of unmeasured disturbances on the true values of the variable of interest. It is shown that bias updated inferences are unbiased estimates of the true value but yields estimates whose variance are 100% larger than the ones obtained with no use of bias updating. It is suggested the use of a weighting factor to bias updating in order to balance statistical benefits and penalties. A case study of a soft sensor for weathering of LPG in oil refinery exemplifies the concepts discussed.

Keywords: Soft sensor, Bias Updating, Error Analysis, Statistics.

1. INTRODUCTION

The main goal of an industry is to operate as close as possible to the point where profit is maximum. It means that there should be no off-spec product and the lowest degree of product quality give-away should be achieved. Maximum profit is also related to the fact that the set of manipulated variables leads to lower costs by minimizing use of heat, steam, electricity, water etc..

It may be hard if not impossible to accomplish this goal. Real processes are likely to be nonlinear and highly integrated causing modeling and identification prone to errors. In addition, long term operation makes processes more susceptible to hardware upsets (corrosion, fouling, mechanical failures) and to experience environmental disturbances as well qualitative/quantitative changes in physical-chemical properties of feed streams.

Accurate knowledge of process actual model structure and parameters is essential if one intends to predict future states (for control and optimizing) or to diagnose safety risks. Unfortunately many relevant process variables are not available as frequently as desirable or even not available at all. For example, it is very common that physical-chemical properties related to quality control are measured by laboratory tests performed with a very low frequency when compared to process variables acquired by online sensors. Such process with differing sample rates for measured variables are known as multirate process (Ragahavan *et al.*, 2006).

Most of times the long period of time to be awaited before new information about low frequency variables become available is unacceptable. It is necessary to make use of some inferential knowledge based on high frequency information about the process. If a sufficiently accurate model is available, the variable of interest can be estimated from high frequency process measurements $\mathbf{x}$ as long as model structure and parameters $\boldsymbol{\alpha}$ are known:

$$\hat{y} = f(\mathbf{x}, \boldsymbol{\alpha}) + bias \tag{1}$$

Every time a new measurement of the *true* value of y is available, an adaptive procedure can be used to adapt the inferential model. The only parameter updated through this one parameter correction is the independent coefficient in (1): $bias = y - f(\mathbf{x}, \boldsymbol{\alpha})$. This simple strategy is very common in industry as well in literature for optimizing purposes (Mercangöz and Doyle 2008; Jesus 2004; Singh 1997) or for soft sensors inferences (Sharmin *et al.* 2006; Mu *et al.* 2006; Tran *et al*. 2005).

Some questions should be posed regarding the use of inferences as (1) for anyone who has to cope with a multirate process:

- What is the best model structure $f(\mathbf{x},\boldsymbol{\alpha})$?
- How often should bias be updated?
- How are inference errors affected by bias updating?
- What are the effects of unmeasured disturbances on inference errors?

Those questions usually receive unequal importance. A lot of effort has been spent along time to answer the first question. Models have progressively become more complex by using the mathematical weaponry of process modeling

(multivariable regression, PCA, neural networks, fuzzy logic). The second question is often answered based on practical matters as availability of laboratory technicians. The last two questions are normally disregarded in spite of their huge consequences on the estimates.

The aim of this work is to pay attention to those usually forgotten questions by remembering the mathematical considerations implicit in models as (1) and answering, from a statistical point of view, what the benefits and penalties of bias updating are.

2. MATHEMATICAL FOUNDATIONS OF BIAS UPDATING

For a steady state system, the generic mathematical relationship linking the output variable, y, and all pertinent process variables, **w**, required by fundamental physical laws, may be expressed as:

$$F(y, \mathbf{w}, \mathbf{c}) = 0 \tag{2}$$

where **w** represents the NW necessary variables to perfectly predict the unknown behavior of y given the NC constants in the vector of parameters, **c**.

Two practical reasons explain why it is unlike that any real model would incorporate the whole set of NW necessary variables. The first one is the fact that NW may be large and would conflict with science´s parsimony principle. In this sense, a less complete description would be acceptable in a trade-off for simplicity under a certain allowable tolerance. The other reason is that several of the NW variables either are not measured or are not considered relevant by the scientist due to a methodological error.

Taking these reasons under consideration one can split **w** into the subsets **x** and **z**. The first subset contains the NX measured variables that were chosen as relevant for the model. The second subset contains the remaining NZ = NW-NX variables. It contains measured and unmeasured variables that should be part of a perfect model but were set apart. The complete description of the system behavior is then expressed as:

$$F(y, \mathbf{x}, \mathbf{z}, \mathbf{c}) = 0 \tag{3}$$

In the process of justifying the possibility of a correction as proposed in (1) it is required that (3) be partially separable with respect to addition at least with respect to y. It requires that $(1/F)\partial \exp(F)/\partial y$ depends only on y (Viazminsky 2008). If this condition is satisfied one can express (3) as:

$$g(y) = F_1(\mathbf{x}, \mathbf{z}, \mathbf{c}_1) \tag{4}$$

Additionally, if the inverse function g^{-1} exists, then:

$$y = g^{-1}(F_1(\mathbf{x}, \mathbf{z}, \mathbf{c}_1)) = F_2(\mathbf{x}, \mathbf{z}, \mathbf{c}_2) \tag{5}$$

Physical knowledge or empirical insight may lead to an attempt to predict *y* based on measurements **x** and parameters $\boldsymbol{\alpha}$ by means of a model $f(\mathbf{x}, \boldsymbol{\alpha})$. If **z** is an empty set and the whole influence of **x** on *y* is taken into account by $f(\mathbf{x}, \boldsymbol{\alpha})$ we have a perfect model. Otherwise one should expect a relationship as (6), where $F_3(\mathbf{x}, \mathbf{z}, \mathbf{c}_3)$ plays the role of bias as in (1). It should be noticed that (6) is derived from (5) if $F_3(\mathbf{x}, \mathbf{z}, \mathbf{c}_3)$ is a separable function with respect to the set **z**.

$$y = f(\mathbf{x}, \boldsymbol{\alpha}) + F_3(\mathbf{x}, \mathbf{z}, \mathbf{c}_3) \tag{6}$$

The model built by the experimenter is $f(\mathbf{x}, \boldsymbol{\alpha})$. The invisible part of the true model is $F_3(\mathbf{x}, \mathbf{z}, \mathbf{c}_3)$. This term is captured by the bias term in a very common pragmatic approach assuming the form (1).

Inference structure (6) is very attractive but it is valid only if the assumptions that allowed disregarding more generalized expressions (3)-(5) are true. If not, there will be no guarantee that successive inferred values will express the true values y even if no further disturbances alter the values of the set **z**. This can be seen by comparing two simple models. One represents a model as expressed in (5) (type A model) and the other one represents the less generic model expressed in (6) (type B model), for instance:

type A true model: $y = (x+z)/x$

type B true model: $y = x + z$

It should be noticed that the type B true model in this example shows no dependence of F_3 on x. This class of true models yields the best possible performance for an adaptive experimental model as (1).

Assuming that: 1) experiments to identify the inference $f(x, \alpha)$ were carried out under controlled conditions in order to keep z at a constant value z_0 in both cases and 2) perfect model identification led to inferences with the same mathematical structure than true models:

type A inferred model: $\tilde{y} = (x+ z_0)/x$

type B inferred model: $\tilde{y} = x + z_0$

If the inferred models were parameterized by means of proper statistical criticism both inferred models will adequately represent the behavior of the variable of interest. However, as time passes, it is possible that z assumes values different of the one kept controlled along identification phase. So, if z assumes the value z_1 and $x=x_1$ at the moment of correction in both cases, according to the bias updating routine:

type A true value: $y_1 = (x_1+z_1)/ x_1$,

type A inferred value: $\tilde{y}_1 = (x_1 + z_0)/ x_1$

$\Rightarrow$ bias = $y_1 - \tilde{y}_1 = (z_1 - z_0)/x_1$

corrected inference: $\hat{y}_1 = (x + z_0)/x + ((z_1 - z_0)/x_1)$

type B true value: $y_1 = x_1 + z_1$,

type B inferred value: $\tilde{y}_1 = x_1 + z_0$

$\Rightarrow$ bias = $y_1 - \tilde{y}_1 = z_1 - z_0$, corrected inference: $\hat{y}_1 = x + (z_1 - z_0)$

It is clear that, after bias correction, inferences derived from type B models will produce results as close to the truth as they were before the change of z value as long as this variable is kept constant from this change on. On the other hand, inferences derived from type A models will not behave this way because accuracy of the corrected inference will be affected not only by further changes of z value but also by additional changes in the x value because the nonlinear behavior is not captured by a single point correction.

3. BIAS UPDATING PROCEDURE

In order to describe the behavior of predictions of the value *y* along time it is interesting to write inference model to allow time course to be taken into account:

$$\tilde{\mathbf{y}} = f(\mathbf{X}, \boldsymbol{\alpha}), \quad \mathbf{X} = \begin{bmatrix} \mathbf{x_1} \\ \mathbf{x_2} \\ \dots \\ \mathbf{x_{NS}} \end{bmatrix}, \quad \mathbf{x_i} = \begin{bmatrix} x_{i1} & x_{i2} & x_{i3} & \dots & x_{i,NX} \end{bmatrix},$$

$$\tilde{\mathbf{y}} = \begin{bmatrix} \tilde{y}_1 \\ \tilde{y}_2 \\ \dots \\ \tilde{y}_{NS} \end{bmatrix} \tag{7}$$

where NS is the number of time samples of the process variable signals.

Corrected values of *y* along time are obtained from bias updating according to:

$$\hat{\mathbf{y}} = \tilde{\mathbf{y}} + \mathbf{bias} \tag{8}$$

where the array of time values of bias is built according to:

$bias_1 = 0$

$bias_k = \left(y_k^m - \tilde{y}_k\right) s_k + (1 - s_k) bias_{k-1}$

leading to:

$$\mathbf{bias} = \begin{bmatrix} 0 \\ \left(y_2^m - y_2\right) s_2 + (1 - s_2) bias_1 \\ \left(y_3^m - y_3\right) s_3 + (1 - s_3) bias_2 \\ \dots \\ \left(y_{NS}^m - y_{NS}\right) s_{NS} + (1 - s_{NS}) bias_{NS-1} \end{bmatrix} \tag{9}$$

Vector $\mathbf{y^m}$ contains measurements of the true values **y** sampled with period at a lower rate, T_{meas}, than primary variables of the model. Vector **s** is a binary set that indicates when true values $\hat{y}$ are available:

$$\mathbf{y^m} = \left[[0]_{1x(Tmeas-1)} \; y_{Tmeas} \; [0]_{1x(Tmeas-1)} \; y_{2Tmeas} \dots \right]^T$$

$$\mathbf{s} = \left[[0]_{1x(Tmeas-1)} \; 1 \; [0]_{1x(Tmeas-1)} \; 1 \dots \right]^T$$

4. STATISTICAL IMPACT OF BIAS UPDATING

Although equations (7-9) indicate the *modus operandi* of inference correction, it is not clear how our expectation about error values is affected. Since corrections are made at a low frequency the duration of their benefits will be affected by the probability of occurrence of new disturbances before a new gold standard measurement is ready, thus making possible another correction. A reasonable question would be: what benefits are obtained with periodic bias updating comparing with no bias correction at all?

In fact, bias updating and no updating schemes are extreme points of a continuous range of possible single point corrections. Considering the weight parameter $\varphi \in \Re$, $\varphi \subset [0\ 1]$, the time values $\bar{\mathbf{y}}$ are a weighted mean of bias corrected values (8) and values from the original inference model (7):

$$\bar{\mathbf{y}} = \varphi \hat{\mathbf{y}} + (1 - \varphi) \tilde{\mathbf{y}} \tag{10}$$

If samples of true values are taken with period T_{meas} the n^{th} element suffers the effects of the last bias updating made at sample $i = \text{int}(n/T_{meas})T_{meas}$, where int(x) retains the integer part of the floating point real number x:

$$\overline{y_n} = \varphi\left(\tilde{y}_n + bias_n\right) + (1 - \varphi)\tilde{y}_n \tag{11}$$

$$\overline{y_n} = \varphi\left(\tilde{y}_n + y_i - \tilde{y}_i\right) + (1 - \varphi)\tilde{y}_n = \tilde{y}_n + \varphi\left(y_i - \tilde{y}_i\right) \tag{12}$$

Inference error at the n^{th} element will be:

$$\varepsilon_n = y_n - \overline{y_n} = y_n - \tilde{y}_n - \varphi y_i + \varphi \tilde{y}_i \quad (13)$$

Since n^{th} and i^{th} elements of the true values come from the same sample space as well n^{th} and i^{th} elements of the inferred values, their statistical moments are the same, i.e., $E[y_n] = E[y_i]$ and $E[\tilde{y}_n] = E[\tilde{y}_i]$. Dropping indexes to simplify notation, it is possible to say that the expected error value is:

$$E[\varepsilon] = (1-\varphi)E[y] + (\varphi - 1)E[\tilde{y}] \quad (14)$$

$$if \begin{cases} \varphi = 1, & E[\varepsilon] = \varepsilon_{\min} = 0 \\ \varphi = 0, & E[\varepsilon] = \varepsilon_{\max} = E[y] - E[\tilde{y}] \end{cases}$$

It can be seen that the bias update scheme expressed in (8) ($\varphi = 1$) guarantees mean error value of zero if length of **y** tends to infinity. If no correction is made ($\varphi = 0$), long term error mean depends on the ability of model $f(\mathbf{X}, \boldsymbol{\alpha})$ to be an unbiased estimate of the true value. It is also possible to investigate the dependence of error variance on the choice of φ. From (13) it is possible to write:

$$\mathrm{var}(\varepsilon_n) = \mathrm{var}(y_n - \tilde{y}_n - \varphi y_i + \varphi \tilde{y}_i) \quad (15)$$

$$\begin{aligned} \mathrm{var}(\varepsilon_n) = {} & \mathrm{var}(y_n) + \mathrm{var}(\tilde{y}_n) + \varphi^2 \mathrm{var}(y_i) + \varphi^2 \mathrm{var}(\tilde{y}_i) \\ & - 2\,\mathrm{cov}(y_n, \tilde{y}_n) + 2\varphi\,\mathrm{cov}(y_n, \tilde{y}_i) - 2\varphi\,\mathrm{cov}(y_i, \tilde{y}_n) \\ & - 2\varphi^2\,\mathrm{cov}(y_i, \tilde{y}_i) \end{aligned} \quad (16)$$

For the same reason explained above $\mathrm{var}(y_n) = \mathrm{var}(y_i)$ and $\mathrm{var}(\tilde{y}_n) = \mathrm{var}(\tilde{y}_i)$, making it more convenient to drop subscripts and simplify (16):

$$\begin{aligned} \mathrm{var}(\varepsilon) = {} & \mathrm{var}(y) + \mathrm{var}(\tilde{y}) + \varphi^2(\mathrm{var}(y) + \mathrm{var}(\tilde{y})) - 2\mathrm{cov}(y, \tilde{y}) \\ & - 2\varphi^2\,\mathrm{cov}(y, \tilde{y}) \end{aligned} \quad (17)$$

At the extreme points of φ:

$$if \begin{cases} \varphi = 1, & \mathrm{var}(\varepsilon) = v\varepsilon_{\max} = 2\,\mathrm{var}(y) + 2\,\mathrm{var}(\tilde{y}) - 4\,\mathrm{cov}(y, \tilde{y}) \\ \varphi = 0, & \mathrm{var}(\varepsilon) = v\varepsilon_{\min} = \mathrm{var}(y) + \mathrm{var}(\tilde{y}) - 2\,\mathrm{cov}(y, \tilde{y}) \end{cases}$$

With respect to the error variance the progressive updating ($\varphi = 1$) doubles the value obtained when no correction is made ($\varphi = 0$). Confronting this result with the expected value of the error one can see that bias updating is associated with an expectation of unbiased mean value of estimates but it also causes a 100% increase in error variance. There would be a choice of φ to cope with these consequences? In order to answer this question it is necessary to create a single objective function that combines both effects.

As an example, a possible choice for such function could be $\psi = E[\varepsilon] + \mathrm{var}(\varepsilon)$, choosing φ that minimizes its value. However this function is too dependent of the problem specificities and units of measurement. In fact even the choice the objective function depends on the problem to be solved and on the needs of the plant personnel in order to fulfill several goals related to the industrial process.

Taking this into consideration, it is suggested a very simple objective function, derived from the previous one. It represents an attempt to equalize the importance of the effects of φ regarding each statistical moment. Such function could assume the normalized form:

$$\psi = E[\varepsilon]_{norm} + \mathrm{var}(\varepsilon)_{norm} \quad (18)$$

where

$$E[\varepsilon]_{norm} = \frac{E[\varepsilon] - \varepsilon_{\min}}{\varepsilon_{\max} - \varepsilon_{\min}} \quad (19)$$

and

$$\mathrm{var}(\varepsilon)_{norm} = \frac{\mathrm{var}(\varepsilon) - v\varepsilon_{\min}}{v\varepsilon_{\max} - v\varepsilon_{\min}} \quad (20)$$

Substituting (19-20) in (18):

$$\begin{aligned} \psi = {} & \frac{(1-\varphi)E[y] + (\varphi - 1)E[\tilde{y}]}{E[\hat{y}] - E[y]} \\ & + \frac{\varphi^2(\mathrm{var}(y) + \mathrm{var}(\tilde{y})) - 2\varphi^2\,\mathrm{cov}(y, \tilde{y})}{\mathrm{var}(y) + \mathrm{var}(\tilde{y}) - 2\,\mathrm{cov}(y, \tilde{y})} \end{aligned} \quad (21)$$

The choice of φ is made in order to minimize ψ and is represented by the solution of:

$$\frac{\partial \psi}{\partial \varphi} = 1 - \varphi - \varphi^2 = 0 \;\Rightarrow\; \varphi = 1/2 \quad (22)$$

It is interesting to see how formalism of (21) and (22) conducts to a common sense value of ½ for the weighting factor in this case.

5. CASE STUDY

In this section it will be shown the statistical features of bias updating in a soft sensor to be implemented in an oil refinery. The process unity at study is a FCC debutanizer showed in figure 1. In order to improve quality control of liquefied petroleum gas (LPG) it is desirable to have online information about the relative amount of molecules with more than four carbon atoms present on LPG stream. A laboratory or field test usually carried out a few times a day measures weathering of LPG, expressed in temperature units, which is correlated to the ratio of heavier molecules.

An empirical mathematical model of LPG weathering based on NX = 3 process variables feeds the model predictive control of the process unity with inferred values along time as in (7).

For the purposes of this work, actual behavior of the unity is represented by data from customized process simulation software. The discrete mathematical space of operating scenarios has its basis formed by the N_{inp} = 4 process simulation input parameters as shown in figure 1.

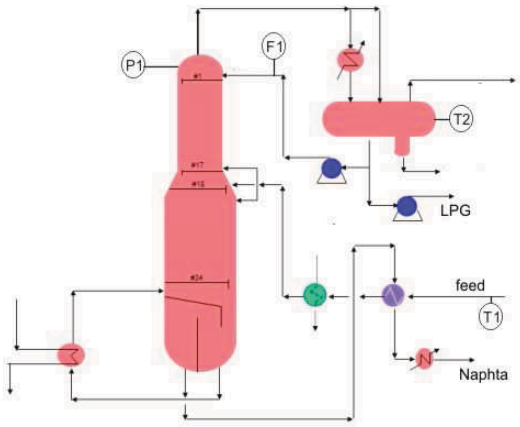

Figure 1 – FCC debutanizer. Process variables used as inputs for the process simulator: P1, F1, T1, T2.

The subregion of operation considered for analysis was the regular mesh **S** (N_{sc} x N_{inp}) of equally spaced points around nominal condition of operation. This region of operation induces the subregion $\boldsymbol{\chi}$ (N_{sc} x NX) of the input variables of the empirical model of weathering. For simulation of long term operation a string of scenarios, $\mathbf{S}^{str}$ (L_{sc} x N_{inp}), representing the time course of conditions of operation, was assembled:

$ind_i \sim \text{Unif}(1, N_{sc})$; $ind_i \in \mathbb{N}$; i = [1 2 ... L_{sc}]

Each choice ind_i is a uniformly distributed random variable that indicates where, in the subregion **S**, is the i^{th} line of $\mathbf{S}^{str}$ and, as consequence, maps **X** (L_{sc} x NX) as in (7):

$$\begin{aligned} &\mathbf{S}(ind_i, \mathbf{j}) \rightarrow \boldsymbol{\chi}(ind_i, \mathbf{k}) \\ &\mathbf{S}^{str} = \mathbf{S}(\mathbf{ind}, \mathbf{j}) \rightarrow \mathbf{X} = \boldsymbol{\chi}(\mathbf{ind}, \mathbf{k}) \\ &\mathbf{j} = [1 \quad 2 \quad \ldots \quad N_{inp}] \; \mathbf{k} = [1 \quad 2 \quad \ldots \quad NX] \end{aligned} \tag{22}$$

Since quality of the feed is a major unmeasured disturbance the set of variables **z** is represented by the ratio of the slope of the true boiling point curve of the actual feed related to the one at nominal operating condition. If feed stream may have three different compositions symmetrically disturbed:

$\mathbf{r}$=[0.95 1 1.05]

$ind_i \sim \text{Unif}(1, 3)$; $ind_i \in \mathbb{N}$; i = [1 2 ... L_{sc}]

$$\mathbf{z} = \mathbf{r}(\mathbf{ind}) \tag{23}$$

In order to allow a better understanding of the different effects observed in the results there will be considered two cases of study. In the more generic case A it is supposed that the set of variables **z** is represented by (23) and that the inference model is the actual one used in industrial practice. Case B will also take disturbances as in (23) into account but it is supposed that the inference model was perfectly modeled in the absence of disturbances. It is perfect in the sense that all the effects of the model input variables perfectly propagate to the output variable. In other words, at $z=z_{nominal}$, $F_3 = F_3(z,c3)$ as in (6) and the inference is correct for any value of **x**.

As it can be seen in figure 2, in both cases bias updating procedure yields an expected mean value of zero although values show less dispersion when no bias correction is used.

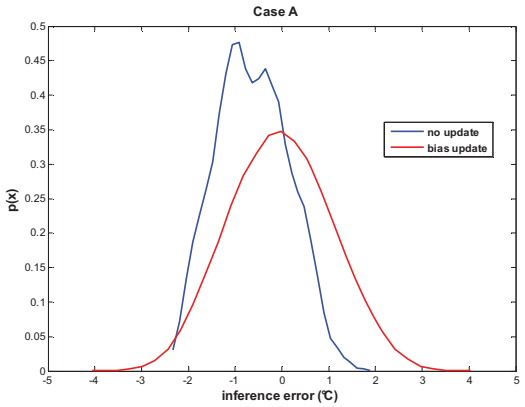

Figure 2 – Estimated probability density function of inferred weathering values for case A.

Estimated probability density function for case B (fig. 3) shows additional features. In this case it is clear that, with no update, the inference will be correct every time $z=z_{nominal}$ whatever the **x** values. The two triangular areas under the blue line around the central peak in figure 3 are originated when $z= z_{nominal} \pm \Delta z$. It should be noticed that the fact that those areas are not as thin as the central peak is due to the dependence of F3 (6) on **x**. When bias update is implemented, two more regions appear as well all regions become flatter. It is because bias expected values will be the result of the difference of all possible two random samples respectively chosen from the sample space of the non corrected inferred values and from the sample space of true values. These bias values will be summed to the inferred ones creating the oscillations of the red line at extreme inference errors observed in figure 3.

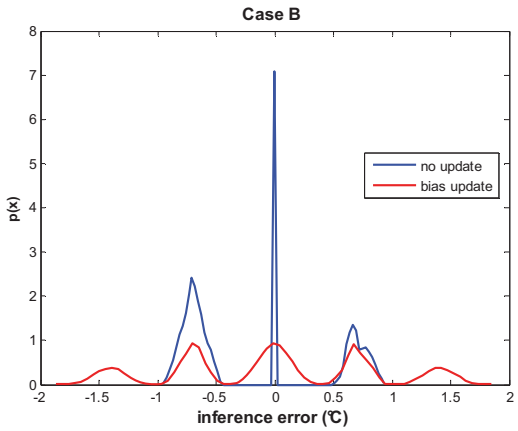

Figure 3 – Estimated probability density function of inferred weathering values for case B.

6. CONCLUSIONS

This work addressed the problem of continuous time monitoring in processes with differing sample rates for measured variables. Bias updating is a common adaptive procedure to periodically correct soft sensor models estimates. It was shown that this strategy is associated with long term zero mean error but at very high cost of 100% increase in variance of estimates. Our intention was to shown that a procedure to implement periodical parameter update should be problem-specific. It means to take into account statistical impact on estimates based on prior knowledge of probability density of disturbances as well error magnitude of soft sensor estimates.

ACKNOWLEDGMENT

The authors are grateful to Eng. Cristina Neves Passos, from Petrobras, for providing simulation files from FCC plant that were used as templates for our work.

Abstract: In this paper, we present an application of data derived approaches for analyzing and monitoring an industrial deethanizer column. The discussed methods are used in visualizing process measurements, extracting operational information and designing an estimation model. Emphasis is given to the modeling of the data obtained with standard paradigms like the Self-Organizing Map (SOM) and the Multi-Layer Perceptron (MLP). The SOM and the MLP are classic methods for nonlinear dimensionality reduction and nonlinear function estimation widely adopted in process systems engineering; here, the effectiveness of these data derived techniques is validated on a full-scale application where the goal is to identify significant operational modes and most sensitive process variables before developing an alternative control scheme.

Keywords: Process monitoring, Process supervision, the Self-Organizing Map

1. INTRODUCTION

A modern process plant is under tremendous pressure to maintain and improve product quality and profit under stringent environmental and safety constraints. For efficient operation, any decision-making action related to the plant operation requires the knowledge of the actual state of the process. The availability of easily accessible displays and intuitive knowledge of the states is thus indispensable, with immediate implications for profitability, management planning, environmental responsability and safety.

Due to the advances in measuring and information technology, historical data are available in abundance. Remarkable characteristics of the data acquired in industrial facilities are redundancy and possibly insignificance, not to mention the presence of disturbances that corrupt the measurements. Very often, the amount and quality of the data together with their high-dimensionality can be a limiting factor for the analysis; therefore, it is necessary the availability of effective methods that: i) model the data to extract the structures existing in the measurements, ii) identify and reconstruct the most relevant structures for the scope at hand and, iii) allow for easily interpretable displays where the states' information is presented to the plant operators. Intuitive knowledge of all visited states is invaluable for safe plant operation and trustworthy methods become necessary when considering statistical process monitoring as part of a supervision and control strategy.

In this paper, we discuss the implementation and direct application of a strategy to model, visualize and analyze the information encoded in industrial process data. The approach is based on a classical machine learning method for dimensionality reduction and quantization, the Self-Organizing Map, SOM (Kohonen, 2001). The SOM combines many of the main properties of other general techniques and shares many commonalities with two standard methods for data projection (Principal Components Analysis, PCA (Jolliffe, 2002)) and clustering (K-means, (Hartigan et al., 1979)). In addition, the SOM is also provided with a set of tools that allow for efficient data visualization in high-dimensional settings.

The use of the Self-Organizing Map in the exploratory stage of data analysis is discussed in (Kaski, 1997; Vesanto, 2002) and it is widely employed in many fields. In general terms, the main contributions in applying the SOM on industrial process data are collected by Alhoniemi (2002) and Laine (2003), whereas more domain specific developments can be found in the SOM's bibliography (Oja et al., 2003). Here, the SOM is used as a framework for the identification of the process modes with their time of occurence and present the information on simple displays.

To support the presentation, the analysis is discussed on a full-scale deethanizer where the goal is to identify significant operational modes and most sensitive process variables before developing an alternative control scheme. The study relies on an regression model for estimating an important quality variable (the ethane concentration in the bottom) otherwise difficult to measure in real-time from a set of easily measurable process variables. Inference is based on the Multi-Layer Perceptron Haykin (1998).

2. THE SELF-ORGANIZING MAP

The Self-Organizing Map (Kohonen, 2001) is an adaptive formulation of vector quantization performing in unison:

- a reduction of the data dimensionality by projection; that is, the reduction of the dimensionality of the data by mapping all the observations onto a meaningful subspace with lower dimensionality;
- a reduction of the amount of data by clustering; that is, the retention of the original dimensionality of the data space while reducing the amount of observations by prototyping them by similarity.

The SOM nonlinearly projects vast quantities of high-dimensional data onto a low-dimensional array of few prototypes in a fashion that aims at preserving the topology of the observations. By choosing a conventional bi-dimensional array of prototypes, the main advantage of the map is in a wealth of visualization techniques that allows the analysis of the structures existing in the data.

The following overviews the SOM algorithm and its analogies with other projection and clustering methods. A brief presentation of the most common SOM-based visualization methods for exploratory data analysis is also reported.

Algorithm and properties The basic Self-Organizing Map consists of a low-dimensional and regular array of K nodes, where a prototype vector $\mathbf{m}_k \in \mathbb{R}^p$ is associated with each node k. Each prototype acts as an adaptive model vector for the N observations $\mathbf{v}_i \in \mathbb{R}^p$. During the computation of the SOM, the observations are mapped onto the array of nodes and the model vectors adapted according to:

$$\mathbf{m}_k(t+i) = \mathbf{m}_k(t) + \alpha(t) h_{k,c(\mathbf{v_i})} \Big(\mathbf{v}_i(t) - \mathbf{m}_k(t) \Big). \quad (1)$$

In the learning rule in Equation 1, t denotes the discrete-time coordinate of the mapping steps and $\alpha(t) \in (0,1)$ is the monotonically decreasing learning rate. The scalar multiplier $h_{k,c(\mathbf{v_i})}$ denotes a neighborhood kernel centered at the Best Matching Unit (BMU); that is, at the model vector $\mathbf{m}_c(t)$ that, at time t, best matches with the observation vector $\mathbf{v}_i$. The matching is based on a competitive criterion on the Euclidean metric $d(\mathbf{m}_k(t), \mathbf{v}_i(t))$, for all $k = 1, \ldots, K$. At each step t, the BMU is thus the prototype $\mathbf{m}_k(t)$ that is the closest to observation $\mathbf{v}_i(t)$:

$$c(t) = \underset{k}{\operatorname{argmin}} \Big(d(\mathbf{m}_k(t), \mathbf{v}_i(t))^2 \Big), \ \forall k \text{ and } \forall i. \quad (2)$$

The kernel $h_{k,c(\mathbf{v_i})}$ centered at $\mathbf{m}_c(t)$ is often a Gaussian:

$$h_{k,c(\mathbf{v_i})} = \exp\Big(- \frac{||\mathbf{r}_k - \mathbf{r}_c||^2}{2\sigma^2(t)} \Big), \quad (3)$$

where the vectors $\mathbf{r}_k$ and $\mathbf{r}_c$ represent the geometric location of the nodes on the array and $\sigma(t)$ denotes the monotonically decreasing width of the kernel. The effect of the kernel decreases with the distance from the BMU.

The SOM is computed recursively for each observation. As $\alpha(t) h_{k,c(\mathbf{v_i})}$ tends to zero with t, the set of prototype vectors $\{\mathbf{m}_k\}_{k=1}^K$ are adaptively updated to represent similar observations in $\{\mathbf{v}_i\}_{i=1}^N$, and converge toward their asymptotic limits. The resulting model vectors learn a nonlinear manifold in the original embedding space such that the relevant topological and metric properties of the observations are preserved on the map. Thus, the SOM is to be understood as an ordered image of the original high-dimensional data modeled onto a low-dimensional manifold, where the complex data structures are represented by simple geometric relationships.

A rigorous analysis of the SOM has demonstrated difficult. However, in the case of the basic algorithm with a fixed kernel function, also the SOM algorithm can be understood from the optimization of a cost function:

$$\mathtt{E(SOM)} = \sum_{i=1}^{N} \sum_{k=1}^{K} h_{k,c(\mathbf{v_i})} d(\mathbf{m}_k, \mathbf{v}_i)^2. \quad (4)$$

The cost function in Equation 4 is closely related to the objective optimized with the K-mean algorithm (Lloyd, 1982). The only difference is in the neighborhood function that smoothly weights all the distances between the observations and the prototypes, instead of just the closest one. In that sense, the SOM operates as the conventional clustering method where the width of the kernel is zero. Moreover, there is no need to explicitly specify the number of taxonomies; in fact, the number of prototypes in the SOM can be chosen without any specific concern on the actual number of clusters. The SOM has also neat projection properties. In fact, the cost in Equation 4 closely resembles the objective optimized by Curvilinear Components Analysis CCA (Demartines et al., 1997); CCA is a modification of metric Multi-Dimensional Scaling MDS (Cox et al., 2000) and Principal Components Analysis PCA (Jolliffe, 2002). Similarity is in the decreasing and smoothing nature of the neighborhood function that emphasizes smaller distances in the projection. Conversely, the notion of locality in the SOM does not correspond to the global concern on small distances characterizing CCA.

Data exploration methods In the typical case of projections onto 2D arrays, the SOM offers excellent techniques for data exploration. In that sense, the approach to data analysis with the SOM is mainly visual and focuses on the low-dimensional displays specifically designed for the map.

The data visualization techniques based on the SOM assume that the prototype vectors are representative models for groups of similar observations, and projecting the data onto the low-dimensional array allows for an efficient display of the dominant relationships existing between them. For instance, the displays permit to identify the shape of the data distribution, cluster borders, projection directions and dependencies between variables. The visualizations techniques considered here are i) the component planes and ii) the distance matrix. Such techniques were thoroughly studied by Kaski (1997) and Vesanto (2002).

A component plane shows on the SOM's array the coordinates of the prototype vectors along a specific direction in the data embedding space; that is, each component plane is associated to one original variable and there are as many planes as directions in the embedding. The coordinate values are encoded into gray levels or colors, and the area of each unit on the array is dyed with the color associated to the component value. A component plane thus displays the distribution of the corresponding variable among the prototype vectors. The component planes are useful in order to visually identify possible dependencies between variables. The dependencies between variables can be seen as similar patterns (the colors corresponding to the values

of the variables) in identical locations on the component planes. Such representations can be also used to quantify dependencies. In that sense, the SOM reduces the effect of noise and outliers in the observations and, therefore, may actually make any existing dependence simpler to detect.

A distance matrix visualizes on the SOM's array the average distance between each prototype vector and its adjacent neighbors. In a distance matrix, distances are encoded into gray levels or colors and each unit on the array is dyed with the color associated to the distance with the neighbors. The most widely used distance matrix for the SOM is the Unified Distance Matrix, or U-matrix (Ultsch, 1993). Here, the dominant clustering structure of the observation can be seen as clearly separated areas (large distances) characterized by a homogeneous coloring. In the U-matrix, visualization of the clusters is improved by augmenting the distance matrix with additional entries (nodes) between each prototype vector and each of its neighbors. Unconventional alternatives to the U-matrix are reported by Oja et al. (2003) but not considered here.

3. CASE STUDY

To illustrate the potentialities of topological data analysis using the Self-Organizing Map, the overviewed methods are applied on a set of measurements from a full-scale process. The monitoring problem consists of modeling and analyzing the operational behaviour of an industrial deethanizer, starting from a set of online process measurements. The objective of the deethanizer (in Figure 1) is to separate ethane from the feed stream (a light naphta) while minimizing the ethane extracted from the bottom of the column (an economical constraint for the subsequent unit in the plant). Such a constraint is quantified by the maximum amount of ethane lost from the column bottom; the operational threshold is set be smaller than 2%. The

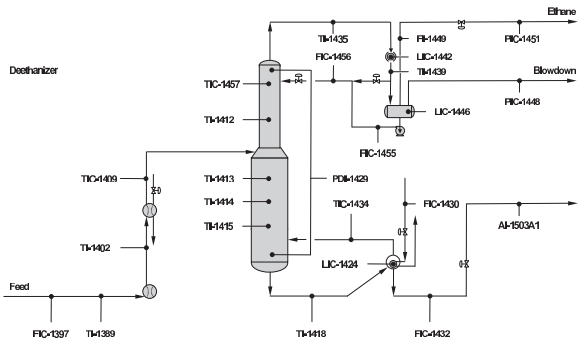

Fig. 1. Deethanizer: Simplified flowsheet.

motivation for choosing this unit is merely illustrative; in fact, the considered deethanizer offers an ample variety of behavior that reflects the operational usage; hence, an interesting groundwork for presentation and discussion.

Table 1. Deethanizer: Process variables

In order to analyze the behaviour of the unit, a set of process variables was collected from the plant's distributed control system (DCS). The measurements correspond to three weeks of continuous operation in winter asset and three weeks in summer asset. The data are available as 3-minute averages and 27 process variables (in Table 1) are available for a macroscopic characterization of the unit.

In addition, there are a number of control loops in the process. Briefly, the temperature $TIC-1457$ and the vapor temperature $TIC-1434$ out of the reboiler are controlled by manipulating the reflux flow $FIC-1456$ and the steam rate $FIC-1430$ to the reboiler, respectively; with both loops cascaded with the corresponding flowrates. The distillate pressure $PIC-1451$ is controlled by the distillate flowrate $FI-1449$ and the level in the reboiler $LIC-1424$ by the bottom flowrate $FIC-1432$.

3.1 Analysis and inference

The operational objective of the column is to produce as much ethane as possible (minimizing concentration of propane from the top of the column) while satisfying the constraint on the amount of impurity from the bottom (maximum concentration of ethane in the bottom $\leq 2\%$). With respect to the loss of ethane from the bottom, such considerations led to the definition of 3 operational modes:

- a *normal* status, corresponding to the operation of the column, where the concentration of ethane is within allowable bounds (within the $1.8-2.0\%$ range)
- a *high* status, corresponding to the operation of the column, where the concentration of ethane is exceeding the allowable upper bound (above 2%)
- a *low* status, corresponding to the operation of the column, where the concentration of ethane is below the allowable lower bound (below 1.8%).

The two abnormal conditions have a direct and important economic implication. In fact, when at low status, the process is delivering a product out of specifications whereas, when at high status the product is within the specifications, but an unnecessary operational cost is observed.

To understand under which conditions such modes are experienced, in a recent study (Corona et al., unpublished) we analyzed the clustering structure of the data and visualized the operating conditions of the unit. Starting from a selection of important process variables, we expanded this

subset by incorporating an additional *dummy* indicator, specifically calculated to indicate the status. As such, the new variable was defined as to take values $+1$, -1 or 0, according to the operational status of the process. Value 0 is assigned to the normal operation, whereas values $+1$ and -1 correspond to high and low operations, respectively. Notice that the calculation of the *dummy* variable requires the availability of a real-time measurement for the ethane concentration; such a variable ($AI - 1503A1$) is presently acquired from a continuos-flow chromatograph. The subset of selected process variables augmented by the *dummy* indicator was used to calibrate a SOM over which the resulting component planes and U-matrix were analyzed; the exploration was perfomed as a direct application of the techniques discussed by Alhoniemi (2002). The study allowed us to extract the clustering structure of the data and illustrate on simple displays how it corresponds to the operational modes of the unit.

However, the delay associated with the analytical measurements of the ethane concentration from the bottom of the column can pose severe limitations to the online analysis. Moreover, the existing instrumentation setup available for the unit may benefit from a backup measurement for such an important variable. In this study, we are thus extending the analysis of the operational modes of the deethanizer, by validating the functionality of the approach when replacing the analytical measurements of ethane with online estimates. In that sense, the availability of an inference model would allow the development of a fully automated system to be implemented online in the plant's DCS.

For the purpose, a soft sensor based on the standard Multi-Layer Perceptron MLP (Haykin, 1998) with one hidden layer and sigmoidal activation functions was developed to infere the ethane concentration from the bottom. The estimates are obtained starting from the same input subset of easily measurable process variables used for the SOM and selected according to the guidelines provided by Baratti et al. (1995). The parameters of the MLP (that is, number of hidden nodes, one, and the connection weights) were optimized using the Levemberg-Marquard method and cross-validation. In Figure 2, the response of the soft sensor on a set of independent testing observations is reported for about a week of continuous operation.

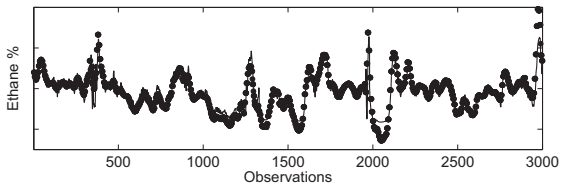

Fig. 2. Ethane concentration from the bottom: Analytical measurements ($\cdot$) and MLP estimates ($-$).

Based on the MLP estimates, a bidimensional Self-Orgaznizing Map was calibrated using only the winter data. The map consists of a hexagonal array of prototype vectors initialized in the space spanned by the eigenvectors corresponding to the two largest eigenvalues of the covariance matrix of the data. As usual, the ratio between the two largest eigenvalues was used to calculate the ratio between the two dimensions of the SOM; the resulting map consists of a 70×24 array of 15-dimensional prototype vectors, where the dimensionality of the vectors equals the number of variables used for calibration. On the SOM, we analyzed the clustering structure of the data and visualized the operating conditions of the unit using the U-matrix.

The U-matrix is based on distances between each prototype vector and its immediate neighbors. A common way to visualize it consists of an initial projection of all the distances onto a color axis and the subsequent display with colored markers between each prototype vector. On the display, areas with homogeneous coloring correspond to small within-cluster distances (recognized as clusters), whereas cluster borders are areas with homogeneous coloring but corresponding to large between-cluster distances. The use of the U-matrix in clustering the operational regimes of the deethanizer column is shown in Figure 3.

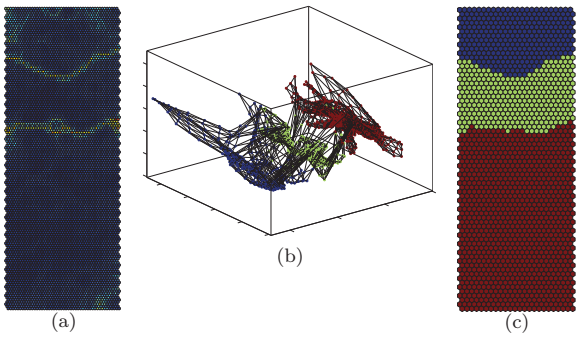

Fig. 3. The U-Matrix (a), the clustered SOM projected onto the 3D principal components space (b) and the SOM colored according to the K-means clustering (c).

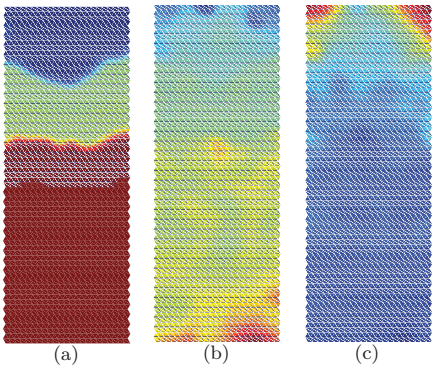
In Figure 3(a), distances are depicted with dark blue colors shading toward dark red as the proximity between the prototypes decreases. The visualization permits to clearly recognize the presence of three distinct clusters of prototypes, as well as several other data substructures. An analogous visualization of the grouping is achieved by projecting the map onto a low-dimensional subsapce; in Figure 3(b), a tridimensional principal components space learned by the metric MDS. Indeed, also this visualization permits to illustrate the actual clustering structure of the process measurements and displays a good separateness also in this space of reduced dimensionality. However, to obtain a quantitative characterization of the clustering structure, the prototypes of the SOM should be regarded as a reduced data set and modeled with a standard clustering algorithm. For simplicity, we are here adopting a standard K-means algorithm coupled by the Davier-Bouldin index, a measure of cluster validity to identify an optimal number K of taxonomies from data Milligan et al. (1985). As expected, optimality was found for $K = 3$ clusters, corresponding to the modes of the unit.

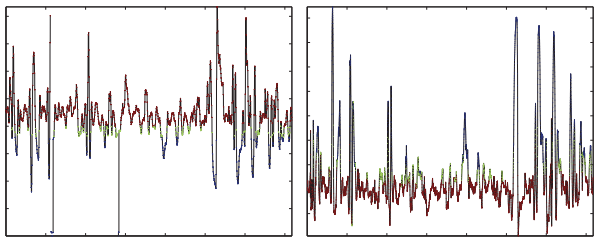
On the SOM, such clusters are located in the lower, middle and upper part of the map. After coloring the SOM according to the cluster membership obtained by using the K-means algorithms, in Figure 3(c), and comparing it with the component plane of the *dummy* variable (and equivalently, the MLP estimated ethane concentation), it is straightforward to associate the three taxonomies to the



(a) (b) (c)

Fig. 4. The component planes for the *dummy* variable (a), the estimated ethane concentration (b) and the temperature $TI-1414$ (c), with a coloring scheme that assigns blue to high values of the variables fading toward red as the values decrease. This scheme differs from the what defined for the clustering with blue and red corresponding to -1 and $+1$, respectively.

three main operational modes of the deethanizer, Figure 4. Specifically, Figure 3(c) shows the clusters on the SOM as distinct regions dyed in blue, green and red with a cloring scheme that assignes those colors to the operational modes ($+1$, 0 and -1, respectively). As expected, a similar structure is also retrieved from the component plane for the *dummy* variable, Figure 4(a). Though apparently less evident, the same structuring is retrieved from the component planes of the estimated ethane concentration (Figure 4(b)) and one of the temperatures in the exhausting section of the dethanizer; namely, $TI-1414$ in 4(c). Looking for similar patterns in similar positions in such components planes allows the visualization of a neat dependence between the ethane composition and such temperature indicator. Such pair of variables shows near identical but reversed component planes, thus highlighting the inherent inverse correlation that exists between them.



(a) AI-1503A1 (b) TI-1414

Fig. 5. The colored time series (3 winter weeks) for the ethane concentration $AI-1503A1$ (a) and the temperature in the enriching section $TI-1414$ (b). The actual values of the variables could not be reported because of the confidentiality agreement.

Information about this dependence can be further enhanced by applying the coloring scheme resulting from clustering directly to the original observations in the time domain. In fact, all points can be dyed using the cluster color of the corresponding Best Matching Unit, as in Figure 5. The figure shows how $TI-1414$ is mostly responsible for the transition between the aformentioned operational

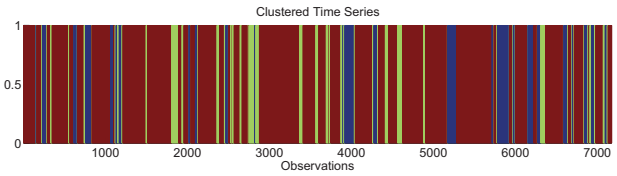


Fig. 6. The temporal evolution of the winter operational modes colored according to the SOM clustering.

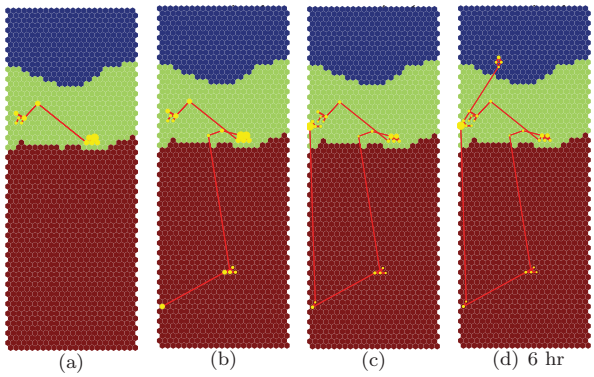
conditions. The correspondence with the ethane concentration is observed as clear banded regions and indicates that, in order to maintain the column at optimality (withing the $1.8-2.0\%$ range of ethane from the bottom), such a temperature should be controlled (possibily, within the $52-55°C$ range). A possible variable to manipulate is the steam flowrate $FIC-1430$. However, such a variable is not used in the present control scheme and induces an overall 85% of off-spec operation of the unit, during the given winter period. Such information is obtained by calculating the number of point measurements that falls outside the normality conditions over the total count and pictorially depicted also as clustered time series (in Figure 6).

So far, we have restricted the analysis only to the measurements observed under winter asset. However, it is also possible to directly use the calibrated SOM as a reference model for new and unseen observations; in our setting, the three weeks of data corresponding to the summer operation of the deethanizer column. To validate this idea, the winter SOM was used to explore the behaviour of the deethanizer under summer asset. Again, the summer measurements from $AI-1503A1$ were replaced by the estimates from the soft sensor. The analysis was accomplished by initially projecting the new data onto the calibrated SOM, being the mapping based on a nearest neighbor criterion between the new sample vectors and the prototype vectors of the SOM. In this respect, novelty detection using the SOM is based on finding the BMU. Once the mapping is completed, the inspection is performed for the new data.

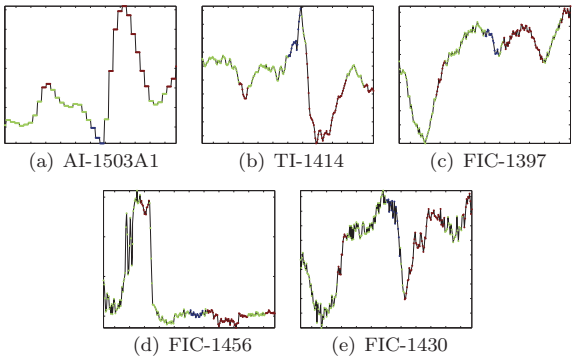


(a) (b) (c) (d) 6 hr

Fig. 7. Trajectory of a selection the summer observations (approximatively, 6hr) displayed on the winter SOM.

The results in extrapolation are presented by illustrating another technique for visualization on the SOM. The approach allows to follow operational changes in the process and tries to provide a simple display for identifying reasons of specific behaviors. For the purpose, the map calibrated on the winter data can be enhanced by the inclusion of

the summer point trajectories followed by the process. The trajectory permits to intuitively indicate the current mode of the process and observe how it has been reached. In Figure 7, the process trajectory is sequentially reported for a small time window corresponding to six hours of continuous summer operation of the deethanizer. The process trajectory on the SOM's domain passes through all the BMUs of each new data vector and it is shown as red line connecting the visited prototypes (the nodes are marked as yellow dots and thicken with the count of visits).



(a) AI-1503A1 (b) TI-1414 (c) FIC-1397

(d) FIC-1456 (e) FIC-1430

Fig. 8. Status transitions on the time domain (approximatively, 6hr), for a set of relevant process variables.

Following the temporal evolution from Figure 7 and 8, the diagrams show a process that is initially operated in the green area, or *normal* condition (as for the ethane in the bottom and reference temperature). As the process has moved further in time, new prototype vectors are visited and added to the trajectory until the column eventually leaves the normality region and crosses the boundary towards the region of high ethane composition (in red). In a similar fashion, all the process variables changed coloring to match the visited modes allowing to appreciate that the change in the operation was mainly due to an abrupt change in the feed flowrate ($FI-1397$), in Figure 8(c), and possibly its composition. In turns, the variation triggered the action on steam to reboiler flowrate ($FIC-1430$), in Figure 8(e), as well as the reflux to control the top temperature ($FIC-1456$), in Figure 8(d). The events initiated a sequence of oscillations around normality that could be reestablished only after several hours.

4. CONCLUSIONS

In this work, we implemented and discussed a strategy to model, visualize and analyze the information encoded in industrial process data. In particular, the proposed strategy was applied to a full-scale distillation column.

From a methodological point of view, the process monitoring problem was casted in a topological framework by using the Self-Organizing-Map. On the SOM, the identification of the process modes was approached as a clustering task rather than classification; that is, in an unsupervised rather than supervised fashion. Moreover, in order to overcome the limitations associated with the time delay and costs of the analytical instrumentation, a software sensor based on a Multi-Layer Perceptron was developed to infer a primary process variable, thus favoring the possibility to directly use such a strategy also for online monitoring.

The application allowed the definition of simple displays capable to present meaningful information on the actual state of the process and also suggested an alternative control strategy for maintaining the unit in normal conditions.

Abstract: Nearly 20-30% of all process control loops oscillate due to stiction and lead to loss of productivity. Thus, the detection and quantification of stiction in control valves using just the raw operating data is an important component of any automated controller performance monitoring application. Many techniques have been proposed for the detection and quantification of stiction. Pattern based identification approaches use unique shapes of the PV and OP data to identify stiction. Other approaches that include some measure of nonlinearity index have also been used to identify stiction. A solution technique for stiction detection in nonlinear processes with known process models is also available. In this paper, one possible approach to detect stiction in nonlinear process control loops with unknown process models is discussed.

1. INTRODUCTION

Research on developing automated controller performance monitoring systems has been increasing in the past decade. Control strategies such as Model Predictive Control (MPC) or other supervisory control are crucial for optimization of process operations. Performance gains from such advanced control techniques depend on how effectively the lowest control elements in the control strategy track the desired set points. A spate of surveys on the performance of control loops [Bialkowski, 1993, Ender, 1993, Entech, 2005, Desborough and Miller, 2001] indicate that a majority of control loops in processing industries perform poorly. Performance demographics of 26,000 PID controllers collected across a wide variety of processing industries in a two year time span indicate that the performance of 16% of the loops can be classified as excellent, 16% as acceptable, 22% as fair, 10% as poor, and the remaining 36% are in open loop [Desborough and Miller, 2001]. The impact of this has to be seen from the fact that PID is the dominant control algorithm in the industry accounting for 97% of the regulatory loops [Desborough, 2003]. This has led to increasing interest in automated Controller Performance Assessment (CPA) tools in recent years. The three major reasons for deterioration of control performance are: badly tuned controllers, oscillating load disturbances, or nonlinearities in control valves. 20% to 30% of all control loops oscillate due to valve problems caused by static friction or hysteresis [Bialkowski, 1993, Miller, 2000] resulting in performance deterioration. It was found that over 80% of all valves adjusted by Entech Control Engineering failed dynamic performance standards due to stiction, backlash or oversized design. Thus the task of detecting stiction or other nonlinearities in valves from routine operating data is a challenging task and is an important component in any CPA suite.

2. PROBLEM DEFINITION

A typical process control loop with stiction in the control valve can best be depicted as shown in the Figure 1. As seen, the stiction precedes the control valve dynamics and the process transfer function also includes the valve dynamics. The fundamental problem that is being solved in this paper is one of identifying the root cause of oscillation in the process variable (PV) as being due to either stiction or external oscillations. In this work, the focus is on a model-based solution approach to this problem. There are solutions for stiction detection based on the analysis of the input-output data such as the shape based analysis proposed by Rengaswamy et al. [2001], Srinivasan et al. [2005a] and higher order statistics based approach proposed by Choudhury et al. [2004]. Most of these approaches rely on the process being linear. For non-linear process Nallasivam and Rengaswamy [2008] proposed a solution strategy that works when the process model is known. However, there is no work on detecting stiction in nonlinear control loops when the process model is not known.

Previous attempts at quantifying stiction were mostly based on measures developed from the data characteristics such as the span of controller output (OP) data, apparent stiction, maximum width of the ellipse fitted by PV-OP plot etc. The first attempt at quantifying stiction through a joint identification procedure was by Srinivasan et al. [2005b]. Srinivasan et al. [2005b] proposed a model-based approach and solved this problem for a linear process. Their approach is based on the identification of a Hammerstein model of the system comprising of the sticky valve and the process (see Figure 1(b)). The identification of the linear dynamics is decoupled from the nonlinear element. The decoupling between the nonlinear and the linear component is achieved by an iterative procedure. The solution proposed in Srinivasan et al. [2005b] is shown in Figure 2. Several stiction quantification attempts based on this approach have started to appear. A similar approach but

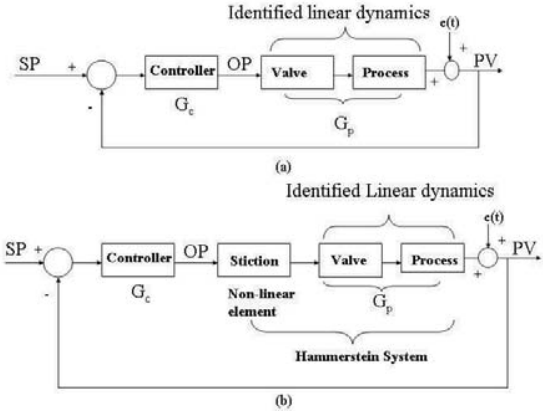

Fig. 1. (a) General process control loop, (b) Process control loop with stiction element

with a two parameter model to quantify stiction is discussed in Choudhury et al. [2008]. Another work using a Hammerstein ID approach with a two parameter model can be found in Jelali [2008]. The difference between Choudhury et al. [2008] and Jelali [2008] seem to be that while a gird search, similar to Srinivasan et al. [2005b], is used in Choudhury et al. [2008], genetic algorithms (GAs) are used to identify the stiction parameters in Jelali [2008]. However, all these methods assume that the process is linear. Nallasivam and Rengaswamy [2008] have shown that these approaches fail if the underlying process is nonlinear and solved this problem for the nonlinear case when the process model is known. The present work is on detecting stiction in nonlinear control loops when the process model is unknown.

Figure 3 depicts the control loop that is being addressed in this work. From this figure,

$$\begin{aligned} y &= y_p + y_d \\ y &= N(u) + y_d \\ y &= N(V(v)) + y_d \end{aligned} \tag{1}$$

where y is the measured process variable pv, which includes the process component y_p and the disturbance component y_d, which are additive. N is the non linear process transfer function and u is the valve output, which might not be a measured variable. The valve output u is a function (V) of the op (v) dictated by the stiction phenomenon. In this paper, the detection, quantification and isolation of stiction from external disturbances for the system given in equation 1 is addressed.

$$x(t) = \begin{cases} x(t-1) & if\ |u(t) - x(t-1)| \le d, \\ u(t) & otherwise \end{cases} \tag{2}$$

3. SOLUTION APPROACH

A single parameter stiction model is given by equation 2. In this model, the value of the parameter d goes to zero when stiction is absent in the valve. Thus a non-zero value for this parameter d indicates the presence of stiction and also quantifies the stiction level. The estimation of this parameter is achieved by decoupling the stiction parameter estimation from the estimation of the process dynamics. This is achieved by

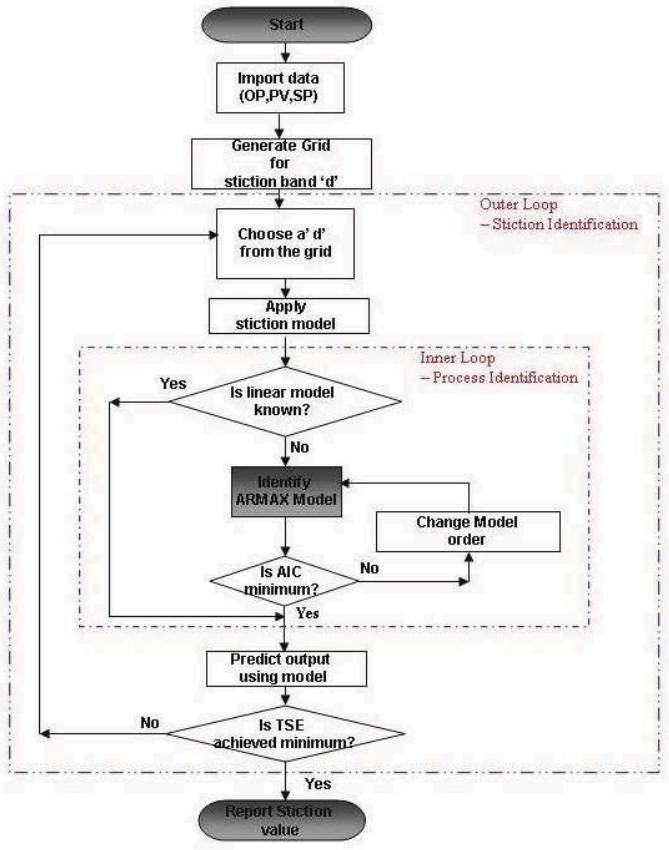

Fig. 2. Solution algorithm proposed by Srinivasan et al. [2005b]

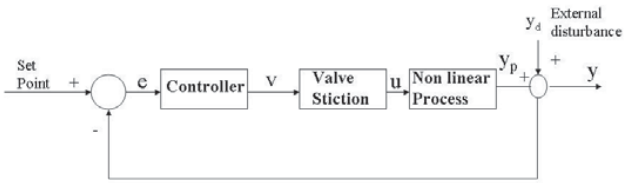

Fig. 3. Nonlinear control loop in presence of stiction

an iterative process in which a value for d is assumed in an outer loop and the best fit model for the remaining dynamics in the inner loop is identified. From Figure 3, since the controller parameters θ_c are known, v (op) can be calculated from y. Using the equation 2 for a given selected value of d, u can be calculated. Thus the identification problem becomes,

$$\begin{aligned} y &= y_p + y_d \\ y &= N(u) + y_d \end{aligned}$$

Since the process model is not known, by considering y_d as a moving average process, we can write

$$A(q)y(t) = B(u,q) + C(q)e(t) \tag{3}$$

where

$$A(q) = [1 + a_1 q^{-1} + ... + a_{n_a} q^{-n_a}]$$
$$C(q) = [1 + c_1 q^{-1} + ... + c_{n_c} q^{-n_c}]$$

$B(u,q)$ represents a general nonlinear process. As before u is known based on the actual output, the controller parameters and the assumed d value. A predictor form can be obtained for the system given by equation 3. In the linear model case, this will lead to a pseudolinear regression problem. One approach to retain the pseudolinear regression framework in the nonlinear case would be to parameterize the nonlinear function using a N^{th} order discrete Volterra series approximation as below

$$B(u,q) = \sum_{n=1}^{N} \sum_{i_1=1}^{M_1} ... \sum_{i_n=1}^{M_n} h_n(i_1,...,i_n) q^{-i_1} u(k) ... q^{-i_n} u(k)$$

With this expression, equation 3 now represents a Volterra MA model. By considering only the first and second order terms in the above Volterra series,

$$B(u,q) = \sum_{i=1}^{n_b} h_1(i) q^{-i} u(k) + \sum_{i=1}^{n_b} \sum_{j=1}^{n_b} h_2(i,j) q^{-i} u(k) q^{-j} u(k)$$

Now the predictor for equation 3 can be derived as

$$y(k/k-1) = B(u,q) + [1 - A(q)]y(k) + [C(q) - 1]e(k)$$

which is

$$y(k/k-1) = \sum_{i=1}^{n_b} h_1(i) q^{-i} u(k) + \sum_{i=1}^{n_b} \sum_{j=1}^{n_b} h_2(i,j) q^{-i} u(k) q^{-j} u(k) - a_1 y(k-1) - a_2 y(k-2) - ... - a_{n_a} y(k-n_a) + c_1 e(k-1) + c_2 e(k-2) + ... + c_{n_c} y(k-n_c)$$

When this predictor is applied to n samples, one would get n equations which results in the following equation in the matrix form

$$Y = XH$$

This equation can be solved iteratively till the solution converges for a given given selected model order of n_a, n_b and n_c using the following relationship.

$$H = [X^T X]^{-1} X^T Y$$

Based on this second order approximation of the Volterra series, an approach similar to the one that was used by Nallasivam and Rengaswamy [2008] for the known model case can be followed. However, now the model parameters and the MA process parameters have to be jointly estimated and evaluated through the AIC criteria. The overall best fit could then be chosen based on the d parameter that results in the minimum TSE. This approach is shown in Figure 4.

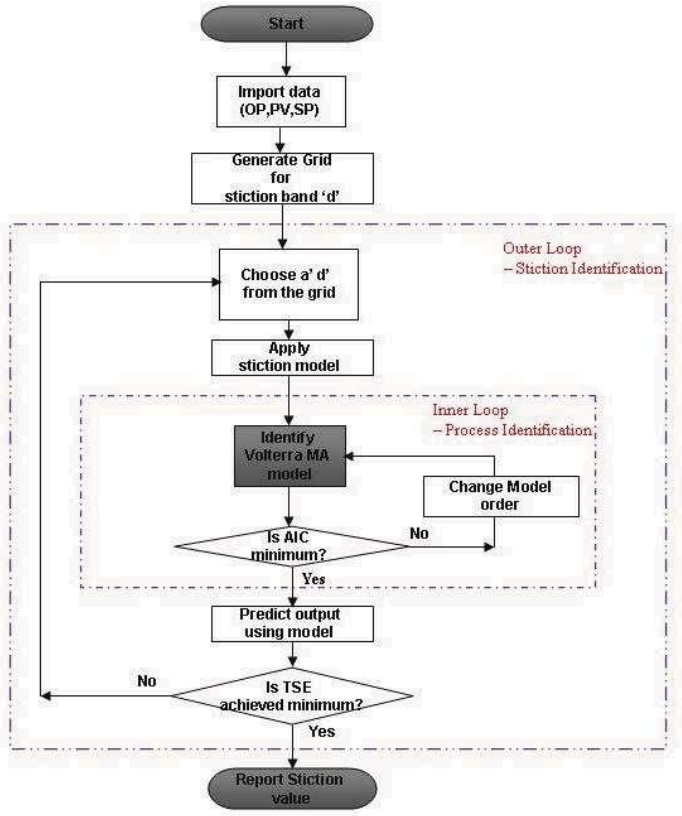

Fig. 4. Proposed approach

4. CASE STUDY

In this case study, a nonlinear polymerization reactor process from Doyle et al. [1995] is used. In this nonlinear process a polymerization reaction takes place in a jacketed CSTR where the controlled variable is the number-average molecular weight and the manipulated variable is the volumetric flowrate of the initiator. A second-order Volterra model in the frequency domain as given below describes this non-linear process.

$$P_1 = c_1^T (sI - A_{11})^{-1} b_1$$
$$P_2 = c^T [(s_1 + s_2)I - A]^{-1} N (s_1 - A)^{-1} b \tag{4}$$

Details on the matrices c, A, N, b can be found in Doyle et al. [1995].

4.1 Data for testing of the solution approach

This case study is used to demonstrate the effectiveness of the proposed solution approach in three different scenarios for stiction detection. These are:

(a) No stiction case
(b) Stiction alone case
(c) Stiction and external oscillation case

Three datasets were generated by using equation 4 as the nonlinear process in Figure 3 to address all the above three scenarios. A PI controller with $K_p = 0.3$, $T_i = 1.0$ was used. Data were

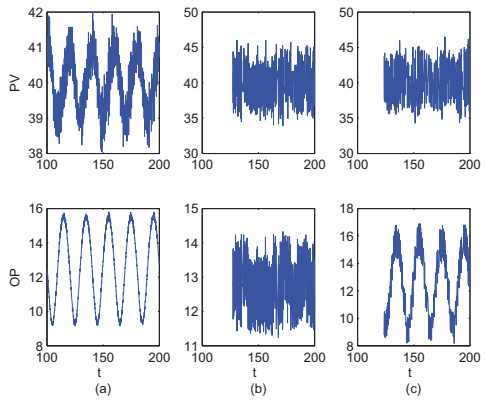

Fig. 5. Data for (a) No stiction (b) Stiction alone (c) Stiction and external oscillation

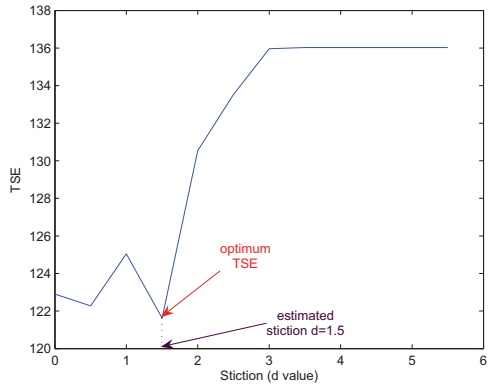

Fig. 6. Result for the approach of Srinivasan et al. [2005b]

simulated for scenario (a) using an external sine oscillation disturbance of amplitude 20 at a frequency of $0.3142 rad/sec$ as y_d. For scenario (b), a stiction value of $d = 1.5$ was used. For scenario (c), both the sine oscillation of scenario (i) and a stiction value of $d = 1.5$ were used. The data that are generated are shown in Figure 5.

4.2 Discussion on the existing approaches

The existing techniques based nonlinearity detection as in Choudhury et al. [2004] and qualitative pattern matching approaches as the one proposed in Rengaswamy et al. [2001] will not work for this dataset. As shown in Nallasivam and Rengaswamy [2008], the model-based approach proposed by Srinivasan et al. [2005b] is also not likely to work for this dataset. To verify this, the data shown in Figure 5(a) for the no stiction case is tested using the approach suggested in Srinivasan et al. [2005b] (approach shown in Figure 2). The resulting d vs TSE plot is shown in Figure 6. As expected, the value of d is incorrectly identified. In other words, stiction is detected where it is not actually present.

5. RESULTS

The dataset (Figure 5(a)), where the approach of Srinivasan et al. [2005b] failed is used to test the performance of the

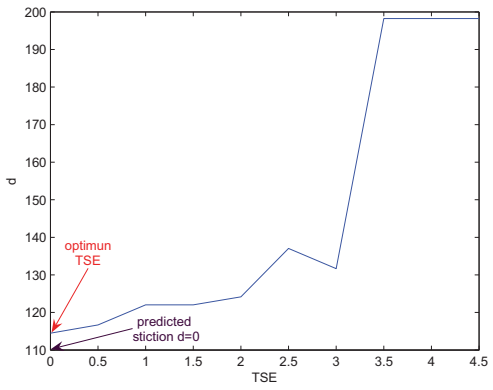

Fig. 7. Result for the no stiction case

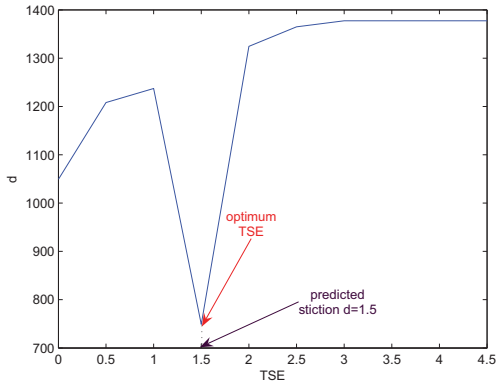

Fig. 8. Result for the stiction alone case

proposed approach shown in Figure 4. Figure 7 shows the result and as seen, it is clear that the scenario is correctly diagnosed as being a no stiction case. The minimum TSE is achieved at $d = 0$.

The dataset for the other two scenarios (Figures 5(b) and 5(c)) are also tested using this proposed approach. The results are shown in Figures 8-9. It can be seen from Figure 8, the case of stiction is also correctly identified with an accurate estimation of the stiction level. The more difficult third scenario is where both stiction and an external oscillating disturbance are present, with the process being nonlinear. The result for this case is shown in Figure 9. In this case also, not only is stiction detected but the magnitude of stiction is also accurately estimated. From these observations, it clear that the proposed solution approach works well in detecting and isolating the root cause of oscillation in nonlinear SISO loops.

6. VALIDATION USING DATA FROM PHYSICAL STICTION MODEL

The aim of this section is to verify how the proposed approach works when process data is generated by considering physical stiction model instead of single parameter stiction model. The physical stiction model that was used for this simulation is the same as the one used by Srinivasan et al. [2008]. The various parameters that were used for the physical stiction model are given in Table 1.

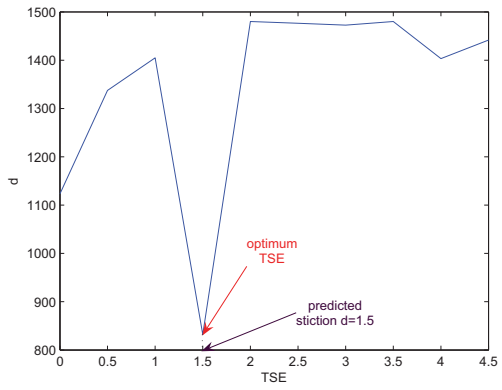

Fig. 9. Result for the case of both stiction and an external oscillating disturbance case

Table 1. Valve Parameters

Parameter	Description	Value
P	Applied Actuator Pressure	psi
A	Effective Diaphragm Surface area	100 in^2
m	Mass of Stem and Plug	3 lb
K	Spring rate	300 lbf/in
b	Viscous coefficient	0.15 lb/s
F_c	Coulomb friction	24 lbf
F_s	Static friction	34 lbf
v_s	Stribeck constant	0.01 in/s

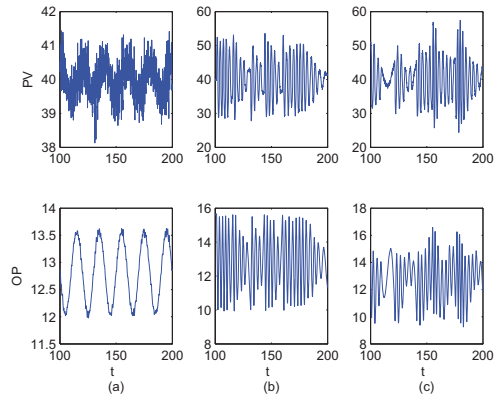

Fig. 10. Data set 2 for (a) No stiction (b) Stiction alone (c) Stiction and external oscillation

Data were simulated for scenarios (a) and (c) using an external sine oscillation disturbance of amplitude 5 at a frequency of $0.3142 rad/sec$ as y_d. A PI controller with $K_p = 0.01$, $T_i = 0.5$ was used for this data generation. The data that are generated are shown in Figure 10.

This data are tested using the proposed approach and the results are given in the Table 2. As seen, the absence or presence of stiction is predicted correctly in all the scenarios as indicated by a zero or non zero d value respectively. However the d parameter estimated for scenarios b and c are not the same as one would expect because of the use of the physical stiction model in generating the data. The reason for this is that the single parameter stiction model used in the detection algorithm is only an approximation of the physical stiction model. Nonetheless, stiction detection is not compromised.

Table 2. Validation Results

Scenario	Predicted stiction
No stiction case	d=0
Stiction alone case	d=3
Stiction and disturbance case	d=0.5

7. DISCUSSION

The proposed approach takes advantage of the fact that the stiction nonlinearity is discontinuous, whereas the process transfer function is continuous for stiction detection. It was shown that it might be possible to detect and isolate stiction in some cases in nonlinear SISO control loops when the process model is not known. However, extensive studies are needed before any definite conclusions can be drawn. There are several possible extensions to the proposed approach. The obvious ones include the use of two parameter stiction model for stiction quantification, the use of optimization algorithms such as GA for estimating the stiction parameters and validation with industrial data. Also, further theoretical work is needed to formalize the approach proposed in this paper.

8. CONCLUSIONS AND FUTURE WORK

In this paper, the problem of detection of stiction and isolation of stiction from external oscillations in nonlinear process control loops was addressed for the unknown model case. While Nallasivam and Rengaswamy [2008] have demonstrated the solution strategy for known nonlinear model case, almost no work exists in the case of unknown nonlinear processes. A solution approach for the unknown model case was proposed. The advantages and the limitations of the proposed approach were discussed.

It is essential to analyze the theoretical basis of the proposed method for using Volterra models. In addition, it would be interesting to study the use of Volterra second-order models to higher order nonlinear systems or linear systems. The former results in under-modeling of the original process while the latter results in over-modeling of the underlying linear process. We are in the process of developing a theoretical basis to analyze these interesting phenomena [Nallasivam et al. [2009]]. In future, the efficacy of the proposed approach along with the underlying theory needs to be further validated with other examples for different types of disturbances and different stiction models.

Abstract: Motivated by the need of developing stochastic nonlinear model-based methods to characterize uncertainty for chemical process estimation, control, identification, and experiment design purposes, in this paper the problem of characterizing the global dynamics of single-state nonlinear stochastic system is addressed. An isothermal CSTR with Langmuir-Hinshelwood kinetics is considered as representative example with steady state multiplicity. The dynamics of the state probability distribution function (PDF) is modeled within a Fokker-Planck's (FP) global nonlinear framework, on the basis of FP's partial differential equation (PDE) driven by initial state and exogenous uncertainty. A correspondence between global nonlinear deterministic (stability, multiplicity and bifurcation) and stochastic (PDF stationary solution and mono/multimodality) characteristics is identified, enabling the interpretation of tunneling-like stationary-to-stationary PDF transitions, and the introduction of a bifurcation diagram with the consideration of stochastic features in the context of the CSTR case example.

Keywords: isothermal CSTR, multistability, nonlinear system, stochastic model, Fokker-Planck

1. INTRODUCTION

The study of stochastic nonlinear systems is motivated by the need of characterizing the effect of model uncertainty for model-based applications such as chemical process modeling, system identification, experiment design, estimation and control purposes, process safety assessment. While the deterministic approaches for nonlinear chemical processes are a rather mature field, the development of nonlinear stochastic approaches lags far behind. Deterministic descriptions suffice for chemical processes described by nonlinear models over the neighborhood of a steady-state (or nominal motion) for a continuous (or batch) process, but the same cannot be said for processes which evolve over ample (nonlocal) state-space domains, where nonlinearities become significant, and consequently, the inexorable presence of uncertainty due to measurement and modeling errors and its effect on the stability, observability and controllability features must be regarded within a stochastic global nonlinear framework. In chemical processes, the combination of measurement errors with high-frequency unmodeled dynamics manifests itself as random-like uncertainty, which imposes limits of estimation and control behavior.

In most of previous studies in chemical process engineering, the issue of uncertainty characterization has been performed with the so-called model sensitivity analysis with respect to initial values and/or parameters (Morbidelli and Varma, 1989, Dutta *et al*., 2001), on the basis of a linear model truncation. The drawback of this approach is that it does not allow the assessment of the combined effect of the uncertainties caused by the neglected nonlinear dynamics, which manifest itself when testing or implementing the model with the data generated by the actual nonlinear process (Horenko *et al.*, 2005).

In the nonlinear systems theory field, there are rather well established approaches to address the model uncertainty problem for multi-state nonlinear processes, with rigorous probability distribution function (PDF) evolution descriptions in terms of a set of Fokker-Planck (FP) partial differential equations (Risken, 1996). In fact, the nonlinear EKF estimator design can be seen as a second-order statistics approximation of the FP equation approach. However, in spite of being the EKF the most widely used estimation technique in chemical process systems engineering, its employment for uncertainty assessment purposes has been rather limited, and the consideration of the full nonlinear statistics FP equation approach has been circumscribed to a rather limited set of studies.

While the rigorous FP equation approach has been successfully applied in a diversity of problems in applied science, including physics, medical sciences (Mei *et al*., 2004; Lo, 2007), biology (Soboleva and Pleasants, 2003; Huang *et al*., 2008) and electronic circuits (Hanggi and Jung, 1988), in the chemical process systems engineering field only a few chemical reactor studies have been performed according to the FP equation approach. In a pioneering work, Pell and Aris (1969) studied the local-stochastic behavior of a

chemical reactor on the basis of a linear model truncation. In spite of the limited nature of the local results, recognized by the authors themselves, this work evidenced the benefit and possibilities of modeling the presence of random fluctuations within a stochastic framework. Later, Rao *et al.* (1974) addressed the same problem with a numerical algorithm to solve the associated nonlinear equation drawing nonlocal results and establishing that the linearization approach breaks down when the system is close to a saddle-node bifurcation. In a subsequent study, Ratto (1998) applied the FP equation approach to the linearization of a stable closed-loop reactor with PI temperature control subjected to measurement noise, sufficiently away from the possibility of Hopf bifurcations (whose consideration is a central point of the present study). This study evidenced the advantages of the FP equation-based theoretical approach (with quasi-analytical solutions), with respect to Monte Carlo methods (Ratto and Paladino 2000, Paladino and Ratto 2000, Sherer and Ramkrishna, 2008; Hauptmanns, 2008).

In the context of a combustion engineering science problem, Oberlack *et al.* (2000) studied the stationary solution of the FP equation associated to a multistable homogeneous adiabatic flow reactor described by a one-dimensional deterministic system. In spite of having addressed only the steady-state aspect of the problem, this study further evidenced the capabilities and possibilities of the FP equation-based approach to tackle the chemical reactor stochastic modeling problem. These considerations on the employment of the FP equation-based approach for the treatment of dynamical nonlinear systems, in general, and of chemical reactor, in particular, motivate the present study on the global-stochastic dynamical behavior of chemical reactors with emphasis on: the presence of multistability, transient behavior and the connection between deterministic and stochastic modeling approaches.

As an inductive step towards the development of nonlocal, global, nonlinear stochastic uncertainty characterization methodology, in this work the problem of characterizing the concentration stochastic dynamical behavior of single-state nonlinear isothermal CSTR with Langmuir-Hinshelwood kinetics as representative case example with multistability phenomena has been addressed. The problem is treated within a global-nonlinear framework by combining deterministic multiplicity and bifurcation analysis tools with a FP equation-based stochastic behavior characterization, in the light of the particular system characteristics. The stochastic dynamical behavior is studied by looking at the response solution of the dynamic FP partial differential equation (PDE) to: (i) initial state uncertainty and (ii) modeling error described as a white noise exogenous input injection. As a result, a correspondence between stochastic features (mono or multimodality, potential, quasi-stability, and escape time) and deterministic features (stability, multiplicity and bifurcation) is established, enabling a better understanding of the nonlinear stochastic behavior and opening the possibility of extending the approach to multi-state chemical processes.

2. THE STOCHASTIC MODEL

Consider the single-state (x) nonlinear stochastic dynamical system:

$$\dot{x} = f[x, u(t)] + w(t), \quad x(0) = x_o, \qquad w(t) \sim N[0, q(x)] \qquad (1)$$
$$x \in X = [0, \infty)$$

with exogenous deterministic input u, and driven by input uncertainty modeled as white noise with intensity $q(x)$. In the absence of noise, with $w(t) = 0$, the (single or multiple) steady-states satisfy, for the nominal input $\bar{u}$, the static-algebraic equation $f(\bar{x}, \bar{u}) = 0$. Due to the nonlinearity of $f(x)$, the deterministic system (i.e. when $w(t)=0$) can show structural instability, meaning the existence of steady-state bifurcation points as system parameters or inputs are varied. In the one-dimensional case, the more generic bifurcation is the saddle-node, which may imply the presence of multistability regions. This means that the deterministic system reaches one of the stable equilibrium points, depending on initial conditions and system input (Wiggins, 1990). Assuming the noise intensity $q(x)$ is constant for a fixed value of the input, $u(t) = \bar{u}$, the dynamics of the concentration (normalized) probability density function (PDF) $p(x,t)$ is governed by the Fokker-Planck partial differential equation (Risken, 1996):

$$p_t(x, t) = [d\, p_x(x, t)]_x - \{f(x, \bar{u})\, p(x, t)\}_x, \; 0 \le x < \infty, \; t > 0 \qquad (2a)$$

$$x = 0: \; d\, p_x(0, t) - f(0, \bar{u})\, p(0, t) = 0, \quad x = \infty: \; p_x(\infty, t) = 0 \qquad (2b\text{-}c)$$

$$t = 0: \; p(x, 0) = p_0(x), \qquad d = q^2/2 \qquad (2d)$$

where d is the "diffusion constant" set by the noise intensity, (2b)-(2c) is the boundary condition pair and (2d) is the initial condition with initial PDF p_o. Condition (2b) establishes that x can have only positive values (Gardiner, 1997), in the understanding that this condition is easily met by writing the chemical process states in suitable scales.

2.1 Stationary probability density function

The stationary solution of (2) is given by:

$$p_s(x) = N_0 e^{-\frac{\phi(x)}{d}}, \quad \phi(x) = -\int_x f(s)ds \qquad (3a\text{-}b)$$

where N_0 is the integration constant associated to the normalization of $p_s(x)$ and $\phi(x)$ is the potential function.

From the examination of the stationary solution (3) in the light of multiplicity features of the deterministic system, the next conclusions follow. When the deterministic system has a unique global attractor $\bar{x} \in X$, the potential function $\phi(x)$ has a single well shape with minimum at $\bar{x}$, and the stationary PDF $p_s(x)$ is monomodal with maximum at $\bar{x}$, meaning that the solution $\bar{x}$ is the more probable state over X. As noise intensity decreases (d tends to zero) the monomodal PDF tends to the Dirac Delta function $\delta(x - \bar{x})$ about $\bar{x}$. When the deterministic system has multiple steady state $\bar{x}_1, \ldots, \bar{x}_m \in X$,

with domains of attraction $X_1,\ldots, X_m$ such as $\bigcup_{i=1}^{m} X_i = X$: (i) the potential function $\phi(x)$ has a multi well shape potential with minima at $\bar{x}_1,\ldots, \bar{x}_m$, (ii) the multivalued stationary PDF $p_s(x)$ has maxima at $\bar{x}_1,\ldots, \bar{x}_m$, (iii) the most probable steady state solution is the one with the deepest potential well $\phi(\bar{x}_m)$ and therefore with the largest maximum, and (iv) the difference among PDF maxima grows exponentially with the decrease of d. As a consequence of (iv), at low d values the distribution appears monomodal and tends to a Dirac Delta when the noise intensity tends to zero. Multimodality is maintained, even at low d values, when the potential minima are equal and in this case the limit as d tends to zero is a multi Dirac Delta.

2.3 *Probability distribution function evolution*

The right hand side of (2a) can be written as follows:

$$p_t = d\, p_{xx} - f(x, \bar{u})\ p_x - f_x(x, \bar{u})\, p \tag{4}$$

evidencing that: (i) the shape of the PDF over time is due to a source/sink mechanism $-f_x\ p$ combined with two transport mechanisms, one diffusive $d\ p_{xx}$ and one convective $-f\ p_x$, and (ii) the PDF temporal evolution is obtained by giving an initial value $p(x,0) = p_0(x)$ and integrating numerically the FP equation. If the deterministic system has a unique global attractor, the potential function has a single minimum, and the PDF reaches asymptotically a monomodal distribution, regardless the initial PDF shape. Otherwise, when there is deterministic steady-state multiplicity with multiple potential minima, the PDF evolution may exhibit some behaviors, which seem atypical from a deterministic nonlinear system perspective. In fact, the PDF settles at some multimodal PDF with largest maximum at (probability around) the attractor $\bar{x}_1$, then after some time, the PDF eventually starts moving and reaches another multimodal shape with a different largest maximum at (probability around) the attractor $\bar{x}_2$. In fact, for the case of steady-state multiplicity with an asymptotic (stationary) bimodal PDF, the time necessary for a state x at the steady state $x = \bar{x}_1$, with domain of attraction X_1, to escape to the steady-state $x=\bar{x}_2$, with domain of attraction X_2, is approximated by the formula (Gardiner, 1997):

$$T \propto \exp[(\phi(\bar{x}_2)-\phi(\bar{x}_1))/d] \tag{5}$$

which resembles Arrhenius' equation in chemical kinetics.

Thus stationary-to-stationary ($\bar{x}_1$-to-$\bar{x}_2$) state transition probability is favored by: i) a small well potential difference $[\phi(\bar{x}_1)-\phi\bar{x}_2)]$ and (ii) a well potential with large minima. When the minima have the same ordinate, there is not a dominant attractor and the probability of leaving one of the wells is the same.

3. STOCHASTIC MODEL OF AN ISOTHERMAL CSTR

3.1 CSTR with Langmuir-Hinshelwood kinetics

As a representative example in catalytic reactors, let us consider an isothermal CSTR with Langmuir – Hinshelwood kinetics, with the corresponding mass balance being described by the nonlinear differential deterministic system:

$$\dot{x} = f(x, Da, \sigma),\ x(0) = x_o, \tag{6}$$
$$f(x, Da, \sigma) = (1 - x) - Da(1 + \sigma)^2\, x/(1 + \sigma x)^2$$
$$x = c/c_i,\quad \tau = t/(V_R/Q),\quad Da = (V_R/Q)k/(1 + \sigma)^2,\ \sigma = K\, c_i.$$

x is the dimensionless concentration (referred to the feed concentration c_i), t and τ are, respectively, the actual and dimensionless time, Q the volumetric feedrate, V_R the reactor volume, k the reaction-rate constant, K the equilibrium adsorption constant and Da the Damkohler number. In spite of its simplicity, the above single-state system exhibits a rather rich behavior over the parameter space pair (Da, σ), showing multiple steady-states for a specified range of parameter values. In the case of multiplicity, there are two (low and high concentration) stable steady-states and one (intermediate concentration) unstable steady-state. Moreover system (6) captures the important nonlinearities which underline the lack of global and local observability at the value $x = 1/\sigma$ (where the reaction rate is maximum), in the understanding that this feature makes difficult the design of nonlinear observers and controllers of an important class of chemical reactors with nonmonotonic kinetics (Schaum *et al*., 2008).

The stochastic system associated to the deterministic reactor (6) is given by (1) replaced by $f(x,Da,\sigma)$, and the corresponding stationary PDF is given by:

$$p_s(x) = N_0 \exp\left[-\frac{1}{d}\left(-x + \frac{x^2}{2} + \frac{Da(1+\sigma)^2}{\sigma^2(1+\sigma x)} + \frac{Da(1+\sigma)^2 \ln(1+\sigma x)}{\sigma^2}\right)\right]. \tag{7}$$

3.1 *Deterministic nonlinear dynamics*

The bifurcation analysis of system (6) evidences the occurrence of saddle-node bifurcation when $Da > 0$ (see Figure 1) and, on the parameter space (Da, σ), the deterministic reactor steady-state (SS) exhibits either: (i) a unique global attractor $\bar{x}$ with domain of attraction X[0, 1], or (ii) three-SS multiplicity, with two (low and high concentration) stable and one (intermediate concentration) unstable steady-state.

In the multiplicity case, there are two basins of attraction (X_1 and X_2), one per attractor. Thus, in the single SS case any state motion $x(t)$ beginning in $x_0 \in X$ remains in X, and asymptotically converges to the steady state $\bar{x}$ in X (see Figure 2a):

$$x_o \in X = [0, 1] \Rightarrow\ x(t) \in X,\ x(t) \to \bar{x}$$

In the three-SS case (with two stable attractors $\bar{x}_i$, i = 1, 2 with domain of attraction X_i) any state motion $x(t)$ beginning in $x_o \in X_i$ remains in X_i, and asymptotically converges to the steady-state $\bar{x}_i$ in X_i, this is (see Figure 2b):

$$x_o \in X_i = [0, 1] \Rightarrow x(t) \in X_i,\ x(t) \to \bar{x}_i,\ i = 1, 2$$

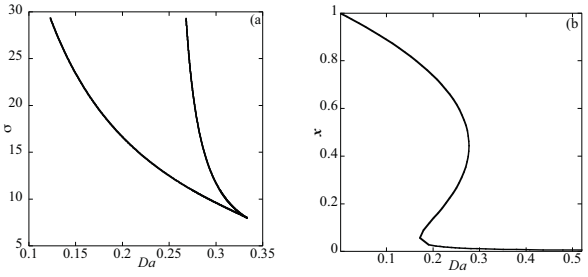

Figure 1: a) bifurcation diagram of system (6) and b) corresponding solution diagram at σ=20.

In particular, for σ = 20, the deterministic reactor system (6) exhibits: (i) a low (or high) concentration unique global attractor for $0 < Da < Da^- \approx 0.172$ (or $Da > Da^+ \approx 0.277$), (ii) three steady-states for $Da^- < Da < Da^+$, and (iii) two saddle-node bifurcations at Da equal to Da^- and Da^+ (see Figure 1).

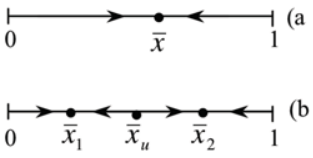

Figure 2: Phase diagram (a) in the single-SS case and (b) in the three-SS case.

3.2 *Stationary stochastic behavior*

The stationary (asymptotic) behavior of the PDF which satisfies the FP equation was investigated by setting σ equal to 20 (cf. Section 3.1), varying the value of Damkohler number $0 < Da < 1.0$ and the noise-related diffusion coefficient $10^{-5} < d < 10^{-3}$ (Ratto, 1998). The normalization constant in (3a) was calculated through the orthogonal collocation method on finite elements.

In Figure 3a (or 3b) the stationary PDF for $Da = 0.226$ (or $Da = 0.231$) with three SSs and two attractors, for two noise levels $d = 5.0\ 10^{-4}$ (continuous line) and $5.0\ 10^{-3}$ (dashed line) is shown. At the lowest d value only one peak is clearly detectable at $x \approx 0.683$ (or $x \approx 0.0178$), while the second peak corresponding to $x \approx 0.018$ (or $x \approx 0.671$) becomes evident only at the highest d value.

In Figure 4a (or 4b) is presented the potential function $\phi(x)$ (or stationary PDF for $d = 10^{-4}$) at three values of Da: 0.226 (dotted line), 0.229 (continuous line), and 0.231 (dashed line). In accordance with the deterministic bistability properties there are two attracting minima for the potential $\phi(x)$, meaning the possibility of well-to-well steady-state transition with longer residence in the deepest well. As expected, at low diffusion value only one peak is clearly visible for $Da = 0.226$ (extinction) and for $Da = 0.231$ (ignition). When the two minima have the same value, $Da \approx 0.229$, the stationary PDF exhibits bimodality made of nearly non overlapping monomodal PDFs or equivalently, a well-to-well potential without a dominant attractor.

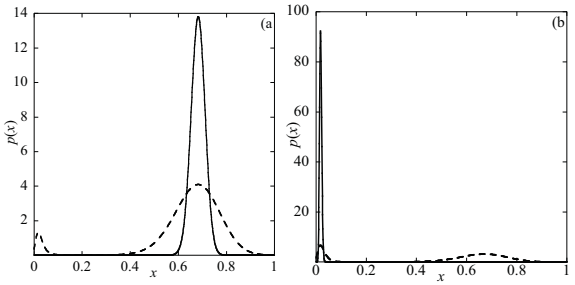

Figure 3: Stationary PDF when a) $Da = 0.226$ and b) $Da = 0.231$ for $d = 5.0\ 10^{-4}$ (solid line) and $d = 5.0\ 10^{-3}$ (dashed line).

The latter case could be considered as an important bifurcation characteristic related to the stochastic behavior, and not to the deterministic one. This Damkohler critical number Da_C is determined by the enforcement of the next equipotential conditions:

$$\left.\frac{d\phi}{dx}\right|_{(\bar{x}_1;Da_C)} = \left.\frac{d\phi}{dx}\right|_{(\bar{x}_2;Da_C)} = 0 \qquad (\bar{x}_1 \neq \bar{x}_2)$$
$$\phi(\bar{x}_1;Da_C) = \phi(\bar{x}_2;Da_C) \qquad (8)$$

In conclusion, the Da_C value corresponds to a transition between two qualitatively different behaviors of the stochastic reactor system. This transition appears smooth for high d values, meaning that a bimodal distribution is apparent in a wider neighborhood of Da_C, and becomes sharper as the diffusion coefficient tends to zero.

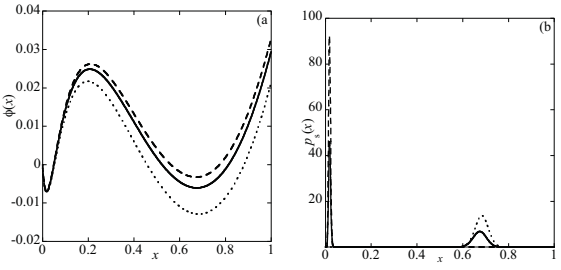

Figure 4: a) Potential function and b) stationary PDF (d=10^{-4}) for different Da values: Da=0.226 (dotted line), Da=0.229 (solid line), Da=0.231 (dashed line).

The one-dimensional manifold satisfying (8) can be derived by resorting to standard continuation algorithms (Doedel *et*

al., 1997), and the stochastic bifurcation diagram, over the (*Da*-σ) plane, was constructed and reported in Figure (5) together with the bifurcation diagram of (6).

Observe that the passage from the deterministic (Figure 1a) to the stochastic (Figure 5) bifurcation diagram evidences: (i) the correspondence between the deterministic steady-state and stochastic stationary nonlinear features, and (ii) the kind of information contained in the stochastic diagram and not in the deterministic one.

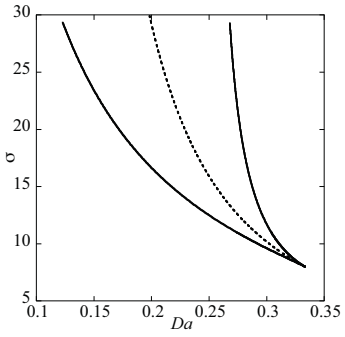

Figure 5: Diagram of the saddle-node bifurcation of the deterministic system (solid line) and the (Da_C, σ) curve (dashed line).

3.3 *Dynamic behavior*

According to the preceding developments, in a deterministic framework, the domain of attraction determines the steady-state which will be reached asymptotically by the system. However, from a stochastic point of view it may happen that one of the deterministic steady states has a low or negligible asymptotic probability of being reached, regardless the initial condition.

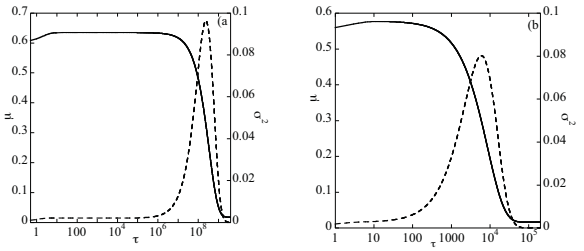

Figure 6: Dynamic behavior of mean (solid line) and variance (dashed line) of the PDF when $d = 10^{-3}$ at a) Da = 0.244 and b) Da = 0.260. The time scale is logarithmic.

Figure 6 represents the transient of mean and variance of the probability distribution function when $d = 10^{-3}$, and the initial condition is a Gaussian distribution with mean equal to 0.6 and variance equal to 0.02, at Da = 0.244 (Figure 6a) and Da = 0.260 (Figure 6b). In both cases, the absolute minimum of the potential function is positioned on the lower branch of the solution diagram, but the initial distribution is inside of the basin of attraction of the other solution, meaning that the probability that the initial condition is outside the weaker attractor is almost negligible.

The responses of the PDF show that during the transient, the mean of the distribution does not directly move towards its steady state value in the ignited zone, but first approaches the higher solution. It should be noted that, at Da = 0.244 (Figure 6a), mean and variance are almost constant for a wide interval of time (the time scale in Figure 6 is logarithmic), looking as if a stable stationary solution was definitely reached. Thus, the high concentration solution appears as a *quasi-stationary* solution. In other words, only after a long transient the system departs from the extinction steady-state and eventually reaches the ignited region. The variance reaches a maximum during the transition from the quasi-stationary to the stationary solution, implying that the PDF becomes bimodal with its two peaks corresponding to the two deterministic attractors. As time elapses, one of the peaks becomes negligible and the other one finally prevails. When Da = 0.260 (Figure 6b), the system again moves first towards the solution contained in the attraction basin where the initial distribution is centered (low conversion solution), but after a while the mean starts decreasing towards its stationary value. Some snapshots of the evolving probability distribution are shown in Figure 7 for Da = 0.244. It must be pointed out that the *quasi-stationary* condition duration can range from several to orders of magnitude the reactor natural deterministic dynamics (set by the residence time), depending on the noise intensity, and this is a fact that must be carefully accounted for in long-term prediction assessments, with applicability in safe process design.

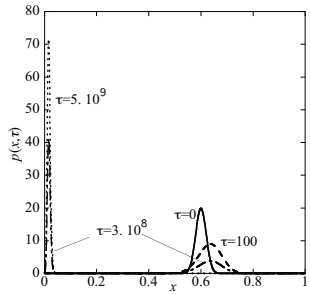

Figure 7: Snapshots of the PDF at τ=0 (solid line), τ =100 (dashed line), τ =3.0 10^8 (dashed-dotted line) and τ =5.0 10^9 (dotted line).

The duration of the *quasi-stationary* state can be related to the escape time, evaluated by means of (5). Calculating the escape time for Da = 0.244 and Da = 0.260 we found, respectively, T_1=4.3 10^8 and T_2=8.4 10^3. These results establish that stationary conditions are reached for a time greater than the calculated escape time, as confirmed by the simulation. The decreasing of the escape time as Da approaches the bifurcation value reflects the fact that the relative minimum is less and less deep until it disappears at the bifurcation point.

6. CONCLUSIONS

The global-nonlinear stochastic behavior of the concentration in an isothermal CSTR reactor with multistability has been characterized on the basis of standard deterministic tools in conjunction with FP equation theory. In addition to issues considered in previous studies in chemical reactor (Pell and Aris, 1969; Ratto 1998) and combustion engineering (Oberlack, 2000), in this study the presence of multistability, transient behavior, and the connection between deterministic and stochastic modeling approaches were considered. In particular, the interplay between the stochastic (mono or multimodality, potential, quasi-stability, and escape time) and deterministic (stability, multiplicity and bifurcation) features was identified. The stationary analysis revealed that, even when multistability was expected for the deterministic model, the probability distribution function usually appeared as monomodal, indicating that there is one dominant attractor, with higher probability of being reached asymptotically. However, the occurrence of multi-stabilities in the deterministic model did affect the behavior of the transient dynamics and the system could stay in a neighborhood of the weaker attractor for a long time interval, thus appearing as a *quasi-stationary* state.

The results of this paper constitute a point of departure: (i) to study the multi-state nonlinear stochastic system case, and (ii) to explore the implications and applications for global nonlinear estimation, control, and safe process designs.

Nonlinear Model Predictive Control Using Multiple Shooting Combined with Collocation on Finite Elements

Jasem Tamimi and Pu Li

Simulation and Optimal Processes Group, Institute of Automation and Systems Engineering, Ilmenau University of Technology, P. O. Box 10 05 65, 98684 Ilmenau, Germany. (Tel.:+49-3677-691427, e-mail:{jasem.tamimi/pu.li}@tu-ilmenau.de)

Abstract: A new approach to nonlinear model predictive control (NMPC) is proposed in this paper. The multiple shooting method is used for discretizing the dynamic system, through which the optimal control problem is transformed to a nonlinear program (NLP). To solve this NLP problem state variables and their gradients at the end of each shooting need to be computed. Here we employ the method of collocation on finite elements to carry out this task. Due to its high numerical accuracy, the computation efficiency for the integration of model equations can be enhanced, in comparison to the existing multiple shooting method where an ODE solver is applied for the integration and the chain-rule for the gradient computation. The numerical solution framework is implemented in C++. Two examples are taken to demonstrate the effectiveness of the proposed NMPC algorithm.

Keywords: Optimal control, NMPC, multiple shooting, collocation on finite elements.

1. INTRODUCTION

Solving optimal control problem is highly motivated nowadays, since these solutions are very important in almost all industrial fields such as chemical, electrical, mechanical, and economical systems. One of the optimal control algorithms is MPC which refers to a class of computer control strategies that utilize an explicit process model to predict the future response of the plant (Qin and Badgwell, 2003). MPC, also known as receding horizon control, has the ability to handle input as well as output constraints and transparent tuning capabilities (Gatlu and Zafiriou, 1992).

The main goal of MPC is to find an optimal vector of control functions that minimize or maximize a performance index subject to a given process model (usually a nonlinear differential equation system) as equality constraints, and boundary conditions as inequality constraints on the states and controls. Simple problems can be solved by the so-called *indirect method* which is based on the first order optimality condition of variation (Diehl *et al.,* 2006, Schäfer *et al.*, 2007). This leads to a two-point-boundary value problem in ordinary differential equations (ODE). For more details see e.g. Bryson and Ho (1975), Kirk (1970), and Lewis and Syrmos (1995).

On the other hand, the *direct method* which follows the philosophy of "first discretize then optimize", transforms the optimal control problem into a NLP problem which can then be solved by the method of sequential quadratic programming (SQP). In this way inequality constraints and equality path constraints can be easily treated, and we can also successfully deal with highly nonlinear complex optimal control problems (Diehl *et al.*, 2006, Schäfer *et al.*, 2007).

In all direct methods, the control trajectory will be parameterized and the state trajectories computed using either sequential or simultaneous approaches. In the *sequential approach*, the state variables are considered as an implicit function of control trajectories, where the ODEs are addressed as an initial value problem using one of the dedicated integration methods like Runge-Kutta or Euler algorithms (Sargent and Sullivan, 1977; Kraft, 1985; Biegler *et al.,* 2002). In the *simultaneous approach*, state trajectories are parameterized, too, and we deal with all of parameterized variables (states and controls) as optimization variables in the NLP. The ODEs will be represented as equality constraints, either with collocation on finite elements (Biegler *et al.,* 2002; Hong *et al.,* 2006; Li, 2007) or with multiple shooting (Bock and Plitt, 1984; Leineweber, 1995; Diehl, 2001; Diehl *et al.,* 2002a; Diehl *et al*., 2002b).

In this work, we propose a new approach to the solution of nonlinear model predictive control (NMPC) problems. This control strategy is a combination of the multiple shooting and the collocation method. We use multiple shooting for discretizing the dynamic system, so that the optimal control problem is transformed to a NLP problem in which continuity conditions in each shooting are considered as equalities and state constraints at the end of each shooting as inequalities. To solve this NLP problem the values of state variables and their gradients at the end of each shooting have to be computed. Here we employ collocation on finite elements to carry out this task. Due to its high numerical accuracy, the computation efficiency for the integration of the ODEs can be enhanced, in comparison to the existing multiple shooting method where an ODE solver is applied for the integration and chain-rules for the gradient computation. We implement the proposed approach with a numerical solution framework in C++. Two examples are taken to demonstrate the effectiveness of the proposed NMPC algorithm. The results from our approach are compared with

those achieved from the multiple shooting method (using the software MUSCOT II (Diehl *et al.*, 2001)).

2. NONLINEAR MODEL PREDICTIVE CONTROL

2.1 Optimal control problem

We will consider the following optimal control problem

$$\min \int_{t_0}^{t_f} L(x(t),u(t),t)dt + E\left(x(t_f)\right)$$

s.t.

$$\begin{aligned} &\text{(i)} && x(t_0) = x(0), \\ &\text{(ii)} && \dot{x}(t) = f(x(t),u(t),t),\ t \in [t_0,t_f] \\ &\text{(iii)} && g(x(t),u(t),t) \geq 0\ ,\ t \in [t_0,t_f] \\ &\text{(iv)} && r\left(x(t_f)\right) = 0, \end{aligned} \tag{1}$$

where $x(t), u(t)$ are the state and control variables, respectively, t_0 and t_f are initial and final time of the receding horizon, and constraint (i) is the initial value condition, (ii) the nonlinear ODE model, (iii) the path constraint, and (iv) the terminal constraint.

2.2 Direct multiple shooting scheme

The direct multiple shooting algorithm proposed by Bock and Plitt (1984) for solving problem (1) can be summarized in the following steps:

1) Discretize the time horizon $[t_0, t_f]$ into equal subintervals $[t_i, t_{i+1}]$, such that

$$t_0 < t_1 < \cdots < t_n = t_f \tag{2}$$

where *n* is the total number of subintervals.

2) Parameterize the control function $u(t)$ for each subinterval:

$$u(t) = v_i \quad for \quad t \in [t_i, t_{i+1}] \tag{3}$$
$$i = 0,1,\dots,n-1$$

3) Parameterize the initial condition of the state vector for each subinterval:

$$x(t_i) = h_i \tag{4}$$
$$i = 0,1,\dots,n-1$$

4) Evaluate the state trajectories in each subintervals and the value of h_i from the final state subinterval considering the parameterized state initial value in the previous step:

$$\dot{x}_i(t) = f(x_i(t),v_i,t),\ t \in [t_i, t_{i+1}] \tag{5a}$$
$$x_i(t_i) = h_i \tag{5b}$$

5) Define the continuity constraints:

$$h_{i+1} - x_i(t_{i+1}; h_i, v_i) = 0 \tag{6}$$

6) Compute the objective function for each subinterval, so we need to solve the following NLP

$$\min_{h_i,v_i} \sum_{i=0}^{n-1} \int_{t_i}^{t_{i+1}} L(x_i(t),v_i)dt + E\left(x_n(t_n)\right)$$

s.t. (7)

$$h_0 - x(0) = 0$$
$$h_{i+1} - x_i(t_{i+1}; h_i, v_i) = 0,\ i = 0,1,\dots,n-1,$$
$$g(h_i, v_i) \geq 0$$

Eq. (7) can be described as

$$\min_w\ A(w) \qquad s.t. \qquad \begin{cases} B(w) = 0 \\ C(w) \geq 0 \end{cases} \tag{8}$$

where $w = [h_0, v_0, h_1, v_1, \dots, h_n, v_{n-1}]$,

$$B(w) = \begin{bmatrix} h_0 - x(0) \\ h_1 - x_0(t_1; h_0, v_0) \\ \vdots \\ h_{n-1} - x_{n-2}(t_{n-1}; h_{n-2}, v_{n-2}) \end{bmatrix},$$

$$C(w) = \begin{bmatrix} g(h_0, v_0) \\ g(h_1, v_1) \\ \vdots \\ g(h_{n-1}, v_{n-1}) \end{bmatrix}.$$

We can use the spars nonlinear optimizer (SNOPT) to solve the above NLP problem. In SNOPT equality constrains will be transformed into inequality constraints by introducing a set of slack variables, i.e.

$$\min_w A(w)$$

s.t. (9)

$$\left(\begin{pmatrix} B(w) \\ C(w) \end{pmatrix} - s = 0\right), \text{ and } \ l \leq \begin{pmatrix} w \\ s \end{pmatrix} \leq u$$

where $s = (s_0, \cdots, s_{n-1}, s_n, \cdots s_{2n-2})^T$. For more information on SNOPT see Gill *et al.* (2005) and Gill *et al.* (2008). Consequently, problem (8) can now be rewritten as:

$$\min_w A(w)$$

s.t. (10)

$$l \leq D(w) \leq u$$

$$\text{where, } D(w) = \begin{bmatrix} h_0 - x(0) \\ h_1 - x_0(t_1; h_0, v_0) \\ \vdots \\ h_{n-1} - x_{n-2}(t_{n-1}; h_{n-2}, v_{n-2}) \\ g(h_0, v_0) \\ g(h_1, v_1) \\ \vdots \\ g(h_{n-1}, v_{n-1}) \end{bmatrix},$$

$$l = \begin{bmatrix} l_0 \\ \vdots \\ l_{n-1} \\ l_n \\ \vdots \\ l_{2n-2} \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix} and\ u = \begin{bmatrix} u_0 \\ \vdots \\ u_{n-1} \\ u_n \\ \vdots \\ u_{2n-2} \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ \infty \\ \vdots \\ \infty \end{bmatrix}.$$

2.3 SQP iteration

Fig. 1 shows all of the information needed for each SQP iteration.

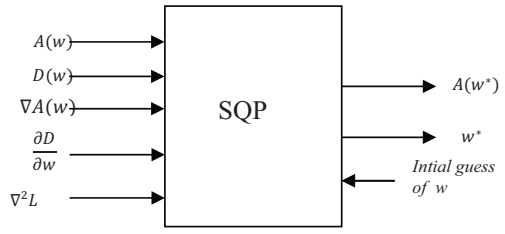

Fig. 1: Inputs and outputs of each SQP iteration.

In Fig. 1, $\nabla A(w)$ and $\frac{\partial D}{\partial w}$ are the gradient of the objective function and Jacobian of the equality constraints in (7), respectively. $A(w^*)$ and w^* are the objective function value and the optimization variables at the solution. ∇^2L denotes the Hessian of the Lagrangian. The sensitivity information, i.e. $\nabla A(w)$ and $\frac{\partial D}{\partial w}$, plays the most important role in the SQP iteration and its computation requires much CPU-time. In the existing multiple shooting algorithm it is done by integrating the ODEs with an ODE solver and then using the chain-rule for the sensitivity computation. In this work we employ the method of collocation on finite elements to carry out the ODE integration and compute these sensitivities for each shooting. This proposed method is described in the next section.

3. SOLVING ODE AND SENSITIVITIES

To solve NLP (9) we have to solve the set of ODEs (5a). If we use piece-wise constant parameters for v_i, we can rewrite the ODE in each subinterval as

$$\begin{pmatrix}\dot{x}_i(t)\\ \dot{v}_i\end{pmatrix} = \begin{pmatrix}f(x_i(t), v_i, t)\\ 0\end{pmatrix} \Rightarrow \begin{matrix}\dot{z}_i = f(z_i(t), t)\\ z_i(t_i) = [x_i\ v_i]^T\end{matrix} \quad (11)$$

Using collocation method the state variables $z_i(t)$ will be approximated by the following Lagrangian polynomials (Finlayson, 1980)

$$z(t) = \sum_{j=0}^{M}\left[\prod_{\substack{k=0\\ j\neq k}}^{M}\frac{(t-t_k)}{(t_j-t_k)}\right] z_j \quad (12)$$

where M is the number of the collocation points. Using the three-point-collocation to compute the vector z, we yield

$$z(t) = T_0 z_0 + T_1 z_1 + T_2 z_2 + T_3 z_3 \quad (13)$$

where $T_j = \prod_{\substack{k=0\\ k\neq j}}^{3}\frac{t-t_k}{t_j-t_k}$.

To define the end time point of a subinterval to be the beginning point of the next one, we yield inside each shooting

$$t_0 = t_i, \quad t_1 = \alpha_1(t_{i+1} - t_i),$$
$$t_2 = \alpha_2(t_{i+1} - t_i), \text{ and } t_3 = t_{i+1} \quad (14)$$

where $\alpha_1 = 0.127$ and $\alpha_2 = 0.5635$. Then

$$\dot{T}_{i,k} Z_{i,k} + \dot{T}_{i,0} Z_{i,0} - f_{i,k}(z_i(t), t) = 0 \quad (15)$$

where $T_{i,k} = \begin{bmatrix} T_{i,1}(t_1) & T_{i,2}(t_1) & T_{i,3}(t_1)\\ T_{i,1}(t_2) & T_{i,2}(t_2) & T_{i,3}(t_2)\\ T_{i,1}(t_3) & T_{i,2}(t_3) & T_{i,3}(t_3)\end{bmatrix}, Z_{i,k} = \begin{bmatrix} z_{i,1}\\ z_{i,2}\\ z_{i,3}\end{bmatrix}$

$$T_{i,0} = \begin{bmatrix} T_{i,1}(t_0) & 0 & 0\\ 0 & T_{i,2}(t_0) & 0\\ 0 & 0 & T_{i,3}(t_0)\end{bmatrix}, Z_{i,0} = \begin{bmatrix} z_{i,0}\\ z_{i,0}\\ z_{i,0}\end{bmatrix}$$

We solve the nonlinear equations (15) on the collocation points by using the Newton-Raphson method to find $Z_{i,k}$ and z_i. The first Taylor-expansion of (15) leads to

$$\dot{T}_{i,k}\frac{\partial Z_{i,k}}{\partial z_{i,0}} + \dot{T}_{i,0} - \frac{\partial f_{i,k}(z_i(t),t)}{\partial z_{i,0}} = 0 \quad (16)$$

We define $\frac{\partial Z_{i,k}}{\partial z_{i,0}} = \Psi_{i,k}$, then

$$\dot{T}_{i,k}\Psi_{i,k} + \dot{T}_{i,0} - \frac{\partial f_{i,k}(z_i(t),t)}{\partial z_{i,k}}\Psi_{i,k} = 0 \quad (17)$$

or

$$\Psi_{i,k} = -\left[\dot{T}_{i,k} - \frac{\partial f_{i,k}(z_i(t),t)}{\partial z_{i,k}}\right]^{-1}\dot{T}_{i,0} \quad (18)$$

In fact, equation (18) is a linear equation system and thus can be solved by a LU factorization using forward and backward substitution, for more details see Golub and van Loan (1996). From the computed value of $\Psi_{i,3}$ we receive the Jacobian $\frac{\partial D}{\partial w}$, since

$$\frac{\partial D}{\partial w} = \begin{bmatrix} I & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \cdots & 0\\ \Psi_{0,3} & I & 0 & 0 & 0 & 0 & 0 & 0 & \cdots & 0\\ 0 & 0 & \Psi_{1,3} & I & 0 & 0 & 0 & 0 & \cdots & 0\\ 0 & 0 & 0 & 0 & \Psi_{2,3} & I & 0 & 0 & \cdots & 0\\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & 0\\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \Psi_{n-1,3} & I\end{bmatrix} \quad (19)$$

where I is a unit matrix. In the same way, we can calculate the gradient vector of $\nabla A(w)$.

4. THE PROPOSED ALGORITHM

As we have seen above, the multiple shooting method depends mainly on the SQP iteration. Inside each SQP iteration the gradient values of the objective function and Jacobian of the constraints as well as the approximated Hessian need to be computed. Based on the theoretical development in Sections 2 and 3, we propose the following algorithm to solve the nonlinear optimal control problem.

Algorithm 1:

1. *Initialize SQP*
   - 1.1. *Time horizon.*
   - 1.2. *Subintervals.*

This algorithm is realized in the framework of the numerical algorithm group (NAG) library Mark 8 (Numerical Algorithms Group Ltd, 2005) and IPOPT (Wächter, 2008) for SQP and in C/C++ for the rest of computations.

5. A CASE STUDEIS

We consider the following optimal control problems to demonstrate the performance of the proposed algorithm.

Example 1: Batch reactor - temperature profile. Maximize yield of x_2 after one hour's operation by manipulating a transformed temperature $u(t)$. This example is taken from Diehl *et al.* (2001).

$$\max_{u,x1,x2} \quad x_2(t_f)$$

s.t. (20)

$$\dot{x}_1(t) = -(u(t) + \frac{u^2(t)}{2})x_1(t)$$
$$\dot{x}_2(t) = u(t)x_1(t), \qquad t \in [0,1]$$
$$x_1(0) = 1, x_2(0) = 0.$$
$$0 \le x_1(t), x_2(t) \le 1$$
$$0 \le u(t) \le 5$$

We discretize the dynamic system with 20 subintervals. The computation was done using a PC with an intel processor "Pentium 4", 3 GHz and 1G Byte RAM. The solution took 350 ms and provides the final value of objective function with $x_2(t_f) = 0.57329$. Fig. 2 shows the optimal control trajectory and Fig. 3 the corresponding state trajectory x_1 while x_2 is shown in Fig. 4. These profiles of states (x_1 and x_2) and optimal control trajectory are identical, by using both MSCOD II and the proposed algorithm.

If we solve this problem with different number of subintervals, e.g. 5, 10, 20, 40, 80 and 160 subintervals, we can note from the results, as shown in Table 1, that the number of optimization variables (z) and the number of constrains will be increased when the number of subintervals increases. The CPU-time will increase exponentially. However, if we compare the CPU-time taken by MUSCOD II with that of the proposed algorithm, it can be seen at a large number of subintervals (i.e. a high dimension of the NMPC), the proposed algorithm will be more effective.

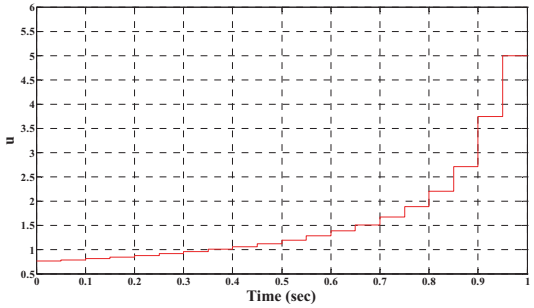

Fig. 2: The optimal control trajectory $u(t)$

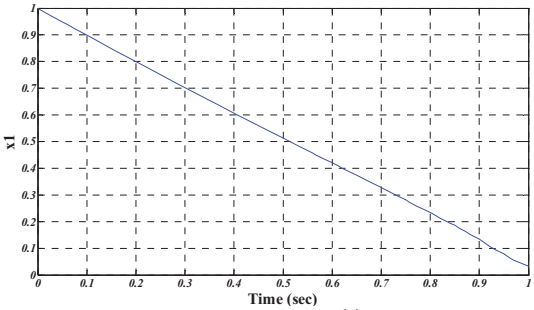

Fig. 3: The optimal state trajectory $x_1(t)$

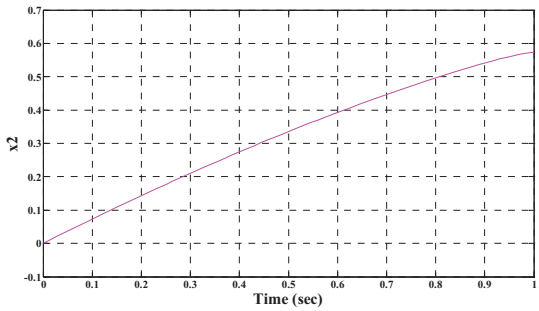

Fig. 4: The optimal state trajectory $x_2(t)$

Table 1: Results of using different number of subintervals

n	*z's*	*Co. eq.*	MUSCOD II		Algorithm 1	
			CPU-Time (ms)	*J*	CPU-Time (ms)	*J*
5	18	12	43	0.573117	188	0.568171
10	33	22	53	0.573080	290	0.572162
20	63	42	146	0.573527	350	0.573290
40	123	82	940	0.573544	480	0.573478
80	243	162	3620	0.573545	547	0.573528
160	483	322	21612	0.573545	735	0.573541

n: number of subintervals; *z's*: total number of variables; *Co. eq.*: total number of constraints; *J*: value of objective function.

Example 2: Optimal control of a continuous stirred tank reactor (CSTR): We consider a CSTR as shown in Fig. 5.

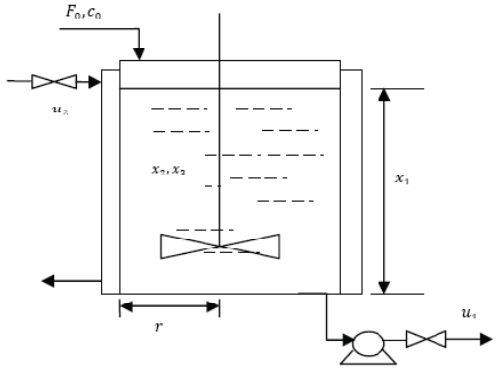

Fig. 5: CSTR example

An exothermic, irreversible, first order reaction A B occurs in the liquid phase and the temperature is regulated with external cooling. This highly nonlinear example is taken form Henson and Seborg (1997) or Pannocchia and Rawlings (2003) with the assumption that the level liquid is not constant. The constrained optimal control problem is formulated as follows:

$$\min_{x,u} \int_0^{t_f} [(x_1 - x_1^s)^2 + 100(x_2 - x_2^s)^2 + 0.1(u_1 - u_1^s)^2 + 0.1(u_2 - u_2^s)^2]dt$$

s.t. (21)

$$\dot{x}_1 = \frac{F_0 - u_1}{\pi r^2}$$

$$\dot{x}_2 = \frac{F_0(c_0 - x_2)}{\pi r^2 x_1} - k_0 x_2 e^{-E/RT}$$

$$\dot{x}_3 = \frac{F_0(T_0 - x_3)}{\pi r^2 x_1} + \frac{-\Delta H}{\rho C_p} k_0 x_2 e^{-E/RT} + \frac{2U}{r\rho C_p}(u_2 - x_3)$$

$$x_1(0) = 0.659, \quad x_2(0) = 0.877 \text{ and } x_1(0) = 324.5$$

$$0.5 \le x_1 \le 2.5, \quad 0.8 \le x_2 \le 1.0$$

$$85 \le u_1 \le 115, \quad 299 \le u_2 \le 301$$

where x_1 is the level of the tank in meter, x_2 the product concentration in mol and x_3 the reaction temperature in (K), and the controls are u_1 and u_2 the outlet flow rate in (L/min) and coolant liquid temperature, respectively. In addition the inlet flow rate F_0 or the inlet concentration c_0 is acting as a disturbance to CSTR. The desired steady-state operating points: x_1^s, x_2^s, u_1^s and u_2^s are 0.659 meter, 0.877 mol/L, 100L/min and 300K, respectively. The model parameters in nominal conditions are shown in Table 2. We consider the operation case that at the tenth minute a disturbance enters the plant at a level of 0.05 mol/L on the inlet molar concentration c_0. A time horizon of $t_f = 50$ min is considered.

Table 2: Parameters of the CSTR

F_0	100 L/min	E/R	8750 K
T_0	305 K	U	915.6 $Wm^{-2}K^{-1}$
c_0	1.0 mol/L	ρ	1 kg/L
R	0.219	C_p	0.239 $Jg^{-1}K^{-1}$
k_0	0.219	ΔH	-5×10^4 J/mol

To solve problem (21) using the proposed algorithm we divide the time horizon into 50 subintervals and so that the number of resulted NLP will be 306 variables with 204 constraints, and the same PC is used to make the optimization. We used the IPOPT 3.4.0 to solve the NLP and NAG mark 8 to solve the Newton-Raphson equations and linear equation systems.

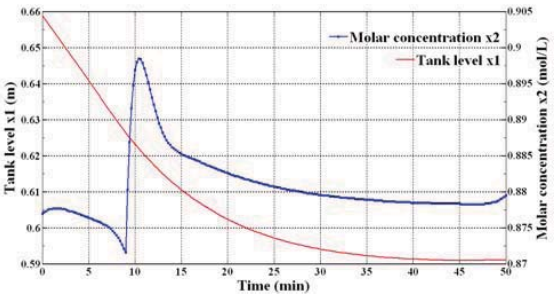

Fig. 6: The optimal output flow $x_1(t)$ and coolant temperature $x_2(t)$.

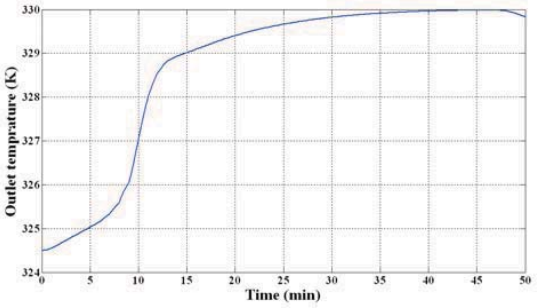

Fig. 7: The optimal outlet temperature $x_3(t)$.

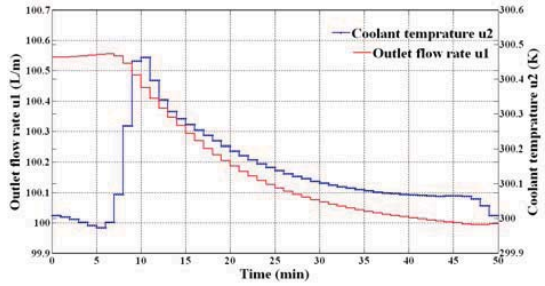

Fig. 8: The optimal control profiles $u_1(t)$ and $u_2(t)$.

Figures 6 and 7 show the optimal control profiles of the states $x_1(t)$, $x_1(t)$ and $x_3(t)$, respectively and Fig. 8 shows the optimal control profiles $u_1(t)$ and $u_2(t)$. The objective function value at the optimum is 0.9015886. Moreover, the algorithm was converged in 35 iterations and with the CPU-time in 0.954s. In comparison, this problem was also solved by Hong *et al.* (2006) using a quasi-sequential approach and it was converged in 16 iterations and 5.56 s of CPU time of SUN Ultra 10 Station with identical solutions.

6. CONCLUSIONS

In this paper we proposed a novel algorithm for NMPC. It is a combination of the multiple shooting, where the NLP problem will be handled, with the collocation method, where function values and gradients required in the NLP will be computed. We use piecewise constant for controls and the three-point collocation for states to parameterize the vector of optimization variables. The proposed algorithm has been realized in the framework of the numerical algorithm group (NAG) and IPOPT in the C/C++ environment. In addition, two demonstrative examples have been taken as case studies to show and compare the results from our algorithm and the well known MUSCOD II code. From these results it can be seen that the proposed algorithm is more efficient when a large-scale NMPC problem is to be solved. Stability and error control issues as well as practical applications of this algorithm will be considered in our future work.

Abstract: This work proposes a robust control strategy for the optimizing control of fed-batch cultures of S. cerevisae. The process dynamics is characterized by a nonlinear kinetic model based on the bottleneck assumption and ethanol inhibition for a possible excess of substrate feeding. The control strategy is based on the feedback linearization technique, where the resulting free linear dynamics is designed so as to ensure a certain robustness to plant parameter variations. A feedforward loop achieves the correct critical substrate value, which is a function of the ethanol and oxygen in the culture medium. In addition, a robust Luenberger-like observer is designed taking plant parameter variations into account. Numerical experiments demonstrate the potential of the proposed approach as a tool for control design of fed-batch cultures.

Keywords: robust control, feedback linearisation, Luenberger observer, fermentation process.

1. INTRODUCTION

The culture of host recombinant micro-organisms is probably the only economical way of producing pharmaceutical biochemicals. The cell cultures or the culture of micro-organisms are basically operated in three different modes – batch, fed-batch and continuous. The fed-batch operation is popular in industrial practice, because it is advantageous from an operational and control point of view (Roeva and Tzonkov, 2005). In this mode of operation, the bioreactor is manipulated by controlling its feeding rate. The off line design of the optimal feeding profile in general does not give high productivity, since in open-loop an excess of substrate leads to the accumulation of by-products (ethanol for yeast and acetate for bacteria), which in turn yields an inhibition of the cell respiratory capacity.

To avoid high concentrations of inhibitory by-product, a closed-loop solution is in general applied leading to a wide diversity of approaches (Chen et al., 1995; Boskovic and Narendra, 1995; Hisbullah et al., 2002; Rocha et al., 2004; Renard and Vande Wouwer, 2008; Ignatova et al., 2008). Nevertheless, the closed-loop control optimization of yeast fed-batch process is still a challenging task for two main reasons. Firstly, the process kinetics is governed by highly nonlinear functions with uncertain model parameters. Secondly, there is a lack of reliable and low cost online sensors for the measurement of key state variables.

In the control context, many researchers are applying online algorithms to cope with time-varying model uncertainties by either adaptive control (Renard and Vande Wouwer, 2008; Dewasme and Vande Wouwer, 2008; Ignatova et al., 2008) or computational intelligence based algorithms (Rocha et al., 2004; Karakuzu et al., 2006). However, the use of online adaption schemes may lead to closed-loop instability in the presence of unmodeled dynamics. In this paper, we follow a different direction by applying the robust control theory to design a nonlinear controller (with a fixed parametrization) taking model uncertainties into account. The control strategy is based on the classical feedback linearizing technique which is widely applied in fermentation process (Bastin and Dochain, 1990). However, feedback linearizing control schemes are very sensitive to model uncertainties. To handle the lack of robustness, the resulting linear dynamics is designed in order not only to improve the overall performance but also to achieve robustness against model uncertainties.

On the other hand, complex control methods need in general full state information which in most of the situations is not practical. In this case, many approaches have been proposed in the process control literature to estimate some unavailable key states based on Luenberger observer (LO) and Kalman filter (KF) (Bastin and Dochain, 1990; Klockow et al., 2008). However, these state estimators are implemented iteratively (e.g., extended LO and KF) to deal with the nonlinearities exhibited in the fermentation dynamics making difficult the task of tuning the observer gain in order to achieve a nice convergence behaviour. In this paper, we propose a robust nonlinear observer for which a nonlinear static gain is designed to improve the estimation convergence as well as to cope with model uncertainties. The rest of this paper is as follows. Section 2 introduces the problem to be addressed in this paper. The control strategy is proposed in Section 3 and the robust observer design is derived in Section 4. Numerical experiments are carried out in Section 5 to validate the approach and Section 6 ends the paper.

2. PRELIMINARIES

The yeast strain *S. cerevisiae* presents a metabolism that is macroscopically described as follows (Bastin and Dochain, 1990):

$$\text{Substrate oxidation:} \quad S + k_5 O \xrightarrow{r_1} k_1 X + k_7 P \tag{1}$$

$$\text{Substrate fermentation:} \quad S \xrightarrow{r_2} k_2 X + k_4 E + k_8 P \tag{2}$$

$$\text{Ethanol oxidation:} \quad E + k_6 O \xrightarrow{r_3} k_3 X + k_9 P \tag{3}$$

where X, S, E, O and P are, respectively, the concentration in the culture medium of biomass, substrate (typically glucose), ethanol, dissolved oxygen and carbon dioxide. The k_i, $i = 1, \ldots, 9$, are the constant yield coefficients and the r_i, $i = 1, 2, 3$, are the specific growth rates. We model these rates by the following discontinuous functions:

$$r_1 = \min\{r_S, k_5^{-1} r_O\} \tag{4}$$

$$r_2 = \max\{0, r_S - k_5^{-1} r_O\} \tag{5}$$

$$r_3 = \max\left\{0, \frac{r_O - k_5 r_S}{k_6} \cdot \frac{E}{E + K_E}\right\} \tag{6}$$

where the kinetic terms related to the substrate consumption r_S, the oxidative or respiratory capacity r_O and the ethanol oxidative rate r_E are represented as follows

$$r_S = \mu_S \ \frac{S}{S + K_S} \tag{7}$$

$$r_O = \mu_O \ \frac{O}{O + K_O} \cdot \frac{K_{i_E}}{K_{i_E} + E} \tag{8}$$

$$r_E = \mu_E \ \frac{E}{E + K_E} \tag{9}$$

with the constants μ_S, μ_O and μ_E being the maximal values of the specific growth rates and K_S, K_O and K_E expressing the saturation of the respective elements. Note that we are taking the effect of ethanol on the cells growth into account by considering the inhibition ethanol constant K_{i_E} in (8).

The component-wise mass balances of the above reaction scheme lead to the following state-space representation (Dewasme and Vande Wouwer, 2008)

$$\dot{x} = K r(x) x_1 + A x - u x + B(u) \tag{10}$$

where $x = [\, x_1 \ x_2 \ x_3 \ x_4 \ x_5 \ x_6 \,]' = [\, X \ S \ E \ O \ P \ V \,]'$ is the state vector with $x_6 = V$ being the culture medium volume, $r(x) = [\, r_1 \ r_2 \ r_3 \,]'$ is the vector of reaction rates, and $u = F_{in}/x_6$ is the control input (the dilution rate) with F_{in} denoting the inlet feed rate. The matrices K and A, and the vector function $B(\cdot)$ are given by:

$$K = \begin{bmatrix} k_1 & k_2 & k_3 \\ -1 & -1 & 0 \\ 0 & k_4 & -1 \\ -k_5 & 0 & -k_6 \\ k_7 & k_8 & k_9 \\ 0 & 0 & 0 \end{bmatrix}, \ B(u) = \begin{bmatrix} 0 \\ S_{in} \ u \\ 0 \\ k_L a \ O_{sat} \\ k_L a \ P_{sat} \\ 0 \end{bmatrix}, \tag{11}$$

$$A = \begin{bmatrix} 0_3 & 0_{3\times 2} & 0_{3\times 1} \\ 0 & -k_L a \ I_2 & 0 \\ 0_{1\times 3} & 0_{1\times 2} & 0 \end{bmatrix},$$

where $k_L a$ is the volumetric transfer coefficient, S_{in} is the feeding substrate concentration, and O_{sat} and P_{sat} are respectively the saturations of dissolved oxygen and carbon dioxide concentrations.

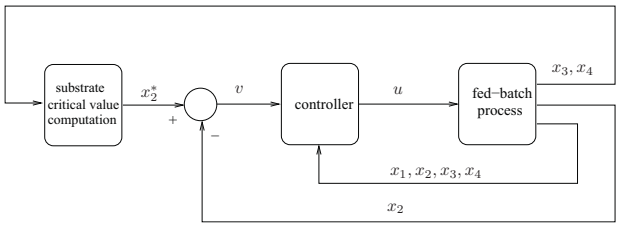

Fig. 1. Control Scheme for Optimal Operation Regime.

To analyze the biomass productivity, we recall the Sonnleitner's bottleneck assumption (Sonnleitner and Käppeli, 1986) which states that during a culture the yeast cells are likely to change their metabolism because of limited respiratory capacity. When the substrate concentration is large, the yeast cells produce ethanol (respiro-fermentative regime). If the substrate concentration becomes small, the available substrate (and possibly the ethanol) are oxidized (respirative regime). Thus, the optimal operating point to maximize the biomass productivity is at the boundary of the two regimes (Valentinotti et al., 2004), i.e., when the fermentation and oxidation reaction rates are equal to zero. Hence, the optimal operating point can be easily computed through the equality $r_O = k_5 r_S$ leading to the following equation

$$x_2^* = \frac{K_S \ r_O}{k_5 \mu_S - r_O} \tag{12}$$

where x_2^* refers to the substrate critical value.

In view of (8), we note that the operating point x_2^* is in fact a nonlinear function of x_3 and x_4. To simplify the control problem, many references either consider a constant set-point (Klockow et al., 2008) or alternatively choose a sub-optimal solution by imposing a low-level of ethanol concentration (Renard and Vande Wouwer, 2008).

3. CONTROL STRATEGY

In this paper, we aim at maintaining the system as close as possible to its optimal operating condition. To this end, we have to determine on-line the value of x_2^* and design a controller such that x_2 tracks approximately x_2^*. In addition, to simplify the analysis, we suppose in this section that all states are available on-line for feedback. For practical purposes, a nonlinear observer is proposed in the next section to estimate some state variables which are difficult to measure.

The proposed control scheme is illustrated in Figure 1. The internal feedback loops correspond to a standard feedback linearizing controller, where the free linear dynamics is designed to give a good tracking response as well as to assure a certain level of robustness against plant parameter variations. The external feedforward loop is to compute on-line the substrate critical level. We stress that instead of computing an adaptive controller to handle plant parameter variations (as, e.g., Dewasme and Vande Wouwer (2008)), we design a fixed controller that will have a guaranteed performance in the admissible parameter space.

To control the substrate level, consider the following dynamics for x_2 taken from (10)

$$\dot{x}_2 = -(r_1 + r_2)x_1 + (S_{in} - x_2)u \tag{13}$$

where r_1 and r_2 are nonlinear functions of x_2, x_3 and x_4 as given by (4) and (5). With respect to the above system dynamics, we assume that the values of $x_1, \ldots, x_6$ are bounded to a given polytopic region $\mathcal{X}$ with know vertices, that is, $x \in \mathcal{X} \subset \mathbb{R}^6$.

A feedback linearizing control law can be easily derived:

$$u = \frac{F_{in}}{x_6} = \frac{1}{S_{in} - x_2}((\tilde{r}_1 + \tilde{r}_2)x_1 + v) \tag{14}$$

where $\tilde{r}_1$ and $\tilde{r}_2$ are respectively the nominal values of r_1 and r_2, which may vary due to parameter variations, and v is the new input of the resulting linearized system.

In view of (13) and (14), we obtain the following dynamics for x_2

$$\dot{x}_2 = v - (e_{r_1} + e_{r_2})x_1 \tag{15}$$

where $e_{r_1} := r_1 - \tilde{r}_1$ and $e_{r_2} := r_2 - \tilde{r}_2$ are nonlinear functions of (x_2, x_3, x_4) representing possible inexact cancelations of nonlinear terms due to uncertain model parameters.

Borrowing the ideas of the *Quasi-LPV* approach (Leith and Leithead, 2000), we bound the term $e_{r_1} + e_{r_2}$ by a time-varying parameter $\delta = \delta(t)$ which is supposed to belong to a known set $\Delta := \{\delta : \underline{\delta} \leq \delta \leq \overline{\delta}\}$ with $\underline{\delta}$ and $\overline{\delta}$ respectively representing the minimal and maximal admissible uncertainty.

To approximately track the time-varying reference signal x_2^*, we consider the following additional control loop

$$v = \lambda(x_2^* - x_2) \tag{16}$$

where $\lambda \in \mathbb{R}$ is a free parameter to be designed.

In this paper, we design the parameter λ to ensure some robustness and a certain tracking performance to the overall closed loop system. To this end, we model the closed loop system as follows

$$\mathcal{M} : \begin{cases} \dot{x}_2 = -\lambda x_2 + a(\lambda, \delta)w \\ z = -x_2 + c\,w\ ,\ \delta \in \Delta \end{cases} \tag{17}$$

where $w = [\, x_2^* \quad x_1 \,]' \subset \mathcal{L}_{2,[0,T]}$ is a disturbance input to the system $\mathcal{M}$, $z = x_2^* - x_2$ the performance output and

$$a(\lambda, \delta) = [\, \lambda \quad -\delta \,]\ ,\ c = [\, 1 \quad 0 \,]\ .$$

Now, consider the following definition for the finite horizon $\mathcal{L}_2$-gain of system $\mathcal{M}$:

$$\|\mathcal{M}_{wz}\|_{\infty,[0,T]} = \sup_{\delta \in \Delta, 0 \neq w \subset \mathcal{L}_{2,[0,T]}} \frac{\|z\|_{2,[0,T]}}{\|w\|_{2,[0,T]}} \tag{18}$$

Thus, we design the parameter λ based on the $\mathcal{H}_\infty$ control theory (Skogestad and Postlethwaite, 2001). In other words, we solve the following optimization problem

$$\min_{\lambda, \delta \in \Delta}\ \gamma : \|\mathcal{M}_{wz}\|_{\infty,[0,T]} \leq \gamma \tag{19}$$

while ensuring the robust stability of system (17).

Note 1. The parameter λ can be easily obtained through the LMI framework either via a quadratic Lyapunov function (Boyd et al., 1994) or a parameter dependent one (de Souza et al., 2000) if we assume $\dot{\delta}$ is also bounded, since we can easily perform a line search on λ. □

4. ROBUST OBSERVER

To implement the control law proposed in the latter section, we have to measure several state variables such as X, S, E and O. In spite of existing specific probes to measure all these signals on-line, some sensors can be quite expensive and are not always available in a practical set-up. Particularly, in the proposed control strategy, we are dealing with very low levels of substrate (glucose) and ethanol concentrations making their measurements expensive and inaccurate.

Alternatively, we propose a robust Luenberger-like nonlinear observer to estimate the substrate and ethanol concentration levels from the measurement of $x_1 = X$, $x_4 = O$, $x_5 = P$ and the dilution rate $u = F_{in}/x_6$. As we are dealing with a nonlinear system, the exponential observability property of the system is state dependent (Bastin and Dochain, 1990). In other words, for large estimation errors, the observer may diverge from the system operating point since the exponential observability is lost. To overcome this problem, we assume the initial conditions $x_2(0)$ and $x_3(0)$, which are respectively the initial substrate and ethanol concentration levels, are partially known (likely through inaccurate off-line measurements).

Firstly, we model the reaction rates by the following uncertain functions:

$$r_i(x) \cong r_i(\theta_i) = \alpha_i(1 + \beta_i\theta_i)\ ,\ \theta_i \in [-1, 1] \tag{20}$$

where, for $i = 1, 2, 3$, α_i is the steady-state value of r_i, θ_i is an uncertain time-varying parameter which models the displacement of r_i from its steady-state regime and also a possible inaccuracy on the system parameters, and β_i is a given constant added in light of the unitary normalization of the uncertain parameter space. Then, we propose the following state space representation for the observer

$$\begin{cases} \dot{\hat{x}} = K\hat{r}\hat{x}_1 + \hat{A}(u)\hat{x} + \hat{B}(u, y) + L(y, u)(y - \hat{y}) \\ \hat{y} = C_y\hat{x} \\ \hat{z} = C_z\hat{x} \end{cases} \tag{21}$$

where $\hat{x} \in \mathbb{R}^6$ is the state estimation, $y = C_y x$ is the on-line measurement, $\hat{y}$ is the measurement estimation, $\hat{z}$ is the signal to be estimate, K is as in (11), $L(y, u) \in \mathbb{R}^{6\times 4}$ is a nonlinear matrix function of y and u to be determined, $\hat{r}$ is as defined in (24), and

$$\begin{aligned} \hat{A}(u) &= -\mathrm{diag}\{0, u, u, k_L a, k_L a, 0\} \\ \hat{B}(u, y) &= [\, -x_1 u \quad S_{in}u \quad 0 \quad (k_L a O_{sat} - x_4 u) \\ &\qquad (k_L a P_{sat} - x_5 u) \quad -x_6 u \,]' \end{aligned} \tag{22}$$

$$C_y = \begin{bmatrix} 1&0&0&0&0&0 \\ 0&0&0&1&0&0 \\ 0&0&0&0&1&0 \\ 0&0&0&0&0&1 \end{bmatrix}\ ,\ C_z = \begin{bmatrix} 0&1&0&0&0&0 \\ 0&0&1&0&0&0 \end{bmatrix}\ .$$

Accordingly to (20), we define the estimates of $r_i(\theta_i)$ as follows

$$\hat{r}_i := \alpha_i \tag{23}$$

where, for $i = 1, 2, 3$, $\hat{r}_i$ is the estimate of the approximate reaction rates.

Now, considering the following notation

$$r(\theta) = \begin{bmatrix} \alpha_1(1+\beta_1\theta_1) \\ \alpha_2(1+\beta_2\theta_2) \\ \alpha_3(1+\beta_3\theta_3) \end{bmatrix}\ ,\ \theta = \begin{bmatrix} \theta_1 \\ \theta_2 \\ \theta_3 \end{bmatrix}\ ,\ \hat{r} = \begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{bmatrix}\ , \tag{24}$$

we can approximate the error dynamics as follows

$$\begin{aligned}\dot{e} &\cong (K\hat{r}N_r + \hat{A}(u) - L(y,u)C_y)e + K(r(\theta) - \hat{r})x_1 \\ &\cong (K\hat{r}N_r + \hat{A}(u) - L(y,u)C_y)e + K\Omega(x_1)\theta\end{aligned}$$

where $N_r = [\,1\ 0\ \cdots\ 0\,]$, $\theta \in \Theta := \{\theta \in \mathbb{R}^3 : |\theta_i| \leq 1\ ,\ i = 1,2,3\}$ and $\Omega(x_1) = x_1 \cdot \mathrm{diag}\{\alpha_1\beta_1, \alpha_2\beta_2, \alpha_3\beta_3\}$.

In light of the above developments, we can pose the problem of determining $L(y,u)$ in an ℓ_1 optimal control setting (Dahleh and Diaz-Bobillo, 1995). To this end, consider the following error dynamics representation:

$$\mathcal{E} : \begin{cases} \dot{e} &= A_e e + B_e \theta \\ z_e &= C_z e\ ,\ \|\theta\|_\infty \leq 1 \end{cases} \tag{25}$$

where θ is an energy-peak bounded disturbance signal, z_e the estimation error to be minimized and

$$A_e = K\hat{r}N_r + \hat{A}(u) - L(y,u)C_y\ ,\ B_e = K\Omega(x_1)\ .$$

In this paper, we consider the following definition for the ℓ_1-norm of system (25):

$$\|\mathcal{E}_{\theta z_e}\|_1 = \sup_{\substack{e \in \mathbb{E}, e(0) = 0 \\ \|\theta\|_\infty \leq 1}} \|z_e\|_\infty \tag{26}$$

where $\mathbb{E} := \{e : V(e) \leq 1\}$ is an estimate of the reachable set and $V(e)$ is a Lyapunov function for system $\mathcal{E}$, which guarantees the system internal stability.

An upper-bound σ on $\|\mathcal{E}_{\theta\ e_z}\|_1^2$ can be determined via the following optimization problem (Nagpal et al., 1994)

$$\min_{\substack{V(e),\eta \\ e \in \mathbb{E}}} \sigma : \begin{cases} V(e) > 0\ ,\ \eta > 0 \\ \dot{V}(e) + \eta(V(e) - \theta'\theta) < 0 \\ V(e) - \dfrac{z_e' z_e}{\sigma} \geq 0 \end{cases} \tag{27}$$

Notice the set invariance property of $\mathbb{E}$ is guaranteed for zero initial conditions and the constraints on (27) may not hold when $e(0) \neq 0$. As a result, the error state trajectory may leave $\mathbb{E}$ and do not return since the state observer is nonlinear and the stability properties are not necessarily global. In this paper, we assume the initial error is sufficiently close to zero such that $\mathbb{E}$ is attractive.

5. NUMERICAL EXPERIMENTS

In this section, we perform several numerical experiments considering small-scale culture conditions. In particular, we borrow the 20 $[l]$ bioreactor studied in (Dewasme and Vande Wouwer, 2008), where the initial and operating conditions are:

$$\begin{gathered} x_1(0) = 0.4\ [g/l]\ ,\ x_2(0) = 0.5\ [g/l]\ ,\ x_3(0) = 3\ [g/l]\ , \\ x_4(0) = O_{sat} = 0.035\ [g/l]\ ,\ x_5(0) = P_{sat} = 1.286\ [g/l]\ , \\ x_6(0) = 6.8\ [l] \quad \text{and} \quad S_{in} = 350\ [g/l]\ . \end{gathered}$$

We study two different scenarios. Firstly, supposing the state variables are available online for feedback, we design the robust linearizing feedback controller proposed in Section 3 aiming for tracking as close as possible the estimation of the substrate critical value. In this setup, we consider a noisy ethanol measurement, since the level of ethanol is likely to be very close to zero making difficult its measurement. Secondly, we design a robust observer to estimate the substrate and ethanol concentration levels, which in the proposed strategy are very low and difficult to measure in current practice, applying the result proposed in Section 4. In this case, we analyze the observer robustness and verify the set of initial conditions in which the convergence properties hold.

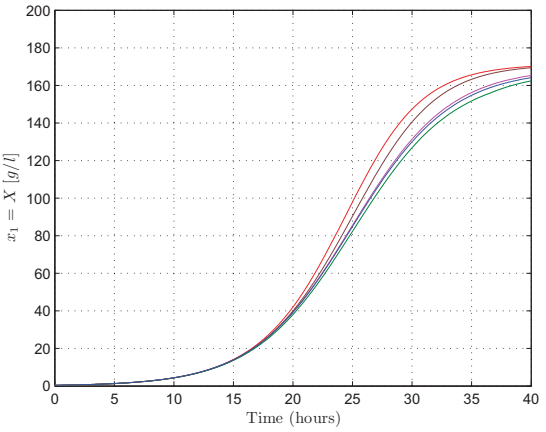

Fig. 2. Biomass concentration – state feedback case.

5.1 State Feedback

We refer to state feedback the control law proposed in (14) and (16), where x_1, x_2, x_3, x_4 and u are available online. To design the parameter λ in (16) via the optimization problem (19), we suppose the parameters K_S, K_E, K_O and K_{i_E} may vary $\pm 20\%$ from their nominal values. Simulating the operating conditions of the control strategy in (14), we may infer that $\overline{\delta} = -\underline{\delta} = 1.0$, which in light of (17) and (19) yields $\lambda = 44.8511$.

Figures 2 to 4 show the closed-loop response of biomass x_1, substrate x_2 and ethanol x_3 concentrations, for five different values of K_S, K_E, K_O and K_{i_E} (which were randomly chosen). In all simulations, we have added a white noise on the ethanol concentration measurement with a maximal amplitude of ± 0.25 $[g/l]$. Notice in all cases the biomass productivity does not significantly vary against parameter uncertainty and noise measurement.

5.2 Output Feedback

In order to design the state observer as proposed in Section 4, we have considered

$$\begin{gathered} \alpha_1 = 3.2 \times 10^{-5}\ ,\ \alpha_2 = 1.3 \times 10^{-6}\ ,\ \alpha_3 = 4 \times 10^{-7}\ , \\ \beta_1 = \beta_2 = \beta_3 = 1\ ,\ x_1 \in [0.4, 180]\ ,\ F_{in} \in [10^{-7}, 10^{-4}]\ , \end{gathered}$$

which are obtained from the noiseless simulations of the state-feedback case.

We can compute the observer gain through the LMI framework, see for instance (Coutinho et al., 2005). Assuming that u is available online, we have chosen an observer gain as follows:

$$L(y,u) = L(u) = L_0 + uL_1\ ,$$

where L_0 and L_1 are constant matrices to be determined. In addition, to simplify the computations, we constraint the Lyapunov function to be quadratic, i.e., $V(e) = e'Pe$ with $P = P' > 0$.

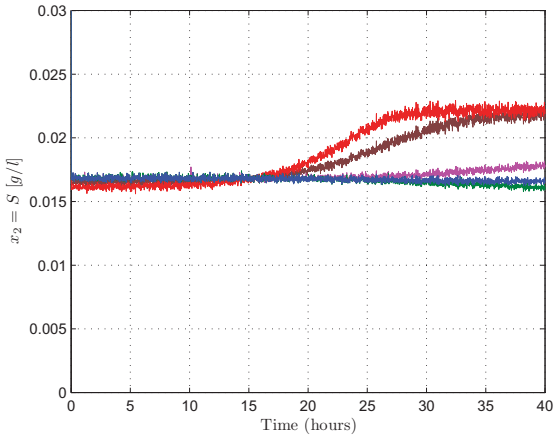

Fig. 3. Substrate concentration – state feedback case.

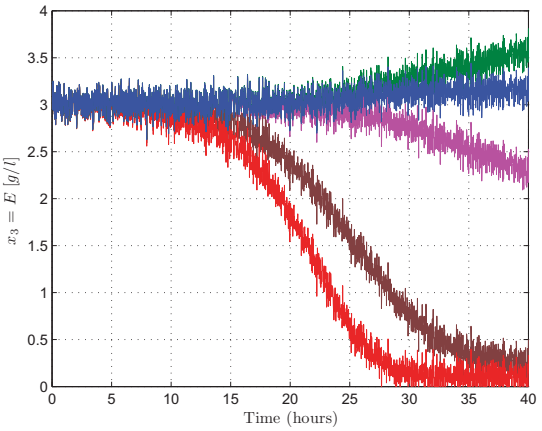

Fig. 4. Ethanol concentration – state feedback case.

Thus, solving (27) for all $(x_1, u) \in \mathcal{V}([0.4, 180] \times [10^{-7}, 10^{-4}])$ with the parametrization $Q(u) = PL(u)$ and a line search on η, we obtain the following matrices

$$L_0 = 10^6 \times \begin{bmatrix} 0.267 & -0.380 & 1.006 & 0.000 \\ -0.208 & 1.421 & -3.759 & 0.000 \\ 0.058 & -0.341 & 0.903 & 0.000 \\ -0.041 & 0.283 & -0.747 & 0.000 \\ 0.109 & -0.747 & 1.978 & 0.000 \\ 0.000 & 0.000 & 0.000 & -2\times10^{-7} \end{bmatrix}$$

$$L_1 = 10^2 \times \begin{bmatrix} 0.143 & -0.256 & 0.679 & 0.000 \\ -0.172 & 1.217 & -3.220 & 0.000 \\ 0.045 & -0.290 & 0.768 & 0.000 \\ -0.034 & 0.241 & -0.639 & 0.000 \\ 0.090 & -0.639 & 1.690 & 0.000 \\ 0.000 & 0.000 & 0.000 & 0.000 \end{bmatrix}$$

where $\mathcal{V}(\cdot)$ stands for the set of vertices of $(\cdot)$.

From several simulations, the observer initial conditions that guarantee the stability of the error system are as follows

$$\hat{x}_2(0) = x_2(0) \pm 50\% \ , \ \hat{x}_3(0) = x_3(0) \pm 50\% \ . \qquad (28)$$

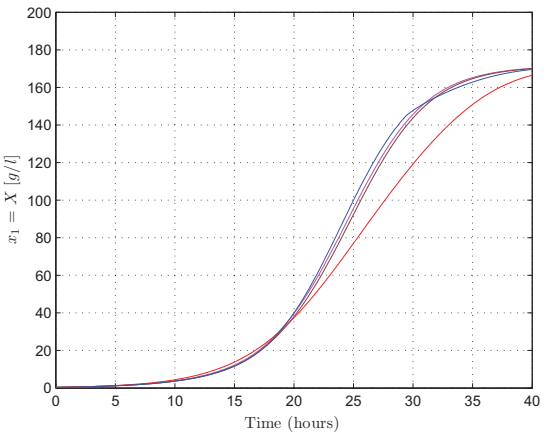

Fig. 5. Biomass concentration – output feedback case.

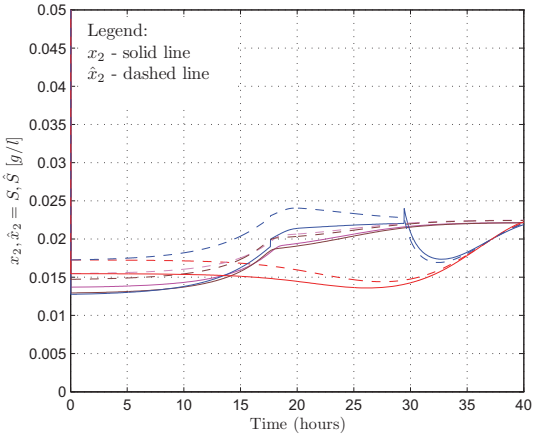

Fig. 6. Substrate concentration – output feedback case.

To test the output feedback closed-loop performance, we carried out several simulations for randomly chosen values of K_S, K_E, K_O, K_{i_E} and $\hat{x}_2(0), \hat{x}_3(0)$ from the admissible parameter space leading to the results detailed in Figures 5, 6 and 7.

5.3 Remarks and Future Research

The simulations indicate that the overall performance of the biomass concentration productivity is robust against uncertainties on model parameters and some initial condition estimates. The biomass productivity is similar to the one obtained in (Dewasme and Vande Wouwer, 2008), where an adaptive control is applied for a similar setup, but the proposed approach achieved a better transient performance. However, the ethanol concentration level does not always converge to zero indicating an error on the estimation of x_2^*. Notice we determine x_2^* from (12) which is a function of some partially known parameters. Further developments are needed to improve the estimation of the substrate concentration critical level.

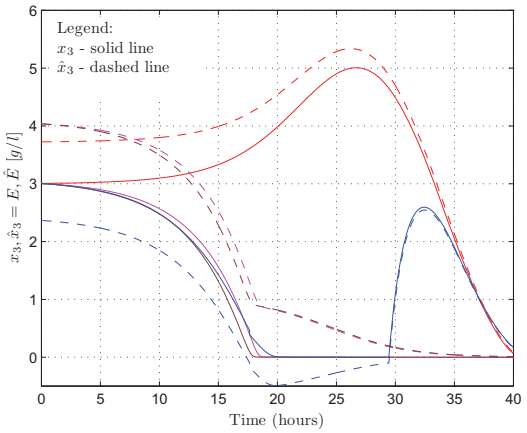

Fig. 7. Ethanol concentration – output feedback case.

6. CONCLUSION

This paper has proposed a robust control strategy to optimize the production of yeast cultures in fed-batch operation. Firstly, assuming full state information, a robust controller is designed for ensuring a guaranteed performance in spite of parameter uncertainty. Then, a nonlinear robust observer is derived in order to estimate the states that are not available online for feedback. Numerical examples have demonstrated the applicability of the proposed approach to control yeast fed-batch fermentation processes.

Abstract: A recent study (Desborough and Miller, 2001) revealed that a great majority of the control loops that operate in industry use the PID (Proportional-Integral-Derivative) controllers. Furthermore, the study has shown that more than one third of these loops were switched to manual for a considerable period of time, indicating poor behaviour of the controllers' performance. As was also reported, the gap between the industrial practice and the process control theory remains unchanged over the years, indicating that industry is looking for simple and easy to use technologies. The present research offers an alternative control scheme that intends to be a step towards introducing a new technology for practical implementation in industry. The controller is developed aiming to emulate human operators' actions when manually controlling SISO systems, subject to disturbances. The developed control scheme is based on an intuitive hypothetical model that describes the way human operators (HO) act in a manual control loop, generating the Human Operator Based Intuitive Controller (HOBIC). Since human operators typically use vague terms when describing control actions, it is natural to use fuzzy logic to express manual control actions. The HOBIC is then extended using the Fuzzy Logic theory. Membership functions within Fuzzy-HOBIC are tuned using a genetic algorithm (GA). The tuning does not require a process model. It is based on historical process operation data containing manual operation actions from experienced operators. The traditional GA is modified to cope with real valued optimisation variables and their constraints. Results show that the hypothetic model created for the HO's actions is appropriate, since the generated control actions by the HOBIC and Fuzzy-HOBIC can approximate those of human operators. The control signal generated has the same discontinuous nature of the HO's one.

Keywords: advanced control strategy, human operator model, auto-tuning, fuzzy logic, genetic algorithm

1. INTRODUCTION

Process Control theory has been well explored over decades to, at first, automate the manual control loops and thereafter, to maintain and improve them. However, it is observed that there is a gap between the Industry and the state of the art theory (Desborough and Miller, 2001). Industry presents, very often, a high resistance to put into practice what was recently developed. As a result, the vast majority of the control loops observed operates using traditional PID (Proportional-Integral-Derivative) controllers. Such kinds of controllers are very simple to apply and understand, when compared to other more advanced approaches.

However, recent studies have revealed that a great part of those PID control loops are having a poor behaviour or are operating in manual. As an example, Desborough and Miller (2001) published a survey showing that 97% of the regulatory controllers from over 11,000 control loops of refining, chemicals, pulp and paper industries use the PID strategy. Furthermore, this work mentions that only one third of these controllers provide an acceptable performance. It is also commented that this fact is in accordance with the work of Bialkoski (1993).

This leads to the challenge of investigating those control loops to verify if they can be improved by simply reviewing the applied PID strategies or, in some cases, by studying the applicability of new techniques. Nevertheless, being aware of Industry's inertia to new developments, the challenge is even greater: to develop a control strategy with a great practical appeal, so it can be easy to understand and apply.

In the authors' experience, very often, newly developed control strategies are difficult to understand by the operators, the end users of the controllers. Hence, at the first indication of bad behaviour of the loop, the operators simply switch the controller to manual and if the process engineer does not verify what caused the problem, the operator normally will not turn it into automatic again. This will reinforce the statistics of loops in manual in Industry and quickly put the new technology into disrepute.

The review by Desborough and Miller (2001) also explicitly shows that 36% of the analysed PID loops are operating in manual for at least 30% of the observed data (5,000 samples

at the dominant system time constant). Hence, almost 4,000 controllers have been switched to manual for a considerable amount of time.

This work has the objective of developing a technique which is easily understandable by the operators. By doing so, the end users of the control loop will tend to support the idea and maintain the controller in automatic.

One way of getting support of the operators is to make the control loop behave as if the loop is in manual. In other words, the controller has to give actions to the final control element in the same way as the operator would do, if he was controlling the loop. If the new controller manages to mimic this behaviour, it is less likely that the operator will switch the controller to manual.

Nevertheless, trying to emulate the operator's actions in a control scheme is not something new. Until 1966, over 200 works related to this subject were published, according to Costello and Higgins (1966).

The great majority of the research on Human Operator (HO) modelling in the past was for application in mechanical systems, such as aircrafts and vehicles dynamics (Kleinman, Baron and Levison, 1970). Investigating more recent papers in this field, it can be noticed that this area of modelling the human behaviour for applications in control systems still attracts the researchers' attention as can be seen by the works of Enab (1995); Zapata, Galvão and Yoneyama (1999); Ertugrul and Hizal (2005). However, there is still a lack of real applications of such control technique in the Process Control field.

The present research aims to construct a control system with direct application in the continuous Process Control Industry, also by modelling Human Operator actions. However, it is different from the vast majority of the previous works in this modelling field. Due to the fact that the system dominant time-constants in the Process Control area are, in general, greater than in the mechanical systems, the concern about the HO's reaction time becomes negligible. Hence, the HO modelling techniques applied by Kleinman, Baron and Levison (1970a, b) are not suitable for sluggish Process Control applications. In the same manner, Zapata, Galvão and Yoneyama (1999) presented a mechanical application where the system time-constant had the same order of magnitude of the HO responses. As a result, an ARMA (autoregressive with moving average) model for the HO had to be identified to smooth the operator actions, considered to be noisy and less consistent than the ARMA model ones.

Another important issue to be discussed is the implementation strategy that the recent works used to model the HO control actions. They applied a model-free type technique. In other words, the model was extracted based upon input-output data, either by using Neural Networks approach (Enab, 1995), Neuro-Fuzzy techniques (Ertugrul and Hizal, 2005) or simply by extracting Fuzzy rules directly (Zapata, Galvão and T. Yoneyama, 1999).

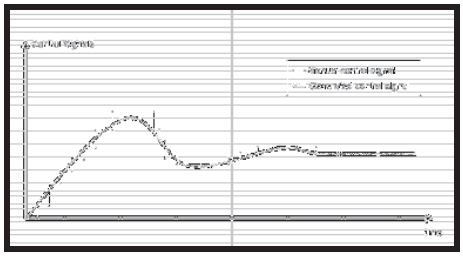

Fig. 1: Fictitious representation of a Manual control signal and a generated control signal using a model-free approach.

Although the model-free approach is able to approximate the HO behaviour, as the results of these works show, it fails to present a clear and easily understandable description of how the HO behaves and which rule system it uses to generate the actions. Even when applying Fuzzy Logic (FL) technique directly, as done by the work of Zapata, Galvão and T. Yoneyama (1999), the model-free approach generated a set of 15625 rules, which is quite difficult to understand and maintain in a practical application.

In the present work, a model-based approach is applied using the FL theory. Hence, the number of generated Fuzzy rules is expected to be much less than when using the model-free approach, and therefore easier to understand and apply in the Process Industry.

The work developed by Enab (1995) is of particular interest because it was related specifically to Process Control. The application presented was the control of the level in a tank, which has a nonlinear behaviour. This paper shows that the manual operation can be approximated using a Neural Networks approach. However, the generated control signal is continuous, compared with a "stair-like" manual signal, as can be seen by Fig.1. The difference in the signal's nature is clear. On the other hand, a FL model-based approach would be able to produce a "stair-like" signal, if the proposed rules that comprise the Human Operator model are designed to perform this task. Nevertheless, one disadvantage of the FL model-based system is that the resultant Fuzzy Logic Controller (FLC) will need to have its parameters adjusted so it will be able to reflect the behaviour of a given operator. Thus, these Membership Functions (MFs) have to be appropriately adjusted so that the generated control signal approximates the HO behaviour.

One way to cope with this disadvantage of the model-based FL approach is to come up with an automatic procedure for finding the appropriate adjustments of the MFs. In this work, this procedure is called "tuning". As there are many possible combinations for the MFs parameters, the search space for the tuning procedure is inevitably large. To solve such kind of high dimensional search space problems, Genetic Algorithms can be applied (Orvosh and Davis, 1994). In this work, a Genetic Algorithm (GA) is developed to tune and validate the proposed FL model.

The remainder of this work is organised as follows. Section 2 gives a general idea of the desired behaviour of the developed controller based on a hypothetic model for the way the HO acts in a manual control loop. In Section 3, the controller is

formally presented and its natural extension, via FL approach is achieved. In Section 4, a Genetic Algorithm (GA) is used to select the appropriate FLC parameters. A nonlinear Process Control application is tested with the developed FLC to compare the generated control actions with the manual operation in Section 5, where the results of the system simulation and discussion are presented. Section 6 summarises the conclusions of this paper and recommendations for future work.

2. HUMAN OPERATOR BASED INTUITIVE CONTROLLER DEVELOPMENT

2.1 Human Operator tasks and responsibilities

In a process plant, commonly, the HO has the responsibility of maintaining the plant under control, mainly by manipulating the final control elements, in manual loops, or by changing the controllers' set-point (SP) values.

The first concern of the operators is about safety. Right after the security concern is the production task. The production throughput should not decrease in time. Supervisors are always checking for production problems and possible causes of such incidents.

2.2 Human Operator's behaviour model

Two modes of operation may be defined for the HO:

A. When changing the operating conditions (SP-Tracking);

B. When rejecting disturbances (Disturbance Rejection).

In the first mode of operation (Mode A), the operator, to not disturb the system, will change the operating conditions only when necessary by slow changes in the final control element. This tends to minimise some problems such as interactions between loops, for example. This manual procedure is equivalent to changing the controller SP, when it is in automatic. Hence, Mode A is called SP-Tracking mode of operation. In Mode B, to reject a given disturbance, the behaviour of the operator is normally more aggressive. This is natural, since his task is to maintain the process plant under control.

An intuitive algorithm to describe the way the operator adjusts the final control element (Control Valve, for example), considering a single input single output system, subject to disturbances, can be described as follows:

1) Is the PV following the desired path (SP)?

If 'Yes' then "Do nothing. The process is under control"

Else

If Mode A: - apply Mode A procedure;

If Mode B: - apply Mode B procedure;

End

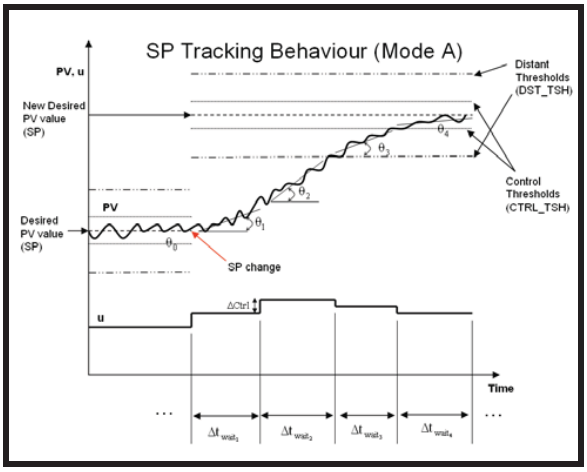

Fig.2: Intuitive HO behaviour when in Mode A of operation.

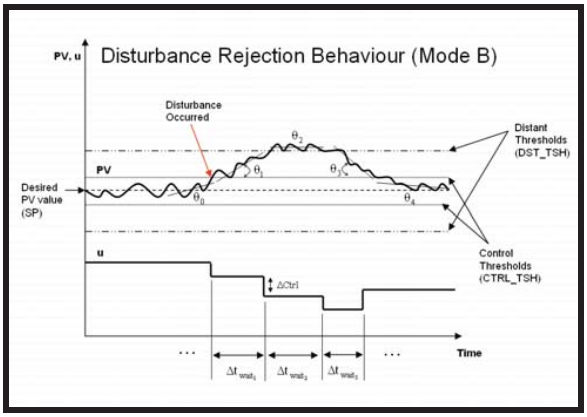

Fig. 3: Intuitive HO behaviour when in Mode B of operation.

2) When in Mode A:

Manipulate the Control Valve appropriately and wait for the system to react. If the trend of the PV is already going to the desired SP with an appropriate "velocity" do not change the Control Valve value. However, if the PV trend is going too "fast" or too "slow" to the desired SP, change the Control Valve appropriatelly and wait for the system's response

3) When in Mode B:

Perform the same actions done in Mode A, but with more aggressiveness, that depends upon the value of the PV.

From Fig. 2 and Fig. 3, some subjective terms mentioned in items 1, 2 and 3 such as "velocity", "slow" and "fast", are clarified. It can be observed that as the operator inspects the PV, he determines if the PV is under control by observing three variables, mainly:

- Variable 1 – Angle that the PV trend makes with respect to the desired SP;
- Variable 2 – Distance between the PV and SP;
- Variable 3 – Is the error increasing or decreasing?

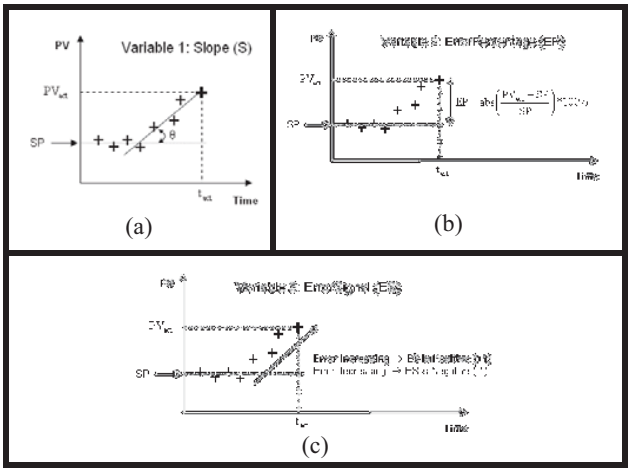

Fig.4: Variables used to encapsulate the HO's behaviour in the HOBIC.

Hence, the action taken in the Control Valve will be generated after analysing these three variables. After the action, the operator has to wait some time until the system reacts to it. The minimum time to wait (Δt_{wait}) should be greater than the Process time-delay. Thus, after observing the result of his action, the HO judges again the variables 1, 2 and 3 and takes another action or waits, if the PV is already under control again or if the PV trend is behaving as intended.

The PV is considered to be "behaving as intended" if it is approaching the SP within a given range of angles ("velocity") at a given distance from the SP that the operator establishes in his mind for that specific system. Therefore, if the angle is not within the desired range of values for a specific distance away from SP, then the control action is increased or reduced appropriately. From Fig.2 and Fig.3 it is clear that for SP-tracking (Mode A) the actions are less aggressive than when rejecting disturbances (Mode B). These figures also show that the HO has in his mind imaginary thresholds to determine how far from the SP the PV is (CTRL_TSH and DST_TSH).

2.3 The HOBIC and its natural extension –Fuzzy-HOBIC

Fig. 4 suggests the way variables 1, 2 and 3 are obtained. Variable 3, denoted as ErrorSignal (ES), reflects whether the error between SP and PV is increasing ("+1") or decreasing ("-1"). Variable 2, shown in Fig. 4(b), defines the absolute value of the error percentage between PV_{act} and SP, i.e. ErrorPercentage (EP). The reason for defining the distance between PV and SP as an error percentage measure is because the operator tends to analyse the PV value relatively to its desired value to judge if the PV is close or far from the SP. For example, for SP values of 100 units, deviations of 3 units can be considered to be "small" (3%) by the operator, and no action would be taken. However, if the SP is zero, the EP will be, by definition, the absolute value of the PV times 100%. Variable 1 defines the angle, in degrees, that the PV trend makes with the SP, denoted by Slope (S) in Fig.4(a).

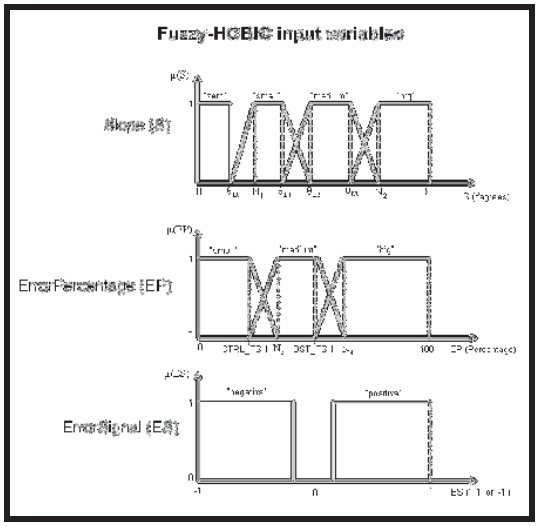

Fig. 5: Fuzzy-HOBIC Linguistic variables.

The Slope can be obtained numerically using Multi-variable Least Squares (LS). From Fig. 4(a), one can notice that the angle is obtained by using five samples (PV_{act} and the past four samples). This is a good compromise between being less sensitive to the presence of noise and getting the actual PV trend. It is being assumed here that the sampling period used is sufficiently low to capture the system dynamics (eg.: 10% of the dominant time-constant) and sufficiently high to not to capture only the noise dynamics.

After defining how the variables 1, 2 and 3 are determined in the HOBIC, the next step is to specify the thresholds CTRL_TSH and DST_TSH. The Control Threshold is, by definition, the limits within which the operator judges that the system is under control and no action is taken, when the PV has "small" Slope values. The Distant Threshold is obtained by determining the distance between PV and SP, when the operator's actions start to increase significantly. These limits are also automatically detected (Section 3).

2.4 Determining the HOBIC's rules

To be able to embed in the HOBIC the rules that the operator is using, four angle limits are defined: $\theta_{L0}, \theta_{L1}, \theta_{L2}, \theta_{L3}$. The first angle limit (θ_{L0}) is a dead band limit. In other words, the HOBIC will consider that the Slope is zero if S is less than θ_{L0}. The other three limits are distributed from θ_{L0} to 90 degrees, dividing this region into intervals. For each region of Slope values and considering the EP and ES variables, a specific action is taken in the Control Valve. Judgment about what action is to be taken given the system state (S, EP, ES) is performed by a set of 20 rules. However, these rules can be simplified by applying the FL approach.

The actual HOBIC variables S, EP and ES are considered to be linguistic input variables. The Linguistic values for these variables are as follows:

Table 1: Fuzzy-HOBIC rules definition.

Rule N°	Rule Definition	*Abs (deltaAction)*
1	IF (S is zero) and (EP is small)	*zero*
2	IF (S is zero) and (EP is medium)	*small*
3	IF (S is zero) and (EP is big)	*medium*
4	IF (S is small) and (EP is small)	*small*
5	IF (S is small) and (EP is medium)	*small*
6	IF (S is small) and (EP is big)	*medium*
7	IF (S is medium) and (EP is small)	*small*
8	IF (S is medium) and (EP is medium) and (ES is negative)	*Zero*
9	IF (S is medium) and (EP is medium) and (ES is positive)	*medium*
10	IF (S is medium) and (EP is big) and (ES is negative)	*zero*
11	IF (S is medium) and (EP is big) and (ES is positive)	*big*
12	IF (S is big) and (EP is small)	*medium*
13	IF (S is big) and (EP is medium)	*medium*
14	IF (S is big) and (EP is big) and (ES is negative)	*small*
15	IF (S is big) and (EP is big) and (ES is positive)	*max*

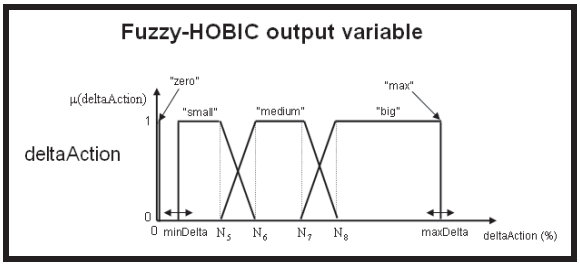

Fig. 6: Fuzzy-HOBIC output variable description.

• Slope (S): “zero”, “small”, “medium”, “big”

• ErrorPercentage (EP): “small”, “medium”, “big”

• ErrorSignal (ES): “positive”, “negative”

The Fuzzy-HOBIC input variables are described in Fig. 5. Each linguistic value is mathematically defined as a MF. Applying FL approach, the rules number is reduced to 15. They are shown in Table 1. This happens without loss of generality because of the advantage that the fuzzy rules give of activating more than one rule at a time.

It is important to notice that the control action is shown in Table 1 as an absolute value. The sign of deltaAction, is determined by observing the ES value. The Fuzzy-HOBIC output variable (deltaAction) is shown in Fig.6. About Fig. 6, the linguistic values “zero” and “max” are applied to force the Defuzzification process to give the numeric outputs zero and maxDelta, according to its respective fuzzy rules.

The process time-delay, minDelta and maxDelta values are assumed to be known inputs that depend upon the application and the HO’s behaviour, as well as the times involved to wait for the system to react, after the control actions are given.To cope with the disadvantage of having many parameters to tune for this controller, an automatic method of tuning the developed Fuzzy-HOBIC using a Genetic Algorithm (GA) is developed.

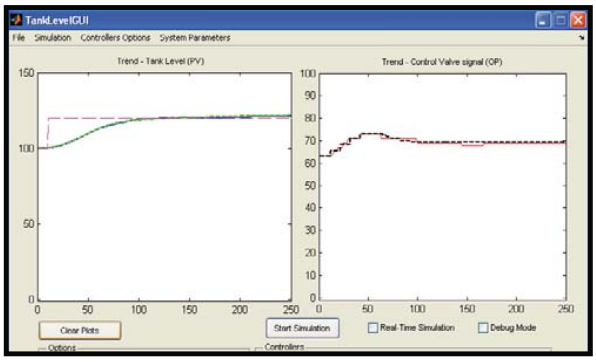

Fig. 7: Fuzzy-HOBIC (dashed lines) vs. Manual Operation (solid lines). Step up test (+20%).

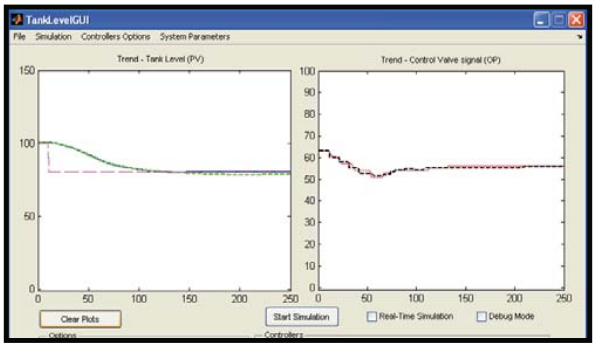

Fig. 8: Fuzzy-HOBIC (dashed lines) vs. Manual Operation (solid lines). Step down test (-20%).

3. APPLYING A GENETIC ALGORITHM TO TUNE THE FUZZY-HOBIC

The objective of the GA is to find values of the 14 parameters (P1-P14) that will make the Fuzzy-HOBIC approximate a given HO’s behaviour. The closer the Fuzzy-HOBIC’s actions are to the HO’s ones the better is the tuning. A suitable objective function, is given by (1), where $U_{man}(i)$ and $U_{FHOBIC}(i)$ represent the sample ‘i’ of the manual and the Fuzzy-HOBIC actions from a total of N

available samples, respectively.

$$J = \sum_{i=1}^{N} \frac{(U_{man}(i) - U_{FHOBIC}(i))^2}{N} \qquad (1)$$

For the developed GA, an elitist strategy is used (Chipperfield, Fleming, Pohlheim and Fonseca, 1994). The initial population is split into two sets which are used to compose three sub-populations. The first set is composed of the best individuals of the population (smallest J values). This set composes the first and the second sub-populations. The first one has a low mutation rate, while in the second a high mutation rate is applied. The low mutation rate in the first sub-population is used to search for local minimums, while the high mutation rates for the second population is applied to find new regions of minimums, trying to avoid getting trapped in local minimums.

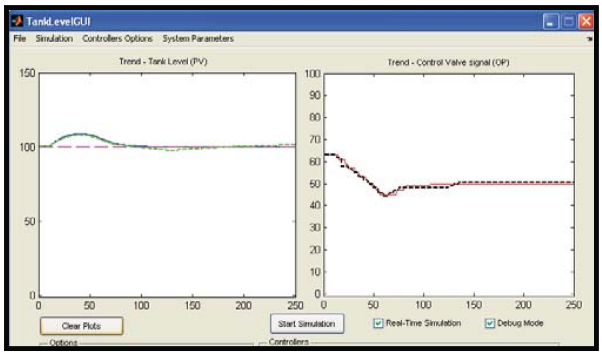

Fig. 9: Fuzzy-HOBIC (dashed lines) vs. Manual Operation (solid lines). Disturbance Rejection up test (+20%).

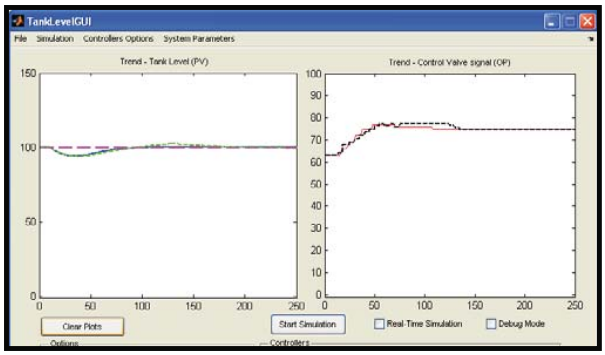

Fig. 10: Fuzzy-HOBIC (dashed lines) vs. Manual Operation (solid lines). Disturbance Rejection down test (-20%).

A third sub-population is composed of the second set of the population. In this case, a high mutation is applied, because of the same reasoning used for the second population.

The convergence criteria applied in this work is either when the best individual from the population does not change for more than 10 generations or when the maximum number of generations is exceeded.

4. RESULTS AND DISCUSSION

The application chosen for testing the Fuzzy-HOBIC is controlling the level of liquid in a Tank, in the same manner as performed by Enab (2005). This is a very common nonlinear application in the process industry. For this specific application, it is also supposed that the level needs a tight control. The input flow control valve is used to regulate the tank level, while the output flow control valve generates the non-measured disturbance. After defining the application to test the Fuzzy-HOBIC it is necessary to develop a simulation environment that reflects the proposed system to be controlled. A Graphical User Interface (GUI) was implemented to simulate the tank level system.

Figures 7-10 show the results obtained when tuning the Fuzzy-HOBIC using the GA approach. It is important to notice, however, that two different tunings where used here: one for sp-tracking and the other for disturbance rejection. The manual operations where generated using the developed GUI, by an operator that got experienced by using the system. When controlling the level in manual, two objectives where followed: 1) Do not produce any overshoot, when tracking set-point; 2) Try to eliminate the disturbance as fast as possible without making large changes in the control valve. These objectives are in accordance with the HO's behaviour, described in sub-section 2.2. As can be seen by the results, the operator's behaviour could be well approximated the tuned Fuzzy-HOBICs, showing its "stair-like" signals nature.

5. CONCLUSIONS

The results of applying the Fuzzy-HOBIC in a process control simulation have indicated that:

• The rules used to describe the HO's behaviour were adequate for approximating his manual operations in the application tested;

• A process model is not needed to tune the Fuzzy-HOBIC.

As recommendations for future work, it is suggested to test the developed controller in a real Process Control Application. Another possible application of Fuzzy-HOBIC would be to train apprentice operators, as already suggested by Zapata, Galvão, and Yoneyama (1999).

Abstract: This paper's aim is to present an analysis of the influence of the 2-DoF controllers proportional set-point weight over the servo-control performance and to show that the removal of the existing constraint for its selection ($0 \leq \beta \leq 1.0$) will allow to improve its performance when a high robust regulatory control system is required. A concrete analysis is conducted by using 2-DoF PID tuning approaches that explicitly take the desired robustness level as a design parameter. It is seen that as the desired robustness increases the tuning methods suggest values $\beta > 1.0$. Performance looses are evaluated if we are to be constrained to the case $\beta \leq 1.0$.

Keywords: PID Control, Two-Degree-of-Freedom, Set-Point Weights

1. INTRODUCTION

Since their introduction in 1940 (Babb, 1990; Bennett, 2000) commercial *Proportional - Integrative - Derivative* (PID) controllers have been with no doubt the most extensive option found on industrial control applications. Their success is mainly due to its simple structure and meaning of the corresponding three parameters. This fact makes PID control easier to understand by the control engineers than other most advanced control techniques.

With regard to the design and tuning of PID controllers, there are many methods that can be found in the literature over the last sixty years. Special attention is made of the IFAC workshop PID'00 Past, Present and Future of PID Control held in Terrassa, Spain, on April 2000, where a glimpse of the state-of-the-art on PID control was provided. It can be seen that most of them are concerned with feedback controllers which are tuned either with a view to the rejection of disturbances (Cohen and Coon, 1953; López et al., 1967; Ziegler and Nichols, 1942) or for a well-damped fast response to a step change in the controller set-point (Martin et al., 1975; Rivera et al., 1986; Rovira et al., 1969). The Two-Degree-of-Freedom (2-DoF) formulation is aimed at trying to met both objectives. This second degree of freedom is aimed at providing additional flexibility to the control system design. See for example (Araki, 1984a,b, 1985) and its characteristics revised and summarized in (Taguchi and Araki, 2000, 2002) and (Taguchi et al., 2002), as well as different tuning methods that have been formulated over the last years (Alfaro et al., 2008; Åström et al., 1992; Åström and Hägglund, 2004; Åström et al., 1998; Gorez, 2003; Hang and Cao, 1996; Hägglund and Åström, 2002; Taguchi and Araki, 2000).

This second degree of freedom is found on the presented literature as well as in commercial PID controllers under the form of the well known set-point weighting factor (usually called β) that ranges within $0 \leq \beta \leq 1.0$, being the main purpose of this parameter to avoid excessive proportional control action when a set-point change takes place. Therefore the use of *just a fraction* of the set-point.

There is however a shift of perspective with the introduction of Robustness considerations (Åström and Hägglund (1995, 2004, 2006)). As a result, less aggressive control actions are generated and smooth responses are achieved. However, if the desired level of robustness is high, step response performance can be seriously degraded. This is the analysis conducted in this paper that leads us to conclude that the use of values of β that are beyond the constraint, are definitively needed in order to get better step response performance. The analysis is conducted by using two existing tuning rules for 2-DoF PID controllers that include, as an explicit design parameter, the desired robustness level in terms of the Maximum Sensitivity value. This allows to analyze the effect of going on increasing the desired robustness level. The suggested value for β goes to values $\beta > 1.0$ in many of the cases therefore constraining the achievable performance if we are to be limited to a maximum of $\beta = 1.0$.

It is worth to notice that even the suggestion of allowing $\beta > 1.0$ seems quite common sense and natural, to the knowledge of the authors it has not still been considered. In this paper this proposal is raised within the motivation of the increased use of robustness considerations on what we could call *modern* control design approaches.

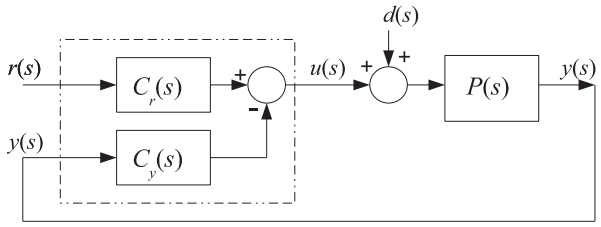

Figure 1. Closed-loop Control System

The paper is organized as follows. Section 2 introduces the control setup and the 2-DoF PID formulation. Discussion about the selection of the β parameter is also introduced. Section 3 analyzes the effects of constraining the set-point weight on robustness based tuning rules and suggests to relax that constraint in order to met a high demanding robustness-performance *tradeoff*. On Section 4 an example illustrates how performance increases if larger values of β are allowed. The paper ends in Section 5 with some conclusions.

2. 2-DOF PID FORMULATION

Consider the closed-loop control system of Fig. 1, where $P(s)$ is the *controlled process* transfer function, $C_r(s)$ the *set-point controller* transfer function, $C_y(s)$ the *feedback controller* transfer function, and $r(s)$ the *set-point*, $d(s)$ the *load-disturbance*, and $y(s)$ the *controlled variable* (process output).

The output of the controller is given by

$$u(s) = C_r(s)r(s) - C_y(s)y(s) \tag{1}$$

Without loss of generality we will use an error feedback *Ideal* PID controller which equation is

$$\begin{aligned} u(s) = & K_c \left(1 + \frac{1}{T_i s}\right) r(s) \\ & - K_c \left(1 + \frac{1}{T_i s} + \frac{T_d s}{T_d/N s + 1}\right) y(s) \end{aligned} \tag{2}$$

where K_c is the *controller gain*, T_i the *integral time constant*, T_d the *derivative time constant* and N the *derivative filter constant* (usually $N = 10$ (Visioli, 2006)). Then, the controllers' transfer functions are

$$C_r(s) = K_c \left(1 + \frac{1}{T_i s}\right) \tag{3}$$

and

$$C_y(s) = K_c \left(1 + \frac{1}{T_i s} + \frac{T_d s}{0.1 T_d s + 1}\right) \tag{4}$$

The closed-loop control system response to a change in any of its inputs, will be given by

$$y(s) = \frac{C_r(s)P(s)}{1 + C_y(s)P(s)} r(s) + \frac{P(s)}{1 + C_y(s)P(s)} d(s) \tag{5}$$

or in a compact form by

$$y(s) = M_{yr}(s)r(s) + M_{yd}(s)d(s) \tag{6}$$

where $M_{yr}(s)$ is the transfer function from set-point to controlled process variable: the *servo-control* closed-loop transfer function or complementary sensitivity function; $T(s)$; and $M_{yd}(s)$ is the one from load-disturbance to controlled process variable: the *regulatory control* closed-loop transfer function or disturbance sensitivity function $S(s)$.

Since all parameters of $C_r(s)$ are identical to the ones of $C_y(s)$ it is not possible to specify the dynamic performance of the control system to set-point changes, independently of the performance to load-disturbances changes.

If the degrees of freedom in control system are defined as the number of closed-loop transfer functions that may be selected independently (Horowitz, 1963), we have in this case a *One-Degree-of-Freedom* (1-DoF) control system.

The above constraint forces the designer to use a tuning rule developed for the specific required application (servo-control o regulatory control) finding in the literature tuning rules for regulatory control (Cohen and Coon, 1953; López et al., 1967; Ziegler and Nichols, 1942), for servo-control applications (Martin et al., 1975; Rivera et al., 1986; Rovira et al., 1969) or separate tuning rules for both applications (Chien et al., 1952; Kaya, 2004; Sung and Lee, 1999) only to mention a few. Alternatively the 1-DoF can be forced to operate in order to provide a balanced performance with respect to both operation modes. This is the so called *implicit* 2-DoF PID and has been presented in (Arrieta and Vilanova (2007b,c); Arrieta et al. (2008)). A collection of tuning methods may be found in O'Dwyer (2003).

It has been widely reported elsewhere that a control system with a controller optimized for load-disturbance rejection, normally presents high overshoots to set-point step inputs requiring a detuning with the consequential reduction in its regulatory performance. In such case, considerations about performance degradation of optimal tunings have to be taken into account (Arrieta and Vilanova (2007a)).

In order to provide additional flexibility for the control system design, a second degree of freedom was introduced into the PID algorithms in Araki (1984a,b, 1985) and its characteristics revised and summarized in Taguchi and Araki (2000, 2002) and Taguchi et al. (2002).

Consider now the PID controller equation (Åström and Hägglund, 2006)

$$\begin{aligned} u(s) = & K_c \left(\beta + \frac{1}{T_i s} + \frac{\gamma T_d s}{0.1 T_d s + 1}\right) r(s) \\ & - K_c \left(1 + \frac{1}{T_i s} + \frac{T_d s}{0.1 T_s s + 1}\right) y(s) \end{aligned} \tag{7}$$

where β and γ are the *set-point weights*.

The γ parameter is more frequently applied as a derivative mode *switch* (0 or 1) for the signal reference r. To avoid extreme instantaneous change in the controller output signal when a set-point step change occurs normally γ is set to zero. In this case the new set-point controller transfer function is

$$C_r(s) = K_c \left(\beta + \frac{1}{T_i s}\right) \tag{8}$$

and the one for the feedback controller

$$C_y(s) = K_c \left(1 + \frac{1}{T_i s} + \frac{T_d s}{0.1 T_d s + 1}\right) \tag{9}$$

which is the same as (4) above.

In commercial controllers the proportional set-point weight β may be selected only in the $0 \leq \beta \leq 1.0$ range.

Given a controlled process $P(s)$, the feedback controller $C_y(s)$ parameters (K_c, T_i, T_d) may be selected to achieve a target performance for the regulatory control $M_{yd}(s)$,

and then using the proportional set-point weight (β), in the set-point controller $C_r(s)$, to modify the servo-control performance $M_{yr}(s)$.
Under the above degree of freedom definition, we have now a *Two-Degree-of-Freedom* (2-DoF) control system. This option allowed the development of sets of tuning methods for the 2-DoF controllers as the ones found in (Alfaro et al., 2008; Åström et al., 1992; Åström and Hägglund, 2004; Åström et al., 1998; Gorez, 2003; Hang and Cao, 1996; Hägglund and Åström, 2002; Taguchi and Araki, 2000).
With regard to the commercial implementation of the PID algorithms, it is usually to find that most of them are of 1-DoF type like the ones described in (ABB ((n.d.); Foxboro (1998); Fuji (2001); Honeywell (2007); Rockwell (2003, 2005)) a few include a set-point filter ((Omron, 2007; Yokogawa, (n.d.)) and very few have 2-DoF capabilities ((Emerson, 2008; Mitsubishi, 2002)). In particular, the 2-DoF PID controller in (Emerson (2008)) allows both weights in (7) (β and γ) to be selected in the full 0 to 1 range.

3. PROPORTIONAL SET-POINT WEIGHTING ANALYSIS

From (5) and (6) the servo-control closed-loop transfer function is

$$M_{yr}(s) = \frac{C_r(s)P(s)}{1 + C_y(s)P(s)} \tag{10}$$

and the one for the regulatory control

$$M_{yd}(s) = \frac{P(s)}{1 + C_y(s)P(s)} \tag{11}$$

which are related by

$$M_{yd}(s) = C_r(s)M_{yr}(s) \tag{12}$$

Using (8) in (12) we have

$$M_{yd}(s) = K_c\left(\frac{\beta T_i s + 1}{T_i s}\right) M_{yr}(s) \tag{13}$$

On the other hand, the characteristic polynomial of the closed-loop control system is

$$p(s) = 1 + C_y(s)P(s) \tag{14}$$

from where it can be obtained the closed-loop poles location; therefore the closed-loop stability; depends only on the $C_y(s)$ parameters, hence not affected by β.
This fact makes possible to design first the feedback controller considering the *regulatory control performance* and the *closed-loop control system robustness* and, on a second step to modify the set-point controller considering only the *servo-control performance* (by the introduction of β).
Although, the instant change in the controller output signal to a step set-point change is given by

$$\Delta y_r = K_c\beta\Delta e_r = K_c\beta\Delta r \tag{15}$$

Since the performance optimization of a regulatory control system requires controllers' gains higher than the optimization of the same loop for servo-control operation, the use of a proportional set-point weight $\beta < 1$ allows to shift to the left the controller integral mode zero to a desired position to reduce the controlled signal overshoot and also to decrease the instant change in the controller output.
From the above presented analysis, it is clear that the use of a 2-DoF controller improves the servo-control performance and no questions arise about the manufactures imposed constraint on the proportional set-point weight selection range. It is along this framework that the above indicated tuning rules for 2-DoF PI and PID controllers; including the ones that take into consideration the control system robustness; constraint the set-point weight to $0 \leq \beta \leq 1$ respecting the allowed range in commercial controllers (see for example (Alfaro et al., 2008; Åström and Hägglund, 2004; Åström et al., 1998; Gorez, 2003; Hägglund and Åström, 2002; Taguchi and Araki, 2000)).
However, within a more *modern* framework robustness considerations are an integral part of practically every design approach. In such cases, as it will be explicitly shown in next section, extending the allowed range for the set-point weight will be definitively needed in order to be able to improve the servo-control performance. When a highly robust control system is required due to the expected variations in the controlled process characteristics, a significant reduction in the controller gain is needed and the performance of the control-loop will decrease. The system responses to load-disturbance and set-point changes will be slower.
This situation motivates the analysis of the proportional set-point weighting effect over the control system performance when the set-point changes, using two of the available tuning rules for 2-DoF controllers. The choice of the presented tuning rules is based on the fact that they include, as an explicit design parameter, the desired robustness level for the closed-loop control system. This setup allows for a more concrete and objective analysis. However the analysis can be easily extended to other tuning rules as the effect of getting a more robust feedback system is by sure to generate more conservative responses.

3.1 ART_2 PI Controller Tuning

The *Analytical Robust Tuning* for 2-DoF PI controllers (ART_2) follows (Alfaro et al., 2008) and is outlined here:

- *Controlled Process Model:*
$$P(s) = \frac{K_p e^{-Ls}}{Ts + 1} \tag{16}$$
where K_p is the *process gain*, T is the *time constant*, and L is the *dead-time*. It will be referred to $\tau_o = L/T \leq 1.0$ as the controlled process *normalized dead-time*.
- *Controller's Parameters:* The ART_2 tuning equations are
$$\kappa_c = K_c K_p = \frac{2\tau_c - \tau_c^2 + \tau_o}{(\tau_c + \tau_o)^2} \tag{17}$$
$$\tau_i = \frac{T_i}{T} = \frac{2\tau_c - \tau_c^2 + \tau_o}{1 + \tau_o} \tag{18}$$
where κ_c and τ_i are the controller *normalized parameters* and $\tau_c = T_c/T$ the *design parameter* (T_c is the target regulatory control closed-loop time constant).
- *Set-point Weighting:* The proportional set-point weight selection criteria is
$$\beta = \min\left\{\frac{1}{K_c}, \frac{\tau_c T}{T_i}, 1\right\} \tag{19}$$
- *Design Parameter:* The design parameter τ_c may be selected within the range
$$\max(0.50, \tau_{cmin}) \leq \tau_c \leq 1.50 + 0.3\tau_o \tag{20}$$
where τ_{cmin} is given by

$$\tau_{cmin} = k_{11}(M_s) + \left[\frac{k_{21}(M_s)}{k_{22}(M_s)}\right]\tau_o \qquad (21)$$

$$k_{11}(M_s) = 1.384 - 1.063M_s + 0.262M_s^2$$

$$k_{21}(M_s) = -1.915 + 1.415M_s - 0.077M_s^2$$

$$k_{22}(M_s) = 4.382 - 7.396M_s + 3.0M_s^2$$

allowing to design the control system with a robustness higher than the minimum required (give it by the maximum sensitivity M_s).

Using (20) and (21), the lower limits for the design parameter τ_c may be estimated. These are shown in Table 1 for robustness $1.2 \leq M_s \leq 2.0$ and controlled process model normalized dead-time $0.1 \leq \tau_o \leq 1.0$.
As it can be seen in Table 1 the lower and higher recommended limits in (20) were reached for the extreme cases (low normalized dead-time and robustness and high normalized dead-time and robustness). For the first case this means that, slow responses with high robustness system requirements will be obtained, and for the second one, that it is not possible to obtain a system with the high robustness specified.
The controller's proportional set-point weight may be obtained with (19) and they are shown in Table 2. As can be seen in this Table the existing upper limit constraint of 1.0 for β was intentionally relaxed (bold).

According to the ART_2 tuning rules, when the normalized dead-time is in the upper side of the range ($\tau_o \approx 1$) and the required system robustness is high, the recommended proportional weight would be higher than 1.0. As it can be seen in the last column of Table 2, this is the situation for practically all values of τ_o when a robustness $M_s = 1.2$ is specified. Therefore, the imposed constraint for the β value selection, in the available commercial Two-Degree-of-Freedom PID controllers, does not allow the designer to use the full capabilities of these controllers.

3.2 Integrated Absolute Error (IAE) Optimized PID Tuning

A tuning method for 2-DoF PI and PID controllers that optimizes their performance under a IAE cost functional ensuring at the same time a minimum closed-loop robustness (M_s) is described in Méndez (2008). Bellow are presented the controller parameters for one particular robustness level, say $M_s = 1.4$.

- *Controlled Process Model:*
$$P(s) = \frac{K_p e^{-Ls}}{(Ts+1)(aTs+1)} \qquad (22)$$
where K_p is the process gain, T is the dominant time constant, a is the *time constants ratio* and L is the dead-time ($\tau_o = L/T$).
- *Controller's Set-Point Weight:* Table 3 shows the PID_2 controller's set-point weighting factor for the $M_s = 1.4$ case corresponding to different values of τ_o and a. As shown in this table for this robustness most of the recommended proportional set-point weights exceed the 1.0 upper limit (bold).

Table 3. $IAE - M_s$ PID_2 Controller Set-Point Weight β

	τ_o						
a	0.1	0.25	0.50	0.75	1.0	1.50	2.0

4. EXAMPLE

This section provides an example to show the effect of the proportional set-point weighting over the servo-control system performance.
In order to have simulation results more close to industrial practice, in the example it is assumed that all variables can vary in the 0 to 100% normalized range and that in the normal operation point, the controlled variable, the set-point and the control signal, have all values close to 70%. For the tests a 20% change in set-point followed by a 10% change in load-disturbance will be used in all cases.
Performance: Performance will be evaluated for a set-point change and under the presence of a load-disturbance. The Integrated-Absolute-Error (IAE) that is defined as

$$J_{IAE} \doteq \int_0^\infty |r(t) - y(t)|\, dt \qquad (23)$$

and provides a measure for control system *output performance.*
Control input usage: On the other hand to evaluate the manipulated input usage, the total variation of the control effort $u(t)$ (TV_u) is computed. This value is defined, for a discrete signal as the sum of the size of its increments

$$TV_u \doteq \sum_{k=1}^{\infty} |u_{k+1} - u_k| \qquad (24)$$

This quantity should be as small as possible and provides a measure of the *smoothness of the control signal.*
Robustness: The maximum sensitivity value

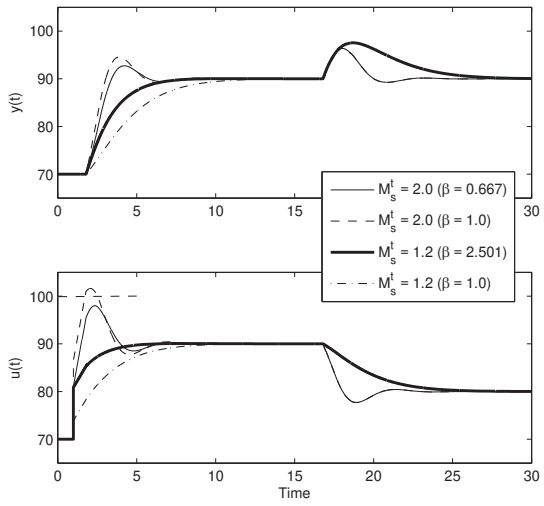

Figure 2. PI Control System Responses

Table 4. ART_2 PI Controller Parameters

M_s^t	τ_c	K_c	T_i	β
2.0	0.611	0.828	0.916	0.667
1.2	1.740	0.194	0.988	2.501

$$M_s = \max_{\omega} |S(\mathrm{j}\omega)| = \max_{\omega} \frac{1}{|1 + C_y(\mathrm{j}\omega)P(\mathrm{j}\omega)|} \qquad (25)$$

is used as a measure of the control system *robustness*. Recommended values for M_s are typically within the range 1.2 - 2.0.

Consider the particular case of controlled process (16) with $K_p = 1.0$, $T = 1.0$ and $L = 0.80$ ($\tau_o = 0.80$). The PI_2 controller's parameters obtained with the ART_2 tuning method in Section 3.1, in order to have a low robustness ($M_s^t = 2.0$) and a high robustness ($M_s^t = 1.2$) control system, are shown in Table 4 (the upper limit constraint for β was not taken into account).
System responses are shown in Fig. 2. The figure includes also the responses obtained with $\beta = 1.0$ in both cases.
The servo-control performance (J_{IAEr}) and control effort smoothness (TV_{ur}) as well as the obtained control system robustness (M_s^r) are shown in Table 5.
For the low robustness case ($M_s^t = 2.0$) the use of a proportional set-point weight lower than 1.0 ($\beta = 0.667$) allows to reduce: the servo-control controlled variable overshoot, the control effort upper value and helps to made it smoother compared with the $\beta = 1.0$ case. This last case is equivalent to the use of a 1-DoF PI controller.
In the high robustness case ($M_s^t = 1.2$) the use of a proportional set-point weight higher than 1.0 ($\beta = 2.501$) allows to improve the servo-control performance reducing J_{IAEr} without deterioration of the control effort behavior TV_{ur} compared with the case of $\beta = 1.0$. This is when the use of the set-point weight, in the 2-DoF PI controller, is setted to the upper limit allowed by the manufacturer.

Table 5. PI Control Performance and Robustness

M_s^t (β)	J_{IAEr}	J_{IAEr}(%)	TV_{ur}	TV_{ur}(%)	M_s^r
2.0 (0.667)	0.363	100%	0.398	81%	2.009
2.0 (1.0)	0.363	100%	0.489	100%	2.009
1.2 (2.501)	0.471	66%	0.201	101%	1.239
1.2 (1.0)	0.717	100%	0.200	100%	1.239

5. CONCLUSIONS

The use of a Two-Degree-of-Freedom (2-DoF) PID controller must allow the control-loop designer to take into consideration the *regulatory control performance* and *control effort* requirements in conjunction with the *control system robustness* and then improve the *servo-control performance*.
However the analysis of the recommended tuning for its proportional set-point weight has shown that the established constraint by controller's manufactures for its values to the $0 \leq \beta \leq 1.0$ range, avoids the designer to exploit the full potential of these controllers.
The allowed range for the proportional set-point weight could make sense when the controller design main objectives were only to optimize its performance but nowadays, the *performance-robustness trade-off* is taken into account within the *modern* control design formulations. Even included explicitly into the tuning equations as it has been shown in the concrete tuning rules analyzed in this paper. It has been shown that this constraint reduces the performance of the control-loop responses, to a set-point step change, when a high robustness control system is required.
The control system designer will be able to use the full inherent capabilities of the Two-Degree-of-Freedom PID controllers, only when the existing constraint in the set-point weight selection will be removed by the manufacturers.

A nonlinear control strategy for a Bidirectional Flow Process

Pablo Zúñiga Salas Héctor Ramírez Estay Daniel Sbarbaro Hofer

Department of Electrical Engineering, Universidad de Concepción,
Concepción, Chile (Tel: +56 41 2204353; e-mail: pablozuniga, hectrami, dsbarbar @udec.cl).

Abstract: A nonlinear control strategy based on Interconnection Damping Assignment Passivity Based Control (IDA-PBC) is proposed for a process with bidirectional flow. The bidirectional flow condition introduces singularities in the control action under certain operation conditions. A solution to this problem is proposed such that operation through the singular points is possible and the stability conditions around the desired operation point are exactly preserved. In addition, a passivity based integral action is included in order to take into account the effects of model uncertainties and unknown step like disturbances. A description of the process and the controller design methodology is presented along with some numerical simulations illustrating the closed-loop behavior of the proposed controller.

1. INTRODUCTION

There are many applications where the characteristic of the process changes and there is the possibility of having singular points associated to the control variable. This condition means that the states of the process are not controllable at the singular point and the control variable became unbounded. This condition can be found for instance in chemical reactors (E.J. McColm and M. T. Tham, 1995) and in electromechanical systems (F. Zhang and B. Fernandez, 2006). In most cases this problem is overcome by modifying the control law such that the singular point is eliminated. There are two approaches for dealing with this problem: the first one is based on differentiation (E. J. McColm and Ming T. Tham, 1995), and the second one on a modification of the control law (H. Xu and P.A. Ioannou, 2004). In this work, the second option is used to design an IDA-PB controller that can deal with singular points without affecting the closed loop stability when the system is outside the set of singular points.

Port-Hamiltonian (PH) systems and Interconnection Damping Assignment Passivity Based Control (IDA-PBC) are two powerful approaches for modeling and control of nonlinear systems. PH representations are physical motivated, since they are based on models representing mass and energy balances; where the structure of the model takes into account the interaction between the system and it environment.

IDA-PBC control approach relies on the notions of interconnections, dissipation and energy balance, (Ortega et al., 2001, 2002). The capability to define precisely the interconnections and energy dissipations of non-linear processes makes the use of PH representation an attractive modeling tool and hence, IDA-PBC an effective alternative to design high performance non-linear controllers for complex processes.

The IDA-PBC approach has been shown to be very effective when the system characteristics changes from one operation mode to another. For instance, in (Ramírez et al., 2008) the same IDA-PB controller is used to stabilize a minimum and a non-minimum phase system, and in (Batlle et al., 2005) this approach is used to stabilize a bidirectional power systems, where the direction of power is reversed depending on the operation mode of a power converter. In this work, a nonlinear bidirectional flow process with singular points operation is used as an application example. The process consists of three serials tanks at same height; hence flow inversion between tanks is possible. The process also considers an unknown disturbance.

This paper is organized as follows: Section 2 describes a process comprising three tanks in series with the possibility of having reversing flow, and the model of this system. Section 3 presents the design of a IDA-PBC plus integral action. In section 4, a solution to the singular point operation is proposed and the system stability is analyzed. Some simulations results are presented in section 5 and finally, in section 6, some closing remarks are given.

2. THE THREE TANKS CONTROL PROBLEM

The multi tank serial circuit is a multivariable system, fully actuated and minimum phase. This process has three tanks of the same height in a serial arrangement, as depicted in Fig. 1.

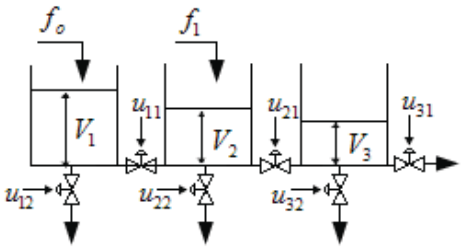

Fig. 1. Proposed system of serial tanks

In Fig. 1 the control valves are u_{11}, u_{21} and u_{31}. The remaining valves, u_{12}, u_{22} and u_{32} are manual valves, whose openings remain constant during the entire operation. On other hand, the feed flow rate into the first tank is measurable and the feed flow rate into the second tank is unknown. The last tank does not have any independent feed flow rate.

The control objective is to operate the tanks at different heights by allowing flow reversing operations.

The tanks are at the same height so the flow direction between tanks depends on the bottom pressure on each of them; i.e. the flow will go from the tank with higher water level to the tank with lower one. This reversing flow phenomenon occurs only in the first and second tanks because they are the only ones with an independent feed flow rate, f_o and f_1 respectively. The maximum water level in the third tank is the level of the second tank, because it does not have an independent water flow rate. Another phenomenon, that arises during the flow reversing process, is the lack of controllability, this occurs when the water level in the first and second tank are the same.

Physically, given a set of feed flow rates the processes always operate in one of these modes. In order to model the process using mass balance equations, the following variables are defined: $x_i \in \mathbb{R}_+$ is the volume inside of a tank i, A_i the cross section (they are constant and the same for all tanks) and $k_{ij}(u_{ij}) = u_{ij}$ linear valve opening functions. Thus, the equations representing the system are:

$$\dot{x}_1 = f_o - u_{11} \cdot sign(x_1 - x_2) \cdot a_1 - b_1 , \quad (1)$$

$$\dot{x}_2 = f_1 + u_{11} \cdot sign(x_1 - x_2) \cdot a_1 - u_{21} \cdot sign(x_2 - x_3) \cdot a_2 - b_2 , \quad (2)$$

$$\dot{x}_3 = u_{21} \cdot sign(x_2 - x_3) \cdot a_2 - u_{31} \cdot a_3 - b_3 , \quad (3)$$

where, for notational convenience, we have defined:

$$a_1 = \sqrt{2g\left(\frac{x_1}{A_1} - \frac{x_2}{A_2}\right)} \; ; \; a_2 = \sqrt{2g\left(\frac{x_2}{A_2} - \frac{x_3}{A_3}\right)} \; ; \; a_3 = \sqrt{2g\frac{x_3}{A_3}}$$

$$b_1 = \sqrt{2g\frac{x_1}{A_1}} \cdot u_{12} \; ; \; b_2 = \sqrt{2g\frac{x_2}{A_2}} \cdot u_{22} \; ; \; b_3 = \sqrt{2g\frac{x_3}{A_3}} \cdot u_{32} .$$

In order to invert the flow rate direction, between the first and second tank, the feed flow rate in the first tank must satisfy $f_o \le b_1$. This can be obtained by calculating the operation point for u_{11}

$$u_{o11} = \frac{f_o - b_1}{a_1 \cdot sign(x_{o1} - x_{o2})} . \quad (4)$$

Thus, in order to have $u_{o11} \ge 0$, for a operation point $x_{o1} < x_{o2}$ with $x_{o1}, x_{o2} \in \mathbb{R}_+$, the following inequality has to be satisfied that $f_o - b_1 \le 0$. To get a flow from the first to the second tank we need $f_o - b_1 \ge 0$.

We will also define the set of singular points as all the $x_1, x_2 \in \mathbb{R}_+$, such that $x_1 = x_2$.

From the knowledge of the process and given a set of possible combinations of feed flow rates, the following operating modes can be identified:

Operation Mode 1: The feed flows are: $f_o > b_1, f_1 \ge 0$, the initial state $x_1^0 > x_2^0 > x_3^0$, with $x_1^0, x_2^0, x_3^0 \in \prod \subset \mathbb{R}_+$ and references $x_1^* > x_2^* > x_3^*$, with $x_1^*, x_2^*, x_3^* \in \mathbb{R}_+$. The set $\prod$ represents the physical admissible levels. The flow goes from the first to the second tank.

Operation Mode 2: The feed flows are: $f_o \le b_1, f_1 > 0$, the initial state $x_1^0 > x_2^0 > x_3^0$, with $x_1^0, x_2^0, x_3^0 \in \prod \subset \mathbb{R}_+$ and references $x_1^* < x_2^*$ and $x_3^* < x_2^*$, with $x_1^*, x_2^*, x_3^* \in \mathbb{R}_+$. The flow is inverted and goes from the second to the first tank.

Operation Mode 3: The feed flows are: $f_o \le b_1, f_1 > 0$, the initial state $x_1^0 < x_2^0$ and $x_3^0 < x_2^0$, with $x_1^0, x_2^0, x_3^0 \in \prod \subset \mathbb{R}_+$ and references $x_1^* < x_2^*$ and $x_3^* < x_2^*$, with $x_1^*, x_2^*, x_3^* \in \mathbb{R}_+$. The flow goes from the second to the first tank.

Operation Mode 4: The feed flows are: $f_o > b_1, f_1 \ge 0$, the initial state $x_1^0 < x_2^0$ and $x_3^0 < x_2^0$, with $x_1^0, x_2^0, x_3^0 \in \prod \subset \mathbb{R}_+$ and references $x_1^* > x_2^* > x_3^*$, with $x_1^*, x_2^*, x_3^* \in \mathbb{R}_+$. The flow is inverted and goes from the first to the second tank.

3. CONTROLLER DESIGN USING IDA-PBC

It is convenient to represent the system in a PH form, to simplify the application of the IDA-PBC.

Consider a process described by a PH system of the form

$$\dot{x} = \left[J(x) - \Re(x)\right]\frac{\partial H}{\partial x}(x) + g(x)u + q(x)f \quad (5)$$

Where $x \in \mathbb{R}^n$ and $u \in \mathbb{R}^m$ are the mass (volume) variables and the control, respectively. The smooth function $H(x)$ typically represents the total stored mass, $f = \begin{bmatrix} f_o & f_1 \end{bmatrix}^T \in \mathbb{R}^m$ represents constant disturbances and $q(x)$ defines the interaction between the system and *f*. the skew-symmetric matrix $J(x) = -J^T(x)$ represents the interconnection between the different system's components, and $\Re(x) = \Re^T(x) \ge 0$ is the dissipation matrix, while $g(x)$ defines the interconnection of the system with its

environment. A detailed overview of PH systems can be found in (van der Shaft, 2004).

To represent the tank processes as PH model, the following storage function is selected, which represents the total mass (volume) in the system

$$H(x) = x_1 + x_2 + x_3 \geq 0 \,. \tag{6}$$

The IDA-PBC methodology allows to find a static control feedback $u = \beta(x)$ such that the desired performance is specified by a closed loop dynamic as

$$\dot{x} = \left[J_d(x) - \Re_d(x)\right]\frac{\partial H_d(x)}{\partial x}, \tag{7}$$

where $H_d(x)$ is the desired total mass function fixed by the designer and which has a strict minimum in x^*. The matrices $J_d(x) = -J_d{}^T(x)$ and $\Re_d(x) = \Re_d{}^T(x) \geq 0$ are the desired interconnection and damping matrices respectively. In order to get decoupled outputs, the closed loop port Hamiltonian system has to have a null interconnection matrix and a diagonal damping matrix. For accomplishing this objective, it is possible to define the open-loop PH system such that it satisfies these characteristics. The PH matrixes are

$$J(x) = -J^T(x) = 0 \,, \tag{8}$$

$$\Re(x) = \Re^T(x) = diag\{b_1, b_2, b_3\} \,, \tag{9}$$

$$g(x) = \begin{bmatrix} -sign(x_1 - x_2)\cdot a_1 & 0 & 0 \\ sign(x_1 - x_2)\cdot a_1 & -sign(x_2 - x_3)\cdot a_2 & 0 \\ 0 & sign(x_2 - x_3)\cdot a_2 & -a_3 \end{bmatrix}, \tag{10}$$

$$q(x) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}^T \,. \tag{11}$$

The closed loop interconnection and damping matrices have to be equal to the open loop matrices; i.e. $J_d(x) = J(x)$ and $\Re_d(x) = \Re(x)$. If this is satisfied, the closed-loop process has decoupled outputs. The references levels are constant, so the following desired storage function (Ramírez *et al,* 2008) can be used,

$$H_d(x) = \sum_{i=0}^{n} x_i + \sum_{i=0}^{n} -(1-k_i)x_i - k_i x_i^* \ln(x_i)$$

$$= \sum_{i=0}^{n}\left[x_i - k_i x_i^* \ln(x_i)\right]. \tag{12}$$

For the given desired storage function and for previously defined open and closed loop PH matrices, by matching (5) and (7) the following control law, where $\hat{f}_1$ is an estimation of f_1, is obtained

$$u_{11} = \frac{f_o - b_1 + b_1 \cdot k_1\left(1 - \dfrac{x_1^*}{x_1}\right)}{sign(x_1 - x_2)\cdot a_1}, \tag{13}$$

$$u_{21} = \frac{\hat{f}_1 - b_2 + b_2 k_2\left(1 - \dfrac{x_2^*}{x_2}\right) + u_{11}\cdot a_1 \cdot sign(x_1 - x_2)}{sign(x_2 - x_3)\cdot a_2}, \tag{14}$$

$$u_{31} = \frac{-b_3 + b_3 k_3\left(1 - \dfrac{x_3^*}{x_3}\right) + u_{21}\cdot a_2 \cdot sign(x_2 - x_3)}{a_3} \,, \tag{15}$$

If the control inputs (13), (14) and (15) are replaced in (5), then the time derivate of the desired storage function, will be negative, thereby the closed-loop system is asymptotically stable.

Equations (13) and (14) require to know the system parameters and flow rates f_o and f_1. In order to compensate the lack of knowledge about the values of these flow rates, an integral action is considered in the final control law. The solution used in this paper was presented in (Ortega and García-Canseco, 2004) and consists in adding an integral term of the passive output to the control.

Let's consider the system presented in (5) in closed loop with $u = \beta(x) + \upsilon$, where υ is an integral action added to the system trough a state variable and defined as

$$\dot{\upsilon} = -K_I g^T(x)\nabla H_d(x) \tag{16}$$

With $K_I = K_I{}^T > 0$. Then, all stability properties of x^* are preserved. In fact the closed loop clearly takes the PCH form

$$\begin{bmatrix} \dot{x} \\ \dot{\upsilon} \end{bmatrix} = \begin{bmatrix} J_d(x) - \Re_d(x) & g(x)K_I \\ -K_I g^T(x) & 0 \end{bmatrix}\begin{bmatrix} \nabla_x W \\ \nabla_\upsilon W \end{bmatrix} \,, \tag{33}$$

where

$$W(x,\upsilon) = H_d(x) + \frac{1}{2}\upsilon^T K_I{}^{-1}\upsilon \tag{17}$$

is the new total storage function which now qualifies as Lyapunov function. For this application it is convenient to use a diagonal gain matrix, i.e. $K_I = diag\ \{k_{I1}, k_{I2}, k_{I3}\}$, $g(x)$ like in (10) and $H_d(x)$ like in (12).

4. SINGULAR POINT REGULARIZATION

The control action (13), (14) and (15), have singulars points arising when two tanks have the same level. In this case, the flow between these tanks becomes null and the control action becomes inexistent. Operating the system on this singulars point is not required in this application. However, if the controller attempts to invert the flow between two contiguous tanks, it is necessary to pass from a state $x_1 > x_2$ to a state

$x_1 < x_2$. Along the trajectory is necessary to pass trough $x_1 = x_2$, which make the control law unfeasible. This only happens between the first and second tank, hence, the solution is only used in the first control input.

Based on the work of Haojian and Ioannou (2004), a singular point solution is proposed. Assume a function $\eta(x) \in \mathbb{R}$ such that $\eta(0) = 0$. The inverse of $\eta(x)$ is undetermined at zero. To avoid this, the following solution is proposed:

$$\frac{1}{\eta(x)} \Rightarrow \frac{\eta(x)}{\eta^2(x) + \delta(x)}, \tag{18}$$

where $\delta(x)$ is defined as follows:

$$\delta(x) = c_1 \cdot \left(1 - \frac{1}{1 + e^{-c_2 \cdot |x_1 - x_2|}}\right) \cdot \left| e_{ctrl}(x, x^*) \right| \cdot k_{sp}, \tag{19}$$

where k_{sp}, c_1 and c_2 are real positive constants and they are considered as tuning parameters. Equations (19) means that $\delta(x)$ will be zero if x is at the reference x^*. Of course, the references x_1^* and x_2^* must be different, otherwise (18) will be unbounded.

The control input (13) including the singular point solution becomes:

$$u_{11} = \frac{sign(x_1 - x_2) \cdot a_1 \cdot \left(f_o - b_1 + b_1 \cdot k_1 \left(1 - \frac{x_1^*}{x_1}\right)\right)}{a^2{}_1 + \delta(x)} \quad . \tag{20}$$

The control variables u_{21} and u_{31} do not require changes since they do not have singular points.

4.1 Stability Analysis

In this section a brief and simple stability analysis is carried out. Replacing (20), (14) and (15) in (1), (2) and (3), respectively, the closed loop system takes the form:

$$\dot{x}_1 = -\frac{a_1^2}{a_1^2 + \delta(x)} b_1 k_1 \left(1 - \frac{x_1^*}{x_1}\right) + \left(f_o - b_1\right) \frac{\delta_1(x)}{a_1^2 + \delta(x)} \tag{21}$$

$$\dot{x}_2 = -b_2 k_2 \left(1 - \frac{x_2^*}{x_2}\right) + \Delta f_1 \tag{22}$$

$$\dot{x}_3 = -b_3 k_3 \left(1 - \frac{x_3^*}{x_3}\right) \tag{23}$$

where $\Delta f_1 = f_1 - \hat{f}_1$ is the estimation error of the unknown disturbance in the second tank.

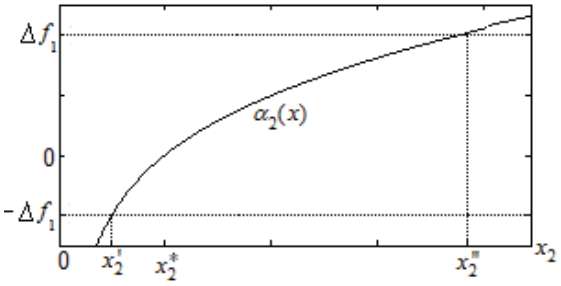

Fig. 2. Right hand terms of equation (22)

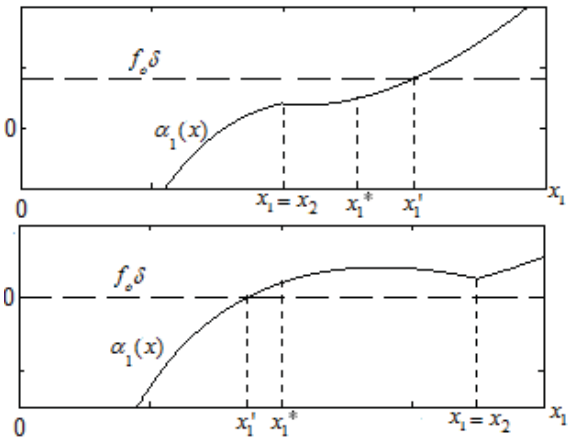

Fig. 3. Right hand terms of equation (21) for a constant δ

Then stability of the closed-loop system can be analyzed as follows: Since equation (23) only depends on x_3 and the term $b_3 k_3$ is positive, x_3^* will be an asymptotically stable equilibrium point. From equation (22) we have that the dynamic only depends on x_2. The stability analysis can be carried out by analyzing the right hand terms, as they are depicted in Fig. 2., where Δf_1 and the term $\alpha_2(x) = b_2 k_2 (1 - x_2^*/x_2)$ have been drawn in terms of x_2. From this plot can be seen that the system will converge to a unique equilibrium point x_2'', so that $\|x_2'' - x_2^*\| < \gamma$, where $\gamma(\Delta f_1) > 0$ is a real positive constant that depends on Δf_1. If $\Delta f_1 = 0$, then x_2^* will be asymptotically stable equilibrium point, as x_3^*. The analysis for x_1 consider the perturbation term $(f_o - b_1)\delta/(a_1^2 + \delta(x))$, which vanishes at the equilibrium, hence x_1 could converge asymptotically to x_1^*. In fact, the expression for the equilibrium point is:

$$\left(f_o - b_1\right) \delta(x) - a_1^2 b_1 k_1 \left(1 - \frac{x_1^*}{x_1}\right) = 0 . \tag{24}$$

Equation (24) can be verified at the desired operation point x_1^* or if $(f_o - b_1) = 0$ and $a_1 = 0$. The last case can only be possible if the system is at the singular point; i.e. if $x_1^* = x_2^*$ and $f_o = b_1 = (2g x_1)^{1/2}$. Fig. 3 depicts the right hand terms of (21); $\alpha_1(x)$ defined as:

$$\alpha_1(x) = b_1 \delta(x) + a_1^2 b_1 k_1 \left(1 - \frac{x_1^*}{x_1}\right), \tag{25}$$

and for both condition $(f_o - b_1) > 0$ and $(f_o - b_1) < 0$. From this figure can be seen that there exist only one asymptotically stable equilibrium point x_1^*, which is not the desired reference value, the steady state error will depend on δ and f_o. Fig. 5, shows the effect of making δ dependant on the variable x, as in (20). In this case, the desired reference value is an asymptotically stable equilibrium point.

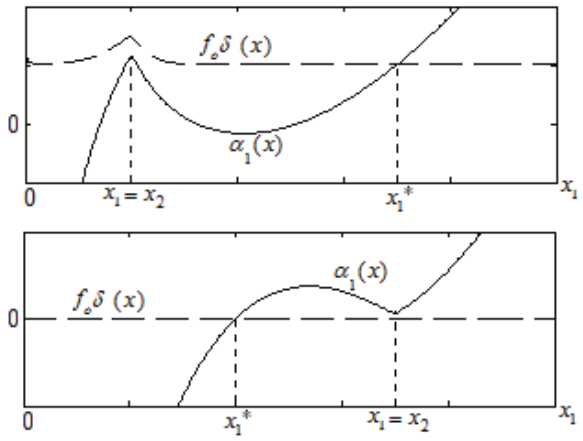

Fig. 4. Right hand terms of equation (21) for a variable δ (x)

5. NUMERICAL SIMULATIONS

In this section, some simulation results illustrating the controller characteristics are presented. The tuning parameters were selected to obtain a closed loop response with overshoots smaller than 15% and small settling times according with the open loop dynamics.

This simulation considers the following: linear control valves, i.e. $k_{ij}(x) = u_{ij}$ and the cross section of all tanks are the same and constant, i.e. $A_1 = A_2 = A_3 = 1731.3$. The tuning parameters for the singular points solution where selected as $C_1 = 500$ y $C_2 = 0.0004$. The feed flows rates have their maximum value at 4000 cm^3/s and are represented in percentage values.

If the flow direction, between the first and second tank, is inverted, then the system go through a singular point. The following simulations show the performance of the system with a flow rate inversion. The parameters were k_1=4, k_2=2, k_3=1 and the integrator parameter were set at k_{I1}=0.0001, k_{I2}=0.01, k_{I3}=0.01.

In the first part, the system is working with a level of 10cm in the first tank and 5 cm in the second one, and the flow between the tanks goes from the first to the second. Fig.5 depicts the closed loop behavior. At 4250 the both set points were increased at the same time. to 35cm and 25cm respectively. At 5000 sec. the level reference of the first tank is set to 15cm and for the second one is kept at 25cm, leading to an inversion of the flow direction. From Fig. 5 can be seen that while the level in the first tank changes, the control tries to maintain the level in the second tank constant, and it invert the flow direction without discontinuities in the control inputs. The coupling between the outputs is due to the integrator compensation, since the static feedback was designed considering a null interconnection matrix. These good results are achieved due to the joint action of the integral action and the methodology used to deal with the singular point.

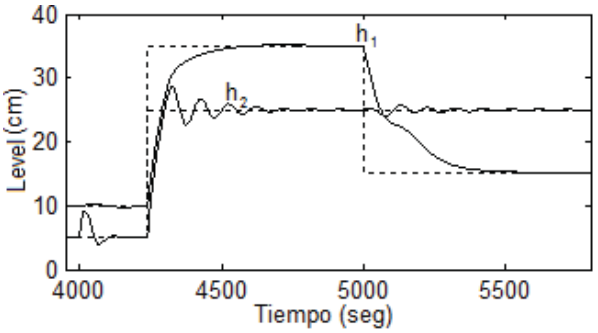

Fig. 5. Levels in first and second tank. Integral action and flow rate inversion

From Fig. 6, can be seen that the control input, in both tanks (1 and 2), are smooth, continuous and bounded. Beside, Fig. 7 shows the flow rate inversion (5070 seconds approx.), and the sudden changes of the flow rate when the control inputs changes their values due to references changes.

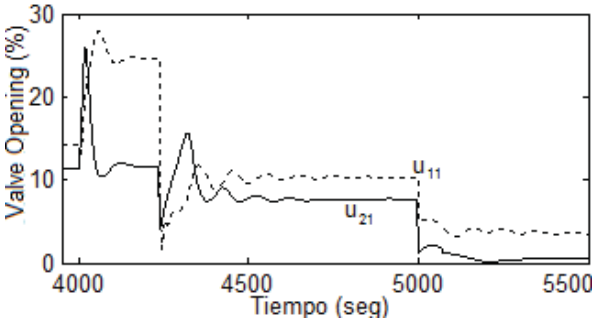

Fig. 6. Control input of the first and second tank. Integral action and flow rate inversion

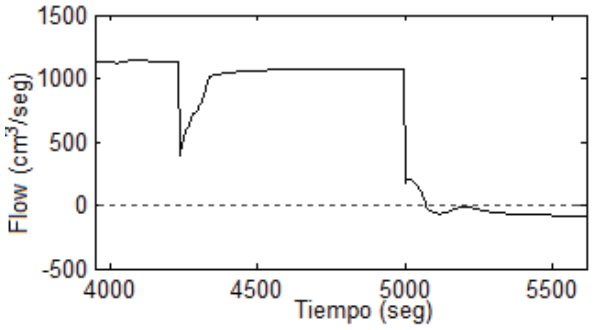

Fig. 7. Flow rate between the first and second tank. Integral action and flow rate inversion

A simple PI controller can not deal with reversing flows, since the process open-loop gain changes sign when the flow changes direction.

6. CONCLUDING REMARKS

This paper presents a novel nonlinear control strategy based on IDA-PBC for a non-linear process with bidirectional flow. The process was modeled as PH model, and by a proper selection of the process closed-loop matrices. A passivity based strategy was designed, and in order to deal with model uncertainties and unknown disturbances, integral action was also considered in the control law. Since the process exhibits uncontrollable operation conditions; i.e. singular points in the control law, a singular point solution was proposed without compromising the stability conditions of the closed-loop process. A nice feature of the proposed singular point solution is that outside the set of singular points the desired closed-loop interconnection and damping specifications are preserved, hence no special considerations must be taken into account when selecting the desired closed-loop PH system in the IDA-PBC design. The closed-loop behavior of the proposed controller has been illustrated by numerical simulations.

Future works will consider a more detailed stability analysis for the general case, including integral actions. Implementation of the controller in a laboratory application is also part of the future work to be carried out.

Characteristics-based MPC of a fixed bed reactor with catalyst deactivation

Abstract: In this work characteristics-based model predictive control (CBMPC) of a fixed bed reactor with catalyst deactivation is studied. Performance of CBMPC has been analyzed for two cases: one that incorporates the catalyst deactivation within the reactor model and another that ignores the deactivation. Simulation results show that the performance of first controller that incorporates the catalyst deactivation is better than the controller that ignores the deactivation.

Keywords: Fixed bed reactor, Catalyst deactivation, Characteristics-based model predictive control

1. INTRODUCTION

A catalyst loses its activity during operation. Catalyst deactivation can have variety of consequences. It may cause thermal instability of the reactor. It also affects the conversion and selectivity of the desired reaction. Consequently, it will affect the productivity and energy efficiency of the plant. In order to compensate for the effect of catalyst deactivation, the operating conditions are changed gradually to ensure maintaining the quality of product and the rate of production. Then designing a controller that can ensure changing optimal process operating conditions are tracked as they vary, is an important issue in operation of catalytic reactors.

Integration of the catalyst deactivation dynamics into the reaction system model results in a model that can describe the dynamical behavior of the system more precisely. By using this model in model-based algorithms, one can design a more efficient controller.

The objective of this work is to study the control of a fixed bed reactor with catalyst deactivation. In order to capture all of the main "macroscopic" phenomena (i.e., reactions, diffusion, convection, and so forth), the model of a fixed bed reactor takes the form of a mixed set of partial differential, ordinary differential, and algebraic equations. Such systems and many others (e.g., systems modeled by partial difference equations, integral equations and delay differential equations) are called distributed parameter systems (DPS) or infinite dimensional systems. Since we will consider the catalyst deactivation in the reactor's model, the resulting infinite dimensional system will be time varying.

Aksikas et al. (2009) and Aksikas et al. (2008) studied the control of the time varying infinite dimensional systems. In these works linear-quadratic controllers are developed by solution of the classical Riccati equation. This work is extended by Mohammadi et al. (2009) to cover the two-time scale property of the fixed bed reactors.

Model Predictive Control (MPC) is an optimal control technique that uses a model of the system to predict the future plant behavior and determines a sequence of control moves so that the predicted response moves to the desired set point in an optimal manner. Unfortunately, MPC algorithms for distributed parameter systems are relatively scarce. For diffusion-reaction systems, which are described by parabolic PDEs, Dubljevic et al. (2005) used modal decomposition to derive finite-dimensional systems that capture the dominant dynamics of the original PDE and are subsequently used for controller design. For the convection dominated parabolic PDEs, the modal decomposition methods result in high-order finite dimensional systems. MPC for high-order systems is computational demanding and cannot be applied on-line. For hyperbolic systems, the eigenvalues of the spatial differential operator cluster along vertical or nearly vertical asymptotes in the complex plane[Christofides (2001)], and the modal decomposition methods may not be used. Dubljevic et al. (2005) used the finite difference method to convert the hyperbolic equations to a set of ODEs and the MPC is designed for the resulting model. Using discretization methods may result in improperly capturing the dynamics of the system. More-

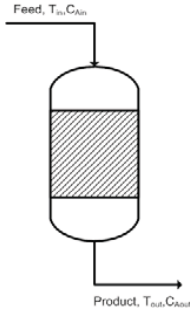

Fig. 1. Schematic diagram of Fixed-Bed reactor

over, the resulting ODEs are high-order and may result in an MPC that has high computational computational requirements.

Characteristics-based MPC is an approach for model predictive control of DPS proposed by Shang et al. (2004) and Shang et al. (2007). The method of characteristic allows controller design for linear, quasilinear, nonlinear low dimensional PDEs. In this method, partial differential equations are transformed to a set of ordinary differential equations along the characteristic curves, which exactly describe the original DPS. Then the controller design can be performed on ODEs instead of PDEs without approximation.

The process considered in this work is a catalytic hydrotreating reactor. Hydrotreating is the conventional means for removing sulfur from petroleum fractions. A schematic diagram of this reactor is shown in Fig.1. An important feature of a fixed bed reactor is the two time scale property of the system. In the other words, the dynamic behavior of the material balance is faster than the energy dynamics. Due to this property, the system has two characteristic curves. Furthermore, by incorporating the catalyst deactivation equation within reactor's model another very slow dynamic will be added to the system.

In this work the problem of controlling a fixed-bed catalytic reactor with catalyst deactivation is considered. We applied nonlinear characteristic-based MPC on-line algorithm to control the temperature of the reactor at the desired setpoint during the reactor's operation. Two cases have been considered. In the first one, the designed MPC uses a model of the system that considers the catalyst deactivation. In the second one, the catalyst deactivation is ignored for model predictive control development. Then performance of the two cases has been compared.

2. MODEL DESCRIPTION

The dynamics of a fixed-bed reactor can be described by partial differential equations derived from mass and energy balances. To model the reactor, a plug-flow pseudo-homogeneous model is considered. Moreover, we consider a one-spatial dimension model where there are no gradients in the radial direction. In the simplified system considered here, a lumped reaction kinetics equation was assumed and has the following form (see Chen et al. (2001)):

$$r_A = k(t)e^{\left(-\frac{E}{RT}\right)}C_A^{n_1}C_H^{n_2} \tag{1}$$

Under the above mentioned assumptions, the dynamics of the process are described by the following energy and mass balance partial differential equations (PDE's).

$$\epsilon\frac{\partial C_A}{\partial t} = -u\frac{\partial C_A}{\partial z} - \rho_B k(t)e^{-\frac{E}{RT}}C_A^{n_1}C_H^{n_2} \tag{2}$$

$$\frac{\partial T}{\partial t} = -u\frac{\partial T}{\partial z} + \frac{\rho_B \Delta H_r}{\rho C_p}k(t)e^{-\frac{E}{RT}}C_A^{n_1}C_H^{n_2} \tag{3}$$

Initial and boundary conditions are:

$$\begin{array}{lll} C_A(0,t) & = C_{A,in}, & C_A(z,0) = C_{A0}(z), \\ T(0,t) & = T_{in}, & T(z,0) = T_0(z) \end{array} \tag{4}$$

In the equations above, $C_A, T, \epsilon, \rho_B, \rho, C_p, E, C_H, \Delta H_r, u$ denote the reactant concentration, the temperature, the porosity of the reactor packing, the catalyst density, the fluid density, the heat capacity, the activation energy,the hydrogen concentration, the enthalpy of reaction, and the superficial velocity respectively. k is the pre-exponential factor. Catalysts lose their activity with time and as a result this coefficient varies with time. The parameter k is proportional to the catalyst activity, which is a function of time and the operating conditions and can be described by an ODE (see Furimsky and Massoth (1999)). Here, we assume that the operating conditions are maintained in narrow ranges and in this case k is only a function of time, which can be described by:

$$k = k_0 + k_1 e^{-\alpha t} \tag{5}$$

The above expression for the kinetics of naphtha hydrotreating reaction is in agreement with the observations that after a rapid initial deactivation of the hydrotreating catalyst there is a slow deactivation phase and finally a stabilization of the catalyst activity phase.

3. CHARACTERISTICS-BASED MPC

The method of characteristics is a technique for solving hyperbolic partial differential equations. The idea is that every hyperbolic PDE has characteristic curves along which the dynamics evolve and as a result, the PDE can be represented as an equivalent ODE.

Consider a quasilinear system of first-order equations with two dependent variables ν_1,ν_2 and two independent variables t and x.

$$\begin{aligned} \frac{\partial \nu_1}{\partial t} + a_1\frac{\partial \nu_1}{\partial z} &= f_1(\nu_1, \nu_2, u) \\ \frac{\partial \nu_2}{\partial t} + a_2\frac{\partial \nu_2}{\partial z} &= f_2(\nu_1, \nu_2, u) \end{aligned} \tag{6}$$

if $a_1 \neq a_2$, the system has two different characteristics determined by:

$$\begin{aligned} \text{Characteristic C}_1: \quad & \frac{dz}{dt} = a_1 \\ \text{Characteristic C}_2: \quad & \frac{dz}{dt} = a_2 \end{aligned} \tag{7}$$

along these characteristics dynamic of the system is described by:

$$\begin{aligned} \frac{d\nu_1}{dt} &= f_1(\nu_1, \nu_2, u) \quad \text{along characteristic C}_1 \\ \frac{d\nu_2}{dt} &= f_2(\nu_1, \nu_2, u) \quad \text{along characteristic C}_2 \end{aligned} \tag{8}$$

Then, by using the method of characteristics, the set of partial differential equations (6) is transformed to a set of ODEs along the characteristic curves. This set of ODEs can be used to predict the future behavior of the system.

For a fixed-bed reactor which is modeled by equations (2) and (3) the characteristic curves are:

$$\text{C}_1 = \frac{dz}{dt} = \frac{u}{\epsilon} \tag{9}$$

$$\text{C}_2 = \frac{dz}{dt} = u \tag{10}$$

and the state variables C_A and T are described by the following ODEs along the characteristic curves:

$$\frac{\partial C_A}{\partial t} = -\frac{\rho_B}{\epsilon} k(t) e^{-\frac{E}{RT}} C_A^{n_1} C_H^{n_2} \tag{11}$$

$$\frac{\partial T}{\partial t} = \frac{\rho_B \Delta H_r}{\rho C_p} k(t) e^{-\frac{E}{RT}} C_A^{n_1} C_H^{n_2} \tag{12}$$

The characteristic ODEs are coupled with respect to the two characteristic curves, and the future state variables at one spatial point should be determined by simultaneous integration of both characteristic ODEs along two nonparallel characteristic curves. Fig. 2 illustrates the calculation of the future output variables using method of characteristics. This method for prediction of the future behavior is proposed by Shang et al. (2004). The idea is that at $t = t_k$ the measurements of the state variables are available at discretization points and these measurements are used to determine the value of the state variables at intersections of the characteristic curves. This algorithm provides us with the future values of the output variable. For example for point P we have:

$$C_A(P) = \int_{t(Q)}^{t(P)} f_1(Q) \tag{13}$$

$$T(P) = \int_{t(R)}^{t(P)} f_2(R) \tag{14}$$

where:

$$t(P) = \frac{a_1 t(Q) - 2a_2 t(Q) + a_2 t(R) + Z(R) - Z(Q)}{a_1 - a_2} \tag{15}$$

and a_1 and a_2 are $\frac{u}{\epsilon}$ and u respectively. The position of the point P is calculated by:

$$Z(P) = \frac{a_1 Z(R) - a_2 Z(Q) + a_1 a_2 [t(R) - t(Q)]}{a_1 - a_2} \tag{16}$$

This procedure is repeated for all nodes and then values of the future output variables are available and one can use common NMPC algorithm to compute the control action. The control action is calculated by solving the following optimization problem in receding horizon manner.

$$\min \int_t^{t+H_p} (T - T_{sp})^2 dt + \int_t^{t+H_c} \lambda (\Delta u)^2 \tag{17}$$

Where H_p is the prediction horizon, H_c is the control horizon, and λ is the weight of the input in the objective function. These parameters are tuning parameters for MPC.

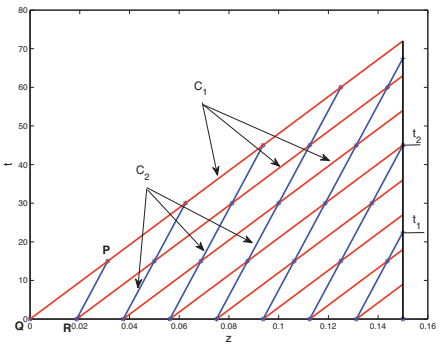

Fig. 2. Calculation of future outputs using characteristic curves

The values of T in the objective function are calculated using the method that described in this section. Since f_1 and f_2 in equations (13) and (14) are nonlinear functions, this optimization problem is a nonlinear optimization and can be solved numerically.

4. NUMERICAL SIMULATIONS

Our case study is a naphtha hydrotreating reactor. The simulation of the reactor was performed using COMSOL® Multi-physics. Using the MPC controller formulated in section 3, the control of the outlet temperature can be achieved. The manipulated variable is the superficial velocity of the feed.

To simulate the closed loop behavior of the system, we performed two cases. In the first one, we considered the deactivation equation of the catalyst and applied the MPC controller to time-varying equations.

In the second case, the model of the system that is used for MPC ignores the catalyst deactivation and assumes constant activity over operation time of the reactor.

Model parameters are given in Table 1. The objective is to control the reactor's outlet temperature at specified setpoint. The objective function is given in Equation (17).

The characteristic curves (9) and (10) are functions of the input variable. Then for the cases that the control horizon, H_c, is greater than one, the characteristic curves will not have constant slope and the calculation of the future values of the output variable will be challenging. In order to simplify the calculations, for the purpose of this example, we assumed that the control horizon is equal to 1, so the MPC problem becomes the following optimization problem:

$$\min \int_t^{t+H_p} (T - T_{sp})^2 dt + \lambda(\Delta u)^2 \tag{18}$$

$$\frac{\partial C_A}{\partial t} = -\frac{\rho_B}{\epsilon} k(t) e^{-\frac{E}{RT}} C_A^{n_1} C_H^{n_2} \quad \text{along characteristic } C_1$$

$$\frac{\partial T}{\partial t} = \frac{\rho_B \Delta H_r}{\rho C_p} k(t) e^{-\frac{E}{RT}} C_A^{n_1} C_H^{n_2} \quad \text{along characteristic } C_2$$

The number of discretization points was taken to be $m = 9$. The prediction horizon is set to the residence time of the reactor, and λ is 1×10^3. The difference between the two cases is in the characteristic equations (11) and (12), which for the first case are functions of time.

This optimization problem can be solved by any optimization method for differential algebraic equations (DAE). Here we used sequential approach, which assumes piecewise constant inputs at each time interval and integrates the differential equations in each interval. This method is an easy method for solving optimization problems for MPC, but it is slower than other algorithms such as that proposed by Bock et al. (2000). The sequential algorithm is good enough for purpose of this illustration example, but for actual implementation the optimization algorithm should be improved.

Fig. 3 illustrates the performance of the CBMPC for the first and second case. This figure shows that the performance of the standard MPC algorithm for the first case is better than the second one. The second case, which considers a constant activity for the catalyst results in an steady state offset. Fig. 5 is the plot of the outlet concentration for two cases and Fig. 4 illustrates the computed control actions for two cases. As Fig. 4 shows, for the second case the input trajectory is almost constant except for first few time intervals; For the first case, due to inclusion of the time varying catalyst activity, the MPC provides more accurate control. Since we assumed

Table 1. Model Parameters

Parameter	Values	unit
ϵ	0.4

α	0.005	
k_1	1.2384	
k_2	2.8896	

piecewise constant profiles for input variable, resulting output trajectory for the first case is non-smooth. But the fluctuations are not greater than $\pm 0.01 \times Y_{sp}$.

In order to deal with the steady state offset problem in the second case, one should implement offset elimination algorithms on standard MPC. These algorithms increase the computational demand of the MPC. Moreover the best offset elimination algorithm may achieve a performance similar to that of the first case.

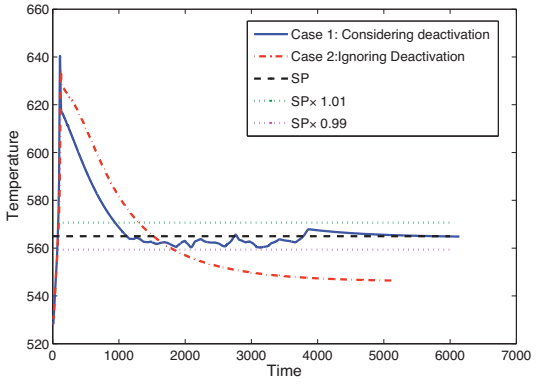

Fig. 3. Outlet temperature(Controlled variable)

Fig. 6 compares the conversion of the reactor for two cases. Although the conversion of the second case is higher at beginning, after a while the reactor's conversion decreases. Lower conversion results in decrease in the profitability of the plant.

5. CONCLUSION

In this work we studied the model predictive control of a naphtha hydrotreating reactor with catalyst deactivation. A characteristic-based MPC is developed to control the reactor. Two different case studies are studied: One that

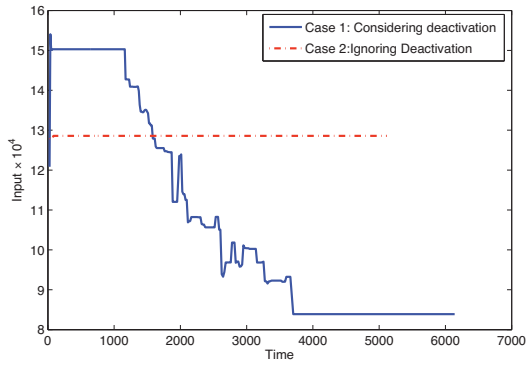

Fig. 4. Computed Input variable

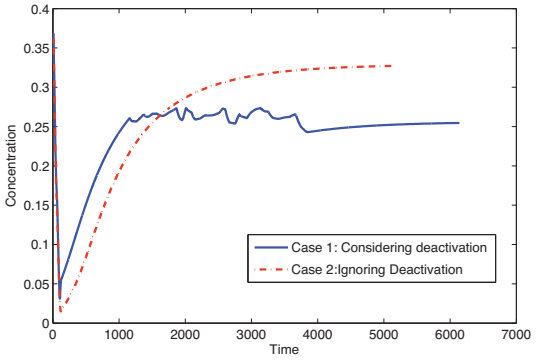

Fig. 5. Computed Input variable

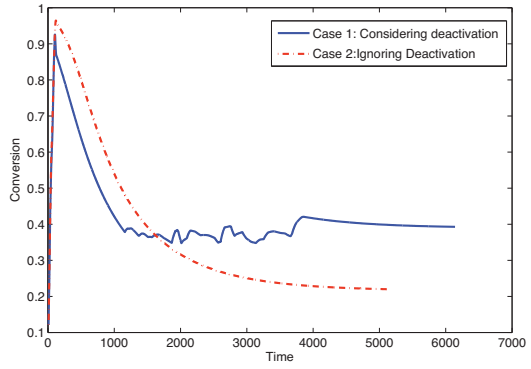

Fig. 6. Conversion at reactor outlet

incorporates the catalyst deactivation kinetics in the controller model and the second one that ignores the catalyst deactivation. The performance of two controllers are compared. The key result of this study is that integration of the catalyst deactivation kinetics with the reactor model, provides improved performance of the characteristic based MPC. This improvement in temperature control results in an improvement in conversion of the reaction, which may increase the plant profitability.

Abstract: In oil production *waterflooding* is a popular recovery technology, which involves the injection of water into an oil reservoir. Studies on model-based dynamic optimization of waterflooding strategies have demonstrated that there is a significant potential to increase life-cycle performance, measured in Net Present Value. However, in these studies the complementary desire of oil companies to maximize daily production is generally neglected. To resolve this, a hierarchical optimization structure is proposed that regards economic life-cycle performance as primary objective and daily production as secondary objective. The existence of redundant degrees of freedom allows for the optimization of the secondary objective without compromising optimality of the primary objective.

Keywords: Optimal control, hierarchical structures, redundant DOF, numerical simulation, oil recovery, waterflooding.

1. INTRODUCTION

Oil is produced from subsurface reservoirs. In these reservoirs the oil is contained in the interconnected pores of the reservoir rock under high pressure and temperature. The depletion process of a reservoir generally consists of two production stages. In the primary production stage the reservoir pressure is the driving mechanism for the production. During this phase, the reservoir pressure drops and production gradually decreases. In the secondary production stage liquid (or gas) is injected into the reservoir using injection wells. The most common secondary recovery mechanism involves the injection of water and is referred to as *waterflooding*. It serves two purposes: sustaining reservoir pressure and sweeping the oil out of pores of the reservoir rock and replacing it by water.

Due to heterogeneity of the reservoir rock, the flowing fluids do not experience the same resistance at different points and in different directions in the reservoir. As a result, the oil-water front may not move uniformly towards the production wells, but has a rather irregular shape as depicted schematically in Figure 1. Due to this phenomenon - referred to as *fingering* - the oil-water front may reach the production wells while certain parts of the reservoir are not be properly drained. The produced water must be disposed of in an environmentally friendly way, bringing along additional production costs. At some point the production is no longer economically viable and the wells are closed (shut-in). At the end of the life of the reservoir all production wells are shut-in, while large amounts of oil may still be present in the reservoir.

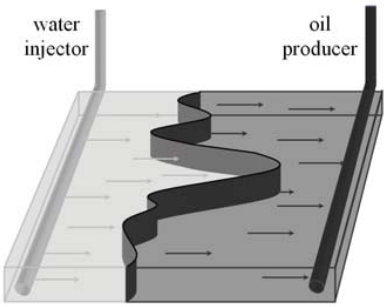

Fig. 1. *Process of waterflooding using a (horizontal) injection and production well. The irregular-shaped oil-water front is a result of the heterogeneous nature of the reservoir, after Brouwer and Jansen (2004).*

Although the injection and production rates of the wells can be manipulated dynamically, they are generally held constant at the maximum capacity of the wells until they are shut-in. Replacing this reactive waterflooding strategy by a dynamic, more proactive one can vastly improve sweep efficiency. Different optimization studies have demonstrated using a numerical reservoir model that there is a potential increase possible of up to 15%, see Brouwer and Jansen (2004) and Jansen et al. (2008). In these optimization studies the objective function is usually of an economic type, most often Net Present Value (NPV), evaluated over the life of the reservoir.

Although many oil companies acknowledge the need for improving economic efficiency over the entire life of the

waterflooding project, many of them adopt maximizing daily production as objective, due to the uncertainty in future economic circumstances. These two objectives, the long-term (life-cycle) objective and the short-term (daily) objective, lead to different, generally conflicting waterflooding strategies.

The goal of this paper is to address the problem of multiple objectives in the optimization of oil recovery from a petroleum reservoir. To that end, a hierarchical optimization structure is proposed that requires a prioritization of the objectives.

This paper proceeds as follows. In Section 2 the properties and characteristics of the reservoir model are described. In Section 3 the life-cycle optimization problem is presented and a hierarchical optimization procedure is proposed. Section 4 deals with identifying redundant degrees of freedom in the optimization problem. The hierarchical optimization procedure is applied to a 3D reservoir model in Section 5. Finally, in Section 6 the results are discussed and alternative approaches are proposed.

2. RESERVOIR MODELING

Reservoir simulators use conservation of mass and momentum equations to describe the flow of oil, water or gas through the reservoir rock. For simplicity reasons, in the oil reservoirs models used within this work only the oil and water phase are assumed to be present.

The mass balance is expressed as follows:

$$\nabla \left(\rho_i u_i\right) + \frac{\partial}{\partial t}\left(\phi \rho_i S_i\right) = 0, \quad i = o, w, \tag{1}$$

where t is time, ∇ the divergence operator, ϕ is the porosity (volume fraction of void space), ρ_i is the density of the phase i, u_i the superficial velocity and S_i the saturation, defined as the proportion of the pore space occupied by phase i.

Conservation of momentum is governed by the Navier-Stokes equations, but is normally simplified for low velocity flow through porous materials, to be described by the semi-empirical Darcy's equation as follows:

$$u_i = -k\frac{k_{ri}}{\mu_i}\nabla p_i, \quad i = o, w, \tag{2}$$

where p_i is the pressure of phase i, k is the absolute permeability, k_{ri} is the relative permeability and μ_i is the viscosity of phase i. The permeability k is an inverse measure of the resistance a fluid experiences flowing through the porous medium. The relative permeability k_{ri} relates to the additional resistance phase i experiences when other phases are present, due to differences in viscosity. As a result, it is a strongly non-linear function of the saturation S_i. In (2) gravity is discarded for simplicity reasons. However, within the 3D example presented in this paper, gravity does play a role. For a more complete description of Darcy's equation we refer to literature, see Aziz and Settari (1979).

Substituting (2) into (1) results into 2 flow equations with 4 unknowns, p_o, p_w, S_o and S_w. Two additional equations are required to complete the system description. The first is the closure equation requiring that the sum of phase saturations must equal 1:

$$S_o + S_w = 1 \tag{3}$$

Second, the relation between the individual phase pressures is given by the capillary pressure equation:

$$p_{cow}(S_w) = p_o - p_w \tag{4}$$

Common practice in reservoir simulation is to substitute (3) and (4) into the flow equations, by taking the oil pressure p_o and water saturation S_w as primary state variables:

$$\nabla(\tilde{\lambda}_o \nabla p_o) = \frac{\partial}{\partial t}\left(\phi \rho_o \cdot [1 - S_w]\right), \tag{5}$$

$$\nabla\left(\tilde{\lambda}_w \nabla p_o - \tilde{\lambda}_w \frac{\partial p_{cow}}{\partial S_w}\nabla S_w\right) = \frac{\partial}{\partial t}\left(\phi \rho_w S_w\right), \tag{6}$$

where $\tilde{\lambda}_o = k\frac{k_{ro}}{\mu_o}$ and $\tilde{\lambda}_w = k\frac{k_{rw}}{\mu_w}$ are the oil and water mobilities. Flow equations (5) and (6) are defined over the entire volume of the reservoir. It is assumed that there is no flow across the boundaries of the reservoir geometry over which (5)-(6) is defined (Neumann boundary conditions).

Due to the complex nature of oil reservoirs, (5)-(6) generally cannot be solved analytically, hence they are evaluated numerically. To this purpose the equations are discretized in space and time. The discretization in space leads to a system built up of a finite number of blocks, referred to as *grid blocks*. This results in the following state space form:

$$\mathbf{V}(\mathbf{x}_k) \cdot \mathbf{x}_{k+1} = \mathbf{T}(\mathbf{x}_k) \cdot \mathbf{x}_k + \mathbf{q}_k, \quad \mathbf{x}_0 = \bar{\mathbf{x}}_0, \tag{7}$$

where k is the time index and $\mathbf{x}$ is the state vector containing the oil pressures (p_o) and water saturations (S_w) in all grid blocks. Vector $\bar{\mathbf{x}}_0$ contains the initial conditions, which are assumed to be known. In the discretization of (5)-(6), the units are converted from $[\frac{kg}{m^3 s}]$ to $[\frac{m^3}{s}]$. In (7) a source vector $\mathbf{q}_k$ is added to model the influence of the wells on the dynamic behavior of the reservoir. The source terms are usually represented by a so-called well model, which relates the source term to the pressure difference between the well and grid block pressure:

$$q_k^j = w^j \cdot (p_{bh,\,k}^j - p_k^j), \tag{8}$$

where $p_{bh,\,k}$ is the well's bottom hole pressure, j the index of the grid block containing the well and p_k^j the grid block pressure in which the well is located. The term w is a well constant which contains the well's geometric factors and the rock and fluid properties of the reservoir directly around the well.

The geological properties inside each grid block are assumed to be constant. The strongly heterogeneous nature of the reservoir can be characterized by assigning different property values to each of the grid blocks. Usually a very large number of grid-blocks is required ($10^3 - 10^6$) to adequately describe the fluid dynamics of a real petroleum reservoir.

The reservoir simulations used within this study are performed using the reservoir simulation software package MoReS, which has been developed by Shell.

3. WATERFLOODING OPTIMIZATION PROBLEM

Flooding a reservoir with water to increase oil production is essentially a batch process, with the additional characteristic that there is no repetition involved. Due to the fact that performance is evaluated at the end of the process and the time constants associated with the nonlinear dynamics are very long, a receding horizon approach will most likely not result in optimal depletion of a reservoir. Dynamic optimization over the entire life of the reservoir is required which can be expressed by the following mathematical formulation:

$$\max_{\mathbf{u}} J(\mathbf{u}), \tag{9}$$

$$s.t.\ \mathbf{x}_{k+1} = \mathbf{f}\left(\mathbf{x}_k, \mathbf{u}_k\right),\ k = 1, .., K, \quad \mathbf{x}_0 = \bar{\mathbf{x}}_0, \tag{10}$$

$$\mathbf{g}(\mathbf{u}) \leq 0 \tag{11}$$

where $\mathbf{u}$ is the input trajectory, $\mathbf{f}$ represents the system equations as described in (7) and $\bar{\mathbf{x}}_0$ is a vector containing the initial conditions of the reservoir. The inequality constraints $\mathbf{g}(\mathbf{u})$ relate to the capacity limitations of the wells.

The objective function J is of an economic type, generally Net Present Value:

$$J = \sum_{k=1}^{K} \left[\frac{r_o \cdot q_{o,k} - r_w \cdot q_{w,k} - r_{inj} \cdot q_{inj,k}}{(1+b)^{\frac{t_k}{\tau_t}}} \cdot \Delta t_k \right], \tag{12}$$

where r_o is the oil revenue $[\frac{\$}{m^3}]$, r_w the water production costs $[\frac{\$}{m^3}]$ and r_{inj} the water injection costs $[\frac{\$}{m^3}]$, which are all assumed constant. K represents the total number of time steps k of a fixed time span and Δt_k the time interval of time step k in $[day]$. The term b represents the discount rate for a certain reference time τ_t. The terms $q_{o,k}$, $q_{w,k}$ and $q_{inj,k}$ represent the total flow rate of respectively produced oil, produced water and injected water at time step k in $[\frac{m^3}{day}]$. An economic objective functions like (12) does not necessarily provide a unique solution to the optimization problem. Although it relates to realistic business conditions, it may well cause ill-posedness of the problem.

Several methods are available for dynamic optimization of large scale problems, see Bryson (1999), Schlegel et al. (2005) and Biegler (2007). *Simultaneous* methods have attractive convergence and constraint handling properties, but even though their capacity to cope with large-scale problems has increased considerably over the recent years, models of order 10^6 still remain very difficult to handle. Although *sequential* methods require repeated numerical integration of the model equations, only the control vector is parameterized and as a result can deal with larger problems. Secondly, due to the fact that the flooding process is very slow much time is available to perform the usually large number of required simulations. However, if the number of control parameters grows the required simulation time may still become unfeasible at some point, unless a method is available to efficiently calculate the gradients of the objective function with respect to the control parameters. This can be done by integration of the adjoint equations or directly through sensitivity equations of model equations.

In the reservoir simulation package used within this work, the adjoint equations are implemented to calculate the gradients. For simplicity reasons, a Steepest Ascent (SA) algorithm is adopted to determine improving control parameters.

3.1 Hierarchical optimization

In the life-cycle waterflooding problem as expressed by (9)-(11), the desire of many oil companies to maximize short-term (daily) production is discarded. A balanced objective provides a possibility to address both objectives in a single function. However, finding an suitable weighting between the objectives may prove to be difficult. Alternatively, we propose a hierarchical (or lexicographic) optimization structure that requires a prioritization of the multiple objectives, as described in Haimes and Li (1988) and Miettinen (1999). In this structure, optimization of a secondary objective function J_2 is constrained by the requirement of the primary objective function J_1 to remain close to its optimal value J_1^*. This structure can be expressed mathematically as follows:

$$\max_{\mathbf{u}} J_2(\mathbf{u}), \tag{13}$$

$$s.t.\ \mathbf{x}_{k+1} = \mathbf{f}\left(\mathbf{x}_k, \mathbf{u}_k\right),\ k = 1, .., K, \quad \mathbf{x}_0 = \bar{\mathbf{x}}_0 \tag{14}$$

$$\mathbf{g}(\mathbf{u}) \leq 0 \tag{15}$$

$$J_1^* - J_1(\mathbf{u}, \mathbf{x}) \leq \varepsilon \tag{16}$$

where ε is an arbitrary small value compared to J_1^*. Solving (13) - (16) requires the knowledge of J_1^*, which is obtained through solving optimization problem (9) - (11).

4. REDUNDANT DEGREES OF FREEDOM

In Jansen et al. (2009) it was observed that significantly different optimized waterflooding strategies result in nearly equal values in NPV. They concluded that the flooding optimization problem is ill-posed and contains many more control variables than necessary. This suggests that optimality of an economic life-cycle objective in waterflooding optimization does not fix all degrees of freedom (DOF) of the decision variable space $\mathcal{D}$, i.e. there exist redundant DOF in the optimization problem. Huesman et al. (2008) found similar results for economic dynamic optimization of plant-wide operation.

A consequence of these redundant DOF is that even if ε in (16) is chosen equal to 0, DOF are left to improve the secondary objective function J_2. A straightforward way of investigating this is to imbed (16) as an equality constraint in the adjoint formulation by means of an additional Lagrange multiplier. Unfortunately, the adjoint functionality in MoReS is not yet capable of dealing with (additional) state constraints. Alternatively, unconstrained gradient information can be used to investigate the redundant DOF, as described in the next section.

4.1 Quadratic approximation of the objective function

A solution $\mathbf{u}$ for which no constraints are active is an optimal solution $\mathbf{u}^*$ if and only if the gradients of J with respect to $\mathbf{u}$ are zero, i.e. $\frac{\partial J}{\partial \mathbf{u}} = 0$. As a result, at $\mathbf{u}^*$ the

gradients do not provide any information on possible redundant degrees of freedom under the optimality condition on J.

Second-order derivatives of J with respect to $\mathbf{u}$ are collected in the Hessian matrix $\mathbf{H}$. If $\mathbf{H}$ is negative-definite, the considered solution $\mathbf{u}$ is an optimal solution, but no DOF are left when the optimality condition on J holds. If $\mathbf{H}$ is negative-semidefinite it means that the Hessian does not have full rank. An orthonormal basis $\mathbf{B}$ for the indetermined directions of $\mathbf{H}$ can than be obtained through a singular value decomposition:

$$\mathbf{H} = \mathbf{U} \cdot \mathbf{\Sigma} \cdot \mathbf{V} \tag{17}$$

The orthonormal basis $\mathbf{B}$ consists of those columns of $\mathbf{V}$ that relate to singular values of zero, i.e. $\mathbf{B} = \{\mathbf{v}_i \mid \sigma_i = 0, \quad i = 1, \ldots, N_{\mathbf{u}}\}$, where $N_{\mathbf{u}}$ is the number of parameters that represent the DOF in the input.

Not all orthogonal directions spanned by the columns of $\mathbf{B}$ will be redundant DOF. These directions are redundant DOF, if they are linear and all higher order derivatives are zero as well, which at this point in time is impossible to proof for reservoir models. $\mathbf{B}$ is however a basis for redundant DOF for a quadratic approximation $\hat{J}$ of objective function J. As $\hat{J}$ can be considered to be an acceptable approximation for small deviations from $\mathbf{u}^*$, $\mathbf{B}$ can be regarded as an acceptable basis for the redundant DOF for small deviations from $\mathbf{u}^*$.

Approximate Hessian matrix Unfortunately, no reservoir simulation package is currently capable of calculating second-order derivatives. However, using the gradient information second-order derivatives can be approximated. Within this work a forward-difference scheme is adopted:

$$\frac{\partial^2 J}{\partial u_i \partial u_j} \approx \frac{\nabla J_i(\mathbf{u} + h_j \mathbf{e}_j) - \nabla J_i(\mathbf{u})}{2h_j} + \frac{\nabla J_j(\mathbf{u} + h_i \mathbf{e}_i) - \nabla J_j(\mathbf{u})}{2h_i} \tag{18}$$

Where $\mathbf{e}_i$ is a canonical unit vector, i.e. a vector with a 1 at element i and 0 elsewhere and h_i is the perturbation step size that relates to parameter u_i of $\mathbf{u}$. In total $N_{\mathbf{u}} + 1$ simulations (function evaluations) are required to obtain the approximate Hessian matrix $\hat{\mathbf{H}}$ at a particular optimal solution $\mathbf{u}^*$.

4.2 Hierarchical optimization method

Adopting the approximation of $\mathbf{H}$ as described in Subsection 4.1, the following iterative procedure is proposed to attack the hierarchical optimization problem (13) - (16) with $\varepsilon = 0$:

(1) Find a (single) optimal strategy $\mathbf{u}^*$ to primary objective function J_1 and use $\mathbf{u} = \mathbf{u}^*$ as starting point in the secondary optimization problem.
(2) Approximate the Hessian matrix $\mathbf{H}$ of J_1 with respect to the input variables at (initial input) $\mathbf{u}$ and determine an orthonormal basis $\mathbf{B}$ for the null-space of $\hat{\mathbf{H}}$.
(3) Find the improving gradient direction $\frac{\partial J_2}{\partial \mathbf{u}}$ for the secondary objective function J_2.

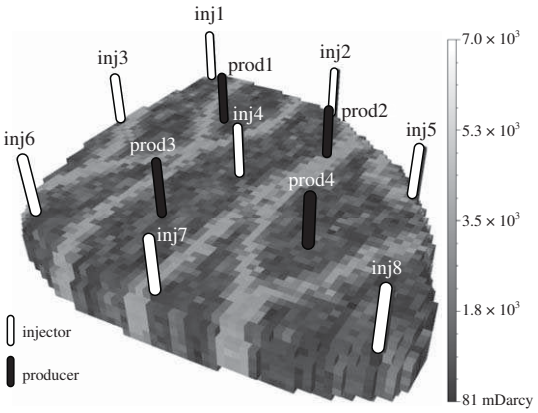

Fig. 2. *3D reservoir model with 4 production and 8 injection wells. The geological structure involves a network of meandering channels in which the fluids flows experience less resistance, due to higher permeability.*

(4) Project $\frac{\partial J_2}{\partial \mathbf{u}}$ onto the orthonormal basis $\mathbf{B}$ to obtain projected direction $\mathbf{d}$, such that $\mathbf{d}$ is an improving direction for J_2, but does not affect J_1. The projection is performed using projection matrix $\mathbf{P}$, see Luenberger (1984):

$$\mathbf{d} = \mathbf{P} \cdot \left(\frac{\partial J_2}{\partial \mathbf{u}} \right)^T \tag{19}$$

$$\mathbf{P} = \mathbf{B} \cdot \left(\mathbf{B}^{\cdot T} \mathbf{B} \right)^{-1} \cdot \mathbf{B}^T \tag{20}$$

(5) Update $\mathbf{u}$ using projected direction $\mathbf{d}$ in a SA method.

$$\mathbf{u}_{new} = \mathbf{u}_{old} + \tau \cdot \mathbf{d}, \tag{21}$$

where τ is an appropriately small step size such that the quadratic approximation of J_1 is justified.
(6) Perform steps 2 through 6 until convergence of J_2.

In the next section a numerical example is presented where the iterative hierarchical optimization structure is tested on a 3D heterogeneous reservoir model.

5. NUMERICAL EXAMPLE

The hierarchical optimization procedure is applied to a 3-dimensional oil reservoir model, introduced in Van Essen et al. (2006). The life-cycle of the reservoir covers a period of 3,600 days and is chosen such that all oil can be produced within that time frame. The length of the life-cycle is in this example not incorporated as additional optimization parameter. The reservoir model consists of 18,553 grid blocks, as depicted in Figure 2, and has dimensions of $480 \times 480 \times 28$ meter. Its geological structure involves a network of fossilized meandering channels in which the flowing fluids experience less resistance, due to higher permeability. The average reservoir pressure is 400 $[bar]$.

The reservoir model contains 8 injection wells and 4 production wells. The production wells are modeled using a well model (8) and operate at a constant bottom hole pressure p_{bh} of 395 $[bar]$. The flow rates of the injection wells can be manipulated directly, i.e. the control input $\mathbf{u}$ involves injection flow rate trajectories for each of the 8

injection wells. The minimum rate for each injection well is 0.0 $[\frac{m^3}{day}]$, the maximum rate is set at a rate of 79.5 $[\frac{m^3}{day}]$.

The control input $\mathbf{u}$ is re-parameterized in time using a zero-order-hold scheme with input parameter vector θ. For each of the 8 injection wells, the control input $\mathbf{u}$ is re-parameterized into 4 time periods t_{θ_i} of 900 days over which the injection rate is held constant at value θ_i. Thus, the input parameter vector θ consists of $8 \times 4 = 32$ elements.

5.1 Life-cycle optimization

The objective function for the life-cycle optimization is defined in terms of NPV, as defined in Equation (12), with $r_o = 126\,[\frac{\$}{m^3}]$, $r_w = 19\,[\frac{\$}{m^3}]$ and $r_i = 6\,[\frac{\$}{m^3}]$. The discount rate b is set to 0. Thus, the life-cycle objective relates to undiscounted cash flow.

The optimal input - denoted by ${\mathbf{u}_\theta}^*$ - obtained after approximately 50 iterations, is shown in Figure 3. None of the input constraints (11) are active for ${\mathbf{u}_\theta}^*$. The value of the objective function corresponding to input ${\mathbf{u}_\theta}^*$ is 47.6×10^6 \$.

5.2 Hierarchical optimization

A secondary objective function J_2 was defined to emphasize the importance of short-term production. To that end, J_2 is chosen identical to the primary objective function but with the addition of a very high annual discount rate b of 0.25. As a result, short-term production is weighed far more heavily than future production. Note that due to the very high discount rate, the actual value of J_2 no longer has a realistic meaning in an economic sense.

The hierarchical approach as presented in Subsection 4.2 is applied. The total number of simulation runs needed to approximate the Hessian ($\hat{\mathbf{H}}$) is 33. However, the required simulation time was vastly reduced by parallel processing the simulations.

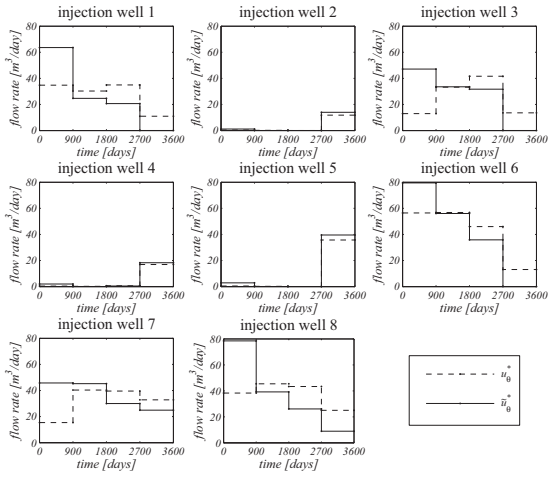

Fig. 3. *Input trajectories for each of the 8 injection wells for the initial optimal solution ${\mathbf{u}_\theta}^*$ to J_1 (dashed line) and the optimal solution $\tilde{\mathbf{u}}_\theta^*$ after the constrained optimization of J_2 (solid line)*

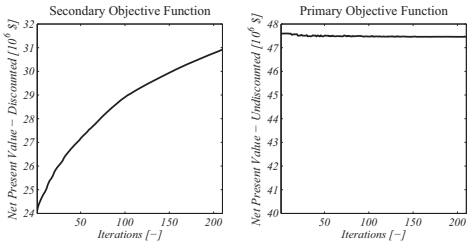

Fig. 4. *Values of the secondary J_2 and primary J_1 objective function plotted against the iteration number for the constrained secondary optimization problem.*

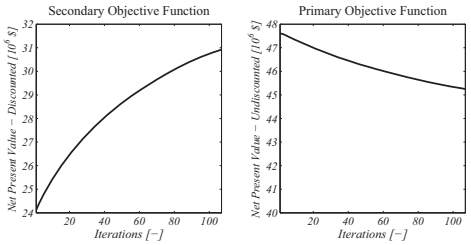

Fig. 5. *Values of the secondary J_2 and primary J_1 objective function plotted against the iteration number for the secondary optimization problem, no longer constrained by the orthonormal basis $\mathbf{B}$.*

Due to the fact that this example involves a numerical model and an approximation of the second-order derivatives, the selection criterion for $\mathbf{B}$ is relaxed. Those columns $\mathbf{v}_i$ of $\mathbf{V}$ were selected that correspond to singular values for which $\frac{\sigma_i}{\sigma_1} < 0.02$ instead of $\sigma_i = 0$. The projected gradients $\mathbf{d}$ were again used in a steepest-ascent scheme. For the quadratic approximation of J_1 to be justified, $\mathbf{u}_{\theta,new}$ must remain close to $\mathbf{u}_{\theta,old}$. To achieve that, $\mathbf{d}$ was normalized and a constant step size τ of 1 was used. Due to time restrictions, the hierarchical optimization of J_2 was terminated after 210 iterations with final control input $\tilde{\mathbf{u}}_\theta^*$. To evaluate the results of the hierarchical optimization, a second optimization case was carried out, where optimization of J_2 was performed *without* projection on $\mathbf{B}$. As a result, the obtained control input - denoted by $\tilde{\mathbf{u}}_\theta$ - does in this case not ensure optimality of J_1.

Figure 4 displays the values of J_1 and J_2 plotted against the iteration number for the hierarchical optimization problem. It shows a considerable increase of J_2 of 28.2% and a slight drop of J_1 of -0.3%. In Figure 3 the input strategy after the final iteration step is presented. It can be observed that the injection strategy shows a substantial increase in injection rates at the beginning of the production life and a decrease at the end. The values of J_1 and J_2 plotted against the iteration number for the *unconstrained* optimization of J_2 are shown in Figure 5. Again an increase of J_2 of 28.2% is realized, but now at a cost of a decrease of J_1 of -5.0%. Finally, Figure 6 shows the value of the primary objective function J_1 over time until the end of the producing reservoir life for ${\mathbf{u}_\theta}^*$, $\tilde{\mathbf{u}}_\theta^*$ and $\tilde{\mathbf{u}}_\theta$. Input $\tilde{\mathbf{u}}_\theta^*$ shows a steeper ascent of J_1 than ${\mathbf{u}_\theta}^*$, while their final values are nearly equal. Input $\tilde{\mathbf{u}}_\theta$ shows initially the same steep ascent as $\tilde{\mathbf{u}}_\theta^*$, but J_1 drops at the end of the life of the reservoir.

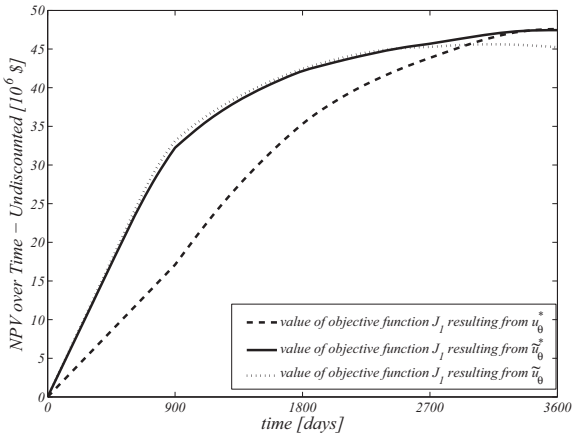

Fig. 6. *Value of the primary objective function J_1 over time for initial optimal input $\mathbf{u}_\theta{}^*$ to J_1 (dashed line), the optimal input $\tilde{\mathbf{u}}_\theta^*$ after the constrained optimization of J_2 (solid line) and input $\tilde{\mathbf{u}}_\theta$ after the unconstrained optimization of J_2 (dotted line)*

6. CONCLUSION

Model-based optimization is a relatively new approach to oil recovery from petroleum reservoirs. Optimization studies have shown a considerable potential increase in life-cycle performance. However, increased understanding of the optimal control problem and characteristics of the optimal solutions is necessary to take the next step towards a real-life application.

Within this work the issue of multiple objectives in oil production is addressed. A hierarchical approach is investigated by means of a simulation experiment. For the presented experiment we conclude that:

- There exist redundant DOF in the input strategy $\mathbf{u}$ with respect to the optimality of the life-cycle objective. This implies the existence of an optimal subset $\mathcal{S}$ of connected optimal solutions within the solution space $\mathcal{D}$.
- The redundant DOF create enough freedom to significantly improve the secondary objective function. Moreover, the difference between the initial and final input strategy to the secondary optimization problem is substantial. This suggest that $\mathcal{S}$ occupies a considerable space within decision variable space $\mathcal{D}$.
- The presented hierarchical optimization procedure provides a method to incorporate short-term performance objectives into problem setting of maximizing life-cycle performance of oil recovery. Using the hierarchical structure, optimization of the secondary objective may be executed without significantly compromising the primary objective.

Under which conditions these conclusions also apply to different life-cycle waterflooding problems and/or different reservoir models will be subject for further investigation.

6.1 Discussion

The presented hierarchical optimization approach is computationally very demanding and becomes infeasible for more realistic reservoir models with an increased number of input parameters. A different method to approximate the Hessian requiring less simulation runs may be considered to resolve this, e.g. the secant method. However, calculating second-order derivatives may be avoided altogether when the hierarchical optimization problem is imbedded in the adjoint formulation, as mentioned in Section 4. This approach will be the focus of future research.

Within this work, uncertainty - of the model and/or the objective function parameters - was neglected. In literature, a number of methods are presented to attack the problem of life-cycle optimization under uncertainty, using a closed-loop approach. For a good overview see Jansen et al. (2008). Without considerable effort, the presented hierarchical optimization structure can be integrated into this closed-loop framework.

Abstract: In the stochastic context, expected value of the cost function is optimized either by changing the mean values of the manipulated variables or by reducing their variance. An extension is to look for an optimal shape for the entire probability density function (PDF). Though the use of asymmetric PDFs is proposed in the literature, no formal proof that justifies their use has been provided. In this paper, it is shown that an asymmetric PDF is required if and only if the cost function is asymmetric and the manipulated variable is penalised. The proof uses an analytical solution of the Fokker-Planck-Kolmogorov equation derived to calculate the shape the output PDF for scalar systems. In particular, this analytical solution is adapted to a switching proportional controller. The theoretical concepts are illustrated on a simulation example, where the advantage of choosing an asymmetric PDF is shown.

Keywords: Stochastic control, Optimization, Probability Density Functions, Switching Algorithms

1. INTRODUCTION

Optimization in a stochastic context involves studying the influence of decisions variables on the expected value of the objective function. In the stochastic context, not only the mean values of the decision variables but the entire distribution plays a role in optimization. Typically, in the presence of constraints, variability is reduced first using appropriate controllers, and secondly by shifting the set point closer to the constraint. Use of minimum variance controllers for optimization purposes has been well studied in the literature (Muske, 2003).

However, shaping the entire probability density function (PDF) could be a viable option to reduce costs. The first mention of this possibility was made in Kàrnỳ (1996). Then, Wang (1998) developed a PDF shaping algorithm based on the weights of a neural B-Spline that parameterized the output PDF. This method has been improved ever since by the same authors (Wang ,2002; Wang & Zhang 2002; Wang & Wang, 2002; Guo & Wang 2005). Crespo and Sun (2002) used an analytical solution of Fokker-Plank-Kolmogorov equation in steady-state to develop a PDF shaping algorithm. On the other hand, Forbes et al. (2004) developed an algorithm based on the parametrization of the target PDF using Gram-Charlier basis functions. In all the above cited works, though the motivation is to improve an optimization objective, only the sub-problem of getting close to a target PDF is addressed. No indication is given on how to compute a target PDF that is suited for the optimization problem at hand.

It has been argued in all the above works that the advantage of PDF shaping lies in shaping it in an asymmetric manner. The necessity of an asymmetric PDF arises from the asymmetry of the objective function. This is normally due to the presence of process and operational constraints. With constraints, typically, an approach based on penalty (barrier) function is used for resolution. An additional cost is added when the constraint is violated (or in the barrier function case an additional cost is added when operated close to the constraint), which inturn causes asymmetry.

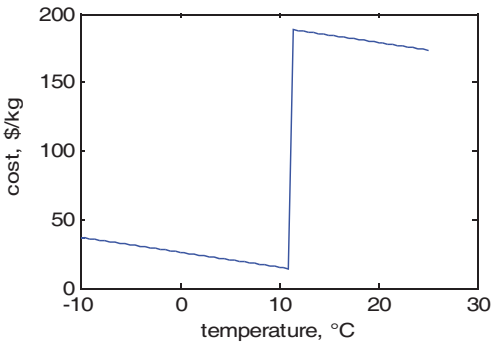

Figure 1: Example of an asymmetric objective function

Figure 1 shows an example with a penalty function where a constant penalty is added if the manipulated variable is above the constraint set at 11°C. As seen, such penalty/barrier functions cause a huge asymmetry around the optimal solution. The optimal solution without any stochastic behaviour would be on the constraint 11°C. However with process noise, a controller needs to be used to reduce the variance of the manipulated variable, and the set point must be lower than 11°C, so that only a small

part of the distribution violates the constraint. The minimum variance controller tries to squeeze and shift the distribution towards the constraint. On the other hand, the PDF shaping solution tries to match the asymmetry in the objective function using an asymmetric PDF with its tail on the opposite side of the constraint.

Though intuitive arguments were given for using asymmetric PDFs, no formal results are available to distinguish the cases where an asymmetric PDF would be more beneficial than the symmetric one. So, the main question asked in this paper is, "which class of problems requires an asymmetric PDF?" It is shown that not only the asymmetry of the objective function but also an input weighting is needed to necessitate an asymmetric PDF. The importance of input weighting is one of the core contributions of this paper. In the minimum variance controller, by reducing the variability of the output variable, the variability of the manipulated variables would increase, straining the process equipment. Contrarily, with an asymmetric PDF, the set point can be shifted toward the constraint and with less impact on the manipulated variables.

This paper first presents an analytical solution of the Fokker-Planck-Kolmogorov (FPK) equation for general scalar systems. This analytical solution is then applied to the switching controller case, using which, the optimality or non-optimality of symmetric solution is ascertained. The last section is devoted to a simulation example where the improvement in cost using an asymmetric controller is shown.

2. PROBLEM FORMULATION

2.1Optimization problem formulation

Consider the dynamic system given by equation (1), where u is the scalar manipulated variable, x the scalar state variable, and w the zero-mean Gaussian process noise input with standard deviation η .

$$\dot{x} = f(x) + g(x)u + w \tag{1}$$

The functions *f(x)* and *g(x)* represent the unforced and the forced parts of the system dynamics. Consider the optimization of the above system at steady state:

$$\begin{matrix} \min_{u} \Phi(x,u) \\ C(x,u) \leqslant 0 \\ f(x) + g(x)u = 0 \end{matrix} \quad , \tag{2}$$

where Φ is the function to be optimized, C the constraints. Note that the optimization considers the system equations without noise at steady state as equality constraints.

In the context of this paper, a penalty function is introduced to handle the constraints as show below:

$$\begin{matrix} \min_{u} [\bar{\Phi}(x,u) + D(C(x,u))] = \phi(x,u) \\ f(x) + g(x)u = 0 \end{matrix} \quad , \tag{3}$$

where *D(.)* is any appropriate penalty function and $\phi(.)$ the augmented cost. As discussed earlier, *D(.)* is asymmetric which would lead to an asymmetry in the cost function.

In the context of this paper, x is considered stochastic due to the presence of the noise term w. So, the expectation of the cost function needs to be calculated for optimization purposes. The cost function that is minimized is given by:

$$J = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \phi(x,u)\, p(x,u)\, dx du \quad , \tag{4}$$

where *p(x,u)* is the joint probability density function.

2.3 Controllers for PDF shaping

In this section, the nonlinear controller used for PDF shaping is presented. Nonlinearity is crucial since, if the process and the controller were linear, and the input is Gaussian, the output PDF would just be Gaussian.

In order to have a full control on the nonlinearity, all the system nonlinearities are eliminated by feedback linearization. In addition, the controller *h(x)* is used to bring the state to its desired set point. Then, the controller would introduce the nonlinearities required to shape the PDFs. For the system under consideration, the linearizing feedback is given by:

$$u = \frac{-f(x) + h(x)}{g(x)} \quad . \tag{5}$$

Here, a switching controller of the following form will be studied. The nonlinearity arises from the gain schedule and results in an asymmetrical PDF.

$$h(x) = \begin{Bmatrix} k_1(x_{sp} - x) & if & x < x_{sp} \\ k_2(x_{sp} - x) & if & x > x_{sp} \end{Bmatrix} \quad . \tag{6}$$

To simplify the development, no measurement noise is considered, while a zero-mean Gaussian measurement noise, z, with standard deviation λ will be added to the set point. Thus, the the system reads

$$\begin{matrix} \dot{x} = h(x) + w + k_{cont}(x) z \\ k_{cont}(x) = \begin{Bmatrix} k_1 & if & x < x_{sp} \\ k_2 & if & x > x_{sp} \end{Bmatrix} \end{matrix} \tag{7}$$

3.ANALYTICAL SOLUTION OF THE SCALAR FPK EQUATION FOR SWITCHING CONTROLLER

In this section, the analytical solution of the FPK equation will be developed for the general *h(x)* and later exploited to suit the switching controller.

3.1 General case

Consider the system (8) where the two random variables are Brownian processes :

$$dx = h(x)dt + \eta\ d\beta_w + k_{cont}(x)\lambda\ d\beta_z, \quad t \geq t_0 \quad , \qquad (8)$$

where η and λ are the standard deviations of the process and measurement noise respectively, $d\beta_w$ and $d\beta_z$ are unit variance Brownian processes. These two noises can be clubbed together into a general equation as follows:

$$dx = h(x)dt + \rho(x)\ d\beta, \quad t \geq t_0 \qquad (9)$$

where $\rho(x)$ represents the agglomerated standard deviation.

The evolution of its probability density function of *x* is given by the Fokker-Planck-Kolmogorov equation (Jazwinsky (1968)):

$$\frac{\partial p(x,t)}{\partial t} = \frac{-\partial[p(x,t)h(x)]}{\partial x} + \frac{1}{2}\frac{\partial^2[p(x,t)\rho(x)^2]}{\partial x^2} \quad . (10)$$

with boundary conditions $lim_{x\to\infty} p = lim_{x\to-\infty} p = 0$

$lim_{x\to\infty} \frac{\partial p}{\partial x} = lim_{x\to-\infty} \frac{\partial p}{\partial x} = 0$, $\int_{-\infty}^{\infty} p(x)\,dx = 1$.

At steady state, this equation reads

$$\frac{d\,ph}{dx} = \frac{1}{2}\frac{d^2\rho^2 p}{dx^2} \quad . \qquad (11)$$

By integrating both sides of the equation:

$$2\,ph = \frac{d\rho^2 p}{dx} + c \quad . \qquad (12)$$

Using the boundary conditions it can be seen that, $c = 0$. Rearranging the terms gives,

$$\frac{dp}{p} = \left(\frac{2h}{\rho^2} - \frac{2}{\rho}\frac{d\rho}{dx}\right)dx \quad . \qquad (13)$$

The solution of the above equation is given by:

$$p(x) = p_0\, e^{\int_{-\infty}^{\infty}\left(\frac{2h}{\rho^2} - \frac{2}{\rho}\frac{d\rho}{dx}\right)dx} \quad , \qquad (14)$$

where p_0 is the normalizing constant to render the integral of the probability to 1.

3.2 Switching controller case

The analytical solution developed in Section 3.1 is applied to a case of the switching controller. Let p_{sp} be the value of the probability density function at $x = x_{sp}$. From (6) and (7) it can be seen that to the left of the set point

$$h(x) = k_1(x - x_{sp}),\ \rho^2(x) = \eta^2 + k_1^2\lambda^2 \quad , \qquad (15)$$

and to the right

$$h(x) = k_2(x - x_{sp}),\ \rho^2(x) = \eta^2 + k_2^2\lambda^{2.} \quad . \qquad (16)$$

Thus, it can be seen that

$$p(x) = \begin{cases} p_{sp}\, e^{\frac{-2k_1(x-x_{sp})^2}{\eta^2 + k_1^2\lambda^2}} & \text{for } x < x_{sp} \\ p_{sp}\, e^{\frac{-2k_2(x-x_{sp})^2}{\eta^2 + k_2^2\lambda^2}} & \text{for } x \geq x_{sp} \end{cases} \quad . \qquad (17)$$

This can be interpreted as Gaussian function where the two branches are not symmetric. The variance on one side is different from that of the other. The variances on either side can be computed as follows:

$$\sigma_1 = \frac{\sqrt{\eta^2 + k_1^2\lambda^2}}{2\sqrt{k_1}} \quad \text{and} \quad \sigma_2 = \frac{\sqrt{\eta^2 + k_1^2\lambda^2}}{2\sqrt{k_2}} \quad . \qquad (18)$$

Also, the normalisation constant can be computed analytically as follows:

$$p_{sp} = \frac{2}{\sqrt{2\pi}(\sigma_1 + \sigma_2)} \quad . \qquad (19)$$

From the expression of *h(x)* it can also be shown that

$$p(h) = \begin{cases} p_{h0}\, e^{\frac{-2h^2}{k_1(\eta + k_1\lambda)^2}} & \text{for } h < 0 \\ p_{h0}\, e^{\frac{-2h^2}{k_2(\eta + k_2\lambda)^2}} & \text{for } h \geq 0 \end{cases} \qquad (20)$$

with

$$\sigma_{1h} = \frac{\sqrt{\eta^2 + k_1^2\lambda^2}\sqrt{k_1}}{2} \quad , \quad \sigma_{2h} = \frac{\sqrt{\eta^2 + k_2^2\lambda^2}\sqrt{k_2}}{2} \qquad (21)$$

$$p_{h0} = \frac{2}{\sqrt{2\pi}(\sigma_{1h} + \sigma_{2h})} \quad . \qquad (22)$$

4.NON-OPTIMALITY OF THE SYMMETRIC SOLUTION

In this section, it is be shown that a symmetric PDF is sufficient even for an asymmetric objective function, when there is no input weighting. Also, when the objective function is symmetric, with or without input weighting a symmetric PDF is indeed optimal. However, when there is asymmetry and input weighting, then it is shown that a symmetric solution is not optimal.

Consider equation (4). Since, *u* is a function of *x*, the objective function $\phi(x,u)$ is just a function of *x*. In particular, consider a special case where the squared deviation of the control action *h(x)* is included in the cost function. The remaining part of the objective function is termed *l(x)*. So,

$$\phi(x,u) = l(x) + \gamma h^2(x) \qquad (23)$$

Due to the imposed control structure, the degree of freedom for the optimization problem is no longer u, but the parameters x_{sp}, k_1 and k_2. So, the optimization problem reads,

$$\min_{x_{sp},k_1,k_2} J=\int_{-\infty}^{+\infty} l(x)\,p(x)\,dx+\int_{-\infty}^{+\infty}\gamma h^2\,p(h)\,dh \quad . \tag{24}$$

The proof of non-optimality proceeds by deriving the necessary conditions of optimality of the above optimization problem by considering that k_1 and k_2 are varied independently. Then an additional condition of symmetry, i.e. $k_1 = k_2$ is imposed. This gives four conditions (3 necessary conditions and one condition of symmetry) for three variables. If these four conditions are consistent then the symmetric solution is indeed optimal. On the other hand, if it leads to an inconsistency or contradiction then it shows that the symmetric solution is not optimal in the case considered.

Theorem 1: The symmetric switching controller is locally optimal if and only if (i) l(x) is symmetric around the optimum, i.e., the third derivative evaluated at the optimum is zero, or (ii) the input weighting γ is zero.

Proof: Without loss of generality let $x = 0$, $l(x) = 0$, $J = 0$ be the optimum in the absence of noise. Consider the third order Taylor series expansion of $l(x)$ around $x = 0$. The first two terms are zero since $l(0) = 0$ and the first derivative is zero due to optimality. Thus the expansion is given by

$$l(x)=\alpha x^2+\delta x^3 \quad , \tag{25}$$

where α and δ are the second and third derivatives, respectively, at the origin. The expected cost (5) is then given by,

$$J=\alpha\int_{-\infty}^{+\infty} x^2\,p(x)dx+\delta\int_{-\infty}^{+\infty} x^3\,p(x)\,dx+\gamma\int_{-\infty}^{+\infty} h^2\,p(h)\,dh \quad .(26)$$

Analytical expressions for all the three terms can be obtained.

$$\int_{-\infty}^{+\infty} x^2\,p\,dx=x_{sp}^2-\frac{4\,x_{sp}(\sigma_1-\sigma_2)}{\sqrt{2\pi}}+(\sigma_1^2-\sigma_1\sigma_2+\sigma_2^2) \tag{27}$$

$$\int_{-\infty}^{+\infty} x^3\,p\,dx=x_{sp}^3-\frac{6\,x_{sp}^2}{\sqrt{2\,\pi}}(\sigma_2-\sigma_1)+3\,x_{sp}(\sigma_2^2-\sigma_1\sigma_2+\sigma_1^2)\frac{+4}{\sqrt{2\,\pi}}(\sigma_2-\sigma_1)(\sigma_1^2+\sigma_2^2) \tag{28}$$

$$\int_{-\infty}^{+\infty} h^2\,p(h)\,dh=(\sigma_{h1}^2-\sigma_{h1}\sigma_{h2}+\sigma_{h2}^2)-\frac{2}{\pi}(\sigma_{h1}-\sigma_{h2})^2 \tag{29}$$

The optimality condition requires that the derivatives of J with respect to x_{sp}, k_1 and k_2 be zero, the expressions for which can be readily obtained. To analyse the symmetric solution, consider $k_1 = k_2 = k$. Substituting this in the derivatives leads to

$$\frac{\partial J}{\partial x_{sp}}=2\alpha x_{sp}+3\delta x_{sp}^2+\frac{3\delta}{4k}(\eta^2+k^2\lambda^2)=0 \quad , \tag{30}$$

$$\frac{\partial J}{\partial k_1}-\frac{\partial J}{\partial k_2}=\frac{(\eta^2-k^2\lambda^2)}{\sqrt{2\pi k^3}}\left(2\alpha x_{sp}+3\delta x_{sp}^2+\frac{\delta}{k}(\eta^2+k^2\lambda^2)\right)=0 \quad , \tag{31}$$

and

$$\frac{\partial J}{\partial k_1}+\frac{\partial J}{\partial k_2}=\frac{\eta^2-k^2\lambda^2}{4k^2}(\alpha+3\delta x_{sp})+\frac{\gamma}{4}(\eta^2+3k^2\lambda^2)=0 \quad . \tag{32}$$

It can be seen that there are 3 equations for 2 unknowns, k and x_{sp}. Replacing the terms with x_{sp} in (31) using (30), it can be seen that

$$\frac{\partial J}{\partial k_1}-\frac{\partial J}{\partial k_2}=\frac{(\eta^2-k^2\lambda^2)}{\sqrt{2\pi k^3}}\frac{\delta}{4k}(\eta^2+k^2\lambda^2)=0 \quad . \tag{33}$$

Only if part: $\delta\neq 0,\gamma\neq 0\Rightarrow non-optimality$

When $\delta\neq 0$, the only solutions of (33) are $k=\pm\eta/\lambda$ But, plugging these values of k in the sum of derivatives lead to $\gamma=0$. So, if $\gamma\neq 0$ the symmetric controller is not optimal .

If part: $\gamma=0\Rightarrow optimality$

When $\gamma=0$ note that $k=\pm\eta/\lambda$ satisfies all the three necessary conditions of optimality .

If part: $\delta=0\Rightarrow optimality$

Since $\delta=0$, (31) gives $x_{sp} = 0$. (33) is not useful in determining k. However from (32), it can be seen that the following 4th order equation can be used to compute k.

$$3\gamma\lambda k^4+(\gamma\eta+\lambda\alpha)k^2-\alpha\eta=0 \tag{34}$$

■

5. EXAMPLE

In this section, an asymmetric example with input weighting is presented. The optimal switching controller is computed using the output PDF obtained through the analytical solution. It will be shown that such a controller indeed leads to an asymmetric PDF.

A cost function analogous to the one in Figure 1 is considered here.

$$\begin{gathered}\phi(x)=26-10x+D(c(x))+10h^2(x)\\ D(c(x))=0\ if\ x\leq 11\\ D(c(x))=10^5\ if\ x>11\end{gathered} \tag{35}$$

The system dynamics is given by

$$\dot{x}=-0.4\mathrm{x}+0.2\mathrm{u}+w \quad , \tag{38}$$

where the process noise w has a mean of 0 and a standard deviation $\eta=1$. A measurement noise of standard deviation $\lambda=0.01$ was considered. Though it is unrealistic to consider a ratio of 100 between the standard deviations of

process and measurement noises, it is required in this case to prove the principle. The asymmetric PDF gives better results only in a narrow range of parameter values and so is such a choice made.

5.1 Controller design

The controller (6) is used here. It has 3 parameters; gains k_1, k_2 and the set point x_{sp}. These parameters are found via non linear programming where the equation (24) is minimized. Equation (24) for the given example can be written as follows:

$$J = 26 - 10\int_{-\infty}^{+\infty} x\,p(x)dx + 10^5\int_{11}^{+\infty} p(x)dx + 10\int_{-\infty}^{+\infty} v^2\,p(v)dv \tag{39}$$

Also, in this case an analytical expression for all the three terms can be derived using *p(x)* given in (20). The analytical expression of the last term is already provided in (31). The expressions for the other terms are given as follows:

$$\int_{c}^{+\infty} p(x)dx = \frac{\sigma_2}{\sigma_1+\sigma_2}\left(1+\mathrm{erf}\left(\frac{x_{sp}-c}{\sqrt{2}\sigma_2}\right)\right) \tag{48}$$

$$\int_{-\infty}^{+\infty} x\,p(x)dx = x_{sp} + \sqrt{\frac{2}{\pi}}\left(\sigma_2-\sigma_1\right) \quad . \tag{49}$$

5.2 Results

The optimal parameters for a switching controller and a constant gain control have been found numerically. For calculating the optimal single-gain controller, the same calculations are used with $k_1 = k_2$. The optimal gains and the value of the cost function are presented in Table 1. It can be seen that with the switching controller, the cost is reduced by around 6.7%. It is because by having 2 gains, the controller can be aggressive on one side, the side of the constraint, while having a low gain and thereby low input variance on the other side.

Table 1: Results of the example

Controller type	Switching controller	Single gain controller
Set point	10.6	10.53
k_1	0.41	2.94
k_2	4.99	2.94
Cost	5.39	5.78

Figure 2 shows the output PDF for the both controllers. It can be seen that the single proportional controller leads to a symmetric Gaussian PDF, while with the switching controller results in an asymmetric PDF. It is equally interesting to see in Figure 3 that the asymmetry in the input PDF is reversed. It can be explained by the fact that closer to the constraint, the input works hard and has a larger variance, while far from the constraint, the input does not work in order to reduce the cost by decreasing its variance.

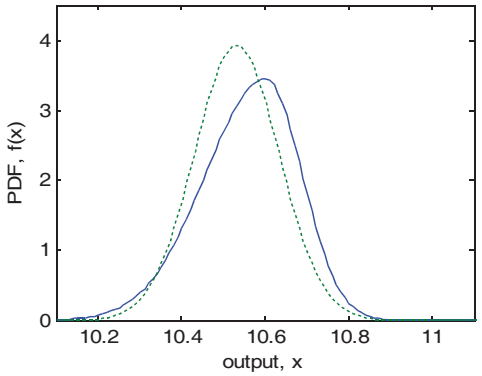

Figure 2: Output PDF with a switching controller (solid line) and with a non-switching controller (dotted line)

Several tests were performed with varying penalties, with varying input weights, and varying measurement noise levels. Figure 4 shows the effect changing the penalty. It can be seen that increasing the weighting for the penalty increases the difference between the cost functions of the symmetric and asymmetric PDF. This tendency can be attributed to the fact that increasing the penalty increases the asymmetry of the cost function. Note that the x axis is logarithmic, i.e, a small increase in the difference calls for a order of magnitude change in the weighting.

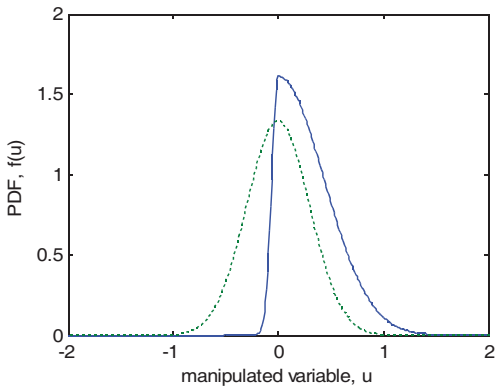

Figure 3: Manipulated variable PDF with a switching controller (solid line) and with a non-switching controller (dotted line)

Figure 5 shows the effect of changing the input weight. An interesting effect can be observed here. The difference first increases, while it decreases after reaching a maximum. Intuitively, when the input weight is zero, the symmetric solution is indeed optimal and there can be no gain by using an asymmetric controller. On the other hand, since the input weighting is symmetric, for large input weightings the asymmetry of the cost function becomes negligible and so a symmetric controller is again optimal.

Figure 6 shows the influence of measurement noise on the difference. The larger the measurement noise, lesser is the gain that can be obtained by using an asymmetric PDF. This is due to the fact that with increasing measurement noise the minimum variance controller as such has a fairly low gain and not much manoeuvrability is left.

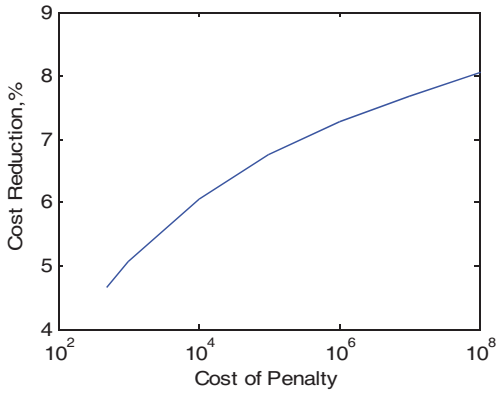

Figure 4: Effect of the weighting of the penalty on the cost reduction due to switching controller

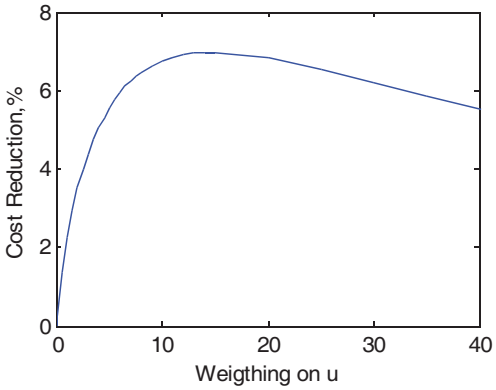

Figure 5 Effect of the input weighting on the cost reduction due to switching controller

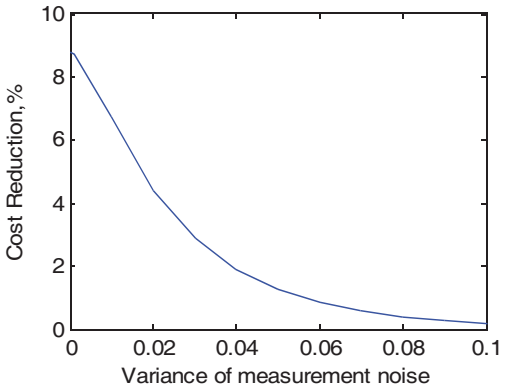

Figure 6: Effect of the measurement noise on the cost reduction due to switching controller

6. CONCLUSION

This paper showed the non-optimality of a symmetric PDF when the cost function was asymmetric and the manipulated variable was constrained. The result is derived using the analytical solution of the FPK equation for a scalar system and a switching controller. Finally, a numerical example was shown where the asymmetric PDF gave a better result than the symmetric one.

The importance of this result lies in the fact that it clearly demarks the cases where an asymmetric PDF is required. Also, a simple switching controller structure for PDF shaping is proposed that can be easily implemented in an industrial context. Finally, the analytical solution of the FPK equation is not only limited to PDF shaping, but could have more impact in the general context of stochastic optimization.

Abstract: While batch processes are gaining ever increasing importance in the manufacturing industries, control of the product quality remains to be a serious challenge. To improve overall process understanding and control, new analytical techniques, such as Near-Infrared (NIR) Spectroscopy, are starting to be employed in industry. Currently, these techniques are primarily used for process monitoring purposes and have not yet been explicitly included in feedback control systems. This paper investigates the ability of three different control systems to adequately control a simulated batch reactor using the NIR spectra as feedback information such that the product meets quality specifications. The particular problem considered in this paper is adequate representation of the NIR spectrum using a single variable that is then controlled by employing Model Predictive Controller (MPC). It is shown that the resulting controller performances are highly variable if the controlled variable is chosen by selecting a single peak in the NIR spectrum to represent that variable. On the other hand, by using Principal Component Analysis (PCA) to extract information from all of the wavenumbers and represent it using a single composite variable, which is then controlled, it is shown that the process can be adequately regulated.

Keywords: Batch Process, Near Infrared Spectroscopy, Model Predictive Control, Chemical Reactor

1. INTRODUCTION

Batch processes are gaining ever increasing importance in the manufacturing industries. They are particularly prevalent in the polymer, pharmaceutical and specialty chemicals industries where the focus is on the production of low-volume, high-value added products. However, a major problem that is faced by those involved in batch processing is the application of reliable control systems. The characteristics associated with batch processes that make them particularly challenging to control include the presence of time-varying and nonlinear dynamics, multitude of unmeasured disturbances such as concentrations of various raw materials, and the presence of irreversible behaviour (Bonvin 1998).

This paper deals with the application of control systems to a chemical batch reactor for which the requirement to manufacture high quality product often translates into the control problem of tracking the reference temperature profile (Cott and Macchietto 1989). This is because the reaction rates involving raw materials, intermediates and products are highly dependent on the temperature. As a result, the composition of the product is also highly dependent on the reactor temperature. The reference profile design consists of characterising, in terms of the reactor temperature, the following three main stages of batch reactor operation: heating up the reactor; controlling the reactor temperature to meet the process requirement and then cooling down the reactor. However, temperature control of batch reactors can be a difficult task due to the process nonlinearities and the absence of the steady-state operation (Shinskey 1996). Aziz et al. (2000) analyzed the performance of different types of controllers in terms of their ability to track a reference profile of reactor temperature.

Even if the adequate temperature control system is in place and the reactor temperature does follow closely its reference profile, there is no guarantee that the final product will meet its specifications. For example, changes in the reaction rates and/or inclusion of a new raw material (as an impurity) can introduce new reaction pathways, which may cause the final composition of the product to change significantly. As a result, product quality can deteriorate even in the presence of a satisfactory temperature control system. Hence, it would be highly useful to construct a control system that would focus on regulating not the reactor temperature but some other variables that are much more directly related to product quality. As a result, such control system should be able to maintain high quality product in the presence of disturbances.

Near-infrared (NIR) spectroscopy represents a set of non-destructive analytical techniques that have been extensively used to extract chemical and physical information from a product sample based on scattered light (Reich 2005). NIR spectroscopy has been widely used in the pharmaceutical industry to test raw materials, control product quality and

monitor processes (M. Blanco 1998; Donald A. Burns 2001; Luypaert, Massart 2007). In the food industry there have been several applications of NIR spectroscopy being used for continuous process monitoring and control (Huang 2008).

Since the NIR spectra reflect the composition of the product, they represent excellent feedback information that could be used by control system to ensure the high quality of a product. So far NIR spectroscopy has been widely used for monitoring of manufacturing processes (Reich 2005; Jorgensen 2004; Scarff 2006). However, there is currently no publication proposing a method of explicitly using NIR spectra as feedback information to control the temperature of a reactor in order to ensure that the manufactured product conforms to high quality standards.

One clear problem in using NIR spectra as feedback information is the large number of variables that are needed to replicate information contained within the NIR spectrum. Arguably the number of variables should be equal to the number of spectral channels (wavenumbers) in order to completely characterise a given NIR spectrum. However, if this guideline is followed then the resulting control problem will potentially have several hundred controlled variables which could not be simultaneously controlled using typically only a handful or even just one or two manipulated variables.

In this paper, the problem of incorporating NIR spectrum as feedback information is addressed by using two different approaches. Both approaches utilise Model Predictive Control (MPC) framework but with a different definition of a controlled variable. The first approach is based on an idea of selecting wavenumber corresponding to one of the spectral peaks as a controlled variable. However, there are currently no clear guidelines regarding the selection of the peak to be considered as a controlled variable. The second approach is to use multivariate statistical analysis tools, namely Principal Component Analysis (PCA), in order to extract the information from NIR spectrum and represent it in a format of a single composite variable. This composite variable can then be regulated by means of a control system. Assessment of the controllers' performances is conducted using a simulated chemical batch reactor. The NIR spectrum is simulated by assuming that it is a linear combination of pure spectra related to individual compounds.

2. PRELIMINARIES

In this section the general concepts of Model Predictive Control (MPC) and Principal Component Analysis (PCA) are briefly introduced in order to facilitate the understanding of the control methodologies employed in the paper.

2.1 Model Predictive Control (MPC)

MPC (Maciejowski 2002) refers to a class of control algorithms that utilise an explicit process model to predict the future response of a plant. At each sampling instant, the MPC algorithm attempts to optimise future process behaviour by computing a sequence of adjustments that should be made to the manipulated variables. The first input in the optimal sequence is then implemented, and the entire calculation is repeated at the next sampling instant.

The key ingredient of the MPC controller is a prediction model used to forecast future process behaviour. In this paper the ARX structure (auto regressive with exogenous inputs) is chosen as the prediction model, and it is given as follows:

$$y(k) = -\sum_{i=1}^{n_y} a_i y(k-i) + \sum_{j=1}^{n_u} b_j u(k-j) + e(k) \qquad (1)$$

where $y(k)$ and $u(k)$ are the controlled and manipulated variable, respectively, at a sampling instant k. The model error is represented by $e(k)$. The order of the ARX model is determined by the values of n_y and n_u.

This cost function for the selection of the appropriate control action is given in (2).

$$J = \sum_{i=1}^{p} \alpha \left(y_r(k+i/k) - \hat{y}(k+i/k) \right)^2 + \sum_{j=1}^{m} \beta \Delta u(k+j-1/k)^2 \qquad (2)$$

Where J is the cost function to be minimized, p and m are the prediction and control horizons, respectively. y_r and $\hat{y}$ are the reference (set-point) values and estimated future output values, respectively, α and β are the weighting parameters for the controlled and manipulated variables, respectively. Finally, Δu is the change in manipulated variable (incremental control move) that is to be computed by the MPC algorithm.

The target of the cost function in (2) is to force the future output to track the reference trajectory over the specified prediction window p, while taking into account the balance between error energy and incremental control energy.

2.2 Principal Component Analysis (PCA)

The primary objective of Principal Component Analysis (PCA) is to capture the majority of variation present in data using a minimal number of composite variables, named principal components (PCs) (Johansson 2001; Berrar 2003). This dimensionality reduction is performed by exploiting the inter-dependence between measured process variables, such as individual wavenumbers in the NIR spectra.

For the analysis of spectroscopic data, such as that obtained from the NIR instruments, the power of PCA lies in its ability to condense the correlated information from hundreds of wavenumbers into a small number of mutually orthogonal principal components (PCs). Formally, PCA performs the following matrix decomposition:

$$\mathbf{X} = \mathbf{T}\mathbf{P}^{\mathbf{T}} + \mathbf{E} \qquad (3)$$

where $\mathbf{X}$ represents measured process data organised in n rows and m columns. PCA decomposes this data matrix into

the product of two matrices **T** and **P**, as shown in (3). **T** and **P** matrices contain as columns the so-called PCA scores and PCA loadings, respectively. **E** matrix represents the information contained within the matrix **X** that is not represented in the first nc principal components. Normally, each column of the data matrix **X** corresponds to a particular process variable, while the particular row is related to a specific sampling instant in time. In the context of NIR spectra, the columns of **X** represent specific spectral channels or wavenumbers while the rows contain data related to the whole NIR spectrum measured at a particular instance in time.

Due to the fact that the columns of the loadings matrix P are orthogonal, the expression for the calculation of scores is given as:

$$\mathbf{T} = \mathbf{XP} \tag{4}$$

It is the expression in equation (4) that will be utilised in this paper in order to condense information from hundreds of wavenumbers present in **X** into a single composite variable, namely the score associated with the first principal component.

3. CONTROL METHODOLOGY

3.1 Temperature Cascade Control (TCC)

A standard control problem in chemical reactor operation is that of controlling reactor temperature such that it follows a certain pre-computed reference trajectory, which should in turn ensure that the product quality will be satisfactory. Ultimately, reactor temperature is controlled by manipulating the flow of coolant or steam into the reactor's jacket. However, due to the presence of numerous disturbances, such as the feed temperature and the temperature of the incoming coolant, this control problem is addressed by employing two controllers in master-slave configuration, as shown in Fig.1.

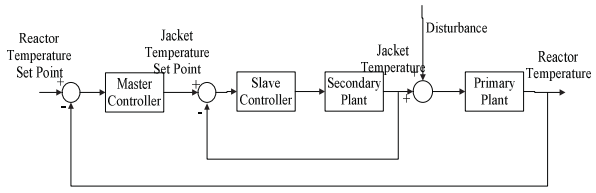

Fig. 1. Control of Reactor Temperature Using TCC System

The primary control loop, also known as the Master control loop, controls reactor temperature by adjusting the inlet jacket temperature set-point. The secondary control loop, known as the slave control loop, regulates jacket temperature by manipulating the flow of either coolant or steam into the jacket. Hence, the manipulating variable of the master control loop is the set-point for the slave control loop. This method of cascading controllers is very popular in the process industries and is particularly useful when there are disturbances associated with the slave controller's manipulated variable (Seborg 2004).

In this paper, a PI controller is used in the primary (slave) control loop while the PID controller is employed in the master (primary) control loop.

Note that the TCC system controls product quality implicitly, through the regulation of reactor temperature. The main problem with such implicit control arises with the occurrence of specific disturbances and process dynamics' changes, which adversely affect the underlying relationship between the reactor temperature and the product quality. As a result, optimal temperature profile will change. However, unless the optimal profile is calculated in real-time, TCC system will typically not have access to it. Instead, TCC will use existing reference trajectory, which is sub-optimal and may result in unsatisfactory product quality as demonstrated in the results section of this paper.

3.2 Wavenumber-Based MPC Control (Wn-MPC)

Spectroscopic instrumentation is being increasingly used to provide measurements, such as NIR spectra, that are in some way closely related to the product quality. By incorporating these measurements as feedback information into the control system the product quality control is addressed more explicitly when compared to the TCC scheme. One possible control system structure that incorporates NIR spectra as feedback information is shown in Fig. 2.

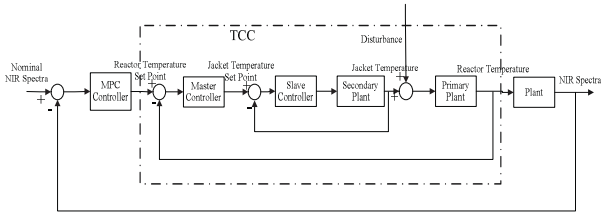

Fig. 2. Basic Structure of Wn-MPC Control

This new control structure incorporates the TCC system from Fig. 1 and augments it with the additional outer control loop, namely MPC control loop. The manipulated variable of the MPC controller is the reactor temperature set-point while controlled variables are the intensities of NIR spectra at a particular set of wavenumbers. Hence, within this control system structure, the TCC system can be viewed as a slave controller while MPC can be viewed as a master controller. This control system structure will be referred to as Wn-MPC.

The reference profile for the wavenumber is obtained by collecting NIR spectra from a 'nominal' batch, during whose progression no major disturbances were present and the standard TCC control scheme was used.

Since each wavenumber in the NIR spectra represents a candidate variable to be used as feedback information, there may be hundreds of potential controlled variables. Therefore, serious practical problem that arises when attempting to implement Wn-MPC is to decide on the set of wavenumbers that will be used as controlled variables. Currently, there are no clear guidelines as to which wavenumber should be selected for control purposes. In this paper a range of

wavenumbers was selected and their suitability was evaluated by incorporating them into Wn-MPC as controlled variables.

3.3 PCA Score-Based MPC Control (Sc-MPC)

In order to incorporate information from all of the wavenumbers into a feedback signal, a modified control system structure is used, as shown in Fig. 3.

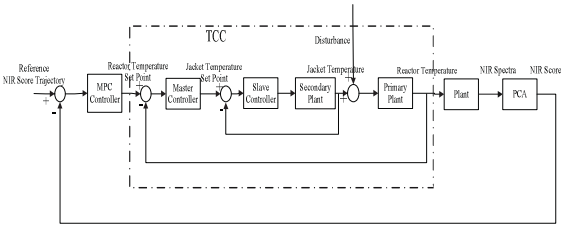

Fig. 3. Basic Structure of the Sc-MPC Control

This control scheme differs from Wn-MPC in that it includes a block containing the PCA model that pre-processes feedback information, namely NIR spectra. The result of PCA processing is a small set of variables, called scores, that contain information related to all of the measured wavenumbers. This is in contrast to Wn-MPC where the feedback information relates to only a few wavenumbers.

In this paper it is assumed that a PCA model is constructed using NIR spectra collected from a nominal batch. This nominal batch is run in the absence of any major disturbances using TCC control scheme. Hence, the resulting NIR spectra are assumed to represent reference profile that is to be replicated by Sc-MPC. In order to extract the main features from the highly multivariate NIR spectral data into a single variable, PCA model is applied. The resulting score trajectory is used as a reference profile that Sc-MPC is required to follow.

4. CASE STUDY

4.1 Chemical Reactor Simulation

This paper documents the application of three different control systems to a simulated chemical batch reactor taken from Cott (Cott and Macchietto 1989). The reactions taking place are given as follows:

$$A + B \xrightarrow{k_1} C;\ A + C \xrightarrow{k_2} D \qquad (5)$$

where *A*, *B* are the raw material, *C* is the desired product and *D* is the waste product, while k_1 and k_2 are the rates of the two reactions.

The control objective is to track the reactor temperature T_r reference trajectory by adjusting the jacket temperature T_{jsp}.

4.2 Disturbance Description

Three different control systems, described in section 3, were evaluated by injecting large disturbance and observing the control system response. Disturbance was chosen to be a reduction in a value of a reaction rate constant k_1 by 8%.

4.3 Prediction Model Identification

Training data for the Recursive Least Squares (RLS) algorithm was obtained using the TCC system structure, shown in Fig. 1. To excite the process dynamics, reference temperature trajectory was perturbed for three batches by adding a PRBS signal of amplitude 0.1 degrees C and switching time of 60 seconds.

In this particular case study ARX based prediction models were developed with $n_y = 2$ and $n_u = 80$. The data-driven identification method of RLS was used to develop dynamic models for both Wn-MPC and Sc-MPC controllers.

The output signal considered during the prediction model identification is the deviation of a controlled variable from its nominal trajectory. This controlled variable may be spectral intensity at the particular wavenumber (in the case of Wn-MPC control) or the value of the PCA score (in the case of Sc-MPC control).

4.4 Wavenumber Selection

In the case of Wn-MPC, candidate controlled variables were taken to be those wavenumbers that corresponded to a local peak of the measured NIR spectrum. In this particular case study the wavenumbers corresponding to the local peaks in the NIR spectra and, therefore, representing the candidate controlled variables were 2, 77, 98, 127, 161 and 232, as illustrated in Fig. 4.

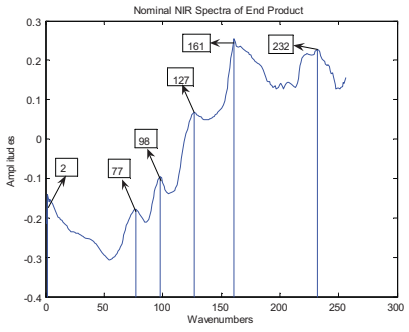

Fig. 4. Selection of spectral peaks as controlled variables

For each of these wavenumbers prediction model was identified and the corresponding MPC controller was constructed and evaluated. The corresponding controllers are designated with a chosen wavenumber written within brackets following a label Wn-MPC. For example, Wn-

MPC(127) designates Wn-MPC controller that utilises wavenumber 127 as the controlled variable.

4.5 PCA Model Development

A PCA model was developed using NIR spectra collected from a single nominal batch. The first PCA score captured 93.8% of the variation present in the NIR spectra and was used as a reference trajectory in the subsequent implementation of Sc-MPC controller. The loadings vector associated with the first PCA score was then used in real-time to compute score value from the measured NIR spectra according to equation (4).

4.6 Results and Discussion

For each controller (TCC, Wn-MPC and Sc-MPC) the process was perturbed using the identical large disturbance described in section 4.2. The resulting NIR spectra that corresponded to particular controllers along with the reference spectrum are plotted in Figures 5 and 6.

Fig. 5 shows the NIR spectra obtained when the controllers used to regulate the batch reactor were TCC, Sc-MPC and Wn-MPC(77). Sc-MPC can be seen to outperform both TCC and Wn-MPC(77). In fact, the NIR spectrum obtained when using Sc-MPC controller was found to be very similar to the reference spectrum, as shown in Fig. 5. On the other hand, both TCC and Wn-MPC(77) clearly failed to reject the disturbance as evidenced by considerable deviation of their respective NIR spectra from the reference spectrum.

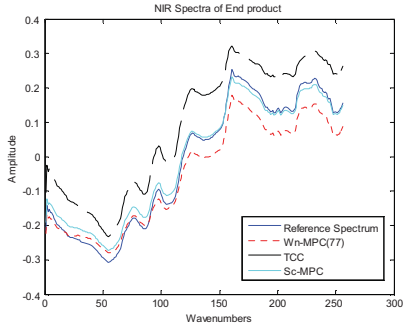

Fig. 5. NIR spectra of end product obtained when using TCC, Wn-MPC(77) and Sc-MPC

The reason for the discrepancy in performance between the TCC and Sc-MPC lies in the fact that the TCC control system does not consider NIR spectra as its feedback information and, furthermore, its reference temperature profile is not adjusted to account for the presence of the large disturbance, which has modified the underlying relationship between temperature and product quality. On the other hand, Sc-MPC explicitly considers regulation of the NIR spectra by using the composite of spectral measurements as its feedback information. Wn-MPC(77) also delivered sub-optimal performance because the spectral data contained in wavenumber 77 appeared not to be sufficient to characterise the majority of information contained in the entire NIR spectrum. Wn-MPC(77) is an example of Wn-MPC controller with its controlled variable obtained by randomly selecting one of the prominent peaks in the NIR spectrum, which is not an unlikely scenario in real applications.

The performances obtained by controlling NIR trajectories at different wavenumbers (77 127 161) using Wn-MPC controllers change largely, as demonstrated in Fig. 6.

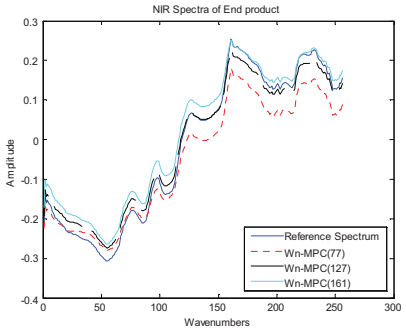

Fig. 6. NIR spectra of end product obtained when using Wn-MPC(127), Wn-MPC(161) and Wn-MPC(77)

The sum of square errors of the NIR spectra and its nominal values by Wn-MPC at every wavenumber are calculated and showed in Fig. 7. This figure shows a large variation in performance achieved by Wn-MPC controllers that utilise different wavenumbers (2, 77, 98, 127, 161, 232) as their controlled variables.

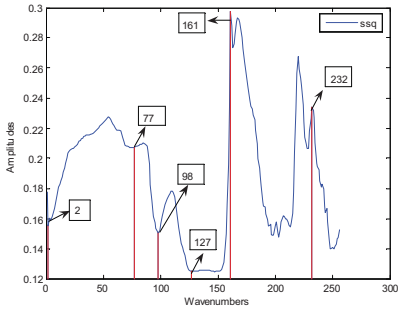

Fig. 7. The sum of square errors (ssq) by Wn-MPC at different wavenumbers

Even if the Wn-MPC is used with an optimally selected wavenumber, which is wavenumber 127 in this particular case study, the resulting control performance was found to be very similar to the performance of the Sc-MPC controller. This is demonstrated in Fig. 8 where the NIR spectra shown were obtained when the process was being controlled using Sc-MPC and Wn-MPC(127).

Hence, the improvement in performance delivered by Wn-MPC(127) is not considerable while the trial-and-error procedure involved in selection of the wavenumber to be controlled may be prohibitively time-consuming and expensive. On the other hand, Sc-MPC delivered satisfactory

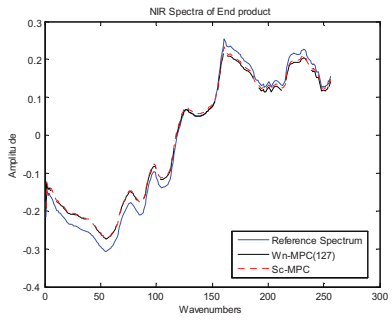

Fig. 8. NIR spectra of end product obtained when using Wn-MPC(127) and Sc-MPC

performance that was similar to that of the Wn-MPC(127) controller. In addition, the controlled variable is automatically selected requiring no trial and error in the case of Sc-MPC. Hence, Sc-MPC controller was found to require minimal user interaction when selecting appropriate controlled variable while also delivering a highly satisfactory performance.

Observed variability in performance can be explained by the fact that all of the considered Wn-MPC controllers focus on the feedback information contained within a single wavenumber. Hence, there may be cases where a chosen wavenumber conveys little information related to other segments of the overall NIR spectrum, such as the wavenumber 77. In these cases the resulting Wn-MPC will not deliver satisfactory performance, as is the case with Wn-MPC(77). Similarly, there may be cases where a single wavenumber does reflect many of the features of the entire NIR spectrum, such as the wavenumber 127. Resulting controller, namely Wn-MPC(127), will then deliver a satisfactory performance.

5. CONCLUSIONS

This paper investigated the ability of three different control systems to adequately control a simulated batch reactor using the NIR spectra as feedback information such that the product meets quality specifications. The first of the three controllers ignored the presence of NIR spectra and was solely concerned with the regulation of reactor temperature such that it follows pre-specified reference trajectory. This controller was found to be inadequate when the large disturbances altered the underlying relationship between reactor temperature and product quality. The other two controllers utilised aspects of the measured NIR spectrum in their formulations. One of these two controllers used spectral intensities at specific wavenumbers (spectral channels) that corresponded to local peaks in NIR spectra as feedback information and was referred to as Wn-MPC. The other controller used multivariate statistical tool, namely Principal Component Analysis (PCA) in order to extract the main features present in all of the wavenumbers and condense this information into a single composite variable that was controlled. This controller was referred to as Sc-MPC. Results of implementing these three controllers on a simulated batch reactor reveal that the Sc-MPC achieved satisfactory control while also requiring no user interaction when deciding on the variable to be controlled. On the other hand, performance achieved by Wn-MPC was found to be highly dependent on the choice of the wavenumber that is to be controlled. However, due to the lack of rigorous guidelines when selecting appropriate wavenumber and the resulting trial and error necessary to determine optimal wavenumber, it is questionable whether Wn-MPC can be used as a practical solution in industrial process control area.

Abstract: In this article, we describe the development of a modular online optimization solution. This solution can be configured to deal with different plant layouts and therefore allows for a re-usable and hence profitable advanced optimization solution. The industrial process for which the model was developed is divided into separate stages. Each stage represents a production step, which may or may not be present in a particular plant. Inputs and outputs of each stage are defined in a flexible way to ensure that the sequence of the production stages can vary and can be easily connected. Optimization results are shown for two alternative plant configurations and are discussed together with the benefits and cost that come with the pursuit of a modular solution.

Keywords: Online optimization, modularity, advanced solutions, nonlinear optimization, multi-stage processes, configuration.

1. INTRODUCTION

Most advanced industrial control and optimization solutions are developed on a case-by-case basis and are tailored to a production process at a particular plant. A large part of the implementation is spent on expert manpower; to model the plant behaviour with a deterministic or stochastic model and to adjust the control algorithm of the model (Bauer and Craig, 2008).

From a vendor's point of view, the business case of developing advanced solutions will often only achieve a breakeven if the model and the control algorithm can be re-used and installed multiple times without long and tedious adaptation of the model and algorithm. The development cost can then be split between the several implementation projects and the solutions is offered at a price that will result in an acceptable net present value (NPV) – both for the vendor and the customer.

Achieving re-usable and thus profitable advanced control and optimization solutions, however, are as rare as hen's teeth. Darby and White (1988) point out that this can be a question of modelling the process with one single model or in a decentralized approach. A modular approach is often easier to implement and maintain, especially when model updates are required.

In some industrial plants, production stages resemble each other and show enough common features to be generalized by a basic building block. A modular approach is achieved by configuring and connecting the basic building blocks. Other processes might be constructed by the same basic building block with different parameterization that is configured to adjust to the plant layout, including the use of a different number of blocks.

In this article, we describe a modular nonlinear real-time optimization approach that maximizes the throughput in a production process. Nonlinear online optimization is still not applied as widely as linear optimization problems in industry but some applications have been reported (De Gouvea and Odloak, 1998, Jockenhövel et al., 2003). The approach has been developed for an industrial environment to be implemented for online application.

Here, we describe an example of a production process for which a modular model will be developed. This model is derived using the following steps.

- Identify a basic building block;
- Define the block equations;
- Define the block connections;
- Define the process' objective function;
- Package the basic building block.

If a model is available in such a way, it significantly reduces the effort required to adapt the model to a new plant configuration. The solution can be re-used once implemented on an appropriate platform. One of the keys to a profitable advanced solution is furthermore the easy configuration and implementation of any modelling approach. An example is ABB's Expert Optimizer that provides the framework for implementing hybrid model predictive controllers. An example of such an implementation is given by Stadler and co-workers (2007).

The paper is structured as follows. In the next section, the process is described and two examples of possible configur-

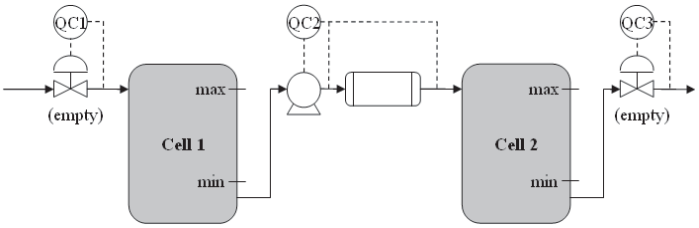

Fig. 1. Process schematic of Configuration I consisting of two cells.

ations are given together with the objective of the optimization problem. The different types to which the basic building block can be configured are identified and listed. Section 3 describes the model derivation along the steps stated above. Results are given in Section 4 together with a discussion on the advantages and disadvantages of the modular solution.

2. PROCESS DESCRIPTION

The continuous process under consideration consists of a set of sequential cells. An example of a configuration of this process is shown in Fig. 1. The medium flows from one cell with a certain flow rate. Valves or pumps control the flow rate into each cell. The flow rate is limited and so is the volume contained in the cell. What makes the process particular and difficult to control is the fact that the medium to be processed changes almost completely and abruptly. The medium consists, in fact, of different separate products with different attribute affecting the flow rate. The products do not mix but instead are processed successively. Thus, the flow rate changes whenever the next product enters a cell. A sensor therefore measures the consistency at the entry of the cell and the flow rate is adjusted accordingly.

The particular are characteristics concerning the operation of the two cells. The first cell has to be emptied before a new product enters it. Thus, the valve or alternatively pump is closed off for a period of time until the tank has been emptied to a certain level. The second cell is preceded by a heat exchanger that warms up the medium before it enters the cell. While the first part of the medium is in the heat exchanger, the heat has to be adjusted to a certain temperature and the flow rate has to be lower than its normal maximum. In any configuration, an outflow valve controls the last flow in the process. The outflow is interrupted as one product is filled into a container, the container is sealed off, removed and a new container is placed in this position.

Altogether, there are four basic cell types, each with or without a heat exchanger and/or emptying during transition, as listed in Table 1. A plant can consist of a number of sequential cells, ranging from two up to about eight cells.

The process is very difficult to control as all cells interact and disturbances directly travel through the process. Minimum and maximum constraints of the level in the cells and of the flow rate are hard and cannot be violated without causing a complete shut-down of the plant. An important process characteristic is that the flow rates have to be constant while one product is filled into a cell. The level is therefore constantly increasing or decreasing, depending on the difference between the in- and outflow of the cell. If in- and outflow are identical for a certain period of time the level stays constant for that period of time. Determining the optimal set-points is therefore crucial for an uninterrupted operation of the process that also maximizes the throughput.

2.1 Configuration 1

The process can have different setups of the basic cell types described in Table 1. The one such configuration is shown in Fig. 1 and, as described earlier, consists of two cells where Cell 1 has to be emptied before the next product can enter it (Case B). During this period, the valve is closed off. Cell 2 is preceded by a heat exchanger (Case C). The consistency is measured before and after the heat exchanger so that a product change is noticed thereafter so that the flow rate can be adjusted when the medium enters and exits the heat exchanger. The opening and closing of the cells in- and outflow depends on the different material and the control is indeed already very complex when considering only these two cells.

2.2 Configuration II

Fig. 2 shows the process schematic of the second configuration to be investigated in this paper. Here, three cells are connected where the first cell has to be emptied after a product changeover (Case B). The second cell adjusts the speed according to a product change but neither has it a heat exchanger nor is it emptied (Case A). The third case has a heat exchanger but does not have to be emptied between product changeovers (Case C). The plant parameters such as maximum flow rate and cell volume differ from Configuration I. This naturally affects the different operational routines.

Table 1. Alternative cell types

		Emptying during transition	
		No	Yes
Heat exchanger	No	Case A	Case B
	Yes	Case C	Case D

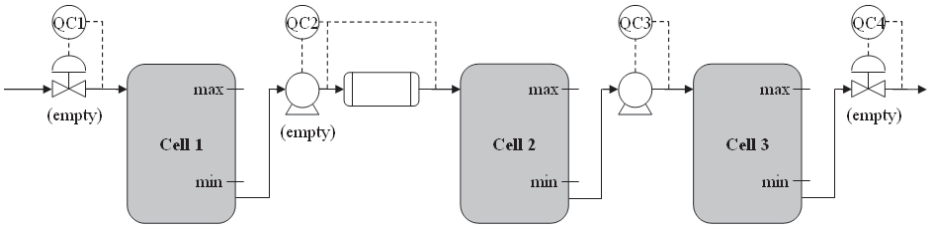

Fig. 2. Process schematic of Configuration II consisting of three cells.

2.3 Online process optimization

The described process is somewhat different to a standard continuous chemical process. Here, we deal with different products in operation with changing attributes. The controller has to deal with different states that alter with a product changeover: emptying, heating and normal operation. The aim of this study is to determine the flow rate set-points for a sequence of products under the given constraints, that is, limits of the constant flow rates and minimum and maximum cell levels. The objective is to maximize the outflow of the last cell. New setpoints are determined repeatedly, either:

a) Time based, that is, on a fixed time grid for example every ten seconds;
b) Event based, that is, if a defined event occurs, for example if a new product enters the process.

If an event occurs, the time grid is reset and restarted after the event. The high update frequency requires a fast result from the online optimization routine.

3. MODULAR MODELLING

The processes described in the previous section can be modelled as one single problem since the number of variables is limited. However, in order to re-use the optimization solution for both Configuration I and II and possibly other configurations, it is advantageous to model a basic building block and then configure and connect the blocks using the same description and connections. In the following, the basic building block is identified, the equations are identified, connections established and the objective function for the complete process is derived.

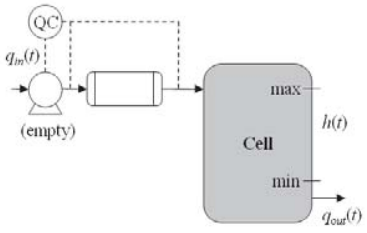

Fig. 3. Basic building block from which Configuration I and II can be constructed.

3.1 Identification of basic building block

By looking at Fig. 1 and Fig. 2 one can easily identify the repeating elements in the process such as the cell and inflow control. A basic building block that describes all cells and their inflow control is shown in Fig. 3. It consists of one cell and the adjustable flow rate of the inflow. The heat exchanger preceding the cell is included in the generic block and its parameters and equations will be set to zero if no heat exchanger is present. Variables are also introduced for emptying the cell. In case that the cell does not have to be emptied, these variables are also set to zero.

3.2 Building block equations

First, the decision variables to be optimized are introduced for each cell. These variables are noted with lower case letters and include the following. There are p products with $p=\{1...P\}$.

$h(t)$	Cell level
$q_p^{in}(t)$	Inflow to cell
$q_p^{out}(t)$	Outflow of cell
τ_p	Time duration during which the product flows into the cell
τ_p^{empty}	Time duration during which the cell and the heat exchanger are emptied
τ_p^{warmup}	Time duration during which the product is warmed up in the heat exchanger

The flow rates are fixed for the duration while processing product p. If the flow rate is constant then the level is a linear function. The durations are auxiliary variables.

Parameters to be configured for each cell are as follows.

V_p	Volume of product p
V^C	Volume of cell C
V^{HE}	Volume of the heat exchanger
$Q_p^{\min}$, $Q_p^{\max}$	Minimum and maximum flow rate

$H^{\min}$, $H^{\max}$ Minimum and maximum cell level

If no heat exchanger is located ahead of the cell (Case A and B) then volume V^{HE} is set to zero.

The duration during which the product flows into the cell is defined as the volume of product *p* minus the volume of the heat exchanger divided by the flow rate of product *p*. When the next product enters the cell the flow rate changes to q_{p+1}^{in}.

$$\tau_p = \frac{V_p - V^{HE}}{q_p^{in}} \tag{1}$$

This equation is nonlinear and thus can cause difficulties for most solvers. It is therefore necessary to reformulate this equation as well as the following into a bilinear form by multiplication ($\tau \cdot q_p^{in} = V_p - V^{HE}$).

When emptying the cell, the valve or pump is closed off and the inflow rate is hence set to zero. The duration during which the tank is emptied is determined by the outflow rate. The volume to be emptied is the volume in the cell plus the volume in the heat exchanger.

$$\tau_p^{empty} = \frac{V^C + V^{HE}}{q^{out}} \tag{2}$$

The duration during which the product is warmed up is defined by the volume of the heat exchanger divided by the inflow rate. It is independent from the outflow rate as one might initially expect.

$$\tau_p^{warmup} = \frac{V^{HE}}{q_p^{in}} \tag{3}$$

The level is proportional to the difference between the in- and outflow rate. The proportional coefficient depends on the area of the cell.

$$h(t) \sim q^{in}(t) - q^{out}(t) \tag{4}$$

Eq. (1)–(4) describe the dynamics of the cell. Inflow, outflow and level have to be defined for each time point for which a switch occurs, that is, when a new product reaches a measuring point. There are two measuring points in case of the presence of a heat exchanger, one before and one after. At these switching points, the level reaches its minimum or maximum value as the function increases and decreases only linearly. If the cell level does not violate the constraints at two consecutive switching points, it will not violate the constraints at any time between those switching points. The reformulation of the inflow, outflow and level for these switching points is rather cumbersome in notation but straight forward otherwise. It will therefore not be detailed in this article.

In addition to the equations describing the process dynamics there are also constraints that determine the operation of the cells. These constraints are considered for the inflow rate q^{in} and for the cell level *h*.

$$Q_p^{\min} \le q_p^{in}(t) \le Q_p^{\max} \tag{5}$$

Table 2. Parameter adaptation for cell types

		Emptying during transition	
		No	Yes
Heat exchanger	No	$V^{HE} = 0 ; \tau_p^{empty} = 0$	$V^{HE} = 0$
	Yes	$\tau_p^{empty} = 0$	none

$$H^{\min} \le h(t) \le H^{\max} \tag{6}$$

The constraints on the outflow rate do not have to be considered as they are defined in the successive cell.

3.3 Connection of building blocks

The cells are connected by the flow through the process. The connection is formulated by equating the outflow rate of cell *C* with the inflow rate of the subsequent cell *C*+1.

$$q^{out,C}(t) = q^{in,C+1}(t) \tag{7}$$

3.4 Objective function

The objective of the optimization problem is to maximize the throughput of the process. As the throughput is determined by the outflow rate of the last cell, this is the quantity to be maximized.

$$\max \int q^{out,C=C_{last}}(t)dt \tag{8}$$

Alternatively, it is possible to minimize the sum of all durations defined in Eq. (1)–(3). In some cases, a better solution is obtained by maximizing the flow rate in all cells and not only the one of the last. This is particularly valid for very short product sequences as the first cells may not process with the highest rate as the finishing of the product sequence in the last cell does not depend on it. As a result, the objective function is set to Eq. (8) plus an additional term including the flow rates in the other cells multiplied by a weighting factor smaller than one.

3.5 Configuration

The basic building block can be packaged into a stand alone function with input and output variables as shown in Fig. 4.

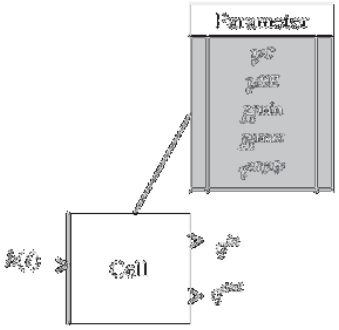

Fig. 4. Configuration block for implementation.

The parameters have to be set for each block. The differentiation between the cell types as given in Table 1. leads to a parameter configuration that is summarized in Table 2. The final step is the connection between the in- and outflows of the consecutive cells as given in Eq. (7) to derive the complete plant setups of Fig. 1 and Fig. 2.

4. OPTIMIZATION RESULTS

The same model is applied for both Configuration I and II with only changes to the parameters and the number of cells. The optimization problem was implemented in GAMS and as a nonlinear program solved with CONOPT. CONOPT is based on the generalized reduced gradient method which transforms inequality constraints into equality constraints by introducing slack variables. The solver then searches along the steepest slope of the super-basic variables.

In some instances, nonlinear models can easily lead to infeasibility. However, as the initialization of the optimization routine is already close to the optimum results can be found reliably. Upper constraints of flow rate and level are used as initial values. The solution is also not necessarily the global optimum. This decision is left to the writer of the GAMS code and the model developer.

Fig. 5 shows the results of Configuration I of Fig. 1. Here, two cells were connected with a heat exchanger between the cells. The first cell had to be emptied/flushed in preparation for a product change. The outflow of the process was also interrupted to allow the product to be filled into tanks. The tanks have to be removed and the process outflow closed off during that period. The process operation can be best seen in the flow rates. The left hand side of Fig. 5 shows the three flow rates, q_1-q_3 for three products. The first flow rate is the process inflow and is interrupted each time a new product enters the cell. The maximum flow rate into the first cell is large for both products, however, the set point is set to a lower level to not exceed the level in the cell as the outflow of the first cell is limited by significantly lower constraints. Flow rate $q_2(t)$ is at its maximum constraint as it poses, together with $q_3(t)$ the bottle neck in the process. While the first part of a product is processed in the second cell, a reduced flow rate is applied. The flow rate $q_3(t)$ is at a higher value than $q_2(t)$ but a stop time interrupts the flow during the product changeover.

The cell levels shown in the right hand side of Fig. 2 indicate that the cell level of the first cell is in the region of its upper limit, i.e., the cell is filled during most time of the operation. The second cell, on the other hand, hits on some occasions the lower constraints.

The results of the optimization routine of Configuration II are shown in Fig. 6. Here, four flows and three cell levels are shown for three products. The first cell is emptied with every product changeover, as can be seen in $q_1(t)$. A heat exchanger is placed ahead of the second cell which affects the flow rate $q_2(t)$. The flow rate $q_3(t)$ changes only with the different products while the last flow rate includes stops during which a new tank is replaced. The stop times for the tanks are constant.

The last cell level is somehow cyclic as the cell is emptied for the new product and then filled up again. The cycle would be repeated if the optimization would have been carried out for more products. The level $h_1(t)$ shows similar features while $h_2(t)$ decreases and then stays at its minimum level for the last product as the in- and outflow rates are identical.

Because of the modular approach, the same model could be re-used for both configurations. The model changes are only changes to the input parameters but not the model equations. In both cases, the outflow rate was optimized which ensures that the flow rates are at their maximum for the bottleneck cells.

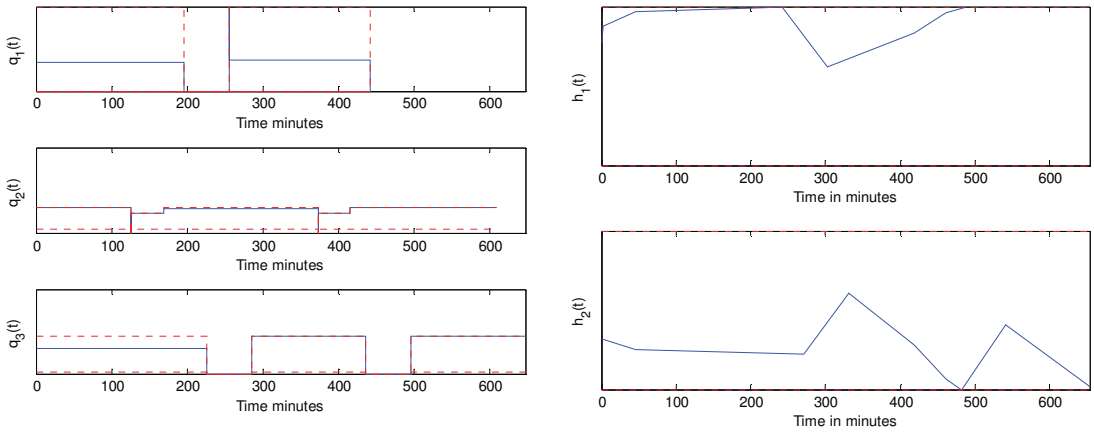

Fig. 5. Results for process Configuration I: cell inflow rates $q(t)$ and levels $h(t)$. Dashed lines indicate the upper and lower constraints.

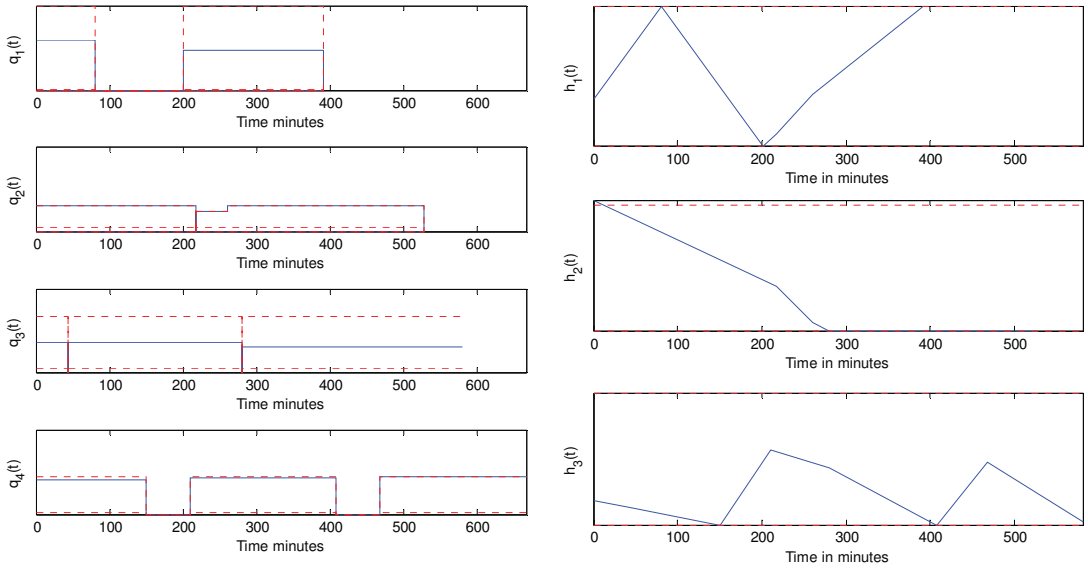

Fig. 6. Results for process Configuration II: cell inflow rates $q(t)$ and levels $h(t)$. Dashed lines indicate the upper and lower constraints.

5. CONCLUSIONS

To achieve a viable business model of advanced control and optimization solutions the modelling, implementation and maintenance effort has to be as small as possible. Re-usable solutions do not only decrease the modelling effort but also make it easier to maintain the solution as the development and commissioning engineers have to be familiar with one solution type. It is therefore attractive to build a modular solution that can be applied to different process setups. In this article a modular solution for a process with different configurations has been derived. The model has been applied to industrial processes and is currently in the process of deployment.

The key steps followed were as follows. A basic building block was identified and the equations introduced, including the connection between the blocks. Optimization results were discussed. Deriving this kind of modular approach is key when developing solutions that can be easily adapted and therefore have the potential to become a business success.

A PID automatic tuning method for distributed-lag processes ⋆

Massimiliano Veronesi * **Antonio Visioli** *

* *Dipartimento di Elettronica per l'Automazione, University of Brescia, Italy*
e-mail: antonio.visioli@ing.unibs.it

Abstract: In this paper we present an automatic tuning methodology for PID controllers for distributed-lag processes. The technique is based on the evaluation of a closed-loop set-point or load disturbance step response and it can be therefore employed with process routine operating data. Further, a performance assessment index is also proposed in order to establish when the performance of a PID controller can be improved by retuning it according to the proposed method. Simulation results show the effectiveness of the approach.

1. INTRODUCTION

Distributed-lag processes are frequently encountered in the process industry. For example, transmission lines, heat exchangers, stirred tanks and distillation columns might have a dynamic characteristic so that they can be modelled as an infinite series of infinitesimally small interacting lags and therefore as a distributed lag (Shinskey, 1994). Despite this fact, this kind of processes are rarely considered in the academic literature (Shinskey, 2002), with the notable exception of the works of Shinskey (see, for example, (Shinskey, 2001)). Therein a tuning tule for Proportional-Integral-Derivative (PID) controllers has been proposed based on process parameters that are obtained by evaluating an open-loop step response.
Indeed, many tuning rules have been developed for PID controllers (O'Dwyer, 2006) and the great majority of them are based on a first-order-plus-dead-time (FOPDT) or second-order-plus-dead-time (SOPDT) model of the process that can be obtained typically by evaluating an open-loop step response. However, this experiment can be time-consuming and, above all, it can imply that the normal process operations are stopped, which is obviously not desirable. For this reason, automatic tuning methodologies have been developed also based on closed-loop experiments, usually by considering a relay-feedback experiment (Yu, 1999).

In this paper we present a methodology for the automatic tuning of PID controllers for distributed-lag processes which is based on the evaluation of a *closed-loop* set-point or load disturbance step response. In particular, we assume that a (possibly badly tuned) PID controller is operating and the evaluation of the step response is employed to retune the PID controller if the achieved performance is not satisfactory, as in (Veronesi and Visioli, 2009). In order to assess the performance of the controller, a performance index is proposed, so that the methodology can be applied both for tuning-on-demand (namely, the controller is tuned after an explicit request of the operator) and for self-tuning (namely, the controller itself determines that the control performance is not satisfactory and a new tuning is provided). It is worth stressing that the tuning rule applied is devoted to the load disturbance rejection task which is usually of main concern in the above mentioned processes.

The paper is organised as follows. A model for distributed-lag processes is given in Section 2. The autotuning method is presented in Section 3, where we explain how the relevant process parameters can be obtained and how the PID parameters can be selected. Finally, the practical implementation of the method is addressed. Simulation results are given in Section 4, and conclusions are drawn in Section 5.

2. MODELLING

A distributed-lag process can be described by the following transfer function (Shinskey, 1994)

$$P(s) = \frac{2\mu}{e^{\tau s} + e^{-\tau s}} = \frac{\mu}{\cosh\sqrt{\tau s}} \tag{1}$$

where μ is the process gain. The hyperbolic cosine can be expanded into an infinite-product series, so that we obtain

$$P(s) = \frac{\mu}{[1 + (2/\pi)^2\tau s][1 + (2/3\pi)^2\tau s][1 + (2/5\pi)^2\tau s]\cdots} \tag{2}$$

It is worth noting that the sum of all time constants, denoted as T_0, is equal to 0.5τ. If a unit step is applied to the process input, the sum of all time constants can be estimated easily as the time the process variable takes to attain the 63.2% of its steady-state value (see Figure 1). Then, the process gain can be estimated easily by considering the steady-state value of the process output and the amplitude of the step input (Visioli, 2006a). However, the open-loop experiment can be time-consuming and, in order to perform it, it can be necessary to stop the routine process operations. Thus, we propose a method to estimate the value of T_0 and of the process gain μ with a closed-loop experiment, namely by employing a PID controller with any values of the parameters (provided that the closed-

⋆ This work was partially supported by MIUR scientific research funds.

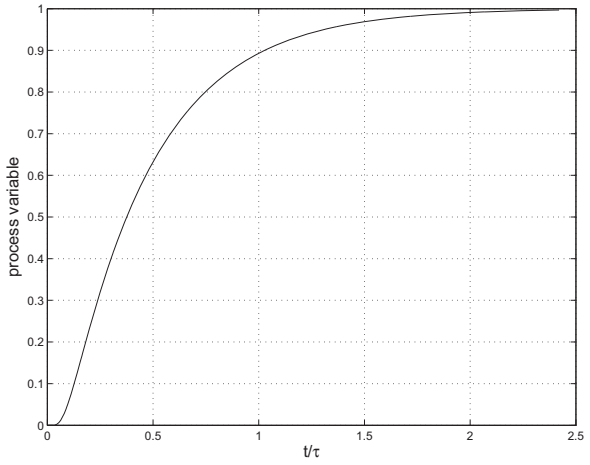

Fig. 1. Open-loop step response of a distributed-lag process. The process variable attains the 63.2% of its steady-state value at time $t = T_0 := 0.5\tau$.

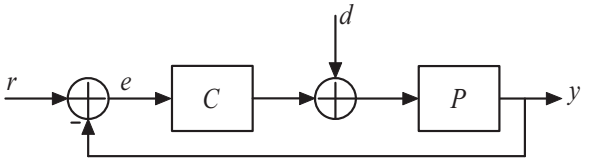

Fig. 2. The considered control scheme.

loop system is asimptotically stable).
Note that, for the purpose of simulation, transfer function (2) can be written as

$$P(s) = \frac{\mu}{\prod_{i=0}^{n-1}\left[1 + \left(\frac{2}{(2i+1)\pi}\right)^2 \tau s\right]} \tag{3}$$

with n at least equal to 20, because the dynamics of the process does not change significantly for $n > 20$ (Shinskey, 2001).

3. AUTOMATIC TUNING

3.1 Estimation of the process parameters from set-point step response

We consider the unity-feedback control system of Figure 2 where the process P is controlled by a PID controller whose transfer function is in series ("interacting") form:

$$C(s) = K_p\left(\frac{T_i s + 1}{T_i s}\right)(T_d s + 1). \tag{4}$$

The series form has been chosen for the sake of simplicity, however, the use of other forms is straightforward by suitably applying translation formulae to determine the values of the parameters (Visioli, 2006a). Note also that the use of a first-order filter that makes the controller transfer function proper has been neglected for the sake of clarity but it can be easily selected so that it does not influence the PID controller dynamics significantly.
We assume that the PID controller has been (roughly) tuned and a step signal of amplitude A_s is applied to the set-point. The process gain μ can be determined by considering the following trivial relations which involve the final steady-state value of the control variable u and of the control error e:

$$\lim_{t\to+\infty} u(t) = \frac{K_p}{T_i}\int_0^\infty e(t)dt = \frac{A_s}{\mu} \tag{5}$$

and therefore we have

$$\mu = A_s\frac{T_i}{K_p\int_0^\infty e(t)dt}. \tag{6}$$

The determination of the sum of the time constants T_0 of the process can be performed by considering the following variable:

$$e_u(t) = \mu u(t) - y(t). \tag{7}$$

By applying the Laplace transform to (7) and by expressing u and y in terms of the reference signal r we have

$$E_u(s) = \mu U(s) - Y(s) = \frac{C(s)(\mu - P(s))}{1 + C(s)P(s)}R(s). \tag{8}$$

At this point, for the sake of clarity, it is convenient to write the controller and process transfer functions respectively as

$$C(s) = \frac{K_p}{T_i s}\tilde{C}(s) \tag{9}$$

where

$$\tilde{C}(s) := (T_i s + 1)(T_d s + 1) \tag{10}$$

and (see (3))

$$P(s) = \frac{\mu}{q(s)} \tag{11}$$

where

$$q(s) = \prod_i(\tau_i s + 1) = \prod_i \tau_i s^n + \cdots + \sum_i \tau_i s + 1 \tag{12}$$

with

$$\tau_i := \left[\frac{2}{(2i+1)\pi}\right]^2 \tau, \qquad i = 0, 1, \ldots. \tag{13}$$

Then, expression (8) can be rewritten as

$$E_u(s) = \frac{\mu K_p\tilde{C}(s)}{T_i s q(s) + \mu K_p\tilde{C}(s)}(q(s) - 1)R(s). \tag{14}$$

By applying the final value theorem to the integral of e_u when a step is applied to the set-point signal we finally obtain (see (12))

$$\begin{aligned}\lim_{t\to+\infty}\int_0^t e_u(v)dv &= \lim_{s\to 0} s\frac{A_s}{s}\frac{\mu K_p\tilde{C}(s)}{T_i s q(s) + \mu K_p\tilde{C}(s)}\frac{q(s) - 1}{s} \\ &= A_s\lim_{s\to 0}\frac{q(s) - 1}{s} \\ &= A_s\sum_i \tau_i \\ &= A_s T_0.\end{aligned} \tag{15}$$

Thus, the sum of the time constants of the process can be obtained by evaluating the integral of $e_u(t)$ at the steady-state when a step signal is applied to the set-point and by dividing it by the amplitude A_s of the step.
Remark 1. It is worth noting that both the value of the gain μ and of sum of the time constants T_0 of the process are determined by considering the integral of signals and therefore the method is inherently robust to the measurement noise.
Remark 2. Note also that the set-point step signal can be applied just for the purpose of (re)tuning the PID

controller (in this case its amplitude should be as small as possible in order perturb the process as less as possible) but also a step response during routine process operations can be employed. This issue will be further discussed in subsection 3.5.

Remark 3. It is worth stressing that the value of T_0 is obtained independently on the values of the PID parameters. This is an advantage with respect to the use of other methods for the identification of the process transfer function, whose result depends on the control variable and process variable signals.

3.2 Estimation of the process parameters from load disturbance step response

The process parameters can be estimated by evaluating also a load disturbance step d of amplitude A_d. However, in this case the amplitude A_d is not known and therefore must be estimated as well. This can be determined by considering the final value of the integral of the control error. In fact, the expression of the Laplace transform of the control error is:

$$E(s) = -\frac{P(s)}{1+C(s)P(s)}D(s) = -\frac{T_i s\mu}{T_i s q(s) + K_p\tilde{C}(s)\mu}\frac{A_d}{s}, \tag{16}$$

and therefore we obtain

$$\begin{aligned}\lim_{t\to+\infty}\int_0^t e(v)dv &= \lim_{s\to 0} s\frac{1}{s}\frac{A_d}{s}\left(-\frac{T_i s\mu}{T_i s q(s) + K_p\tilde{C}(s)\mu}\right)\\ &= -\frac{A_d T_i}{K_p}.\end{aligned} \tag{17}$$

Thus, the amplitude of the step disturbance can be determined as

$$A_d = -\frac{K_p}{T_i}\int_0^\infty e(t)dt. \tag{18}$$

Once the amplitude of the step disturbance has been determined, the process gain μ can be determined by first considering the Laplace transform of the process input $i = u + d$, that is:

$$\begin{aligned}I(s) &= U(s) + D(s)\\ &= -\frac{C(s)P(s)}{1+C(s)P(s)}D(s) + D(s)\\ &= \frac{1}{1+C(s)P(s)}\frac{A_d}{s}\\ &= \frac{T_i s q(s)}{T_i s q(s) + K_p\tilde{C}(s)\mu}\frac{A_d}{s}.\end{aligned} \tag{19}$$

Thus, if we integrate $i(t)$ and we determine the limit for $t \to +\infty$ we obtain

$$\lim_{t\to+\infty}\int_0^t i(v)dv = \lim_{s\to 0} s\frac{1}{s}\frac{T_i s q(s)}{T_i s q(s) + K_p\tilde{C}(s)\mu}\frac{A_d}{s} = \frac{T_i A_d}{\mu K_p} \tag{20}$$

The process gain μ can be therefore found easily, once the value of A_d has been determined by using (18), as

$$\mu = A_d\frac{T_i}{K_p\int_0^\infty (u(t)+A_d)dt}. \tag{21}$$

Finally, the determination of the sum of the time constants of the process can be performed by initially considering the variable

Table 1. Tuning rules for distributed-lag processes.

	K_p	T_i	T_d
PI	$5/\mu$	$0.54T_0$	0
PID	$100/15/\mu$	$0.25T_0$	$0.10T_0$

$$e_i(t) := \mu(u(t)+d(t)) - y(t). \tag{22}$$

By applying the Laplace transform to (22) and by expressing u and y in terms of d we have

$$\begin{aligned}E_i(s) &= \frac{\mu - P(s)}{1+C(s)P(s)}D(s)\\ &= \frac{\mu - P(s)}{1+C(s)P(s)}\frac{A_d}{s}\\ &= \frac{\mu T_i A_d s}{T_i s q(s) + K_p\mu\tilde{c}(s)}\frac{q(s)-1}{s}.\end{aligned} \tag{23}$$

By twice integrating e_i and by applying the final value theorem we obtain (see (15))

$$\begin{aligned}&\lim_{t\to+\infty}\int_0^t\int_0^{v_2} e_i(v_1)dv_1dv_2\\ &= \lim_{s\to 0} s\frac{1}{s^2}\frac{\mu T_i A_d s}{T_i s q(s) + \mu K_p\tilde{C}(s)}\frac{q(s)-1}{s}\\ &= \frac{T_i A_d}{K_p}T_0.\end{aligned} \tag{24}$$

Thus, T_0 can be obtained as

$$T_0 = \frac{K_p}{T_i A_d}\int_0^\infty\int_0^t e_i(v)dvdt. \tag{25}$$

Remark 4. Note that also in this case the estimation of the process parameters is based on the integral of signals and therefore the method is inherently robust to the measurement noise. Further, the process parameters are obtained independently on the values of the PID parameters, because the estimation is based on steady-state values of the variables. Finally, as for the set-point step response, the step disturbance signal can be applied just for the purpose of (re)tuning the PID controller (in this case its amplitude should be as small as possible in order to perturb the process as less as possible) but also a step response during routine process operations can be employed.

Remark 5. In the proposed method, the occurrence of an abrupt (namely, step-like) load disturbance has been assumed. Indeed, this is the most relevant case for the control system, as the disturbance excites significantly the dynamics of the control system itself. Thus, the performance assessment technique has to be implemented together with a procedure for the detection of abrupt load disturbances. Methods for this purpose have been proposed in (Hägglund and Åström, 2000; Veronesi and Visioli, 2008).

3.3 Tuning of the controller

Once the sum of the time constants has been estimated by evaluating the set-point or the load disturbance step response, the PID controller can be tuned properly by considering the load disturbance rejection task, which is usually of main concern in practical applications. We propose to use the tuning rules devised by Shinskey and explained in (Shinskey, 1994, 2001). They are reported in Table 1, for the sake of clarity, for both PI and PID controller.

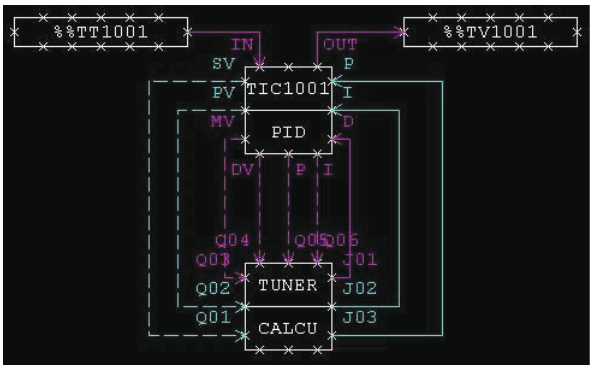

Fig. 3. The implementation of the proposed technique by means of the Yokogawa Centum VP Distributed Control System (courtesy of Yokogawa Italia).

3.4 Practical implementation

If a set-point step response is employed for estimating the process parameters, the proposed methodology can be easily implemented in a DCS with a suitable software development environment, as shown in Figure 3. The PID block (TIC1001) executes the standard PID control: its input and output are indicated respectively as TT1001 and TV1001. The calculation block TUNER determines the value of T_0 by computing the integral of the process variable (PV) and of the control output (MV) it receives from the PID block. Further, it computes the process gain. For this reason it needs also the setpoint (SV) and the PI parameters, namely, the proportional gain (or, equivalently, the proportional band) and the integral time constant. Finally the block TUNER computes the new values of the PID parameters by implementing the tuning rules shown in Table 1 and send them back to the PID block. Note that Q01..08 and J01..03 are the conventional name of the ports that the calculation block uses for exchanging data with the other function blocks.
If a load disturbance response is employed, the estimation procedure has to be estimate first the step amplitude A_d and then its value has to be employed to determine the μ and T_0 as indicated in (21) and (25).

3.5 Performance assessment

In a practical context it is also useful to evaluate the performance of a (PID) controller in order to determine if it has to be retuned or not. This is especially necessary if a self-tuning procedure has to be implemented, namely, the control system itself evaluates the control performance during process routine operations and a new tuning is provided in case it is not satisfactory. In this context, a measure of the performance of a control system can be effectively based on the integrated absolute error

$$IAE = \int_0^\infty |e(t)|dt \tag{26}$$

which implicitly considers both the peak error value and the settling time. For the technique proposed in this paper it is of interest to assess the control performance when a load disturbance occurs. For this purpose, the integrated absolute error obtained by applying the tuning rules of Table 1 to distributed-lag processes (2) with different

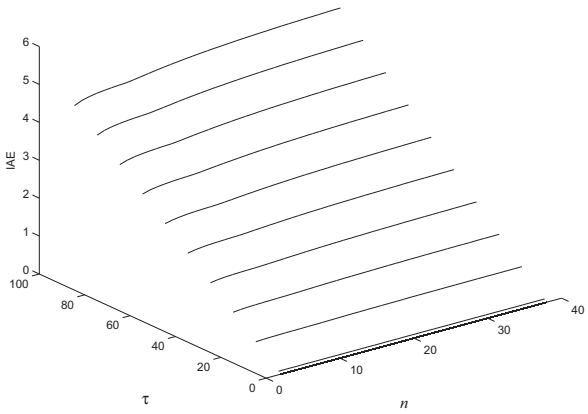

Fig. 4. Values of IAE for different values of τ and n (process order) with a PI controller tuned according to Table 1.

values of μ and τ, and different process order n has been computed. Results for $\mu = 1$ are shown in Figure 4 and 5 for PI and PID controller respectively. By interpolating these results, we obtain that the value of IAE achieved by applying the tuning rules of Table 1 are (for PI and PID controllers respectively):

$$IAE_{PI} = 0.058\tau\mu = 0.116T_0\mu \tag{27}$$

$$IAE_{PID} = 0.02\tau\mu = 0.04T_0\mu \tag{28}$$

Thus, the integrated absolute error achieved by a PI(D) controller should be ideally that expressed in (27) and (28). A performance index can be therefore defined as

$$J_{PI} = \frac{IAE_{PI}}{\int_0^\infty |e(t)|dt} \tag{29}$$

$$J_{PID} = \frac{IAE_{PID}}{\int_0^\infty |e(t)|dt} \tag{30}$$

and it can be determined, once the process parameters have been estimated by applying the technique described previously, by considering the obtained integrated absolute error.
In principle, the performance obtained by the control system is considered to be satisfactory if $J_{PI} = 1$ or $J_{PID} = 1$. From a practical point of view, however, the controller can be considered to be well-tuned if J_{PI} or J_{PID} is greater than a threshold (less than one) which can be selected by the user depending on how tight are its control specifications. In any case a sensible default value of 0.8 can be fixed.
Remark 6. It turns out from the presented results that using the derivative action allows to improve the performance significantly with respect to a PI controller.
Remark 7. It is worth noting that a performance index J greater than one can result because of the (small) interpolation error in determining (29) and (30) and because in any case the tuning formulae of Table 1 does not guarantee that the integrated absolute error is globally minimized.

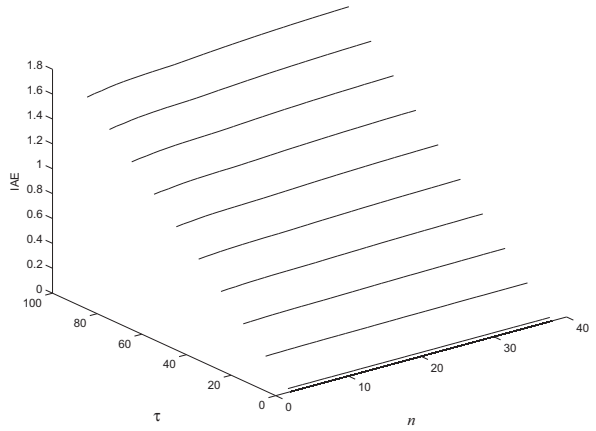

Fig. 5. Values of *IAE* for different values of τ and n (process order) with a PID controller tuned according to Table 1.

4. SIMULATION RESULTS

4.1 Example 1 - PID control

As a first example we consider a process with $\mu = 1$, $\tau = 10$ and $n = 30$ lags. Initially, the PID controller parameters are selected as $K_p = 3.3$, $T_i = 1.9$, $T_d = 0.25$. Then, a unit step load disturbance is applied to the process and the amplitude of the disturbance, the gain of the process and the sum of the time constants are estimated as $A_d = 1$, $\mu = 1.0$, and $T_0 = 4.97$. Based on these values, the PID parameters are retuned, according to Table 1, as $K_p = 6.66$, $T_i = 1.24$, $T_d = 0.5$. The load disturbance step response provided by the new values of the PID controller parameters is shown as a solid line in Figure 6, where the load disturbance step response provided by the initial values is also plotted as a dashed line. The control signal is not shown for the sake of brevity, in any case there are no significant differences between the two cases. By retuning the controller, the performance index is improved from $J_{PID} = 0.32$ to $J_{PID} = 1.03$ while the integrated absolute error decreases from IAE = 0.62 to IAE = 0.19. It is worth noting that the same result is achieved if a set-point step response is employed for estimating the process parameters.

4.2 Example 2 - PI control

As a second example we consider the same process of Example 1, but the use of a PI controller is assumed. Initially, the controller parameters are selected as $K_p = 7$ and $T_i = 2$ (note that the controller is aggressive). Then, a unit step load disturbance is applied to the process and the amplitude of the disturbance, the gain of the process and the sum of the time constants are estimated as $A_d = 1$, $\mu = 0.99$, and $T_0 = 4.97$ (the same parameters are estimated by considering a set-point step response). Based on these values, the PI parameters are retuned, according to Table 1, as $K_p = 5.06$ and $T_i = 2.68$. The load disturbance step responses provided by the initial and new values of the PI controller parameters are shown in Figure 7 as a dashed and solid line respectively. As

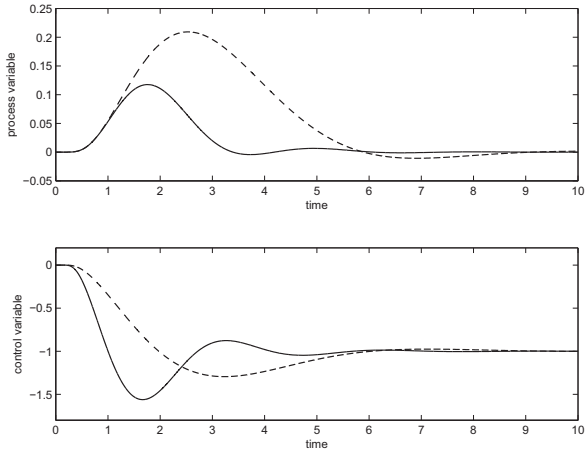

Fig. 6. Load disturbance step response for example 1. Dashed line: initial tuning. Solid line: automatic tuning.

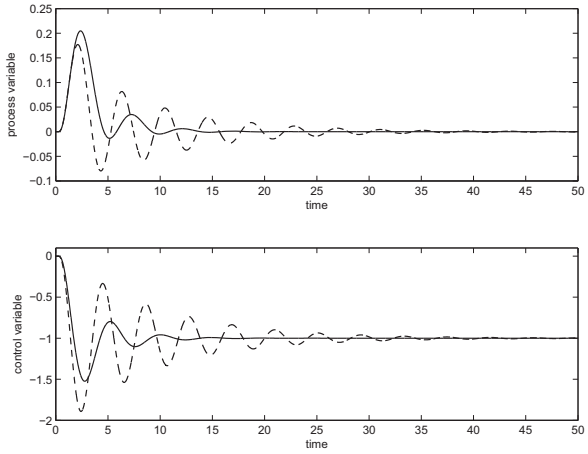

Fig. 7. Load disturbance step response for example 2. Dashed line: initial tuning. Solid line: automatic tuning.

in Example 1, retuning the controller allows to increase the performance. In particular, the performance index is improved from $J_{PI} = 0.64$ to $J_{PID} = 1.01$ while the integrated absolute error decreases from IAE = 0.88 to IAE = 0.56.
It turns out that the proposed autotuning method is effective and, by comparing these results with those of Example 1, it appears that the use of the derivative action allows to increase the controller performance significantly.

4.3 Example 3 - Measurement noise

As a third example we consider again the same process of Example 1, but the process output is corrupted with zero-mean white noise with a variance of $0.1 \cdot 10^{-3}$. The load disturbance step response obtained by selecting the controller parameters as $K_p = 3$, $T_i = 2$, and $T_d = 0.5$ is shown in Figure 8. In order to determine the performance index J_{PID} correctly, it is necessary to discard from the computation of the integrated absolute error those areas

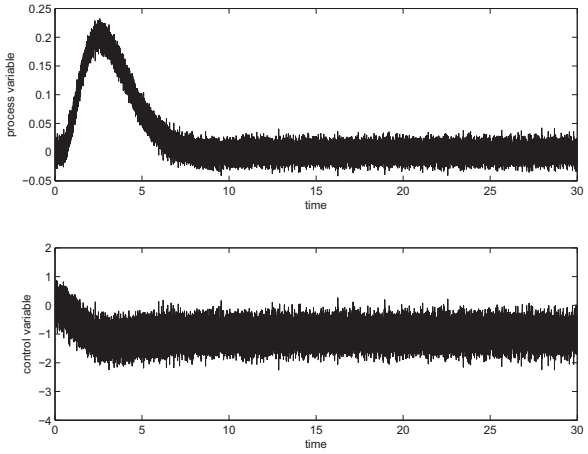

Fig. 8. Load disturbance step response for example 3 with $K_p = 3$, $T_i = 2$, and $T_d = 0.5$.

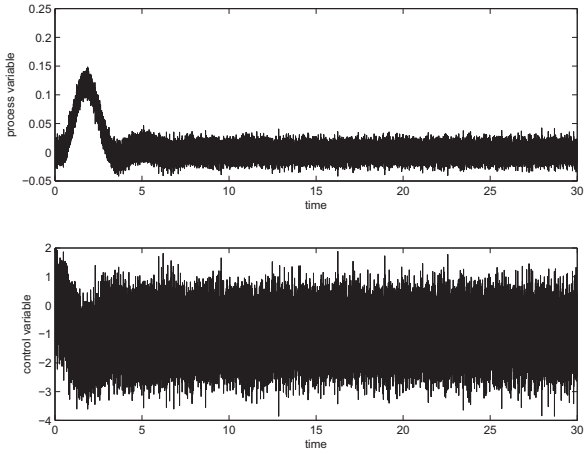

Fig. 9. Load disturbance step response for example 3 with $K_p = 6.87$, $T_i = 1.26$, and $T_d = 0.51$.

whose value is less than a predefined threshold (because they are actually due to the noise) (Visioli, 2006b). It results $J_{PID} = 0.29$, which suggests that the controller needs to be retuned. The gain of the process and the sum of the time constants are then estimated as $A_d = 1$, $\mu = 0.97$, and $T_0 = 5.06$ (once again, note that virtually the same values are obtained by considering a set-point step response). Based on these values, the PID parameters are retuned, according to Table 1, as $K_p = 6.87$, $T_i = 1.26$, and $T_d = 0.51$. The load disturbance step response obtained with the new PID controller is shown in Figure 9. In this case the performance index is $J_{PID} = 1.06$. By retuning the controller the integrated absolute error is decreased from IAE = 0.68 to IAE = 0.19. It turns out that the presence of noise does not impair the effectivess of the method, as expected because the considered variables are integrated.

5. CONCLUSIONS

In this paper we have proposed an automatic tuning methodology for distributed-lag processes based on a closed-loop experiment. Being based on the evaluation of a set-point or load disturbance step response, the technique can employ process routine operating data and can therefore be extended straightforwardly as a self-tuning method. Indeed, a performance index has been devised in order to assess the performance of the controller based on the achieved integrated absolute error. Illustrative examples have shown the effectiveness of the method and that it is robust to the measurement noise. Thus, the methodology appears to be suitable to implement in an industrial setting.

Abstract: This paper presents new tuning rules for PI and fractional PI control of processes that are typically found in process control. The rules are based on characterization of process dynamics by three parameters that can be obtained from a simple step response experiment. The rules are obtained by minimizing a frequency objective function subject to a constraint on the maximum sensitivity. Comparisons with classical tuning rules show that they are very simple but give substantially better performance.

Keywords: Fractional control, PID control, design, tuning methods, optimization, process control.

1. INTRODUCTION

In spite of all the advances in process control over the past several decades, the proportional integral (PI) and the proportional integral derivative (PID) controller remains to be certainly the most extensive option that can be found on industrial control applications, see Åström and Hägglund (2001). The transparency of the PID control mechanism, the availability of a large number of reliable and cost-effective commercial PID modules, and their widespread acceptance by operators are among the reasons of its success, see Gude and Kahoraho (2007).

Over the last half-century, a great deal of academic and industrial effort has focused on improving PID control, primarily in the area of tuning rules. In fact, since Ziegler and Nichols proposed their popular tuning rules, Ziegler and Nichols (1942), an intensive research has been done. Works include from modifications of the original tuning rules, see Chien *et al.* (1952), Hang *et al*. (1991), and Åström and Hägglund (2004), to a variety of new techniques, see Åström and Hägglund (1995).

Fractional calculus, which is the expansion to fractional orders, has been known since the development of the regular calculus. However, fractional-order control was not incorporated into control engineering mainly due to the lack of sufficient mathematical knowledge and the limited computational power available at that time.

More recently, Podlubny (1999) has proposed a generalization of the PI and PID controllers, namely the PI^{λ} and $PI^{\lambda}D^{\mu}$ controllers, involving an integrator of order λ and a differentiator of order μ (the orders λ and μ may assume real non-integer values). Podlubny has also demonstrated the better response of these types of controllers, in comparison with the classical PI and PID controllers, when used for the control of fractional-order systems. A frequency domain approach by using fractional PID controllers has also been studied in Vinagre et al. (2000). However, the design methods for fractional controllers are a recent research area, see Capponetto *et al.* (2002) and Monje *et al.* (2005).

Given that the most common control structure used in the process industry is the PI controller, Åström and Hägglund (2001), an immediate approach that should be taken into account is to use the fractional PI^{λ} controller. Because of the widespread use of PI controllers and the potentials of fractional PI^{λ} controllers, see Gude and Kahoraho (2009), it is interesting to have simple but efficient methods for tuning these kind of controllers.

In this paper, we have developed new simple tuning methods for PI and PI^{λ} controllers that give significantly better performance for a wide range of processes.

The layout of this paper is the following. The different controllers and the test batch considered in this paper are presented in Section 2. The design method is treated in Section 3. This is followed by the main results obtained in this paper: new tuning rules for PI and PI^{λ} controllers in Section 4. In Section 5 the developed tuning rules are applied to a process and a comparison between different tuning rules is made. Finally conclusions and final remarks are drawn in Section 6.

2. CONTROLLERS AND TEST BATCH

2.1 Plant knowledge

To be accepted in industrial applications controller tuning rules must be based on a limited amount of plant knowledge that is easy to obtain. The plant can the be characterized by its τ value:

$$\tau = \frac{L}{L+T} \quad (1)$$

This parameter is usually called the *normalized dead time*. It is essentially the classical *controllability ratio* L/T, but the parameter τ has the advantage that it is in the range from 0 to 1. The *controllability ratio* was often mentioned in the early process control literature, see Cohen and Coon (1953). This parameter can be used to characterize the difficulty of controlling a process. Roughly speaking, processes with small τ can be considered easy to control and the difficulty in controlling the system increases as τ increases.

2.2 The test batch

The design method presented in the next section requires the transfer function of the process to be known. The results of this investigation depend critically on the chosen test batch. To apply the method we therefore have to choose process models that are representative for the dynamics of typical industrial processes. Processes with the following transfer functions have been used:

$$G_1(s) = \frac{e^{-s}}{(1+sT)^2}$$

T = 0.01, 0.05, 0.1, 0.2, 0.3, 0.5, 0.7, 1, 2, 4, 6, 8, 10

$$G_2(s) = \frac{1}{(s+1)^n}$$

n = 3, 4, 5, 6, 7, 8

$$G_3(s) = \frac{1}{(1+s)(1+\alpha s)(1+\alpha^2 s)(1+\alpha^3 s)} \quad (2)$$

α = 0.1, 0.2, 0.5, 0.7

$$G_4(s) = \frac{1-\alpha s}{(s+1)^3}$$

α = 0.1, 0.2, 0.5, 1, 2

$$G_5(s) = \frac{1}{(1+s)(1+sT)}$$

T = 0.02, 0.05, 0.1, 0.2, 0.5

The process (3) is the standard model that has been used in many investigations of PID tuning.

$$G(s) = K_P \frac{e^{-Ls}}{(1+sT)} \quad (3)$$

The test batch (2) does, however, not include this transfer function because this model is not representative for typical industrial processes, see Åström and Hägglund (1995). Tuning based on the model (3) typically gives controller gains that have a different behaviour from the other processes in the test batch, see Hang *et al.* (1991). This is remarkable because tuning rules have traditionally been based on this model.

The processes selected in the test batch (2) are representative for many of the processes typically found in process control, see for example Åström and Hägglund (2000) and Gorez (2003), suggested as standard benchmark models for testing PID controllers. The test batch includes processes that range from delay-dominated to lag-dominated processes. They include all kinds of plants with poles strictly on the negative real axis, such as plants with time delay or non-minimum phase zeros, plants of high and low orders, plants with multiple and spread poles, etc. All processes are normalized to have unit steady state gain and have a parameter that can be changed to influence the response of the process. The parameter ranges have been chosen to give a wide variety of responses. The normalized time delay ranges from 0.17 to 1 for G_1. The rest of the processes have values of τ in the range $0 < \tau < 0.5$

2.3 PI and PI$^{\lambda}$ controllers

In this paper, two different controllers are considered: the PI and the fractional PI$^{\lambda}$ controller, which is a generalisation of the PI controller. It is a non-integer order controller of the form:

$$C(s) = K + \frac{k_i}{s^{\lambda}} \quad (4)$$

where K is the proportional gain, k_i the integral gain, and λ the fractional order of the integral part.

The interest of this kind of controller is justified by a better flexibility, since it exhibits a fractional integral part of order λ. Thus, three parameters can be tuned in this structure (K, k_i, and λ), that is, one more parameter than in the case of conventional PI controller (λ = 1). We can take advantage of the fractional order λ to improve the performance.

3. THE DESIGN METHOD

Within the process industry, regulation performance is often of primary importance since most controllers operate as regulators, see Shinskey (1996). Regulation performance is often expressed in terms of the control error obtained for certain disturbances. A load disturbance is typically applied at the process input. Typical criteria are to minimize a loss function of the form:

$$I = \int_0^{\infty} t^n |e(t)|^m dt \quad (5)$$

where the error is defined as e(t) = r(t) – y(t). Common cases are IAE (n = 0, m = 1), ISE (n = 0, m = 2), or ITSE (n = 1, m = 2).

However, Kristiansson and Lennartson (2002) defined another performance criterion in the frequency domain as an alternative to the above criteria based on a function of the error signal. It is formulated as:

$$J_v = \left\| \frac{1}{s} G(s) S(s) \right\|_{\infty} = \max_{\omega} \left| \frac{1}{j\omega} \cdot \frac{G(j\omega)}{1 + L(j\omega)} \right| \quad (6)$$

The proposed performance criterion is mainly a measure of the system ability to handle low-frequency load disturbances.

Robustness is an important consideration in control design. There are many different criteria for robustness. Many of them can be expressed as restrictions on the Nyquist curve of

the loop transfer function L(s) = G(s)C(s). Åström and Hägglund (1995) introduced the maximum sensitivity function of the closed-loop system, M_S, as a tuning parameter for PID controllers. The constraint (7) that sensitivity function S(jω) is less than a given value M_S implies that the loop transfer function should be outside a circle with radius $1/M_S$ and center at –1.

$$\|S(s)\|_\infty = \max_\omega |S(j\omega)| = \max_\omega \left|\frac{1}{1+L(j\omega)}\right| \le M_S \qquad (7)$$

The design problem discussed in this paper can be formulated as an optimisation problem: *Find parameters of the different controllers that minimize performance criterion (6) subject to the robustness constraint (7).*

A reasonable ambition in all control design is to keep the control signal as small as possible. Control system design very often deals with the trade-off between performance and control effort, provided that a reasonable mid-frequency robustness is guaranteed, see for example Gude and Kahoraho (2009). Therefore, introduce the control effort criterion:

$$J_u = \|C(s)S(s)\|_\infty = \max_\omega \left|\frac{C(j\omega)}{1+L(j\omega)}\right| \qquad (8)$$

4. RESULTS

An empirical method is used to develop the new tuning rules. The design method proposed in Section 3 with $M_S = 1.4$ was applied to all processes in the test batch (2). This value of M_S provides a good compromise between performance and robustness. This gave the corresponding parameters K, T_i, for the PI, and K, T_i, and λ, for the fractional PI controller. The process parameters K_P, L and T were also computed from the step response experiment. The controller gain is normalized by multiplying it either with the static process gain K_P or with the parameter $a = K_P L/T$. Integration time is normalized by dividing by T or by L. We will represent normalized controller parameters as functions of τ. Data obtained can be well approximated by functions having the form:

$$f(\tau) = a\tau^b + c \qquad (9)$$

4.1 PI controller

Simplified tuning rules for PI controllers will be first obtained. Figures 1 and 2 show the normalized proportional gains and integration times, respectively, as a function of normalized time delay τ when the design procedure is applied to all processes in the test batch (2). The curves drawn correspond to the results obtained by curve fitting. Both figures show that there appears to be a good correlation between the normalized controller parameters and the normalized time delay τ. This indicates that it is possible to develop good tuning rules based on the *KLT*-model. However, Figures 1 and 2 also show that parameters KK_P, aK, T_i/L, and T_i/T range from 0.16 to 23.8, from 0.21 to 3.15, from 0.34 to 8.2, and from 0.1 to 6.8, respectively.

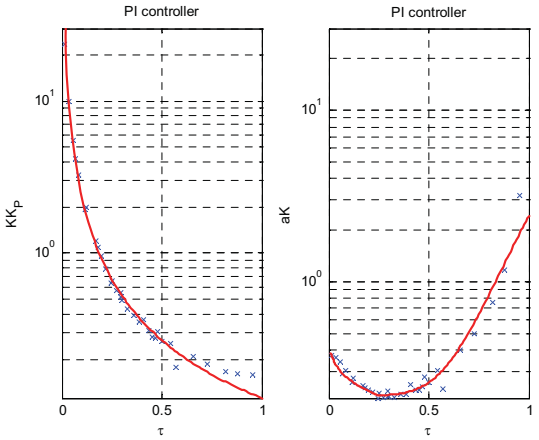

Fig. 1. Normalized PI controller proportional gains plotted versus normalized time delay τ for the test batch. The solid lines correspond to the tuning rules obtained in Table 1.

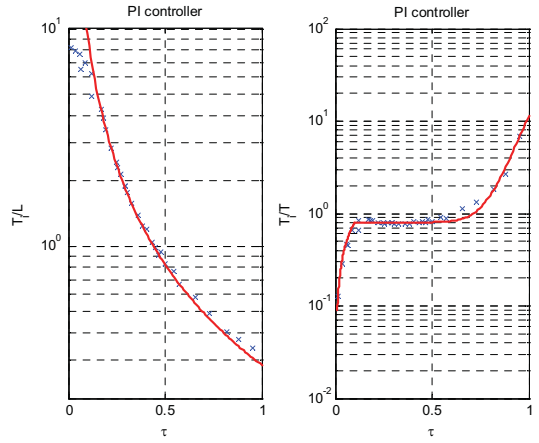

Fig. 2. Normalized PI controller integration times plotted versus normalized time delay τ for the test batch. The solid lines correspond to the tuning rules obtained in Table 1.

This indicates clearly that it is not possible to obtain good tuning rules that do not depend on τ. The deviations from the solid lines in the figure is about ± 15%

Table 1. Tuning formulae for the PI controller. The table gives the parameters of the functions of the form (9) for the normalized controller parameters and $M_S = 1.4$.

f(τ)	a	b	c	τ
KK_P	0.09793	–1.3676	0.01378	$0 < \tau < 1$
aK	–0.6473	0.1128	0.77	$0 < \tau < 0.25$
	2.212	5.7	0.2163	$0.25 < \tau < 1$
T_i/L	0.2967	–1.497	–0.01252	$0 < \tau < 1$
T_i/T	5.479	0.8154	–0.03853	$0 < \tau < 0.1$
	10.7	11.79	0.8028	$0.1 < \tau < 1$

Table 1 gives the coefficients for functions of the form (9) fitted to the data available in Figures 1 and 2. The corresponding graphs are shown in solid lines in figures.

4.2 *PI$^{\lambda}$ controller*

Simplified tuning rules for fractional PI controllers will be now obtained. Figures 3, 4, and 5 show the normalized proportional gains, the normalized integration times, and the controller fractional order, respectively, as a function of normalized time delay τ when the design procedure is applied to all processes in the test batch (2). The curves drawn correspond to the results obtained by curve fitting. Both figures show that there appears to be a good correlation between the normalized controller parameters and the normalized time delay τ. This indicates that it is possible to develop good tuning rules for fractional PI controllers based on the *KLT*-model.

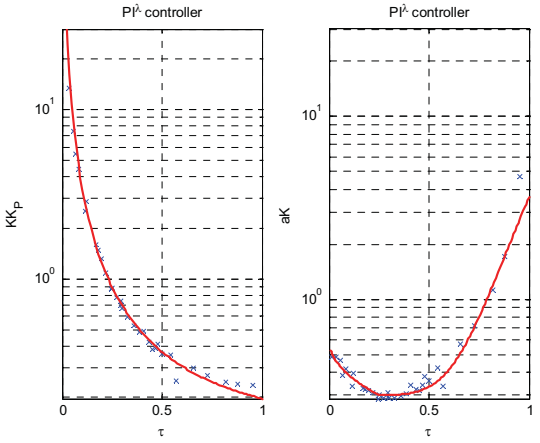

Fig. 3. Normalized PI$^{\lambda}$ controller proportional gains plotted versus normalized time delay τ for the test batch. The solid lines correspond to the tuning rules obtained in Table 2.

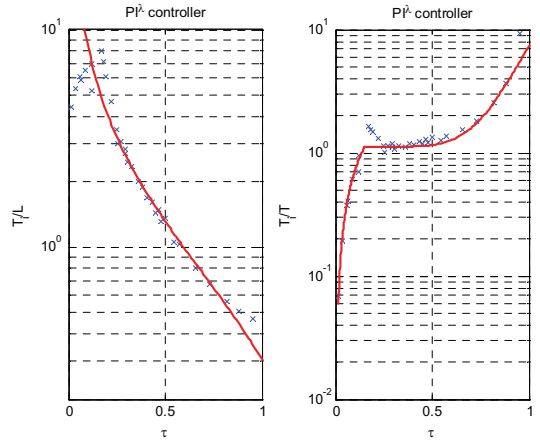

Fig. 4. Normalized PI$^{\lambda}$ controller integration times plotted versus normalized time delay τ for the test batch. The solid lines correspond to the tuning rules obtained in Table 2.

As in the case of the PI controller, it is not possible to obtain good tuning rules that do not depend on τ. The deviations from the solid lines in the figure is about ± 15%. Table 2 gives the coefficients of functions of the form (9) fitted to the data available in Figures 3, 4, and 5. The corresponding graphs are shown in solid lines in these figures.

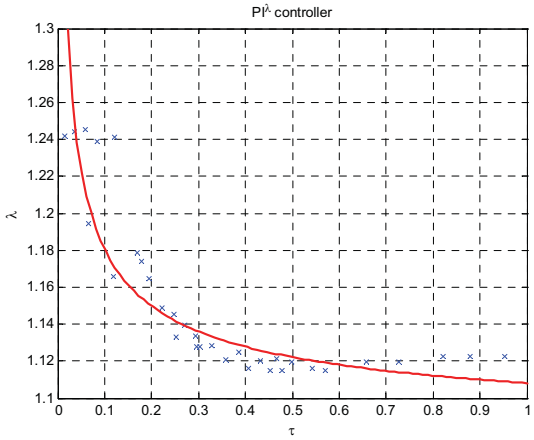

Fig. 5. Fractional order λ plotted versus normalized time delay τ for the test batch. The solid lines correspond to the tuning rules obtained in Table 2.

Table 2. Tuning formulae for the fractional PI$^{\lambda}$. The table gives the parameters of the functions of the form (9) for the normalized controller parameters and M_S = 1.4.

f(τ)	a	b	c	τ
KK_P	0.08621	–1.594	0.1096	0 < τ < 1
aK	–0.5643	0.2715	0.6866	0 < τ < 0.25
	3.327	6.593	0.2983	0.25 < τ < 1
T_i/L	1.17	–0.8997	–0.8666	0 < τ < 1
T_i/T	8.549	1.052	–0.04380	0 < τ < 0.15
	6.271	7.304	1.12	0.15 < τ < 1
λ	0.03512	–0.4862	1.073	0 < τ < 1

Figure 6 shows the ratio between the optimal J_v–values obtained with a PI$^{\lambda}$ and PI controller applied to the processes in the test batch. It shows that the benefit in using a PI$^{\lambda}$ instead a PI controller is more than 12% for delay–dominated processes, about 11% for balanced lag and delay processes, and tends to 18% for lag–dominated processes.

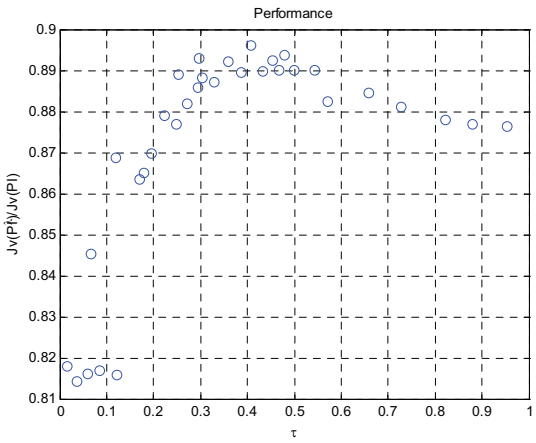

Fig. 6. Ratio of the J_v–values obtained for a PI$^{\lambda}$ and a PI controller for different values of τ applied to the processes of the test batch.

4.3 A simpler tuning rule for PI$^\lambda$ controllers

As can be seen in Figure 5, optimal λ–value is approximately equal to 1.12 for $0.3 < \tau < 1$. Provided that the maximum difference between the optimal value of λ and 1.12 is, in the worst case, equal to 0.12, i.e. 10%, we will try to develop simple tuning rules for PI$^\lambda$ controllers, fixing the value of λ to 1.12. Figures 7 and 8 show the optimal normalized proportional gains and integration, for a constant value of $\lambda = 1.12$, as a function of the normalized time delay τ. The curves drawn correspond to the results obtained by curve fitting in Table 3.

Figure 9 shows the ratio between the optimal J_v–values obtained with a PI$^\lambda$ with all its parameters free and a PI$^\lambda$ with $\lambda = 1.12$ applied to the test batch. It shows that the J_v–values obtained in both cases are nearly the same for $0.3 < \tau < 1$, and the loss for lag–dominated processes increases but it is, in all cases, less than 5%.

KK_P	0.2154	–1.169	–0.1592	$0 < \tau < 1$
aK	–0.4645	0.3182	0.5795	$0 < \tau < 0.25$
	3.271	5.75	0.28	$0.25 < \tau < 1$
T_i/L	9.242	–0.1966	–9.171	$0 < \tau < 1$
T_i/T	5.479	0.8154	–0.03853	$0 < \tau < 0.3$
	6.06	7.066	1.18	$0.3 < \tau < 1$
λ	$\lambda = 1.12$			$0 < \tau < 1$

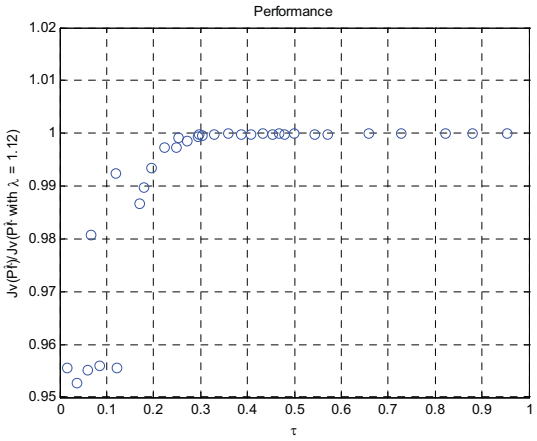

Fig. 9. Ratio of the J_v–values obtained for a PI$^\lambda$ and a PI$^\lambda$ with $\lambda = 1.12$ for different values of τ applied to the processes of the test batch.

5. COMPARISON WITH OTHER DESIGN METHODS

Extensive simulations have been done. Comparisons with classical tuning rules show that proposed tuning rules are very simple but give substantially better performance. However, due to page limitations, only one simulation has been included in this paper. There are many methods for tuning PI controllers. In this Section, the proposed methods for PI and PI$^\lambda$ controllers are compared with the Ziegler-Nichols step response method, Ziegler and Nichols (1942), the Cohen-Coon method, Cohen and Coon (1953), and optimal controllers in terms of J_v, IAE, J_u, and M_S.

For simplicity we will denote the Ziegler Nichols step response method by ZN, the Cohen-Coon method by CC, the optimal PI and PI$^\lambda$ controller obtained using the design method by opt-PI and opt-PI$^\lambda$, respectively, the proposed method for PI controllers by GK, the one for PI$^\lambda$ controllers by f-GK, and the approximation for PI$^\lambda$ controllers with $\lambda = 1.12$ by af-GK.

Consider the process with the following transfer function: $G(s) = 1/(1+s)(1+0.5s)$. We find that the apparent time delay and time constants are $L = 0.193$ and $T = 1.407$. Hence, the controllability index is $L/T = 0.1372$ and $\tau = 0.12$ for this process.

Table 4 contains the values of the different controller parameters obtained with the considered design methods. This table shows that results obtained by GK, f-GK and af-GK are very close to their respective optimal values. The performance obtained for PI^{λ} is substantially better than for PI. ZN and CC give controllers that reduce load disturbances very effectively, however they exhibit a very poor robustness and excessively large control effort.

Table 4. Controller parameters obtained for the different design methods for the considered transfer function.

Method	K	T_i	λ	k_i	M_S	J_u	J_v	IAE
ZN	6.56	0.58	1	11.34	3.11	22.59	0.12	0.16
CC	6.65	0.50	1	13.32	3.62	28.90	0.14	0.18
GK	1.78	1.13	1	1.58	1.38	2.65	0.63	0.63
opt-PI	2.04	1.21	1	1.68	1.40	3.02	0.59	0.59
f-GK	2.62	1.24	1.17	2.12	1.41	3.58	0.45	0.58
opt-PI^{λ}	2.86	1.34	1.24	2.13	1.40	3.79	0.46	0.61
af-GK	2.40	1.32	1.12	1.82	1.39	3.28	0.50	0.60

Parameters obtained by f-GK and optimal PI^{λ} are very close which indicates that little is lost by not using the full transfer function. The improvement in J_v of using a PI^{λ} instead of a PI is about 22%. The value of J_v for GK is about 28% higher compared with f-GK. These improvements are also evaluated in Gude and Kahoraho (2009).

6. CONCLUSIONS

This paper presents new tuning rules for PI and fractional PI control of typical processes found in process control. The rules are based on characterization of the process dynamics by three parameters, i.e. gain K_P, apparent time constant T and apparent time delay L, that can be obtained by a simple step response experiment. The design method consists on minimizing a frequency objective function subject to a constraint on the maximum sensitivity function. Based on these parameters it is possible to develop very simple tuning rules for PI and PI^{λ} controllers that only depend on the normalized time delay τ.

In this paper it is also demonstrated that substantially better performance can be obtained using PI^{λ} instead of PI controllers. These tuning rules are shown to give good results compared to a couple of well established classical tuning methods, especially when simplicity, performance and robustness are emphasized.

Future investigation should rely on extending these tuning rules to fractional PID controllers.

ACKNOWLEDGEMENTS

Abstract
In this paper, a new method for the identification of self-optimizing control structure designs (CSDs) based on generalized singular value decomposition (GSVD) is proposed. The method is primarily dedicated to find optimal CSDs where all controlled variables (CVs) are represented by a common set of linear combinations of process variables (PVs). It is shown that the implementation of the GSVD into iterative solution approaches is beneficial in order to find CSDs where an individual PV subset is mapped to each CV. The developments will be tested on a simple process.

Keywords: Control system design; Linear control systems; Controlled variables; Optimal control; Self-optimizing control

1. INTRODUCTION

With more than 4000 completed plant projects, the Engineering Division of the Linde AG ranks among the leading international plant contractors, with focus on the key market segments olefin plants, natural gas plants, air separation plants, as well as hydrogen and synthesis gas plants. This paper relates to new process developments for liquefied natural gas plants whose steady state and dynamic behavior are currently under investigation in order to provide design guidelines and to ensure reliable and economic operation. In the context of this work, new methods for the identification of regulatory control structure designs (CSDs) have been developed. They will be presented in this paper.

Steady state process optimization by regulation was first motivated by Morari et al. [1980]. They articulated the idea that a constant set point policy will lead to optimal operation if the underlying control structure is properly designed. Skogestad and Postlethwaite [1996, p. 428-433] extended this idea and gave an approximate criterion for finding CSDs with self-optimizing abilities, the so-called minimum singular value (MSV) rule. Assuming a linear process model and a quadratic cost function, an exact local criterion for the worst-case loss of CSDs was developed by Halvorsen et al. [2003]. Based on the resulting worst-case loss criterion, a multivariate non-convex problem subject to structural constraints needs to be solved in order to obtain a self-optimizing CSD. These structural constraints refer to limitations on the size of the process variable (PV) subset and the particular selection of PVs. For instance, it must be decided whether only PV selection or PV combination is taken into account. Several methods have been developed which solve the constrained optimization problem. An optimal CSD subject to PV selection can be found by either screening all possible PV combinations or applying branch and bound (BAB) algorithms in order to avoid time consuming calculations as proposed by Cao and Saha [2005], Kariwala and Skogestad [2006/07/09-13], Cao and Kariwala [2008], Kariwala and Cao [2009]. PV combination methods have been published by Alstad and Skogestad [2007], Alstad et al. [2008], Kariwala [2007] and Kariwala et al. [2008]. They all have in common that the same PV subset is considered for all CVs.

In Section 2, the mathematical framework of self-optimizing control theory will be briefly introduced. In the following sections, two variants of a new PV combination method will be proposed. In Section 3 the focus is on CSDs where a common PV subset is considered for all CVs. Section 4 is dedicated to CSDs where individual PV subsets are mapped to each CV. For illustration, the new developments will be applied to a process example in Section 5. Concluding remarks are given in Section 6.

2. MATHEMATICAL FRAMEWORK

The scheme in Figure 1 represents a general regulatory CSD applied to an arbitrary process plant. Based thereon the exact local method by Halvorsen et al. [2003] will be introduced. The vectors $\boldsymbol{u} \in \mathbb{R}^{n_{\boldsymbol{u}}}$, $\boldsymbol{d} \in \mathbb{R}^{n_{\boldsymbol{d}}}$, $\boldsymbol{y} \in \mathbb{R}^{n_{\boldsymbol{y}}}$ and $\boldsymbol{c} \in \mathbb{R}^{n_{\boldsymbol{u}}}$, respectively, correspond to the manipulated variables (MVs), disturbance variables (DVs), measured process variables (PVs) and controlled variables (CVs). A constant set point policy is applied. That is, the MVs are adjusted by the controller(s) until, feasibility provided, the CVs equal the set point vector $\boldsymbol{c}_s$. To account for measurement errors, the PVs and CVs are affected by the implementation errors $\boldsymbol{n}^{\boldsymbol{y}} \in \mathbb{R}^{n_{\boldsymbol{y}}}$ and $\boldsymbol{n}^{\boldsymbol{c}} \in \mathbb{R}^{n_{\boldsymbol{u}}}$.

Morari et al. [1980], the inventors of self-optimizing control, state that it is desirable "(...) to find a function of PVs which when held constant, leads automatically to the optimal adjustments of the MVs, and with it, the optimal operating conditions." In other words, self-optimizing con-

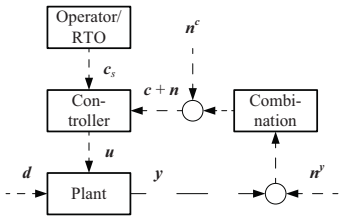

Figure 1. General representation of regulatory CSDs in chemical plants (after Alstad et al. [2008]).

trol may be achieved by an appropriate mapping of PVs towards CVs, denoted by $\boldsymbol{c} = \mathcal{H}(\boldsymbol{y})$, where $\mathcal{H} \in \mathbb{R}^{n_u}$ represents the "combination" block in Figure 1. For deriving the exact local method, Halvorsen et al. [2003] considered a linear map $\boldsymbol{H} = \frac{\partial \boldsymbol{c}}{\partial \boldsymbol{y}^T}$. The cost function of a plant denoted by J are usually affected by both, MVs and DVs. In order to operate the plant optimally (at minimum cost), MVs need to be adjusted subject to variations in DVs. The solution to the problem

$$\boldsymbol{u}_{\text{opt}}(\boldsymbol{d}) = \arg\left(\min_{\boldsymbol{u}} J(\boldsymbol{u}, \boldsymbol{d})\right) \text{ s.t. } g(\boldsymbol{y}, \boldsymbol{u}, \boldsymbol{d}) = 0 \qquad (1)$$

gives the best input leading to the lowest achievable cost. Problem (1) will be referred to as feed-forward re-optimization. Here $g \in \mathbb{R}^{n_y}$ denotes the steady-state model equations of the plant. The following simplifying assumptions are made.

(1) Nonlinearities of the plant are treated as locally negligible. Then, the steady-state I/O model of the plant can be represented as

$$\boldsymbol{y} = \boldsymbol{G^y}\,\boldsymbol{u} + \boldsymbol{G_d^y}\,\boldsymbol{d}, \qquad (2)$$

where $\left[\,\boldsymbol{G^y}\;\boldsymbol{G_d^y}\,\right] = -\left(\frac{\partial g}{\partial \boldsymbol{y}^T}\right)^{-1} \frac{\partial g}{\partial\left[\,\boldsymbol{u}^T\;\boldsymbol{d}^T\,\right]}$.

(2) The cost function J is locally approximated by a second order Taylor series.

(3) The number of MVs might be reduced as some of them need to be spend in "a priori" controller loops in order to either stabilize the plant or fulfill optimally active constraints. It is assumed that $\boldsymbol{u}$ represents only the remaining MVs available for self-optimizing CSD. The "a priori" controller loops are considered part of the model equations g.

Figure 2 shows exemplarily the operational cost of a process plant versus one DV. The cost of feed-forward re-optimization is indicated by the solid line and gives the lower bound for the cost of feedback control with constant set points. It is thus convenient to define a loss function as

$$L(\boldsymbol{d}) = J(\boldsymbol{u_H}(\boldsymbol{d}), \boldsymbol{d}) - J(\boldsymbol{u}_{\text{opt}}(\boldsymbol{d}), \boldsymbol{d}).$$

Here $\boldsymbol{u_H}(\boldsymbol{d})$ represents the influence from DVs to MVs for feedback control, easily derived for the linear case. From $\boldsymbol{c} = \boldsymbol{H}\,\boldsymbol{y} \overset{!}{=} \boldsymbol{c}_s = \boldsymbol{0}$ and (2) it follows that

$$\boldsymbol{u_H} = -(\boldsymbol{H}\,\boldsymbol{G^y})^{-1}\;\boldsymbol{H}\,\boldsymbol{G_d^y}\,\boldsymbol{d}.$$

According to Halvorsen et al. [2003] the worst-case loss is given by

$$L_{\text{worst}} = \frac{1}{2}\,\boldsymbol{z}^T\,\boldsymbol{z}, \qquad (3)$$

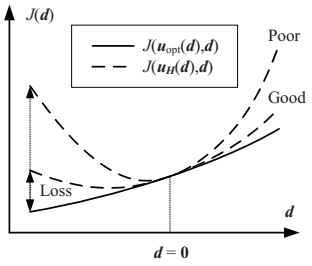

Figure 2. Objective functions for a poor and a good self-optimizing CSD compared with the case of re-optimized MVs (after Skogestad [2000]).

where the loss variables $\boldsymbol{z}$ are given by

$$\boldsymbol{z} = \boldsymbol{M}\,\boldsymbol{f}, \qquad (4)$$

for feedback control with

$$\boldsymbol{M} = J_{\boldsymbol{uu}}^{1/2}\;(\boldsymbol{H}\,\boldsymbol{G^y})^{-1}\;\boldsymbol{H}\,\tilde{\boldsymbol{F}}$$
$$\tilde{\boldsymbol{F}} = \left[\,-\left(\boldsymbol{G^y}\,J_{\boldsymbol{uu}}^{-1}\,J_{\boldsymbol{ud}} - \boldsymbol{G_d^y}\right)\,\boldsymbol{W_d}\;\boldsymbol{W_{n^y}}\,\right].$$

Here, the matrices $J_{\boldsymbol{uu}}$ and $J_{\boldsymbol{ud}}$ indicate the second derivatives (Hessians) of the cost function J with respect to $\boldsymbol{u}$ and $\boldsymbol{d}$. The disturbance variation $\Delta\boldsymbol{d}$ and the implementation error $\boldsymbol{n_y}$ are commonly represented by the scaled variable $\boldsymbol{f}$, *i.e.*,

$$\begin{bmatrix}\Delta\boldsymbol{d}\\ \boldsymbol{n_y}\end{bmatrix} = \begin{bmatrix}\boldsymbol{W_d} & \boldsymbol{0}\\ \boldsymbol{0} & \boldsymbol{W_{n^y}}\end{bmatrix}\boldsymbol{f} \text{ with } \|\boldsymbol{f}\|_2 \le 1,$$

where the matrices $\boldsymbol{W_d}$ and $\boldsymbol{W_{n^y}}$ are diagonal scaling matrices. From observation of (3) and (4) it is evident that a self-optimizing CSD with least worst-case loss may be obtained by solving the problem

$$\boldsymbol{H} = \arg\min_{\boldsymbol{H}} \overline{\sigma}(\boldsymbol{M}), \qquad (5)$$

where $\overline{\sigma}$ indicates the largest singular value. In a more recent work, Kariwala et al. [2008] proved that the average loss given by

$$L_{\text{average}} = \frac{1}{6\,(n_{\boldsymbol{y}} + n_{\boldsymbol{d}})}\;\|\boldsymbol{M}\|_{\text{F}}^2 \qquad (6)$$

is a better estimate of the loss as the worst-case loss (3) tends to overestimation. Here, $\|.\|_F$ indicates the Frobenius norm also known as the Euclidean norm. Besides, Kariwala et al. [2008] proved that the average loss is super-optimal in the sense that it also minimizes the worst-case loss. According to (6), they suggested solving

$$\boldsymbol{H} = \arg\min_{\boldsymbol{H}} \|\boldsymbol{M}\|_{\text{F}} \qquad (7)$$

instead of (5).

The solution of problems (5) and (7) is nontrivial since the matrix $\boldsymbol{M}$ depends in a nonlinear fashion on $\boldsymbol{H}$. Moreover, the problem may be structurally constrained, as indicated in Section 1. *E.g.*, the dimension of the PV subset could be limited or special PVs may be excluded from PV subset etc. Many authors such as Alstad and Skogestad [2007], Alstad et al. [2008], Kariwala [2007] and Kariwala et al. [2008] addressed the problem of finding a global solution to either (5) or (7) with focus on PV combination. All of these

methods are limited to the structural constraint that the same PV subset is used for each CV. Based on the method developed in the next section, iterative solution strategies will be developed which focus on finding CSDs without structural limitations except for rank $(\boldsymbol{H}) = n_{\boldsymbol{u}}$.

3. THE GSVD METHOD

In this section a new solution method is presented for the worst-case and average loss problem, (5) and (7), subject to a common PV subset for all CVs. It will be referred to as the GSVD method. In a first step, (4) is restated as

$$\boldsymbol{z}^T \left(\boldsymbol{G}_{\boldsymbol{z}}^{\boldsymbol{y}}\right)^T \boldsymbol{H}^T = \boldsymbol{f}^T \tilde{\boldsymbol{F}}^T \boldsymbol{H}^T, \tag{8}$$

where

$$\boldsymbol{G}_{\boldsymbol{z}}^{\boldsymbol{y}} = \boldsymbol{G}^{\boldsymbol{y}} J_{\boldsymbol{uu}}^{-1/2}.$$

Suppose, that the rank condition

$$\operatorname{rank}\left(\begin{bmatrix} \left(\boldsymbol{G}_{\boldsymbol{z}}^{\boldsymbol{y}}\right)^T \\ \tilde{\boldsymbol{F}}^T \end{bmatrix}\right) = n_{\boldsymbol{y}} \tag{9}$$

is satisfied which will be generally the case if the condition $n_{\boldsymbol{u}} + n_{\boldsymbol{f}} \geq n_{\boldsymbol{y}}$ holds (the case $n_{\boldsymbol{u}} + n_{\boldsymbol{f}} < n_{\boldsymbol{y}}$ is discussed below in Remark 4). Then, according to Hogben [2007, p. 15.12f], the generalized singular value decomposition (GSVD) of the matrix pair $\left\{\left(\boldsymbol{G}_{\boldsymbol{z}}^{\boldsymbol{y}}\right)^T, \tilde{\boldsymbol{F}}^T\right\}$ exists and (8) can be written as

$$\boldsymbol{z}^T \boldsymbol{U} \boldsymbol{\Sigma} \boldsymbol{V}^T \boldsymbol{H}^T = \boldsymbol{f}^T \tilde{\boldsymbol{U}} \tilde{\boldsymbol{\Sigma}} \boldsymbol{V}^T \boldsymbol{H}^T, \tag{10}$$

where the decomposed matrices have the following properties.

The matrices $\boldsymbol{U} \in \mathbb{R}^{n_{\boldsymbol{u}} \times n_{\boldsymbol{u}}}$ and $\tilde{\boldsymbol{U}} \in \mathbb{R}^{n_{\boldsymbol{f}} \times n_{\boldsymbol{f}}}$ are unitary, *i.e.*, $\boldsymbol{U}^T \boldsymbol{U} = \boldsymbol{I}_{n_{\boldsymbol{u}}}$ and $\tilde{\boldsymbol{U}}^T \tilde{\boldsymbol{U}} = \boldsymbol{I}_{n_{\boldsymbol{f}}}$. The matrix $\boldsymbol{V} \in \mathbb{R}^{n_{\boldsymbol{y}} \times n_{\boldsymbol{y}}}$ is regular. The matrix $\boldsymbol{\Sigma} \in \mathbb{R}^{n_{\boldsymbol{u}} \times n_{\boldsymbol{y}}}$ is tailing diagonal, with $\boldsymbol{\Sigma}^T \boldsymbol{\Sigma} = \operatorname{diag}\left(\alpha_1^2, \alpha_2^2, ..., \alpha_{n_{\boldsymbol{y}}}^2\right)$ and $0 \leq \alpha_i \leq \alpha_{i+1} \leq 1$. The matrix $\tilde{\boldsymbol{\Sigma}} \in \mathbb{R}^{n_{\boldsymbol{f}} \times n_{\boldsymbol{y}}}$ is leading diagonal, with $\tilde{\boldsymbol{\Sigma}}^T \tilde{\boldsymbol{\Sigma}} = \operatorname{diag}\left(\beta_1, \beta_2, ..., \beta_{n_{\boldsymbol{y}}}\right)$ and $1 \geq \beta_i \geq \beta_{i+1} \geq 0$. Note that the number of $r = \max\left(0, n_{\boldsymbol{y}} - n_{\boldsymbol{u}}\right)$ leading α_i and β_i are 0 and 1, respectively, and that the number of $s = \max\left(0, n_{\boldsymbol{y}} - n_{\boldsymbol{f}}\right)$ tailing α_i and β_i are 1 and 0, respectively. For more information on GSVD and on how the resulting matrices can be computed, the reader is referred to standard linear algebra textbooks, *e.g.*, Golub and VanLoan [1996, pp. 465-467].

Theorem 1. If $n_{\boldsymbol{y}} \geq n_{\boldsymbol{u}}$, the minimum worst-case and average loss are given by

$$L_{\text{worst}} = \frac{1}{2}\left(\frac{\beta_{r+1}}{\alpha_{r+1}}\right)^2 \tag{11}$$

and

$$L_{\text{average}} = \frac{1}{6\ (n_{\boldsymbol{y}} + n_{\boldsymbol{d}})} \sum_{i=r+1}^{n_{\boldsymbol{y}}} \left(\frac{\beta_i}{\alpha_i}\right)^2, \tag{12}$$

respectively. They may be obtained by selecting

$$\boldsymbol{H} = \boldsymbol{M}_{\boldsymbol{n}} \begin{bmatrix} \boldsymbol{p}_{r+1} & \cdots & \boldsymbol{p}_{n_{\boldsymbol{y}}} \end{bmatrix}^T,$$

where $\boldsymbol{p}_i$ is the i^{th} column of $\boldsymbol{P} = \boldsymbol{V}^{-T}$ and $\boldsymbol{M}_{\boldsymbol{n}} \in \mathbb{R}^{n_{\boldsymbol{u}} \times n_{\boldsymbol{u}}}$ is an arbitrary regular matrix.

Proof. By selecting $\boldsymbol{H} = \boldsymbol{M}_{\boldsymbol{n}} \begin{bmatrix} \boldsymbol{p}_{r+1} & \cdots & \boldsymbol{p}_{n_{\boldsymbol{y}}} \end{bmatrix}^T$ it follows that

$$\boldsymbol{V}^T \boldsymbol{H}^T = \boldsymbol{V}^T \begin{bmatrix} \boldsymbol{p}_{r+1} & \cdots & \boldsymbol{p}_{n_{\boldsymbol{y}}} \end{bmatrix} \boldsymbol{M}_{\boldsymbol{n}}^T = \begin{bmatrix} \boldsymbol{0}_{r \times n_{\boldsymbol{u}}} \\ \boldsymbol{I}_{n_{\boldsymbol{u}}} \end{bmatrix} \boldsymbol{M}_{\boldsymbol{n}}^T. \tag{13}$$

and

$$\boldsymbol{\Sigma}\, \boldsymbol{V}^T \boldsymbol{H}^T = \operatorname{diag}\left(\alpha_{r+1}, ..., \alpha_{n_{\boldsymbol{y}}}\right) \boldsymbol{M}_{\boldsymbol{n}}^T$$

$$\tilde{\boldsymbol{\Sigma}}\, \boldsymbol{V}^T \boldsymbol{H}^T = \begin{bmatrix} \boldsymbol{0}_{r \times n_{\boldsymbol{u}}} \\ \operatorname{diag}\left(\beta_{r+1}, ..., \beta_{n_{\boldsymbol{y}}}\right) \\ \boldsymbol{0}_{\bar{s} \times n_{\boldsymbol{u}}} \end{bmatrix} \boldsymbol{M}_{\boldsymbol{n}}^T,$$

where $\bar{s} = \max\left(0, n_{\boldsymbol{f}} - n_{\boldsymbol{y}}\right)$. Inserting these results into (10) yields

$$\boldsymbol{z}^T = \boldsymbol{f}^T \underbrace{\tilde{\boldsymbol{U}} \begin{bmatrix} \boldsymbol{0}_{r \times n_{\boldsymbol{u}}} \\ \operatorname{diag}\left(\sigma_{r+1}, ..., \sigma_{n_{\boldsymbol{y}}}\right) \\ \boldsymbol{0}_{\bar{s} \times n_{\boldsymbol{u}}} \end{bmatrix}}_{=\boldsymbol{M}^T} \boldsymbol{U}^T,$$

where $\sigma_i = \beta_i / \alpha_i$ indicate the i^{th} largest generalized singular value of the matrix pair $\left\{\left(\boldsymbol{G}_{\boldsymbol{z}}^{\boldsymbol{y}}\right)^T, \tilde{\boldsymbol{F}}^T\right\}$. Note that the maximum singular value and the Frobenius norm of a matrix are invariant to unitary transformations thereof. Thus, the worst-case loss (3) and the average loss (6) depend only on the selected generalized singular values and the derivation of (11) and (12) is trivial. As the minimum generalized singular values were selected, both, the worst-case loss and the average loss are minimal.

Remark 2. The GSVD method is written in terms of the complete PV set $\mathcal{Y}$. Note that it work as well for a selected PV subset $\mathcal{Y}_{\text{c}} \subseteq \mathcal{Y}$. Then, in all formulas stated above the respective rows in $\boldsymbol{G}_{\boldsymbol{z}}^{\boldsymbol{y}}$ and $\tilde{\boldsymbol{F}}$ must be extracted and $n_{\boldsymbol{y}}$ must be substituted by $n_{\mathcal{Y}_{\text{c}}}$.

Remark 3. For perfect disturbance rejection, *i.e.*, $\boldsymbol{M} = \boldsymbol{0}$, it is required that at least $n_{\boldsymbol{u}}$ tailing β_i are 0. As indicated above, the number of $s = \max\left(0, n_{\boldsymbol{y}} - n_{\boldsymbol{f}}\right)$ tailing β_i are in fact 0. Thus, perfect disturbance rejection occurs if the inequality

$$s \geq n_{\boldsymbol{u}}$$

is satisfied. The necessary condition therefore is $s > 0$, *i.e.*, $n_{\boldsymbol{f}} < n_{\boldsymbol{y}}$, which can only be satisfied if the implementation error is disregarded, *i.e.*, $\boldsymbol{W}_{\boldsymbol{n}^{\boldsymbol{y}}} = \emptyset$ and $n_{\boldsymbol{f}} = n_{\boldsymbol{d}}$. The sufficient condition for perfect disturbance rejection is then $n_{\boldsymbol{y}} \geq n_{\boldsymbol{u}} + n_{\boldsymbol{d}}$. This is in agreement with the combination methods from Alstad and Skogestad [2007], Alstad et al. [2008] and Kariwala [2007], Kariwala et al. [2008].

Remark 4. If $n_{\boldsymbol{u}} + n_{\boldsymbol{f}} < n_{\boldsymbol{y}}$, the rank condition (9) is violated and the GSVD as stated above cannot be performed. Note that this is only a formal issue and will not be treated here for the sake of brevity.

Remark 5. The GSVD method is related to the method by Kariwala et al. [2008] and the "constrained average loss minimization" method by Alstad et al. [2008]. It can be shown that all three methods minimize the average loss subject to the same structural constraint and thus provide the same results. However, it will be omitted here for the sake of brevity.

4. BEYOND COMMON PV SUBSETS

For better legibility of this section, definitions for CSDs will be introduced.

Definition 6. A CSD is said to be *column-structured*, if all CVs are linear combinations of the same PV subset $\mathcal{Y}_\mathrm{c}$ of size $n_{\mathcal{Y}_\mathrm{c}} = \dim(\mathcal{Y}_\mathrm{c})$. A *common-sized* CSD refers to a CSD in which the i^{th} CV is a linear combination of an individual PV subset $\mathcal{Y}_i$ with the constraint that all PV subsets have the same set size $n_\mathrm{s} = \dim(\mathcal{Y}_i)\,\forall i \in \{1,\ldots,n_{\boldsymbol{u}}\}$. In a more general *loosely-structured* CSD, the i^{th} CV is a linear combination of an individual PV subset $\mathcal{Y}_i$ with individual set size $n_{\mathcal{Y}_i} = \dim(\mathcal{Y}_i)$.

Theorem 7. Let $\boldsymbol{H}_\mathrm{c}$ represent a column-structured CSD of size $n_{\mathcal{Y}_\mathrm{c}}$ with finite worst-case/average loss, *i.e.*, $\operatorname{rank}(\boldsymbol{H}_\mathrm{c}) = n_{\boldsymbol{u}}$. Then, for every $\boldsymbol{H}_\mathrm{c}$ there exists a common-sized CSD $\boldsymbol{H}_\mathrm{s}$ with a PV subset size of $n_\mathrm{s} = n_{\mathcal{Y}_\mathrm{c}} - (n_{\boldsymbol{u}} - 1)$ and the same worst-case/average loss as $\boldsymbol{H}_\mathrm{c}$. The proof will be omitted due to the lack of space.

Corollary 8. Let $\boldsymbol{H}_\mathrm{c}$ be a column-structured CSD with PV subset size $n_\mathrm{c} = n_{\boldsymbol{u}}$ and finite loss. Then, the worst-case/average loss of $\boldsymbol{H}_\mathrm{c}$ is independent of the coefficients in $\boldsymbol{H}_\mathrm{c}$. Rather, the worst-case/average loss of $\boldsymbol{H}_\mathrm{c}$ depends only on the selection of the PV subset $\mathcal{Y}_\mathrm{c}$. The proof will be omitted due to the lack of space.

Some advantages of common-sized and loosely-structured CSDs over column-structured CSDs are pointed out below.

(1) A smaller PV subset size is, on the one hand, favorable due to better practical acceptance but, on the other hand, usually accompanied by a larger worst-case/average loss. From Theorem 7 it can be concluded that for $n_{\boldsymbol{u}} > 1$ a reduction in PV subset size without affecting the worst-case/average loss can be achieved if, instead of a column-structured CSD, a common-sized CSD is taken into account. In particular, the PV subset size reduction with invariant worst-case/average loss can be as large as $n_{\boldsymbol{u}} - 1$ PVs.
(2) By implication of the first argument, it is evident that a smaller worst-case/average loss can be achieved if, instead of a column-structured CSD, a common-sized CSD with equal PV subset size is taken into account.
(3) For $n_{\mathcal{Y}_\mathrm{c}} = n_{\boldsymbol{u}}$ the optimality of column-structured CSDs is only a matter of PV subset selection as pointed out in Corollary 8 presented above.
(4) Column-structured CSDs $\boldsymbol{H}_\mathrm{c}$ fail if $n_{\mathcal{Y}_\mathrm{c}} < n_{\boldsymbol{u}}$ holds. This is due to the fact that $\operatorname{rank}(\boldsymbol{H}_\mathrm{c}) < n_{\boldsymbol{u}}$ which leads to a singular $\boldsymbol{H}_\mathrm{c}\,\boldsymbol{G}^{\boldsymbol{y}}$ and, by observation of (4) and (5), to infinite loss.
(5) Input/output (I/O) selection based on heuristic rules is a common practice. Physical closeness between CVs and MVs is probably the most common rule, in order to achieve good cause and effect between MVs and CVs. If decentralized controllers are used and the MVs are far apart from each other (*e.g.*, in large scale processes), it is desirable to have an individual PV subset for every CV as in common-sized and loosely-structured CSDs.
(6) PV combinations including different measurement units have poor practical acceptance. If the structural constraint was imposed on the prospective CSD that only PVs of the same type can be selected for each CV, then, in the case of a column-structured CSD with $n_{\boldsymbol{u}} > 1$, one would be forced to omit information of all PVs not part of the selected unit group. In common-sized and loosely-structured CSDs, for each CV another PV subset can be selected which allows to use information of more than only one unit group.

For loosely-structured CSDs, no explicit expression for $\boldsymbol{H}$ can be derived by the solution to problems (5) and (7). Thus, iterative solution methods need to be applied. In the following, a framework for advanced iterative methods will be presented.

In order to take loosely-structured CSDs into account, (4) is restated as

$$\boldsymbol{z}^T \sum_{i=1}^{n_{\boldsymbol{u}}} (\boldsymbol{G}_{\boldsymbol{z}}^{\boldsymbol{y}})^T\, \boldsymbol{h}_i\, \boldsymbol{e}_i^T = \boldsymbol{f}^T \sum_{i=1}^{n_{\boldsymbol{u}}} \tilde{\boldsymbol{F}}^T\, \boldsymbol{h}_i\, \boldsymbol{e}_i^T, \tag{14}$$

where $\boldsymbol{h}_i^T \in \mathbb{R}^{n_{\boldsymbol{y}}}$ is the i^{th} row vector of $\boldsymbol{H}$, *i.e.*, $\boldsymbol{H}^T = [\,\boldsymbol{h}_1\ \ldots\ \boldsymbol{h}_{n_{\boldsymbol{u}}}\,]$, and $\boldsymbol{e}_i \in \mathbb{R}^{n_{\boldsymbol{u}}}$ is the i^{th} standard basis vector. The vector $\boldsymbol{h}_i$ represents the map from the PVs of the subset $\mathcal{Y}_i$ towards the i^{th} CV, hence $h_{ij} = 0 \forall j \notin \mathcal{Y}_i$. It is thus convenient to write (14) as

$$\boldsymbol{z}^T \sum_{i=1}^{n_{\boldsymbol{u}}} (\boldsymbol{G}_{\boldsymbol{z}}^{\boldsymbol{y}})_{\mathcal{Y}_i}^T\, \boldsymbol{h}_{i\mathcal{Y}_i}\, \boldsymbol{e}_i^T = \boldsymbol{f}^T \sum_{i=1}^{n_{\boldsymbol{u}}} \tilde{\boldsymbol{F}}_{\mathcal{Y}_i}^T\, \boldsymbol{h}_{i\mathcal{Y}_i}\, \boldsymbol{e}_i^T, \tag{15}$$

where the subscript $\mathcal{Y}_i$ denotes that those columns/elements of $(\boldsymbol{G}_{\boldsymbol{z}}^{\boldsymbol{y}})^T$, $\tilde{\boldsymbol{F}}^T$ and $\boldsymbol{h}_i$ are selected whose index is part of $\mathcal{Y}_i$.

By performing the GSVD of the corresponding matrix pairs $\left\{(\boldsymbol{G}_{\boldsymbol{z}}^{\boldsymbol{y}})_{\mathcal{Y}_i}^T, \tilde{\boldsymbol{F}}_{\mathcal{Y}_i}^T\right\}$, (15) can be written as

$$\boldsymbol{z}^T \underbrace{\sum_{i=1}^{n_{\boldsymbol{u}}} \boldsymbol{U}_i\, \boldsymbol{I}_{n_{\boldsymbol{u}} \times n_{\mathcal{Y}_i}}\, \tilde{\boldsymbol{h}}_i\, \boldsymbol{e}_i^T}_{=\boldsymbol{X}} = \boldsymbol{f}^T \sum_{i=1}^{n_{\boldsymbol{u}}} \tilde{\boldsymbol{U}}_i\, \boldsymbol{\mathcal{S}}_i\, \tilde{\boldsymbol{h}}_i\, \boldsymbol{e}_i^T, \tag{16}$$

where $\boldsymbol{\mathcal{S}}_i = \left[\, \boldsymbol{0}_{n_{\mathcal{Y}_i} \times r_i}\ \operatorname{diag}\left(\sigma_{i1}, \ldots, \sigma_{in_{\mathcal{Y}_i}}\right)\ \boldsymbol{0}_{n_{\mathcal{Y}_i} \times \bar{s}_i}\, \right]^T$, $r_i = \max(0, n_{\mathcal{Y}_i} - n_{\boldsymbol{u}})$, $\bar{s}_i = \max(0, n_{\boldsymbol{f}} - n_{\mathcal{Y}_i})$ and $\sigma_{ij} = \begin{cases} \alpha_{ij}/\beta_{ij} & \text{if } \beta_{ij} \neq 0 \\ 1 & \text{otherwise} \end{cases}$; $\boldsymbol{U}_i \in \mathbb{R}^{n_{\boldsymbol{u}} \times n_{\boldsymbol{u}}}$ and $\tilde{\boldsymbol{U}}_i \in \mathbb{R}^{n_{\boldsymbol{f}} \times n_{\boldsymbol{f}}}$ are unitary; $\boldsymbol{I}_{n_{\boldsymbol{u}} \times n_{\mathcal{Y}_i}}$ is the $n_{\boldsymbol{u}} \times n_{\mathcal{Y}_i}$ tailing diagonal identity matrix; and $\tilde{\boldsymbol{h}}_i = \operatorname{diag}\left(\beta_{i(r_i+1)}, \ldots, \beta_{in_{\mathcal{Y}_i}}\right) \boldsymbol{V}_i^T\, \boldsymbol{h}_{i\mathcal{Y}_i}$, with $\boldsymbol{V}_i \in \mathbb{R}^{n_{\mathcal{Y}_i} \times n_{\mathcal{Y}_i}}$ if $n_{\boldsymbol{u}} + n_{\boldsymbol{f}} \geq n_{\mathcal{Y}_i}$. The decomposed formulation (16) has several advantages over (10) as pointed out below.

(1) From observation of (16) it can be seen that the first $r_i = \max(0, n_{\mathcal{Y}_i} - n_{\boldsymbol{u}})$ elements in $\tilde{\boldsymbol{h}}_i$ do not contribute to $\boldsymbol{X}$. It is generally close to optimal to set them to zero as the corresponding columns in $\tilde{\boldsymbol{U}}_i\, \boldsymbol{\mathcal{S}}_i$ vanish. Thus, if any $r_i > 0$ then one can reduced the variable space from $\sum_{i=1}^{n_{\boldsymbol{u}}} n_{\mathcal{Y}_i}$ to $\sum_{i=1}^{n_{\boldsymbol{u}}} n_{\mathcal{Y}_i} - r_i$. The maximum dimension of the reduced space is $n_{\boldsymbol{u}} \times n_{\boldsymbol{u}}$. (16). This approach will be referred to as the reduced space (RC) method. The starting values for the RC method will be $\tilde{\boldsymbol{h}}_i = \boldsymbol{e}_{n_{\mathcal{Y}_i}}$ which corresponds to the selection of the smallest generalized singular values.
(2) From (16), it can be shown that a suboptimal solution to (7) can be obtained by setting the first r_i elements in $\tilde{\boldsymbol{h}}_i$ are zero and solving the substitute problem

$$\boldsymbol{X} = \arg\min_{\boldsymbol{X}} \sum_{i=1}^{n_{\boldsymbol{u}}} \boldsymbol{X}_i^T\, \tilde{\boldsymbol{\mathcal{S}}}_i^T\, \tilde{\boldsymbol{\mathcal{S}}}_i\, \boldsymbol{X}_i \text{ s.t. } \boldsymbol{X}^T\, \boldsymbol{X} = \boldsymbol{I}, \tag{17}$$

where $\tilde{\boldsymbol{\mathcal{S}}}_i = \boldsymbol{\mathcal{S}}_i\, \boldsymbol{I}_{n_{\boldsymbol{u}} \times n_{\mathcal{Y}_i}}^T\, \boldsymbol{U}_i^T$ and $\boldsymbol{X}_i$ is the i^{th} column of $\boldsymbol{X}$. Problem (17) is still nonconvex but has the

advantage that an efficient steepest descend method can be developed. Due to the lack of space, the method cannot be outlined here but will be an issue of a subsequent publication. It will be referred to as the unitary matrix constraint (UMC) method. The starting value for the iterative solution of $\boldsymbol{X}$ will be the identity matrix.

(3) From (16) a lower bound for the minimum worst-case/average loss can be derived. This is particularly helpful in reducing computational expense as described below.

The large number of alternative control structures can be reduced by excluding candidate CVs which cannot lead to an optimal solution. This strategy is known as the BAB principle. BAB algorithms have been formerly applied to CSD problems by several authors such as Cao and Saha [2005], Kariwala and Skogestad [2006/07/09-13], Cao and Kariwala [2008] and Kariwala and Cao [2009]. Lower bounds on the minimal worst-case/average loss are helpful for discriminating candidate CVs. From the conclusion that the lower bounds corresponds to the ideal case that $\tilde{\boldsymbol{h}}_i = \boldsymbol{e}_{n_{\mathcal{Y}_i}}$, $\boldsymbol{U}_{i\mathcal{Y}_i} \perp \boldsymbol{U}_{j\mathcal{Y}_j}$ and $\tilde{\boldsymbol{U}}_{i\mathcal{Y}_i} \perp \tilde{\boldsymbol{U}}_{j\mathcal{Y}_j} \forall i \neq j$ it follows from observation of (16) that

$$\boldsymbol{M} = \sum_{i=1}^{n_{\boldsymbol{u}}} \sigma_{in_{\mathcal{Y}_i}} \boldsymbol{e}_i \boldsymbol{e}_i^T.$$

This yields the inequalities

$$L_{\text{worst}} \geq \frac{1}{2} \max_i \left(\sigma^2_{in_{\mathcal{Y}_i}} \right) \tag{18}$$

$$L_{\text{average}} \geq \frac{1}{6\ (n_{\mathcal{Y}_\cap} + n_{\boldsymbol{d}})} \sum_{i=1}^{n_{\boldsymbol{u}}} \sigma^2_{in_{\mathcal{Y}_i}}. \tag{19}$$

Note that $n_{\mathcal{Y}_\cap}$ indicates the size of the merged PV subset $\mathcal{Y}_1 \cap \cdots \cap \mathcal{Y}_{n_{\boldsymbol{u}}}$. It is important to state that (18) and (19) also hold for incomplete set of candidate CVs, *i.e.*, the lower bound of one candidate CV is also the lower bound of all possible control structures which include this CV. If an upper bound for the worts-case/average loss of all alternatives L_{ub} is known, the evaluation of structures (and substructures) can be omitted which show a lower bound $L_{\text{lb}} > L_{\text{ub}}$. Unfortunately, the bounds given above are not very tight, so that computational savings are relatively small.

5. EVAPORATOR CASE STUDY

In this section, the proposed CSD methods will be applied to the evaporation process presented in Figure 3. This forced-circulation evaporation was originally treated by Newell and Lee [1989] and has been investigated subsequently by Heath et al. [2000] and Kariwala et al. [2008], among others. The purpose of the process is the concentration of dilute liquor from the feed to the product stream by evaporation and separation of the solvent. The analytic model equations including the cost function and operational constraints can be found in Kariwala et al. [2008]. The process model has three state variables, the level L_2, the composition X_2 and the pressure P_2 with eight degrees of freedom. Table 1 lists the important stream properties, their value at the nominal operating point and

Table 1. Key process variables in the evaporation process

their classification into MVs, DVs and PVs. Three out of five MVs indicated by † are used to keep the three PVs L_2, X_2 and P_{100} at their set points. Note that the level in the separator L_2 has no steady-state effect but needs to be controlled for stabilization. The other two controlled PVs need to be kept at their constraints in order to achieve optimality over the given disturbance region. Generality is not lost by this particular selection of the unconstrained MVs. In Table 1, the (embraced) expected variations of the DVs and measurement errors of the PVs are given in % from their nominal value except for temperature measurement errors which are indicated on an absolute scale.

The model equations were implemented in a modeling environment (ME) of the in-house tool OPTISIM® [1], an equation-oriented process simulator. The model has been optimized with respect to the DVs' nominal values given in Table 1 and operational constraints. This led to the operating conditions of the MVs and DVs presented in Table 1. As the ME provides first derivatives by automatic differentiation, the linear I/O gains $G_{\boldsymbol{u}}^{\boldsymbol{y}}$ and $G_{\boldsymbol{u}}^{\boldsymbol{y}}$ at the operating point are directly available. Second derivatives $J_{\boldsymbol{uu}}$ and $J_{\boldsymbol{ud}}$ were estimated by finite difference approx-

Table 2. Worst-case/average loss of best column-structured CSDs

imation and the use of the NAG routine E04XAF. The numerical results of the I/O gains and the Hessians are in agreement with those of Kariwala et al. [2008]. CSDs for the evaporation process have been identified using the methods presented in Sections 3 and 4. The calculations were conducted in Matlab®R2008b using a Windows XP SP2 desktop with an Intel®Core™Duo CPU E8400 (3.0 Ghz, 3.5 GB RAM).

At first, column-structured CSDs were identified by average loss minimization using the GSVD method. The best control structure was determined by screening over all possibilities satisfying the PV subset size condition imposed. Some results are given in Table 2. They reproduce the results by Kariwala et al. [2008] with an deviation of less than 0.6 %. Both, the minimum worst-case and average loss of the best structure decrease with the PV subset size and approach a lower bound (at $n_{\mathcal{Y}_c} = 10$) asymptotically. According to Corollary 8, the case $n_{\mathcal{Y}_c} = n_{\boldsymbol{u}} = 2$ indicates as well the best PV selection structure.

Next, common-sized CSDs PVs were sought. According to Theorem 7, for each $n_{\mathcal{Y}_c}$-sized column-structured CSD there exists a common-sized CSD of size $n_s = (n_{\mathcal{Y}_c} - n_{\boldsymbol{u}} + 1)$ which can be obtained by a simple linear transformation of the former. Thus, the results in Table 2 indicate also possible common-sized CSDs of PV subset size n_s from one to nine. For instance, Table 3 shows the transformation of the best column-structured CSD with set size three, indicated by $\boldsymbol{H}_{c3}$, into $\boldsymbol{H}_{s2}$ where only combinations of two PVs per CV occur. Despite its small PV subset size, $\boldsymbol{H}_{s2}$ achieves a considerably small average loss. Note that CSDs obtained by this approach are generally not the best among all CSDs satisfying the particular structural constraint of a common-sized set with set size two. In order to find a CSD with lower average loss, the RC method was applied. The best solution found among the $\left(C_{10}^2\right)\left(C_{10}^2 - 1\right)/2 = 990$ alternatives is indicated as $\hat{\boldsymbol{H}}_{s2}$ in Table 3. Due to the BAB algorithm only 103 problems with an average of 0.07 s expense per problem had to be solved. The total computation time was 8.3 s. Using the UMC method, the computational efficiency could be reduced to 6 ms expense per problem leading to a total computation time of 3.3 s at 144 iterative problem solutions. The solution $\tilde{\boldsymbol{H}}_{s2}$ showed a larger average loss than $\hat{\boldsymbol{H}}_{s2}$ structurally identical though.

Suppose that due to cost issues, only one flow meter can be afforded. Since temperature and pressure indicators are rather cheap, their numbers are not limited by cost considerations. In this situation, the task is to find the two best CVs out of $C_6^1 + 2$ candidates, *i.e.*, one out of six flows, one pressure and one temperature set. The best CSD indicated as $\boldsymbol{H}_{s1F}$ in Table 3 was found by applying

CSD	L_{average} (in \$/h)
$\boldsymbol{H}_{c3} = \begin{bmatrix} -0.99 & 0.15 & 0.00 \\ -0.99 & -0.12 & 0.01 \end{bmatrix} \begin{bmatrix} F_2 & F_{100} & F_{200} \end{bmatrix}^T$	0.6533
$\boldsymbol{H}_{s2} = \begin{bmatrix} -6.27 & 1.0 & \\ -143.08 & & 1.0 \end{bmatrix} \begin{bmatrix} F_2 & F_{100} & F_{200} \end{bmatrix}^T$	0.6533
$\hat{\boldsymbol{H}}_{s2} = \begin{bmatrix} -6.27 & 1.0 & & \\ & & 1.0 & -23.30 \end{bmatrix} \begin{bmatrix} F_2 & F_{100} & F_{200} & F_1 \end{bmatrix}^T$	0.5673
$\tilde{\boldsymbol{H}}_{s2} = \begin{bmatrix} -6.22 & 1.0 & & \\ & & 1.0 & -13.34 \end{bmatrix} \begin{bmatrix} F_2 & F_{100} & F_{200} & F_1 \end{bmatrix}^T$	0.6682
$\boldsymbol{H}_{s1F} = \begin{bmatrix} 1.0 & & & \\ & 0.36 & 0.33 & 0.87 \end{bmatrix} \begin{bmatrix} F_3 & T_2 & T_3 & T_{201} \end{bmatrix}^T$	2.9704
$\boldsymbol{H}_{c3T} = \begin{bmatrix} 0.59 & 0.53 & -0.61 \\ 0.02 & 0.01 & 1.0 \end{bmatrix} \begin{bmatrix} T_2 & T_3 & T_{201} \end{bmatrix}^T$	3.6573

Table 3. CSD results

the RC method. It shows slightly better average loss than $\boldsymbol{H}_{c3T}$ which is the best column-structured CSD where all temperatures are used.

6. CONCLUSION
