In this paper new insights into the identification problem of self-optimizing CSDs were given. The GSVD method was proposed which allows finding CVs, altogether linear combinations of a common PV subset. It minimizes the average loss super-optimal to the worst-case loss by taking expected disturbances and measurement errors into account. The GSVD method can be beneficially implemented into iterative solution approaches in order to find loosely-structured CSDs where for each CV an individual PV subsets is taken into account. The new methods were successfully applied to an evaporation process. It could be shown that loosely structured CSDs are favorable in terms of flexibility, practical acceptance and economic considerations.

An Online Algorithm for Robust Distributed Model Predictive Control

Walid Al-Gherwi. Hector Budman. Ali Elkamel

Chemical Engineering Department, University of Waterloo, Waterloo, Canada

Abstract: Distributed Model Predictive Control (DMPC) has received significant attention in the literature. However, the robustness of DMPC with respect to model errors has not been explicitly addressed. In this paper, an online algorithm that deals explicitly with model errors for DMPC is proposed. The algorithm requires decomposing the entire system into *N* subsystems and solving *N* convex optimization problems to minimize an upper bound on a robust performance objective by using a time-varying state-feedback controller for each subsystem. Simulations on two typical examples were considered to illustrate the application of the proposed method.

Keywords: Distributed Model Predictive Control; Robust Control.

1. INTRODUCTION

Distributed model predictive control (DMPC) has received significant attention in the literature in recent years. The key potential advantages of DMPC are: i) it can provide better performance than fully decentralized control especially when the interactions ignored in the latter are strong, and ii) it can maintain the flexibility with respect to equipment failure and partial plant shutdowns that may jeopardize the successful operation of centralized MPC. The basic idea of DMPC is to partition the total system of states and controlled and manipulated variables into smaller subsystems and to assign an MPC controller to each subsystem. The design of all the reported DMPC strategies is composed of three parts: (1) Modeling; each controller has access to a local dynamic model of the corresponding subsystem along with an interaction dynamic model that represents the influence of the other subsystems. These models can be obtained by directly decomposing a centralized model of the process (Rawlings and Stewart 2008). (2) Optimization; each MPC solves a local optimization problem. Some reported strategies use modified objective functions that take into account the goals of other controllers to achieve full coordination (Venkat 2006; Zhang and Li 2007) whereas some others use strict local objectives (Li *et al.* 2005), e.g. a Nash-equilibrium objective. (3) Communication; at every control time interval all the controllers exchange the measurements of their local states that are used for subsequent local optimization. These 3 steps are executed at each time interval in an iterative manner until convergence among the controllers is reached. Venkat (2006) showed that increasing the iterations allows the DMPC strategy to reach the optimal centralized solution and the termination at any intermediate iteration maintains system-wide feasibility. Zhang and Li (2007) analyzed the optimality of the iterative DMPC scheme and derived closed-form solution for an unconstrained DMPC and showed that it is identical to centralized MPC solution. The common feature of the reported strategies is that they employ a nominal model of the plant and rely on feedback to account for plant-model mismatch. However, plant–model mismatch may have a significant impact on stability and performance. Thus, the robustness of DMPC to model errors has been identified as a key factor for a successful application of DMPC (Rawlings and Stewart 2008). Kothare *et al.* (1996) proposed a methodology for robust centralized constrained MPC design that maintains robust stability and minimizes a bound on performance in the presence of model errors. The problem is formulated as a convex optimization problem with linear matrix inequalities LMI that is solved efficiently using available algorithms (Boyd *et al.* 1994) and can be used for on-line implementations. This method has been recognized as a good potential candidate for use in process industry to handle the issue of plant-model mismatch (Qin and Badgwell 2003).

The aim of this paper is to present a methodology for Robust DMPC (RDMPC) that explicitly deals with model errors. An LMI-based predictive control formulation (Kothare *et al.* 1996) has been modified to design an on-line iterative algorithm for RDMPC. Issues of robust stability and convergence are analyzed and discussed. Two case studies are used to illustrate the algorithm: a distillation column example (Venkat 2006) when "bad" input-output pairings are chosen and a high-purity column example (Skogestad and Morari, 1988) with high condition number.

2. Definitions and Methodology

2.1 Models

In this work, it is assumed that the process model is given by a linear time-varying (LTV) model of the form:

$$\boldsymbol{x}(k+1) = \boldsymbol{A}(k)\boldsymbol{x}(k) + \boldsymbol{B}(k)\boldsymbol{u}(k) \tag{1}$$

where the real plant lies within a polytope that is represented by the convex hull:

$$[\boldsymbol{A}(k)\ \boldsymbol{B}(k)] = \sum_{l=1}^{L} \beta_l [\boldsymbol{A}^{(l)}\ \boldsymbol{B}^{(l)}] \quad ; \sum_{l=1}^{L} \beta_l = 1;\ \beta_l \geq 0 \tag{2}$$

Each vertex l corresponds to a linear model obtained from linearizing a nonlinear model or identification of a linear model in the neighbourhood of a particular operating point. It is assumed that the states are fully measured. The states and the controlled and manipulated variables in model (1) can be decomposed into N subsystems as follows:

$$\begin{bmatrix} \boldsymbol{x}_{11}(k+1) \\ \vdots \\ \boldsymbol{x}_{ii}(k+1) \\ \vdots \\ \boldsymbol{x}_{NN}(k+1) \end{bmatrix} = \begin{bmatrix} \boldsymbol{A}_{11}(k) & \cdots & \cdots & \cdots & \boldsymbol{A}_{1N}(k) \\ \vdots & \ddots & & & \vdots \\ \boldsymbol{A}_{i1}(k) & \cdots & \ddots & \cdots & \boldsymbol{A}_{iN}(k) \\ \vdots & & & \ddots & \vdots \\ \boldsymbol{A}_{N1}(k) & \cdots & \cdots & \cdots & \boldsymbol{A}_{NN}(k) \end{bmatrix} \begin{bmatrix} \boldsymbol{x}_{11}(k) \\ \vdots \\ \boldsymbol{x}_{ii}(k) \\ \vdots \\ \boldsymbol{x}_{NN}(k) \end{bmatrix} + \begin{bmatrix} \boldsymbol{B}_{11}(k) & \cdots & \cdots & \cdots & \boldsymbol{B}_{1N}(k) \\ \vdots & \ddots & & & \vdots \\ \boldsymbol{B}_{i1}(k) & \cdots & \ddots & \cdots & \boldsymbol{B}_{iN}(k) \\ \vdots & & & \ddots & \vdots \\ \boldsymbol{B}_{N1}(k) & \cdots & \cdots & \cdots & \boldsymbol{B}_{NN}(k) \end{bmatrix} \begin{bmatrix} \boldsymbol{u}_1(k) \\ \vdots \\ \boldsymbol{u}_i(k) \\ \vdots \\ \boldsymbol{u}_N(k) \end{bmatrix} \tag{3}$$

where $i \in \{1,\cdots,N\}$; $\boldsymbol{x}_{ii} \in \Re^{n_{ii}}$; $\boldsymbol{u}_i \in \Re^{m_i}$. For example, in model (3) the i[th] controller for the i[th] subsystem is based on the following model:

$$\boldsymbol{x}_i(k+1) = \boldsymbol{A}_i(k)\boldsymbol{x}_i(k) + \boldsymbol{B}_i(k)\boldsymbol{u}_i(k) + \sum_{\substack{j=1 \\ j\neq i}}^{N} \boldsymbol{B}_j(k)\boldsymbol{u}_j(k) \tag{4}$$

and similar to the representation given in (2) it is assumed that for the i[th] subsystem (4):

$$[\boldsymbol{A}_i(k)\ \boldsymbol{B}_i(k)..\ \boldsymbol{B}_j(k)..] = \sum_{l=1}^{L} \beta_l [\boldsymbol{A}_i^{(l)}\ \boldsymbol{B}_i^{(l)}..\ \boldsymbol{B}_j^{(l)}..] \quad \forall j \in \{1,...,N\},\ j \neq i \tag{5}$$

where $\boldsymbol{x}_i' = \left[\boldsymbol{x}_{11}', \cdots\cdots, \boldsymbol{x}_{ii}', \cdots\cdots, \boldsymbol{x}_{NN}'\right]'$ is the vector of states of subsystem i containing states $\boldsymbol{x}_{ii}$ that can be measured locally augmented with states $\boldsymbol{x}_{jj}$ that affect subsystem i measured in the other subsystems and communicated among the subsystems. Therefore the matrix $\boldsymbol{A}_i(k)$ contains all the elements of the matrix $\boldsymbol{A}(k)$. Model (4) also includes the effect of local controller $\boldsymbol{u}_i$ and the other controllers $\boldsymbol{u}_j$ with their corresponding matrices defined as:

$$\begin{aligned} \boldsymbol{B}_i'(k) &= \left[\boldsymbol{B}_{1i}'(k), \cdots\cdots, \boldsymbol{B}_{Ni}'(k)\right]' \\ \boldsymbol{B}_j'(k) &= \left[\boldsymbol{B}_{1j}'(k), \cdots\cdots, \boldsymbol{B}_{Nj}'(k)\right]' \end{aligned} \tag{6}$$

The model in (4) is general and can be used to represent special limiting cases such as the decentralized case where all the interactions are ignored, e.g. $\boldsymbol{B}_j' = [\boldsymbol{0}]\ \forall j \in \{1,...,N\},\ j \neq i$.

2.2 Robust Performance Objective

Kothare *et al.* (1996) proposed a formulation for a centralized problem whereby an upper bound on a robust performance objective is minimized. In the current work a similar formulation is used but the minimization is simultaneously done for every subsystem i defined by (4) for which the following min-max problem is solved:

$$\begin{aligned} &\min_{\boldsymbol{u}_i(k+n|k)} \ \max_{[\boldsymbol{A}_i(k+n)\ \boldsymbol{B}_i(k+n)\ \boldsymbol{B}_j(k+n)],n\geq 0} J_i(k) \\ &s.t. \\ &\left|\boldsymbol{u}_i(k+n|k)\right| \leq \boldsymbol{u}_i^{max},\ n \geq 0 \end{aligned} \tag{7}$$

In general, the local objective $J_i(k)$ is defined as follows:

$$\begin{aligned} J_i(k) = \sum_{n=0}^{\infty} [&\boldsymbol{x}_i'(k+n|k)\mathbb{Q}_i\boldsymbol{x}_i(k+n|k) \\ &+ \boldsymbol{u}_i'(k+n|k)\boldsymbol{R}_i\boldsymbol{u}_i(k+n|k) \\ &+ \sum_{\substack{i=1 \\ i\neq j}}^{N} \boldsymbol{u}_j^{\bullet\prime}(k+n|k)\boldsymbol{R}_j\boldsymbol{u}_j^{\bullet}(k+n|k)] \end{aligned} \tag{8}$$

where $\mathbb{Q}_i > 0$, $\boldsymbol{R}_i > 0$, $\boldsymbol{R}_j > 0$. The local objective given in (8) takes into account the goals of the other controllers, third summation in the RHS, in order to achieve the global objective of the entire system. The superscript "$\bullet$" indicates that the solution was obtained in a previous iteration and remains fixed in the current iteration as will be explained later. It should be pointed out that one can easily modify the problem in (8) to solve particular objectives such as Nash equilibrium or decentralized control. Both strategies are based on minimizing strictly local objectives of the subsystems. The difference is that for Nash the interaction information is shared among the subsystems while for decentralized control the interaction information is neglected. Accordingly, for both Nash and decentralized control $\mathbb{Q}_i$ and $\boldsymbol{R}_i$ in (8) are modified to contain all zeros except for the weights corresponding to the local subsystem and the third summation in the RHS of (8) is excluded. On the other hand the interaction term in (4) is included for Nash but it is ignored for decentralized control.

Since the objective in (8) has an infinite horizon, the problem of finding infinite $\boldsymbol{u}_i$ is computationally intractable. Instead, a state-feedback law is sought for each subsystem i as follows:

$$\begin{aligned} \boldsymbol{u}_i(k+n|k) &= \boldsymbol{F}_{ii}\boldsymbol{x}_{ii}(k+n|k) + \sum_{\substack{j=1 \\ j\neq i}}^{N} \boldsymbol{F}_{ij}\boldsymbol{x}_{ij}(k+n|k) \\ &= \boldsymbol{F}_i\boldsymbol{x}_i(k+n|k) \end{aligned} \tag{9}$$

similarly,

$$\begin{aligned} \boldsymbol{u}_j^{\bullet}(k+n|k) &= \boldsymbol{F}_{jj}^{\bullet}\boldsymbol{x}_{jj}(k+n|k) + \sum_{\substack{i=1 \\ i\neq j}}^{N} \boldsymbol{F}_{ji}^{\bullet}\boldsymbol{x}_{ji}(k+n|k) \\ &= \boldsymbol{F}_j^{\bullet}\boldsymbol{x}_i(k+n|k) \end{aligned} \tag{10}$$

Using these state-feedback laws in (4) leads to the following closed loop model:

$$\boldsymbol{x}_i(k+1) = \left(\tilde{\boldsymbol{A}}_i(k) + \boldsymbol{B}_i(k)\boldsymbol{F}_i\boldsymbol{u}_i(k)\right)\boldsymbol{x}_i(k) \tag{11}$$

where $\tilde{A}_i(k) = A_i(k) + \sum_{\substack{j=1 \\ j\neq i}}^{N} B_j(k)F_j^{\bullet}$

It is assumed that there exists a quadratic function $V_i(k) = \boldsymbol{x}_i'(k)\boldsymbol{P}_i\boldsymbol{x}_i(k)$, $\boldsymbol{P}_i > 0$, so that, for any plant in (6), this function satisfies the following stability constraint:

$$\begin{aligned} V_i(k+n+1|k) - V_i(k+n|k) \leq -[&\boldsymbol{x}_i'(k+n|k)\mathbb{Q}_i\boldsymbol{x}_i(k+n|k) \\ &+ \boldsymbol{u}_i'(k+n|k)\boldsymbol{R}_i\boldsymbol{u}_i(k+n|k) \\ &+ \sum_{\substack{i=1 \\ i\neq j}}^{N} \boldsymbol{u}_j^{\bullet\prime}(k+n|k)\boldsymbol{R}_j\boldsymbol{u}_j^{\bullet}(k+n|k)] \\ n \geq 0 \end{aligned} \tag{12}$$

Using (11), the robust stability constraint in (12) becomes:

$$\begin{aligned} V_i(k+n+1|k) - V_i(k+n|k) \leq -[&\boldsymbol{x}_i'(k+n|k)\tilde{\mathbb{Q}}_i\boldsymbol{x}_i(k+n|k) \\ &+ \boldsymbol{u}_i'(k+n|k)\boldsymbol{R}_i\boldsymbol{u}_i(k+n|k)] \end{aligned}$$

where $\tilde{\mathbb{Q}}_i = \mathbb{Q}_i + \sum_{\substack{i=1 \\ i\neq j}}^{N} \boldsymbol{F}_j^{\bullet\prime}(k+n|k)\boldsymbol{R}_j\boldsymbol{F}_j^{\bullet}(k+n|k)$ (13)

which, for all $n \geq 0$, turns out to be:

$$\begin{aligned} \left[\tilde{\boldsymbol{A}}_i(k+n) + \boldsymbol{B}_i(k+n)\boldsymbol{F}_i\right]'\boldsymbol{P}_i\left[\tilde{\boldsymbol{A}}_i(k+n) + \boldsymbol{B}_i(k+n)\boldsymbol{F}_i\right] \\ - \boldsymbol{P}_i + \boldsymbol{F}_i'\boldsymbol{R}_i\boldsymbol{F}_i + \tilde{\mathbb{Q}}_i \leq 0 \end{aligned} \tag{14}$$

By defining an upper bound, i.e.

$$J_i(k) \leq \boldsymbol{x}_i'(k)\boldsymbol{P}_i\boldsymbol{x}_i(k) = V_i(k) \leq \gamma_i \tag{15}$$

and substituting the parameterization $\boldsymbol{F}_i = \boldsymbol{Y}_i'\boldsymbol{Q}_i^{-1}$, $\boldsymbol{Q}_i = \gamma_i\boldsymbol{P}_i^{-1}$, followed by performing Schur complements (Boyd et al. 1994) on (14) and (15) it can be easily shown that the minimization of $J_i(k)$ is equivalent to the minimization of its upper bound γ_i as in the following linear minimization problem with LMI constraints (Kothare *et al.* 1996):

$$\begin{aligned} &\min_{\gamma_i, \boldsymbol{Q}_i, \boldsymbol{Y}_i} \ \gamma_i \\ &s.t. \\ &\begin{bmatrix} 1 & \boldsymbol{x}_i'(k) \\ \boldsymbol{x}_i(k) & \boldsymbol{Q}_i \end{bmatrix} \geq 0 \\ &\begin{bmatrix} \boldsymbol{Q}_i & \boldsymbol{Q}_i\tilde{\boldsymbol{A}}_i^{\prime(l)} + \boldsymbol{Y}_i'\boldsymbol{B}_i^{\prime(l)} & \boldsymbol{Q}_i\tilde{\mathbb{Q}}_i^{1/2} & \boldsymbol{Y}_i'\boldsymbol{R}_i^{1/2} \\ * & \boldsymbol{Q}_i & \boldsymbol{0} & \boldsymbol{0} \\ * & * & \gamma_i\boldsymbol{I} & \boldsymbol{0} \\ * & * & * & \gamma_i\boldsymbol{I} \end{bmatrix} \geq 0 \\ &\qquad \forall l \in \{1,\ldots,L\} \\ &\begin{bmatrix} \left(\boldsymbol{u}_i^{max}\right)^2\boldsymbol{I} & \boldsymbol{Y}_i \\ \boldsymbol{Y}_i' & \boldsymbol{Q}_i \end{bmatrix} \geq 0 \end{aligned} \tag{16}$$

The key difference between the centralized control algorithm proposed by Kothare *et al.* (1996) and the distributed strategy proposed in this work is that every controller in the set $i \in \{1,\cdots,N\}$ solves a local problem as in (16) and then the solutions are exchanged in an iterative scheme that is further explained in the next subsection. It should be remembered that one of the key reasons to use distributed MPC strategies is to address real time computation issues when dealing with large-scale processes (Li *et al.* 2005). Although the proposed iterative scheme tends to increase the computational time, the problem defined in (16) is numerically advantageous as compared to solving the same problem for the whole system (centralized control). The reason is that the state feedback controller for each subsystem i is obviously of smaller dimensions than a state feedback controller of the centralized MPC strategy. For instance, $\boldsymbol{Y}_i$ for subsystem i is of dimension $(n \times m_i)$ instead of $(n \times m)$ for centralized system where m is the total number of manipulated variables of the entire process.

2.3 Robust DMPC Algorithm

This section presents the main result of the paper where an on-line algorithm for RDMPC is proposed. It is assumed that there is an ideal communication network available so that the controllers can exchange their information with no delays. The goal of performing communication and exchanging solutions among controllers is to achieve the optimal solution of the entire system in an iterative fashion. The algorithm proceeds according to the Jacobi iteration method used for the solution of systems of algebraic equations. The procedure is summarized in *Algorithm 1* below.

Algorithm 1 (RDMPC)

Step0 (initialization)*: at control interval k=0 set* $\boldsymbol{F}_i$*=0.*

Step1 (updating) *at control interval (k) all the controllers exchange their local states measurements and initial estimates* $\boldsymbol{F}_i$*'s via communication, set iteration t = 0 and* $\boldsymbol{F}_i = \boldsymbol{F}_i^{(0)}$.

Step2 (iterations)

while $t \leq t_{max}$

Solve all N LMI problems (16) in parallel to obtain the minimizers $\boldsymbol{Y}_i^{(t+1)}, \boldsymbol{Q}_i^{(t+1)}$ *to estimate the feedback solutions* $\boldsymbol{F}_i^{(t+1)} = \boldsymbol{Y}_i'^{(t+1)}\boldsymbol{Q}_i^{-1(t+1)}$. *If problem is infeasible set* $\boldsymbol{F}_i^{(t)} = \boldsymbol{F}_i^{(t-1)}$. *Check the convergence for a specified error tolerance* ε_i *for all the controllers*

if $\left\|\boldsymbol{F}_i^{(t+1)} - \boldsymbol{F}_i^{(t)}\right\| \leq \varepsilon_i \quad \forall i \in \{1,\ldots,N\}$

break

end if

Exchange the solutions ($\boldsymbol{F}_i$*'s) and set t = t + 1*

end while

Step3 (implementation) *apply the control actions* $\boldsymbol{u}_i = \boldsymbol{F}_i\boldsymbol{x}_i$ *to the corresponding subsystems, increase the control interval* $k = k + 1$*, return to step1 and repeat the procedure.*

Algorithm1 is implemented in MATLAB® and problem (16) is solved via MATLAB® LMI solver. Convergence of the iterations in Step 2 and stability properties are discussed in the following subsection.

2.4 Convergence and Robust Stability Analysis of RDMPC Algorithm

Regarding convergence, it can be shown that at each time interval, each one of the *N* convex problems defined in *Algorithm1* will converge to the same solution which is the solution of the centralized problem, i.e. $\gamma_1 = \gamma_2 = \cdots = \gamma_i = \cdots = \gamma_N = \gamma$ where γ is the performance upper bound of centralized MPC. For brevity, a two subsystem situation, i.e. *N*=2 is considered without loss of generality. It is also assumed that the solutions are feasible.

Define:

$$\textit{for subsystem 1} \quad \gamma_1^{(t)} = \min_{\boldsymbol{F}_1^{(t)}} \gamma_1(\boldsymbol{F}_1^{(t)}, \boldsymbol{F}_2^{(t-1)})$$

$$\textit{for subsystem 2} \quad \gamma_2^{(t)} = \min_{\boldsymbol{F}_2^{(t)}} \gamma_2(\boldsymbol{F}_1^{(t-1)}, \boldsymbol{F}_2^{(t)})$$

$$\textit{Then,} \quad \gamma_1^{(t)} \le \gamma_2^{(t-1)} \tag{a}$$

and the reason being that both sides of this inequality are using the same value of $\boldsymbol{F}_2 = \boldsymbol{F}_2^{(t-1)}$ but the LHS minimizes γ with respect to $\boldsymbol{F}_1$ whereas the RHS of the inequality uses a not necessarily optimal value of $\boldsymbol{F}_1 = \boldsymbol{F}_1^{(t-1)}$. Following the same argument:

$$\gamma_2^{(t)} \le \gamma_1^{(t-1)} \tag{b}$$

Thus, the γ_i's decrease until (a) or (b) become equalities. Since the minimizations are convex and lead to global optimal solutions, this occurs only when $\boldsymbol{F}_1^{(t)} = \boldsymbol{F}_1^{(t-1)}$ and $\boldsymbol{F}_2^{(t)} = \boldsymbol{F}_2^{(t-1)}$ and consequently $\gamma_{sub1}^{(t)} = \gamma_{sub2}^{(t)} = \gamma$, i.e. the minimization with respect to both $\boldsymbol{F}_1$ and $\boldsymbol{F}_2$ give the same solution which must be, following convexity of problem (16), equal to the global optimum of the centralized control problem that has an identical formulation to (16). The robust stability of *Algorithm1* follows from the fact that for each subsystem, a robust stability related constraint is enforced by one of the linear matrix inequalities in problem (16). Thus each one of the *N* controllers satisfies robust stability. Although theoretical convergence of the Jacobi iteration can be proven, it was found that numerical noise exists due to inaccuracies of the LMI solvers in obtaining the solution of problem (16). Consequently, to speed up convergence in the presence of this numerical noise when *Algorithm1* is implemented, the *successive Relaxation* (SR) method is employed (Hageman and Young 1981). The SR method is applied to the solution obtained from (16) for each subsystem to estimate a weighted average between the current and previous iterate solutions. The method is given by the following recurrence formula:

$$\boldsymbol{F}_i^{(t+1)} = \alpha\bar{\boldsymbol{F}}_i^{(t+1)} + (1-\alpha)\boldsymbol{F}_i^{(t)} \tag{17}$$

where α is a parameter to be specified by the user in order to accelerate convergence. $\bar{\boldsymbol{F}}_i^{(t+1)}$ denotes the solution obtained at the current iteration from (16) whereas $\boldsymbol{F}_i^{(t+1)}$ is the estimate to be used in the next iteration. Typically, α can be chosen from values between 0 and 2 and when it is set to 1 the normal iterative scheme is retrieved. Since there is no systematic way to select a value for α in advance, simulations with different values of α have to be performed as shown in the first example.

3. Case Studies

3.1 Example 1

A distillation column control problem studied by Venkat (2006) is considered with the difference that uncertainties in the steady-state gains of the model are added to illustrate the robustness of the proposed algorithm. Accordingly, the real model lies within a polytope defined within the two vertices:

$$G_1 = \begin{bmatrix} \dfrac{32.63}{(99.6s+1)(0.35s+1)} & \dfrac{-33.89}{(98.02s+1)(0.42s+1)} \\ \dfrac{34.84}{(110.5s+1)(0.03s+1)} & \dfrac{-18.85}{(75.43s+1)(0.3s+1)} \end{bmatrix}$$

$$G_2 = \begin{bmatrix} \dfrac{326.3}{(99.6s+1)(0.35s+1)} & \dfrac{-338.9}{(98.02s+1)(0.42s+1)} \\ \dfrac{348.4}{(110.5s+1)(0.03s+1)} & \dfrac{-188.5}{(75.43s+1)(0.3s+1)} \end{bmatrix} \tag{21}$$

A state-space model, not shown for brevity, is obtained from a canonical realization of equation (21). To demonstrate the effectiveness of the proposed method the bad pairings, according to the *Relative Gain Array* RGA, are selected, i.e. the RGA element λ_{11} is -1.0874 and accordingly the "bad" pairings are u_1-y_1 (*subsystem1*) and u_2-y_2 (*subsystem2*). The physical constraints on manipulated variables are given by:

$$|u_1(k+n)| \le 1.5; \quad |u_2(k+n)| \le 2; \quad n \ge 0 \tag{22}$$

For the purpose of comparison between different cases, a cost function is defined as follows:

$$J_{cost} = (1/2Ns)\sum_{j=0}^{Ns}\sum_{i=1}^{N}\left(\boldsymbol{x}_i'(j)\mathbb{Q}_i\boldsymbol{x}_i(j) + \boldsymbol{u}_i'(j)\boldsymbol{R}_i\boldsymbol{u}_i(j)\right) \tag{23}$$

where *Ns* is the simulation time. The following parameters are used for the two controllers: $\mathbb{Q}_{y1} = \mathbb{Q}_{y2} = 50$ so that $\mathbb{Q}_i = \boldsymbol{C}_i'\mathbb{Q}_{yi}\boldsymbol{C}_i + 10^{-6}\boldsymbol{I}$ where $\boldsymbol{C}_i$ is the measurement matrix such that $\boldsymbol{y}_i = \boldsymbol{C}_i\boldsymbol{x}_i$; $\boldsymbol{R}_1 = \boldsymbol{R}_2 = 1$; $\alpha = 0.95$. The value of α is selected, as mentioned above, based on simulations by trial and error to speed convergence of the Jacobi iteration. The number of iterations that was required to satisfy the convergence criteria of *Algorithm1* for different values of α

is given in Table1. α=*0.95* resulted in the fastest convergence.

Table 1. Effect of α on convergence with $\varepsilon_1=\varepsilon_2=10^{-3}$

α	# iterations
1.05	55
1.00	38
0.95	28
0.90	32
0.8	38

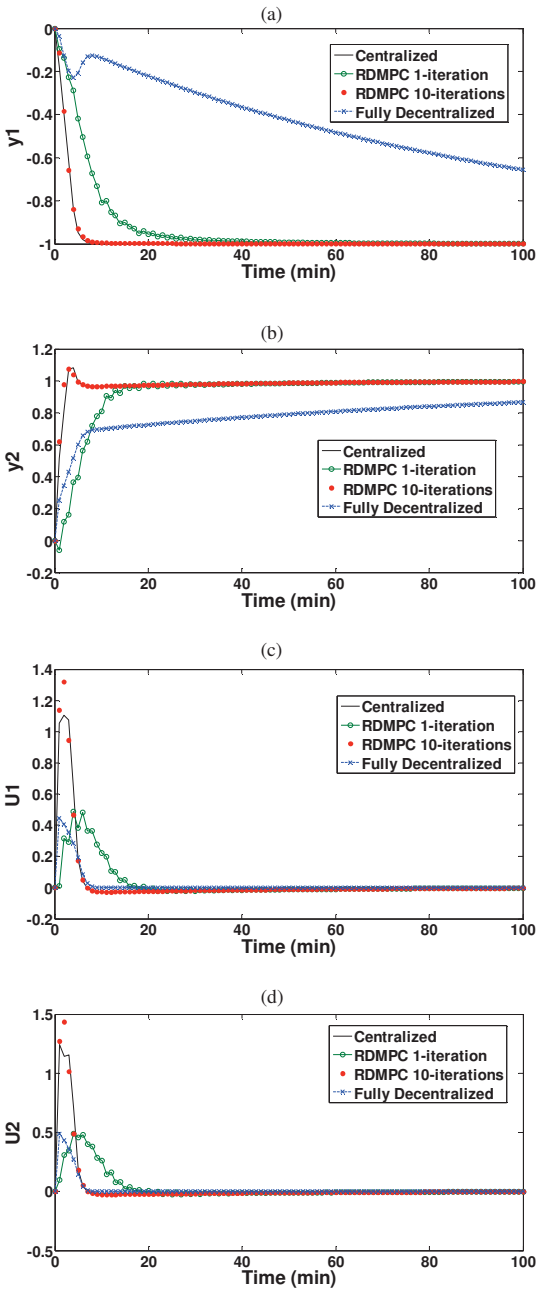

Fig. 1. Dynamic response in controlled and manipulated variables for set-point changes in y1 and y2.

Three cases are considered for the application of *Algorithm1*; fully decentralized, RDMPC with one iteration, and RDMPC with 10 iterations. It should be remembered that as indicated in section 2, the cost γ decreases monotonically with the number of iterations. Thus, even after one iteration, a performance improvement is expected. The motivation for using a small number of iterations, as mentioned earlier, is to use distributed MPC strategies to address real time computation issues when dealing with large scale processes. The decentralized strategy used in this study is obtained, as explained in Section 2.2, with *Algorithm1* by ignoring interactions in equation (4). Then, the performance of *Algorithm1* with these 3 different schemes was compared to the centralized strategy in Figure1. The simulations correspond to simultaneous changes in set-points of both controlled variables y1 and y2 by -1 and 1; respectively.

In comparison with the centralized scheme, the performance of RDMPC approaches that of the centralized scheme as the number of iterations is increased. The fully decentralized case resulted as expected in the worst performance. A comparison of the cost in (23) for different schemes is given in Table2. This table illustrates that *Algorithm1* can be used, depending on the chosen number of iterations, to obtain a performance that varies between two extremes corresponding to the fully decentralized and the centralized strategies; respectively. It is also clear, from figures 1(c) and 1(d), that the constraints given in (22) are satisfied.

Table 2. Cost for different strategies (example1)

Strategy	Cost (23)
Centralized	0.92
RDMPC (10 iteration)	0.93
RDMPC (1 iteration)	2.43
Fully decentralized	35.9

3.2 Example 2

This example considers the high-purity column originally studied by Skogestad and Morari (1988). The nominal transfer function of this system is given by:

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \frac{1}{75s+1}\begin{bmatrix} 0.878 & 0.864 \\ 1.082 & 1.096 \end{bmatrix}\begin{bmatrix} u_1 \\ u_2 \end{bmatrix} \qquad (24)$$

A state-space model is obtained based on a canonical realization of equation (24) and not shown for brevity. Due to the high condition number, this process has been used in the past to illustrate closed-loop sensitivity to model errors. The model uncertainty is given by errors in steady-state gains. The gains in the first column of the transfer matrix in (24) are expected to change by up to +80% whereas the gains in the second column are expected to change by up to -80%. The constraints on manipulated variables are represented by $|\boldsymbol{u}(k+n)| \le 1$, $n \ge 0$. The system given above was decomposed into two subsystems; *viz.*, y_1-u_1 (*subsystem1*) and y_2-u_2 (*subsystem2*). The controllers parameters used in simulation are; $\mathbb{Q}_1 = \mathbb{Q}_2 = 1$, $R_1 = R_2 = 1$, $\alpha = 1$, $\varepsilon_1 = \varepsilon_2 = 10^{-2}$.

Figure 2 depicts the performance of *Algorithm1* compared with centralized MPC for a unit set-point change in y_1 and it illustrates that RDMPC algorithm results in an identical response as the centralized MPC. For this example, the RDMPC algorithm converges very quickly in about three iterations after which the error tolerances specified above ($\varepsilon_1=\varepsilon_2=10^{-2}$) are met. Figure 3 shows the convergent behaviour of the RDMPC algorithm obtained in the first sampling interval. The upper bounds γ_1 and γ_2 for subsystems 1 and 2 respectively, obtained by solving (16) in parallel and by applying *Algorithm1*, converge to the same value after about 3 iterations and this value is identical to that obtained for centralized MPC. The cost, defined by equation (23), for both strategies, is equal to *7.48*. To show the ability of the method to deal with different objective functions an RDMPC with a Nash equilibrium objective and a robust decentralized MPC were designed by proper choice of the weights $\mathbb{Q}_i$ and $\boldsymbol{R}_i$ as explained in section 2.2. The results with the Nash-equilibrium based controller, shown also in Figure 2, are similar to the centralized case and the cost was *7.55*, slightly larger than the centralized MPC cost. The decentralized MPC, not shown in the Figure, resulted as expected in a slightly higher cost than Nash of *7.73*.

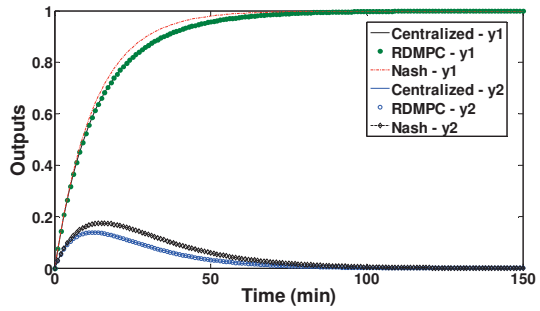

Fig. 2. Dynamic response to unit set-point change in y1.

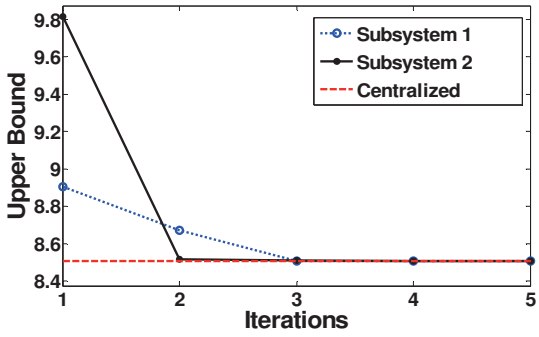

Fig. 3. Convergence characteristics of *Algorithm1* at the first sampling time.

4. CONCLUSIONS

The main goal of this work was to propose an on-line algorithm for DMPC strategy that explicitly considers model errors. The main idea of the proposed method is to decompose the model of the whole system into *N* subsystems and then obtain a local state feedback controller by minimizing an upper bound on a robust performance objective for each subsystem. The subsystem performance takes into account the objectives of the other subsystems in order to achieve the goal of the entire system. The method was also suitable for pursuing other objectives such as Nash equilibrium or decentralized control in the presence of model errors. The problem was converted into *N* convex problems with linear matrix inequalities and solved iteratively by using the Jacobi iteration method with successive relaxation (SR). Although convergence of the iterative solution was proven, the SR feature was helpful for filtering numerical noise in the LMI solutions resulting in faster convergence. When convergence was reached, the algorithm led to the same solution of the centralized MPC problem. The examples showed that RDMPC can achieve, after a sufficient number of iterations, equivalent performance to centralized control. Moreover, the examples illustrated that improvements in RDMPC performance as compared to decentralized control can be achieved with a relatively small number of iterations.

Abstract: In this paper we propose a model for the design of an optimal network integration of multisite refinery and petrochemical systems under uncertainty. The proposed model was formulated as a two-stage stochastic mixed-integer problem with the objective of minimizing the refining cost over a given time horizon and maximizing the added value by the petrochemical network. Uncertainties considered in this study were in terms of imported crude oil price, refinery product price, petrochemical product price, refinery market demand, and petrochemical lower level product demand. The proposed method adopts the sample average approximation (SAA) method for scenario generation and optimal gap statistical bounding. The model performance was tested on an industrial case study of multiple refineries and a polyvinyl chloride (PVC) complex.

Keywords: Integration, petrochemical planning, multirefinery optimization, planning under uncertainty

1. INTRODUCTION

Process integration in the refining and petrochemical industry includes many intuitively recognized benefits of processing higher quality feedstocks, improving value of byproducts, and achieving better efficiencies through sharing of resources. This is evidently seen from the current projects around the world for building integrated refineries and the development of complex petrochemical industries that are aligned through advanced integration platforms.

Despite the fact that petroleum refining and petrochemical companies have recently engaged in more integration projects, relatively little research in the open literature have been reported mostly due to confidentiality reasons. Such concerns render the development of a systematic framework of network integration and coordination difficult. Pervious research in the field assumed either no limitations on refinery feedstock availability for the petrochemical planning problem or fixed the refinery production levels assuming an optimal operation. In this paper, we present a mathematical model for the determination of the optimal integration and coordination strategy for a refinery network and synthesize the optimal petrochemical network required to satisfy a given demand from any set of available technologies. Therefore, achieving a global optimal production strategy by allowing appropriate trade offs between the refinery and the downstream petrochemical markets. The refinery and petrochemical systems were modeled as MILP problems that will also lead to an overall refinery and petrochemical process production levels and detailed blending levels at each refinery site. Furthermore, we apply the sample average approximation (SAA) method within an iterative scheme to generate the required scenarios. The solution quality is then statistically evaluated by measuring the optimality gap of the final solution.

2. MODEL FORMULATION

The proposed formulation addresses the problem of the simultaneous design of an integrated network of refineries and petrochemical processes. The proposed model is based on the formulations proposed by Al-Qahtani and Elkamel (2008) and Al-Qahtani et al. (2008). All material balances are carried out on a mass basis with the exception of refinery quality constraints of properties that only blend by volume where volumetric flowrates are used instead. Uncertainty was accounted for using two-stage stochastic programming with recourse approach. Parameters uncertainties considered in this study included uncertainties in the imported crude oil price $CrCost_{cr}$, refinery product price Pr_{cfr}^{Ref}, petrochemical product price Pr_{cp}^{Pet}, refinery market demand $D_{Ref_{cfr}}$, and petrochemical lower level product demand $D_{Pet_{cp}}^{L}$. Uncertainty is modeled through the use of mutually exclusive scenarios of the model parameters with a finite number N of outcomes. For each $\xi_k = (CrCost_{cr,k}, Pr_{cfr,k}^{Ref}, Pr_{cp,k}^{Pet}, D_{Ref_{cfr,k}}, D_{Pel_{cp,k}}^{L})$ where $k = 1,2,...,N$, there corresponds a probability p_k. The generation of the scenarios will be briefly explained in a later section. The proposed stochastic model is as follows:

$$
\begin{aligned}
Min\ & \sum_{cr\in CR}\sum_{i\in I}\sum_{k\in N} p_k\ CrCost_{cr,k}\ S^{Ref}_{cr,i} + \sum_{p\in P}\sum_{cr\in CR}\sum_{i\in I} z_{cr,p,i}\ OpCost_p \\

$$

The above formulation is a two-stage stochastic mixed-integer linear programming (MILP) model. Objective function (1) represents a minimization of the annualized cost which consists of crude oil cost, refineries operating cost, refineries intermediate exchange piping cost, refinery production system expansion cost, less the refinery export revenue, added value by the petrochemical processes, plus the recourse variables of refinery and petrochemical networks; respectively. Inequality (2) corresponds to each refinery raw materials balance where throughput to each distillation unit $p\in P'$ at plant $i\in I$ from each crude type $cr\in CR$ is equal to the available supply $S_{cr,i}$. Constraint (3) represents the intermediate material balances within and

across the refineries where the coefficient $\alpha_{cr,cir,i,p}$ can assume either a positive sign if it is an input to a unit or a negative sign if it is an output from a unit. The multirefinery integration matrix $\xi_{cr,cir,i,p,i'}$ accounts for all possible alternatives of connecting intermediate streams $cir \in CIR$ of crude $cr \in CR$ from refinery $i \in I$ to process $p \in P$ in plant $i' \in I'$. The variable $xi^{Ref}_{cr,cir,i,p,i'}$ represents the transshipment flowrate of crude $cr \in CR$, of intermediate $cir \in CIR$ from plant $i \in I$ to process $p \in P$ at plant $i' \in I$. Constraint (3) also considers the petrochemical network feedstock from the refinery intermediate streams $Fi^{Pet}_{cr,cir,i}$ of each intermediate product $cir \in RPI$. The material balance of final products in each refinery is expressed as the difference between flowrates from intermediate steams $w_{cr,cir,cfr,i}$ for each $cir \in CIR$ that contribute to the final product pool and intermediate streams that contribute to the fuel system $w_{cr,cfr,rf,i}$ for each $rf \in FUEL$ less the refinery final products $Ff^{Pet}_{cr,cfr,i}$ for each $cfr \in RPF$ that are fed to the petrochemical network as shown in constraint (4). In constraint (5) we convert the mass flowrate to volumetric flowrate by dividing it by the specific gravity $sg_{cr,cir}$ of each crude type $cr \in CR$ and intermediate stream $cir \in CB$. This is needed in order to express the quality attributes that blend by volume in blending pools. Constraint (6) is the fuel system material balance where the term $cv_{rf,cir,i}$ represents the caloric value equivalent for each intermediate $cir \in CB$ used in the fuel system at plant $i \in I$. The fuel production system can either consist of a single or combination of intermediates $w_{cr,cir,rf,i}$ and products $w_{cr,cfr,rf,i}$. The matrix $\beta_{cr,rf,i,p}$ corresponds to the consumption of each processing unit $p \in P$ at plant $i \in I$ as a percentage of unit throughput. Constraints (7) and (8), respectively, represent a lower and an upper bounds on refinery quality constraints for all refinery products that either blend by mass $q \in Q_w$ or by volume $q \in Q_v$. Constraint (9) represents the maximum and minimum allowable flowrate to each processing unit. The coefficient $\gamma_{m,p}$ is a zero-one matrix for the assignment of production unit $m \in M_{Ref}$ to process operating mode $p \in P$. The term $AddC_{m,i,s}$ accounts for the additional refinery expansion capacity of each production unit $m \in M_{Ref}$ at refinery $i \in I$ for a specific expansion size $s \in S$. The integer variable $y_{exp}{}^{Ref}_{m,i,s}$ represents the decision of expanding a production unit and it can take a value of one if the unit expansion is required or zero otherwise. Constraint (10) sets an upper bound on intermediate streams flowrates between the different refineries. The integer variable $y_{pipe}{}^{Ref}_{cir,i,i'}$ represents the decision of exchanging intermediate products between the refineries and takes on the value of one if the commodity is transferred from plant $i \in I$ to plant $i' \in I$ or zero otherwise, where $i \neq i'$. When an intermediate stream is selected to be exchanged between two refineries, its flowrate must be below the transferring pipeline capacity $F^{U}_{cir,i,i'}$. Constraint (11) stipulates that the final products from each refinery $x^{Ref}_{cfr,i}$ less the amount exported $e^{Ref}_{cfr',i}$ for each exportable product $cfr' \in PEX$ from each plant $i \in I$ must satisfy the domestic demand $D_{Ref_{cfr}}$. The recourse variables $V^{Ref+}_{cfr,k}$, $V^{Ref-}_{cfr,k}$, $V^{Pet+}_{cp,k}$ and $V^{Pet-}_{cp,k}$ in equations (11) and (13) represent the refinery production shortfall and surplus as well as the petrochemical production shortfall and surplus, respectively, for each random realization $k \in N$. These variables will compensate for the violations in equations (11) and (13) and will be penalized in the objective function using appropriate shortfall and surplus costs C^{Ref+}_{cfr} and C^{Ref-}_{cfr} for the refinery products, and C^{Pet+}_{cp} and C^{Pet-}_{cp} for the petrochemical products, respectively. Resources are limited by constraint (12)

Constraints (13) and (14) represent the material balance that governs the operation of the petrochemical system. The petrochemical network receives its feed from potentially three main sources. These are, 1) refinery intermediate streams $Fi^{Pet}_{cr,cir,i}$ of an intermediate product $cir \in RPI$, 2) refinery final products $Ff^{Pet}_{cr,cfr,i}$ of a final product $cfr \in RPF$, and 3) non-refinery streams Fn^{Pet}_{cp} of a chemical $cp \in NRF$. For a given subset of chemicals $cp \in CP$, the proposed model selects the feed types, quantity and network configuration based on the final chemical and petrochemical lower and upper product demand $D_{Pet}{}^{L}_{cp}$ and $D_{Pet}{}^{U}_{cp}$ for each $cp \in CFP$, respectively. Furthermore, in equation (13) an additional term xi^{Pet}_{cp} was added to the left hand side representing the flow of intermediate petrochemical stream of $cp \in CIP$. In constraint (15), defining a binary variables $y_{proc}{}^{Pet}_{m}$ for each process $m \in M_{pet}$ is required for the process selection requirement as $y_{proc}{}^{Pet}_{m}$ will equal 1 only if process m is selected or zero otherwise. Furthermore, if only process m is selected, its production level must be at least equal to the process minimum economic capacity B^{L}_{m} for each $m \in M_{pet}$, where K^{U} is a valid upper bound. Finally, we can specify limitations on the supply of feedstock Fn^{Pet}_{cp} for each chemical type $cp \in NRF$ through constraint (18).

3. SCENARIO GENERATION

The solution of stochastic problems is generally very challenging as it involves numerical integration over the random continuous probability space of the second stage variables (Goyal & Ierapetritou, 2007). An alternative approach is the discretization of the random space using a finite number of scenarios. In our study, the Sample Average

Approximation (SAA) method, also known as stochastic counterpart, is employed. The SAA problem can be written as (Verweij et al., 2003):

$$v_N = \min_{x \in X} c^T x + \frac{1}{N} \sum_{k \in N} Q(x, \xi^k) \quad (19)$$

It approximates the expectation of the stochastic formulation (usually called the "true" problem) and can be solved using deterministic algorithms. Problem (19) can be solved iteratively in order to provide statistical bounds on the optimality gap of the objective function value. The validation procedure was originally suggested by Norkin et al. (1998) and further developed by Mark et al. (1999).

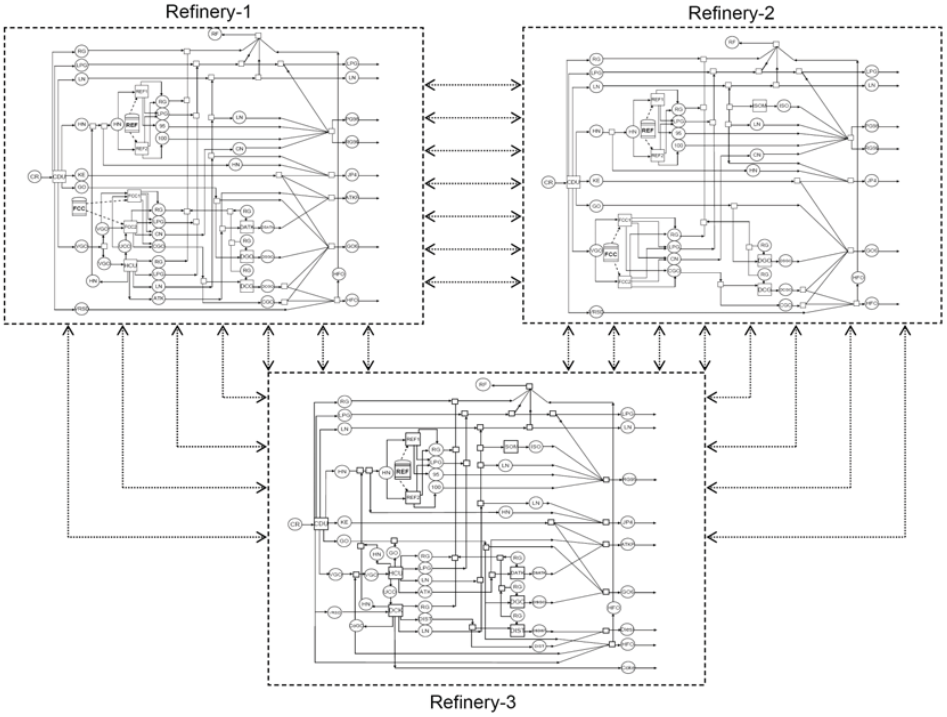

Fig. 1. Refinery Integration Network

4. ILLUSTRATIVE CASE STUDY

This section presents the computational results of the proposed model and sampling scheme. The case study considers a subsystem of the petrochemical industry for the integration problem with the refinery network as apposed to considering the full scale petrochemical industry, which might have limited applications. The case study will examine the integration between a multirefinery network with a polyvinyl chloride (PVC) petrochemical complex. PVC is a major ethylene derivative with many important applications and uses (e.g. pipe fittings, automobile bumpers, toys, bottles, etc.).

In this paper, we consider the planning for three refineries in one industrial location, which is a common situation in many

areas around the world. The state equipment network (SEN) representation of the three refineries is shown in Fig. 1. The final products of the three refineries network consists of liquefied petroleum gas (LPG), light naphtha (LT), two grades of gasoline (PG98 and PG95), No. 4 jet fuel (JP4), military jet fuel (ATKP), No.6 gas oil (GO6), diesel fuel (Diesel), heating fuel oil (HFO), and petroleum coke (coke). The major capacity constraints for the refinery network are given in Table 1. The petrochemical complex, on the other hand, starts with the production of ethylene from the refineries feedstocks by steam cracking. The main feedstocks

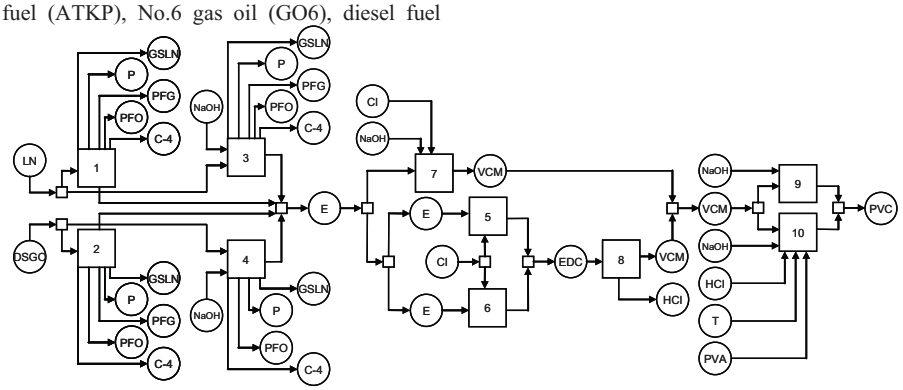

Fig. 2. PVC complex possible production alternatives

to the ethylene plant in our study are light naphtha (LN) and gas oil (GO). The selection of the feedstocks and hence the process technologies is decided upon based on the optimal balance and trade-off between the refinery and petrochemical markets. The process technologies considered in this study for the production of PVC are list in Table 2. The overall topology of all petrochemical technologies for the PVC production is shown in Fig. 2. The modeling system GAMS (Brooke et al., 1996) is used for setting up the optimization models and the MILP problems were solved with CPLEX (CPLEX Optimization Inc., 1993).

Product	Price ($/ton)	Process Technology	Index	Min. Prod. (10^3 ton/yr)
Ethylene (E)	$\mathcal{N}$(1570,10)	Pyrolysis of naphtha (LS)	1	250
		Pyrolysis of gas oil (LS)	2	250
		Steam cracking of naphtha (HS)	3	250
		Steam cracking of gas oil (HS)	4	250
Ethylene Dichloride (EDC)	$\mathcal{N}$(378,10)	Chlorination of ethylene	5	180
		Oxychlorination of ethylene	6	180
Vinyl chloride monomer (VCM)	$\mathcal{N}$(1230,10)	Chlorination and Oxychlorination of ethylene	7	250
		Dehydrochlorination of ethylene dichloride	8	125
Polyvinyl chloride (PVC)	$\mathcal{N}$(1600,10)	Bulk polymerization	9	50
		Suspension polymerization	10	90

In our study, we considered uncertainty in the imported crude oil price, refinery product price, petrochemical product price, refinery market demand, and petrochemical lower level product demand. In the presentation of the results, we focus on demonstrating the sample average approximation computational results as we vary the sample sizes and compare their solution accuracy and the CPU time required for solving the models.

The problem was solved for different sample sizes N and N' to illustrate the variation of optimality gap confidence intervals, while fixing the number of replications R to 30. The replication number R need not be very large to get an insight of $\bar{v}_N$ variability. Table 4 shows different confidence interval values of the optimality gap when the sample size of N assumes values of 1000, 2000, and 3000 while varying N' between 5000, 10000, and 20000 samples. As the sample sizes N and N' were limited to these values due to computational considerations. In our case study, we ran into memory limitations when N and N' values exceeded 3000 and 20000, respectively. The solution of the three refineries network and the PVC complex using the SAA scheme with N = 3000 and N'=20000 required 1114 CPU sec to converge to the optimal solution.

Table 4 depicts the results of the optimal integration network between the three refineries and the PVC petrochemical complex. As shown in Table 5, the proposed model designed the refinery network and operating policies and also devised the optimal production plan for the PVC complex from all available process technologies. The model selected gas oil as the refinery feedstock to the petrochemical complex. PVC production was proposed by first high severity steam cracking of gas oil to produce ethylene. Vinyl chloride monomer (VCM) is then produced through the chlorination and oxychlorination of ethylene and finally, VCM is converted to PVC by bulk polymerization. The annual production cost across the refineries and the PVC complex was $8,802,000.

Abstract: Kalman filter and its variants have been used for state estimation of systems described by ordinary differential equation (ODE) models. Moving Horizon Estimation (MHE) has been a popular approach in chemical engineering community for the estimation of both ODE and differential algebraic equation (DAE) systems but is computationally demanding. There has been some work on applying Extended Kalman filter for state estimation of DAE systems with measurements as functions of only the differential states. This work describes the estimation of nonlinear DAE systems with measurements being a function of both the differential and algebraic states. An Unscented Kalman filter (UKF) formulation is also derived for semi-explicit index 1 DAE systems. The utility of these formulations are demonstrated through a case study.

1. INTRODUCTION

Differential algebraic equation (DAE) models naturally arise in several chemical/physical systems, where some rate processes are much faster than the others and admit quasi steady-state approximations. Common examples of these can be found in separation and reaction systems. Many chemical engineering systems can be modeled as DAE systems. Examples of algebraic equations include mole fraction summations, vapor-liquid equilibrium relationships and so on. The algebraic equations can be either linear or nonlinear. Other areas where DAE models arise are mechanical systems, electrical systems and biological systems. A DAE system is characterized by the index of the system. The index of a DAE system is defined as the number of differentiations that are required to convert the DAE system into an explicit ODE system. It is not always possible and easy to convert DAE into ODE systems [Petzold, 1988]. In this paper. the focus is on estimation of nonlinear index one DAE systems that are common in chemical engineering.

The Kalman filter (KF) is an optimal estimator for linear dynamical systems in the presence of state and measurement uncertainties [Gelb, 1988, Sorenson, 1985]. Extended Kalman filter (EKF) is an extension of the Kalman filter for nonlinear systems described by a class of ordinary differential equations. Simultaneous parameter and state estimation is achieved in KF and EKF by augmenting the states [Jazwinski, 1970].

The KF has been used by several researchers for state estimation of systems describing linear DAE models [Nikoukhah et al., 1992, Chisci and Zappa, 1992]. The state estimation of nonlinear DAEs has already been studied by Albuquerque and Biegler [1997] using Moving -horizon estimation technique. Moving-horizon estimation (MHE) is considered as an efficient optimization based method for state estimation. Moving-horizon estimation can also be extended to parameter estimation of nonlinear DAEs [Tjoa and Biegler, 1991].

Moving-horizon estimator can handle constraints and bounds at every sampling instant [Rao et al., 2003]. However, questions remain about the computational complexity for on-line implementation of MHE estimators. The main advantage of the EKF lies in their predictor-corrector recursive form that has the potential for online deployment [Muske and Edgar, 1997].

There has been some work on the application of EKF for nonlinear DAE systems. One of the first attempts at this can be found in Becerra et al. [1999]. Becerra et al. [2001] extend this work further and demonstrate their approach on an experimental case study. They also explore the use of square root formulation of the EKF which has better numerical stability than the standard EKF [Park and Kailath, 1995]. However, the measurements available to the estimator are all assumed to be functions of differential states. In this paper, we extend Becerra et al. [2001] approach to cases where the measurements are functions of both the differential and algebraic states. Further, we develop an approach for the use of Unscented Kalman filter (UKF) for estimation in index 1 nonlinear DAE systems.

The paper is organized as follows. Section 2 provides an introduction to DAE systems. EKF and UKF algorithms

for DAE systems are discussed in section 3 and section 4 respectively. Simulation results with discussions are presented in section 5 followed by conclusions in section 6.

2. DIFFERENTIAL ALGEBRAIC SYSTEMS

As discussed in the previous section, DAE systems consist of both differential and algebraic equations. DAE systems are characterized by the index of the system. The index of the DAE system is defined as the number of differentiations required to convert the DAE into an ODE. As a simple example, consider

$$\dot{y_2}(t) = y_1(t) + \lambda_1(t) \tag{1}$$

$$0 = y_2(t) + \lambda_2(t) \tag{2}$$

Differentiating the algebraic equation 2 once, we get

$$0 = \dot{y_2}(t) + \dot{\lambda_2}(t) \tag{3}$$

Differentiating the algebraic equation 3 once more yields

$$0 = \ddot{y_2}(t) + \ddot{\lambda_2}(t) \tag{4}$$

Putting these equations together we now get an ODE as shown in equation .

$$\begin{aligned} \dot{y_2}(t) &= y_1(t) + \lambda_1(t) \\ \dot{y_1}(t) &= -\dot{\lambda_1}(t) - \ddot{\lambda_2}(t) \end{aligned} \tag{5}$$

Since the equations had to be differentiated twice this is an index 2 DAE system. While there are DAE systems of orders higher than 1 in chemical engineering, index 1 DAE systems are common as seen in electrochemistry, reactive distillation and biochemical engineering applications. As mentioned before, this work considers index 1 DAE systems.

3. EKF FOR DAE SYSTEMS

While EKF has been studied extensively for ODE systems, the application of EKF approaches to DAE systems are not many. Becerra et al. [2001] developed an EKF estimation approach for for nonlinear index 1 DAEs. The EKF approach follows the same predictor-corrector form with some modifications. In the prediction step, a DAE solver is used for propagating the prior state through the system model. This is in contrast to the use of an ODE solver in standard EKF. The covariance matrix of the differential states are propagated by linearizing the system model. The correction step is performed only for the differential states through a linearization of the measurement model. This is possible because it is assumed that the measurements are functions of differential states alone. Once the corrected differential states are available, the corrected algebraic states are calculated using the algebraic portion of the system model. The corrected covariance matrix for the differential states is calculated using the standard EKF procedure. The mathematical details of the algorithm are explained below. The nonlinear DAE system is considered with discrete measurements sampled at regular intervals with sampling period Δt

$$x_{k+1} = x_k + \int_{(k)\Delta t}^{(k+1)\Delta t} f(x(\tau)), z(\tau))\, d\tau + w_{k+1} \tag{6}$$

$$g(x_{k+1}, z_{k+1}) = 0 \tag{7}$$

$$y_{k+1} = h(x_{k+1}) + v_{k+1} \tag{8}$$

where w_{k+1} and v_{k+1} are assumed to be independent Gaussian white noise processes with known covariance matrix Q_{k+1} and R_{k+1}

For a fixed input, the linearized equation is given by

$$\dot{x} = Ax \tag{9}$$

where

$$A = (J_1 - J_2 J_4^{-1} J_3) \tag{10}$$

$$\begin{bmatrix} J1 & J2 \\ J3 & J4 \end{bmatrix} = \begin{bmatrix} \frac{\partial f}{\partial x} & \frac{\partial f}{\partial z} \\ \frac{\partial g}{\partial x} & \frac{\partial g}{\partial z} \end{bmatrix} \tag{11}$$

Following are the steps involved in the algorithm

- The differential states are propagated by integrating the DAE model from time t_k to t_{k+1}. The predicted state estimate $\hat{x}_{k+1/k}$ is obtained with u_k, which is the constant input between sampling intervals.
- The predicted covariance matrix in differential states is propagated using
$$P_{k+1/k} = \bar{A}_k P_{k/k} \bar{A}_k^T + Q_k \tag{12}$$
where $\bar{A} = exp(A\Delta t)$
- The kalman gain is computed using
$$K_{k+1} = P_{k+1/k} G_{k+1}^T (G_{k+1} P_{k+1/k} G_{k+1}^T + R_{k+1})^{-1} \tag{13}$$
where G_{k+1} is the linearized measurement model and the actual measurement model is a function of only differential states.
- The updated differential estimates are obtained from kalman update equation
$$\hat{x}_{k+1/k+1} = \hat{x}_{k+1/k} + K_{k+1}(y_{meas} - h(\hat{x}_{k+1/k})) \tag{14}$$
- The updated estimate $\hat{z}_{k+1/k+1}$ is obtained from the set of algebraic equations defining the DAE system once differential state estimate $\hat{x}_{k+1/k+1}$ is obtained
- The updated covariance matrix is computed as
$$P_{k+1/k+1} = (I - K_{k+1} G_{k+1}) P_{k+1/k} \tag{15}$$
In this method, $\hat{z}$ is computed only from the $\hat{x}$ using algebraic equation and there is no dependence or use of prior estimates of z (algebraic states). This method cannot be applied to cases where there is an availability of algebraic states measurements.

4. PROPOSED APPROACH: EXTENDED KALMAN FILTER FOR DAE SYSTEMS

In DAE systems, the measurements can, in general, be a function of both the differential and algebraic states. In the proposed work, we extend the EKF approach to this case. The algorithm deviates from the work of Becerra et al. [2001] in that the EKF works with an augmented system (with both the differential and algebraic states). A linearized ODE model involving both differential and

algebraic states (augmented) is derived. This linearized ODE model is used for the covariance propagation of augmented state as opposed to just the differential states as in Becerra et al. [2001]. The gain matrix is calculated form the augmented predicted covariance matrix and the linearized measurement model which is a function of both the differential and algebraic measurements. The corrected augmented state is computed. From these corrected augmented states, only the differential states are retained. As the algebraic constraints are to be met, the algebraic states are calculated from the corrected differential states using algebraic equations. The details of the algorithm are explained below. The nonlinear DAE system is considered with discrete measurements sampled at regular intervals with sampling period Δt

$$x_{k+1} = x_k + \int_{(k)\Delta t}^{(k+1)\Delta t} f(x(\tau)), z(\tau))\, d\tau + w_{k+1} \tag{16}$$

$$g(x_{k+1}, z_{k+1}) = 0 \tag{17}$$

$$y_{k+1} = h(x_{k+1}) + v_{k+1} \tag{18}$$

where w_{k+1} and v_{k+1} are assumed to be independent Gaussian white noise processes with known covariance matrix Q_{k+1} and R_{k+1}

Linearizing the differential equations and algebraic equations of index 1 DAE system, we get

$$\begin{aligned} \dot{x} &= Ax + Bz \\ 0 &= Cx + Dz \end{aligned} \tag{19}$$

where

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix} = \begin{bmatrix} \frac{\partial f}{\partial x} & \frac{\partial f}{\partial z} \\ \frac{\partial g}{\partial x} & \frac{\partial g}{\partial z} \end{bmatrix} \tag{20}$$

Differentiating the linearized algebraic equation once , we get

$$0 = C\dot{x} + D\dot{z} \tag{21}$$

Then

$$\dot{z} = -D^{-1}C\dot{x} \tag{22}$$

$$\dot{z} = -D^{-1}CAx - D^{-1}CBx \tag{23}$$

Writing in matrix form

$$\begin{bmatrix} \dot{x} \\ \dot{z} \end{bmatrix} = \begin{bmatrix} A & B \\ -D^{-1}CA & -D^{-1}CB \end{bmatrix} \begin{bmatrix} x \\ z \end{bmatrix} \tag{24}$$

The augmented form is

$$\dot{X}^{aug} = A^{aug} X^{aug} \tag{25}$$

The transition matrix is evaluated as

$$\phi = exp(A^{aug}\Delta t) \tag{26}$$

The algorithm consists of following steps

- Both differential and algebraic states are propagated using a DAE solver from t_k to t_{k+1} starting from the latest updated estimate $\hat{X}_k^{aug}$ and the latest input u_k.
- The predicted covariance matrix of the augmented states is computed as
$$P_{k+1/k}^{aug} = \phi P_{k/k}^{aug} \phi^T + \Gamma Q_{k+1} \Gamma^T \tag{27}$$
where
$$\Gamma = \begin{bmatrix} I \\ -D^{-1}C \end{bmatrix} \tag{28}$$
- The augmented Kalman gain is computed as
$$K_{k+1}^{aug} = P_{k+1/k}^{aug} G_{k+1}^T (G_{k+1} P_{k+1/k}^{aug} G_{k+1}^T + R_{k+1})^{-1} \tag{29}$$
where G_{k+1} is the linearised measurement model.
- The updated state estimate is given by
$$X_{k+1/k+1}^{aug} = X_{k+1/k}^{aug} + K_{k+1}^{aug} (y_{meas} - h(X_{k+1/k}^{aug}) \tag{30}$$
- As the algebraic constraints are to be met, differential terms (x) of the updated estimate are retained and the updated estimates of the algebraic states (z) are calculated from the algebraic equation of DAE system.
- The updated covariance matrix is calculated as
$$P_{k+1/k+1}^{aug} = (I - K_{k+1}^{aug} G_{k+1}) P_{k+1/k}^{aug} \tag{31}$$

5. UNSCENTED KALMAN FILTER FOR DAE SYSTEMS

Unscented Kalman filter (UKF) is an approach that was developed to improve on EKF. The UKF approach uses the idea of unscented transforms for predicting the mean and covariance when a random variable passes through a nonlinear transformation. In EKF, linearization of the nonlinear transformation is used to predict the mean and covariance of the transformed variable. Unscented transformation is a sampling technique where a small number of deterministic samples are chosen such that their weighted mean and covariance exactly equal the mean and covariance of the random variable undergoing the nonlinear transformation. The transformed sample points are used to calculate the *a posteriori* mean and covariance. This results in much better accuracy than the linearization approach [Julier et al., 2000].

UKF estimation for ODE systems is well developed and several application studies have appeared [Romanenko and Castro, 2004, Romanenko et al., 2004, van der Merwe et al., 2000, Julier, 2002, Wan et al., 2000, Wan and van der Merwe, 2000]. In this paper, we extend the UKF approach for semi-explicit index 1 DAE systems. The proposed approach also follows the predictor-corrector form. First, unscented samples are chosen for the differential states. The unscented samples for the algebraic states are generated from the algebraic equations. This makes all the sigma points consistent. These sigma points are propagated through the system through a DAE solver. Unscented samples for the differential and algebraic states are again generated using the propagated covariance matrix. The sample points for the measurements are calculated by passing the unscented differential and algebraic state samples through the measurement function. The sample covariances are used to calculate the Kalman gain. Using the Kalman gain, the corrected differential states are obtained. The corrected algebraic states are calculated using the algebraic equations in the system model. This algorithm of unscented Kalman filter for DAE systems is

explained below. The nonlinear DAE system is considered with discrete measurements sampled at regular intervals with sampling period Δt

$$x_{k+1} = x_k + \int_{(k)\Delta t}^{(k+1)\Delta t} f(x(\tau)), z(\tau)) \, d\tau + w_{k+1} \quad (32)$$

$$g(x_{k+1}, z_{k+1}) = 0 \quad (33)$$

$$y_{k+1} = h(x_{k+1}, z_{k+1}) + v_{k+1} \quad (34)$$

where w_{k+1} and v_{k+1} are assumed to be independent Gaussian white noise processes with known covariance matrix Q_{k+1} and R_{k+1}

- The first step is the generation of sigma points. At the k^{th} instant, $\hat{x}_{k/k}$ is the filtered estimate of differential states and $P_{k/k}$ is the covariance matrix associated with it. A set of 2n+1 sigma points $\hat{X}_{k/k,i}$ with associated weights are chosen symmetrically about $\hat{x}_{k/k}$ where n is the dimension of the state.

$$\hat{X}_{k/k,0} = \hat{x}_{k/k}; W_0 = \frac{\kappa}{(n+\kappa)} \quad (35)$$

$$\hat{X}_{k/k,i} = \hat{x}_{k/k} + (\sqrt{(n+\kappa)P_{k/k}})_i; W_i = \frac{1}{2(n+\kappa)} \quad (36)$$

$$\hat{X}_{k/k,i+n} = \hat{x}_{k/k} - (\sqrt{(n+\kappa)P_{k/k}})_i; W_{i+n} = \frac{1}{2(n+\kappa)} \quad (37)$$

where $(\sqrt{P_{k/k}})_i$ is the i^{th} column of matrix square root of $P_{k/k}$ and W_i is the weight associated with the corresponding point. The parameter κ is a tuning parameter. The weights W_i add to one and the weighted mean of the set X is same as $\hat{x}_{k/k}$. The weighted covariance matrix of the sample is equal to $P_{k/k}$.

$$P_{k/k} = \sum_{i=0}^{2n} W_i (\hat{X}_{k/k,i} - \hat{x}_{k/k})(\hat{X}_{k/k,i} - \hat{x}_{k/k})^T \quad (38)$$

- Calculate $\hat{Z}_{k/k,i}$ from $g(\hat{X}_{k/k,i}, \hat{Z}_{k/k,i}) = 0$
- Propagate $\hat{X}_{k/k,i}$ and $\hat{Z}_{k/k,i}$ through DAE system to get $\hat{X}_{k+1/k,i}$ and $\hat{Z}_{k+1/k,i}$

  The predicted differential state estimate $\hat{x}_{k+1/k}$ is given by

$$\hat{x}_{k+1/k} = \sum_{i=0}^{2n} W_i \hat{X}_{k+1/k,i} \quad (39)$$

- Calculate $P^{xx}_{k+1/k}$

$$P^{xx}_{k+1/k} = \sum_{i=0}^{2n} W_i (\hat{X}_{k+1/k,i} - \hat{x}_{k+1/k}) (\hat{X}_{k+1/k,i} - \hat{x}_{k+1/k})^T + Q_{k+1} \quad (40)$$

- Do unscented sampling with $\hat{x}_{k+1/k}$ as mean and $P^{xx}_{k+1/k}$ as covariance matrix
- Recalculate $\hat{Z}_{k+1/k,i}$ from $g(\hat{X}_{k+1/k,i}, \hat{Z}_{k+1/k,i}) = 0$
- Form $\hat{X}^{aug}_{k+1/k,i}$ by augmenting $\hat{X}_{k+1/k,i}$ with $\hat{Z}_{k+1/k,i}$
- Calculate $\hat{x}^{aug}_{k+1/k}$

$$\hat{x}^{aug}_{k+1/k} = \sum_{i=0}^{2n} W_i \hat{X}^{aug}_{k+1/k,i} \quad (41)$$

- The predicted sigma points are propagated through the nonlinear measurement equation to obtain the predicted measurement as

$$Y_{k+1,i} = h(\hat{X}^{aug}_{k+1/k,i}) \quad (42)$$

Using the set of predicted measurements, the covariance matrix of innovations and the cross covariance between predicted state estimate errors and innovations are computed as

$$P_{\nu\nu,k+1} = \sum_{i=0}^{2n} W_i (Y_{k+1,i} - \hat{y}_{k+1}) (Y_{k+1,i} - \hat{y}_{k+1})^T + R_{k+1} \quad (43)$$

$$P_{x\nu,k+1} = \sum_{i=0}^{2n} W_i (\hat{X}^{aug}_{k+1,i} - \hat{x}^{aug}_{k+1/k})(Y_{k+1,i} - \hat{y}_{k+1})^T \quad (44)$$

where

$$\hat{y}_{k+1} = \sum_{i=0}^{2n} W_i Y_{k+1,i} \quad (45)$$

- The Kalman gain matrix is computed as

$$K_{k+1} = P_{x\nu,k+1} (P_{\nu\nu,k+1})^{-1} \quad (46)$$

- The Kalman gain corresponding to differential states is K^{diff}_{k+1}
- The updated differential estimates are obtained using the linear update equation as in Kalman filter

$$\hat{x}_{k+1/k+1} = \hat{x}_{k+1/k} + K^{diff}_{k+1} (y_{k+1} - \hat{y}_{k+1}) \quad (47)$$

- The updated estimate $\hat{z}_{k+1/k+1}$is obtained from the set of algebraic equations defining the DAE system once differential state $\hat{x}_{k+1/k+1}$ is obtained
- The covariance matrix of error in the updated differential estimates is computed using

$$P_{k+1/k+1} = P_{k+1/k} - K^{diff}_{k+1} P_{\nu\nu,k+1} K^{diff\,T}_{k+1} \quad (48)$$

6. CASE STUDY

The utility of the proposed approaches is tested on an electrochemical case study. The case study considers the galvanostatic charge /open-circuit/ discharge processes of a thin film nickel hydroxide electrode [Celik et al., 2002]. The modeling equations are

$$\frac{\rho V}{W} \frac{dy_1}{dt} = \frac{j_1}{F} \quad (49)$$

$$j_1 + j_2 - i_{app} = 0 \quad (50)$$

where

$$j_1 = i_{01}[2(1-y_1) exp(\frac{0.5F}{RT}(y_2 - \phi_{eq,1})) - 2y_1 \times exp(\frac{-0.5F}{RT}(y_2 - \phi_{eq,1}))] \quad (51)$$

$$j_2 = i_{02}[exp(\frac{F}{RT}(y_2 - \phi_{eq,2})) - exp(\frac{-F}{RT}(y_2 - \phi_{eq,2}))] \quad (52)$$

The first equation is the species balance equation, the second equation is the charge balance equation and j_1 and j_2 are derived using the Butler-Volmer kinetics. For the purpose of demonstrating the utility of the proposed approaches we assume that the differential state is corrupted with process noise w_{k+1} and the algebraic equation is exact. The values of parameters used are $F = 96487$, $R = 8.314$, $T = 298.15$, $\phi_{eq,1} = 0.420$, $\phi_{eq,2} = 0.303$, $\rho = 3.4$, $W = 92.7$, $V = 1 \times 10^{-5}$, $i_{app} = 1 \times 10^{-5}$, $i_{01} = 1 \times 10^{-04}$, $i_{02} = 1 \times 10^{-08}$. The units of parameters and variables are omitted for the simplicity. y_1 is the mole fraction of Nickel hydroxide and y_2 is potential difference between at the solid-liquid interface.The initial guess to the estimator is $[x0, z0] = [0.5322, 0.4254]$ and the actual value is [0.35024, 0.4071]. The tuning parameters used in EKF are

The following parameters are used

$$\Delta t = 15$$
$$P_0 = \begin{bmatrix} 0.005 & 0 \\ 0 & 0.005 \end{bmatrix}$$
$$Q_{k+1} = 0.00001$$
$$R_{k+1} = 0.0001$$

where Δt is the sampling time , P_0 is the error covariance matrix of differential and algebraic states, Q_{k+1} is the process noise associated with differential states and R_{k+1} is the measurement covariance matrix. The measurement in this case study is y_2, which is the potential difference at the solid-liquid interface. The important point to note is that the augmented covariance matrix should be taken into consideration if the measurement model is a function of differential and algebraic states. Figure 1 and Figure 2 show the estimates for the mole fraction and potential difference.

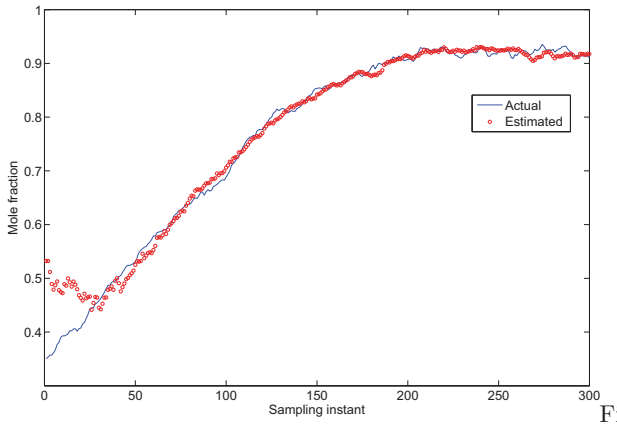

Fig. 1. EKF estimates of mole fraction for case study

The same differential algebraic system is considered and the UKF approach proposed in this paper is tested. The main advantage of UKF lies in the fact that it does not require linearization to compute covariance matrices. The UKF estimator gives very good estimates of mole fraction and potential difference as shown in Figure 3 and Figure

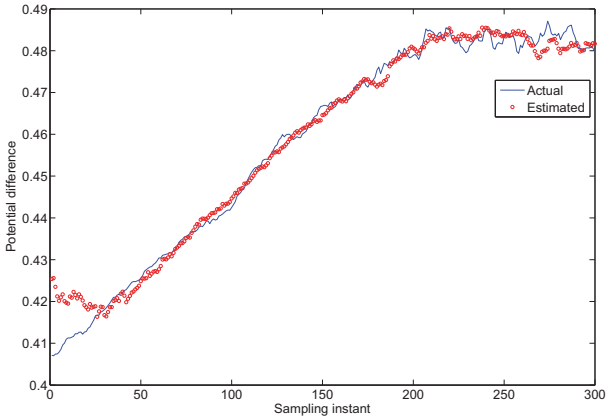

Fig. 2. EKF estimates of potential difference for case study

4. The tuning parameters for the UKF are same as used in EKF implementation. Figure 5 shows the comparison of UKF and EKF estimates and the their performances are compared by computing the root mean square error (RMSE) of the two states. Table 6 shows the RMSE values of estimates of UKF and EKF. It can clearly be seen that the UKF performs better than the EKF for this case study. Further, the UKF also avoids linearization in the computation of the covariance matrices.

RMSE values of EKF and UKF		
Method	RMSE y_1	RMSE y_2
EKF	0.0305	0.0035
UKF	0.0035	0.0035

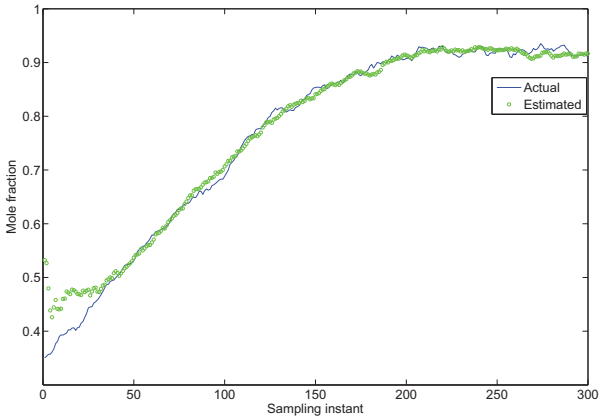

Fig. 3. UKF estimates of mole fraction for case study

7. CONCLUSIONS

In this paper, EKF and UKF formulations for nonlinear DAEs were proposed. The proposed EKF approach handles the case where the measurement functions are a function of both the differential and algebraic states. While UKF for ODE systems are well studied, there is very little work on the application of the UKF approach to DAE

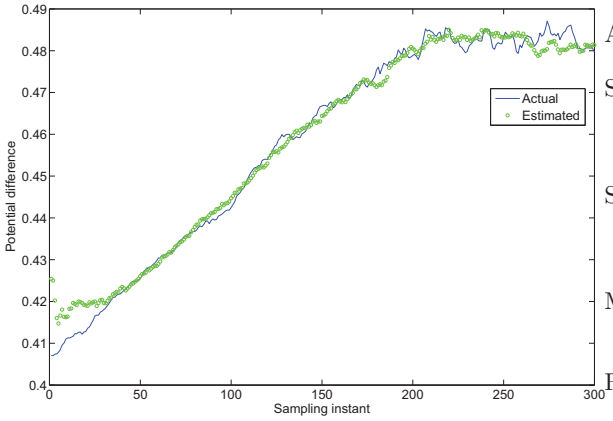

Fig. 4. UKF estimates of potential difference for case study

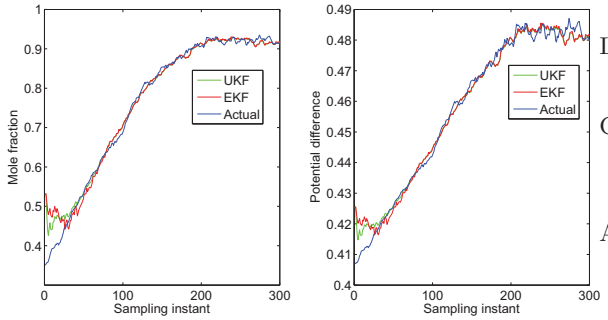

Fig. 5. Comparison of UKF and EKF estimates

systems. One possible approach to use unscented transformation in the estimation of DAE systems is proposed in this work. A case study is presented to demonstrate both the approaches. In this case study, the algebraic state is directly measured. It is shown that while both the proposed approaches provide satisfactory estimation, the UKF approach outperforms the EKF approach.

Abstract: Research and development attempts on water quality models created valuable resources in the sense of model calibration and verification techniques. Recognizing the current degree of pollution in rivers and the importance of the sustainable water resources management, the interactive river monitoring appears to be at the center of recent focus. However the available information in this area is still far from expectations. On one side, the Geographical Information Systems (GIS) are gaining widespread acceptance and on the other side fast and reliable water quality models and parameter estimation techniques are becoming available. However, previous work on integrating water quality models and GIS is very limited. This work brings an integrated platform on which ArcMap as a GIS and a water quality model in Matlab™ are brought together in an interactive and user-friendly manner. The software developed allows the user to enter the data collected from the river, runs the dynamic model in the Matlab™ environment, predicts the values of pollution constituents along the river, extracts the results and displays the water quality on the map in different forms. The software thus provides a considerable ease in future real time application for on site river monitoring and environmental pollution assessment.

Keywords: water quality modeling, GIS, GUI, water management, systems analysis.

1. INTRODUCTION

Water pollution is gradually becoming one of major threats for aquatic as well as human life. In order to assess the impact of wastewater discharges into the surface waters, mathematical models are of great importance. Over the past there have been considerable developments in the area of water quality modeling for rivers. A summary can be found in the review by Rauch *et al.* (1998) who gave the then state of the art in river water quality modeling. The most widely used model in the world is pronounced to be QUAL2E, which was developed by US Environmental Protection Agency (EPA), and known as almost the standard for river water quality modeling (Shanahan *et al.* 1998). In addition; WASP, SALMANQ and SIMCAT are probably the ones that have been frequently referred to in the literature. The water quality models can be classified from many perspectives, ranging from model complexity to the simulation method employed, and the number and type of water quality indicators incorporated. Just to give an idea, Cox (2003), for example, selected 6 models in conceptualization and solution for detailed comparison. Three of them were steady state and the rest was of dynamic character. Cox (2003) noted that water quality modeling was an active area of research around the world, and underlined that only few papers referred to specific models with majority of the papers reporting applications with QUAL2E.

In the authors' research group, a dynamic modeling strategy based on QUAL2E and coupled with a parameter estimation technique was introduced by Karadurmus and Berber (2004). The suggested strategy assumed that river reach could be modeled as a single CSTR. The model predicted and compared to the field data for 10 quality constituents observed; except those for the total coliform, total chloride and BOD_5, good agreement was obtained. Later a user-interactive software code in Matlab™ (The MathWorks Inc., USA) named as RSDS (River Stream Dynamics and Simulation) for the implementation of the suggested technique was presented, and the model predictions were compared against experimental data collected in field observations along the Yesilirmak river basin in Turkey and predictions from QUAL2E (Yuceer *et al.* 2007). In a following work, a water reach was represented by a series of CSTRs rather than a single one. Taking the trade-off between the computing load and the prediction accuracy into account, the number of CSTRs to be used to represent a river section was determined. Then, for simulating a 500 m long reach of the river between the two sampling stations, 20 CSTRs were used (Berber *et al.* 2009). Furthermore, this work included a parameter identification study.

Despite the progress that has been observed in the field of modeling, only few reports are available in the current literature on integrated software development for river water quality monitoring. It is seen that the recent efforts are now concentrating on the incorporation of a geographical information system to water quality models. Within this framework, Marsili–Libelli *et al.* (2001) described the interfacing of a Matlab™ based quality model to a popular geographical information system ArcView™ (ESRI Inc., USA) by a communication protocol through which data could be exchanged between the two platforms. The same research group later provided a new software package developed entirely in the Matlab™ platform based on the Mapping Toolbox™ and reported enhanced interactivity and portability. The features of the program are illustrated through a case study (Marsili–Libelli *et al.* 2002).

From the perspective of using web-based technologies for remote monitoring, Cianchi *et al.* (2000) used internet technologies to follow water quality with river quality sensors. Data from sensor signals were transmitted to information warehouse by internet. In a more recent work, web based Geological Information System was used to visualize and assess water quality over the web for end user with minimum knowledge and computing experience (Ganapathy and Ernest, 2004). The spatial 'Decision Support System' developed for their study focused on the lower Rio Grand river basin.

The use of Geographical Information System (GIS) computing platforms, as they represent a process for looking at geographic patterns in data and provide nice display options, has been increasing. GIS incorporates computer hardware, software, and geographic data for capturing, managing, analyzing, and displaying all forms of geographically referenced information. This rapidly growing technological field brings graphical features with tabular data in order to assess real-world problems. The opportunities that GIS systems provide may range from simple applications where one layer data display and analysis is done on a digital map, to more complex cases that mimic the real world by combining many data layers (Mitchell, 1999). Distributions of nitrate, nitrite and ammonium at various monitoring sites across the Humber basin were examined by Davies and Neal (2004) within a GIS framework. Empirical relationships between land characteristics and water quality for the whole catchment draining to each water quality monitoring site were established. The main water quality data source was the Land Ocean Interaction Study dataset. The land characteristics were classfied as lowland arable, urban, upland and coniferous woodland. The relationship between water quality and the catchment characteristics were assessed using linear regression. The study has proved success in showing the broad patterns across the region based on regression analysis of environmental measurements on the nitrogen species and simple land characteristics. (Davies and Neal, 2004). In a particular work by Ruelland *et al.* (2007) the Riverstrahler model that describes the biological functioning of an entire river system was coupled to a GIS interface to make the model entirely generic to be run on any river system for which a suitable database was available. They examined the effect of increasing the spatial resolution of the drainage network representation on the performance of the Riverstrahler model.

In this study we have developed an interactive GIS based software for water quality monitoring in rivers. The water quality model that has been previously developed in our research group was used for simulation and prediction. The software created has been tested with off-line water quality data gathered from a 36.5 km long section of Yesilirmak river in the central northern region of Turkey.

2. GIS PLATFORM INTEGRATING A WATER QUALITY MODEL IN MATLAB

A software has been created in this work to analyze the river water quality data in GIS platform. The program, called RSDS-C, and particularly designed to simulate Yesilirmak river in the central northern part of Turkey, allows user interaction and visual effects so that the predictions for pollution constituents can be represented on a digital map of the river. The River Stream Dynamic Simulation (RSDS) software previously developed in Matlab™ in our research group (Yuceer *et al.* 2007) was used as the water quality model, and was incorporated into the GIS platform ArcMap™ 9.1.

One critical point in combining a Matlab model with a GIS system is integrating the geographical data (which come from digital maps of GIS) with river pollution variables that are handled in Matlab. Data exchange between these two platforms requires that the graphical indications used to represent the geographical object in GIS be adapted to the data structure in the model embodied in Matlab. We used the data transfer strategy depicted in Fig. 1, which shows that the ASCII formatted text files were the medium of transfer between GIS (ArcMap™) and Matlab™. As ArcMap™ employs database files for displaying the digital maps, Microsoft Access™ was employed as the database-handling platform.

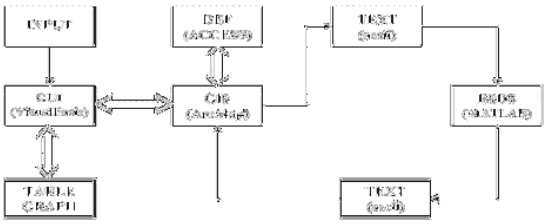

Fig. 1. ASCII file transfer strategy between different computing platforms.

A special graphical user interface (GUI) was designed for data input related to the river. The input comprise initial conditions for simulation, parameters related to integration of differential equations, flow characteristics of the river, or real measured data that has been observed at a particular location along the river (particularly when a parameter estimation study is intended). The GUI allows the user to interactively enter the observed quality of the river, which may be used as

the initial conditions at the beginning of simulations, or as the experimental value for the embedded simulation algorithm in case if parameter identification is to be performed. As for the water quality constituents, we use 11 variables comprising dissolved oxygen, carbonaceous BOD, four nitrogen forms (organic, ammonia, nitrite, and nitrate), two phosphorus forms (organic and dissolved), coliforms, nonconservative constituent chloride and phytoplanktonic algae. Those are the state variables of the embedded rigorous water quality model (Yuceer *et al.* 2007). The entered data also include variables related to the physical conditions in the river such as flow rate, temperature, cross-sectional area; and numerical parameters pertaining to the simulation (integration time, step size, method, etc.). The data was combined with the GIS system and transferred to Matlab™ platform for simulation. The simulations run on the Matlab platform determine the predictions of water quality along the river. Simulation results are relayed back to the GIS platform, and combined with the geographical data for display and analysis. The GUI was coded in Visual Basic™. The software allows the ArcMap and Access package programs to run interactively. This was accomplished through interlinking the ArcMap with Access (mdb) files, thus the data can be handled interactively. All graphics and tables were created from 'mdb' files.

In the previous work reported by Marsili–Libelli *et al.* (2002) data was transferred between the platforms by special 'avenue' script. This was appropriate in their case because the GIS platform that they used, ArcView (ESRI, 1996a), has a procedural language called Avenue (ESRI, 1996b) to define "scripts" that can implement the dynamic data exchange (DDE) procedure. However, the ArcMap™ 9.1 used here reads 'txt' files, so the data conveyed in ASCII format from Matlab are known. This data is then converted into dimensional variables in Visual Basic to be represented in tabulated form. For this procedure, the following SQL statements were used. These database connection statements make the data such that it can be viewed in graphs and tables, and also be used for color coding of the river information in GIS system.

```
Set m_pAdoCon = New ADODB.Connection
        m_pAdoCon.Open
"Provider=Microsoft.Jet.OLEDB.4.0; Data
            Source=C:\...\....mdb;Persist Security Info=False"
        Set pRecset = New ADODB.RecordSet
```

First of these statements opens database connections, second shows 'mdb' file path, name and table; and the third one starts the actual connection procedure. With these SQL statements, data become interconnected to ArcMap tables.

All windows and menus of the GUI, which are illustrated in the following figures, were designed in Visual Basic editor of ArcMap. The opening menu of the program is depicted in Fig. 2 together with the input sheet for entering initial water quality conditions. The table on the left hand side of the window lists the water quality variables that can be monitored on the screen. Prior to any run for simulation and prediction, the user is expected to enter the initial water quality conditions at starting point of working area where the simulation will begin. If there is a point source to the river, it can also be taken into account and respective values can be entered via additional input sheets that will open.

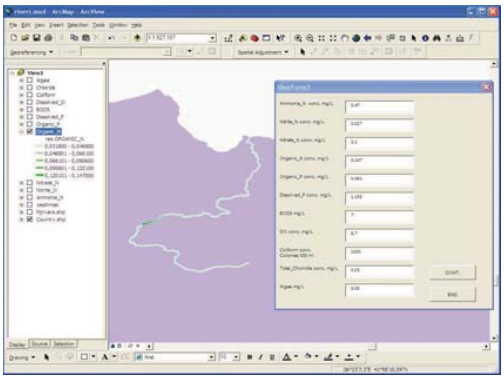

Fig. 2. View of the opening menu of the software (with the map of Yesilirmak river indicating the study area, and user input sheet).

Once the simulation is run, the user can select any variable from the list, shown in left hand side of the menu, to be displayed in table or graphical form.

The working area was divided into 100 parts of equal length to illustrate water quality variables, and thus the user can follow the concentration of the selected quality variable in different color at desired locations on map. The geographical point where the variables are sought is selected by the movement of the mouse along the river displayed on map. It then becomes possible to follow the water quality in terms of the selected pollutants along the river. For example, Fig. 3 depicts the change in the ammonia nitrogen concentration following a point source. With this feature, the simulation results are linked to the GIS database, and thus the user can easily follow the spatial distribution of the major constituents of river water quality. It is also possible to display more than one quality variable in graphical or table form at any location indicated.

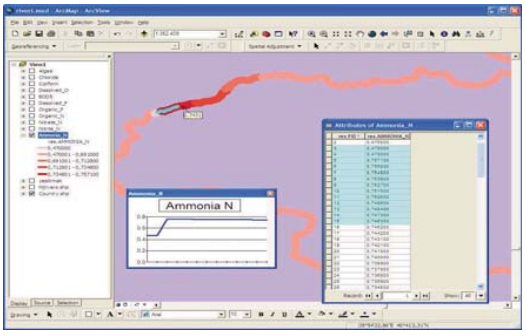

Fig. 3. Water quality display in table and graph form on the map.

In Fig. 3 the list on the left hand side shows the water quality variables considered. The user can select a location on the river map by moving the mouse, and if it is a point on the river the data table associated with this particular location opens on the screen. On the other hand, if the user scans a

region along the river, the software allows the user to see the changes in the concentration of the selected quality variables along this site by different colors. The color intensity on the map changes from light to dark with increased concentration, and this feature makes keeping track of water quality very easy. The user can select the concentration range (maximum and minimum values) and the number of intervals between. The color codes corresponding to those selected concentrations may be also determined by the user. If no choice has been made, the software picks up the maximum and minimum concentration values encountered in the simulations, and allocates five intermediate color codes (as default) to 5 intermediate values between the maximum and minimum. This feature of the GUI is illustrated in Fig. 4. It is also possible to see the changes in concentration in graphical form.

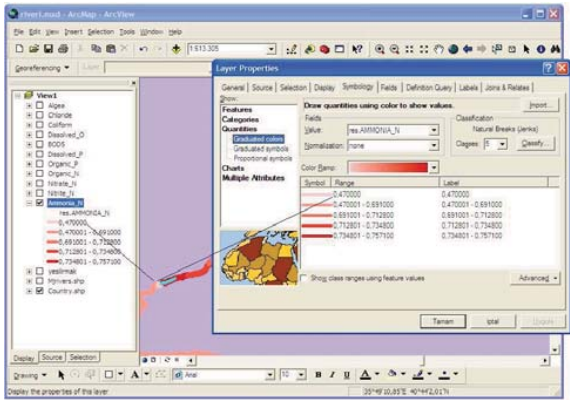

Fig. 4. Selection of color codes between maximum and minimum concentration intervals.

3. TESTING ON YESILIRMAK RIVER IN TURKEY

The software developed was tested with off line data collected from field studies around the city of Amasya along Yesilirmak river in Turkey. Yesilirmak is one of the major rivers in Turkey with 519 km length, and a basin of 36114 km^2 comprising 4.63 % of the territorial area of Turkey. Fig. 5 shows the study area on the river map. Pollution level in Yesilirmak affects the agricultural and rural development directly by distorting the ecological balance. The basin is a predominantly rural area and suffers from quite high level of pollution, in particular from agriculture, urban and industrial sources. Water quality in the river is classified in III and IV level according to the Water Pollution Control Act of Turkey, when physical, chemical, organic and bacteriological parameters are considered. An interactive river management decision support system for the region in order to protect the river from pollution becomes important for sustainable development in the future. Therefore, Yesilirmak was chosen as the study area, where our previous studies had also been concentrated.

The concentrations of ten water-quality constituents indicative of the level of pollution in the river were determined either on-site by portable analysis systems or in laboratory after careful conservation of the samples. For determination of dissolved oxygen, YSI Model 51/B portable oxygen meter in compliance with the Turkish Standard-TS 5677 were used. Nitrite, nitrate and ammonia forms of nitrogen were analyzed with HACH (Model DR2000) portable spectrophotometer. Total nitrogen was determined by Kjeldahl method. The organic nitrogen was calculated as the difference between the total nitrogen and the sum of ammonia, nitrite and nitrate forms. Phosphorous was analyzed by the methods of colorimetric ascorbic acid amino reduction and molibdo vanado phosphate (Greenberg, 1992) in the same spectrophotometer. BOD analysis and coliform analysis were done in the laboratory, after careful transportation of the samples, with manometric method in HACH spectrophotometer, and with multiple tubes and filtering method respectively. The chloride analysis was done in HACH spectrophotometer for free chloride and total chloride. Out of the 11 state variables, 10 were determined from field measurements. Only a representative data for the concentration of algae was taken from literature (Brown, 1987).

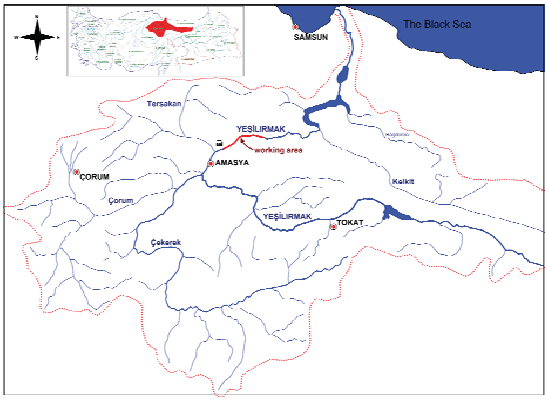

Fig. 5. Yesilirmak river basin and the study area.

During the dynamic sample collection period, the effluent from the wastewater treatment plant of a baker's yeast production plant was being discharged right beyond the starting point. Therefore, the results of the study indicated the extent of the pollution caused by the discharge from this industrial plant. In the simulations, addition of this discharge was considered as a continuous disturbance to the system, and its effect on the water quality, thus, was determined. Table 1 gives the characteristics of discharge from this local industrial plant.

Water quality data was collected for a 36.5 kms long section of the river adjacent to the city of Amasya. The study area started from the location 8.9 kms east of the city center where a baker's yeast plant was situated. The treated wastewater of this plant was considered as a point source to the river. The river water was sampled at 7 different locations in the downstream direction towards Durucasu gauging station of State Hydraulic Works (DSI) and the town of Tasova.

The initial conditions of the river and the characteristics of the point source as measured from points 1 and 2 indicated on Fig. 6 were introduced into the software, and dynamic simulation was run.

Table 1. Characteristics of discharge from the local baker's yeast plant

Variables	Waste water of baker's yeast plant
Temperature (^oC)	25.3
Flow (m^3/s)	0.25
Ammonia-N (mg/L)	27.4
Nitrite-N (mg/L)	1.3
Nitrate-N (mg/L)	52
Organic-N (mg/L)	0
Organic-P (mg/L)	0.52
Dissolved-P (mg/L)	12.4
BOD (mg/L)	210
DO (mg/L)	7.2
Coliform, (colonies/100 ml)	2900
Chloride (mg/L)	0

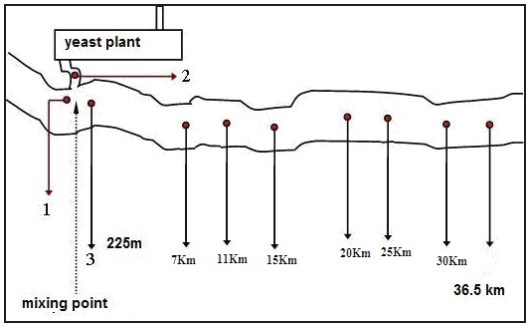

Fig. 6. Experimental study area for model verification, and sample collection points (distances indicated are measured from point 1).

Predictions from the software were compared to field data for a section of 36.5 kms of the river after the point source. Measured and predicted profiles of the pollution variables are shown in the following figures. Fig. 7, 8 and 9 reveal the pollution load due to the point source, and indicate that after some distance from the point where the effluent enters, remarkable recovery was observable. Fig. 10 shows the change in dissolved oxygen concentration along the study area. The points in the Figs. 7-8 indicate measurements whereas the continuous lines are predictions from the model.

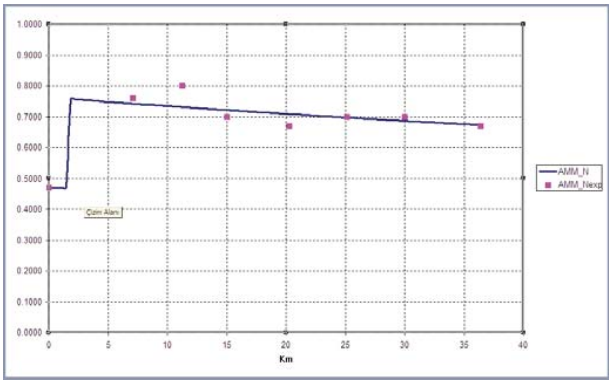

Fig. 7. Ammonia nitrogen profile.

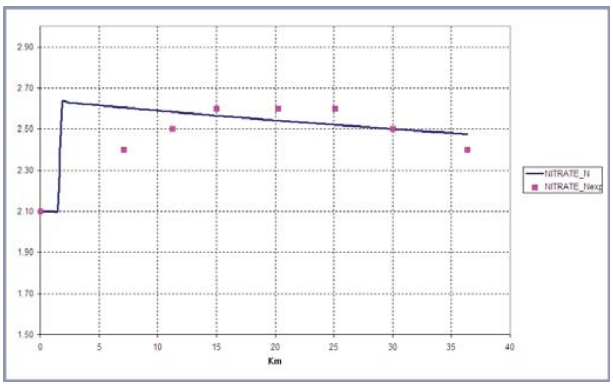

Fig. 8. Nitrate nitrogen profile.

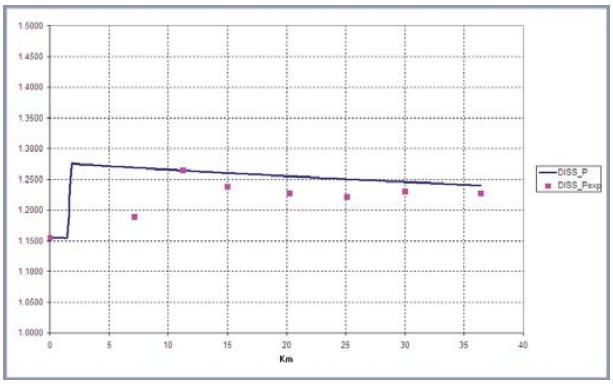

Fig. 9. Dissolved phosphorus profile.

For quantitative evaluation and comparison, Absolute Average Deviation (AAD) values were calculated. Table 2 indicates that, except nitrite nitrogen and chloride, the predicted values of all quality variables are in compliance with measured values.

Fig. 11 presents the predicted water quality results in tabulated form as a function of geographical space indicated on the first row. The columns represent the water quality variables predicted. The water quality data displayed can be viewed in graphical form or as color coded displays on the river map.

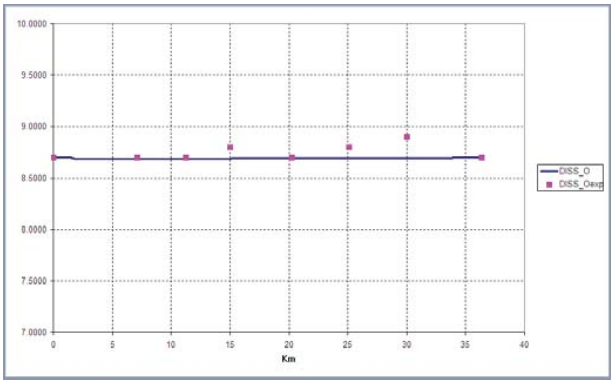

Fig. 10. Dissolved oxygen profile.

Table 2. Absolute Average Deviation (AAD) values for comparison of pollution variables

Water Quality Variables	(AAD %)
Ammonia Nitrogen	2.86
Nitrite Nitrogen	29.59
Nitrate Nitrogen	2.71
Organic Nitrogen	9.01
Organic Phosphorus	2.09
Dissolved Phosphorus	1.89
BOD	5.49
Dissolved Oxygen	0.64
Coliform	6.87
Chloride	20.19

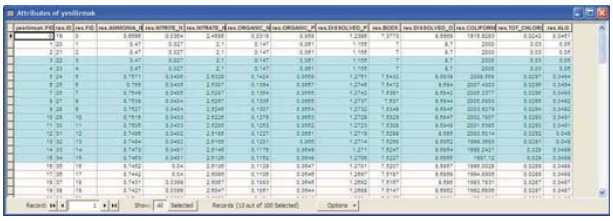

Fig. 11. Simulation results in tabulated form.

4. CONCLUSION

Although many models have been developed, they appear to be available to limited number of professionals who are capable of using and interpreting water quality simulation models. However, increased awareness in surface water pollution dictates that these models be used by non-experts who may be interested in knowing the consequences of various scenarios on river pollution. Availability and affordability of GIS systems offer alternative solutions to this problem.

Starting from this point, a software integrating a Geographical Information System and a water quality model in a single convenient package has been developed in this study. The effects of a discharge on the river can be predicted by simulation and the results are displayed on the map. The software was tested off-line with data collected from field measurements on Yesilirmak river in Turkey.

The integration strategy developed and the GUI created provide an interactive environment for the user and will help decision making process in river basin management systems, and can be fairly easily adapted to other rivers.

The results indicated that the model was able to satisfactorily estimate the water quality along the downstream section of a point load.

In our ongoing work, the software has been implemented for real time applications, and these results will be reported later.

Abstract: Microalgae have many applications such as the production of high value compounds (source of long-chain polyunsaturated fatty acids, vitamins, and pigments), in energy production (e.g. photobiological hydrogen, biofuel, methane) or in environmental remediation (especially carbon dioxide fixation and greenhouse gas emissions reduction). However, the photobioreactor microalgae process needs complex and costly hardware sensors, especially for biomass measurement. Thus, state and parameter estimation seems to be a critical issue and is studied in this paper in the case of a culture of the microalga Porphyridium purpureum. This paper is an extension of the previous work of Becerra-Celis et al. (2008) where the principal objective is to design a biomass estimator of this microalga production in a photobioreactor based on the total inorganic carbon measurement.
Unscented Kalman filtering is applied to estimation of states and model parameters, producing better performances in comparison with Extented Kalman filtering. Numerical simulations in batch mode, and real-life experiments in continuous mode have been carried out. Corresponding results are given in order to highlight the performance of the proposed estimator.

Keywords: Unscented Kalman Filter, state and parameter estimation, microalgae photobioreactor

1. INTRODUCTION

In chemical and biochemical processes, often chemical reactions have to be monitored and controlled using different sensor measurements. Typically, measurements of reactant and product concentrations, operating temperatures, pressures, and other parameters are needed. In general, a measurement has to be reliable, i.e. it has to be available and accurate. However, there are several reasons why required measurements may not be reliable. Some of such reasons are the impracticability of building an appropriate sensor due to lack of technology, the difficulty to position the sensor, the associated cost. In such cases, an attempt to use estimation techniques may be done.

Dochain (2003) presents an interesting overview of available results on state and parameter estimation in chemical and biochemical processes. A comparison of several traditional state and parameter estimation approaches is given, discussing pros and cons in different cases, and describing how the most common implementation problems are solved (see Dochain (2003) and references therein). In this work particular attention is given to Kalman filtering. Its application to nonlinear systems is tipically implemented by the well known and widely used Extended Kalman Filter (EKF). Even though there are issues due to the inherent linearization procedure in the algorithm, the scientific and industrial communities have obtained successful EKF applications. However, it is the authors' opinion that in systems with strong nonlinearities it could be interesting to exploit the benefits of the Unscented Kalman Filter (UKF). Thus, the UKF is introduced as a valid EKF alternative, and it is shown how to obtain improvement due to its implementation flexibility, extending then its applicability. The first works introducing the Unscented transformation idea and the UKF algorithm are Julier and Uhlmann (1996), and Julier and Uhlmann (1997). In Wan and Van Der Merwe (2000) several UKF algorithms are described, which could be used for state estimation, parameter estimation, and joint state and parameter estimation. This work aims to present UKF advantages in terms of performance and implementation ease, compared to the EKF. The work of Becerra-Celis et al. (2008) is considered as starting point, where it is shown how to implement an

⋆ The authors wish to acknowledge support from the French-Norwegian research cooperation project AURORA

EKF for state estimation in a photobioreactor. Moreover, experimental data is used to validate the results.

Next section explains how to use the UKF for joint state and parameter estimation. Section 3 describes the photobioreactor used for microalgae production, and its model. Section 4 analyzes the application of the UKF to the photobioreactor. In addition, it is shown that when parameter estimation is considered, the UKF produces improved results, particularly when experimental data, collected from continuous cultures, is used. Finally, conclusions and future work are presented.

2. STATE AND PARAMETER ESTIMATION

Consider the following nonlinear system

$$\begin{aligned}\dot{\xi}(t) &= g(\xi(t), u(t), v_\xi(t)) \\ y(t) &= l(\xi(t)) + n(t)\end{aligned} \tag{1}$$

where ξ is the state vector, u is the input vector, y is the measurement vector, v_ξ is the process noise vector, n is the measurement noise vector, of appropriate dimensions, respectively. Simply stated, the state estimation problem consists to reconstruct the state vector knowing the measurement and input vectors, some information on noise distributions, and the nonlinear functions $g(\cdot)$ and $l(\cdot)$. When the parameters used in the model (1) are uncertain the estimation problem may be more difficult to solve. One method to obtain sufficiently good estimates is to make the estimator algorithm robust with respect to the parameter variations. Another method is to try to estimate the uncertain parameters improving the model accuracy. However, joint parameter and state estimation may lead to observability problems. A general framework to introduce the parameter estimation is to extend the state with the uncertain parameters vector and then estimate the augmented state. In cases where the actual parameters are slowly varying, it is common to model the parameters vector η as a random walk driven by a white noise process $v_\eta(t)$. Thus the following differential equation

$$\dot{\eta}(t) = v_\eta(t) \tag{2}$$

is used to augment the system (1). Associating then a relatively small covariance to $v_\eta(t)$, it is possible to consider the slowly varying nature of the parameters. The section below describes the particular UKF used in this work. The algorithm describes the case of joint parameter and state estimate. The equations are still valid if only state estimate is considered. However, the procedure to augment the state vector and covariance matrix, with the parameter vector and its covariance matrix, respectively, must be omitted.

2.1 Unscented Kalman Filter algorithm

Consider the following discretization of the system (1-2)

$$\begin{aligned}\xi_{k+1} &= f(\xi_k, u_k, v_k^\xi, \eta_k) \\ \eta_{k+1} &= \eta_k + v_k^\eta \\ y_k &= h(\xi_k, \eta_k) + n_k\end{aligned} \tag{3}$$

obtained using an appropriate numerical integration routine. To estimate jointly the state and parameters of the system (3), the following augmented vector is defined:

$$\hat{x}_k^a = [\hat{x}_k',\ v_k']' \tag{4}$$

where $\hat{x}_k = [\hat{\xi}_k',\ \hat{\eta}_k']'$ has as elements the state and parameter estimates, respectively. The vector $v_k = [v_k^{\xi'}, v_k^{\eta'}]'$ contains the process noises in the evolution of ξ and η. Analogously, the augmented covariance matrix is defined as

$$P_k^a = \begin{bmatrix} P_k^x & P_k^{x,v} \\ P_k^{v,x} & P_k^v \end{bmatrix} \tag{5}$$

where P_k^x consists of the state and parameter error covariances, while P_k^v includes the process noise covariance associated to state and parameters. In addition, the off diagonal entries are cross covariance terms represented by the notation $P_k^{\cdot,\cdot}$. Obviously, all elements of $\hat{x}_k^a$ and P_k^a are of appropriate dimensions.

Given the initial conditions

$$\hat{x}_0^a = \begin{bmatrix} \hat{x}_0 \\ 0_v \end{bmatrix}, \qquad P_0^a = \begin{bmatrix} P_0^x & 0 \\ 0 & P_0^v \end{bmatrix}, \tag{6}$$

the dimension L of the augmented system state $\hat{x}^a$, and the following scalar weigths W_i

$$W_0^{(m)} = \lambda/(L+\lambda) \tag{7}$$

$$W_0^{(c)} = \lambda/(L+\lambda) + (1-\alpha^2+\beta) \tag{8}$$

$$\begin{aligned}W_i^{(m)} &= W_i^{(c)} \\ &= 1/[2(L+\lambda)]\end{aligned} \tag{9}$$

for $i = 1, \ldots, 2L$, $\lambda = \alpha^2(L+\kappa) - L$, and where α, β, κ are parameters to be chosen.

For $k = 1, \ldots, \infty$

- Calculate the sigma points defined as

$$\begin{aligned}\left(\mathcal{X}_{k-1}^a\right)_0 &= \hat{x}_{k-1}^a \\ \left(\mathcal{X}_{k-1}^a\right)_j &= \hat{x}_{k-1}^a + \gamma\left(\sqrt{\mathrm{P}_{k-1}^a}\right)_j \\ \left(\mathcal{X}_{k-1}^a\right)_{j+L} &= \hat{x}_{k-1}^a - \gamma\left(\sqrt{\mathrm{P}_{k-1}^a}\right)_j\end{aligned} \tag{10}$$

  where $\left(\sqrt{\mathrm{P}_{k-1}^a}\right)_j$ is the j-th column ($j = 1, \ldots, L$) of the square root of the augmented covariance matrix (5) at the previous time step. The parameter $\gamma = \sqrt{L+\lambda}$ can be interpreted as a scaling factor used to move the position of sigma points around the mean value $\hat{x}_{k-1}^a$. Finally, the sigma points are regrouped in the following matrix of L rows and $2L+1$ columns:

$$\mathcal{X}_{k-1}^a = \begin{bmatrix} \mathcal{X}_{k-1}^x \\ \mathcal{X}_{k-1}^v \end{bmatrix} \tag{11}$$

  where $\mathcal{X}_{k-1}^x$ contains the sigma point rows associated to state and parameters, and $\mathcal{X}_{k-1}^v$ the sigma point rows associated to the state and parameters process noises.

- Propagate the sigma points through the nonlinear dynamics F[·], and compute the predicted state estimate, where the index i is used to select the appropriate sigma point column:

$$\mathcal{X}_{k|k-1} = \mathrm{F}\left[\mathcal{X}^a_{k-1}, u_{k-1}\right] \tag{12}$$

$$\hat{x}^-_k = \sum_{i=0}^{2L} W_i^{(m)} \mathcal{X}_{i,k|k-1} \tag{13}$$

- Compute the predicted covariance:

$$P^-_k = \sum_{i=0}^{2L} W_i^{(c)} \left[\mathcal{X}_{i,k|k-1} - \hat{x}^-_k\right] \left[\mathcal{X}_{i,k|k-1} - \hat{x}^-_k\right]' \tag{14}$$

- Using the predicted mean (13) and covariance (14), recompute a new set of sigma points as defined in (10-11):

$$\mathcal{X}^-_k = \left[\mathcal{X}^{x\prime}_k, \mathcal{X}^{v\prime}_k\right]' \tag{15}$$

- Instantiate the new sigma points through the observation model H[·], and calculate the predicted measurement:

$$\mathcal{Y}_{k|k-1} = \mathrm{H}\left[\mathcal{X}^-_k\right] \tag{16}$$

$$\hat{y}^-_k = \sum_{i=0}^{2L} W_i^{(m)} \mathcal{Y}_{i,k|k-1} \tag{17}$$

- Obtain the innovation covariance and the cross covariance matrices:

$$P_{\tilde{y}_k\tilde{y}_k} = \sum_{i=0}^{2L} W_i^{(c)} \left[\mathcal{Y}_{i,k|k-1} - \hat{y}^-_k\right] \left[\mathcal{Y}_{i,k|k-1} - \hat{y}^-_k\right]' + P^n \tag{18}$$

$$P_{y_k x_k} = \sum_{i=0}^{2L} W_i^{(c)} \left[\mathcal{X}_{i,k|k-1} - \hat{x}^-_k\right] \left[\mathcal{Y}_{i,k|k-1} - \hat{y}^-_k\right]' \tag{19}$$

where P^n is the measurement noise covariance;

- Perform the measurement update using the regular Kalman filter equations:

$$\mathcal{K}_k = P_{y_k x_k} P^{-1}_{\tilde{y}_k\tilde{y}_k} \tag{20}$$

$$\hat{x}_k = \hat{x}^-_k + \mathcal{K}_k\left(y_k - \hat{y}^-_k\right) \tag{21}$$

$$P^x_k = P^-_k - \mathcal{K}_k P_{\tilde{y}_k\tilde{y}_k} \mathcal{K}'_k \tag{22}$$

In (12), F[·] is the modified nonlinear dynamics of (3). The changes are made to consider the discretization and the augmented state, and also to guarantee the proper propagation of each sigma point. Analogously, in (16) H[·] is the modified observation function. Due to the fact that measurement noise is assumed additive with zero mean, it is possible to write (18). Thus, the algorithm computational complexity is reduced because there is no need to associate more sigma points. Regarding filter design parameters, in most cases typical values are $\beta = 2$, and $\kappa = 0$ or $\kappa = 3 - L$, leaving only the parameter α as free parameter. Moreover, considering that $1 \leq \alpha \leq 10^{-4}$ the tuning of the UKF becomes simpler. For a finer tuning and a more accurate description about the meaning of the UKF parameters one can refer to Wan and Van Der Merwe (2000). Finally, in (11) and (15) a square root of a matrix has to be calculated, thus an appropriate algorithm must be used, for instance the Cholesky factorization.

3. PHOTOBIOREACTOR FOR MICROALGAE PRODUCTION

3.1 Strain and growth conditions

The photobioreactor is used to produce the red microalgae *Porphyridium purpureum* SAG 1830-1A obtained from the Sammlung von Algenkulture Pflanzenphysiologister Institut Universität Göttingen, Germany. The strain is growth and maintained on Hemerick medium (Hemerick (1973)). The pH of the Hemerick medium is adjusted to 7.0 before autoclaving it for 20 minutes at 121 °C. Cultures are maintained at 25 °C in 500 ml flask containing 400 ml culture under continuous light intensity of 70 $\mu E m^{-2} s^{-1}$ and aerated with air containing 1% (v/v) CO_2 at 100 rpm on an orbital shaker. During the exponential growth phase, within an interval of two weeks, 200 ml of culture are transferred to a new flask containing fresh medium.

3.2 Culture conditions and measurements

Figure 1 illustrates the photobioreactor diagram where the growth of cultures is performed. The bubble column photobioreactor has a working height of 0.4 m and a diameter of 0.1 m. The total culture volume is 2.5 l, and the cylindrical reactor, made of glass, has an illuminated area of 0.1096 m^2. To agitate the culture an air mixture with 2% (v/v) CO_2 is continuously supplied at a flow rate of 2.5 $V.V.H$ (gas volume per liquid culture volume per hour). 0.22 μm Millipore filters, appropriate valves and flowmeters are used to filter and to control the air flow rate entering the photobioreactor. Four OSRAM white fluorescent tubes (L30W/72) and three OSRAM pink fluorescent tubes (L30W/77) are arranged around the bubble column as an external light source. The incident light intensity on the reactor surface is measured at ten different locations with flat surface quantum sensors (LI-COR LI-190SA). The average light intensity is computed by the weighted average of all measurements. The optimal value of irradiance on surface for the reactor is 120 $\mu E m^{-2} s^{-1}$. A transparent jacket connected to a thermostat unit allows the temperature control, which is regulated at 25 °C. Other sensors are a pH sensor (Radiometer Analytical) and a dissolved oxygen sensor (Ingold type 170). A sampling port is applied to the top of the column, from where samples for off line analysis are collected after 6, 8, and 12 hours. The number of cells is counted using an optical microscope ZEISS Axioplan-2 on Malassez cells. The total inorganic carbon (T.I.C.) in the culture medium is calculated by gas phase chromatography. This method, proposed by Marty et al. (1995), is used to measure low inorganic carbon concentrations down to ($10^{-6} mol\ l^{-1}$) within an accuracy of 10%.

3.3 Mathematical model

In this work the bioprocess model presented in Baquerisse et al. (1999) is used. It consists of two sub models, one describing the growth kinetics, and one representing the gas-liquid mass transfer in the photobioreactor. This

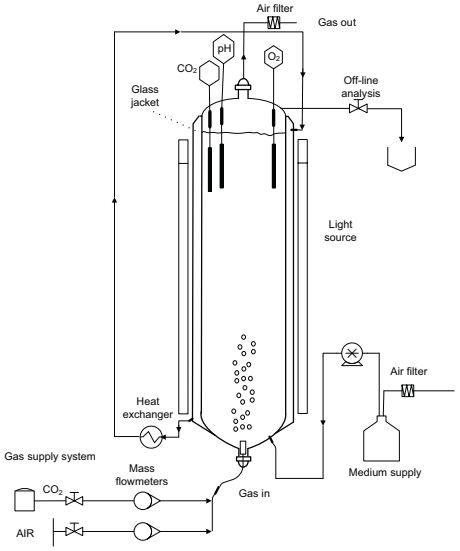

Fig. 1. Photobioreactor diagram.

results in two differential equations describing the state of the reactor:

$$\begin{aligned}\frac{dX}{dt} &= \frac{F_{in}}{V}X_{in} + \mu X - \frac{F_{out}}{V}X \\ \frac{d[TIC]}{dt} &= \frac{F_{in}}{V}[TIC]_{in} - \frac{F_{out}}{V}[TIC]_{out} - \mu\frac{X}{Y_{X/S}} \\ &\quad - mX + k_L a\left([CO_2^*] - [CO_2]\right) \end{aligned} \tag{23}$$

where X is the biomass, and $[TIC]$ is the inorganic carbon concentration associated with cell density increase. The subscripts $[\cdot]_{in}$ and $[\cdot]_{out}$ indicate quantities flowing into, and out from the reactor, respectively. V is the culture volume, and F is the medium flow rate. The mass conversion yield is defined by $Y_{X/S}$, m is the maintenance coefficient, and $k_L a$ is the gas-liquid transfer coefficient. The carbon dioxide concentration in the medium fresh is defined as:

$$[CO_2^*] = \frac{PCO_2}{\mathcal{H}} \tag{24}$$

where PCO_2 is the partial pressure of carbon dioxide, and $\mathcal{H}$ is the Henry's constant for Hemerick medium. Moreover, the carbon dioxide concentration in the medium is given by:

$$[CO_2] = \frac{[TIC]}{\left[1 + \frac{K_1}{[H^+]} + \frac{K_1 K_2}{[H^+]^2}\right]} \tag{25}$$

where K_1, K_2 are kinetics constants, and $[H^+]$ is defined as:

$$[H^+] = 10^{-pH} \tag{26}$$

representing the hydrogen ions concentration in the culture media.

In addition, a light transfer model is considered, which describes the evolution of incident and outgoing light intensity:

$$E = \frac{(I_{in} - I_{out})A_r}{VX} \tag{27}$$

$$I_{out} = C_1 I_{in} X^{C_2} \tag{28}$$

where E is the light "energy" accessible per cell, I_{out} is the outgoing light intensity, I_{in} is the ingoing light intensity. C_1, C_2 are constants depending on the reactor geometry, and A_r is its area.

The light intensity and the total carbon concentration influence the specific growth rate, defined as

$$\mu = \mu_{max}\frac{E}{E_{opt}}e^{\left(1-\frac{E}{E_{opt}}\right)}\frac{[TIC]}{[TIC]_{opt}}e^{\left(1-\frac{[TIC]}{[TIC]_{opt}}\right)} \tag{29}$$

where μ_{max}, E_{opt}, and $[TIC]_{opt}$ are model parameters identified from the batch data experiments. Finally, in (29) substrates limitation effect is taken into account.

3.4 Batch and continuous operating conditions

The photobioreactor can work in two different operating conditions, batch mode and continuous mode. In batch mode:

$$F_{in} = F_{out} = 0; \qquad [TIC]_{in} = 0; \qquad X_{in} = 0. \tag{30}$$

In continuous mode, instead:

$$F_{in} = F_{out} \neq 0. \tag{31}$$

3.5 Model parameters

The model parameters used in this work are the ones identified in Becerra-Celis et al. (2008). For more details on the system identification procedure the reader is referred to their work. Tables 1 and 2 contain the parameters for the microalgae and the total inorganic carbon dynamics, respectively.

Table 1. Model parameters for *Porphyridium purpureum* at 25 °C.

Parameter	Unit	Value
μ_{max}	h^{-1}	0.0337
E_{opt}	$\mu Es^{-1}(10^9 cell)^{-1}$	1.20
$[TIC]_{opt}$	$mmolel^{-1}$	12.93
$k_L a$	h^{-1}	41.40
C_1		0.28
C_2		−0.55

Table 2. Model parameters for [TIC] dynamics.

Parameter	Unit	Value
K_1		$1.02 \cdot 10^{-6}$
K_2		$8.32 \cdot 10^{-10}$
m	$h^{-1}mmole(10^9 cell)^{-1}$	0.004
$Y_{X/S}$	10^9 *cell per mole TIC*	198.1
$\mathcal{H}$	*atm l mole*$^{-1}$	34.03

4. BIOMASS ESTIMATION

Controlling a photobioreactor has some difficulties associated to the implicit nonlinear and time varying nature of the system. There are also problems with the practicability

to find reliable online sensors able to measure the state variables (Shimizu (1996)). To overcome the lack of online sensors, Becerra-Celis et al. (2008) show how to implement an Extended Kalman Filter (EKF) to estimate the biomass for the photobioreactor, described in Section 3, using the measurement of T.I.C.. In this work, it is shown how the use of an UKF gives better performance, particularly for continuous cultures. There are several reasons for which the UKF may be considered as an EKF alternative. There is no linearization procedure in the UKF, as can be seen in section 2.1. This is relevant when strong nonlinearities are present in the process because no linearization error is introduced. It is straightforward to extend the state estimation to joint estimation, just augmenting the estimated vector and covariance matrix, while calculation of system derivatives with respect to the parameters, are required in an EKF algorithm.

4.1 UKF applied to the photobioreactor

Using the UKF, described in Section 2.1, the main objective is to estimate the biomass X in the photobioreactor of Section 3. Focusing on the two different working conditions defined in Section 3.4, it is observed how in batch mode the UKF has an excellent performance, which also is the case for the EKF designed in Becerra-Celis et al. (2008). This is due to the fact that the model parameters are identified in batch mode, and the measurements have a constant sampling time. A more complex scenario appears for continuous cultures. The model parameters are still the ones from the batch experiments, and the experimental data are collected at variable instant intervals. Due to the variable time steps, Becerra-Celis et al. (2008) implements a continuous discrete version of the EKF. In this work, this problem is tackled in two steps. Firstly, a zero order hold is applied to the measurements, secondly the standard UKF algorithm is properly modified. More in detail, the discrete UKF algorithm with an augmented state to consider parameter estimation and process noise is implemented. The sigma points are recomputed in (15) and then used to obtain the predicted measurement in (16-17). Those modifications give the possibility to use the discrete algorithm with the irregular measurement sampling time of the continuous culture case. Furthermore, the parameter μ_{max} in (29) is chosen to be estimated. Finally, despite the fact that a zero order hold is used to permit a discrete UKF implementation, the UKF accuracy and speed of convergence are improved with respect to the EKF ones.

4.2 Simulation results with experimental data

The following results show the efficiency of the proposed method when the photobioreactor works either in batch mode or in continuous mode. Figure 2 illustrates the convergence of the UKF in simulated batch mode, for which conditions (30) hold. In this case the nonlinear model (23) is discretized at sampling time $T_s = 0.5\ h$ and used to simulate the state of the process, starting from initial conditions $X_0 = 2.44 \cdot 10^9 cell/l$, $[TIC]_0 = 2.55\ 10^{-3} mole/l$. After that, $[TIC]$ is corrupted by additive Gaussian white noise with standard deviation $\sigma = 0.2\ 10^{-3} mole/l$, and used as measurement for the UKF. Thus, the state is

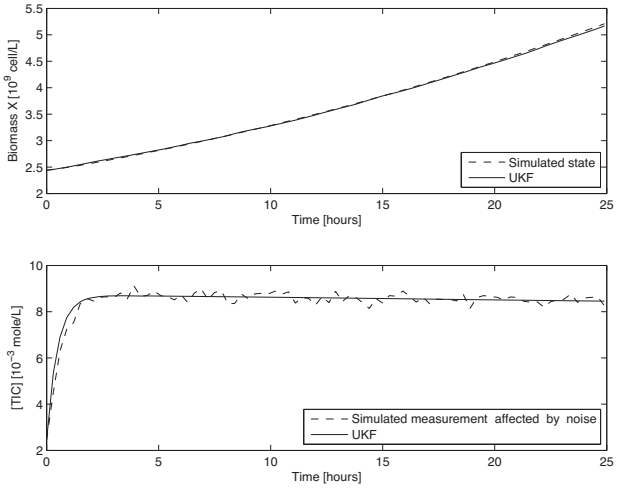

Fig. 2. UKF estimation for simulated batch mode.

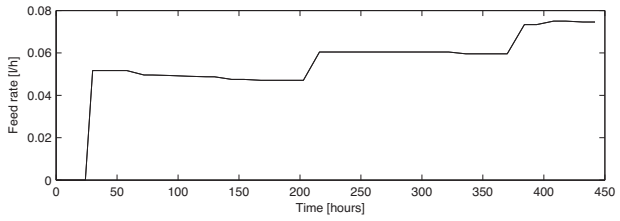
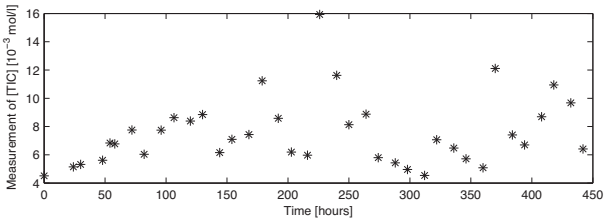


(a) Culture medium feeding profile



(b) Measurement of [TIC]

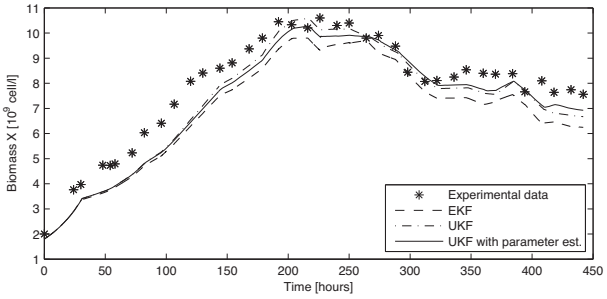
Fig. 3. Experimental data: input and output of the photobioreactor collected in continuous mode.

estimated successfully with excellent noise rejection in T.I.C.. The results obtained for continuous cultures are even more interesting. Initial conditions are $X_0 = 1.8 \cdot 10^9 cell/l$, $[TIC]_0 = 4.51 \cdot 10^{-3} mole/l$, and in addition real experiment data, presented in Figure 3, are used as input to the filters. The EKF designed in Becerra-Celis et al. (2008), the UKF with only state estimation, and the UKF with joint state and parameter estimation are simulated. The results obtained are shown in Figure 4 and here discussed. In Figure 4(a) it is noticeable how both UKF implementations have faster speeds of convergence than the EKF. In Figure 4(b) the state estimation error of the three different approaches are compared, and it is evident how the UKFs give smaller estimation errors. Moreover the mean squared error (MSE) between the biomass and its estimate is computed. Table 3 shows the MSE index, which is obtained averaging the MSE along the entire simulation period. From both figures it is noticeable how the UKF performs better than the EKF, and how the introduction

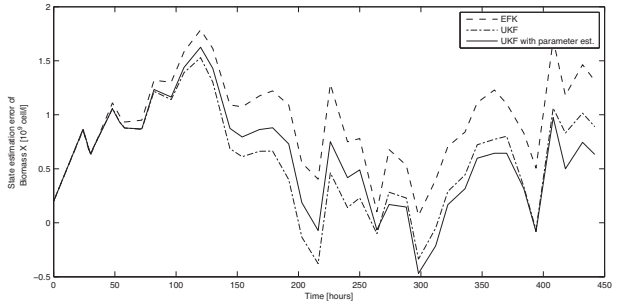
Table 3. Mean Squared Error Index

EKF	UKF	UKF with par. est.
13.60	6.12	6.12

of parameter estimation in the UKF improves the accuracy of the estimation in the final part (after 300 hours), although slightly reduces the speed of convergence. Since the parameters are identified from batch experiments, as shown in Becerra-Celis et al. (2008), adding parameter estimation may be useful when the photobioreactor is run in continuous mode. Figure 5 shows the evolution of the μ_{max} estimation, the estimated value is compared with the identified value and moreover the UKF error covariance is shown.



(a) Biomass estimate

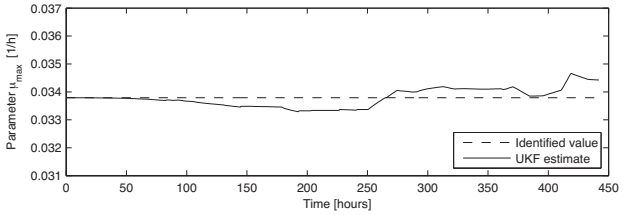


(b) State Estimation Error

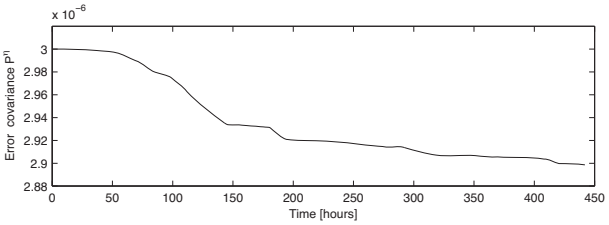
Fig. 4. Biomass estimation comparison for continuous cultures.

5. CONCLUSION

This work can be considered as an extension of Becerra-Celis et al. (2008), where the main objective is to design an efficient, reliable and applicable biomass estimator for a microalgae photobioreactor. A more recent nonlinear estimator (UKF) is used, obtaining improved results. In both batch and continuous mode, the approach presented produces a faster estimate convergence and a better estimate accuracy. The capacity and ease to introduce parameter estimation jointly with state estimation, the absence of linearization, the comparable computational complexity make the UKF an attractive estimator for nonlinear systems. The particular UKF framework described in section 2.1 showed to be well suited for the case when measurements, arriving at variable time instants, are subject to a zero holder filter. The extra set of sigma points calculated in (15) are needed to obtain a smoother estimate. Future work is needed to design a feedback based controller using



(a) UKF estimate and identified value of μ_{max}



(b) UKF error covariance of μ_{max}

Fig. 5. UKF parameter estimate and its covariance for continuous culture.

the UKF estimate, and to better understand which parameter would improve the filter performance without introducing observability issues. It is also interesting to explore how the UKF performs with other processes compared to the traditional methods in use in practice.

Abstract: Sludge incineration in fluidized bed is a very complex process, producing gaseous pollutants (carbon monoxide (CO) and nitrogen oxides (NOx)). The legislative norms need to be respected in spite of variations of sludge in composition and in quantity. The NOx formation, due to lots of chemical reactions from sludge nitrogen, is partly unknown. This paper deals with the design of a dynamic model of NOx emissions for a fluidized bed sludge combustor to be used in control strategy. The model is validated with industrial data, and the simulation results validate the simplification hypotheses, but need the reconstruction of sludge composition.

Keywords: sludge incineration, fluidized bed, NOx, chemical reaction, modelling, validation.

1. INTRODUCTION

The treatment and disposal of sewage sludge is an expensive and environmentally sensitive problem. It is also a growing worldwide problem since sludge production will continue to increase and since environmental quality standards become more stringent. Compared with landfill and agricultural compost, incineration presents some advantages: large volume reduction, stabilized ash production (heavy metals included) and toxic organic matters destruction. However to be economically viable, sludge has to be burned without fuel supply locally in wastewater treatment plant (Reimann, 1999).

Fluidized bed combustors are industrially largely used for coal, wastes and sewage sludge combustion (Werther and Ogada, 1999). The incineration process produces gaseous pollutants, mainly carbon monoxide (CO) and nitrogen oxides (NOx), which have to respect the legislative norms. Carbon monoxide formation can be limited by oxygen supply regulation, which is widely used in industrial plants. However, nitrogen oxides emissions should be controlled during combustion because its post-treatments are rather expensive. Linear dynamic models of coal combustion to be used in control strategy (Muir et al., 1997), (Bittanti et al., 2000) (Ikonen and Kortela, 1994), have showed that the combustion process presents a highly non linear behaviour, which needs a control strategy based on nonlinear models. Therefore, a suitable model has to be developed.

Models of coal combustion for simulation purpose (Gogebakan and Selçuk, 2004), (Huilin et al., 2000), (Adanez et al., 2001), and models of other fuels, as waste combustion (Marias et al., 2001), are based on accurate considerations on combustor hydrodynamics, which are highly complex and lead to models that do not fit to be used in control strategy. In addition, most of them target combustion efficiency without considering pollutant formation.

The sludge thermal decomposition in fluidized bed is based on the reference (Werther et Ogada, 1999). The NOx formation and reduction, due to lots of chemical reactions from sludge nitrogen, are partly unknown. Only one model, dedicated to biomass combustion (Liu and Gibbs, 2002), includes many chemical reactions of NOx formation and reduction, and will be our reference for reaction scheme. The proposed model is based on the molar and energy conservation balances, and is validated with industrial data.

2. MODEL DEVELOPMENT

2.1 Sludge thermal decomposition

A typical sludge analysis is shown in Table 1.

Table 1. Sludge analysis (Werther and Ogada, 1999).

Proximate analysis	
moisture (f_{H2O} wt% raw)	76.0
char (f_{char} wt% dry)	3.6
volatiles (f_{vol} wf% dry)	45.4
ash (f_{ash} wf% dry)	51.0

After entering the furnace, sludge is decomposed into four phases under heat effect: water vapour, char, volatiles and ash, which play different roles:

- To guarantee self-combustion, the sludge produced by the wastewater treatment process sludge is dewatered mechanically to about 76% of moisture (f_{H2O}).

- Sludge char, in a solid phase that can burn, presents a very low fraction (f_{char}), unlikely carbon and biomass chars. Based on numerous laboratory analyses, J. Werther and T. Ogada (Werther and Ogada, 1999) concluded that sludge combustion behaviour is mostly governed by the gaseous phase of volatiles. So char particles can be neglected.
- Volatiles fraction (f_{vol}) is large, the volatiles combustion lead to exothermic combustion and dominate the sludge combustion process, the furnace temperature and the air input.
- Ash fraction (f_{ash}) is large.

A composition of volatiles gas, issued from off-line studies, is presented in Table 2.

Table 2. Volatiles gas composition after sludge devolatilization at temperature 760°C (Werther and Ogada, 1999).

f_{CO} wt%	43.43
f_{CO2} wt%	15.39
f_{CnHm} wt%	31.12
f_{H2} wt%	3.20
Others	6.86

The chemical species, ammonia (NH_3) and cyanide (HCN), are responsible of NOx formation, and are generally not represented in volatiles. At a relatively low combustion temperature, and with a few char but many volatiles in fuel composition, NH_3 is the dominant specie (Aho *et al.*, 1993).

2.2 Fluidized bed combustor

The fluidized sludge combustor can be divided into two beds: bubbling fluidized bed and post-combustion bed, shown in fig. 1.

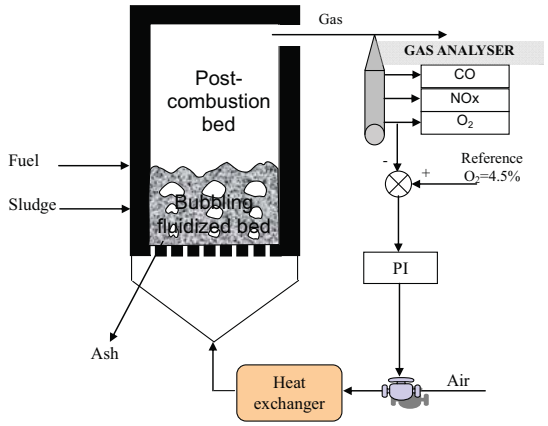

Fig. 1. Fluidized sludge combustor.

Sludge is introduced at the bottom of the furnace, i.e. the bubbling fluidized bed. Some fuel may be used as supply for starting combustion or for compensating sludge disturbances in composition or in flow. Air is preheated by a heat exchanger, and then injected with a sufficient velocity to insure the fluidization of inert sand in bubbling fluidized bed. High weight sand guarantees thermal inertia of the furnace and provides a great surface for sludge combustion and maintains a uniform temperature (~760°C). In the higher section, the post-combustion bed, volatiles gases continue post-combustion which increase the bed temperature (850°C-900°C). Temperature at the top of the furnace is limited up to 920°C, to avoid both furnace overheating and NOx formation.

The oxygen concentration is regulated up to 4.5% by air flow rate. This regulation loop provides an excess of oxygen which guaranties complete gas combustion, so as to avoid carbon monoxide (CO) formation.

On-line industrial measurements are sludge flow input in dry basis ($Q_{b,MS}^{in}$); air temperature input (T_a^{in}), air flow input (F_{am}^{in}), two bed temperatures (T^B, T^P), gas concentrations output (y_{O2} %, y_{CO} ppmv, y_{NO} mg.Nm^{-3}). As CO concentration is very low and its measurement presents lots of noise, unfortunately, this measurement can't be used for parameter estimation.

2.3 Modeling strategy and main hypothesis

The temperature and CO behaviors are described by combustion reactions. NOx formation and reduction can be considered as a separated model, using temperatures as input variables. Considering that two models has some advantages: they can be used simultaneously for simulation purpose, or separately for control purpose.

A difficulty is that sludge input flow is as constant as possible, and that sludge composition is not available on-line. So the dynamical behavior is only measured on the furnace outputs. We propose to reconstruct this composition with output measurements in the model.

As char particles can be neglected, the bubbling fluidized bed can be supposed perfectly mixed. The post-combustion bed is also approximated to a perfectly mixed reactor for model simplicity, but it is rather a plug flow reactor.

2.4 Chemical reactions

The reference (Liu and Gibbs, 2002) proposes 25 chemical reactions describing biomass combustion, including 20 reactions for NOx and N_2O formation and reduction. These reactions are selected and simplified with consideration on sludge specificities, as listed bellow:

- Due to low char content, the reactions using char as reactant and catalyst are all neglected.
- C_nH_m is supposed to be only CH_4. Its reaction is supposed to be complete in bubbling fluidized bed.
- Reaction of H_2 is supposed to be instantaneous and complete in bubbling fluidized bed.

- Catalyst as limestone (CaO), which is not used in sludge combustion, is not included.
- The lack of knowledge both on ash composition and its catalytic role (Tran et al., 2007) leads to suppose it chemically inert.
- N_2O can be decomposed rapidly in the post-combustion area where the temperature reaches 900°C. So N_2O is not considered in the model.

Five reactions are finally retained, as shown in table 3. The first reaction is NOx reduction, the second is NOx formation, and the last three are combustion reactions, which are independent from the NOx reactions. The first three reactions are supposed to be dynamically available, and the last two ones are supposed to be complete, so they do not need kinetic expression. The reactions R22, R23 and R24 are endothermic, their reaction enthalpies are noted as ΔH_{22}, ΔH_{23} and ΔH_{24}. The energy consumed or produced by the reactions R1 and R2 are negligible.

Table 3. Chemical reactions of sludge combustion model

No.	Reaction	Reaction rate r_i (mol.m^{-3}.s^{-1})	Enthalpies
R1	$NO + NH_3 + {}^1/_4O_2 \rightarrow N_2 + {}^3/_2 H_2O$	$r_1 = k_1[NH_3]^{0.5}[NO]^{0.5}[O_2]^{0.5}$	Negligible
R2	$NH_3 + {}^5/_4O_2 \rightarrow NO + {}^3/_2 H_2O$	$r_2 = k_2[NH_3][O_2]$	Negligible
R22	$CO + ½\ O_2 \rightarrow CO_2$	$r_{22} = k_{22}[CO][O_2]^{0.5}[H_2O]^{0.5}$	ΔH_{22}
R23	$CH_4 + {}^3/_2\ O_2 \rightarrow CO_2 + {}^3/_2 H_2O$	complete	ΔH_{23}
R24	$H_2 + ½\ O_2 \rightarrow H_2O$	Instantaneous	ΔH_{24}

The reaction rate r_i depends on the kinetic constant k_i and on the reactant concentrations. The kinetic constant k_i is given by the Arrhenius equation:

$$k = k_0 \exp(-\frac{Ea}{RT}) \quad (1)$$

Where k_0 is the pre-exponential factor or simply the *prefactor*, E_a is the activation energy, R is the perfect gas constant, R=8.31 J.mol^{-1}.K^{-1}, and T is the temperature (in Kelvin).

To simplify validation procedure, kinetic constant k_i is supposed to be constant in one bed, so the rate constant of reaction j in bubbling fluidized bed and post-combustion bed are named as k_j^B and k_j^P.

2.5 Combustion modelling

Combustion reactions are mostly responsible of temperature and oxygen concentration in the furnace. As the combustion reactions are independent of the NOx reactions, a model of combustion can be proposed individually.

After entering the furnace, sludge particles are decomposed physically and chemically at high temperature. Firstly, drying and devolatilization take place simultaneously, splitting sludge into species described previously in table 1 and table 2. Flux of gas species can be reconstructed:

$$\begin{bmatrix} F_{H_2O}^{in} \\ F_{CO}^{in} \\ F_{CH_4}^{in} \\ F_{H_2}^{in} \end{bmatrix} = \begin{bmatrix} Q_{b,MS}^{in} \dfrac{f_{H_2O}}{1-f_{H_2O}} / M_{H_2O} \\ Q_{b,MS}^{in} f_{vol} f_{CO} / M_{CO} \\ Q_{b,MS}^{in} f_{vol} f_{CH_4} / M_{CH_4} \\ Q_{b,MS}^{in} f_{vol} f_{H_2} / M_{H_2} \end{bmatrix} \quad (2)$$

Where F_i^{in} is the molar flow rate of component i after sludge drying and devolatilization, mol.h^{-1}; M_i is the molecular weight of component i, kg.mol^{-1}.

The volatile gas repartition is taken from table 2 without adaptation, though some relations between species fractions and temperature and fuel composition should be more realistic. With this assumption, only two sludge characteristics are needed: water fraction (f_{H2O}) and volatile fraction (f_{vol}). They are calculated by two static global balances: one is the balance of oxygen; the other is the balance of thermal energy, as shown in fig. 2.

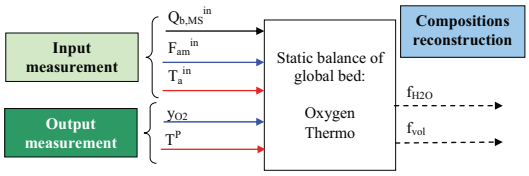

Fig. 2. Reconstruction f_{H2O} and f_{vol} from measurements (dashed line: unmeasured data, solid line: measured data).

Figure 3 presents the model structure. Three macroscopic inputs that can be easily measured (solid line): sludge flow rate in dry basis ($Q_{b,MS}^{in}$), air flow rate (F_{am}^{in}), input air temperature (T_a^{in}). State variables are gaseous species concentrations (C_{H2O}^B, C_{CO}^B, C_{O2}^B and C_{H2O}^P, C_{CO}^P, C_{O2}^P) and bed temperatures (T^B and T^P). Only four variables are measured (solid lines: C_{CO}^P, C_{O2}^P, T^B and T^P).

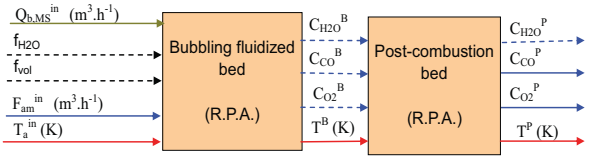

Fig. 3. Structure of combustion model (dashed line: unmeasured data, solid line: measured data).

The combustion model is written by molar and energy conservation balances (^{B} bubbling bed, ^{P} post-combustion):

$$\begin{pmatrix} \dfrac{dC_{H_2O}^B}{dt} \\ \dfrac{dC_{CO}^B}{dt} \\ \dfrac{dC_{O_2}^B}{dt} \end{pmatrix} = \begin{bmatrix} F_{H_2O}^{in} \\ F_{CO}^{in} \\ F_{O_2}^{in} \end{bmatrix} / V_B - \begin{pmatrix} C_{H_2O}^B \\ C_{CO}^B \\ C_{O_2}^B \end{pmatrix} \times \frac{F_g^B}{V^B} + \begin{pmatrix} \varphi_{H_2O}^B \\ \varphi_{CO}^B \\ \varphi_{O_2}^B \end{pmatrix} \quad (3)$$

$$\begin{pmatrix}\varphi^B_{H_2O}\\ \varphi^B_{CO}\\ \varphi^B_{O_2}\end{pmatrix}=\begin{bmatrix}0\\ -1\\ -0.5\end{bmatrix}\times r^B_{22}+\begin{pmatrix}F^{in}_{H_2}+2F^{in}_{CH_4}\\ F^{in}_{CH_4}\\ -0.5F^{in}_{H_2}-1.5F^{in}_{CH_4}\end{pmatrix}/V_B \quad (4)$$

Where F_{O2}^{in} is the oxygen molar flow rate brought by input air flow, mol.h^{-1}; F_g^{in} is the global gas flow rate (calculated by a global static balance on input and output flows), m^3.h^{-1}; V_B is the bubbling bed volume, m^3; φ_i^B is the production or consumption flux of component i by chemical reactions; r_{22}^B is the reaction rate of R22 (see table 3).

$$\begin{aligned}c_{ps}m_s^B\frac{dT^B}{dt}&=\left(c_{pa}F^{in}_{am}\rho_{a(T^{in}_{am})}T^{in}_a+c_{pb}\frac{Q^{in}_{b,MS}}{1-f_{H_2O}}T^{in}_b\right)\\&-\left(c_{pg}\rho_{g(T^B)}F^B_gT^B+c_{p,ash}Q^{in}_{b,MS}(1-f_{vol})T^B\right)\\&-\left(F^{in}_{H_2O}L_{H_2O}\right)-\left(r^B_{22}\Delta H_{R22}V^B+F^{in}_{CH_4}\Delta H_{R23}+F^{in}_{H_2}\Delta H_{R24}\right)\end{aligned} \quad (5)$$

Where c_{ps}, c_{pa}, c_{pg} and $c_{p,ash}$ are specific heat capacities of sand, air, gas and ash, J.kg^{-3}.K^{-1}; m_s^B is the sand mass in bubbling fluidized bed, kg; ρ is the density, kg.m^{-3}; L_{H2O} is the water latent heat of vaporisation, J.mol^{-1}.

Post-combustion balances can be similarly written:

$$\begin{pmatrix}\frac{dC^P_{H_2O}}{dt}\\ \frac{dC^P_{CO}}{dt}\\ \frac{dC^P_{O_2}}{dt}\end{pmatrix}=\begin{pmatrix}C^B_{H_2O}F^B_g-C^P_{H_2O}F^P_g\\ C^B_{CO}F^B_g-C^P_{CO}F^P_g\\ C^B_{O_2}F^B_g-C^P_{O_2}F^P_g\end{pmatrix}/V^P+\begin{pmatrix}\varphi^P_{H_2O}\\ \varphi^P_{CO}\\ \varphi^P_{O_2}\end{pmatrix} \quad (6)$$

$$\begin{pmatrix}\varphi^P_{H_2O}\\ \varphi^P_{CO}\end{pmatrix}=\begin{bmatrix}0\\ -1\end{bmatrix}\times r^P_{22} \quad (7)$$

$$\begin{aligned}c_{pg}m_g^P\frac{dT^P}{dt}&=\left(c_{pg}\rho_{g(T^B)}F^B_gT^B-c_{pg}\rho_{g(T^P)}F^P_gT^P\right)\\&-\left(r^P_{22}\Delta H_{R22}V^P\right)\end{aligned} \quad (8)$$

Only kinetic parameters (k_{22}^B and k_{22}^P) need to be estimated, other parameters are known from literature.

2.6 NOx modelling

As the combustion model has modelled the bed temperatures and the oxygen concentrations, which can be used as inputs of the NOx model. They are provided either from the combustion model or directly by measurements.

The NOx model can be then established and simulated independently of the combustion model, as shown in fig.4.

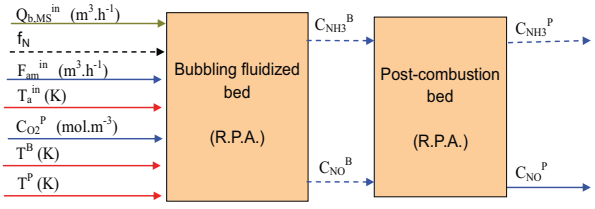

Fig. 4. Structure of NOx model.

One input cannot be measured on-line: the sludge nitrogen content (f_N), it is supposed to change slightly, and may be an additional parameter to be estimated. State variables are gaseous nitrogen species (C_{NH3}^B, C_{NO}^B, C_{NH3}^P and C_{NO}^P) among which only one is measured (C_{NO}^P).

After devolatilization, flux of NH_3 is reconstructed:

$$F^{in}_{NH_3}=Q^{in}_{b,MS}f_{vol}f_N/M_N \quad (9)$$

The balance equations are:

$$\begin{pmatrix}\frac{dC^B_{NH_3}}{dt}\\ \frac{dC^B_{NO}}{dt}\end{pmatrix}=\begin{pmatrix}F^{in}_{NH_3}\\ 0\end{pmatrix}/V_B-\begin{pmatrix}C^B_{NH_3}\\ C^B_{NO}\end{pmatrix}\times\frac{F^B_g}{V^B}+\begin{pmatrix}\varphi^B_{NH_3}\\ \varphi^B_{NO}\end{pmatrix} \quad (10)$$

$$\begin{pmatrix}\varphi^B_{NH_3}\\ \varphi^B_{NO}\end{pmatrix}=\begin{bmatrix}-1 & -1\\ -1 & 1\end{bmatrix}\times\begin{pmatrix}r^B_1\\ r^B_2\end{pmatrix} \quad (11)$$

$$\begin{pmatrix}\frac{dC^P_{NH_3}}{dt}\\ \frac{dC^P_{NO}}{dt}\end{pmatrix}=\begin{pmatrix}C^B_{NH_3}F^B_g-C^P_{NH_3}F^P_g\\ C^B_{NO}F^B_g-C^P_{NO}F^P_g\end{pmatrix}/V^P+\begin{pmatrix}\varphi^P_{NH_3}\\ \varphi^P_{NO}\end{pmatrix} \quad (12)$$

$$\begin{pmatrix}\varphi^P_{NH_3}\\ \varphi^P_{NO}\end{pmatrix}=\begin{bmatrix}-1 & -1\\ -1 & 1\end{bmatrix}\times\begin{pmatrix}r^P_1\\ r^P_2\end{pmatrix} \quad (13)$$

Only kinetic parameters (k_1^B, k_1^P, k_2^B and k_2^P) need to be estimated, other parameters are known from literature.

3. VALIDATION

3.1 Validation strategy

Because of bad numerical results, it is not possible to simulate the model with the parameters at their literature values. The proposed validation strategy is based on some physical considerations and sensitivity analysis. As the number of parameters is numerous, only some kinetic parameters are estimated. This choice is made on the consideration that they influence directly the dynamic behaviour of the model, and that the literature values were proposed from chemical engineering laboratory analysis of coal combustion, which means that the identified values may very different.

Another important choice was to identify the parameters with two separated models or with a global one. In the first step, we choose the first solution considering that NOx content can't influence the furnace temperature. In addition, temperature is difficult to be estimated accurately with a model, though its measurement is quite reliable. Some attempts for identification with the global model have not improved the results. The main drawback of validation is that part of sludge composition (f_N, f_H) has to be fixed for each data set. Now it is adjusted by trial and error, but it would have to be further included in global parameters.

3.2 Industrial data file for parameter estimation

Two industrial data files of an industrial fluidized sludge combustor with different events are used for parameters estimation and model validation. The data used for identification corresponds to the introduction of fat matters in furnace. Model input measurements are shown in fig. 5.

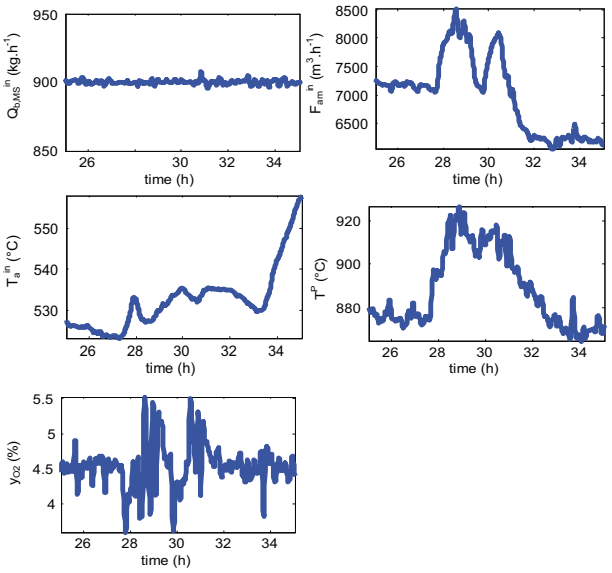

Fig. 5. Measurements of model input of data file 1.

Sludge flow ($Q_{b,MS}^{in}$) in Fig. 5 is constant, which is a necessity as sludge has to be treated continuously. The dynamic event is revealed by output measurements, which affect the input by the heat exchanger (T_a^{in} is defined by T^P) and the oxygen control loop (F_{am}^{in} is the action which regulates y_{O2}). The post-combustion temperature presents an increasement due to the dynamic event. The oxygen concentration (y_{O2}) is regulated at reference point 4.5%.

3.3 Parameter estimation methodology

For parameter estimation, minimisation of a least square criterion on the difference between the measured value and the model value has been carried out.

For combustion model, only temperature to be used is T^B, as T^P is used to reconstruct the sludge compositions f_{H2O} and f_{vol}. Consequently, the parameter k_{22}^P, can't be estimated. Some additional measurements, such as y_{CO}, may be useful for estimating this parameter. In the model, k_{22}^P is taken as a great value to guarantee a complete CO combustion, because CO in the measurement is almost null in the sake of oxygen regulation.

For NOx model, four kinetic parameters k_1^B, k_2^B, k_1^P and k_2^P need to be identified. Their literature values, calculated from steady temperature values (T^B=752°C, T^P=870°C) are presented in table 4.

Table 4. Literature values of parameters to be estimated

$k_1^B = 0.4$	$k_1^P = 7.2$
$k_2^B = 0.02$	$k_2^P = 0.87$

Because of the great number of parameters to be estimated with only one measured data y_{NO}, a sensitivity analysis is made to select the more influent parameter. Figure 6 shows that k_1^P is the most sensitive parameter with respect to y_{NO}. Finally, only the parameter k_1^P is estimated as a constant, the others are used with their reference values.

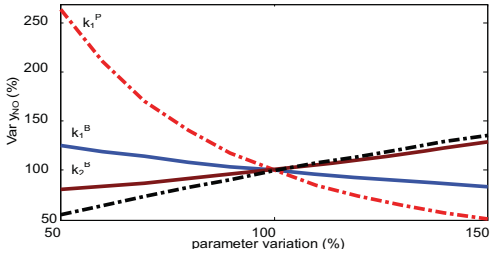

Fig. 6. Sensitivity analysis of k_1^B, k_2^B, k_1^P and k_2^P with respect to y_{NO}.

3.4 Estimated Parameters

The initial value of k_{22}^B=$3.25\times10^7\exp(-15098/T^B)$ (14)

Which lead the equation (15) after estimation:

k_{22}^B=$(2211\pm5)\exp(-(7743\pm2)/T^B)$ (15)

The estimated value of k_1^P:

k_1^P=0.9981 ± 0.0035 (16)

The estimated values are all very small compared to the literature values. These differences can be attributed to the great simplifications of chemical reactions: neglected char, instantaneous and complete reactions of H_2 and CH_4 in the bubbling bed, which need to slow the global combustion reactions. For post-combustion, perfectly mixed reactor may also be revised. Some tests with other initial values have leading the same results. However, the precision interval points out that no better values can be estimated.

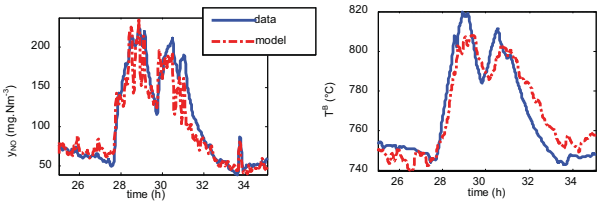

Fig. 7. Comparison of data file and model with kinetic parameter estimated k_{22}^B and k_1^P.

With the estimated values in equation (15) and (16), simulation results are shown in fig. 7. Bubbling fluidized bed temperature (T^B) in combustion model is tracking well the measurement, and NOx model fits also very well the measured data. In conclusion, we can consider that the model

is realistic and these results are good enough to continue a validation step.

3.5 Validation with data file 2

The main characteristic of data file 2 (fig. 8) is an increase of the operating point: NOx concentration exceeds the norm of 400 mg.Nm^{-3}, post-combustion bed temperature (T^P) is upper the limitation value of 920°C. The sludge flow rate ($Q_{b,MS}^{in}$) remains constant at 900 kg.h^{-1} and is not represented. The air flow rate (F_{am}^{in}) and the oxygen concentration present small fluctuations around a reference point.

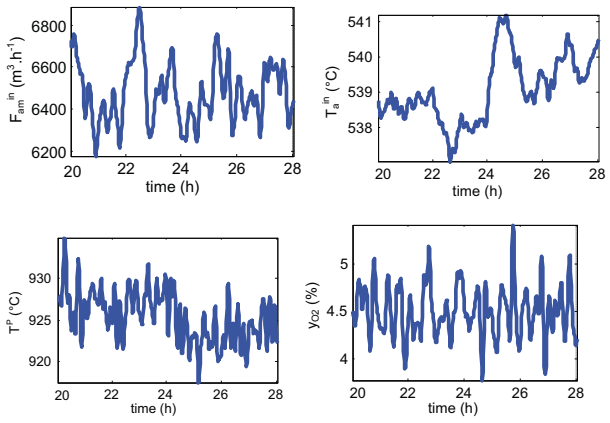

Fig. 8. Measurements of model input of data file 2

When analysing the measurements, we can notice that the bed temperatures increase greatly but fewer oxygen is consumed due to perturbation reconstruction of water fraction and volatile fraction. Trying to translate this behaviour in the model, the following adjustments are made: the hydrogen fraction (f_{H2}) after devolatilization is decreased from 3.2% to 2% (see table 2), the nitrogen fraction (f_N) is increased from 1% to 2.5%. Both corrections are used to fill up the unknown perturbations.

Figure 9 compares the simulation results with the measurements. We can see that the global tendency is good, and that means that our model is able to fit the data. The fluctuations observed for the model are due to algebraic equations for the reconstruction of f_{H2O} and f_{vol}. The main drawback is that the lack of knowledge on the input composition is a major obstacle to such modelling.

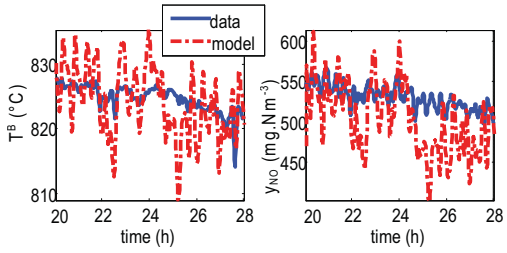

Fig. 9. Model validation.

4. CONCLUSIONS

A dynamic model of fluidized bed sludge combustor has been designed to predict NOx emissions. The main hypothesis is the lack of reactant particles in the furnace, leading to only five chemical reactions and simplifying hydrodynamics into two perfectly mixed reactors. As the sludge composition is not available, it has been reconstructed with output measurements. This point represents the main drawbacks of the model: more knowledge on devolatilization and/or more output measurements would be very helpful to have a deterministic model. However this model has been partly validated with industrial data files, and it is sufficiently representing the NOx formation behaviour, to be used in a control strategy and therefore to contribute to improve combustion quality and control NOx emissions.

Abstract: This study investigates different modeling approaches and compares for drying of baker's yeast in a fluidized bed dryer. Four modeling concepts were investigated: modeling based on the mass and energy balance, modeling based on diffusion mechanism in the granule, modeling based on recurrent Artificial Neural Network (ANN) and modeling based on Adaptive Neural Network Fuzzy Inference System (ANFIS). Dry matter of product, product temperature and product quality were predicted using these model structures. To evaluate performances of the modeling structures, industrial scale drying process data were used.

Keywords: Drying process, spatial distribution, product quality, modeling, ANN, ANFIS

1. INTRODUCTION

Biological products, such as agricultural products, foods, pharmaceuticals, enzyme preparations, bacterial and yeast cultures, are particularly sensitive to drying conditions, including moisture content and temperature (Yüzgeç et al., 2008). There are different modeling concepts for the drying processes reported in the literature. In general, three possible approaches can be taken to the modeling: a physical approach based on energy and mass balance (Temple et al., 2000; Türker et al., 2006), black-box modeling (Castellanos et al., 2002; Köni et al., 2009) and hybrid modeling (Ciesielski et al., 2001). In contrast with the physical approach, the black-box modeling approach does not require prior theoretical knowledge.

The objective of this study is to examine alternative and novel modeling techniques based on the physical approaches and based on mathematical approaches, such as ANN and ANFIS structures, for an industrial-scale drying process of baker's yeast. Four model structures which are different from each other were investigated. First model was developed by using mass and energy balances in the fluid-bed. The second mathematical model is based on the spatial distribution of moisture, temperature and quality. In the third model, the recurrent ANN structure was selected according to the results of the regression analysis in their study presented by Köni et al.(2009). The last model is constructed using ANFIS architecture. The vast numbers of industrial data (570 data sets) used for training and testing of the models were collected from a production-scale baker's yeast drying process. As a result of this work, advantages and disadvantages of the model structures investigated for drying process were presented.

2. MATHEMATICAL MODELS

2.1 Model based on mass and energy balances

Model equations are constructed by combining mass and energy balances (Temple and Boxtel, 1999; Kanarya, 2002).

The model equations consist of four basic balance equations: Dry solid balance, water conservation, air conservation and energy balance. All of these equations are presented below:

$$\frac{dM_{b,y}}{dt} = m_y^i - m_y^o \tag{1}$$

$$\frac{dW_{b,y}}{dt} = w_y^i - r_w - w_y^o \tag{2}$$

$$\frac{dM_{b,a}}{dt} = m_a^i - m_a^o \cong 0 \tag{3}$$

$M_{b,y}$ is dry solid mass of product in the bed and m_y^i is the flow rate of the product into the bed and m_y^o is the flow rate of the product out of the bed. $W_{b,y}$ represents the water mass inside the bed, w_y^i is the flow rate of water in product fed to the system, r_w is the flow rate of water removed from product by means of evaporation, and w_y^o represents the flow rate of water in product entrained through cyclones. $M_{b,a}$ is the mass of air in the bed, m_a^i, m_a^o represent the flow rates of the inlet and outlet air.

The energy accumulation of the process H is assumed as adiabatic. The energy accumulation in the bed can be written as dynamic balance between energy flows to and from the system as given in Eq.(4):

$$H = h_y^i + h_a^i - h_y^o - h_a^o. \tag{4}$$

In this equation, h_a^i represents the energy introduced by air, h_y^i is the energy introduced by yeast, h_a^o is the energy removed by air and h_y^o represents the energy removed by yeast. The detail informations related to this model can be found in the paper presented by Türker et al. (2006).

2.2 Model based on spatial distributions of moisture and quality

This modeling of the drying comprises four main parts: moisture diffusion equation, heat balance equation, shrinking model, product activity in the granule. The model also includes dependence of the moisture and temperature of granules on several parameters like moisture diffusion coefficient, heat and mass transfer coefficients and water activity. The batch fluidized bed is assumed to be an ideally mixed bed, with uniform temperature and humidity of the air which equal the outgoing air conditions. The particles are all at the same stage of drying at any instant of the batch operation. Furthermore, there is no interaction between the particles, as far as drying is concerned (Yüzgeç et al., 2008).

A generalized formulation of the moisture diffusion equation is presented by a nonlinear partial differential equation (Schoeber, 1976) as given below:

$$\frac{\partial(\rho_s X)}{\partial t} = \frac{1}{r^v}\frac{\partial}{\partial r}\left(r^v \rho_s D(X,T)\frac{\partial X}{\partial r}\right). \tag{5}$$

X (*kg water/kg dry solid*) is the moisture content inside the granule, *D* (m^2/s) is the moisture diffusion coefficient which is the function of material's moisture content (*X*) and temperature (*T*) and *v* represents geometry factor with *v* = 0 slab, *v* = 1 cylinder, *v* = 2 sphere. The initial and boundary conditions:

$$t = 0; 0 \le r \le R_d \Rightarrow X(0,r) = X_0 \tag{6}$$

$$t > 0 \Rightarrow \left.\frac{\partial X}{\partial r}\right|_{r=0} = 0 \tag{7}$$

$$t > 0 \quad r = R_d \Rightarrow j_{m,i} = -D\rho_s \left.\frac{\partial X}{\partial r}\right|_{r=R_d} = k\left(\rho_{wv,i} - \rho_{wv,g}\right). \tag{8}$$

$j_{m,i}$ is the moisture flux at the interface, *k* is the liquid film mass transfer coefficient around the granule, $\rho_{wv,i}$ represents the water vapor concentration at the interface and $\rho_{wv,g}$ represents the water vapor concentration in the bulk air.

The heat balance can be described as heat transfer both to and from the surface and within the material. The equation of the heat balance inside a granule is described by the following non-linear partial differential equation (Quirijns et al., 1998; Quirijns et al., 2000),

$$\frac{\partial(T(\rho_s c_{p,s} + \rho_m c_{p,m}))}{\partial t} = \frac{1}{r^v}\frac{\partial}{\partial r}\left(r^v \lambda \frac{\partial T}{\partial r}\right) \tag{9}$$

where *T* is the temperature, ρ_m is the moisture concentration, ρ_s is the dry solid concentration inside the granule, $c_{p,s}$ and $c_{p,m}$ are the heat capacities of the solid and moisture, λ is the thermal conductivity of the granule. The initial and boundary condition are given by

$$t = 0; 0 \le r \le R_d \Rightarrow T(0,r) = T_0 \tag{10}$$

$$t > 0 \Rightarrow \left.\frac{\partial T}{\partial r}\right|_{r=0} = 0 \tag{11}$$

$$t > 0 \quad r = R_d \Rightarrow j_{T,i} = -\lambda \left.\frac{\partial T}{\partial r}\right|_{r=R_d} \tag{12}$$

$$j_{T,i} = \alpha(T(t,R_d) - T_a) + \Delta H_v\big|_{T(t,R_d)}\, j_{m,i} \tag{13}$$

where $j_{T,i}$ is the heat flux at the interface, α is the heat transfer coefficient, T_a is the inlet air temperature and ΔH_v is the evaporation enthalpy of water.

The product quality can be described as first-order kinetics (Lievense, 1991):

$$\frac{dQ}{dt} = -k_e Q \tag{14}$$

where *Q* is the concentration of the active product and k_e is the specific rate of product activity. According to the Arrhenius equation, the rate of the product activity can be expressed as a function of the temperature (Liou et al., 1984). Lievense (1991) has described that following equation for dependency of $\ln(k_e)$ on temperature and moisture:

$$\begin{aligned}\ln(k_e) = &\left[\left(a_1 - \frac{a_2}{RT}\right)X + \left(b_1 - \frac{b_2}{RT}\right)\right] \\ &+ \left[1 - \exp\left(pX^q\right)\right]\left[\left(a_3 - \frac{a_4}{RT}\right)X + \left(b_3 - \frac{b_4}{RT}\right)\right]\end{aligned} \tag{15}$$

where *p, q, a_i, b_i* are the parameter values in the equation. If *p<0* and $q \ge 1$, at high moisture content, $\exp\left(pX^q\right) \approx 0$ and $\ln(k_e)$ consists of the linear sum of the two parts; at low moisture content, $\exp\left(pX^q\right) \approx 1$ and $\ln(k_e)$ is described with the first linear part of the equation.

The volume of the granule consists of volumes of both moisture and solid:

$$V = V_m + V_s \tag{16}$$

According to Coumans (1987), the volume of the granule is a linear function of the average moisture content $\overline{X}$ during shrinkage that is expressed by

$$V = V_s\left(1 + \tau \frac{d_s}{d_m}\overline{X}\right) \tag{17}$$

where τ is the shrinkage coefficient within $0 \le \tau \le 1$. The detail informations related to this model can be found in the paper presented by (Yüzgeç et al., 2008).

2.3 Model based on Artificial Neural Network (ANN)

The fifteen different ANN structures were investigated in the study introduced by Köni et al. (2009) in order to determine the suitable model which represents drying process. The essential differences for all of the proposed ANN structures are in the input layer and in the relations of the hidden layers. The ANN-9 model had the best performance according to the results of regression analysis of all model approaches. Fig.1 presents the architecture of this ANN model. This recurrent neural network model has nine layers each of whose hidden neurons are twelve and it consists of five inputs and three outputs (*DM* is dry matter of product (%), T_m is product temperature (^oC) and ΔDM is change in dry matter of product).

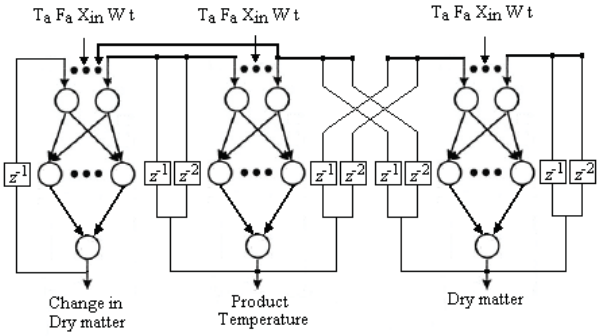

Fig.1. Drying model architecture designed using recurrent ANN. *t*: the drying time (s), *W*: loading (kg), X_{in}: moisture content of inlet air (kg water/kg air), F_a: flow rate of inlet air (m^3/h) and T_a: temperature of inlet air (^oC).

The drying process should be performed under optimal conditions in order to minimize quality loss. The change in the quality loss (ΔQ) is given as:

$$\Delta Q = \frac{Q_n - Q_f}{Q_n} \tag{18}$$

where Q_n is the quality at the beginning of the drying and Q_f is final quality at the end of the drying. In the industrial scale production, product quality is measured at the beginning and at the end of the drying process. In this study, a neural network model with three layers was used as quality model based on the results of regression analyses done by Köni et al. (2009). In this model shown in Fig.2, the inputs were considered as the process output variables, such as dry matter of product (*DM*) and product temperature (T_m). The values of dry matter and product temperature were stored in each drying time and a database forms for the product quality obtained at the end of the process. The inputs of quality model are all sampled values of dry matter of product *DM(i)* and product temperature $T_m(i)$, i denotes the sample in a drying period (Köni et al., 2009).

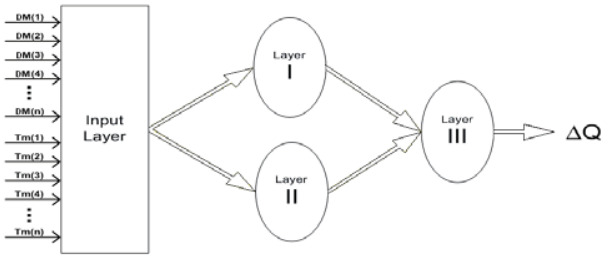

Fig. 2. Architecture of ANN model for quality.

The first layer represents the quality effect of drying on baker's yeast and the second layer denotes the effect arising from fermentation process. The tansig functions in layer 1 and layer 3 and logsig function in layer 2 are used as activation functions.

2.4 Model based on Adaptive Neural Network-Based Fuzzy Inference System (ANFIS)

The basic difference between ANFIS and ANN architecture is that ANFIS has a single output. This means that different ANFIS structures are constructed for each output parameter to be predicted, without changing the input parameters. Five input parameters were applied to the proposed ANFIS model approach: drying time, loading weight, moisture content of inlet air, flow rate of inlet air and temperature of inlet air. ANFIS structures were constructed separately for fuzzy modeling to predict the dry matter of the product (*DM*), the product temperature (T_m) and the change in dry matter of the product (ΔDM). In Fig. 3, the ANFIS architecture proposed for the dry matter of the product is given in detail. A_i, B_i, C_i, D_i and E_i (i = 1,2,3) represent the drying time (t), loading weight (W), moisture content of inlet air (X_{in}), flow rate of inlet air (F_a) and temperature of inlet air (T_a) membership functions, respectively.

All of the outputs are predicted by linear output functions. The ANFIS structures are the same for the other two output parameters, namely, *Tm* and *ΔDM*. Only output parameters change, while the inputs are kept the same. In this model, all of the ANFIS structures have five inputs and a single output, using the Sugeno-type fuzzy model. Three membership functions are defined for each input parameter. Although the model causes overloads during operation, all output membership functions were defined as first-order (linear). In the neuro-fuzzy model, the parameters associated with each membership function were adjusted by a hybrid learning algorithm consisting of a combination of least-squares and back propagation gradient descent methods. This algorithm used back propagation for the parameters related to the input membership functions and least squares estimation for the parameters related to the output membership functions (Jang, 1993; Azeem et al., 2000). As a result of using the hybrid learning algorithm, the training error decreased during the learning process.

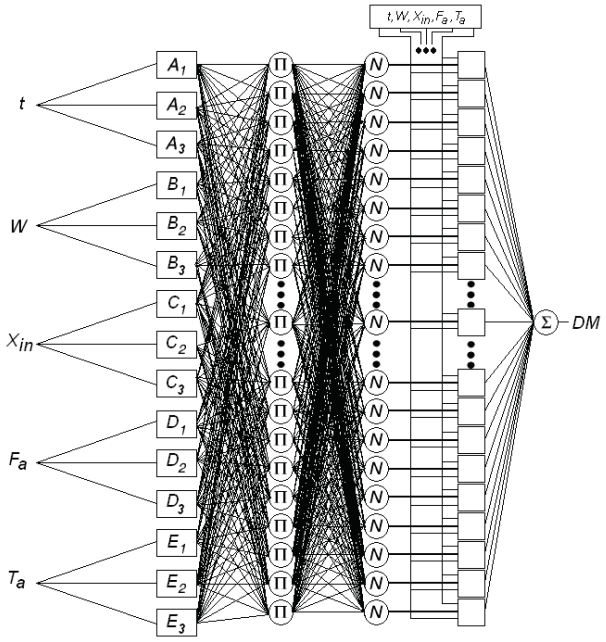

Fig. 3. Inputs and output of fuzzy model structure for dry matter of product (*DM*).

3. MATERIALS & METHODS

Data obtained from an industrial scale drying plant, which is produced baker's yeast (*Saccharomyces cerevisiae*), were used to test the models in this study. Yeast cake was extruded into the dryer through a perforated plate of a different diameter to obtain the desired granule size (Türker et al., 2006). In general, baker's yeast with a value of 33-34% dry matter prior to loading in the dryer eventually dried to a value of 94-96% dry matter. The fluid bed contained a centrifugal fan to supply air drawn from the ambient air. There are two essential output parameters for the drying processes: moisture content and product temperature. The product temperature was measured by Pt-100 sensors in the fluid bed. The temperature on the dryer outlet was also measured regularly. Moisture content is more difficult to measure than temperature. Infrared sensors are used to measure the moisture content in the drying material at third drying stage. The data set consisted of measurements obtained from the dryer under different loading conditions and different air profiles over one year of training and testing for the ANN and ANFIS model approaches. The sampling period of the data collection was 30 seconds.

The quality of the product was defined as the volume of carbon dioxide produced per unit time upon introduction of the yeast into the dough. This method is commonly used in the yeast industry to assess the performance of baker's yeast (Yüzgeç et al., 2008). To measure product quality, yeast samples are taken from the dryer at specific times during the drying, and then the volume of carbon dioxide in the laboratory is measured. Relative activity is expressed as the ratio of the activity of the product at time t to the activity of the yeast cake at the beginning time of the drying. A database which consists of 570 data was divided into the two parts: 60% training and 40% testing (Köni et al., 2009).

The first mathematical model is based on the first order ordinary differential equation with initial and boundary conditions. Therefore Runge-Kutta finite difference method has been used for the solution of the equation describing product temperature (Türker et al., 2006). There are two nonlinear partial differential equations in the second mathematical model. Due to the complex nature of the analytical solutions, numerical methods especially Crank-Nicholson method were used for the solution of non-linear partial temperature and moisture diffusion (Yüzgeç et al., 2008). The equations were subject to a Robin boundary condition. The mass flux at the interface is variable in the Robin type boundary condition. The sample time was chosen as one second and the particle was divided into ten grids.

4. RESULTS & DISCUSSION

To evaluate the performances of developed model structures, outputs of the models (dry matter of product and product temperature) were compared with the industrial scale data obtained from drying process of baker's yeast. Fig.4 show the simulation results for the energy and mass balance based model and the spatial distributions of moisture and quality based model.

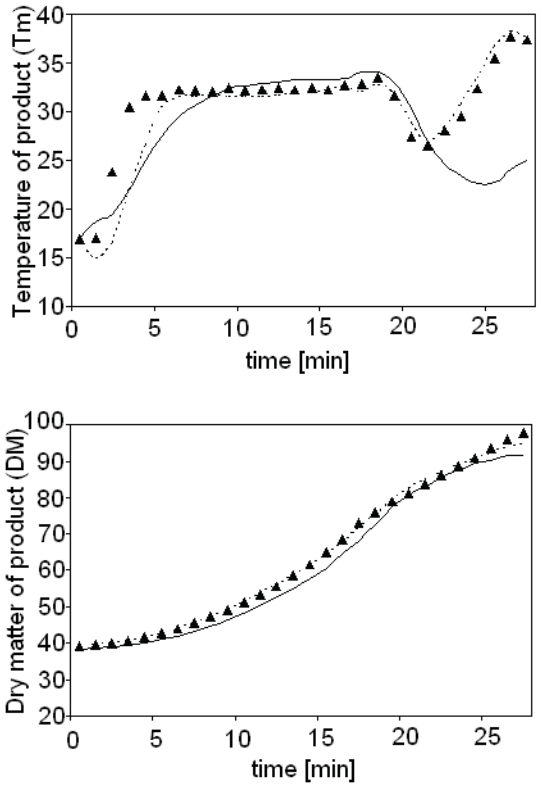

Fig. 4. Simulation results of the energy and mass balance based model (—) and granule based model (---). Industrial data (▲).

Note from this figure that there is good correspondence between the results obtained by developed model approaches and experimental data. Compared to the energy and mass balance based model, the granule based model significantly improves the predictions during the drying of granular product with spatial distribution of moisture. The simulation result of ANN based model is shown in Fig.5, together with experimental data chosen randomly from the database. The features of this experimental data is: loading weight 550-650 kg, moisture content of inlet air 0.0037-0.0056 kg water/kg air, flow rate of inlet air 34000-47500 m^3/h and temperature of inlet air 54-132 ^{0}C. In these figures, the predicted values for the drying process match very well with the experimental data; the differences can only be seen on a much finer scale. Comparison between the simulation results obtained by ANFIS based model and experimental data set is presented in Fig. 6. It can be seen from these figures that the ANFIS based model approach has a little more performance than that of the ANN based model. There is no vital difference between the results of the last two model structures. Both of them can be used as alternatives to one another with respect to response time and system definition. ANFIS based models have more advantages due to their adaptive structure.

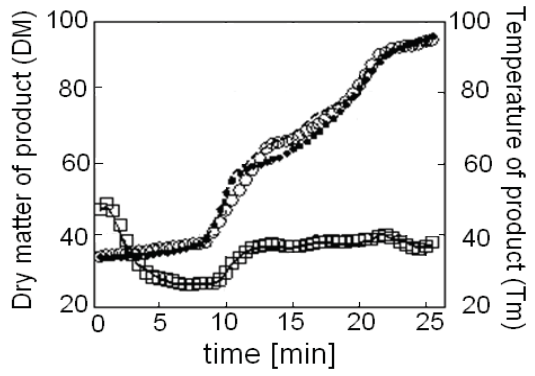

Fig. 5. The simulation results of the ANN based model. *DM* experimental, (o) *DM* simulation (---), *ΔDM* simulation (•••), T_m experimental (□),T_m simulation (—).

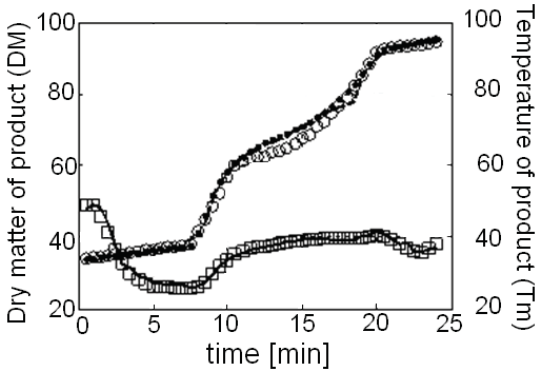

Fig. 6. The simulation results of the ANFIS based model. *DM* experimental, (o) *DM* simulation (---), *ΔDM* simulation (•••), T_m experimental (□),T_m simulation (—).

For modeling of the product quality loss or product activity using ANN and ANFIS approaches, which is the most difficult variable in the design of a proper physical model for biomass drying, only the ANN based model was used because ANFIS based model has a serious operational load in the training process. In energy and mass balance based model and ANFIS based model, the product quality is not used among the model outputs. Fig.7 shows the profiles of the product activity, which was obtained by drying model based on spatial distribution of quality and moisture inside the granule, according to the drying time and radial distance. The average product activity during drying is also presented in this figure with experimental data. As can be noted this figure, the product activity is retained at the surface of the granule due to the diffusion limitation of the drying process. Accordingly, the product activity is preserved in a thin layer at the surface of the granule. The product activity is decreased from the surface of the granule to the center. Fig. 8 shows that the comparison of real industrial data related to the change of the quality loss and simulation results of the ANN based quality model. For entire experimental data, it can be shown from this figure, the performance of the ANN based model is quite satisfactory.

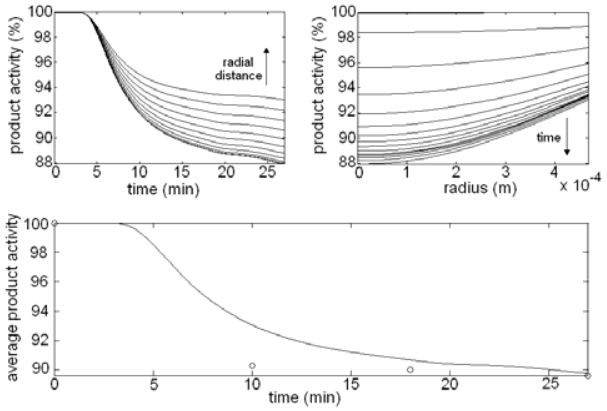

Fig. 7. The profiles of the product activity in the granule and average product activity for the model based on the spatial distribution of product activity. Experimental data (o), drying time 27 min, $R_0 = 5.10^{-4}$m, $X_0 = 1.563$ kg/kg, $T_0 = 16.9^oC$.

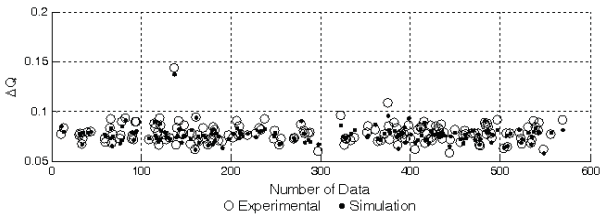

Fig.8. The change in the quality loss (ΔQ) obtained by ANN based quality model with experimental data.

The average root mean square error (RMSE) of ANN based quality model for five experimental data was calculated as 0.004742. For the second model based on spatial distributions of moisture and quality, the RMSE value is 0.005976. ANN based quality model has better performance than the

performance of the other model according to RMSE values. The coefficient of determination R^2 is the proportion of variability in a data set, as given below:

$$R^2 = \left(1 - \frac{SSE}{SST}\right) \tag{19}$$

SSE represents the sum of squared errors and *SST* denotes the total sum of squares. y_i and f_i denote a data set and the modeled values, respectively, and $\overline{y}$ represents the mean of the modeled values. Table 1 represents the R^2 values associated with all of the model approaches for only one experimental data selected randomly from database. An R^2 of 1.0 indicates that the regression line perfectly fits the data.

Table 1. The performance results of the all model approaches

Model	Dry matter of product R^2	Product temperature R^2
Model_1	0.97925	0.62711
Model_2	0.98743	0.72643
Model_3	0.98387	0.85256
Model_4	0.98525	0.81776

Model_1: Model based on the mass and energy balance,
Model_2: Model based on the spatial distribution in granule,
Model_3: Model based on ANN
Model_4: Model based on ANFIS

As can be noted from Table 1, R^2 values are fairly good for the dry matter of product, but R^2 values related to the product temperature are different from the each other. ANN and ANFIS based model approaches have better performances than the others.

5. CONCLUSIONS

In this study, four different modeling structures were considered for an industrial scale drying process. In all of the models, dry matter of product and the product temperature were used as model outputs. As comparing to the mass and energy balance based model, the second drying model provides significantly improved predictions by providing spatial distributions of moisture and quality inside the granule. Besides, the model accurately predicts the change of granule size during drying by the effect of the shrinkage of the granule. In the production plant, the product quality is measured with offline laboratory conditions as the amount of carbon dioxide produced upon introduction of the yeast into dough per unit time. The product quality is only predicted in ANN based model and the model based on spatial distributions of moisture and quality. It has been provided that the product activity can be observed online by these proposed model structures such as a soft sensor. In contrast with the physical approach based modeling, ANN or ANFIS based modeling approaches does not need prior theoretical knowledge. In order to overcome modeling difficulties, easily self-updating modeling structures can be designed to capture all of the system's operating conditions, as well as details that may have escaped observation. The investigated modeling structures may be an alternative to predict many parameters, such as the moisture content, dry matter of product, product temperature and the product quality or quality loss, in the biomass drying process industry.

Abstract: The presented research work focuses on the mathematical description and control analysis of an integrated power unit that uses hydrogen produced by methanol autothermal reforming. The unit consists of a reformer reactor where methanol, air and water are co-fed to produce a hydrogen rich stream through a series of reactions. The hydrogen main stream is fed to a preferential oxidation reactor (PROX) for the reduction of CO at levels below 50ppm with the use of air. In the end, the PROX outlet stream enters the anode of a PEM fuel cell where power production takes places to serve a load demand. The operation of the two reactors is described by a combination of partial differential equations (mass and energy balances) and non-linear equations (kinetic expressions of the reactions), while the power production in the fuel cell is based on the inlet hydrogen flow and on operational characteristics. A simple case sceanrio is employed when a step change on methanol flowrate is imposed. Main target is to identify and analyze the changes occuring in the main variables of concern (H_2, CO and temperature levels) that affect the overall system operation. Based on the results, an insight on the challenging control scheme will be applied in order to identify possible ways of setting up a reliable and robust control structure according to the developed mathematical model.

Keywords: methanol reforming, preferential oxidation, hydrogen, PEM fuel cell, dynamic modeling

1. INTRODUCTION

Hydrogen can be considered an energy carrier for the future and when derived from renewable energy sources can be totally non-polluting when used in fuel cells (Ipsakis D. et al., 2008). Fuel cells advantages include (Larminie J. and Dicks A., 2003) the low operation temperatures (~ 80^{o}C), the CO_2 tolerance by the electrolyte, the fast cold start and their few moving parts, which enhances their role as back-up units in vehicles. Nevertheless, the main disadvantage of fuel cells refers to the hydrogen supply. Natural gas, gasoline and higher hydrocarbons have been proposed for hydrogen production via steam reforming, but methanol carries the most advantages from all (Lindström B. and Petterson L.J., 2001). Methanol is a liquid that does not require special conditions of storage, while it is also free from high reforming temperatures and sulphur oxides that are met in methane and gasoline reforming. Moreover, methanol has a high H:C ratio and no C:C ratio and thus, prevents the soot formation (Lindström B. and Petterson L.J., 2001), while biomass resources can be used to produce methanol (bio-methanol). Production of hydrogen from methanol can be achieved in three ways: (i) steam reforming of methanol, (ii) partial oxidation of methanol and (iii) autothermal reforming of methanol (Lindström B. and Petterson L.J., 2001). Autothermal reforming has the asset of eliminating the disadvantages of steam reforming (endothermic process which requires a heating source) and partial oxidation (highly exothermic process which leads to the formation of hot spots in the catalyst) by properly selecting the reactants ratios in such a way, so that adiabatic conditions can be achieved. One of the drawbacks of hydrocarbons reforming however, is the production of CO at high levels that degrade the electrochemical performance of low temperature PEM fuel cells. Several processes used for the minimization of CO content at acceptable levels (less than 50ppm) have been discussed in the past, where among them preferential oxidation is considered to be the simplest and the least expensive method (Cipitì F. et al., 2007).

Most of the simulation and modeling studies on methanol reforming, focus on each subsystem as an individual part. Steam reformers have been modelled using axial distribution models (Suh J. S. et al., 2007), while PROX reactors have also been modelled using 2D models (Cipitì F. et al., 2007). In one of the very few papers that deal with an integrated system, Stamps A. T. and Gatzke E.P. (2006), developed and implemented a system level model of a vehicular reformer PEM fuel cell stack power system without the use however, of a hydrogen purification system, while the dynamic operation results were not provided explicitly. As can be seen, literature references lack in studies that deal with the detailed mathematical description of all the involved subsystems and on their overall dynamic interactions. The objective of this study is to analyze the dynamic behaviour of the two reactors based on a step change imposed in methanol flowrate. The reactors temperature and CO content will be continuously monitored, since they mostly affect the power production of the fuel cell. In the end, an analysis on the demanding task of the control of such an integrated power system will be applied, in order to identify all the necessary actions need to be taken for the development of a robust control scheme.

2. DESCRIPTION OF THE INTEGRATED POWER SYSTEM

Figure 1, shows the overall process flow diagram of the methanol autothermal reforming unit.

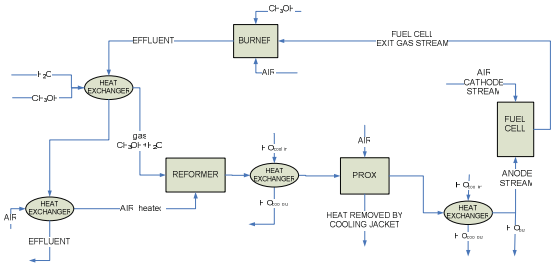

Fig. 1: Overall operation scheme of the methanol autothermal reforming unit.

Methanol, air and water are co-fed to the reformer (0.15m length and 0.1m diameter) after they are preheated by the effluent gases of a burner. The main reaction that takes place at the reformer is the steam reforming of methanol (R1), but because it is an endothermic reaction, oxygen also reacts with methanol (R2) to provide the necessary heat to the system.

Table 1. Reactions taking place at the reformer

$CH_3OH + H_2O \rightarrow CO_2 + 3H_2$ $\Delta H_{R,298} = 49kJ/mol$, (R1)	$CH_3OH + 0.5O_2 \rightarrow CO_2 + 2H_2$ $\Delta H_{R,298} = -193kJ/mol$, (R2)
$CO + H_2O \leftrightarrow CO_2 + H_2$ $\Delta H_{R,298} = -41.2kJ/mol$, (R3)	$CH_3OH \rightarrow CO + 2H_2$ $\Delta H_{R,298} = 90.1kJ/mol$, (R4)

The autothermal reforming of methanol is based on the effective selection of the reactants ratios at the inlet of the reformer. For the current study, it was found from steady-state simulations using Aspen Plus® (Ouzounidou M. et al., 2008a) that the optimum values for H_2O/CH_3OH and O_2/CH_3OH are between 1.5-1.7 and 0.1-0.15 respectively. Steam reforming is considered as the sum of the water gas shift (R3) and methanol decomposistion (R4) reactions.

The reduction of CO after steam reforming, takes place at the PROX reactor (0.1m length and 0.1m diameter). There, besides CO oxidation, H_2 oxidation also takes place, but it is kept at low rate through the effective selection of the catalyst. The reactions of the PROX can be seen in table 2:

Table 2. Reactions taking place at the PROX

$CO + 0.5O_2 \rightarrow CO_2$ $\Delta H_{R,298} = -283kJ/mol$, (R5)	$H_2 + 0.5O_2 \rightarrow H_2O$ $\Delta H_{R,298} = -242kJ/mol$ (R6)

The main objective of the PROX reactor is to keep the CO concentration at a maximum limit of 50 ppm by using efficiently the O_2/CO ratio. From ASPEN Plus® simulations (Ouzounidou M. et al., 2008a), its optimum value is 1, but could vary severely with CO concentration. The PROX reactor due to the presence of the two highly exothermic reactions is surrounded by a jacket to cool the system from undesirable extreme heat generation. The kinetic expressions for all the involved reactions can be found in (Ouzounidou M. et al., 2008b) where an analysis on their selection is provided.

Finally, the hydrogen rich stream is fed to the anode of the fuel cell where it ionises releasing protons (H^+) and electrons (e^-). Protons pass through the proton exchange membrane to the cathode, while electrons flow through an external electric circuit and produce current. In the cathode, oxygen is fed via air supply and reacts with the protons and electrons to form water (Table 3).

Table 3. Reactions taking place at the PEM fuel cell

$H_2 \rightarrow 2H^+ + 2e^-$ Anode, (R6)	$0.5O_2 + 2H^+ + 2e^- \rightarrow H_2O$ Cathode, (R7)

3. MATHEMATICAL DESCRIPTION OF THE SUBSYSTEMS

In this section, the mathematical models of the involved subsystems will be presented and discussed. All parameters, variables and symbols are explained in the nomenclature section. gPROMS® was used to simulate the operation of the integrated power system (PSE®, 2002).

3.1 Reformer and PROX Reactors

The model equations for the catalytic reactors consist of the standard material and energy balances for a pseudo-homogeneous system (packed-bed type). These equations are in partial differential form with spatial and radial distributions. In order to simplify the model and reduce the computational effort needed to simulate all the subsystems, a number of assumptions have been made. It is highlighted, that the description of the system does not lose its accuracy

and the crucial phenomena can be easily described by the developed mathematical model.

- The ideal gas law is applied for all gas components.
- No diffusion phenomena are assumed to take place from the gas phase to the surface of the catalyst.
- Constant reactor pressure and fluid velocity.
- Constant physical properties (component density and heat capacity) over the range of conditions.
- The temperature in the cooling jacket of the PROX reactor is approximately uniform and the resistance to heat transfer occurs primarily between the reactor contents and the wall of the tube (being at the cooling medium temperature).

Material Balance Equation

$$\frac{\partial \mathrm{C_i}}{\partial \mathrm{t}} + \mathrm{u}\cdot\frac{\partial \mathrm{C_i}}{\partial \mathrm{z}} - \varepsilon_{\mathrm{cat}}\cdot D_z\frac{\partial^2 C_i}{\partial z^2} - \varepsilon_{\mathrm{cat}}\cdot D_r\cdot\left(\frac{\partial^2 C_i}{\partial r^2}+\frac{1}{r}\cdot\frac{\partial C_i}{\partial r}\right) = \sum_{i=1}^{N}\sum_{j=1}^{R}\nu_{i,j}\cdot R_j \quad (1)$$

Energy Balance Equation

$$\sum_{\mathrm{i}=1}^{\mathrm{N}}\rho_{\mathrm{i}}\cdot \mathrm{C_{p,i}}\cdot\frac{\partial \mathrm{T}}{\partial \mathrm{t}} + \sum_{\mathrm{i}=1}^{\mathrm{N}}\rho_{\mathrm{i}}\cdot \mathrm{C_{p,i}}\mathrm{u}\cdot\frac{\partial \mathrm{T}}{\partial \mathrm{z}} - k_z\frac{\partial^2 T}{\partial z^2} - k_r\left(\frac{\partial^2 T}{\partial r^2}+\frac{1}{r}\cdot\frac{\partial T}{\partial r}\right) = -\sum_{\mathrm{j}=1}^{\mathrm{R}}\mathrm{R_j}\cdot(\Delta \mathrm{H}_{R,T,j}) \quad (2)$$

Coolant Energy Balance Equation

$$\rho_c\cdot V_c\cdot Cp_c\cdot\frac{\partial \mathrm{T_c}}{\partial \mathrm{t}} = F_c\cdot Cp_c\cdot(T_{c,in}-T_c)+Q \quad (3)$$

$$Q = U\cdot A\int_0^{\mathrm{Reactor\,Length}}(T-T_c)\cdot dz \quad (4)$$

Ideal Gas Law

$$P_i\cdot V = n_i\cdot R\cdot T \Rightarrow P_i = C_i\cdot R\cdot T \quad (5)$$

Species Flowrate

$$F_i = C_i\cdot Q_o \quad (6)$$

$$Q_o = u\cdot S = \frac{\sum F_{i,in}\cdot R\cdot T_{in}}{P_{reactor}} \quad (7)$$

Boundary Conditions (Eqs. 1-4)

z=0

$C_i=C_{i,in}$ *and* $T=T_{in}$, r ε [0,R] (8)

z=L

$$\frac{\partial \mathrm{C_i}}{\partial \mathrm{z}} = 0 \text{ and } \frac{\partial \mathrm{T}}{\partial \mathrm{z}} = 0 \text{ , r ε [0,R]} \quad (9)$$

r=0

$$\frac{\partial \mathrm{C_i}}{\partial \mathrm{r}} = 0 \text{ and } \frac{\partial \mathrm{T}}{\partial \mathrm{r}} = 0 \text{ , z ε (0,L)} \quad (10)$$

r=R

$$\frac{\partial \mathrm{C_i}}{\partial \mathrm{r}} = 0 \quad and \quad -k_r\cdot\frac{\partial \mathrm{T}}{\partial \mathrm{r}} = h_w\cdot(T-T_c), z\varepsilon(0,L) \quad (11)$$

In the solution of the reformer, h_w is 0 and for the PROX ≠0. For the discretization of the distributions the method of centered finite difference (2nd order) was used. The discretization of the axial and radial distribution was performed for 50 and 5 intervals, respectively. More intervals showed that the results are not affected, but the increase in the required computational effort leads to inefficient solution procedure.

3.2 PEM Fuel Cell

Larminie J. and Dicks A., (2003), presented an equation that relates the power production with the hydrogen flow and the operational characteristics of the fuel cell:

$$\mathrm{P_{fc}} = \mathrm{F_{H2}}\cdot n_e\cdot F\cdot\eta_F\cdot V_{cell} \quad (12)$$

The hydrogen flow predicted by the reactors mathematical model is used in the above equation to predict the power production as a function of time. V_{cell} is usually around 0.7V/cell (Larminie J. and Dicks A., 2003).

The same authors also concluded that if all the enthalpy of reaction of a hydrogen fuel cell was converted into electrical energy then the output voltage would be 1.48V (water in liquid form) or 1.25V (water in vapour form). Therefore, the difference between the actual cell voltage and this voltage represents the energy that is converted into heat instead. For the vapour case in our fuel cell, heat is calculated as:

$$\mathrm{Q_{fc}} = \mathrm{P_{fc}}\cdot\left(\frac{1.25}{V_{cell}}-1\right) \quad (13)$$

3.3 Model validation

Based on the experimental results presented in (Ouzounidou M. et al., 2008b), validation with the above mathematical model (kinetic parameters and the axial and radial distributed paramaters were estimated) has been performed, where it has been found that the model accurately simulates the performance of both reactors. Figures 2 and 3 show the comparison between the experimental data and mathematical model for the two reactors, respectively and the deviation between simulated and experimental values is within the expected error (less than 5%). Only in low PROX temperatures a higher deviation is detected but considered negligible, since PROX operates in temperatures >150°C.

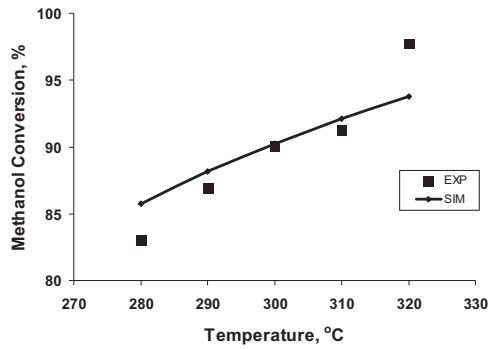

Fig. 2. Comparison between simulated and experimental results for the reformer

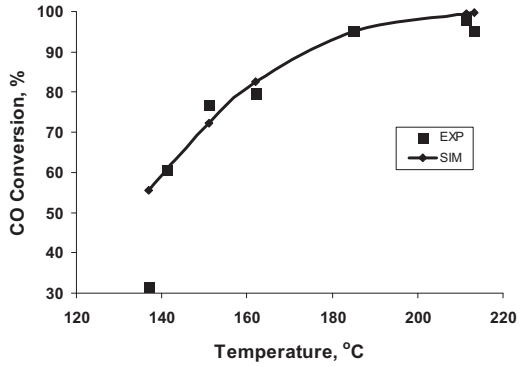

Fig. 3. Comparison between simulated and experimental results for the PROX

4. SIMULATION RESULTS FROM THE DYNAMIC OPERATION OF THE INTEGRATED POWER SYSTEM

The dynamic operation of the integrated power unit will be presented based on an imposed step change. The conditions of the simulated case study are: inlet methanol at 0.02mol/s, reformer temperature at 300°C, PROX temperature at 200°C, H_2O/CH_3OH at 1.5, O_2/CH_3OH at 0.14 and O_2/CO at 2. It is noted that the flowrates of the reactants and reactor temperature at the inlet of the reformer do not have a sharp constant value at the start of the simulation time, but a value that increases smoothly with time and reaches its steady state value after a few seconds. Fig.4 shows the 50% step change on the inlet methanol flowrate at t=30s (inlet water and oxygen flowrates are also increased based on the selected ratios). As can be seen, at the same time an increase at the exit hydrogen flowrate starts to appear and after 80s the increase in hydrogen flowrate is calculated at 49.6%, which shows that methanol conversion is practically unaffected by the increase in the methanol flowrate for the selected conditions.

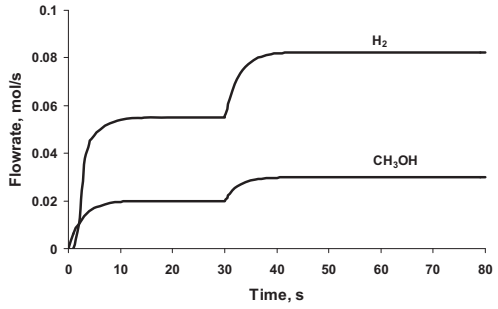

Fig. 4. Methanol inlet and hydrogen outlet flowrates

Similarly Fig.5 shows the CO content (ppm) where a 13% decrease is observed at the time that the step change occurs. This decrease is excpected due to the fact that water flowrate is increased (according to the methanol step change) and the water gas shift reaction is favored. This can also be concluded by the fact that CO flowrate increase is calculated at 22.5% which differs significantly from the 50% increase detected in other products, such as hydrogen.

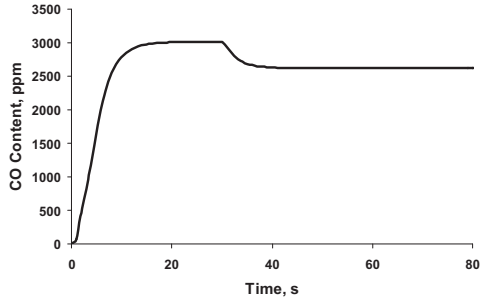

Fig. 5. Carbon monoxide content at the reformer exit

Fig.6 shows the reformer inlet and outlet temperature levels. The inlet gas temperature follows a smooth increase in order to prevent hot spots due to the rigorous exothermic partial oxidation of methanol.

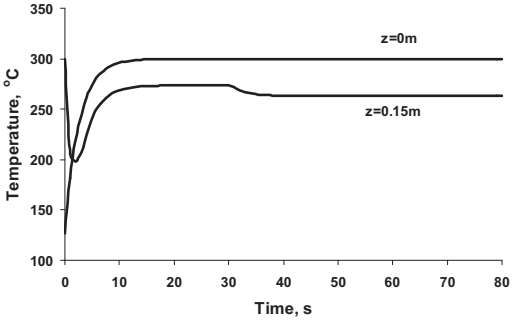

Fig. 6. Temperature levels at the reformer inlet and outlet

This smooth increase is based on the operation of the assumed preheater that heats the reactants mixture. On the

other hand, the outlet temperature of the reformer (at t=0s the reformer is assumed to be at 300°C) is initially decreased due to the fact that low temperature gas mixture exits the reactor at t<10s, but as the reformer operation proceeds, the exit temperature is gradually increased to 260-270 °C. As can be seen for the present conditions, the endothermic reactions prevail and the exit temperature is 30-40 °C lower than the inlet (at steady-state conditions) and also the step change seems to affect the temperature levels by lowering them by 10 °C.

Unlike the reformer, where negligible changes are observed in the radial domain, in the PROX the species concentration and temperature varies severely along the reactor radius. Fig.7 shows the CO content at the wall of the reactor, at its center and the average value that indicates the exit flow. As can be seen, the CO content is higher away from the center due to the lower temperature at that region (see Fig.8). As we move to the reactor center, the CO levels are quite low (practically zero at the reactor center) due to the increased temperature while the average value is always lower than 50ppm for the current conditions. It is highlighted that the CO at the exit of the reformer is measured and according to the selected O_2/CO ratio, the air feed rate is manipulated and introduced to the PROX reactor, so as to always provide a constant O_2/CO ratio. If the O_2 flow was constant based on the initial conditions, then the CO levels would have been higher indicating a possible fuel cell deterioration.

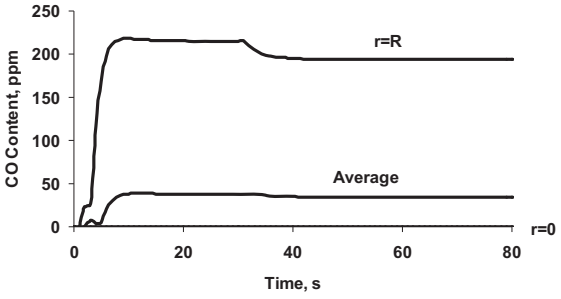

Fig. 7. Carbon monoxide content at the PROX wall, center and average value in the radial domain

Fig.8 shows the temperature levels at the wall of the reactor, at the center and the average (exit) value. Initially (t=0s), the reactor is assumed to be at 200°C and as the oxidations take place, the reactor center is found to have increased temperature in contrast with the reactor wall temperature that is maintained at low levels due to the presence of the cooling medium. Eventually, the exit (average) temperature is initially decreased, but as the gas mixture approaches the reactor exit, the temperature levels are increased. It can also been said, that at t=30s, a small increase is detected due to the increased flowrate at the inlet of the PROX which is not considered severe (less than 15°C). The presence of a controller to maintain the reaction temperature at specific levels is of primary importance and the manipulated value will be the coolant flowrate. It is noted that the hydrogen main stream is assumed to be cooled down before entering the PROX and the fuel cell, but the dynamic simulation of the heat exchangers is omitted for this study, since we focus on the main subsystems.

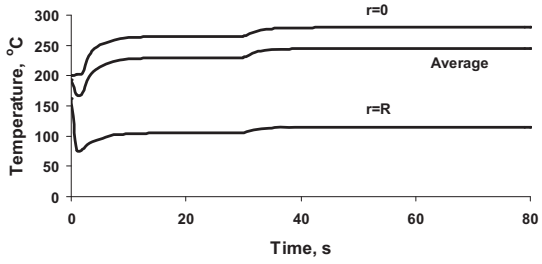

Fig. 8. Temperature levels at the PROX wall, center and average value in the radial domain

Finally, Fig. 9 shows the power and heat production levels based on the inlet hydrogen flow. As can be seen, at t=30s a 49.8% increase in power and heat production is detected, which should be taken into consideration at the developed control scheme that will always try to meet the load demand (see next section).

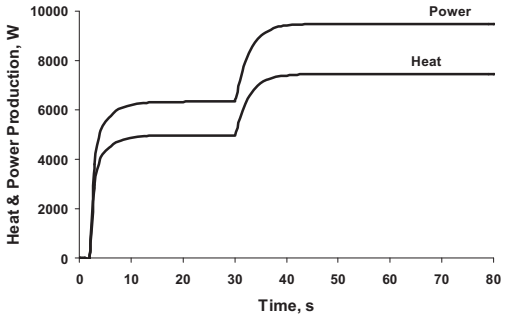

Fig. 9. Power and heat production in the fuel cell

5. CONTROL ISSUES ON THE INTEGRATED POWER SYSTEM

As it is obvious from the above analysis, the operation of the integrated power system, requires the development of a robust control scheme. The variables that constantly need to be monitored are: the reactor temperatures, the CO levels and finally, the power to be supplied to the load. In the reformer, the temperature will be controlled by the O_2/CH_3OH ratio and in the PROX through the coolant flowrate. The CO composition will be controlled by the effective selection of the H_2O/CH_3OH and O_2/CO ratios. Nevertheless, the main variable of concern is the power that needs to be provided to the load. Changes in the demanded load power level will be handled by manipulating the methanol flowrate in order to produce the hydrogen needed in the fuel cell to operate. As was presented, step changes in methanol flowrate affect the overall operation and model predictive control (MPC) is the more suitable control scheme of such an integrated power system. The control algorithm must also satisfy the bounds for CO and temperature levels in order to protect the various subsystems from deterioration (mainly PROX and fuel cell).

All these consequent changes will be decided based on the minimization of an objective function (MPC) that will take into account all the system necessary constraints. Special care, however, should be given to the fact that that slow and fast dynamics occur in the system (e.g. the fast PROX oxidation versus the slow coolant effect) that might need to be specially treated. Perturbation Theory is proposed to alleviate such problems, because it can be applied to mathematical systems that combine non-linear algebraic equations and differential ones (Kumar A. and Daoutidis P., 1999).

6. CONCLUSIONS

An integrated power system for the production of hydrogen via autothermal reforming of methanol has been studied in this paper. The developed mathematical model for the two reactors was validated and used for the simulation of the operation of the power unit where a step change was imposed. The next step will be the integration of the heat management system (burner and heat exchangers), while the developed control scheme will try to maintain the operational variables of concern at their desired values (set points).

Nomenclature

A:	heat transfer area, m^2
C_i:	concentration of the component i, mol/m^3
Cp_c:	coolant specific heat capacity, J/ K Kg
C_{pi}:	component i specific heat capacity, J/K kg
D_r:	radial effective diffusivity, m^2/s
D_z:	axial effective diffusivity, m^2/s
F:	Faraday's constant, Cb/mol
F_c:	coolant flowrate, kg/s
F_i:	flowrate of the component i, mol/m^3
h_w:	wall heat transfer coefficient, W/m^2 K
i:	component that takes part at the system
in:	inlet conditions
j:	number of reaction at the reactors
k_r:	radial thermal conductivity, W/m^2 K
k_z:	axial thermal conductivity, W/m^2 K
n_c:	number of cells of the PEM fuel cell
n_e:	number of electrons
n_F:	Faraday's efficiency, %
P_i:	parital pressure of the component i, bar
P_{fc}:	fuel cell power, Watt
$P_{reactor}$:	reactor pressure, bar
Q:	heat removed by the cooling jacket, Watt
Q_o:	volumetric flow, m^3/s
Q_{fc}:	heat, W
r:	radius of the reactor, m
R:	universal gas constant bar m^3/ mol K
R_j:	kinetic expression of the reaction j, mol/kg_{cat} s
S:	cross section of the reactor, m^2
t:	time, s
T:	temperature, K
T_c:	coolant temperature, K
u:	superficial gas velocity, m/s
U:	overall heat transfer coefficient, W/m^2 K
V_c:	coolant jacket volume, m^3
V_{cell}:	cell voltage, V/cell
z:	length of the reactor, m
$\Delta H_{R,T,j}$:	enthalpy of reaction j at temperature T, J/mol
ε_{cat}:	void fraction of the catalyst
$\nu_{i,j}$:	coefficient of the component i in the reaction j
ρ_i:	density of the component i, kg/m^3
ρ_c:	coolant density, kg/m^3

Abstract: Three-phases chemical reactions are widely applied industrially. They are highly non-linear, multivariable, exothermal processes. The aim of the present work is to propose a dynamic model of an intensified continuous three-phases mini-reactor. This model is developed to enable the transient phase monitoring of the mini-reactor. The reactor is treated as an association of J stirred tank reactors in series with back mixing effect. The model is used to describe the dynamic behaviour of the reactor during the hydrogenation of o-cresol on Ni/SiO_2 catalyst. The model consists in mass and energy balance equations for the catalyst particles, the gas and liquid bulk phases. The transient heat transfers between the metal body of the reactor, the coolant fluid and the bulk fluid are also taken into account.

Keywords: Intensification; Three-phase reactor; Hydrogenation; Dynamic modelling; Control; Dynamic behaviour.

1. INTRODUCTION

The pharmaceutical and the fine chemical industries produce molecules of high added values mainly in batch or fed-batch agitated reactors. Indeed, batch reactors, even if they provide the characteristics of flexibility and versatility required in the field of fine chemicals production, have a number of limitations: in particular, poor conditions of heat released by the chemical reactions leads to a serious safety problem for highly exothermal chemical reactions.

For some years, there is an alternative in the use of batch reactors, thanks to process intensification progresses and to mini-reactors development. The idea is to perform the reactions in continuous intensified reactors. On the one hand, the intensification leads to a better control of heat transfer that allows concentrating the reagent and thus limiting the quantities of solvent to be treated. On the other hand, intensification leads to reduce mass transfer limitations in the case of multiphase chemical reactors.

Nowadays, the control and safety of these reactors are important features in the design as well as in the operation of industrial processes. Such processes carry out complex reactions with constraints on thermal stability and/or selectivity as, for example, exothermal hydrogenation reactions (Vasco de Toldeo *et al.*, 2001).

Hydrogenation reactions are widely applied industrially. Development of efficient and reliable models for three phase reactors is still a difficult task because it involves many aspects including hydrodynamics, gas-liquid and liquid-solid mass transfer, heat transfer, reaction kinetics (Bergault *et al*, 1997).

In the literature, we can find many studies proposing dynamic modelling of catalytic three phase reactors (P.A Ramachandran and J.M. Smith, 1976; R.J. Wärnä and T. Salmi, 1995; Vasco de Toldeo *et al.*, 2001) but as far as we know, the problem of mini-reactors modelling is not addressed.

The aim of this paper is to propose a dynamic model of a continuous three-phases intensified mini-reactor. This model is developed to enable the transient period monitoring of the three phases mini-reactor. It will allow better predictions of the behaviour of the system and therefore secure and effective studies of the reactor control.

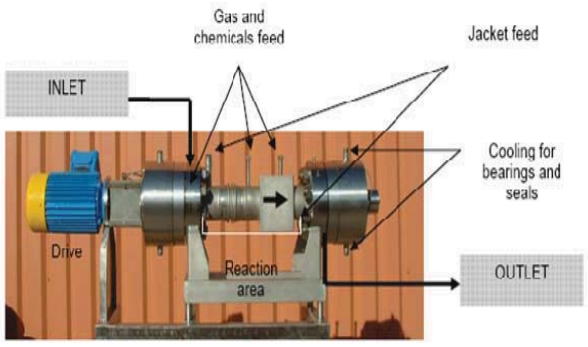

Fig.1. The "RAPTOR® (***R**éacteur **A**gité **P**olyvalent à **T**ransfert **O**ptimisé **R**ectiligne)*".

The mini-reactor under consideration, the "RAPTOR®" (presented by the figure 1) is developed by AETGOUP SAS Company a French society whose main activity is to offer a broad range of services mainly focused on chemical process industrialisation, in the field of pharmaceuticals, fragrances and aromas, cosmetics and specialty chemicals. For confidentiality reasons, we cannot give here a detailed description of the RAPTOR®.

2. MATHEMATICAL MODELLING

The model is used to describe the dynamic behaviour of the reactor during the hydrogenation of o-cresol on Ni/SiO_2 catalyst, taken as an example. A three-phase catalytic reactor is a system in which gas and liquid phases are in contact with a porous solid phase. The reaction occurs between a dissolved gas and a liquid-phase reactant in presence of a catalyst on the surface of the porous solid support (P.A. Ramachandran and R.V. Chaudhari, 1983), according to the following global stoichiometric equation:

$$A_{(g)} + \nu_B B_{(l)} \rightarrow \nu_C C_{(l)} \quad (1)$$

The chemical process involves several steps in series (see figure 2):

- diffusion of A from gas-liquid interface to the bulk liquid;
- diffusion of A and B from bulk liquid through liquid-solid interface;

- intraparticle diffusion of A and B into the pores of the solid;
- adsorption of the reactants;
- adsorbed phase reaction.

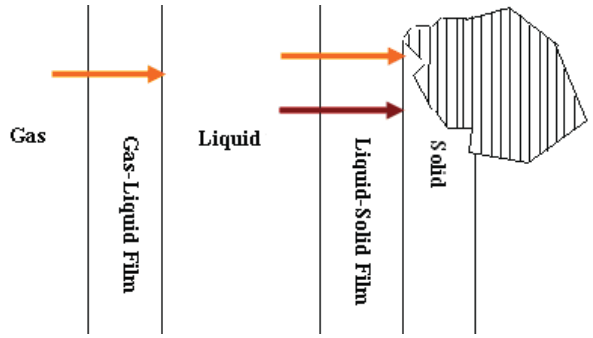

Fig.2. Steps of catalytic reaction.

The reactor is treated as an association of J stirred tank reactors in series with back mixing effect. Similarly, the jacket is treated as an association of J perfectly stirred tank reactors series. This way to consider the flows in the reactor is highly flexible and leads to a finite dimension model. Since an intensified reactor has to be compact, the influence of the reactor body itself may be significant with respect to the thermal transient behaviour of the system. Consequently, a piece of reactor body is associated to each perfectly mixed reactors used to model the flows (see figure 3).

The model consists in mass and energy balance equations for the catalyst particles, the gas phase and liquid-bulk phase, and also energy balance equations for the body of the reactor and for the coolant fluid into the jacket.

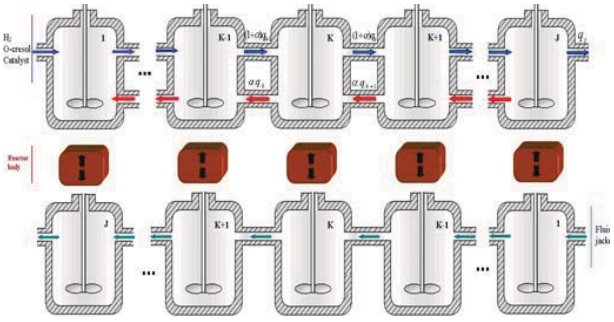

Fig.3. Flow model of the mini-reactor.

2.1 Kinetic model

Hydrogenation of o-cresol on Ni/SiO_2 catalyst (Hichri *et al.*, 1991) is taken as an example of chemical process that can be intensified. In this case, hydrogen reacts with o-cresol without any solvent due to the high heat and mass transfer capacities of the mini-reactor. The reaction can be represented by equation (1). In this case, A stands for hydrogen, B for o-cresol, C for 2-methylcyclohexanol.

Langmuir-Hinshelwood model represents in a realistic way the adsorption phenomena involved in heterogeneous catalysis processes. The reaction rate is calculated as follows (Hichri *et al*, 1991):

$$R = k\frac{K_A K_B C_{As} C_{Bs}}{(1+K_A C_{As})(1+K_B C_{Bs})} \quad (2)$$

C_{As} and C_{Bs} are respectively the hydrogen and o-cresol concentrations within the catalyst pores. The Arrhenius law gives the variation of the rate constants k with temperature while adsorption constants K_A and K_B variations derive from mass action law. The following expressions are taken from (Hichri *et al.*, 1991):

$$k(mol/kg.cat.s) = 5{,}46.10^{8}\exp(-82220/RT_s) \quad (3)$$

$$K_A(m^3/mol) = 10{,}55.10^{-3}\exp(+5003/RT_s) \quad (4)$$

$$K_B(m^3/mol) = 7{,}54.10^{-6}\exp(+16325/RT_s) \quad (5)$$

where $T_s\,(K)$ is the catalyst pellet temperature.

2.2 Mini-reactor model

The following assumptions are considered to derive the model (Vasco De Toledo *et al.*, 2001; Santana, 1999):

- the liquid and gas phases homogeneous suspension is considered as a pseudo-fluid with respect to the temperature;

- a global mass transfer coefficient is used to represent hydrogen transfer from the liquid surface to the bulk. Equilibrium conditions at the liquid surface are assumed;

- the pressure variations are negligible;

- the resistances to mass and heat transfer at the catalyst pellet surface and within the pores are lumped into global heat and mass transfer coefficients;

- the material balance in the gas phase, that is assumed to be pure hydrogen, is written at steady state.

Mass balance of reactant A in the gas phase

$$F_{Ag}^{0k} + V_k k_l a^k \left(C_{Al}^{k*} - C_{Al}^k\right) = F_{Ag}^{Ik} \tag{6}$$

Mass balance of reactant A in the liquid phase

$$\varepsilon_l^k V_k \frac{dC_{Al}^k}{dt} = (1+\alpha) q_l^{k-1} C_{Al}^{k-1} + \alpha q_l^{k+1} C_{Al}^{k+1} - (1+2\alpha) q_l^k C_{Al}^k$$
$$- V_k k_s a \left(C_{Al}^k - C_{As}^k\right) + V_k k_l a^k \left(C_{Al}^{*k} - C_{As}^k\right) \tag{7}$$

Mass balance of reactant A in the solid phase

$$\varepsilon_s V_k \frac{dC_{As}^k}{dt} = (1+\alpha) q_s^{k-1} C_{As}^{k-1} + \alpha q_s^{k+1} C_{As}^{k+1} - (1+2\alpha) q_s^k C_{As}^k$$
$$+ V_k k_s a \left(C_{Al}^k - C_{As}^k\right) - \nu_A \varepsilon_s \rho_s V_k R(C_{As}^k, C_{Bs}^k, T_s^k) \tag{8}$$

Mass balance of reactant B in the liquid phase

$$\varepsilon_l^k V_k \frac{dC_{Bl}^k}{dt} = (1+\alpha) q_l^{k-1} C_{Bl}^{k-1} + \alpha q_l^{k+1} C_{Bl}^{k+1}$$
$$- (1+2\alpha) q_l^k C_{Bl}^k - V_k k_s a (C_{Bl}^k - C_{Bs}^k). \tag{9}$$

Mass balance of reactant B in the solid phase

$$\varepsilon_s V_k \frac{dC_{Bs}^k}{dt} = (1+\alpha) q_s^{k-1} C_{Bs}^{k-1} + \alpha q_s^{k+1} C_{Bs}^{k+1} - (1+2\alpha) q_s^k C_{Bs}^k$$
$$+ V_k k_s a (C_{Bl}^k - C_{Bs}^k) - \nu_B \varepsilon_s \rho_s V_k R(C_{As}^k, C_{Bs}^k, T_s^k) \tag{10}$$

Energy balance in the fluid (gas + liquid) phase

$$V_k (\varepsilon_g^k \rho_g C_{pg} + \varepsilon_l^k \rho_l C_{pl}) \frac{dT_f^k}{dt} = hS (T_m^k - T_f^k)$$
$$+ V_k h_s a_{ls} (T_s^k - T_f^k) - (\varepsilon_g^k \rho_g C_{pg} + \varepsilon_l^k \rho_l C_{pl})$$
$$\left((1+\alpha) q_{k-1} (T_f^k - T_f^{k-1}) + \alpha q_{k+1} (T_f^k - T_f^{k+1})\right) \tag{11}$$

Energy balance in the solid phase

$$\varepsilon_s V_k \rho_s C_{ps} \frac{dT_s^k}{dt} = V_k h_s a_{l:s} (T_f^k - T_s^k)$$
$$- (\rho_s C_{ps}) \left((1+\alpha) q_{sk-1} (T_s^k - T_s^{k-1}) + \alpha q_{sk+1} (T_s^k - T_s^{k+1})\right)$$
$$- \varepsilon_s V_k \rho_s \Delta_r HR(C_{A,s}^k, C_{B,s}^k, T_s^k). \tag{12}$$

Energy balance of the body of the mini-reactor

$$(V_k \rho C_p)_m \frac{dT_m^k}{dt} = hS(T_f^k - T_m^k)$$
$$+ h_j S(T_j^k - T_m^k) \tag{13}$$

Energy balance of the refrigerant fluid into the jacket

$$(V_k \rho C_p)_j \frac{dT_j^k}{dt} = h_j S(T_m^k - T_j^k)$$
$$- (\rho C_p)_j q_j^{k-1} (T_j^k - T_j^{k-1}). \tag{14}$$

3. SIMULATION RESULTS

Kinetic and thermodynamic parameters are taken from (Hichri *et al.*, 1991). The other physical parameters are taken from (Vasco de Toledo *et al.*, 2001; Adriano Pinto Mariano *et al.*, 2005).

We have performed a sensitivity study to define the optimum conditions that enable to achieve a high conversion rate under the constraint of the thermal runaway. One can see on the figure 5 the dynamic behaviour of the reactor and on the figure 4 the steady-state conversion profile that we have obtained. The operating conditions resulting from the sensitivity analysis lead to a conversion up to 90% at the reactor outlet, which is a very common industrial target.

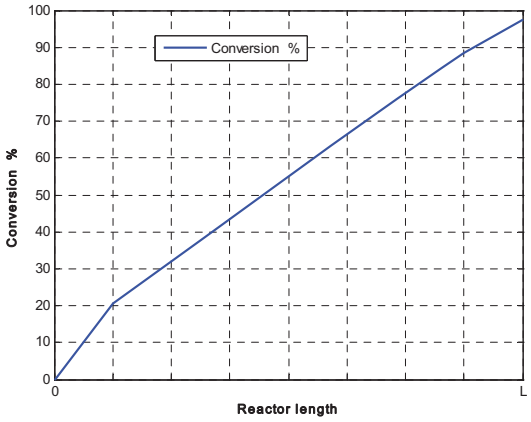

Fig.4. The steady-state conversion profile along the mini-reactor.

In figure 5, the dynamic behaviour of the reactor outlet temperature is represented. We observe that the fluid temperature is limited and increases by 24 %.

The catalyst temperature is slightly higher than that of reactant fluid since the reaction takes place in the pores catalyst. We also observe that the jacket temperature remains nearly constant while the temperature of the reactor body heats up by 15%. In fact the reactor body tends to store up the energy released by the reaction; it therefore appears that the reactor can work in hard reactive conditions, but safely.

When the optimum operating conditions have been established, we performed a steady-state characterization of the model; this feature allows not only steady analysis of model sensitivity with respect to the variation of input variables, but also consistency verification of the model.

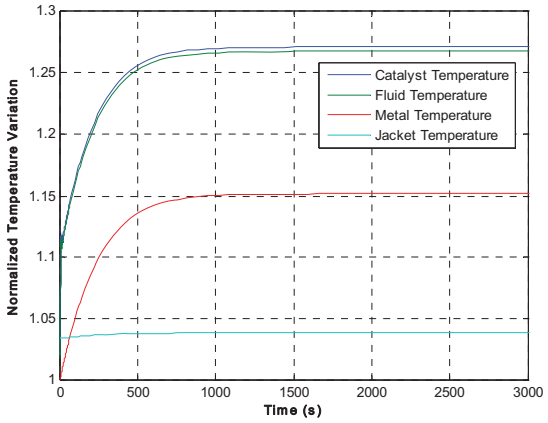

Fig.5. The dynamic behaviour of outlet reactor temperatures.

As far as intensified reactors are concerned, where the reaction takes place at very high temperature, the jacket plays a dual role in the evolution of the reaction. On the one hand, it is related to safety problems since the jacket fluid allows cooling the temperature of the bulk in order to avoid thermal runaway. On the other hand, it allows the indirect control of the outlet conversion by controlling the temperature of the bulk.

Figure 6 illustrates the steady-state characterization of outlet temperatures and conversion with respect to the inlet jacket fluid temperature (variations ranging from -5% to 5% around T_{j0}).

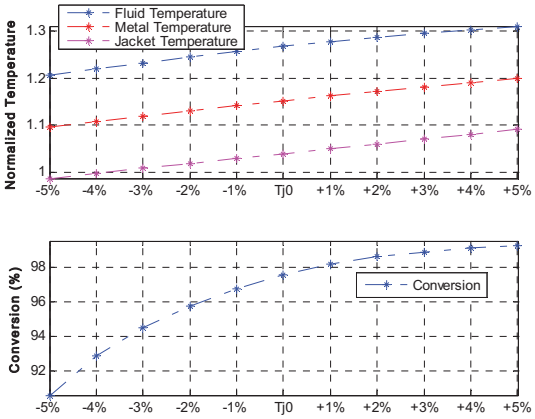

Fig.6. The steady-state characterization of outlet temperatures and conversion with respect to the inlet jacket fluid temperature.

From this figure, it is observed that both of outlet temperatures and conversion are very sensitive to changes in the inlet temperature of the jacket fluid. This sensibility of the dynamic behaviour of the reactor in relation to changes in the coolant fluid is observed mainly in industrial situations.

Figure 7 shows the steady characterization of outlet temperatures and conversion with respect to the inlet gas flow (ranging from -30% to 30% around q_{A0}). We can observe that the variations of q_{A0} have more impact on the conversion than the outlet temperatures.

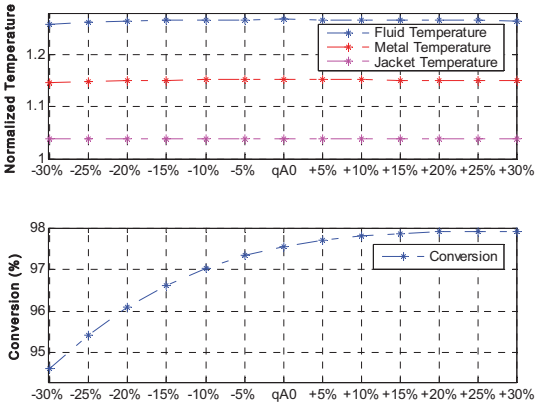

Fig.7. The steady-state characterization of outlet temperatures and conversion with respect to the inlet gas flow.

Figure 8 shows the effect of the inlet fluid temperature on the behaviour of outlet temperatures and conversion (variations ranging from -5% to 5% around T_{f0}). This figure points out that only conversion is sensitive to the variations of T_{f0}, as a result, disturbance on the inlet fluid temperature greatly affects the quality of the output product.

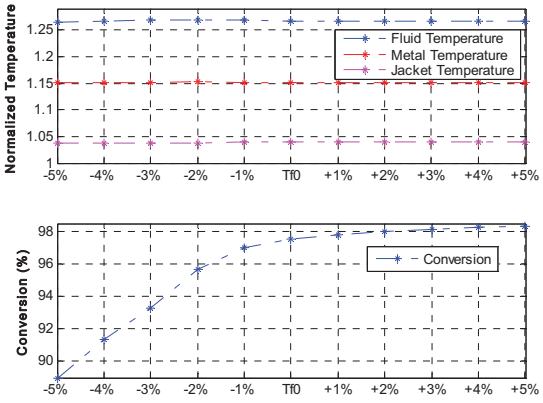

Fig.8. The steady-state characterization of outlet temperatures and conversion with respect to the inlet fluid temperature.

In figure 9, the steady-state characterization of outlet temperatures and conversion with respect to the inlet fluid flow (ranging from -30% to 30% around q_{f0}) is highlighted. We remark that the temperatures and conversion are very sensitive to q_{f0}. In fact, a decrease in the inlet fluid flow (-30%) allows obtaining a good conversion (=99.9%) with better thermal conditions. However this result leads to lower productivity.

According to the observations of these figures, the steady-state characterization of the model confirms the consistency of the model sets.

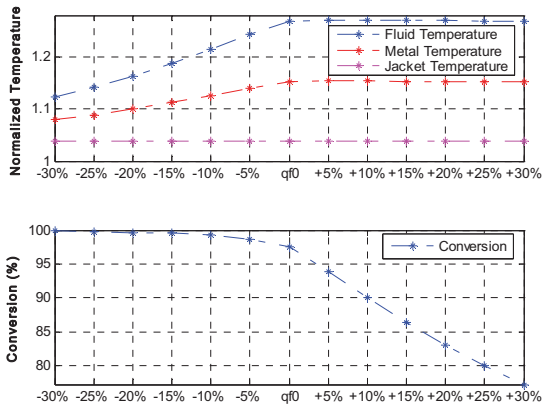

Fig.9. The steady-state characterization of outlet temperatures and conversion with respect to the inlet Fluid flow.

We observed that system's output variables are very sensitive to the variations of inlet jacket temperature. We could also highlight the fact that the conversion is very sensitive to the variations of inlet gas flow. Thus it may be concluded that these two variables may be chosen as an efficient control variables.

4. CONCLUSION

Reactions performed in multiphase catalytic intensified reactors have a complex behaviour due to heat and mass transfers and chemical kinetic interactions. The objective of the dynamic mathematical model developed in this work is to perform a detailed study of the process dynamic behaviour in order to define a suitable control structure. This structure has to control the outlet conversion and preserve safety conditions of the reactor. Others objectives such as high product quality and economy gain can also be considered.

Identification of an Ill-Conditioned Distillation Column Process using Rotated Signals as Input

M.S. Sadabadi and J. Poshtan

(e-mails: sadabadi@iust.ac.ir, jposhtan@iust.ac.ir)

Abstract: The standard uncorrelated test signals estimate the low-gain direction of ill-conditioned multivariable systems poorly. Therefore, the low-gain information needs to be excited more. In this paper, identification of an ill-conditioned distillation column process using rotated signals is proposed. Rotated input signals allow more excitation to be applied in the weak gain direction of the process and less excitation in the strong gain direction. In this approach, the singular value decomposition (SVD) of the steady state gain matrix is used to rotate the input signals along the directions of the right singular vectors. Simulation results show good accuracy of the proposed method in identifying low and high gain directions.

Keywords: Rotated Input Design, Ill-conditioned Process, System Identification, Subspace Method, Distillation Column.

1. INTRODUCTION

Unlike SISO processes, MIMO processes may show ''directions'' (in the input vector space) in which the (steady-state or dynamic) effect of the inputs on the process outputs is much larger than in other directions (Zhu *et al.*, 2001, 2006). In such situations the process is said to be ill-conditioned. An ill-conditioned problem is a specific problem for multivariable processes.

Control-relevant identification of an ill-conditioned system requires special techniques. The directionality of such systems should be taken into account in the identification test signal design. Traditional uncorrelated open-loop step tests tend to excite the system mostly in high-gain directions. Therefore, the input test signals should be selected correctly (Zhu *et al.*, 2001, 2006).

In MIMO processes, the existing input test signal design methods can be divided in two categories, sequential input testing and simultaneous input testing (Conner *et al.*, 2004).

In sequential input testing, one signal, often PRBS (pseudo random binary sequence) or GBN (generalized binary noise) signal, is applied to each input separately while the other inputs are kept at their nominal values (Conner *et al.*, 2004). This input excitation usually takes a long time because the inputs are perturbed one at a time (Li *et al.*, 2008).

Simultaneously input testing excites more than one input at a time (Conner *et al.*, 2004). This method leads to more efficient use of the plant testing time (Conner *et al.*, 2004). Gevers *et al*. (Gevers *et al*., 2006) using variance analysis shows that it is better to excite all inputs simultaneously. However, simultaneous uncorrelated open-loop tests cannot usually excite the ill-conditioned processes in low-gain direction (Zhu *et al.*, 2001, 2006). In these systems, the information of low gain direction is dominated by the noise (low SNR) and no good identification results can be achieved. This problem is caused by poor data not related to identification methods or model structure (Zhu *et al.*, 2001, 2006).

In order to increase the SNR in the low gain direction, one can replace the standard uncorrelated PRBS or GBN inputs with highly correlated signals as inputs. Koung and MacGregor (Koung *et al.*, 1993) proposed rotated inputs. These signals allow more excitation to be applied in the weak gain direction of the process and less excitation in the strong gain direction (Conner *et al.*, 2004). In their approach, the singular value decomposition (SVD) of the steady state gain matrix is used to rotate the input signals along the directions of the right singular vectors (Li *et al.*, 2008). Therefore, for constructing a rotated input signal, preliminary knowledge of the steady-state gain matrix is needed (Conner *et al.*, 2004).

In this paper, MIMO rotated input design for an ill-conditioned distillation column process identification is proposed.

The paper is organized as follows: In Section 2 and 3, ill-conditioned processes and rotated input design are respectively described. In Section 4, the application of the proposed method is carried out on high-purity distillation column as an ill-conditioned process. Finally, section 5 concludes the paper.

2. ILL-CONDITIONED PROCESS

Consider the multivariable (MIMO) system with n inputs and n outputs as follows

$$y(j\omega) = G(j\omega)u(j\omega) \tag{1}$$

The singular value decomposition (SVD) of G can be written (Skogestad *et al.*, 2001) as:

$$G(j\omega) = U(j\omega)\Sigma(j\omega)V^H(j\omega) \tag{2}$$

where U and V are the left and the right singular unitary matrices, respectively. Matrix Σ is the singular value matrix which is diagonal containing the singular values σ_i in decreasing order. The complex frequency $j\omega$ denotes that the SVD in general is a frequency dependent measure. For 2×2 processes, we can write (Jacobsen, 1994)

$$U = [\bar{u}\ \ \underline{u}],\ \ \Sigma = diag(\bar{\sigma},\underline{\sigma}),\ \ V = [\bar{v}\ \ \underline{v}] \tag{3}$$

and

$$G\bar{v} = \bar{\sigma}\bar{u},\ G\underline{v} = \underline{\sigma}\underline{u} \tag{4}$$

where $\bar{\sigma}$ denotes the maximum gain of G (in terms of 2-norm), $\bar{v}$ and $\bar{u}$ are the corresponding input and output directions, respectively. Similarly, $\underline{\sigma}$ is the minimum gain of G with corresponding input direction $\underline{v}$ and output direction $\underline{u}$. Note that the singular values and the corresponding input and output directions are frequency dependent; however, for simplicity $j\omega$ is omitted.

The condition number of gain matrix G is given by the ratio of the upper and lower singular values as follows (Jacobsen, 1994)

$$\gamma(G) = \bar{\sigma}/\underline{\sigma} \tag{5}$$

A process is said to be ill-conditioned if $\gamma(G) >> 1$ in some frequency range (Jacobsen, 1994).

In these processes, the process gain is strongly dependent on the direction of the input vector (Jacobsen, 1994). Therefore, the response of the plant is much stronger if input vector is in the high gain direction than if it lies along the low gain direction (Jacobsen, 1994). This can cause difficulties in the identification of ill-conditioned processes. In other words, ill-conditioned processes represent one of the most difficult kinds of linear processes to be identified (Micchi *et al*. 2008).

The ill-conditioned processes also have strongly interactions. The relative gain array (RGA), proposed by Bristol (Bristol, 1966), is a valuable criterion for evaluating the degree of interactions or directionality. The elements of the RGA is defined as follows (Zhu *et al.*, 2006)

$$\lambda_{ij}(j\omega) = g_{ij}(j\omega)[G^{-1}(j\omega)]_{ji} \tag{6}$$

where g_{ij} is the i,j element of G. As the elements in each row and column in the RGA adds up to unity, it is sufficient to consider the 1,1 element for the 2×2 case (Jacobsen, 1994). When one refer to the RGA, it means the 1,1 element of the RGA, i.e., λ_{11}. Large value of λ_{11} denotes that the process is strongly interactive (Jacobsen, 1994).

Note that there are differences between strongly interactive and ill-conditioned processes. A strongly interactive process is always ill-conditioned while the opposite is not always true (Jacobsen, 1994).

3. ROTATED INPUT DESIGN

Consider the singular value decomposition (SVD) of the steady state gain matrix $\bar{G}$.

$$\bar{G} = \bar{U}\bar{\Sigma}\bar{V}^H \tag{7}$$

Using the above equation, the steady state output of process, with N input-output data, can be written as (Conner *et al.*, 2004)

$$\bar{Y}^T = \bar{G}\hat{U}^T = \bar{U}\bar{\Sigma}\bar{V}^H\hat{U}^T \tag{8}$$

where

$$\bar{Y} = [\bar{Y}_1\ \bar{Y}_2 \dots \bar{Y}_n] \tag{9a}$$

$$\hat{U} = [U_1\ U_2 \dots U_n] \tag{9b}$$

and

$$\bar{Y}_i = [\bar{y}_i(1)\ \bar{y}_i(2) \dots \bar{y}_i(N)]^T \tag{10a}$$

$$U_j = [u_j(1)\ u_j(2) \dots u_j(N)]^T \tag{10b}$$

In theses equations, an overbar indicates steady state of a variable if inputs are held constant from the current time forward.

Now, the original inputs, $\{U_i\}$, are scaled by the singular values $\{\sigma_i\}$ to give new inputs $\tilde{U}$ (Conner *et al.*, 2004).

$$\tilde{U} = [U_1\ \ U_2(\frac{\sigma_1}{\sigma_2})\ \ U_3(\frac{\sigma_1}{\sigma_3})\ \ \dots\ \ U_n(\frac{\sigma_1}{\sigma_n})] \tag{11}$$

Then the rotated inputs are produced as follows (Conner *et al.*, 2004)

$$\Xi = \alpha\tilde{U}V^H \tag{12}$$

where α is a factor that should be adjusted so that the outputs do not exceed prespecified limits.

By using the rotated inputs, Ξ, instead of the original inputs, $\hat{U}$, equation (8) can be rewritten as (Conner *et al.*, 2004)

$$\bar{Y}^T = \alpha\bar{U}\bar{\Sigma}\tilde{U}^T \tag{13}$$

Therefore, the modes of the steady-state gain matrix are individually excited by scaled, uncorrelated PRBS or GBN signals (Conner *et al.*, 2004).

A generalization of the rotated inputs design procedure to non-square multivariable systems of arbitrary dimensions is presented at Micchi *et al*., 2008.

4. CASE STUDY: HIGH-PURITY DISTILLATION COLUMN

A binary distillation column as in Fig. 1 is considered as an ill-conditioned process. The column is running in LV-configuration.

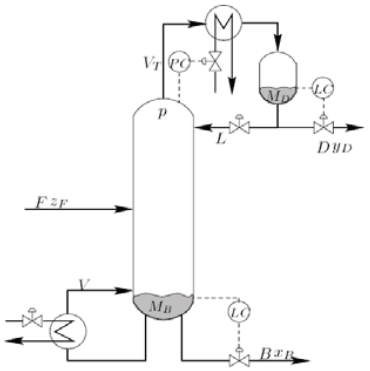

Fig. 1. High-purity distillation column

In this study, reflex (L) and boilup (V) flow rates are considered as the inputs and distillate (y_d) and bottom (x_b) compositions are considered as the outputs of the distillation column. For more detailed description, one can refer to Skogestad, 1997.

High-purity distillation is a challenging process application for system identification because of its nonlinear and strongly interactive dynamics (Rivera *et al*., 2007). Despite their nonlinear behavior, the ability to control high-purity distillation columns using linear controllers is desirable in practice for reasons of simplicity (Rivera *et al*., 2007). Thus, in many studies like this study, a linearized model is used.

The linear model of a distillation column can be described as (Jacobsen, 1994)

$$\begin{bmatrix} y_1(j\omega) \\ y_2(j\omega) \end{bmatrix} = G(j\omega) \begin{bmatrix} u_1(j\omega) \\ u_2(j\omega) \end{bmatrix} \tag{14}$$

where the state space model of *G* is as follows

$$\dot{x} = \begin{bmatrix} -0.0051 & 0 & 0 & 0 & 0 \\ 0 & -0.0737 & 0 & 0 & 0 \\ 0 & 0 & -0.1829 & 0 & 0 \\ 0 & 0 & 0 & -0.4620 & 0.9895 \\ 0 & 0 & 0 & -0.9895 & -0.4620 \end{bmatrix} x + \begin{bmatrix} -0.629 & 0.624 \\ 0.055 & -0.172 \\ 0.030 & -0.108 \\ -0.186 & -0.139 \\ -1.230 & -0.056 \end{bmatrix} u \tag{15a}$$

$$y = \begin{bmatrix} -0.7223 & -0.5170 & 0.3386 & -0.0163 & 0.1121 \\ -0.8913 & 0.4728 & 0.9876 & 0.8425 & 0.2186 \end{bmatrix} x \tag{15b}$$

Fig.2 and Fig.3 respectively show the singular values and RGA plotted as functions of frequency for the high-purity distillation column.

It can be seen that the process has large condition number and high RGA in the low frequency range.

At steady state, the high-gain singular value and the low-gain singular value are equal to $\bar{\sigma} = 198.2$ and $\underline{\sigma} = 1.36$, respectively. Steady state condition number is $\gamma \approx 146$.

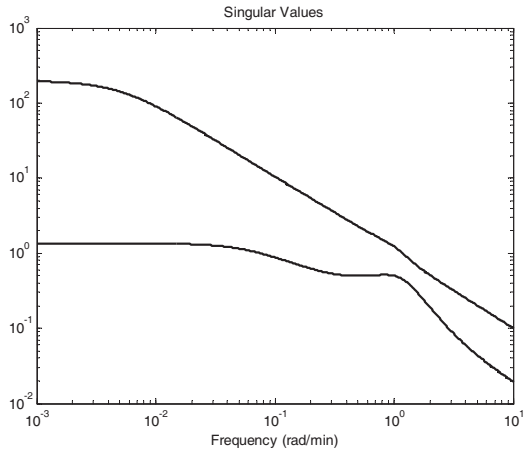

Fig. 2. Singular values of the distillation column

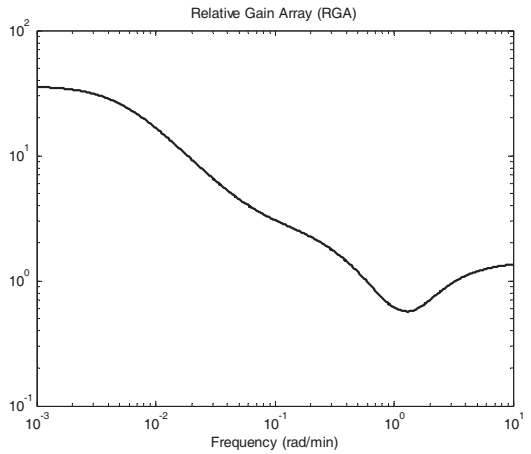

Fig. 3. RGA of the distillation column

Therefore, the largest effect on the outputs is obtained by moving the inputs in opposite directions which causes the two outputs to move in the same direction. The smallest effect is obtained by moving the inputs in the same direction which moves the two outputs in opposite directions.

4.1 Input Test Signals

For identification of the high purity distillation column, two open-loop test signals are considered: uncorrelated signals and rotated signals as outlined in Section 3.

Identification data are constructed by using generalized binary noise (GBN) signals as inputs, both uncorrelated and correlated in the case of rotated inputs. GBN signals, proposed by Tulleken (Tulleken, 1990), have many favorable features, in particular in terms of frequency content, which is typically superior to that of pseudo-random binary noise (PRBS) and of step signals (Zhu, 2001).

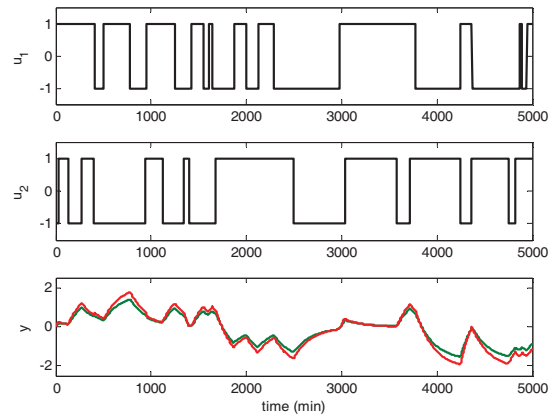

Fig. 4. Data collected using uncorrelated GBN signals as inputs

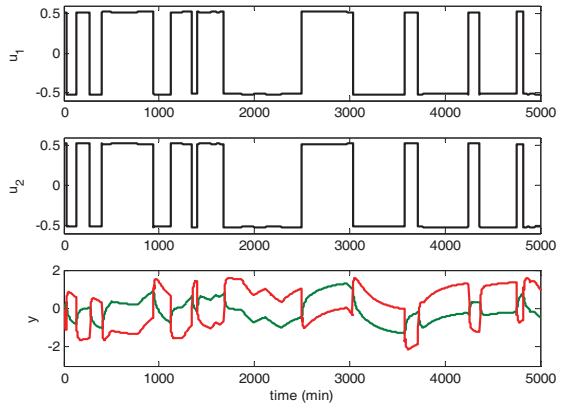

Fig. 5. Data collected using rotated GBN signals as inputs

Hence, two independent GBN signals with amplitude ± 1, switching time $T_{sw} = 300\,\text{min}$, and final time $T_f = 5000\,\text{min}$ are applied on the inputs of the plant simultaneously. The sampling time is selected to be 1 min.

Normally, distributed output noise with a signal-to-noise ratio (SNR) of 10 is added to both outputs. The input-output data from the two experiments are shown in Fig. 4 and Fig. 5.

Fig. 6 and Fig. 7 show the excitations of output directions in the uncorrelated and the correlated tests.

It can be seen that the uncorrelated test inputs only excite the high gain direction. In other words, in this case, the outputs of the process have no information about the low-gain direction of the model. It is clear that the low-gain direction information needs to be excited more in order to obtain good estimates of model. Therefore, strongly correlated test inputs with larger amplitudes are needed (see Fig. 7).

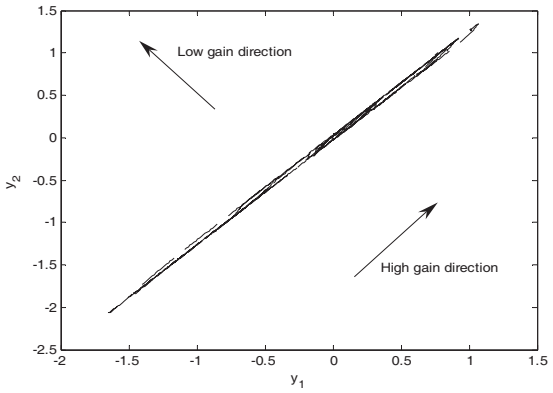

Fig. 6. Excitation of output directions in the uncorrelated test

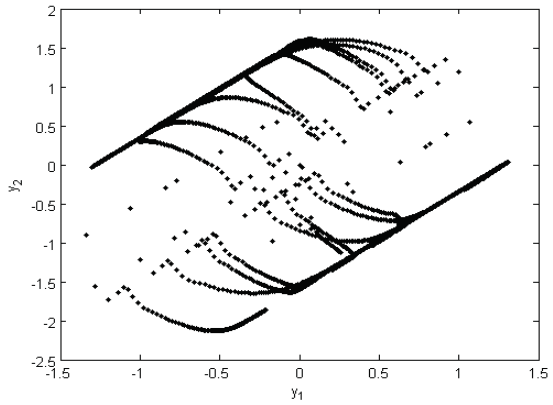

Fig. 7. Excitation of output directions in the rotated test

4.2 Subspace Identification

In this paper, a MIMO structure for the model is considered. In other words, there is a common model for all outputs. System identification is performed using subspace identification (SID) method. This method involves particular matrices obtained from output and input data and performs projection operations to cancel out the noise contributions. Thus, the system model is obtained in state-space form using these projected data matrices. A detailed treatment of this method can be found in Van Overschee *et al.*, 1996.

For identifying the system using subspace method, model order should be selected. In this paper, the model order is determined using number of nonzero singular values of matrix M given by (Misra *et al.*, 2003)

$$M = Y_f \underset{U_f}{/} W_p \prod\nolimits_{U_f^T}^{\perp} \tag{16}$$

$$= Y_f \prod\nolimits_{U_f^T}^{\perp} \left[[W_p \prod\nolimits_{U_f^T}^{\perp}]^{+} [W_p \prod\nolimits_{U_f^T}^{\perp}] \right]$$

where

$$Y_f \underset{U_f}{/} W_p = [Y_f \prod_{U_f^T}^{\perp}][W_p \prod_{U_f^T}^{\perp}]^{+} W_p;\ W_p = \begin{bmatrix} U_p \\ Y_p \end{bmatrix} \quad (17a)$$

$$\prod_{U_f^T}^{\perp} = I - \prod_{U_f^T}^{\perp} \quad (17b)$$

$$= I - U_f (U_f^T U_f)^{+} U_f^T$$

(Y_f, U_f) and (Y_p, U_p) are future and past output-input data, respectively, that is:

$$Y_f = \begin{bmatrix} y_r & y_{r+1} & \cdots & y_{r+M-1} \end{bmatrix} \quad (18a)$$
$$U_f = \begin{bmatrix} u_r & u_{r+1} & \cdots & u_{r+M-1} \end{bmatrix}$$

$$Y_p = \begin{bmatrix} y_0 & y_1 & \cdots & y_{M-1} \end{bmatrix} \quad (18b)$$
$$U_f = \begin{bmatrix} u_0 & u_1 & \cdots & u_{M-1} \end{bmatrix}$$

where r is greater than the system order n ($r > n$) and $M = N - 2r + 1$. The order of system is determined using singular value decomposition of matrix M in equation (16) as follows:

$$M = \begin{bmatrix} \hat{Q}_s & \hat{Q}_n \end{bmatrix} \begin{bmatrix} \hat{S}_s & 0 \\ 0 & \hat{S}_n \end{bmatrix} \begin{bmatrix} \hat{V}_s^T \\ \hat{V}_n^T \end{bmatrix} \quad (19)$$

In the absence of noise, the rank of this matrix is exactly *n*. Thus there are exactly *n* nonzero singular values in the SVD in equation (19). In the presence of noise, however, the data matrix on the left hand side of (19) becomes a full rank matrix. The selection of the sizes of $\hat{S}_s$ and $\hat{S}_n$ then requires determining which singular values can be considered small, hence essentially zero, and which ones large. If the noise level is not too high, there is usually a significant difference between noise and signal singular values, and their separation is easily achieved (Misra *et al*., 2003). However, for ill-conditioned systems, even a small magnitude of noise can make it very difficult to determine the system order correctly (Misra *et al*., 2003).

For solving this problem, additional requirements must be posed on the input signals. In other words, input signals must excite ill-conditioned system in order to produce output signals as uncorrelated as possible. Therefore, rotated input signal is one of the most appropriate input signals to be used in subspace identification of ill-conditioned multivariable systems.

Fig.8 shows the singular values of the matrix M (for $r = 6$) in the rotated inputs case. As can be observed in this figure, the system order is 5.

After model order determination, subspace method MOESP is used to identify the system. Identification for both types of input test is performed over 20 simulation runs. For estimated model validation, the singular values and RGA are checked. Fig. 9-12 show the singular values and RGA of 20 simulation runs.

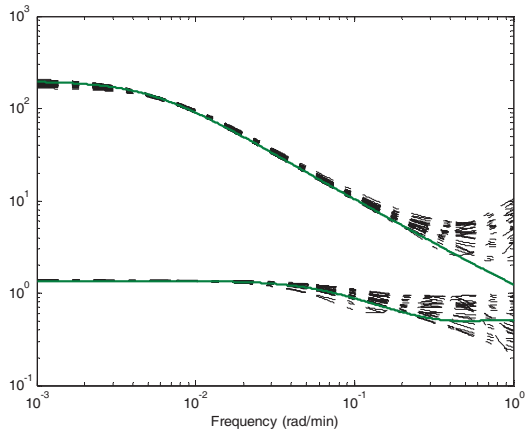

Fig. 11. Singular values of MIMO MOESP models from 20 simulations using rotated input test

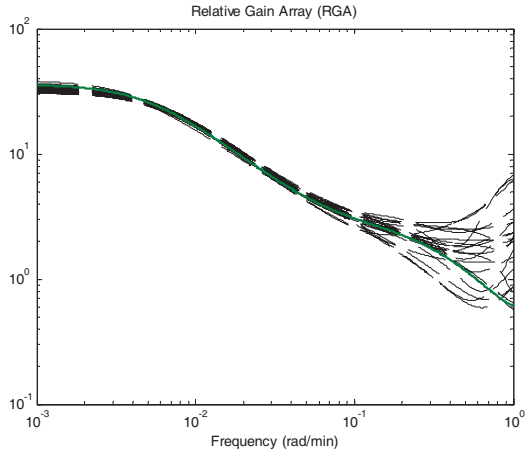

Fig. 12. RGA of MIMO MOESP models from 20 simulations using rotated input test

Note that in these figures, solid lines are the true values and dashed lines are the estimates. It can be seen that the high gain of process is easily estimated whereas the low-gain is very poorly estimated using the uncorrelated test signals. However, by using rotated input signal, good estimates of both low and high gain directions are achieved.

5. CONCLUSIONS

The standard uncorrelated test signals estimate the low-gain direction of ill-conditioned systems poorly. Therefore, the low gain information needs to be excited more in order to obtain good estimates. In this paper, MIMO rotated input design for ill-conditioned process identification was described. Rotated input signals allow more excitation to be applied in the weak gain direction of the process and less excitation in the strong gain direction. In this approach, the singular value decomposition (SVD) of the steady state gain matrix is used to rotate the input signals along the directions of the right singular vectors. The application of the proposed method was carried out on a high-purity distillation column as an ill-conditioned process. Simulation results show good accuracy of the proposed method in identifying both low and high gain directions.

Abstract: We address the problem of linear parameter estimation in discrete time state space models in the presence of serially correlated error in variables. The common way to solve parameter estimation problem is least squares (LS) methods. LS method is not considered to be effective when both dependent and independent variables are contaminated by noise. Total Least Squares (TLS) has been introduced as the method for parameter estimation in the case of noisy response and predictor variables. However, TLS solution is not optimal when number of data is limited and noise is correlated. Constrained TLS is a variant of TLS that considers correlation of noise in the data as additional constraints. We introduced a novel method based on a stochastic sampling method to solve estimation problem from correlated noisy measurements, and we compared it with the existing methods through in silico examples. Our method demonstrates significant improvement over other common estimation algorithms, LS, TLS and Constrained TLS under the different amount of correlated noise and data points. It has the potential to be the valuable tool for the difficult real life problems, such as, biological systems where data is limited and noisy.

Keywords: Linear parameter estimation; Least Squares; Total Least Squares; Constrained Total Least Squares; Multiplicative noise; additive noise; correlation; state space models; stochastic.

1. INTRODUCTION

The problem of linear parameter estimation arises in a broad class of scientific disciplines such as signal processing, automatic control, system theory, general engineering, statistics, physics, economics, biology, medicine, etc (Huffel ,1991). Linear estimation problem becomes challenging in the presence of correlated noise. Errors are unavoidable and can be related to many sources, such as modelling, human or instruments. They may appear in different forms depending on the source of error and nature of the system. Noise can be proportional to the signal itself (multiplicative),simply additive or it can include both components. In this paper, we will particularly focus on parameter estimation in linear discrete time state space models in the presence of measurements that include both multiplicative and additive error terms. One can write the linear discrete time system as follows;

$$\hat{x}_i^{k+1} = a_{i1}\hat{x}_i^k + a_{i2}\hat{x}_2^k + ,...,+a_{iN}\hat{x}_N^k \qquad i = 1,...,N \tag{1}$$

In this equation this equation, value of observed state at time $k+1$ is linear function of all N observed states at time point, k . This model can be extended for all states and time points in a compact form as follows:

$$\hat{X}' = A^{(N\times N)}\hat{X} \tag{2}$$

$$\hat{X}'^{(N\times(M-1))} = \{\vec{x}^{\,2},..., \vec{x}^{\,M}\} \qquad \hat{X}^{(N\times(M-1))} = \{\vec{x}^{\,1},..., \vec{x}^{\,(M-1)}\}$$

where M is the number of time points and N is the number of states. Each column of X and X' is represented with the vector,

$$\vec{x}^{\,j} = [\hat{x}_1^{\,j},..., \hat{x}_N^{\,j}]^T . \tag{3}$$

The parameters are collected in matrix,

$$A^{(N\times N)} = \{ a_{ij} \}. \tag{4}$$

This paper is organized as follows. In next section we will briefly summarize common methods to solve linear estimation problem. Furthermore, we will introduce our novel approach based on a sampling algorithm. Section 3 will summarize assessment of the performance of our method compared to some common existing methods. Finally, section 4 will present the concluding remarks.

2. METHODS

2.1 Common methods

Many methods have been introduced to solve the linear estimation problem (Ljung ,1987 and Huffel ,1991). The classic way to solve the linear estimation problem is least squares. In the classical least squares regression theory, the errors are assumed to be confined only to $\hat{X}'$ (response variables) , and $\hat{x}$ (predictor variables) are assumed to be error free. One can write least squares estimate for parameters as follows,

$$A^T = \left(\hat{X}\hat{X}^T\right)^{-1}\hat{X}\hat{X}'^T \tag{5}$$

However, in our problem, it is not realistic to assume $\hat{X}$ to be error free as it shares the same columns with $\hat{x}'$except for the first column. (See (2)). This results in serial correlation between $\hat{X}$, and $\hat{X}'$.

Total least squares (TLS) is another method of linear parameter estimation when there are errors in both sides of the equation ($\hat{X}$ and $\hat{X}'$) (Huffel ,1991).

$$\hat{X}' = X' - \Delta X' \qquad \hat{X} = X - \Delta X$$

$$\Delta X' = \left[\Delta x^2,...,\Delta x^M\right] \qquad \Delta X = \left[\Delta x^1,...,\Delta x^{M-1}\right] \tag{6}$$

where, $\Delta X'$ and ΔX are the noise terms. Since X and $X'$are not known, for each state ($i = 1,...,N$), equation (2) can be written in the following format;

$$x_i + \Delta x_i = a^{(1\times N)}\left(\hat{X} + \Delta\hat{X}\right)$$

(7)

where $x_i = \left[x_i^2,...,x_i^M\right]$ and $\Delta x_i = \left[\Delta x_i^2,...,\Delta x_i^M\right]$ are the i^{th}rows of $\hat{X}'$ and $\Delta X'$respectively (See (2, 6)). $a = \left[a_{i1},..,a_{iN}\right]$ is the i^{th} row of A .

Let,

$$C = \left[\hat{X}^T\ x_i\right] \text{ ,and } \quad \Delta C = \left[\Delta\hat{X}^T\ \Delta x_i^T\right] \tag{8}$$

Then, equation (6) can be written as;

$$\left(C + \Delta C\right)\cdot\begin{bmatrix} a^T \\ -1 \end{bmatrix} = 0$$

where a is the i^{th} row of A . The TLS problem then can be posed as follows;

$$\min\left\|\Delta C\right\|_2^F \quad \text{subject to} \quad (C+\Delta C)\cdot\begin{bmatrix} a^T \\ -1 \end{bmatrix} = 0 \tag{9}$$

The solution to this problem given as;

$$a^T = \left(\hat{X}\cdot\hat{X}^T - \lambda^2 I\right)^{-1}\hat{X}\cdot\hat{X}'^T \tag{10}$$

where λ is the smallest singular value of C . Compared to least squares solution (5), the TLS solution has a correction term, λ at the inverse of the matrix. This reduces the bias in the solution which is caused by noise in X (Kim et al, 2007). However, TLS solution inherently assumes that the noise terms, $\Delta X'$and Δx_i are independent , which is not the case here.

The correlation between two noise term requires the total least squares solution to have additional constraints instead merely satisfying the existence of a solution (Cadzow and Wilkes, 1985). Recently, Kim et al. (2007) applied constrained least squares algorithm in the context of gene network identification problem on a linear discrete time model. In their model, they rewrite error term, ΔC in an open form and as follows;

$$\Delta C^{(M-1)\times(N+1)} = \left[\Delta\hat{X}^T\ \Delta x_i^T\right] = \begin{bmatrix} \Delta x_1^1 & ... & \Delta x_i^1 & .... & \Delta x_N^1 & \Delta x_i^2 \\ . & . & . & . & . & . \\ . & . & . & . & . & . \\ . & . & . & . & . & . \\ \Delta x_1^{M-1} & ... & \Delta x_i^{M-1} & ... & \Delta x_N^{M-1} & \Delta x_i^M \end{bmatrix} \tag{11}$$

They introduced the vector, $e_i^{(N\times 1)} = [0,...,1,..,0]^T$ whose elements are zero except for the i^{th} element, which is equal to 1. All error terms are rewritten in a vector form as follows;

$$\Delta Y^{1\times(N(M))} = \left[\left(\Delta x^1\right)^T,...,\left(\Delta x^M\right)^T\right] \tag{12}$$

The first N columns of ΔC can be written as follows;

$$\Delta C^i = G_i\cdot\Delta Y^T \tag{13}$$

Where $G_i = \left[\left(I_{M-1}\otimes e_i\right)^T\ 0_{(M-1)\times N}\right]$ and I_{M-1} denotes the identity matrix of size $(M-1)\times(M-1)$ and the symbol, $\otimes$, denote Kronecker product of two matrices. $0_{(M-1)\times N}$ represents the matrix of zeros with size, $(M-1)\times(N)$

After several steps and simplifications, they posed this as optimization problem as follows;

$$\min\left\|\Delta C\right\|^2 = \min_a\left[a\ \ -1\right]C^T\left(H_a^{-1}\right)^T\left(H_a^{-1}\right)C\begin{bmatrix} a^T \\ -1 \end{bmatrix} \tag{14}$$

where $H_a = \sum_i a_i\cdot G_i$. This is a nonlinear, non-convex optimization problem without constraints. They initialized the optimization problem with least squares solution.

2.2 Our method

In this paper, we introduced a new method to solve linear parameter estimation problem when both sides of the equation are contaminated by error. This method based on a stochastic sampling approach. In this method, observations $(\hat{X}, \hat{X}')$ are perturbed by adding a negative noise term in each sample.

$$ {}^{(j)}y_i^k = \hat{x}_i^k - {}^{(j)}\varepsilon_i^k \qquad {}^{(j)}\varepsilon_i^k \propto N\left(0, \sigma_i^k\right) \tag{15} $$

$$ i = 1,...,N \qquad j = 1,...,S \qquad k = 1,...,M $$

Where ${}^{(j)}y_i^k$ is the j^{th} perturbed observation for i^{th} state at time point k and ${}^{(j)}\varepsilon_i^k$ is the amount of perturbation sampled from Gaussian distribution of zero mean and σ_i^k variance in the j^{th} sample. N is the number of states, S is the number of samples and M stands for the number of time points. Variance for perturbation σ_i^k is chosen roughly close to variance of the observation error in i^{th} state and k^{th} time point. (μ_{ik} , see equation (20)). The amount of perturbation , ${}^{(j)}\varepsilon_i^k$, is selected through Monte Carlo Sampling procedure.

Finally, all data points for each state i at each sample j are collected in a vector form. This is performed for both sides of equation (2). Let,

$$ {}^{(j)}y_i = \left[{}^{(j)}y_i^1,...,{}^{(j)}y_i^k,...,{}^{(j)}y_i^{M-1}\right]^T $$

$$ {}^{(j)}y_i' = \left[{}^{(j)}y_i^2,...,{}^{(j)}y_i^k,...,{}^{(j)}y_i^M\right]^T \tag{16} $$

Equation (16) can be written in a matrix form for all states, $i = 1,...,N$

$$ Y^{(j)} = \left[{}^{(j)}y_1 \ldots {}^{(j)}y_i \ldots {}^{(j)}y_N\right]^T $$

$$ Y'^{(j)} = \left[{}^{(j)}y_1' \ldots {}^{(j)}y_i' \ldots {}^{(j)}y_N'\right]^T \tag{17} $$

Next, equation (17) can be written for all samples, $j = 1,...,S$;

$$ Y^{Total} = \left[Y^{(1)} \ldots Y^{(j)} \ldots Y^{(S)}\right] $$

$$ Y'^{Total} = \left[Y'^{(1)} \ldots Y'^{(j)} \ldots Y'^{(S)}\right] \tag{18} $$

The parameters are estimated using least squares solution;

$$ A^T = \left(\left(Y^{Total}\right)^T \cdot Y^{Total}\right)^{-1}\left(Y^{Total}\right)^T Y'^{Total} \tag{19} $$

3. ASSESSING THE PERFORMANCE

To test the performance of our method against least squares (LS), Total Least Squares , and Constrained TLS solutions, we created ensemble of 50 linear time discrete systems with different parameters, each consisting of 10 states. This is achieved by creating random $A^{10\times10}$ matrices. We assumed sparse structure for each $A^{10\times10}$ matrix, therefore the number of non-zero elements are fixed to 30 out of 100 total connections. Each system is simulated for certain number of time points (M) starting from a random initial condition. However, we assumed limited number of data for the systems, as most of the real systems have small number of data (Most biological systems, gene networks, etc.). Multiplicative and additive noise terms are added to the simulation results as follows;

$$ \hat{x}_{ik} = x_{ik} + x_{ik}\mu_{ik} + \eta_{ik} $$

$$ \mu_{ik} \approx N(0, \sigma_1) \qquad \eta_{ik} \approx N(0, \sigma_2) \tag{20} $$

In this equation, $\hat{x}_{ik}$ is the observed value of i^{th} state at k^{th} time point. ε_{ik} and η_{ik} are random variables assumed to have Gaussian distribution with zero mean and variances σ_1 and σ_2 respectively. The term, $x_{ik}\mu_{ik}$ corresponds to the multiplicative noise term, whereas η_{ik} stands for the additive noise term. Our algorithm is tested against the other algorithms for different level of noise and number of time points. Performances of methods for parameter estimation are quantified as the Frobenius norm of the deviation of estimated parameters from their true values relative to the Frobenius norm of true parameters according the following formula;

$$ E_A = \frac{\left\|A - A^R\right\|_F}{\left\|A^R\right\|_F} \tag{21} $$

where A^R and A stand for the true and estimated parameters respectively. In addition, fitness of the system is evaluated and compared to true values of states similar to (15);

$$ E_X = \frac{\left\|X - X^R\right\|_F}{\left\|X^R\right\|_F} \tag{22} $$

where X and X^R indicates estimated and true values of states, respectively. E_A and E_X are calculated for ensemble of 50 different systems at each number of sample point and averaged. In figure 1, one can see the comparison of the methods with respect to number of samples when multiplicative and additive noise terms are set to $\sigma_1 = 0.10$, and $\sigma_2 = 0.0001$ and number of time points is 10.

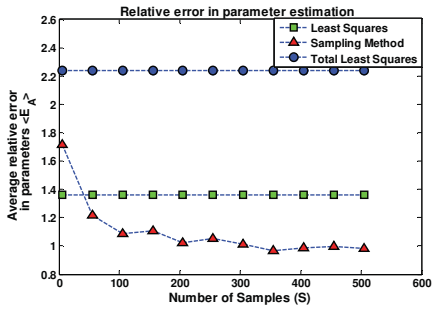

Fig.1. Relative error in parameter estimation vs number of samples for 10 time points at $\sigma_1 = 0.10$

Our method shows significant decrease in relative error in parameters compared to total least squares and least squares with increasing number of samples.

Methods	M=12	M=18	M=24
Least Squares	2730.1	1.1925	0.59776
Sampling Method **(at S=500)**	**0.11563**	**0.48125**	**0.44043**
Total Least squares	200.95	29.465	35.352
Constrained TLS	0.72001	289.98	3.7678

Table1. Average relative error in fitness for different methods for different time points at $\sigma_1 = 0.10$

Table 1 depicts the average relative error in fitness across the different methods and for different number of data. Our method outperforms all methods for 500 samples.

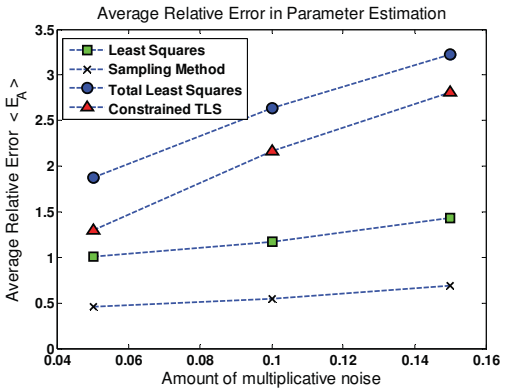

Fig.2. Average relative error in parameters versus amount of multiplicative noise for 18 time points

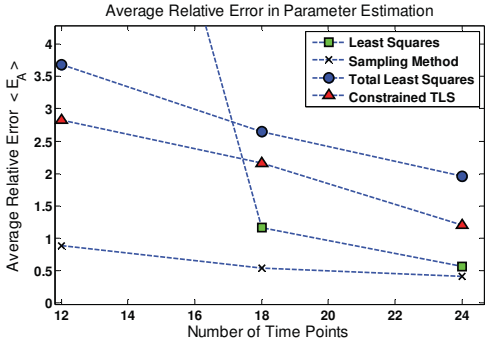

Fig.3. Average relative error in parameters versus number of time points at $\sigma_1 = 0.10$

Figure 2 indicates that our method performs significantly better than LS, TLS and constrained TLS across different levels of noise. TLS is expected to perform better in the case of noisy dependent and independent variables if enough data points are available. However, in this particular problem, due to the serially correlated multiplicative error and limited number of data, its performance is even below least squares solution. We assumed relatively small number of data, because for most of the interesting real systems, data is usually limited and noisy. Constrained TLS solution resolves the serial correlation problem and performs better than TLS, however, its performance still falls behind least squares solution because of limited data. When the number of data increases, the performances of all methods converge (See Figure (3)).

In Fig.3, one can observe that sampling method gives least amount of error in parameters at different number of time steps.

Methods	$\sigma_1 = 0.05$ $\sigma_2 = 0.0001$	$\sigma_1 = 0.10$ $\sigma_2 = 0.0001$	$\sigma_1 = 0.15$ $\sigma_2 = 0.0001$
Least Squares	7.3e+007	2730.1	9.9e+10
Sampling Method **(at S=500)**	**0.059484**	**0.11563**	**0.16913**
Total Least squares	11.331	200.95	21.864
Constrained TLS	1.2951	0.72001	8.4658

Table 2. Average relative error in fitness for different methods for 10 time points at different levels of noises.

In table 2, it is seen that the fitness of our method is much better than other methods for different noise levels.

4. CONCLUSIONS

The contribution of this work can be summarized in two ways. First, our method outperforms the common estimation methods in parameter estimation in the presence of correlated noise. Second, fitness of the estimated parameters through our method is significantly better than LS, TLS and Constrained TLS method. This method is particularly promising in the application of gene network identification problem. The biological measurements are notorious for having a high level of multiplicative noise which makes the network identification problem difficult. Our method has the potential to be the valuable tool for this difficult problem.

Abstract: Modeling of esterification reaction of ethanol with acetic acid in a reactive batch distillation column is investigated. The dynamic model developed is verified using the data of a theoretical study available in the literature. However, the existing models are found to be inappropriate for this system when compared with the experimental data. Then the model is improved using the data obtained from the experiments performed on a lab-scale column. In the model, different rate expressions and different thermodynamic models ($\phi-\phi$, EOS-G_{ex}, and $\gamma-\phi$ methods) considering different equations of state (EOS), mixing rules and activity coefficient models are used. It is found that the $\gamma-\phi$ approach considering van der Waals mixing rule and NRTL activity coefficient model gives the best fit between the dynamic model and the results of the experiments for the system under study.

Keywords: Reactive Distillation, Batch Column, Mathematical Modeling, Dynamic Simulation, Ethyl Acetate Production.

1. INTRODUCTION

Reactive distillation, which is combination of reaction and separation operations in a single unit, has many advantages over conventional processes. Modeling of this process is a challenging task due to its complex dynamics, highly nonlinear behaviour, complex interactions between vapor-liquid equilibrium (VLE) and chemical kinetics.

The system studied in this work is an esterification reaction where ethanol (EtOH) reacts with acetic acid (AcAc) to produce ethyl acetate (EtAc) and water (H_2O). In this quaternary system, azeotropes are formed between EtOH-H_2O, EtAc-H_2O, EtAc-EtOH, and EtAc-H_2O-EtOH. In the literature, most of the studies on this reaction utilized the numerical methods of solution (Chang and Seader, 1988; Bogacki et al., 1989; Simandl and Svrcek, 1991) and some others worked on its thermodynamics for phase equilibrium (Okur and Bayramoglu, 2001; Park et al., 2006) with very simple models in simulation. Assumptions considered are; ideal plates with constant molar holdup, negligible tray hydrodynamics and steady state condition. Alejski and Duprat (1996) dealt with the dynamic simulation of a reactive distillation column for EtAc system in presence of a catalyst. Tang et al. (2003) showed that, NRTL activity coefficient model parameters predict the VLE data of this system well. Both of these dynamic studies are done on continuous column. On the other hand, unlike continuous columns very few studies are done for modeling of reactive batch columns. Mujtaba and Macchietto (1997) developed an optimization algorithm and Monroy-Loperena and Alvarez-Ramirez (2000) developed an output-feedback control algorithm for a reactive batch column. However, in their studies they used very simplified VLE models and the model is not checked with experimental data.

The objective of this study is to develop a dynamic mathematical model for the esterification reaction of EtOH and AcAc in a reactive batch distillation column (RBDC) by verifying it with experimental data. Thus, different thermodynamic models are used for VLE calculations in order to obtain a good fit with the experimental data.

2. EXPERIMENTAL

The batch distillation column (Fig. 1) used in this study (Bahar, 2007) has an inner diameter of 5 cm, a height of 40 cm, and 8 sieve plates. The overall column parameters and experimental operating conditions are given in Table 1. The column is first operated at total reflux. After steady state is reached, reflux ratio is set to a predefined value. Analyses of the collected samples are done through Gas Chromatography.

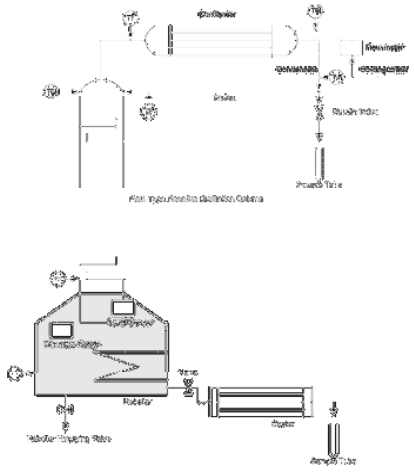

Fig. 1. Reactive Batch Distillation Column.

Table 1. Experimental Column Parameters and Operating Conditions

Total fresh feed, mol	311.67
Feed composition (EtAc, EtOH, H_2O, AcAc), mole fraction	0.0, 0.5, 0.0, 0.5
Column holdup, mol	
condenser+drum	30
internal plates	0.779
Reboiler heat duty, J/h	2.016×10^6
Column pressure, bar	1.013
Cooling water flow rate, lt/min	1.0

3. RBDC MODELING

The unsteady state model of RBDC is based on model of Yıldız et al. (2005). The assumptions employed are negligible vapour holdup, constant volume of tray liquid holdup, constant liquid molar holdup in the reflux drum, total condenser, negligible fluid dynamic lags, linear pressure drop profile, Murphree tray efficiency, approximated enthalpy derivatives and adiabatic operation. The balance equations for column reboiler, trays and reflux-drum-condenser system are given as follows:

Reboiler: j = 1,…,NC

$$dM_1/dt = L_2 - V_1 \qquad (1)$$

$$d(M_1 x_{1j})/dt = L_2 x_{2j} - V_1 y_{1j} + \varepsilon_j R_1 M_1 \qquad (2)$$

$$d(M_1 h_1)/dt = L_2 h_2 - V_1 H_1 + Q_1 \qquad (3)$$

where the reboiler holdup, M_1, is as given in (4) where M_f^0 is the molar amount of feed initially charged to the column.

$$M_1 = M_f^0 - \sum_{n=2}^{NT+2} M_n - \int_0^t D(\tau)d\tau \qquad (4)$$

Trays: i = 2,…,N_{T+1}; j = 1,…,NC

$$dM_i/dt = L_{i+1} + V_{i-1} - L_i - V_i \qquad (5)$$

$$d(M_i x_{ij})/dt = L_{i+1}x_{i+1,j} + V_{i-1}y_{i-1,j} - L_i x_{ij} - V_i y_{ij} + \varepsilon_j R_i M_i \qquad (6)$$

$$d(M_i h_i)/dt = L_{i+1}h_{i+1} + V_{i-1}H_{i-1} - L_i h_i - V_i H_i \qquad (7)$$

where $M_i = (\rho_i^{avg} / Mw_i^{avg})v_i$ is the molar holdups on trays where ρ_i^{avg} is the average density of the mixture on the i[th] tray, Mw_i^{avg} is the average molecular weight of the mixture on the i[th] tray, v_i is the volume of the liquid tray holdup.

Reflux-drum-condenser system: j = 1,…,NC

$$dM_{NT+2}/dt = V_{NT+1} - L_{NT+2} - D \qquad (8)$$

$$\frac{d(M_{NT+2}x_{NT+2,j})}{dt} = V_{NT+1}y_{NT+1,j} - L_{NT+2}x_{NT+2,j} - Dx_{NT+2,j} + \varepsilon_j R_{NT+2} M_{NT+2} \qquad (9)$$

$$\frac{d(M_{NT+2}h_{NT+2})}{dt} = V_{NT+1}H_{NT+2} - L_{NT+2}h_{NT+2} - Dh_{NT+2} - Q_{NT+2} \qquad (10)$$

where R_i is the reaction rate at i[th] stage in mol/h and can be expressed as given in (11) and the rate expression, r_i, without catalyst is expressed as $r = k_1 x_2 x_4 - k_2 x_3 x_1$. The forward and backward reaction rate constants in lt/gmol.min are k_1=29100exp(-7190/T(K)) and k_2=7380exp(-7190/T(K)), respectively (Alejski and Duprat, 1996).

$$R_i = r_i \rho_i / MW_i \quad \text{for i = 1,…,}N_{T+2} \qquad (11)$$

The reflux ratio is defined as $R = L_{NT+2}/D$. The subscripts i and j are for stage and component numbers, respectively. i=1 for reboiler, i=2,.,N_{T+1} for trays and i=N_{T+2} for reflux-drum-condenser unit. The components are numbered in the subscripts as follows: EtAc-1, EtOH-2, H_2O-3, and AcAc-4.

In energy balance equations, no additional term for the heat of reaction is included because, the enthalpies are referred to their elemental state for which the heat of reaction is accounted automatically and thus, no separate term is needed (Mujtaba and Macchietto, 1997). The linear pressure drop profile is given as $P_i = P_1 - i(P_1 - P_{NT+2})/NT$ where P_i is the pressure in i[th] tray, P_1, the pressure in the reboiler and P_{NT+2}, the pressure in the reflux drum.

4. MODELS FOR VAPOR-LIQUID EQUILIBRIUM

In modeling of batch distillation column, the selection of proper thermodynamic model affects the estimation of compositions highly and therefore is very crucial. In simulation studies, four different models are used for phase equilibrium and these models are explained below in detail.

4.1 Model-I:Phase Equilibrium Using VLE data in Literature

VLE data for EtAc-EtOH-H_2O-AcAc system given in Table 2 is taken from literature (Suzuki et al., 1971). This data is utilized in the simulation as a preliminary check.

Table 2. Vapor Liquid Equilibrium Data.

EtAc	log K = -2.3 x 10^3/T + 6.742
EtOH	log K = -2.3 x 10^3/T + 6.588
H_2O	log K = -2.3 x 10^3/T + 6.484
AcAc	K = (2.25 x 10^{-2})/T - 7.812 for T > 347.6 K
	K = 0.001 for T ≤ 347.6 K

4.2 Model-II: Phase Equilibrium Using $\phi - \phi$ Approach

In this approach, Peng Robinson EOS (PR) with van der Waals one-fluid mixing rule is used to calculate the fugacity of species for both liquid and vapor phases. The binary interaction parameters are given in Table 3 (Burgos-Solorzano, 2004).

Table 3. Binary interaction parameters, k_{ij}.

k_{ij}	EtAc	EtOH	H_2O	AcAc
EtAc	0.0	0.022	-0.280	-0.226
EtOH	0.022	0.0	-0.935	-0.0436
H_2O	-0.280	-0.935	0.0	-0.144
AcAc	-0.226	-0.0436	-0.144	0.0

4.3 Model-III: Phase Equilibrium Using Combination of EOS with Excess Free Energy Models (EOS-G_{ex} Approach)

In this method, activity coefficient models are incorporated into EOS. NRTL, Wilson, and UNIQUAC models are used

and performances for the system under consideration are compared. The parameters for these models are obtained from Tang et al. (2003), Okur and Bayramoğlu (2001), and Kang et al., (1992).

In this study, as EOS; PR and Peng-Robinson-Stryjek-Vera (PRSV) (Stryjek and Vera, 1986) are used. κ_1 parameters for components are given in Table 4 (Stryjek and Vera, 1986). As the mixing rule, van der Waals one-fluid mixing rule, Huron-Vidal (Original) Mixing Rule (HVO), and Orbey-Sandler modification of the Huron-Vidal mixing rule (HVOS) are used.

Table 4. PRSV EOS parameters, κ_1 .

Components	κ_1
EtAc	0.0693
EtOH	-0.03374
H_2O	-0.06635
AcAc	-0.19724

4.4 Model-IV: Phase Equilibrium Using $\gamma-\phi$ Approach

In VLE descriptions with the $\gamma-\phi$ approach, an activity coefficient model can be used for the liquid phase and an EOS is used for the vapor phase.

5. RESULTS AND DISCUSSION

This study is done in three phases. In first phase, modeling studies are done and then checked with a simulation study found from the literature which has the same reactive system. In second phase, experimental studies are done and data is collected for total and different reflux ratios. In third phase, the experimental findings and the simulation results are compared and the dynamic model is finalized by selecting the appropriate thermodynamic model for VLE calculations.

The properties of the column which is used in simulation are given in Table 5. Monroy-Loperena and Alvarez-Ramirez (2000) used the VLE data of Model-I and temperature independent rate constants with k_1 of $4.76\text{x}10^{-4}$ lt/(gmol.min) and k_2 of $1.63\text{x}10^{-4}$ lt/(gmol.min). The comparison of dynamic model using same rate expression at total reflux is given in Fig. 2. As can be seen, the results are almost the same. This indicates that the developed dynamic model is quite satisfactory to represent this non-linear and complex problem of RBDC behaviour.

Table 5. RBDC Specifications

No. of stages (including reboiler and total condenser)	10
Total fresh feed, kmol	5.0
Feed composition (EtAc, EtOH, H_2O, AcAc), mole fraction	0.0, 0.45, 0.1, 0.45
Column holdup, kmol	
condenser	0.1
internal plates	0.0125
Condenser vapor load, kmol/h	2.5
Column pressure, bar	1.013

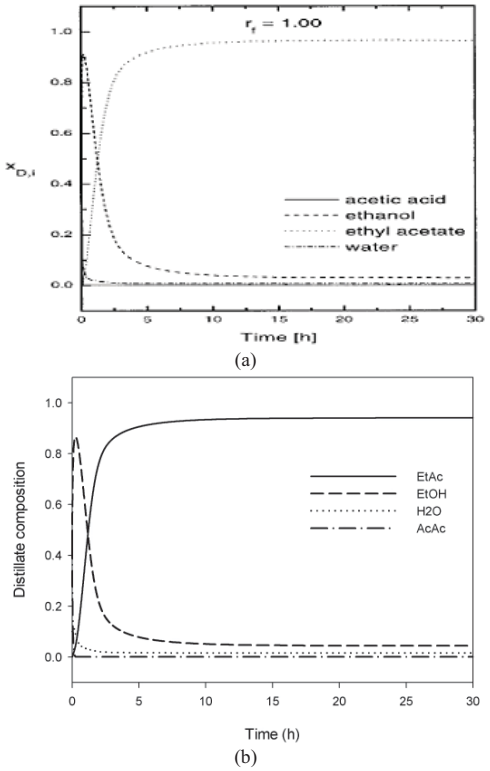

Fig. 2. Distillate compositions at total reflux. (a) Results from literature (b) Results from the simulation in this study.

After obtaining similar results with literature, experiments are performed in order to improve the model. Column is first operated at total reflux until the steady state is reached. Then it is operated with arbitrary reflux ratios and data for distillate and reboiler compositions are collected with respect to time.

5.1 Dynamic Analysis of the Results of Experimental and Simulation Studies

There is a difference in initialization of the experiments and simulation program. Therefore, although the trends of the profiles of compositions are similar, they cannot be compared up to steady state point. Consequently, if the two results match at total reflux steady state, then comparisons of dynamic response can be done. Thus, for each model explained in Section 4, the experimental data collected is checked with the simulation results.

Model-I: In Table 6, simulation result of Model-I and experiments at total reflux steady state are given. It can be seen that, when steady state values are compared, they are too different from each other and there is no need to check the dynamic behaviour. More accurate VLE model is needed.

Table 6. Total Reflux Steady State Composition Values

Comp.	Distillate		Reboiler	
	Exp.	Sim.	Exp.	Sim.
EtAc	0.5222	0.9384	0.1434	0.2582
EtOH	0.2408	0.0476	0.3189	0.1829
H_2O	0.2371	0.0135	0.1918	0.3684
AcAc	0.0000	$5.61\text{x}10^{-4}$	0.3459	0.1906

Model-II: The results of simulation that uses Model-II and experiments are given in Fig. 3. It is found that total reflux steady state values are better compared to Model-I. The comparison is further continued dynamically for a constant reflux ratio of 5.72. The time at total reflux steady state is shown as zero. It can be seen that there are great differences in the distillate and reboiler liquid composition trends with respect to time.

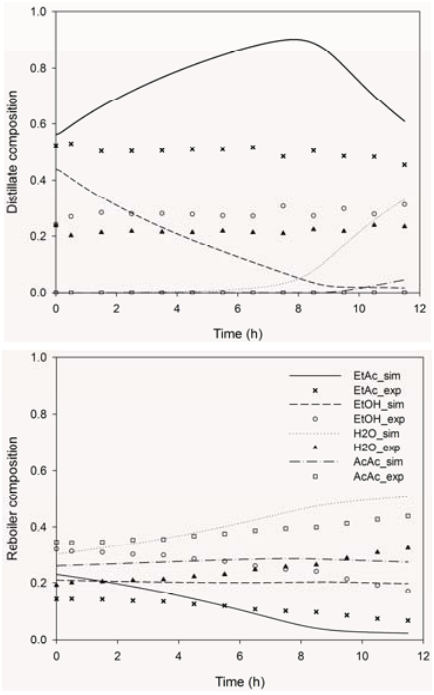

Fig. 3. Results with Model-II

Model-III: In Model-III, first of all PR with HVO mixing rule and NRTL activity coefficient model (Model-III-A) is tested. It can be seen from Fig. 4 that the results are somewhat improved compared to Model-II, especially for the reboiler compositions. However, the results for distillate compositions are not satisfactory. Therefore, EOS is changed to PRSV with same mixing rule and activity coefficient model; the performance of the system with this model (Model-III-B) is given in Fig. 5. Distillate compositions are much better than that of Model-III-A. However, reboiler compositions become worse and therefore this result is also found to be not satisfactory. As a further step, mixing rule is changed to HVOS and it is used together with PRSV and NRTL activity coefficient model (Model-III-C). The results are given in Fig. 6. The results for both distillate and reboiler compositions are improved significantly with this thermodynamic model.

In order to see the effects of different activity coefficient models, Wilson and UNIQUAC models are used in EOS-G_{ex} approach. The distillate and reboiler liquid compositions with Wilson model (Model-III-D) and UNIQUAC model (Model-III-E) are given in Fig. 7 and Fig. 8, respectively. It can be seen from the figures that, while NRTL and Wilson models give similar results, UNIQUAC performs poorly. NRTL model is selected to be the most proper activity coefficient model for this system, since it gives slightly better results than Wilson model, and will be used also in Model-IV.

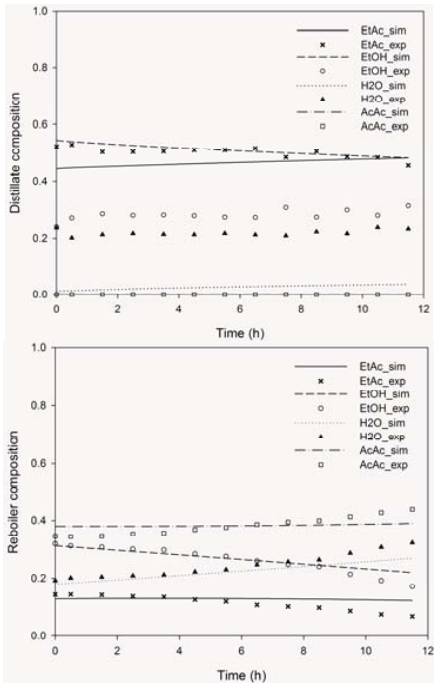

Fig. 4. Results with Model-III-A

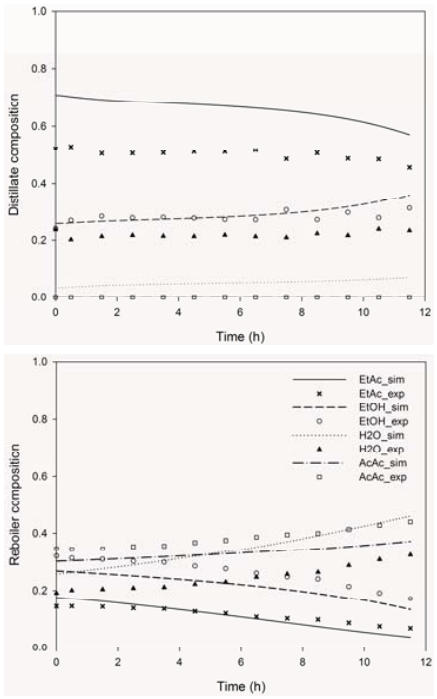

Fig. 5. Results with Model-III-B

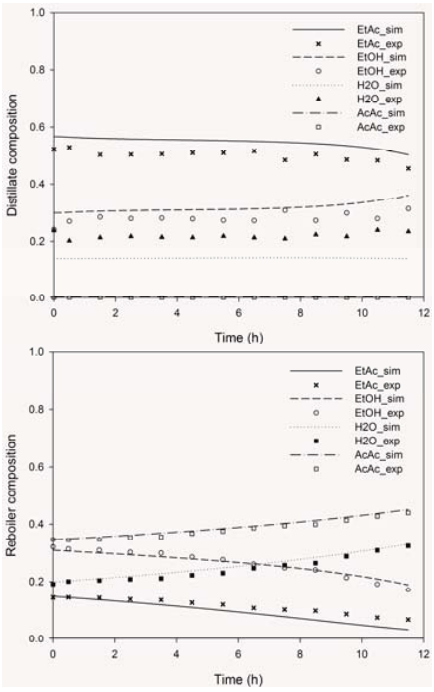

Fig. 6. Results with Model-III-C

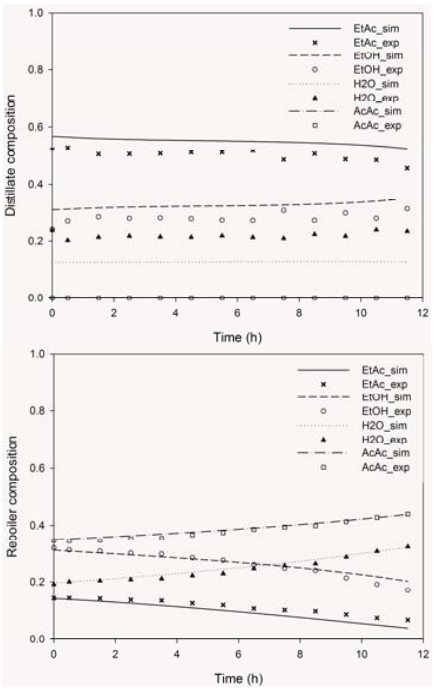

Fig. 7. Results with Model-III-D

Model-IV: In Model-IV, NRTL activity coefficient model is used for liquid phase, PRSV (Model-IV-A) and PR (Model-IV-B) with van der Waals mixing rule is used for vapor phase. It can be seen from Fig. 9 that the distillate compositions are improved compared to Model-III. Although the reboiler compositions become a little worse, they are in an acceptable range. Unlike Model-III, PR also gives similar results with PRSV in Model-IV as can be seen in Fig. 10.

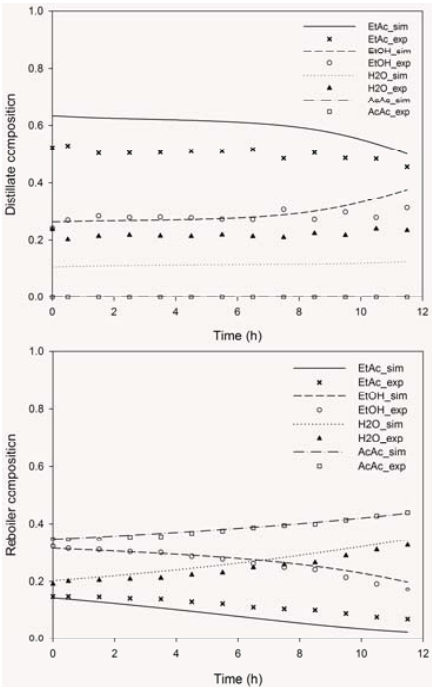

Fig. 8. Results with Model-III-E

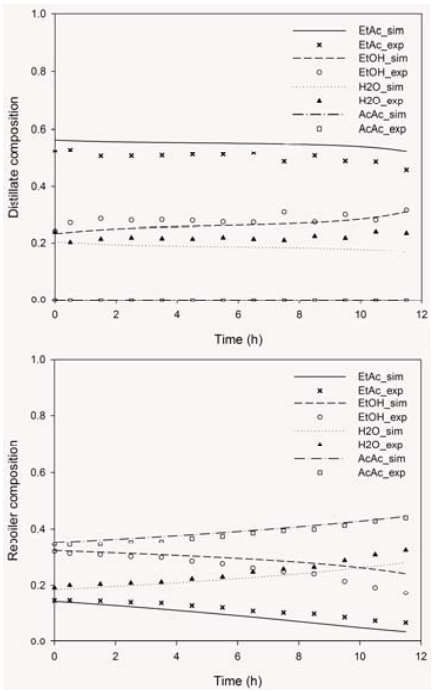

Fig. 9. Results with Model-IV-A

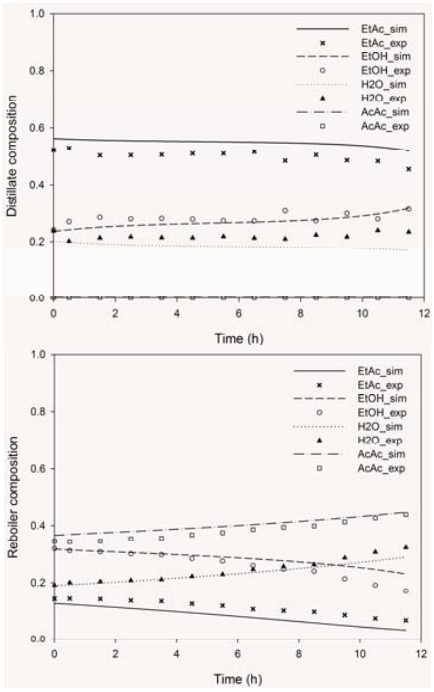

Fig. 10. Results with Model-IV-B

Table 7. Summary of Thermodynamic Models.

Model	*Description*	*IAE Scores*		
		Distillate	*Reboiler*	*Overall*
Model-I	VLE data from literature	-	-	-
Model-II	$\phi-\phi$ method (PR+van der Waals)	-	-	-
Model-III-A	EOS-G^{ex} method (PR + HVO + NRTL)	6.080	1.049	7.129
Model-III-B	EOS-G^{ex} method (PRSV + HVO + NRTL)	4.514	2.805	7.320
Model-III-C	EOS-G^{ex} method (PRSV+HVOS+NRTL)	2.131	0.621	2.751
Model-III-D	EOS-G^{ex} method (PRSV+HVOS+Wilson)	2.437	0.552	2.989
Model-III-E	EOS-G^{ex} method (PRSV+HVOS+UNIQUAC)	2.915	0.877	3.791
Model-IV-A	$\gamma-\phi$ method (PRSV+van der Waals+NRTL)	1.321	1.026	2.347
Model-IV-B	$\gamma-\phi$ method (PR+van der Waals+NRTL)	1.279	1.072	2.351

6. CONCLUSIONS

A summary of results for different thermodynamic models are given in Table 7 with Integral Absolute Error (IAE) scores of response curves. Model-IV-A, which uses traditional $\gamma-\phi$ approach with NRTL activity coefficient model for liquid phase and PRSV for vapor phase gives the smallest IAE score for the quaternary EtOH-AcAc-EtAc-H_2O system. Nevertheless, Model-IV-B which uses the traditional approach with NRTL activity coefficient model for the liquid phase and the PR-EOS for the vapor phase, which is simple to use also gives similar result with a slightly higher IAE score. Thus, both methods are suggested to be used in the simulation of EtOH esterification reaction with AcAc in a RBDC system.

Abstract: This paper addresses the application of a new MPC to a distillation system where isobutane and light butenes are separated from butane and heavier compounds. This system is located in the alkylation unit of an oil refinery. The MPC considered here is based on the infinite horizon MPC extended to the case where the system has stable and integrating modes. The controller is developed based on a particular state space model in the incremental form, which considers the existence of time delays. The proposed controller provides nominal stability to the closed loop system. Practical tests in a distillation system show that the performance of the new controller, which can be extended to consider robustness to model uncertainty is similar to the performance of the conventional MPC with finite prediction horizon.

Keywords: Predictive control; Stability; Infinite horizon; Integrating system.

1. INTRODUCTION

One of the key issues in the application of MPC to industrial processes is the requirement that the closed loop system should remain stable for a large set of tuning parameters and any possible control structure in terms of active controlled outputs and available manipulated inputs. Rawlings & Muske (1993) have demonstrated that, in the regulator operation of stable systems, the infinite horizon MPC preserves stability even in the presence of constraints in the inputs and states. These ideas have been extended to the case of output tracking of stable systems (Odloak, 2004) and to systems with stable and integrating modes (Carrapiço & Odloak, 2005; González et al., 2007). However, a recent review by Qin & Badgwell (2003) points out that these developments have not been incorporated into the available MPC technology. Thus, the main scope of this work is to report the application of an infinite horizon MPC with nominal stability to an industrial system of small dimension but that presents the typical ingredients of a practical application: time delay, measured and unmeasured disturbances and integrating modes.

The state space model considered here is an extension of the model developed by Gouvêa & Odloak (1997) and Rodrigues and Odloak (2003) and implemented by Porfírio et al. (2003) to include time delays and integrating modes and is represented as follows:

$$\begin{aligned} x(k+1) &= Ax(k) + B\Delta u(k) \\ y(k) &= Cx(k) \end{aligned} \tag{1}$$

where

$$x(k) = \left[y(k|k)^T \quad y(k+1|k)^T \quad \cdots \quad y(n+np|k)^T \quad x^s(k)^T \quad x^d(k)^T \quad x^i(k)^T \right]^T \tag{2}$$

$$A = \begin{bmatrix} 0 & I_{ny} & 0 & \cdots & 0 & 0 & 0 & 0 \\ 0 & 0 & I_{ny} & \cdots & 0 & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & I_{ny} & 0 & 0 & 0 \\ 0 & 0 & 0 & \cdots & 0 & I_{ny} & \Psi((np+1)\Delta t) & I^*((np+1)\Delta t) \\ 0 & 0 & 0 & \cdots & 0 & I_{ny} & 0 & I_{ny}\,\Delta t \\ 0 & 0 & 0 & \cdots & 0 & 0 & F & 0 \\ 0 & 0 & 0 & \cdots & 0 & 0 & 0 & I_{ny} \end{bmatrix} \tag{3}$$

$$B = \left[S(\Delta t)^T \quad S(2\Delta t)^T \quad \cdots \quad S((np+1)\Delta t)^T \quad [D^0 + \Delta t\, D^i]^T \quad [D^d F\ N]^T \quad [D^i]^T \right]^T$$

$$C = \left[I_{ny} \quad 0 \quad \ldots \quad 0 \right]$$

In the model defined in (1), $u \in \Re^{nu}$ is the manipulated input. The first np components of the state vector defined in (2) correspond to the output predictions computed at time k based solely on past control actions and disturbances, x^s are the state components associated with the integrating modes created by the incremental form of the model, x^d are the state components associated with the stable modes of the system and x^i are the state components associated with the integrating modes of the system. To represent systems with time delays, it is assumed that $np \geq m + \text{int}\left\{\max(\theta_{i,j}/\Delta t)\right\}$, where m is the control horizon of the MPC, Δt is the sampling time and $\theta_{i,j}$ is the time delay associated with output y_i and input u_j. In the state matrix defined in (3), one has

$$\Psi\left((np+1)\Delta t\right)=$$
$$\begin{bmatrix} \Phi_1\left((np+1)\Delta t\right) & & & \\ & \Phi_2\left((np+1)\Delta t\right) & & 0 \\ 0 & & \ddots & \\ & & & \Phi_{ny}\left((np+1)\Delta t\right) \end{bmatrix}$$

$$\Phi_i\left((np+1)\Delta t\right)=\begin{bmatrix} f_{i,1,1} & \cdots & f_{i,1,na} & f_{i,2,1} & \cdots & f_{i,2,na} \\ \cdots & f_{i,nu,1} & \cdots & f_{i,nu,na} \end{bmatrix}$$

where $f_{i,j,g}=r_{i,j,g}^{(np+1)\Delta t-\theta_{i,j}}$, r is a stable pole of the system. States $y(k/k),\ y(k+1/k),\ ....,\ y(k+np/k)$ correspond to the output predictions calculated at time k based solely on past control actions and disturbances.

$$I^*[(np+1)\Delta t]=\begin{bmatrix} (np+1)\Delta t-\theta_1 & 0 & \cdots & 0 \\ 0 & (np+1)\Delta t-\theta_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & (np+1)\Delta t-\theta_{ny} \end{bmatrix} \in \Re^{ny\times ny}$$

θ_i is the time delay associated with the integrating mode related to output y_i.

$D^0\in\Re^{ny\times nu}$ and $D^i\in\Re^{ny\times nu}$

$$F=\text{diag}\left(r_{1,1,1}\cdots r_{1,1,na}\cdots r_{1,nu,1}\cdots r_{1,nu,na}\cdots r_{ny,1,1}\cdots r_{ny,1,na}\cdots r_{ny,nu,1}\cdots r_{ny,nu,na}\right),$$

$F\in C^{nd\times nd}$

$$D^d=\text{diag}\left(d^d_{1,1,1}\cdots d^d_{1,1,na}\cdots d^d_{1,nu,1}\cdots d^d_{1,nu,na}\cdots d^d_{ny,1,1}\cdots d^d_{ny,1,na}\cdots d^d_{ny,nu,1}\cdots d^d_{ny,nu,na}\right),$$

$D^d\in C^{nd\times nd}$

$$N=\begin{bmatrix} J_1 \\ J_2 \\ \vdots \\ J_{ny} \end{bmatrix},\ N\in\Re^{nd\times nu};\ J_i=\begin{bmatrix} 1 & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 0 & \cdots & 0 \\ & & \ddots & \\ 0 & 0 & \cdots & 1 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 \end{bmatrix},$$

$J_i\in\Re^{nu\,na\times nu}$, $i=1,2,\ldots,ny$

In the above matrix, it is assumed that either output y_i integrates only input u_i, or if this output integrates other inputs, the time delays between the integrated inputs and the output are the same for all the inputs. If this condition is not satisfied, the model proposed above is not observable. The step response of the system can be calculated by the following equation

$S(t)=D^0+\Psi(t)D^dN+I^*(t)D^i$

where t is supposed to be larger than any time delay included in the process model.

2. THE INFINITE HORIZON MPC

The infinite horizon MPC considered here is based on the following control cost

$$V_k=\sum_{j=0}^{\infty}\left[e(k+j|k)-\delta_k^s-j\Delta t\delta_k^i\right]^T Q\left[e(k+j|k)-\delta_k^s-j\Delta t\delta_k^i\right]+\sum_{j=0}^{m-1}\Delta u(k+j|k)^T R\,\Delta u(k+|k)+\delta_k^{sT}S_1\delta_k^s+\delta_k^{iT}S_2\delta_k^i \quad (4)$$

where

$e(k+j|k)=\tilde{y}(k+j|k)-y^{sp}$ and $\tilde{y}(k+j|k)$ is the output prediction at time $k+j$ computed at time k and considering the future control actions. Weight matrices Q, R, S_1 and S_2 are assumed positive definite.

The control objective defined in (4) can be expanded as follows

$$V_k=V_k^{(1)}+V_k^{(2)}+\sum_{j=0}^{m-1}\Delta u(k+j|k)^T R\,\Delta u(k+j|k)+\delta_k^{sT}S_1\delta_k^s+\delta_k^{iT}S_2\delta_k^i \quad (5)$$

where

$$V_k^{(1)}=\sum_{j=0}^{np}\left[e(k+j|k)-\delta_k^s-j\Delta t\delta_k^i\right]^T Q\times\left[e(k+j|k)-\delta_k^s-j\Delta t\delta_k^i\right]$$

$$V_k^{(2)}=\sum_{j=1}^{\infty}\left[e(k+np+j|k)-\delta_k^s-(np+j)\Delta t\delta_k^i\right]^T Q\times\left[e(k+np+j|k)-\delta_k^s-(np+j)\Delta t\delta_k^i\right] \quad (6)$$

It can be shown that

$$V_k^{(1)}=\left[\bar{C}\,x(k|k)+\tilde{C}\Delta u_k-y_1^{sp}-\bar{I}\,\delta_k^s-\tilde{I}\,\delta_k^i\right]^T\bar{Q}\times\left[\bar{C}\,x(k|k)+\tilde{C}\Delta u_k-y_1^{sp}-\bar{I}\,\delta_k^s-\tilde{I}\,\delta_k^i\right] \quad (7)$$

where

$$\bar{C}=\begin{bmatrix} C \\ CA \\ \vdots \\ CA^{np} \end{bmatrix},\ \tilde{C}=\begin{bmatrix} 0 & 0 & 0 & \cdots & 0 \\ CB & 0 & 0 & \cdots & 0 \\ CAB & CB & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots \\ CA^{np-1}B & CA^{np-2}B & & \cdots & CA^{np-m}B \end{bmatrix},$$

$\Delta u_k=\left[\Delta u(k|k)^T\quad \Delta u(k+1|k)^T\quad\cdots\quad \Delta u(k+m-1|k)^T\right]^T$

$\bar{Q}=diag(\left[Q\quad Q\quad ...\quad Q\right])\in\Re^{np.ny\times np.ny}$,

$y_1^{sp}=[y^{spT}\quad y^{spT}\quad ...\quad y^{spT}]^T\in\Re^{np.ny}$

$\bar{I}=[I_{ny}\quad I_{ny}\quad ...\quad I_{ny}]^T\in\Re^{np.ny\ x\ ny}$,

$\tilde{I}=[0\quad \Delta t\,I_{ny}\quad ...\quad np\Delta t\,I_{ny}]^T\in\Re^{np.ny\ x\ ny}$

In order to develop the infinite sum defined in (6), one needs to consider an expression for the calculation of the output prediction at time steps beyond time *np*. Using the model expressions defined in (1) to (3), the output prediction at time step *np*+1 can be written as follows:

$$\tilde{y}(k+np+1|k) = \tilde{x}^s(k+m|k) + \Psi((np+1)\Delta t)\tilde{x}^d(k+m|k) + (np+1)\Delta t\, I_{ny}\tilde{x}^i(k+m|k)$$

where $\tilde{x}^s$, $\tilde{x}^d$ and $\tilde{x}^i$ are computed considering the future control actions. Analogously, the prediction at any time step *np+j* can be written as follows:

$$\tilde{y}(k+np+j|k) = \tilde{x}^s(k+m|k) + \Psi((np+1)\Delta t)F^{j-1}\tilde{x}^d(k+m|k) + (np+j)\Delta t\ \tilde{x}^i(k+m|k)$$

In order to guarantee that $V_k^{(2)}$ will be bounded, it is necessary to force the state components related to the integrating modes to be zero at the end of the control horizon:

$$\tilde{x}^s(k+m|k) - y^{sp} - \delta_k^s = 0 \quad (8)$$

$$\tilde{x}^i(k+m/k) - \delta_k^i = 0 \quad (9)$$

If constraints (8) and (9) are satisfied, $V_k^{(2)}$ can be written as follows:

$$V_k^{(2)} = \sum_{j=1}^{\infty} \tilde{x}^d(k+m/k)^T (F^{j-1})^T \left(\Psi((np+1)\Delta t)\right)^T Q \times \Psi((np+1)\Delta t)F^{j-1}\tilde{x}^d(k+m/k)$$

$$V_k^{(2)} = \tilde{x}^d(k+m/k)^T \tilde{Q}\tilde{x}^d(k+m/k) \quad (10)$$

where $\tilde{Q}$ satisfies

$$F^T\tilde{Q}F - \tilde{Q} = \left(\Psi((np+1)\Delta t)\right)^T Q\Psi((np+1)\Delta t)$$

and

$$x^d(k+m/k) = F^m x^d(k/k) + F_u \Delta u_k$$

$$F_u = \left[F^{m-1}B^d \quad F^{m-2}B^d \quad \cdots \quad B^d\right], \quad B^d = D^d F\, N$$

Substituting (7) and (10) in (4), the control objective becomes

$$V_k = \left[\Delta u_k^T \quad \delta_k^{sT} \quad \delta_k^{iT}\right] H \begin{bmatrix}\Delta u_k \\ \delta_k^s \\ \delta_k^i\end{bmatrix} + 2C_f^T \begin{bmatrix}\Delta u_k \\ \delta_k^s \\ \delta_k^i\end{bmatrix}_k + c \quad (11)$$

where

$$H = \begin{bmatrix} H_{11} & H_{12} & H_{13} \\ H_{12}^T & H_{22} & H_{23} \\ H_{13}^T & H_{23}^T & H_{33}\end{bmatrix}$$

$$C_f = \begin{bmatrix} \left[x(k/k)^T\bar{C}^T\bar{Q}\tilde{C} - y_1^{spT}\bar{Q}\tilde{C} + x^d(k/k)^T F^{mT}\tilde{Q}F_u\right]^T \\ \left[-x(k/k)^T\bar{C}^T\bar{Q}\bar{I} + y_1^{spT}\bar{Q}\bar{I}\right]^T \\ \left[-x(k/k)^T\bar{C}^T\bar{Q}\tilde{I} + y_1^{spT}\bar{Q}\tilde{I}\right]^T \end{bmatrix}$$

$$H_{11} = \tilde{C}^T\bar{Q}\tilde{C} + F_u^T\tilde{Q}F_u + \bar{R}$$

$$c = x(k/k)^T\bar{C}^T\bar{Q}\bar{C}x(k/k) - 2y_1^{spT}\bar{Q}\bar{C}x(k/k) + y_1^{spT}\bar{Q}y_1^{sp} + x^d(k/k)^T F^{mT}\tilde{Q}F^m x^d(k/k)$$

$$\bar{R} = diag(\left[R \quad R \quad \ldots \quad R\right]) \in \Re^{m.nu \times m.nu}$$

$$H_{12} = -\tilde{C}^T\bar{Q}\bar{I}, \quad H_{13} = -\tilde{C}^T\bar{Q}\tilde{I}, \quad H_{22} = \bar{I}^T\bar{Q}\bar{I} + S_1,$$
$$H_{23} = \bar{I}^T\bar{Q}\tilde{I}, \quad H_{33} = \tilde{I}^T\bar{Q}\tilde{I} + S_2$$

It is easy to show that for the model defined in (1), the constraint defined in (8) can be written as follows

$$x^s(k/k) - y^{sp} + m\Delta t\, x^i(k/k) + \tilde{D}\Delta u_k - \delta_k^s = 0 \quad (12)$$

where

$$\tilde{D} = [D^0 + m\Delta t\, D^i \quad D^0 + (m-1)\Delta t\, D^i \quad \ldots \quad D^0 + \Delta t\, D^i]$$

Analogously, the constraint defined in (9) becomes

$$x^i(k/k) + \tilde{D}^i\ \Delta u_k - \delta_k^i = 0 \quad (13)$$

where

$$\tilde{D}^i = \left[\underbrace{D^i \quad \cdots \quad D^i}_{m}\right]$$

Therefore, the infinite horizon MPC that is implemented here is based on the following optimization problem:

$$\min_{\Delta u_k, \delta_k^s, \delta_k^i} V_k \quad (14)$$

subject to

(12), (13) and

$\Delta u(k+j) \in \mathbb{U},\ j \geq 0$,

where

$$\mathbb{U} = \left\{ \Delta u(k+j) \left| \begin{array}{l} -\Delta u^{\max} \leq \Delta u(k+j) \leq \Delta u^{\max} \\ \Delta u(k+j) = 0; \quad j \geq m \\ u^{\min} \leq u(k-1) + \sum_{i=0}^{j} \Delta u(k+i) \leq u^{\max}; \\ j = 0,1,\cdots,m-1 \end{array} \right. \right\}$$

Carrapiço & Odloak (2005) showed that the problem defined in (14) produces a nominally stable MPC if it is solved in a two step approach. In the first step, the objective is to minimize slack δ_k^i, which is related to the integrating modes. Then, in the second step, the objective is to minimize V_k while δ_k^i is kept at the same value computed in the first step. In practical terms, the two step approach would be equivalent to adopting the value of the slack weight S_2 large enough to force the controller to minimize δ_k^i before considering the other control objectives. Thus, the IHMPC, which is implemented here, is obtained through the solution to the problem defined in (14) with suitable tuning parameters that produce the nominal stability of the controller.

3. PROCESS OVERVIEW AND CONTROL STRATEGY

A schematic representation of the de-isobutanizer distillation column where the infinite horizon MPC was implemented is illustrated in Figure 1. The system is part of an alkylation unit in the PETROBRAS/Cubatão oil refinery. The feed stream distillation column comes from the FCC unit and consists of a mixture of isobutane, 1-butene, cis-2-butene, trans-2-butene, n-butane and n-pentane. The top product, which is sent to the alkylation reactor, is composed mainly of isobutane and light butenes. The bottom stream that is

composed of n-butane and heavy butenes is sent to storage and sold as a special product.
The feed flowrate is defined by the refinery production plan and usually remains constant over long periods of time. The feed temperature is the main disturbances to the control system. A recycle stream of isobutane and steam are used as sources of heat to the reboiler. The pressure in the top drum is controlled by manipulating the bypass of the top condenser. In the original regulatory strategy, a PID controller of the temperature of tray 68 cascades the steam flowrate to the reboiler and there was no control on the level of liquid in the top drum. The main control objective is to keep the composition of the top product composition at desired values.

As shown in Figure 1, in the control strategy implemented in the IHMPC there are two manipulated inputs: u_1 (ton/h) is the steam flowrate to the reboiler and u_2 (m^3/d) is the reflux flowrate. The feed temperature d_1 (ºC) is a measured disturbance. The outputs of the distillation column are: y_1 (%) the level of liquid in the top drum, y_2 (ºC) the temperature of tray 68 and y_3 (%) the percentage of flooding in the column. The flooding is calculated based on the measured values of some variables of the process. The two degrees of freedom (inputs) are used to control the liquid level in the drum at a fixed set-point and the other two outputs are controlled by zone: the column flooding has to be kept below an upper limit and the temperature in tray #68 has to be kept above a minimum value. Two other outputs that will be included in this control strategy in the near future are the volumetric ratio iC4/(∑ olefin components) in the top product and the volumetric fraction of iC4 in the bottom stream.
Step tests were performed in the distillation column and the resulting transfer function model is the following:

$$\begin{bmatrix} y_1(s) \\ y_2(s) \\ y_3(s) \end{bmatrix} = \begin{bmatrix} \frac{2.3}{s} & \frac{-0.7\times10^{-3}}{s} \\ \frac{4.7e^{-7s}}{9.3s+1} & \frac{1.4\times10^{-3}e^{-2s}}{6.8s+1} \\ \frac{1.9e^{-s}}{10.1s+1} & \frac{61\times10^{-3}e^{-3s}}{6.6s+1} \end{bmatrix} \begin{bmatrix} u_1(s) \\ u_2(s) \end{bmatrix} + \begin{bmatrix} \frac{0.2}{s} \\ \frac{0.4e^{-3s}}{11.6s+1} \\ \frac{0.2e^{-3s}}{12.3s+1} \end{bmatrix} d_1(s)$$

During the identification tests, it was observed that the control valve of the reflux flow rate has shown an erratic behavior probably due to stickiness. Although, this problem could be easily repaired, we found it interesting to perform the evaluation test of the proposed IHMPC in these conditions, as this scenario may be frequently found in industry. So, the sticking reflux control valve becomes an unmeasured disturbance to the MPC controller. The transfer functions represented above relates the outputs to the set points to the regulatory flow control loops.

4. PRACTICAL RESULTS

Figures 2 and 3 show the typical responses of the industrial system with IHMPC when a step disturbance is introduced in the set point of the liquid level. The tuning parameters of the controller are the following: $m = 2$, $\Delta t = 1$, $Q = diag(6,4,1)$, $R = diag(0.1,5)$, $S_1 = S_2 = diag(1,1,1)\times10^3$.

In this case, the column flooding (y_3) was controlled at a fixed set point of 91%, while the temperature in tray #68 (y_2) was kept above the minimum constraint (52ºC). Fig. 3 clearly shows that there is a sticking problem in the valve of the reflux flow rate (u_2), where the process variable (*PV*) has a significant delay in comparison to the corresponding set point (*SV*). The consequence is a continuous cycling of this variable with a period of about 30min. This disturbance is transferred to the controlled variables of the system, but the IHMPC can cope with this situation quite nicely as the amplitude of the resulting oscillation is largely attenuated. Concerning the tuning parameters of the proposed IHMPC, they can be borrowed from the conventional MPC, except the prediction horizon, which is infinite, and the slack weights S_1 and S_2. Typically, these parameters should be two or three orders of magnitude larger than the output weights. The main point related to the slack weights is that they should be large enough to make the hessian matrix H defined in (11) positive definite. If this condition is not satisfied, the integrating outputs may become unbounded or the stable outputs may show offset.

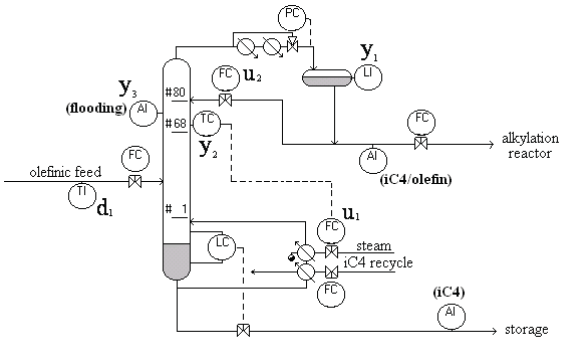

Fig. 1. Schematic diagram of the de-isobutanizer column.

There was a question if the proposed IHMPC would amplify this sort of periodic disturbance, as the controller includes equality constraints (12) and (13) related to cancellation of the integrating modes. Apparently, the inclusion of slacks δ_k^s and δ_k^i greatly reduced this problem. To verify if the gain in stability associated with the use of an infinite prediction horizon would result in a loss of performance, the proposed controller was compared with the conventional MPC. For this purpose, a finite horizon MPC was also implemented in this distillation column. Although, in practice, one cannot repeat exactly the experiment reported above but considering the conventional MPC, Figures 4 and 5 show the responses of the conventional MPC for a similar step disturbance in the set point of the liquid level. The tuning parameters for the two controllers are the same except, for the prediction horizon, which is infinite in the IHMPC and the slacks weights, which do not exist in the conventional MPC. Observing figs. 4 and 5, one may conclude that there is no significant difference between the performances of the two controllers and consequently, there is no practical disadvantage in implementing the infinite horizon MPC that introduces nominal stability.

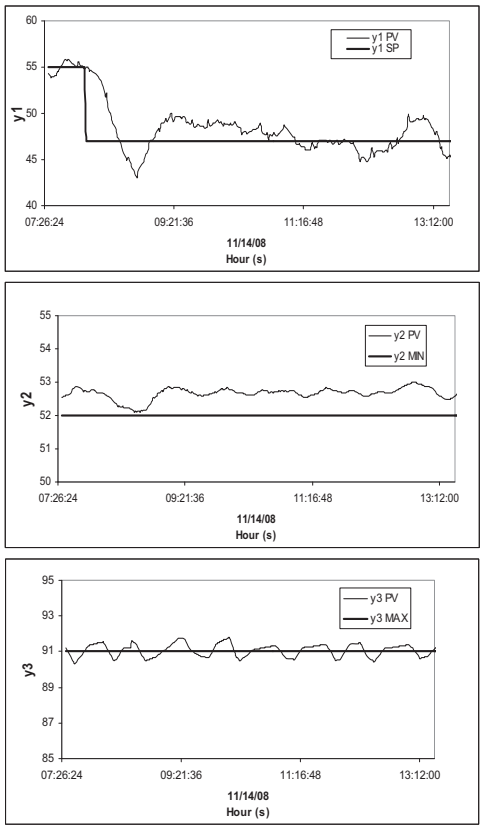

Fig. 2 – Outputs for the IHMPC. Step change in the liquid level set-point.

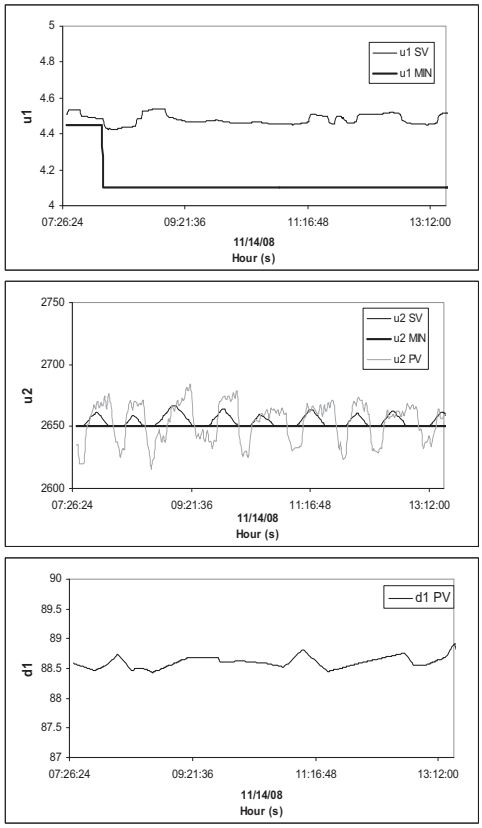

Fig. 3 – Inputs for the IHMPC. Step change in the liquid level set-point.

Another practical experiment performed with the IHMPC is shown in figures 6 and 7. In this case, the set point to the flooding percentage (y_3) in the column is successively decreased along a series of step changes, while the set point to liquid level in the reflux drum (y_1) is fixed and the column temperature (y_2) is controlled by zone. Although the performance of the controller can be considered satisfactory, the sticking problem in the reflux control valve seems more serious and heavily affects the behavior of the system, mainly the reflux flow rate (u_2) and the column flooding. It is not represented here, but the same kind of behavior is observed when the system is controlled with the conventional MPC.

5. CONCLUSIONS

A MPC with infinite prediction horizon was successfully implemented in an industrial distillation column and has been in continuous operation for several months. The proposed controller can be applied to systems with stable and integrating outputs. The IHMPC was compared to the conventional finite horizon MPC and the performances of the two controllers seem quite similar. The new controller has some additional parameters related to the weighting of slack variables that are introduced in the control problem in order to guarantee that this control problem will remain always

Abstract: This paper presents an approach which uses a multivariable control strategy with distributed action in order to minimize operation transients in distillation columns when a disturbance in the temperature feed is introduced. Experiments were carried out adjusting multivariable PID controllers by static decoupling of the temperature loops of the bottom and distillate trays, characterizing a 2 x 2 system. The dynamics was compared to the distributed approach (same controllers on the bottom and top and an additional control loop on a tray). The controllers adjustment of this new system (3 x 3) was carried out considering the temperature control loop stage in two different ways: decentralized and coupled with the bottom and top temperature control loops. The minimization of transients was verified in both distributed approaches.

Keywords: control schemes, distillation columns, dynamics, multivariable systems, transient analysis.

1. INTRODUCTION

A well designed and adjusted control system is not sufficient to eliminate operation transients of a distillation process. One aspect that contributes to this situation, besides the column operation stage, is the centralization of the control system in the bottom and top column variables. In this way there is the propagation of the corrective control action through the whole unit, generating a production period out of the desired specification. The formation of transients in a distillation column occurs when the process is disturbed and its characteristics reduce the control system efficiency or when an external factor induces the modification of the unit operation point. In the first case there are factors such as variable coupling, nonlinearities, deadtime, high time constants and process constrains. In the second case there are aspects such as the mixture to be distillated, feed composition changes and operation transitions that are necessary due to changes in the market. In both cases, the process dynamics influences the way the transient operation will be generated and what the final result will be.

The current proposals to minimize the transient time of distillation columns use control techniques which consider process dynamics only to study the efficiency of these algorithms, without changing the process conception or evaluating the minimization of transients (Zhu and Liu, 2005). Stricter product specifications and greater demands in terms of environmental control, together with the design of more and more integrated units, require a better performance of these systems. Thus, economic incentives for the development and application of high performance control systems in industrial plants have grown considerably.

The proposal here developed, which is the object of this study, consists of the distribution of the control action throughout the column stages aiming at the minimization of the transient operation. This approach is based on the study of diabatic distillation columns (Koeijer, Rosjorde and Kjestrup, 2005), where intermediate heating points are used instead of only one heat input (reboiler) and one heat remover (condenser). These additional points keep a certain desired temperature profile throughout the column. Previous research (Marangoni and Machado, 2007) has demonstrated the feasibility of this proposal with the use of classic controllers (PID). The unit dynamics was evaluated and the results showed a reduction in the operation transition time when feed disturbances are introduced into the distillation column. Although 90% of industrial processes use classic controllers (Astrom and Hagglun, 2001), it was also necessary to evaluate the use of advanced controllers (model-based) which consider the process dynamics. Multivariable and predictive control seem to be the most used techniques due to their great flexibility. Here, it is worth mentioning the studies carried out with model-based controllers: Model Predictive Control (MPC) (Bezzo et al., 2005); Dynamic Matrix Control (DMC) (Jana et al., 2005); and Generalized Predictive Control (GPC) (Karanca, 2003). On the other hand, some studies have been carried out with proportional-integral-derivative (PID) controllers, aiming at a more flexible adjustment considering the distillation characteristics (Zhu and Liu, 2005). However, even in these recent studies, the controllers used to obtain the quality profile are implemented with the control action only in the bottom and top column stages.

Thus, aiming at the application of easy implementation strategies, the objective of this study was to evaluate the use of a 2 x 2 control system (controllers of the temperature loops

of the bottom and distillate trays) and compare it to a new distributed approach (same controllers on the bottom and top and an additional temperature control loop on a tray) implemented in two different ways: the first considering the additional control stage without interaction with the other two control loops (decentralized), and the second considering the system as 3x3 multivariable.

2. MATERIALS AND METHODS

Experiments were carried out in a pilot unit processing an ethanol-water mixture. The conditions used are summarized in Table 1. Composition measurements were carried out during the experiments using a densimeter for alcohol.

Table 1. Operation conditions used in the experiments.

Variable	Value
Ethanol feed volumetric fraction	0.15
Feed Temperature	92°C
Volumetric feed flow	300 $L.h^{-1}$
Column top pressure	1.25 bar
Drop pressure	0.25 bar
Reflux ratio (Reflux stream/Distillate)	5
Bottom Holdup	4 L
Accumulator Holdup	5 L

2.1 The pilot unit

The unit, illustrated in Figure 1, represents a tray distillation process. It operates in a continuous way and thus there is a main tank responsible for the feed.

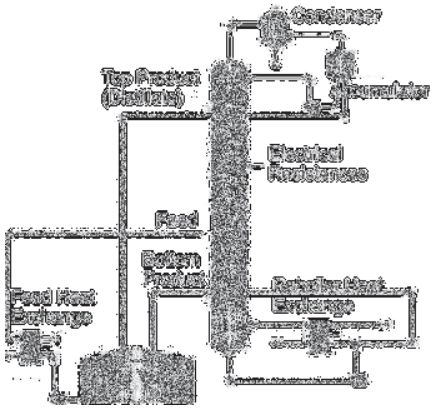

Fig. 1. Schematic illustration of the experimental unit's.

The column has 13 equilibrium stages and each module has one point for temperature measurement, one for sample collection and a third for the distributed heating adaptation. The latter was carried out by means of electrical resistances designed with up to 3.5kW power each. Temperature sensors (Pt-100) were used to monitor this variable in all equilibrium stages, as well as the main tank and the reflux accumulator. The feed was carried out on the fourth tray, with the reboiler as the zero stage.

The control configuration of the distillation column was formulated based on Nooraii et al. (1999), and is illustrated in Figure 2. The following control loops were defined: (1) bottom level control through the bottom product flow rate adjustment; (2) reflux accumulator level control by manipulating the top product flow rate; (3) feed flow rate control as a function of the adjustment of the same stream flow rate; (4) feed temperature control through the fluid flow rate adjustment in the heat exchanger of this stage; (5) last tray (distillate) temperature control by means of the manipulation of the reflux flow rate; (6) reboiler temperature control through the vapor flow rate in the heat exchanger of this stage; and (7) temperature control of pre-defined stages of the column through the adjustment of the dissipated power in the tray electrical resistance.

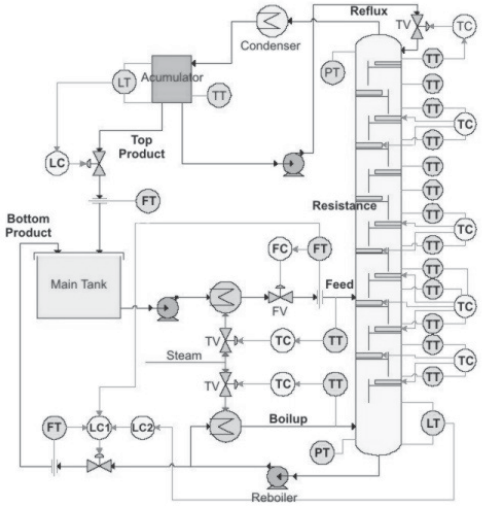

Fig. 2. Control configuration of the distillation unit.

The first, second and third loops represent the column mass balance (inventory) control. The fifth and sixth loops comprise the quality control – in this case represented by the temperature. The use of these two loops in combination is referred to herein as conventional control. When these two loops are combined with the seventh loop mentioned above, it is considered herein as the distributed strategy.

All control loops are instrumented with fieldbus protocols, along with the acquisition and indication of the bottom and distillate stream flows and the pressures at the same stages. The temperatures of all the trays, reboiler, accumulator and feed are monitored by a programmable logic controller and used in the dynamic study of the distributed control. The pressures were monitored in order to assure the proper functioning of the equipment and the process.

2.2 The control strategies tested

For this study, the experiments were carried out with three different control strategies: (1) conventional 2 x 2 – with multivariable control applied to the reboiler and distillate temperatures; (2) distributed 2 x 2 – with multivariable control applied to the reboiler and distillate temperatures and decentralized control in only one stage (PID without interaction with the other loops); and (3) distributed 3 x 3 – with multivariable control applied to the reboiler, second stage and distillate temperatures.

2.3 Controller's tuning

PID controllers are used in the three strategies tested. This kind of controller was employed since it is the most widely used (Astrom and Hagglund, 2001). Multivariable tuning was applied as the experiments consider both loops (reboiler and distillate temperatures) coupled to control the process.

Thus, for strategies 1 and 3 a static decoupler was used (Lee et al, 2005) to cancel the undesired effects of the interaction and adjustment of the multivariable controllers. This procedure can be designed from steady-state process gains, which are easier to obtain and can be tuned in the field. As an initial estimate the PID controller parameters were calculated using the criterion of the integral absolute error (ITAE). A fine adjustment was then made in the plant.

For strategy 2, the same controllers obtained in strategy 1 were used for the reboiler and distillate temperature loops. For the tray temperature controller the ITAE criterion was used to estimate the parameters followed by a fine adjustment (considering this loop decentralized from others, i.e., with weak interaction).

2.4 Stage selection

To identify the most sensitive stage for the consequent application of the distributed control, three different methods were applied (Luyben, 2006). In the first method, the difference between the temperatures of two successive trays was calculated throughout the column and the most sensitive tray was that which presented the greatest difference in relation to its adjacent tray. In the second method, a temperature profile for a given value of the manipulated variable (in this case, the reflux flow and the reboiler heat) is obtained. The most sensitive tray gives a symmetrical response to positive and negative equally variations. Finally, the third method analyzes the tray with the highest derivative of the temperature in relation to the stage when the process is disturbed. To analyze the first method, the temperature profile for three different conditions of ethanol feed composition (15, 25 and 35%) was observed. In the second and third methods it was necessary to disturb the process and evaluate its behavior. The feed flow used was 400L.h^{-1} as the standard condition, which was increased to 600L.h^{-1} and also decreased to 200L.h^{-1}.

It is important to emphasize that the different methods can produce different answers. The definition was based on this analysis together with the characteristics of the plant.

2.5 Disturbances

To analyze the control strategies, changes in the temperature feed were introduced, decreasing this variable by around 15^{o}C (from 92^{o}C to 77^{o}C). This was achieved by controlled cooling of this stream.

This study aimed to interfere in the column temperature profile in order to minimize the response time when some disturbance occurs. Thus, it was not tested for set point tracking.

3. RESULTS

The first step of this study was to determine the stage were distributed heating could be applied. As cited before, this was achieved through a sensitivity analysis employing three different methods. The results obtained with the first method (successive trays) using three feed ethanol composition conditions demonstrated the possibility of using trays 1, 2, 3, 5 and 7. As the fifth and seventh trays are located in the rectifying section, they were discarded. It was assumed, following diabatic studies upon which this proposal was based, that in this section it is better to remove heat than supply it.

In addition, as this is an initial study, it was defined that only one tray will be used to test the proposal. To define this stage, since method 1 was not conclusive, the analysis of symmetrical response and maximum derivative (methods 2 and 3) was used. The derivative method again pointed to stages 5 and 7, which were previously discarded, but the symmetrical response method indicated tray 2 as the most appropriate for this study. Figure 3 shows this analysis, where it can be observed that tray 2 is almost the same distance from steady state when the process is disturbed with positive and negative perturbations in the feed flow.

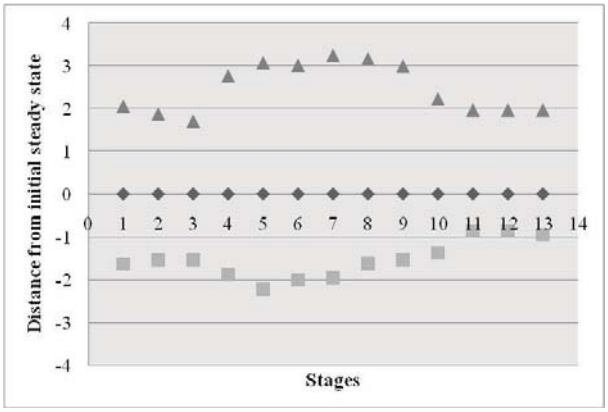

Fig. 3. Results of sensitivity analysis using symmetrical response method (■ negative disturbance, ◆ steady state, ▲ positive disturbance).

Based on this sensitivity analysis, the distributed action of the proposal was used only in tray 2. The simultaneous action of the trays was not tested because the main objective was to analyze the distributed proposal with a multivariable system, and its behavior, through the coupling of control loops.

In sequence, the process transfer functions were determined and the relative gain array matrix was evaluated.

Multivariable control algorithms were studied since the process has multiple inputs and outputs and it is characterized by the high coupling degree among the variables. These kinds of controllers require process models for which an approximated model was used, obtained by the transfer

functions of the reboiler, second stage and distillate temperature control loops. In fact, a multivariable system can be easily modeled through transfer functions. These functions associate the system outputs (Y) with the disturbances (L) and the inputs (U), and integrate the transfer function matrix with the disturbance (G_L) and inputs (G).

The transfer functions were obtained by means of experimental tests, through input and output data collection and later numeric treatment of this information, disturbing the variables that are used for the manipulation of the control loops. The equations obtained are presented below (time values expressed in seconds and deadtime obtained by Taylor series approximation).

Equation (1) presents the matrix which represents the 3 x 3 system, where Tb is the reboiler temperature, Td the distillate temperature and T_2 the second stage temperature, corresponding to the system outputs. Q_b (steam valve opening at the reboiler entrance), R (reflux flow valve opening) and Q_2 (dissipated power at the electrical resistance stage), represent the inputs.

$$\begin{bmatrix} Y_1 = Tb(s) \\ Y_2 = Td(s) \\ Y_3 = T_2(s) \end{bmatrix} = \begin{bmatrix} G_{11}(s) & G_{12}(s) & G_{13}(s) \\ G_{21}(s) & G_{22}(s) & G_{23}(s) \\ G_{31}(s) & G_{32}(s) & G_{33}(s) \end{bmatrix} \begin{bmatrix} U_1 = Qb(s) \\ U_2 = R(s) \\ U_3 = Q_2(s) \end{bmatrix} \quad (1)$$

Equations (2) to (10) present the transfer functions obtained, which consist of the input/output relations presented in (1). For the calculations, the deadtime of these functions were expressed using a simple first-order Taylor series approximation.

$$G_{11} = \frac{0.69}{112s+1} \quad (2)$$

$$G_{12} = \frac{3.12e^{-13s}}{203s+1} \quad (3)$$

$$G_{13} = \frac{0.56e^{-1s}}{145s+1} \quad (4)$$

$$G_{21} = \frac{-0.08e^{-26s}}{172s+1} \quad (5)$$

$$G_{22} = \frac{-0.04e^{-4s}}{364s+1} \quad (6)$$

$$G_{23} = \frac{-0.06e^{-17s}}{135s+1} \quad (7)$$

$$G_{31} = \frac{0.02e^{-1s}}{74s+1} \quad (8)$$

$$G_{32} = \frac{0.14e^{-2s}}{407s+1} \quad (9)$$

$$G_{33} = \frac{0.02}{85s+1} \quad (10)$$

Experimental tests were carried out, data were evaluated and with the process equations the existing interactions were verified by controlling the process with and without the proposed approach. Experiments were carried out in order to construct the relative gain array matrix (RGA) (Shinskey, 1996) for the 2 x 2 system (reboiler and distillate temperature control loops) and for the 3 x 3 systems (reboiler, second stage and distillate temperature control loops). In this case, the cited method was used to identify the degree of coupling among the proposed systems and not to define the control structure, which is the usual purpose. This evaluation is important since the intermediate column stages also influence the temperature profile and the process composition.

Equation (11) presents the matrix obtained for the 2 x 2 system and (12) the matrix for the 3 x 3 system.

$$\Lambda = \begin{bmatrix} 0.89 & 0.11 \\ 0.11 & 0.89 \end{bmatrix} \quad (11)$$

$$\Lambda = \begin{bmatrix} 0.77 & 6.80 & -6.57 \\ -4.92 & -0.07 & 6.03 \\ 5.50 & -5.69 & 1.54 \end{bmatrix} \quad (12)$$

Although the selection of the best control structure is not the main objective of this study, the 2 x 2 system is adequate as shown in (11), where the sum of the matrix columns and lines are 1 (one).

In (12) we can observe some values above one for seven of the nine possible combinations of control loops, which indicates strong interactions in these combinations. It is well known that the closer the element is to +1, the weaker the interaction between the loops, and the elements with high modulus values indicate strong interactions between the loops, or it could be that the system is sensitive to parameter changes (less robustness).

With this phase completed, the studies were followed by experimental tests using multivariable control algorithms. As mentioned above, the common technique of controller adjustment by decoupling was used. This tuning was defined since it provides good results (Waller, et al. 2003, Liu et al., 2006). It is important to note that the objective is to improve the control of a new column and the operation approach, and therefore the application of techniques used industrially is the aim.

In decoupled control, it is implicit that the design objective is to obtain a system that reduces the interaction between the loops through specific additional controllers, called decouplers. These are used to improve the performance of multivariable control systems through interaction compensation, though they are sensitive to changes in the process and require detailed process models, which are often difficult to obtain. These disadvantages often limit the use of multivariable controllers industrially. However, the static decouplers approach can be designed from the gains in the process in steady state, which are easy to obtain and can be adjusted in the field (Lee et al. 2005). Because of these

advantages, the static decouplers approach was used, based on the gain of each control loop.

Besides the objective of the implementation and study of advanced techniques using the distributed approach, these studies were carried out to evaluate whether or not it is possible to work with the hypothesis that the interactions caused by the tray can be eliminated when the reboiler interactions are reduced or eliminated.

Figures 4 and 5 show the reboiler and distillate temperature profiles for the strategies applied. In these experiments, the disturbance was applied by decreasing the feed temperature.

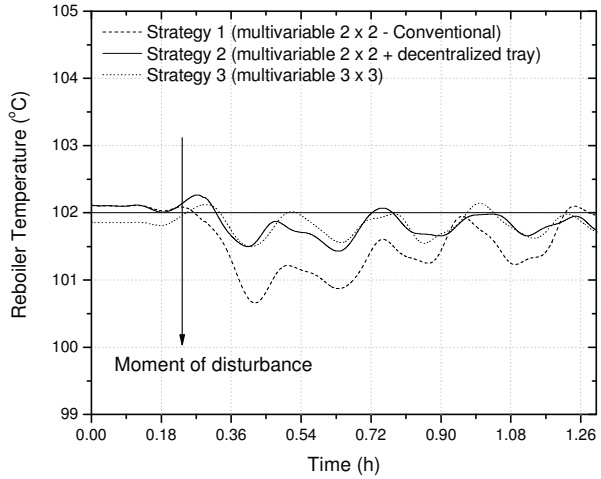

Fig. 4. Effect of the disturbance on reboiler temperature control loop response in relation to setpoint.

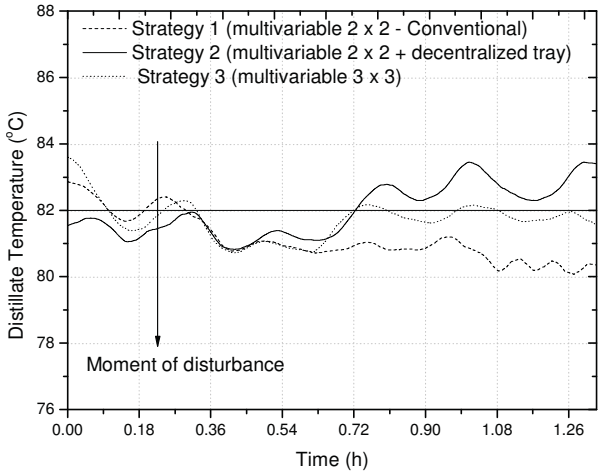

Fig. 5. Effect of the disturbance on distillate temperature control loop response in relation to setpoint.

It can be observed, in both figures, that the disturbance is quickly rejected when the distributed approach is used. Both strategies 2 (2 x 2 multivariable adjustment and decentralized adjustment at stage 2) and 3 (3 x 3 multivariable adjustment) showed that the steady state was reached faster than with strategy 1 (conventional multivariable control – 2 x 2 system). This result indicates that the distributed control action maintains the temperature profile in the column and thus it allows the reduction of the transients generated.

However, strategy 2, which assumes that the interactions between the tray temperature control loops and the other quality controllers is weak, leads to a value slightly higher than that desired. This case is better observed in relation to the distillate temperature. For this same variable, the disturbance applied was not completely rejected using the conventional control, and the distillate temperature stabilized at a lower value.

When reboiler and distillate temperature loops are evaluated together, the 3 x 3 distributed approach allows a better performance. It is possible that this adjustment, considering the interactions between the three control loops, made the system a bit slower, although it is still faster and less oscillatory than the conventional approach.

Figure 6 gives the second stage temperature profile, where the distributed control was implemented. As expected, the performance of the 2 x 2 multivariable adjustment strategy with decentralized adjustment at stage 2 leads to a value closer to the set point. In fact, using a decentralized PID controller at this stage, leads to faster dynamics than applying a multivariable 3 x 3 system which consider all interactions of this tray with the reboiler and distillate temperature control loops. However, strategy 3 showed a slight overshoot and rejected the disturbance quickly, in contrast to the conventional strategy.

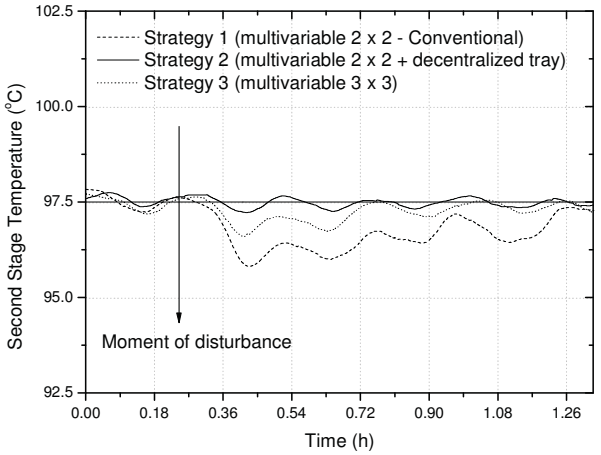

Fig. 6. Effect of the disturbance on the tray 2 temperature control loop response in relation to the setpoint.

In order to carry out a final evaluation regarding which strategy leads to the best performance, the effect of the disturbance on the temperature of the accumulator tank was studied. Since this is the last unit stage, it is the one with the highest transition time. Therefore, its behavior was observed by analyzing the temperature derivative in relation to the time required for the disturbance rejection, as illustrated in Figure 7.

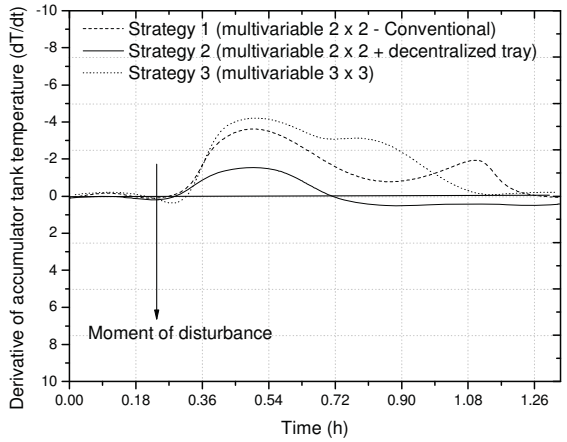

Fig. 7. Derivative of the temperature of the reflux accumulator tank in relation to the setpoint.

The figure demonstrates that the time required to reduce the effects on feed temperature disturbance is shorter when the distributed control approach is applied, considering the second stage temperature control loop not interacting with the others. This hypothesis will be true if the interaction at this stage can be eliminated by the reboiler temperature control loop decoupling. However, it is important to note that the value of the accumulator tank temperature did not return to the same steady state present before the disturbance. It is possible that the use of a PID decentralized controller at stage 2 allowed the production of a greater vapor phase inside the column as the temperature of the last stage was higher in this case. If this occurred, the condenser would produce more distillate and the accumulator temperature tank would stabilize at a different value, as was in fact observed.

4. CONCLUSIONS

The evaluation of the conventional and distributed approach, for a feed temperature disturbance, allowed a reduction in the column transition time and in the oscillations of the controlled variable when the strategy with control at stage 2 was used (independent of the tuning of this loop – decentralized or not).

It is also necessary to consider that the decentralized utilization of the temperature control loop which comprises the distributed approach gives better results than the conventional control system. This is an important result since most industrially implemented controllers are considered decentralized (Garelli et al. 2006).

The comparison between the use of a distributed control loop, decentralized or not with the reboiler and distillate temperature loops, shows that the hypothesis of weak interaction of an intermediate stage can be assumed. When a decoupler was used to tune the quality controllers of the base and top it is possible that the interactions with the trays were reduced. Thus, with the application of an advanced control algorithm, it is observed that the introduction of heat to one of the column stages allows a reduction in the operation time out of the desired conditions. As with classic controllers tested in previous research studies, the introduction of distributed heat throughout the column was shown to be a valid option for the reduction of transients, enabling faster dynamics and lower volumes of products processed out of the pre-defined quality parameters.

Abstract: This work presents the simultaneous synthesis, design and control of an activated sludge process using a Multivariable Model-based Predictive Controller (MPC). The process synthesis and design are carried out simultaneously with the MPC tuning to obtain the most economical plant which satisfies the controllability indices that measure the control performance (H∞ and l1 norms of different sensitivity functions of the system). The mathematical formulation results into a mixed-integer optimization problem with non-linear constraints that is solved using a real coded genetic algorithm. The solutions reflects the effect of applying different bounds over the controllability norms. The results are encouraging for the development of integrated design approaches with advanced control schemes which usually results in complex optimization problems difficult to solve with conventional techniques.

Keywords: Process Design, Controllability indices, Model Based Predictive Control, Genetic Algorithms.

1. INTRODUCTION

The fact that the incorporation of controllability issues at the early stage of process design improves the dynamical behaviour of the plants have motivated the development of different methodologies to deal with the simultaneous process and control system design as Kookos and Perkins (2001), Revollar et al. (2004), Sakizlis et al (2004), Francisco et al. (2005) and more recently Tlacuahuac-Flores and Biegler (2007) and Tlacuahuac-Flores and Biegler (2008).

The simultaneous process and control system design leads to a non linear optimization problem where economic objectives, operability specifications and control performance are considered. The most comprehensive applications contemplate, also, the process synthesis or the control structure selection resulting into a mixed-integer-non-linear optimization problem (MINLP). The controllability analysis might require the evaluation of dynamic performance indices, which translates the problem into a mixed-integer-dynamical optimization (MIDO).

Even thought, the contribution in the field of integrated design is considerable, most of the approaches use conventional PID controllers. Only few works (Sakizlis et al., 2003; Sakizlis et al., 2004; Francisco and Vega, 2006) have been addressed to the application, in the integrated design, of advanced control techniques as Model-Based Predictive Controllers (MPC). The reason is that the advanced control schemes involve solving an optimization problem on-line, leading to a drastic increase in the complexity of the design framework (Sakizlis, et al, 2003; Sakizlis, et al, 2004).

Model based predictive control (MPC or MBPC) makes use of a process model to calculate the optimal control law. The MPC have been mainly accepted due to its natural way of incorporating operating constraints in multivariable process and the successful results in industrial applications (Maciejowsky, 2002; Qin and Badgwell, 2003). The shortcomings of conventional control schemes can be overcome by pursuing an advanced model-based predictive control (MPC) scheme (Sakizlis et al, 2003).

There are several strategies to deal with automatic tuning of MPC based on optimization of dynamical performance index (Ali et al., 1993; Francisco et al, 2005; Li and Du, 2002) but its evaluation requires time-consuming dynamical simulations which is an important drawback of these methodologies. Vega et al (2007) proposed the use of frequency domain methods as controllability indexes to speed up the MPC automatic tuning procedure by solving a mixed sensitivity problem with constraints. It avoids dynamical simulations but the use of linearized models, caused some problems of stability and robustness in the presence of nonlinearities and load disturbances on the process.

The aim of this work is to perform the integrated synthesis and design of a process using model-based predictive controllers (MPC) that will be tuned automatically using the strategy proposed by Vega et al (2007). The activated sludge process of the Manresa's plant was selected to apply the integrated design methodology as has been done in previous work using a conventional PI control technique (Revollar, et al., 2004, Revollar, et al., 2005). Francisco and Vega (2006) applied advanced control techniques for the integrated design of the

mentioned plant, but the structure selection was not taken into account in the problem formulation.

The main difficulty for solving the problem is the existence of continuous process and MPC variables, integers for the prediction and control horizon and binary variables for the structural decisions, which leads to a complex mixed integer non linear optimization problem. Therefore, it is necessary the use of advanced algorithms that handle both, continuous and discrete decisions, to lead the optimization to economically optimal processes operating in an efficient dynamic mode around the nominal working point.

Several deterministic mathematical programming optimization techniques have been used for solving the simultaneous design and control problem (Sweiger and Floudas, 1997; Kookos and Perkins, 2001, Sakizlis et al, 2003; Sakizlis et al, 2004) but complex formulations and a considerable computational effort are required for its implementation. On the other hand, stochastic optimization methods as genetic algorithms have been a good alternative for solving such difficult problems with a minimum effort for its implementation. A genetic algorithm has been proposed for the solution of this non linear mixed integer optimization problem.

The paper is organized containing, first, the description of the MPC and the controllability metrics used for the automatic tuning in the integrated design procedure, the formulation of the optimization problem and the description of the process and in section 3. The analysis of the results is presented in section 4. Finally, conclusions and different projections of this work are included.

2. MPC FORMULATION AND CONTROLLABILITY METRICS

The basic MPC formulation consists of the on-line calculation of the future control actions by solving the following optimization problem subject to constraints on inputs, predicted outputs and changes in manipulated variables.

$$\min_{\Delta\hat{u}} V(k) = \sum_{i=Hw}^{Hp} \left\| \hat{y}(k+i\,|\,k) - r(k+i\,|\,k) \right\|_{Wy}^2 + \sum_{i=0}^{Hc-1} \left\| \Delta\hat{u}(k+i\,|\,k) \right\|_{Wu}^2 \qquad (1)$$

where k denotes the current sampling point, $\hat{y}(k+i\,|\,k)$ is the predicted output vector at time $k+i$, depending of measurements up to time k, $r(k+i\,|\,k)$ is the reference trajectory, $\Delta\hat{u}$ are the changes in the manipulated variables, *Hp* is the upper prediction horizon, *Hw* is the lower prediction horizon, *Hc* is the control horizon, *Wu* and *Wy* are positive definite matrices representing the weights of the change of control variables and the weights of the set-point tracking errors respectively. In this work the matrices *Wy* and *Wu* are diagonal but not time dependent, so the error vector $\hat{y}(k+i\,|\,k) - r(k+i\,|\,k)$ is penalized at every point in the prediction horizon and the changes in the control signal $\Delta\hat{u}(k+i\,|\,k)$ are penalized at every point in the control horizon.

The problem (1) is a Quadratic Programming (QP) problem that gives a sequence of control moves $\Delta\hat{u}(k+i\,|\,k)$. The first component of this sequence is applied to the system in time $k+1$, and the optimization problem (1) is repeated at the next sampling time (receding horizon strategy).

The MPC prediction model used in this paper is a linear discrete state space model of the plant obtained by linearizing the first-principles nonlinear model of the process Maciejowsky (2002):

$$\begin{cases} x(k+1) = Ax(k) + Bu(k) + B_d d(k) \\ y(k) = Cx(k) \end{cases} \qquad (2)$$

where *x(k)* is the state vector, *u(k)* is the input vector and *d(k)* the disturbance vector. Matrices ***A***, ***B***, ***Bd*** and ***C*** are of adequate dimensions. For this model the prediction is:

$$\hat{y}(k+i|k) = C\hat{x}(k+i|k) = C\left[A^i x(k) + \sum_{j=1}^{i} A^{j-1} Bu(k+i-j|k) \right] \qquad (3)$$

One reason for choosing state space models is that a significant part of the recent research literature on MPC shows contributions based on this type of models. Connections between the standard linear quadratic regulator (LQR) theory and unconstrained MPC when the horizons approach infinity could be another reason for that.

When the MPC controller is linear and unconstrained, it can be represented with a transfer function KMPC. The corresponding transfer function is:

$$u = \begin{pmatrix} K_1 & K_2 & K_3 \end{pmatrix} \cdot \begin{pmatrix} r \\ y \\ d \end{pmatrix} = K_1 r + K_2 y + K_3 d \qquad (4)$$

where Ki are the transfer functions between the control signal and the different inputs (r,y,d) which depend on the control system tuning parameters (Wu, Hp, Hw and Hc). Particularly, in our MPC formulation $K_2 = -K_1$ (Maciejowsky, 2002), then, control law can be stated as:

$$u = K_1(r - y) + K_3 d \qquad (5)$$

Consequently, taking into account control law and the transfer function of the open loop system, the closed loop response can be obtained from

$$y = \frac{GK_1}{1+GK_1} r + \frac{1}{1+GK_1} \tilde{d} \qquad (6)$$

where $\tilde{d}$ are the filtered disturbances

$$\tilde{d} = \left(GK_3 + G_d \right) d \qquad (7)$$

In order to state the automatic tuning problem, is necessary to define: The Sensitivity function *S(s)* between the load disturbances (*d*) and the outputs (*y*) and the Control Sensitivity transfer function *M(s)* between the load disturbances (*d*) and the control signals (*u*) when the reference is zero .

$$S(s)=\frac{y(s)}{d(s)}=\frac{k_3G+G_d}{1+GK_1} \tag{8}$$

$$M(s)=\frac{u(s)}{d(s)}=\frac{K_3-K_1G_d}{1+GK_1} \tag{9}$$

For solving the MPC optimization problem, MPC Toolbox of MATLAB has been used, with some specific modifications (Maciejowsky, 2002) implementing an extended state space representation.

Regarding to the controllability indices, some norm based metrics were considered. The first controllability index considered in this work is:

$$\|N\|_\infty=\max_w|N(jw)| \tag{10}$$

where N is a mixed sensitivity index that takes into account both disturbance rejection and control effort objectives. The function N is defined as:

$$N=\begin{pmatrix} Wp\cdot S \\ Wesf\cdot s\cdot M \end{pmatrix} \tag{11}$$

Wesf(s) is chosen to penalize control efforts adequately, and *Wp(s)* is chosen based on the spectra of disturbances to ensure proper disturbance rejection. *Wp(s)* and *Wesf (s)* are suitable weights for optimization. The selection of *Wp(s)* is explained below, and the weight *Wesf(s)* is selected to complete the H∞ mixed sensitivity problem and allows for the significance of control efforts. Note that control efforts rather than magnitudes of control are included in the objective function by considering the derivative of the transfer function *M(s)*.

In order to ensure disturbance rejection we need (considering normalized disturbances):

$$|S(jw)|\cdot|d(w)|<1 \tag{12}$$

in the disturbances frequency range where *S(jw)* is the frequency response of the sensitivity function, and *d(w)* is the disturbance spectra. By choosing a weight *Wp(s)* satisfying

$$20\cdot\log|Wp(jw)|^{-1}<20\cdot\log|d(w)|^{-1} \tag{13}$$

disturbance rejection can be assured imposing the following constraint in the optimization tuning procedure:

$$\|Wp\cdot S\|_\infty<1 \tag{14}$$

A typical choice for the weight *Wp(s)* is a rational function with one zero and one pole. *B* is the weight gain for high frequencies, *a* is the gain for low frequencies and w_b represents the required bandwidth for the closed loop system. The parameter *a* is very small to impose integral action to the system but avoiding numerical problems.

$$Wp(s)=\frac{\frac{s}{B}+w_b}{s+w_ba} \tag{15}$$

The maximum value of the manipulated variables (for the worst case of disturbances) can be constrained to be less than u_{max}, by means of the *l1* norm and the following condition:

$$\|M\|_1<u_{\max} \tag{16}$$

3. PROCESS DESCRIPTION AND PROBLEM FORMULATION

The activated sludge process was selected to study the simultaneous synthesis and control system design methodology. A simple model (Moreno et al., 1992) was selected, to avoid the excessive complexity of models like the ASM1 developed by the IAWPRC.

Moreno et al. (1992) model is based on the wastewater treatment process of the Manresa plant (Spain). It is founded in the classical Monod and Maynard-Smith model. It is assumed that the reactions take place in only one perfectly-mixed tank. However, in this work two possible structural alternatives consisting in one or two aeration tanks are considered.

The activated sludge process corresponds to the secondary wastewater treatment stage. In the aeration tanks or bioreactors, the activity of a mixture of microorganisms is used to reduce the substrate concentration in the water. The dissolved oxygen required is provided by a set of aeration turbines. Water coming out of each reactor goes to the settler, where the clean water is separated from the activated sludge that is recycled to both bioreactors. The control of this process aims to keep the substrate at the output (s_1 or s_2) below a legal value despite the large variations on the incoming substrate concentration (*si*) using the recycling flows qr_1 and qr_2 as manipulated variables (Moreno et al, 2002). The frequency and magnitude of the disturbances at the *si* input make the control of the plant a difficult task. The set of disturbances used for evaluate the control performance while tuning the MPC has been determined by COST 624 program Copp (2002).

3.1. Mathematical Optimization Problem

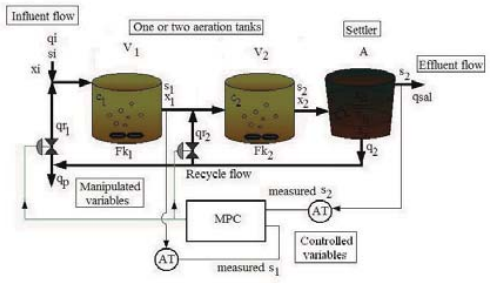

Fig. 1. Activated sludge process superstructure

The simultaneous synthesis, design and control of the activated sludge process pretend to obtain the most economical plant that satisfies the desired control performance. A cost function is defined to measure the economical issues while a predictive controller is tuned to achieve the desired closed loop behaviour according to the controllability norms described in section 2.

The two possible structural alternatives proposed for the plant are represented in a superstructure shown in figure 1. The model equations take the appropriated values for each structural alternative according to the binary y_1.

The mathematical formulation results into a mixed-integer-non-linear optimization problem where the objective is to minimize a cost function considering as decision variables: the structure (y_1), dimensions and controller parameters. Some constraints based in process model are set to find dimensions and initial working point, together with constraints over the norms used to measure the controllability of the plant with the actual controller parameters.

The cost function is:

$$f = p_1 \cdot (v_1 + v_2)^2 + p_2 \cdot A^2 + p_3 \cdot Fk_1^2 + p_3 \cdot Fk_2^2 + p_4 \cdot q_2^2 \qquad (11)$$

where v_1, v_2 are the reactor volumes and A is the cross-sectional area of the settler, Fk_1 and Fk_2 are the aeration factors for each reactor and q_2 is the overall recycle flow. The first three terms are associated to the construction cost that is proportional to the volume of the reactors and the area of the settler. The terms proportional to Fk_1, Fk_2 represent the aeration turbines costs, and the term proportional to q_2 represents pumping costs (purge and recycling).

Logical conditions must be imposed to guarantee the mathematical coherence of the model for any possible structure: if the second reactor does not exist: $y_1=0 \Rightarrow v_2=0$, $x_1=x_2$, $s_1=s_2$, $c_1=c_2$, $Fk_2=0$, $qr_2=0$, if the second reactor exist, then, $y_1=1$ and all the variables take values within their ranges.

The constraints imposed over mass balances in aeration tanks and the settler, are used to define the plant dimensions and the initial stationary working point.

$$\left| v_1 \frac{dx_1}{dt} \right| = \left| \mu_{\max} Y \frac{s_1 x_1}{(K_s + s_1)} v_1 - K_d \frac{x_1^2}{s_1} v_1 - K_c x_1 v_1 + q_{12} (xir_1 - x_1) \right| \le \varepsilon \qquad (17)$$

$$\left| v_1 \frac{ds_1}{dt} \right| = \left| -\mu_{\max} \frac{s_1 x_1}{(K_s + s_1)} v_1 + f_{kd} K_d \frac{x_1^2}{s_1} v_1 + f_{kd} K_c x_1 v_1 + q_{12} (sir_1 - s_1) \right| \le \varepsilon \qquad (18)$$

$$\left| v_1 \frac{dc_1}{dt} \right| = \left| K_{la} Fk_1 (c_s - c_1)\, v_1 - K_{01} \mu_{\max} \frac{s_1 x_1}{(K_s + s_1)} v_1 - q_{12} c_1 \right| \le \varepsilon \qquad (19)$$

$$\left| v_2 \frac{dx_2}{dt} \right| = \left| \mu_{\max} Y \frac{s_2 x_2}{(K_s + s_2)} v_2 - K_d \frac{x_2^2}{s_2} v_2 - K_c x_2 v_2 + q_{22} (xir_2 - x_2) \right| \le \varepsilon \qquad (20)$$

$$\left| v_2 \frac{ds_2}{dt} \right| = \left| -\mu_{\max} \frac{s_2 x_2}{(K_s + s_2)} v_2 + f_{kd} K_d \frac{x_2^2}{s_2} v_2 + f_{kd} K_c x_2 v_2 + q_{22} (sir_2 - s_2) \right| \le \varepsilon \qquad (21)$$

$$\left| v_2 \frac{dc_2}{dt} \right| = \left| K_{la} Fk_2 (c_s - c_2) v_2 - K_{01} \mu_{\max} \frac{s_2 x_2}{(K_s + s_2)} v_2 - q_{22} c_2 + W_1 \right| \le \varepsilon \qquad (22)$$

$$\left| AL_d \frac{dx_d}{dt} \right| = \left| q_{sal} x_b - q_{sal} x_d - A \cdot nnr \cdot x_d \exp(aar \cdot x_d) \right| \le \varepsilon \qquad (23)$$

$$\left| AL_b \frac{dx_b}{dt} \right| = \left| \begin{matrix} q_{22} x_2 - q_{22} x_b + A \cdot nnr \cdot x_d \exp(aar \cdot x_d) \\ -A \cdot nnr \cdot x_b \exp(aar \cdot x_b) \end{matrix} \right| \le \varepsilon \qquad (24)$$

$$\left| AL_r \frac{dx_r}{dt} \right| = \left| q_2 x_b - q_2 x_r + A \cdot nnr \cdot x_b \exp(aar \cdot x_b) \right| \le \varepsilon \qquad (25)$$

If the second reactor does not exist ($y_1=0$), the values of the variables given by the logical conditions mentioned above, annul the equations (20) and (21), a $W_1 = q_{22} \cdot c_2$ term is used to cancel equation (22).

The operation constraints for the activated sludge process are:

Residence times:

$$2.5 \le \frac{v_1}{q_{12}} \le 8 \qquad (26)$$

$$2.5 \le \frac{v_2 + (1 - y_1) \cdot W_2}{q_{22}} \le 6 \qquad (27)$$

where W_2 annul de constraint for $y_1=0$.

Mass loads in the aeration tanks:

$$0.001 \le \frac{q_i s_i + qr_1 s_2}{v_1 x_1} \le 0.12 \qquad (28)$$

$$0.001 \le \frac{q_{12} s_1 + qr_2 s_2 - (1 - y_1) W_3}{v_2 x_2} \le 0.12 \qquad (29)$$

where W_3 annul de constraint for $y_1=0$.

Sludge age in the settler:

$$2 \le \frac{v_1 x_1 + v_2 x_2 + AL_r x_r}{q_p x_r 24} \le 10 \qquad (30)$$

Limits in hydraulic capacity:

$$\frac{q_{22}}{A} \le 1.5 \qquad (31)$$

Limits in the relationship between the input, recycled and purge flow rates:

$$0.03 \le \frac{q_p}{q_2} \le 0.3 \qquad (32)$$

$$0.05 \le \frac{q_2}{q_i} \le 0.9 \qquad (33)$$

The controllability constraints are the limits over the norms described in section 2 where the transfer functions are referred to s_2 as the output, si y qi as the disturbances, and recycling flows qr_1, qr_2 as control variables. The parameter u_{max} is an upper bound for the magnitude of control variables. These constraints: $\|N\|_\infty < 1$, $\|Wp \cdot S\|_\infty < 1$, $\|M\|_1 < u_{\max}$ ensure a satisfactory control performance with the tuned MPC.

The main difficulties when solving this problem is the existence of continuous, integer and binary variables and the evaluation of controllability norms that implies the linearization of the process model for each possible solution. GA are particularly suitable, due to its robustness and the straightforward method to compute the objective function and constraints avoiding gradient evaluation.

4. RESULTS

For solving the problem using genetic algorithms (Gen and Cheng, 2000), a fixed length real coded chromosome is defined, containing the continuous normalized process variables, the controller parameters (Wu, Hp, Hc) and a binary variable to set the structure of the plant: [x_1, x_2, S_{sab}, xd xb xr qr_1 qr_2 qp Fk_1 Fk_2 v_1 v_2 A Wu Hp Hc y_1].

The location of the variables in the chromosome is important for the objective function and constraints evaluation procedure.

The genetic algorithm starts by generating randomly a population of possible solutions, that contains the same quantity of individuals for the two structural alternatives ($y_1=0$ and $y_1=1$). Each solution is manipulated to fulfil the logical conditions mentioned in section 3.1, according to the actual value of y_1. The new candidate solutions are manipulated also, according to the logical conditions. The population in the succeeding generation consists of 50% of the best individuals from the previous generation and 50% of the individuals generated by crossover.

The problem is solved using a population size of 200 individuals and 300 maximum iterations. Roulette selection and arithmetic crossover were used. The mutation rate decreases with generations from 0.1 to 0.02 and the crossover probability used is 85%. A penalization strategy is applied to deal with constraints. The genetic algorithm was run 10 times for each case study, giving optimal feasible solutions for each run with an average computing time of 9657 seconds.

Two scenarios with different demands on control performance were proposed. For the case 1 the norm $\|M\|_1 < 1000$ and for the case 2 the norm $\|M\|_1 < 1500$. The weights Wp for both cases are: $Wp(s) = \frac{8s+19.2}{s+0.0001}$

Table 1. Numerical results for integrated synthesis and design with MPC for the case 1

Cost (MU)	0.13	Wu	0.0122
V_1 (m^3)	8640	Hp	9
A (m^2)	2728.9	Hc	3
S_1 (mg/l)	115.66	$\|N\|_\infty$	0.97
Qr_1 (l/hr)	371.47	$\|M\|_1$	987.47
Fk1	0.035	$\|Wp \cdot S\|_\infty$	0.92
Residence times	2.5		
Mass loads	0.08		
Hydraulic capacity	0.55		
Sludge age	2.08		

The results for the two scenarios are presented in tables 1 and 2. In both cases, the transfer functions and weights are referred to disturbances in si and qi. It is observed that the solution gives small economical plants that satisfy all the process and control constraints. It is important to notice the flexibility of the method for different limits imposed over the constraints leading to plants of different dimensions. In the case 1, where an stringent bound is imposed over l1 norm is obtained a plant with 8640m^3 reactor while, for the case 2, with a relaxed bound in l1 norm is possible to obtain an smaller plant with a reactor of 5858.1 m^3 which is reflected in cost.

The optimization case 1 produces a plant with better disturbance rejection because the weight Wp_1 is more restrictive for sensitivity function S. On the other hand, with a smaller bound for $\|M\|_1$, the magnitude of control is less relaxed than in case 2 giving a smaller range of action to the manipulated variable to reject disturbances. The values of Wesf for qr_1 and qr_2 control sensitivity functions are fixed to:

$$Wesf_{qr1}(s) = \frac{0.0117s+0.14}{s+0.0004} \qquad Wesf_{qr2}(s) = \frac{0.0183s+0.22}{s+0.0004}$$

Table 2. Numerical results for integrated synthesis and design with MPC for the case 2

Cost (MU)	0.064	Wu	0.0069
V_1 (m^3)	5858.1	Hp	8
A (m^2)	2178.4	Hc	3
S_1 (mg/l)	118.06	$\|N\|_\infty$	0.979
Qr_1 (l/hr)	273.9	$\|M\|_1$	1454.9
Fk1	0.021	$\|Wp \cdot S\|_\infty$	0.786
Residence times	4.11		
Mass loads	0.0856		
Hydraulic capacity	0.65		
Sludge age	5.03		

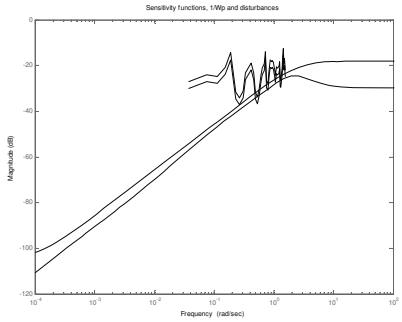

Fig.2. Sensitivity function S, Wp^{-1} and disturbances inverse spectrum for case 1

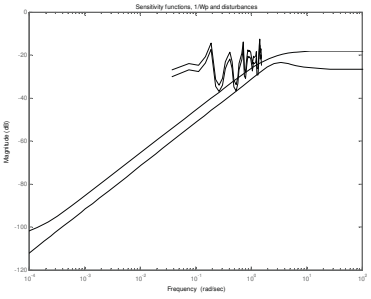

Fig.3. Sensitivity function S, Wp^{-1} and disturbances inverse spectrum for case 1

In figures 2 and 3 sensitivity functions S are presented for both cases. In the case 1 the inverse spectrum of disturbances is over Wp^{-1}, and in case 2 this weight is a bit more relaxed representing worse disturbance rejection. In figures 4 and 5 the dynamical responses of the optimal plants for both cases are

presented, to illustrate the better disturbance rejection for case 1 as have been previously mentioned.

5. CONCLUSIONS

In this work, the synthesis and integrated design of an activated sludge process with an advanced controller (MPC) was addressed. The problem was translated into a mixed-integer-non-linear optimization problem, with the evaluation of controllability norms to ensure the most economical design with a suitable control performance.

The MINLP was solved using a real-coded genetic algorithm which leads to good quality feasible solutions with desired disturbance rejection, which is the main control objective. The solutions obtained are sensible to the bounds imposed over controllability indices.

The controllability norms were set as constraints in the formulation of the optimization problem, but it could be formulated as a multiobjective optimization problem considering costs and controllability.

These results are encouraging for the development of simultaneous design and control approaches with advanced control schemes which usually results in complex optimization problems difficult to be solved. In this framework, the use of advanced control techniques represent a significant advance due to the advantages of these control strategies respect to conventional PID.

Abstract: Fuel cell systems can produce clean energy and have attracted the interest of both industrial and basic research in the recent years. They are part of a promising benign and environmentally friendly technology and they can be used both in mobile and stationary applications. A dynamic model was constructed and validated using experimental data based on a specific application, consisting of a high temperature PEM Fuel Cell (FC) working at a constant pressure and a Power Conversion Device that controls the current drawn from the FC. An integrated framework that consists of an online maximum power point prediction algorithm and a non-linear model based control scheme is presented. The proposed framework aims to maintain the fuel cell close to the optimum power point and the corresponding oxygen excess ratio level. Simulation studies show that the proposed control framework results in improved performance regarding the efficient and safe fuel cell operation under varying operating conditions.

Keywords: fuel cell control, model predictive control, power management

1. INTRODUCTION

Fuel cells are electrochemical devices that convert the chemical energy of a fuel directly into electricity and are under intensive development by several manufacturers. They are categorized according to the type of electrolyte used, operating conditions or fuel. The Polymer Electrolyte Membrane or Proton Exchange Membrane fuel cells (PEMFC) are currently considered by many to be in a relative more developed stage for ground vehicle applications and portable devices. PEMFC's have high power density, solid electrolyte, long cell and stack life, as well as low corrosion. Lately PEM fuel cells working at higher temperatures of up to 200°C have appeared such as those that use phosphoric acid doped polybenzimidazole (PBI) membrane, which is considered one of the most successful membrane systems so far [Jensen, 2007]. The benefits of operation at elevated temperature are mainly the tolerance to carbon monoxide concentration at the hydrogen feed, commonly present when operating with reformate streams, that can be increased by many orders of magnitude compared to that of a common PEM and also the water management which is a lesser issue, since the water is in vapor state. Additionally, the PBI membranes are conductive at very low relative humidity and consequently no moisture management is needed. Moreover, the high working temperature eliminates the possibility of water condensation in pores or channels of the fuel cell. Due to the higher temperature difference to the surroundings thermal management can be satisfactorily performed by a smaller cooling system [Jensen, 2007]. However, due to material limitations, the power of the fuel cell cannot be arbitrary used without prior consideration on the internal effects such as the provision for fuel and oxidant supply, temperature gradients, condition of the membrane (humidity) and so forth. The choice of the operating region leads to different characteristics for the unit regarding its profitability, effectiveness and safety. The dynamic response of a fuel cell is affected when the power demand fluctuates or when the fuel cell does not operate at its optimal steady-state design point [Golbert, 2007]. An optimization algorithm is used to search off-line for the optimum excess oxygen ratio level and the corresponding near maximum power. The primary objective of this paper is to demonstrate that model-based predictive control (MPC) is a suitable approach for efficient and safe fuel cell operation. The paper is organized as follows: Section 2 gives an overview of the dynamic fuel cell mathematical model. In section 3, the model validation procedure is presented. Section 4 presents the model-based predictive control structure along with the conventional control that is present for the pressures of the anode and the cathode compartments of the FC. Section 5 discusses the maximum power targeting algorithm The simulated results of the proposed MPC framework are presented and discussed in section 6.

2. MODELING AND ANALYSIS

The application is consisting of a high temperature PEM Fuel Cell working at a constant pressure and a Power Conversion Device capable of controlling the current drawn from the FC. In order to define a model based control strategy it is important to have an accurate model that reflects the transient dynamics and fuel cell system behavior and in the same time fast in execution in order to be useful for a real-time application. The mathematical model equations that describe the operation of the fuel cell consists of the voltage-current characteristics and a relationship for the consumption of the reactants as a function of the current drawn from the fuel cell. The main purpose of the detailed model is to describe the dynamic behavior in a way that the fundamental operating parameters current and pressure are established as manipulated variables and temperature as disturbance and power and excess oxygen ratio as controlled variable.

2.1 General

The main components of a PEM fuel cell are three - an anode, typically featuring platinum-containing catalyst, a thin, solid polymeric layer which acts as electrolyte, and a cathode, also coated with platinum [Mann, 2000]. In the PEM fuel cell the only reaction that takes place is the production of water from hydrogen and oxygen. In order to accurately describe the fuel cell behavior the mass balance and the equations that affect the voltage calculation are analyzed in the following section. The development of the fuel cell model is based on some assumptions. The gases are ideal and uniformly distributed inside anode and cathode. The stack is fed with hydrogen and air. The temperature is constant and uniform for each experiment. The gas channels along the electrodes have a fixed volume with small lengths, so that it is only necessary to define one single pressure value in their interior.

2.2 Electrochemistry and Voltage Calculation

Typical characteristics of FC are normally given in the form of polarization curve, which is a plot of cell voltage versus cell current density. To determine the voltage-current relationship of the cell, the cell voltage has to be defined as the difference between an ideal, Nernst voltage and a number of voltage losses and it is described in the current section. The main losses are categorized as activation, ohmic and concentration losses. The activation losses are caused by the slowness of the reactions taking place on the surface of the electrodes. A portion of the voltage generated is lost in driving the chemical reaction that transfers the electrons to or from the electrodes. The activation losses are described by the Tafel equation, which can be calculated as [Mann, 2000]:

$$\Delta V_{act} = \xi_1 + \xi_2 T + \xi_3 T \ln(C_{O_2}) + \xi_4 T \ln(i) \quad (1)$$

where ξ(i = 1–4) are parametric coefficients for each cell model. The term C_{O_2} is the concentration of oxygen on the electrolyte membrane at the gas/liquid interface (mol/cm^3), which can be expressed as [Zhong, 2008]:

$$C_{O2} = \frac{p_{O2}}{5.08 \cdot 10^6 e^{\left(\frac{-498}{T}\right)}} \quad (2)$$

The ohmic losses are caused by the resistance to the flow of electrons through the material of the electrodes and the various interconnections, as well as by the resistance to the flow of protons through the electrolyte. The ohmic losses are given by:

$$\Delta V_{ohm} = R_{mem} \cdot i \quad (3)$$

The ohmic resistance is described by:

$$R_{mem} = \frac{r_m \cdot mem_{thick}}{A} \quad (4)$$

where r_m is membrane resistivity (Ωcm) to proton conductivity, mem_{thick} is the membrane thickness (cm) and A is the active cell area (cm^2). Membrane resistivity depends strongly on membrane humidity and temperature, and can be described by an empirical expression given by Mann et. al. [Mann, 2000]. Finally the mass transport or concentration losses result from the change in concentration of the reactants at the surface of the electrodes as the fuel is used [Larminie J., 2003]:

$$\Delta V_{conc} = me^{ni} \quad (5)$$

where m and n are constants that can be estimated to give better fit to measured results. Thus, the actual voltage will be less due to the aforementioned losses that occur because of the various electrochemical phenomena. The Nernst voltage or open circuit voltage falls as the current supplied by the stack increases. The reversible thermodynamic potential is calculated using the Nerst equation and can be expressed as:

$$E = E^0 + \frac{RT}{2F} \ln\left[\frac{P_{H2} P_{O2}^{\frac{1}{2}}}{P_{H2O}}\right] \quad (6)$$

where F is the Faraday's constant (C/kmol) and p_i are the partial pressures (atm) (with i=H_2, O_2, H_2O). The equation that combines the above irreversibilities expresses the actual cell voltage:

$$V_{cell} = E - V_{act} - V_{ohm} - V_{conc} \quad (7)$$

The above equation is able to predict the voltage output of PEM fuel cells of various configurations. Depending on the amount of current drawn the fuel cell produces the output voltage according to (7). The electric power delivered by the system equals the product of the stack voltage V_{cell} and the current drawn I:

$$P = I \cdot V_{cell} \quad (8)$$

2.3 Mass Balance Equations

The model equations consist of the standard material balance of each component. Every individual gas follows the ideal gas equation. Therefore mass is described through partial pressures of each gas in the material balances:

$$\frac{d}{dt}p_g = \frac{R \cdot T}{V}\left[q_g^{in} - q_g^{out} - q_g^r\right] \quad (9)$$

where R is the universal gas constant (J (kmol K)$^{-1}$)), T is the temperature (K), V is the anode or cathode volume (1). For each gas q_g^{in} is the input flow, q_g^{out} is the output flow and q_g^r is the consumption or production due to the reaction. The same expression is used for oxygen, hydrogen and the produced water by replacing the term g with the corresponding gas. The amount of hydrogen consumed due to reaction is calculated as:

$$q_{H2}^r = \frac{I}{2F} \quad (10)$$

and for the oxygen :

$$q_{O2}^r = \frac{1}{2}\frac{I}{2F} \quad (11)$$

while the water production can be described by :

$$q_{H2O}^r = -\frac{I}{2F} \quad (12)$$

The water production rate is the same as the hydrogen's reaction rate, since water is produces as hydrogen is consumed. The oxygen reaction rate is the half of that of the hydrogen due to the stoichiometry of the reaction. As the load draws current, the reactants become depleted in the fuel cell and partial pressure of oxygen and hydrogen drop accordingly. A common practice to protect the fuel cell from reactants starvation is to supply it with excessive amounts of hydrogen and oxygen.

2.4 Oxygen Excess Ratio

There are two phenomena that can deteriorate or even destroy the fuel cell, flooding and oxygen starvation. Flooding is related to temperature and humidity, which are assumed constant and stable in the developed model since it is a high temperature FC where flooding is rather avoidable. The second one, the oxygen starvation, when it occurs the operation of the FC must be stopped in order to prevent fuel cell malfunction. The lack of oxygen is a complicated phenomenon that occurs when oxygen falls below a critical level at any location within the cathode. This phenomenon entails a rapid decrease in cell voltage, which in severe cases can cause a hot spot, or even burn-through on the surface of a membrane. To prevent this catastrophic event, the system must either remove the current from the stack or trigger a shut-down procedure. For all these reasons in a PEM fuel cell it is considered important to control the amount of available oxygen in the cathode. The air flow needs to be controlled rapidly and efficiently to avoid oxygen starvation and extend the life of the stack [Pukrushpan, 2004]. Although the oxygen concentration is not homogenous throughout the cathode, the control can be achieved by defining a parameter that indicates the oxygen level status in the cathode, named excess oxygen ratio level λ_{O2}. The excess ratio level is an unmeasured but observable variable that can be expressed as the inlet flow q_{O2}^{in} to the rate of oxygen consumption q_{O2}^r :

$$\lambda_{O2} = \frac{q_{O2}^{in}}{q_{O2}^r} \quad (13)$$

As can be observed by (11) and (13) the oxygen excess ratio level depends on the current drawn from the cell. This relationship can cause an abrupt and momentarily drop of the λ_{O2}, while it is related to the fuel consumption High values of λ_{O2}, and thus higher partial oxygen pressure improves the overall power. Low values of λ_{O2} indicate low oxygen concentration that could lead to oxygen starvation. Moreover, the temperature within the fuel cell may rapidly increase when oxygen concentration is too low. Therefore, the oxygen should be replenished quickly as it is depleted in the cathode [Vahidi, 2006].

3. PARAMETER IDENTIFICATION

The dynamic process model described in the previous section is validated using experimental data from a high temperature PEMFC. Nonlinear regression techniques are used to estimate the model parameters. The selected estimated parameters are the following: the parametric coefficient in activation losses (ξ_1) and the parameters in concentration losses (m, n). The characteristic cell voltage and the applied current density were measured through an on-line supervisory control and data acquisition system. Experiments were performed at the single cell system at constant temperatures between 170°C to 200°C. The activation area of the cell is 25cm2. The estimated values of the parameters are presented in Table 1.

Table 1 Estimated parameters

Parameter	Estimated value
ξ_1	-1.771
m	7.04E-05 V
n	9.44 E-03 cm^2 mA

Fig 1 compare the model predictions with the experimental data for various operating temperature levels for the polarization curves Fig 1 reveal that model predictions are in good agreement with the experimental data. As can be observed in the experimental results, a temperature increase raises cell voltage and consequently the fuel cell power output.

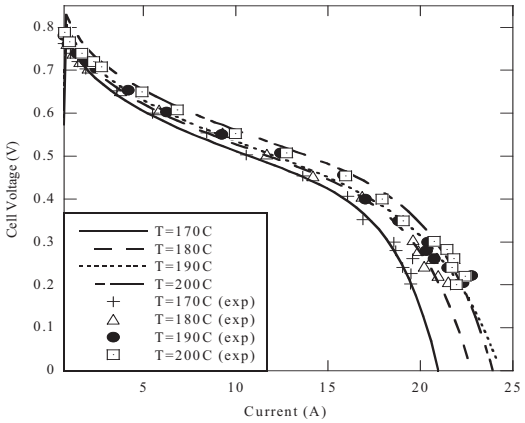

Fig. 1 Model predicted and experimental polarization curves

4. MAXIMUM POWER TARGETING

The power of the fuel cell depends nonlinearly on the applied current. As it is observed from the power curve there exists a unique operating point for each set of operating conditions, where the delivered power reaches a maximum power point (MPP). The operation of the system beyond MPP is not safe and should be avoided. The purpose of the control strategy is to deliver a near optimum power and at the same time to choose the proper operating region to ensure high fuel cell efficiency and avoid oxygen starvation. Thus a MPP tracking algorithm is developed that calculates the highest possible power as operating conditions vary. Fuel cell operation at the MPP is not very beneficial because the corresponding fuel efficiency is at best 50%. [Zhong, 2008]. As illustrated in Fig. 2 there exists an area where the power is near its MPP and the corresponding oxygen excess ratio level guarantees a safe and efficient fuel cell operation. The calculation of the MPP from process measurements is not possible as it depends on numerous factors that change during operation (e.g., relative humidity, gas mole fractions) and furthermore the entire power curve needs to be inferred to identify its maximum. Therefore, the fuel cell mathematical model is used in order to determine a desired trajectory towards the near MPP.

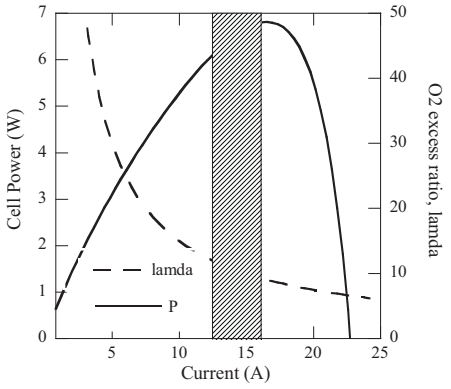

Fig. 2 Power curve and λ_{O2} (lamda) trajectory. Desired area of operation is shadowed.

Numerous methods have been proposed for maximum power tracking such as the perturbation and observe, adaptive extremum seeking algorithm, artificial intelligence methods and model-based methods to name a few [Zhong 2008, Krstic, 2000]. The current approach utilizes the developed non-linear dynamic model to determine off-line the near optimum region of operation and calculate the corresponding oxygen concentration level at the specific operating point usually defined as a function of temperature and pressure. The higher oxygen excess ratio level leads to a safer operation. The resulting strategy aims to an operation where a compromise between the maximum achievable power output and the optimal oxygen excess ratio is sought.

5. MODEL PREDICTIVE CONTROL FRAMEWORK

A Model Predictive Control (MPC) framework is formulated for the satisfaction of the control objectives described in the previous section. The fuel cell system presents a number of control challenges, the most significant of which is the nonlinearity in the area of the maximum power. Also an important control objective is the effective regulation of the oxygen concentration in the cathode. Furthermore, it is of interest to ensure safe operation during transients and sudden load changes. MPC is able to satisfy multiple control objectives under the presence of changes in process characteristics. Another important feature is its ability to deal with constraints. When a fuel cell operates near the MPP and consequently close to its operation limits constraints violations are critical in the achieved control performance.

5.1 Anode and Cathode Pressure Control

To regulate the anode and the cathode pressure a fast proportional-integral (PI) controller is implemented as used in the real system. The conventional PI controllers are used independently of the MPC scheme, which assumes that the anode and cathode pressure is held at a constant level as the dynamics of the PI control system are relatively fast. In the performed experiments it is assumed that the cathode and anode pressure is at 2 barg. These secondary loops are tightly controlled and assumed not to interact with the main control objectives of the system.

5.2 Model Predictive Control

Model predictive control (MPC) is part of a family of optimization-based control methods, which are based on on-line optimization of future control moves. Also MPC is based on the fact that past and present control actions affect the future response of the system. Using a process model, the optimizer predicts the effect of past inputs on future outputs. The deviation of the model prediction from the actual response is recorded and considered as the error of the process model, as shown in the block diagram of the MPC framework. The calculated error defines a bias term that is used to correct future predictions and it is constant for the entire prediction horizon. The block diagram describing the MPC scheme and the near optimum power targeting scheme is illustrated in Fig. 3.

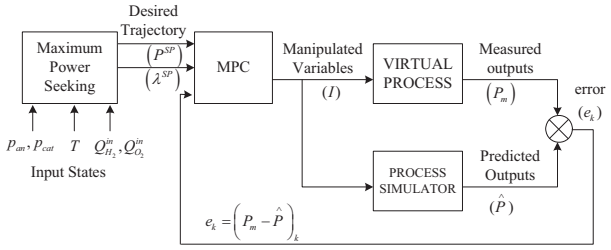

Fig. 3 Block diagram of the MPC control framework

The control structure utilizes two instances of the aforementioned dynamic model; the one corresponds to the Virtual Process (VP) and the second one to the Process Simulator (PS) or Model, and they are concurrently executed. Successive iterations between the optimizer, that evaluates the optimum value for the manipulated variable, and the model, that calculate the response of the process to the imposed control action are performed. The mathematical representation of the MPC algorithm is as follows:

$$\min_{k+j-1} J = \sum_{j=1}^{Np} \left\| \hat{P}_{k+j} - P_{k+j}^{SP} \right\|_{w_P}^2 + \left\| \hat{\lambda}_{k+j} - \lambda_{k+j}^{SP} \right\|_{w_\lambda}^2 \quad (14)$$

Subject to :

$$e_{k+j-1} = \left(y^{meas} - y^{pred} \right)_{k+j-1}, \; y_k = P_k \quad (15)$$

$$\hat{y}_{k+j} = y_{k+1}^{pred} + e_{k+j-1} \quad (16)$$

$$N_c = (T_c - T_k) / \Delta t_c \quad (17)$$

$$N_p = (T_p - T_k) / \Delta t_p \quad (18)$$

Where vectors $\hat{P}_k^{SP}$ and $\hat{\lambda}_k^{SP}$ denotes the desired response trajectories. The difference e_k between the measured variables y^{meas} and their predicted values y^{pred} at time instance *k* is assumed to persist constant for the entire number of time intervals N_p of the prediction time horizon T_p. While T_c denotes the control horizon reached through N_c time intervals. Also this minimization is subject to constraints on the manipulated and controlled variables:

$$I_{\min} \le I_{k+j-1} \le I_{\max} \quad (19)$$

$$\lambda_{O_2,\min} \le \lambda_{O_2} \le \lambda_{O_2,\max} \quad (20)$$

Eq (19) imposes a constraint to the input variables that corresponds to their physical limits. Eq (20) imposes a constraint on lamda to avoid starvation. Tuning parameters of the algorithm are the weight factors in the objective function (w_p, w_λ) and the length of the prediction and control horizon. The selection of the appropriate prediction horizon is mainly dictated by the time scale characteristics of the system. The computational time to reach a solution of the nonlinear dynamic program may affect the duration of the control interval.

6. SIMULATION RESULTS

The performance of the proposed MPC framework is evaluated through a number of simulated examples for a high temperature PEMFC. In all cases, unless otherwise stated, the system operates at constant temperature ($T_{sim} = T_{process} = 180^\circ C$) and constant cathode pressure ($p_{an} = p_{cat} = 2\text{barg}$). The influence of the controller tuning parameters on the closed-loop performance of the MPC is investigated. The main parameters are the control and the prediction horizons and the weighting factors of the power and oxygen concentration terms. Both prediction and control horizons were chosen equal to 15 seconds while the intervals of the control actions were chosen equal to 5 seconds. The length between two consecutive control actions (Δt_c) was selected according to the required computational time of the optimization problem.

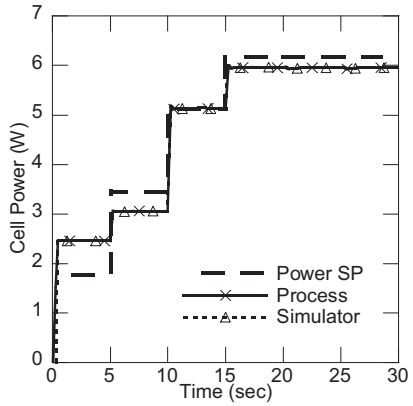

Fig. 4 Power response with unequal weights $w_p = 0.8,\ w_\lambda = 0.2$

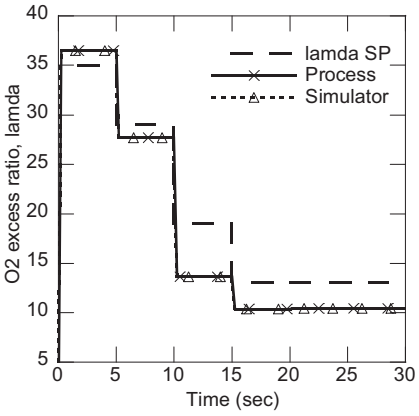

Fig. 5 Oxygen excess ratio level with unequal weights $w_p = 0.8,\ w_\lambda = 0.2$

Fig 4-7 show the sensitivity of the MPC performance on the weighting factors in the objective function. In the first case (Fig 4-5) more importance is given on the tracking of the power output while in the second case (Fig 6-7) an equal importance to both control objectives is imposed. In both

cases the desired setpoints were followed satisfactorily. However, in the first case excess O_2 is quite low which may cause difficulties in the fuel cell operation (i.e. oxygen starvation). The power output offset is small in the first case where a larger weight is used for the power output difference term. A better compromise is achieved in the second case with the excess oxygen closer to the desired level.

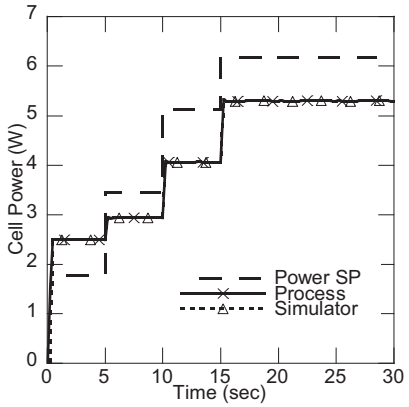

Fig. 6 Power response with equal weights $w_p = 0.5,\ w_\lambda = 0.5$

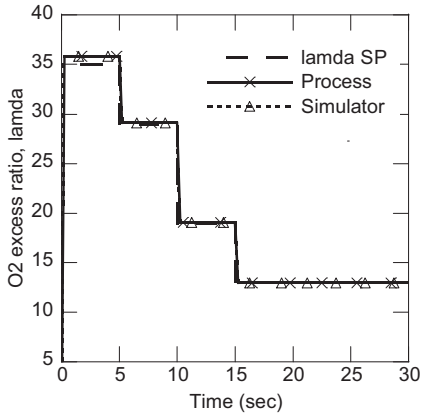

Fig. 7 Oxygen excess ratio level with equal weights $w_p = 0.5,\ w_\lambda = 0.5$

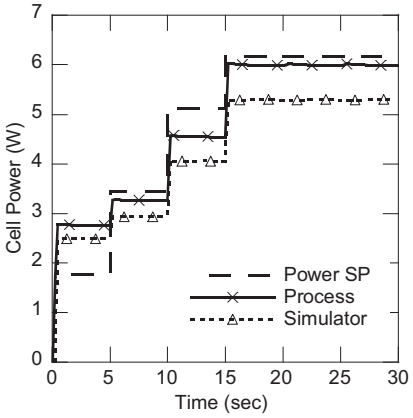

Fig. 8 Power response with altered process temperature

In another case study (Fig 8), significant mismatch in the fuel cell temperature between the Virtual Process and Process Model ($T_{sim} = 180^{\circ}C, T_{process} = 140^{\circ}C$) is deliberately introduced in order to asses the robustness of the proposed strategy to a significant disturbance. Fig. 8 illustrates the ability of the nonlinear MPC scheme to compensate for the temperature variation and successfully satisfy the control objective by close tracking of the desired power output level. The application of the constrained MPC framework allowed for an accurate targeting of the desired oxygen concentration and was able to give a near maximum power.

7. CONCLUSIONS

In this work a dynamic model for a high temperature PEM fuel cell stack based on single cell was developed and an advanced constrained predictive control framework was implemented. Having tested and verified some selected operational parameters a reliable MPC scheme was resulted. The MPC framework that combines two contradictive operational objectives, can safely lead to an operation that maximizes the power of a given size FC. The proposed MPC will be implemented and verified in the experimental fuel cell system. In order to improve the overall efficiency and safe operation, the controller would further include mathematical models for the auxiliary subsystems.

Abstract: This paper presents the simulation and real time implementation of an adaptive predictive PI controller for the control of Chlorine dosing in secondary water disinfection rigs. This trial is part of a project that looks at the optimisation of process control specifically in the water industry. As one of the main treatment processes, Chlorine dosing is one of the processes that naturally imposes very long dead times for the controller to deal with. Although PI controllers are still commonly used for controlling this process, previous literature as well as trials carried as part of this project proved that the performance of PI controllers, no matter how tuned they are, is very sluggish and unreliable. A pilot rig was used instead of a live secondary disinfection rig, and a number of open loop step tests were performed for system identification. Once the process dynamics became known, complementary functions that estimate the process transfer function based on the water flow were introduced. A standard tuned PI controller configuration was simulated for the process, and then a Smith predictor was used in order to be able to compare the performance of the predictive PI with a standard PI controller. Tuning functions were derived for the PI to make it a self-tuning predictive controller, and parameter estimation functions were also used so that the final outcome is an adaptive self-tuning system. This system was then implemented on the same pilot rig, and real time implementation proved the findings obtained from the simulation. Both simulation and pilot rig tests show a very good dynamic response with excellent accuracy.

Keywords: Water process control; Chlorine dosing; PI tuning; Smith predictor; adaptive self-tuning.

1. INTRODUCTION

Process dead time is one of the most challenging issues in process control system design, as it makes the process difficult to control using standard feedback techniques mainly because the control action takes some time affect the controlled variable, and therefore the control action that is applied based on the actual error tries to correct a situation that originated some time before [1]. There can be several causes of this time delay, but in most process industries, the delay is caused by mass or energy transportation (also known as transport delay).

Processes with long dead times can not often be controlled effectively using a simple PI/PID controller. This is because the additional phase lag caused by the time delay tends to destabilise the closed loop system. The stability of such system can be improved by decreasing the controller gain, but that will certainly slow the controller down and make the response very sluggish [2]. Most water treatment processes incur relatively long transport delays, simply because the process variable is controlled by the addition of certain chemicals where a reaction time (Time taken for the chemical to dissolve/react in water) is to be allowed before the process variable can be sampled. It therefore, becomes part of the design requirements to allow enough distance between the chemical dosing and sampling points, and the time delay is then a function of the water flow within this distance as well as the flow in the sample line. A valid estimation of the delay may be expressed as:

$$Td = V/Q \quad (1)$$

Where Td is time delay, V is the volume of the pipe work between the dosing and sampling points, and Q is the water flow rate through the pipe. Another element that may have to be considered is the delay that might be caused by the sample line unless this delay is much smaller than the time delay caused by the pipe work. Previous research showed that PI controllers have been used to control dead-time processes, and the performance was acceptable when the dead time was small, but the performance deteriorates as the dead time increases, and in such cases a significant amount of detuning is required to maintain closed loop stability [5, 6].

2. THE CHLORINATION PROCESS

This research project focused on the implementation of predictive control for time varying water treatment processes that can generally be represented by a first order plus dead time (FOPDT) transfer function. Chlorine dosing is one of the essential treatment processes in most treatment plants as Chlorine is the most commonly used disinfectant and has been for the last hundred years [4]. The disinfection process takes place mainly in the main treatment plant, but there are usually secondary disinfection points spread around the distribution network in order to ensure that water provided to customers is microbiologically safe. Chlorine has many advantages that make it a more desirable disinfectant to use than other disinfectants (e.g. Ozone), but there are also disadvantages on using Chlorine. One of the main concerns in using Chlorine as a disinfectant is the formation of disinfection by products (DBP). Chlorine reacts with natural organic matter in water to form DBP's, and researchers are becoming increasingly concerned about the health problems those products can cause. A trade-off between the protection from infectious diseases and limiting exposure to DBP's has to be considered when using chlorine as a disinfectant [4]. This highlights the sensitivity of the Chlorination process, and the importance of having a reliable accurate control system to ensure that the amounts of Chlorine dosed in drinking water is what is needed.

3. PARAMETER ESTIMATION

The process described here is implemented on a pilot rig to study the effects of time varying processes on the performance of the controller. The advantage of using this pilot rig is the flexibility it gives in terms of controlling the parameters defining the dynamics of the process (i.e. water flow, pressure, and incoming Chlorine residual). These parameters have a direct impact on the process transfer function, and are normally hard to control in live disinfection rigs as they depend on water consumption by consumers.

Open loop step tests were performed at various flow rates and repeated several times. As expected, the variation of flow affected the dead time and the process time constant. Theoretically the dead time can be calculated using equation (1) provided that the precise volume of the pipe work as well as the precise flow rate are both known. Because of the relatively small size of the rig where even small inaccuracies in either the flow or the volume would affect the estimated process parameters, it was necessary to estimate the dead time using the open loop step test results. Figure 1 shows the relationship between the water flow rate and the process parameters.

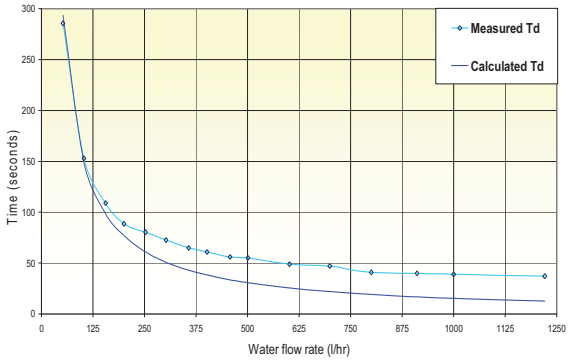

Fig. 1. Calculation and measurement of process dead time in relation to water flow rate.

It can be clearly noticed that at low flow rates, the measured dead time is almost identical to the calculated values, but as the flow increases beyond the lower 10% of this trial's flow range, the decrease in process dead time is not as expected. This highlights the importance of using real time data analysis when optimising the control system in this application.

4. PROCESS SIMULATION

Based on the open loop step test results, a model was built to represent both the process and the PI controller as implemented in most water treatment processes. Most chemical dosing process in water treatment use feedback plus feed forward control in a layout known in industry as Flow paced plus trim (Compound) control. The idea here is to combine the outputs of the feedback controller (usually a standard PI controller) and the feed forward controller (a gain element that is proportional to the water flow rate) in what will become the manipulated variable. In an ideal case, the feed forward controller output should keep the process variable equal to or very close to the set point. However, due to offsets in the dosing and measurement equipment, mismatch between the nominal and actual Chlorine strength, as well as the usual possibility of Chlorine presence in the incoming water, the feed forward controller will have to be supported by a feedback controller to act as a final trim and make up for all existing offsets.

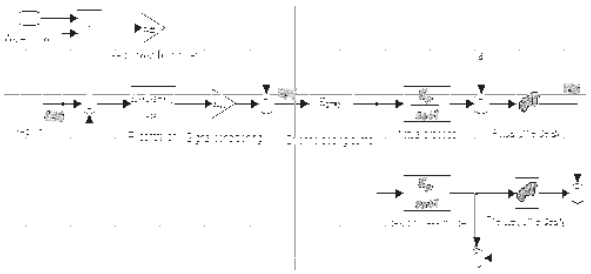

Fig. 2. Layout of Chlorine Dosing control loop.

A Smith predictor layout is shown in figure 2 combined with the PI controller and a proportional flow pacing function for feed forward control. The two main disturbances that can affect the process are the variation of water flow over time, and the incoming residual to the process. Many secondary disinfection rigs are installed on varying flow lines, where the flow rate changes over time by a ratio of up to 1:8. Therefore, it's important to consider the effect such big changes will have on the transfer function of the process, especially on the dead time of the process. Figure 3 shows a plot of real time data collected over a week from a time varying secondary dosing rig that is controlled by a PI controller.

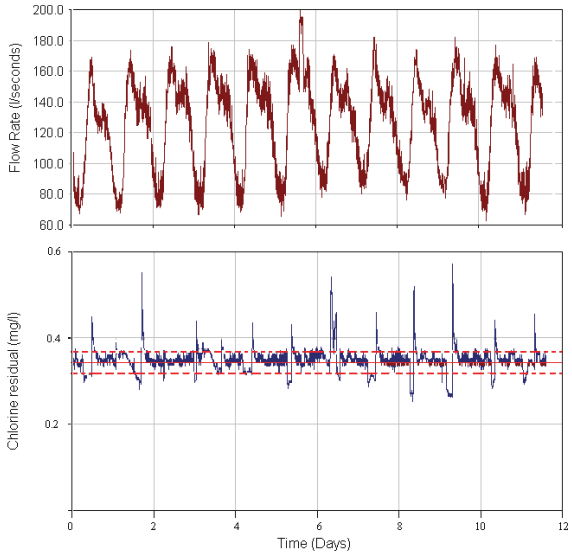

Fig. 3. Effect of time varying flow on the process variable (Chlorine residual).

The plot in figure 3 shows a clear link between changes in the water flow rate and variation in the Chlorine residual. Ideally, the Chlorine residual is supposed to remain within the band defined by the dashed lines for 99 % of the time for the system performance to be considered acceptable. Open loop step tests proved that the process time constant is also affected considerably by significant changes in the water flow rate. It is, therefore, obvious that in real applications, the practical approach would be to design a controller that will compensate for the inherent long dead times, and that will also be robust enough to the two major disturbances (i.e. Water flow rate changes, and incoming residual). For processes that are not time varying or where the variation is not that significant, PI controllers could produce what can be considered an acceptable performance. The more realistic scenario is the process where either one or sometimes all disturbances are significant, and that was the focus of this trial. The model in figure 2 was simulated. The process gain, time constant and dead time were all replaced with functions of the water flow rate that would make this an adaptive predictive controller. All the other gains are representative of the actual dosing and flow pacing constants. Figure 4 shows the closed loop step response of the simulated Smith predictor.

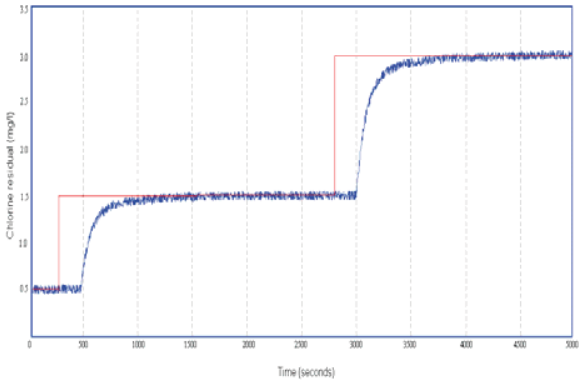

Fig. 4. Closed loop response of a simulated Smith predictor.

As mentioned earlier, the process parameters are flow dependent. A relatively low flow rate of 100 l/hr was chosen here to be able to simulate a challenging operational condition compared to a fast process. The above response shows that the controller performs well at set point tracking, and that accuracy and stability are maintained. The speed of response of the controller to the step changes is also very good considering the fact the dead time in this particular case was around 3 minutes. The same process model was simulated in closed loop using a standard PI controller that was also tuned using the same method that was used to tune the Smith predictor. It was noticed that at low flow rates, the dynamic response exhibits large un-damped oscillations as shown in figure 5.

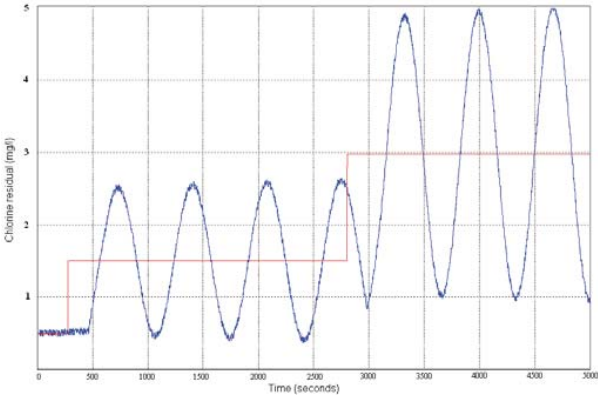

Fig. 5. Performance of a standard PI controller for a relatively long dead time process.

PI controllers are still being widely used in such processes. The only explanation as to why they are still being used is that in most cases the controller gain will be kept at a minimum value that is enough to allow the controller to track large process variable offsets, but at a very low speed of response. In a particular real time test on a live dosing rig, the response to a closed loop step test using a standard PI controller with a low gain took more than four hours to be completed due to the sluggish response of the controller.

5. IMPLEMENTATION AND TESTING

The water industry like most other process industries uses a combination of conventional analogue (4 – 20 mA) instruments and actuators with digital control PLC's, which nowadays have the resolution that allows them to control continuous processes. That said, PLC's still have their limitations when it comes to the implementation of advanced control methods as they seem to lack some important functionalities needed for continuous process control. It was also noticed with this particular application that offsets in the analogue modules interfacing between the PLC and the equipment (water flow meter, Chlorine analyser, and Chlorine dosing pump) can either exaggerate or dampen signals to and from the controller respectively. It is therefore important to obtain a process model that is a valid representation of the actual process so that the effect of the above mentioned offsets will be minimal; otherwise, those offsets will add to the uncertainties caused by the mismatch between the actual process and the process model and make the control system design process much more complicated.

The control algorithm was written in PLC ladder logic. Therefore, all continuous functions and the process model had to be written in that form. The dead time was then implemented using a data array that stores data in sequence at a frequency that is equal to the process sampling frequency, and the length of this array is equivalent to the predicted process dead time. To be able to test the Smith predictor for different flow rates, the control algorithm included functions to calculate the process parameters from online water flow rate measurements, and update the process model as well as the length of the delay array accordingly. There is also a tuning routine that uses the minimisation of the Integral of Absolute Error (IAE) tuning method to calculate the PI parameters (Kc and Ti). Many tuning methods have been suggested for Smith predictor applications, and many of them seem to have produced a robust performance [3, 5-8]. The following equations provide a good starting point for the minimum IAE method which is used to obtain the optimum PI parameters:

$$Kc = 0.984/Kp*(\tau/Td)^{0.986} \quad (2)$$

$$Ti = \tau/0.608*(Td/\tau)^{0.707} \quad (3)$$

Where Kc is the controller gain, Kp is the process gain, τ is the process time constant, Td is the process dead time, and Ti is the controller integration time. To make the controller self-tuning, these formulae were written in the control algorithm, and as part of the cyclic scan sequence, the PLC would calculate the process parameters based on the online flow rate measurement, then calculate the PI parameters as shown above and update them in the PI controller function block instantly. The following plot of real time data of closed loop step tests of the Smith predictor as explained above also shows the effect of sudden variation in the water flow rate on the process:

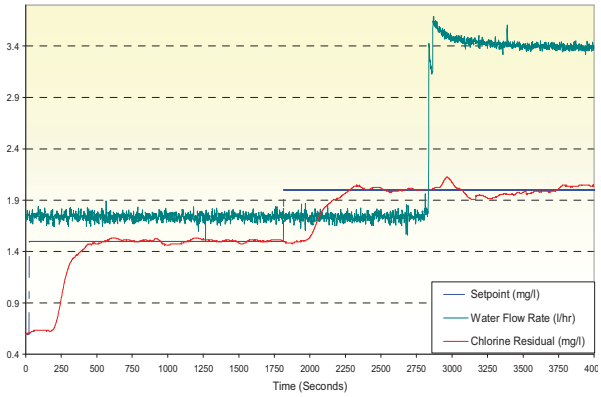

Fig. 6. Setpoint tracking performance of the Smith Predictor and its response to a major (Flow rate) disturbance.

The response achieved here conforms to the simulation results in terms of setpoint tracking, stability of the system, and the speed of its response. Also, the disturbance caused by the change in water flow rate did not have a significant effect on the process dynamics. The same test rig was used to test the same process under the same operating conditions using just a tuned PI controller in order to compare it to the performance of the Smith predictor, and the response is shown below.

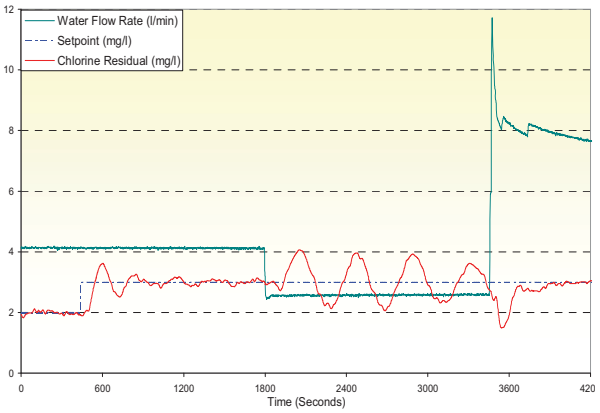

Fig. 7. Performance of a PI controller at various water flow rates.

The controller here was tuned well enough to produce an acceptable performance at a medium flow rate of 4.2 l/min, but when the flow was reduced to about 1.7 l/m, the controller became incapable of keeping the process variable at steady state until the flow was increased to a much high rate, where the controller slowly tracked the setpoint. Retuning the controller at this flow rate, would produce a faster response than the response shown, but at the low flow rate, the only option was to detune the controller (by keeping the controller gain as low as possible) so that it will respond to the step input, but at a relatively low speed of response, and hence not causing the oscillations seen in figure 7.

It is important to emphasise that without an accurate process model, the Smith predictor performance deteriorates. During this trial, initially the dead time was under estimated by around 20% and as a result the controller reacted earlier than required causing an overshoot in the Process variable of nearly 15%.

6. CONCLUSION

Simulation of PI controllers on FOPDT processes shows that the performance of the PI controller is dependent on the process dead time. In this trial the PI controller was found incapable of handling very long time delays regardless of the method used to tune it. The Smith predictor provides a reliable solution as long as the process model used is an accurate estimation of the actual process. In challenging process control applications where the process is time varying, adaptive Smith predictor configurations can be used effectively to overcome the uncertainty caused by the changes in process dynamics. Simulations and practical tests have shown that this method can be implemented successfully in water treatment processes.

MODEL PREDICTIVE CONTROL OF A CRUDE DISTILLATION UNIT AN INDUSTRIAL APPLICATION

Serdar Kemaloğlu Emre Özgen Kuzu
Dila Gökçe Özgur Çetin

Turkish Petroleum Refineries Corporation, Izmit 41780
Turkey

Abstract: This paper reviews the application of a model predictive controller algorithm to a crude oil unit in Izmit Refinery of Turkish Petroleum Refineries Corporation as a summary of nearly eight months of practical study. The controller is designed to control the crude heating via process flows followed by furnace heating and distillation column with product strippers. After a process overview, the fundamental control loop considerations are discussed. Steps of determining inferred qualities and step test response tests are outlined. The controller design considerations, constraint handling and economic variables are presented. Finally, a comparison of before and after commissioning in the kerosene quality and rate is tabulated as well as simulation results of the system response for different set point changes in the product qualities.

Keywords: Advanced process control, multivariable predictive control, crude distillation processes, model identification.

1. INTRODUCTION

Model predictive control (MPC) strategies have found a wide range of applications from refineries to food processing and become a standard control algorithm for process industries. In 1999 nearly five thousand applications were reported with an increase of about 80 % in the following years (Qin and Bagdwell, 2003). MPC algorithm utilizes an explicit process model to optimize an open loop performance objective to constraints over a future time horizon, based on current measured variables and the current and the future inputs (Rossitier, 2003).

Turkish Petroleum Refineries Corporation (TUPRAS) is the largest industrial enterprise in Turkey. TUPRAS controls all of Turkey's refining capacity with operating four refineries with a total annual process capacity of 28.1 million tons crude oil. TUPRAS Izmit Refinery is the biggest refinery of four with annual refining capacity of 11.0 million tons of crude oil.

After privatization in 2006, implementation of advanced process control (APC) applications were initiated to increase operational excellence with many other projects. In this paper, an APC application to one of the crude units in Izmit Refinery is presented. After the process overview, base layer control strategies developed to sustain healthy layer for APC studies are explained. The main elements of the controller, controlled, manipulated and disturbance variables are discussed. Following the methods for obtaining inferred qualities, response tests and dynamic modelling strategies are outlined. The dynamic models obtained during tests are used in the commercial MPC algorithm SMOCPro. The control strategies, economic concerns and commissioning issues are discussed in the Section 4. The results of the commissioned plant data is tabulated as well as simulation of the controller for different set point changes in product qualities.

It is desired to give an outline of an industrial MPC application, but also some practical issues on implementation details. Finally, Section 5 outlines the study.

2. PROCESS OVERVIEW AND BASE LAYER CONTROL STRATEGIES

Plant-5 is one of the three crude oil units in TUPRAS Izmit Refinery and its simplified flow diagram is depicted in Figure1.

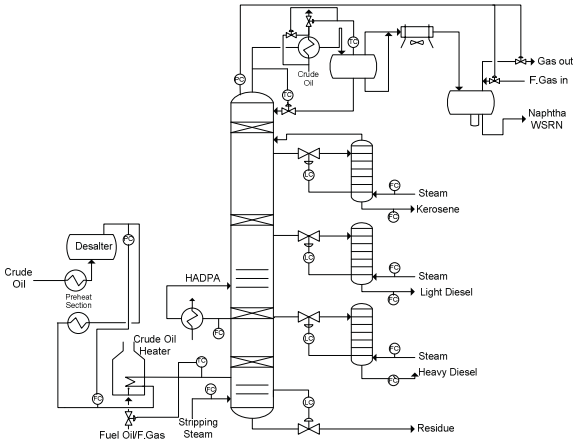

Fig. 1. CDU layout

The crude unit consists of mainly five operations. Advanced control strategies of steps 1,2 and 3 are in the scope of this paper:

1. Before and after desalter operation, the crude is heated via the hot streams available in the plant.
2. The crude is heated at a temperature around 320-350 ºC in two parallel furnaces.
3. The heated crude oil is distilled into products. Kerosene, light diesel and heavy diesel are drawn off after strippers. The bottom product, residue, is the feed to the vacuum unit.
4. The upstream of distillation column, a mixture of LPG, light straight run naphtha and heavy straight run naphtha, is fed to the naphtha splitter column where LPG and light naphtha are separated from heavy naphtha.
5. The liquid product of naphtha splitter upstream is separated into light naphtha and LPG in the debutanizer column.

Before implementation of advanced process control algorithm, a preliminary study comprising a base layer PID-based control is running successfully in normal operation. This study includes check of all instrumentation, checking for sticky valves, process feedback effects, process interactions, noisy measurements, retuning of PID controllers and possible configuration changes in the control strategies. In this scope, 56 regulatory PID controllers were retuned before starting testing.

Two base layer enhancements were carried out in distillation column control. There has been no bottom flow controller in the distillation column. Operators would manipulate the residue flow manually to keep level at operating ranges. This resulted continuous monitoring by operators and also discrete sudden changes in residue flow, which is the feed of vacuum unit as well. In the reviews, a new base layer of a level controller cascaded to the bottoms flow controller is implemented. With an appropriate tuning, the level is controlled while the bottoms flow does not vary significantly to create big disturbances to the vacuum unit.

The overhead drum temperature was manually controlled via bypassing from crude oil preheat heat exchangers at above 102 ºC to avoid corrosion problems. A new temperature controller has been implemented that closes the bypass valve in the line directing overheads product through the overheads cooler / crude preheat exchange.

3. CONTROLLER DESIGN

3.1 Variables

At the beginning of an APC project, the controller design requires selection of manipulated (MV), disturbance (DV) and controlled (CV) variables. These variables in this project:

- 28 manipulated variables are considered, 17 of which are for preheat and 11 for crude distillation column. These manipulated variables are feed flow controllers, furnace coil flow controllers and distillation column pressure, temperature and flow controllers.
- 3 disturbance variables are selected; amount of total feed and inlet flow rates to two furnaces.
- 19 controlled variables, where 4 variables are in preheat section and remaining in the crude distillation column.

Controlled variables for preheat section are desalter temperature and pressure and furnace outlet temperatures for the preheat section.

Some key variables are tabulated in Table 1 at the end of the paper. Distillation column controlled variables can be classified in three categories; inferred qualities, variables of economic importance and operational constraints.

The inferred qualities are the four main product qualities, heavy naphtha, light diesel and heavy diesel 95% distillation points and kerosene flash point. In order to control these qualities, inferential measurements have been developed. All the qualities have been inferred based on statistical regression of empirical data. The data was collected during a test period of two weeks, where manipulated variables and important column dynamics were changed one by one and held constant for two to three hours, while subsequent lab results were gathered. This data was used as a training period and inferential measurements were modelled using RQE Pro, software in the Process Control Technology Package (PCTP) of Shell Global Solutions International BV. Various combinations of process variables were regressed and good fits were achieved. Regular laboratory data of nearly eight months was also used to validate the model. The inferred qualities are mainly functions of pressure compensated temperatures. In some cases, vapour / liquid ratio below the draw-off tray of the product of which the quality was to be inferred. In the online application, the inferred qualities' equations' biases are updated with regular laboratory results. Before defining these qualities as a CV to the controller, several lab results were introduced to obtain a healthy estimation. These results correct any prediction error in the calculation that might arise in a local problem occurred during tests. Reducing the laboratory analysis amount after a certain period is another advantage of this method. Also in the online application, sudden change in bias may result in a change in the predicted quality, hence an aggressive MV output. To overcome this local disturbance, a filter time of thirty minutes to one hour has been applied to smoothen the update mechanism.

Operational constraints are usually the design specifications. Controlling column pressure valve opening prevents any loss of gas during operation. Reflux and heavy diesel pump around amount and top drum level as a CV sustains a safe operation. The level in the strippers is a major constraint where light diesel stripper level can be operated successfully to only a certain amount and is the main drawback of the light diesel amount.

Although they are not a part of the controller, reducing stripping steam amount and transferring the maximum heat from heavy diesel pump around are two economically beneficial CV's. The controller controls the stripping steam / feed ratio and heavy diesel inlet/outlet temperature difference multiplied by heavy diesel pump around amount at certain ranges.

3.2 Response Testing

During the commissioning of a predictive controller, testing and modelling efforts can take up to 90 % of the cost and time (Andersen and Kummel, 1992). Successful modelling engenders controller stability and performance on the predictive capability of the process model used. The most important element of a good modelling is the high quality clean data obtained form response testing. Also it should be noted that data analysis and model identification enhances process understanding and behaviour.

In the APC application in TUPRAS Izmit Refinery crude distillation unit, the response tests were carried out for three weeks in two shifts. For each of the 28 manipulated variables, tests were carried out separately in sequence, groups of six to eight steps were made in each. The sequence was repeated afterwards, obtaining a test data of sixteen to twenty moves for each variable. Repeating sequence allows preventing unmeasured disturbances that might happen in one of the sequences. The step sizes were defined in a way to see clear effects in the other variables, and steps were held for periods of one to one and a half of the settling time. The step sizes were changed sometimes to identify the presence of nonlinearities.

During step testing, it is very important to carefully observe the steps. The correlation of the independent variables, possible operator interventions and insufficient move sizes may result in poor data, hence poor modelling. Good signal-to-noise ratio enables that the effects of test changes in inputs could be clearly visible in process outputs. To overcome possible operator interventions, trainings were carried out before start of tests. Also changes in the regulatory configuration, PID tunings and possible controller saturations must be prevented during the test period.

3.3 Dynamic Modelling

Majority of industrial MPC applications use linear empirical models (Qin and Bagdwell, 2003). While analyzing the plant data, such an empirical dynamic process-modelling tool, AIDAPro –another PCTP software- was used. The results of step tests were analyzed and mathematically fit to obtain predictive process models.

In dynamic modelling, the interactions of all variables are taken into account, hence the effect of intermediate variables and disturbances can be tolerated in identification. Basically, multivariable higher order parametric models were created for each variable. These models are then approximated and reduced to a parametric model on individual relationship basis of two variables. Based on the data analyzed, the process knowledge and step test experience dynamic response of the variables are determined. Numerical representation of these dynamic response curves can be of any degree from first order zero gain to second order beta.

During modelling 31(28 manipulated and 3 disturbance variables) X 19 response curves were fitted. Of these 589 possible independent / dependent variable response curves, 53 responses are identified for the controller design. The other responses are either zero gain or insignificant.

4. CONTROLLER COMISSIONING

4.1 Controller Design

The dynamic models from observed plant data were used to design the controller. Shell Multivariable Optimizing Controller, SMOCPro is used to implement predictive controller in TUPRAS Izmit Refinery Crude Unit. SMOCPro, a part of the Process Control Technology Package (PCTP) of Shell Global Solutions International BV, and its algorithm was summarized by Qin and Bagdwell (2003) :

- An explicit disturbance model described the effect of unmeasured disturbances; the constant output disturbance was simply a special case,
- A Kalman filter was used to estimate the plant states and unmeasured disturbances from output measurements,
- A distinction was introduced between controlled variables appearing in the control objective and feedback variables that were used for state estimation
- Input and output constraints were enforced via a quadratic program formulation

As well as most advanced process control algorithms, SMOC algorithm also follows a reference trajectory by the future outputs on the prediction horizon and penalizes the control effort on the control horizon. General objective function of the controller can be written as

$$\min_{\Delta u(n)\ldots\Delta u(n+C-1)} \sum_{i=1}^{P} \left\| \hat{y}(n+i) - r(n+i) \right\|^2 w_1 + \sum_{j=1}^{C} \left\| \Delta u(n+i-1) \right\|^2 w_2 \quad (1)$$

in which 'u' represents inputs, 'y' is used to define outputs and the superscript ^ denotes the predicted values. Δu is the input variation and r is the reference trajectory of the outputs. In this optimization problem, the first term is used to minimize the error resulting from the difference between predicted outputs and reference trajectory during prediction horizon, P. The second term is the difference of control actions taken at each time step during control horizon, C. Weighting matrices w_1 and w_2 are positive definite matrices, with different magnitudes for all MV's and CV's. These matrices were used in controller tuning. The optimal input sequence's only first input is implemented to the system and the calculations are re-executed in the next sampling time.

The controller was tuned in offline program with simulations. While simulating both control considerations and economic variables, discussed in the next part, were considered.

Increasing w1, CV weights, increases the priority in decreasing the deviation in set point and reference trajectory, in other words makes the control tighter. Low w1 values allow bigger trade-offs. Increasing w2, MV weights, prioritizes minimum input variation and results in smoother moves.

As a base decision, the weights for column pressure, column top temperature and furnace outlet temperature controllers were given higher values than other MV's. The controller was expected to move these MV's smoother. CV weights for kerosene flash point, heavy diesel 95 % distillation and level of light diesel stripper were set higher than other weights to sustain tighter control. The weight tunings were completed by evaluating simulations.

4.2 Economic Variables

A key factor of SMOCPro is the economic function. Economic function is a bilinear function that the controller minimises. As long as the control objectives are met, the controller drives the defined economic function to minimum. Economic function in crude distillation unit consists of:

- Minimizing column top temperature, column pressure and stripping steam ratio to the feed
- Maximizing heavy diesel pump around duty, product draws to stripper level constraints and furnace heater duties. Maximizing the amount of heavy diesel by letting heavier cuts into heavy diesel and leaning to high limit. Maximizing the amount of kerosene by letting heavy naphtha into kerosene and approaching to low limit.

The constants of elements of economic function can be changed based on the plant needs or operational conditions.

4.3 Commissioning and Online Tuning

The controller was commissioned over a three- week period. The controller tunings determined in the offline studies were rechecked to prevent any model-process mismatch. After sustaining successful control, economic variables were commissioned by extending / restricting the limits. Operator trainings were also a major part of the commissioning period. All operators were trained to understand the basics of controller's function and philosophy.

4.4 Results

Over a two months period of controller running, the overall throughput of desired products increased significantly. Figure 2 shows the decrease in the naphtha yield, whole straight run naphtha (WSRN), and increase in the kerosene yield for a five weeks period of pre-commissioning and four weeks period of post-commissioning of the controller. The crude oil density was assumed to be constant, 32.46 and 32.43 API for pre and post-commissioning respectively. As seen from the figure, 11 % increase in the kerosene yield was achieved as a result of decrease in naphtha yield.

The change in the naphtha yield was also observed in the kerosene flash point. The naphtha in the kerosene product decrease the flash point of kerosene and by the high weight in the kerosene quality, the quality approaches to low limit. This approach shown in Figure 3 resulted in very significant economic benefits.

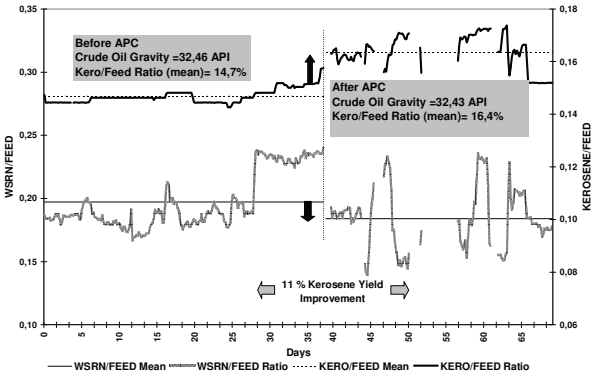

Fig. 2. Change in the naphtha yield before and after commissioning.

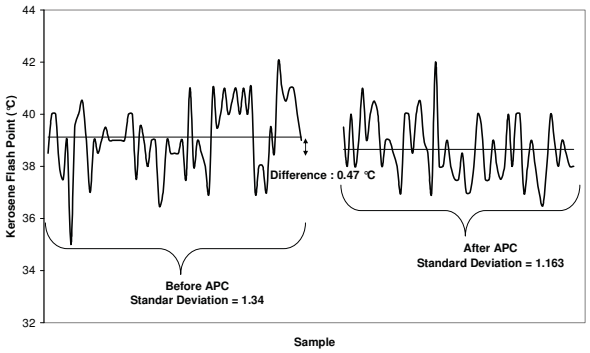

Fig. 3. Change in kerosene flash point before and after commissioning.

To illustrate the controller's performance on different situations, a simulation was studied using real plant data and specifications. When analyzing the results, a few points in controller tuning should be noted. Highest priority was assigned to kerosene and heavy diesel. Controller objective was to keep these qualities to low limit for kerosene and high limit for heavy diesel. On the other hand light diesel was assigned a low priority that its product rate was manipulated mainly in control of heavy diesel quality.

Figure 4 shows the changes in the product quality set points for kerosene flash point, heavy diesel, heavy naphtha and light diesel 95 % distillation points and their responses to these changes. The changes in critical column dynamics were reported in Figure 5. Figure 6 illustrates the product rate changes occurred during these set point changes.

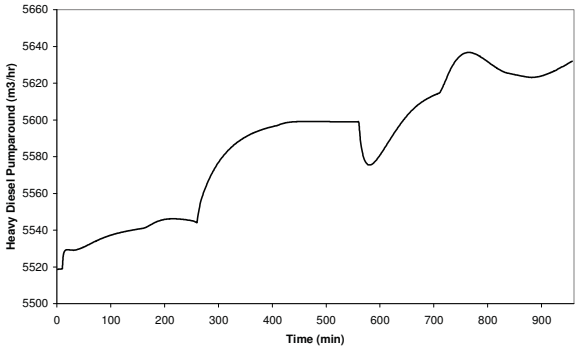

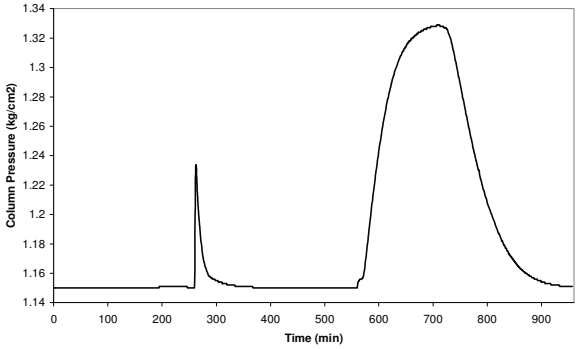

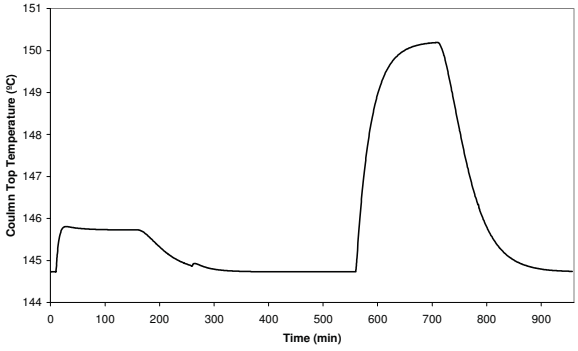

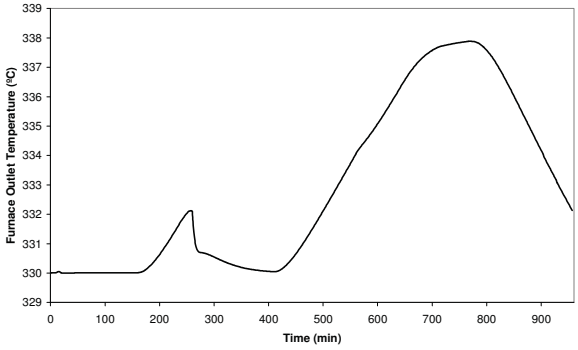

Fig. 5. Controller results in the distillation column critical controllers for the changes in the product quality limits.

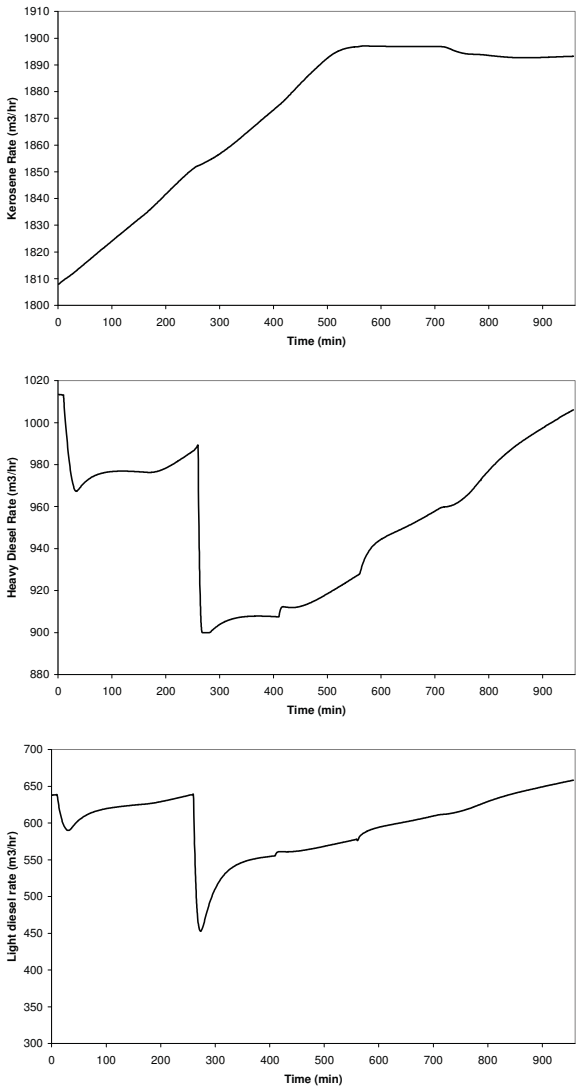

Fig. 6. Controller results in the product flow rates for the changes in the product quality limits.

5. CONCLUSIONS

In this paper, an industrial application of a model predictive controller algorithm has been presented. The controller has been designed for predictive control of crude oil preheat and distillation column of a crude oil unit in Izmit Refinery of Turkish Petroleum Refineries Corporation. A base layer control study has been performed to observe any nonconformity in the present control scheme. Tests have been carried out to obtain a mathematical model of the inferred product qualities. Dynamic step tests have been done for determined 28 manipulated variables. Dynamic modelling showed 53 responses to validate the controller.

Priorities for controlled variables and desired variation limits of manipulated variables were determined and the controller performance was tested using simulations in SMOCPro. Obtained model was commissioned for a three week period. It has been observed that the product throughputs and its economic benefit have been increased significantly.

Abstract: In the present work a novel inferential control strategy cascaded with a nonlinear profile position controller is employed to control the top and bottom product compositions of a simulated depropanizer column. The inferential model for estimating product compositions is developed using the wave propagation model, and the composition profile position of both rectifying and stripping section is calculated using one temperature measurement from the respective section of the column. It is found that the estimation of the end product compositions using proposed technique may lead to an offset. The accuracy of the proposed inferential model can be further improved by providing an intermittent feedback of composition measurement in the form of an integral action. The wave propagation model of the depropanizer column is used in the Generic Model Control (GMC) architecture to design the profile position controllers.

Keywords: distillation column, nonlinear control, inferential control, profile position observer.

1. INTRODUCTION

A depropanizer column is used to separate propane from a mixture of components ranging from ethane to hexane. It is important to maintain the column product qualities on specification, to limit the negative effects of disturbances and upsets, and to reduce the switching time from one operating condition to another. An effective control strategy is therefore needed to control the depropanizer column. In this work, an inferential model based generic model control strategy is used which can handle disturbances and input uncertainties.

An inferential model is often used in process control when a measurement of the true variable being controlled is not available in real time. Reasons for the lack of real-time measurement include cost, reliability, and long analysis times or long dead times for sensors located far downstream. In these cases, an inferential model provides an estimate of the process variable, which can be used in the design of a controller to provide approximate regulation of the true variable. Tray temperatures are commonly used inferential measurements for product compositions. The temperature control is based on the assumption that the product composition can satisfy its specification when an appropriate tray temperature is kept constant at setpoint. In ideal situation, for a binary distillation column at constant pressure, the temperature at an end of the column is an indicator of the corresponding product composition. However, in case of a multi-component distillation column, tray temperatures do not uniquely determine the product composition. As a result, for these cases it is essential that an on-line analyzer or, at least, periodic laboratory analysis be used to adjust the tray temperature set point to the proper level.

In a Brosilow estimator [Weber and Browsilow (1972), Joseph and Brosilow (1978)] temperatures and flow rates were used for estimating unmeasured disturbances and then the derived disturbance values were used to estimate the product compositions. This estimator is based on a linearized process model. Mejdell and Skogestad (1991a, b) found that the steady state Brosilow estimator was very sensitive to modeling error for the ill-conditioned plant. In the last few decades, the development of composition estimators using partial least squares (PLS) regression have been proposed [Kresta et al. (1994)]. Furthermore, Mejdell and Skogestad dealt mainly with binary distillation columns. For a multicomponent column, tray temperatures do not correspond exactly to the product compositions. Mejdell and Skogestad have shown that the performance of the steady state PLS model for a multicomponent column is worse than that for a binary column. From the results, Mejdell and Skogestad seem to indicate the necessity of a dynamic regression estimator, which was implemented by Kano et al. (2000) in the form of dynamic partial least squares regression.

Gilles et al. (1980) reported the presence of a temperature front within a small area of the column in their extensive experimental study and showed that the locus of the temperature front is related to the product compositions. Gilles and Retzbach (1983) and Marquardt (1988, 1989) characterized the nonlinear behavior of distillation columns by the propagation of concentration profile (C-profile) and temperature profile (T-profile) in the column sections. Lang and Gilles (1990) presented an estimation technique that can be applied to complex processes in chemical industries. Adapting well advanced theories of fixed bed adsorption,

Hwang (1991) proposed a nonlinear wave theory for distillation columns which views the movement of composition and temperature profiles as nonlinear waves. They reported that these waves tend to sharpen for most situations and become constant pattern waves. Han and Park (1993) proposed a model based composition controller design incorporating Hwang's nonlinear wave model into the generic model control (GMC) framework of Lee and Sullivan (1988). To overcome the difficulty of composition measurements, Shin et al. (2000) proposed a C-profile position observer based on the temperature measurements. However, their proposed profile position estimation algorithm is applicable only for a binary system. Recently Gupta et al. (2009) has extended the application of profile position control to a debutanizer column.

In this work distillate and bottom propane compositions of a simulated depropanizer column are controlled by using composition to C-profile position cascaded controllers (Figure 1). The compositions are inferred from the C-profile position observer using one temperature measurement from each section (rectifying/ stripping). The objective of this article is to present a new approach to infer and control product compositions using the C-profile position of a depropanizer column, which uses one temperature measurement from the respective (rectifying/stripping) section.

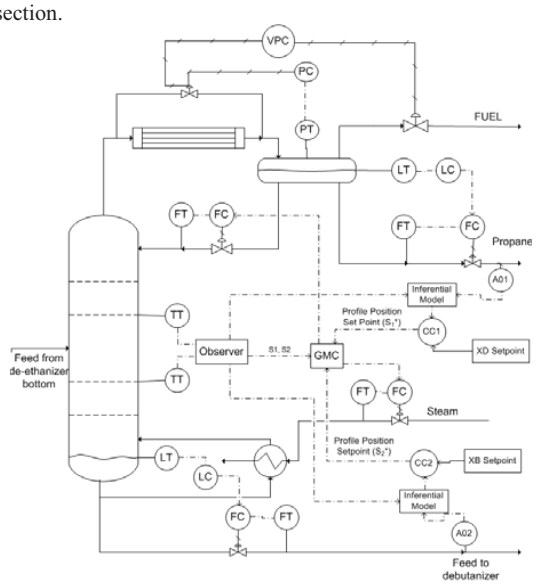

Figure 1: Depropanizer column with control strategy

2. PROCESS DESCRIPTION AND CONTROL STRATEGY

The depropanizer column of a gas recovery unit is simulated in this work [Huang and Riggs (2002)]. The depropanizer column consists of 40 trays, and feed, a mixture of C_2-C_6 components, is fed to the column at 22nd tray (counted from the bottom). The column has a partial condenser and the pressure is controlled via a hot vapor bypass around the overhead condenser. The distillate accumulator level is controlled by adjusting propane product flow rate. In a depropanizer column, the control objective should be to remove impurities (C_4+ components) in the distillate and maintain minimum possible propane loss in the bottom product to maximize the yield of propane in the distillate. This is a separate optimal control problem and is not in the scope of this work. Here the control is achieved by controlling the propane compositions in the distillate and bottom product to their already known optimum targets. The control scheme is shown in Figure 1 and the nominal values required for the distillation column simulation is presented in Table 1. The composition controllers (CC1 & CC2) are PI controllers which generate the profile position setpoints by using the inferred values of propane composition from the inferential model.

reflux rate (k mol/sec)	0.30		
reboiler duty (k joule/sec)	5248.8		
condenser duty (k joule/sec)	-4881.7

Table 1: Operating variables for depropanizer column

3. NONLINEAR WAVE MODEL

The dynamic behavior of distillation columns is characterized by the propagation of concentration or temperature profile in the column sections. Numerical simulation results of this typical dynamic behavior for the depropanizer column presented in figure 2 for 10% heavier and 10% lighter feed (Table 2). Propane composition and temperature profile moves up or down to the column ends as a result of increase or decrease of heavier components in the feed. It is also evident from the figure that both the waves ultimately tend to become steep and constant pattern as they move up or down the column.

The travel of such a constant-pattern self-sharpening wave can be characterized by the 'shock wave' velocity [Hwang (1991)] tracking the propagation of specific value of concentration. This wave velocity is derived from the material balance across the wave:

$$u_{\Delta} \equiv \left(\frac{\partial \sigma}{\partial \tau}\right)_{\Delta} = \frac{V}{F} \cdot \frac{\Delta y / \Delta x - L/V}{1 + r\left(\Delta y / \Delta x\right)} \qquad (1)$$

where r is vapor to liquid holdup ratio, τ is normalized time ($\tau = tF / NM$), and σ is normalized distance from bottom of the column ($\sigma = k / N$). Assuming the liquid flow is so slow that local equilibrium is attained, y in equation (1) can be

substituted with the vapor liquid equilibrium relation. The concentration and temperature waves will travel to either one of the column ends unless the balance of convective transports is carefully maintained to have a zero shock wave velocity with the compositions and flow rates of all streams entering the column sections including feed, reflux, and reboiler vapor flow. Therefore, the behavior of the column is severely nonlinear and sensitive since even a small upset of the balanced condition will lead to a large shift of the composition/temperature profile, giving dramatic changes in the product purity. By analyzing the profile positions for each section and the compositions at the column ends (distillate/bottoms) a model equation can be obtained to correlate the profile position with the compositions from the steady state data for the profile position and the top/bottom compositions collected from the steady state plant model simulation.

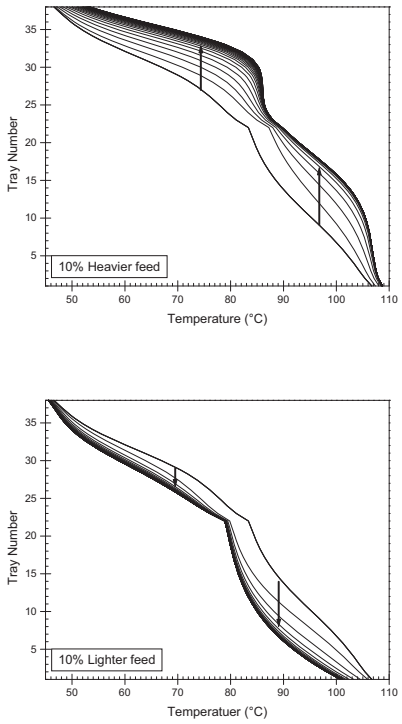

Figure 2: Dynamic profiles of the depropanizer column to a step disturbance (10% heavier feed and 10% lighter feed) of feed composition in open loop (each curve is separated by 5 minutes).

Feed composition

Composition (mol %)	normal	10% lighter	10% heavier	20% heavier	30% heavier

4. DEPROPANIZER CONTROLLER DESIGN

4.1. Profile position controller

The profile position controller is a nonlinear model-based controller, and is designed by embedding a nonlinear wave model directly into the generic model control (GMC) control framework.

The GMC equation can be written as the following in the case that state vector is a composition profile position S.

$$\frac{dS}{dt} = K_1\left(S^* - S\right) + K_2 \int_0^t \left(S^* - S\right) dt' \tag{2}$$

where, S and S^* are the profile position and its setpoint respectively; dS/dt is the propagation rate of profile. S is expressed in terms of the normalized distance from the bottom of the column ($S = 0$ at the bottom; $S = 1$ at the top). The propagation rate can be expressed from the nonlinear wave model as follows:

$$\frac{dS}{dt} = u = \frac{V}{F}\frac{\Delta y/\Delta x - L/V}{1 + r\left(\Delta y/\Delta x\right)} \tag{3}$$

Distillation columns, in general, have two sections: one is the rectifying section and other is the stripping section. Combining equations (2) and (3) gives one equation for each section as follows:

$$\frac{V}{F}\frac{\Delta y/\Delta x - L/V}{1 + r\left(\Delta y/\Delta x\right)} - K_{11}\left(S_1^* - S_1\right) - K_{12}\int_0^t \left(S_1^* - S_1\right) dt' = 0 \tag{4}$$

$$\frac{\bar{V}}{F}\frac{\Delta \bar{y}/\Delta \bar{x} - \bar{L}/\bar{V}}{1 + r\left(\Delta \bar{y}/\Delta \bar{x}\right)} - K_{21}\left(S_2^* - S_2\right) - K_{22}\int_0^t \left(S_2^* - S_2\right) dt' = 0 \tag{5}$$

where, subscripts 1 and 2 represent rectifying section and stripping section respectively, and L and V are the liquid and vapor flow rates respectively in the rectifying section and $\bar{L}$ and $\bar{V}$ in the stripping section. The profile position and the slope of the equilibrium curve at the representative concentration can be estimated by the profile position observer. Mass balance around the feed tray gives

$$\bar{L} = L + qF \tag{6}$$

$$V = \bar{V} + (1 - q)F \tag{7}$$

where, q is the liquid mole fraction of the feed. Knowing the feed conditions L, V, $\bar{L}$ and $\bar{V}$ is calculated from equations (4)-(7).

4.2. Online estimation of the profile position

The success of the inferential controller is mainly dependent on the ability to estimate the profile positions for both rectifying and stripping sections. The profile position in each section can be regarded as the location of the constant pattern wave representing a single point corresponding to a representative temperature. The profile position of the constant pattern wave can be determined by tracking the representative temperature instead of the entire wave.

In this case, the profile position observer is designed using the nonlinear wave model for the depropanaizer with an

additional feedback of weighted output error of temperature(s) feedback.

$$\dot{S} = \frac{dS}{dt} = \frac{V}{F}\frac{\Delta y/\Delta x - L/V}{1 + r\left(\Delta y/\Delta x\right)} + \sum_{i=l}^{m} k_1\left(T_i\right)\left(T_i - \hat{T}_i\right) \quad (8)$$

$$\frac{\Delta y}{\Delta x} = \frac{\dot{S} + L/F}{V/F - r\dot{S}} \quad (9)$$

$$\hat{T}_i = k_2\left(S_i - S\right) + T_s \quad (10)$$

$$k_1\left(T_i\right) = k_0 \exp\left[-b\left(T_i - T_s\right)^2\right] \quad (11)$$

where, i is the measurement tray number and l and m are the number of first measurement tray and the number of last measurement tray in a column section respectively. For $\Delta y/\Delta x$ and T relationship the steady state plant data can be used which will be associated with the tray efficiencies also. The tray temperature measurement location (26th and 18th tray) in each section is selected based on the inflection points in the temperature waves. The above equations are solved with initial estimates of the profile position S and representative slope $\Delta y/\Delta x$ to obtain the profile position. The sample time for the composition controller has been taken as 2 seconds while that of the profile position controller was 0.2 seconds.

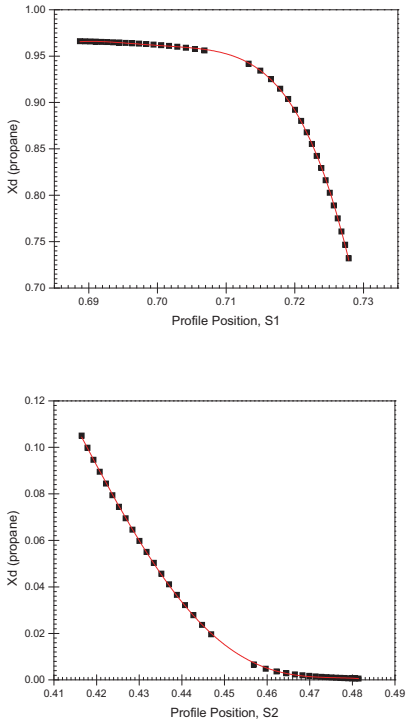

Figure 3: Graphical representation of steady state data set, of rectifying section profile position vs X_D (propane), and stripping section profile position vs X_B (propane).

5. INFERENTIAL CONTROL

In earlier work, the column end compositions were estimated using more than one measurement in the form of temperature, flow rate, and heat duty etc. In the proposed estimator one temperature measurement from each section (rectifying/ stripping) is used to find out the distillate and bottom composition of propane in the depropanizer.

5.1. Model identification using profile position

In this section we are proposing a model based inferential control using the profile position estimation. By analyzing the profile positions for each section and the compositions at the column ends (distillate/bottoms) a model equation can be obtained to correlate the profile position with the compositions. The steady state data for the profile position and the top/bottom compositions collected from the steady state plant model. Figure 3 shows that the data obtained from the plant model can be expressed by a 3rd order polynomial.

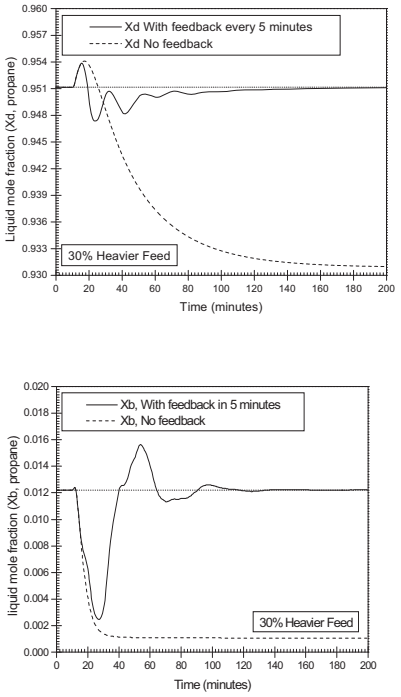

Figure 4: Closed loop transient response of the distillate composition (propane) and bottoms composition (propane) for 30% heavier feed using inferential control, with feedback /no feedback to the inferential composition estimator for the depropanizer column

Figure 4 shows that the proposed model is fair enough to control the end compositions of the depropanizer column. However, the current structure of the model leads to an offset with the final setpoint compositions.

5.2. Model identification using profile position with feedback

Our study leads that the composition measurements are required for the tight control of the end compositions of the depropanizer column. To remove the offset, an integral action

as a feedback to the estimator is proposed. The final form of the composition estimator can be expressed as follows:

$$x^{est.} = x^{\text{model}} + k' \int \left(x^{\text{last measurement}} - x^{\text{model}} \right) dt \quad (8)$$

where, k' is a tuning parameter. Figure 4 shows that the proposed model with feedback is able to control the end compositions of the column without any offset. For the depropanizer column value of tuning parameter k' is tuned at 1 and 0.1 for rectifying section and stripping section respectively, and a lag of 5 minutes allowed for the composition measurement.

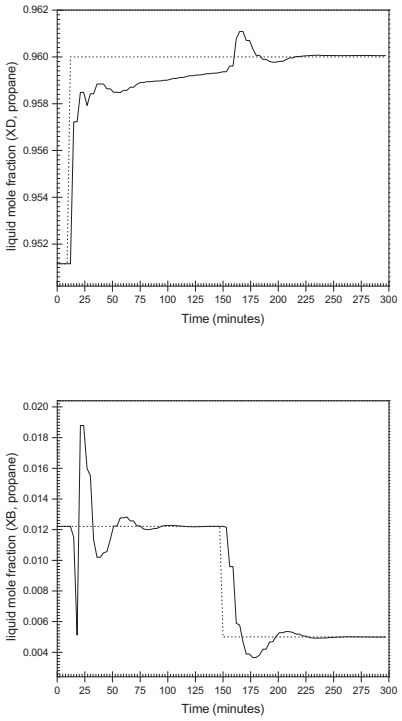

Figure 5: Closed loop transient response for the distillate and bottoms composition (propane) for setpoint change in X_D (propane) of 0.009 (0.951 to 0.96) at 10 minutes followed by a setpoint change in X_B (propane) of 0.007 (0.012 to 0.005) at 150 minutes, with feedback to the inferential composition estimator

6. RESULTS AND DISCUSSION

The depropanizer column with all control loops is simulated to verify the proposed control strategy.

6.1. Effect of composition setpoints change

Two concurrent setpoint changes are implemented to the top and bottom composition controllers. Closed loop transient response for the distillate and bottoms composition (propane) for a setpoint change in X_D (propane) of 0.009 mole fraction (0.95 to 0.96) at 10 minutes followed by a setpoint change in X_B (propane) of 0.007 mole fraction (0.012 to 0.005) at 150 minutes is shown in Figure 5. Increasing the propane purity in the distillate caused an immediate loss in propane content in the bottom causing a shift in the profile position. To maintain the propane composition in the bottom product the GMC controller has to put back the profile position in place which causes a sluggish response in the top composition response after the initial jump. When the bottom composition setpoint is also changed, both the controllers acted speedily because the changes are in favored direction from the viewpoint of the process dynamics.

6.2. Effect of noise and input uncertainty

To examine the robustness aspects of the controller about input uncertainty and temperature measurement noise, a simulation experiment is conducted on the depropanizer controlled by the proposed control strategy. During the simulation experiment following setpoint changes and disturbances are given to the system:

Setpoint change in X_D (propane) at 10 minutes (from 0.95 to 0.96).

Setpoint change in X_B (propane) at 150 minutes (from 0.012 to 0.01).

Step disturbance in the feed composition at 300 minutes (20% heavier feed, Table 2).

The following uncertainties have been taken into account during the simulation experiment:

Random disturbance in the feed flowrate (±5%)

Random disturbance in the reboiler heat duty (±10%) and reflux rate (±10%)

Temperature measurement noise (±0.5 °C)

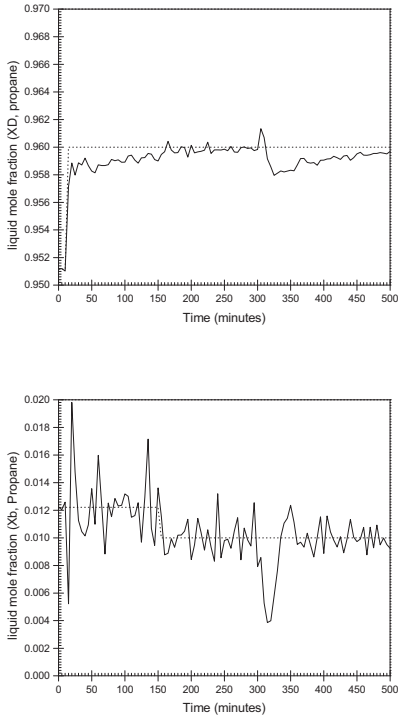

Figure 6: Effect of noise and input uncertainty: closed loop transient response in X_D (propane) and X_B (propane)

The distillate and bottom propane composition responses are shown in Figure 6. In spite of the severe input disturbances and measurement noise, the proposed controller is able to control the product propane compositions with reasonable speed of response and accuracy.

7. CONCLUSIONS

This study has shown a method of developing an inferential model for process control of depropanizer column using the observed profile position. A nonlinear profile position observer has also been developed to estimate the profile position of the column section with sufficient accuracy using temperature measurement. The profile position has been shown to be a powerful approach to building such models and uses the existing available measurements in the depropanizer. However, steady state plant data is needed for design of such models which may be collected while the process is operating under a feedback structure. Under a process/model mismatch, cascaded inferred composition to nonlinear profile position controller performed adequately well in controlling the depropanizer column. It will be interesting to compare the performance of the proposed controller with other nonlinear controller using input-output linearization controller or nonlinear model predictive controller which are much more computationally intensive than the proposed controller.

Abstract: The most competitive environment generated the need of process performance optimization. Performance optimization means produce the same amount of product, more effectively and spending less money. On the alumina market, that's fundamental in this economy scenario. Robust Multivariable Predictive Control Technology becomes one of the main tools to optimize this class of plants. This paper will discuss the application and benefits of this technology to alumina digestion units, implemented in 5 interconnected digesters. This digestion interconnection is a whole digestion train, and the plant has 5 of those. The APC philosophy is based on process variability reduction, and consequently operations optimization, against plant constraints. Since alumina – caustic ratio (A/C) is the key plant variable, it has a fundamental role in this variability reduction. The main challenge in this project was to coordinate the use of 5 bauxite grinders and 2 more grinder bauxite flows to the 5 digesters. The implementation was made in 3 phases and the project length was approximately 18 months, generating more than 1.00% increase in overall production, rather than A/C variability reduction.

1. INTRODUCTION

Significant economic savings can be generated to alumina plants, through the utilization of new control technologies that uses the existing infrastructure and require a reduced support team. The global market and supplier consolidation created a more competitive environment, which drives the need of production and performance optimization. The multivariable predictive control becomes one of the main tools in this scenario. This paper will discuss the application and benefits of this technology to the alumina digestion units.

The challenge to any alumina refinery is to minimize the cost of production per tonne of alumina, consistently with safety and environmental considerations. It is translated into alumina production maximization (plant flow and yield) and energy costs per tonne of alumina minimization.

In this scenario, the digestion process is the one that has the biggest potential to the robust multivariable predictive control technology (RMPCT) implementation. Rather than this, the digestion is considered by most of refineries as a key-unit to the production and also is the one that offers the best data for an APC modelling.

1.1 Process Description

The process for obtaining alumina from bauxite ore was developed and patented by Karl Josef Bayer in 1888. Typically, depending on the quality of the ore, between 1.9 and 3.6 tonnes of bauxite are required to produce 1 tonne of alumina.. Bayer process is cyclical and involves many unit operations, like digestion, solid – liquid separation and crystallization.

Overall, bauxite ore is digested in caustic solution concentrate in temperatures ranging from 145 to 270°C, depending on the nature of the ore. Under these conditions, most mineral species that contains aluminum is dissolved, forming sodium aluminate, soluble, as shown in equations (1) and (2).

$$Al(OH)_3 + NaOH \rightarrow NaAlO_2 + 2H_2O \quad (1)$$

$$AlO(OH) + NaOH \rightarrow NaAlO_2 + H_2O \quad (2)$$

The portion of the ore that is insoluble in caustic solution after digestion (red mud) is removed by sedimentation and filtration process. The pregnant liquor in alumina is send to the precipitation, which is almost pure crystals of $Al(OH)_3$. The hydrate precipitate is removed, washed and sorted. Alumina is then obtained by their calcination.

1.2 RMPCT (Robust Multivariable Predictive Control Technology)

RMPCT technology represents an advance of the traditional MPC technologies. Like the others, this technology models the process, calculate the necessary predictions and use multivariable control movements in order to: optimize the process, maintain the variables inside operational limits and respect the process and plant constraints. The performance gain and robustness is due to a feature called "range control algorithm" (RCA), which makes that the disturbances and prediction errors inherent to the process are considered in the future movement plan. Figure 1 sketches how the RCA technology works.

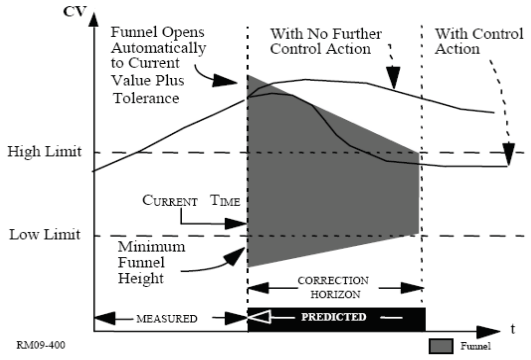

Figure 1 - RCA Technique Controlling a CV Inside Limits

The correction horizon concept is that CV errors are reduced to zero at the correction horizon in the future. Prior to the correction horizon, the controller is free to determine any trajectory for the CV as long as the CV is brought within limits or to setpoint at the correction horizon. Because no trajectory is imposed on the controller, the controller has the freedom to determine a trajectory that requires minimum MV movement and is least sensitive to model error.

However, the correction horizon by itself does not say anything about what happens to the CV prior to the horizon. It is important that the controller does not transiently move a CV farther outside a limit while correcting other CV errors, even though all CVs are brought to zero error by their correction horizons. Limit funnels are used to prevent the controller from introducing transient errors prior to the correction horizons, by defining constraints on the CVs that are imposed at intervals from the current interval out to the horizon.

These features drives the application to deal smoother and more efficiently with model mismatches (gain inversion, colinearities, bigger or smaller gains than the real, dynamic errors). Rather than this, the tuning in this technology is based on the controlled variables and not in the manipulated variables.

2. APPLICATION OF RMPCT IN ALUNORTE DIGESTION UNIT

2.1 Digestion Process Description

The digestion unit is designed to extraction alumina from bauxite using caustic solution in high temperature and remove dissolved silica from the liquor leaving the digesters to ensure product hydrate of the desired quality.

The alumina extraction is carried out in a train consisting of five vertical digesters arranged in series. The first step is to dissolve a most part of alumina in ore mixing slurry bauxite and heater spent liquor, in small digesters, equipped with agitators. The large digesters, without agitators, in series are to keep the residence time to reduce the silica dissolved by desilication reaction to a tolerable level.

The five vertical digesters are sized to provide a total of 60 minutes nominal retention time. Varying the liquor outlet temperature from the second live steam heater controls the digestion temperature. In occasion when one digester is taken out of operation the temperature is increased approx 1°C to compensate.

2.2 General Control Strategies

The Advanced control strategies of the Bayer plant are used to control blow off ratio, caustic concentration and to keep productivity and quality.

Alumina refineries generally operates with advanced A/C ratio control systems, involving feed forward with feedback trim and utilizing on-line measurement of liquor properties, such as electrical conductivity and density.

In 2006, ALUNORTE concluded the project of expansion 2 with five lines, in operate, with total liquor flow of 5610 m3/hr and installed capacity of 4.3 Mt/year.
The project to implement RMPCT control is divided in three phases:

- Phase I : Implementation of control on digestion 3.
- Phase II : Implementation of control on digestions 1 and 2.
- Phase III: Implementation of control on digestions 4 and 5.

2.3 Controller Objectives

The advanced control objectives for the digestion section are described below:

- Control A/C ratio to operator specified target
- Maximize productivity (bauxite and liquor flows), subject to process constraints
- Provide safe and stable operation
- Protect the unit when possible from defined, measurable constraints such as hydraulic, mechanical and environmental constraints.

2.4 Application Methodology

The RMPCT implementation consisted on the following steps:
Data and information gathering → Pre-Step Test → Step Test → Mathematical Modeling → Installation and sustaining

The implementation methodology is detailed bellow:

- Collection of: historical data, operation screens, process flow diagrams, engineers and operators information by interviews;
- Instrumentation review, control strategy setup and related loops tuning;
- After the analysis of all data, a preliminary controller design matrix is defined and discussed. This matrix will drive the initial plant tests (Pre-Step test);
- Prior to starting a test, the process and control system must be brought to a suitable starting condition, and allowed to settle if any changes were made. This will involve ensuring that the process is away from limits or "wind-up" conditions, and making sure that all control loops are in the correct modes.
- Pre-Step Testing is necessary to determine the steady state gain and settling times to be able to conduct precise Step Testing. After analyze of the collected data, final decisions of controller structure and step size will be issued in a report that acts as the basis for the formal step testing
- After the Pre-Step test, the Step Test is performed, applying steps to the considered manipulated variables. The steps are applied with variable time and amount, in order to indentify the actual interactions that will build the definitive multivariable control matrix.
- Using the data gathered on the Step Test, the models are constructed and the RMPCT is built. The matrix is validated, analyzing the predictions and controller offline simulation.
- After the matrix and control construction, the software connections with DCS are configured and an initial software tuning is performed.

2.5 Basic Controller Structure

The main manipulated variables are:
- Bauxite slurry flow
- Liquor flow
- Steam flows of relevant plant heat exchangers

The main controlled variables are:
- Alumina/Caustic Amount Ratio
- Digestion Conditions (temperatures, pressures and volume controls)
- Feed to digestion conditions.

The following table represents the controller gain matrix. MVs 1 to 4 refer to the unit mass balance variables. MVs from 5 to 7 refer to the unit energy balance variables. CVs from 3 to 6 refer to the unit energy balance variables. Other CVs are related to the unit mass balance parameters.

Table 1 – RMPCT Gain Matrix to the Digestion

	MV1	MV2	MV3	MV4	MV5	MV6	MV7
CV1	+	+	-	-			
CV2	-	-	-	-			
CV3	-	-	-	-	+	+	
CV4	-	-	-	-	+	+	
CV5	-	-	-	-	+	+	
CV6	+						
CV7		+					
CV8			+				
CV9				+			
CV10					+		
CV11							
CV12							
CV13						+	
CV14							-
CV15	+	+					

For example, MV1 is the bauxite flow and CV1 is the Alumina – Total Caustic ratio. If the bauxite flow is increased, the A/TC ratio is increased, after a dead time. CV2 is the residence time and the CV's 3, 4 and 5 are digestion temperatures. It can be noticed that, if the bauxite flow is increased, the residence time on the digestion system decreases and the digestion temperature decreases, too. In this controller, the A/TC ratio is controlled on a target, not inside operational limits.

MV3 is the liquor flow to the digestion system. This variable has a significant influence on the A/TC ratio as is one of the main handles for it. For the digestion temperature and residence time, it can be expected the same behaviour as on the interaction between the bauxite MV and the same controlled variables.

CV's from 6 to 13 are valves and they are controlled as constraints on the controller.

3. MODELLING RESULTS

3.1 Modelling Achievement

The historical data gathered was enough to get good models to build the control matrix. To the mass balance variables, around 10 steps were used and to the energy balance variables, around 6 steps were used. This difference is due to the bigger relevancy of the mass balance, since the main variable (A/C) is influenced by this group of variables.

The following figure represents one of the models between the manipulated and controlled variables. In this case, the model represents the behaviour of the Alumina – Caustic Concentration ratio, against on of the mass balance manipulated variables.

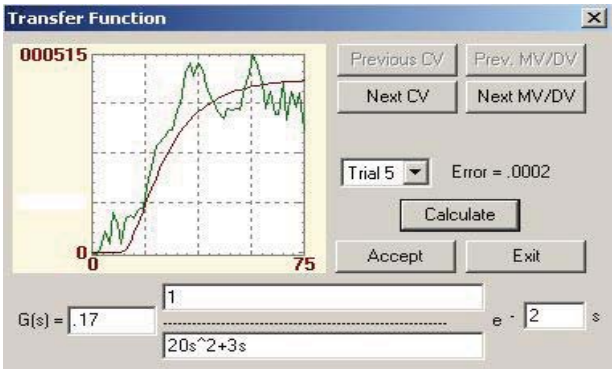

Figure 2 – Model Between Bauxite and the Alumina-Caustic Concentration Ratio (CV)

The unit studied has some valve opening problems on the liquor and pulp heating section. These problems are due plugging, caused by the material that goes inside the heat exchanger tubes. In order to minimize this problem, the valves were modelled, against their steam flows. A model example is showed on the Figure 3.

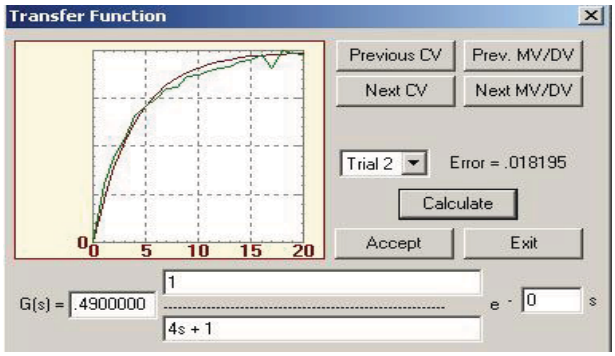

Figure 3 – Valve modelling against the steam flow

3.2 Model Validation

After the modelling, the predictions were analyzed, in order to check if the model is coherent with the real process data, found on the plant test. This validation is one of the last steps, before the controller implementation. The following pictures show the prediction results.

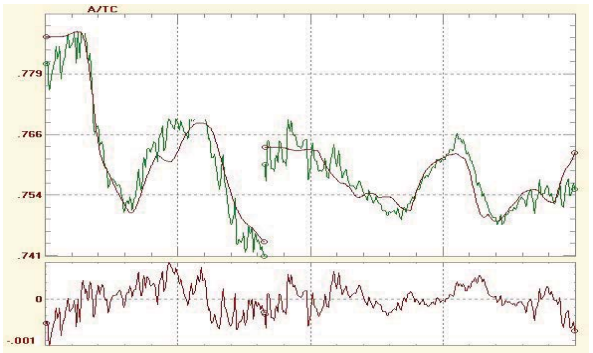

Figure 4 –A/TC Prediction

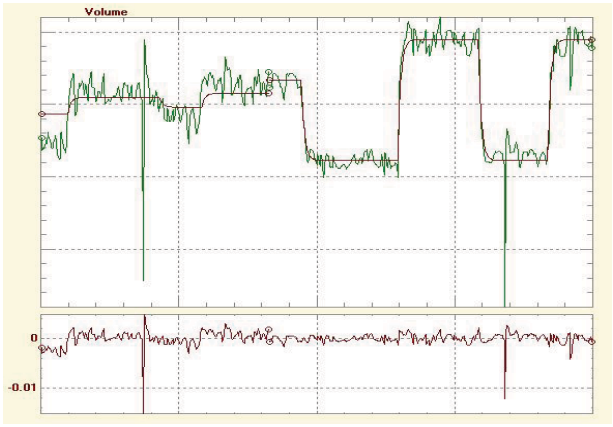

Figure 5 – Digestion Volume Prediction

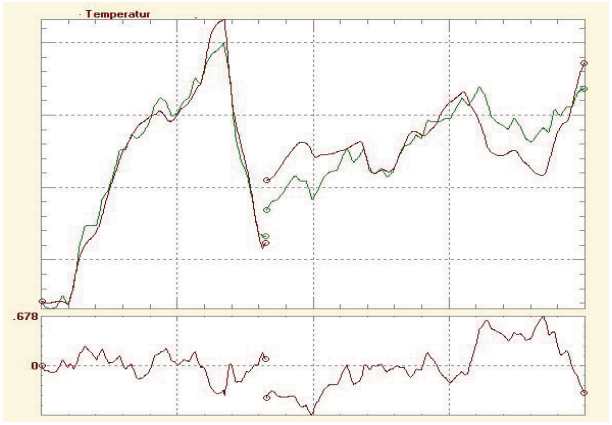

Figure 6 – Temperature Prediction

The Figures show good prediction results. Thus, the proposed and modelled matrix could be tested on the offline controller simulations. In the simulation mode, the control strategies and controller tuning are tested. Rather than this, the controller behaviour against critical situations can be validated. After this last validation, the controller was ready to be implemented on this alumina digestion unit

4. IMPLEMENTATION RESULTS

4.1 Overview

The main reason to implement RMPCT in digestion unit is to keep A/C control at the set point, decrease variability of the system, to increase digestion yield and to keep safety and stable operational conditions.

The main controllers are: DG4B_CLT (Digestion 3 controller). The others controllers are called: DG4A1_CLT, for digestion 1 and DG4A2_CLT, for digestion 2, DG4C1_CTL, for digestion 4 and DG4C2_CTL for digestion 5.

In order to evaluate digestion operation results with RMPCT, it's necessary to consider two parameters:

- Digestion Blow Off (DBO) ratio;
- Digestion Yield

4.2 Digestion Blow off (DBO) ratio

DBO ratio is the main parameter to determinate digestion yield. A good control of this parameter means smaller variability, which allows a higher yield at the digestion outlet. For digestion lines 1,2 and 3, the set point DBO ratio is 0,750. For the digestion lines 4 and 5, the set point DBO ratio is 0,759.

4.3 Digestion Yield

To calculate the digestion yield, the equation 3 is used:

$Y = (((C_{SL}\text{-}S_l)\ .\ A/C_{DBO})\text{-}(C_{SL}.A/C_{SL}))\text{-}C_{STT}$ (3), where:

CSL = Spent liquor caustic concentration (g/l)
SL = Silica lost
A/CDBO = Digestion blow off ratio
A/CSL = Spent liquor ratio
CSTT = Spent liquor solids concentration

5. RMPCT PERFORMANCE

5.1 DG4B_CTL

Controller performance was evaluated through the comparison between two different periods of digestion 3 operation. Those periods represent the time when RMPCT was turned on and off.

In the digestion operation without RMPC, the average DBO standard deviation was 0,005 higher, when compared with the digester operation with RMPC (0,002). It represents that the controller performed satisfactorily. Table 2 shows draft of DBO ratio performance with and without RMPCT operation.

Table 2- Draft DBO ratio performance

RMPCT Operation	Average DBO Ratio	Average δDBO
Controller off	0,748	0,005
Controller on	0,751	0,002

This improvement on the DBO represented a gain of 1,02% on the digestion yield. The total time spent for this project phase was 8 months.

Figure 9 and 10 show DG04B_CLT performance when RMPCT was on and off. When RMPCT was on, A/C values were more stable than when the controller was off. A DBO standard deviation of 0,003 was achieved when the Profit Controller was turned on, instead of 0,006, when controller was off.

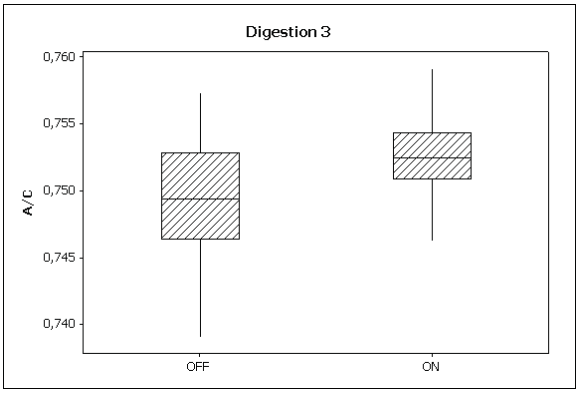

Figure 7 – Digestion 3 A/C when RMPCT on and off

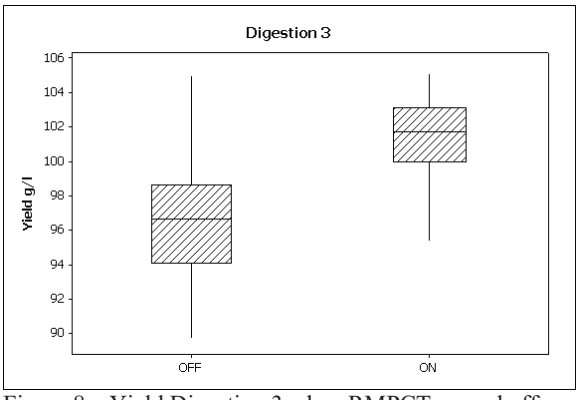

Figure 8 – Yield Digestion 3 when RMPCT on and off

5.2 DG4A1_CTL and DG4A2_CTL

RMPCT for digestion 1 and 2 was evaluated, in order to define a gain with controller in these units. The evaluation followed the same methodology as in the digestion 3.
Figure 11 shows behaviour of A/C in periods when RMPCT is off and on, with average of 0.749 and 0.753, respectively. Standard deviation of the DBO in periods where RMPCT was turned on was better than when the controller was turned off, with averages of 0,02 and 0,01, respectively.

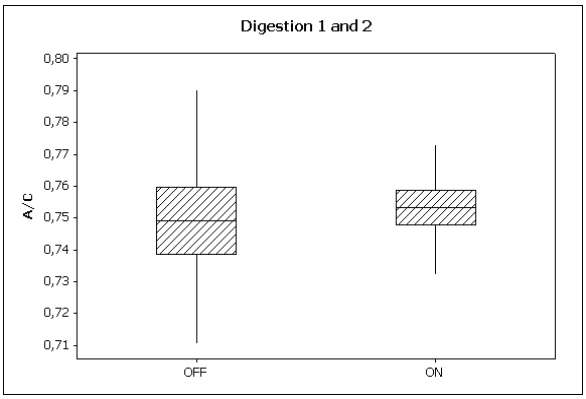

Figure 9 – Digestion 1 and 2 A/C when RMPCT on and off

Figure 12 shows an yield digestion gain of 1,85%. The yield when the controller was turned off was 98,93 g/l and when the controller was turned on was (100,77 g/l).

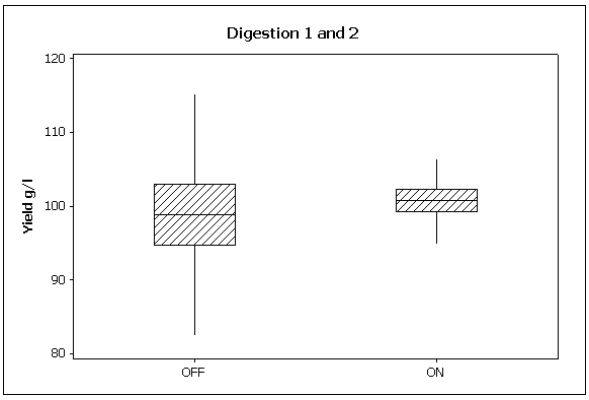

Figure 10 – Yield Digestion 1 and 2 when RMPCT on and off

5.3 DG4C1_CTL and DG4C2_CTL

RMPCT for digestion 4 and 5 was evaluated, in order to measure the gain obtained with its implementation. The evaluation follows the same methodology as in the other digestion trains.

Figure 13 shows behaviour of A/C in periods when RMPCT is off and on, with average of 0.756 and 0.759, respectively. Standard deviation δDBO in periods where RMPCT is on is better than it's off, with average of 0,02 and 0,01.

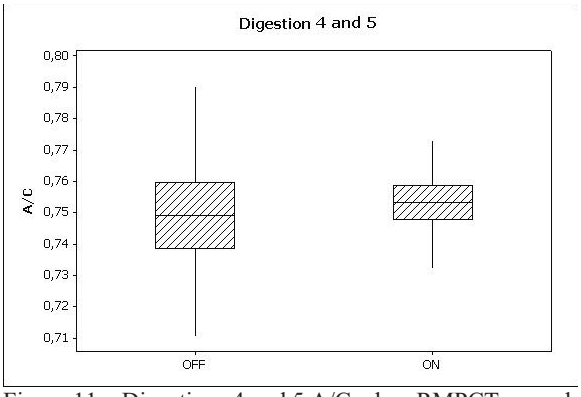

Figure 11 – Digestions 4 and 5 A/C when RMPCT on and off

Figure 14 shows yield digestion gain of 1,69%. The yield when the controller was turned off was 99,72 g/l and when the controller was turned on was 101,44 g/l.

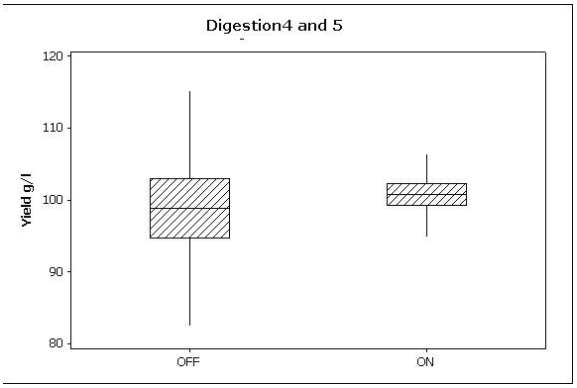

Figure 12 – Yield Digestion 4 and 5 when RMPCT on and off

6. CONCLUSION

A good RMPCT implementation on Alumina Digestion was described. The A/TC variability reduction and a bigger operation stability were proven. Also, the opportunity to operate the plant close to the operational constraints represents a productivity increase and a plant debottlenecking. The steam and liquor consumption didn't change significantly, since the objective was to use the debottlenecking to increase alumina production.

Nevertheless, in this application the liquor flow was maintained constant, due to operational restrictions. If the liquor could move, probably the results would be better than the achieved. Other source of improvement (which wasn't explored in this work) is the increase of operator training on this tool. Since the operators are the heaviest users of the system, training them to help on the optimization, pushing constraints and widening the operation limits can generate a bigger production improvement, than it was achieved.

Abstract: Type 1 diabetes mellitus must rely on daily insulin injection/infusion for the control of blood glucose. The treatments on those patients to maintain their blood glucose within an acceptable level is thus of essential importance. A good mathematical model of blood glucose may facilitate such a control. In this research, modeling and open-loop control of blood glucose for a type-1 patient using a model extended from the works of Hovorka and his coworkers (Hovorka *et al*., 2002; Hovorka *et al.*, 2004; Wilinska *et al*., 2005) are studied. Clinical data from a continuous glucose monitoring system is used to develop the model for such use. Open-loop control strategies for patients that use basal and bolus subcutaneous infusions via an insulin pump are presented.

1. INTRODUCTION

Some relevant studies indicate that good metabolic control of diabetes may decrease the risk of chronic complications. The averaged blood glucose (BG) levels as reflected by the HAb1c levels are generally considered an indication of goodness of such a control. Nevertheless, a good control in terms of HAb1c levels is only necessary but not sufficient, because, high glycemic excursion can not be detected by measuring the HAb1c values only. Recently, a system known as CGMS (Continuous Glucose Monitoring System) has been available for continuously measuring glucose concentrations in subcutaneous tissue. Clinic physicians can make uses of the recorded continuous profiles to learn the excursion of BG and modify their treatments on the patients. Meanwhile, the appearing of real time CGMS on the market also provides a basis for implementation of on-line blood glucose control in the future.

The motivation of this paper is to show, by making uses of a modification to the Harvoka's model (Hovorka *et al*., 2002; Hovorka *et al.*, 2004; Wilinska *et al*., 2005) and real CGMS data, an open-loop control that aims to desired HAb1c and blood glucose levels for type 1 patients can be developed.

2. MODEL DESCRIPTIONS

As mentioned, many physiological models have been proposed that describe glucose and/or insulin dynamics. In this paper, the model for study is based on the works of Hovorka and his coworkers (Hovorka, *et al*. ,2002; Hovorka, *et al*. ,2004; and Wilinska *et al*. ,2005). The reasons that this model is adopted for study is due to the inclusion of more detail insulin action that describes the physiological effect of insulin on glucose transport, removal and endogenous glucose production. Also it provides the insulin absorption through two compartmental channels that can be used to model the short acting and long acting effects from the bolus and basal insulin. Two subsystems are used to describe the glucose concentrations in the accessible compartment such as vein and organs, where measurements are made, and the inaccessible compartment such as tissue in human body, where measurements are not made. The insulin action describes the physiological effect of insulin on glucose transport, removal and endogenous glucose production. The original Harvokal model for IVGTT test is given as the following:

$$\frac{dQ_1}{dt} = -F_{01}^c - x_1(t)Q_1 + k_{12}Q_2(t) - F_R + U_G + \mathrm{W}\cdot EGP_0\left[1 - x_3(t)\right]; \quad (1)$$

$$\frac{dQ_2}{dt} = x_1(t)Q_1(t) - \left[k_{12} + x_2(t)\right]Q_2(t) \quad (2)$$

$$U_G = \sum_{i=1}^{N} \frac{D_G A_G (t - T_i) e^{\frac{-(t-T_i)}{t_{\max,G}}}}{t_{\max,G}^2} S(t - T_i); \quad T_i, i = 1, \cdots, M \quad (3)$$

$$F_R = \begin{cases} 0.003(G-9)V_G \cdot W & \text{, for G} \geq 9 mmole/L \\ 0 \text{ , else} \end{cases};$$

$$F_{01}^c = \begin{cases} F_{01} \cdot W & \text{; if } G \geq 4.5 mmole/L \\ F_{01} G \cdot W / 4.5 & \text{; otherwise} \end{cases};$$

and $G(t) = \dfrac{Q_1}{V_G W}$ $(mmole/L)$

$$\frac{dq_{1a}}{dt} = k_{ba}u_{ba} + k_{bo}\sum_i \frac{u_{bo,i}}{\tau}\exp\left\{-\frac{(t-T_i)}{\tau}\right\} - k_{a1^*}\cdot q_{1a} - \frac{V_{\max,LD}q_{1a}}{\left(k_{M,LD}+q_{1a}\right)} \quad (4)$$

$$\frac{dq_{1b}}{dt} = \left(1-k_{ba}\right)u_{ba} + (1-k_{bo})\sum_i \frac{u_{bo,i}}{\tau}\exp\left\{-\frac{(t-T_i)}{\tau}\right\} - k_{a2^*}\cdot q_{1b} - \frac{V_{\max,LD}q_{1b}}{\left(k_{M,LD}+q_{1b}\right)} \quad (5)$$

$$\frac{dq_2}{dt} = k_{a1^*}q_{1a} - k_{a1^*}q_2 \quad (6)$$

$$\frac{dq_3}{dt} = k_{a1^*}q_2 + k_{a2^*}q_{1b} - k_e q_3 \quad (7)$$

$$\frac{dx_1}{dt} = -k_{a1}x_1(t) + \frac{k_{a1}S_{IT}^f q_3}{V_I \cdot W} \quad (8)$$

$$\frac{dx_2}{dt} = -k_{a2}x_2(t) + \frac{k_{a2}S_{ID}^f q_3}{V_I \cdot W} \quad (9)$$

$$\frac{dx_3}{dt} = -k_{a3}x_3(t) + \frac{k_{a3}S_{IE}^f q_3}{V_I \cdot W} \quad (10)$$

where, Q_1 and Q_2 (*mmole/l*) represent the glucose in accessible and non-accessible compartments, G (*mmole/l*) is the measurable glucose concentration, k_{12} represents the transfer rate constant from non-accessible to accessible compartment, V_G represents the distribution volume of the accessible compartment, and EGP_0 represents endogenous glucose production at the zero insulin concentration. F_{01}^c is the non-insulin-dependent glucose flux and F_R is the renal glucose clearance thresholds of 9 mmol/L. W is the patient's weight. U_G is the gut absorption rate, $t_{\max,G}$ is the time-of-maximum appearance rate of glucose in the accessible glucose compartment, D_G is the amount of carbohydrates (CHO) digested and A_G is the carbohydrate bioavailability. Variable q_2 represents the insulin mass (mU) in the nonaccessible subcutaneous compartment, q_3 represents the insulin mass (mU) in the plasma compartment. The quantities q_{1a} and q_{1b} represent the masses of insulin administered as continuous infusion (mU) through the slow and fast compartment channels (Wilinska *et al*. 2005). The variable u represents the basal insulin input (mU/min). The parameters k_{a1^*}, k_{a2^*}, and k_e are transfer rates ($\min^{-1}$), $V_{\max,LD}$ is the saturation level (mU/min) for Michaelis-Menten dynamics of insulin degradation, $k_{M,LD}$ is the value of insulin mass (mU) at which insulin degradation is equal to half of its maximal value for continuous infusion. The dimensionless constant k and $1-k$ represent the proportions of the total input flux of insulin passing through the slower and faster compartment channels, respectively. The variables, x_1, x_2, and x_3 represent the (remote) effects of insulin on glucose distribution/transport, glucose disposal and endogenous glucose production (Harvoka, *et al*. 2002). Finally, k_{ai}, i=1,⋯,3, represent the deactivation rate constants.

The modeling form given above is based on the work of Seborg and his coworkers (2008). On this basis, the addition of carbohydrates in-take from different meals (i.e. Eq.(3)) and the basal insulin and bolus insulin infusion/injection at different times (i.e. Eq.(4) and Eq.(5)) are considered as an extensions to the original model. Notations u_{ba} and u_{bo} are used to designate the quantities of basal insulin and bolus insulin, respectively.

The complete model for modelling the BG consists of equations from Eq.(1) through Eq.(10). V_G and A_G are assumed to be constant as: V_G=0.16 (L^{-1}·kg) and A_G=0.8. Totally seventeen parameters in the model will be determined:

F_{01}, k_{12} ,EGP_0, k_{a1^*}, k_{a2^*}, $t_{MAX,G}$, S_{IT}^f/V_I, S_{ID}^f/V_I, S_{IE}^f/V_I, $V_{\max,LD}$, $k_{M,LD}$, k_{ba}, $k_{bo,}$ k_e, k_{a1}, k_{a2}, k_{a3}

For patient undertaking same insulin in basal and bolus injections, k_{ba} and k_{bo} in the model are assumed to have the same value.

3. PARAMETER ESTIMATION FOR MODELING

The model described above was applied to one real patient who has type-1 diabetes. The subject undergoing the experiment weighted 55kg and wore an insulin pump for insulin infusion. She also wore the MiniMed CGMS for five days during the experiment period. During that period, the meal contents and the insulin doses were recorded on a diary. These meal contents then were quantified by a dietician. No special arrangement was made for this experiment. The patient was asked to live on her normal way with meals and works as usual. The data from the patient accompanied with a complete diary on meals and insulin dosages are recorded. These data are then fitted into the model abovementioned. The modelling is aimed to find the parameters that minimize the sum of squares of the output errors. To compute these output errors, BG is computed by integrating the modified Hovorka model described in Section 2, starting with a set of parameters and initial conditions. The initial parameters are taken from the parameters of Marchetti *et al*. (2008). The steady-states values of the modified Hovorka model which correspond to a fasting level of BG are prepared in advance from the same model and are taken to initiate the integration for optimization. These initial states for integration are then updated from iteration to iteration using the resulted states in the last fasting stage of the previous run.

The modelling starts to fit themodel to the CGMS data of the first two days by making uses of the reported quantified CHOs and insulin doses. The parameters thus obtained are given as follows:

Parameter	Value	Unit	Parameter	Value	Unit
S_{IT}^f / V_I	0.019	$Min^{-1} \cdot mU^{-1} \cdot kg$	k_{12}	0.237	min^{-1}
S_{ID}^f / V_I	0.003	$Min^{-1} \cdot mU^{-1} \cdot kg$	k_{a1}	0.017	min^{-1}
S_{IE}^f / V_I	0.052	$mU^{-1} \cdot kg$	k_{a2}	0.273	min^{-1}
EGP_0	0.051	$mmole \cdot kg^{-1} \cdot min^{-1}$	k_{a3}	0.128	min^{-1}
F_{01}^c	1.899	$mmole \cdot min^{-1}$	k_e	0.036	min^{-1}
k	0.34	–	$t_{MAX,G}$	22.91	min
$V_{MAX,LD}$	2.156	$mU \cdot min^{-1}$	k_{a1^*}	0.005	min^{-1}
$k_{M,LD}$	64.182	mU	k_{a2^*}	0.054	min^{-1}

With the resulting parameters, the fitting of the real CGMS data to the model is shown in Figure 1. In this figure, the fitting of the model to the reported CGMS data in the first 48 hours looks good. The model is then used to predict the blood glucose in the remaining days. Figure 2 shows that the fitting is not good enough, but the trend is alright. The lack of fit in the extending time horizon is due to imprecise quantification of CHO intakes. If the remaining CHOs are allowed for some modifications, the fitting turns out to be more satisfactory (see Figure 3).

4. OPEN-LOOP CONTROL VIA SUBCUTANEOUS INSULIN INFUSION/INJECTION

Using an artificial pancreas, subcutaneous infusion of insulin according to a pre-programmed basal and bolus dosages is one approach to control the blood glucose of a type-1 diabetic patient in an open-loop manner. However, artificial pancreas is somewhat an expensive device that most of the patients may not afford. Fortunately, due to the availability of effective long acting insulin, the pre-programmed subcutaneous insulin injection can also be applied to patients who do not use artificial pancreas. The multiple subcutaneous injections with long acting and short acting insulin can be used to mimic the insulin secretions in a normal body. The basal insulin rate is aimed to maintain a given fasting level of blood glucose (e.g. 100 mg/dl). The bolus insulin dose is taken to enhance the control of blood glucose at each CHO intake.

4.1 Development of bolus dosage plan for Prandial CHO-uptake

While planning the bolus dosage under a prandial condition, some constraints should be considered. These constraints come from clinical demands for normal control of blood glucose. For example,

(1). Fasting blood glucose ≤ 100 mg/dl (≤ 5.6 mmol/l)

(2). Two-hour Post-prandial blood glucose $\leq$ 120 mg/dl

(3). In all time, blood glucose $\geq$ 70 mg/dl and never less than 50 mg/dl

The above standards may not be achievable by a type-1 diabetic patient in real practice. Apart from keeping patients from a hyperglycemia status, type-1 diabetic patient should be cautious to keep from having hypoglycaemia, especially during midnight (i.e. approx. 6 hours after dinner). Thus, in order to accommodate properly the blood glucose concerns in many aspects, the determination of bolus dosage for a CHO-intake is thus formulated as the problem of the following:

$$\underset{u_{bo}}{Min}\left\{\left|G_{av}(t^*,u_{bo}(x_i))-\gamma_1^*\right| \text{ given } |\, CHO=x_i \text{ and } G_{fasting}=\gamma_o\right\} \quad (13)$$

$$s.t. \quad \begin{cases} (1)\ G(t)\geq \gamma_*, \\ (2)\ G(t)<\gamma^* \ \forall t\geq 0\ , \end{cases}$$

Where, x_i, i=1, 2, 3 is the grams of CHO-intake in each meal, $\gamma^*, and\ \gamma_*$ are parameters to be assigned, which may vary according to the physician on a patient-to-patient basis for constraining blood glucose. Notice that, here, γ_* is taken as 70mg/dl. In other words, $\underline{G}\geq 70\ mg/dl$ is a hard constraint for patient to avoid from having hypoglycemia. The value of t^* is taken as 6hrs, since each meal is usually 6 hours apart from one to the other. $G_{av}(6hrs,u_{bo}(x_i))$ is the average value of G in a 6-hours period with x_i CHO-intake and $u_{bo}(x_i)$ bolus dosage.

To solve the problem in Eq. (13), first, we need the function $u_{bo}(x_i)$ and a basal insulin amount, $u_{ba}(G_{fasting})$, to maintain the blood glucose at a specified fasting level. The latter is used to mimic the secretion of the basal insulin in a normal human body. Mathematically, basal insulin can be considered as a step dose lasting for 24 hours a day that leads G to a fasting level. In fact, this value can be obtained by solving the set of algebraic equations obtained from setting the derivatives in the extended Hovorka model to zeros. The fasting glucose to mimic the effect of the secretion of basal insulin in a normal human body is taken as 100 mg/dl in this study (γ_0=100 mg/dl). A lower value may also be taken, however, a too low value may lead Eq.(13) without having feasible solution. Based upon this basal insulin amount (or, in other words, the targeting blood glucose) the bolus dosage plan will then be computed.

Next, we need to develop the function, $u_{bo}(x_i)$, which describes the required bolus dosage to a CHO intake from meals. The parameters $\gamma^*, and\ \gamma_1^*$ are considered for type-1 diabetic patients to have an acceptable glycated hemoglobin (i.e., hemoglobin HbA_{1c} or, simply, A1c) value. The use of hemoglobin A1c for monitoring the degree of control of glucose metabolism in diabetic patients was proposed in 1976 by Koenig and coworkers. A buildup of A1c within the red cell reflects the average level of glucose to which the cell has been exposed during its life cycle (approx. 120 days). Thus,

the A1c level is proportional to the averaged blood glucose concentration over the previous four weeks to three months. According to ADA (American Diabetes Association), the mean plasma glucose concentration (MPG) is related to HbA_{1c} with an empirical equation of the following:

MPG (mg/dl) = (35.6* HbA_{1c}) - 77.3, or, MPG (mmol/l) = (1.98* HbA_{1c}) - 4.29 (14)

A simpler and approximately equivalent formula can also be written as:

$$MPG(mg/dl) = 35*(A1c-5)+100 \quad (15)$$

Where, MPG is the mean plasma glucose concentration in the last three months. Thus,

$$A1c = \left(MPG-100\right) \div 35+5 \quad (16)$$

If the daily average blood glucoses (i.e. $G_{av}(24hrs)$) are equal from day to day in a period of at least three months, the MPG will equal to its daily time-average. Notice that the glucose concentration in the plasma is higher than the glucose concentration in the whole blood by about 11%. In the mathematical model, the glucose concentration G is referred to the whole blood. As a result, in terms of blood glucose as described by the model, Eq.(16) needs to be updated as:

$$A1c \cong \left[G_{av}(24hrs)\times 1.1-100\right] \div 35+5 \quad (17)$$

For easier application, one may consider to replace the $G_{av}(24hrs)$ with the following:

$$G_{av}(24hrs) \cong \left[\sum_{i=1}^{3} G_{av}(6hrs, u_{bo}(x_i)) + G_{fasting}\right] * 0.25 \quad (18)$$

And,

$$A1c \cong \left[\left\{\sum_{i=1}^{3} G_{av}(6hrs, u_{bo}(x_i)) + G_{fasting}\right\} * 0.25\times 1.1-100\right] \div 35+5 \quad (19)$$

Where, x_1, x_2, x_3 are CHO amounts in terms of grams taken from the daily three meals. Eq.(18) compute the mean BG by assuming that daily BG has a level at $G_{av}(6hrs)$ in a period of three meals (i.e.18 hours) and at 100mg/dl in the fasting period (i.e. another 6 hrs). Thus, specifying γ_1^* in Eq.(13) is to specify the target A1c as shown in Figure 4. An effective control of blood glucose should make this A1c value to remain below 7. In practical treatment, the values of γ^*, and γ_1^* may differ from subject to subject. If a bolus-to-CHO relation is available, then, given a daily CHO-plan, the average blood glucose can be computed from integrating the model. A graphical approach to the solution of a bolus-to-CHO relation will be demonstrated in the example that follows.

4.2 Case study

As mentioned, the basal insulin amount versus the fasting blood glucose levels can be calculated from the steady-state solution to the modified Hovorka model given in Section 2. For this case, the basal insulin amounts corresponding to each possible fasting glucose level are prepared and plotted in Figures 4. On the other hand, under a basal dose that leads to a fasting glucose of 100mg/dl, the responses of the blood glucose to different CHO intakes are computed. Based on these responses, the average blood glucoses at 4hrs and 6 hrs, together with maximum and minimum values under the same dosage are computed and plotted in Figure 5 and Figure 6, , with an insulin increment of 0.5 unit. The values of γ^*, and γ_1^* are then specified in order to obtain the bolus dose. As an example in this case, they are selected as 320, and 120, respectively.

The feasible regions to satisfy condition (1) and condition (2) of Eq. (13) are plotted for specific CHO intakes, starting from 15grams to 60grams, with an increment of 15grams. As shown in Figure 5, the feasible region that satisfies condition (1) and condition (2) is the region spanned by the pink and red lines. In each case (e.g. Figure 5 and Figure 6), there is u_{bo} that corresponding to the given CHO value, x. However, in case there is no feasible solution exists that will give $G_{av}(6hrs)$ exactly at 120 mg/dl, the bolus dosage at the boundary of the feasible region will be taken. By increasing the CHO amount, x, at an increment of 15 grams, a curve of bolus insulin required for different prandial CHOs can be obtained as shown in Figure 7. Thus, under a give basal insulin amount, the bolus dosage required for each CHO-intake can be read from these curves. If, a CHO meal-plan is taken (e.g., breakfast: 30gm, lunch: 60gm, dinner:60gm) with the bolus dosage plan as shown in Fig. 7 (e.g. breakfast: 1.05U, lunch: 2.1U, dinner: 2.1U), the averaged blood glucose could be expected to be 113.5 which gives 5.76 for the A1c value. Compared to the current record from the CGMS, the A1c value as well as the blood glucose could be significantly improved.

5. CONCLUSIONS

Modeling glucose-insulin interactions with real CGMS data and a model extended from Hovorka and his coworkers (Hovorka *et al*., 2002; Hovorka *et al.*, 2004) are studied. Using the mathematical model as a frame work, dynamic models are built for a case study. Data from a continuous glucose monitoring system (CGMS, MiniMed) are used to estimate the parameters in the model. As the CHO contents in various foods are fuzzy due to natural language, the CHO values thus quantified are subject to certain extent of uncertainties. As a result, during the parameter estimation, these quantified CHO values need to be modified. The resulting models are then used to determine the daily basal and bolus dosages to mimic the secretion of insulin of a human body and control the blood glucose to an acceptable level. The basal amount is to be determined to maintain the fasting glucose value at a given level. The bolus dosage is then determined based upon this basal insulin and the CHO intake in each meal. The bolus is aimed to keep the blood glucose within upper and lower bounds. The lower bound is

70 mg/dl which is normally considered in medical treatment to prevent the occurrence of hypoglycermia. The upper bound can be considered on a person-to-person basis. Besides setting the glucose value in the upper/lower bounds, the bolus dosage plan is also aimed to have a targeted A1c value, which is normally less than 7.0 in general medical treatments for the diabetes patients. The basal insulin amount and the bolus dosage plan are demonstrated with the utilization of the developed models.

Abstract: This work focuses on the design and implementation of a nonlinear model-based control system on an experimental reverse osmosis (RO) membrane water desalination system in order to deal with large set-point changes and variations in feed water salinity. A dynamic nonlinear lumped-parameter model is derived using first-principles and its parameters are computed from experimental data to minimize the error between model predictions and experimental RO system response. Then, this model is used as the basis for the design of a nonlinear control system using geometric control techniques. The nonlinear control system is implemented on the experimental RO system and its set-point tracking capabilities are successfully evaluated.

Keywords: Process control, process monitoring, model based control, nonlinear process systems

1. INTRODUCTION

Reverse osmosis (RO) membrane desalination has emerged as one of the leading methods for water desalination due to the low cost and energy efficiency of the process (Rahardianto et al. (2007)). Lack of fresh water sources has necessitated further development of these desalination plants, especially in areas with dry climates. Even with advances in reverse osmosis membrane technology, maintaining the desired process conditions is essential to successfully operating a reverse osmosis desalination system. Seasonal, monthly, or even daily changes in feed water quality can drastically alter the conditions in the reverse osmosis membrane modules, leading to decreased water production, sub-optimal system performance, or even permanent membrane damage. In order to account for the variability of feed water quality, a robust process control strategy is necessary. In a modern reverse osmosis (RO) plant, automation and reliability are elements crucial to personnel safety, product water quality, meeting environmental constraints, and satisfying economic demands. Industrial reverse osmosis desalination processes primarily use traditional proportional and proportional-integral control to monitor production flow and adjust feed pumps accordingly (Alatiqi et al. (1999)). While such control strategies are able to maintain a consistent product water (permeate) flow rate, they may fail to provide an optimal closed-loop response with respect to set-point transitions owing to the presence of nonlinear process behavior (Chen et al. (2005)). In some cases, permeate production can decrease due to scaling or fouling on the membrane surface. When this occurs, traditional control algorithms force the feed pumps to increase feed flow rate leading to an increased rate of scaling, irreversible membrane damage, and eventual plant shutdown. Traditional process control schemes are also unable to monitor plant energy usage and make adjustments toward energy-optimal operation. Model based control is a promising alternative to traditional RO plant control strategies. Several model based methods such as model-predictive control (MPC) and Lyapunov-based control have been evaluated via computer simulations for use in reverse osmosis desalination (Abbas (2006); McFall et al. (2008); Bartman et al. (2009b); Gambier and Badreddin (2002)). Experimental system identification and MPC applications can also be found in the literature (Assef et al. (1997); Burden et al. (2001)). Model based control methods have also been used in conjunction with fault detection and isolation schemes to improve robustness of control methods in the presence of sensor and actuator failures (McFall et al. (2008)). Other automatic control methods utilize model based control based on a linear model (Alatiqi et al. (1989)); using step tests to create a model that is a linear approximation around the desired operating point. Several other traditional control methods have also been studied in the context of RO system integration with renewable energy sources (Herold and Neskakis (2001); Liu et al. (2002)). Motivated by these considerations, the goal of this work is to evaluate the effectiveness of a feedback linearizing nonlinear model-based controller through application to an experimental reverse osmosis desalination system. The nonlinear model-based controller is shown to possess excellent set-point tracking capabilities. The nonlinear controller is also shown to outperform a proportional-integral control system.

2. RO SYSTEM MODEL

In this section, a fundamental model of a representative RO desalination system is developed including all of the basic elements present in UCLA's experimental RO desalination system. In this system, shown in Fig. 1, water enters the feed pump, which is equipped with a variable frequency drive (VFD), and is pressurized to the feed pressure P_{sys}. The pressurized stream enters the membrane module where it is separated into a low-salinity product (or permeate) stream with velocity v_p, and a high-salinity brine (or retentate) stream with velocity v_r. In the model, the individual spiral-wound membranes in series are assumed to be one large spiral-wound membrane in one large vessel, where any effects of individual membrane vessel interconnections are neglected. The pressure downstream of the actuated valve and at the permeate outlet is assumed to be equal to atmospheric pressure.

The model is based on a mass balance taken around the entire system and an energy balance taken around the actuated retentate valve. In the model derivation, it is assumed that the water is an incompressible fluid, all components are operated on the same plane (so potential energy terms due to gravity can be neglected), and the density of the water is assumed to be constant. It is also assumed that the effective concentration in the membrane module is a weighted average of the feed concentration and the brine stream concentration (see Eq. 6 below). The model derivation results in a nonlinear ordinary differential equation for the retentate stream velocity and an algebraic relation for the system pressure. This model is an adaptation of a model developed in our previous work used to describe a similar reverse osmosis desalination system (McFall et al. (2008)). In the previous work, the system utilized a feed pump with a constant feed flow rate, but used a separate bypass stream with an actuated valve to control the velocity of the water feeding to the membrane units. An equation for the osmotic pressure based on effective concentration and temperature in the membrane unit was also developed in (Lu et al. (2007)), and is used as an estimate in the model. Specifically, an energy balance is first taken around the retentate valve which leads to the following differential equation:

$$\frac{dv_r}{dt} = \frac{P_{sys}A_p}{\rho V} - \frac{1}{2}\frac{A_p e_{vr} v_r^2}{V} \tag{1}$$

where v_r is the retentate stream velocity, P_{sys} is the system pressure, A_p is the pipe cross-sectional area, ρ is the fluid density, V is the system volume and e_{vr} is the retentate valve resistance. To compute an expression for the system pressure in terms of the other process variables, an overall steady-state mass balance is taken to yield:

$$0 = v_f - v_r - v_p \tag{2}$$

where v_f is the feed stream velocity and v_p is the permeate stream velocity. In order to get an expression for the system pressure, the following classical expression is used for the computation of the permeate stream velocity:

$$v_p = \frac{A_m K_m}{\rho A_p}(P_{sys} - \Delta\pi) \tag{3}$$

where A_m is the membrane area, K_m is the membrane overall mass transfer coefficient, and $\Delta\pi$ is the difference in osmotic pressure between the feed side of the membrane and the permeate side. Substituting Eq. 3 into Eq. 2, the following expression for the system pressure (P_{sys}) is obtained:

$$P_{sys} = \frac{\rho A_p}{A_m K_m}(v_f - v_r) + \Delta\pi \tag{4}$$

where the osmotic pressure ($\Delta\pi$) and effective average concentration at the membrane surface (C_{eff}) on the feed side can be computed from the following relations:

$$\Delta\pi = \delta C_{eff}(T + 273) \tag{5}$$

$$C_{eff} = C_f(a + (1-a)((1-R) + R(\frac{v_f}{v_r}))) \tag{6}$$

where C_f is the amount of total dissolved solids (TDS) in the feed, a is an effective concentration weighting coefficient, δ is a constant relating effective concentration to osmotic pressure, T is the water temperature in degrees Celsius, and R is the fractional salt rejection of the membrane. Substituting Eq. 4 into the energy balance equation of Eq. 1 yields the following nonlinear ordinary differential equation for the dynamics of the retentate stream velocity:

$$\frac{dv_r}{dt} = \frac{A_p^2}{A_m K_m V}(v_f - v_r) + \frac{A_p}{\rho V}\Delta\pi - \frac{1}{2}\frac{A_p e_{vr} v_r^2}{V} \tag{7}$$

Using the above dynamic equation, various control techniques can be applied using the valve resistance value (e_{vr}) as the manipulated input. As the valve resistance goes to zero, the valve behaves as an open pipe; as the valve resistance approaches infinity, the valve behaves as a total obstruction and the flow velocity goes to zero (Bird et al. (2002)). To accurately model the valve dynamics and to relate the experimental results to the concept of valve resistance value (e_{vr}), the concept of valve C_v is used. The definition of C_v for a valve in a water system is:

$$C_v = \frac{Q_r}{\sqrt{P_{sys}}} \tag{8}$$

where Q_r is the volumetric flow rate ($Q_r = A_p v_r$) through the retentate valve. In order to obtain an expression for C_v as a function of the retentate valve resistance (e_{vr}), we consider the steady state form of the energy balance of Eq. 1, solve the resulting equation for P_{sys} and substitute the resulting expression for P_{sys} into Eq. 8 to yield:

$$C_v = \frac{A_p}{\sqrt{\frac{1}{2}\rho e_{vr}}} \tag{9}$$

Depending on the type of valve and its flow characteristics, it is assumed that the C_v values (and in turn, the e_{vr}

values) can be related to the valve position (percentage open) through the following empirical logarithmic relation based on commercially available valve data (Bartman et al. (2009b)):

$$O_p = \mu \ln e_{vr} + \phi \tag{10}$$

where μ and ϕ are constants depending on the valve properties. The values of μ and ϕ for this model are taken from a paper based on the same experimental system at UCLA (Bartman et al. (2009b)). For the model presented in this paper, the curve relating valve position (O_p) to resistance value (e_{vr}) is shown in Fig. 2. It can be seen in Fig. 2 that as the valve position goes to zero (fully closed), the valve resistance values begin to grow at an increasing rate; and as the valve approaches the fully-open position, the resistance values change slowly. The data from the experimental system is also plotted on the figure, and it can be seen that the data does not fit the same logarithmic relation as the ideal valve curve. Due to the shape of the experimental data curve, the data is fit in three segments with curve fits following a similar form as the theoretical curve. The first curve fit is applied to valve resistance (e_{vr}) values of approximately 205 to 212 and takes the form:

$$O_p = -84.428 \ln(e_{vr}) + 459.21 \tag{11}$$

For e_{vr} values between 212 and 6200, O_p is computed by:

$$O_p = -2.0473 \ln(e_{vr}) + 18.141 \tag{12}$$

while for e_{vr} values above 6200, O_p is computed by:

$$O_p = -0.0778 \ln(e_{vr}) + 0.9476 \tag{13}$$

This treatment of the valve characteristics allows for conversion of the experimental values of O_p to values of e_{vr} in the model-based nonlinear control algorithm, and allows for values of e_{vr} generated by the control algorithm to be translated to values of O_p to be sent to the actuated valve on the experimental system. Capturing the nonlinearity present in the valve is extremely crucial when applying the control algorithms to the experimental system.

2.1 Computation of Nonlinear Model Parameters Based on Experimental Data

Most of the parameters of the model of Eqs. 7-13 such as the membrane area (A_m), water density (ρ), pipe cross-sectional area (A_p), and system volume (V) have constant values which can be obtained from the experimental system. Another key model parameter, the overall mass transfer coefficient (K_m) was computed to match the model response to experimental step-test data. Specifically, K_m was computed using steady state data from the experimental system by minimizing the difference between the model steady state and the experimental system steady state for various step tests. The computed values of K_m were then averaged to determine the best value for use in the model used for controller design. The values of the model parameters can be found in Table 1.

3. CONTROL ALGORITHMS

Two separate control loops are present in the control problem formulation. The first loop regulates the system pressure by adjusting the variable frequency drive (VFD) speed directly (effectively changing the feed flow rate). This control loop will be termed "loop I". In each set of experiments presented below, a proportional-integral (PI) feedback controller is used to keep the system pressure (P_{sys}) at the set-point value (P_{sys}^{sp}) of 150 psi. This control algorithm takes the form:

$$S_{VFD} = K_f(P_{sys}^{sp} - P_{sys}) + \frac{K_f}{\tau_f}\int_0^{t_c}(P_{sys}^{sp} - P_{sys})dt \tag{14}$$

where S_{VFD} is the control action applied to the variable frequency drives (VFD speed), K_f is the proportional gain and τ_f is the integral time constant. The second control loop (termed "loop II") uses a nonlinear model-based controller (for the purposes of comparison, and a PI controller is also used in loop II). The nonlinear controller utilizes the error between the retentate velocity and its corresponding set-point, but it also takes into account many additional system variables (El-Farra and Christofides (2001, 2003); Christofides and El-Farra (2005)). Specifically, the nonlinear model-based controller manipulates the actuated retentate valve position by using measurements of the feed flow velocity (v_f), feed salinity (C_f), and retentate flow velocity (v_r). The nonlinear controller is designed following a feedback linearization approach. To derive the controller formula, the following linear, first-order response in the closed-loop system between v_r and v_r^{sp} is requested:

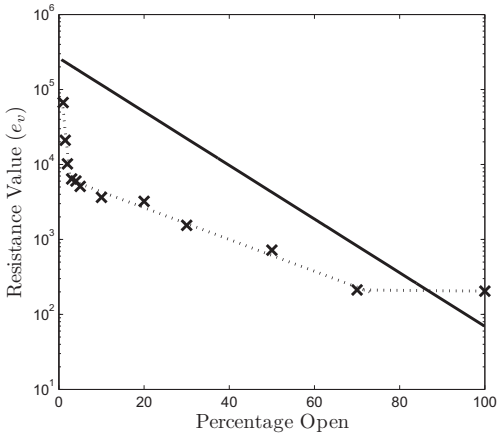

Fig. 2. Correlation between valve resistance value (e_{vr}) and valve percentage open (O_p) : commercial theoretical data (solid line), experimentally measured data (x), and curve fittings to experimental data (dashed lines) using Eqs. 11-13.

Table 1. Process model parameters based on experimental system data.

ρ	=	1007	kg/m^3
V	=	0.6	m^3
A_p	=	0.000127	m^2
A_m	=	15.6	m^2
K_m	=	6.4×10^{-9}	s/m
C_f	=	4842	mg/L
a	=	0.5	
T	=	22	$^\circ C$
R	=	0.97	

$$\frac{dv_r}{dt} = \frac{1}{\gamma}(v_r^{sp} - v_r) \tag{15}$$

It is noted that a first-order response is requested because the relative degree between v_r and e_{vr} is one (Christofides and El-Farra (2005)). Using this approach, the following formula is obtained for the nonlinear controller:

$$e_{vr} = \frac{\frac{1}{\gamma}(v_r^{sp} - v_r) - \frac{A_p^2}{A_m K_m V}(v_f - v_r) - \frac{A_p \delta (T+273)}{\rho V} C_{eff}}{\frac{-A_p}{2V}(v_r^2)} \tag{16}$$

To achieve offset-less response, integral action is added to the controller in Eq. 16 and the resulting controller takes the form:

$$e_{vr} = \frac{\frac{1}{\gamma}(v_r^{sp} - v_r) + \frac{1}{\tau_{NL}}\int_0^{t_c}(v_r^{sp} - v_r)dt}{\frac{-A_p}{2V}(v_r^2)} + \frac{-\frac{A_p^2}{A_m K_m V}(v_f - v_r) - \frac{A_p \delta (T+273)}{\rho V} C_{eff}}{\frac{-A_p}{2V}(v_r^2)} \tag{17}$$

As a baseline, the performance of the nonlinear controller is compared to a traditional form of control. Loop II, using PI control, uses the retentate (or concentrate) stream flow velocity to manipulate the actuated valve in order to regulate the retentate stream velocity/flow rate. Under PI control, the control system for loop II takes the form:

$$O_p = K_r(Q_r^{sp} - Q_r) + \frac{K_r}{\tau_r}\int_0^{t_c}(Q_r^{sp} - Q_r)dt \tag{18}$$

where Q_r is the retentate stream volumetric flow rate and Q_r^{sp} is the retentate stream flow rate set-point. In the experiments, the performance of the nonlinear controller implemented on the experimental system is compared to the performance of the nonlinear controller implemented on the process model and to the performance of the proportional-integral controller implemented on the experimental system. The control algorithms were programmed into the data acquisition and control software to operate in real-time with a sampling time of 0.1 seconds. Additionally, the actuated retentate valve is powered by an electric motor with a maximum operating speed which must be taken into account when attempting to simulate the nonlinear controller action. From testing on the experimental system, it was found that the actuated valve could travel its entire range in approximately 45 seconds; this provides an important constraint on the speed of valve opening/closing in the simulations of the form:

$$\left|\frac{dO_p}{dt}\right| \leq 2.22\frac{\%}{s} \tag{19}$$

To derive the constraint of Eq. 19, it is assumed that the valve speed is independent of valve position (valve always turns at maximum speed). This is a physical constraint which is intrinsically accounted for in the experimental results and is programmed into the nonlinear model-based controller simulation as well (to facilitate comparison). Additionally, when using the experimental system, the valve position is not allowed to fall under 1%, and any values sent to the valve above 100% are translated to the max value of 100% open. The lower constraint ($< 1\%$) is enforced so that the system pressure will not rise too rapidly. A constraint on the variable frequency drive is also placed to avoid pressure spikes (a maximum VFD speed of 4.5/10 is used). In the experiments presented in this work, the actuators do not reach these constraints.

4. EXPERIMENTAL SYSTEM DESCRIPTION

The experimental reverse osmosis water desalination system constructed at UCLA's Water Technology Research (WaTeR) Center was used for conducting the control experiments. This experimental system is comprised of a feed tank, two low-pressure feed pumps in parallel which provide enough pressure to pass the feed water through a series of cartridge filters while also providing sufficient pressure for operation of the high-pressure pumps, two high-pressure pumps in parallel (each capable of delivering approximately 4.3 gallons per minute at 1000 psi), and a bank of 18 pressure vessels containing Filmtec spiral-wound RO membranes. The high-pressure pumps are outfitted with variable frequency (or variable speed) drives which enable the control system to adjust the feed flow rate by using a 0-10V output signal. The bank of 18 membranes are arranged into 3 sets of 6 membranes in series; and for the control experiments presented below, only one bank of 6 membrane units was used. The experimental system uses solenoid valves controlled by the data acquisition and control hardware to enable switching between multiple arrangements of the membrane modules (2 banks of 6 in parallel to one bank of 6 in series, or any number of the modules in series) while also allowing for control of the flow direction through the membrane banks. After the membrane banks, an actuated valve is present to control the cross-flow velocity (v_r) in the membrane units, while also influencing system pressure. This valve is used as an actuator for the control system utilizing the control algorithms presented in section 3. The resulting permeate and retentate streams are currently fed back to the tank in an overall recycle mode, but for field operation the system can be operated in a one-pass fashion. The experimental system also has an extensive sensor and data acquisition network; flow rates and stream conductivities are available in real-time for the feed stream, retentate stream and permeate stream. The pressures before each high pressure pump, as well as the pressures before and after the membrane units (feed pressure and retentate pressure) are also measured. The system also includes sensors for measuring feed pH, permeate pH, in-tank turbidity, and feed turbidity after filtration (in real-time). A centralized data acquisition system takes all of the sensor outputs (0-5V, 0-10V, 4-20mA) and converts them to process variable values on the local (and web-accessible) user interface where the control system is implemented. The data is logged on a local computer as well as on a network database where the data can be accessed via the internet, while the control portion of the web-based user interface is only available to persons with proper authorization. The data acquisition and control system uses National Instruments software and hardware to collect the data at a sampling rate of 10 Hz and perform the necessary control calculations needed for the computation of the control action to be implemented by the control actuators. A photograph of the system can be seen in Fig. 3.

5. EXPERIMENTAL CLOSED-LOOP RESULTS

In the control experiments presented in this paper, the experimental system was turned on and the PI loop controlling the variable frequency drives (loop I) was activated to bring the system pressure to a set-point of $P_{sys} = 150$ psi. The retentate flow rate was set to 1.5 gallons per minute (gpm). After the system had been operating at this steady state for a sufficient period of time, loop II was activated to manipulate the retentate valve. All data taken from the experimental system was averaged (after the experiments) using a 19 point moving average to remove most of the measurement noise. The following sets of experiments compare the performance of the nonlinear controller with the performance of the proportional and proportional-integral controllers. The closed-loop response observed for the nonlinear controller applied to the dynamic process model is used as a baseline for comparison of controller performance, as well as to determine an approximate range of controller tunings for the experimental system. In this set of experiments, the retentate flow rate set-point was changed from an initial value of 1.5 gpm to a new value of 0.8 gpm, while the VFD control loop is again maintained at a pressure set-point of 150 psi. In this set of experiments, the performance of the nonlinear controller with integral term is evaluated against the performance of a proportional-integral (PI) controller (both of these controllers are implemented experimentally), and the performance of the nonlinear controller with integral action applied to the dynamic process model via simulations. The feed salt concentration for these experiments was approximately 8200 ppm of NaCl. The tuning parameters for the controllers in this set of experiments can be found in Tables 2 and 3.

The results for these experiments are plotted in Figs. 4 - 5. In Fig. 4, it can be seen that all of the closed-loop results (simulated and experimental) decrease at the same rate initially (due to the valve opening/closing rate constraint). As expected, the simulated nonlinear model-based controller with integral term immediately converges to the set-point with no offset since it is not subject to any plant-model mismatch or measurement noise. As it is evident in Table 2, the integral time constant for the simulated controller is slightly different ($\tau_f = 0.01$, $\tau_f^{sim} = 0.0091$). The simulations where the nonlinear controller was applied to the process model were used to find an approximate range of controller parameters, but these values were implemented on the experimental system and changed slightly to achieve better closed-loop performance in the presence of plant-model mismatch. The speed of the closed-loop response under the nonlinear controller applied to the experimental system is slower in terms of convergence to the set-point than the one in the simulated case and the retentate flow rate reaches the set-point in about 145 seconds. The proportional-integral

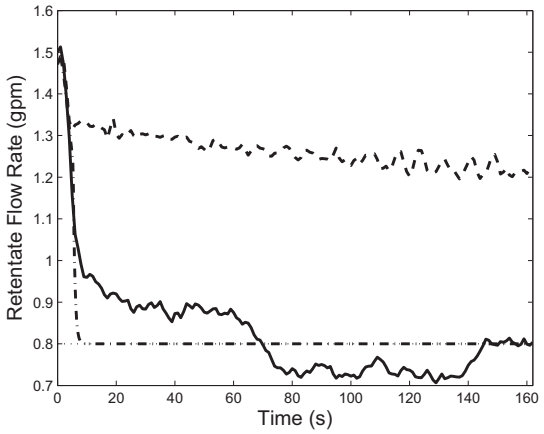

Fig. 4. Profiles of retentate flow rate (Q_r) with respect to time for retentate flow rate set-point transition from 1.5 to 0.8 gpm under proportional-integral control (dashed line), nonlinear model-based control with integral action (solid line) and nonlinear model-based control with integral action implemented via simulation on the process model (dash-dotted line). The horizontal dotted line denotes the retentate flow rate set-point ($Q_r^{sp} = 0.8$ gpm).

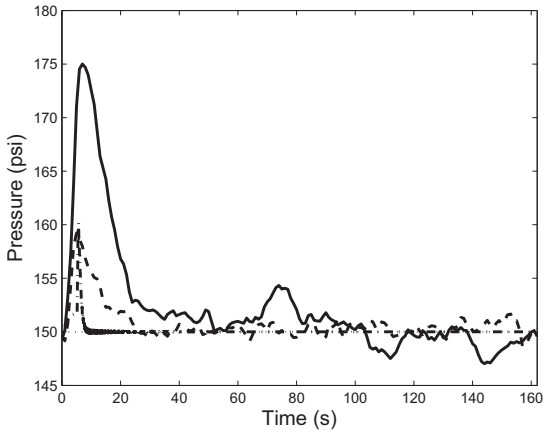

Fig. 5. Profiles of system pressure (P_{sys}) with respect to time for retentate flow rate set-point transition from 1.5 to 0.8 gpm under proportional-integral control (dashed line), nonlinear model-based control with integral action (solid line) and nonlinear model-based control with integral action implemented via simulation on the process model (dash-dotted line). The horizontal dotted line denotes the system pressure set-point ($P_{sys}^{sp} = 150$ psi).

(PI) controller with $\tau_r = 5$ leads to an extremely slow convergence to the set-point (on the order of 10 minutes). It is also seen that when a smaller integral time constant is used, it results in significant oscillations around the set-point due to the coupling between the two control loops. These oscillations cause large fluctuations in the feed flow rate (due to the VFD control loop) and could damage the feed pumps and cause fatigue on system components. Similar results are evident in Fig. 5. The application of the nonlinear controller to the experimental system causes the most deviation from the pressure set-point due to the speed at which it converges to the set-point. It can be seen that the PI controller causes almost no deviation from the set-point (approximately the same as the simulated nonlinear controller) because the convergence (change in valve position) is much slower. As the valve closes, it causes the system pressure to rise, forcing loop I to take action in order to keep the system pressure at the set-point. Slower valve actions allow more time for loop I to act and keep the system pressure at the set-point, such as in the case of the PI control with $\tau_r = 5$. Additional results from the experiments can be seen in the submitted journal paper (Bartman et al. (2009a)).

Periodic Control of Gas-phase Polyethylene Reactors

Al-haj Ali, M., Ali, E.

Chemical Engineering Department, King Saud University
P.O.Box: 800, 11421 Riyadh, Saudi Arabia, (alhajali@ksu.edu.sa)

Abstract: Nonlinear model predictive control algorithm is used for the on-line control of polymer molecular weight distribution. The control of chain-length distribution is achieved by selecting a collection of points in the distribution and using it as set points for the control algorithm. An on-line Kalman filter is used to incorporate infrequent and delayed off-line molecular weight measurements. Through simulation; the control algorithm is evaluated, under tracking conditions as well as plant-model mismatch. The results demonstrate that the control algorithm can regulate the entire molecular weight distribution with high computational efficiency and minimum steady state error.

Keywords: Molecular weight distribution, nonlinear model predictive control, Kalman filter, polymerization reactor control, fluidized bed reactor, polyethylene

1. INTRODUCTION

Polymers today are crucial products that are used in all parts of our daily life. The range of applications includes standard applications as packaging materials and textile fibers, and special ones in the automobile and electrical industries. Molecular weight distribution (MWD) is considered as one of the fundamental properties that determines polymer properties and thus its applications. Therefore, it is important to monitor and control MWD during the industrial production of polymers. A significant amount of research has been done in the area of control, monitoring and modelling of polymerization reactors; Excellent reviews have been given by several researchers (Elicabe and Meira, 1988, Embirucu et al., 1996, Congalidis and Richards, 1998, Richards and Congalidis, 2006). A careful study of previous works, with focus on the description of polymer MWD, results in the following conclusions:

1. Most of the work that was done described polymer MWD by the weight average molecular weight (M_w), in addition to polydispersity index (PDI). Few researchers used the entire molecular weight distribution in their control studies. The use of Mw and PDI to describe polymer quality is helpful. However, sometimes, the molecular weight averages can be misleading when the molecular weight distribution shows bimodalities and/or it has high molecular weight tails. Besides, it is very useful to describe polymer quality by using the entire molecular weight distribution because in many polymer applications such as paints and paper coatings, it is required to specify such distribution properly (Sayer et al., 2001).

2. In polyolefins polymerization, the work done to control the entire MWD of the produced polymer used mixtures of different metallocenes (Chatzidoukas et al., 2007, Heiland and kaminsky, 1992) or a hybrid catalyst of Ziegler-Natta and metallocene catalysts in a one stage process (Shamshoum et al., 2003). The use of single reactor to produce the desired polymer is cost-efficient alternative. However, the mixture of different catalysts may lead to complex undesirable catalyst interactions and non-reproducible catalyst behaviour due to the high variability of the polymerization rate of each catalyst (Nele and Pinto, 2000). Additionally, the implementation of such catalyst systems requires a deep understanding of polymerization mechanisms using these catalysts; which is not a simple task. Finally, this method is still in the research phase and, it may take a long time before it can be (if it is developed successfully) widely implemented in industry. An alternative approach is to vary the polymerization conditions periodically in a single polymerization reactor. The periodic operation of continuous chemical reactors can improve the performance of the reacting system and allow better design and control of the molecular weight distribution in a single reactor (Nele and Pinto, 2000, Schiffino, 1995).

The scope of this work is to investigate the production of polyethylene, in a fluidized bed reactor, with a well-defined molecular weight distribution using nonlinear model predictive controller (NLMPC).

2. PROCESS MODEL

In fluidized-bed polyethylene reactors, the co-polymerization of ethylene and -olefin monomers is carried out using a multi-site Ziegler-Natta catalyst, which consists of three different types of active sites. Each active site produces polymer with molecular weight distribution that can be described by Schulz-Flory distribution. The polyethylene reactor process is depicted in Fig 1. The process model was

developed by (McAuley et al., 1995), modifications made in this model were described in (Ali et al., 2003).

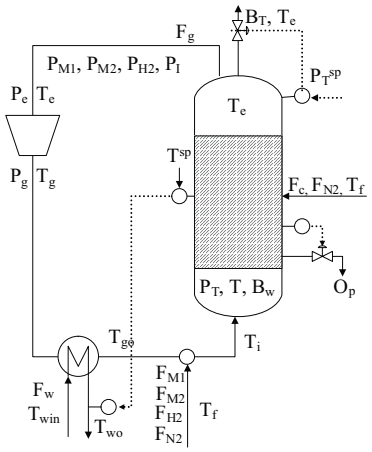

Fig. 1. Polyethylene reactor.

2.1 Molecular Weight Distribution Model

The instantaneous molecular weight distribution for each type of active sites can be described by Flory-Schulz exponential function (Kissin et al., 2005)

$$y_j^d = j \cdot q^2 \cdot \exp(-j \cdot q) \tag{1}$$

with q is the termination probability, j is the number of repeating units and y_j^d instantaneous weight distribution. As assumed above, the catalyst consists of three different active sites and the distribution of the polymers produced by each site type can be represented by Flory's most probable distribution. Thus, the overall distribution of the produced polymer can be calculated by the weighted sum of the three distributions as given below

$$y_{j,ins} = \sum_{i=1}^{3} w_i \cdot (y_j^d)_i \tag{2}$$

where $y_{j,ins}$ is the overall instantaneous molecular weight distribution, and w_i is the mass fraction of each site. The molecular weight distribution of the polymer accumulated in the reactor after a certain polymerization time can be calculated using the following equation:

$$\frac{dy_j}{dt} = \frac{O_p \cdot (y_{j,ins} - y_j)}{B_w} \tag{3}$$

here y_j is the cumulative molecular weight distribution, O_p is polymer production rate and B_w is mass of polymer in the reactor bed. Finally the GPC reading of the MWD is calculated by the following equation:

$$GPC = j \cdot y_j \cdot ln(10) \tag{4}$$

3. ON-LINE NLMPC ALGORITHM

In this work, the structure of the MPC version developed by Ali and Zafiriou (1993) that utilizes directly the nonlinear model for output prediction is used. A usual MPC formulation solves the following on-line optimization:

$$\min_{\Delta u(t_k),\ldots,\Delta u(t_{k+M-1})} \sum_{i=1}^{P} \left\| \Gamma(y(t_{k+i}) - R(t_{k+i})) \right\|^2 + \sum_{i=1}^{M} \left\| \Lambda \Delta u(t_{k+i-1}) \right\|^2 \tag{5}$$

subject to

$$A^T \Delta U(t_k) \le b \tag{6}$$

For nonlinear MPC, the predicted output, y over the prediction horizon P is obtained by the numerical integration of:

$$\frac{dx}{dt} = f(x,u,t) \tag{6}$$

$$y = g(x) \tag{7}$$

from t_k up to t_{k+P} where x and y represent the states and the output of the model, respectively. The symbols || . || denotes the Euclidean norm, k is the sampling instant, Γ and Λ are diagonal weight matrices and $R = [r(k+1) \ldots r(k+P)]^T$ is a vector of the desired output trajectory. $\Delta U(t_k)=[\Delta u(t_k) \ldots \Delta u(t_{k+M-1})]^T$ is a vector of M future changes of the manipulated variable vector u that are to be determined by the on-line optimization. The control horizon (M) and the prediction horizon (P) are used to adjust the speed of the response and hence to stabilize the feedback behavior. Γ is usually used for trade-off between different controlled outputs. The input move suppression, Λ, on the other hand, is used to penalize different inputs and thus to stabilize the feedback response. The objective function (Eq. 5) is solved on-line to determine the optimum value of $\Delta U(t_k)$. Only the current value of Δu, which is the first element of $\Delta U(t_k)$, is implemented on the plant. At the next sampling instant, the whole procedure is repeated.

To compensate for modeling error and eliminate steady state offset, a regular feedback is incorporated on the output predictions, $y(t_{k+1})$ through an additive disturbance term. Therefore, the output prediction is corrected by adding to it the disturbance estimates. The latter is set equal to the difference between plant and model outputs at present time k as follows:

$$d(k) = y_p(k) - y(k) \tag{7}$$

The disturbance estimate, d, is assumed constant over the prediction horizon due to the lack of an explicit means of predicting the disturbance. However, for severe modeling errors, or open-loop unstable processes the regular feedback is not enough to improve the NLMCP response. Hence, state or parameter estimation is necessary to enhance the NLMPC performance in the face of model-plant mismatch. In this work, Kalman filtering (KF) will be incorporated to correct the model state and thus, to address the robustness issue. Utilization of the NLMPC with KF requires adjusting an additional parameter, σ. More details on the integration of KF

with the NLMCP algorithm are given elsewhere (Ali and Zafiriou, 1993). In addition to state estimation by KF, the predicted output will be also corrected by the additive disturbance estimates of Eqn.7.

The main objective of the NLMPC is to control the entire MWD. It is also necessary to maintain acceptable polymer production rate. Process stability is another important issue which is handled through regulating the total gas pressure and the bed temperature. These two controlled variables are adapted via separate PI control loops. The design and tuning parameters of these loops are given elsewhere (Ali et al., 2003).

4. RESULTS AND DISCUSSION

It is worth mentioning that determining input trajectories that provide the desired distribution is difficult as the final polymer quality is sensitive to hydrogen concentration (X) value and the mass of the produced polymer. In this sense, maintaining the desired MWD during process operation is even more challenging. In the presence of model-plant mismatch and/or when unmeasured disturbances enter the plant, the situation becomes more complex. The control objective here is to produce broad polyethylene with well-defined MWD starting from narrow distribution and maintain it there. The results of this case are shown in Figs. 2 and 3. Four manipulated variables, which are the monomer, hydrogen, nitrogen and catalyst flow rates, are used. The weighting factors for these inputs are Λ=[0 0 20 50]. Four controlled variables, which represent specific points in the target MWD, are considered as shown by the dots in Fig 3. The weighting factor for all outputs is given the same value of Γ=[1 1 1 1]×100. The lower limit for the manipulated variables is set to zero and the upper limit is set to twice their nominal values. The MWD target function contains 103 points, however only four points were selected as controlled outputs to reduce the computation effort consumed by the NLMPC calculations. The input horizon (M) and output horizon (P) are taken equal to 1 and 4, respectively. A sampling time of 1 hr is used. Usually the GPC measurements are available at low frequency. Advanced measurement sensors that can provide measurements in the order of minutes are available but at high cost.

Fig. 3 demonstrates the ability of NLMPC to maintain the new set point for the polymer distribution with minor distortion in the distribution function. More interesting is the response of the manipulated variables as shown in Fig. 2. The resulted response of the manipulated variables is in the form of periodic functions. Long prediction and moving horizon capability of NLMPC helped the controller to understand the dynamic nature of the process to an extent that it produced cyclic input sequences. Moreover, Fig. 2 shows how the bleed flow rate (B_T) and the cooling water inlet temperature (T_w) varies by separate PI controllers to maintain the total pressure at 20 atm and the reactor temperature at 82 ^oC. Note that the manipulated variables used by NLMPC are plotted in discrete form because the NLMPC works in discrete time fashion.

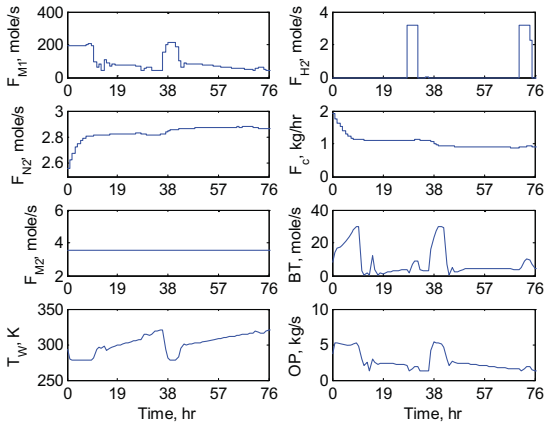

Fig. 2. Manipulated variable response using NLMPC.

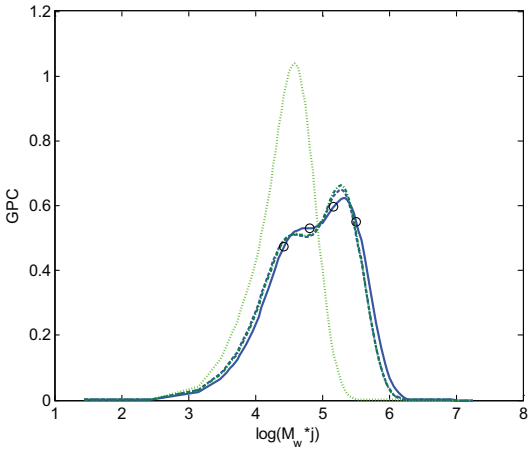

Fig. 3. MWD using NLMPC. Dotted line: initial distribution, solid: target, dashed: controlled distribution.

Next the algorithm was tested for targeting another MWD. In this case, seven points on the GPC curve is taken as the controlled variables with their weights are fixed at G=[1 100 100 200 100 50] ×102. The lower limit of F_{M1} is set to 40 mole/s to keep high monomer concentration in the reactor. The value of the rest of the parameters remains the same as before. The simulation results are shown in Figs. 4 - 5. Evidently, NLMPC generated suitable periodic input sequences that produce MWD close to the desired one as shown in Fig. 5. The MWD suffered from minor distortion; however exact match of the target function is not necessary especially when we know that the relative error in GPC measurements is around 10%. This outcome can be obtained at shorter simulation time. The small production rate is obvious from Fig. 4; in fact, the average production rate is found to be 2.42 kg/s. To improve the production rate, the latter is incorporated as a controlled variable in the NLMPC algorithm. Using γ=0.1 for the production rate, NLMPC managed to increase the polymer production to 2.86 kg/s but with notable loss of the MWD. Results are not shown here for simplicity. Increasing the weight of the designated

controlled output further will of course propagates the production rate but the MWD will depart away from the desired set point. Our investigation revealed the existence of trade-off between the production rate and broadening the MWD. Widening the distribution requires pronounced changes in hydrogen concentration inside the reactor. Increasing hydrogen concentration is achieved by feeding more hydrogen to the reactor this reduces ethylene polymerization rate and as a consequence reduces the overall production rate. Whereas, reducing hydrogen concentration is achieved by opening the vent (Lo and Ray, 2006) that allows hydrogen concentration in the reactor to escape, causing hydrogen concentration to fall quickly. Such reduction in the concentration affects positively on the production rate.

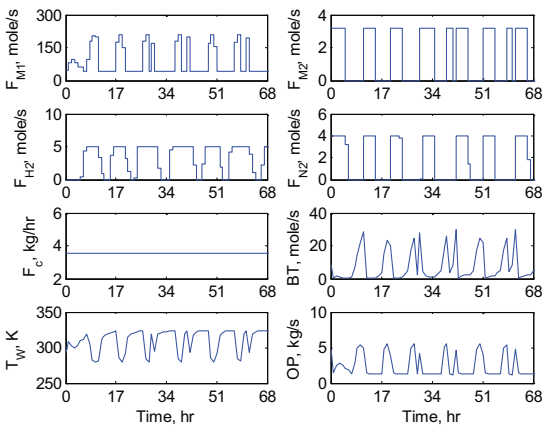

Fig. 4. Manipulated variable response using NLMPC. Decreasing polymer average molecular weight.

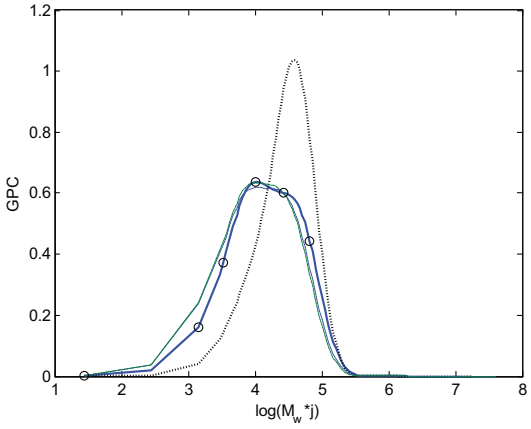

Fig. 5. MWD using NLMPC. Dotted line: initial distribution, solid: target, dashed: controlled distribution.

The previous simulations are carried out assuming perfect model. However, this is not always true in real practice. To test the robustness of NLMPC to reject the effect of modeling errors, the simulation of targeting higher molecular weight is repeated with−20% error in the reaction rate constant and catalyst activity. The results are shown in Figs. 6 - 7. It is evident that NLMPC is able to keep good control performance despite minor loss of controller performance.

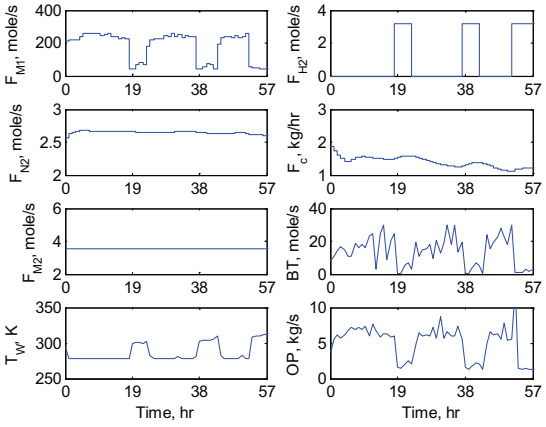

Fig. 6. Manipulated variable response using NLMPC in the presence of -20% in catalyst activation and reaction rate constant.

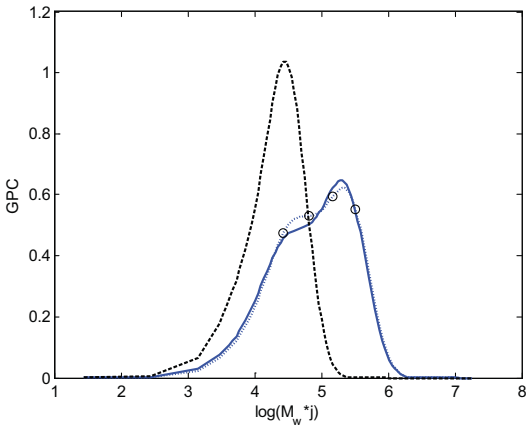

Fig. 7. MWD using NLMPC in the presence of -20% error in catalyst activation and reaction rate constant. Dotted line: initial distribution, solid: target, dashed: controlled distribution.

It is worth mentioning that controller performance could be improved more if the dynamics of hydrogen is faster. Since, hydrogen is not consumed in the reactor and large fluctuations in hydrogen concentration are required to broaden polymer distribution, improving controller performance would not be an easy task. This challenge can be solved using either a catalyst that is highly-sensitive to hydrogen as metallocenes or hydrogen consuming agent. The first approach depends on implementing a relatively new catalyst that is not widely used industrially (Galli and Vecellio, 2001). The second approach still needs more investigation to prove its applicability for the studied process. Finally, note that venting is usually used to reduce hydrogen concentration, as described above, however; venting reactor contents is not an economical choice because monomer also

escapes from the reactor. Nonetheless, no other choices are available.

5. CONCLUSIONS

In industrial applications, the molecular weight distribution of the produced polymer is usually measured using molecular weight averages and polydispersity index. In this article, we have presented an on-line MWD control technique to produce polymers with a target distribution in a fluidized-bed polymerization process. This strategy uses detailed polymerization process model, and Kalman filter to correct model states. A NLMPC controller is designed to control polymer MWD and polymerization process productivity. For the calculation of the MWD, selected points in polymer distribution curve are used as set-points for the controller that manipulates monomer, hydrogen, nitrogen and catalyst feed rates. To test the feasibility of the proposed MWD control technique, simulations have been carried out for ethylene gas-phase polymerization using conventional Zielger-Natta catalyst. The simulations suggest that the proposed control strategy can be useful new technique to control the MWD of polymer in continuous polymerization processes. The performance of the developed control algorithm can be improved more if the dynamic response of hydrogen concentration inside the polymerization reactor is less sluggish.

Abstract: The goal of this paper is to propose suitable control methods for controlling of the highly nonlinear system represented by the mathematical model of the continuous stirred tank reactor (CSTR) with so called van der Vusse reaction inside. Temperature of the reactant is controlled by the heat removal of the cooling liquid in the reactor's jacket. Two control strategies were suggested – adaptive control and predictive control. The adaptive approach uses recursive identification for the optimal setting of the controller. The predictive control computes input sequence by the minimizing of the cost function constructed by the difference between output variable and reference signal. Both control strategies shows good control results and pertinence for the controlling of such type of systems.

1. INTRODUCTION

Unfortunately, most of the processes in the technical praxis have nonlinear properties. Typical example of the nonlinear system can be found in the chemical or the biochemical industry where so called chemical reactor is used for production of the several chemicals or drugs (Corriou, 2004).

Controlling of these devices with the conventional methods where parameters of the controller are set at the beginning fixed during the control could result in non-optimal control responses because of changing parameters of the system. This inconvenience could be overcome with use of other control strategies which takes into account these changes, for example adaptive or predictive control. These two control strategies are compared in this paper in order to compare obtained simulation results.

The basic idea of adaptive control is that parameters or the structure of the controller are adapted to parameters of the controlled plant according to the selected criterion (Bobál *et al.*, 2005). Adaptation can be done for example by the modification of the controller's parameters by the change of the controller's structure or by generating an appropriate input signal, which is called "adaptation by the input signal".

The polynomial synthesis (Kučera, 1993) is one of the methods used in adaptive control for control synthesis of the system. This method is based on the input-output model of the controlled system or its transfer function. It can be classified as an algebraic method and is based on algebraic operations in the ring of polynomials. Polynomials are usually described in *s*-plane for continuous systems, in *z*-plane for discrete systems and in δ-plane for systems which come from δ-models of both the controlled system and the controller too (Middleton and Goodwin, 2004) and (Mukhopadhyay *et al.*, 1992).

One of the biggest advantages of the polynomial method compared to the conventional method is that it provides not only relations for computing of the controller's parameters but the structure of the controller too. This structure fulfils general requirements for control systems and input signals (reference signal and disturbance) and it can be used for controlling of the systems with negative properties from the control point of view, such as non-minimum phase systems or unstable systems. Another advantage is that the resulted relations are easily programmable.

Polynomials in the numerator and denominator of the transfer function of the controller result from the solution of Diophantine equations, which have so called characteristic polynomial of the closed loop system on the right side of the equation. The roots of this polynomial are then poles of the closed-loop system, which affects the quality of control. The method of choosing the poles is called Pole-placement or Pole-assignment (Kučera, 1991).

The idea of the predictive control is based on the calculation of the control sequence from the actual time point minimizing the deviation of the reference signal and the output signal of the plant in the future horizon (Clarke *et al.*, 1987). The future values of the reference signal are given in advance or are assumed to be equal to the present one. The future values of the plant can be predicted from a process model. If disturbances are measurable, then their future values are predicted using some assumptions.

All approaches are verified by the simulation in the simulation program Matlab®, version 6.5.

2. ADAPTIVE CONTROL

The adaptive approach in this work is based on choosing an external linear model (ELM) of the original nonlinear system

whose parameters are recursively identified during the control. Parameters of the resulted continuous controller are recomputed in every step from the estimated parameters of the ELM (Bobál *et al.*, 2005).

2.1 External Linear Model

The main types of ELM are continuous-time (CT) models and discrete-time (DT) models.

The general description of the CT ELM can be formulated via transfer function $G(s)$:

$$G(s)=\frac{b(s)}{a(s)}=\frac{Y(s)}{U(s)}=\frac{b_m s^m+b_{m-1}s^{m-1}+\ldots+b_1 s+b_0}{a_n s^n+a_{n-1}s^{n-1}+\ldots+a_1 s+a_0} \tag{1}$$

The continuous-time ELM is supposed to be more accurate and corresponding to the real model because data are estimated continuously during the control. On the contrary, CT identification is difficult.

On the other hand, identification of the DT models are easy to realize. We can say that discrete models are used in the cases where the usage of continuous ones is complicated or the realization is impossible. An important variable in the discrete-time models is sampling period T_v.

The transfer function G in this case is defined as Z-transform of the output variable y to the input variable u

$$G(z)=\frac{Y(z)}{U(z)}=\frac{b(z)}{a(z)}=\frac{b_m z^m+b_{m-1}z^{m-1}+\ldots+b_1 z+b_0}{a_n z^n+a_{n-1}z^{n-1}+\ldots+a_1 z+a_0} \tag{2}$$

where $a(z)$ and $b(z)$ are discrete polynomials and $U(z)$ and $Y(z)$ are Z-transform images of the input and output variables.

2.2 Identification

The use of the discrete model for nonlinear system can cause problems with the sampling period T_v. This sampling period cannot be small because of the stability and the big sampling period is unacceptable because we do not know what will happen with the system during this sample.

The inconvenience with the sampling period could be overcome with the use of so called delta (δ-) models. Although the delta operator belongs to the class of discrete models with the operator described as

$$q\cdot x(k)\triangleq x(k+1) \tag{3}$$

it can been seen from

$$\delta=\frac{q-1}{T_v} \tag{4}$$

that this operator is related to sampling period T_v and it means that δ-models are close to the continuous ones in d/dt.

A new complex variable in "δ" plane called "γ", which is defined for example in (Mukhopadhyay *et al.*, 1992) as

$$\gamma=\frac{z-1}{\beta\cdot T_v\cdot z+(1-\beta)\cdot T_v} \tag{5}$$

need to be introduced. We can obtain an infinite number of δ–models for different values of optional parameter β in Equation (5) from the range $0\le\beta\le 1$.

The forward δ-model described for $\beta = 0$ by

$$\gamma=\frac{z-1}{T_v} \tag{6}$$

is dealt with in this work.

The Recursive Least-Squares (RLS) method is used for the parameter estimation in this work. The RLS method is well-known and widely used for the parameter estimation (Fikar and Mikleš, 1999). It is usually modified with some kind of forgetting, exponential or directional (Kulhavý and Karny, 1984), because parameters of the identified system can vary during the control which is typical for nonlinear systems and the use of some forgetting factor could result in better output response.

The RLS method with exponential forgetting is describe by the set of equations:

$$\begin{aligned}
&\varepsilon(k)=y(k)-\varphi^T(k)\cdot\hat{\theta}(k-1)\\
&\gamma(k)=\left[1+\varphi^T(k)\cdot\mathbf{P}(k-1)\cdot\varphi(k)\right]^{-1}\\
&\mathrm{L}(k)=\gamma(k)\cdot\mathbf{P}(k-1)\cdot\varphi(k)\\
&\mathbf{P}(k)=\frac{1}{\lambda_1(k-1)}\left[\mathbf{P}(k-1)-\frac{\mathbf{P}(k-1)\cdot\varphi(k)\cdot\varphi^T(k)\cdot\mathbf{P}(k-1)}{\lambda_1(k-1)+\varphi^T(k)\cdot\mathbf{P}(k-1)\cdot\varphi(k)}\right]\\
&\hat{\theta}(k)=\hat{\theta}(k-1)+\mathrm{L}(k)\varepsilon(k)
\end{aligned} \tag{7}$$

Several types of exponential forgetting can be used, e.g. like RLS with constant exponential forgetting, RLS with increasing exp. forgetting etc. RLS with the changing exp. forgetting is used for parameter estimation, where the changing forgetting factor λ_1 is computed from the equation

$$\lambda_1(k)=1-K\cdot\gamma(k)\cdot\varepsilon^2(k) \tag{8}$$

Where K is small number, in our case $K = 0.001$.

2.3 Polynomial Synthesis

The structure of the controller is designed via polynomial synthesis. The simple one degree-of-freedom (1DOF) control configuration was used. The block scheme of this configuration in Fig. 1.

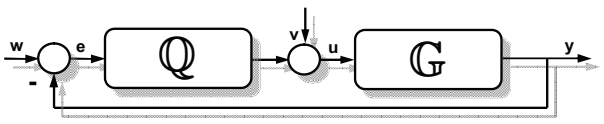

Fig. 1 1DOF control configuration

Block Q in Fig. 1 represents the transfer function of the controller, G denotes the transfer function of the plant, w is

the reference signal, e is used for the control error, v is the disturbance at the input to the system, u determines the input variable, and finally y is the output variable.

Transfer functions of the controller and controlled plant could be described in the continuous time by equations:

$$Q(s)=\frac{q(s)}{s\cdot p(s)};\ G(s)=\frac{b(s)}{a(s)} \tag{9}$$

where polynomials $p(s)$ and $q(s)$ are designed by the polynomial approach and parameters of these polynomials are computed by the Method of uncertain coefficients which compares coefficients of individual s-powers from Diophantine equation (Kučera, 1993):

$$a(s)\cdot s\cdot p(s)+b(s)\cdot q(s)=d(s) \tag{10}$$

Although parameters of the polynomials $a(s)$ and $b(s)$ are reflected to be in continuous-time, the identification runs recursively in discrete time periods related to the sampling period T_v. This simplification is supported by the use of δ-models where each input and output variable is recomputed to this sampling period, T_v, which shifts these discrete polynomials closer to the continuous ones. It was proofed for example in (Stericker and Sinha, 1993) that the parameters of the delta model for the small sampling period approach to the continuous ones in (9).

The feedback controller $Q(s)$ in Fig. 1 ensures all basic control requirements – i.e. stability, load disturbance attenuation and asymptotic tracking of the reference signal. It is required that each controller could be tuned somehow. This option can be found in this controller in the stable optional polynomial $d(s)$ on the right side of the Diophantine equation (10). As it is mentioned above, there are several methods for choosing of this polynomial. The method used here is Pole-placement or Pole-assignment method. Polynomial $d(s)$ can be divided into two parts – $m(s)$ and $n(s)$, so

$$d(s)=m(s)\cdot n(s) \tag{11}$$

where polynomial $n(s)$ is computed from the spectral factorization of polynomial $a(s)$ in the denominator of the transfer function $G(s)$ (9)

$$n^*(s)\cdot n(s)=a^*(s)\cdot a(s) \tag{12}$$

and polynomial $m(s)$ is a stable one $m(s)=(s+\alpha_i)^{\deg d-\deg n}$ and $\alpha_i>0$ are (deg d – deg n) optional stable roots, usually called poles of the control system. A disadvantage of this method can be found in the uncertainty of the polynomial $m(s)$ – there is no general rule how to choose roots α_i.

3. PREDICTIVE CONTROL

3.1 Generalized Predictive Control

Generalized Predictive Control (GPC) is one of the most popular predictive methods based on Model Predictive Control (MPC) (Clarke *et al.*, 1987), and has been successfully used in praxis for different types of control problems from this time.

The GPC has many common ideas with the ordinary predictive methods but it has some differences to such as the solution of the GPC controller is analytical, it can be used for unstable and non-minimum phase systems etc.

The general single-input single-output (SISO) after linearization can be described through the discrete backshift operators z^{-1} as

$$A(z^{-1})\cdot y(t)=z^{-d}\cdot B(z^{-1})\cdot u(t-1)+C(z^{-1})\cdot e(t) \tag{13}$$

where $u(t)$ is control variable, $y(t)$ output variable, $e(t)$ denotes a zero mean white noise, and d is dead time of the system. Polynomials $A(z^{-1})$, $B(z^{-1})$ and $C(z^{-1})$ are

$$\begin{aligned}A(z^{-1})&=1+a_1z^{-1}+a_2z^{-2}+\ldots+a_{n_a}z^{-n_a}\\ B(z^{-1})&=b_0+b_1z^{-1}+b_2z^{-2}+\ldots+b_{n_b}z^{-n_b}\\ C(z^{-1})&=1+c_1z^{-1}+c_2z^{-2}+\ldots+c_{n_c}z^{-n_c}\end{aligned} \tag{14}$$

Equation (23) is called the *Controller Auto-Regressive Moving-Average* (CARMA) *model*. This model is not suitable in most industrial processes where disturbances are non-stationary. In these cases, the integrated CARMA (CARIMA) model is more suitable

$$A(z^{-1})\cdot y(t)=z^{-d}\cdot B(z^{-1})\cdot u(t-1)+C(z^{-1})\cdot\frac{e(t)}{\Delta} \tag{15}$$

where $\Delta=1-z^{-1}$.

The GPC algorithm can be then formulated as minimization of the cost function

$$\begin{aligned}J_{GPC}=&\sum_{j=N_1}^{N_2}\delta_u(j)\left[\hat{y}(t+j|t)-w(t+j)\right]^2+\ldots\\ &\ldots+\sum_{j=1}^{N_u}\lambda_u(j)\left[\Delta u(t+j-1)\right]^2\end{aligned} \tag{16}$$

where $\hat{y}(t+j|t)$ is an optimum j-ahead prediction of the output on data up to time t, further, N_1 and N_2 denote minimum and maximum costing horizons, respectively, N_u is control horizon, $w(t+j)$ means reference signal, Δu stands for manipulated variable and finally $\delta_u(j)$ and $\lambda_u(j)$ denote weighting sequences.

The values of these factors are for simplification assigned as $\delta_u=1$, and λ_u is constant through the whole time interval of the control.

4. MODEL OF THE PLANT

The nonlinear system under the consideration is the Continuous Stirred Tank Reactor (CSTR). The reaction inside the reactor is called *van der Vusse* reaction can be described by the following reaction scheme (Chen, *et al.*, 1995):

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C$$
$$2A \xrightarrow{k_3} D \qquad (17)$$

The graphical scheme of this reactor can be seen in Fig. 2

The mathematical model of this reactor is described by the following set of ordinary differential equations (ODE):

$$\frac{dc_A}{dt} = \frac{q_r}{V_r}\left(c_{A0} - c_A\right) - k_1 c_A - k_3 c_A^{\,2} \qquad (18)$$

$$\frac{dc_B}{dt} = -\frac{q_r}{V_r} c_B + k_1 c_A - k_2 c_B \qquad (19)$$

$$\frac{dT_r}{dt} = \frac{q_r}{V_r}\left(T_{r0} - T_r\right) - \frac{h_r}{\rho_r c_{pr}} + \frac{A_r U}{V_r \rho_r c_{pr}}\left(T_c - T_r\right) \qquad (20)$$

$$\frac{dT_c}{dt} = \frac{1}{m_c c_{pc}}\left(Q_c + A_r U\left(T_r - T_c\right)\right) \qquad (21)$$

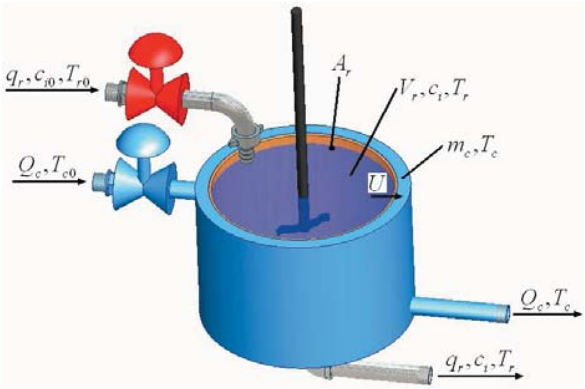

Fig. 2: Continuous Stirred Tank Reactor (CSTR)

This set of ODE together with simplifications then mathematically represents examined CSTR reactor. The model of the reactor belongs to the class of *lumped-parameter nonlinear systems*. Fixed parameters of the system are shown in Table 1 (Chen, *et al*., 1995).

Table 1 Fixed parameters of CSTR

$k_{01} = 2.145 \cdot 10^{10}\ min^{-1}$	$k_{02} = 2.145 \cdot 10^{10}\ min^{-1}$
$k_{03} = 1.5072 \cdot 10^{8} min^{-1}.mol^{-1}$	$E_1/R = 9758.3\ K$
$E_2/R = 9758.3\ K$	$E_3/R = 8560\ K$
$h_1 = -4200\ kJ.kmol^{-1}$	$h_2 = 11000\ kJ.kmol^{-1}$
$h_3 = 41850\ kJ.kmol^{-1}$	
$V_r = 0.01\ m^3$	$\rho_r = 934.2\ kg.m^{-3}$
$c_{pr} = 3.01\ kJ.kg^{-1}.K^{-1}$	$q_r = 2.365 \cdot 10^{-3}\ m^3 min^{-1}$
$c_{pc} = 2.0\ kJ.kg^{-1}.K^{-1}$	$Q_c = -18.5583\ kJ.min^{-1}$
$U = 67.2\ kJ.min^{-1}m^{-2}K^{-1}$	$A_r = 0.215\ m^2$
$c_{A0} = 5.1\ kmol.m^{-3}$	$c_{B0} = 0\ kmol.m^{-3}$
$T_{r0} = 387.05\ K$	$m_c = 5\ kg$

The reaction heat (h_r) in eq. (20) is expressed as:

$$h_r = h_1 \cdot k_1 \cdot c_A + h_2 \cdot k_2 \cdot c_B + h_3 \cdot k_3 \cdot c_A^2 \qquad (22)$$

where h_i means reaction enthalpies.

Nonlinearity can be found in reaction rates (k_j) which are described via Arrhenius law:

$$k_j\left(T_r\right) = k_{0j} \cdot \exp\left(\frac{-E_j}{RT_r}\right), \text{ for } j = 1,2,3 \qquad (23)$$

where k_0 represent pre-exponential factors and E are activation energies.

Static analysis has shown (Vojtesek, *et al.*, 2004), that system has an optimal working point for volumetric flow rate of the reactant $q_r = 2.365 \times 10^{-3}\ m^3.min^{-1}$ a heat removal $Q_c = -18.56\ kJ.min^{-1}$. The difference between actual and initial temperature of the reactant T_r was taken as controlled output and changes of the heat removal Q_c was set as control input, i.e.

$$y(t) = T_r(t) - T_r^s(t)\,[K]$$
$$u(t) = 100 \cdot \frac{Q_c(t) - Q_c^s(t)}{Q_c^s(t)}\,[\%] \qquad (24)$$

On the other hand, dynamic analysis results in ELM represented by a second order transfer function with relative order one, which is generally:

$$G(s) = \frac{b(s)}{a(s)} = \frac{b_1 s + b_0}{s^2 + a_1 s + a_0} \qquad (25)$$

Equation (25) can be rewritten for the identification to the form of the differential equation

$$y_\delta(k) = -a_1 y_\delta(k-1) - a_0 y_\delta(k-2) + \\ + b_1 u_\delta(k-1) + b_0 u_\delta(k-2) \qquad (26)$$

where y_δ is recomputed output to the δ-model:

$$y_\delta(k) = \frac{y(k) - 2y(k-1) + y(k-2)}{T_v^2}$$
$$y_\delta(k-1) = \frac{y(k-1) - y(k-2)}{T_v} \quad y_\delta(k-2) = y(k-2) \qquad (27)$$
$$u_\delta(k-1) = \frac{u(k-1) - u(k-2)}{T_v} \quad u_\delta(k-2) = u(k-2)$$

where T_v is the sampling period, the data vector is

$$\phi^T(k-1) = \left[-y_\delta(k-1), -y_\delta(k-2), u_\delta(k-1), u_\delta(k-2)\right] \qquad (28)$$

and the vector of estimated parameters

$$\hat{\Theta}^T(k) = \left[\hat{a}_1, \hat{a}_0, \hat{b}_1, \hat{b}_0\right] \qquad (29)$$

could be computed from the ARX (Auto-Regressive eXogenous) model

$$y_\delta(k) = \hat{\Theta}^T(k)\phi(k-1) \qquad (30)$$

by the recursive least squares methods described in part 2.2.

The ELM is of the second order, which means that degrees of polynomials $p(s)$, $q(s)$, and $d(s)$ are then:

$$\deg q = 2; \deg p = 1; \deg d = 4 \qquad (31)$$

and polynomials $m(s)$ and $n(s)$ in the equation (11) are

$$n(s) = s^2 + n_1 s + n_0; \quad m(s) = \left(s + \alpha_i\right)^{\deg d - \deg n} = \left(s + \alpha_i\right)^2 \qquad (32)$$

and coefficients of the polynomial $n(s)$ are computed via spectral factorization (12) as

$$n_0 = \sqrt{a_0^2}, n_1 = \sqrt{2n_0 + a_1^2 - 2a_0} \tag{33}$$

Transfer functions of the feedback and feedforward parts of the controller for 1DOF and 2DOF configurations are

$$Q(s) = \frac{q_2 s^2 + q_1 s + q_0}{s(s + p_0)} \tag{34}$$

Where parameters of the polynomials $q(s)$ and $p(s)$ by the comparison of the coefficients of the s-powers a in diophantine equations (10).

The identified parameters of the delta ELM from the predictive control were recomputed to the discrete-time ELM:

$$G(z^{-1}) = \frac{-0.0021z^{-1} + 0.0010z^{-2}}{1 - 1.5851z^{-1} + 0.6197z^{-2}} \tag{35}$$

which was used for computation of the predictive controller in Equation (25). Zero mean white noise $e(t)$ is not take into account.

5. SIMULATION RESULTS

Both control strategies were verified by simulation experiments. The sampling period was set to $T_v = 0.3$ *min*, all simulations took 500 min and 5 different step changes $w = [2, -1, 1\ -1, 1.5]$ were done during this interval.

The first simulation study was done for adaptive controller with the various values of the root α_i = 0.05, 0.1 and 0.2 in Equation (32). The predictive controller was verified again for different values of the weighting factor λ_u = 0.05, 0.5 and 2 in (16).

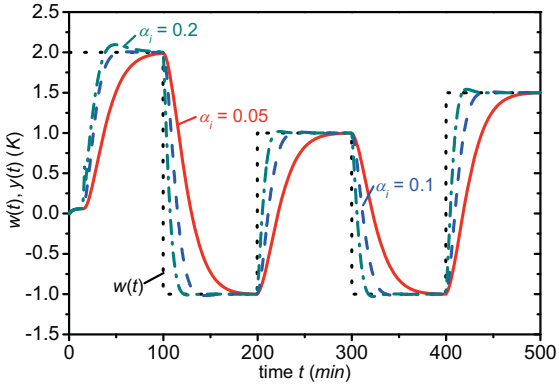

Fig. 3: Course of the reference signal $w(t)$ and the output variable $y(t)$ for various of the root α_i in adaptive control

Figures 3 and 4 represents simulation results for adaptive control. It can be clearly seen, that the increasing value of the parameter α_i results in the quicker output response, $y(t)$, but small overshoots. On the other hand, lower value of this root position is parsimonious to the input variable, $u(t)$, in Fig. 4 which could be in this case considered as a twist of the valve on the feeding of the cooling pipe.

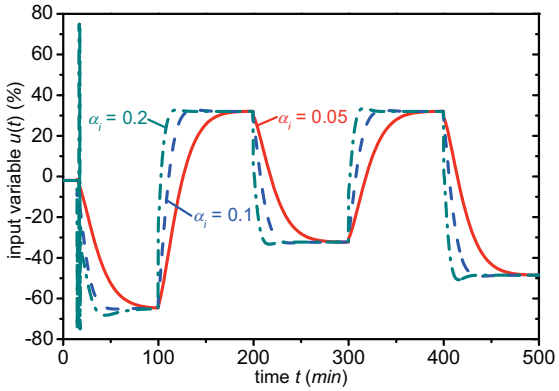

Fig. 4: Course of the input variable $u(t)$ for various of the root α_i in adaptive control

The quality of control was evaluated by the quality criteria S_u and S_y computed for a time interval as:

$$S_u = \sum_{i=2}^{N} \left(u(i) - u(i-1)\right)^2 [-]; \quad S_y = \sum_{i=1}^{N} \left(w(i) - y(i)\right)^2 [K^2] \quad \text{,for } N = \frac{T_f}{T_v}. \tag{36}$$

The results for both control strategies are shown in Table 2.

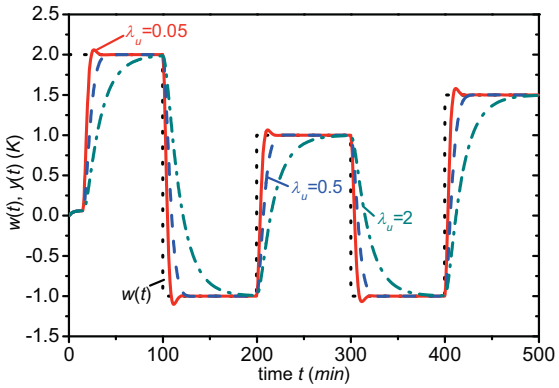

Fig. 5: Course of the reference signal $w(t)$ and the output variable $y(t)$ for various of the root λ_u in predictive control

The simulation results of the second control strategy, predictive control, are shown in Fig. 5 and Fig. 6. This controller is tuned via weighting parameter λ_u which is constant during the control and the second weighting parameter is δ_u = 1 as it is written above in the theoretical part. In this case, increasing value of the λ_u results in slower response of the output variable $y(t)$.

The last two graphs in Fig. 7 and Fig. 8 compares the best results for both control strategies – adaptive control with α_i = 0.1 and predictive control with λ_u = 0.5.We can say, that in this case both control strategies are comparable but the output response $y(t)$ in the predictive control reaches the reference signal (wanted value) $w(t)$ a little bit quicker than the adaptive controller.

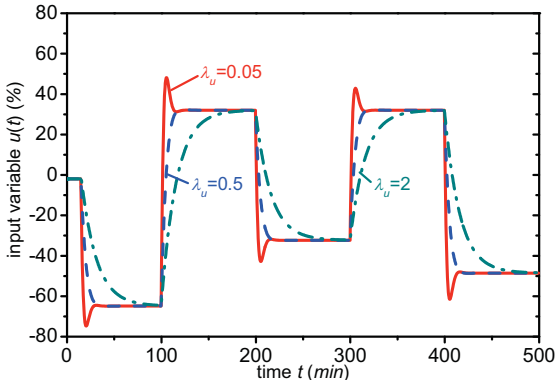

Fig. 6: Course of the input variable $u(t)$ for various of the root λ_u in predictive control

Table 2 The results of control quality criteria S_u and S_y

	Adaptive control, α_i =			**Predictive control, λ_u =**		
	0.05	0.1	0.4	0.05	0.5	2
S_u[-]	192.4	492.3	8571.5	3265.1	868.3	265.3
S_y[K^2]	1664.4	934.7	532.7	430.3	653.3	1194.8

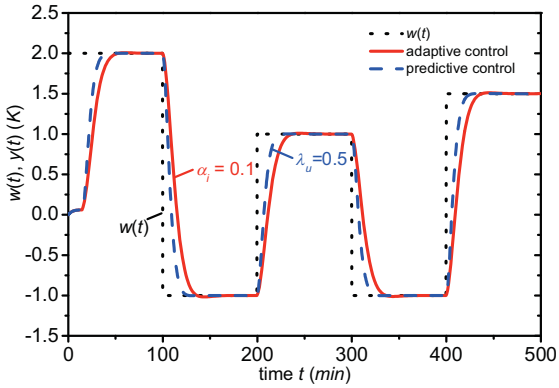

Fig. 7: The best courses of the output variable $y(t)$ for adaptive and predictive control

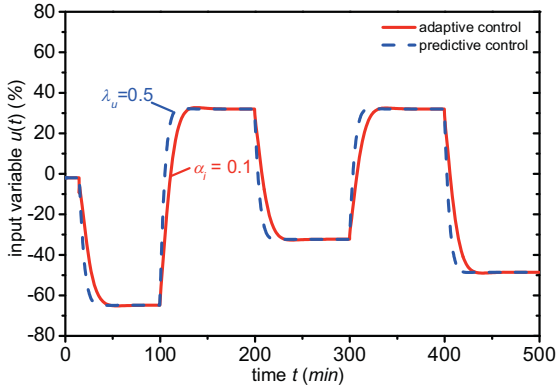

Fig. 8: The best courses of the input variable $u(t)$ for adaptive and predictive control

6. CONCLUSIONS

This paper presents two approaches which could be used for controlling of the temperature of the reactant inside the CSTR which is typical member of the nonlinear process with lumped parameters. Both, adaptive and predictive, controllers have good control results although the system has negative properties from the control point of view. The adaptive controller could be tuned by the parameter α_i while predictive controller has its weighting factor λ_u as a tuning parameter too. Final comparison of both control techniques results better for the predictive controller but the difference is minimal. The future work will be focused on the verification of the obtained results on the real plant which could increase reliability of these methods.

Abstract: More than 70% of the oil production in Brazil employs gas-lift as the artificial lift method. An effort is being done by some operators to complete new gas-lift wells with down hole pressure gages. This paper proposes a Non-Linear MPC algorithm to control a group of wells receiving gas from a common Gas-Lift Manifold. The objective is to maximize an economic function while minimizing the oscillations of the pressures at the manifold and at the bottom of the wells.

Keywords: Gas-Lift, Nonlinear MPC,

1. INTRODUCTION

Advanced Control Techniques like Nonlinear MPC have not arrived yet at the upstream processes of the oil industry. Many gas-lift wells with significant daily production are operating with manual driven gas injection and production chokes. In the last few years some Petroleum Exploration and Production companies have initiated efforts to introduce automation and control techniques in the operation of production wells. These initiatives resulted in technical approaches with names as smart wells, intelligent wells, smart fields or Digital Oilfield Management-GEDIG in Petrobras, Campos et al. (2006). The introduction of Information Technology in the oil production system is slow mainly due to the prohibitive cost of well intervention to install new sensors and actuators. Apart from that, sensors and actuators to be used in oil wells will have to cope with very harsh conditions caused by high pressure, temperatures and vibrations. There are several important works related to modeling, control and optimization of gas-lift wells operations like Boisard et al. (2002), Eikrem et al. (2004), L. Singre and Lemetayer (2006), Imsland et al. (2003), Camponogara and Nakashima (2006), Plucenio et al. (2006) to cite only a few. Not all control and optimization techniques discussed in the literature will be ready to be applied with the present instrumentation level of most gas-lift wells. This work discuss the automation of gas-lift wells equipped with downhole pressure measurement sensor, gas injection control valve and manually operated production choke. This is a realistic scenario in Brazil for new gas-lift wells. To our knowledge this is the first work that attempts to control the Gas Lift Manifold and the wells connected to it using Nonlinear MPC (NMPC). Section 2 discusses the NMPC formulation, section 3 presents and discusses the main results and section 4 concludes the paper.

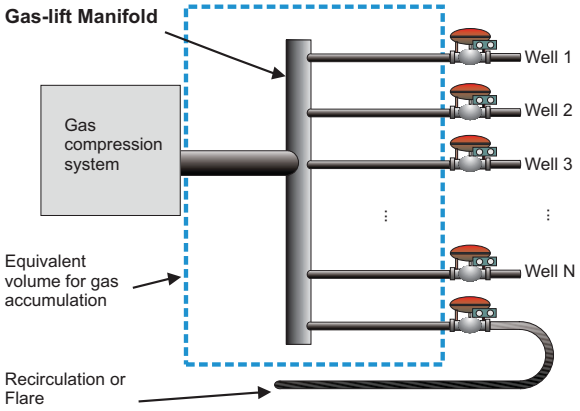

Fig. 1. Gas-lift Manifold

2. THE NMPC FORMULATION

We deal with a system where N gas-lifted wells with downhole pressure measurement and gas injection valves receive gas from a common Gas-lift Manifold (GLM). Gas from the compressor system enters the GLM and is distributed to the gas-lift wells and to an output which can be directed to the flare or to the recirculation of the compressor system. This output is a mechanism which allows gas to be discharged in cases where the gas flow-rate entering the GLM is higher than what is needed to operate the wells at their unconstrained optimum. This will be referred in the paper as the excess gas flow rate. The pressure at the GLM has to be kept at level high enough to allow injection in the annular of all gas-lift wells. For such a system shown in Figure 1 we wish

- to keep the GLM pressure close to a set-point designed according to the needs of the gas-lift wells,
- to distribute the gas flow-rate delivered by the compressor system among the gas lift wells in a way that maximizes an economic objective and

- to minimize the production oscillations caused by changes in the gas injection flow-rates. These oscillations cause problems to the separation process.

Some constraints should be introduced.

- To keep the gas injection flow rate of each well above a minimum value.
- To keep the pressure at the GLM between an upper and lower bound.

Table 1 presents the nomenclature used.

Table 1. Nomenclature

Symb.	Variable description	Unit
qo_i	Well i oil flow rate	std $m^3.d^{-1}$
$qliq_i$	Well i liquid flow rate	std $m^3.d^{-1}$
qw_i	Well i water flow rate	std $m^3.d^{-1}$
qg_i	Well i gas flow rate	std $m^3.d^{-1}$
p_{wf}	Bottom hole pressure with well flowing	$kgf.cm^{-2}$
$\bar{p}$	Average reservoir pressure	$kgf.cm^{-2}$
p_{sat}	Oil saturation pressure	$kgf.cm^{-2}$
q_{sat}	Liquid flow rate at $p_{wf} = P_{sat}$	std $m^3.d^{-1}$
q_{max}	Maximum well liquid flow rate ($p_{wf} = 0$)	std $m^3.d^{-1}$
qo_{max}	Maximum well oil flow rate	std $m^3.d^{-1}$
$qinj_i$	Well i gas injection flow rate	std $m^3.d^{-1}$
q_{exc}	GLM excess gas flow rate (flare or recirc.)	std $m^3.d^{-1}$
P_m	Gas Lift Manifold Pressure	$kgf.cm^{-2}$
P_{msp}	Gas Lift Manifold Pressure set point	$kgf.cm^{-2}$
p^*_{wf}	Value of p_{wf} used for normalization	$kgf.cm^{-2}$
$qinj^*$	Value of $qinj$ where $p_{wf} = p^*_{wf}$	std $m^3.d^{-1}$
q_{out}	Mass flow rate exiting the GLM	kgs^{-1}
q_{in}	Mass flow rate entering the GLM	kgs^{-1}
$\widetilde{x}$	Predicted or modeled value of x	

Symb.	Constants	Unit
V	Equivalent GLM volume	m^3
R	Universal Gas Constant, 8.314472	$Pa.m^3/Kmol$
M	Gas molecular weight	$kg.mol^{-1}$
BSW	Water saturation	-
GOR	Gas Oil Ratio	-

2.1 The NMPC Cost Function

The NMPC Cost Function should be tailored in such a way that its minimization provides the objectives discussed previously. There are several economic objectives that can be introduced in the Cost Function. A more general economic objective should express the net economic result of the gas lift operation taking into account the revenue from the oil production, gas production and the costs associated with the gas compression, water treatment, etc. Every well i has a maximum attainable oil production rate, qo_{maxi} , which can be obtained with an unique gas injection flow rate. Since there is a cost to implement the gas injection flow rate it becomes interesting to consider an economic objective which takes into account the gas compression cost and the revenue due to the oil produced. This is done at every sample time kTs computing the total amount of oil that will not be produced and the total amount of gas that will be injected between the actual time kTs and the future time T defined by the prediction horizon p and the sampling time Ts, $T = (k+p) * Ts$. An expression for the revenue loss due to oil production below unconstrained optimum is

$$L = P_o \sum_{i=1}^{N} \sum_{j=1}^{p} [qo_{maxi} - qo_i(k+j)]\, Ts, \text{ where} \quad (1)$$

P_o is the oil price per 1 $stdm^3$. The gas injection compression cost can be expressed as

$$C_{comp.} = C_c \sum_{i=1}^{N} \sum_{j=0}^{p-1} [qinj_i(k+j)]\, Ts, \text{ where} \quad (2)$$

C_c is the cost to compress $1stdm^3$ of gas to the GLM nominal pressure P_{msp}. The economic objective can be obtained by determining for every well i the vector

$$\Delta \mathbf{Q}inj_i = [\, \Delta qinj_i(k)\ \Delta qinj_i(k+1)\ \ldots\ \Delta qinj_i(k+m-1)\,]^T, \quad (3)$$

that minimize the objective function J_1, or,

$$\min_{\Delta \mathbf{Q}inj} J_1 \quad (4)$$

$$J_1 = \sum_{i=1}^{N} \sum_{j=1}^{p} [qo_{maxi} - qo_i(k+j)] + \frac{p}{m} \frac{C_c}{P_o} \sum_{i=1}^{N} \sum_{j=0}^{m-1} [qinj_i(k+j)]$$

The factor $\frac{p}{m}$ compensates the fact that the accumulated production loss is computed along an interval of time pTs while the total gas injected is computed along the time mTs where p and m are respectively the prediction and control horizon length. This formulation, in the absence of constraints is equivalent to the equal slope method, Kanu et al. (1981). One way to implement the cost function in matrix representation is to define for each well i the oil production loss qo_{Li},

$$qo_{Li} = qo_{maxi} - \tilde{qo}_i(p_{wfi}), \quad (5)$$

where $\tilde{qo}(p_{wf}))$ is computed with the predicted p_{wf}. We assemble the vector $\tilde{\mathbf{Qo}}_L$ with the difference between the maximum attainable oil flow rate and the predicted flow rate for every well i along the prediction horizon p.

$$\tilde{\mathbf{Qo}}L = [\, qo_{L1}(1)\ \cdots\ qo_{L1}(p)\ \cdots\ qo_{LN}(1)\ \ldots\ qo_{LN}(p)\,]^T \quad (6)$$

In order to damp the production oscillations we propose to minimize the sum of the time differential square of the production losses of all wells along the prediction horizon.

$$J_2 = \sum_{i=1}^{N} \sum_{j=1}^{p} \left(\frac{dqo_{Li}(k+j)}{dt} \right)^2 \quad (7)$$

The time differential is obtained using the matrix T equivalent to the $\Delta = 1 - z^{-1}$ operator.

$$T = \begin{bmatrix} -1 & 1 & 0 & 0 & \cdots & 0 \\ 0 & -1 & 1 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \cdots & 0 \\ 0 & 0 & 0 & \cdots & -1 & 1 \end{bmatrix} \quad (8)$$

The final Cost Function used is

$$J = \mathbf{W_1}\tilde{\mathbf{Qo}}_L + \mathbf{W_2}\mathbf{Qm_{out}} + (\mathbf{P}_{msp} - \tilde{\mathbf{P}}_m)^T \mathbf{W}_3 (\mathbf{P}_{msp} - \tilde{\mathbf{P}}_m) + \left(\mathbf{T}\tilde{\mathbf{Qo}}_L\right)^T \mathbf{W}_4 \left(\mathbf{T}\tilde{\mathbf{Qo}}_L\right) + \Delta \mathbf{Qm}_{out}^T \mathbf{W}_5 \Delta \mathbf{Qm}_{out}, \text{where}$$
$$\mathbf{Qm}_{out} = [\, \mathbf{Q}inj_1;\ \mathbf{Q}inj_2;\ \cdots\ \mathbf{Q}inj_N;\ \mathbf{Q}_{exc.}\,], \text{ and}$$
$$\mathbf{Q}_{exc.} = [\, q_{exc}(k)\ q_{exc}(k+1)\ \ldots\ q_{exc}(k+m-1)\,]^T \quad (9)$$

The first two terms implement the economic objective, the third term forces the pressure at the GLM to its nominal value or set-point, the fourth term minimizes the production losses oscillation and consequently the oil production rate oscillations and the fifth term minimizes the changes in the gas injection flow-rates. The vectors $\mathbf{W}_1$ and $\mathbf{W}_2$ can be adjusted to implement the economic objective in steady state. The matrix $\mathbf{W}_3$, $\mathbf{W}_4$ and $\mathbf{W}_5$ must be adjusted to weight the dynamic response objectives against the economic objective. There is no doubt that the optimum gas distribution is reached in steady state since in this case terms 3, 4 and 5 vanish but a proper tuning should provide optimization also during production transients. An excessive requirement for the oil production oscillation attenuation may induce a production loss compared to softening this objective.

2.2 Prediction models

The main purpose of applying automatic control to a group of gas-lift wells is to maximize an economic objective. That means to distribute the available gas flow rate entering the GLM among the wells in order to maximize the oil production for instance. Using the available downhole pressure measurements, the parameters of the Inflow Performance Relationship (IPR) of each well as well as parameters like BSW and GOR, it is possible to estimate the oil production flow rate entering the well. For under-saturated reservoir (formation pressure above the bubble point pressure),

$$qo = J(\bar{p} - p_{wf}), \tag{10}$$

where J is the productivity index, p_{wf} is the well flowing pressure in front of the perforated zone, $\bar{p}$ is the static pressure, and qo is the oil flow rate produced by the well. For saturated reservoirs, Vogel's formula Vogel (1968) gives

$$qo = qv_{max}\left[1 - 0.2\frac{p_{wf}}{\bar{p}} - 0.8\left(\frac{p_{wf}}{\bar{p}}\right)^2\right], \tag{11}$$

where qv_{max} is the maximum oil flow rate (for $p_{wf} = 0$). Defining the bubble pressure as p_{sat}, Patton and Goland (1980) proposed an expression considering the case where $\bar{p} > p_{sat}$ and the well operating with $p_{wf} \geq p_{sat}$ or $p_{wf} < p_{sat}$:

$$\text{if } p_{wf} \geq p_{sat}$$

$$q_{liq} = \frac{q_{sat}}{\bar{p} - p_{sat}}(\bar{p} - p_{wf}), \tag{12}$$

$$\text{if } p_{wf} < p_{sat}$$

$$q_{liq} = q_{sat} + (q_{max} - q_{sat})\left[1 - 0.2\frac{p_{wf}}{p_{sat}} - 0.8\left(\frac{p_{wf}}{p_{sat}}\right)^2\right]$$

$$qw = BSW\, q_{liq}. \tag{13}$$

$$qo = (1 - BSW)q_{liq}, \tag{14}$$

$$qg = RGO q_o \tag{15}$$

where q_{liq} is an IPR relationship that accounts for liquid flow rate in saturated and under-saturated wells, qw is the water flow rate, qo is the oil flow rate and qg is the gas flow rate. Other IPR models are found in Fetkovich (1973), Richardson and Shaw (1982), Raghavan (1993), Wiggins et al. (1996), and Maravi (2003). Due to the difficulty to have on line measurements for oil, water and gas flow rate of each well, and taking advantage of the availability of downhole pressure measurements an effort was done to derive an empirical model relating steady state gas injection flow rate to downhole pressure. For a real application the cost to obtain steady state values of downhole pressure and gas injection rate is significant since the well will have to operate at downhole pressures which translate into lower oil flow rate. Therefore it is highly desirable that the steady state model relating $p_{wf} = f(q_{inj})$ could be adjusted with measurements close to the point (p^*_{wf}, q^*_{inj}) where the production loss is minimum. A mathematical model with good extrapolation capability is most welcome. Most gas-lift wells do not produce naturally and for those the knowledge of the average reservoir static pressure, even with some uncertainty, gives an important information that can be used in the model since $p_{wf}(q_{inj} = 0) = \bar{p}$. In order to avoid numerical problems the relationship proposed uses normalized variables. Downhole pressure and injection flow rate are normalized to the pair (p^*_{wf}, q^*_{inj}). This would be an operational point corresponding to an observed lowest downhole pressure. The exact point chosen to normalization is not too important as long as the curve adjustment can use points to the right and left of (p^*_{wf}, q^*_{inj}).

$$u = \frac{q_{inj.}}{q^*_{inj.}}$$

$$y = \frac{p_{wf}}{p^*_{wf}}$$

$$y = \Theta_1 e^{-\Theta_2 u^m} + \Theta_3 + \Theta_4 u^2$$

$$\tilde{p}_{wf} = p^*_{wf} y. \tag{16}$$

A simplified SQP algorithm was developed for the curve fitting

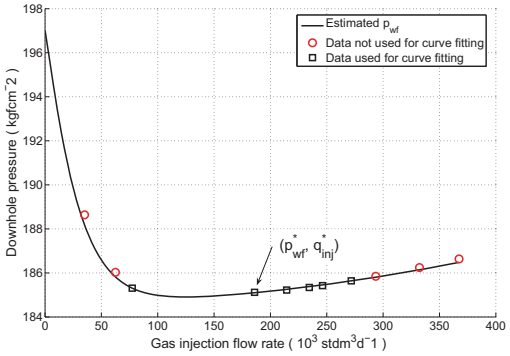

Fig. 2. Estimated p_{wf}

which uses the information about the average reservoir static pressure and its uncertainty. Figure 2 shows an example of curve fitting for data obtained from a rigorous steady state gas lift simulator. In order to verify the model extrapolation capability some points with lower values of downhole pressure were not used for the curve parameters adjustment. All points are plotted to show that the model adjusts well to the data even with a narrow data range used for the curve fitting. The points used for the curve fitting present downhole pressure close to the minimum which means that the production loss for obtaining these measurements would be minimum. Because one of the control objectives is to damp the oil production flow rate oscillations caused by changes in gas injection flow rates, it is also important to have a dynamic model for prediction. Since the main objective is economic, the dynamic prediction

model needs to exhibit a very accurate steady state relationship. Modern wells are being completed with Venturi gas-lift operating valves. These valves can provide critical flow for the injection gas at very low pressure drops (about 10% of the upstream pressure). This is normally enough to make sure that the gas-lift flow will be critical for most of its operating range. Critical flow in the gas-lift operating valve eliminates the heading phenomena but does not help to avoid the density wave oscillations, Hu (2004). In order to take advantage of the steady state model developed for $p_{wf} = f(q_{inj.})$ a Hammerstein model is proposed to be used for prediction. Figure

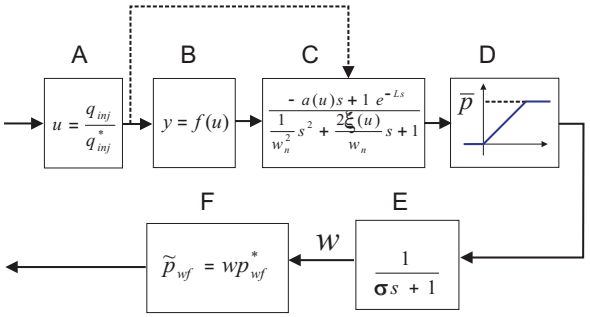

Fig. 3. Hammerstein dynamic model $p_{wf}(t) = f(q_{inj}(t))$

3 shows the dynamic model structure. Block A performs the normalization to the gas injection flow rate, block B applies the steady state function shown in equation (16), block C is a second order transfer function with transport delay and an adaptive zero and damping factor. Block D applies a saturation limiting the pressure values between zero and static pressure $\bar{p}$. Block E filters the saturation effect and block F multiplies the incoming signal by p^*_{wf} to recover the final estimated $\tilde{p}_{wf}$. It is assumed that the operating valve is working in critical mode so the gas flow rate crossing it is approximately the same gas flow rate that entered the casing head L seconds earlier. An approximate expression for L, ξ and the zero a are

$$L = \frac{H}{\sqrt{\frac{\gamma RT}{M}}},$$
$$\xi = k_1(.99 - e^{-3u(t-L)^2}) \text{ and}$$
$$a = \frac{k_2}{k_3 + u(t-L)}, \text{ where} \quad (17)$$

H is the distance from the casing head to the operating valve, γ is the gas ratio $\frac{c_p}{c_v}$, R is the universal gas constant, T is the gas temperature, $u(t-L)$ is the normalized gas injection flow rate at the casing head L seconds before the actual time and the constants k_1, k_2 and k_3 need to be tuned for each well together with the natural frequency w_n. In order to develop this empirical model several well cases were simulated with the OLGA^{TM} [1]. The pressure at the manifold, (P_m) is modeled as the pressure of a volume (V) filled with gas that results from the balance of gas that arrives from the compressor system and gas leaving to the wells and to the flare or to recirculation depending on the setup. The volume V is the sum of the internal volumes of all pipes between the compressor system and wells casing head. The pressure at the GLM is modeled as

[1] http://www.sptgroup.com/Products/olga/

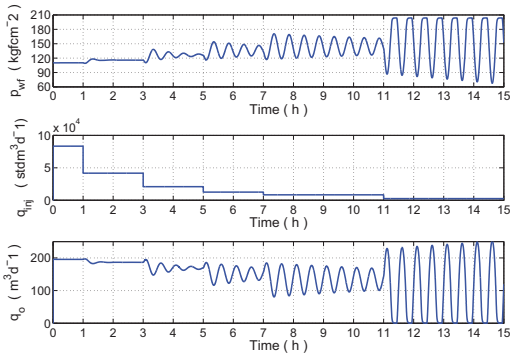

Fig. 4. Dynamic model response

$$\dot{P}_m = k_{GLM}(q_{in} - q_{out}),$$
$$k_{GLM} = \frac{RT}{MV}, \text{where} \quad (18)$$

T is the gas temperature, R is the gas universal constant and M is the gas molecular weight. The compressibility factor is assumed to be one. It is assumed that the gas mass flow rate entering the GLM is measured.

3. RESULTS AND DISCUSSION

In order to test the strategy proposed a total of 4 wells were modeled. These wells were simulated with a rigorous steady state simulator and the parameters of the empirical model given by equation (16) were tuned. The wells details are shown in table 2. A hypothetical dynamic model was added according to the model structure shown in figure 3. The Nonlinear MPC

Table 2. Well data

Parameter	*Well 1*	*Well 2*	*Well 3*	*Well 4*

m	0.56	1.11	0.09	1.04

algorithm used is discussed in Plucenio et al. (2008b) and with more details in Plucenio et al. (2008a). The NMPC algorithm, named PNMPC, employs a continuous linearization technique where the vector of the predicted variable $\tilde{\mathbf{Y}}$ is represented by

$$\tilde{\mathbf{Y}} = \mathbf{F} + \mathbf{G}\Delta\mathbf{u} + \Gamma. \quad (19)$$

The matrix $\mathbf{G}$ is the Jacobian of $\tilde{\mathbf{Y}} = f(\Delta\mathbf{u})$ and is obtained by a numerical procedure realized in two steps at every iteration. The first step uses the matrix $\mathbf{G}$ of the previous iteration to produce an intermediate $\Delta\mathbf{u}$. Next, another matrix $\mathbf{G}$ is obtained using the $\Delta\mathbf{u}$ just computed. The matrix $\mathbf{G}$ used to compute the final $\Delta\mathbf{u}$ is an average of the two matrix. The vector Γ represents the correction factors which are an explicit version of the CARIMA error treatment.

3.1 NMPC Tuning

One way to tune the NMPC objective function weights is to start by the economic function as described by equation (4). Next the other weights are tuned to balance production oscillation attenuation with the economic objective. For numerical efficiency it may be interesting to multiply all weights by a common factor. The tuning parameters are shown in table 3. Controlling the system composed by the GLM and the wells

Table 3. NMPC Tuning Parameters

Symb.	Variable description	Value
Ts	Sampling time	5s
p	Prediction horizon for qo_L	150
p_1	Prediction horizon for P_m	18
w_1	Element of vector $\mathbf{W}_1$ $1 \times 4p$	.020
w_2	Element of vector $\mathbf{W}_2$ $1 \times 5m$	5e-4
w_3	Diagonal element of Matrix $\mathbf{W}_3$ $p_1 \times p_1$	(1)
w_4	Diagonal element of Matrix $\mathbf{W}_4$ $4p \times 4p$	(2)
w_5	Diagonal element of Matrix $\mathbf{W}_5$ $5m \times 5m$	(3)

(1) $w_3(i)$ varies linearly from 1 to 10 for $i = 1 : 18$
(2) w_4 is a linear function of the filtered and normalized gas mass flow rate q_{in} entering the GLM. 1 for $q^*_{in} = 1$ and 12 for $q^*_{in} = 0.25$
(3) $\mathbf{W}_5(i,i) = 1x10^{-5}$ for i=1:12. For Δu_{flare}, $\mathbf{W}_5(i,i)$ for i=13:15, a linear function of the filtered and normalized gas mass flow rate q_{in} entering the GLM was used. $\mathbf{W}_5(i,i)$ goes from $1x10^{-5}$ for $q^*_{in} = 0.25$ to $15x10^{-5}$ for $q^*_{in} = 0.25$.

has a great advantage of eliminating the gas lift availability constraint. Many gas-lift optimization studies consider gas lift availability as a constraint while this information is not always available. Another advantage is the possibility to apply optimization during the transients which can be more or less frequent depending on the setup used. On the other hand the GLM pressure dynamic behavior is highly dependent on the associated pipe internal volume and it will be normally faster than the downhole pressure. This requires the sampling time to be adjusted based on the GLM pressure dynamics. To overcome a bit the problem the qo_L predictions were done every 3 sampling time resulting in a prediction horizon p equal to 150. A constraint was used to make sure that the excess gas flow rate would be always positive. Besides, a minimum flow rate was imposed to all wells to avoid entering in the density wave limit cycle. A constraint was used to imposed a limit on the GLM Pressure deviation from the set point at +- 5%.

3.2 Results obtained

In order to test the control strategy proposed an operation of 24 hours was simulated covering different gas-lift availabilities. It was assumed an equivalent volume for the GLM (sum of all associated pipes internal volume) equal to 1 m^3. The initial gas injection flow rate was the sum of all gas flow rates values which corresponded to the values used for normalization. This value was considered as the nominal input GLM flow rate. Next the gas entering the GLM was changed to 50%, 25% and 110% of nominal value as shown on figure 5. Figure 6 top shows all the wells downhole pressure (normalized values) and the GLM pressure (normalized to the set-point value). It can be noticed that they change smoothly. The GLM pressure presents a small deviation from its set-point at moments of significant ramp type changes on the gas flow rate entering

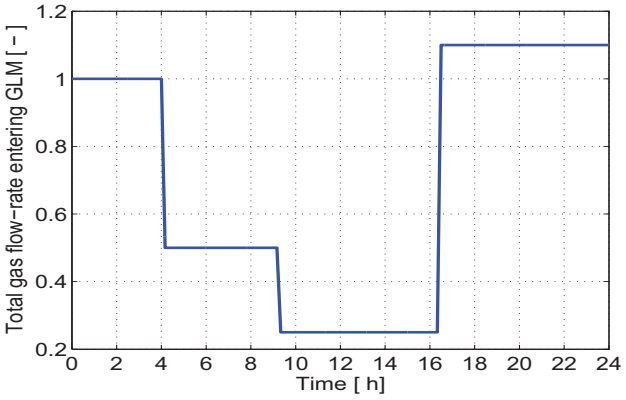

Fig. 5. Normalized gas flow-rate entering the GLM

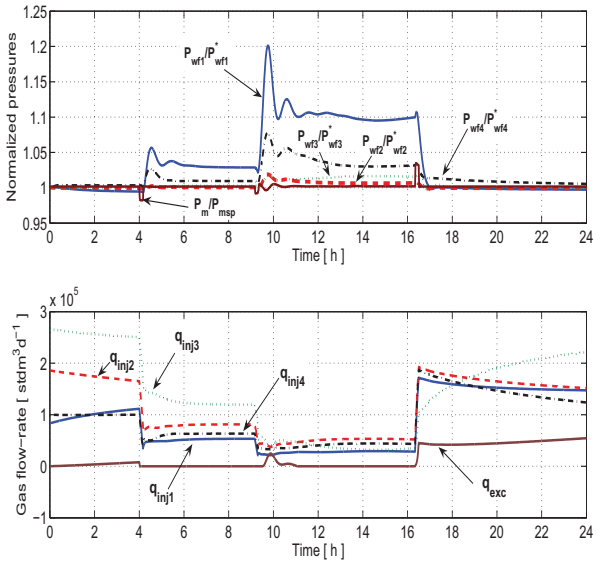

Fig. 6. GLM and gas lift wells behavior

the GLM although not enough to exceed the constraints. The bottom plot of figure 6 shows all the gas injection flow rates for the four wells and the excess gas flow rate. It is interesting to observe that when the gas flow rate entering the GLM goes to 110% of the nominal value the excess gas flow rate rises to keep the GLM pressure at its reference and to avoid production losses. When the gas entering the GLM decreases from 50% to 25% of the nominal value, the excess gas flow rate helped on avoiding too much change in the wells gas injection flow rate what would cause excessive oil production oscillation. This behavior can be controlled by tuning the Cost Function parameters. Figure 7 shows the evolution of the total oil production flow rate as the gas entering the GLM was changed. Both, 100% and 110% of nominal GLM input flow-rate give the same total oil production flow-rate. The gas flow rate not used for injection in the wells returns on the recirculation line as excess gas as shown in figure 6. The oil production flow rate of all the four wells is shown in figure 8. The solid lines were obtained with the simulation including the

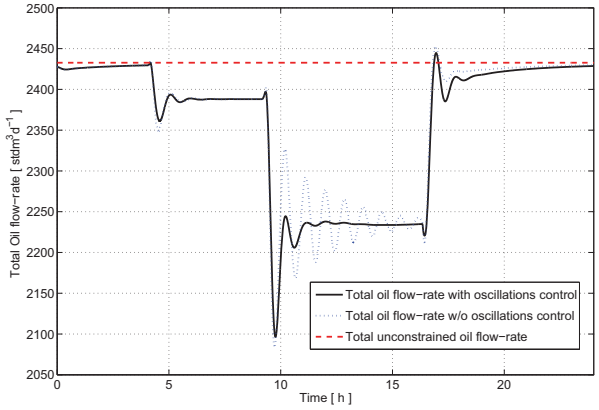

Fig. 7. Total oil production flow rate

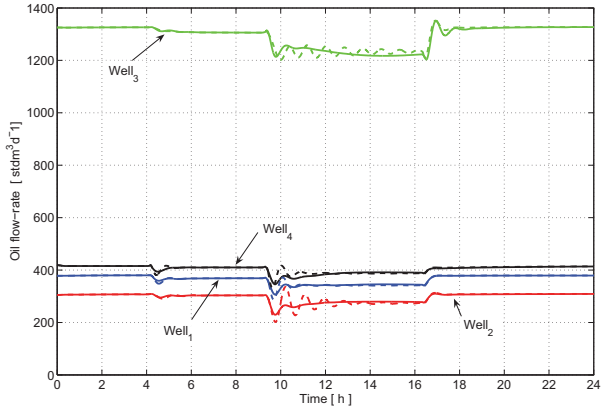

Fig. 8. Oil Production flow rate for all wells

oscillation attenuation control while the dashed lines not. The well 3 is the main producer. It is interesting to notice that the production decay is not much affected by the decrease in the total gas injection flow rate due to the appropriate gas allocation made by the NMPC algorithm. Despite the limited degree of freedom (only gas injection flow-rate manipulation) all the objectives are met; optimum gas distribution, GLM pressure control and attenuation of oil production oscillations.

4. CONCLUSION

Downhole permanent pressure measurement is becoming a reality for new wells. This work proposes the utilization of the PNMPC control technique discussed in Plucenio et al. (2008b) and demonstrates its applications on the control of 4 gas-lift wells using simulation. More work has to be done to investigate the quality of the empirical gas lift well dynamical model proposed.

Abstract:
In this paper, a new scheme for adaptive unfalsified control with non-ideal measurements is presented and demonstrated for a well-known example of a nonlinear plant, the continuous stirred tank reactor (CSTR) with the van-der-Vusse reaction scheme. In our adaptive control algorithm, there are two adaptation mechanisms: 1. Switching of the active controller in a fixed set of candidate controllers by the ϵ-hysteresis switching algorithm. 2. Adaptation of the set of controllers performed by a population-based evolutionary algorithm. In this paper, the effect of measurement errors on the adaptive control scheme is investigated. The total least squares method is used to perform the deconvolution of noisy signals.

Keywords: Adaptive Control; Unfalsified Control; Nonlinear Control, Reactor Control, Measurement Error

1. INTRODUCTION

The adaptive unfalsified control scheme was initially introduced by Safonov et al. (1997). The basic idea is to switch among candidate controllers in a predefined set of controllers. This approach does not require a plant model but uses the observed plant input-output data while one controller is active to decide on the switching to the next active controller. Further developments by Wang et al. (2005) led to the concept of cost-detectability, the proposal of a cost-detectable cost function, and the ϵ-hysteresis switching algorithm. Stability of the adaptive system was proven in Wang et al. (2005) in the sense that if the set of controllers contains stabilizing controllers with satisfactory performance, the scheme will ultimately switch to one of them. In Engell et al. (2007), Manuelli et al. (2007) and Dehghani et al. (2007), it was pointed out that the scheme in Wang et al. (2005) cannot detect instability of controllers that are not in the loop and may temporarily switch to destabilizing controllers. For this reason, the cost function proposed in Wang et al. (2005) is not suitable for evaluating controllers that are not in the loop, and cannot be used to adapt the controllers in the set.

To resolve this problem, a new scheme of adaptive unfalsified control was proposed in Engell et al. (2007). The key point was the introduction of a new fictitious error signal that can be computed using the estimated sensitivity function obtained by deconvolution between the fictitious reference signal and the fictitious error signal. This new signal is used in a new cost function that can measure the true performance of non-active controllers correctly. Based upon this new cost function, an adaptation of the set of controllers using evolutionary algorithm was performed. The scheme was demonstrated to work for the well-known non-minimum phase CSTR example with undisturbed measurements in Wonghong and Engell (2008).

In this paper, we extend the approach in Engell et al. (2007) to the case of noisy measurements. In the next section, we first review the new concept of unfalsified control with the ϵ-hysteresis switching algorithm as a switching mechanism for the active controller and the adaptation of the set of candidate controllers using evolution strategies. Then we investigate the effect of noise added to the plant output signal on the observed plant input-output data, the fictitious reference signal, and the fictitious error signal. We introduce the total least squares technique to solve the noisy deconvolution problem. This leads to an estimation of the sensitivity function in the non-ideal situation. In section 5, we present simulation studies for the CSTR example. We show that the adaptation of the controller parameters can be performed successfully under non-ideal measurements.

2. A NEW SCHEME FOR ADAPTIVE UNFALSIFIED CONTROL

We consider a SISO adaptive unfalsified control system $\Sigma(P, \hat{K})$ mapping r into (u, y). The system is defined on $\Sigma(P, \hat{K}) : \mathcal{L}_{2e} \rightarrow \mathcal{L}_{2e}$. The scheme of an adaptive unfalsified control system $\Sigma(P, \hat{K})$ is shown in Fig. 1.

The disturbed unknown plant $P : \mathcal{U} \rightarrow \mathcal{Y}$ is defined by

$$\mathbf{P} = \{(u, y, w) \subset \mathcal{U} \times \mathcal{Y} \times \mathcal{W} \mid y = Pu + w\}. \quad (1)$$

⋆ This work was supported by the NRW Graduate School of Production Engineering and Logistics at Technische Universität Dortmund.

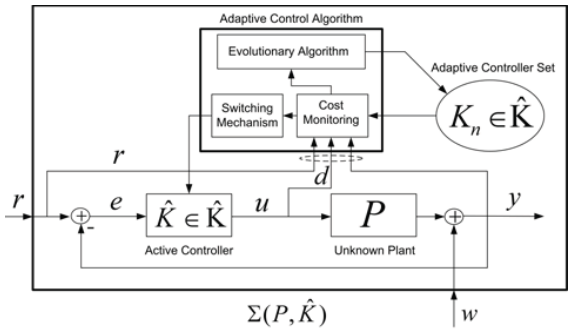

Fig. 1. Adaptive Unfalsified Control Scheme

The set of controllers $K : \mathcal{R} \times \mathcal{Y} \to \mathcal{U}$ is defined by

$$\hat{\mathbf{K}} = \{(r, u, y) \subset \mathcal{R} \times \mathcal{U} \times \mathcal{Y} \mid u = K_n \begin{bmatrix} r \\ y \end{bmatrix}\}, n = 1, 2, ..., N. \tag{2}$$

The signals $r(t), u(t), y(t)$ are assumed to be square-integrable over every bounded interval $[0, \tau], \tau \in \mathbb{R}_+$. The adaptive control algorithm maps vector signals $d = [r(t), u(t), y(t)]^T$ into a choice of a controller $K_n \in \hat{\mathbf{K}}$, where K_n satisfies the *stable causal left invertible* (SCLI) property [Wang et al. (2005)]. The true error signal is

$$e(t) = r(t) - y(t). \tag{3}$$

The adaptive control law has the form:

$$u(t) = \hat{K}(t) * e(t) \tag{4}$$

where $\hat{K} = K_{n(t)}$ denotes the active controller. $n(t)$ is a piecewise constant function with a finite number of switchings in any finite interval and $*$ denotes the convolution integral.

Let $d = (r(t), u(t), y(t)), 0 \le t \le T$ denote experimental plant data collected over the time interval T, and let $\mathbf{D}$ denote the set of all possible vector signals d. d_τ denotes the truncation of d, e.g., all past plant data up to current time τ. The data set $\mathbf{D}_\tau$ is defined by

$$\mathbf{D}_\tau = \{(r, u, y) \subset \mathcal{R} \times \mathcal{U} \times \mathcal{Y} \mid d_\tau = (r_\tau, u_\tau, y_\tau)\}.$$

We consider linear time-invariant control laws of the form:

$$K_n = \{(r, u, y) \subset \mathcal{R} \times \mathcal{U} \times \mathcal{Y} \mid u = c_n * e\} \tag{5}$$

where c_n is the impulse response of the n^{th} controller. $C_n(s)$ denotes the Laplace transform of c_n.

We assume that we have observed the excitation r_τ, the plant input data u_τ and the plant output data y_τ.

In unfalsified control, these data are used to evaluate whether the controller K_n meets a specified closed-loop performance criterion

$$J_n^*(r_\tau, u_\tau, y_\tau) \le \alpha \tag{6}$$

where α is called the unfalsification threshold. If this condition is not met, the control law switches to a different controller and the previous controller is discarded. After at most N switchings, a suitable controller is found, if there is such a controller in the set.

The key idea of unfalsified control is to compute the cost $J_n^*(d_\tau, \tau)$ based upon the available measurements. For this purpose,

$$\tilde{r}_n = c_n^{-1} * u + y \tag{7}$$

and

$$\tilde{e}_n = \tilde{r}_n - y \tag{8}$$

are defined where c_n^{-1} is the impulse response of the inverse controller transfer function $C_n^{-1}(s)$. These signals are called the *fictitious reference signal* and the *fictitious error signal*, respectively. $\tilde{r}_n$ is the reference signal that produces the measured plant input u and output y if the controller K_n is in the loop instead of the currently active controller.

In Engell et al. (2007), the *new fictitious error signal*

$$e_n^* = \tilde{s}_n * r \tag{9}$$

where $\tilde{s}_n$ is the impulse response of the sensitivity function with the n^{th} controller in the loop,

$$\tilde{S}_n(s) = \frac{1}{1 + C_n P} \tag{10}$$

was introduced. e_n^* is the error that results for the true reference signal r with the controller K_n in the loop. As $\tilde{S}_n(s) = \frac{\tilde{E}_n(s)}{\tilde{R}_n(s)}$, $\tilde{s}_n$ can be computed via the deconvolution of $\tilde{r}_n$ and $\tilde{e}_n$ [Engell et al. (2007)].

When $J_n^*(e_{n_\tau}^*, d_\tau, \tau) > \alpha$, this implies that if the controller K_n were in the loop, it would not satisfy the performance criterion (6). In this case, it is said that the controller K_n is a *falsified* controller. Otherwise the controller K_n is an *unfalsified* controller.

The new adaptive control algorithm consists of two adaptation mechanisms:

1. Switching of the active controller
The closed-loop performances of all candidate controllers are computed using sampled signals

$$J_n^*(d_{\tau_k}, \tau_k) = \max_{\tau_j \le \tau_k} \frac{\sum_{i=0}^{j} |e_n^*(i)|^2 + \gamma \cdot \sum_{i=0}^{j} |u(i)|^2}{\sum_{i=0}^{j} |r(i)|^2} \tag{11}$$

where γ is a positive constant.

The ϵ-hysteresis switching algorithm of Morse et al. (1992) is applied for the switching of the active controller:

(1) Initialize: Let $k = 0, \tau_0 = 0$; choose $\epsilon > 0$. Let $\hat{K}(0) = K_1, K_1 \in \hat{\mathbf{K}}(0)$, be the first active controller in the loop.
(2) $k = k + 1, \tau_k = \tau_{k+1}$
If $J^*(\hat{K}(k-1), d_{\tau_k}, \tau_k) \ge \min_{K_n \in \hat{\mathbf{K}}(k)} J_n^*(d_{\tau_k}, \tau_k) + \epsilon$,
then $\hat{K}(k) \leftarrow \arg\min_{K_n \in \hat{\mathbf{K}}(k)} J_n^*(d_{\tau_k}, \tau_k)$,
else $\hat{K}(k) \leftarrow \hat{K}(k-1)$.
(3) Go to 2.

2. Adaptation of the set of controllers $\hat{\mathbf{K}}(t^*)$
An evolutionary algorithm (EA) is used for the adaptation of the set of controllers because EA manipulate a population of candidate controllers and can handle nonconvex cost functions and are able to escape from local minima. The EA is executed only at units of time t^* after a sufficiently large change of $r(t)$ was detected. For accurate results, t^* should approximately match the settling time of the controlled system. Insufficient excitation leads to numerical problems due to an ill-conditioned matrix in the deconvolution. Thus, we restrict the activation of the EA to a suitable interval after a sufficient excitation by a change of $r(t)$. In this work, the evolutionary algorithm is a so-called *evolution strategy* where each individual is

represented by a vector of controller parameters and by a vector of strategy parameters that control the mutation strength.

The *evolution strategy* as introduced by Rechenberg (1965) and later developed by Schwefel (1975) is based on a population P of μ individuals $\mathbf{a} = (\mathbf{x}, \mathbf{s})$, which represent search points $\mathbf{x} = (x_1, \ldots, x_m) \in \mathbb{R}^m$ and vectors of strategy parameters $\mathbf{s} = (s_1, \ldots, s_m) \in \mathbb{R}_+^m$ that handle the evolution of the population. The size of the population is equal to the number of candidate controllers $\mu = N$. The μ parent individuals in the parent set are randomly selected from the population. The new offspring λ are generated by recombination of two parent individuals and by subsequent perturbation of single variable $x_j, j \in \{1, ..., m\}$ with a random number drawn from a Gaussian distribution $\mathcal{N}(0, s_j)$ by

$$x_j' = x_j + s_j \cdot \mathcal{N}(0, 1). \tag{12}$$

According to the self adaptation mechanism of evolution strategies, each strategy s_j is modified log-normally

$$s_j' = s_j \cdot \exp(\delta \cdot \mathcal{N}(0, 1)) \tag{13}$$

where δ is an external parameter. Normally it is inversely proportional to the square root of the problem size ($\delta \propto \frac{1}{\sqrt{N}}$). To preserve a constant number of individuals, the survivor selection chooses the μ best ($1 \leq \mu < \lambda = 7 \cdot \mu$) individuals out of the set of λ offspring ((μ, λ)-selection) or out of the union set of parents and offspring ($(\mu + \lambda)$-selection). The quality of each individual is evaluated by the fitness function $f(\mathbf{a}) = J^*(\mathbf{x}, d_{t^*}, t^*)$. As long as a fitness improvement ($\Delta f > min_{\Delta f}$) of the best individual within a certain number of generations can be observed, the termination criterion of the evolution strategy is not fulfilled and the μ selected individuals from the previous generation are used for the next iteration.

3. CONSIDERATION OF NOISE AT THE PLANT OUTPUT

For the scheme in Fig. 1 with a linear plant and a linear controller, in the Laplace domain,

$$\begin{aligned} Y(s) &= P(s)U(s) + W(s) \\ &= P(s)\hat{C}(s)(R(s) - Y(s)) + W(s) \\ &= \hat{T}(s)R(s) + \hat{S}(s)W(s) \\ &= Y_{true}(s) + Y_w(s) \end{aligned} \tag{14}$$

with the active complementary sensitivity function,

$$\hat{T}(s) = \frac{\hat{C}(s)P(s)}{1 + \hat{C}(s)P(s)} \tag{15}$$

and the active sensitivity function,

$$\hat{S}(s) = \frac{1}{1 + \hat{C}(s)P(s)}. \tag{16}$$

The observed disturbed plant input signal is,

$$\begin{aligned} U(s) &= \hat{C}(s)(R(s) - Y(s)) \\ &= \hat{C}(s)(R(s) - Y_{true}(s)) - \hat{C}(s)Y_w(s) \\ &= U_{true}(s) - \hat{C}(s)Y_w(s). \end{aligned} \tag{17}$$

Hence $y(t)$ and $u(t)$ consist of deterministic and stochastic components,

$$y(t) = y_{true}(t) + y_w(t) \tag{18}$$

$$u(t) = u_{true}(t) - \hat{c}(t) * y_w(t) \tag{19}$$

where

$$y_{true}(t) = \hat{t}(t) * r(t) \tag{20}$$

$$u_{true}(t) = \hat{c}(t) * (r(t) - y_{true}(t)) \tag{21}$$

$$y_w(t) = \hat{s}(t) * w(t). \tag{22}$$

Therefore, the error propagation in the measured plant input-output data depends on the closed-loop performance of the active controller.

4. STOCHASTIC DECONVOLUTION

4.1 Stochastic Fictitious Signals

Using (7), the stochastic fictitious reference signal $\tilde{R}_{i,w}$ of C_i using the noisy observed plant input-output data (U, Y) while controller $\hat{C}$ is active results as

$$\begin{aligned} \tilde{R}_{i,w} &= C_i^{-1}U + Y \\ &= C_i^{-1}\hat{C}(R - Y) + Y \\ &= C_i^{-1}\hat{C}(R - Y_{true} - Y_w) + Y_{true} + Y_w \\ &= \tilde{R}_{i,true} + \Delta\tilde{R}_i \end{aligned}$$

where $\Delta\tilde{R}_i = (1 - C_i^{-1}\hat{C})\hat{S}W$. Note that $\Delta\tilde{R}_{\hat{C}} = 0$.

Using (8), the stochastic fictitious error signal $\tilde{E}_{i,w}$ of C_i can be computed from (U, Y),

$$\begin{aligned} \tilde{E}_{i,w} &= C_i^{-1}U \\ &= C_i^{-1}\hat{C}(R - Y) \\ &= C_i^{-1}\hat{C}(R - Y_{true} - Y_w) \\ &= \tilde{E}_{i,true} + \Delta\tilde{E}_i \end{aligned}$$

where $\Delta\tilde{E}_i = -C_i^{-1}\hat{C}\hat{S}W$. Note that $\Delta\tilde{E}_{\hat{C}} = -Y_w \neq 0$.

Using (9), the new fictitious error signal $e_{i,w}^*(t)$ of C_i is

$$E_{i,w}^* = \tilde{S}_{i,w}R. \tag{23}$$

$\tilde{S}_{i,w}$ can be obtained using (10),

$$\begin{aligned} \tilde{E}_{i,w} &= \tilde{S}_{i,w}\tilde{R}_{i,w} \\ \tilde{e}_{i,w}(t) &= \tilde{s}_{i,w}(t) * \tilde{r}_{i,w}(t). \end{aligned} \tag{24}$$

From (24), $\tilde{s}_{i,w}(t)$ can be computed from $u(t)$ and $y(t)$ via $\tilde{e}_{i,w}(t)$ and $\tilde{r}_{i,w}(t)$. The noisy deconvolution is performed using sampled signals:

$$\begin{aligned} \tilde{\mathbf{R}}_{i,w} \cdot \tilde{\mathbf{s}}_{i,w} &= \tilde{\mathbf{e}}_{i,w} \\ (\tilde{\mathbf{R}}_{i,true} + \Delta\tilde{\mathbf{R}}_i) \cdot \tilde{\mathbf{s}}_{i,w} &= \tilde{\mathbf{e}}_{i,true} + \Delta\tilde{\mathbf{e}}_i \end{aligned} \tag{25}$$

where

$$\tilde{\mathbf{R}}_{i,true} = \begin{bmatrix} \tilde{r}_{i,true}(0) & 0 & \cdots & 0 \\ \vdots & \tilde{r}_{i,true}(0) & 0 & 0 \\ \tilde{r}_{i,true}(l-1) & \ddots & \tilde{r}_{i,true}(0) & 0 \\ \tilde{r}_{i,true}(l) & \tilde{r}_{i,true}(l-1) & \cdots & \tilde{r}_{i,true}(0) \end{bmatrix}$$

and $\tilde{\mathbf{e}}_{i,true} = [\tilde{e}_{i,true}(0) \ \cdots \ \tilde{e}_{i,true}(l-1) \ \tilde{e}_{i,true}(l)]^T$. The unknown matrix $\Delta\tilde{\mathbf{R}}_i$ is defined similar to $\tilde{\mathbf{R}}_{i,true}$ and the unknown vector $\Delta\tilde{\mathbf{e}}_i$ is defined similar to $\tilde{\mathbf{e}}_{i,true}$. Examples

of the computation of $\tilde{\mathbf{R}}_{i,true}, \tilde{\mathbf{e}}_{i,true}, \tilde{\mathbf{s}}_{i,true}$ can be seen in Engell et al. (2007) and Wonghong and Engell (2008).

The deconvolution problem (25) contains error terms both in the matrix and in the right hand side, and therefore it is not adequate to approach it as an ordinary least squares problem. Instead we employ the *total least squares* (TLS) method.

The total least squares method was originally proposed by Golub et al. (1980). The motivation comes from the asymmetry of the *least squares* (LS) method where no error term in the matrix $\tilde{\mathbf{R}}$ is taken into account. The idea of TLS is to find the minimal (in the Frobenius norm sense) error terms $\Delta\tilde{\mathbf{R}}$ and $\Delta\tilde{\mathbf{e}}$ in the matrix $\tilde{\mathbf{R}}$ and in the vector $\tilde{\mathbf{e}}$ that make the linear equations system (25) solvable, i.e.,

$$\{\tilde{\mathbf{s}}_{TLS}, \Delta\tilde{\mathbf{R}}_{TLS}, \Delta\tilde{\mathbf{e}}_{TLS}\} = \arg \min_{\tilde{\mathbf{s}}, \Delta\tilde{\mathbf{R}}, \Delta\tilde{\mathbf{e}}} \|\Delta\tilde{\mathbf{R}} \;\; \Delta\tilde{\mathbf{e}}\|_F$$

$$\text{subject to } (\tilde{\mathbf{R}} + \Delta\tilde{\mathbf{R}}) \cdot \tilde{\mathbf{s}} = \tilde{\mathbf{e}} + \Delta\tilde{\mathbf{e}}.$$

4.2 Solution of the Total Least Squares Problem

The conditions for the existence and the uniqueness of a TLS solution can be found in Markovsky et al. (2007):

$$\mathbf{Z} = [\tilde{\mathbf{R}} \;\; \tilde{\mathbf{e}}] = \mathbf{U}\Sigma\mathbf{V}^T$$

where $\Sigma = diag(\sigma_1, ..., \sigma_{l+1})$ is a singular value decomposition of $\mathbf{Z}$, $\sigma_1 \geq \cdots \geq \sigma_{l+1}$ are the singular values of $\mathbf{Z}$. Partitioned matrices are defined as

$$\mathbf{V} = \begin{bmatrix} \mathbf{V}_{11} & \vdots & \mathbf{v}_{12} \\ \cdots & & \cdots \\ \mathbf{v}_{21} & \vdots & v_{22} \end{bmatrix}, \Sigma = \begin{bmatrix} \Sigma_{11} & \vdots & \mathbf{0}_{12} \\ \cdots & & \cdots \\ \mathbf{0}_{21} & \vdots & \sigma_{l+1} \end{bmatrix},$$

where $\mathbf{V}_{11}, \Sigma_{11} = diag(\sigma_1, ..., \sigma_l) \in \mathbb{R}^{l\times l}, \mathbf{v}_{12}, \mathbf{0}_{12} \in \mathbb{R}^{l\times 1}, \mathbf{v}_{21}, \mathbf{0}_{21} \in \mathbb{R}^{1\times l}, v_{22}, \sigma_{l+1} \in \mathbb{R}$. A TLS solution exists if and only if v_{22} is not zero. In addition, it is unique if and only if $\sigma_l \neq \sigma_{l+1}$. In the case when a TLS solution exists and is unique, the solution is given by

$$\tilde{\mathbf{s}}_{TLS} = -\frac{\mathbf{v}_{12}}{v_{22}}. \tag{26}$$

Therefore, the new fictitious error signal $e^*_{i,w}(t)$ for controller C_i can be computed by

$$\mathbf{e}^*_{i,w} = \mathbf{R} \cdot \tilde{\mathbf{s}}_{i,w} = \mathbf{R} \cdot \tilde{\mathbf{s}}_{i_{TLS}}. \tag{27}$$

4.3 Ill-conditioned Matrix $\tilde{R}_{i,w}$

In the error-free case, the computation fails if $\tilde{\mathbf{R}}_{i,true}$ is ill-conditioned, in particular if $\tilde{r}_{i,true}(0) \to 0$. Using the relationship of $\tilde{r}_{i,true}(t)$ and $r(t)$

$$\tilde{R}_{i,true} = \frac{\hat{C}}{C_i} \frac{1 + C_i P}{1 + \hat{C} P} R \tag{28}$$

and applying the initial value theorem,

$$\tilde{r}_{i,true}(0) = \lim_{s\to\infty} s \frac{\hat{C}}{C_i} \frac{1 + C_i P}{1 + \hat{C} P} R. \tag{29}$$

If a unit step function is applied to $r(t)$ and P is strictly proper and $C_i(s) = k_{p_i}(1 + \frac{1}{T_{n_i} s})$,

$$\tilde{r}_{i,true}(0) = \frac{\hat{k}_p}{k_{p_i}}, \tag{30}$$

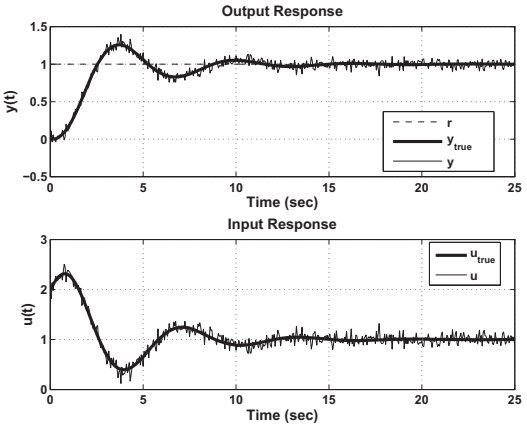

Fig. 2. The measured plant input-output data

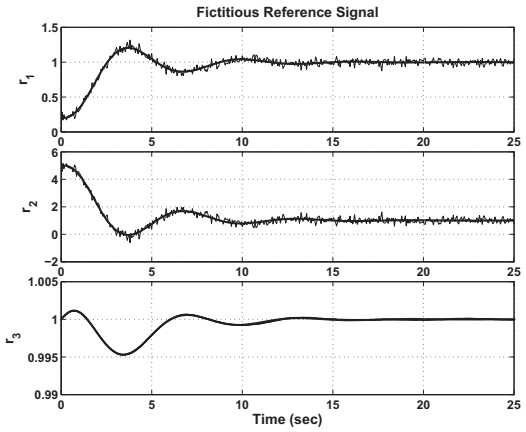

Fig. 3. Fictitious reference signals

so $|k_{p_i}| \gg |\hat{k}_p|$ leads to ill-conditioned matrices $\tilde{\mathbf{R}}_{i,true}$. For $\tilde{\mathbf{R}}_{i,w}$

$$\tilde{r}_{i,w}(0) = \tilde{r}_{i,true}(0) + \Delta\tilde{r}_i(0) = \frac{\hat{k}_p}{k_{p_i}} + \Delta\tilde{r}_i(0). \tag{31}$$

Hence the presence of measurement noise alleviates the ill-conditioning problem for the deconvolution technique.

4.4 Example of Estimated Fictitious Error Signals

We assume that $P = \frac{1}{(s+1)^3}$ and $\hat{C} = 2(1 + \frac{1}{3s})$ and a unit step was applied to $r(t)$. $d_\tau = (r_\tau, u_\tau, y_\tau)$ was observed up to $\tau = 25s$. We assume measurement errors in the plant output data as shown in Fig. 2. Three candidate controllers are tested: 1. $C_1 = 10(1+\frac{1}{3s})$ 2. $C_2 = 0.4(1+\frac{1}{3s})$ 3. $C_3 = 2(1 + \frac{1}{3s})$. $\tilde{r}_{i,true}(t)$ and $\tilde{r}_{i,w}(t)$ result as shown in Fig. 3. Note that the computation of $\tilde{r}_{3,w}(t)$ is error-free. $e^*_{i,true}(t)$ and $e^*_{i,w}(t)$ are shown in Fig. 4. The closed-loop instability of the loop with C_1 is detected and the performances of C_2 and C_3 are estimated well.

5. ADAPTIVE CONTROL OF A CSTR WITH NONMINIMUM PHASE BEHAVIOR

As an example of the application of the new adaptive control scheme to a nonlinear process we investigate the

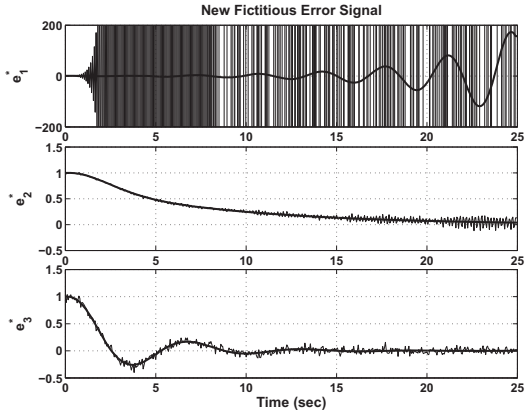

Fig. 4. New fictitious error signals

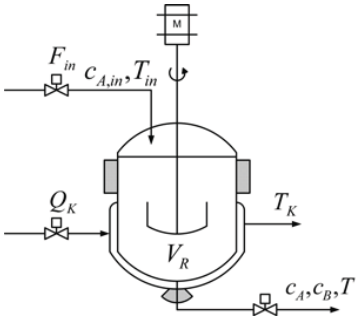

Fig. 5. Continuous Stirred Tank Reactor

well-known case study of the control of a CSTR with the van-der-Vusse reaction scheme. The parameters of the model are the same as in Engell et al. (1993), Klatt et al. (1998).

A sketch of the reactor is shown in Fig. 5. The reaction scheme is

$$A \overset{k_1}{\rightarrow} B \overset{k_2}{\rightarrow} C,$$
$$2A \overset{k_3}{\rightarrow} D.$$

The reactor is operated at a constant holdup, i.e., the volume of the contents is constant. The manipulated input $u(t)$ is the flow through the reactor, represented by the inverse of the residence time (F_{in}/V_R). u is in the range $0 \leq u(t) \leq 30h^{-1}$. We assume that the temperature control is tight so that the dependency of the kinetic parameters on the reactor temperature can be neglected. Under these assumptions, a SISO nonlinear model results from mass balances for the components A and B:

$$\begin{aligned} \dot{x}_1 &= -k_1 x_1 - k_3 x_1^2 + (x_{1,in} - x_1)u \\ \dot{x}_2 &= k_1 x_1 - k_2 x_2 - x_2 u \\ y &= x_2 \end{aligned} \tag{32}$$

where x_1 is the concentration of component A, x_2 is the concentration of component B and $x_{1,in}$ is the feed concentration of A, assumed to be constant. The parameter values are $k_1 = 15.0345h^{-1}, k_2 = 15.0345h^{-1}, k_3 = 2.324l \cdot mol^{-1} \cdot h^{-1}, x_{1,in} = 5.1mol \cdot l^{-1}$.

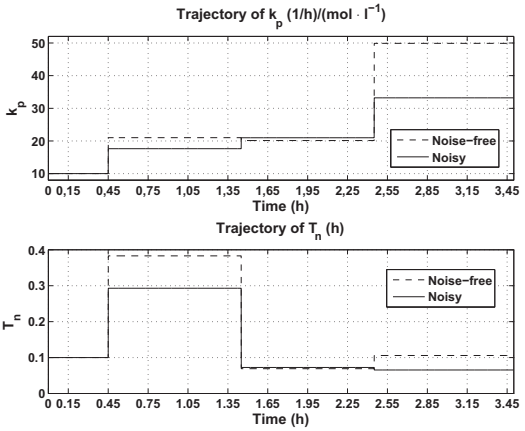

Fig. 6. Evolution of the active controller

We assume that the unknown plant P consists of the continuous stirred tank reactor as described by the above model plus a delay of $0.02h$ for the analytic instrument. The controller structure is a PI-controller defined by

$$C(s) = k_p(1 + \frac{1}{T_n s}).$$

The initial set of the controller parameters is given by the proportional gains $\mathbf{k}_{p_a} = \{10, 50, 100\}$ and the integral times $\mathbf{T}_{n_b} = \{0.1, 0.5, 1\}$. The initial set of candidate controllers consists of 9 candidate controllers with PI-controller parameter vectors $\Theta = \{\theta_i = [k_{p_a}, T_{n_b}]^T, 1 \leq a, b \leq 3\}$. The first active controller assigned to the feedback loop is $\theta_1 = [10, 0.1]^T \in \Theta$. All initial conditions at $\tau = 0$ are zero and the simulation horizon is $t_f = 3.5h$. The constant ϵ in the ϵ-hysteresis switching algorithm is 0.1 and $\gamma = 10^{-9}$ in the cost function J_i^*.

The reference signal is

$$r(t) = \begin{cases} 0mol \cdot l^{-1} & : \quad 0 \leq t < 0.15h; \\ 0.7mol \cdot l^{-1} & : \quad 0.15h \leq t < 1.15h; \\ 0.9mol \cdot l^{-1} & : \quad 1.15h \leq t < 2.15h; \\ 1.09mol \cdot l^{-1} & : \quad 2.15h \leq t < 3.5h. \end{cases}$$

EA activation times are at $t^* = 0.3h$ after each change of $r(t)$ at $t = 0.15h, 1.15h, 2.15h$.

CSTR with adaptation of the set of controllers with noisy measurements

The EA is executed three times at $0.45h$,$1.45h$, and $2.45h$. The EA used is a standard evolution strategy (ES) with adaptation of the search parameters according to Schwefel (1995) and Quagliarella et al. (1998). In this application, the size of the population is equal to the number of candidate controllers $\mu = N$. The $(\mu + \lambda)$ selection is chosen with $\mu = 9$ and $\lambda = 63$. This means that the best controllers are kept from the set of the old controllers and 63 offspring. The search space of solutions $\mathbf{k}_p \times \mathbf{T}_n$ is restricted to $[-100, 100] \times [0.01, 1]$ and the initial strategy parameters are set to 10% of the ranges of the variables. We assume Gaussian i.i.d. measurement errors and the TLS solution is used to compute the estimated sensitivity functions.

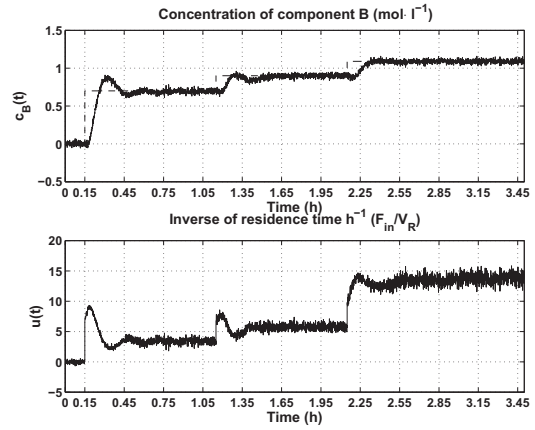

Fig. 7. Noisy control performance

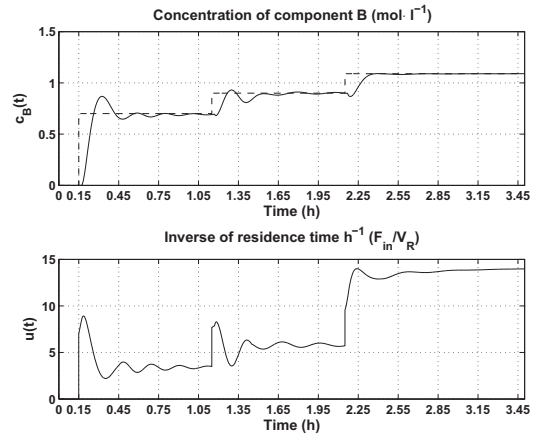

Fig. 8. Noise-free control performance

The first execution of the evolutionary algorithm was performed using measured data $d_{(0.15h,0.45h)}$ obtained with the first active controller θ_1 that was in the loop during $t \in (0.00h, 0.45h)$. At the first execution of the ES at $t = 0.45h$, the evolution strategy returns a new set of controllers for the first operating point after 38 generations. As shown in Fig. 6, the new active controller is $\theta^*_{p_{1_w}} = [17.6214, 0.2929]^T$.

The evolutionary algorithm was executed for the second time using the data $d_{(1.15h,1.45h)}$ with the active controller $\theta^*_{p_1}$. After 19 generations, the new active controller is $\theta^*_{p_{2_w}} = [20.9662, 0.0725]^T$ (see Fig. 6).

The evolutionary algorithm was executed for the third time using the data $d_{(2.15h,2.45h)}$ with the active controller $\theta^*_{p_2}$. After 12 generations the ES returned a new set of controllers and the new active controller is $\theta^*_{p_{3_w}} = [33.1989, 0.0652]^T$ (see Fig. 6). The control performance and the manipulated variable for the case with measurement noise are shown in Fig. 7 and can be compared with the noise-free case in Fig. 8. We can see that the active controller is well adapted to the change of the dynamics of the unknown plant under measurement error.

6. CONCLUSIONS

In this paper, the new scheme for adaptive unfalsified control was investigated for the case with noisy measurement. The deconvolution with noisy plant data can be solved by the total least squares method. The example of a CSTR with nonminimum phase nonlinear dynamics showed that a good performance can still be achieved for noisy measurements.

Model Based Control of Large Scale Fed-Batch Baker's Yeast Fermentation

Akif Hocalar and Mustafa Türker

Pakmaya, P.K. 149, 41001 İzmit, Kocaeli, Türkiye
akifh@pakmaya.com.tr
mustafat@pakmaya.com.tr

Abstract : Two different control methods are applied to the technical scale (25 m^3) fed-batch baker's yeast fermentation. Feedback linearizing control design is used to manipulate the substrate feeding rate in order to maximize the biomass yield and minimizing the production of ethanol. Firstly, the specific growth rate controller is developed and applied to maintain the specific growth rate at specified trajectory. Secondly, the minimal ethanol controller is developed to maximize biomass productivity, by controlling specific growth rate just above the maximum oxidative growth rate by controlling ethanol concentration. The both controllers worked successfully and can be combined to follow required specific growth rate trajectory and respond successfully to disturbances in overflow fermentations such as *Saccharomyces cerevisiae.*

Keywords: Nonlinear control, feedback linearizing control, fed-batch, baker's yeast, specific growth rate, ethanol concentration, biocalorimetry.

1. INTRODUCTION

Fed-batch bioprocesses have extensive applications in industry for production of baker's yeast, enzymes, antibiotics, growth hormones, microbial cells, vitamins, amino acids and other organic acids (Perulekar and Lim, 1985; Yamane and Shimizu, 1984). *Saccharomyces cerevisiae* is used in many applications such as beverage products (beer, wine), baker's yeast for bread production, heterologous protein production, bio-transformations, flavour components, single cell protein, bio-ethanol, glycerol and food additives (Walker, 1998; Renard and Wouwer, 2008). The specific growth rate is a key variable for the growth-associated biotechnological processes and determines the physiological state of the cells and the capacity of cell's protein-synthesizing machinery that is important for recombinant protein production or biomass production in several fermentations (Cannizzaro et. al., 2004; Gnoth et. al., 2008). Similarly, *Escherichia coli* show similar metabolic behaviour in the presence of excess substrate and shortage of oxygen. In the production of recombinant proteins with *E. coli*, acetate is produced as an overflow metabolite both when *E.coli* grown under anaerobic or oxygen limiting conditions. It is important to maintain the specific growth rate below a certain threshold in order to avoid the accumulation of acetate throughout the fermentation (Rocha and Ferreira, 2002; Jana and Deb, 2005).

In the literature, many works have been reported by several authors for the control of fed-batch fermentation, most of these studies report experimental results either at laboratory scale or simulation results (Chen and Bastin, 1995; Pomerleau and Viel, 1992; Soons et al., 2006; Rocha and Ferreira, 2002; Cannizzaro et al., 2004; Valentinotti et al., 2003).

The main objective of this study is to develop a robust control scheme to cope with changing process dynamics during fermentation, set point tracking, required minimum process measurements and batch-to-batch consistency for the technical scale fed-batch baker's yeast fermentation. The control methods are based on previously developed and verified state estimation model and reliable measurement system (Hocalar et. al., 2006).

In this work, different key process variables are controlled with the state feed-back linearizing control scheme at technical scale fermentations: 1. nonlinear control of specific growth rate, 2. nonlinear control of ethanol concentration. In the first part, the derivation of nonlinear specific growth rate controller ant its results are discussed. The restrictive conditions of the controlling of specific growth rate are given at the end of first section. In the second part, the control of nonlinear ethanol concentration is presented. By means of controlling of overflow metabolite concentration at minimal concentration, specific growth rate can be maintained near the maximum values.

2. STOICHIOMETRY OF THE PROCESS

General stoichiometry of the baker's yeast fermentation process can be written with respect to reaction rates as (Türker, 2003; Türker, 2004):

$$r_s CH_2ON_{0.0125} + r_n NH_3 + r_o O_2 \rightarrow r_x CH_{1.8}O_{0.5}N_{0.2} + r_p CH_3O_{0.5} + r_c CO_2 + r_w H_2O + r_q \quad (1)$$

and the rate vector is

$$r = (-r_s\ ,\ -r_n\ ,-r_o\ ,\ r_x\ ,\ r_p\ ,\ r_c\ ,\ r_w\ ,\ r_q)^T \quad (2)$$

Metabolic heat production rate is added to reaction rates. The unknown process states are determined by the metabolic black-box modeling and the integration of estimated reaction rates. The redundant reaction rates are used in the derivation of reconciliated reaction rates *(Hocalar et. al., 2006)*.

3. RESULTS AND DISCUSSIONS

3.1. Nonlinear Control of Specific Growth Rate

The feedback linearizing control of the specific growth rate is based on the assumption of the presence of sufficient oxygen concentration and the absence of ethanol in the fermentation broth (Claes, 1999). In order to implement the control approach, the oxygen concentration has to be maintained high enough not to run into oxygen limitation throughout fermentation and the specific growth rate has to be below the critical value in order not to form ethanol.

The starting point for the derivation of the controller expression is the general dynamical mass balance equation for the substrate feeding as shown in Eq. 3.

$$\frac{dS}{dt} = D\,(S_{in} - S) - \left(\frac{\mu_x^{ox}}{Y_{X/S}^{ox}} + \frac{q_{e,pr}}{Y_{E/S}^{red}} + m \right) X \quad (3)$$

By rearranging the Eq. 3, Eq. 4 can be written as;

$$\frac{dC_s}{dt} = -\sigma X + \frac{F_s}{V}(C_{s,in} - C_s) \quad (4)$$

where $\sigma = \left(\frac{\mu_x^{ox}}{Y_{X/S}^{ox}} + \frac{q_{s,red}}{Y_{E/S}^{red}} + m \right)$, C_s is substrate concentration, X biomass, F substrate feed rate. The second step is to set up a stable linear reference model for tracking error. The reference model determines to the decreasing trajectory of the tracking error.

$$\frac{d}{dt}(C_s' - C_s) + \lambda\,(C_s' - C_s) = 0 \quad (5)$$

The λ is arbitrary adjustment coefficient and have to be chosen such that the differential equation (Eq. 5) is stable. At steady state conditions, the substrate concentration can be accepted zero, $(\frac{dC'}{dt} \approx 0)$ and Eq. 5 can be written as $\lambda\,(C_s' - C_s) = \frac{dC_s}{dt}$ and by substituting the Eq. 4 in the Eq. 5,

$$F_s = \frac{\sigma X - \lambda (C_{s,in} - C_s')}{C_{s,in} - C_s'} V \quad (6)$$

obtained as a final controller equation. Under oxidative conditions and in the absence of ethanol in the fermentation broth, specific growth rate is a function of substrate concentration. Therefore, specific growth rate (μ) can be written instead of substrate concentration term in Eq. 6. By rearranging the Eq. 6, the expression for substrate feed rate controller can be written as follows;

$$F_s = \frac{\frac{\mu_x}{Y_{X/S}^{ox}} X - \lambda\,(\mu_s - \mu')}{C_{s,in}} V \quad (7)$$

where λ is the arbitrary adjustment coefficient for the decrease of tracking error. When the Eq. 7 is applied to the fermentation, steady state errors are observed between the estimated specific growth rate and set profiles. In order to eliminate this difference, an integral term is added to the Eq. 7. and the obtained results are presented in Fig. 1 for the controlling of time varying specific growth rate profile.

$$F_s = \frac{\frac{\mu_x}{Y_{X/S}^{ox}} X - \lambda_P \left\{ (\mu_s - \mu') - \frac{1}{\lambda_i} \Sigma (\mu_s - \mu') \right\}}{C_{s,in}} V \quad (8)$$

The results of the implementation of Eq. 8 in a fed-batch fermentation are given Fig. 1. The adjustment parameters are $\lambda_p = 0.14$, $\lambda_i = 1800$ for the ascending and $\lambda_p = 0.27$, $\lambda_i = 1800$ for the descending specific growth rate region.

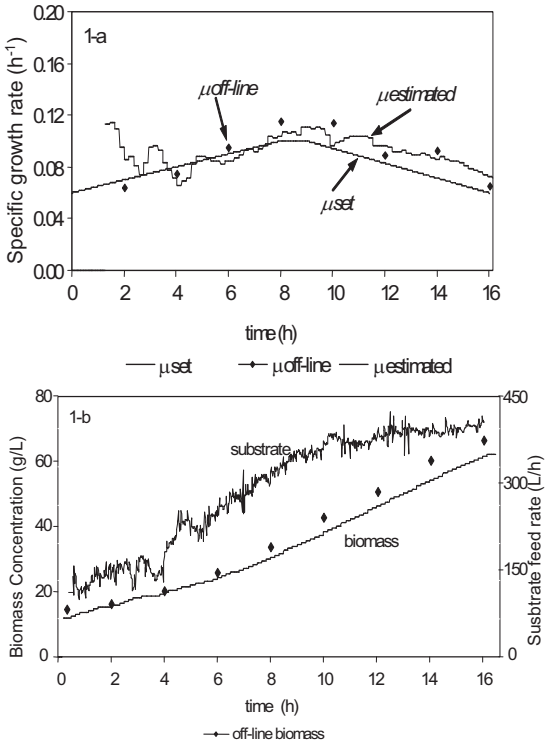

Figure 1.a- Specific growth rate b- biomass concentration and substrate.

The estimation of biomass concentration can be accepted successfully (Fig. 1-b) and is used in the calculation of specific growth rate (fig. 1-a). The specific growth rate estimations and off-line measurements are close to each other

with acceptable accuracy. The time varying specific growth rate profile is controlled successfully by the controller and obtained substrate feed rate resemble the predetermined substrate feeding profiles widely used in practice.

In Fig. 2, the results of different specific growth rate controlled fermentation are given. In this fermentation, ethanol formation is observed at the different times during the process and cause's decrease in the specific growth rate. The controller increased the substrate feed rate in order to compensate the decrease in the specific growth rate that caused more ethanol formation (Fig. 2-a). The unexpected decreases in the specific growth rate estimation are given in Fig. 2-b. The excess in the substrate feed rate puts the process more instability and results in failure of the control of specific growth rate. As a result, the substrate feed rate is manually intervened to consume the ethanol in the broth.

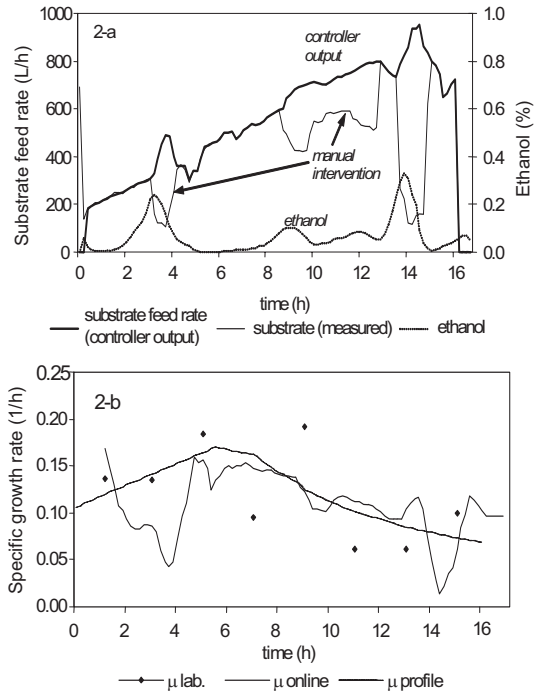

Figure 2.a- substrate feed rate and ethanol concentration, b-specific growth rate.

This controller has successfully controlled the specific growth rate at trajectory under defined conditions as shown in Fig. 1. Once the fermentation went to beyond the restrictive conditions the controller failed as shown in Fig. 2.

3.2. Nonlinear Control of Minimum Ethanol Concentration

An alternative way to control the specific growth rate at maximum oxidative rate is to use the overflow metabolite as an indicator of how close the actual value to critical growth rate to maximize biomass production. If ethanol concentration can be controlled at constant minimal concentration, it is possible to keep the specific growth rate slightly above the critical value (Cannizzaro et. al., 2004). In order to control the ethanol concentration, the regulator design is based on a feedback linearization of a reduced-order model of the process obtained by singular perturbation of the state space model under the following assumptions: the stoichiometric (yield) coefficients are known, the gaseous outflow rates (ethanol, CO_2, O_2) are measured on-line, the influent substrate concentration S_{in} is fixed and known, the specific growth rate is unknown. The singular perturbation techniques can be used for systems in which some reactions proceed at much faster rates than the others (Bastin and Dochain, 1990; Pomerleau and Viel, 1992; Chen et. al., 1995).

The dynamical process equations for five process states with known yield coefficients can be given as follows;

$$\frac{d}{dt}\begin{bmatrix} X \\ S \\ E \\ O \\ C \end{bmatrix} = \begin{bmatrix} 1 & 1 & 1 \\ -Y^{ox}_{X/S} & -Y^{red}_{X/S} & 0 \\ 0 & Y^{red}_{X/E} & -Y^{eth}_{X/E} \\ -Y^{ox}_{X/O} & 0 & -Y^{eth}_{X/O} \\ Y^{ox}_{X/C} & Y^{red}_{X/C} & Y^{eth}_{X/C} \end{bmatrix} \begin{bmatrix} \mu^{ox}_x \\ \mu^{red}_x \\ \mu^{ox}_e \end{bmatrix} X - D \begin{bmatrix} X \\ S \\ E \\ O \\ C \end{bmatrix} + \begin{bmatrix} 0 \\ DS_{in} \\ 0 \\ r_o \\ -r_c \end{bmatrix} \tag{9}$$

The general state space dynamical model can be written as follows (Bastin and Dochain, 1990);

$$\frac{d\xi}{dt} = K\varphi(\xi) - D\xi + F - Q \tag{10}$$

$$\xi^T = [X, S, E, O, C]$$

where ξ, Q, F involves n components, φ involves m reaction rates ve K is (NxM) size yield coefficient matrix. In Eq. 9, the first term $K\varphi(\xi)$ describes the kinetics of microbiological reactions, the remaining term $-D\xi + F - Q$ describes the transport dynamics of the components through the bioreactor. The yield coefficients used in the design is shown in Table 1.

Table 1. Parameters used in nonlinear controller design (Cmol/mol) (Beşli et. al. 1995).

k_1, $Y^{ox}_{X/S}$	3.65	k_2, $Y^{red}_{X/S}$	0.36
k_3, $Y^{red}_{X/E}$	0.19	k_4, $Y^{eth}_{X/E}$	1.35
k_5, $Y^{ox}_{X/O}$	1.56	k_6, $Y^{eth}_{X/O}$	0.83
k_7, $Y^{ox}_{X/C}$	1.45	k_8, $Y^{red}_{X/C}$	0.2
k_9, $Y^{eth}_{X/C}$	1.99		

By the systematic application of singular perturbation technique, fully reduced model can be established and in the case of $\dim(\xi_F) = M$ and K_F full rank, the process states can be partitioned as slow $\xi^T_S = [X, E]$ and fast varying state variables $\xi^T_F = [S, O, C]$. The substrate, oxygen and carbon-dioxide are fast varying state variables and biomass and ethanol are slow varying state variables for the fed-batch yeast fermentation process. The general dynamical model can be written as given in Eq. 11 by the assumption of the fast

varying state variables dynamics allow the singular perturbation (Bastin and Dochain, 1990);

$$\frac{d\xi_S}{dt} = K_S\,\varphi - D\,\xi_S + F_S - Q_S$$
$$K_F\,\varphi + F_F - Q_F = 0 \tag{11}$$

The reaction rate vector , $\varphi(\xi)$, can be written as;

$$\varphi(\xi) = -K_F^{-1}\,(F_F - Q_F) \tag{12}$$

By substituting Eq. 12 in Eq. 11, the dynamics of slow varying state variables can be obtained as in Eq. 13.

$$\frac{d}{dt}\begin{bmatrix} X \\ E \end{bmatrix} = -D\begin{bmatrix} X \\ E \end{bmatrix} + \begin{bmatrix} 1 & 1 & 1 \\ 0 & k_4 & -k_3 \end{bmatrix} * inv(K_F) \begin{bmatrix} DS_{in} \\ r_o \\ -r_c \end{bmatrix} \tag{13}$$

In steady state, singular perturbation allows the fast varying state's dynamics to consider to equal to zero and unknown reaction rates can be determined by simple matrixes operations as shown below if the inverse of the yield coefficient matrices can be calculated (Hocalar, 2007).

$$\begin{bmatrix} \mu_s^{ox} \\ \mu_s^{red} \\ \mu_e^{ox} \end{bmatrix} = -K_F^{-1} \begin{bmatrix} DS_{in} \\ r_o \\ -r_c \end{bmatrix} \tag{14}$$

By inserting the Eq. 14 in Eq. 13, slow varying process states can be calculated by means of basic matrice operations:

$$\psi = det(K_F) = \left(k_7 k_6 k_2 - k_5 k_9 k_2 - k_1 k_8 k_6\right)$$
$$\upsilon_1 = \left(-k_4 k_1 k_6 + k_3 k_2 k_5\right)\psi^{-1}$$
$$\upsilon_2 = \left(-k_4 k_1 k_9 + k_3 k_2 k_7 - k_3 k_1 k_8\right)\psi^{-1}$$
$$\upsilon_3 = \left(k_4 k_5 k_9 - k_4 k_6 k_7 + k_3 k_5 k_8\right)\psi^{-1}$$
$$\frac{dE}{dt} = -D\,E + \upsilon_3\,DS_{in} + \upsilon_2\,r_o - \upsilon_1\,r_c \tag{15}$$

By inserting the Eq. 15 into the first order reference model equation in Eq. 16, the controller law for substrate feed rate can be obtained as in Eq. 17.

$$\frac{d}{dt}(y^* - y) + (\lambda_1 + \lambda_2 x)(y^* - y) = 0 \quad (\lambda_1, \lambda_2 > 0) \tag{16}$$

$$F_s = \frac{1}{\upsilon_3}\left\{\frac{dE^*}{dt} + (\lambda_1 + \lambda_2 \hat{X})(E_s - E) + DE + \upsilon_1 r_c - \upsilon_2 r_o\right\} \tag{17}$$

The tracking ethanol error is tried to minimize using λ adjustment parameters. Several fed-batch experiments were conducted in a 25 m^3 fermentor to validate the control strategy. The results are given in Fig. 3.

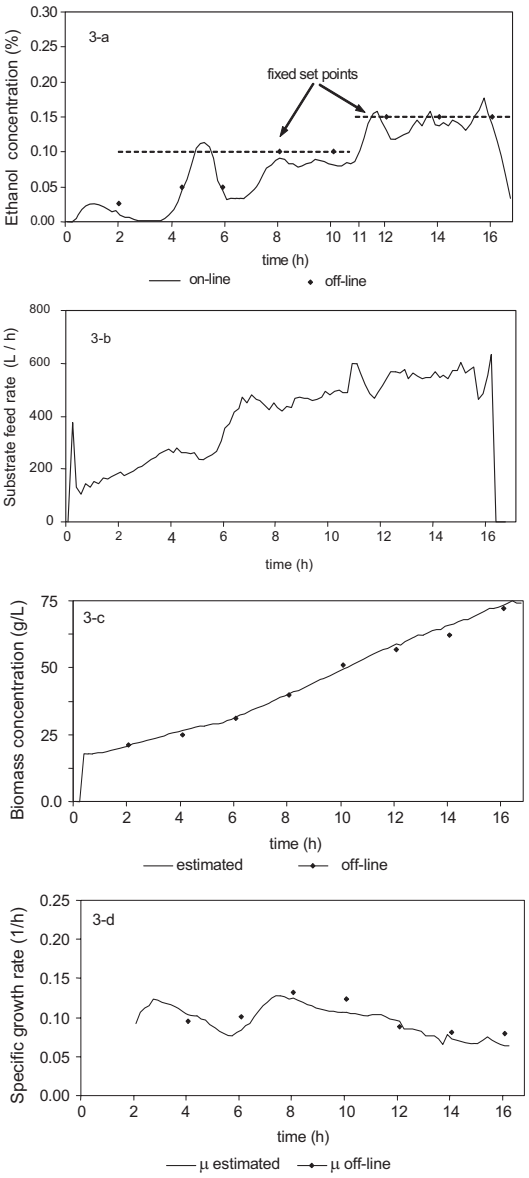

Figure 3: a- Ethanol concentration, b- substrate feed rate, c- biomass concentration and d- specific growth rate curves obtained from the industrial fermentation.

The controller was started at second hour and two fixed set points were tried to control for certain periods with ethanol set values E_s= % 0.10 and then with E_s= % 0.15. The ethanol concentration was successfully controlled at different set values from the 7th hour to the end of fermentation. The manipulated variable substrate feed rate and biomass concentration are given in Fig. 3-b and 3-c respectively. The biomass concentration increased exponentialy (Fig. 3.c) and the specific growth rate estimation is given in Fig. 3-d and quite close to experimental results. The controller developed stable response to the step change in the ethanol set point. The controller automatically adapted the feed rate of substrate to compensate for step changes. The difficulty of controlling the ethanol concentration can be seen in first

hours of fermentation (exponential growth phase). During the first hours, the controller increased the substrate feed rate and because of the time delay of the ethanol formation, slightly excess substrate feeding suggested by the controller.

4. CONCLUSION

The state feedback linearizing control strategy is applied to the industrial fed-batch baker's yeast fermentations. The control of specific growth rate and minimal ethanol concentration are attempted at technical scale fermentations. The control of specific growth rate at specificed trajectory is required in many fermentation processes. In this work, this approach has been successfully applied to baker's yeast fermentation. In order to maximize biomass concentration and productivity, the process has to be controlled at its maximum oxidative growth rate, minimizing by-product ethanol formation. This strategy is applied in second controller and specific growth rate was maintained slightly above maximum oxidative growth rate by maintaining and controlling by product ethanol at minimal concentration. This approach can also be applied to similar overflow processes such as the growth of *E. coli*. The ethanol concentration was controlled successfully at minimal concentrations. Both controllers can be combined to control specific growth rate at any trajectory and to minimize ethanol production.

Modeling and Control of Free Radical Co-Polymerization

Harshad Ghodke, Siddarth Raman, B. Erik Ydstie

Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh, USA (e-mail: ydstie@cmu.edu).

Abstract: In this work, we develop a model and a control system for a 4 monomer acrylate - methacrylate - styrene free-radical co-polymerization reaction. The model was implemented in PREDICI, and parameter estimation was carried out using nonlinear optimization from semi-batch experiments. Molecular weight distribution (MWD) determine utility. Stringent control over reactor conditions is critical. An inventory control scheme was demonstrated to work well for this complex polymerization process. A correlation mapping among the steady state initiator and monomer concentrations, molecular weight distributions and poly-dispersity was used to assign set-points for the inventory controller.

Keywords: polymerization, process control, passivity, automotive paint.

1. INTRODUCTION

We have developed a kinetic model for the free-radical polymerization of the Hydroxypropyl acrylate/ Styrene/ Butyl acylate/ Butyl methacrylate (HPA/ Sty/ BA/ BMA) copolymerization system. Unknown model parameters were estimated using data from semi-batch experiments and an inventory control strategy has been proposed for operation in continuous mode. The kinetic model has been implemented in PREDICI while the control system was implemented in MATLAB. The motivation of this current work stems from the need for effective operation of industrial continuous polymerization reactors to make resins from acrylates, methacrylates and styrene. These resins are an important constituent of automotive coatings.

Homopolymerization and butyl acrylate systems have previously been studied, and rate-constants are available in literature (Beuermann and Buback (2002), Maeder and Gilbert (1998), Curteanu (2003), Curteanu and Bulacovschi (2005)). For example, Congling Quan and Grady (2003) have developed a kinetic model of the high-temperature free-radical polymerization of butyl acrylate capable of predicting polymer molecular weight for a semi-batch process. D. Li and Hutchinson (2005) developed kinetic models for butyl acrylate - butyl methacrylate free radical polymerization system. In this study, the modeling tool PREDICI was used to show good predictions for the outputs, without a need for further refinement of the kinetic parameters. However, it is uncommon to find models with parameters that have been refined using a combination of experimentation and parameter optimization for this system.

The processability and utility of polymer products depend upon reactor operating conditions, and, good control is needed to achieve desired properties (Amrehn (1977), Elicabe and Meira (1988), MacGregor (1986)). Several promising control strategies applied to polymerization processes such as adaptive control (W. R. Cluett (1985)), optimal control (Choi (1997)), output feedback control (Soroush and Zambare (2000)) and nonlinear model predictive control (H. Seki (2001)) have been proposed. None of these approaches however, have been applied to very complex polymerization systems with several monomer inputs and few advanced schemes have found industrial application.

The purpose of our paper is to investigate the feasibility of using inventory control to control polymer properties. Inventory control is based on the idea of manipulating process flows so that the inventories follow their set points. The operator mapping flows to inventories in a macroscopic system is passive and any input strictly passive (ISP) feedback controller can be used in order to achieve input-output stability. The inventory control approach, which can be viewed as a way to chose candidate measured and manipulated variables for output linearization, was proposed by C. A. Farschman (1998). The method has been applied to transport reaction systems by M. Ruszkowski (2005). M. D. Díez (2007) applied the method to control particulate systems and Ydstie and Jiao (2006) applied the method to control a float glass plant for automotive windshield production. The HPA/ Sty/ BA/ BMA copolymerization system central to our work, has not been previously studied in literature from a modeling and control point of view. The model we propose combines literature data with experimental studies using nonlinear optimization.

2. KINETIC MODEL FOR FREE-RADICAL POLYMERIZATION

The model for free-radical polymerization consists of the following sets of reactions: Initiation, Propagation, Chain-transfer and Termination.

⋆ This work was supported by PPG Inc.

Initiation: The initiator used in this study is Di-*t*-amyl peroxide (DTAP) with a half life of 2 minutes at 160 °C (AkzoNobel (2006)). It decomposes with an efficiency f, to form two free radicals that can initiate propagation by reaction with any of the four monomers present in the system, abstract hydrogen atoms from other species in the system or recombine to form the initiator. Equation (1) represents the initiator decomposition reaction

$$I \xrightarrow{k_d} 2\,f\,I^{\cdot} \tag{1}$$

The dissociation rate constant k_d for DTAP is known to be given by eq (2) (AkzoNobel (2006))

$$k_d = 4.08 \times 10^{15} e^{-\frac{17831.36}{T}} \quad (s^{-1}) \tag{2}$$

The free radicals generated by initiator decomposition can initiate polymerization by reacting with the monomer species present in the solution. This process is described by the initiation reactions as shown in eq (3).

$$I^{\cdot} + M_i \xrightarrow{k_{p_{ii}}} P_1^{i\cdot} \tag{3}$$

Propagation: The polymer chain is then propagated by the products of the initiation reactions by reaction with monomers via the propagation reactions given in eq (4).

$$P_n^{i\cdot} + M_j \xrightarrow{k_{p_{ij}}} P_{n+1}^{j\cdot} \tag{4}$$

The rate constants for the homo-polymerization reactions, $k_{p_{ii}}$ (Asua (2007); D. Li and Hutchinson (2005)) were evaluated at 433 K and 10 psi. $k_{p_{11}}$ was assumed to be identical to $k_{p_{33}}$ because of lack of literature values. $k_{p_{33}}$ (and hence $k_{p_{11}}$) was assumed to be insensitive to pressure. Where possible, $k_{p_{ii}}$ were calculated using (6) and (5).

$$k_{p_{ii}} = A_i\, e^{-\frac{E_i + 1\times10^{-6}\Delta V_p\, P}{R\,T}} \qquad \forall i \in \{2,4\} \tag{5}$$

$$k_{p_{ii}} = A\, e^{-\frac{E_a}{R\,T}} \qquad \forall i \in \{1,3\} \tag{6}$$

The rate constants for the hetero-propagation reactions, $k_{p_{ij}}$, are obtained by defining reactivity ratios, r_{ij}, as shown in (7)

$$r_{ij} = \frac{k_{p_{ii}}}{k_{p_{ij}}} \tag{7}$$

Reactivity ratios were obtained from literature (Ham (1964); Chow (1975)). For the particular set of monomers present in the HPA/Sty/BA/BMA system, it was difficult to obtain reactivity ratios at the desired temperature. The values obtained from literature or calculated from *Q-e* data are available at temperatures different from the reactor temperature and hence, were treated as estimates.

Chain Transfer: Chain transfer in the context of free-radical polymerization involves the transfer of the radical from a live polymer chain to any other species present in the system which may be initiator, monomer, solvent molecules, dead polymer or live polymer or another species specifically added to the system which behaves as a chain transfer agent (CTA) (Asua (2007)). In this work, three types of chain transfer reactions are considered - chain transfer to monomer, chain transfer to solvent and chain transfer to live polymer.

Chain Transfer to Monomer: Chain transfer to monomers that contain aliphatic hydrogens such as acrylates and methacrylates involves H-atom abstraction to form an unsaturated radical (Asua (2007)). This unsaturated radical may then undergo further reaction as shown in eq (8). Transfer to monomer rates were not available in literature and were calculated using eq (9).

$$P_n^{i\cdot} + M_j \xrightarrow{k^{mon}_{tr_{ij}}} P_1^{j\cdot} + D_n \tag{8}$$

$$k^{mon}_{tr_{ij}} = \frac{k_{p_{ij}}}{C^{mon}_{tr}} \tag{9}$$

C^{mon}_{tr} is the coefficient for chain-transfer to monomer and typically lies in the range $1 - 50 \times 10^{-5}$ (Asua (2007)). For this work, the value C^{mon}_{tr} was taken to be 1×10^{-5}.

Chain-transfer to solvent: Chain transfer to solvent occurs according to reactions eq (10) and eq (11). In this system, for lack of literature values, we assume that both the solvents behave identically, and hence, have identical rate constants. The rate constants for chain transfer to solvent are obtained from eq (12) using a value for $C^{S_k}_{tr}$ is taken to be 3.16×10^{-5}, which is the logarithmic mean of the range in which it lies in 1×10^{-6} - 1×10^{-3}.

$$P_n^{i\cdot} + S_k \xrightarrow{k^{S_k}_{tr_{ii}}} S_k^{\cdot} + D_n \tag{10}$$

$$S_k^{\cdot} + M_i \xrightarrow{k^{S_k}_{ii}} P_1^{i\cdot} \tag{11}$$

$$k^{S_k}_{tr_{ii}} = \frac{k_{p_{ii}}}{C^{S_k}_{tr}} \tag{12}$$

Further, for lack of literature values, the rate constants $k^{S_k}_{ii}$, are assumed to be identical to the rate constant for propagation.

Chain transfer to Polymer: Chain transfer to polymer occurs according to reaction eq (13). In this system, for lack of literature values, we assume that the chain transfer to polymer is similar to chain transfer to monomer, and hence, has similar rate constants. The rate constants for chain transfer to polymer are obtained from eq (14), using a value of C^{pol}_{tr} equal to 1×10^{-5} which is the logarithmic mean of the range in which it lies 1×10^{-6} - 1×10^{-4}.

$$P_n^{i\cdot} + D_m \xrightarrow{k^{pol}_{tr_{ij}}} P_m^{j\cdot} + D_n \tag{13}$$

$$k^{pol}_{tr_{ij}} = \frac{k_{p_{ij}}}{C^{pol}_{tr}} \tag{14}$$

Termination: Termination occurs via two competing routes - combination (eqn (15)) and disproportionation (eqn (16)). Termination by combination results in the formation of a single dead polymer chain from two live polymer chains, whereas, termination by disproportionation results in the formation of one dead polymer chain and a live polymer chain with an unsaturated terminal residue which may react further.

$$P_n^{i\cdot} + P_r^{j\cdot} \xrightarrow{k_{tc_{ij}}} D_{n+r} \tag{15}$$

$$P_n^{i\cdot} + P_r^{j\cdot} \xrightarrow{k_{td_{ij}}} D_n + D_r \tag{16}$$

The termination rate constant is defined as the sum of the individual rate constants for termination by combination and disproportionation (eq (17)).

$$k_t = k_{tc} + k_{td} \tag{17}$$

Termination rates for free radical polymerization are diffusion controlled (Asua (2007)) and any available estimates are system specific. Thus, for the HPA/Sty/BA/BMA system, termination rates that were obtained from literature (Asua (2007)) were treated as estimates. The rate constant

for homo-termination for M_1 was not available in literature and was assumed to be identical to that of M_3.

The relative importance of the mechanism of termination by disproportionation versus termination by combination is measured using a parameter δ, which is defined in eq (18).

$$\delta = \frac{k_{td}}{k_{tc} + k_{td}} \tag{18}$$

δ_{ij} values for styrene and acrylates lie in the range of 0.05 - 0.2 while those for methacrylates lie in the range 0.5 - 0.8 (Asua (2007)). In this work, δ_{ii} for acrylates and styrene is taken to be 0.05, while that for methacrylates is taken as 0.65 (D. Li and Hutchinson (2005)). δ_{ij} value was evaluated as the arithmetic mean of δ_{ii} and δ_{jj}. The values for δ_{ii} were taken to be 0.05 for acrylates, 0.65 for methacrylates.

For the copolymerization reactions, $k_{tc_{ij}}$ and $k_{td_{ij}}$ are calculated using equations (19), (20) and (21). Equation (19) was obtained by generalizing eq (16) from D. Li and Hutchinson (2005) for the case of more than 2 monomers. Here, f_i represents the instantaneous mole fraction of M_i.

$$k_{t,copo_{ij}} = k_{t_{ii}}^{f_i}\, k_{t_{jj}}^{f_j} \tag{19}$$

$$k_{tc_{ij}} = (1 - \delta_{ij})\, k_{t,copo_{ij}} \tag{20}$$

$$k_{td_{ij}} = \delta_{ij}\, k_{t,copo_{ij}} \tag{21}$$

3. EXPERIMENTAL DATA AND PARAMETER ESTIMATION

Polymerization of the HPA/Sty/BA/BMA system was carried out in a well mixed, semi-batch reactor. The feed to the reactor consists of four monomers and an inhibitor dissolved in two solvents. The polymerization is carried out in semi-batch mode, in a 4000 mL vessel isothermally at a temperature of 160 °C and pressure of 10 Psi. The temperature of the vessel is maintained constant using electrical heating.

The reactor is initially charged with solvent mix (76 g S_1, 549.4 g S_2) and heated to 210 °C and then allowed to cool to 160 °C at atmospheric pressure. Feed A (293.6 g S_1 and 65 g I) and Feed B (827.2 g M_1, 393.9 g M_2, 374.2 g M_3 and 374.3 g M_4) are then fed to the reactor simultaneously for a period of 125 min and 120 min respectively. For the semi-batch process the outputs of interest are the residual monomer concentrations, weight average molecular weight (MW_w), number average molecular weight (MW_n), z-average molecular weight (MW_z) and the polydispersity index (PDI). Experimental data was obtained from two different sets of experiments. In one set, only data for the first 1000 seconds was collected and in the second set, data for times from 1000 - 7000 seconds was collected.

This model was implemented in PREDICI (Polyreaction Distributions by Countable System Integration), a comprehensive simulation package for the numerical integration of differential equations arising out of the kinetic equations describing polymerization systems. The results for the integration of the differential equations generated for the semi-batch process model in PREDICI are compared with the experimental data. The integration was performed in the *moment mode* with the values for the rate constants as listed in the tables and the relevant outputs were tracked. The model matches the experimental results poorly using literature data for the kinetic parameters.

Sensitivity and Estimability Analyses: The kinetic model for the HPA/Sty/BA/BMA system has a total of 79 parameters which can be estimated. To improve the fit of the model predictions and the experimental data, parameter estimation was carried out. The set of estimable parameters was obtained following the methodology of K. Zhen Yao (2003). Hence, as a first step toward identifying estimable parameters, a sensitivity study was carried out to identify the sensitivity of the model outputs with respect to the set of parameters as functions of time. The estimable parameters represent the set of parameters that affect the relevant set of outputs the most, among all the parameters, based on the initial values of the parameters at which the sensitivity derivatives are evaluated. The algorithm use to identify this set is called the Estimability analysis (K. Zhen Yao (2003)).

In order to be able to compare the measure of the sensitivity of a parameter, the sensitivity derivatives are non-dimensionlized using a scaling factor φ_{ijk} defined so that

$$\tilde{S}_{ijk} = \varphi_{ijk} \frac{\Delta y_{i,k}}{\Delta \theta_j}, \quad \varphi_{ijk} = \frac{\hat{\theta}_j}{\hat{y}_{i,k}} \tag{22}$$

$\hat{\theta}_j$ and $\hat{y}_{i,k}$ are used for scaling because they reflect the approximate magnitudes of changes in parameter estimates and model predictions respectively. Here, θ_j represents the j^{th} paramater and $y_{i,k}$ represents the value of the i^{th} output at the k^{th} time point.

It is important to note that the number of estimable parameters depends on the number of output variables, the number of observations per output variable and the linear dependence of the parameters on each other. Further, the global identifiability of the parameters depends on the size of the space of input-output variable values in which experimental data is available. For the purpose of estimability calculations, the scaled sensitivity derivatives defined in eq (**??**) were used to construct the *Scaled Sensitivity Matrix,* $\tilde{S}$ given in eq (23).

$$\tilde{S} = \begin{bmatrix} \varphi_{111}\dfrac{\partial y_{1,1}}{\partial \theta_1} & \cdots & \varphi_{1p1}\dfrac{\partial y_{1,1}}{\partial \theta_p} \\ \vdots & \ddots & \vdots \\ \varphi_{r11}\dfrac{\partial y_{r,1}}{\partial \theta_1} & \cdots & \varphi_{rp1}\dfrac{\partial y_{r,1}}{\partial \theta_p} \\ \varphi_{112}\dfrac{\partial y_{1,2}}{\partial \theta_1} & \cdots & \varphi_{1p2}\dfrac{\partial y_{1,2}}{\partial \theta_p} \\ \vdots & \ddots & \vdots \\ \varphi_{r1n}\dfrac{\partial y_{r,n}}{\partial \theta_1} & \cdots & \varphi_{rpn}\dfrac{\partial y_{r,n}}{\partial \theta_p} \end{bmatrix} \tag{23}$$

The cut-off (ϵ) value for which the algorithm is terminated is fairly arbitrary. From the estimability analysis for an $\epsilon = 1 \times 10^{-2}$, only 8 parameters may be estimated with $\mathcal{L} \equiv \{f, k_{t_{22}}, k_{p_{23}}, k_{p_{21}}, k_{p_{11}}, \delta_{22}, k_{p_{31}}, k_{p_{24}}\}$ in order of estimability.

Parameter Estimation: The parameter estimation algorithm was implemented by combining PREDICI and MATLAB using an MS Excel interface. The PREDICI-Excel link was set up to integrate the differential equations

based on initial conditions for parameters obtained from literature values. Updated estimates for the parameters were obtained from a weighted non-linear least squares Gauss - Newton algorithm with line search implemented in MATLAB. Table 1 shows the optimized values of the parameters.

Table 1. Optimized values of the estimable parameters

Parameter	Optimal value
f	0.95
$k_{t_{22}}$	1×10^9
$k_{p_{23}}$	8483. 5
$k_{p_{21}}$	426. 6
$k_{p_{11}}$	3.5114×10^5
δ_{22}	0.2
$k_{p_{31}}$	100
$k_{p_{24}}$	2136

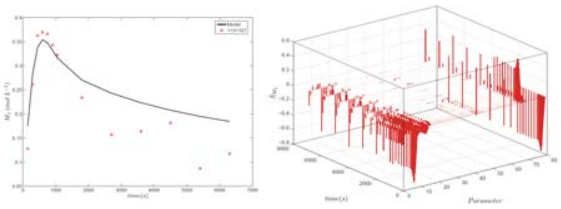

Fig. 1. Model results (solid) vs experiments (circles) for Monomer 1 (Left). Scaled sensitivity for Mononmer 1 shown with respect to time and the 79 parameters (Right).

Comparison plots shows that the model over-predicts some of the outputs and under-predicts some others. A typical result is shown in Figure 3.The sensitivity plot Figure 3 in shows that the sensitivity derivatives for the set of estimable parameters are of the same sign. This necessarily implies, that there is a trade-off between the outputs for which the model over-predicts and those for which the model under-predicts. This means that we can only obtain 'good' fits for either the set of outputs which are over-predicted or the set of outputs which are under-predicted. We conclude that the model we have developed misses some reaction mechanisms and that good fit with the semi-batch data is not possible.

4. CONTROL SYSTEM FOR THE COPOLYMERIZATION SYSTEM

Let the vector x represents the state of a process system, m a vector of control variables, d a vector of disturbance variables and y a vector of measurements. An inventory for the system described above is defined to be an additive continuous function v: $\mathbf{X} \rightarrow \Re$. For the system described above and using the nomenclature introduced in C. A. Farschman (1998) we have:

$$\frac{\mathrm{d}v}{\mathrm{d}t} = \phi(m, x, d) + p(x), \qquad v = g(z) \tag{24}$$

where $v \in \mathbb{R}_{+}^{dimv}$ are the inventories (mass, component mass,...). C. A. Farschman (1998) showed that the synthetic input and output pair

$$u = \phi + p + \frac{\mathrm{d}v^*}{\mathrm{d}t} \qquad e = (v - v^*) \tag{25}$$

is passive with the storage function $\psi = \frac{1}{2}(v-v^*)^T(v-v^*)$. C. A. Farschman (1998) implement a feedback-feedforward control in the form

$$u = -\mathbf{C}(e) = \phi(m, z, d) + p(z, d) + \frac{\mathrm{d}v^*}{\mathrm{d}t} \tag{26}$$

This control law is input strictly passive (ISP). Khalil (2002) showed that when a passive system is connected in feedback with an ISP controller, the closed loop is also passive. Hence the operator $\mathbf{C}$(e), which maps errors into synthetic controls, should be strictly passive. Most controllers in use are strictly passive. The control law is easy to implement if the inventories can be estimated from process data and the mapping $\phi(m, z, d)$ can be inverted with respect to the control variables m. In the simulations below we use a proportional controller ($\mathbf{C}(e) = Ke$ where K is a positive constant). It can be observed that an inventory controller linearizes the system dynamics.

In our application, the manipulated variables are the input flows of monomers (F_{M_1} to F_{M_4}) and initiator (F_I). The concentrations of the monomers and initiator are selected as the inventories and are forced to track their respective set-points. This gives a 5×5 multivariable control system for our system. Using the differential equation model (Equations 24 and 25), we generate the control equations for the required manipulated variables which force the concentration of the initiator and the respective monomers to its set-point. The control scheme generated is shown below: Control equation for initiator I,

$$F_{I_{in}} = F_{I_{out}} + k_d I V - K(I - I^*) \tag{27}$$

Control equations for the monomers,

$$F_{M_{1,in}} = F_{M_{1,out}} + \Big(2fk_dI + \sum_{j=1}^{4} P_n^{j\cdot} M_1 (k_{p_{j1}} + k_{tr_{j1}} + \sum_{l=1}^{2} k_{11}^{S_l} S_l M_1)\Big)V - K(M_1 - M_1^*) \tag{28}$$

$$F_{M_{2,in}} = F_{M_{2,out}} + \Big(2fk_dI + \sum_{j=1}^{4} P_n^{j\cdot} M_2 (k_{p_{j2}} + k_{tr_{j2}} + \sum_{l=1}^{2} k_{22}^{S_l} S_l M_2)\Big)V - K(M_2 - M_2^*) \tag{29}$$

$$F_{M_{3,in}} = F_{M_{3,out}} + \Big(2fk_dI + \sum_{j=1}^{4} P_n^{j\cdot} M_3 (k_{p_{j3}} + k_{tr_{j3}} + \sum_{l=1}^{2} k_{33}^{S_l} S_l M_3)\Big)V - K(M_3 - M_3^*) \tag{30}$$

$$F_{M_{4,in}} = F_{M_{4,out}} + \Big(2fk_dI + \sum_{j=1}^{4} P_n^{j\cdot} M_4 (k_{p_{j4}} + k_{tr_{j4}} + \sum_{l=1}^{2} k_{44}^{S_l} S_l M_4)\Big)V - K(M_4 - M_4^*) \tag{31}$$

In the above equations, K is a positive constant and I^* and $M_i^*(i \in \{1, 2, 3, 4\})$ are the predetermined set-points for the initiator and monomer concentrations. The theory provides guidance for how to chose K since $1/K$ corresponds to the closed loop time-constant. The control

system assumes that the initiator and four monomer concentrations are measured. If these variables are not measured then it is necessary to develop an estimator to estimate these variables from the model.

To illustrate the performance of the control system we have introduced set point changes, first in M_1 at time 330 seconds and then in I at time 510 seconds to study how the system responds to these set point changes after the effect of initial conditions have died out. The results for the setpoint tracking performance for initiator and 3 monomers are shown in Figure 2 [1] . The proportional gain for all four controllers is $K = 0.01$ so that the closed loop time constant for all the four outputs is equal to 100 secs. The results show that the inventory controller decouples the response so that a setpoint change in one variable does not lead to a change in the other variables [2] . In practice there will be a mismatch between the real system and the controller equations and it may not be possible to achieve perfect decoupling.

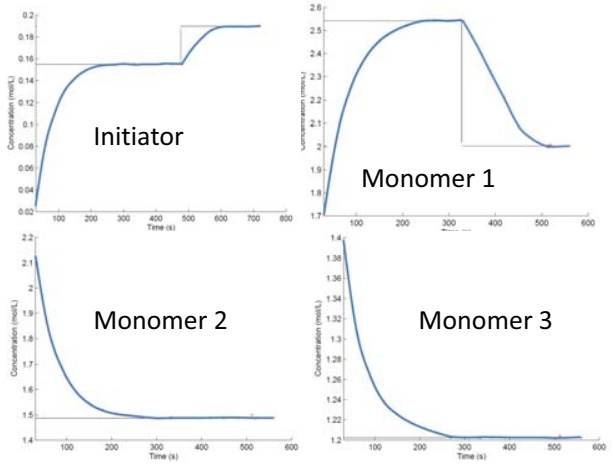

Fig. 2. Initiator, 3 Monomer Concentrations and Setpoints

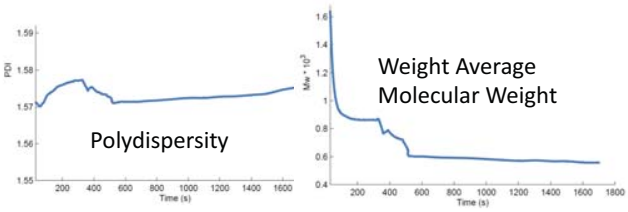

Fig. 3. Polydispersity and Weight Average Molecular Weight

5. THE CORRELATION MAPPING

The inventory control scheme allows the user to define setpoints in terms of inventories. In our case these are the initiator concentration and concentrations of monomers inside the reactor. These variables are related to the flow variables in a passive manner and they are easy to control. In practice it is often necessary to control secondary variables like molecular weight and polydispersity. These variables are more difficult to control since the relative degree of the control system now may be much higher. In this work we have solved the problem by developing a correlation mapping to identify how the steady state monomer set points correspond to target molecular weights and polydispersity for use in the inventory control scheme. The idea now is to use the mapping to generate inventory setpoint and control to the calculated setpoints. Model uncertainty can be compensated for using a separate estimation algorithm to fit the mapping to the data in real time.

One example of such a correlation is shown in Figure 4. The x-axis consists of the different molecular weight distributions. the numbers 1 to 3 are indices corresponding to M_w, M_n and M_z respectively. The z-axis shows the number value of each of the molecular weight distributions, while the y-axis shows the values of the input flow rates. These maps provide a means to chose set points for monomer inventories to achieve desired polymer properties. Similar plots were developed for the initiator and the other monomers.

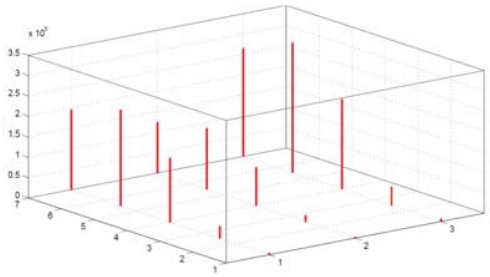

Fig. 4. M1-MWD correlation plot

Table 2. Simulation Results for varying M1

Flow rate of $M1$(kg/s)	M_w	M_n	M_z
1	4574	2439	6844
2.5	30003	15813	44928
4	158560	93652	219070
5.5	235980	149230	319110
7	195670	123340	264750

6. CONCLUSIONS

A kinetic model for free radical polymerization of the monomers in HPA/Sty/BA/BMA was developed and implemented in PREDICI. Kinetic parameters obtained from literature were found to predict the experimental data poorly. Further refinement was carried by implementing a parameter estimation algorithm based on nonlinear optimization. A sensitivity study and an estimability analysis were carried out to identify the set of estimable parameters. The estimable parameters were then optimized using a weighted, constrained non-linear least squares Gauss-Newton algorithm with backtracking line search. The optimized values of the parameters were found to yield better fits for the experimental data. However, there seems to be

[1] Due to space limitation we do not show the 4th monomer which is similar to the third and fourth.

[2] The simulated controller used a sampling time of 30 sec during the period when the setpoints were constant. It was decreased to one sample every 2 seconds for a brief period during the setpoint change

a trade-off between the two types of outputs (molecular weights and residual monomer concentrations) that may be optimized. It is possible to fit only either set of outputs very well, using this model. Certain features of the experimental data were not captured, indicating that the need for further refinement of the model by adding other reactions that are relevant to the process. An inventory control approach was proposed to force monomer concentrations to track some pre-determined set points. These set points can be appropriately selected based on the requirements using a correlation mapping such as the one performed in this study.

NOMENCLATURE

I ≡ Initiator
M_i, M_j ≡ Monomer
S_k ≡ Solvent
$P_n^{i\cdot}$, $P_r^{i\cdot}$, $P_{n+r}^{i\cdot}$, $P_m^{i\cdot}$ ≡ Live Polymer Chain
D_n, D_r, D_m, D_{n+r} ≡ Dead Polymer Chain
φ_{ijk} ≡ Scaling factor

Sets

$\mathcal{M} \equiv \{M_1, M_2, M_3, M_4\}$ ≡ set of all monomers
$\mathcal{A} \equiv \{M_1, M_2, M_3\}$ ≡ set of Acrylate monomers
$\mathcal{MA} \equiv \{M_4\}$ ≡ the set of Methacrylate monomers
$\mathcal{P} \equiv \{P_n^{i\cdot}, P_r^{i\cdot}, P_m^{i\cdot}, P_{n+r}^{i\cdot}\}$ represents the set of Live Polymer Chains
$\mathcal{S} \equiv \{S_1, S_2\}$ represents the set of solvents
$\mathcal{D} \equiv \{D_n, D_r, D_m, D_{n+r}\}$ represents the set of dead polymer chains

Indices

$i, j \in \{1,2,3,4\}$, $k \in \{1,2\}$, $n, r, m \in [1, \ldots, \infty)$

Abstract: This work focuses on simultaneous control of surface roughness and film porosity in a porous thin film deposition process modeled via kinetic Monte Carlo simulation on a triangular lattice. The microscopic model of the thin film growth process includes adsorption and migration processes. Vacancies and overhangs are allowed inside the film for the purpose of modeling thin film porosity. Appropriate closed-form dynamic models are first derived to describe the evolution of film surface roughness and porosity and used as the basis for the design of a model predictive control algorithm that includes penalty on the deviation of surface roughness and film porosity from their respective set-point values. Closed-loop simulations demonstrate that when simultaneous control of surface roughness and porosity is carried out, a balanced trade-off is obtained in the closed-loop system between the two control objectives of surface roughness and porosity regulation.

Keywords: thin film processing, roughness, porosity, model predictive control

1. INTRODUCTION

Thin film deposition processes play an important role in the semiconductor industry. Thin film microstructure, including surface roughness and film porosity, strongly affects the electrical and mechanical properties of thin films and of the resulting devices. Motivated by this, recent research efforts on modeling and control of thin film microstructure have focused mostly on thin film surface roughness on the basis of microscopic thin film growth models which utilize a square lattice. Specifically, kinetic Monte Carlo (kMC) models based on a square lattice and utilizing the solid-on-solid (SOS) approximation for deposition were initially employed to develop an effective methodology to describe the evolution of film microstructure and design feedback control laws for thin film surface roughness (Lou and Christofides (2003); Christofides et al. (2008)). This control methodology was successfully applied to surface roughness control of: a) a gallium arsenide (GaAs) deposition process (Lou and Christofides (2004)), and b) a multi-species deposition process with long range interactions (Ni and Christofides (2005a)). Furthermore, a method that couples partial differential equation (PDE) models and kMC models was developed for computationally efficient multiscale optimization of thin film growth (Varshney and Armaou (2005)). However, kMC models are not available in closed-form and this limitation restricts the use of kMC models for system-level analysis and design of model-based feedback control systems. To overcome this problem, model identification of linear deterministic models from outputs of kMC simulators was used for controller design using linear control theory (Siettos et al. (2003); Armaou et al. (2004)). However, deterministic models are only effective in controlling the expected values of macroscopic variables, i.e., the first-order statistical moments of the microscopic distribution. For higher statistical moments of the microscopic distributions such as the surface roughness (the second moment of height distribution on a lattice), deterministic models are not sufficient, and stochastic differential equation (SDE) models may be needed.

SDEs arise naturally in the modeling of surface morphology of ultra thin films in a variety of thin film preparation processes (Edwards and Wilkinson (1982); Villain (1991); Vvedensky et al. (1993)). Advanced control methods based on SDEs have been developed to address the need of model-based feedback control of thin film microstructure. Specifically, methods for state feedback control of surface roughness based on linear (Lou and Christofides (2005); Ni and Christofides (2005b)) and nonlinear (Lou and Christofides (2008)) SDE models have been developed. However, state feedback control assumes full knowledge of the surface morphology at all times, which may be a restrictive requirement in certain practical applications. To this end, output feedback control of surface roughness was recently developed (Hu et al. (2008)) by incorporating a Kalman-Bucy type filter, which utilizes information from a finite number of noisy measurements.

In the context of modeling of thin film porosity, kMC models have been widely used to model the evolution of porous thin films in many deposition processes and to investigate the influence of the macroscopic parameters on the porous thin film microstructure (Wang and Clancy (1998); Zhang et al. (2004)). Deterministic and stochastic ordinary differential equation (ODE) models of film porosity were recently developed (Hu et al. (2009a)) to model the evolution of film porosity and its fluctuation and design model predictive control (MPC) algorithms to control film porosity to a desired level and reduce run-to-run porosity variability. Despite recent significant efforts on modeling and control of surface roughness and film porosity, simultaneous regulation of surface roughness and film porosity within a unified control framework has not been investigated.

Motivated by these considerations, the present work focuses on simultaneous regulation of surface roughness and film porosity in a porous thin film deposition process modeled via kMC simulation on a triangular lattice. The definition of surface height profile is first introduced and the dynamics of surface height of the thin film are described by an Edwards-Wilkinson (EW)-type equation. Subsequently, an appropriate definition of film site occupancy ratio (SOR) is introduced to represent the porosity and a deterministic ODE model is derived to describe the time evolution of film SOR. The model parameters are estimated on the basis of data obtained from the kMC simulator of the deposition process using least-square methods. The developed dynamic models are used as the basis for the design of a model predictive control algorithm that includes penalty on the deviation of surface roughness square and film SOR from their respective set-point values. Simulation results demonstrate the applicability and effectiveness of the proposed modeling and control approach in the context of the deposition process under consideration.

2. PROCESS DESCRIPTION AND MODELING

2.1 On-lattice kinetic Monte Carlo model of film growth

The thin film growth process considered in this work includes two microscopic processes: an adsorption process, in which particles are incorporated into the film from the gas phase, and a migration process, in which surface particles move to adjacent sites (Wang and Clancy (1998); Levine and Clancy (2000); Yang et al. (1997)). Specifically, the film growth model used in this work is an on-lattice kMC model in which all particles occupy discrete lattice sites. The on-lattice kMC model is valid for temperatures $T < 0.5T_m$, where T_m is the melting point of the crystal. At high temperatures ($T \lesssim T_m$), the particles cannot be assumed to be constrained on the lattice sites and the on-lattice model is not valid. In this work, a triangular lattice is selected to represent the crystalline structure of the film, as shown in Fig.1. All particles are modeled as identical hard disks and the centers of the particles deposited on the film are located on the lattice sites. The diameter of the particles equals the distance between two neighboring sites. The width of the lattice is fixed so that the lattice contains a fixed number of sites in the lateral direction. The new particles are always deposited vertically from the top side of the lattice where the gas phase is located; see Fig.1. Particle deposition results in film growth in the direction normal to the lateral direction. The direction normal to the lateral direction is thus designated as the growth direction. The number of sites in the lateral direction is defined as the lattice size and is denoted by L. The lattice parameter, a, which is defined as the distance between two neighboring sites and equals the diameter of a particle (all particles have the same diameter), determines the lateral extent of the lattice, La.

The number of nearest neighbors of a site ranges from zero to six, the coordination number of the triangular lattice. A site with no nearest neighbors indicates an unadsorbed particle in the gas phase (i.e., a particle which has not been deposited on the film yet). A particle with six nearest neighbors is associated with an interior particle that is fully surrounded by other particles and cannot migrate. A particle with two to five nearest neighbors is possible to diffuse to an unoccupied neighboring site with a probability that depends on its local environment. In the triangular lattice, a particle with only one nearest neighbor is considered unstable and is subject to instantaneous surface relaxation.

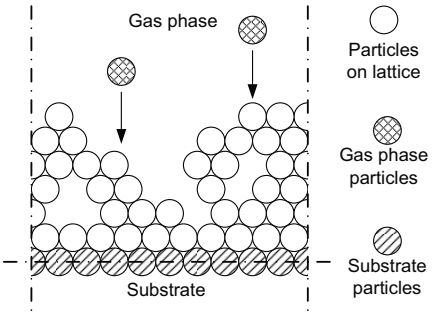

Fig. 1. Thin film growth process on a triangular lattice.

In the simulation, a bottom layer in the lattice is initially set to be fully packed and fixed, as shown in Fig.1. There are no vacancies in this layer and the particles in this layer cannot migrate. This layer acts as the substrate for the deposition and is not counted in the computation of the number of the deposited particles, i.e., this fixed layer does not influence the film surface roughness and porosity (see Section 2.2 below). All microscopic processes (Monte Carlo events) are assumed to be Poisson processes. These Monte Carlo events occur randomly with probabilities proportional to their respective rates. The events are executed instantaneously upon selection and the state of the lattice remains unchanged between two consecutive events. The specific rules used to carry out the adsorption and migration processes and their simulation are discussed in detail in Hu et al. (2009b) and are not presented here due to space limitations.

2.2 Definitions of surface roughness and site occupancy ratio

Utilizing the continuous-time Monte Carlo algorithm, simulations of the kMC model of a porous silicon thin film growth process can be carried out. Snapshots of film microstructure, i.e., the configurations of particles within the triangular lattice, are obtained from the kMC model at various time instants during process evolution. To quantitatively evaluate the thin film microstructure, two variables, surface roughness and film porosity, are introduced in this subsection.

Surface roughness, which measures the texture of thin film surface, is represented by the root mean square (RMS) of the surface height profile of the thin film. Determination of surface height profile is slightly different in the triangular lattice model compared to a SOS model. In the SOS model, the surface of thin film is naturally described by the positions of the top particles of each column. In the triangular lattice model, however, due to the existence of vacancies and overhangs, the definition of film surface needs further clarification. Specifically, taking into account practical considerations of surface roughness measurements, the surface height profile of a triangular lattice model is defined based on the particles that can be reached from abobe in the vertical direction, as shown in Fig.2. In this definition, a particle is considered as a surface particle only if it is not blocked by the particles in both neighboring columns. Therefore, the surface height profile of a porous thin film is the line that connects the sites that are occupied by the surface particles. With this definition, the surface height profile can be treated as a function of the spatial coordinate. Surface roughness, as a measurement of the surface texture, is defined as the standard deviation of the surface height profile from its average height. The definition expression of surface roughness is given later in Section 3.1.

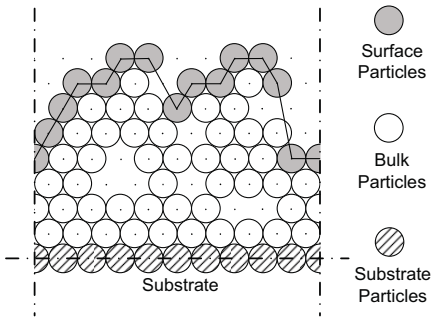

Fig. 2. Definition of surface height profile. A surface particle is a particle that is not blocked by particles from both of its neighboring columns in the vertical direction.

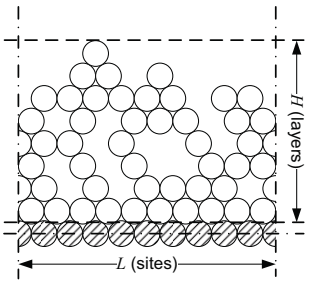

Fig. 3. Illustration of the definition of film SOR of Eq.1.

In addition to film surface roughness, the film site occupancy ratio (SOR) is introduced to represent the extent of the porosity inside the thin film. The mathematical expression of film SOR is defined as follows:

$$\rho = \frac{N}{LH} \tag{1}$$

where ρ denotes the film SOR, N is the total number of deposited particles on the lattice, L is the lattice size, and H denotes the number of deposited layers. Note that the deposited layers are the layers that contain only deposited particles and do not include the initial substrate layers. The variables in the definition expression of Eq.1 can be found in Fig.3. Since each layer contains L sites, the total number of sites in the film that can be contained within the H layers is LH. Thus, film SOR is the ratio of the occupied lattice sites, N, over the total number of available sites, LH. Film SOR ranges from 0 to 1. Specifically, $\rho = 1$ denotes a fully occupied film with a flat surface. The value of zero is assigned to ρ at the beginning of the deposition process since there are no particles deposited on the lattice.

3. DYNAMIC MODEL CONSTRUCTION AND PARAMETER ESTIMATION

3.1 Edwards-Wilkinson-type equation of surface height

An Edwards-Wilkinson (EW)-type equation can be used to describe the surface height evolution in many microscopic processes that involve thermal balance between adsorption (deposition) and migration (diffusion). In this work, an EW-type equation is chosen to describe the dynamics of the fluctuation of surface :

$$\frac{\partial h}{\partial t} = r_h + \nu \frac{\partial^2 h}{\partial x^2} + \xi(x,t) \tag{2}$$

subject to PBCs:

$$h(-\pi,t) = h(\pi,t), \quad \frac{\partial h}{\partial x}(-\pi,t) = \frac{\partial h}{\partial x}(\pi,t) \tag{3}$$

and the initial condition:

$$h(x,0) = h_0(x) \tag{4}$$

where $x \in [-\pi,\pi]$ is the spatial coordinate, t is the time, r_h and ν are the model parameters, and $\xi(x,t)$ is a Gaussian white noise with the following expressions for its mean and covariance:

$$\begin{aligned} \langle \xi(x,t) \rangle &= 0 \\ \langle \xi(x,t)\xi(x',t') \rangle &= \sigma^2 \delta(x-x')\delta(t-t') \end{aligned} \tag{5}$$

where σ^2 is a parameter which measures the intensity of the Gaussian white noise and $\delta(\cdot)$ denotes the standard Dirac delta function.

To proceed with model parameter estimation and control design, a stochastic ODE approximation of Eq.2 is first derived using Galerkin's method. Consider the eigenvalue problem of the linear operator of Eq.2, which takes the form:

$$\begin{aligned} A\bar{\phi}_n(x) &= \nu \frac{d^2\bar{\phi}_n(x)}{dx^2} = \lambda_n \bar{\phi}_n(x) \\ \bar{\phi}_n(-\pi) &= \bar{\phi}_n(\pi), \quad \frac{d\bar{\phi}_n}{dx}(-\pi) = \frac{d\bar{\phi}_n}{dx}(\pi) \end{aligned} \tag{6}$$

where λ_n denotes an eigenvalue and $\bar{\phi}_n$ denotes an eigenfunction. A direct computation of the solution of the above eigenvalue problem yields $\lambda_0 = 0$ with $\psi_0 = 1/\sqrt{2\pi}$, and $\lambda_n = -\nu n^2$ (λ_n is an eigenvalue of multiplicity two) with eigenfunctions $\phi_n = (1/\sqrt{\pi})\sin(nx)$ and $\psi_n = (1/\sqrt{\pi})\cos(nx)$ for $n = 1,\cdots,\infty$. Note that the $\bar{\phi}_n$ in Eq.6 denotes either ϕ_n or ψ_n. For fixed positive value of ν, all eigenvalues (except the zero-th eigenvalue) are negative and the distance between two consecutive eigenvalues (i.e. λ_n and λ_{n+1}) increases as n increases.

To this end, the solution of Eq.2 is expanded in an infinite series in terms of the eigenfunctions as follows:

$$h(x,t) = \sum_{n=1}^{\infty} \alpha_n(t)\phi_n(x) + \sum_{n=0}^{\infty} \beta_n(t)\psi_n(x) \tag{7}$$

where $\alpha_n(t)$, $\beta_n(t)$ are time-varying coefficients. Substituting the above expansion for the solution, $h(x,t)$, into Eq.2 and taking the inner product with the adjoint eigenfunctions, $\phi_n^*(x) = (1/\sqrt{\pi})\sin(nx)$ and $\psi_n^*(x) = (1/\sqrt{\pi})\cos(nx)$, the following system of infinite stochastic ODEs is obtained:

$$\begin{aligned} \frac{d\beta_0}{dt} &= \sqrt{2\pi} r_h + \xi_\beta^0(t) \\ \frac{d\alpha_n}{dt} &= \lambda_n \alpha_n + \xi_\alpha^n(t), \frac{d\beta_n}{dt} = \lambda_n \beta_n + \xi_\beta^n(t), n = 1,\ldots,\infty \end{aligned} \tag{8}$$

where

$$\xi_\alpha^n(t) = \int_{-\pi}^{\pi} \xi(x,t)\phi_n^*(x)dx, \quad \xi_\beta^n(t) = \int_{-\pi}^{\pi} \xi(x,t)\psi_n^*(x)dx. \tag{9}$$

The covariances of $\xi_\alpha^n(t)$ and $\xi_\beta^n(t)$ can be computed as follows: $\langle \xi_\alpha^n(t)\xi_\alpha^n(t') \rangle = \sigma^2\delta(t-t')$ and $\left\langle \xi_\beta^n(t)\xi_\beta^n(t') \right\rangle = \sigma^2\delta(t-t')$.

Since the stochastic ODE system is linear, the analytical solution of state variance can be obtained from a direct computation as follows:

$$\begin{aligned} \left\langle \alpha_n^2(t) \right\rangle &= \frac{\sigma^2}{2\nu n^2} + \left(\left\langle \alpha_n^2(t_0) \right\rangle - \frac{\sigma^2}{2\nu n^2} \right) e^{-2\nu n^2 (t-t_0)} \\ \left\langle \beta_n^2(t) \right\rangle &= \frac{\sigma^2}{2\nu n^2} + \left(\left\langle \beta_n^2(t_0) \right\rangle - \frac{\sigma^2}{2\nu n^2} \right) e^{-2\nu n^2 (t-t_0)} \\ & n = 1,2,\ldots,\infty \end{aligned} \tag{10}$$

where $\langle \alpha_n^2(t_0) \rangle$ and $\langle \beta_n^2(t_0) \rangle$ are the state variances at time t_0. The analytical solution of state variance of Eq.10 will be used in the parameter estimation and the MPC design.

When the dynamic model of surface height profile is determined, surface roughness of the thin film is defined as the standard deviation of the surface height profile from its average height and is computed as follows:

$$r(t) = \sqrt{\frac{1}{2\pi}\int_{-\pi}^{\pi} [h(x,t) - \bar{h}(t)]^2 dx} \tag{11}$$

where $\bar{h}(t) = \frac{1}{2\pi}\int_{-\pi}^{\pi} h(x,t)dx$ is the averaged surface height. According to Eq.7, we have $\bar{h}(t) = \beta_0(t)\psi_0$. Therefore, $\langle r^2(t) \rangle$ can be rewritten in terms of $\langle \alpha_n^2(t) \rangle$ and $\langle \beta_n^2(t) \rangle$ as follows:

$$\langle r^2(t) \rangle = \frac{1}{2\pi}\left\langle \int_{-\pi}^{\pi} (h(x,t) - \bar{h}(t))^2 dx \right\rangle$$

$$= \frac{1}{2\pi}\left\langle \sum_{i=1}^{\infty} (\alpha_i^2(t) + \beta_i^2(t)) \right\rangle = \frac{1}{2\pi}\sum_{i=1}^{\infty} \left[\langle \alpha_i^2(t) \rangle + \langle \beta_i^2(t) \rangle \right] \tag{12}$$

where $\bar{h} = \frac{1}{2\pi}\int_{-\pi}^{\pi} h(x,t)dx = \beta_0(t)\psi_0$ is the average of surface height. Thus, Eq.12 provides a direct link between the state variance of the infinite stochastic ODEs of Eq.8 and the expected surface roughness of the thin film. Note that the model parameter r_h does not appear in the expression of surface roughness, since only the zeroth state, β_0, is affected by r_h but this state is not included in the computation of the expected surface roughness square of Eq.12.

3.2 Deterministic dynamic model of film site occupancy ratio

Since film porosity is another control objective, a dynamic model is necessary in the MPC formulation to describe the evolution of film porosity, which is represented by the film SOR of Eq.1. The dynamics of the expected value of the film SOR evolution are approximately described by a linear first-order deterministic ODE as follows:

$$\tau \frac{d\langle \rho(t) \rangle}{dt} = \rho^{ss} - \langle \rho(t) \rangle \tag{13}$$

where t is the time, τ is the time constant and ρ^{ss} is the steady-state value of the film SOR. The deterministic ODE system of Eq.13 is subject to the following initial condition:

$$\langle \rho(t_0) \rangle = \rho_0 \tag{14}$$

where t_0 is the initial time and ρ_0 is the initial value of the film SOR. Note that ρ_0 is a deterministic variable, since ρ_0 refers to the film SOR at $t = t_0$. From Eqs.13 and 14, it follows that

$$\langle \rho(t) \rangle = \rho^{ss} + (\rho_0 - \rho^{ss})\, e^{-(t-t_0)/\tau}. \tag{15}$$

3.3 Parameter estimation

Referring to the EW equation of Eq.2 and the deterministic ODE model of Eq.13, there are several model parameters, ν, σ^2, ρ^{ss} and τ, that need to be determined as functions of the substrate temperature. These parameters describe the dynamics of surface height and of film SOR and can be estimated by comparing the predicted evolution profiles from the dynamic models of Eqs.2 and 13 and the ones from the kMC simulation of the deposition process in a least-square sense (Hu et al. (2009a,b)).

Since surface roughness is a control objective, we choose the expected surface roughness square of Eq.12 as the output for the parameter estimation of the EW equation of Eq.2. Thus, the model coefficients, ν and σ^2, can be obtained by solving the minimization problem as follows:

$$\min_{\nu,\sigma^2} \sum_{i=1}^{n_1} \left[\langle r^2(t) \rangle - \frac{1}{2\pi}\sum_{i=1}^{\infty} \left(\langle \alpha_i^2(t) \rangle + \langle \beta_i^2(t) \rangle \right) \right]^2 \tag{16}$$

where n_1 is the number of the data samplings of surface height profile and surface roughness from the kMC simulations. The predictions of model state variance, $\langle \alpha_i^2(t) \rangle$ and $\langle \beta_i^2(t) \rangle$, can be solved from the analytical solution of Eq.10.

With respect to the parameters of the equation for film porosity, ρ^{ss} and τ can be estimated similarly from the solutions of Eq.15 as follows:

$$\min_{\rho^{ss},\tau} \sum_{i=1}^{n_2} \left[\langle \rho(t_i) \rangle - \left(\rho^{ss} + (\rho_0 - \rho^{ss})\, e^{-(t-t_0)/\tau} \right) \right]^2 \tag{17}$$

where n_2 is the number of the data samplings of film SOR from the kMC simulations. We note that since the dynamic models of film surface height and film SOR may have different dynamics, different numbers of data samplings at different time instants may be used to estimate the parameters of the dynamic models.

The data used for the parameter estimation are obtained from the open-loop kMC simulation of the thin film growth process. The process parameters, i.e., the substrate temperature and the adsorption rate, are fixed during each open-loop simulation. The predictions from the dynamic models with the estimated parameters are close to the open-loop simulation profiles. Detailed data and plots can be found in Hu et al. (2009b).

The parameters that are estimated from fixed operating conditions are suitable for the feedback control design in this work. This is because the control input in the MPC formulation is piecewise, i.e., the manipulated substrate temperature remains constant between two consecutive sampling times, and thus, the dynamics of the microscopic process can be predicted from the dynamic models with estimated parameters. The dependence of the model parameters on substrate temperature is used in the formulation of the model predictive controller in the next section. Thus, parameter estimation from open-loop kMC simulation results of the thin film growth process for a variety of operation conditions is performed to obtain the dependence of the model coefficients on substrate temperature. In this work, the deposition rate for all simulations is fixed at 1 layer/s. The range of T is between 300 K and 800 K, which is from room temperature to the upper limit of the allowable temperature for a valid on-lattice kMC model of silicon film. The dependence of the model parameters on the substrate temperature can be found in Hu et al. (2009b).

4. MODEL PREDICTIVE CONTROL DESIGN

We consider the problem of regulation of surface roughness and of film SOR to desired levels within a model predictive control framework. State feedback control is considered in this work, i.e., the surface height profile and the value of film SOR are assumed to be available to the controller. Real-time film roughness and SOR can be estimated from in-situ thin film thickness measurements (Buzea and Robbie, 2005) in combination with off-line film porosity measurements. Since surface roughness and film SOR are stochastic variables, the expected values, $\langle r(t)^2 \rangle$ and $\langle \rho \rangle$, are chosen as the control objectives. The substrate temperature is used as the manipulated input and the deposition rate is fixed at a certain value, W_0, during the entire closed-loop simulation. To account for a number of prac-

tical considerations, several constraints are added to the control problem. First, there is a constraint on the range of variation of the substrate temperature. This constraint ensures validity of the on-lattice kMC model. Another constraint is imposed on the rate of change of the substrate temperature to account for actuator limitations. The control action at a time t is obtained by solving a finite-horizon optimal control problem. The cost function in the optimal control problem includes penalty on the deviation of $\langle r^2 \rangle$ and $\langle \rho \rangle$ from their respective set-point values. Different weighting factors are assigned to the penalties of the surface roughness and of the film SOR. Surface roughness and film SOR have very different magnitudes, ($\langle r^2 \rangle$ ranges from 1 to 10^2 and $\langle \rho \rangle$ ranges from 0 to 1). Therefore, relative deviations are used in the formulation of the cost function to make the magnitude of the two terms comparable. The optimization problem is subject to the dynamics of the surface height of Eq.2 and of the film SOR of Eq.13. The optimal temperature profile is calculated by solving a finite-dimensional optimization problem in a receding horizon fashion. Specifically, the MPC problem is formulated as follows:

$$\begin{aligned} \min_{T_1,\ldots,T_i,\ldots,T_p} J = \sum_{i=1}^{p} \Big\{ & q_{r^2,i} \left[(r^2_{set} - \langle r^2(t_i) \rangle)/r^2_{set} \right]^2 \\ & + q_{\rho,i} \left[(\rho_{set} - \langle \rho(t_i) \rangle)/\rho_{set} \right]^2 \Big\} \\ \text{subject} \quad & \text{to} \\ \frac{\partial h}{\partial t} = r_h + \nu \frac{\partial^2 h}{\partial x^2} + \xi(x,t), & \tau \frac{d\langle \rho(t) \rangle}{dt} = \rho^{ss} - \langle \rho(t) \rangle \\ T_{min} < T_i < T_{max}, & |(T_{i+1} - T_i)/\Delta| \le L_T \\ i = 1, 2, \ldots, p & \end{aligned} \tag{18}$$

where t is the current time, Δ is the sampling time, p is the number of prediction steps, $p\Delta$ is the specified prediction horizon, t_i, $i = 1, 2, \ldots, p$, is the time of the ith prediction step ($t_i = t + i\Delta$), respectively, T_i, $i = 1, 2, \ldots, p$, is the substrate temperature at the ith step ($T_i = T(t + i\Delta)$), respectively, W_0 is the fixed deposition rate, $q_{r^2,i}$ and $q_{\rho,i}$, $i = 1, 2, \ldots, p$, are the weighting penalty factors for the deviations of $\langle r^2 \rangle$ and $\langle \rho \rangle$ from their respective set-points at the ith prediction step, T_{min} and T_{max} are the lower and upper bounds on the substrate temperature, respectively, and L_T is the limit on the rate of change of the substrate temperature.

The optimal set of control actions, (T_1, T_2, …, T_p), is obtained from the solution of the multi-variable optimization problem of Eq.18, and only the first value of the manipulated input trajectory, T_1, is applied to the deposition process during the time interval $(t, t+\Delta)$. At time $t+\Delta$, a new measurement of ρ and h is received and the MPC problem of Eq.18 is solved for the next control input trajectory.

The MPC formulation proposed in Eq.18 is developed on the basis of the EW equation of surface height and the deterministic ODE model of the film SOR. The EW equation, which is a distributed parameter dynamic model, contains infinite dimensional stochastic states. Therefore, it leads to a model predictive controller of infinite order that cannot be realized in practice (i.e., the practical implementation of such a control algorithm will require the computation of infinite sums which cannot be done by a computer). To this end, a finite dimensional approximation of the EW equation of order $2m$, derived using modal decomposition, is used in the simulations below.

5. SIMULATION RESULTS

In this section, the model predictive controller is applied to the kMC model of the thin film growth process described in Section 2. The value of the substrate temperature is obtained from the solution of the MPC problem at each sampling time and is applied to the closed-loop system until the next sampling time. The optimization problem is solved using a local constrained minimization algorithm using a broad set of initial guesses.

The constraint on the rate of change of the substrate temperature is imposed onto the optimization problem, which is realized in the optimization process in the following way:

$$\left| \frac{T_{i+1} - T_i}{\Delta} \right| \le L_T \Rightarrow T_i - L_T\Delta \le T_{i+1} \le T_i + L_T\Delta \qquad i = 1, 2, \ldots, p. \tag{19}$$

The desired values (set-point values) in the closed-loop simulations are $r^2_{set} = 10.0$ and $\rho_{set} = 0.95$. The order of finite-dimensional approximation of the EW equation in the MPC formulation is $m = 20$. The deposition rate is fixed at 1 layer/s and initial temperature of 600 K. The variation of temperature is from 400 K to 700 K. The maximum of change of the temperature is $L_T = 10$ K/s. The sampling time is fixed at $\Delta = 1$ s. The number of prediction steps is set to be $p = 5$. The simulation duration is determined on the basis of a desired film thickness and the fixed adsorption rate and is chosen as 1000 s for the closed-loop simulations in this work. All expected values are obtained from 1000 independent simulation runs.

Closed-loop simulations of separately regulating film surface roughness and porosity are first carried out. In these control problems, the control objective is to only regulate one of the control variables, i.e., either surface roughness or film SOR, to a desired level. The cost functions of these problems contain only penalty on the error either of the expected surface roughness square, or of the expected film SOR, from their set-point values. The corresponding MPC formulations can be realized by assigning different values to the penalty weighting factors, $q_{r^2,i}$ and $q_{\rho,i}$.

In the roughness-only control problem, the weighting factors take the following values: $q_{r^2,i} = 1$ and $q_{\rho,i} = 0$, $i = 1, 2, \ldots, p$. Fig.4 shows the closed-loop simulation results of the roughness-only control problem. From Fig.4, we can see that the expected surface roughness square is successfully regulated at the desire level, 10. Since no penalty is included on the error of the expected film SOR, the final value of expected film SOR at the end of the simulation, $t = 1000$ s, is 0.988, which is far from the desired film SOR, 0.95.

In the SOR-only control problem, the weighting factors are assigned as: $q_{r^2,i} = 0$ and $q_{\rho,i} = 1$, $i = 1, 2, \ldots, p$. Fig.5 shows the closed-loop simulation results of the SOR-only control problem. Similar to the results of the roughness-only control problem, the desired value of expected film SOR, 0.95, is approached at large times. However, since the error from the expected surface roughness square is not considered in the cost function, $\langle r^2 \rangle$ reaches a very high level around 125 at the end of the simulation.

Finally, closed-loop simulations of simultaneous regulation of surface roughness and film SOR are carried out by assigning non-zero values to both penalty weighting factors. Specifically, $q_{r^2,1} = q_{r^2,2} = \cdots = q_{r^2,p} = 1$ and $q_{\rho,1} = q_{\rho,2} = \cdots = q_{\rho,p} = q_{SOR}$ and q_{SOR} varies from 1 to 10^4. Since substrate temperature is the only manipulated input, the desired-values of r^2_{set} and ρ_{set} cannot be achieved simultaneously. With different assignments of penalty weighting factors, the MPC evaluates and strikes a balance between the two set-points. Fig.6 shows the expected

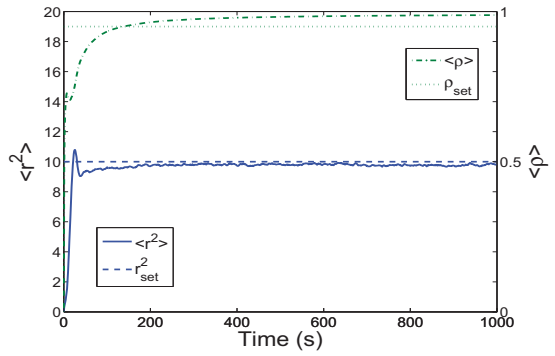

Fig. 4. Profiles of the expected values of surface roughness square (solid line) and of the film SOR (dash-dotted line) under closed-loop operations with cost function including only penalty on surface roughness.

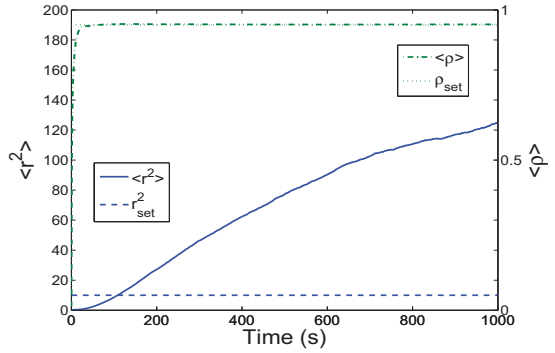

Fig. 5. Profiles of the expected values of surface roughness square (solid line) and of the film SOR (dash-dotted line) under closed-loop operation with cost function including only penalty on the film SOR.

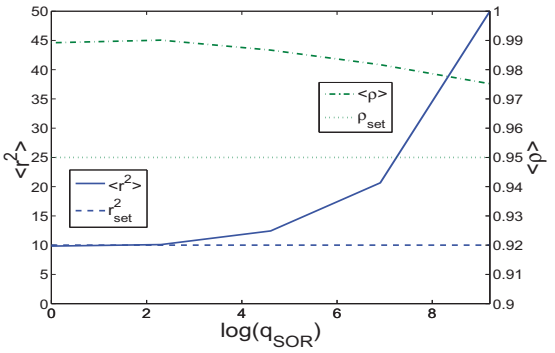

Fig. 6. Profiles of the expected values of surface roughness square (solid line) and of the film SOR (dash-dotted line) at the end of the closed-loop simulations ($t = 1000$ s) with the following penalty weighting factors: $q_{r^2,i}$ fixed at 1 for all i and for different values of q_{SOR}.

values of r^2_{set} and ρ_{set} at the end of closed-loop simulations of the simultaneous control problem with respect to different weighting factors. It is clear from Fig.6 that as the weighting on expected film SOR increases, the expected film SOR approaches its set-point value of 0.95, while the expected surface roughness square deviates from its set-point value of 10.

Abstract: This work presents a strategy for controlling acetaldehyde content in Brazilian bioethanol, based in simulation results of a typical industrial distillation plant. The major problem of acetaldehyde in bioethanol is that, during the storage period, it can oxidize to acetic acid, increasing fuel acidity above the legislation limit. This work tested, by dynamic simulation, simple loops to control acetaldehyde in bioethanol. The dynamic simulation generated a disturbance in the wine to be distilled by increasing acetaldehyde content, and verified how those loops were able to control the acetaldehyde level in bioethanol. Two different column system configurations were investigated. The first one includes a degassing system and a second one that produces pasteurized alcohol without or with a degassing system. Suggestions for the best control system of acetaldehyde contamination in bioethanol were formulated according to the acetaldehyde level in the wine.

Keywords: Fuel ethanol, bioethanol, dynamic simulation, degassing system, aspen plus.

1. INTRODUCTION

There is an increasing interest in bioethanol as a renewable energy source as well as a commodity to be used in other industrial branches, such as the chemical, pharmaceutical, and beverage industries. Brazil is one of the largest bioethanol producers and the largest exporter. For more than 30 years bioethanol is used directly as a biofuel, in this case with a concentration close to the azeotropic one, or added to petrol and, in this last case, it should be anhydrous. The rapid increase in its use as biofuel, the increase of its exports and of its use in other industrial branches is requiring a better control of product quality. Several minor components are generated during bioethanol production by fermentation and most of them are contaminants present in the end product. Although ethanol distillation is a largely investigated subject, most of the research works focus on energy consumption, alternative dehydration techniques and control strategies for separating the binary mixture ethanol-water, not taking into account the series of minor components that influence the distillation process. Those research works also rarely consider the peculiarities of the column systems used for ethanol distillation in the industrial practice.

Some recent works are applying simulations tools in order to investigate spirits and bioethanol distillation, taking into account at least part of the complexity of the multicomponent alcoholic mixture and of the industrial equipments used for its distillation. GAISER et al. (2002) used the commercial software Aspen Plus for simulating a continuous industrial unit for whiskey distillation, validating the results against industrial data. MEIRELLES et al. (2008) simulated a continuous distillation column for spirits production from sugar cane fermented must. DECLOUX and COUSTEL (2005) simulated a typical distillation plant for neutral alcohol production, using the software ProSim Plus. Neutral alcohol is a very pure ethanol product that requires a series of distillation columns to be produced.

Taking into account the increasing importance of bioethanol and the largely untreated subject of controlling its contaminants, this work is focused on investigating strategies for controlling the acetaldehyde content in bioethanol. Acetaldehyde is the contaminant responsible for the increase in biofuel acidity during storage time.

2. DESCRIPTION OF PROCESS

A typical industrial installation for bioethanol production in Brazil, according to MARQUINI et al. (2008), is shown in Fig. 1. This industrial installation is composed by 3 columns, two stripping ones (A and B1) and the rectifying column B. Column A, a equipment for wine stripping, is composed by 22 plates, 1 reboiler and no condenser. These plates have Murphree efficiency of 0.65, the total pressure drop of this column is 18437 Pa, the pressure of stage 1 is 138932 Pa and the reboiler pressure 157369 Pa. The wine or beer, industrial denominations of the fermented sugar cane must, is represented by the standard solution given in Table 1. This mixture is fed into the top of column A. The stream named PHLEGM, a vapor stream with ethanol concentration within the range 35-45 mass%, is fed into the bottom of column B. STILLAGE and WHITE STILLAGE, streams withdrawn from the bottoms of columns A and B1, respectively, must have an ethanol content not larger than 0.02 mass%.

Column B, the phlegm rectification column, is composed by 45 plates plus a condenser, has Murphree efficiency of 0.50, a total pressure drop of 38932 Pa, condenser pressure of

100000 Pa and bottom stage pressure of 138932 Pa. Bioethanol is extracted as top product of column B with 93 mass% of ethanol. Column B1, the phlegm stripping column, is fed with the bottom product of column B. This column is composed by 18 plates plus a reboiler, has Murphree efficiency of 0.60, total pressure drop of 8042 Pa, and the reboiler pressure equal to 146974 Pa.

Component	Concentration (mass fraction)	Reference
Water	0.93495357	By difference.
Ethanol	6.450×10^{-2}	Oliveira (2001)
Methanol	3.200×10^{-7}	Boscolo et al. (2000)
Isopropanol	1.020×10^{-6}	Cardoso et al. (2003)
Propanol	3.000×10^{-5}	Oliveira (2001)
Isobutanol	2.780×10^{-5}	Oliveira (2001)
Isoamyl alcohol	4.250×10^{-5}	Oliveira (2001)
Ethyl Acetate	7.690×10^{-6}	Oliveira (2001)
Acetaldehyde	2.000×10^{-6}	Oliveira (2001)
Acetic Acid	4.351×10^{-4}	Oliveira (2001)

3. MATERIALS AND METHOD

The first part of the present work focused on the steady-state simulation of a typical industrial unit, such as that shown in Fig. 1. The simulations were conducted using the commercial software Aspen Plus, by Aspen Tech, and aimed to investigate the operation of the industrial system by analyzing the effects of operational conditions upon the concentration profiles in columns A, B and B1. The second part was conducted using the module Aspen Dynamic, by Aspen Tech, so that some control strategies could be tested in order to keep the acetaldehyde level in bioethanol within the required limits. In this way the acidity increase of the biofuel during storage period could be prevented. The package RADFRAC for simulating distillation columns within Aspen Plus was selected in order to represent the whole industrial system. This package uses a rigorous method of calculation for solving the set of balance and equilibrium equations based on the MESH system described in detail by KISTER (1992). According to a detailed and rigorous analysis (Meirelles et al., 2008), previously performed for the vapor-liquid equilibrium of the binary mixtures formed by the wine components (Table 1), the NRTL model and a corresponding set of parameters were selected for representing the liquid phase non-ideality and the Virial equation, together with the approach based on HAYDEN-O'CONNELL (1975), for estimating the vapor phase fugacities.

Wine was fed into column A (see Fig. 1) with a mass flow of 202542 kg/h, at 94 ºC and the composition given in Table 1. The ethanol concentration in the bottom product of column A was fixed in 200 mg/kg (0.02 mass %) and the mass flow of bioethanol was varied around 14000 kg/h with at least 93 mass% of ethanol, corresponding to an approximately daily production of 465 m^3. In the bottom of column B1 the ethanol concentration was not fixed but it level was ever less than 200 mg/kg. In accordance with industrial information, the fusel stream mass flow was fixed in 41 kg/h, almost 0.3% of the bioethanol mass flow. Reflux and bioethanol stream mass flows were varied and the corresponding concentration profiles investigated.

For the dynamic simulation, in a first step a PID controller was used with the aim of controlling the acetaldehyde content (controller variable) in bioethanol, by manipulating the reflux stream and bioethanol mass flows (manipulated variables), after a perturbation in acetaldehyde concentration was imposed to the feed stream (wine). In a second step, the degassing system was tested to control the acetaldehyde content in bioethanol.

The degassing system is based on the association of two or more partial condensers in the top of column B. The vapor stream of each partial condenser is fed into the next one and the liquid streams return to the top of the column. In the last condenser, a small amount of vapor phase is withdrawn as a DEGASSING stream. According to the maximum level of allowed acetaldehyde contamination, the temperature of the last condenser can be varied and more or less mass of degassing can be generated.

4. RESULTS AND DISCUSSION

Almost all bioethanol fed into column A was stripped from the liquid phase and transferred via the PHLEGMA stream to column B. Except for acetic acid, all congeners (minor components in wine) are concentrated in the PHLEGMA stream and also transferred to column B. Fig. 2 shows the concentration profiles of water and ethanol along columns B (stages 1, condenser, to 46) and B1 (stages 47 to 65, reboiler). An alcoholic graduation of 93.0 mass% was obtained. Note that this value is within the concentration range required by the Brazilian legislation for hydrous bioethanol (Table 2).

Fig. 3 shows the concentration profiles for high alcohols. High alcohols, containing mainly isoamyl alcohol, are extracted from column B as a side stream named FUSEL stream.

Fig. 4 shows the concentration profile for acetaldehyde and acetic acid in columns B and B1. Acetaldehyde profile

indicates that this contaminant is concentrated in the biofuel stream.

ANP, the Brazilian National Petroleum Agency, is the public institution responsible for setting quality standards for fuels and biofuels. Copersucar, one of the largest Brazilian trading companies for sugar and bioethanol export, also sets specific quality standards according to the requirements of its clients. Table 2 shows the main specifications for bioethanol according to ANP (AEHC) and Copersucar (H1 and H2), and also some of the results obtained by steady-state simulation of the industrial plant (SIM). According to the simulation results the bioethanol produced fulfil the requirements of the Brazilian legislation and even most of the requirements set by Copersucar.

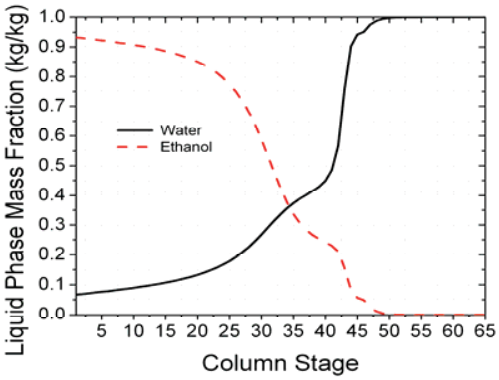

Fig. 2. Concentrations profile of ethanol and water in columns B (stages 1-46) and B1 (stages 47-65).

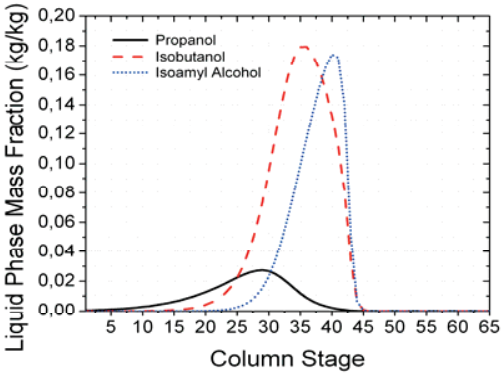

Fig. 3. High alcohols profiles in columns B (stages 1-46) and B1 (stages 47-65).

Acetaldehyde concentration is not a quality parameter fixed by ANP for the biofuel (Table 2). In case of the simulation results, the obtained acidity values, were far below the limit set by the Brazilian legislation. However, during the storage period acetaldehyde can oxidize to acetic acid and deteriorate the biofuel quality, increasing its acidity. If all acetaldehyde content present in the simulated fuel ethanol (Table 2) oxidizes to acetic acid, the product acidity would be increased to 33.5 mg/L. With this value, the biofuel would be outside the standards qualities established by the Brazilian legislation (Table 2). For this reason, the concentration of acetaldehyde in biofusel must be strictly controlled to prevent that the acidity level exceeds the legislation limits along the storage time. On the other hand, Brazil is nowadays the largest bioethanol exporter and the use of this bioproduct is increasing worldwide not only as an alternative energy source as well as an input material for chemical, pharmaceutical, perfume and beverage industries. Although these other uses may require further purification steps, sometimes conducted at the importing country, the Brazilian exporters are opting for defining stricter quality standards, such as the values specified by Copersucar (see Table 2). This highlights the importance of monitoring and controlling the contamination levels of minor components, such as acetaldehyde and high alcohols, in bioethanol.

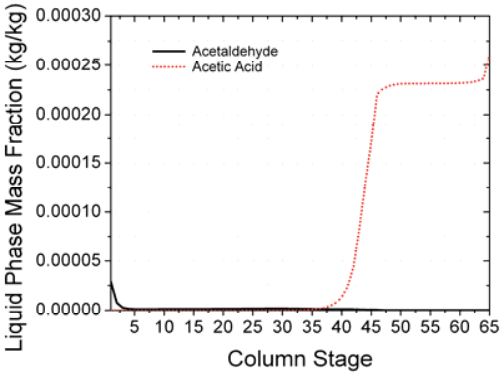

Fig. 4. Acetaldehyde and acetic acid profiles in columns B (stage 1-46) and B1 (stages 47-65)

Table 2. Bioethanol quality standards, ANP (AEHC), Copersucar (H1 and H2) and the simulation results (SIM).

Spec.	Unities	Bioethanol			
		AEHC	H1	H2	SIM
Alcoholic Graduation	mass%	92.6-93.8	≥ 92.8	≥ 93.8	93.2
Acidity (Acetic Ac.)	mg/L	≤ 30	≤ 20	≤ 10	Trace
Density (20ºC)	kg/m^3	807.6-811.0	-	-	807.1
Acetaldehyde	mg/L	-	≤ 50	≤ 10	24.6
High Alcohols	mg/L	-	≤ 400	≤ 50	332.5

Data on the mechanism and kinetics of acetaldehyde oxidation to acetic acid can be found in WANG et al. (1992) and XU et al. (2000). In order to avoid the risk of this oxidation during biofuel storage one of the possible strategies is to reduce acetaldehyde content in biofuel to a minimal value. In the second part of this work, some strategies to control the acetaldehyde content were investigated. All the strategies were based in a PID loop control, with the aim of keeping acetaldehyde concentration in bioethanol constant even if a perturbation increases its content in the wine. Figure 5 shows the simplest configuration of column simulated in the present work. As acetaldehyde is a very light component, the total amount of this substance present in the wine will

contaminate bioethanol if this configuration is used. For this reason no control strategy would be able to avoid an increase of acetaldehyde contamination in bioethanol in case of a slight increase in its concentration in the wine. In fact, attempts to avoid this contamination, by using reflux and/or bioethanol flow, according to the loop control represented in Fig. 5, failed. Thus two alternative solutions are suggested and they include changes in the industrial installation.

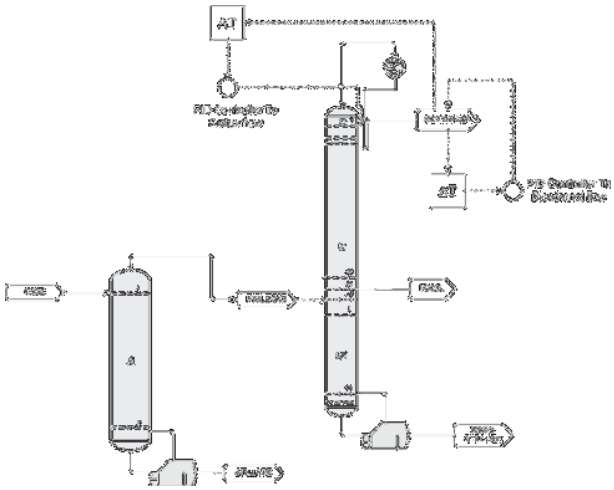

Fig. 5. Loop control for acetaldehyde concentration in bioethanol

The first alternative installation includes a degassing system, as that shown in Fig. 6 and explained above. Such a system makes easier the control of acetaldehyde content in bioethanol. As a very light component, acetaldehyde concentrates in the vapor streams and is eliminated by the DEGASSING stream. Controlling the DEGASSING flow makes possible to eliminate part of the acetaldehyde contamination, although this also causes small losses of the bioproduct.

Fig. 7 shows steady-state results for DEGASSING flow, ethanol mass flow in degassing and acetaldehyde content in bioethanol as a function of the last condenser temperature. The increase of this temperature increases the degassing flow, and by consequence increases the mass flow of ethanol in degassing stream, and decreases the acetaldehyde concentration in the bioethanol. These results show that the control of the temperature of the last condenser in the degassing system can control the concentration of acetaldehyde in the bioethanol. Taking this into account, a simple PID controller was developed to control the temperature of the last condenser of the degassing system (see Fig. 6). In this loop control, the controller variable was the acetaldehyde content in bioethanol and the manipulated variable was the temperature of the last condenser. The stack point (maximum level of the acetaldehyde in bioethanol) was fixed in 25.3 ppm (2.530×10^{-5} kg/kg). With this concentration, even if all the acetaldehyde oxidize to acetic acid, the mass of acid formed will not be sufficient to exceed the acidity maximum level fixed by ANP (Table 2). In order to better represent the industrial process, carbon dioxide (CO_2) produced during fermentation was included in the wine composition in a concentration of 0.0011 kg/kg. This value was determined assuming that the alcoholic fermentation industrial process is performed in closed vat with light over pressure (600 to 800 mm of water) and temperatures close to 35 °C. Considering that gas phase inside the vat is composed of saturated CO_2 with vapors of ethanol and water, the NRTL model and the Henry constant for CO_2 (Dalmolin et al., 2006) was used in order to estimate the solubility of CO_2 in the wine. The estimated values varied within the range 1050 to 1150 mg/kg. The acetaldehyde concentration in the wine was increased to 2.100×10^{-6} kg/kg and after 3 hours decreased to 1.900×10^{-6} kg/kg, in order to demonstrate the efficiency of the degassing system. The concentration of the other wine components were kept constant in the values indicated in Table 1, except for water whose value was appropriately adjusted. The results are present in the Fig. 8.

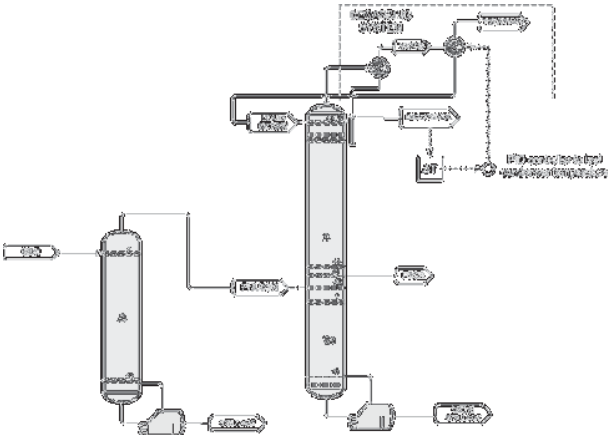

Fig. 6. Industrial plant with degassing system

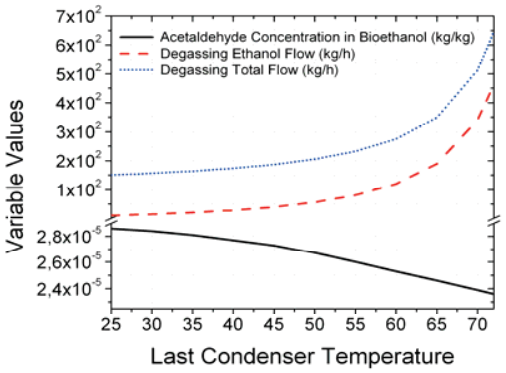

Fig. 7. Acetaldehyde content and degassing flow as a function of last condenser temperature

As is possible to observe in Fig. 8, the control system based in a PID controller has a good performance in avoiding a contamination of acetaldehyde in bioethanol. A direct dependence between the controller variable (biofuel acetaldehyde concentration) and the manipulated variable (last condenser temperature) was observed. In case of an

increase of acetaldehyde concentration in the wine the PID controller increases the last condenser temperature and, in consequence, a large degassing flow is withdrawn of the equipment. The acetaldehyde level in bioethanol reaches safe values after 40 minutes and stabilizes after one hour. The reverse process occurs when the concentration of acetaldehyde in wine is decreased (see Fig. 8).

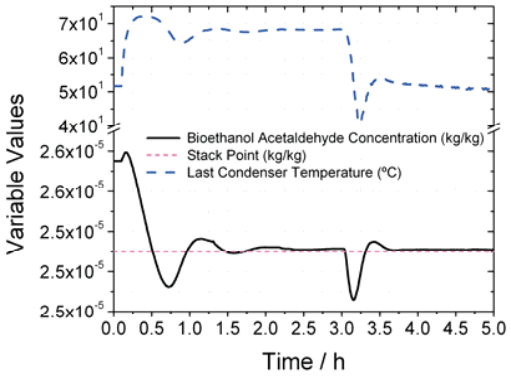

Fig. 8. Results of PID controller in degassing system (industrial installation)

Despite this good performance, the configuration with a degassing system may exhibit some difficulties in case of a large wine contamination with acetaldehyde. Large concentrations of acetaldehyde in wine require larger flow of degassing stream in order to reduce the biofuel contamination. A larger degassing mass flow increases ethanol losses (see Fig. 7). Therefore, the total loss of the ethanol in the production system can reach levels higher than those accepted by industry. An alternative configuration better for a wine with larger acetaldehyde contamination is the pasteurized bioethanol installation shown in Fig. 9. In this kind of installation two news columns (D and A1) are added to the original system. These columns concentrate the major part of wine volatile compounds, including acetaldehyde, and eliminate part of them via the SECOND ALCOHOL stream withdrawn from the top of column D.

In column B bioethanol is withdrawn from a tray close to the column top. In the top of Column B a further SECOND ALCOHOL stream is also withdrawn. According to Fig. 4 acetaldehyde is concentrated in the trays located close to the top of column B. For this reason streams such as the two SECOND ALCOHOL ones are concentrated in acetaldehyde and other light minor components, for instance ethyl acetate. These contaminants are taken away by the top streams and bioethanol, withdrawn from column B as a side stream, has its acetaldehyde content decreased. On the other hand, small amounts of ethanol are not recovered as the main product (bioethanol), being extracted in those byproduct streams. Such scheme is more appropriate for producing bioethanol from a wine with larger contamination of light components or in case the bioproduct must have a higher purity.

Fig. 10 shows the results of steady state simulations performed for the pasteurized bioethanol installation. For this simulation acetaldehyde concentration in the wine was increased to approximately 10 times the value of the previous simulations (new concentration equal to 1.900×10^{-5} kg/kg), representing a larger contamination, closer to the industrial wine, according to Oliveira (2001).

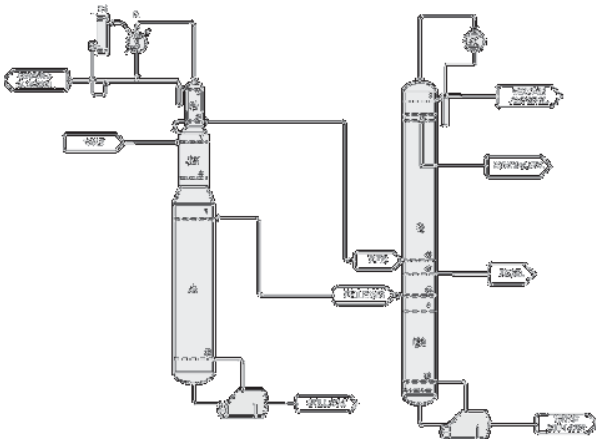

Fig. 9. Industrial plant for bioethanol with second alcohol streams.

The main objective of those simulations was to show that, varying the mass flow of the second alcohol stream in column B, it is possible to reduce considerably the concentration of acetaldehyde in bioethanol. According to Fig. 10, the increase of the mass flow of the second alcohol stream reduces acetaldehyde contamination without influencing, in a significant way, the bioproduct alcoholic graduation. In these simulations only the second alcohol stream in top of column B was varied, keeping the second alcohol stream in top of column D fixed at the value 400 kg/h.

This means that a relative larger acetaldehyde contamination is contained in the second alcohol stream, a result that makes easier the control of this contamination in the main product (pasteurized bioethanol) by means of the degassing system. For this reason a loop control similar to that of Fig. 6, connecting the acetaldehyde concentration in pasteurized bioethanol (controller variable) to the last condenser temperature (manipulated variable), was tested. The wine acetaldehyde concentration was increased to 2.000×10^{-5} kg/kg and the last partial condenser temperature was varied to stabilize the bioethanol acetaldehyde concentration at 2.450×10^{-5} kg/kg. With this value, the problem of acetaldehyde oxidation during storage time was eliminated. The result of this simulation was presented in Fig. 11.

The results show that in almost 2 hours the acetaldehyde concentration reaches the required value although the stabilisation time is approximately 7 hours. This result suggests that the degassing system is an excellent alternative for acetaldehyde control in bioethanol, provided that the wine contamination with acetaldehyde is not too large.

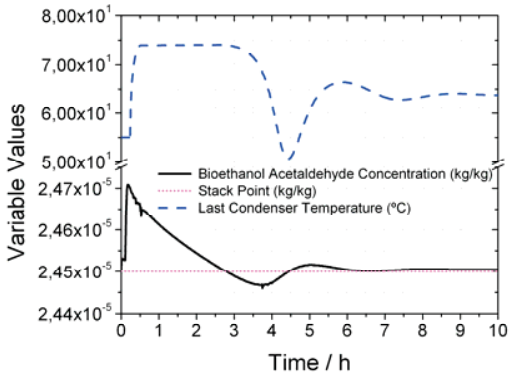

Fig. 11. Results of PID controller in degassing system (pasteurized bioethanol installation)

5. CONCLUSION

Production of bioethanol as a renewable fuel or as an input commodity to be used in other industrial branches requires the reduction and control of several contaminants contained in the fermented must. In the present work special attention was focused on controlling acetaldehyde contamination. Analyzing the results presented it is possible to conclude that the wine (must) acetaldehyde concentration will determine the type of industrial installation and the type of control to be used to regulate the acetaldehyde in bioethanol and prevent problems with its oxidation during storage. Thus, for wine with less than 2.0×10^{-6} kg/kg of acetaldehyde, the industrial installation without degassing system is appropriate. For wine concentrations within the range 2.0×10^{-6} to 2.2×10^{-6} kg/kg, the degassing system is required. In case of wine concentrations within the range 2.2×10^{-6} to 2.0×10^{-5} kg/kg, the pasteurized bioethanol installation is the most appropriate one. For concentrations within the range 2.0×10^{-5} to 2.2×10^{-5} kg/kg the degassing system should be included in the pasteurized bioethanol installation. Finally, for musts with higher acetaldehyde concentration ($\geq 2.2\times10^{-5}$ kg/kg) the pasteurized bioethanol installation with a PID controller to regulate the mass flow of second alcohol is probably the best way to prevent problems with acetaldehyde oxidation during storage.

Sensor fault detection and isolation for single, multiples and simultaneous faults: Application to a waste water treatment process

Fragkoulis D. * **, Roux G. * ** and Dahhou B. * **

* LAAS-CNRS ; Université de Toulouse ;

Abstract: In this paper, sensor fault detection, isolation and identification model-based approach is designed. We introduce a new state variable so that an augmented system can be constructed to treat sensor faults as actuator faults. The approach uses the model of the system and a bank of adaptive observers to generate residuals. Structured residuals are defined in such way to isolate the faulty sensor after detecting the fault occurrence. The advantage of this method is that we can treat single, multiple and simultaneous sensor faults. In this study, we consider that only abrupt faults in the system sensor can occur. The proposed strategy is validated by simulation results of a nonlinear model of a waste water treatment process.

1. INTRODUCTION

In all industrial processes the reliability and the security of the system is a very important task. A fault may occur in all possible location, such as actuators, sensors and system's parameters. Fault detection techniques could prevent from all the undesirable consequences. In order to improve efficiency, the reliability can be achieved by fault-tolerant control, which relies on early fault detection, using fault detection and isolation (FDI) procedures. So FDI is becoming an attractive topic. Model based fault detection and diagnosis systems have found extensive use because of the fast response to abrupt failure and the implementation of the model based FDI in real-time algorithms. A comprehensive review of the different methods for FDI and their applicability to a given physical system has been presented in ([Iserman, 1994] and [Venkatasubramanian *et al.* 2003]). A variety of effective methods can be used to realize FDI, such as differential geometric approach [De Persis and Isidori 2001], sliding mode observer ([Edwards and Spurgeon 1994] and [Xing-Gang and Edwards 2005]), and adaptive control technique ([Frank, 1994] and [Hammouri *et al.* 1999]).

The progressive deterioration of the water resources and the great quantity of polluted water produced in the industrialized companies, give to the waste water treatments (WWT) a great importance in the safeguarding of water quality. The new directives and regulations (the directing 91/271/CEE referring itself to the European countries) impose the adoption of specific indices for the quality of treated waste water. Taking into account the current ecological problems, it is realistic to believe that this tendency will continue. At the same time, the existing factories increase thanks to the growth of the urban sectors and this situation requires more effective treatments of the used water. Consequently, we want that such an industry, almost always, operates with the maximum effectiveness.

Generally, the recent evolution of the legislation of some countries, about the use of surface or subsoil waters, is such that the total reuse of the water used in the processes became a very important issue. So the waste water treatment became a part of the production process, where the quality control of effluent is very important. Since the weak operation of the treatment can carry out to an important loss of production and to ecological problems.

The paper is organized as follows. In Section 2, we present the class of the nonlinear systems that we study, the filter that we apply to form the new extended system and the formulation of the fault problem. Then we give the principle of the fault detection and isolation scheme and the synthesis of the observer. Section 3 describes the waste water treatment process which is used to show the effectiveness of the proposed method. In Section 4, we give simulation results that illustrate the method for single, multiple and simultaneous faults. Conclusion and perspectives end the paper.

2. EXTENTED MODEL AND PROPOSED METHOD

2.1 Filter for the system's output

We consider the following class of nonlinear systems:

$$\begin{cases} \dot{x} = f(x) + g(x)u \\ y = Cx \end{cases} \qquad (1)$$

where $f(x)$ is a nonlinear vector function from $\Re^n$ to $\Re^n$, $g(x) \in \Re^{n\times m}$ is a matrix function whose elements are nonlinear functions, $C \in \Re^{p\times n}$ is a matrix, $u \in \Re^m$ is the input vector and $y \in \Re^p$ is the output vector. Throughout

this paper, we assume that only constant sensor faults can occur $y_j^f(t) = y_j(t) + f_{sj}$, that is $y_j^f \equiv \theta_j$ for $t \geq t_f$, $j \in 1, 2, \cdots p$, and $\lim_{t\to\infty} | y_j(t) - \theta_j | \neq 0$, where θ_j is a constant and $y_j^f(t)$ is the actual output of the j^{th} sensor when it is faulty, while $y_j(t)$ is the expected output when it is healthy.

In [Chee and Edwards 2003] the authors presents a method for the linear system where the output vector passes through two orthogonal matrices $T_{r,1}$ and $T_{r,2}$. At the same time these matrices make the separation of the outputs at $y_1 \in \Re^{p-h}$ and $y_2 \in \Re^h$ where y_1 are the outputs without fault and y_2 are the outputs with a fault. The same manipulation of the outputs for the nonlinear system (1) is impossible but there is a similar method proposed in [Chen and Saif 2006] for the class of the nonlinear systems (1) that we presented above. We will apply to the output vector y a filter of the form:

$$\dot{\xi} = A_f \xi + B_f y \quad (2)$$

Where the state vector is $\xi \in \Re^p$, we select $A_f \in \Re^{p\times p}$ as a Hurwitz matrix and $B_f \in \Re^{p\times p}$ is chosen as an invertible matrix. We form the new input $w = \begin{bmatrix} u \\ y \end{bmatrix}$ and we define the extended system of the form:

$$\dot{z} = \underline{f}(x, \xi) + \underline{g}(x) w \qquad (3)$$

Where the vector $z \in \Re^{n+p}$ is the new state $z = \begin{bmatrix} x \\ \xi \end{bmatrix}$, $\underline{f}(x, \xi) \in \Re^{n+p}$ is a vector with nonlinear and linear elements ($\underline{f}(x, \xi) = \begin{bmatrix} f(x) \\ A_f \xi \end{bmatrix}$). The matrix $\underline{g}(x) \in \Re^{(n+p)\times(m+p)}$ is a matrix with nonlinear and linear elements ($\underline{g}(x) = \begin{bmatrix} g(x) & 0_{n\times p} \\ 0_{p\times m} & B_f \end{bmatrix}$) and finally the vector $w \in \Re^{m+p}$ is the new input vector. So, as we have seen with this transformation we have extended the system and the initial sensor fault problem has become, after the transformation, an actuator fault problem. The output vector y of the system has become a part of the input vector w of the new system. Based on the approach developed in [Blanke *et al.* 2003], it is easy to build the corresponding extended faulty model:

$$\begin{cases} \dot{z} = \underline{f}(x, \xi) + \sum_{j\neq l} \underline{g}_j(x) w_j + \underline{g}_l(x) \theta_l \\ y = \begin{bmatrix} C & 0_{p\times p} \end{bmatrix} z \end{cases} \qquad (4)$$

where we have a fault in the l^{th} actuator and $\underline{g}(x) = [\underline{g}_1(x) \cdots \underline{g}_{m+p}(x)]$.

The new system input as we already mentioned is the vector *w*. This vector includes the inputs and the outputs of the system (1), $w^T = [u_1 \ \cdots \ u_m \ | \ y_1 \ \cdots \ y_p]$. In this paper, we are focusing only in sensors faults. As the method that it will be used is an actuator fault detection and isolation method, the inputs of the new vector *w* that we are interested are from w_{m+1} to w_{m+p}.

2.2 The fault detection and isolation scheme

After this transformation, the problem has become an actuator fault detection and isolation problem where the faults have the same properties with the ones presented in the begin of the subsection *2.1*; only that in the place of the output y we have the input w. For the fault detection and isolation, we will develop a bank of p adaptive observers, where $\hat{\theta}$ is the fault estimation [Chen and Saif 2005]. The form of the adaptive observer that we will use in this bank for the l^{th} actuator is:

$$\begin{cases} \dot{\hat{z}}_l = \underline{f}(x, \xi) + \sum_{j\neq l} \underline{g}_j(x) w_j + \underline{g}_l(x) \hat{\theta}_l + H_l(\hat{z} - z) \\ \dot{\hat{\theta}}_l = -2\gamma(\hat{z}_l - z)^T P_l \underline{g}_l(x) \quad m+1 \leq l \leq m+p \end{cases} \qquad (5)$$

Where H is a Hurwitz matrix that it can be chosen freely, γ is a design constant and P is a positive definite matrix. We can calculate the matrix P and H with the help of the following Lyapunov equation:

$$H^T P + PH = -Q \qquad (6)$$

where Q is a positive definite matrix that it can be chosen freely. The analysis of the method can be found in [Chen and Saif 2005] along with all the proofs and details. An application of this method for an actuator fault detection and isolation to the same system that we studied can be found in [Fragkoulis *et al.* 2007]. The residual r_i that it is proposed in this paper is the difference between the estimation of the fault $\hat{\theta}_i$ determined in (5) and the output of the system so:

$$r_i = \hat{\theta}_{m+i} - y_i, i \in [1 \ldots p] \quad (7)$$

The residuals are designed to be sensitive to a fault that comes from a specific sensor and as insensitive as possible to all the others sensor faults. This residual will permit us to treat not only with single faults but also with multiple and simultaneous faults. To facilitate the isolation of the fault the structured residual will be used, and in particular the Boolean method introduced in [Gertler 1998] with simple thresholds δ_{si}.

$$\varepsilon_i(t) = \begin{cases} 1 & if \quad |r_i(t)| \geq \delta_{si} \\ 0 & if \quad |r_i(t)| < \delta_{si} \end{cases} \qquad (8)$$

$$\Phi = [\varepsilon_1(t)\ \varepsilon_2(t) \ldots \varepsilon_p(t)] \quad (9)$$

$$r_s \leftarrow \Phi f_s \qquad (10)$$

So the five steps for this new FDI scheme are:

1. we determine the filter as in (2) for the augmented space.
2. we form the new faulty model (4) and the new input vector *w*.
3. we build a bank of p observers as in (5) for the detection and isolation of the fault.
4. we generate the residuals r_i (7).
5. from the thresholds δ_{si} we elaborate the structural matrix Φ and then
6. from (10) we generate the structured residuals r_s for the fault isolation and identification.

3. WASTE WATER TREATMENT PROCES MODEL

The process of water treatment by activated sludge, invented in Manchester in 1914, industrially reproduced the purifying effect of the rivers, and became the principal current process of purification. It consists of an aerobic biological system in which the biological floc (biofloc) are continuously recycled and given in contact with organic waste water in the presence of oxygen. Oxygen is usually provided by bubbles of air, insufflated in the mixture of liquid and sludge under conditions of turbulence or by units of surface mechanics or by other aeration types.

A plant of water purification with activated sludge generally consists of a system of treatment in two phases (figure 1). The first phase of the treatment consists in eliminating pollutant in suspension, which mainly includes the degreasing, the de-sanding and the de-oiling. Now, we present the second phase which can be described by three reactors placed in cascade. The first reactor called primary decanter receives polluted water coming from the urban or industrial environments. Water penetrates then in a second reactor, called aerated basin, which constitutes the heart of the plant. The treatment is based on setting in contact of a bacterial population (micro-organisms) with organic matter contained in the effluent to treat. In the aerated basin occur initially a fast adsorption and flocculation of the colloidal matters in suspension and of the organic matter soluble by the activated sludge. Then there is a progressive oxidation of a synthesis of the adsorbed organic matter and of the extracted organic matter. Finally, water undergoes a last treatment in the third reactor, called settling tank. This one delivers purified water after the decantation of sludge. A part of this latter is recycled in the aerated basin (recycled sludge) and sludge in excess is evacuated for a suitable external treatment.

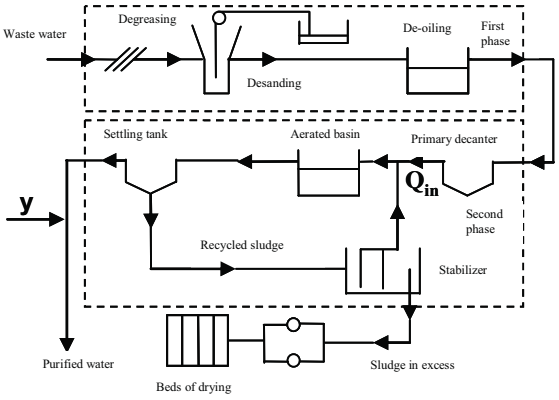

Figure.1 Waste water treatment process

The mathematical model for the activated sludge process (aerated basin and settling tank) is based on the equations, resulting from mass balance considerations, carried out on each of the reactant of the process.

$$Variation = \pm Conversion + Feeding - Drawing\ off$$

All the details about the system and the values of the model parameters can be found in ([Nejjari 2001] and [Fragkoulis *et al.* 2007]). The FDI scheme will monitor the sensors S_I, S_S, X_I, X_S, X_H and S_O, measuring the output vector y of the settling tank (cf. figure 1), by using a bank of adaptive observers. The algorithm for this model is constituted by a bank of six adaptive observers for the fault detection, isolation and identification. More details about the observer synthesis can be found in [Fragkoulis *et al.* 2008].

4. SIMULATION RESULTS

In this section, we will give the results obtained from the developed method for one or more sensor faults. We have to mention that in the case of multiple and simultaneous faults, while the second fault occurs the first fault still acts in the system. The banks of adaptive observers run simultaneously with the system. The considered installation is a closed loop system. So the presence of the controller makes the sensor fault problem more complex. In this case, the fault affects not only the faulty sensors but also the system's dynamic (the other outputs of the system). The sampling period is one sample per hour, the value of all the constant thresholds are $\delta_{si} = 0.5$. Finally we have to mention that all the outputs and so all the faults are in *mg/l*.

4.1 Single fault

We have applied a fault with magnitude $f_{s5} = -2.2\, mg/l$ at time $t = 50$ days in the fifth sensor X_H. In Figure 2, we present the six residuals r_i associated to the six observers. The six residuals in the begin needs a short time period to

converge. This time depends on the initialisation time of the observer's bank, so as to be ready for a fault detection and isolation. After, they reach a constant value and stays there until the fault occurrence.

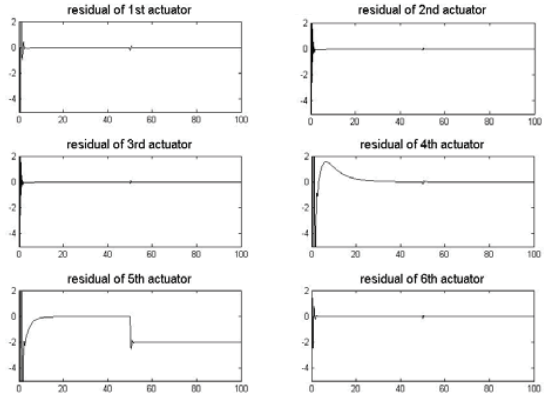

Figure.2 Residuals r_i for a single fault

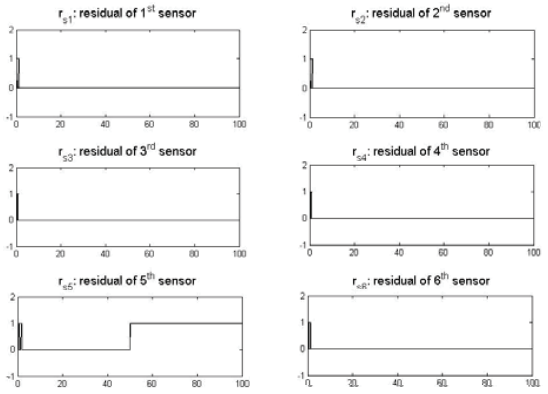

Figure.3 Structured residuals r_{si} for a single fault

At time $t = 50$ days, we can see that the residual of all the six observers leave zero but after a very short period (one day maximum), all of them return to their initial values, except from the residual associated to the fifth observer that corresponds to the output X_H that it takes a new constant value and remains there. In figure 3 we present the structured residuals for this fault. As expected all the residuals stay at zero except from the residual r_{s5} associated to the fifth sensor that at time $t = 51$ days takes and stays at the value "1". Thus, this fact indicates that this is the faulty sensor. Therefore, we isolate the faulty sensor correctly and rapidly enough. As we already mention, this method not only isolates the fault but also identify its value, which can be used for the system reconfiguration. In this case, the actual value of the fault is $f_{s5} = -2.2\, mg / l$ and the estimated value is $\hat{f}_{s5} = -2.1\, mg / l$, so we had identified the fault very accurately.

4.2 Multiple faults

We have applied a constant fault with magnitude $f_{s3} = -5\, mg / l$ at time $t = 50$ days in the third sensor X_I and one with magnitude $f_{s1} = -3\, mg / l$ in the first sensor S_I at time $t = 60$ days. The fault at the third sensor is still occurred when the fault at first sensor has been introduced. Figure 4 shows, the six residuals associated to the observers, where after the initialisation, they have a constant value until $t = 50$ days. There, all the residuals leave their initial values and only the residual associated to the third observer that corresponds at the third sensor stays to the new value. The other five residuals return to their initial values.

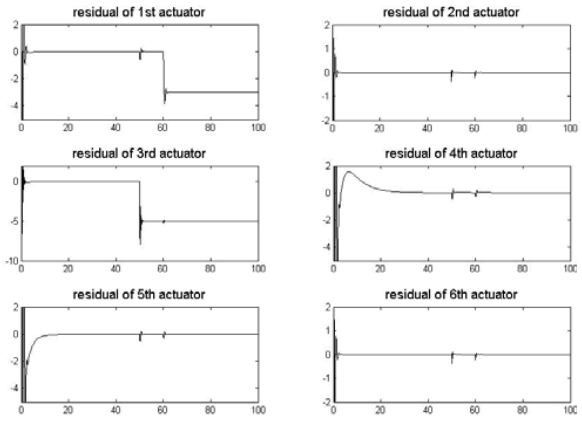

Figure.4 Residuals r_i for multiple faults

At time $t = 60$ days, where the second fault has been entered, the residual that corresponds to the first sensor S_I change from his initial value. It stays at the new value but the other five residuals leave their value and returns to them after a short time period. The third residual, which corresponds to the third sensor where the first fault still occurs, has not been affected by the new fault.

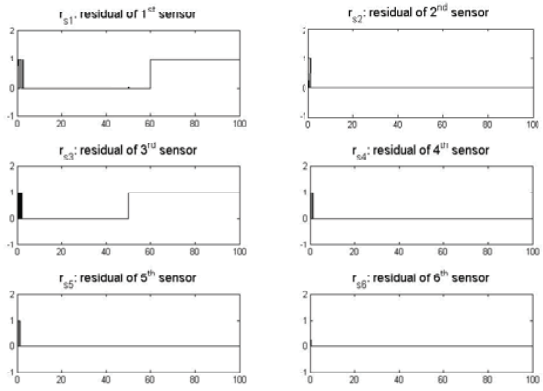

Figure.5 Structured residuals r_{si} for multiple faults

In figure 5, we can see the structured residuals where only the residuals r_{s3} and r_{s1} at time $t = 51$ days and $t = 61$ days respectively leave zero and stay at their new value "1". More generally each fault affects only the corresponding residual and the isolation of the multiple faults has been done. For the fault identification we have: the estimation of the first fault is $\hat{f}_{s3} = -4.5\, mg/l$ and the actual value is $f_{s3} = -5\, mg/l$; the estimation of the second fault is $\hat{f}_{s1} = -2.85\, mg/l$ and the actual value is $f_{s1} = -3\, mg/l$. So we have a good estimation of the fault, not only for the first one where we have a single fault but also for the second one, the multiple fault case.

4.3 Simultaneous faults

We illustrate the case where more than one faults occur at the same time on the system or briefly the simultaneous faults. We have applied two faults: one on the fourth sensor X_S with magnitude $f_{s4} = -13\, mg/l$ and one on the sixth sensor S_O with magnitude $f_{s6} = -2\, mg/l$ at the same time $t = 50$ days.

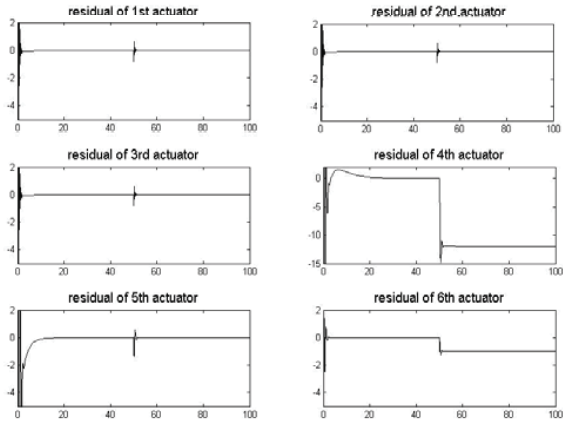

Figure.6 Residuals r_i for simultaneous faults

In Figure 6, we give the residuals associated to the observers and we can see that their values are equal to a constant value until $t = 50$ days where the two faults occur on the system. At that time, all the residuals leaves their initial values and only the residual associated to the fourth observer that correspond to the fourth sensor and the residual associated to the sixth observer that correspond to the sixth sensor stays to their new value; the other four residuals returns to their initials values. Figure 7 presents the structured residuals where only the residuals r_{s4} and r_{s6} leaves zero at time $t = 51$ days, therefore we isolate the two faulty sensors. The identification of the two faults is quite accurate, so for the fourth sensor the estimation is $\hat{f}_{s4} = -12.5\, mg/l$ and for the other one the estimation is $\hat{f}_{s6} = -1.8\, mg/l$.

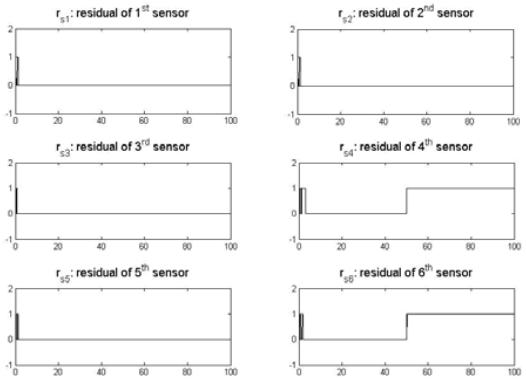

Figure.7 Structured residuals r_{si} for simultaneous faults

4.4 Single fault with real data

We will present the case where the input Q_{in} which is the flow rate input of the aerated basin (cf. figure 1) take his values from a file with real data. These data are collected from a benchmark installed in Terrassa Spain [Nejjari 2001], while the other three inputs have a constant value as in reality. Thus a single fault occurs in one of the six sensors and the method's validity will be presented. In figure 6 we present the input Q_{in}.

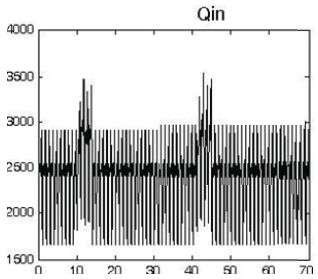

Figure.8 Input Q_{in} with real data

The duration of these data is 70 days and during this time we have two intermittent perturbations, one at the 9th day until the 13th day and another one at the 40th day until the 45th day, caused by the rain. A single fault with magnitude $f_{s4} = -15$ has been occurred at time $t = 50$ days in the fourth sensor X_S.

In figure 9, we show the six residuals associated to the six sensors. As we can see the two perturbations that occurred on the system have a little influence on them. Mainly the first, fourth and fifth residuals have been a little bit affected by them, but the effect can not be misjudged as a fault as long as the residuals remain in the zone defined by the two thresholds δ_{si}. The structured residuals, figure 10, stay at zero during the perturbations.

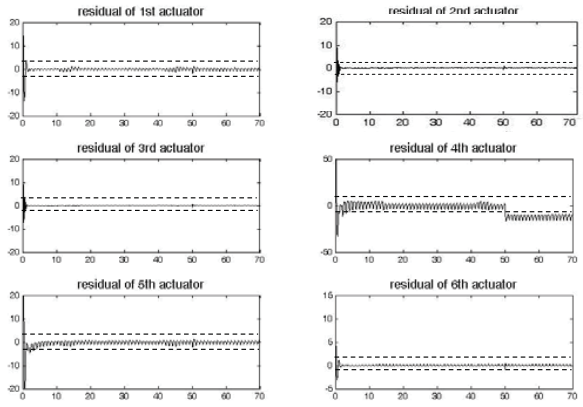

Figure.9 Residuals r_i for single fault with real data

Then at time $t = 50$ days the fourth residual, in both figures, indicates us that there is a fault in the fourth sensor. The simple residual leaves his initial value and gives us the estimation of the fault and the structured residual takes the value "1", so we can easily conclude the source of the fault. For the estimation of the fault we have to use the mean value on a sliding window due to the fact that we have a small oscillation of the value; this mean value is $\hat{f}_{s4} = -16\, mg/l$. In this case the thresholds value is $\delta_{si} = 2$ and they are chosen empirically, also we have to mention that the use of structured residuals facilitates the automatic isolation.

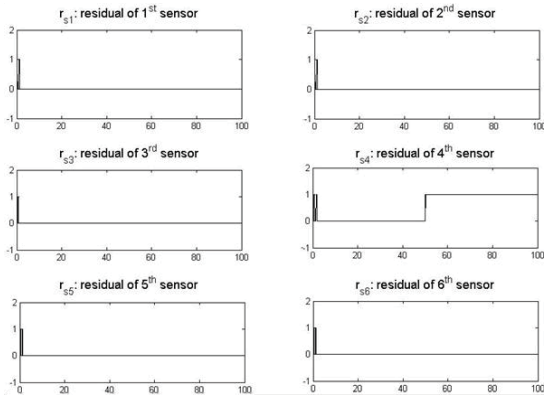

Figure.10 Structured residuals r_{si} for single fault with real data

5. CONCLUSIONS

In this paper, a new method, for sensor fault detection isolation and identification, based on nonlinear observers has been developed. We have reformulated the initial sensor fault problem, by using a transformation filter, to an actuator fault problem. We have designed a known bank of adaptive observers to treat the FDI procedure. Simulation results illustrate the effectiveness of the method for the isolation of single faults, multiple and simultaneous faults. Finally we have validated the proposed method with real data collected from a waste water treatment process benchmark. Our future considerations are to improve the fault estimation in the case of measurement noise by using a better filtering method of the residual. Finally the comparison with the simple method of adaptive observers and mainly the comparison between the isolation time and the fault identification is one of our highly concerns.

Abstract: Dynamics are inherent characteristics of batch processes, which can be divided into short time-scale dynamics within a batch duration and long time-scale dynamics across several batches. The interactions between process variables make different types of dynamics confounded. Under such situations, it is difficult to perform efficient fault diagnosis. In this paper, a batch process monitoring scheme is proposed to separate different types of process variations for modeling and perform monitoring and fault diagnosis with multi-time-scale dynamic principal component analysis (PCA) models. Simulation results show that the fault diagnosis efficiency is enhanced.

Keywords: batch process, monitoring, fault diagnosis, principal component analysis, dynamics.

1. INTRODUCTION

In today's industrial manufacturing, batch processes are widely applied to manufacture high-value-added products. To ensure operation safety and product quality, the multivariate statistical monitoring methods, such as multiway principal component analysis (MPCA) (Nomikos and MacGregor, 1994; Nomikos and MacGregor, 1995) which is an extension of principal component analysis (PCA), have been utilized in batch process monitoring and fault diagnosis.

Dynamics are inherent characteristics of batch processes, including short time-scale dynamics within a batch duration and long time-scale dynamics across several batches. Different types of batch dynamics are usually caused by different values of variable response time which measures the time process variables take to react to given inputs. Fast-response variables have small response time constant, while slow-response variables have large values which may be longer than a batch duration. To model batch process dynamics better, several multivariate statistical monitoring methods have been proposed. Batch dynamic principal component analysis (BDPCA) (Chen and Liu, 2002) captures within-batch dynamic information, while two-dimensional dynamic principal component analysis (2-D-DPCA) (Lu, et al., 2005) can model both long and short time-scale dynamics in a two-dimensional (2-D) model structure.

In batch processes, variable correlations always exist. Especially, changes in slow-response variables can also affect fast-response variable trajectories. This makes different types of variable dynamics confounded, and causes difficulties in process fault diagnosis, as shown later. Therefore, it is desirable to have a method which can decouple process variation information according to dynamic time scales and monitor different types of variations separately. Thus, the fault diagnosis efficiency and accuracy can be enhanced.

Several existing multivariate statistical methods can divide process variations into blocks, scales or levels, but none of them can be utilized directly to handle the situation mentioned above. Multiblock PCA or partial least squares (PLS) methods (Westerhuis et al., 1998) group process variables into meaningful blocks and concern both the inner relationship within each block and the inter relationship among blocks. Although the variables with different response time can be divided into different blocks, two kinds of dynamics information are not separated due to variable correlations. Multiscale PCA (Bakshi, 1998) makes use of wavelet analysis techniques to transform each variable signal from time domain to frequency domain, and performs PCA on wavelet coefficients at each scale. However, the different dynamics characteristics of each variable are not taken into consideration. Multilevel component analysis (MLCA) and multilevel simultaneous component analysis (MLSCA) (Timmerman, 2006) separate within-batch variations and between-batch variations. But only the static variations are extracted, while process dynamics are not modeled. Besides, none of the methods reviewed in this paragraph can deal with long time-scale dynamics across several batches.

In this paper, a batch process monitoring scheme is developed. This scheme makes use of variable response time information which can be easily achieved, and separate process variations into different levels corresponding to dynamics time scales. 2-D-DPCA method is adopted to build multi-time-scale models. Thus, faults occurring to a certain level can be accordingly detected with the level model. Then, diagnosis can also be performed in the corresponding level, indicating the causing of the fault more clearly.

The article is organized as following. In section 2, the 2-D-DPCA method is reviewed. Then, a multi-time-scale batch process monitoring scheme is proposed and described detail in section 3. Simulation results are given in section 4. A batch process with both long time-scale and short time-scale dynamics is simulated to compare the monitoring and diagnosis efficiencies between the conventional 2-D-DPCA method and the proposed scheme. Finally, a conclusion is given in section 5 to summarize the paper.

2. TWO-DIMENSIONAL DYNAMIC PCA (2-D-DPCA)

2-D-DPCA method proposed by the authors can model both long and short time-scale batch process dynamics with a parsimonious two-dimensional (2-D) time series model structure together with PCA technique (Lu, et al., 2005).

Process dynamics can be indicated by the correlations between current measurements and lagged measurements. Long time-scale dynamics often behave as a kind of two-dimensional (2-D) dynamics, which means the current measurements are dependent not only on lagged measurements in the past time direction in the same batch, but also on lagged measurements in some past batches. These lagged variables form a region called the support region or the region of support (ROS). In 2-D-DPCA, an expanded data matrix $\tilde{\mathbf{X}}$ is formed by including all the lagged measurements in ROS, together with current measurements. For more details about ROS determination, please refer to Yao et al.'s work (2008).

Suppose $\tilde{\mathbf{X}}$ has been normalized to have unit variances and zero means. PCA algorithm is performed on it:

$$\tilde{\mathbf{X}} = TP^T + E \,. \tag{1}$$

where T and P are score matrix and loading matrix respectively, and E is the residual matrix. The number of scores retained in the score space can be determined using cross-validation (Wold, 1978). Thus, the original process data are divided into two subspaces. Score space extracts systematic variation information, including both 2-D dynamics and cross-correlation information among variables, while normal distributed noises are retained in residual space. Therefore, *SPE* statistic and corresponding control limits can be calculated for process monitoring in residual space. After a fault is detected by the *SPE* control plot, contribution plots with control limits (Westerhuis et al., 2000) are used in fault diagnosis to find the causes of the faults.

When a batch process only has short time-scale dynamics, its ROS is selected as a region containing several steps of lagged measurements in current batch. In such a case, 2-D-DPCA model is similar to BDPCA model (Chen and Liu, 2002).

3. MULTI-TIME-SCALE MONITORING SCHEME

3.1 Motivations

As mentioned in introduction section, in batch processes, fast-response variable trajectories are often affected by disturbances in slow-response variables. Take injection molding process as an example. In that process, temperature variables' response time constants are often longer than a batch duration, while pressure variables response fast. Suppose a disturbance occurs to barrel temperature. It takes a long time for barrel temperature to recover. During this period, the material properties, such as viscosity and density, change gradually due to the temperature change. This further causes slow drifts in pressure variable trajectories, although pressures are fast-response variables. From this example, it can be seen that both short and long time-scale dynamics are confounded in fast-response variable trajectories.

As shown in the simulation example in section 4, such confounding leads to difficulties in fault diagnosis results. Therefore, it is desirable to decouple process variation information into several levels according to dynamic time scales. Then, level models can be built and different types of variations can be monitored and diagnosed separately, so that the fault diagnosis efficiency and accuracy can be enhanced.

3.2 Variable classification

As a kind of external information, variable response time is easy to be estimated from process open-loop tests which are regular steps in controller designs. Such information is used to classify variables into groups. It is the first step of multi-time-scale modeling and monitoring.

In many cases, the variables can be simply divided into two groups. One contains fast-response variables, while the other contains slow-response variables which can cause long time-scale dynamics beyond a batch. In some other situations, it may be desired to further divide the above two groups into sub-groups. Suppose there are M number of variable divided into the fast-response variable group. Take each variable's response time constant as a pattern. The k-means clustering algorithm (Jain et al., 1999) is adopted for partitioning the M number of patterns. The final cluster number is determined automatically with a specified threshold of the minimal distance between two cluster centers or the maximal radius of a cluster. A larger threshold results in fewer variable groups; vice versa. The slow-response variable group can also be further divided in the same way. By doing so, the process variables with similar response time constants are clustered into the same group.

3.3 Multi-time-scale level separation

Without losing generality, first, suppose the process variables are divided into two groups. As discussed in section 3.1, two types of dynamics may confound in the trajectories of the variable in the fast-response variable group. To solve this problem, the operation data in this group should be decomposed into two parts: one part can be explained by the variable measurements in the slow-response variable group, and the other part can not be explained by them and only contains short time-scale dynamics. The level separation is based on the idea of external analysis, which was originally proposed by Takane and Shibayama (1991) and further

discussed by Yoon and MacGregor (2001). Kano et al. (2004) made use of this idea to distinguish faults from normal changes in operating conditions.

Consider a batch process data matrix $\hat{X}(I \times J \times K)$, where I, J, K are the number of batches, variables and time intervals respectively. Unfold this three-way data matrix into a two-way matrix $X(IK \times J)$ by keeping the variable dimension and merging the other two dimensions. Suppose X have been normalized. After variable classification, X can be described as $X = [F \ S]$, where F consists of J_F number of fast-response variables and S consists of $J_S = J - J_F$ number of slow-response variables. To decompose F, regression analysis is performed by regarding S and F as inputs and outputs respectively. If variables in S are independent of each other, the ordinary least square (OLS) regression can be used:

$$\Phi = (S^T S)^{-1} S^T F, \tag{2}$$

where Φ is the regression coefficient matrix. The significance of regression can be tested (Montgomery, 2005) to show whether there are correlations between S and F. If there is no correlation, the levels are naturally seperated. The short time-scale level consists of $D^S = F$, while the long time-scale level consists of $D^L = S$. Otherwise, calculate (3).

$$E = F - S\Phi, \tag{3}$$

where $S\Phi$ contains a part of information in F which is explained by slow-response variable, while the filtered data matrix E dose not contains long time-scale dynamics. When the slow-response variables are not independent, PLS or principal component regression (PCR) can be utilized to avoid the collinearity problem. Thus, the process variation information is separated into two levels according to different time scales of dynamics: $D^S = E$ and $D^L = [S\Phi \ \ S]$.

When there are more than two groups, the time-scale level separation is performed in an iterative way. Unfolded data matrix X is described as $X = \left[X_1^0 \quad X_2^0 \quad \cdots \quad X_C^0 \right]$, where X_i^j is the filtered data matrix of the ith variable group after the jth iteration run in time-scale level separation, consisting of J_i number of variables. When $j = 0$, X_i^j represents the data before performing iteration steps. C is the total number of variable groups, and the variables in X_i^j response faster than the variables in X_{i+1}^j. In the jth run, let $S^j = X_{C-j+1}^{j-1}$ and $F^j = \left[X_1^{j-1} \quad X_2^{j-1} \quad \cdots \quad X_{C-j}^{j-1} \right]$. Φ^j is then calculated in the similar way as (2), and the data are filtered as

$$\begin{aligned} E^j &= F^j - S^j \Phi^j = \left[X_1^{j-1} \quad X_2^{j-1} \quad \cdots \quad X_{C-j}^{j-1} \right] - X_{C-j+1}^{j-1} \Phi^j \\ &= \left[X_1^j \quad X_2^j \quad \cdots \quad X_{C-j}^j \right] \end{aligned}. \tag{4}$$

After C-1 cycles of iteration, all levels are separated. The shortest time-scale level consists of $D^1 = E^{C-1}$. The second shortest time-scale level consists of $D^2 = [S^{C-1}\Phi^{C-1} \ \ S^{C-1}]$. … The longest time-scale level consists of $D^C = [S^1\Phi^1 \ \ S^1]$.

3.4 Multi-time-scale dynamic PCA modeling, monitoring and fault diagnosis

After level separation, 2-D-DPCA is adopted to construct level models for online monitoring and fault diagnosis.

Take a C level separation as an example. In level j (j>1), $D^j = [S^{C-j+1}\Phi^{C-j+1} \ \ S^{C-j+1}]$. Since $S^{C-j+1}\Phi^{C-j+1}$ is completely dependent on S^{C-j+1}, it only represents redundant information in a process monitoring context. Therefore, the variation information in each level is reorganized as $G^1 = E^{C-1}$, $G^2 = S^{C-1}$, …, $G^C = S^1$ with matrix dimensions of ($IK \times J_1$), ($IK \times J_2$), …, ($IK \times J_C$) respectively. These matrices are rearranged into three-dimensional arrays with dimensions of ($I \times J_1 \times K$), ($I \times J_2 \times K$), …, ($I \times J_C \times K$). Then, following ordinary procedures, 2-D-DPCA models can be established for each level. The *SPE* control limits are calculated for online monitoring. For a level belonging to short time-scale dynamics, the 2-D-DPCA model reduces to a BDPCA model. For these levels, the T^2 control limits can also be calculated, since there is no batch-wise dynamics.

In online monitoring, the new data are firstly filtered based on (4) using coefficient matrices Φ^1, Φ^2, …, Φ^{C-1} in turns. Thus, the variations contained in the new data are separated into different time-scale levels. The corresponding 2-D-DPCA model is utilized to monitor each level. After faults are detected in some levels, the contribution plots can be used for fault diagnosis in these levels accordingly.

4. SIMULATION EXAMPLE

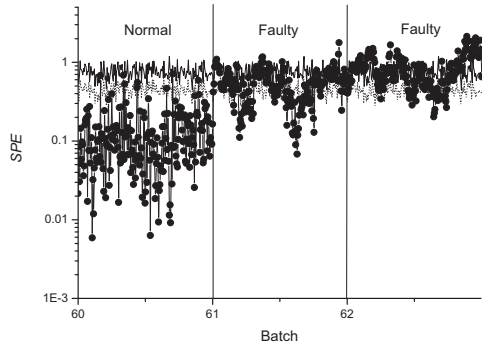
4.1 Batch process modeling

In this section, a simulated batch process with both long and short time-scale dynamics is utilized to compare the monitoring and fault diagnosis efficiency of the proposed multi-time-scale dynamic PCA models with the conventional 2-D-DPCA model. The process model is given as below,

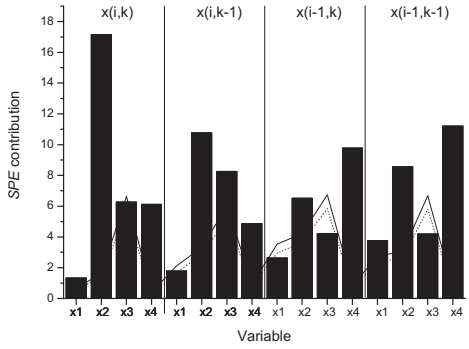
$$\begin{aligned} x_1(i,k) &= 0.5 * x_1(i,k-1) + 0.8 * x_1(i-1,k) - 0.3 * x_1(i-1,k-1) \\ x_2(i,k) &= 0.44 * x_2(i-1,k) + 0.67 * x_2(i,k-1) - 0.11 * x_2(i-1,k-1) \\ x_3(i,k) &= 0.4 * x_3(i,k-1) + 0.25 * x_1(i,k) + 0.35 * x_2(i,k) \\ x_4(i,k) &= 0.8 * x_4(i,k-1) + 0.53 * x_1(i,k) - 0.33 * x_2(i,k) \end{aligned}, \tag{5}$$

where i is the batch index; k is the time index; x_1 and x_2 are two independent slow-response variables with long time-scale dynamics described in a 2-D structure; x_3 and x_4 are fast-response variables correlated to their own values at one step before in the current batch, which are also affected by x_1, x_2. Gaussian noises with variance 0.01 are added into the data.

For conventional 2-D-DPCA modeling, the ROS is determined as $\mathbf{x}(i,k-1), \mathbf{x}(i-1,k), \mathbf{x}(i-1,k-1)$, where $\mathbf{x}(i,k-1) = \left[x_1(i,k) \quad x_2(i,k) \quad x_3(i,k) \quad x_4(i,k) \right]$. So that, there are totally 16 variables in the augmented data matrix $\tilde{\mathbf{X}}$, including 4 current variables and 12 lagged variables in the ROS.

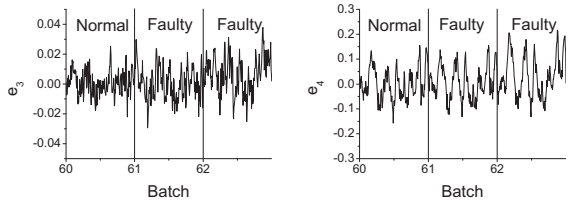


(a)



(b)

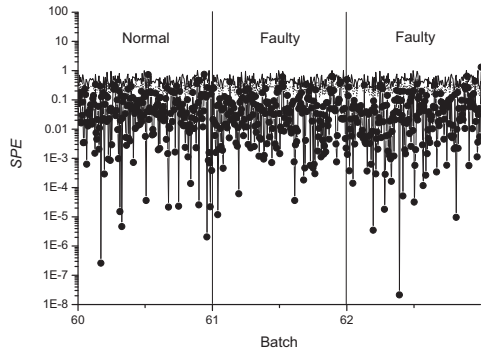
Fig. 1. Monitoring and diagnosis results of fault 1 based on 2-D-DPCA: (a) monitoring result; (b) fault diagnosis result.



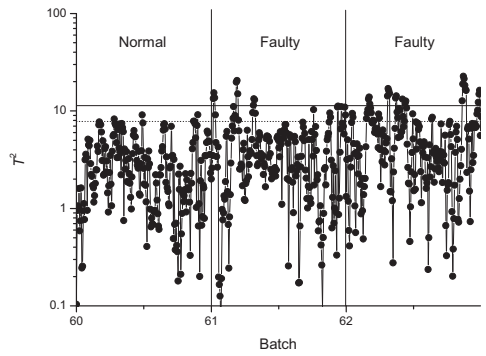
(a) (b)

Fig. 2. Filtered variable trajectories in fault 1: (a) e_3; (b) e_4.

For multi-time-scale dynamic PCA modeling, x_1 and x_2 belong to the slow-response variable group *S*, while x_3 and x_4 are divided into the fast-response variable group *F*. The regression model between *F* and *S* is built to remove the effects of x_1 and x_2 from x_3 and x_4, as described in (2) and (3). Supposing e_3 and e_4 are the filtered values of x_3 and x_4, the variation information is separated into $G^S = \begin{bmatrix} e_3 & e_4 \end{bmatrix}$ as the short time-scale level and $G^L = \begin{bmatrix} x_1 & x_2 \end{bmatrix}$ as the long time-scale level. Then, 2-D-DPCA is performed on each level to model the two different types of dynamics. Let $\hat{\mathbf{x}}(i,k-1) = \begin{bmatrix} x_1(i,k) & x_2(i,k) \end{bmatrix}$. In the long time-scale level, the ROS is selected as $\hat{\mathbf{x}}(i,k-1), \hat{\mathbf{x}}(i-1,k), \hat{\mathbf{x}}(i-1,k-1)$.



(a)



(b)

Fig. 3. Monitoring results of fault 1 based on short time-scale level model: (a) *SPE* plot; (b) T^2 plot.

The 2-D-DPCA model is calculated based on 2 current variables in $\hat{\mathbf{x}}(i,k)$ and 6 lagged variables in the ROS. In the short time-scale level, the algorithm is performed on 4 variables including $e_3(i,k), e_4(i,k), e_3(i,k-1), e_4(i,k-1)$.

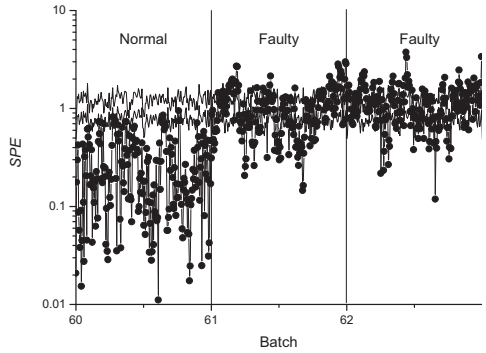
4.2 Online modeling and fault diagnosis

Two faults are introduced into the process. Fault 1 occurs to the slow-response variable x_2. From batch 61, x_2 is formulated as (6) to simulate a fault:

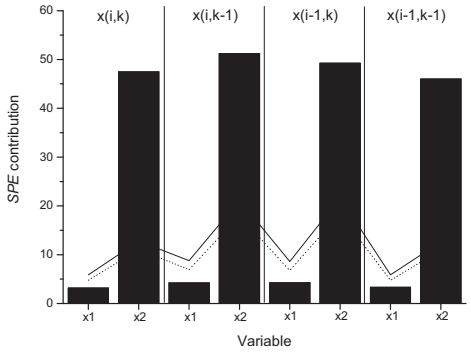
$$x_2(i,k) = 0.6 * x_2(i-1,k) + 0.3 * x_2(i,k-1) + 0.2 * x_2(i-1,k-1) . \quad (6)$$

Fig. 1 shows the monitoring and the fault diagnosis results based on conventional 2-D-DPCA, respectively. The *SPE* control chart shows that the fault can be detected from the beginning of batch 61. However, from the contribution plot of batch 61, Fig. 1(b), it is hard to say which variable is faulty. Due to the variable correlations, many variables (including the lagged variables) are outside the control limits.

In multi-time-scale monitoring, variable x_1 and x_2 are filtered to get short time-scale dynamic signals e_3 and e_4. Since the fault occurs to the slow-response variable x_2, and the effects



(a)



(b)

Fig. 4. Monitoring results of fault 1 based on long time-scale level model: (a) monitoring; (b) diagnosis.

of x_1 and x_2 have been removed from the short time-scale level, there is no significant difference between the trajectories of e_3 and e_4 in a normal cycle and those in the faulty cycles, as shown in Fig. 2. The monitoring results in Fig. 3 confirm this. Neither *SPE* nor T^2 plot in this level is affected by the fault significantly. At the same time, the *SPE* control plot in the other level detects the fault efficiently, as Fig. 4(a) shows. This points out that the fault happens in the long time-scale level. Then, contribution plot in this level is plotted to find out the reason of the fault. From Fig. 4(b), it is very easy to conclude that x_2 is the faulty variable.

Fault 2 is about the fast-response variable x_3. From batch 61, the formulation of x_3 becomes:

$$x_3(i,k) = 0.5 * x_3(i-1,k) + 0.25 * x_1(i,k) + 0.35 * x_2(i,k). \quad (7)$$

As shown in Fig. 5, again, the conventional 2-D-DPCA detects the fault very quickly, but the contribution plot can not give a clear indication about the reason of the fault.

Fig. 6 shows the trajectories of e_3 and e_4. Obviously, significant magnitude differences exist between the trajectory of e_3 in a normal batch and that in faulty batches. So that, this fault is hopefully to be detected by the T^2 control chart in the short time-scale level, which is confirmed by Fig. 7(a). The

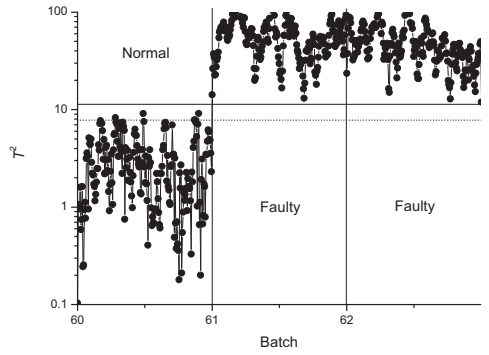
monitoring in the other level, as shown in Fig. 8, dose not show the fault, as it only occurs to a fast-response variable and dose not affect the long time-scale dynamics. The fault diagnosis is only needed to be performed in the short time-scale level. The contribution plot diagnoses the reason of the fault clearly and correctly, as Fig. 7(b) shows.

5. CONCLUSIONS

Batch process variables have various response time constants, causing dynamics with different time scales. The trajectories of the fast-response variables are often affected by the slow-



(a)

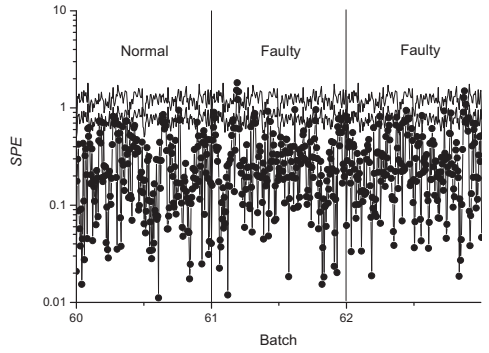

Fig. 8. Monitoring results of fault 2 based on long time-scale level model

response variables, confounding different types of dynamics and causing trouble in fault diagnosis.

A multi-time-scale dynamic PCA monitoring scheme is proposed in this paper. The process variations are separated into different levels according to the dynamics time scales. Then 2-D-DPCA method is adopted to model each level for online monitoring. The simulation results show that the fault diagnosis accuracy is largely improved.

In this paper, variable response time constants are assumed to be known as a kind of external information. It is better if such information can be achieved from the analysis of the operation data. This issue will be studied in the future researches to make the method completely data-based.

Abstract: This paper aims to solve the problems of fault diagnosis and variation reduction by using multivariate statistical techniques when the quality measurements are scarce. Both single stage process and multi-stage process are considered. For the single stage process, the nonparametric statistical method, Wilcoxon rank-sum test is used to identify the key variable/step that causes the fault of the un-qualified wafers. For the multi-stage process, the most important variables are first picked out by systematic statistical analysis, and the specifications of these key variables are designated using nonparametric method to improve the product yield. Gene map which gives visual images is used to assist the analysis. Industrial examples are given to show the effectiveness of the proposed method.

Keywords: semiconductor manufacturing, fault detection, Wilcoxon rank-sum test, cluster analysis, stepwise regression.

1. INTRODUCTION

State-of-the-art semiconductor processes are often pushed to the limits of current technologies, resulting in processes that have little or no margin for error. Advanced process control (APC) and fault detection and classification (FDC) are widely applied in semiconductor industries to reduce cycle-time and improve yield. The focus of this paper is on the fault detection algorithms to find out the variation source and root-cause of scrap wafers by using statistical multivariate analysis techniques.

Detection of process and tool faults in the shortest possible time is critical for minimizing scrap wafers and improving product yields for semiconductor manufacturing. However, most of wafer-states lack in situ sensor to provide real time information and usually are measured offline and less frequently than every wafer, which can lead to a number of scrapped wafers before a fault is detected. In the meanwhile, fortunately, more and more real time measurements of manufacturing equipments like temperature, pressure, power and flow rate, etc., are available due to the advances in metrology technology. These real time measurements provide valuable information about the tool status and can be used to predict final wafer characteristics. Further, it also provides a way to improve product quality by detecting and identifying equipment malfunctions in real time without interrupting the normal operations. The difficulty is, with such an abundant amount of data available, it is usually not clear which tool-state variable is critical or closed related with the final product quality.

Principal component analysis (PCA) and partial least squares (PLS) have drawn increasing interest and have been studied extensively in semiconductor manufacturing industry. PCA and PLS are useful tools for data compression and information extraction and have the advantages of dealing with high dimension and collinearities. PCA/PLS methods find linear combinations of variables that describe major trends in a data set. Considering the batch nature of semiconductor manufacturing, multi-way PCA is usually used to unfold three dimensions data into 2-D data array (Macgregor, 1994). Yue et al. applied multi-way PCA method to optical emission spectra for plasma etchers.

Most of the methods mentioned above require a large amount of training data to build a reliable statistical model to capture the key characteristics of the process. However, in real practice, many fabs are operating with diversified products of small account (Ma, et al., 2008) which means that one has to find out the causes of un-qualified wafers with limited quality data. Compared with principal components which are combined by all process variables, engineers are more eager to know which variable exactly, or linear combinations of several variables, plays an important role on the product quality. It is also of interest to know which step is critical to the whole streamline.

In this paper, a systematic approach is proposed for fault diagnosis and variation reduction by using statistical multivariate techniques. Both single stage process and multi-

stage process are considered. For the single stage process, the nonparametric statistical method, Wilcoxon rank-sum test is used to identify the key variable/step that causes the fault of the un-qualified wafers. For the multi-stage process, homogeneous process variables are first grouped by using cluster analysis, and representative variables or linear combinations of variables of each group are picked out. Then the key clusters are selected by stepwise regression method. Further, the upper and lower limits of these selected representative variables are designated to reduce product variation. It is shown that the proposed method improves the product yield substantially.

Recently, combinatory and high throughput experiments have received widespread attention in biology. Synopsis of large amount of experiment data and subsequent information mining from such data has become a special branch of study known as bioinformatics (Baldi and Brunak, 2001). The key experimental technique that is responsible for the advancement of bioinformatics is the microarray which enables expressions of tens of thousands of genes be measured and represented on a small array of colored image dots. In this paper, we demonstrate that quick diagnosis of the key variable/step that causes the fault in final quality can be achieved by simple statistical analysis of measured values of different sensors and graphical synopsis of results of such analysis. Furthermore, specifications for the key variables, which are usually far from optimal in original settings, can be designated to improve the product yield.

2. FAULT DETECTION FOR SINGLE STAGE PROCESS

2.1 Problem statement

Consider quality data of n wafers are collected from a tool, n_1 wafers are qualified, and n_2 wafers are un-qualified, hence $n_1+n_2=n$. Let's denote that m steps with v variables are implemented during the whole process. It is assumed that in each step t_s seconds are carried out for some certain objective (for instance temperature ramped up, current ramped down,…,etc.), where s=1,…,m. Suppose that the total time for all steps is t, then $t_1 + t_2 + \cdots + t_m = t$; let $T_r = t_1 + \cdots + t_r$, where r=1,…,m. Now, let's define $X_{i,j,k,l}$ to be the kth independent variable at batch time l of jth wafer, where j=1,…,n_i, k=1,…,v, l=1,…,t, and i=1 means the wafer is qualified, i=2 indicates the wafer is not qualified. Now, the problem is what is the p-value of $X_{i,j,k,l}$ to distinguish the wafer is qualified or unqualified in case n_1 and n_2 are small.

2.2 Statistical analysis

It is general to apply t-test to distinguish two set of data whether or not their mean is equal to each other. However, in this case n_1 and n_2 are small, a two sample t-test is not appropriate since the above two set of data may not be in normal distribution. Therefore, a nonparametric analysis, Wilcoxon rank-sum test, is used here.

The Wilcoxon rank-sum test is a nonparametric alternative to the two-sample t-test which is based solely on the order in which the observations from the two samples fall (Higgins, 2004). It is valid for data from any distribution, whether normal or not, and is much less sensitive to outliers than the two-sample t-test. The Wilcoxon test is based upon ranking the n_1+n_2 observations of the combined sample. Each observation has a rank: the smallest has rank 1, the 2nd smallest rank 2, and so on. The Wilcoxon rank-sum test statistic is the sum of the ranks for observations from one of the samples.

In this work, we implement Wilcoxon rank-sum test to find the p-value of the hypothesis of

$$H_0 : \mu_{1,k,l} = \mu_{2,k,l} \quad vs. \quad H_a : \mu_{1,k,l} \neq \mu_{2,k,l} \qquad (1)$$

where $\mu_{1,k,l}$ and $\mu_{2,k,l}$ are the mean of qualified and un-qualified wafers of the kth variable at time l respectively. It is assumed that there is not much prior knowledge of the product and no evidence shows that $\mu_{1,k,l}$ is greater or smaller than $\mu_{2,k,l}$. Therefore, a two-side test is implemented here.

Let $p_{k,l}$ be the above p-value of the kth variable at time l, three different approaches to evaluate the above approach can be implemented

(i) Evaluate the p-value of a process variable by finding the average p-value of the process variable in the whole time horizon:

$$P_k = \sum_{l=1}^{t} p_{k,l} \Big/ t \qquad (k=1,2,\ldots,v) \qquad (2)$$

(ii) Evaluate the average of p-value of each variable at each step

$$P_{k,b} = \sum_{l=T_{b-1}+1}^{T_b} P_{k,l} \Big/ t_b \qquad (k=1,2,\ldots,v\ ; b=1,2,\ldots.m,) \qquad (3)$$

(iii) Direct observe the p-value $p_{k,l}$ of each variable at each different time.

From the statistical analysis of the above approaches, we can determine which process variable, which step, plays an important role on the quality of the wafers, and more specifically, which second is critical for the final product quality. All these information is valuable to the engineers for their further improvement of the product quality.

2.3 Illustrative example

The proposed algorithm is applied to a high-density plasma chemical vapor deposition (HDP-CVD) process. HDP-CVD, which is used as the gap-filling process for the dielectric in semiconductor circuits, features a high gap-fill capability compared with conventional plasma CVD by the excitation

of a high-density plasma. The schematic diagram of the HDP-CVD reactor is shown in Fig. 1.

There are 33 process variables for this manufacturing process. 9 steps are implemented for this process and the processing time is shown in Table 1. The quality data obtained from WAT test of 25 wafers are collected, among which 21 wafers are qualified and 4 wafers are un-qualified.

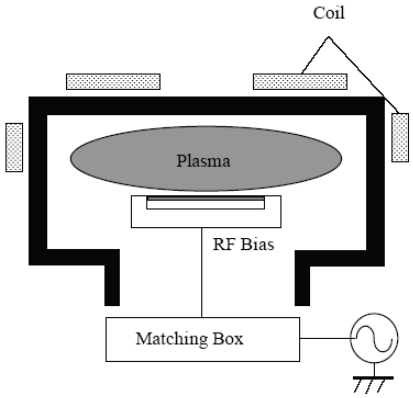

Fig. 1. Schematic diagram of the HDP-CVD reactor.

Table 1 Processing time of each step

Step	1	2	3	4	5	6	7	8	9	Total
Seconds	5	30	53	3	67	5	10	15	5	193

The proposed statistical method is applied to this process. The p-value of hypothesis (1) is calculated for process variables. To find out the key process variable that plays an important role on the process, equation (2) is implemented and the image plot of 1-P_k is shown in Fig. 2. From Fig. 2, we can determine which process variable is more influential for the product quality. This industrial gene map can help engineers to determine which process variable is important and which one is less important at a first glance. Engineers can grasp as much as information in the shortest time with the help of industrial gene map.

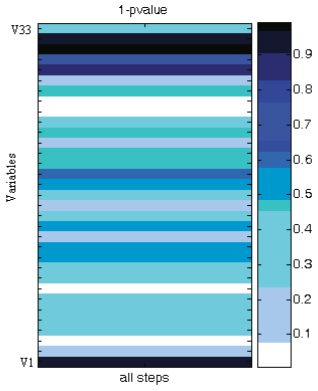

Fig. 2. Image of 1-P_k of total average approach

To further know which step is critical for the process, equation (3) is evaluated for the profile variables of the process and the result is shown in Fig. 3. Similarly, Fig. 3 corresponds to a matrix of dimension 33 by 9. Obviously, the industrial gene map is more visual and straightforward. From Fig. 3, it is observed that most of critical steps are also related with the settings of temperature. The p-value of the profile variables in second are shown in Fig. 4. It can help engineers know when a fault is most likely to happen.

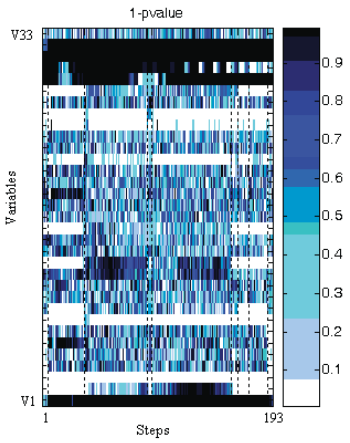

Fig. 4. Image plot of 1-$p_{k,l}$

3. VARIATION REDUCTION FOR MULTI-STAGE PROCESS

3.1 Problem statement

In this section, a statistical method is proposed to find out the key variables that have essential effects on the product quality for the multi-stage manufacturing process. Similarly, the basic assumption is that there is relatively few quality data available compared with process variables. Then, specifications for the key variables which are usually far from optimal in original settings are designated to improve the

product yield. This framework provides a systematic method of drawing inferences from the available evidence without interrupting the normal process operation. The proposed method is directly illustrated by an industrial example. The statistical methods used in the following analysis include cluster analysis, canonical correlation analysis and stepwise regression.

3.2 Statistical analysis and illustrative example

Consider a CVD process. Every wafer must be processed by three chambers A, B, and C successively. Denote the process variables of chamber A, B and C as X_A, X_B and X_C, respectively. The final quality variable is denoted as Y which may contain wafer thickness measurements and wafer electrical measurements. In the following analysis, the method is illustrated for the wafer thickness y, which is one of the most important characteristics of wafers.

The numbers of steps and process variables for chamber A, B and C are list in Table 2. The data set includes measurements of 526 wafers from 22 batches. In this analysis, we want to know which variable, of which chamber, on which step, has an essential effect on the wafer thickness. Every process variable from different chambers on different is treated as an independent variable. Therefore, it is still the case that there are much more process variables than the quality data. Furthermore, process variables are usually highly correlated because of physical and chemical principles governing the process operation. To pick out the most influential variables for the quality variable y, the first step is to reduce the redundancy of the original data set.

Table 2 Number of steps and variables of the three chambers

Chambers	Number of steps	Number of variables
A	13	79
B	5	19
C	12	79

Cluster analysis is a useful technique used for combining observations into groups or clusters such that each group or cluster is homogeneous with respect to certain characteristics. Simultaneously, each group should be different from other groups with respect to the same characteristics (Sharma, 1996). The definition of similarity or homogeneity varies from analysis to analysis, and depends on the objectives of the study. In this study, it is desired to combine variables that are highly correlated into one group. Therefore, the similarity measure is defined as

$$d_{ij} = 1 - \left| r_{ij} \right| \qquad (4)$$

where r_{ij} is the correlation coefficient of variables x_i and x_j. For variables that are highly correlated, d_{ij} would be small which represents similarity and vice versa. The clustering method adopted here is average-linkage method, one of the hierarchical clustering methods.

To determine the number of clusters, the rule that the correlation coefficient of the variables from the same groups should be greater than 0.9 is used. The result of cluster analysis is shown in Fig. 5-7. In these figures, variables that are filled with the same color or indicated with the same number are of the same group.

Then, the next step is to select representative variables from each group. The variables picked out should give good variance explanation which is usually evaluated by the R^2 statistics of the wafer thickness y. For example, the R^2 statistics of one variable selected from group 8 is 0.352 and the total R^2 of the whole group is 0.361. In such case, one process variable is capable of representing the group.

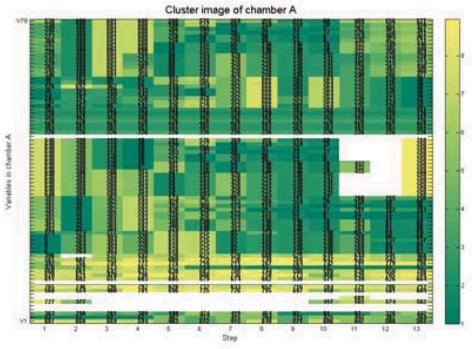

Fig. 5. Cluster image of chamber A.

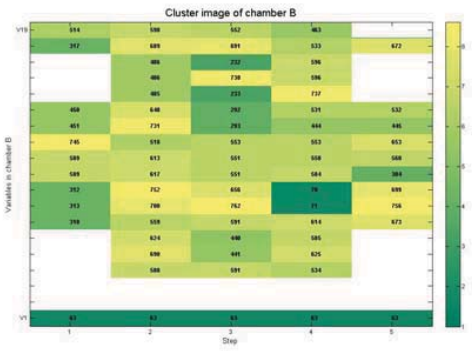

Fig. 6. Cluster image of chamber B.

However, in some circumstances, the R^2 of each individual variable is quite low yet the linear combination of these variables contributes a high R^2. In this case, it is more appropriate to use linear composites of the original variables to represent the group. This problem actually belongs to the field of canonical correlation analysis. The new variables, the linear composites, are called canonical variates. The coefficients of the canonical variates are determined to make the correlation between the linear composites maximum. For this special case, there is only one quality variable, the wafer thickness y. Therefore, canonical correlation analysis is essentially equal to the linear multiple regression.

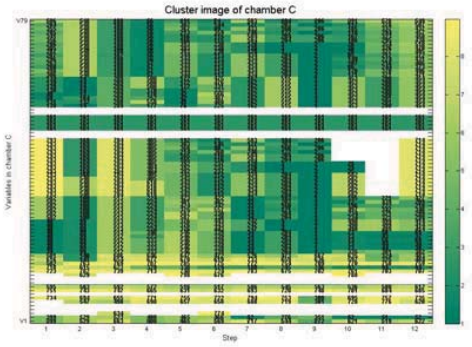

Fig. 7. Cluster image of chamber C.

Then, the question is, when a single variable should be used and when a linear composite should be used to represent a group. In this application, the following rules are adopted: if the R^2 of individual variable is more than eighty percent of the total R^2, then the single variable which has the largest R^2 is used to represent the whole group; otherwise, a linear composite is used. The number of variables in the canonical variate is increased till the R^2 of the linear composite is more than eighty percent of the total R^2. The coefficients of the linear composite are obtained from canonical correlation analysis.

After picking out the representative variable from each group, the next step is to select important representative variables from all the groups. The method used is stepwise regression. Stepwise regression is a statistical method used for variable selection in linear regression. The procedure iteratively constructs a sequence of regression models by adding or removing variables at each step. The criterion for adding or removing a variable at any step is usually expressed in terms of a partial F-test Montgomery, et al., 2001). The changes of R^2 and adjusted R^2 of stepwise regression are shown in Fig. 8. There are 68 representative variables selected by the stepwise regression.

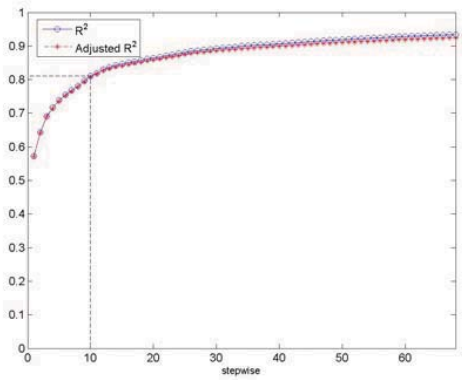

Fig. 8. Representative variables selected by stepwise regression method.

It is not an easy task to monitor 68 variables online simultaneously. Therefore, the first ten representative variables selected by stepwise regression are picked out and analyzed. The first ten representative variables listed in Table 8 give a good variance explanation because the R^2 and adjusted R^2 are higher than 0.8 which can be seen from Fig. 8.

In fact, all the 526 wafers are qualified wafers. To reduce the variance of wafer thickness further, we define $\left[\overline{y}-1.5s_y, \overline{y}+1.5s_y\right]$ as the acceptable region for the wafer thickness. Here, $\overline{y}$ is the average value of y and s_y is the standard deviation of y, respectively. The wafers fall out of this region is treated as "un-qualified" now. Among all the 526 wafers, there are 455 wafers fall into the acceptable region. Therefore, the yield is 0.865. In the following analysis, we will develop a nonparametric method to find out the new specifications for the above ten important representatives to improve the product yield.

First, the center point for all the qualified wafers in a space defined by the 10 important representative variables is determined. The Mahalanobis distance of each qualified wafer from the center point is calculated as

$$MD_i = \left(X_i - \mu\right)^T S \left(X_i - \mu\right) = c_i \quad (5)$$

where X is a 10×1 vector of coordinates and S is a 10×10 covariance matrix, μ is the center point. Then, the yield can be viewed as an implicit function of the Mahalanobis distance. Each value of Mahalanobis distance corresponds to a value of yield which is defined as the ratio between the number of qualified wafers and the number of all the wafers within the Mahalanobis distance. A graphical interpretation of this relationship is shown in Fig. 9. In this figure, the solid line is the relationship between the yield and the Mahalanobis distance and the dashed line is its 95% confidence interval.

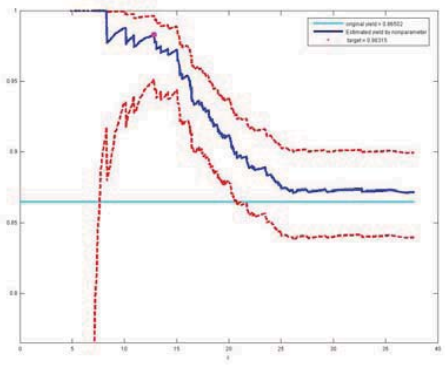

Fig. 9. Plot of Mahalanobis distance versus product yield.

It can be observed that the yield is not reliable when c_i is small because the samples within the corresponding Mahalanobis distance are few. To get a balance between reliability and high yield, the point corresponds to one third of the maximum of c_i which is marked as a dot in Fig. 9 is

used to derive the specifications of the ten representative variables. Once c_i is determined, the joint boundary of the ten representative variables is also determined.

However, the joint boundary which is a function of ten independent variables can not be easily monitored. Therefore, the projections of the joint boundary onto the axes of coordinates are used as the new specifications of the ten representative variables. The yield increased greatly when the upper and lower bounds of the first representative variable are designated. A graphical interpretation of the increase of the yield is shown in Fig. 10. The increases of the yield are not obvious after the designation of the specification of the third representative variable.

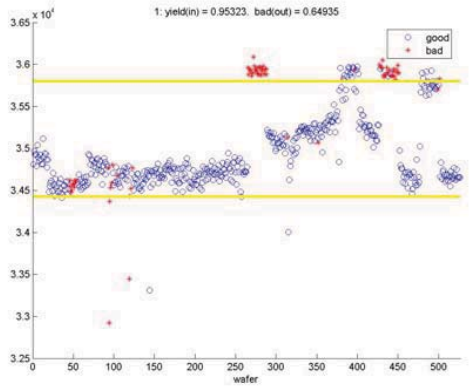

Fig. 10. Specifications of the first representative variable.

It is of interest to study the improvement of process capability ratio after the specifications of the ten representative variables are designated. The process capability ratio (PCR, or C_p) is defined as

$$C_p = \frac{USL - LSL}{6\sigma} \qquad (6)$$

where USL and LSL are the upper and lower specification limits, respectively. Since σ is unknown, it is replaced by the standard deviation s. If the process capability ratio and standard deviation are treated as a function of Mahalanobis distance, then we can get

$$\frac{C_p(c_i)}{C_p} = \frac{s}{s(c_i)} \qquad (7)$$

The relationship between $C_p(c_i)/C_p$ and the Mahalanobis distance is shown in Fig. 11. It can be observed that there is about 40% improvement of process capability ratio for the point we used to designate the specifications of the representative variables. The changing trend of $C_p(c_i)/C_p$ is consistent in the area where the point we used also indicates that the value of c_i we chose is appropriate.

4. CONCLUSIONS

Nowadays, many semiconductor manufacturing foundries are operating with diversified products of small account which makes the fault detection and variation reduction difficult. In this paper, systematic statistical methods are proposed to solve this difficulty. Both single stage process and multi-stage process are considered. The effectiveness of the proposed methods are illustrated by industrial examples.

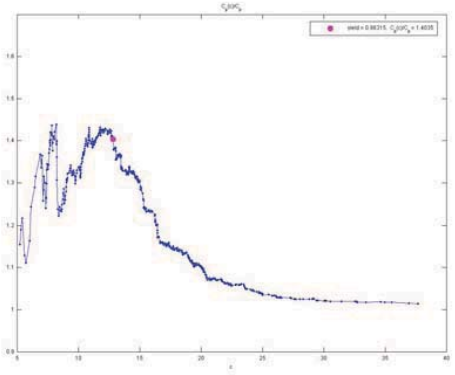

Fig. 11. Plot of Mahalanobis distance versus $C_p(c_i)/C_p$.

Abstract: In this paper Principal Components Analysis (PCA) is used for detecting faults in a simulated wastewater treatment plant (WWTP). Diagnosis tasks are treated using Fisher discriminant analysis (FDA). Both techniques are multivariate statistical techniques used in multivariate statistical process control (MSPC) and fault detection and isolation (FDI) perspectives. PCA reduces the dimensionality of the original historical data by projecting it onto a lower dimensionality space. It obtains the principal causes of variability in a process. If some of these causes change, it can be due to a fault in the process. FDA provides an optimal lower dimensional representation in terms of a discriminant between classes of data, where, in this context of fault diagnosis, each class corresponds to data collected during a specific and known fault. A discriminant function is applied to diagnose faults using data collected from the plant.

Keywords: Fault detection, Fault diagnosis, Statistical process control, Wastewater treatment plant, Discriminant analysis

1. INTRODUCTION

Multivariate statistical methods for the analysis of process data have recently been used successfully for monitoring and fault detection. The safe operation and the production of high quality products are two of the main objectives in industry. Modern control techniques have resolved many problems, but when a special cause occurs in a process, it cannot operate under control. The development of an industrially reliable online scheme for such processes would be a step toward effectiveness and robustness.

Conventional univariate Statistical Process Control (SPC) uses typical control charts, such as Shewhart charts, for monitoring a single variable. When univariate control charts are applied to multivariate systems, with hundreds of variables, the results are improper because, when there is a fault or an abnormality in the operation, several of these charts set off an alarm in a short period of time or simultaneously. This situation is because the process variables are correlated, and a special cause can affect more than one variable at the same time. Multivariate Statistical Process Control (MSPC) uses latent variables instead of every measured variable. All these methods use historical databases to calculate empirical models that describe the system's trend. They are able to extract useful information from the historical data, calculating the relationship between the variables. When a problem appears, it changes the covariance structure of the model and can be detected.

Multivariate statistical approaches, and principal component analysis (PCA) in particular, have been investigated to deal with this problem. Jackson and Mudholkar investigated PCA as a tool of MSPC (Jackson and Mudholkar, 1979) two decades ago. The objective of this approach is to reduce the dimensionality of the original historical data by projecting it onto a lower dimensionality space. PCA finds linear combinations of variables that describe major trends in a data set. Mathematically, PCA is based on an orthogonal decomposition of the covariance matrix of the process variables along the directions that explain the maximum variation of the data. PCA can be studied from two perspectives, one is the cited MSPC, and other is the fault detection and isolation (FDI) perspective, which is discussed by Venkatasubramanian (Venkatasubramanian et al., 2003a,b,c). The author divides the fault detection and diagnosis techniques into three parts: quantitative model-based methods, qualitative models and search strategies and process history-based methods. PCA falls into the third category because it uses historical databases to derive the statistical model (PCA model) (Hwang and Han, 1999; Kourti, 2002; Tien et al., 2004).

The charts most commonly used with PCA techniques are Hotelling statistics, T^2, and the sum of squared residuals, SPE, or Q statistic. The T^2 statistic is a measure of the variation in the PCA model and the Q statistic is a

⋆ This work was supported in part by the national research agency of Spain (CICYT) through the project DPI2006-15716-C02-02 and the regional government of Castilla y Leon through the project VA052A07

measure of the amount of variation not captured by the PCA model.

Once the fault is detected using monitoring techniques, it can be diagnosed by determining the fault region in which the observations are located. The approach used in this paper for fault diagnosis is pattern classification. When the data collected during the *out-of-control* operations have been previously diagnosed, the data can be categorized into separate classes when each class pertains to a particular fault (Chiang et al., 2000).

Fisher discriminant analysis (FDA) is a linear pattern classification method used to find the linear combination of features which best separate two or more classes. It is an empirical method based on observed attributes over the collected examples. FDA provides an optimal lower dimensionality representation in terms of a discriminant between classes of data, where, for fault diagnosis, each class corresponds to data collected during a specific, known fault. FDA has been studied in detail in the pattern classification literature (Duda et al., 2001), but its use for analyzing chemical process data had not been explored until recently (Chiang et al., 2000; He et al., 2005; Fuente et al., 2008).

The purpose of this article is to implement a method for fault detection and diagnosis using multivariate statistical methods and to apply it to a wastewater treatment plant (WWTP). Theoretical aspects of PCA and FDA will be presented and finally the wasterwater treatment plant, the considered faults and the results obtained will be explained and discussed.

2. PRINCIPAL COMPONENT ANALYSIS

Principal component analysis (PCA) is a vector space transformation often used to transform multivariable space into a subspace which preserves maximum variance of the original space in a minimum number of dimensions. The measured process variables are usually correlated to each other. PCA can be defined as a linear transformation of the original correlated data into a new set of uncorrelated data, so, PCA is a good technique to transform the set of original process variables into a new set of uncorrelated variables that explain the trend of the process.

Consider a data matrix $X \in \Re^{n\times m}$ containing n samples of m process variables collected under normal operation. This matrix must be normalized to zero mean and unit variance with the scale parameter vectors $\bar{x}$ and s as the mean and variance vectors respectively. Then next step to calculate the PCA is to construct the covariance matrix R:

$$R = \frac{1}{n-1} X^T X \tag{1}$$

and to perform the SVD decomposition on R:

$$R = V \Lambda V^T \tag{2}$$

where Λ is a diagonal matrix that contains the eigenvalues of R in its diagonal sorted in decreasing order ($\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_m \geq 0$). Columns of matrix V are the eigenvectors of R. The transformation matrix $P \in \Re^{m\times a}$ is generated by choosing a eigenvectors or columns of V corresponding to a principal eigenvalues. Matrix P transforms the space of the measured variables into the reduced dimension space.

$$T = XP \tag{3}$$

The columns of matrix P are called *loadings* and the elements of T are called *scores*. Scores are the values of the original measured variables that have been transformed into the reduced dimension space.

Operating in equation (3), the scores can be transformed into the original space.

$$\hat{X} = TP^T \tag{4}$$

The residual matrix E is calculated as:

$$E = X - \widehat{X} \tag{5}$$

Finally the original data space can be calculated as:

$$X = TP^T + E \tag{6}$$

It is very important to choose the number of principal components a, because TP^T represents the principal sources of variability in the process and E represents the variability corresponding to process noise. There are several proposed procedures for determining the number of components to be retained in a PCA model, such as Zumoffen and Basualdo (2007) and Jackson (1991):

a) The SCREE procedure (Jackson, 1991): It is a graphical method in which one constructs a plot of the eigenvalues in descending order and looks for the *knee* in the curve. The number of selected components are the components between the high component and the *knee*. An example of this graph is shown in Fig. 2.
b) Cumulative Percent Variance (CPV) approach Zumoffen and Basualdo (2007). A measure of the percent variance ($CPV(a) \geq 90\%$) captured by the first a principal components is adopted:

$$CPV(a) = \frac{\sum_{i=1}^{a} \lambda_i}{trace(R)} 100 \tag{7}$$

c) Cross validation.

Having established a PCA model based on historical data collected when only common cause variations are present, multivariate control charts based on Hotelling's T^2 and square prediction error (SPE) or Q can be plotted. The monitoring can be reduced to these two variables (T^2 and Q) characterizing two orthogonal subsets of the original space. T^2 represents the major variation in the data and Q represents the random noise in the data. T^2 can be calculated as the sum of the squares of a new process data vector x:

$$T^2 = x^T P \Lambda_a^{-1} P^T x \tag{8}$$

where Λ_a is a squared matrix formed by the first a rows and columns of Λ.

The process is considered *normal* for a given significance level α if:

$$T^2 \leq T_\alpha^2 = \frac{(n^2-1)a}{n(n-a)} F_\alpha(a, n-a) \tag{9}$$

where $F_\alpha(a, n-a)$ is the critical value of the Fisher-Snedecor distribution with n and $n-a$ degrees of freedom

and α the level of significance. α takes values between 90% and 95%.

T^2 is based on the first a principal components so that it provides a test for deviations in the latent variables that are of the greatest importance to the variance of the process. This statistic will only detect an event if the variation in the latent variables is greater than the variation explained by common causes.

New events can be detected by calculating the squared prediction error SPE or Q of the residuals of a new observation. The Q statistic (Jackson and Mudholkar (1979), Jackson (1991)) is calculated as the sum of the squares of the residuals. The scalar value Q is a measurement of *goodness of fit* of the sample to the model and is directly associated with the noise:

$$Q = r^T r \tag{10}$$

with:

$$r = (I - PP^T)x$$

The upper limit of this statistic can be computed as follows:

$$Q_\alpha = \theta_1 \left[\frac{h_0 c_\alpha \sqrt{2\theta_2}}{\theta_1} + 1 + \frac{\theta_2 h_0 (h_0 - 1)}{\theta_1^2} \right]^{\frac{1}{h_0}} \tag{11}$$

with:

$$\theta_i = \sum_{j=a+1}^{m} \lambda_j^i \qquad h_0 = 1 - \frac{2\theta_1 \theta_3}{3\theta_2^2}$$

where c_α is the value of the normal distribution, with α being the level of significance.

When an unusual event occurs and it produces a change in the covariance structure of the model, it will be detected by a high value of Q.

3. FISHER DISCRIMINANT ANALYSIS

For fault diagnosis, data collected from the plant during specific faults are categorized into classes, where each class contains data representing a particular fault. Define n as the number of observations, m as the number of measurement variables, p as the number of classes and n_j as the number of observations in the j^{th} class. The training data for all classes have been stacked into the matrix $X \in \Re^{n \times m}$. The total-scatter matrix is:

$$S_t = \sum_{i=1}^{n} (x_i - \bar{x})(x_i - \bar{x})^T \tag{12}$$

where $\bar{x}$ is the total mean vector whose elements correspond to the means of the columns of X. Let the matrix X_j be defined as the set of vectors x_j which belong to class j, then the within-scatter matrix for class j is given by:

$$S_j = \sum_{x_i \in X_j} (x_i - \bar{x}_j)(x_i - \bar{x}_j)^T \tag{13}$$

where $\bar{x}_j$ is the mean vector for class j:

$$\bar{x}_j = \frac{1}{n_j} \sum_{x_i \in X_j} x_i \tag{14}$$

The within-class-scatter matrix is:

$$S_w = \sum_{j=1}^{p} S_j \tag{15}$$

and the between-class-scatter matrix is:

$$S_b = \sum_{j=1}^{p} n_j (\bar{x}_j - \bar{x})(\bar{x}_j - \bar{x})^T \tag{16}$$

The total-scatter matrix is equal to the sum of the between-scatter matrix and the within-scatter matrix: $S_t = S_b + S_w$. The objective of the first FDA vector, w_1, is to maximize the scatter between classes while minimizing the scatter within classes:

$$\max_{w_1 \neq 0} \frac{w_1^T S_b w_1}{w_1^T S_w w_1} \tag{17}$$

with $w_1 \in \Re^m$. The second FDA vector, w_2, is computed so as to maximize the scatter between classes while minimizing the scatter within classes on all axes perpendicular to the first FDA vector, and so on for the remaining FDA vectors. These vectors are equal to the eigenvectors w_k of the generalized eigenvalue problem:

$$S_b w_k = \lambda_k S_w w_k \tag{18}$$

where the eigenvalues λ_k indicate the degree of separability between the classes. As it is the direction and not the magnitude of w_k which is important, the norm is usually chosen to be $\|w_k\| = 1$. The first FDA vector is the eigenvector associated with the largest eigenvalue and so on.

Then, the linear transformation of the data x from the m-dimensional space to the reduced space a-dimensional generated by the FDA vectors is:

$$z_i = W_a^T x_i \tag{19}$$

where $W_a \in \Re^a$ has the a FDA vectors as columns, and $z_i \in \Re^a$. FDA computes the matrix W_a that as the data $x_1, \ldots, x_n$ for the p classes are optimally separated when projected into the a-dimensional space.

There are several methods to choose the number of FDA vectors. These methods are very similar to PCA selection methods, cited in section 2. For example, cross validation or the SCREE procedure.

In order to diagnose the faults, FDA takes into account data collected during different faulty conditions, and uses a discriminant function that takes into account the similarity between the actual data and the data belonging to each class. An observation is assigned to the class i when the maximum discriminant function value, g_i, satisfies:

$$g_i(x) > g_j(x) \ \forall j \neq i \tag{20}$$

where $g_i(x)$ is the discriminant function for class i given a measured vector $x \in \Re^m$. The discriminant function that minimizes the error rate, when the event v_i occurs (for example, the fault i), is (Duda et al., 2001):

$$g_i(x) = P(v_i|x) \tag{21}$$

where $P(v_i|x)$ is the *a posteriori* probability of x belonging to class i. It can be shown that identical classification occurs when the equation (21) is replaced by:

$$g_i(x) = \ln p(x|v_i) + \ln P(v_i) \tag{22}$$

Using the Bayes' rule, considering that the data for each class are normally distributed and characterizing the data to this case, i.e., considering $W_a \in \Re^{m \times a}$ containing the eigenvectors $w_1, w_2, \ldots, w_a$ computed from equation (18), the discriminant function for each class can be derived as:

$$g_j(x) = -\frac{1}{2}(x - \bar{x}_j)^T W_a (\frac{1}{n_j - 1} W_a^T S_j W_a)^{-1} W_a^T (x - \bar{x}_j) + \ln(p_j) - \frac{1}{2} \ln[\det(\frac{1}{n_j - 1} W_a^T S_j W_a)] \quad (23)$$

where S_j, $\bar{x}_j$ and n_j are defined in equations (13) and (14) respectively.

4. APPLICATION

The approach presented in this paper has been tested in a simulated wastewater treatment plant (WWTP). This plant is based on the COST benchmark (Copp, -; Alex et al., 2008). This benchmark was developed for the evaluation and comparison of different activated sludge wastewater treatment control strategies. The model is implemented using MATALAB© and SIMULINK©.

Fig. 1 shows an overview of this plant. It is composed of a two-compartment activated sludge reactor consisting of two anoxic tanks followed by three aerated tanks. This type of plant combines nitrification with predenitrification in a configuration that is usually built for achieving biological nitrogen removal in full-scale plants. The reactor is followed by a secondary settler. The settler is modeled as a 10 layer non-reactive unit. The 6^{th} layer is the feed layer. Table 1 shows the physical parameters of the plant.

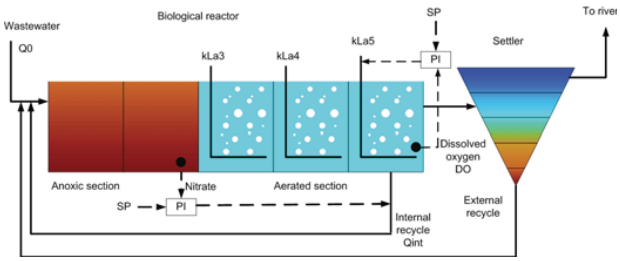

Fig. 1. General overview of the wastewater treatment plant (WWTP)

Table 1. Physical parameters

Elements	Values	Units
Volume - Anoxic section	2000 (2×1000)	m^3
Volume - Aerated tank	4000 (3×1333)	m^3
Volume - Settler (10 layers)	6000	m^3
Area - Settler	1500	m^2
Height - Settler	4	m

The influent used was the dry influent data file Copp (-). In this file, the variation of influent flow is between $15000 - 35000$ m^3/d. The plant, as Fig. 1 shows, has two reflux: external refluxes, from settler to input, which is approximately equal to the influent flow, and internal reflux, from the last aerated tank to input, which is approximately equal to three times the influent flow, but which is a controlable variable.

The objective of the control strategy is to control the dissolved oxygen level in the aerated reactor by manipulation of the oxygen transfer coefficient ($K_L a_5$) and to control the nitrate level in the anoxic tank by manipulation of the internal recycle flow rate. The controllers are of PI type. Tab. 2 shows the principal controller settings.

Table 2. Controllers settings

Variables	Oxygen loop	Nitrate loop
Controller type	PI	PI
Controlled variable	DO $[g/m^3]$	S_{NO} $[gN/m^3]$
Manipulated variable	$K_L a5$ $[1/hr]$	Q_{int} $[m^3/d]$
Setpoint	2 $[g/m^3]$	1 gN/m^3

The model of the plant is formed by 13 state variables. The variables involved are concentrations of:

1. Alkalinity (S_{ALK}).
2. Soluble biodegradable organic nitrogen (S_{ND}).
3. Ammonia nitrogen (S_{NH}).
4. Nitrate (S_{NO}).
5. Dissolved oxygen (S_O).
6. Readily biodegradable substrate (S_S).
7. Active autotrophic biomass ($X_{B,A}$).
8. Active heterotrophic biomass ($X_{B,H}$).
9. Particulate biodegradable organic nitrogen (X_{ND}).
10. Particulate products from biomass decay (X_P).
11. Slowly biodegradable substrate (X_S).
12. Particulate inert organic matter (X_I).
13. Soluble inert organic matter (S_I).

In this case, three faults have been considered. They are not sensors or actuators faults, they are faults in the process. The faults considered are:

- **Toxicity shock.** This fault is due to a reduction in the normal growth of heterotrophic organisms. This type of fault can be produced by toxic substances in the water coming from textile industries or pesticides. This fault is simulated by reducing the maximum heterotrophic growth rate (μ_H).
- **Inhabitation.** This fault can be produced by hospital waste that can contain bactericides, or metallurgical waste that can contain cyanide. This type of fault is due to a reduction in the normal growth of the heterotrophic organisms and an increase in the decay factor of this type of organisms. This fault is similar to toxicity shock but is more drastic. In this case, the fault is caused by reducing the maximum heterotrophic growth rate (μ_H) and increasing the heterotrophic decay rate (b_H).
- **Bulking.** This type of fault is produced by the growth of filamentous microorganisms in the active sludge. This phenomenon causes the impossibility of decantation in the settler. To simulate this fault the settling velocity in layer (v_{sj}) is reduced.

More information about these parameters and mathematical models can be consulted in Copp (-). But in this example the benchmark has been modified in order to introduce the fault parameters.

There are several groups working on fault detection in wastewater treatment plants using PCA (Rosen and Lennox, 2001) or using other fault detection approaches (Genovesi et al., 2000).

Using this dynamic model, the results were obtained in steady state. For this, the plant model has to simulate $100 - 150$ days in open-loop configuration and determines this steady state. Then, the simulation in closed-loop is simulated for 14 days and faults are caused on the 7^{th} day. The samples for monitoring experiments were taken 100 times per day.

The selected variables to calculate principal components analysis (PCA) and Fisher discriminant analysis (FDA) are the first eleven state variables and the effluent flow rate (Q_0). The concentration of particulate inert organic matter (X_I) and soluble inert organic matter (S_I) are not relevant to this study (Tomita et al., 2002).

The number of principal components, calculated using the CPV approach with 95% maximum variance level, are five, but Fig. 2 shows that seven principal components can be a better option because they capture more variability of the process.

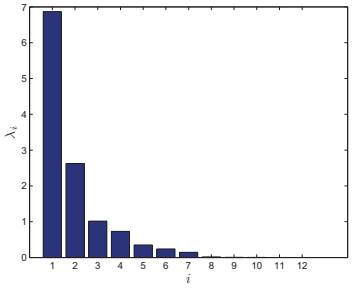

Fig. 2. SCREE graph for principal component selection

The process monitoring under toxicity shock fault can be seen in Fig. 3. The thresholds of both statistics T^2 and Q rise when the fault occurs. In this case, the Q statistic detects this fault better than the T^2 statistic, as this figure shows.

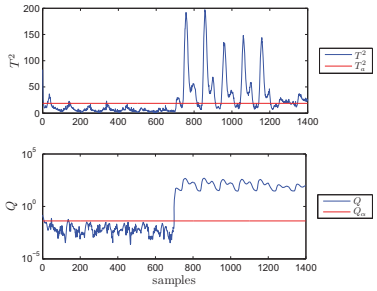

Fig. 3. Toxicity shock fault detection. Logarithmic scale for Q statistic.

The inhabitation fault detection is more effective than the detection of the toxicity shock fault because this type of fault is more drastic, as can be seen in Fig. 4. Finally, the bulking fault detection using PCA is shown in Fig. 5.

The number of selected FDA vectors for fault diagnosis tasks was two using the the SCREE graph method. Fig. 6 shows the discriminant functions (g_i, eq. 23) when a toxicity shock fault has been caused. The solid line corresponds

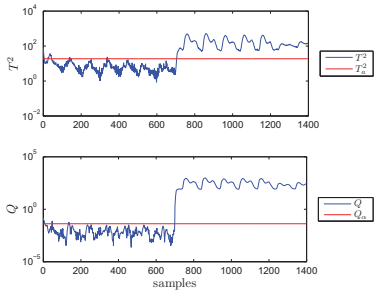

Fig. 4. Inhabitation detection. Logarithmic scale for T^2 and Q statistics.

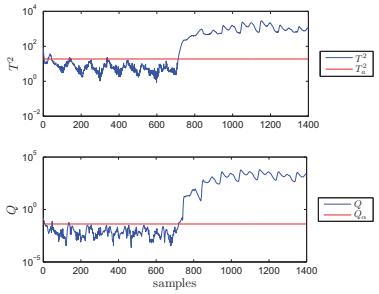

Fig. 5. Bulking fault detection. Logarithmic scale for T^2 and Q statistics.

to the discriminant function for toxicity shock fault, the dotted line corresponds to the discriminant function for inhabitation fault and the dashed line corresponds to the discriminant function for the bulking fault. In this case, once the fault has been detected (7^{th} day) the discriminant function for the toxicity shock fault is greater than the rest of the discriminant functions, so the fault is correctly diagnosed. The experimented faults used to find results are different from the considered faults used in the training data.

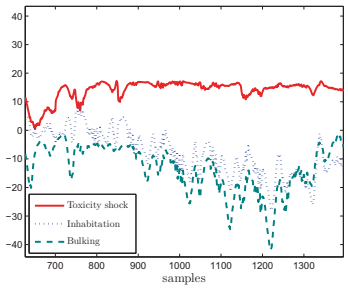

Fig. 6. Toxicity shock fault diagnosis

Fig. 7 shows the discriminant function graphs in the case where the inhabitation fault has occurred. In this situation, the discriminant function for the inhabitation fault is the greatest, so the fault is correctly diagnosed.

Finally, Fig. 8 shows the evolution of the discriminant function for the bulking fault. In this case, the evolution for the bulking fault is always greater than for the rest of the discriminant faults.

5. CONCLUSIONS

This paper proposes an approach to deal with the fault detection and diagnosis using statistical techniques, concretely, the principal component analysis (PCA) is used in detection tasks and the Fisher discriminant analysis (FDA) is implemented in diagnosis tasks.

The approach has been proved in a simulated wastewater treatment plant (WWTP) based on the COST benchmark. The considered faults are critical process faults that affect some plant parameters. Data are collected from the plant for normal conditions in order to calculate the PCA model and the thresholds of the T^2 and Q statistics, used to detect the faults. Data for different classes (parameter faults) are also collected to calculate the FDA models for diagnosis. The used approach shows good results because the faults was detected and correctly diagnosed.

A useful update to this work can be to obtain data when two or more faults occur simultaneously. New discriminant functions can be calculated using this data and these new situations could be diagnosed.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to the department of industrial electrical engineering and automation of Lund University for the implementation of BSM1 model.

Abstract: This work proposes a dynamic PCA modeling method for dynamical non-linear processes. This method uses fault free data to construct data matrix used to compute the correlation matrix and faulty system data in order to fix the dynamic PCA model parameters (the time-lag and the number of principal components). It is shown that the sensitivity of dynamic PCA-based fault detection depends on the parameters used in the model. This method is tested on a three serial interconnected tanks and subject to fluid circulation faults in its pipes.

Keywords: Process and control monitoring; Modeling; Static PCA; Dynamic PCA; Time-lag; Number of components; System fault detection.

1. INTRODUCTION

The use of multi statistical process control tools also known as MSPC became frequent for the modeling, control and diagnosis of complex and over-instrumented processes (chemicals, microelectronics, pharmaceutical..., see Venk (2003)). Static principal component analysis (PCA) is one among the most popular statistical methods, it was used successfully as a modeling tool for statical and slow dynamics processes in linear or non-linear cases, (see Qin (2003)). The extension of PCA for the dynamical modeling, called DPCA, was proposed in Ku (1995). Other work tackled this subject, like in Lee (2004), Li (2003), Mina (2007), Treasure (2004), Xie (2006). In all methods presented in scientific litterature, the model used as reference in the diagnosis procedure is obtained via the minimization of a criterion depending on the nominal data of the process. However, the obtained model can be inadequate for changes detection purposes since the minimized criterion does not necessarily maximize the changement impact of the process on the computed model (see Tamura (2007), Kano (2002)). Many changement types can affect the process, among them one distinguishes : sensors/actuators failures (see Huang (2000)), performance degradation (see Kano (2002)), operating point changes (see Zhao (2004)) and process structure modification or "system fault" (see Huang (2007)). These changes can be highlighted by various statistical tests chosen according to the changement type to be detected. For further details on these tests (also called residuals), the reader can consult Harkat (2006), Kano (2001), Singhal (2005), Guerfel (2008). This work proposes a modeling method of dynamic, linear or non-linear processes via DPCA. This method jointly uses nominal process data to build the correlation matrix to diagonalize and system fault type data to fix the time-lag and the principal component number to retain for the DPCA model. The paper is divided into the following sections. Section 2 recalls shortly the static PCA modeling and its structural parameter. Section 3 defines the dynamic PCA modeling and its structural parameters. The different changes which can affect a process and the statistical test used in this work to detect the system fault type are defined in section 4. The proposed modeling method permitting the choice of the time-lag and the number of principal component to retain for the DPCA model in the case of dynamical non-linear process is presented in section 5. Section 6 illustrates the application of the method on a three serial tanks subject to fluid circulation faults in their pipes. Finally, the last section provides a concluding summary of this work.

2. STATIC PRINCIPAL COMPONENT ANALYSIS

For the vector $z(k) = [z_1(k)\ z_2(k)\ \dots\ z_m(k)]^t$, scaled to zero mean and unity variance and containing the m observed inputs/outputs of the process in the instant k, the data matrix Z_N resulting from the juxtaposition of $z(k)$ in different instants is written :

$$Z_N = [\, z(k)\ \cdots\ z(k+N-1)\,]^t \tag{1}$$

The subscripts N designates the number of observations used in the construction of the matrix Z_N.
Modeling a process via static PCA consists in seeking an optimal linear transformation (with respect to a variance criterion) of the original data matrix Z_N into a new one called T and defined as follows :

$$T = Z_N P \quad ; \quad T = [\, t_1\ \cdots\ t_m\,] \in \mathbb{R}^{N\times m} \tag{2}$$

The vectors $t_q \in \mathbb{R}^N$, $q \in \{1, \dots, m\}$, called principal components are uncorrelated and arranged in the decreasing variance order. The column vectors p_q of the matrix P

represent the eigenvectors corresponding to the eigenvalues λ_q obtained from the diagonalization of the correlation matrix Σ of Z_N :

$$\Sigma = P\Lambda P^t \quad ; \quad PP^t = P^tP = I_m \tag{3}$$

the notation $\Lambda = diag(\lambda_1 \dots \lambda_m)$ designates the diagonal matrix of eigenvalues arranged in the decreasing magnitude order $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_m$. With the triple partitioning :

$$\Lambda = \begin{bmatrix} \hat{\Lambda} & 0 \\ 0 & \tilde{\Lambda} \end{bmatrix}, \quad P = \left[\, \hat{P} \middle| \tilde{P} \,\right], \quad T = \left[\, \hat{T} \middle| \tilde{T} \,\right] \tag{4}$$

The data matrix can be decomposed in the following form :

$$Z_N = \hat{Z}_N + E_N \text{ with } \hat{Z}_N = Z_N\hat{C} \ ; \ E_N = Z_N\tilde{C} \tag{5}$$

The matrices $\hat{C} = \hat{P}\,\hat{P}^t$ and $\tilde{C} = I_m - \hat{C}$ form the static PCA model of the process (for further details see Jollife (2003)). The matrices $\hat{Z}_N$ and E_N represent, respectively, the modeled and the non modeled variations of Z_N from ℓ components ($\ell < m$). The first ℓ eigenvectors forming the matrix $\hat{P} \in \mathbb{R}^{m\times\ell}$ constitute the representation space whereas the last $(m-\ell)$ eigenvectors forming the matrix $\hat{P} \in \mathbb{R}^{m\times\ell}$ constitute the residual space.
The identification of the static PCA model thus consists in estimating its parameters by an eigenvalue/eigenvector decomposition of the matrix Σ and determining its structural parameter which is the number of principal components ℓ to retain. An incorrect choice (too large or too small) of ℓ could mask the changes occurring in the modeled process or gives false alarms which affect the change detection procedure (see Qin (2003)). Many methods were proposed to fix ℓ in the static PCA model. The reader can find more details in Valle (1999). Most of these methods are heuristic and give a subjective number ℓ (see Harkat (2005)). In order to mitigate the disvantages of the heuristic methods, Qin and Dunia have proposed to fix ℓ via the minimization of a criterion called VNR which represents the variance of the reconstruction error of the process variables (see Qin (2000)). However, it is noted that the VNR criterion underestimates the number ℓ exact to retain in real applications cases (see Valle (1999)). All the methods aiming at the determination of ℓ seek to find its theoretical or exact value called (ℓ_{th}) which represents the theoretical number of linear or quasi-linear relations existing between the different components of $z(k)$. These methods are sensitive to the signal noise ratio and depend on the nature of the process non linearity. It is also noted that ℓ can be different from ℓ_{th} in the case of models built for diagnosis purposes provided that the static PCA model (constructed with ℓ components) can detect changes (see Frank (2000)). From this idea was born a new process modeling method via static PCA. Proposed in Tamura (2007), this method uses nominal process data to build the correlation matrix which will be diagonalized and faulty data in order to fix ℓ.

3. DYNAMIC PRINCIPAL COMPONENT ANALYSIS

Dynamic principal component analysis proposed in Ku (1995) and known as DPCA aims at finding dynamical linear relations between the process variables. The principle of this method is identical to the static PCA. Starting from a scaled to zero mean and unity variance data vector $z^d(k) = [z^t(k)\ z^t(k-1)\ \dots\ z^t(k-s)]$, where s designates the used time-lag, the data matrix $Z_N^d(k,s) \in \mathbb{R}^{N\times m(s+1)}$ is built as follows :

$$Z_N^d(k,s) = \begin{bmatrix} z^t(k) & \dots & z^t(k-s) \\ z^t(k+1) & \dots & z^t(k-s+1) \\ \vdots & \ddots & \vdots \\ z^t(k+N-1) & \dots & z^t(k+N-1-s) \end{bmatrix} \tag{6}$$

with $N > m(s+1)$ and $k > s$.
The correlation matrix obtained from $Z_N^d(k,s)$, noted Σ_d, is computed and diagonalized in order to obtain the eigenvectors and the eigenvalues matrices noted respectively P_d and Λ_d. Each one of these two matrices is divided into two parts the first corresponding to the representation space $(\hat{\Lambda}_d,\ \hat{P}_d)$ and the second corresponding to the residual space $(\tilde{\Lambda}_d,\ \tilde{P}_d)$. The principal components vector noted $t^d \in \mathbb{R}^{1\times m(s+1)}$, can be computed in an instant k as follows :

$$t^d(k) = \left[\, \hat{t}^d(k) \mid \tilde{t}^d(k) \,\right] = z^d(k)P_d = z^d(k)\left[\, \hat{P}_d \mid \tilde{P}_d \,\right] \tag{7}$$

The structural parameters in DPCA modeling are the number of principal components ℓ and the time-lag s. The number ℓ can be fixed via the methods used in static PCA after the choice of s which is a very delicate problem. The modeling of data obtained from dynamic process via static PCA constructs an approximate static model of the real process and does not reveal its exact structure (see Ku (1995)). It is possible to detect modifications in dynamical processes via static PCA as in Harkat (2006) and Sharmin (2008), but the theoretical bases of the method are lost since the principal components are no longer uncorrelated and do not follow a normal multivariate statistical distribution. In this case, it will be very difficult to detect small changes in the process parameters as long as the variation domain of the process variales remain the same before and after the change. For a well chosen time-lag $s = s_{min}$, all the static and dynamic relations ruling the process will be represented by the last eigenvectors corresponding to the smallest eigenvalues of Σ_d computed from $Z_N^d(k, s_{min})$. Taking a time-lag s higher than s_{min} in the construction of $Z_N^d(k,s)$ used for the computation of the DPCA model will not bring any supplementary information but will add redundant relations which were obtained from the construction of the DPCA model using the matrix $Z_N^d(k, s_{min})$ (see Ku (1995)). Many methods were proposed for the choice of s. They seek to find the theoritical $s = s_{min}$, most of them are heuristic as in Ku (1995) or resulting from the identification techniques as AIC, see Akaike (1974), Larimore (1990), Li (2003) and MDL, see Simoglou (2002), Rissanen (1978) which privilege the approximation of the data matrix. None of those methods was built in the purpose of minimization of s compared to fault detection.

4. STATISTIC USED FOR SYSTEM FAULT DETECTION

The physical processes are subject to changes in their operating conditions. In the case of non stationary processes, these changes can be sensors/actuators failures (see Huang (2000)), operating point changes, performance degradation or process structure modification. The operating point

changes are characterized by an augmentation in the mean of one or many inputs (see Zhao (2004)). The process performance degradation can be expressed as an augmentation in the variance of one or many process variables under the hypothesis of independent and identically distributed noise (see Kano (2002)). The process structure modifications known as "system fault" appear as changes in the structure or a modification in its model parameters (see Huang (2007)). All these changes can be highlighted by various statistical tests chosen according to the changement type to be detected. Only the system fault type is included in this work. The best indices for the detection of such modification are the ones based on the residual space (see Guerfel (2008)). For this reason, one proposes the use of the D_i statistic, $i = 1, 2, \ldots, (m(s+1) - \ell)$, which is defined in Harkat (2006) as the sum of squared last principal components. This statistic is computed every instant k :

$$D_i(k) = \sum_{j=m(s+1)-i+1}^{m(s+1)} \left(\tilde{t}_j^d(k)\right)^2 \tag{8}$$

The variable $\tilde{t}_j^d(k)$ designates the j^{th} principal component obtained at the instant k. The index D_i represents an SPE (see box (1954)) computed from a DPCA model with $(m(s+1)-i)$ components, its detection threshold $\tau_{i,\alpha}^2$, can be computed in the following way :

$$\tau_{i,\alpha}^2 = g^{(i)} \chi_{h^{(i)},\alpha}^2 \tag{9}$$

The notation χ^2 designates the Chi-square distribution, α designates the used confidence limit, $g^{(i)}$ and $h^{(i)}$ are defined as follows :

$$g^{(i)} = \frac{\sum_{j=m(s+1)-i+1}^{m(s+1)} \lambda_j^2}{\sum_{j=m(s+1)-i+1}^{m(s+1)} \lambda_j} \quad h^{(i)} = \frac{\left(\sum_{j=m(s+1)-i+1}^{m(s+1)} \lambda_j\right)^2}{\sum_{j=m(s+1)-i+1}^{m(s+1)} \lambda_j^2} \tag{10}$$

The quantities $\lambda_j,\ j \in \{m(s+1) - i + 1, \ldots, m(s+1)\}$, designate the j^{th} eigenvalues of Σ_d. A system fault is detected if the D_i index is higher than its threshold $\tau_{i,\alpha}^2$.

5. PROPOSITION FOR DYNAMICAL PROCESSES MODELING

The proposed method is similar to the one defined in Tamura (2007) and called MDM abreviation of *Multi Dimensionnal Monitoring*. Contrary to the MDM, the proposed method allows not only the choice of ℓ but also the choice of the minimum time-lag s to retain for the data matrix $Z_N^d(k, s)$ used in the construction of the DPCA process model. The principle of the method is the following :

(1) Begin method
(2) Initialization $S_{init} = 0$ and $\ell = 0$
(3) Build $Z_N^d(k, S_{init})$, Compute Σ_d, P_d and Λ_d
(4) Compute D_i from system fault data for i varying from 1 to the number of column in $Z_N^d(k, s)$ minus 1
(5) If the fault is detected with any of D_i then go to step 7 else go to step 6
(6) $S_{init} = S_{init} + 1$ go to step 3
(7) $s = S_{init}$ and ℓ is equal to the difference between the number of column in $Z_N^d(k, s)$ and the largest value of i which permits the fault detection.
(8) End method

The disadvantage of the proposed method lies in the fact that a knowledge of information on the system fault is necessary to ensure the choice of structural parameters (s and ℓ) to be retained for the DPCA model. From another point of view, if information on the system fault is available, this method becomes very attractive because it determines the simplest model allowing the system fault detection. Figure (1) summarizes the algorithm of the method in the case of a single system fault "j" affecting the modeled process.

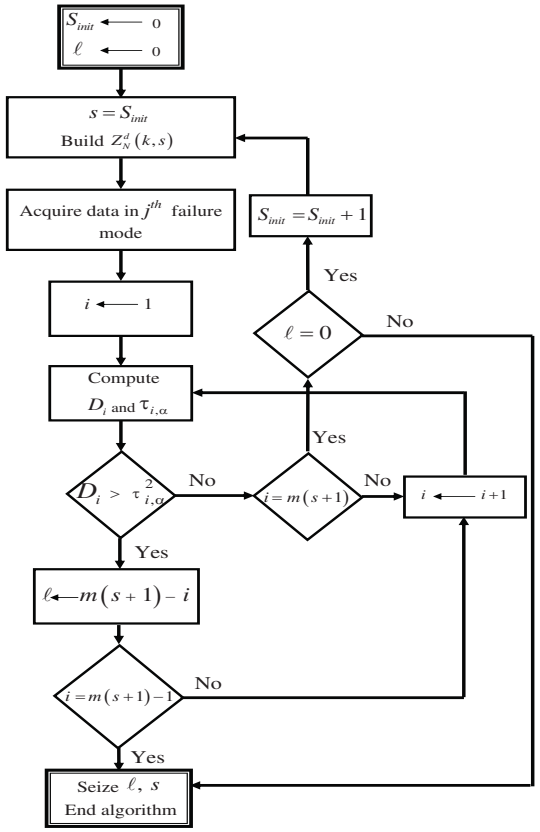

Fig. 1. Algorithm of the proposed method for the determination of s and ℓ in the DPCA model

In order to supress false alarms, the process is considered in failure mode ($D_i > \tau_{i,\alpha}^2$), if D_i has shown eight succeeding values larger than $\tau_{i,\alpha}^2$. The value "eight" is determined in an empirical way and must be adjusted according to the treated application.

6. APPLICATION IN THE MODELING OF THREE TANK SYSTEM

The modeled process illustrated in figure (2), is formed by three identical serial tanks. It contains two inputs : flows q_1, q_2 and three outputs H_1, H_2 and H_3 representing respectively the heights in the first, second and third tanks.

These tanks are interconnected at the bottom by pipes. Two valves V_3 and V_2, separating respectively tank 2 from tank 3 and tank 2 from the outside are introduced in order to model the flows perturbations in the pipes. For a sampling period equal to one second, the discrete process equations are :

$$\left\{\begin{array}{c} H_1(k) = A^{-1}\left(q_1(k) + q_{31}(k) - q_{10}(k)\right) + H_1(k-1) \\ H_2(k) = A^{-1}\left(q_2(k) - q_{23}(k) - q_{20}(k)\right) + H_2(k-1) \\ H_3(k) = A^{-1}\left(q_{23}(k) - q_{31}(k)\right) + H_3(k-1) \\ q_{10}(k) = K_1\sqrt{H_1(k)} \\ q_{20}(k) = K_2\sqrt{H_2(k)} \\ q_{31}(k) = K_{31} f\left(H_3(k) - H_1(k)\right) \\ q_{23}(k) = K_{23} f\left(H_2(k) - H_3(k)\right) \end{array}\right. \tag{11}$$

where A equal to $0.01539\, m^2$, designates the tank section. The constants K_1, K_2, K_{31} and K_{23} respectively equal to $1.816\, e^{-4}$, $9.804\, e^{-5}$, $1.005\, e^{-4}$ and $7.804\, e^{-5}$ are the process characteristics. The term $f(.)$ designates a non linear function defined as follows :

$$f(x) \triangleq sign(x)\sqrt{|x|} \tag{12}$$

The measured process variables are the inputs z_1^b, z_2^b and

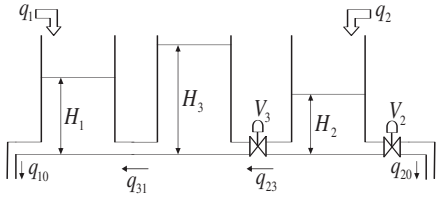

Fig. 2. Three tanks system

the outputs z_3^b, z_4^b and z_5^b. Theses measures are related in the instant k to the physical values via the following equations :

$$\left\{\begin{array}{l} z_1^b(k) = H_1(k) + \varepsilon_1(k) \\ z_2^b(k) = H_2(k) + \varepsilon_2(k) \\ z_3^b(k) = H_3(k) + \varepsilon_3(k) \\ z_4^b(k) = q_1(k) + \varepsilon_4(k) \\ z_5^b(k) = q_2(k) + \varepsilon_5(k) \end{array}\right. \tag{13}$$

The quantities $\varepsilon_r(k)$, $r \in \{1, \ldots, 5\}$ designate gaussian centered measurement noise. Its standard deviation is equal to 3% of that of the entries. The flows q_1 and q_2 are expressed in m^3/s. They are chosen to be random durations crenels with variable amplitudes respectively in $[3.20,\ 6.71] \times 10^{-5}$ for q_1 and in $[5.73,\ 9.57] \times 10^{-5}$ for q_2. The tanks initial heights are expressed in meter. Their values are 0.147, 0.276 and 0.195 respectively for the first, second and third tank. The system is firstly simulated under nominal operation during 4000 samples. After centering and reducing the inputs/outputs measures, the vector z is built at each instant k as follows :

$$z(k) = \left[\, z_1(k)\ z_2(k)\ z_3(k)\ z_4(k)\ z_5(k) \,\right]^t \tag{14}$$

where $z_r(k)$ designates the centered and reduced value of $z_r^b(k)$. The data matrix is constructed via (1). It will be used in the computation of the matrices Λ and P.

In the dynamical case, the vector z^d is constructed in an instant k for a time-lag s using time-lagged vectors z obtained in the static case as following :

$$z^d(k) = \left[\, z^t(k)\ z^t(k-1)\ \ldots\ z^t(k-s) \,\right] \tag{15}$$

The data matrix $Z_N^d(k,s)$ is built via (6). It will be used for the computation of the matrices Λ_d and P_d.

Figure 3 shows the process scree plot for a time-lag s respectively equal to zero, one and two. The eigenvalues of Σ (built for $s = 0$) are not null and do not indicate the presence of any linear or quasi linear relation between the measured process variables at the same instant. The last three eigenvalues of Σ_d built for $s = 1$ are quasi null and show the existance of three quasi linear relations verified by the measured process variables between two sampling instants. The correlation matrix Σ_d built for $s = 2$ shows six quasi null eigenvalues. They indicates the presence of six quasi linear relations verified by the measured process variables between three sampling instants. The approximation of the non linear relations verified by the measured process variables may be better if one uses time-lags higher than two but the computation complexity will increase as well.

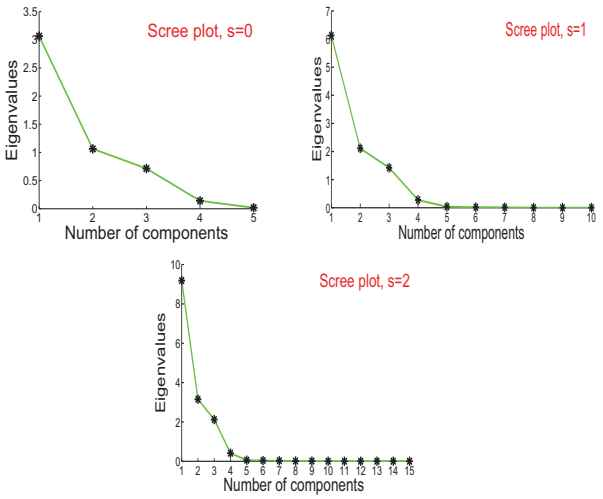

Fig. 3. Scree plots for $s = 0$, $s = 1$ and $s = 2$

Twenty measures representing a system fault are generated in order to fix the time-lag s used for the construction of $Z_N^d(k,s)$. This system fault represents a variation of 1.1 of K_2 from its nominal value. The application of the algorithm in section 5 gives that $s = 1$ and $\ell = 7$ are sufficient to detect such a fault.

A second simulation shown in figure 4 is realized during 4000 instants and perturbations in flows circulation are introduced by varying K_2 in the following way. For the first 1000 instants, K_2 is equal to its nominal value. In the second 1000 instants, K_2 is equal to 1.1× its nominal value. In the third 1000 instants, K_2 is equal to 1.2× its nominal value. For the latest 1000 instants, K_2 is equal to 1.3× its nominal value.

The evolution of the statistics D_i, $i \in \{i, \ldots, 4\}$, respectively for $s = 0$ and $s = 1$ in the case of the second simulation are shown in figure 5 and 6. On one hand, the flows perturbations are not detectable with the statical PCA model. The statistics D_i obtained from its application on

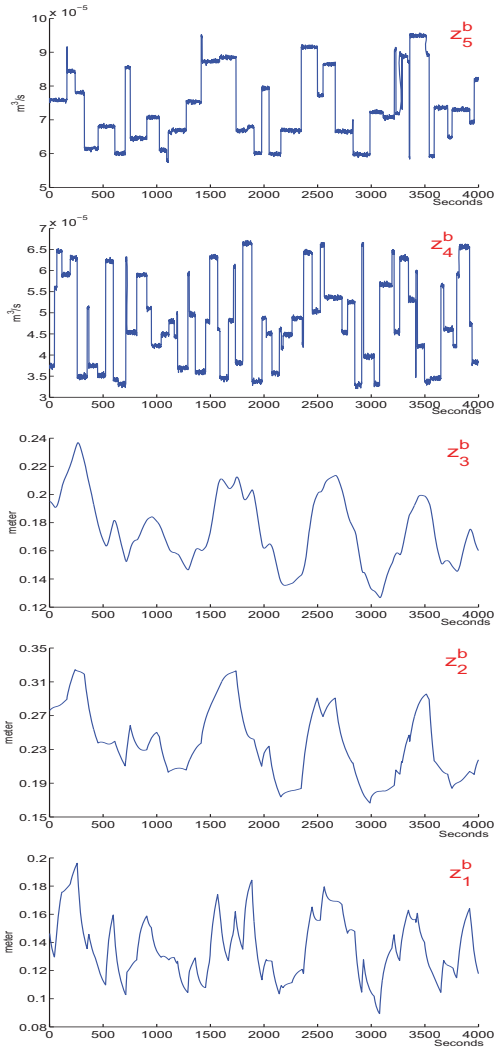

Fig. 4. Evolution of flows z_5^b, z_4^b and heights z_3^b, z_2^b and z_1^b in the second simulation

the current process data are always under their thresholds (figure 5) excepting some aberrant values. On the other hand, the flows perturbations are well detected with a DPCA built with $s = 1$. The statistics D_i, $i \in \{1, \ldots 3\}$, obtained from its application on the current process data allow the detection of all the system faults that were simulated. The maximal dimension of the residual space that can detect the perturbations is equal to three. The time-lag s used to construct the data matrix from which the DPCA model is built depending on the magnitude of the system fault to be detected. Increasing the value of s may lead to a better linear approximation of the real non linear relations existing between the time-lagged process measurements which can reduce the magnitude of the system fault to be detected.

7. CONCLUSION

The proposed method permits the estimation of the time-lag s and the choice of the principal component number ℓ used in the process modeling via DPCA. Contrary to the

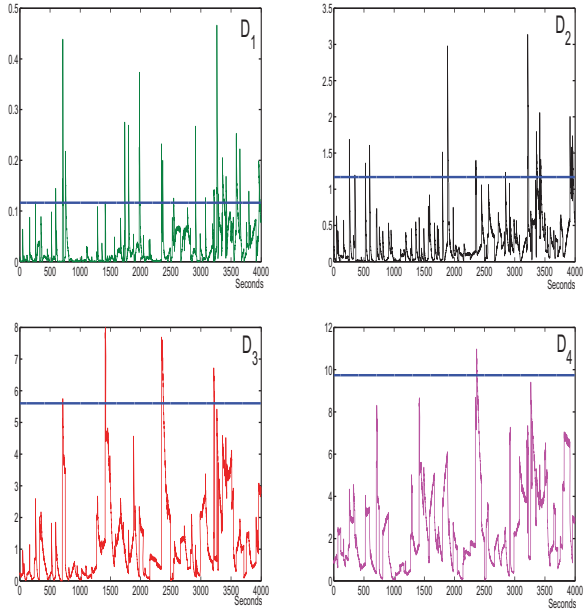

Fig. 5. Evolution of $D_i, i \in \{1, \ldots, 4\}$ in the case of $s = 0$

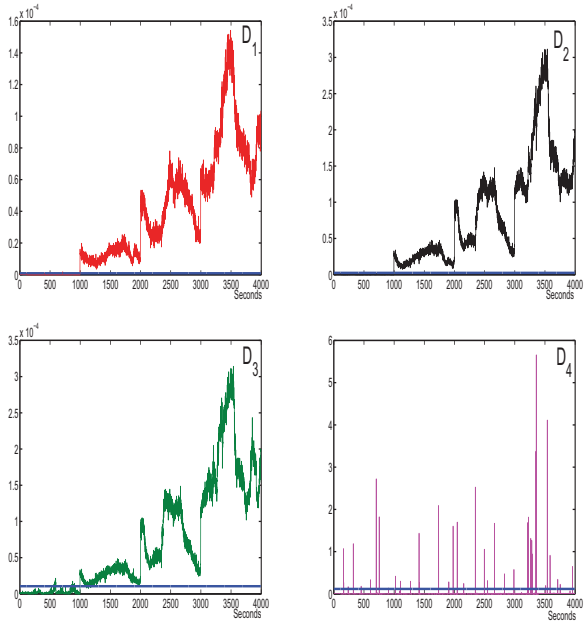

Fig. 6. Evolution of $D_i, i \in \{1, \ldots, 4\}$ in the case of $s = 1$

majority of the existing methods which use data gathered during nominal operation conditions to estimate s and ℓ, the proposed method uses data representing nominal process operating condition to build the data matrix which is used in the computation of DPCA model and other process data belonging to the system fault type to compute the structural parameters s and ℓ. The suggested method proves to be interesting if information relating to the system fault mode is a priori available. In this case, the method determines the least complex model allowing the detection of the considered system fault. Built around a

particular operating point, this method can be sensitive to operating point changes. In the abscence of a system fault, the obtained model presents a risk of generating false alarms due to a shift of the current process variables operating point. The extension of the method to multiple system fault cases and the minimization of the false alarms due to the operating point shift will be considered in forthcoming works.

Abstract: Since the number of loops in refineries or petrochemical plants is very large and the number of loops with poor performance is equally large, to prioritize their maintenance is essential to ensure plant profitability. This work proposes a methodology called *LoopRank* to compute the importance factor of each loop, aiming to prioritize their maintenance. The algorithm is based on the connection among them, which is computed using partial correlation. The algorithm is based on *PageRank*, which analyses connections among nodes recursively and computes a rank for each node using partial correlation. The *LoopRank* assigns an individual score for each loop ranging from 0% to 100%. Based on this score, the loop maintenance can be ranked. The *LoopRank* algorithm is computationally efficient, thus allowing its industrial large-scale application. The proposed algorithm was applied both on simulation and industrial case studies, providing fruitful results.

Keywords: Performance Monitoring, Data correlation, Loop Rank, Partial Correlation, Data-mining.

1. INTRODUCTION

Nowadays, it is a common knowledge the positive impact of control loop performance assessment tools over industrial plants. In the last twenty years, many methodologies and tools have been developed to diagnose the main loops problems:

- Poor performance (Harris, 1989, Huang *et al.*, 1997, Jelali, 2006);
- Plant-wide disturbances (Jiang *et al.*, 2007, Thornhill and Horch, 2007, Xia *et al.*, 2005);
- Valve hysteresis (Choudhury *et al.*, 2004, Hagglund, 2002, Hagglund, 2007, Rossi and Scali, 2005, Ruel, 2000);

It is also well known that most of industrial loops do not perform well (Paulonis and Cox, 2003). However, improve and maintain all loops in their optimal performance are impossible and economically infeasible because of the small number of engineers responsible to maintain a large number of loops. Therefore, a methodology to prioritize loop maintenance is required.

Methodologies to prioritize loop maintenance or to evaluate loop interaction are scarce in the literature. Tangirala et al. (2005) proposed a method based on spectral correlation between loops. Thornhill et al. (2002) proposed tools based on spectral principal component analysis.

The scope of this work is to provide an importance score for each control loop to prioritize its maintenance. Fig. 1 shows one simple case with four loops.

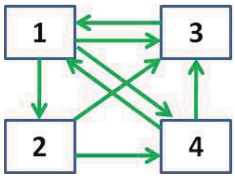

Fig. 1: Case study with four control loops interconnected.

In Fig. 1 scheme, it is easy to see that loop 3 has the most connections from others (3). So, is it the most important loop? On the other hand, loop 1 receives 2 connections, where one of them is very important, coming from loop 3, and it is the only loop 3 connection. Which is more important, loop 1 or 3? It is clear that an algorithm to systematize this procedure that provides an importance score for each loop is strongly required.

In this work is proposed an algorithm, called *LoopRank* that provides a grade based on loops connections. The loops that receive more connections from others, i.e. the loops that have stronger correlation with the remaining should have more importance than a loop that does not have any correlation with the others. To quantify these bounds, partial correlation is used. Subsequently, the priority of each loop is ranked using *PageRank* algorithm (Bryan and Leise, 2006).

The paper is segmented as follows: in section 2 the necessary background will be summarized. In section 3, the methodology to prioritize loop maintenance, proposed in this work is described. In section 4, the methodology is applied in simulation and industrial case studies. The paper ends with the concluding remarks.

2. BACKGROUND

This section provides the necessary background to understand the proposed methodology described in section 3.

2.1 Correlation and Partial Correlation

Correlation can be described as the linear dependence between two random variables (Bilodeau and Brenner, 1999). The correlation (ρ_{XY}) between two variables can be computed as follows:

$$\rho_{XY} = \frac{cov(X,Y)}{\sqrt{var(X)var(Y)}} \quad (1)$$

Where $cov(X,Y)$ is the covariance between X and Y and $var\,var$ is the variance. The correlation is a measurement of variable interaction, independently of the scale which it is measured.

In the case where the inputs and outputs are correlated, a better measure of the interaction is the partial correlation. It provides the degree of association of X and Y, with the effect of a set controlling variables (Z) removed. The partial correlation between X and Y with Z fixed ($\rho_{XY|Z}$) is computed by:

$$\rho_{XY|Z} = \frac{\rho_{XY} - \rho_{XZ}\rho_{YZ}}{\sqrt{(1-\rho_{XZ}^2)(1-\rho_{YZ}^2)}} \quad (2)$$

2.2 Importance score

To rank the relative importance of elements is essential when resources are limited. Rank algorithms have a broad class of applications including financial decisions, searching tools, among others. One rank algorithm that has been highlighted recently is *PageRank* (Bryan and Leise, 2006), which is used by the Google®'s search engine to rank pages relevance. It gives an importance score for each webpage according to an eigenvector of a weighted link matrix. It is based on the links made to a given page from other pages, and the relative impact of each source page.

The algorithm can be summarized as follows. Suppose n elements where the relative connectivity of them (x_k) should be computed, where k is the indexing element ($1 \leq k \leq n$), where this value corresponds to the arrows in each element. In the example (Fig. 1) x_1=2, x_2=1, x_3=3, x_4=2. Thus, loops can be ranked as follows 3, 1 and 4, and 2, based only on the connections. Following, the relative importance of k (x_k) is computed using the number of back links for this page. If page j contains n_j links to other pages, and one of them links to element k, then it will be boosted by a score x_j/n_j. Let $L_k \subset \{1,2,\dots,n\}$ denote the set of pages with link to page k. The relative weight for each k is computed by:

$$x_k = \sum_{j \in L_k} \frac{x_j}{n_j} \quad (3)$$

It is also assumed that the link from a page to itself has zero weight. For loop 1, its impact can be written as $x_1 = \frac{x_3}{1} + \frac{x_4}{2}$, since pages 3 and 4 have back-links to 1 and loops 3 and 4 have 1 and 2 links, respectively.

This linear relation can be written as $Ax = x$, where A is called "link matrix" and $x = [x_1 \;\; x_2 \;\; x_3 \;\; x_4]$. $A(i,j)$ provides the relative weight from loop j to loop i, where the rows show the relative weight of each connection that goes to a given loop and columns show the relative importance of the connections that come from the same loop.

In the scheme of Fig. 1, the A matrix can be written as:

$$A = \begin{bmatrix} 0 & 0 & 1 & \frac{1}{2} \\ \frac{1}{3} & 0 & 0 & 0 \\ \frac{1}{3} & \frac{1}{2} & 0 & \frac{1}{2} \\ \frac{1}{3} & \frac{1}{2} & 0 & 0 \end{bmatrix} \quad (4)$$

In the case of loop 1 (Fig 1): three arrows come out this loop. Then the relative importance added in each loop is $\frac{1}{3}$, as shown in the first column of A.

This procedure transforms the problem into a simple eigenvector problem ($Ax = \lambda x$). It can be proved that λ has always a unitary eigenvalue for this kind of matrices. Thus, the eigenvector x with eigenvalue 1 for matrix A is seek. The importance score (*IS*) for each page is given by the mentioned eigenvector just normalizing each elements by the sum of all components so that at the end the final sum is equal to 1. For the case study, the already normalized importance score are x_1=0.387, x_2=0.129, x_3=0.290, x_4=0.194.

More information about *PageRank* algorithm can be found in Bryan and Leise (2006).

3. METHODOLOGY DESCRIPTION

This section describes the *LoopRank* algorithm to evaluate loop importance.

Initially the loop output data is collected. Only routine data is required and no further information about the loop is required.

The first step is to compute the links between loops and its relative weight, where the impact of a single variable over each other should be computed. The measure of loops connectivity used in this work is the linear dependence among them.

Industrial loops generally have high correlation between them. To overcome this constraint and isolate the individual loop impact over each other, partial correlation is used. Simple correlation between loops has also been tested and results were poorer. This comparison will be shown in the case studies section. Thus, the relative weight between loops i

and j is provided by the partial correlation between these loops, removing the effect of the remaining loops ($\rho_{ij|LI}$), where $L = \{1,2,\dots,n\}$, $LA = \{i,j\}$, and $LI = L \cap LA$. Each element of the relative weight matrix (A_{ij}) is given by the partial correlation between loop i and loop $_j$ ($\rho_{ij|LI}$) :

$$A_{ij} = \rho_{ij|LI} \tag{5}$$

The next step is to evaluate *the LoopRank (LR)*, based on *relative weight matrix* (A), using *PageRank* algorithm that can quantify the relative importance of each loop, allowing to rank the loops for maintenance purposes. This class of algorithm was chosen because of its capacity to prioritize elements based on the connections among them and its computational/numerical efficiency. The *LoopRank* output is then normalized to limit each grade between 0 and 100%, where always the worst important loop has $LR = 0\%$ and the most important $LR = 100\%$.

Some loops can have more impact in plant profitability or help to smooth the operation. The loops that have connections with these "important ones" should have stronger weights. Thus, it is necessary to assign a *loop weight* (w_k), which is dependent on the source loop. The w_k is assigned heuristically, depending on loop type and its profitability. One heuristics is here suggested: flow and level loops are least important ($w=1$), pressure loops have middle importance ($w=1.5$) and temperature and composition are the highest importance ($w=2$). The *connection weight* k is then multiplied by all links where the source is loop k, in A.

The application of *LoopRank* algorithm can be summarized as follows:

1. Collect routine operating data of the loops;
2. Compute the partial correlation between each loop and build the *relative weight matrix (A)*;
3. Based on A, compute the *LoopRank*, using *PageRank* algorithm;
4. To the result in 3, multiply each loop by the corresponding loop weight (w);
5. Normalize the final results to express the result in relative percentage, where each importance is bounded between 0% and 100%.

4. CASE STUDIES

This section shows the application of *LoopRank* algorithm both on simulation and industrial case studies.

4.1 Simulation example I

In the first case study, a set of 10 loops will be analyzed. The first one has oscillatory behaviour. The other loops have been generated from the first loop by a simple addition of different noise levels followed by normalization in the amplitude. Fig. 2 shows the time trends for all loops.

Applying the proposed algorithm with $w = 1$ for all loops produces the results shown in Tab. 1. As it was already expected, the results of Tab. 1 clearly indicates that the source of oscillatory behaviour is related to the most important loop, which is in this case is the first one.

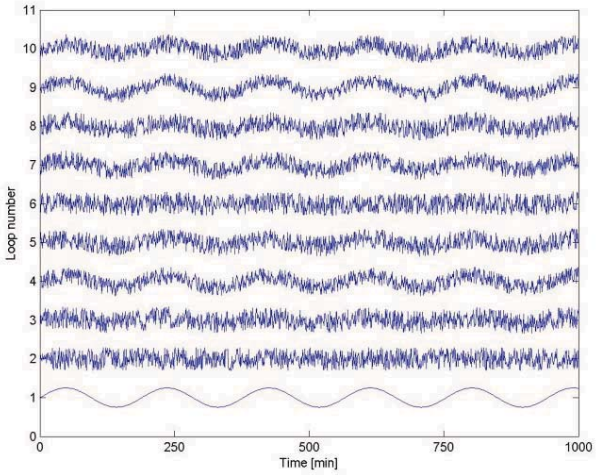

Fig. 2: Time trends of 10 data series.

Tab. 1: *LoopRanks* for case study 1.

k	LR_k	k	LR_k
1	100	**6**	16
2	3	**7**	10
3	1	**8**	20
4	21	**9**	11
5	13	**10**	0

Following, the impact of w_k will be analyzed. In this case study, w_5 will be increased and its impact over loop 4 (LR_4) and loop 8 (LR_8) are shown in Tab. 2. Since interaction between loop 5 and 1 is stronger than all remaining loop 5 connections, it is expected that increase the weight of loop 5, the LR of loop 1 will increase while the LR of all others will decrease, because the connections between loop 5 and all others will become weaker.

Tab. 2: Impact of w_5 in LR_4 and LR_8 *LoopRanks.*

w_5	LR_4	LR_8
1	21.0	20.0
1.5	20.0	18.6
2	19.3	17.3
5	16.1	12.3
10	13.7	8.3

The previous claim is corroborated by Tab. 2, where increasing w_5, the importance factors LR_4 and LR_8 decreased. LR_1 remains for all cases equal to 100%.

4.2 Simulation example II

In the second case study a set of 100 loops are be analyzed. The time trend for each loop is generated using the following procedure:

- Loop 1, loop 2, and loop 4 have oscillatory behaviour with different frequencies;
- Loop 3 and loop 5 data trends are obtained passing white-noise through a first order transfer function with different time constants;
- Loops 6, 7, and 8 are random signals;
- Other 92 data trends are generated by the linear combination of the first 8 data trends. Following, white noise is added in each one of the 92 data trends. Time trends 1, 2, and 3 impact all 92 loops using a random weight between 0.5 and 1.
- Time trends 4 to 8 impact some of 92 loops using a random weight between 0.5 and 1. The probability of each time trend to impact each loop is 50%.

Fig. 3 shows the 8 time trends for the source loops and Fig. 4 shows loops 9 to loop 18 time trends, generated using the previous loops.

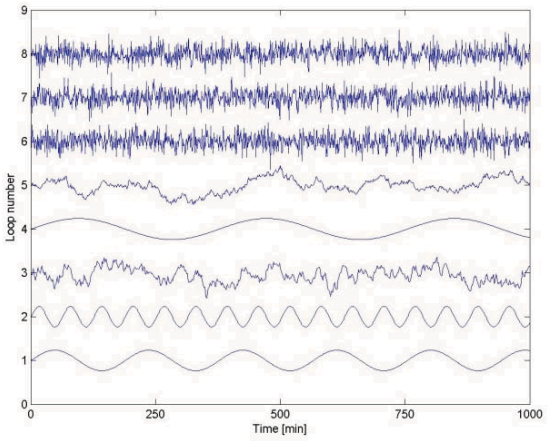

Fig. 3: Time trends for loops 1 to 8 in case study 2.

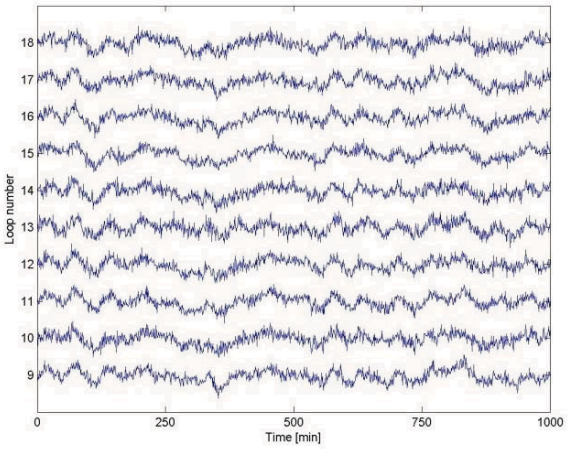

Fig. 4: Time trends for loops 9 to 18 in case study 2.

Applying the *LoopRank* algorithm, the following importance, shown in Fig. 5, is computed:

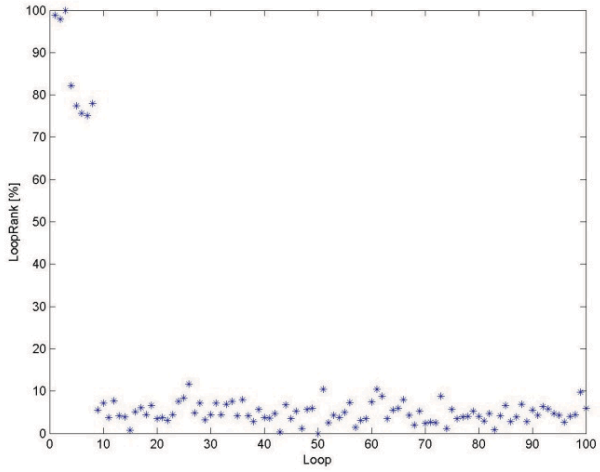

Fig. 5: *LoopRank* for case study 2, using 100 loops.

Fig. 5 reflects the expected result – loops 1, 2, and 3 have the highest importance, because of their impact in all loops. Loops 4 to 8 are less important than loops 1 to 3, but they are more important than the remaining. The remaining loops are less important, because the impact of a single one is not transferred to others.

One question can arise: If instead of partial correlation the correlation would be used, the results would be different? The comparison between *LoopRanks* using partial correlation and correlation is shown in Fig. 6.

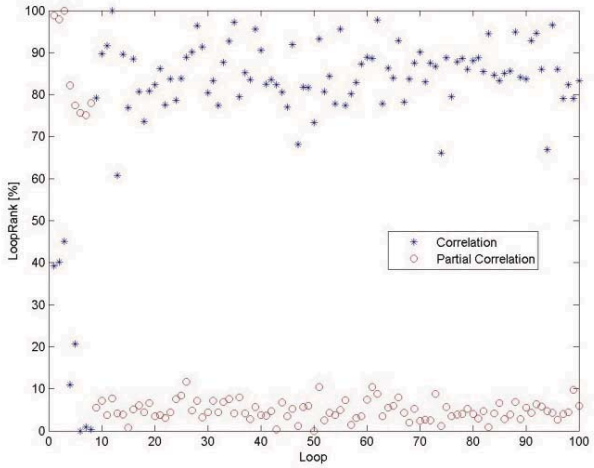

Fig. 6: *LoopRank* for case study 2, using both correlation and partial correlation.

Fig. 6 shows contrasting results, while correlation shows small importance of loops 1-8, partial correlation showed that these loops are the most important. Similar results have been seen in all tests, where correlation cannot point out the loops with major interaction among them, reason why partial correlation is used.

4.3 Industrial data

An industrial data set was provided by the courtesy of a Brazilian refinery. The system is an atmospheric distillation column of a petroleum refinery. The provided data set consists of 25 process variables: 6 level, 12 flow, 5 pressure, and 2 temperature controllers. The whole dataset has 1000 samples with a sampling time of 1 min. Fig. 7 shows the time trends of the variables.

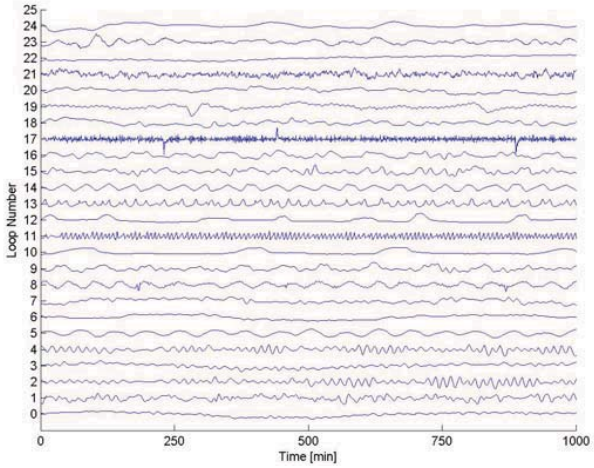

Fig. 7: *Time trends of industrial case study with 19 process variables.*

The *LoopRank* algorithm is then applied, providing the ranking shown in Fig. 8.

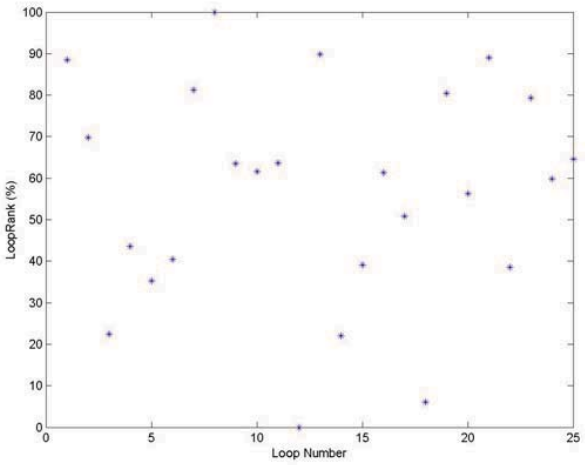

Fig. 8: *LoopRank* for industrial case study.

Fig. 8 clearly ranks the loop importance. It shows that loops 1, 8, 13, and 21 are the most important, because of its impact over the others. Loops 3, 12, 14, and 18 are the least important.

There previous results can be explained by the positions in the process flow diagram. The most important loop, in this case, is the flow of the intermediate recycle in the atmospheric tower (loop 8). The remaining most important loops are:

- Loop 1: crude oil inlet flow;
- Loop 13: Total reflux flow;
- Loop 21:Kerosene flow side-withdraw.

5. CONCLUSIONS

The main conclusions of the proposed work can be summarized as:

Loop ranking is an important tool for loop maintenance – Loop ranking for maintenance is required because of the large number of loops with poor performance in process plants. Unfortunately, the number of methodologies to evaluate loop impact is scarce. In this work a methodology for loop ranking aiming their maintenances, called *LoopRank*, is proposed.

It is better use partial correlation than correlation – *LoopRank* is based on loop interaction, measured by partial correlation. Correlation was also tested, however the results were poorer, therefore should not be used.

The proposed algorithm is similar to the Pagerank algorithm used by Google search engine – the relative importance score for each loop is computed using the *PageRank* algorithm. When the impact of a given loop should be emphasized, a loop weight can be assigned.

Successful applications of the LoopRank algorithm – the proposed algorithm was applied in 3 case studies, where reliable results were provided. One industrial case study was

presented to demonstrate the efficacy of the algorithm. The computational time for all case studies was negligible.

Operational Flexibility of Heat Exchanger Networks

M. Escobar and J.O. Trierweiler

Group of Intensification, Modelling, Simulation, Control and Optimization of Processes (GIMSCOP), Department of Chemical Engineering, Federal University of Rio Grande do Sul (UFRGS) Porto Alegre, Brazil (*e-mail: escobar@enq.ufrgs.br/ jorge@enq.ufrgs.br*)

Abstract Process integration is motivated from economic benefits, but it also impacts on the plant behavior introducing interactions and in many cases making the process more difficult to control and operate. A prerequisite for optimal operation is that the HEN is sufficiently flexible, i.e. it must have the ability to operate over a range of conditions while satisfying performance specifications. In this work it is defined the Operational Flexibility related not only to the size of the feasible region but also to the costs involved to put the HEN into operation. In order to provide an appropriated metric, the operational flexibility index is defined. Five different networks structures designed for the nominal conditions of a case study are used to illustrate the proposed ideas. It was noticed that a great feasible region does not point out the more economic operation, and the costs must be considered together with the flexibility analysis. These characteristics are taken into account by the novel proposed operational flexibility index, which can also consider during the analysis the increasing in the utility duties, extra utility exchangers and bypass installation. These results clearly point out for the need of a simultaneous framework for flexible design and profitability.

Keywords: Heat Exchanger Networks, Optimal Operation, Operational Flexibility.

1. INTRODUCTION

Operability issues are very important for heat integrated process, since the economic performance of a process is greatly affected by process variations and the ability of the system to satisfy its operational specifications under external disturbances or inherent modelling uncertainty.

Methods based on pinch analysis and mathematical programming for fixed operating conditions hve been largely developed. An extensive review of these methods can be found in Furman and Sahinidis (2002). Compared to design of HENs for nominal operating conditions, less effort has been dedicated to the operability and controllability aspects of such networks.

Since the concept of resilient HENs firstly developed by Marselle et al. (1982) and the introduction of the flexibility index by Swaney and Grossmann (1985) several design methods based on the multiperiod approach were proposed. Floudas and Grossmann (1986) introduced a multiperiod case based on the synthesis with decomposition. Papalexandri and Pistikopoulos (1994) and Konukman et al. (2002) extended the simultaneous synthesis to the multiperiod case in an MINLP problem.

All these works relates the flexibility with the size of the feasible region and they do not take into account explicitly all the trade-offs involved in a HEN design. In this work a new metric for comparing different HEN structures is proposed based on the concept of operational flexibility. A case study with 5 different synthesized HENs is used to illustrate the proposed metric.

2. OPERATION OF HENs

A HEN is considered optimal operated if the targets temperatures are satisfied at steady state (main objective); the utility cost is minimized (secondary goal); and the dynamic behaviour is satisfactory (Glemmestad, 1997).

During HEN operation, degrees of freedom or manipulated inputs are needed for control and optimization. The different possibilities are shown in Figure 1: 1-Utility Flowrates; 2-Bypass fraction; 3-Split fraction; 4-Process Streams flowrates; 5-Exchanger area (e.g. flooded condenser); 6-Recycle (e.g. if exchanger fouling is reduced by increased flowrates).

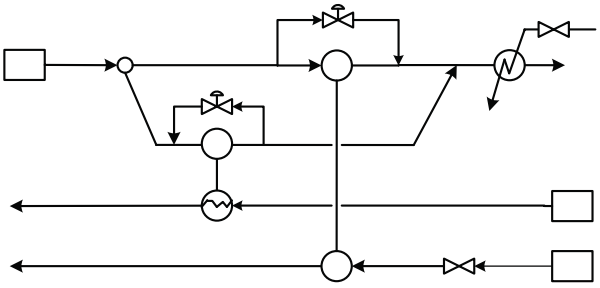

Fig. 1. Possible manipulated inputs in HENs.

In this work, we will consider the outlet target temperatures as controlled variables and utility loads, bypasses or splits, when they are present, as manipulated variables. The idea is to maintain the targets temperatures using the minimal

increase of the external utilities. The best HEN is the one where the effect of a given set of disturbances can be accommodated internally without requiring too much external "help" from the utilities heat exchangers. These ideas are illustrated through the case study of the next section.

3. CASE STUDY

To analyze the flexibility problem we have synthesized 5 different HENs for the plant illustrated in Figure 2.

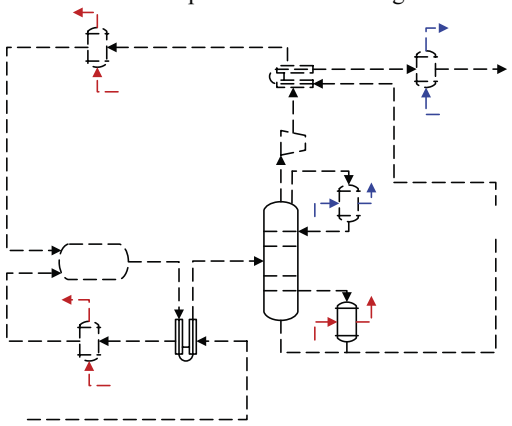

Fig. 2. Simple process with reaction, separation and heat exchangers.

Table 1. Nominal operating condition for the Case Study.

Stream	T_{in} (°C)	T_{out} (°C)	F (kW°C^{-1})	h (kW m^2 °C^{-1})
H1	270	160	18	1
H2	220	60	22	1

Cost of Heat Exchangers (y^{-1}) = 4000+500[Area (m^2)]$^{0.83}$
Cost of Cooling Utility = 20 (kW^{-1}y$^{-1})
Cost of Heating Utility = 200 (kW^{-1}y$^{-1})

Table 1 summarizes the corresponding data of the nominal operating conditions. This data and a ΔT_{min} of 10 °C were used to design the 5 different HENs depicted in Fig. 3. The five HENs have been designed by the following approaches:

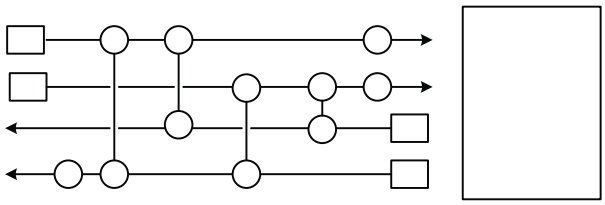
S01-Pinch Technology (Linnhoff & Hindmarsh, 1983);

S02-NLP Superstructure proposed by Floudas, Ciric, and Grossmann (1986) using Pinch Technology as initial guesses;

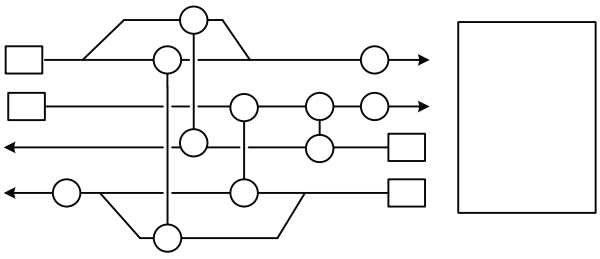
S03-NLP Superstructure in the Sequential procedure (Floudas, Ciric, and Grossmann, 1986);

S04-Hyperstrucutre proposed by Ciric and Floudas (1991); and

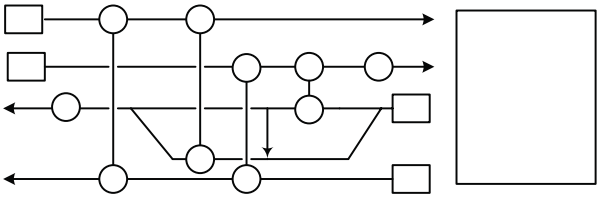
S05- the stage-wise Synheat model proposed by Yee and Grossmann (1990) with the assumption isothermal mixing.



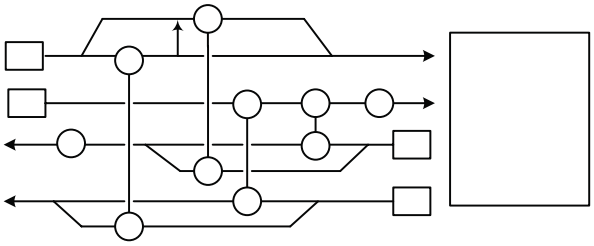
S01: Pinch Technology



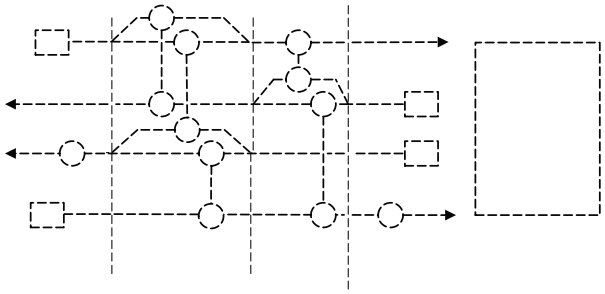
S02: NLP Superstructure (initial point by Pinch Technology)



S03: NLP Superstructure (Sequential Procedure)



S04: MINLP Hyperstrucuture (Simultaneous Procedure



S05: MINLP Synheat Model (Isothermal Mixing)

Fig. 3. Synthesized HENs for the Case Study using different approaches.

4. OPERATIONAL FLEXIBILITY

The flexibility is defined by Swaney and Grossmann (1985) as the size of the region of feasible operation in the space of possible deviations of the parameters from their nominal values. In order to analyze the flexibility, a disturbance scenario is explored on the basis of the vertices of the polyhedral region of uncertainty (Konukman et al., 2002) trough a scalar δ (flexibility target). For a fixed HEN topology and design the 'flexibility index' is defined by Swaney and Grossmann (1985) as the maximum scalar δ* (Figure 4).

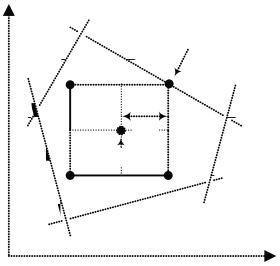


Fig. 4. Geometric representation of vertex-based flexibility target.

As the feasible region is convex when it is considered the inlet temperatures as uncertain parameters, the critical point that limits the operation lies at a vertex of the polyhedral region of uncertainty. For non-convex region the vertex-based formulation should be replaced by a more general active-constraint-strategy-based on MINLP formulation (Floudas, 1995).

Considering the four inlet temperatures as disturbances, a total of 16 vertices are enumerated. Each vertex represents an operating condition and it is formed by a deviation of ±δ from the nominal values In order to calculate the expected variations in the operating conditions that potentially could happen for a given flexibility target, each HEN configuration was implemented in Excel® using the heat exchanger model described by the set of equations (1), (2), and (3) and notation shown in Fig. 5.

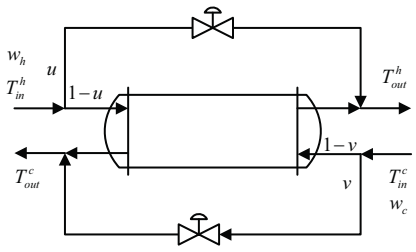

Fig. 5. General structure of a heat exchanger with bypasses.

$$T^h_{out} = (1-u)\left[\frac{(R_h-1)}{R_h-a}T^h_{in} + \frac{(1-a)}{R_h-a}T^c_{in}\right] + uT^h_{in} \quad (1)$$

$$T^c_{out} = (1-v)\left[\frac{R_h(1-a)}{R_h-a}T^h_{in} + \frac{a(R_h-1)}{R_h-a}T^c_{in}\right] + vT^c_{in} \quad (2)$$

Where

$$R_h = \frac{w_h(1-u)}{w_c(1-v)}; NTU_h = \frac{UA}{w_h(1-u)}; a = e^{NTU_h(1-R_h)} \quad (3)$$

The individual heat exchanger model was connected according to the topology for each HEN structure and the outlet temperatures deviations from their target values are calculated together with the additional utility requirement. A free simulation for fixed bypass and split fractions was carried out for each operating condition. Positive values encountered of heat duties at the stream where no utility exchanger exist mean that an extra utility exchanger must be included. Moreover, the negative values indicate an infeasible operation without any structural modifications, even for adding a new utility exchanger.

4.1 Optimal Operation of HENs

To overcome an infeasible operation it is possible to use the degrees of freedom, such as split fractions and bypasses placement in order to increase the feasible region and ensure that the optimal operation can be achieved by minimizing the utility consumption. The optimal steady-state operation or network optimization problem (Marselle et al., 1982):

Optimal Steady State Operation: *(For each operating point n)*

Minimum Utility Consumption ***(secondary objective)***

$$\min_{u,v} \sum_{i=1}^{NH} Q^{CU}_{i,n} + \sum_{j=1}^{NC} Q^{HU}_{j,n}$$

subject to.

Hot and Cold target temperatures ***(primary goal)***

$$T^{out}_{i,n} - T^{sp}_{i} = 0; T^{out}_{j,n} - T^{sp}_{j} = 0$$

Positives or zero heat loads coolers and heaters

$$T^{sp}_{i} - T^{out}_{i-1,n} \le 0; T^{out}_{j,n} - T^{sp}_{j} = 0$$

Hot and Cold Utility loads

$$Q^{HU}_{i,n} = w^{H}_{i}\left(T^{out}_{i-1,n} - T^{out}_{i,n}\right)$$

$$Q^{CU}_{j,n} = w^{C}_{j}\left(T^{out}_{j,n} - T^{out}_{j-1,n}\right)$$

Heat Exchanger Static Model (3), (4), and (5)

*Topology Constraints**

Bypass bounds

$$0 \le u, v \le 1$$

** The topology constraints define the configuration, and are expressed as appropriated model variables connections.*

The optimal optimization problem for each configuration was implemented using the software GAMS and solved using the solver CONOPT considering δ_T is equal to 10°C (flexibility target). The new requirements for the each HEN structure are exhibited in Table 2.

According to the initial analysis, the maximum or critical utility exchanger operation is not a good metric since it was not able to distinguish the configurations S01 and S02. Furthermore, comparing the configurations S03 and S04, even though the critical loads are greater for the first one the total heat load (summation for each operation point) and the averages are not.

Table 2. Utility loads (kW) for a feasible operation for each case study using extra utility units.

Struc.	Utility	Maximum	Average	Total
S01	cold	1000	446	7584
	hot	1300	646	10984
S02	cold	1000	445	7563
	hot	1300	645	10963
S03	cold	1300	570	9886
	hot	1480	769	13073
S04	cold	1287	586	9966
	hot	1466	782	13306
S05	cold	1000	497	8455
	hot	1480	696	11840

According to the results the configurations S03 and S04 are the worst from a flexibility point of view, since they require more utility to a feasible operation. On the other hand, S04 is the HEN with lowest TAC (3.619 x10^5 \$/year) as shown in Fig. 3, but considering the flexibility this is not the best option and clearly points out that flexibility issues must be considered in an early stage of the process design, since the nominal optimum .

4.2 Optimal Operation with no extra utility units

The solution provided in the previous analysis is trivial and may guarantee the operation for a large range. Furthermore, it is an expensive solution. Providing a more reasonable analysis, a second optimal operation problem was considered. The new problem definition differs from the previous one by the addition of constraints that ensure no extra utility exchangers. The general results are presented in Table 3.

Table 3. Utility loads (kW) for a feasible operation for each case study using no extra utility units.

Struc.	Utility	Maximum	Average	Total
S01	cold	1000	494	8425
	hot	1714	694	11825
S02	cold	1003	502	8534
	hot	1540	702	11934
S03*(8)	cold	1058	521	8851
	hot	1480	721	12251
S04*(14)	cold	902	499	8410
	hot	1480	699	11810
S05*(7)	cold	1000	530	9011
	hot	1587	730	12411

* (*ni*) indicate *ni* infeasible operating points.

Due to extra constraints, greater utility consumption in general was need. Moreover, how it was expected not always a feasible solution could be found. The main difficult faced by the configurations S03, S04 and S05 was the presence of only two utility exchangers, i.e. these configurations are more penalized with the additional constraints. The bad performance of the configuration S05 may be also explained possibly by the "inflexible" isothermal mixing constrain applied to the design.

A new analysis was made considering the possibility of variation for the extra degrees of freedom, when they take place. Whereas the configuration S01 has no one split fraction, the best possible results has already presented in Table 3. Conversely, all other configurations have split fractions. For the configurations S03 and S04 was also considered as an extra degree of freedom the recycle stream, from the outlet of a heat exchanger to another. The results are presented in Table 4.

Table 4. Utility loads (kW) for a feasible operation for each case study using no extra utility units but using extra degrees of freedom (split and recycle fractions).

Struc.	Utility	Maximum	Average	Total
S01	cold	1000	494	8425
	hot	1714	694	11825
S02	cold	900	435	7396
	hot	1430	635	10796
S03*(7)	cold	990	458	7780
	hot	1383	658	11180
S04*(8)	cold	780	417	7088
	hot	1368	641	10904
S05	cold	900	456	7745
	hot	1431	656	11145

* (*ni*) indicate *ni* infeasible operating points.

Like it was expected the extra degrees may be used to achieve the targets and decreases the utility consumption increasing the feasible region, which is proven by the increase of the number of feasible operating points. For the configuration S05, allowing the manipulation of the split fractions automatically removes the isothermal mixing assumption and hence increases considerably the flexibility.

Comparing the results, the configurations S03 and S04 must be discarded because they do not provide a suitable operation. The results are a sign of designs with splits are good from the flexibility viewpoint because these extra degrees of freedom can be used to decrease the investment cost during the design phase and be used to decrease the utility consumption during operation. In addition, the installed areas are utilized completely for all operating points, which not occurs using bypasses. In the overall design the dynamic behaviour must be analysed carefully once split fractions can give competitive effects.

4.3 Flexibility Range

All the previous analysis considered the flexibility target (δ_T) of 10°C, in order to analyze the flexibility range, the total utility consumption (δQ) levels corresponding to the critical operating conditions versus the flexibility targets (δ_T) for structures S01, S02 and S05 and the virtual structure (Maximum Energy Recovery) MER were calculated and they are shown in Figure 6.

The illustration reveals plateaus of total utility requirements levels for a given value of δ, under the correspondent δQ level the configuration is operable, i.e. it will not violate the temperatures specifications as long as the deviations in the

source streams temperatures along the vertex directions have magnitudes within $0 < \delta_T < \delta$.

The analysis reveals the trade-off between the flexibility target and the total utility load need to maintain a feasible operation pointing out that a more flexible is more expensive. For practical purposes, increasing the flexibility target trough penalization of total utility consumption is possible until a limit (δ*), which is reached when at least one bypass saturation occurs.

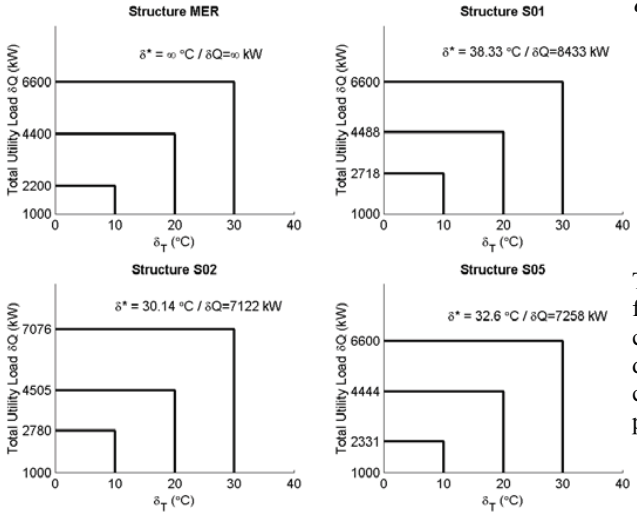

Fig. 6. Total utility consumptions at the critical operating conditions versus the flexibility ranges for structures MER, S01, S02 and S05.

In Table 4, the structure S02 (δ*=38.33^{0}C) depicted the lowest total utility load in general (considering all operating points) and the lowest average utility load. Therein, the critical loads define the feasibility operational range and it must be checked, but a selection of a structure using purely the analysis provided by the Figure 6 will not be appropriated because it would assume that most of the time the process would operate in the critical conditions what is not correct.

5. OPERATIONAL FLEXIBILITY INDEX

An appropriated metric to compare different HENs is based on the operational flexibility that is reached if the operation is possible and the maximum energy recovery is obtained for the entire feasible region with a minimum investment cost.

The structure of the HEN has a direct influence on the flexibility. Disintegrated structures are highly flexible, but that trivial solution is not interesting under an economic point of view. The other highly flexible possibility is a totally integrated structure, with the maximum number of units and maximum areas with bypasses across all units, but very expensive from an investment point of view.

Here we introduce the operational flexibility index to take into account in addition to the feasible range related with a flexibility target the most important costs involved during a "flexible operation". The Operational Flexibility Index for a specific flexibility target (OF_δ) is defined in equation (4), where the two terms correspond to operating cost (φ_{oc}) and the investment cost (φ_{ic}) penalties for an operational flexibility, and these terms are defined in equations (5) and (6). The operational flexibility index varies form 0 to 100%. Its upper bound indicates feasible operation without much economic penalty. On the other hand, when bypasses, new units, increased areas, and increased utility consumption are considered the indice will be penalized.

$$OF_\delta(\%) = 100(1 - \varphi_{oc} - \varphi_{ic}) \tag{4}$$

$$\varphi_{OC} = w_1 \frac{1}{2(V+1)} \sum_{n=1}^{V} \frac{\sum_{k=1}^{NH+NC} \delta q_{k,n}^{U} - \sum_{k=1}^{NH+NC} \delta q_{k,n}^{U,\min}}{\sum_{k=1}^{NH+NC} \delta q_{k,n}^{U,\max} - \sum_{k=1}^{NH+NC} \delta q_{k,n}^{U,\min}} \tag{5}$$

$$\varphi_{IC} = w_2 \frac{N_{bp}}{N_{hx,retrofit}} + w_3 \left(1 - \frac{N_{hx}}{N_{hx,retrofit}}\right) + w_4 \left(N_{hx} - \sum_{m=1}^{N_{hx}} \frac{A_{m,installed}}{A_{m,retrofit}}\right) \tag{6}$$

The parameters w_i (7) correspond to the normalized weight for each contribution to the penalty. A suggested set may be calculated by the constants k_i (8) that depends on economic data from the process, i.e. the utility costs and the exchanger costs, considering the bypass cost. For the case study these parameters are provided in Table 1.

$$w_i = \frac{k_i}{\sum_{i=1}^{4} k_i} \tag{7}$$

$$k_1 = \frac{cu.}{2(V+1)} \left(\sum_{k=1}^{NH+NC} \delta q_{k,n}^{U,\max} - \sum_{k=1}^{NH+NC} \delta q_{k,n}^{U,\min} \right)$$
$$k_2 = 0.2aN_{hx,ret}; k_3 = aN_{hx,ret}; k_4 = b\sum_{m=1}^{N_{hx}} A_{m,ret}^{\beta} \tag{8}$$

The parameters N_{bp}, N_{hx} and A_m correspond to the number of bypasses placed, the number of heat exchangers and the area of the heat exchanger m, respectively. Moreover, the subscript 'retrofit' indicates the variable in the flexible operation, i.e. the retrofitted design.

To evaluate the potential of each structure, the operational flexibility index was calculated. The calculation requires the bounds for the utility loads. It was used the LP transshipment model (Papoulias and Grossmann, 1983) for each operating point to estimate the minimum utility consumption for the design case (ΔT_{min}=10^{0}C) and the minimum case (ΔT_{min}=0^{0}C). Furthermore, it was calculated the utility loads for the no heat integration case; all the targets are exhibited in Table 5.

Table 5. Utility loads (kW) for a feasible operation for each case study using no extra utility units.

Case	*Utility*	*Max.*	*Average*	*Total*
MER	*cold*	900	412	7000
ΔT_{min}=10^{0}C	*hot*	1300	612	10400
MER	*cold*	900	219	3720
ΔT_{min}=0^{0}C	*hot*	1080	360	6120
No Heat	*cold*	5900	5500	93500
Integration	*hot*	6400	5700	96900

The main results are expressed in Table 6. The term corresponding to the energy cost is dominant due to its greater economic impact in the total cost; the investment cost is worthless for most cases. The structure S02 showed the best performance for the required flexibility target. The interpretation inside the context of a feasible operation is that a greater index indicates that operation occurs inside a more economic way, using a lower average utility consumption with the lower investment cost. Otherwise different conditions will penalize the operational flexibility.

Table 6. Operational Flexibility Index for the structures S01, S02 and S05.

	S01	*S02*	*S05*
φ_{oc}	0.0605691	0.0498255	0.0536638
φ_{ic}	0.00203939	0.00271918	0.00000000
$OF_{\delta=10}$	93.73916%	94.74553%	94.63362%

5.1 Flexibility x Installed Area

All the previous analysis was carried out using the areas as fixed parameters, and these areas were designed at nominal conditions. If it was considered the whole feasible region, trough a multi-period design these areas would have better usage in order to reduce the utility consumption in the entire region. A new optimization problem was performed for the structure S01, considering varying areas. In order to avoid extreme solutions, a practical consideration for the areas bounded between 1 and 1000 m^2 were imposed and new optimizations were performed. The areas for each operating point are presented in Table 7. In order to satisfy all operating points, the maximum areas obtained in Table 7 where fixed and the optimal operation problem was solved with the increased areas.

Table 7. Nominal and maximum areas (m^2) for the HEN structure S01.

	$A_{H1,C1}$	$A_{H1,C2}$	$A_{H2,C1}$	$A_{H2,C2}$
Nominal	318.12	56.55	609.97	209.79
Maximum	1000.00	97.46	1000.00	1000.00

Comparing the values obtained with the results presented in Table 4 for the structure S01, the total utility loads decreased from 8425.3kW to 4370.9 kW (cold utility) and 11825.3 kW to 7770.9 kW (hot utility); and the average consumption decreased from 494kW to 257kW(cold utility) and 694kW to 457kW (hot utility). The flexibility index (δ*) provided in the Figure 6 increased from 38.33^{0}C to 49.8^{0}C, i.e. the feasible region increased. Furthermore, the operational flexibility index (OF_δ) exhibited in Table 6 increased from 93.73916% to 98.197858% considering only the energy cost and considering the capital cost for the oversize of the areas the index is 97.02954%.

6. CONCLUSIONS

The flexibility analysis of different structures previously designed was accomplished through optimal operation problem taking into account the trade-offs between energy cost, capital cost and the flexibility in order to ensure an economic operation. The formulation presumed that the feasible region in the space of uncertain input parameters was convex, and thus the optimal solution was explored based on the vertices of the polyhedral uncertainty region in the space of source-stream temperatures. It was defined the operational flexibility index as a measure of operational flexibility that was assumed to be different of structural flexibility. The first one considers the impacts on the total annual cost, since infinity areas, high levels of utility loads and disintegrated structures are according with this work highly structural flexible but present a poor (expensive) operation and hence a low operational flexibility.

The HEN structure provides an upper bound for the flexibility that should be expected during operation. The increasing of flexibility target reveals the flexibility dependent on structural modifications and total utility consumption until the unfeasible operation may be achieved. It was showed that more important that the size of the feasible region it is the cost involved in a feasible operation around the desired flexibility target. It has shown the real need of taking into account the flexibility in a simultaneous framework, once the utility loads, heat exchangers (units and areas), and the arrange (configuration of flows, temperatures) are determined in only one step, and all these variables strongly affect the flexibility.

GPC Controller Performance Monitoring and Diagnosis Applied to a Diesel Hydrotreating Reactor

A. C. Carelli* M. B. da Souza Jr.**

*Chemical Engineering Department, Federal University of Rio de Janeiro, Rio de Janeiro Brazil (e-mails: *alain.carelli@gpi.ufrj.br, **mbsj@eq.ufrj.br)*

Abstract: Control systems tend to lose performance over time if their responses are not monitored and thus there is no support information on to how to make adjustments on them. Reliable controllers have complementary systems to identify and diagnose reductions in performance and also to implement predetermined solutions vis-à-vis the desirable type of output. The goal of this work was to analyze controller performance monitoring and causes diagnosis methods based in two indexes: historical benchmark and model based performance measurement. These methods were applied to situations of degraded performance simulated in the predictive control of a hydrotreating reactor, aiming the identification of the reduction in the controller performance and the discrimination of its causes. The obtained results can also be extended to several other chemical processes, once that the investigated process presents first order with dead-time dynamics, typical of these processes.

Keywords: 1. Process control. 2. Performance reduction detection and diagnosis. 3. Control audit. 4. Refinery.

1. INTRODUCTION

In recent years, the performance requirements for process plants have become increasingly difficult to satisfy. Stronger competition, tougher environmental and safety regulations, and changing economic conditions have been key factors in tightening product quality specifications. A further complication is that modern plants have become more difficult to operate because of their complex and highly integrated processes. The largest emphasis recently given to safety has naturally improved the importance of the process control area. Without process control systems integrated with computers, it would be impossible to operate modern plants safely and lucratively while achieving product quality and environmental requirements. Therefore, it becomes important for chemical engineers to have an understanding both of the theory and of the process control practice. (Seborg, Edgar and Mellichamp, 2004).

Controller performance assessment and monitoring are necessary in order to assure the process control effectiveness and profit of the plant. The initial design of control systems includes many uncertainties caused by approximations in process model, estimations of disturbance dynamics and magnitudes, and assumptions about operating conditions. Many factors can cause their abrupt or gradual performance deterioration overtime. Around 60% of all industrial controllers have some kind of performance problem (Schäfer and Cinar, 2004).

All controllers need to be retuned as the dynamic of the process suffer natural or continuous alterations. The controllers performance should be monitored, because, even though they may have been adequately adjusted, it is expected that their performance decays along years due to variations in the materials, deterioration of the instrumentation, changes in the plant, etc. This reduction in the performance should also be diagnosed, enabling the identification of the needs to readjust the controller tuning parameters.

The main benefit of applying advanced control strategy to catalytic processes in refineries can be related to quality giveaway. For hydrotreating units, quality giveaway is mainly obtained by reducing over-desulphurization. Experimental results showed clearly that the sulfur content of the product is strongly related to the severity of the reaction, which is determined by reactor bed temperatures and the residence time. Operating at higher temperatures yields better product quality, but at the same time shortens the catalyst cycle. Therefore, the better the reaction control is (so as to guarantee only the necessary conversion), the better the utilization of the catalyst cycle and the lower the operational cost of the process (Lababidi, Alatiqi and Ali, 2004). Additionally, in case of accident, the replacement of a reactor and the reconstruction of other damaged equipments can take up to 12 months and the cost of lost production can exceed US$ 50 millions (Ancheyta and Speight, 2007).

2. CONCEPTUAL ASPECTS

This work is structured under three main themes: dynamic process control, process control performance assessment and diesel hydrotreating.

2.1 Model Predictive Control – Generalized Predictive Control

The general set of the available Generalized Predictive Control (GPC) algorithms cover a large variety of control goals in contrast to other methods, so that some of them can even be considered GPC specific cases.

In the SISO case (single-input *u*, single output *y*), a linearized time-invariant discrete process is assumed, where the relations between input and output are described by the following equation:

$$A(q^{-1})y(t) = q^{-d}B(q^{-1})u(t-1) \quad (1)$$

A and *B* are polynomials in the backward shift operator q^{-1} with, respectively, degrees *m* and *n*, and *d* is the dead-time.

With the premise that all process natural disturbances can be characterized by a stochastic disturbance, the principle of the superposition can be used to represent all disturbances as a unique influence in the output. Then, the process can be described by the following CARIMA (controlled auto-regressive and integrated moving average) model:

$$A(q^{-1})y(t) = q^{-d}B(q^{-1})u(t-1) + C(q^{-1})e(t)/\Delta \quad (2)$$

where *C* is also a polynomial in the backward shift operator q^{-1}, *e(t)* is an uncorrelated random sequence and $\Delta(q^{-1})$ is the differencing operator $1 - q^{-1}$.

The CARIMA model may be considered the most appropriated model for many industrial applications with non-stationary disturbances. In practice, it has two main types of disturbance: occurrence of random steps in random intervals (e.g. changing of the product quality) and Brownian motion which is met in plants that depend on the energy balance (Clarke, 1988).

The following Diophantine Equation is employed for the development of the solution:

$$C(q^{-1}) = E(q^{-1})A(q^{-1})\Delta + q^{-d} * F(q^{-1}) \quad (3)$$

where, *E* and *F* are polynomials in the backward shift operator q^{-1} with degrees *d-1* and *m*, respectively.

Multiplying the term $E(q^{-1})\Delta q^{j}$ in the components of (2); considering $C(q^{-1}) = 1$ (alternatively *C* is truncated and absorbed inside the polynomials *A* and *B*); and, assuming the future error values equal to zero, because they do not depend on the past values of *y(t)* and *u(t)*, the following equation is obtained:

$$y(t+j) = G(q^{-1})\Delta u(t+j-d-1) + F(q^{-1})y(t) \quad (4)$$

where, $G(q^{-1}) = E(q^{-1})B(q^{-1})$.

In the GPC, the predictions *y(t+j)* are estimated in order to compare them with a reference trajectory, and to calculate the optimum control actions. The system outputs will be influenced by signals in *u(t)* after of the sampling periods *d+1*, due to the system dead-time of *d* sampling periods.

The following cost function is assumed:

$$J = (Gu + f - w)^T (Gu + f - w) + \lambda u^T u \quad (5)$$

where, *w* is the reference trajectory or *set-point* and λ is a weighting sequence.

Assuming that there are no constraints in the control signals, the minimum of *J* can be met by equating the *J* gradient to zero. Therefore, the following result is used in order to obtain the future control actions:

$$\Delta u = \left(G^T G + \lambda I\right)^{-1} G^T (w - f) \quad (6)$$

2.2 Predictive Control Performance Monitoring and Diagnosing

In order to perform performance reduction diagnosis of the controller, its performance shall initially be monitored preferable on-line. There is a set of techniques conceived for this purpose, named controller performance monitoring (CPM) techniques.

The objective of the CPM is to develop and implement technologies that provide information of the plant to determine if the appropriated performance and the characteristics of behavior are being reached through the controlled variables. For the case SISO, the normalized performance index is an elegant method, which compares the theoretic absolute lower limit in the output variability with the achieved values. This index could configure itself as a benchmark appropriated to measure the performance of a feedback control system (Cinar, Palazoglu and Kayihan, 2007).

Nevertheless, mostly for multivariable MPC controllers, other CPMs methods have been studied based in the calculation of the cost function, which in most cases is the objective function minimized to determine the MPC's strategy. Cinar, Palazoglu and Kayihan (2007) introduced two methods based on monitoring of the cost function values for the controller performance reduction diagnosis, called of historical benchmark and model-based performance measurement.

The cost function J_{ach} is obtained with plant real values that can be described in the following form:

$$J_{ach} = \frac{1}{Pc}\left\{\sum_{j=1}^{Pc}\left[e^T(k+j-Pc)Qe(k+j-Pc) + \Delta u^T(k+j-Pc)R\Delta u(k+j-Pc)\right]\right\} \quad (7)$$

Where, *Pc* is the moving horizon of past data; *e(k)* is the vector of control errors at time *k* (difference between the controlled variable and the reference trajectory); Δu is the change in manipulated variables at time *k*; and, *Q* and *R* are weighting matrices representing the relative importance of each controlled and manipulated variable.

The historical benchmark requires a priori knowledge of good performance during a certain time period according to some expert assessment. The cost function applied in historical benchmark has the same form of (7), where the input and output data are taken from that period. So, the value

achieved through this function is constant until a better performance is reached (Schäfer and Cinar, 2004).

The historical benchmark index is described by the following expression, which supports the control performance reduction or increase detection:

$$\gamma_{his}(t) = J_{his} / J_{ach}(t) \quad (8)$$

The model-based performance measure index compares the achieved performance with the performance in the design case that is characterized by inputs and outputs given by the model (Schäfer and Cinar, 2004).

The model-based performance measure index is described by the following expression:

$$\gamma_{des}(t) = J_{des}(t) / J_{ach}(t) \quad (9)$$

Both cost functions used in the calculation of the model-based performance measure index have the same form of (7).

Monitoring the model-based performance measure is useful in diagnosing causes that affect the design case controller. Two groups of causes may be devised. For instance, increases in unmeasured disturbances, actuator faults, or increase in the model mismatch do not influence the design case performance (group II causes). Accordingly, J_{des} remains constant while J_{ach} increases, reducing the model-based performance measure. Root cause problems such as input saturation or increase in measured disturbance, on the other hand, affect the design case performance as well (group I causes). This lead to an approximately constant value of the model-based performance measure, if the effect is quantitatively equal (Cinar, Palazoglu and Kayihan, 2007).

This diagnostic sequence assumes that only one source cause occurs. If γ_{des} doesn't change significantly, while the model performance and achieved performance decrease quantitatively equal, the diagnosis of the root cause is in the group I. If γ_{des} presents a considerable decrease, the diagnosis of the root cause is in the group II. In the case that multiple causes can occur simultaneously, the diagnosis logic becomes more complex.

Subgroups are defined to further distinguish between the root cause problems in group I. All changes in the controller (e.g. tuning parameters, estimator, constraints) are assumed to be performed manually. These changes are known and their effects can be monitored. However, the action taken is known and the root cause of the effect does not need to be identified by diagnosis tools (subgroup Ia causes). The remaining two root cause problems (change in measured disturbances and input saturation) belong to subgroup Ib. Additional information is needed to distinguish between the two root cause problems in subgroup Ib. Looking at the manipulated variables, input saturation can be determined by visual inspection. A saturation effect in a manipulated variable indicates input saturation as underlying root cause and rules out the increase in measured disturbances (Cinar, Palazoglu and Kayihan, 2007).

2.3 Diesel Hydrotreating

The hydrotrating unit considered in this work is the Trickle Bed Reactor (TBR) with two reactors in series, each reactor formed by two fixed bed, as showed in Figure 1.

The oil feed is combined with makeup hydrogen and recycle hydrogen and heated to the reactor inlet temperature. Heat is provided from heat exchange with the reactor effluent and by a furnace. The reaction of hydrogen and oil occurs in the reactors in the presence of the catalyst. To prevent reactor temperatures from getting too high, quench gas (cold recycled hydrogen gas) is added between reactors and between catalyst beds of multiple-bed reactors to maintain reactor temperatures in the desired range.

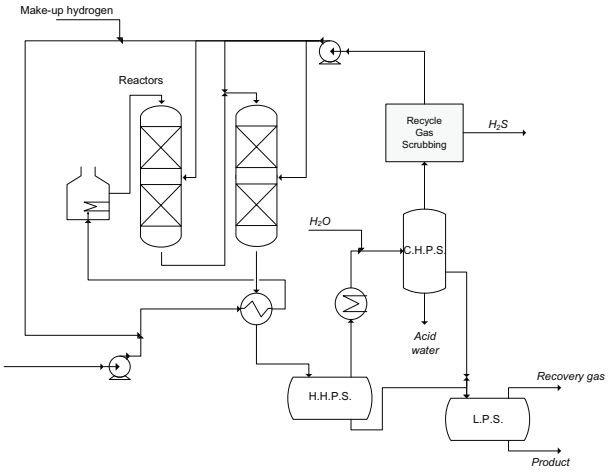

Figure 1 – Diesel hydrotreating process

The second reactor effluent is cooled (by exchange with the reactor feed) to recover the heat released from the hydrotreating reactions. After cooling, the reactor effluent is flashed in the hot, high-pressure separator (HHPS) to recover hydrogen and to make a rough split between light and heavy reaction products. The liquid from HHPS has its pressure lowered, than it is sent to the low-pressure separators, and on to the product fractionator. The HHPS vapor is cooled and water is injected to absorb hydrogen sulfide and ammonia produced in the reactors by the hydrotreating reactors. The mixture is further cooled to condense the product naphtha and gas oil and is flashed in the cold, high-pressure separator (CHPS). The CHPS separates the vapor, liquid water, and the liquid light hydrocarbons. The pressure of the hydrocarbon liquid is lowered and it is sent to the low-pressure separators. The water is sent to a sour water recovery unit for removal of the hydrogen sulfide and ammonia. The hydrogen-rich gas from the CHPS flows to the H_2S absorber. The purified gas flows to the recycle compressor where it is increased in pressure so that it can be used as quench gas and recombined with the feed oil. Liquid from the low-pressure separators is fed to the atmospheric fractionator, which splits the hydroprocessed oil from the reactors into the desired final products.

The model adopted in this work to represent the HDT's process was the model presented by Carneiro (1992) which applies the concept proposed by Hlavácek (1982) in representing fixed beds through the CSTR-CELL model. The CSTR-CELL in series describes the adiabatic fixed bed reactors dynamic. In Figure 2, a scheme of this model is shown.

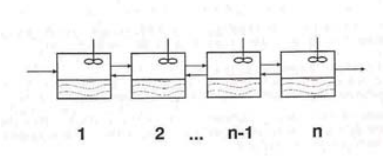

Figure 2 – CSTR-CELL reactor model

The CSTR-CELL reactor model considers mass and heat axial dispersion in the bed, mass diffusion and heat transportation between fluid and solid phases, as illustrated in Figure 3. The following assumptions are adopted in the CSTR-CELL: only one first order reaction – with respect to the mean concentration of a pseudo-reagent "A" in the solid phase porous – occurs and the reaction rate can be described by the Arrhenius equation; there is no volume variation in the reactor; the reactors are adiabatic; there is only one liquid and one solid phase with constant physical-chemical properties; there is only longitudinal transport phenomena; and, there are non-linear interactions between kinetic and thermal processes.

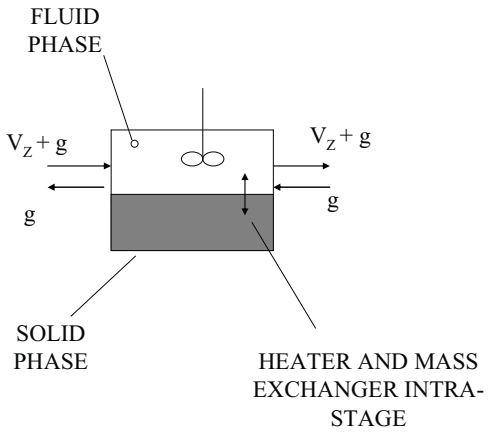

Figure 3 – CSTR-CELL stages

The Carneiro (1992) model was employed in this work for being at the same time able to represent the main process dynamics and simple, as it is composed by ordinary differential equations.

4. METHODOLOGY

This paper focus on the primary controller of the cascade control system applied to the first bed of the first reactor of the HDT unit, which can be seen in the top left hand corner of the diagram shown in Figure 4. This controller controls the bed outlet temperature through the manipulation of the set-point that is sent to the secondary controller. The secondary controller controls the inlet temperature of the bed through the manipulation of the fuel flow that enters the furnace.

The primary controller was performed by the GPC algorithm, using no explicit constraints and weighting in the cost function. The tuning parameters were the prediction horizon (N), the control horizon (NU) and the reference trajectory parameter (α).

The GPC was projected with a first order internal model with dead-time. The function considered for reference trajectory was a first order equation, which has only one tuning parameter: α. The larger α, the more cautious the control actions. If α is zero, the trajectory is constant and equal to the set-point, as can be noticed in the equation to follow:

$$w(t+1) = \alpha\, y(t) + (1-\alpha)SP \qquad (10)$$

As a default option, α was chosen in this study as equal to 0.7.

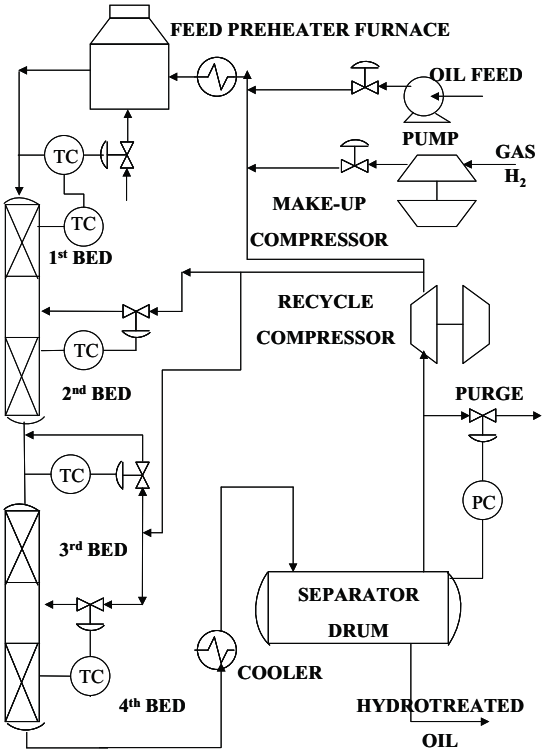

Figure 4 – Diesel Hydrotreating Unit Diagram (De Souza Jr., Campos and Tunala, 2009)

In respect to the assumed performance reduction scenarios, four cause diagnosis cases were tested based in the method presented previously: increased controlled variable variability (group II causes), mismatch between the model and the phenomenological model based simulator (group II causes), saturation of manipulated variable (group Ib causes) and change of the control tuning parameters (group Ia causes).

5. RESULTS

The events responsible for the reductions in performance were introduced in the 80th sampling time, as can be observed in the following figures. Figures 5, 6, 7 and 8 present, respectively, the following situations: increase in the controlled variable variability, mismatch between the internal model of the controller and the phenomenological model based simulator, saturation of the manipulated variable and change of the control tuning parameter. In all figures, the first graph presents the cost functions calculated to obtain the historical benchmark and model-based performance measure indexes. The second graph presents the historical benchmark index (monitoring index), and the third graph presents the model-based performance measure index (diagnosis index).

With the controlled variable variability increased in 5 times (in the phenomenological simulator), the achieved cost function was increased, while the others remained at the same level, as shown in Figure 5. In consequence, both the monitoring and diagnosis indexes had their values reduced. So, these behaviors agree with the expected for causes belonging to the group II which is the case for increases in unmeasured disturbances.

Figure 6 represents the change of CARIMA model parameters – *a* and *b* of (2) – which were multiplied by 20, causing an increase of the achieved cost function. The cost function applied to the model remained at the same level, because the internal model of the controller was affected in the same way.

As the mismatch between the internal model of the controller and the phenomenological simulator belongs to the causes of group II, the monitoring and diagnosis indexes decrease as can be seen in Figure 6.

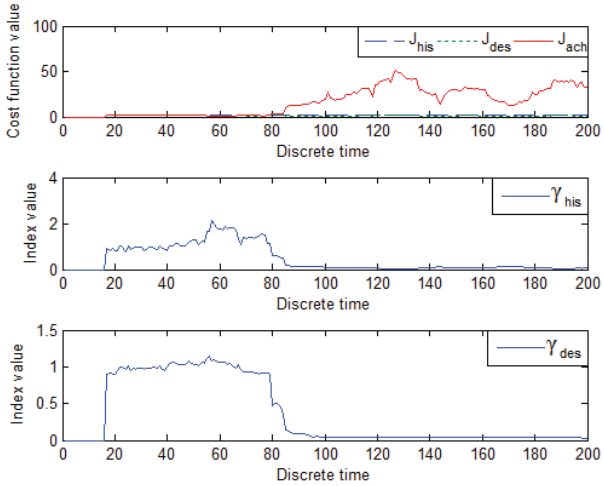

Figure 5 – Control performance reduction diagnosis caused by the controlled variable variability increase

When a constraint in the manipulated variable was applied to limit its lower value to 236.1ºC, the achieved cost function and the based-model cost function showed an increase which resulted in the decrease of the monitoring index and in the maintenance of the diagnosis index (see Figure 7). The observed behavior agrees with the causes belonging to group I, as was expected. Among the causes of group I, this particular cause can be diagnosed by monitoring the control actions, such as presented in the Figure 8, where from the 80th sampling time ahead the manipulated variable did not decrease beyond the value -0.2.

Figure 9 represents the control tuning change situation, where the prediction horizon varied from 4 to 50. In this situation, it can be observed that the indexes presented a similar behavior to the previous situation, due to the fact that this kind of cause also belongs to group I, where the same change affects the internal model and the model of the phenomenological simulator. This cause would not need to be diagnosed, because the modification in the tuning parameters of the controller – and, therefore, the reason of the performance reduction – would be previously known.

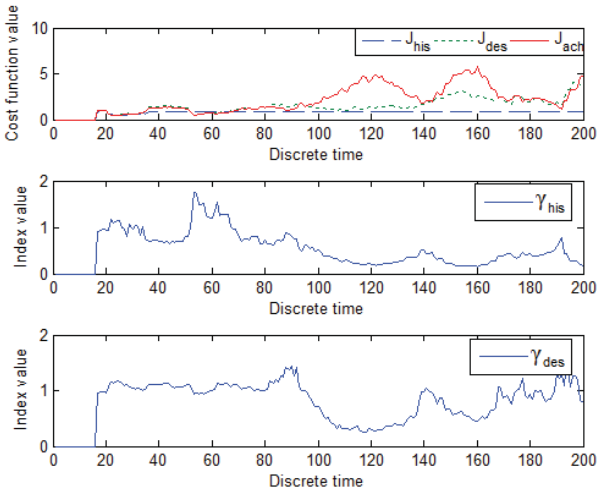

Figure 6 – Control performance reduction diagnosis caused by the mismatch between the model and the phenomenological model based simulator

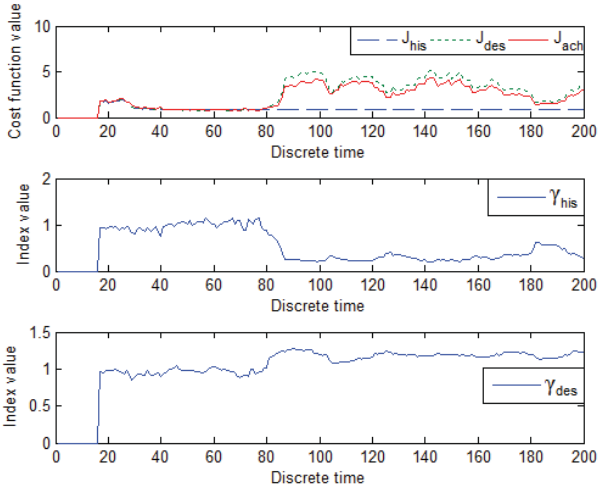

Figure 7 – Control performance reduction diagnosis caused by the saturation of the manipulated variable

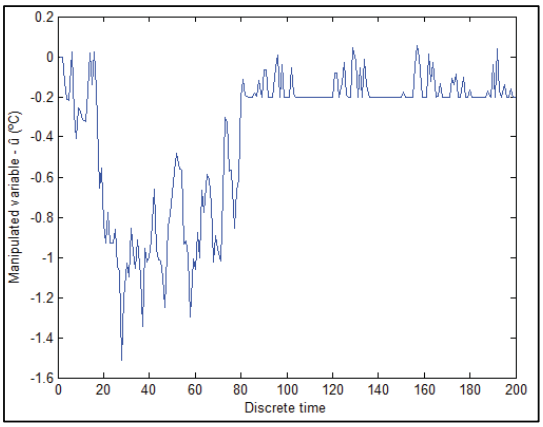

Figure 8 – Saturation of manipulated variable

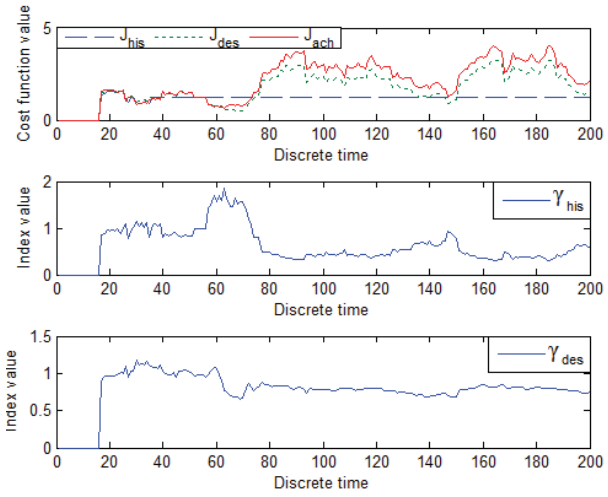

Figure 9 – Control performance reduction diagnosis caused by the change of the control tuning parameter

Even though some situations were potentially easier (e.g. the saturation of the manipulated variable) to detected and diagnose than others (e.g. the mismatch between the model and the phenomenological model based simulator), all the simulated scenarios were safely diagnosed. However, the situations studied in this paper were magnified in order to allow the verification of the differences that were expected for each case in the figures.

6. CONCLUSIONS

Monitoring and diagnosis methods were successfully applied to study control performance reduction scenarios using a GPC algorithm. Four types of performance reduction causes were diagnosed: increase in the controlled variable variability, mismatch between the model and the phenomenological simulator, saturation of manipulated variable and change in the control tuning parameter.

As future developments, it is suggested the implementation of operation support tools that enable the automatic performance monitoring and diagnosis.

Finally, it is expected that – with environmental concern, development of the industrial safety area and evolution of human intellectual capacity – more and more technologies will be developed in order to enable the correction, the prevention and, mostly, the failures prediction, allowing the man to dedicate his work to nobler activities, like process optimization.

Abstract: In this paper, a novel application of state estimation in environmental engineering is presented. Filtering techniques including moving horizon estimator (MHE) and extended Kalman filter (EKF) are used for early concentration estimation of toxic agents existing in water supply. The purpose is to integrate the filtering techniques with an early warning system enabling an early detection of the presence of toxicants in the water supply system and quantifying their concentrations. The estimation is based on dynamic measurements generated by a real-time cell electronic sensor (**RT-CES**) and cytotoxicity dynamic models.

Keywords: state estimation, extended Kalman filter, moving horizon state estimation, cytotoxicity, real-time cell electronic sensor, early warning, water protection.

1. INTRODUCTION

Drinking water may be contaminated by a range of chemical, microbial and physical hazards that could pose risks to health if they are present at high levels. Examples of chemical hazards include mercury, chromium, arsenic, etc. The sources of these toxicants differ with respect to the toxicant. Mercury for instance, occurs as a result of both natural (volcanic, forest fires and oceanic releases) and anthropogenic sources (mining, smelting and other industrial activities) in our environment as mentioned by Wang et al. (2004).

The effects of toxicants on the human cells are referred to as cytotoxicity. In other words, cytotoxicity is the characteristic of being toxic to living cells, including cell killing, cell lysis and certain cellular pathological changes, such as cellular morphological change and adhesion change as reported in Xing et al. (2005). Therefore, citizens must be alerted as early as possible when water is contaminated. For this purpose, an early warning system is necessary for detection of any sudden deterioration in the quality of water supply. An efficient detection must include the ability of an early determination of the presence of a toxicant at low concentration. Thus, our main objective in this paper is to use filtering techniques, such as moving horizon estimation (MHE) and extended Kalman filter (EKF) to determine on-line the concentration of such a toxicant in water supply. To achieve this purpose, mathematical modeling and real-time measurements are necessary. Two mathematical models have been developed and validated by Huang and Xing (2006) to predict cell toxicity response to mercury (II) chloride and sodium dichromate [chromium (VI)] toxicity. The measurements of toxicity response were recorded using Real-Time Cell Electronic Sensor (**RT-CES**). These two models are able to predict cell responses to different values of toxicant concentration and allow assessment of the biological consequences of toxic chemicals in environmental contamination. In this paper, we reverse the modeling procedure. We are interested in the estimation of toxicant concentration for a given dynamic model through on-line monitoring data sampled from **RT-CES**. The organization of this paper is as follows. The monitoring procedure and the mathematical models are revisited in Section 2 and Section 3 respectively. The procedure of concentration estimation and the validation results are presented in Section 4 including concentration estimation using both MHE and EKF. Concluding remarks are given in Section 5.

2. EQUIPMENT AND MONITORING PROCEDURE REVISIT

1) ***Equipment***: The RT-CES system (ACEA Biosciences, CA, U.S.A.) is used for this study and has been described in (Xing et al., 2005; Huang and Xing, 2006). Briefly, as shown in Fig. 1, it consists of a 16x microelectronic sensor devices having 16 plastic wells in microtiter plate format, a device station and an electronic sensor analyzer. Cells are grown onto the surfaces of microelectronic sensors. In operation, the sensor devices with cultured cells are mounted to a device station placed inside a CO2 incubator. Electrical cables connect the device station to the sensor analyzer. Under the control of RT-CES software, the sensor analyzer automatically selects wells to be measured and continuously conducts measurements. The electronic impedance can then be transferred to a computer and recorded. A parameter termed cell index (CI) is derived to represent cell status based on the measured electrical impedance. The frequency dependent

electrode impedance (resistance) without or with cells present in the wells is represented as $R_b(f)$ and $R_{cell}(f)$, respectively. The CI is calculated by:

$$CI = \max_{i=1,\ldots,n} \left[\frac{R_{cell}(f_i)}{R_b(f_i)} - 1 \right] \quad (1)$$

where n is the number of the frequency points at which the impedance is measured. Several features of the CI can be derived: (1) Under the same physiological conditions, if more cells attach onto the electrodes, the larger impedance value leading to a larger CI value will be detected. If no cells are present on the electrodes or if the cells are not well-attached onto the electrodes, $R_{cell}(f)$ is the same as $R_b(f)$, leading to $CI = 0$; (2) A large $R_{cell}(f)$ value leads to a larger CI. Thus, CI is a quantitative measure of the number of cells attached to the sensors; (3) For the same number of cells attached to the sensors, changes in cell status, such as morphological change, lead to change of CI.

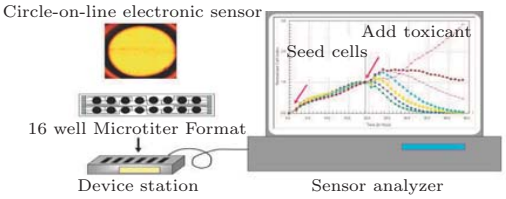

Fig. 1. *The Real-Time Cell Electronic Sensor*

In addition to cell numbers, the impedance also depends on the extent to which cells attach to the electrodes. For example, if cells spread, there will be a greater cell/electrode contact area, resulting in larger impedance. Thus, the cell biological status including cell viability, cell number, cell morphology and cell adhesion will all affect the measurements of electrode impedance that is reflected by CI on the RT-CES system. Therefore, a dynamic pattern of a given CI curve can indicate sophisticated physiological and pathological responses of the living cells to a given toxic compound (Xing et al., 2005).

2) ***Dynamic growth with toxicity***: Two environmental toxicants, mercury (II) chloride and sodium dichromate [chromium (VI)], were used for cytotoxicity assessment on the 16 sensor device. The cell line NIH 3T3 was tested. The starting cell number was 10 000 cells per sensor wells. The cell growth on the sensor device was monitored every hour up to 24 h in real-time by the RT-CES system. When the CI values reached a range between 1.0 and 1.2, the cells were then exposed to either mercury (II) chloride, or chromium (VI) at different concentrations. Fig. 2 shows dynamic cytotoxic response to different doses of chromium (VI). Fig. 3 shows dynamic cytotoxic response to mercury (II) chloride. In both cases the cytotoxicity response is dose dependent and increasing dose leads to decreasing (CI).

3. MATHEMATICAL MODELING

As mentioned in the introduction, the cytotoxicity mechanism is complex and cell response to toxicity depends on cell type, toxicant type, toxicant concentrations and the time of exposure to the toxicant. In Huang and Xing (2006), two types of models were developed and validated

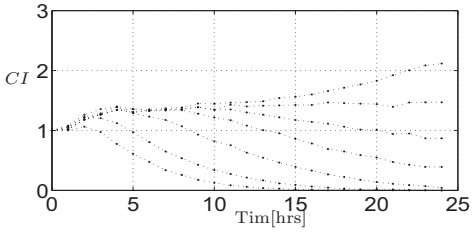

Fig. 2. *Dynamic cytotoxic response of NIH 3T3 cells to different doses of* ***chromium (VI)****: 0; 0.62; 0.91; 1.97; 2.89; 4.25; 5.78 in the unit of μM. Increasing dose leads to decreasing (CI).*

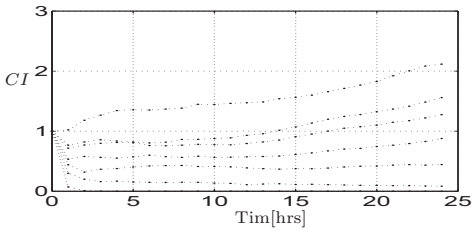

Fig. 3. *Dynamic cytotoxic response of NIH 3T3 cells to different doses of* ***mercury (II)****: 0; 10.43; 15.2; 22.35; 32.8; 48.3; 71 in the unit of μM. Increasing dose leads to decreasing (CI).*

to predict cell toxicity response to mercury (II) chloride, and sodium dichromate [chromium (VI)] stimulations. In both models, it was suggested that the process of cytotoxicity follows two-step mechanism: (1) uptake of toxicant by cells and (2) killing of the cells. The uptake mechanism describes the transport process of the toxicant into a cell as illustrated in Fig. 4 (Huang and Xing, 2006). This mechanism relates the extracellular concentration c_e (representing the concentration of a toxicant in the environment) and the intracellular concentration c_i (concentration inside the cell) and it is described by El-Kareh and Secomb (2005) as follows :

$$\dot{c_i} = k_1(k_2 c_e + \frac{k_3 c_e}{k_4 + c_e} - c_i) \quad (2)$$

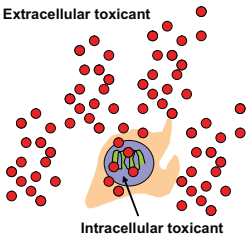

Fig. 4. *Schematic of transport process of toxicant onto cell.*

The first step in cytotoxicity (the uptake mechanism) is supposed to be rather consistent; however the second step (cell killing) differs with respect to the toxicant and can be described through cell population dynamics as $\dot{N} = f(C, N)$ where N is the cell population and C can be the intracellular or the extracellular concentration of the toxicant or a combination of them. It depends on the type of the toxicant. In the following, we present the mathematical models of cell killing under the effect of two toxicants, mercury (II) chloride, and sodium dichromate [chromium (VI)] as described in Huang and Xing (2006).

3.1 Mathematical modeling of [chromium (VI)] toxicity

The cell exposed to dichromate [chromium (VI)] is killed by *apoptosis* mechanism which is a highly regulated process and is described as programmed cell death. The apoptosis mechanism mainly depends on the intracellular concentration of the toxicant. This is described by the dynamics of cell pullulation given by Eliaz et al. (2004) as $\dot{N} = N(k_s - kc_i)$. As proposed by Huang and Xing (2006), this mechanism yields the following system of differential equations for describing dichromate [chromium (VI)] effects on cells population dynamics:

$$\begin{aligned} \dot{c_i} &= k_1(k_2 c_e + \frac{k_3 c_e}{k_4 + c_e} - c_i) \\ \dot{N} &= N(k_s - kc_i) \end{aligned} \tag{3}$$

The parameters of this model (3) are estimated from the experiment data and presented in Table 1.

Table 1. Estimated parameters for model (3)

k_1	k_2	k_3	k_4	k_s	k
0.0146	2.9399	0.0080	29.2418	0.0425	0.1041

3.2 Mathematical modeling of mercury (II) chloride toxicity

In Huang and Xing (2006), mercury cytotoxicity has both necrosis mechanism and apoptosis mechanism. The necrosis describes an accidental cell death caused, for example, by chemical or physical assault to the cell which may make cells die by direct disruption of cell membrane. Thus necrosis mechanism mainly depends on extracellular concentration of the toxicant. The cell population dynamics, together with the uptake mechanism expressed by eqn. (2), under mercury (II) chloride toxicity effect is described as follows:

$$\begin{aligned} \dot{c_i} &= k_1(k_2 c_e + \frac{k_3 c_e}{k_4 + c_e} - c_i) \\ \dot{N} &= N(k_5 + k_6 c_i + k_7 c_e) \end{aligned} \tag{4}$$

The parameters of model (4) are presented in Table 2.

Table 2. Estimated parameters for model (4)

k_1	k_2	k_3	k_4	k_5	k_6	k_7
7.735	1.108	3.21	12.8	0.0312	0.2084	-0.2364

4. RAPID TOXICANT CONCENTRATION ESTIMATION

The on-line estimation of the key parameter (the concentration of toxicant c_e) is critical due to two reasons. First, as being well known the concentration itself is usually not easily measurable due to technical or economical limitations especially for biomedical processes. The key toxicants are usually measured by high performance liquid chromatography (**HPLC**) and liquid chromatography-mass spectrometry (**LC-MS**) which are expensive equipments. Second, an early determination (detection) of the concentration of such a toxicant is important for an early warning system (which we aim to develop) in order to detect any sudden deterioration in the quality of water supply. Deterioration in water quality mainly means increase of the concentrations (or even the presence) of toxicants . For the early warning system, it is necessary to do on-line estimation of c_e.

For on-line estimation, several methods for state estimation are available such as EKF and MHE. EKF is a popular state estimation technique and considered as the standard choice for estimating state for nonlinear systems due to lower computation load and more stable property. However, additional physical insights about the process may help in state estimation to prevent negative concentration for instance. This kind of insights can not be considered in EKF. On the other hand, this physical insights can be added as inequality constraints and integrated with an optimal state estimation scheme formulated as a quadratic problem such as MHE (Rao et al., October 2001).

We use mainly MHE for on-line estimation of the key parameter c_e and we also use EKF as an alternative (usually a quicker method) of the estimation. This may be considered as a comparison to demonstrate by biological application examples the benefits of using MHE on one hand. On the other hand, the EKF is also imbedded in the MHE and is naturally used for a comparison. The superiority of MHE has also been pointed out by several authors through a number of applications such as in Rao and Rawlings (2002) and Haseltine and Rawlings (2005) for instance.

Before starting the procedure of on-line state estimation of the key parameter (the extracellular concentration c_e) for our biological application, an identifiability test is necessary. We present in the next section an identifiability test for mercury (II) chloride toxicity model (4) for an illustration. An identifiability test for chromium (VI) toxicity model (3) can be performed similarly.

4.1 Identifiability

A mathematical model is identifiable if there exist no two parameter sets which have the same input-output behavior. In other words, a model is not identifiable if there exists no unique parameter set to explain the input-output behavior. Identifiability is a pre-analysis for parameter estimation problem to determine the uniqueness of the parameter solution obtained from the estimation process. A number of methods are available for testing identifiability of parametric models. For testing the identifiability of the mercury (II) toxicity model (4), the Taylor series approach is utilized (see Walter and Pronzato (1996)). A brief description of the approach is given below. Consider the following model :

$$\begin{aligned} \dot{x}(t) &= f(x(t), u(t), t, p), \quad x(0) = x_0(p) \\ y(t, p) &= h(x(t), p) \end{aligned} \tag{5}$$

where p is the model parameters set.

If $a_k(p) = \lim_{t \longrightarrow 0+} \frac{d^k}{dt^k} y(t, p)$ then a sufficient condition for model (5) to be uniquely identifiable is :

$$a_k(\hat{p}) = a_k(p^*), \quad k = 0, 1, ..., k_{max}, \Longrightarrow \quad \hat{p} = p^*$$

where k_{max} is a positive integer, small enough for the computations to remain tractable.

Since mercury (II) toxicity model (4) has only one parameter (the concentration c_e), checking for identifiability reduces to checking for conditions under which the parameter can be observed from the Taylor series coefficients. The first two coefficients of the series for the mercury (II) toxicity model can be determined as:

$$a_0(p) = N(0)$$
$$a_1(p) = \dot{N}(0) = N(0)(k_5 + k_6 c_i(0) + k_7 c_e) \quad (6)$$

Solving the equation (6) for c_e yields,

$$c_e = \frac{k_6 c_i(0) N(0) + k_5 N(0) - \dot{N}(0)}{-k_7 N(0)}$$

Therefore c_e is identifiable if:

$$-k_7 N(0) \neq 0 \quad \text{and} \quad (7)$$
$$k_6 c_i(0) N(0) + k_5 N(0) - \dot{N}(0) \neq 0 \quad (8)$$

Measurements evolution shown in Fig. 2 and values of the estimated parameters in table 2 satisfy both conditions, equations 7 and 8.

4.2 Extended Kalman Filter (EKF) formulation

Before presenting EKF formulation, considering the problem of estimating the state of system modeled by the nonlinear state space equation :

$$x_{k+1} = f(x_k, u_k, k) + G w_k \qquad k = 0, 1, 2... \quad (9)$$
$$y_k = g(x_k, k) + v_k$$

where, $x_k \in \mathbb{R}^n$ is the state vector, $y_k \in \mathbb{R}^p$ the measured output, $w_k \in \mathbb{R}^n$ state disturbance and $v_k \in \mathbb{R}^p$ the measurement noise. The EKF linearizes the nonlinear system and then applies the Kalman filter to obtain the state estimation. The method can be summarized in a recursion structure similar to linear Kalman filter for a nonlinear system described above by equations (9) (see Haseltine and Rawlings (2005)):

Prediction step

$$\hat{x}_{k|k-1} = f(\hat{x}_{k-1|k-1}, u_{k-1}, w_{k-1})$$
$$P_{k|k-1} = A_{k-1} P_{k-1|k-1} A_{k-1}^T + G_{k-1} Q_{k-1} G_{k-1}^T$$

Update step

$$\hat{x}_{k|k} = \hat{x}_{k|k-1} + K_k(y_k - g(\hat{x}_{k|k-1}))$$
$$K_k = P_{k|k-1} C_k^T [C_k P_{k|k-1} C_k^T + R_k]^{-1}$$
$$P_{k|k} = P_{k|k-1} - K_k C_k P_{k|k-1}$$

in which, the following linearizations are made

$$A_k = \frac{\partial f(x_k, u_k, k)}{\partial x_k^T}, \quad G_k = \frac{\partial f(x_k, u_k, k)}{\partial w_k^T}, \quad C_k = \frac{\partial g(x_k)}{\partial x_k^T}$$

4.3 Moving Horizon State Estimation (MHE) formulation

The MHE strategy belongs to a class of optimization methods for on-line determination of state. The optimization problem is formulated as a least-squares problem where the decision variables are chosen to minimize the sum of the squared errors between the available measurements and model prediction. When a new measurement becomes available, this optimization is repeated by adding the new measurement to the past measurements each sampling time. This leads to growing computational burden of solving the least-squares optimization, known as full information estimation problem. MHE reduces this computational cost by considering a finite horizon of only the last N_h measurements in the optimization problem and information provided by past data beyond the horizon is captured by arrival cost. This optimization is repeated each sampling time by including a new measurement and discarding the first measurement while keeping a fixed horizon length (N_h). In other words, the MHE algorithm is a least square optimization problem solved over a window of fixed horizon length (N_h). This window moves one step ahead each time after solving an optimization problem with a quadratic cost function (Ψ_k) of the following form (for more details see Rao et al. (2003)):

$$\min_{\{\hat{w}_{k-N_h-1|k}, \ldots, \hat{w}_{k-1|k}\}} \Psi_k : \Psi_k = \hat{w}_{k-N_h-1|k}^T Q_{-N_h|k}^{-1} \hat{w}_{k-N_h-1|k} + \sum_{j=k-N_h}^{k-1} \hat{w}_{j|k}^T Q^{-1} \hat{w}_{j|k} + \sum_{j=k-N_h}^{k} \hat{v}_{j|k}^T R^{-1} \hat{v}_{j|k}$$

subject to the state equality constrains:

$$\hat{x}_{k-N_h|k} = \bar{x}_{k-N_h|k} + \hat{w}_{k-N_h-1|k}$$
$$\text{with} \quad \bar{x}_{k-N_h|k} = f(\hat{x}^*_{k-N_h-1|k-1}, u_{k-N_h-1}, k)$$
$$\hat{x}_{j+1|k} = f(\hat{x}_{j|k}, u_j) + \hat{w}_{j|k}, j = k - N_h, ..., k-1$$
$$y_j = g(\hat{x}_{j|k}, k) + \hat{v}_{j|k}, j = k - N_h, ..., k$$

with the possibility to incorporate inequality constraints on the state, state disturbance and process noise:

$$w_{min} < A w_j < w_{max}, \quad x_{min} < A x_j < x_{max},$$
$$v_{min} < A v_j < v_{max}, \quad j = k - N_h - 1, ..., k-1$$

where Q is the covariance of the state disturbance and R is the covariance of process noise.

The term $\hat{w}_{k-N_h-1|k}^T Q_{-N_h|k}^{-1} \hat{w}_{k-N_h-1|k}$ approximates the arrival cost which summarizes the effects of the past information before $t = k - N_h$. The weighting term $Q_{-N_h|k}$ initially represents the covariance of the prior state estimate $\bar{x}_{k-N_h}$ and is computed according to EKF covariance update formula (Rao et al., 2003):

$$Q_{-N_h|k+1} = A_k Q_{-N_h|k} A_k^T + G_k Q_k G_k^T - A_k Q_{-N_h|k} C_k^T [C_k Q_{-N_h|k} C_k^T + R_k]^{-1} C_k Q_{-N_h|k} A^T \quad (10)$$

where A_k, C_k and G_k result from linearizing the model (9) around the estimated trajectory.

In the full information problem there is no arrival cost because the whole information (all available measurements) is used each sampling time in the optimization while in MHE, only a subset of the information is used and the rest is approximated by the arrival cost. Thus, MHE is an approximation of the full information problem and therefore stability issue arises. The key to preserving

stability is how to approximately summarize the old data, equivalently, how to find the best approximation of the arrival cost, an explicit expression which rarely exists in nonlinear or constrained system. One strategy is to use the EKF covariance update formula as presented in equation (10) (Rao et al., 2003).

Next we present a state estimation based approach for rapid determination of concentrations of mercury (II) and chromium (VI) from the measurement of cell population responses provided by the **RT-CES**.

4.4 Concentrations estimation of chromium (VI)

The key parameter we aim to estimate is the extracellular concentration (c_e) of chromium (VI). This parameter is added to the toxicity equation (3) of chromium (VI) as an augmented state as follow :

$$\begin{aligned} \dot{c_i} &= k_1(k_2 c_e + \frac{k_3 c_e}{k_4 + c_e} - c_i) \qquad (11) \\ \dot{N} &= N(k_s - k c_i) \\ \dot{c_e} &= 0 \quad ; \quad y = N \end{aligned}$$

where, c_i is the intracellular concentration, N is the cell population and y is the observation. We estimate toxicant concentrations from three toxicity responses corresponding to toxicant doses c_e =(0.62; 1.97; 4.25)μM. Note these data have not been used for modeling purpose and thus serve as cross validation data for state estimation. The results presented in Fig. (5-7) show that MHE in general has a better estimation than EKF. In addition, MHE is able to prevent an estimation of negative concentration at all time but EKF can not. It is also observed from these figures that the extracellular concentration can be correctly estimated between 10 to 15 hrs, instead of 24 hrs as traditional the method needs. Thus a rapid estimation is achieved.

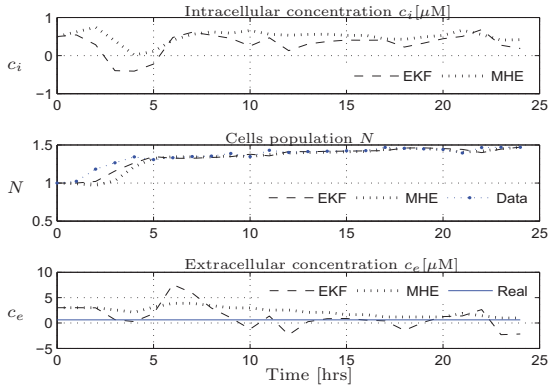

Fig. 5. *Concentration estimation of chromium (VI) corresponding to real $c_e = 0.62\mu M$. Bottom plot : Estimation of c_e converges to the real value (0.62μM) using both estimators. Top plot shows the estimation of c_i which is not measured. The middle plot shows the estimation of cell population that is measured.*

4.5 Concentrations estimation of mercury (II) chloride

Similar to the procedure adopted for estimating the concentration of chromium VI presented in the previous section, we aim here to estimate the concentration of mercury (II) chloride from the available data. The concentration c_e is added to the toxicity equation (4) of mercury (II) chloride as an augmented state similar to the augmented model (eqn. 11) for chromium (VI). We estimate the toxicant concentrations from three toxicity responses corresponding to the toxicant concentration c_e =(10.43; 22.35; 48.3)μM. The results presented in Fig. (8-10) show that both estimators (EKF and MHE) provide a good estimation of c_e while preventing negative concentration estimation when using MHE. This shows clearly the benefits of using constraints by MHE.

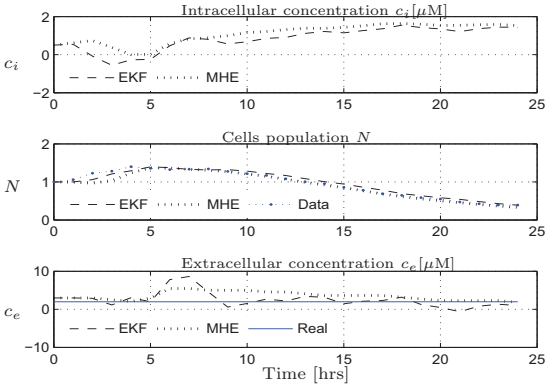

Fig. 6. *Concentration estimation of chromium (VI) corresponding to real $c_e = 1.97\mu M$. Bottom plot : Estimation of c_e converges to the real value (1.97μM) using both estimators. Top plot shows the estimation of c_i which is not measured. The middle plot shows the estimation of cell population that is measured.*

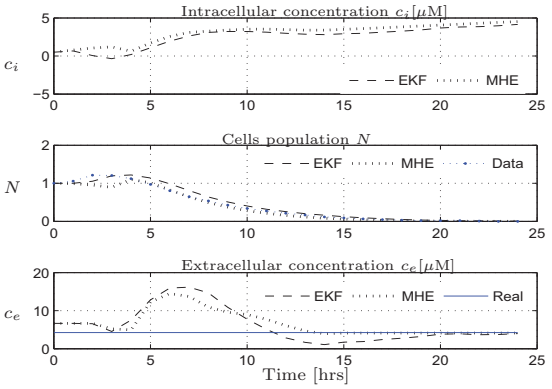

Fig. 7. *Concentration estimation of chromium (VI) corresponding to real $c_e = 4.25\mu M$. Bottom plot : Estimation of c_e converges to the real value (4.25μM) using both estimators. Top plot shows the estimation of c_i which is not measured. The middle plot shows the estimation of cell population that is measured.*

Our experience shows that tuning EKF is simpler. Using MHE requires a more careful tuning of a several parameters, namely, Q, R, Q_{-N_h}, horizon length (N_h), the constraints w_{min}, w_{max} and also the initial conditions. In addition, the tuning may vary from different experiments. The evolution of the estimation converges by using horizon length $N_h = 1$ for mercury (II) chloride case while at least $N_h = 2$ is needed for chromium IV case.

In the selection of the covariance, the Q matrix reflects the uncertainty of the state equations while the R matrix reflects the uncertainty in the measurement of CI due to other phenomena that also affect CI in addition to cell numbers.

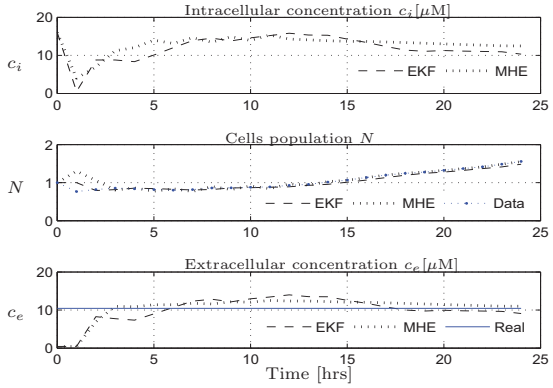

Fig. 8. *Concentration estimation of mercury (II) chloride corresponding to real $c_e = 10.43\mu M$. Bottom plot : Estimation of c_e converges to the real value (10.43μM) using both estimators. Top plot shows the estimation of c_i which is not measured. The middle plot shows the estimation of N that is measured.*

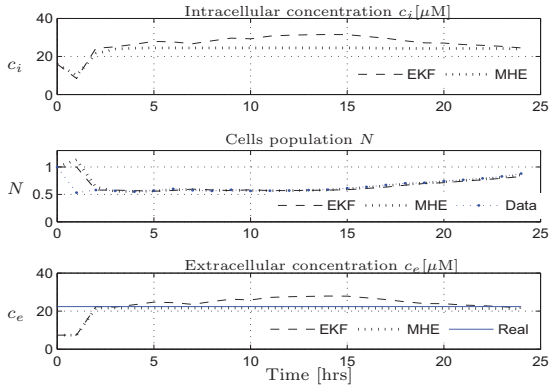

Fig. 9. *Concentration estimation of mercury (II) chloride corresponding to real $c_e = 22.35\mu M$. Bottom plot : Estimation of c_e converges to the real value (22.35μM) using both estimators. Top plot shows the estimation of c_i which is not measured. The middle plot shows the estimation of N that is measured.*

5. CONCLUSION

An early warning system for water supply is our main goal of the work presented. This includes an early determination of the presence of specific toxicants in water by on-line estimation of their concentrations. We use mainly MHE as an on-line estimation tool in this paper. Determination of the concentration is only one of the features of the aimed early warning system. This system will also include prediction of future evolution of toxicity response using only initial measurements and prediction of cells response when the concentration of a toxicant varies. Integrating all these prediction features is the ultimate goal. Intuitively, this includes also the development of toxicity mathematical models for other kinds of common water toxicants such as sodium arsenite [As (III)] for instance.

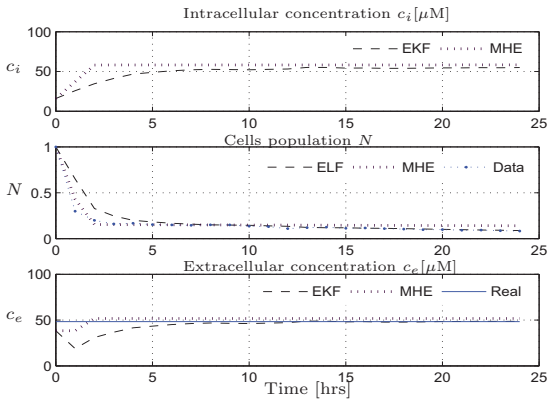

Fig. 10. *Concentration estimation of mercury (II) chloride corresponding to real $c_e = 48.3\mu M$. Bottom plot: Estimation of c_e converges to the real value (48.3μM) using both estimators. Top plot shows the estimation of c_i which is not measured. The middle plot shows the estimation of N that is measured.*

In addition, as has been discussed, the cell index also reflects other sophisticated physiological and pathological responses in addition to cell numbers. A model that considers other properties of the cell index will further improve on-line state estimation.
