The framework supplies the services of a modern GUI-application like module-sensitive dialogs and presentations, flow sheet editing for creating energy system schemes and report generation. Further more, the system provides a special editor that supports the buildup of component templates. Modules can be integrated into the application via a plug-in mechanism that allows the call of module code as well as the insertion of module specific menus.

A detailed description of the developed object model, the framework architecture and its capabilities can be found in [3].

THE SYSTEM SIMULATION MODULE

TOP-Energy was designed to incorporate various computational methods implemented as plug-in modules. The most prominent one to be part of the first release of TOP-Energy is *eSim*, a module for simulation of energy supply systems. The main objective of this module is to determine a set of economic, energy-related and environmental key figures of an energy supply infrastructure for a term of usually one year. The boundary conditions of a system model are demand profiles for the different forms of energy as well as information about the environment.

Overwiev

Energy system simulation is well known in science today. Various different solutions are available [4] although only few meet the usability requirements of engineering applications. Depending on the specific objectives of a simulation system, different mathematical approaches are used. The most sophisticated models base on differential equations (either DAE or ODE), being able to forecast the dynamic behavior of an energy supply system [5]. This, of course, requires a detailed modeling of the feedback control systems. Apart from that, detailed design data is required to calculate a machine's time constants. In a more simple approach, the inertia of the system components is neglected due to the fact that the time resolution of boundary conditions usually is not better than one hour. These quasi-static models result in algebraic systems requiring less detailed design parameters of the system components. However, the problem remains that control rules must be supplied by the user.

An approach that supersedes the specification of any control rules is to determine the system state by means of operation optimization. These systems, usually based on mixed integer linear optimization (MILP) [6], are frequently used to determine optimal power plant schedules [7]. However, this approach is capable of evaluating the design of energy supply systems too [8]. One drawback of these optimizing systems is the fact, that, due to the limitations of the underlying MILP, their models regard media temperatures to be independent from the system state, i.e. constant, or must be estimated before the linear problem is solved.

Basic Concepts

eSim was designed to read network schemes created in the framework's scheme editor and stored in the format of the TOP-Energy object model. Figure 1 shows a simple scheme of an energy supply system created with the scheme editor.

While the component models are formulated using a modelling language designed to the specific numerical needs, the different network types are implemented in the simulator code. Currently these are electrical power lines, fuel distribution networks, hydraulic networks as well as nets modelling air and flue gas lines. Other network types e.g. for steam networks are currently under development. All network types except the electrical network are directed, each distinguishing input and output pins. Reverse flow in directed networks is not considered. As components may include other components in the object model, it is possible to design hierarchical simulation models. The lowest modelling level introduced defines a set of basic operations typical to the respective network type. These low level models can be thought as connectors between the network model and the modelling language. Examples are

sources, sinks, pressure change and heat exchanging in hydraulic or combustion for air and flue gas networks.

The set of equations and algorithms describing the complete system model are assembled from the model descriptions of the single components and equations derived from the structure analysis of the connecting networks. While the network model based on components, pins and nets is the appropriate means to assemble, display and store energy network schemes, the structure analysis and the generation of balance equations is better conducted on graphs. Therefore the network description is transformed into a set of graphs, each describing one single coherent network with the vertices representing balance nodes and the edges describing a state change of the flowing medium through a component. From these graphs, the equations describing the system can be derived. Besides the balances for mass and energy flows, a system of algebraic equations is generated in order to propagate constant parameters, e.g. medium properties, through the system.

Time Step Algorithm

As eSim is thought to be used in an early stage of planning, modelling a system should not be too time consuming and require only data available to the user. Therefore, the operating optimization approach as described above was chosen.

This implies that the problem of modelling dependencies between fluid temperatures and component efficiencies has to be solved: When modelling a conventional boiler, it can be assumed that its efficiency is independent from the inlet temperature at every state of operation. To describe a hydraulic system of a set of such components, it is sufficient to formulate temperature independent energy balances regarding the all heat suppliers and consumers attached to the network.

$$\sum \dot{Q}_{network} = 0 \tag{1}$$

Apart from that, it only has to be assured that the second law is not violated due to unappropriate temperature differences in the heat transferring components. However, assuming constant temperatures this constraint can be checked before the optimizing algorithm is carried out.

This is different if temperature sensitive technologies like condensing boilers, heat pumps or chillers are to be modelled. As the efficiency of such components depends on the inlet temperatures of their heat exchangers, temperatures cannot be assumed to be constant but must be considered as system variables. As a consequence, the equations of mass conservation have to be solved in addition to the energy balances. E.g. for a hydraulic network with no storage effects, this leads to equations 2 and 3 for each vertice and 4 and 5 for each edge in the network graph.

$$\sum \dot{m}_i = 0 \tag{2}$$

$$\sum \dot{H}_i \approx \sum \dot{m}_i c_{il} (T_i - T_0) = 0 \tag{3}$$

$$\dot{m}_{j,in} = -\dot{m}_{j,out} = \dot{m}_j \tag{4}$$

$$\dot{Q}_j = \dot{m}_j (h_{j,in} - h_{j,out}) \approx \dot{m}_j c_{il} (T_{j,in} - T_{j,out}) \tag{5}$$

In order to consider the pumping energy needed for operation of the hydraulic network using a simple pressure loss model, equations 6 and 7 occur for each edge and each cycle in the graph respectively.

$$\sum \Delta p_j = \frac{\lambda}{2\rho A^2} \dot{m}_j^2 \tag{6}$$

$$\sum \Delta p_k = 0 \tag{7}$$

Even under the assumption of an ideal liquid with constant heat capacity, products of two variables occur as well as squares of $\dot{m}$. Being part of the system to be optimized, the equations above introduce nonlinear constraints which cannot be treated with established algorithms like linear or even quadratic programming [6]. Being in need of a robust algorithm as well as integer variables for modelling switching events, ways had to be found to linearize these constraints. This would allow to treat the remaining problem using mixed integer linear programming (MILP) fulfilling the requirements stated. Two approaches for the separation of mass and energy equations were found in literature: Filter [9] discretizes the mass flow variable by creating ”mass flow quantums”. This allows the formulation of both balances in one MILP system for the price of a high number of integer variables, causing a huge branch an bound tree to be calculated. Hackländer [10] separates the variables of the product by a binomial transformation. The remaining squares are then approximated by piecewise linearization. Though beeing very elegant, this approach as well introduces a

huge number of integer variables in order to approximate three parabolas per linearized product. Moreover, the approximation leads to errors in the energy and mass balances depending on the quality of approximations.

In order to avoid a high number of integer variables in the MILP system, the approach proposed here separates the mass flow balances into a an additional system of linear equations and uses a special algorithm to coordinate the latter with the remaining MILP system. In the actual implementation, an optimizer based on evolutionary algorithms [11] was chosen, using the linearly independent mass flow variables as genome.

The principle of the algorithm is shown in figure 2. In order to create an individual of a generation, the optimizer chooses a set of linearly independent mass flow variables, either randomly at the beginning of the optimization run or by recombination and mutation from individuals of the parent generation. The set then is passed to a linear solver in order to calculate the dependent mass flow variables from the mass flow balances (eqn. 2 and 4). Finally, the complete set of mass flow variables is transferred to the MILP system, generated from the network energy balances and remaining constraints specified in the component models. As a result of the MILP solution, the target function value is returned to the optimizer in order to evaluate the relative quality of the individual compared to competing individuals.

As the mass flow variables are chosen stochastically by the optimizer, a relevant number of proposals will lead to a violation of constraints in the MILP system and therefore will end up without a solution. This occurs due to the fact that the vertice enthalpy balances (eq. 3) cannot be satisfied with the given set of mass flows. In order to return information about the proximity to a valid solution, a slack variable is introduced for each network graph vertice. Literally spoken, the slack variable represents a virtual enthalpy source or sink compensating the – otherwise invalid – enthalpy balance of the vertice. In order to let the slack variables converge towards zero during the optimization run, an accordant contribution is added to the target function, referred to as ”virtual target function” in figure 2.

Finally, the time step results including the energy and cost flows as well as the load of the components involved can be obtained from the MILP solution of the best individuum calculated.

In the basic implementation presented here, the calculation effort needed during a simulation is comparable to the algorithm proposed by Filter [9]. This can be ascribed to the fact that the mass flow values are chosen randomly by the optimizer and therefore a high number of linear systems has to be evaluated to find valid solutions of the energy balances. Though not implemented yet, a number of enhancements promise a relevant performance gain:

Evaluating the slack variables of the energy balances after a MILP run, information can be obtained about the local optimization direction in order to create better individuals. Passing this information back to the optimizer, a faster convergence of the time step algorithm can be expected.

As many load profiles show recurring patterns in practice, good starting individuals for the time step optimization can be obtained from previous time step solutions by a least square comparison of the respective system coefficients. This means is expected to speed up the time step calculation with increasing simulation time.

Example Simulation

Figure 3 shows the results of a 48 hour cost optimized simulation run of the system shown in figure 1. The upper diagram shows the split of the heat load between boiler and cogeneration unit, the lower the customer generated fraction of the power demand. The power supply tariff distinguishes two energy rates depending on the time of day, marked by LT (low tariff) and HT (high tariff) in figure 3.

It can be seen that the operation of the cogeneration unit is driven by the heat load in the low tariff hours, feeding superfluous power into the public grid (see 5 a.m. of the first day). During the high tariff time, the cogeneration unit is controlled by the internal electric power demand. In case spare heat is produced, it is released to the environment via the emergency cooler (see 6 p.m. of the first day).

The example shows the capability of the simulator to optimize the system operation depending on the physical and economical boundary conditions given.

CONCLUSIONS AND PERSPECTIVES

The main aim of TOP-Energy was the development of a software system to support the analysis and op-

timization of small to medium energy supply systems. Claiming cheap integration of additional computational methods and user-specific adaptability, a generic framework incorporating technical modules was developed.
In order to supply a simulation module for energy supply systems for the estimation of annual system efficiency and costs, a new algorithm was developed integrating the optimization of the component operation and therefore superseding the costly modelling of feedback control systems. Though the algorithm lacks of performance in the actual implementation, the feasibility of the approach could be proven.
Further development of the TOP-Energy framework will focus on the version control of component and module templates, an enhanced object model and report generation. Future development of the simulator will include the optimization of the actual implementation in terms of performance as well as the research on alternative coordination algorithms and additive network types and model components. Moreover, additional modules are under development, so a module for bench-marking energy demand and CO_2-emissions of industrial sites.
More information about TOP-Energy can be found on the project website at http://top-energy.ltt.rwth-aachen.de.

ACKNOWLEDGEMENTS

The authors would like to thank the following persons which are working in the TOP-Energy project team: Jan Feller, LTT, Aachen; Gregor Wrobel, Matthias Pleßow, Oliver Berndt, GFaI, Berlin; Jörg Meyer, EUtech GbR, Aachen; Rainer Küffmeier, BFT GmbH, Aachen. The authors are also grateful to the Bundesministerium für Wirtschaft und Technologie (BMWA) and the German Federation of Industrial Cooperative Research Associations "Otto von Guericke" (AIF) for the financial support of the project. The work was done from 01.01.2003 to 31.12.2004 under project code 92 ZBG / 1.

ABSTRACT

A conjugate numerical methodology was employed to predict the metal temperature of a three-dimensional gas turbine blade model under different operating conditions. The conjugate heat transfer approach allows the simultaneous solution of the external flow and conduction within the metal vane, eliminating the need for an uncertain additional boundary condition for decoupled solutions.

Taking into account the enormous computational load to deal with the whole processes in the start-up and the shut-down (transient analyses), a reduced model with standard wall function near-wall treatment was considered to simulate the actual blade.

The results obtained by a commercial code, on the basis of finite volume method are presented, where the maximum temperature gradients appear in the trailing edge (ΔT=270 K) followed by the leading edge and the region between cooling holes and suction side (ΔT=250 K).

Keywords: gas turbine, blades, CFD.

INTRODUCTION

Turbine entry temperature has been increased from 1200 K in the 50's up to more than 2000 K at the present time [1], reason why the nozzles and blades made principally with superalloys have become critical elements. The cost of these components is raised, owing principally to the cost of the materials as well as to their manufacturing process, representing approximately 30 % of the cost of the turbine.

Due to the high cost of the blades and the safety at which they must operate, the useful life of the blades must be optimized. For this, it is necessary to have available tools that allow to predict the useful remaining life of the gas turbine blades to determine if the blades can continue operating, if they can be rehabilitated or if they must stop operating to avoid catastrophic faults.

Nowadays methods exist to estimate the useful life of components that work at high temperature, which consider the interaction of fatigue phenomena and thermofluence. Among the methods to predict the useful remaining life for thermofluence, there exist those which relate the time and temperature and extrapolate information of thermofluence. Nevertheless, these models present inaccuracies that are caused by: a) dispersion of the material properties; b) mistakes in the determination of the temperature and stress; c) effects caused by corrosion and coating; and d) degradation of the material during operation [2].

Recently several articles have been published applying the conjugate calculation technique to predict the metal temperature of a three-dimensional gas turbine vane [3, 4, 5]. However there are few works on transient analyses [6] due principally to high computational expense and the lack of experimental data to compare to the results.

The main objective of this study is to predict the transitory profile of temperature inside the first stage blade caused by the process of take-off of the turbine using CFD.

DESCRIPTION OF ANALYSIS

The numerical analysis was conducted by using the CFD commercial code Fluent 6.1 [7] on the basis of the finite volume method. User defined functions were used for creating the numerical conditions of the flow and heat transfer in each time step.

Governing equations

The Navier–Stokes equations for rotating flows are applied. The mass conservation equations or continuity equation derived from the RNG theory is:

$$\frac{\partial \rho}{\partial t}+\frac{\partial}{\partial x_i}\left(\rho w_i\right)=S_m \qquad (1)$$

The momentum conservation equation for flows in rotating domains is modelled by

$$\frac{\partial}{\partial t}\left(\rho\mu_i\right)+\frac{\partial}{\partial x_j}\left(\rho w_i u_j\right)=-\frac{\partial p}{\partial x_i}+\frac{\partial T_{ij}}{\partial x_j} \qquad (2)$$
$$-\varepsilon_{jki}\Omega_j\rho\mu_k+\rho g_i+F_i$$

The energy conservation equation for rotating flows is described by

$$\frac{\partial}{\partial t}(\rho E)+\frac{\partial}{\partial x_i}\left[w_i(\rho E+p)\right]= \frac{\partial}{\partial x_i}\left[k_{eff}\left(\frac{\partial T}{\partial x_i}\right)-\sum_{j'}h_{j'}J_{j'}+u_j\left(\tau_{ij}\right)_{eff}\right]+S_h \quad (3)$$

Energy equation in solid regions includes only the heat flux due to conduction within the solid:

$$\frac{\partial}{\partial t}(\rho E)=\frac{\partial}{\partial x_i}\left(k\frac{\partial T}{\partial x_i}\right) \quad (4)$$

Equation (4) is solved simultaneously with the energy conservation equation (3) in the flow regions to yield a fully coupled conduction-convection heat transfer prediction.

The turbulence model considers the transport equations for κ and ε, provided as

$$\frac{\partial}{\partial t}(\rho\kappa)+\frac{\partial}{\partial x_i}(\rho u_i\kappa)=\frac{\partial}{\partial x_i}\left(\alpha_\kappa\mu_{eff}\frac{\partial\kappa}{\partial x_i}\right) + \mu_t S^2-\rho\varepsilon \quad (5)$$

and

$$\frac{\partial}{\partial t}(\rho\varepsilon)+\frac{\partial}{\partial x_i}(\rho u_i\varepsilon)=\frac{\partial}{\partial x_i}\left(\alpha_\varepsilon\mu_{eff}\frac{\partial\varepsilon}{\partial x_i}\right) + C_{1\varepsilon}\frac{\varepsilon}{\kappa}\mu_t S^2-C_{2\varepsilon}\rho\frac{\varepsilon^2}{\kappa}-R \quad (6)$$

In the high-Reynolds limit $\alpha_k=\alpha_\varepsilon\approx 1.393$, S is the modulus of the mean rate-of-strain tensor, which is defined as

$$S\equiv\left(2S_{ij}S_{ij}\right)^{1/2} \quad (7)$$

R in the equation (6) is given by

$$R=\frac{C\mu\rho\eta^3\left(1-\eta/\eta_0\right)}{1+\beta\eta^3}\frac{\varepsilon^2}{\kappa} \quad (8)$$

where

$\eta=S\kappa/\varepsilon$, $\eta_0\approx 4.38$, $\beta=0.012$, $C_{1\varepsilon}=1.42$, and $C_{2\varepsilon}=1.68$

Finally, ideal gas law was used as the equation of state.

Numerical methods

The turbulence model used was the two equation model RNG (renormalization group) κ-ε [8]. Likewise, in turbulence scalar transport, an algebraic model derived from RNG theory was applied. The SIMPLE algorithm was used to solve the discretized equations with spatial second order accuracy. In the internal circular passages, heat balance was made, using a convective heat transfer coefficient obtained from a previous study [5]. A compressible analysis was developed and thermal properties were set up taking into account the dependency on temperature.

Computational domain and grid

The computational domain consists of a fluid region around the rotor blade and a region of solid material that composes the blade. Figure 1 shows the computational grid on the blade surface (solid) and on the gas surface (fluid).

Hexaedron cells were applied in both solid and fluid regions. The number of cells is 27,680 around the blade and 16,224 inside the blade. The regions of the cooling air were not modelled.

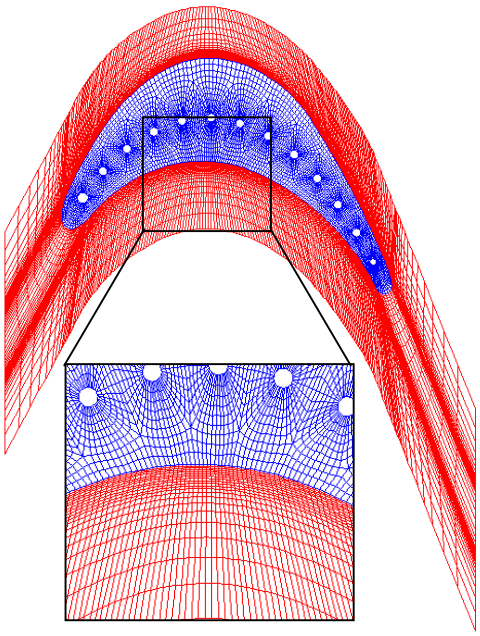

Figure 1: Grids on the gas and blade surfaces

Boundary conditions

The boundary conditions to the computational domain are presented in figure 2 and summarized in table 1. The variation of the gas and air temperature in space and time are presented in figure 3.

The heat transfer coefficient in the wall of the internal circular passages is taken from a study [5], where fully developed turbulent flow in the circular pipe is assumed. Inlet temperature was linearly related to the turbine inlet temperature and to the temperature of the air at the compressor outlet.

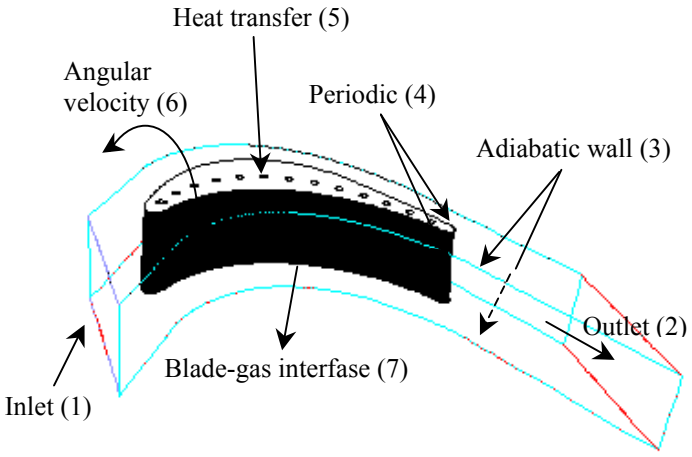

Figure 2: Location of the boundary conditions

Figure 3 shows time variations of inlet total temperature, both gases and air. These conditions were based on characteristic diagrams that simulate a hot start-up process of daily start operation of an actual gas turbine. The rest of the boundary conditions are fixed in time and space. The end walls were assumed adiabatic wall to consider a large blade where no changes occur in radial directions. Wall function [7] was used and the thermal conditions were computed to conjugate between inside and outside of the walls.

Time step for each transient calculation was set from 0.01 to 10, increasing as the time advanced.

RESULTS AND DISCUSSION

Figure 4 shows the vectors of relative velocity distribution in the bucket passage at 50% vane height. The maximum flow velocity of 920 m/s is reached in the throat of passage, the local minimum is on the vane pressure side and the bucket leading edges.

Figure 5 to Figure 7 show time variations of total temperature. They illustrate the temperature

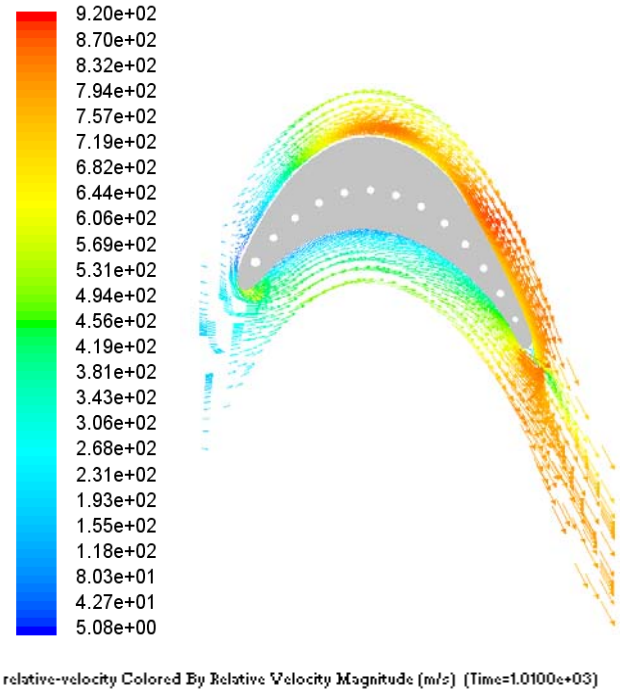

Figure 4: Vectors of relative velocity distribution

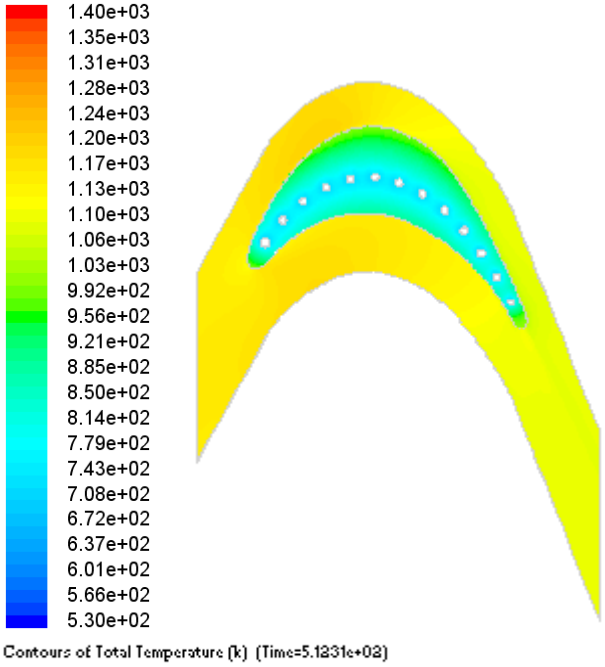

Figure 6: Total temperature contours in the bucket passage at 50% vane height (512 s).

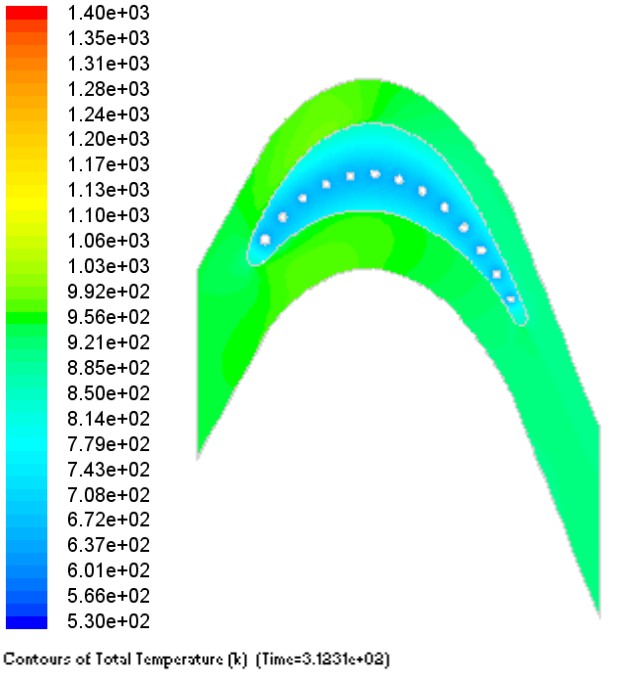

Figure 5: Total temperature contours in the bucket passage at 50% vane height (312 s).

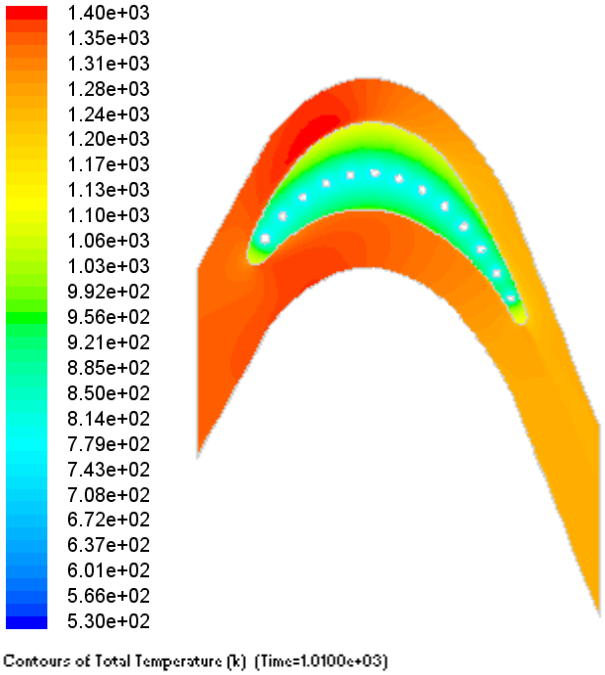

Figure 7: Total temperature contours in the bucket passage at 50% vane height (1010 s).

distribution in the external fluid (combustion gases) and bucket solid body. An asymmetric temperature field distribution can be appreciated in the solid body around the cooling passages due to bucket rotating effect.

The maximum temperature gradients appear in the trailing edge (ΔT=270 K) followed by the leading edge and the region between cooling holes and suction side (ΔT=250 K). These zones must to be taken into account in a succeeding thermal stress analysis, due to the severe gradient of the temperature.

It can be seen that temperature distribution in the blade is markedly influenced by unsteady conditions (Figure 3). The global temperature difference inside the blade increases as the difference of combustion gas and cooling air temperature increases, reaching roughly the value of 300 K. This is higher than temperature gradient presents in a steady-state analysis (220K).

On the other hand, if the initial conditions had been the corresponding ones to t=1010 s, without considering the variation of controlled temperatures, the steady-state would be reached in 180 seconds approximately, but the gradients of temperature would be very higher, affecting seriously the blade life through thermal fatigue.

CONCLUSIONS

The computations were able to simulate the heat transfer of the bucket during transient operation, being a contribution to transient analyses of conjugate heat transfer simulation in gas turbine blades. Temperature predictions were made in a reduced gas turbine blade model, considering time variations of total temperature both in the combustion gas and in the cooling air. However, definite conclusion in this regard may await more experimental data to compare to the results.

The maximum temperature gradients appear in the trailing edge followed by the leading edge. These severe gradients will seriously affect the blade life due to thermal fatigue.

In the future, work time variations of angular velocity and mass flow rate will be taken into account, as well as the whole blade model.

The present predictions will make it possible to estimate stress and creep strain loaded on the bucket and to assess the bucket remaining life based on the evaluation of the damage.

ABSTRACT

Simulation and parameter variation of novel gas turbine-based cycles require a simple yet reliable cooled gas turbine model that is easy to implement. This study proposes a generic cooling model using open-loop cooling. The model has been tuned to represent modern heavy-duty gas turbines in cooperation with the gas turbine manufacturers involved in the ENCAP (Enhanced Capture of CO_2, EU 6th Framework Programme) project, of which this work is a part. Additionally, a commercial gas turbine simulation tool has verified the results of the model. Besides the conventional working fluid air, the model has been investigated for a CO_2/H_2O working fluid typical for a semi-closed oxygen-combustion gas turbine cycle, since the cooling model will be used for simulation of such cycles and pre-combustion cycles within the ENCAP project.

INTRODUCTION

Simulation of gas turbine-based power cycles requires accurate modelling of the turbine cooling. However, the cooling models available in the literature are not always easy to implement, especially for novel power cycles using non-conventional working fluids.

In this study, a cooled gas turbine model has been developed. The main reason for proposing this model is to have a simple and generic method for use in general process simulators. The work is part of the ENCAP (Enhanced Capture of CO_2) project, an integrated project within the 6th EU Framework Programme. ENCAP's objective is to develop new pre-combustion carbon dioxide (CO_2) capture technologies for power generation. Carbon capture can reduce the CO_2 emissions from power production, thus mitigating climate change. Included in this project is the investigation of novel gas turbine-based power cycles with oxygen combustion and pre-combustion CO_2 capture. In cycles where the fuel is combusted in a nitrogen-free atmosphere (oxygen-combustion), the exhaust gas contains mainly CO_2 and steam; thus, CO_2 can be separated by condensation of the steam. In pre-combustion capture cycles, the fuel is processed into mainly hydrogen and CO_2 and the CO_2 is separated before the hydrogen is burnt. Simulation of such novel cycles requires a simple cooled gas turbine model that can easily be implemented within in-house or commercial simulation tools.

This paper presents the theory of the proposed cooling model and calculation results for air and CO_2/H_2O working fluids. The model has been tuned to represent a generic, large, state-of-the-art F-Class gas turbine in cooperation with the gas turbine manufacturers participating in the ENCAP project, Alstom and Siemens. The model has been verified by comparison to the simulation tool Thermoflex [1].

BACKGROUND

Increased turbine inlet temperature, matched with an optimised pressure ratio, generally raises the gas turbine efficiency, as well as the specific work. However, material issues restrain the allowable temperatures. Thus, turbine cooling is necessary when using turbine inlet temperatures above what is acceptable for turbine blade materials. For a given level of cooling technology, a turbine inlet temperature raise results in augmented efficiency, up to a point where the gain from increased temperature is outbalanced by the losses caused by the cooling. The mixing of the hot gas and the cooling fluid results in losses due to:

1) reduced temperature of the gas expanding through the turbine, which decreases the turbine work
2) reduced momentum of the hot gas as the cooling fluid has to be accelerated to the speed and direction of the hot gas
3) disturbances to the flow profile around the blades, which increase the flow losses.

In most gas turbines, blade cooling is accomplished by air extracted from the compressor. In convective cooling, the air flows through the blades, cooling them by convection, then the air exits from the blades and mixes with the hot gas. Film cooling is used in some more advanced designs. Here, the air exits from the blades through a large number of small holes, forming a film that partially shields the blades from the hot gases. Recently, some large gas turbines, intended for combined cycles, using steam from the bottoming cycle as a coolant in a closed loop, have been introduced. The heated steam is led back to the steam cycle, improving the overall plant efficiency.

A detailed analysis of turbine cooling is complex, especially for film cooling. The analysis requires a stage-by-stage method with rigorous heat transfer calculation inside and outside the blade, as well as through the blade wall. Such a detailed analysis may produce information about blade surface temperature profiles. However, for cycle analysis aiming at efficiency prediction for novel cycles, a simplified procedure is needed to achieve a certain number of calculations for various cycle

configurations and parameter values. Most of the models presented in the literature are unsuitable for this purpose. Horlock et al. [2] give an overview of some models suggested in the literature. They divide these into models that consider:

1) the effect of continuous cooling on the turbine expansion line and the resulting changes in polytropic efficiency and reheat factor
2) stage-by-stage analysis of the effect of cooling on individual blade rows.

Horlock et al. [2] suggested a model belonging to the second group. This method estimates the cooling fluid flow rate for each blade row and the losses in stagnation temperature and pressure resulting from the mixing of the cooling fluid and the hot gas. The method applies to convective as well as film cooling.

Jordal et al. [3] presented three models, one belonging to the first group, originally presented by Bolland and Stadaas [4], and two belonging to the second group. The purpose of the paper was to investigate the behaviour of a specified cooled gas turbine when the working fluid was changed from air to CO_2/H_2O. It was found that a CO_2/H_2O gas turbine would need some re-design, due to the lower specific heat ratio for this working fluid compared with air. For a given pressure ratio, both the compression enthalpy increase and the expansion enthalpy drop are lower for CO_2/H_2O.

The model presented by Bolland and Stadaas [4], belonging to the first group, is based on one model of Elmasri [5]. In this model, the turbine is considered to be an expander where work is continuously extracted through the walls. The expansion process is divided into a large number of steps and in each step, three parts are calculated:

1) adiabatic expansion (work extraction)
2) mixing of cooling fluid and hot gas at constant pressure (loss of stagnation temperature)
3) mixing of cooling fluid and hot gas at constant enthalpy (loss of stagnation pressure).

THEORY OF THE MODEL

The layout of the proposed cooled gas turbine model is shown in Figure 1. In this model, the cooling fluid, taken from the compressor exit, is mixed with the hot combustion gas before the turbine inlet. The temperature at which the expansion begins is the ISO TIT[1] [6]. The

[1] The ISO TIT is the temperature resulting from mixing all cooling flows and the combustor exit flow in a single point.

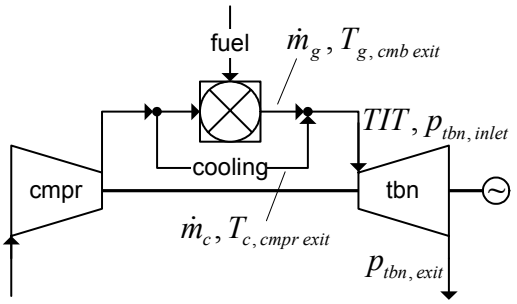

Figure 1: The generic cooled gas turbine model

expansion work is calculated using the sum of the combustor exit and cooling fluid flow rates. Three adjustable parameters (b, K and s) are tuned in order to represent a gas turbine at a given technology level. The cooling model calculates the required cooling fluid flow rate and the reduction of the turbine polytropic efficiency due to the cooling. Compared with models found in the literature, this model is simpler, using merely cooling fluid from the compressor exit and three parameters. The model has been developed for design-point calculations.

The cooling fluid mass flow rate is calculated with Equation (1). The derivation of this equation is described in the appendix.

$$\frac{\dot{m}_c c_{p,c}}{\dot{m}_g c_{p,g}} = b\left(\frac{T_{g,cmb\ exit} - T_b}{T_b - T_{c,cmpr\ exit}}\right)^s \qquad (1)$$

In this equation, b and s are adjustable parameters and T_b is the maximum sustainable blade surface metal temperature. Since the cooling model uses a lumped model approach, no turbine geometry is specified and the blade temperature T_b is a generic surface temperature that describes the ability of the blade material to withstand high gas temperatures. The specific heat capacities $c_{p,c}$ and $c_{p,g}$ are calculated (Equation (2)) as the average values between the blade temperature and the compressor exit and combustor exit temperatures, respectively. The blade enthalpy at compressor exit conditions ($h_{b,c}$) is calculated at the blade temperature and the compressor exit pressure and composition. The blade enthalpy at combustor exit conditions ($h_{b,g}$) is calculated at the same temperature, but using the combustor exit pressure and composition.

$$c_{p,c} = \frac{h_{b,c} - h_{c,cmpr\ exit}}{T_b - T_{c,cmpr\ exit}};\ c_{p,g} = \frac{h_{g,cmb\ exit} - h_{b,g}}{T_{g,cmb\ exit} - T_b} \qquad (2)$$

Mixing of the cooling fluid in the hot gas path reduces the momentum of the hot gas, as the

cooling fluid has to be accelerated to the speed and direction of the hot gas. This can be expressed as a pressure loss for the hot gas, calculated with Equation (3) [4], which is a momentum balance for the mixing. The pressure loss can be added to the combustor pressure loss, or it can be converted to a reduction of the turbine polytropic efficiency. Equation (4) relates the pressure drop to the loss of polytropic efficiency. Equation (5) defines the efficiency loss ($\Delta\eta$).

$$\frac{\Delta p}{p_{tbn,\,inlet}} = -\frac{\dot{m}_c}{\dot{m}_g}\kappa_g M_g{}^2 \zeta = -\frac{\dot{m}_c}{\dot{m}_g} K;\ \Delta p < 0 \quad (3)$$

$$\frac{\eta_{p,\,uc\,tbn} + \Delta\eta}{\eta_{p,\,uc\,tbn}} = \frac{\ln\left(p_{tbn,\,exit} \,/\, p_{tbn,\,inlet}\right)}{\ln\left(p_{tbn,\,exit} \,/\, \left(p_{tbn,\,inlet} + \Delta p\right)\right)} \quad (4)$$

$$\eta_{p,\,c\,tbn} = \eta_{p,\,uc\,tbn} - \Delta\eta;\ \Delta\eta > 0 \quad (5)$$

The mixing loss factor ζ accounts for the direction in which the cooling fluid is injected into the hot gas flow. If the injection is perpendicular to the hot gas flow, ζ is in principle equal to unity. The heat capacity ratio (κ_g), the Mach number (M_g) and ζ are summarized in the parameter K. For most air gas turbines, κ_g is about 1.3 and M_g is 0.6-0.8. A rough estimate gives ζ as 0.3-0.6. Hence, K should be in the range 0.15-0.5. It should be noted that $p_{tbn,\,exit}$ can be selected not only as the turbine exit pressure, but also as an intermediate pressure in the expansion path. When the expansion is divided into a cooled and an uncooled part, it can be convenient to select $p_{tbn,\,exit}$ as the cooled turbine exit pressure. Observe that a higher turbine exit pressure increases the efficiency correction, which depends on the turbine pressure ratio.

To calculate the compression and expansion end point states, the polytropic efficiencies are converted to isentropic efficiencies. The conversion follows the ASME method [7], [8]. For the turbine, the polytropic efficiency including the cooling loss ($\eta_{p,\,c\,tbn}$) is used. The gas turbine net efficiency is calculated with Equation (6), where the compressor work is defined as negative.

$$\eta_{net} = \eta_{mech}\eta_{gen}\left(W_{tbn} + W_{cmpr}\right)\Big/\left(\dot{m}_{fuel} LHV\right) \quad (6)$$

INPUT DATA AND PARAMETER TUNING

Data for a generic gas turbine (Table 1) were supplied by the ENCAP project partners Siemens and Alstom. These values represent well the technology level of large modern gas turbines, like Siemens' SGT5-4000F (formerly V94.3A) and Alstom's GT 26B. This technology level is comparable to that of other manufacturers' gas turbines, like GE's 9351F and Mitsubishi's 701F. The data were derived from actual gas turbine performance data provided by the manufacturers. However, since these data are confidential, the model was set up as a generic gas turbine model that resembles, but does not necessarily replicate, the performance of the aforesaid gas turbines.

$\eta_{p,\,uc\,tbn}$ [%]	87.94	s [-]	1

Table 1: Fixed values, target values and tuned parameters for the generic model

All calculations were performed in the simulation tool gPROMS [9]. Thermodynamic properties were calculated with Multiflash [10], with the advanced Redlich-Kwong-Soave equation of state. Complete combustion and no dissociation were assumed. The ambient air and natural gas specifications are shown in Table 3 in the appendix.

The values of b, K and s were found by tuning the model to the data in Table 1. The parameter s was set to 1 since this gave the most reasonable behaviour of the model. The parameters b and K were adjusted to yield a net efficiency of 38.50 % at a combustor exit temperature of 1425 °C with a cooling fraction of 22 %, at the same time as the maximum efficiency appeared at a combustor exit temperature of 1350 °C. To meet these requirements, the polytropic efficiency of the uncooled turbine had to be reduced from the original value of 89 %. The tuning resulted in the cooling model parameter values in Table 1. Results

[2] The cooling fraction is the cooling fluid mass flow rate divided by the compressor inlet mass flow rate.

from the gas turbine model for these parameters are shown in Table 2.

VERIFICATION

After tuning the generic model to manufacturer data, it was compared to a cooled gas turbine model in the simulation tool Thermoflex [1] as verification. The Thermoflex cooling model is more complex than the generic model in that it models the cooling of the stator and rotor of each stage [1], [11]. The Thermoflex model included a compressor, a combustor and three cooled turbine stages with cooling air taken from the compressor exit. Film cooling was used for the first stage; convective cooling for the second and third stages. The third stage required cooling only for combustor temperatures above 1700 °C for *PR*=17. The input data for the Thermoflex model was the same as for the generic model, except for the values in Table 4 in the appendix.

The Thermoflex model was tuned to give the same gross work output, fuel mass flow rate, turbine outlet temperature and cooling fraction as the generic model base case, see Table 5 in the appendix. The Thermoflex cooling model includes

[3] Based on a compressor inlet mass flow rate of 100 kg/s.
[4] The specific work is defined as the total gross work divided by the compressor inlet mass flow rate.

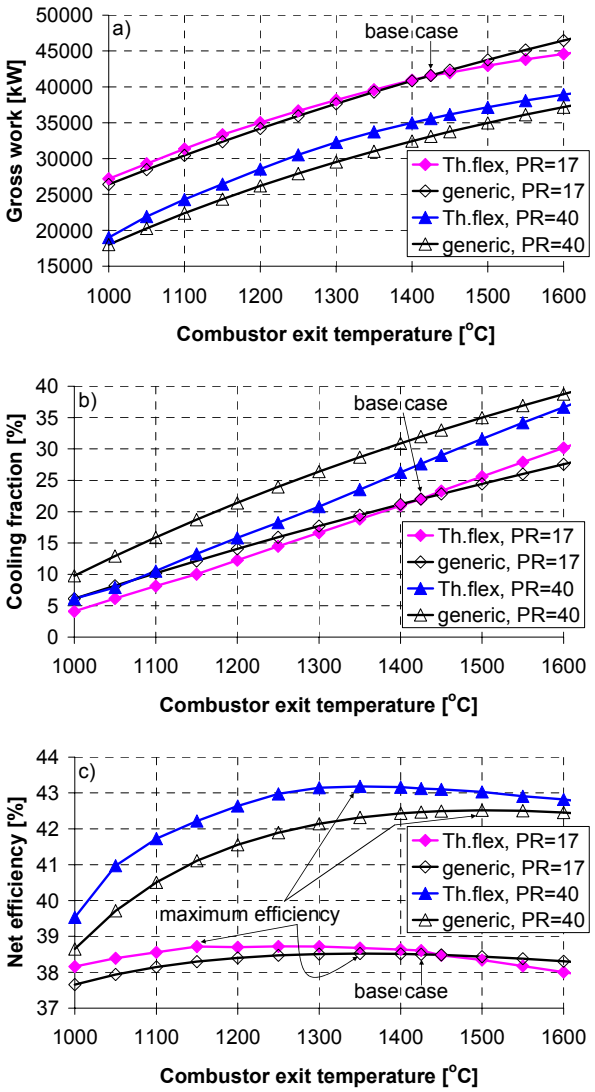

Figure 2: Comparisons of the generic and the Thermoflex models

the parameter *ARC* that corresponds to *b* in the generic model and the parameter *Y* that corresponds to *K*. To tune the Thermoflex model, *ARC* had to be increased to 2.075 times its default value and *Y* had to be decreased to 0.21 times its default value.

The generic model was compared with the Thermoflex model for the combustor exit temperatures 1000-1600 °C, for *PR*=17 and *PR*=40. For *PR*=40, the same *ARC* and *Y* values as for *PR*=17 were used. As can be seen in Figure 2a, the Thermoflex model has a lower work output than the generic model at high temperatures for *PR*=17. For *PR*=40, the Thermoflex model has a higher work output for all temperatures. Comparisons of the fuel mass flow rate and the

turbine exit temperature show the same trends as the work output comparison.

Figure 2b shows the comparison of the cooling fractions. It can be seen that the generic model depends more on the pressure ratio than the Thermoflex model. This is shown by the larger distance between the curves for *PR*=17 and *PR*=40 for the generic model than for the Thermoflex model. For *PR*=40, the generic model gives a significantly higher cooling fraction than the Thermoflex model, for example, at a combustor exit temperature of 1250 °C, the generic model calculates a 30 % higher cooling fraction than the Thermoflex model. However, the difference is smaller at higher combustor exit temperatures since the model was tuned at a combustor exit temperature of 1425 °C. Furthermore, the Thermoflex model is more dependent on the hot gas temperature, as the curves for this model have steeper slopes than the curves for the generic model. The Thermoflex cases with lower cooling fractions than the generic model have correspondingly higher power outputs and net efficiencies.

Figure 2c shows that the Thermoflex model locates the maximum net efficiency at lower combustor exit temperatures for both pressure ratios compared with the generic model. In total, the comparisons between the generic model and the Thermoflex model show that the two models behave similarly.

Another way of verifying the model is to compare the values of *b* and *K* resulting from the tuning with the theoretically estimated intervals for these parameters. The value of *b*, which is estimated in the appendix, depends on the cooling method: convective or film cooling. In this study, convective cooling is applied and the value of *s* is set to 1 (see the appendix). The value of *b* for two convectively cooled stages should be 0.2-0.7 with a conservative estimate of the cooling efficiency and 0.1-0.3 with a less conservative cooling efficiency estimate. The value of *b*=0.1884 falls within the interval estimated for a higher cooling efficiency. The value of *K*=0.237 falls within the range estimated in the theory section (0.15-0.5).

PARAMETER VARIATION

The behaviour of the generic cooled gas turbine model was investigated for different combustor exit temperatures (1000-1600 °C) and pressure ratios (10-40). The compressor inlet mass flow rate was 100 kg/s in all cases.

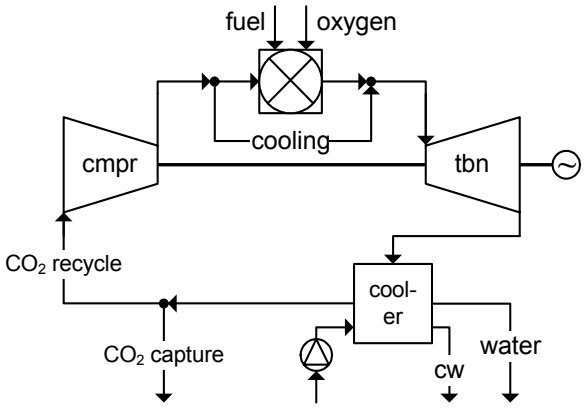

Figure 3: Semi-closed oxygen-combustion gas turbine (SCOC-GT) cycle

Figure 4a shows that for a specific pressure ratio, increasing the combustor exit temperature raises the net efficiency up to a point where the cooling fluid flow rate becomes so large that the losses caused by the cooling outbalance the benefits of the higher temperature. The maximum net efficiency is higher, and occurs at higher combustor exit temperatures, for higher pressure ratios.

Figure 4b and Figure 4c show that a higher pressure ratio for a specific combustor exit temperature results in a higher cooling fraction and thus a lower TIT. Figure 4d shows that the larger cooling fraction for higher pressure ratios reduces the turbine polytropic efficiency more, except for *PR*=10 and *PR*=20 that have approximately the same cooled turbine polytropic efficiencies.

SEMI-CLOSED OXYGEN-COMBUSTION GAS TURBINE CYCLE

The generic cooling model was used for simulation of a semi-closed oxygen-combustion gas turbine (SCOC-GT) cycle [12]. In the SCOC-GT, shown in Figure 3, the fuel is combusted with an oxygen-rich stream. Thus, the exhaust gas mainly contains CO_2 and steam, which can be separated by cooling the exhaust gas in the cooler shown in the figure. In the cooler, part of the steam condenses and is thereby removed. The cooler can be partially replaced by a heat recovery steam generator that generates steam for a steam bottoming cycle, augmenting the cycle efficiency. A steam cycle was not included in this study as the main purpose was to study the turbine cooling and not the cycle efficiency. A large part of the gaseous stream from the cooler is recycled to the compressor, to control the combustor temperature and provide a nitrogen-free working fluid. The remaining part of

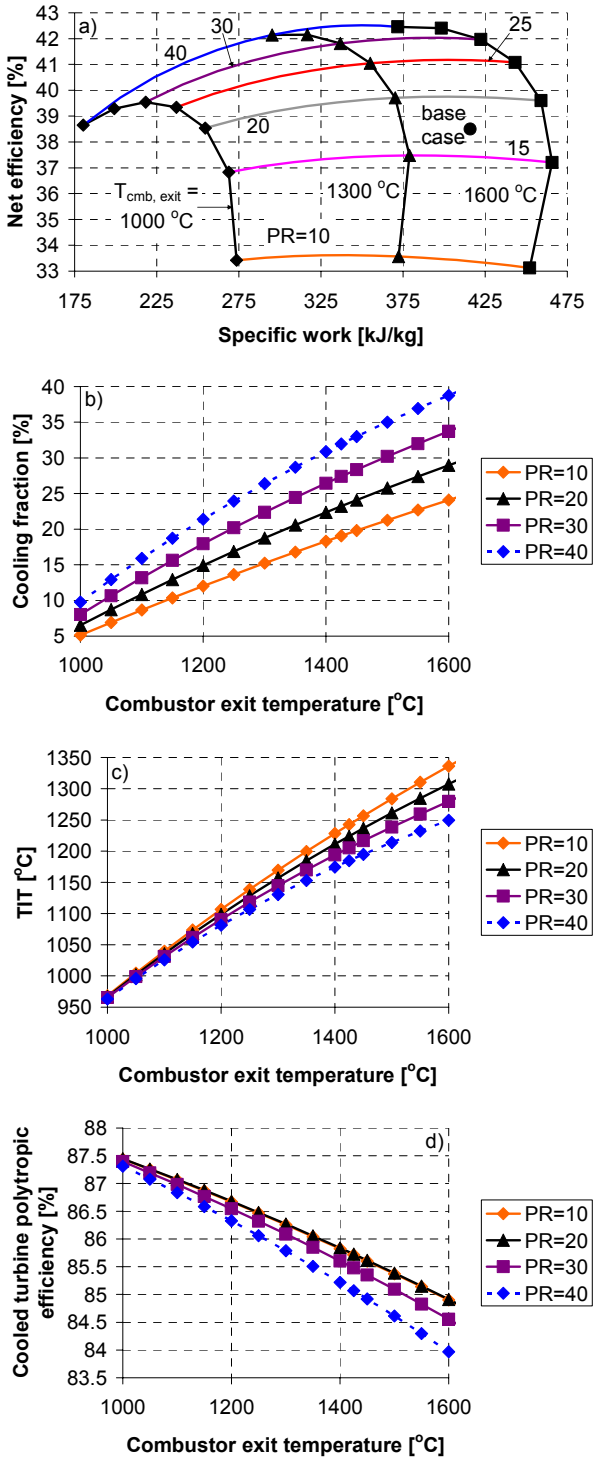

Figure 4: Results for the generic cooled gas turbine

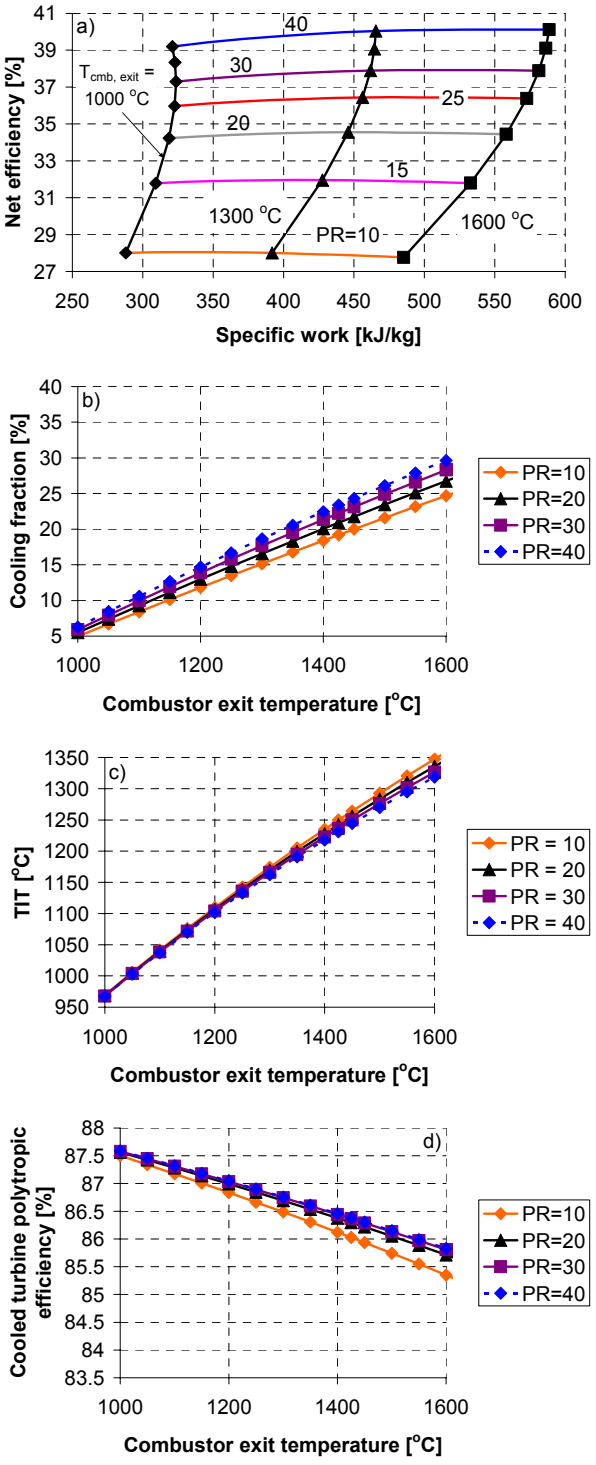

Figure 5: Results for the cooled SCOC-GT cycle

the gaseous stream can be compressed and sequestered.

The SCOC-GT was simulated with the same input data as the air gas turbine (air-GT), except for the data in Table 6 in the appendix. The work required generating the oxygen-rich stream by, for example, cryogenic distillation, the cooling water pump work and the CO_2 compression work were not included in the efficiency. The cooler was modelled as a counter-current heat exchanger and a flash chamber. The values of the parameters b, K, s and $\eta_{p,\ uc\ tbn}$ were the same as for the air-GT. The

cooling model considers the change of the cooling fluid and hot gas compositions by changed specific heat capacities. However, a CO_2/H_2O turbine with the same polytropic efficiency as the air turbine would require another design; this might necessitate other values for *b*, *K* and *s*. On the other hand, this supposition is countered by:

- *b* (see the appendix) depends on the Stanton number and the geometry. It is reasonable to assume that the Stanton number is about the same for both working fluids. A changed turbine design affects the geometry parameter, but it is impossible to quantify the change.
- *K* (see Equation [3]) depends on:
  - the heat capacity ratio, which is only slightly smaller for CO_2/H_2O than for air
  - the Mach number, which should be about the same for both turbines
  - the mixing loss factor, which can be assumed to be the about same for both working fluids.
- It is valid to assume that *s* has the same value for the CO_2/H_2O turbine as for the air turbine, since this parameter describes the type of cooling (convective or film).

Results for the SCOC-GT base case are shown in Table 2, and in Table 7 in the appendix. In addition, the behaviour of the SCOC-GT has been investigated for different combustor exit temperatures (1000-1600 °C) and pressure ratios (10-40).

Figure 5a shows that the SCOC-GT has lower net efficiency and higher specific work than the air-GT for all cases in the investigated pressure and temperature range. Since CO_2/H_2O has a lower specific heat ratio than air, both the compressor enthalpy increase and the turbine enthalpy decrease are lower in the SCOC-GT than in the air-GT for a specific pressure ratio. Although the SCOC-GT compressor work is lower than for the air-GT, the net efficiency is lower since the SCOC-GT turbine work is lower and the fuel flow rate is higher. However, as the compressor work reduction for the SCOC-GT is so large, the specific work is higher than for the air-GT.

Figure 5b shows that the SCOC-GT requires a smaller cooling fraction at a specified pressure ratio and combustor exit temperature than the air-GT, except for *PR*=10 where the required cooling fractions are about the same. The SCOC-GT has a lower compressor exit temperature and a higher cooling fluid heat capacity. According to Equation (1), this implies a lower cooling fraction. However, the SCOC-GT has higher hot gas heat capacity and combustor exit mass flow rate, which increase the cooling fraction. In total, the SCOC-GT has a lower cooling fraction than the air-GT above *PR*=10. Additionally, the impact of the pressure ratio on the cooling fraction is smaller for the SCOC-GT, since the compressor specific work and exit temperature increase less with raised pressure ratio for the SCOC-GT than for the air-GT. The smaller cooling fraction for the SCOC-GT compared with the air-GT results in higher TITs for all pressure ratios above 10, as shown in Figure 5c.

As a consequence of the lower cooling fractions, the reduction of the cooled turbine polytropic efficiency is smaller for the SCOC-GT (Figure 5d) than for the air-GT (Figure 4d). However, for the SCOC-GT, the reduction of the polytropic efficiency is largest for the lowest pressure ratio, while the highest pressure ratio has the lowest reduction. Tendencies of this behaviour can be seen for the air-GT in Figure 4d, where the efficiency reductions for *PR*=10 and *PR*=20 are the same, but for higher pressure ratios; a higher pressure ratio gives a larger reduction. The pressure drop due to the cooling calculated with Equation (3) is always larger for a situation with a larger cooling fraction. However, the conversion of the pressure drop to a polytropic efficiency reduction with Equation (4) will not always result in a larger efficiency reduction for a case with a larger cooling fraction.

DISCUSSION

A simple cooled gas turbine model will show deviations from the behaviour of a real gas turbine, which will increase with the distance from the operating point for which the model was tuned. Additionally, assuming a fixed cooling technology level for a broad range of pressure ratios and turbine inlet temperatures is a very simplified approach. However, including turbine cooling in the model gives more realistic results than using an uncooled model. A cooling model ensures that the efficiency has a maximum for a given pressure ratio and cannot be increased infinitely by raising the combustion temperature.

In the proposed cooling model, all of the cooling fluid is mixed with the combustor exit gas before the turbine inlet. Thus, the whole thermodynamic mixing loss is taken at the turbine inlet. As a result, the mixing losses are overestimated compared with a real turbine, where the mixing of the hot gas and

the coolant takes place at, on average, a smaller temperature difference. In a real gas turbine, the cooling air is extracted from the compressor at different pressure levels to be mixed with the hot gas at several locations in the turbine. When tuning the cooling model to real gas turbine data, the overestimated mixing loss at the turbine inlet is compensated for by reducing the value of the parameter *K*.

The cooled generic gas turbine model will be used for simulation of, for example, combined cycles, oxygen-combustion cycles and pre-combustion cycles. When optimising the efficiency of a gas turbine cycle where the energy in the gas turbine exhaust gas is recovered, it may benefit the overall cycle efficiency to operate at a point where the simple cycle gas turbine efficiency is not maximized. A high turbine exit enthalpy means that there is more energy to recover for a bottoming cycle of some kind.

CONCLUSIONS

This paper presents a simple, generic, cooled gas turbine model, which can be used for simulation and parameter variation of novel and conventional cycles. The model has been tuned to represent a generic large state-of-the-art F-Class gas turbine. The behaviour of the model has been verified as reasonable for such a gas turbine by the gas turbine manufacturers that participate in the ENCAP project, Siemens and Alstom. In addition, the model compares reasonably well with the cooled turbine model in the simulation tool Thermoflex.

In addition to a cooled air gas turbine, the cooling model was used to simulate a semi-closed oxygen-combustion gas turbine cycle, where the working fluid is mainly a mixture of CO_2 and steam. Parameter variations show that the behaviour of the cooled semi-closed cycle is represented reasonably well by the generic model.

Derivation of Equation (1)

The heat transfer between the cooling fluid in the blade and the hot gas is given by Equation (7).

$$\begin{aligned} Q &= \dot{m}_c c_{p,c}\left(T_{c,o}-T_{c,i}\right) = \\ &= \dot{m}_g c_{p,g}\left(T_{g,i}-T_{g,o}\right) = h_{T,g} A_Q \left(T_{g,i}-T_b\right) \end{aligned} \quad (7)$$

The cooling efficiency, η_c, is defined for convective and film cooling in Equation (8).

$$\eta_c = \frac{T_{c,o}-T_{c,i}}{T_b-T_{c,i}}\ (convective);\ \eta_c = \frac{T_{c,o}-T_{c,i}}{T_{g,i}-T_{c,i}}\ (film) \quad (8)$$

[5] The amount of oxygen supplied (moles) divided by the amount of oxygen required for stoichiometric combustion.

The ratio α between the heat transfer area, A_Q, and the hot gas cross-section area, A_c, is assumed to be constant (Equation (9)). The cross-section area is found from the continuity equation.

$$\alpha = A_Q / A_c;\ A_c = \dot{m}_g / \left(\rho_g u_g\right) \quad (9)$$

The convective cooling efficiency is inserted in Equation (7) to remove the cooling fluid outlet temperature and Equation (9) is inserted to remove the heat transfer area. Equation (10) shows the resulting expression, note that this equation contains the Stanton number (Equation (11)).

$$\frac{\dot{m}_c c_{p,c}}{\dot{m}_g c_{p,g}} = \alpha \frac{h_{T,g}}{c_{p,g}\rho_g u_g} \frac{T_{g,i}-T_b}{\eta_c\left(T_b-T_{c,i}\right)} \quad (10)$$

$$\mathrm{St} = h_{T,g} / \left(c_{p,g}\rho_g u_g\right) \quad (11)$$

Convective cooling

For convective cooling, the cooling efficiency is not proportional to the hot gas inlet temperature. Thus, Equation (10) can be rewritten as Equation (12). The parameter b replaces the constant α, the St number and the cooling efficiency. The constant α is 10-20 for one cooled stage and 20-40 for two cooled stages. The St number is approximately 0.005 for blade cooling. Louis et al. [13] give the cooling efficiency as 0.3-0.5, Horlock [14] gives 0.6-0.8. Thus, with a conservative estimate of the cooling efficiency (0.3-0.5), b should be 0.1-0.3 for one cooled stage and 0.2-0.7 for two cooled stages. With a less conservative estimate of the cooling efficiency (0.6-0.8), b should be 0.1-0.2 for one cooled stage and 0.1-0.3 for two cooled stages. Equation (12) is the same as Equation (14) with s=1.

$$\frac{\dot{m}_c c_{p,c}}{\dot{m}_g c_{p,g}} = \frac{\alpha \mathrm{St}}{\eta_c}\left(\frac{T_{g,i}-T_b}{T_b-T_{c,i}}\right) = b\left(\frac{T_{g,i}-T_b}{T_b-T_{c,i}}\right) \quad (12)$$

Film cooling

For film cooling, the cooling efficiency is proportional to the inverse of hot gas inlet temperature, but the dependence is also influenced by the cooling fluid temperature. Consequently, Equation (10) can be rewritten as Equation (13).

$$\frac{\dot{m}_c c_{p,c}}{\dot{m}_g c_{p,g}} \propto \alpha \mathrm{St}\left(\frac{T_{g,i}-T_b}{T_b-T_{c,i}}\right) T_{g,i} \quad (13)$$

When $\alpha \cdot$St is replaced by b and the impact of the hot gas inlet temperature is included by the parameter s, Equation (14) results. s is in the range of 1 to 2, where 1 represents convective cooling. b should be 0.05-0.1 for one cooled stage and 0.1-0.2 for two cooled stages.

$$\frac{\dot{m}_c c_{p,c}}{\dot{m}_g c_{p,g}} = b\left(\frac{T_{g,i}-T_b}{T_b-T_{c,i}}\right)^s \quad (14)$$

MODELING OF AN IGCC PLANT BASED ON AN OXY-FUEL COMBUSTION COMBINED CYCLE

Philippe MATHIEU[1] and Frédéric VAN LOO
University of Liège
Department of Mechanical Engineering
Belgium

ABSTRACT

The objective of the paper is to show that a novel IGCC plant based on an oxy-fuel Matiant combined cycle is a possible alternative to a standard IGCC with pre-combustion capture from the performance viewpoint. From recent studies on new IGCC plants ranging in size from 350-800 MWe and using commercially available physical absorption systems, the average values of energy penalties are around 15% and of CO_2 capture rates within 80-90% per kWh generated. The FutureGen project recently developed in USA is designed to use a 275 MWe IGCC with pre-combustion capture with the objective to evaluate the performance and reduce substantially the costs of both electricity with capture and of hydrogen.
The proposed IGCC is a combination of an O_2/CO_2 gas turbine power cycle with reheat and a steam cycle with 2 pressure levels and a reheat in the heat recovery steam generator. Here a coal gasification unit with clean-up of the syngas is added upstream of the combustion chambers. The cleaned syngas $CO+H_2$ is feeding the oxy-fuel Matiant cycle. After combustion in pure oxygen, the reaction products CO_2 and water are nearly totally extracted out of the cycle by using a cooler/separator. The proposed IGCC takes advantage of the already existing air separation unit which has to be sized in order to produce the total amount of O_2 required.
All in all, the performance of the proposed IGCC cycle is similar to the one of an IGCC with pre-combustion capture but now the CO_2 retention rate is nearly 100% instead of 90%. However the turbo-machines operating on CO_2/water mixtures require a new design and are not commercially available today. In this paper, a sensitivity analysis on the basic parameters is carried out and the best configuration is derived from the discussion of the results.

INTRODUCTION

Deep reductions in CO_2 emissions are critically needed to meet the UNFCCC target of stabilising GreenHouse Gases "*at a level, which will prevent dangerous anthropogenic interference with the climate system*" but without indicating a figure for that level. For example, ensuring an "acceptable" level of 550ppmv in CO_2-equivalent concentration would imply a 80-90% reduction in carbon emissions by the end of the 21st century and by 50% from 2030, much beyond the modest 5% target for world emissions agreed in the 1997 Kyoto protocol [1]. If coal has to be used in this context, such a significant CO_2 emissions reduction is possible only if coal is converted efficiently and cleanly in energy, that means that

[1] Phone : +32-4-3669268 – E-mail : pmathieu@ulg.ac.be

old and low-efficient pulverized-coal-fired power plants be replaced by advanced IGCC plants. An extensive removal of CO_2 from flue gas (post-combustion de-carbonisation) and fuel gas (pre-combustion de-carbonisation) should play an important role but at the cost, however, of a significant loss of plant efficiency and power output [2]. On the other hand, if the world is evolving towards a carbon-free economy, Zero Emissions Technologies are further alternatives likely to play a role within this mix of technologies, as burning fossil fuels will remain a cheap option for a long time, especially in developing countries where huge reserves of coal are still to be exploited. The aim of the present paper is to introduce the technical principles underpinning a nearly zero emission IGCC and compare the performance to the same IGCC with pre-combustion capture.

THE NEARLY ZERO EMISSION IGCC

Pre-combustion systems process the primary fuel in a reactor to produce separate streams of CO_2 for storage and H_2 which is used as a fuel [3-8]. Oxy-fuel combustion uses oxygen instead of air for combustion, producing a flue gas that is mainly H_2O and CO_2 that is readily captured, and is an option still under development. The oxy-fuel combustion process eliminates thus nitrogen from the flue gas. According to the flue gas recycling rate, the flame temperature varies from about 1300°C with a large recycle flow to over 3500°C with no recycle and pure oxygen used for combustion.

In this work, the oxy-fuel combustion power cycle is an O_2/CO_2 cycle, called the MATIANT cycle in the literature [11-18]. In such a cycle, CO_2 is used as the cycle working fluid.Water is extracted from the flue gas, a mixture of water and CO_2, in a cooler/separator while the CO_2 generated in the combustion process is extracted from the recycled CO_2 by opening a valve, either before or after the GT compressor. The key advantage compared to traditional capture methods is the ability to capture 99.5%vol of the CO_2 generated in the combustion chamber as well as nearly all other pollutants, mainly NO_x. This benefit does however come with a cost : a penalty on performance due to production of nearly pure O_2 through cryogenic separation and

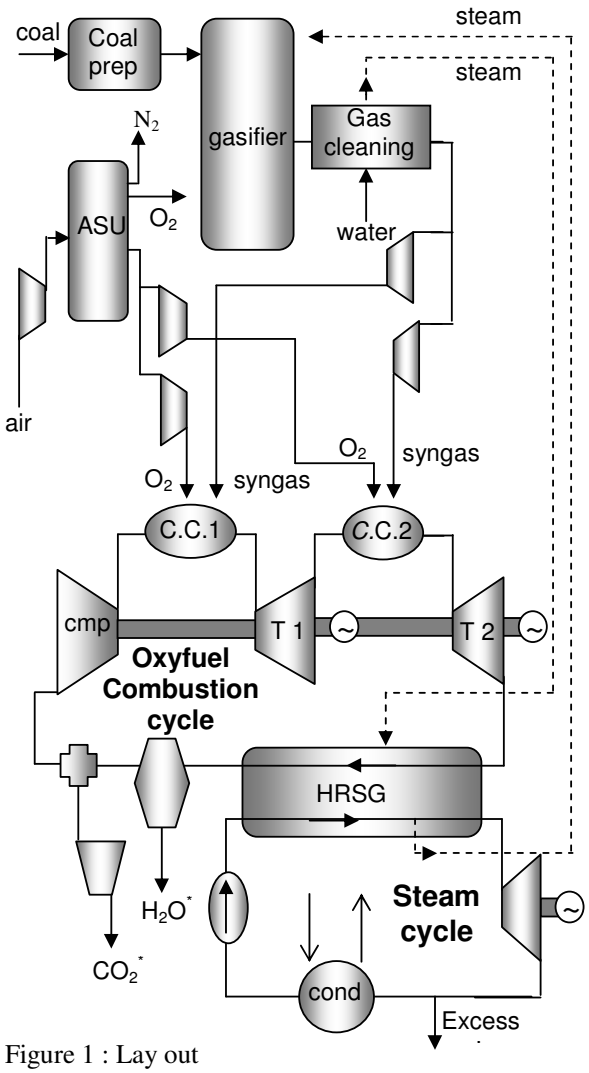

Figure 1 : Lay out

to the compression of CO_2 up to the required delivery pressure for transportation and storage (above 110 bar). However an ASU is already existing in a standard IGCC producing the needed oxygen in the gasification unit. Consequently if this latter feeds a Matiant cycle with a cleaned syngas, the O_2 required for its combustion in stoichiometric proportions may come from the existing ASU provided its production is adapted to the new need. On top, the power consumption of auxiliaries in a standard IGCC is not more than around 6% of the net power output. That is why the O_2 production in the proposed system should be much less penalizing than in an oxy-fuel combustion cycle alone. Figure 1 shows the law out of an IGCC plant based on the Matiant cycle used in a combined cycle configuration. It is

represented on figure 2 as a closed loop O_2/CO_2 Brayton gas cycle with an adiabatic compressor and a staged expansion, namely a reheat in a second combustion chamber, and with 2 near – isobaric processes, namely in the 2 combustion chambers and in the cooling of the flue gas down to the compressor inlet temperature. O_2 is produced in a cryogenic air separation unit (ASU) consuming a lot of electricity, i.e. 0.25kWh/kg O_2 at 1.7 bar, 15°C and a 95% purity (95% mol CO_2 and 5% mol Argon, the other impurities such as nitrogen being in negligible amounts) [19].

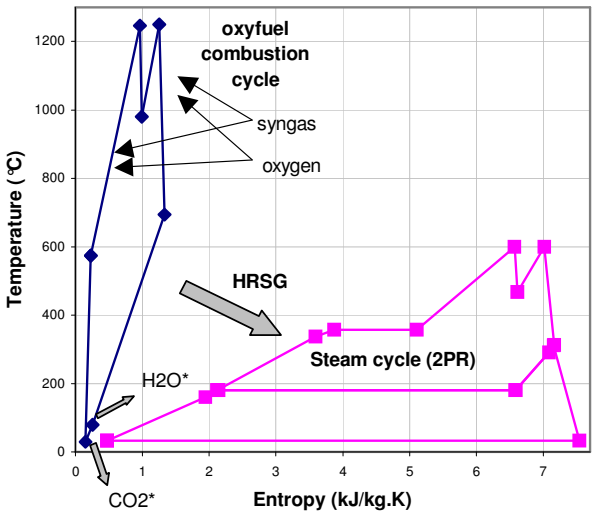

Figure 2: T-s diagram for the IGCC based on a MATIANT cycle

The upper cycle pressure is above the CO_2 critical pressure (73 bar ; 30 °C), 110 – 150 bar being the pressure required for CO_2 transportation under liquid or supercritical state. The heat of the expander exhaust gas is given up to a steam cycle within a heat recovery steam generator with 2 pressure levels and a reheat. In this modelling, the inlet HRSG temperature is limited at 700 °C for technological reasons. At the HRSG outlet, the flue gas is further cooled in a cooler/separator, cooled by an external water circuit. Water is then condensed out of the flue gas before the compressor while the excess CO_2 (produced in the combustion process) is extracted from the cycle either before the compressor at atmospheric pressure or behind the compressor at the upper cycle pressure, in supercritical state. After cooling down to the cold sink temperature (30°C), the extracted CO_2 is ready for a possible use (such as enhanced recovery of oil or methane) or for its long term storage. If necessary, the compressed CO_2 is dried and cleaned up from contaminants coming both from the fuel and the oxygen (N_2, excess O_2, Ar, NO_x) and an additional compressor may be needed to bring about the purified CO_2 flow up to required delivery pressure for transport. A small fraction of CO_2, typically 0.1%vol of the excess CO_2 flow, is however leaving the cycle with the extracted H_2O. This is the reason why the system is called "near zero emission" and not strictly "zero emission". Before its re-use or its storage, the extracted excess CO_2 may be partly cooled and recycled in the hot parts of the cycle for cooling of walls, vanes and blades at the upper cycle temperature. Taking account of the penalties due to this cooling of the hot parts , due to the ASU consumption, due to the compressions and due to the pressure losses, the net efficiency of a Matiant cycle in CC is around 58% when operating on natural gas and with 1300°C upper temperatures of the gas turbines (TIT ISO), compatible with the currently available materials.

In the IGCC configuration, coal is gasified with oxygen and steam and is transformed in a syngas $CO + H_2$ at high temperature (1400 °C). This latter as well as the gasifier walls are cooled. The sensible heat of the hot syngas is recovered in a recovery boiler and the syngas is purified at low temperature. Particles, sulfur and nitrogen are nearly totally removed from the syngas which is now the fuel used in the Matiant cycle together with pure oxygen in stoichiometric proportions. Saturated steam is bled from the HRSG for the syngas cooling, superheated in the recovery boiler and sent to the MP steam turbine.

The already existing ASU in a standard IGCC has here to be sized to supply O_2 to both the gasifier and the combustion chambers of the MATIANT cycle. The O_2 consumption is about 2.5 times higher. Here there is no more need to shift CO since the MATIANT cycle accepts this mixture as the fuel and is designed to extract nearly all the water and the excess CO_2 from the combustion. At the US DOE, a study was conducted on a MATIANT cycle fuelled with a syngas produced in an O_2-blown gasifier, the O_2 being obtained through an Ion Transport Membrane operating on a high temperature pressurized air stream (850°C, 12-20 bar). The efficiency is around 45% (some 4 – 5% points below the efficiency of the same IGCC operating on an air based CC) and the CO_2 retention rate goes up to 99.5% in contrast to the 90% in an IGCC with pre-combustion capture [20].

ENERGY ANALYSIS

Reference IGCC

IGCC is the best emerging technology regarding a high level of CO_2 capture. Using a water gas shift reactor system allows to convert the CO in the syngas into CO_2 and H_2 using H_2O. Sulfur compounds together with around 90 % of the CO_2 generated in the combustion process can then be removed, for instance using a solvent like Rectisol. Here the solvent regeneration is made by flashing the solution, which is much less energy consuming than for a regeneration by heating. For a given coal input and a given GT efficiency , the pre-combustion capture gives rise to a net efficiency penalty resulting first from a decrease in fuel heat input (H_2+N_2 instead of CO+H_2+N_2) in the GT combustion chamber and consequently a drop in the GT power output, second and increase of consumption of auxiliaries whose the ASU and CO_2 compressor and third an increase of the steam flow from the gasification and clean up sections to the HRSG and consequently an increase of the ST power output. In the best cases, the addition of a CO shift and a CO_2/H_2 separation units results in a net plant efficiency drop of about 11 to15% or to a loss of 5 to 7 % points [5;6;21;22;23].

The reference IGCC without capture is an advanced one with a 49% net efficiency in base load and has the following characteristics. The GT with a TIT ISO = 1250 °C and a pressure ratio of 16.6 has a power output of 267.4 MW and an efficiency of 49.2% in open cycle and 58.1% in CC. The Shell gasifier is an entrained fluidised bed fed with dry coal (LHV= 31.44 MJ/kg), O_2 and steam. The steam cycle comprises 3 optimized pressure levels and a reheat (3PR) at 200 bar/600°C/61 kg/s; 38 bar/249°C/50kg/s; 4 bar/389°C/13 kg/s and reheat at 33 bar/600 °C. In the integration of water/steam flows between the gasifier and raw gas coolers and the steam cycle, the IP drum is in the gasification island, receives 58 kg/s IP saturated water and delivers a throughput of 50 kg/s saturated steam at 38 bar to the superheater inlet of the second pressure level, the 8kg/s difference being injected in the fuel gas saturator. The steam turbine power output is 189.3 MW so that the total power is 456.7 MW. The steam cycle efficiency is then 35.7% [8;24;25].

In the energy flow, around 75% of the chemical energy of coal input is transferred to the syngas, the remaining 25% representing losses and steam produced in the cooling of the gasifier walls and of the raw syngas in heat recovery boilers. The heat in that steam represents some 17% of coal input and is converted in electricity with the steam cycle efficiency. The ASU consumes some 8.5% of coal input as electricity $_{for}$ the air compressor. These factors are mainly responsible of the loss of efficiency compared to the standard natural gas fired CC (around 8%points). The global efficiency of the IGCC plant amounts to 49% with a share of 62% for the GT and 38% for the ST with a ratio GT/ST = 1.6 instead of 2 in a standard NGCC that is due to the water/steam integration. When the pre-combustion capture is implemented, the LHV of the fuel decreases by some 30% resulting in a drop of the GT power while the ST power increases (GT/ST power ratio is 1.3) but the net power output decreases by some 11% and so does the net efficiency.

The oxy-fuel combustion IGCC plant

The cycle efficiency is calculated using the ASPEN+ and EES commercial codes. The boundary conditions such as the technical data are given in table 1 and meet technical limitations such as the HRSG inlet temperature at 700°C complying with the requirements of material resistance criteria.

The Shell gasifier consumes 0.61 kg coal and 0.49 oxygen per kg cleaned fuel. The syngas is delivered, after cooling and clean-up, at 22 bar and 315°C, with a composition of 62.7%mol CO, 29.7% hydrogen and 7.6% inert gases resulting in a LHV of 12.45 MJ/kg.

The ASU produces O_2 at 1.7 bar,15°C at a purity of 95%mol, the 5% remaining being Argon with an electricity consumption of 0.25 kWh/kg O_2 [19].

In the 2PR recovery boiler, the superheat and reheat temperatures are taken at 565°C, that is 135°C below the GT exhaust temperature. The results at the design point corresponding to the data mentioned in table 1 are shown on figure 3.

Excess CO_2 is extracted before the compressor and is compressed from 1 to 110 bar. All the figures are given for a unit of working fluid, namely for 1 kg/s CO_2 recycled to the combustion chamber. The calculated syngas mass flow rate is 0.119 kg/s or 0.119 kg syngas/kg CO_2 recycled.

GT cycle

Gas clean up system	16,7 kJ / kg clean syngas
Cleaned syngas Pressure Temperature Composition (molar) LHV HHV	21,9 bar 315,5 °C 62,7 % CO 29,7 % H_2 12,45 MJ/kg 12,91 MJ/kg

Table 1 : data

The total O_2 production is 1.26 kg/kg syngas or 0.15 kgO_2/kg CO_2 recycled split into 2 parts : 40% to the gasifier and 60% to the combustion chambers of the Matiant cycle. Now the need for O_2 is 2.5 times higher than for the gasifier alone in a standard IGCC. The electricity requirement for the ASU is hence 135 kW/ kg CO_2 recycled.
At the design point, taking a TIT of 1250°C and an upper cycle pressure of 120 bar, the net power output is 0.86 MWe/ kg CO_2 recycled (0.71 for the GT, 0.5 for the ST and 0.36 Mwe for the auxiliaries) while the coal input (LHV = 26.16 MJ/kg) in the plant is 1.91 MWth.

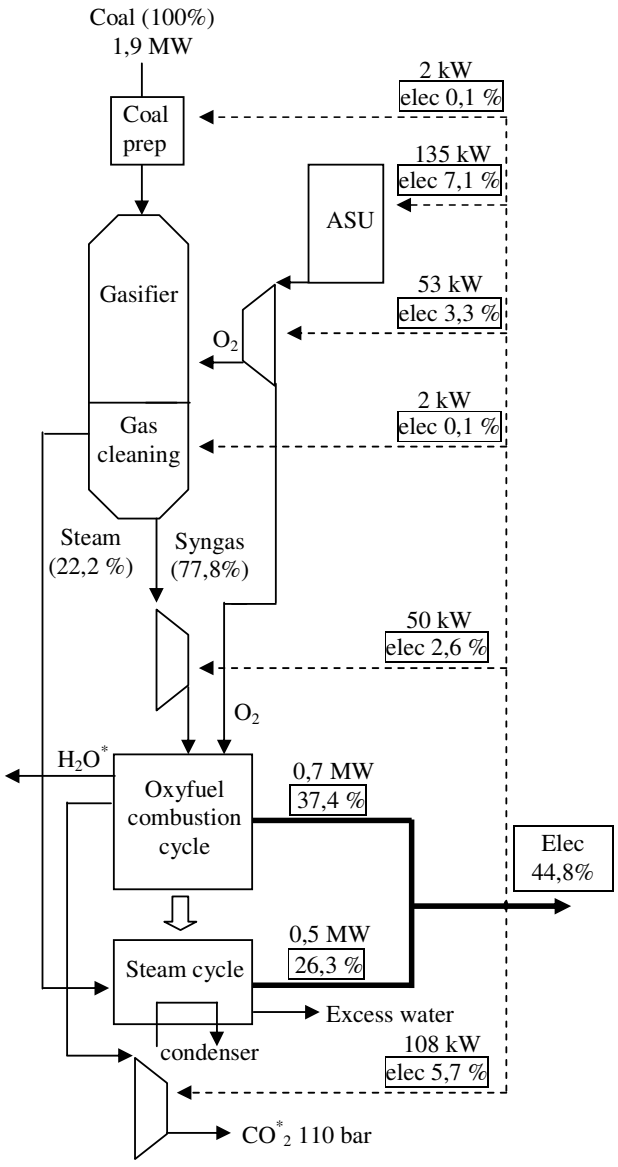

Figure 3 : Energy Cascade

The resulting net efficiency is 44.8%, all the losses being taken into account, including the losses due to CO_2 compression from 1 to 110 bar (13% of the net electricity production), to the ASU consumption (16% of the net electricity production) and to the cooling of the hot parts of the GTs using CO2 bled from the compressor since the TIT used in the calculations are the TIT ISO.
At the design point, in a configuration 2-2-1 with 2 GTs rated at 0.35 Mwe and 1 ST at 0.5 MWe, one of the GTs is used to provide approximately the electricity needed to the auxiliary systems while the ST generates approximately the power required by the GT compressors. Consequently the net plant power output is that of one GT and the ratio of power outputs of GTs and ST is 1.4 instead of 1.6 in the reference IGCC.
The energy cascade on figure 3 shows how the coal energy content is converted into electricity.
Note that the ASU consumes 16% of the net power output of the plant instead of 17.4% in the reference plant .

SENSITIVITY ANALYSIS

From the diagram efficiency against specific work on figure 4, it appears that both efficiency and specific work increase with the upper cycle pressure up to a maximum. The higher the TIT, the higher the maximal efficiency and the corresponding specific work. For a 1250°C TIT, the maximal efficiency (45%) and the maximal specific work (0.86 MJ/kg CO_2 recycled) are reached when the upper cycle pressure is 120 bar. This latter remains nearly constant above the optimal pressure. When the TIT goes up to 1300°C, the optimal pressure is 140 bar. The maximal efficiency increases only slightly by about 0.2 %point (45.2%) and again the specific work remains nearly constant above the optimal pressure. For a 1400°C TIT, the optimal pressure is very high, about 200 bar while the maximal efficiency is not more than 46%. Consequently increasing the TIT incurs indeed an increase of maximal efficiency only if the pressure is also increased. In this type of cycle however, it is not interesting to go on increasing the TIT in contrast to a standard IGCC since, when increasing the TIT from 1200 to 1400 °C, the efficiency climbs by only 2 % points provided the pressure strongly increases from 120 to 220 bar. Consequently it is better to bring about the effort on reducing the consumption for O_2 production than to increase the TIT.

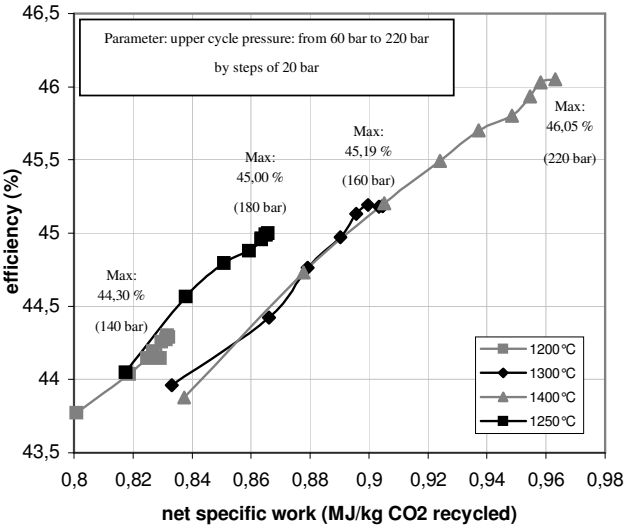

Figure 4 : efficiency against specific work for various TITs, the upper cycle pressure being the parameter

Regarding the consumption for O_2 production, the two most popular systems of O_2 separation are cryogenics and high t° conducting mixed oxide membranes. Both require a compression of the feeding air up to some 20 bar and this is the major part of the consumption in the two processes. Consequently the penalties are similar but on top of the compression, the air feeding the membranes must be heated up to some 900°C.

PURITY OF CO_2

The amounts of CO_2 and H_2O generated in the combustion are respectively 0.16 and 0.03 kg/ kg CO_2 recycled. With a solubility coefficient of 1.26 mg/kg water at 30 °C, the amount of CO_2 leaving the plant dissolved in the extracted water is only 0.1% of the water flow rate or 0.02% of the CO_2 generated in the combustion or about 0.1g/kWh. However, the extracted CO_2 and H_2O flows are not 100% pure CO2 and H_2O .The composition of the fluid extracted at the compressor inlet is 90.5 % CO_2, 4.25 % Ar, 1.4% H_2O and 3.84% unburned CH_4. This fluid needs to be dried and purified before transport to storage. Consequently the calculated amount of CO_2 leaving the cycle together with H_2O is only 0.001% of the CO_2 generated in the combustion or 5 mg CO_2 /kWh.

TECHNICAL ISSUES

Many technical issues have been raised in the development of the MATIANT cycles due to the nature of the working fluid, CO_2 or a mixture CO_2/H_2O. In particular, developments are required on cooled CO_2 expanders operating at high temperatures, on combustion in pure oxygen in a CO_2 atmosphere under pressure, on compressors and on condensers of mixtures of CO_2 and H_2O at low pressures.

As to the IGCC with pre-combustion capture, even if CO shift and CO_2 extraction from a mixture are proven, it still requires the development of H2 fuelled GTs. Such GTs are still appearing on the market today[25] .

CONCLUSIONS

Compared to a reference IGCC plant, the net efficiency of the oxy-fuel base IGCC is about 4 to 5% points lower while that of an IGCC with pre-combustion capture with 90% CO_2 retention rate is 7 to 9 % points lower, when the boundary conditions and the internal losses are the same in both plants and when the CC is optimised, but now the CO_2 emission is nearly zero. The production of oxygen is however now about 2.5 times higher than that of the reference IGCC but the shift of CO in the syngas using steam and the subsequent separation of CO_2 and H_2 using physical absorption are no longer needed. Consequently the proposed IGCC is an alternative to other capture options and more particularly to IGCC with pre-combustion capture, such as designed in the FutureGen project [26].

The main barrier for their implementation lies in their high cost resulting from the production of O_2 and from the need for new designs of the components operating on CO_2. This barrier is however likely to vanish if the value of environmental damages induced by fossil fuel combustion is adequately reflected within the costs (i.e. including externalities). Environmental market and political mechanisms (e.g. Kyoto protocol, carbon taxes, emissions trading market) could soon induce strong financial and regulatory incentives to adopt zero emission technologies and thereby provide a sound and cost-effective way to combat climate change.

POLICY-ORIENTED ENERGY SYSTEM MODELING WITH *XEONA*

Robbie Morrison,* Tobias Wittmann, Jan Heise, and Thomas Bruckner
Technische Universität Berlin
Institute for Energy Engineering
D–10587 Berlin
Germany

ABSTRACT

Energy systems exist to provide industry, commerce, and households with fuels and energy-services. In addition to financial cost and reliability imperatives, these systems are now being asked to perform across a range of sustainability criteria. Most national systems fall well short on this second count and governments need to promote a suitable transition. Market liberalization over the last 20 years has made this task more challenging in public policy terms and yet could provide good incentives for innovation, reinvestment, and user responsiveness, given the right institutional measures. The development of suitable public policy may necessitate sophisticated simulation techniques, particularly considering the technical and commercial complexities involved, the multi-criteria nature of the policy problem, and the fact that most interventions will interact.

This paper presents *xeona* (extensible entity-oriented optimization-based network-mediated analysis), an object-oriented simulation environment designed for such use and currently under development. The modeling ethos is to represent important entities from the problem domain as elements within the simulation domain. Hence a *xeona* model is built from the ground up using the technical plant, controllers, markets, actors, and policy measures that exist in reality or are under consideration. The presence of actors allows low-stake commercial and domestic decision-making to be embedded within the model and thereby drive system evolution in response to commercial pressures and proposed policy interventions.

Model construction is one aspect, but the specifics of policy usage and interpretation are also important. To this end, a technology evaluation issue involving neighborhood fuel cell cogeneration in northern Europe is briefly illustrated with numerical results.

Keywords: complex systems, energy policy, entity-oriented modeling, network dynamics

INTRODUCTION

There is a growing interest by governments and the informed public alike in the role that proactive energy policy might play in promoting a transition to more sustainable energy systems. Energy policy formation is a complicated exercise involving institutional issues as diverse as international treaties, environmental law, market design and regulation, government support, mandatory standards, research funding, and the dynamics of technology innovation and uptake. Nowadays energy policy needs to be evaluated across multiple public interest criteria, including cost-competitiveness, carbon mitigation, energy security, system resilience, and any number of social factors. The underlying technical and commercial systems are now recognized as complex in nature. And the contexts in which such systems operate are increasingly volatile in both economic and environmental terms.

*Author for correspondence: Fax: ++49.30.314 21683 Email: morrison@iet.tu-berlin.de

Many of the established energy policy analysis methods are unable to perform in such circumstances and a number of new strategies are being developed to address some of the more evident shortfalls. One of these strategies makes use of highly disaggregated and relatively literal simulation techniques.

This paper reviews *xeona* and its underlying design. More specifically, *xeona* is a policy-oriented energy system modeling environment currently under development by the authors (however for convenience, the paper is written as though the software is complete). It is both *high resolution* and *bottom-up* in the sense that each plant, connection, actor, decision, and transaction can be depicted if deemed important to the problem at hand. *xeona* supports supply contract competition and nodal market pricing.

Simulations of this type fall under the complex adaptive systems (CAS) paradigm. In the case of *xeona*, a subset of this paradigm is used which might be best described as a dynamical networked systems approach with market and non-market coordination/control protocols and explicit endogenous *low-stake* decision-taking. Conversely, *high-stake* decision-making (for instance, commissioning a major power station) is left as an exogenous input for the modeler to specify prior to or during runtime — that is, as a *fixed* or *interactive* scenario, respectively.

xeona combines sophisticated actors with a rich technology depiction. These actors exhibit *bounded rationality* — which means that, for example, house owners take decisions in a natural way, consistent with their rationality type (related to temperament) and social milieu (related to social status and value orientation). The technology description is likewise based on a consideration of reality and incorporates *context-dependent technical performance* covering plant efficiency, capacity, and cost formation.

The term *actor* is used here to describe decision entities who interact relatively infrequently and warrant a sophisticated decision model. Whereas *agent* is reserved for entities which interact often and tend to make more spontaneous decisions. Hence the somewhat unusual term *actor-based modeling* is adopted.

xeona supports *numerical optimization* where it exists in practice or is under consideration. For instance, a facilities operator can assign unit (plant) commitment based on minimized short-run marginal cost (SRMC) or minimized direct CO_2-e (carbon dioxide equivalent) emissions. Nodal markets based on linear programming (LP) can be similarly included [1]. As will be seen later, *xeona* embraces the idea of *distributed management*.

This style of simulation has been called *entity-oriented* (EO) modeling due to the fact its underpinning ethos is for all relevant entities in the problem domain to be represented in the simulation domain in relatively concrete form — an approach made feasible by object-oriented programming [2, 3].

EO modeling is particularly suited to distributed systems operating in variable circumstances. In such arrangements, network dynamics tend to be a preeminent issue [4]. Briefly, *network dynamics* are the effects and externalities that arise from the capacitated nature of networks and the benefits of membership, respectively. These characteristics impose demands on network coordination and drive recruitment in ways that can be difficult to anticipate without numerical modeling.

The concept of an energy system is accorded a broad interpretation and is defined in terms of purpose. In all but a few specialist circumstances, the *purpose* of an energy system is to supply exergy-services.[1] *Exergy-services* are amenities that are either provided through exergy consumption *or* could have been supplied thus. Hence, the scope of such systems normally extends well beyond the boundaries encompassed by commercial transactions. Examples of exergy-services include: space and water heating, illumination, food and timber drying, and motive power applications.

xeona can be applied and interpreted in a variety of ways [5]. The most adventurous mode is evolutionary, whereby a given simulation is triggered and left to evolve under endogenous low-stake and exogenous high-stake decision-taking. Less ambitious application modes include non-evolutionary simulation and comparative analysis.

xeona itself does not directly prescribe a set of overarching policy goals. But concerns over *climate protection* [6] and *long-run energy security* are certainly

[1] Readers unfamiliar with the term *exergy* can substitute the word *energy* in its colloquial sense. Both indicate the potential of a resource to provide thermodynamic work, although energy tends to be restricted to recognized fuels.

topical, with the Kyoto Protocol having entered into force in early-2005 and the issue of *peak oil* [7] gaining attention. In addition, and given sufficient structural detail, local public interest issues, such as *air pollution load*, can be tallied for policy support — and even constrained or locally minimized. Moreover, *xeona* does not posit perfect markets and can provide a platform for examining *pricing regulation* and *market design* in the presence of strategic commercial behavior.

Some matters of usage conclude this introduction. The phrases *energy system* and *exergy-services supply system* (ESSS) are taken as synonymous. The term *plant* is used in its most general sense and, for instance, would include those features of a house which contribute to thermal comfort. The term *fuel* is also accorded a broad meaning and covers electric power, heating and cooling utility, and carbon dioxide sequestration. The term *intensity* refers to a quantity associated with a resource which remains independent of scale, examples might include: unit price, specific carbon content, and *flo* and *return* temperatures. A *graph* is mathematical structure suitable for depicting networks [8].

RELATED WORK

As indicated, *xeona* combines actor-based modeling and high resolution technical simulation.

Most of the policy-oriented actor/agent-based simulation projects to date have focused on the electricity industry, either to investigate industrial organization or market behavior and abuse. This research orientation is no doubt related to the economic importance of the sector and the fact that liberalization has thrown up a number of counter effects, such as: circular asset valuation (whereby pricing drives valuation and *vice versa*), zonal market power (where network saturation within nodal markets confers dominance), and strategic pricing (more particularly to defend incumbent grids from encroachment).

Actor/agent-based modeling has been used to investigate structural consolidation within the German electricity industry [9] and to scrutinize participant behavior within primary electricity markets in North America [10], Australia [11, 12, 13], and elsewhere.

High resolution technical simulation has played a very limited role in energy policy analysis thus far [4]. That said, European initiatives to better understand neighborhood cogeneration and district heating are starting to employ this approach [14].

The CAS paradigm — or, more precisely, its actor/agent-based and high resolution subsets — is not the only methodology being applied to support *energy policy formation* [15]. Other paradigms (with examples) include: planner-oriented structural optimization [16], system dynamics [17], econometric [18], general equilibrium [19], dynamic input/out [20], optimal growth [21], and climate policy integrated assessment [22] — with many now seeking to better represent technological change [23] and (as necessary) climate issues. Note that these different methodologies can be successfully mixed in some but not all cases. Work in Japan to combine energy system models with other policy models and projections through the AIM suite [24] warrants mention. Integrated analysis based on multi-level control is also emerging as a research theme [25]. More broadly, the notion of using actor/agent-based modeling for investigating social and economic systems is described in [26]. *xeona* also shares some similarities in approach and application with urban development microsimulation [27].

XEONA

xeona has been formulated to be more general than the electricity industry models indicated previously. Key publications include [4, 5, 28].

xeona builds on an earlier high resolution technical modeling environment called *deeco* [29] which was released in 1995 [30].[2] *deeco* remains in active use and development and is well suited to single operator jurisdictions where volatile operation and non-financial additionality considerations (such as carbon mitigation) also apply.

An early application of *deeco* found that sets of technical measures are likely to interact in an adverse way — meaning that the individual contributions are sub-additive. In such cases, the design task becomes one of identifying those configurations which give the least compromised outcome [31] — a result which also has implications for policy-makers [32].

xeona is built around three conceptual layers comprising primarily *actors*, *plant*, and *zones*. Actors

[2] See: `http://www.iet.tu-berlin.de/deeco`

are grouped by *legal entity* for the purposes of individual analysis and reporting. Likewise, plant are grouped by *control domain* for the purposes of single operator unit commitment *or* market clearing and dispatch. Each plant is associated with at least one actor. Zones supply *context information* to actors and plant, thus providing a backdrop covering the prevailing physical, commercial, and institutional conditions.

These ideas are broadly indicated in Figure 1, in a scheme that bears some resemblance to arrangements in New Zealand.[3] In practice, many of plant depicted would be composed of other plant. A low-stake investment option might be to extend the photovoltaic (PV) panel area, perhaps in response to some institutional incentive.

The *technical layer* is structured around the processing of resource stocks and flows, much as is discussed in [29]. Individual unit commitment is multi-dimensional for multiple fuel and/or product processes (including cogeneration). The resource flow conventions adopted for *xeona* are shown in Figure 2, with reverse (or negative) flow now supported. Mandatory and optional sinks and sources are represented by equality and inequality constraints, respectively.

Interconnected control domains are interfaced by *gateways* which pass across the required demand and intensity information. Each gateway is associated with one or more *legal contract*, covering, for instance, connection and supply (banded tariffs are supported) or market participation (through electronic auctioning). In this latter case, the market operator clears price and quantity using forward projections (two hours ahead, say), while the independent system operator (ISO) manages technical dispatch. In more basic models, these two functions can be treated as one in the same.

The control domains form a *control domain graph* (CDG) which is solved sequentially in topological sort order, as shown in Figure 3, for each interval. Hence, the CDG must be directed acyclic [8] in terms of demand transfer — rather than resource

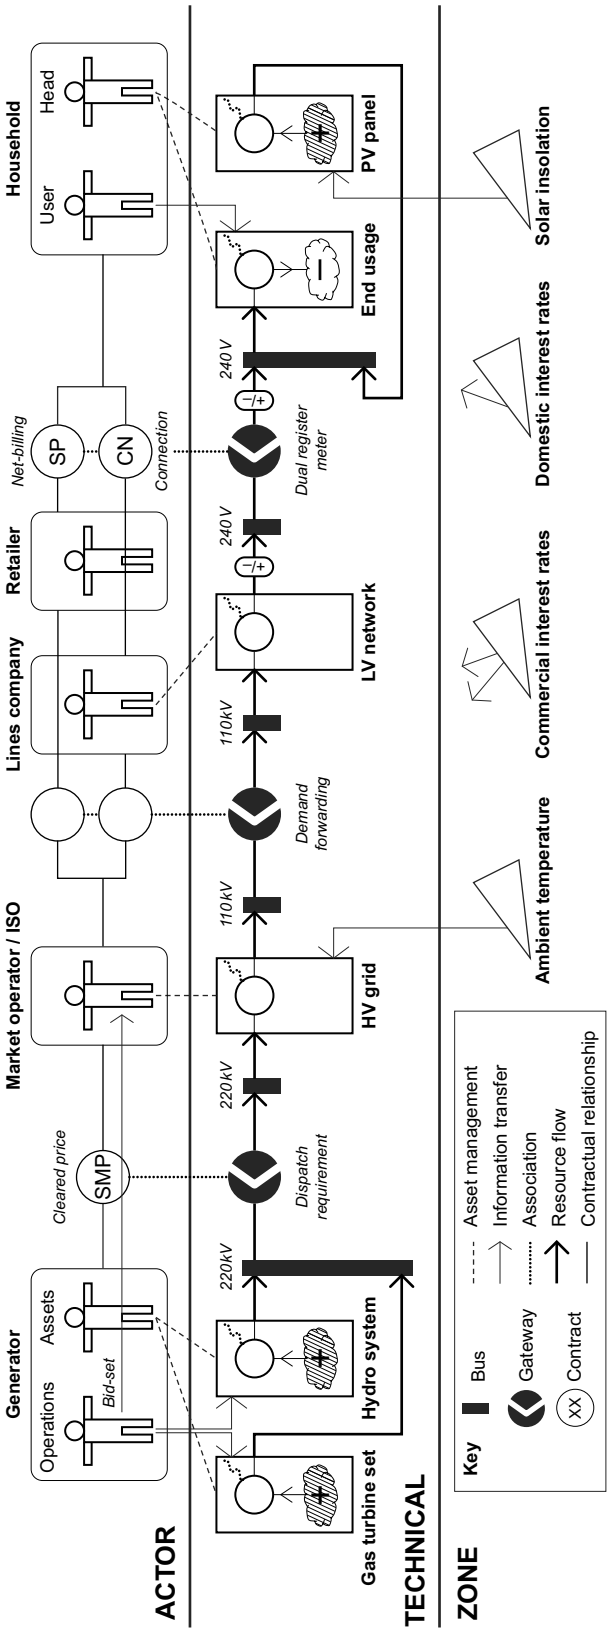

Figure 1: Three-layer diagram showing some of the key abstractions employed by *xeona*.

[3]New Zealand has a number of attributes that make it interesting in relation to the development of sustainable energy policy modeling techniques. These include: island status, an unparalleled renewable resource base, an institutional preference for deregulation, significant network characteristics, and pressing infrastructure renewal decisions.

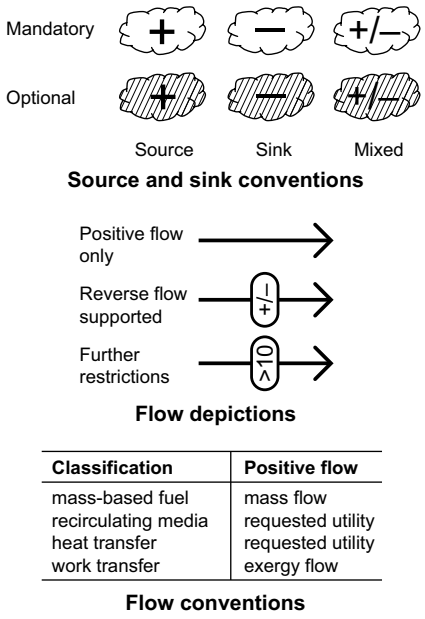

Figure 2: Resource flow conventions for *xeona*.

flow which cannot be guaranteed to be anti-parallel. Moreover, it is the demand for exergy-service and/or fuel provision that *drives* this model — a situation entirely consistent with the purpose of system definition introduced earlier.

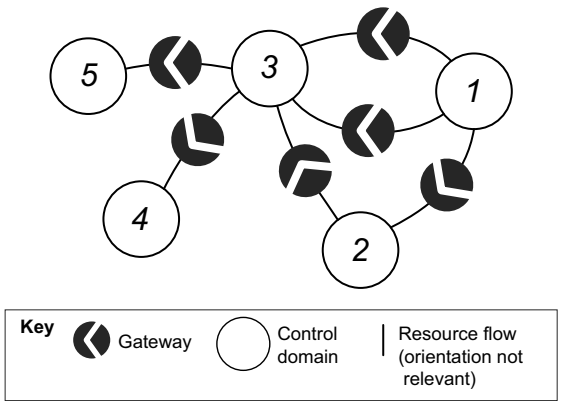

Figure 3: Control domain graph (CDG) with an acceptable solution order indicated.

The *actor layer* facilitates commercial interactions — as enabled by a particular scenario. Actors might therefore participate in nodal markets or purchase publicly posted supply contracts, technical equipment, and third-party services. Actors may also be placed in an *acquaintance network* (not shown) to facilitate bilateral negotiations.

The *zone layer* is where public policy interventions would normally be specified and where extreme external events can be defined. Given a sufficiently sophisticated model, *xeona* would be able to estimate the effects of anticipated climate change on existing and revised exergy-services supply systems.

xeona operates over various *timeframes*. Intervals typically span half or one hour, investment decisions might be revisited every three months or after key events, and scenario horizons may range from a year to a decade or more.

Space considerations meant the following design topics have either been skimmed over or omitted: exergy-services modeling (yielding fuel usage), logical flow and thermal intensity setting (including *flo* and *return* states), plant performance (including context-dependency), optimized shutdown-mode unit commitment (using mixed-integer linear programming), infeasible status responses (including relitigation and rationing), closing inventory matching (for comparative analysis), and the use of dynamic data structures and algorithms (to enable runtime intervention).

In terms of software licensing, both *xeona* and *deeco* are open-source.[4] This permits modelers the freedom to evaluate and develop the source code as they see best.

ACTOR DECISION-MAKING

Decision-making within *xeona* falls under several categories. *Operational* decisions cover unit commitment and market bid-set formulation, while *structural* decisions include plant investment and decommissioning. *Low-stake* decisions are taken within the model using context-specific algorithms, whereas *high-stake* decisions must be supplied externally, either as part of a fixed scenario or during runtime by including human subjects in the decision loop.

Low-stake structural decisions are based on the bounded rationality approach described in detail in [33]. Unit commitment is also low-stake, but relies on nominated protocols such as merit order and/or short-run optimization. Market bid-set formulation is low-stake as well, but has yet to be investigated in

[4]Both projects use the GNU GPL license together with requests to forward code changes to the principal authors and to not redistribute the codebase through anonymous download.

detail — there is, however, a growing literature on this topic [13, 34].

The term *bounded rationality* is used to describe actor decision-making which sidesteps the doctrines of (Bayesian) maximized subjective expected utility and discounted profit stream [35, 36]. And instead recognizes that actors, be they domestic or commercial, have limited knowledge, limited information gathering and processing abilities, and different preferences and perceptions as to future states of the world. Furthermore, actors may take decisions traversing only a subset of the information they hold. Researchers are currently attempting to understand this decision behavior and the particular environments in which it is exhibited. Their resultant models use simple search, stop, and decision rules. As an illustration, *satisfying* is a strategy in which one simply accepts the first decision option encountered that meets current aspiration levels.

POLICY SUPPORT

xeona supports energy policy formation from two distinct directions. First, the overall system performance is reported in terms of key public interest criteria — typically system financial cost, CO_2-e emissions, and depletable (fossil) resource use — thereby enabling informed policy decisions to follow. These results are normally presented using two and three dimensional *trade-off diagrams* [29]. And second, sets of specific policy measures can be embedded in particular scenarios and tested *in situ* against the aforementioned criteria. Such measures can range from: direct financial support, eco-taxation, feed-in laws, accelerated write-down, mandatory performance standards, and point-source air and thermal pollution discharge restrictions [5].

A key premise in this paper is that ESSS development trajectories can be affected by seemingly minor network dynamics in a manner comparable to the *butterfly effect* in long-range weather systems.

Providing insight into the way in which energy systems might be prompted to evolve from their present state is crucial when thinking about pathways to energy sustainability. It is necessary, but not sufficient, for analysts to identify socially beneficial transitions using, say, climate policy, dynamic general equilibrium, or system dynamics models. Such transitions will almost certainly need to be driven by specific policy measures — and their detailed evaluation provides a potential role for EO modeling. In short, both a roadmap and steerage are required.

This paper proposes two analytical roles for EO modeling — which can (and perhaps should) be dealt with jointly. One is examining the contribution that identified energy efficiency responses can make and how governments might best incentivize their uptake. And the other is studying the linkages between commercial strategic behavior, system evolution, and sustainability improvements.

EMBEDDED USE

There is a further reason for developing entity-oriented simulation techniques. It is likely that future energy systems will be strongly *status-awar*e in order to respond to changing circumstances in an intelligent way. This means that sections of the system (probably by control domain) may need to embed a suitable localized high resolution simulation which can cast forward hours and days to analyze and offer adaptive responses. One such action might be the online auctioning of demand deferral.

DISTRIBUTED TECHNOLOGY EXAMPLE

The following example from southern Germany shows how high resolution modeling can be used to assess the attractiveness (or otherwise) of distributed technology deployment from the point of view of both a new entrant *and* the wider public interest.

The study [4, 37] looks at the merits of installing 200 kW_e natural gas-fired PAFC (phosphoric acid) fuel cells, which supply — in parallel with peak-load boilers and other measures — heat and power to low-rise apartment blocks. These various schemes compete with district heat and electricity from the incumbent municipal utility. The study also considered potential network interactions with renewable energy opportunities, in this case, solar thermal systems with seasonal storage and local windfarms. Representative results are summarized in Figure 4. One conclusion is that the multi-criteria performance of technology groupings of this kind are strongly sensitive to the quality of local integration. Even so, in this particular situation and given

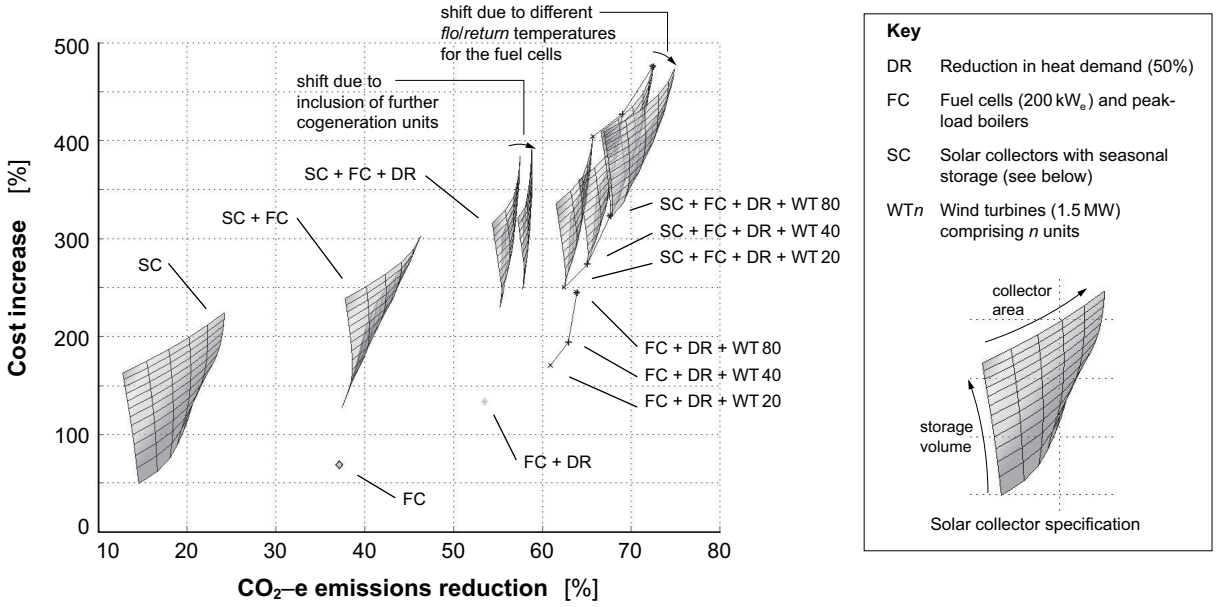

Figure 4: Relative carbon and financial additionalities for 200 kW_e neighborhood fuel cells operating in a range of configurations and control settings. The overall system performance, when combined with other local renewable energy and/or demand reduction opportunities, is also indicated. *Source*: [37, fig. 7.5]

the projected costs and other scenario assumptions, none of the options tested qualify as fully commercial propositions — despite positive social externalities. Hence, this form of modeling can provide a useful test-bed on which to evaluate policy measures designed to support low-carbon technologies.

DISCUSSION

Highly disaggregated and relatively literal energy system simulations — as exemplified by *xeona*— represent an emerging field. Many of the building blocks are still being sketched in and thus yet to be verified and accepted. However the tangible nature of these simulations lends confidence to this venture. And despite being detail intensive, entity-oriented (EO) models should not be fundamentally difficult to calibrate. Other model types, by contrast, often require abstract causalities to be estimated (for example, demand elasticity and feedback delay) and can be quite sensitive to inaccuracies.

EO models capture network dynamics naturally. This means that such models are particularly suited to system architectures and institutional arrangements where these dynamics are likely to develop. Most, if not all, energy efficiency propositions would fall into this category.

EO models maintain a clear separation between the private and public realms. This will avoid, for example, controversy over the choice of a single discount rate — because each actor, together with the public policy-maker, can be assigned an appropriate figure.

Financial cost-effectiveness should continue to be seen as a sustainability issue. This is because non-financial performance will invariably be traded off against financial cost, either explicitly or otherwise.

Such models also provides a useful qualitative description of energy systems and policy issues. This may not appear significant to the modeling community, but policy-makers and analysts often struggle to conceptualize complexity. Having access to a simplified but representative proxy model of the underlying system could assist in this regard.

Previously unreported work includes the concept of a control domain graph and the application of bounded rationality techniques to low-stake consumer and commercial energy efficiency investment decisions. The ability to include explicit decision-making in policy models appears to be a useful step. A number of current energy modeling initiatives attract criticism because they contain too little sociology — in many respects, *xeona* represents an attempt to rectify this shortcoming.

ABSTRACT

This paper focuses on model analysis of a dynamic model of a bottom fired one-pass smoke tube boiler. Linearised versions of the model are analysed to determine how gain, time constants and right half plane zeros (caused by the shrink-and-swell phenomenon) depend on the steam flow load. Furthermore the interactions in the system are inspected to analyse potential benefit from using a multivariable control strategy in favour of the current strategy based on single loop theory.
An analysis of the nonlinear model is carried out to further determine the nonlinear characteristics of the boiler system and to verify whether nonlinear control is needed.
Finally a controller based on single loop theory is used to analyse if input constraints become active when rejecting transient behaviour from the disturbance steam flow.
The model analysis shows large variations in system gains at steady state as function of load whereas gain variations at the crossover frequency are small. Furthermore the interactions in the system prove not to be negligible and a subsequent controller design should take this into account using either Multiple input Multiple output control or Single input Single output controllers supported by a dynamical decoupling.
The results indicate that input constraints will become active when the controller responds to transients in the steam flow disturbance. For this reason an MPC (model predictive control) strategy capable of handling constraints on states and control signals should be considered. Furthermore hard constraint on the level variations also supports the choice of this strategy.

NOMENCLATURE

Symbol	Description
d, $\mathbf{d}$	disturbance (scalar/vector)
D, $\mathbf{D}$	scaling factor (scalar/matrix)
e, $\mathbf{e}$	error (scalar/vector)
k	valve conductance $\left[\frac{\text{kg}}{\text{s}\sqrt{\text{Pa}}}\right]$
L	level [m]
$\dot{m}$	mass flow $\left[\frac{\text{kg}}{\text{s}}\right]$
P	pressure [Pa]
r	reference
T	temperature [°C]
u, $\mathbf{u}$	input (scalar/vector)
x, $\mathbf{x}$	state (scalar/vector)
y, $\mathbf{y}$	output (scalar/vector)
κ	RIM
$\mathbf{\Lambda}$	RGA
Subscripts	**Description**
b	bobbles
f	flue gas
fw	feed water
fu	fuel
m	metal
s	steam
w	water
Abbreviations	**Description**
MIMO	multiple input multiple output
MPC	model predictive control
ORG	origin
PI	proportional and integral
RGA	relative gain array
RHP	right half plane
RIM	Rijnsdorp interaction measure
SISO	single output single input

INTRODUCTION

During the years marine boilers have been controlled using classical SISO controllers. Lately focus has been put on optimising the boiler performance through a more comprehensive and coherent control

strategy. This includes model-based MIMO control to minimise variation in especially drum water level. With this parameter minimised it is possible to reduce the physical dimensions of the boiler which imply lower production costs and gives a more competitive product.
Prior to setting up a control strategy it is important to understand the process to be controlled and the model describing it. The boiler system is nicely described by means of first principles resulting in a model based on nonlinear differential equation, see e.g. [1] and [2]. This model has a MIMO structure meaning that all process inputs affect all the outputs. It is of interest to know how large the interactions in the MIMO system are and also the degree of nonlinearities in the model and if any of these properties will affect the controlled boiler system.
The model which is analysed in this paper is based on the bottom fired one-pass smoke tube boiler (MISSION^{TM} OB) from Aalborg Industries A/S product range. The largest of these has a maximum steam load of 3000 $\frac{\text{kg}}{\text{h}}$.
The paper starts by introducing the boiler model and deriving linear versions of this depending on the operating point. After that follows the analysis based on mostly linear system theory using the concept of decentralised control and decoupling to find interaction.

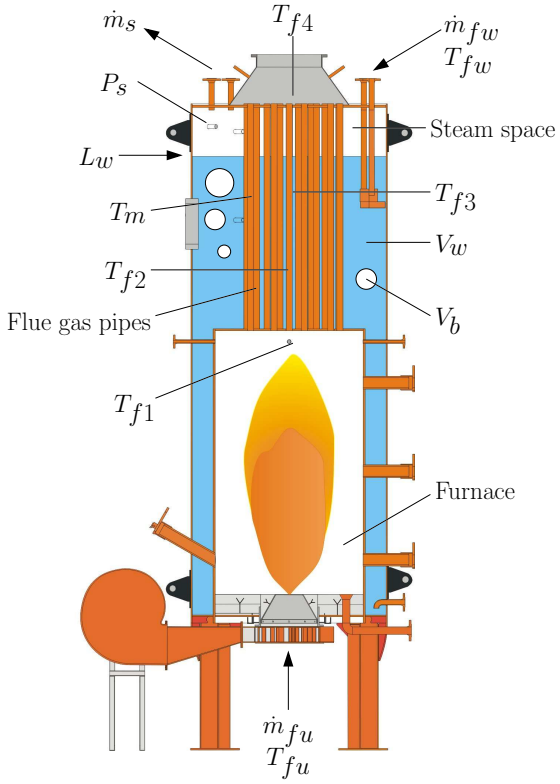

Figure 1: Drawing of the bottom fired one-pass smoke tube boiler.

BOILER MODEL

A drawing of the bottom fired one-pass smoke tube boiler is shown in figure 1 with model variables indicated. A model of this boiler was presented in [2]. The model has the structure:

$$\mathbf{F}(\mathbf{x})\dot{\mathbf{x}} = \mathbf{h}(\mathbf{x},\mathbf{u},\mathbf{d}) \quad (1)$$
$$\mathbf{y} = \mathbf{c}(\mathbf{x}) \quad (2)$$

where $\mathbf{u} = [\dot{m}_{fu}, \dot{m}_{fw}]^T$ (fuel flow and feed water flow), $\mathbf{y} = [P_s, L_w]^T$ (steam pressure and water level), $\mathbf{d} = [k, T_{fu}, T_{fw}]^T$ ("steam flow", fuel temperature and feed water temperature) and $\mathbf{x} = [T_{f1}, T_{f2}, T_{f3}, T_{f4}, T_m, P_s, V_w, V_b]^T$ (T_f being temperatures at four different levels in the furnace and convection parts, T_m is the temperature of the metal separating the heating part and the liquid part and V_w and V_b are volumes of water and steam bobbles under the surface in the drum).
It should be mentioned here that the disturbance k is related to the actual steam flow as $\dot{m}_s = k\sqrt{P_s - P_{atm}}$, and can be interpreted as an overall steam valve and pipe system conductance. k will also be referred to as the steam flow disturbance. P_{atm} is the atmospheric pressure at the pipe outlet.
A parameter estimation was made to find the critical parameters in the model in such a way that it reflects the physical boiler system as well as possible.

Linear Model

Linearised versions of the plant are introduced as most of the model analysis and controllers designed will be based on these. The linearisation is based on a first order Taylor series expansion. Scaling of the models is introduced (according to Skogestad and Postlethwaite [3]) as it makes both model analysis and controller design simpler.
Let the unscaled linear small signal valued plant model including tracking error in the Laplace domain be given as:

$$\check{\mathbf{y}}(s) = \check{\mathbf{G}}_u(s)\check{\mathbf{u}}(s) + \check{\mathbf{G}}_d(s)\check{\mathbf{d}}(s) \quad (3)$$
$$\check{\mathbf{e}}(s) = \check{\mathbf{r}}(s) - \check{\mathbf{y}}(s) \quad (4)$$

Introduce scaling factors put up from system demands; allowable control error, knowledge of disturbance variations and allowable input change e.g. due to valve opening constraints or maximal flow rate etc.:

$$D_{e,i} = \check{e}_{max,i}, \quad D_{u,j} = \check{u}_{max,j}, \quad D_{d,k} = \check{d}_{max,k}$$

where the subscripts i, j, k represent the different numbers of entries in the error, input and disturbance

vector respectively. The specific values are listed below:

	$\check{e}_{max}$	$\check{u}_{max}$	$\check{d}_{max}$
1	0.5 bar	160 $\frac{\text{kg}}{\text{g}}$	$6.0 \cdot 10^{-4}$ $\frac{\text{kg}}{\text{s}\sqrt{\text{Pa}}}$
2	0.1 m	4500 $\frac{\text{kg}}{\text{g}}$	5 °C
3			5 °C

The value of $\check{d}_{max,1} = k_{max}$ is determined from assuming a maximal steam flow of 3000 $\frac{\text{kg}}{\text{h}}$, a steam flow range of 40-100% and assuming that steps in the flow from maximum to minimum and the opposite can occur.
Using vector notation, putting the scaling element on the diagonal of a scaling matrix, the scaled output, input, disturbance and reference vectors are given as:

$$\mathbf{y} = \mathbf{D}_e^{-1}\check{\mathbf{y}}, \quad \mathbf{u} = \mathbf{D}_u^{-1}\check{\mathbf{u}}$$
$$\mathbf{d} = \mathbf{D}_d^{-1}\check{\mathbf{d}}, \quad \mathbf{r} = \mathbf{D}_e^{-1}\check{\mathbf{r}}$$

Substituting these scaled vector representations into equations 3 and 4 gives the scaled model:

$$\begin{aligned} \mathbf{y}(s) &= \mathbf{G}_u(s)\mathbf{u}(s) + \mathbf{G}_d(s)\mathbf{d}(s) \qquad (5) \\ \mathbf{e}(s) &= \mathbf{r}(s) - \mathbf{y}(s) \end{aligned}$$

where $\mathbf{G}_u(s) = \mathbf{D}_e^{-1}\check{\mathbf{G}}_u(s)\mathbf{D}_u$ and $\mathbf{G}_d(s) = \mathbf{D}_e^{-1}\check{\mathbf{G}}_d(s)\mathbf{D}_d$.
Now $\|\mathbf{d}(t)\|_\infty \leq 1$ and the objective is to keep $\|\mathbf{e}(t)\|_\infty \leq 1$ while obeying $\|\mathbf{u}(t)\|_\infty \leq 1$. If needed additional scaling can be applied to the references to keep $\|\mathbf{r}(t)\|_\infty \leq 1$ during reference changes.

Actuator Models

In the aforementioned boiler model the actuator dynamics were omitted. The actuators will enter in the closed loop strategy in a cascade configuration. The actuators used for both the fuel and feed water flow are valves with a pneumatic actuation. Measurements show that these have a rise time from control signal to flow of $t_r < 10$ s. It is assumed that cascade controllers linearising the actuator dynamics can be designed with a dynamic behaviour equal to or faster than the open loop actuator dynamics.
Models of the controlled actuators with reference flows as input and actual flows as output can be put in a matrix form as:

$$\mathbf{G}_a(s) = \begin{bmatrix} G_{a11}(s) & 0 \\ 0 & G_{a22}(s) \end{bmatrix}$$

Both controlled actuators are assumed to be well described by second order systems. Introducing this model in the total linear model gives a new transfer function from input to output: $\mathbf{G}(s) = \mathbf{G}_u(s)\mathbf{G}_a(s)$

MODEL ANALYSIS

During this analysis especially three operating points will be considered; minimum load: 40%, middle load: 70% and maximum load 100%. Expanding the notation of equation 5, including the actuator dynamics, illustrates the transfer functions of the model:

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} + \\ + \begin{bmatrix} G_{d11} & G_{d12} & G_{d13} \\ G_{d21} & G_{d22} & G_{d23} \end{bmatrix} \begin{bmatrix} d_1 \\ d_2 \\ d_3 \end{bmatrix}$$

where the dependency of s is omitted. This will be done throughout the analysis, to simplify expressions, where this dependency is obvious. A block diagram illustration of the system is shown in figure 2. In

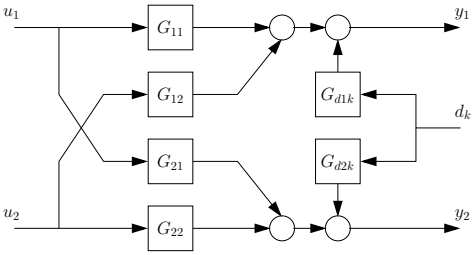

Figure 2: Block diagram of linear boiler model.

figure 3 a magnitude plot of the transfer functions of $\mathbf{G}(s)$ is presented for each of the three mentioned operating points.

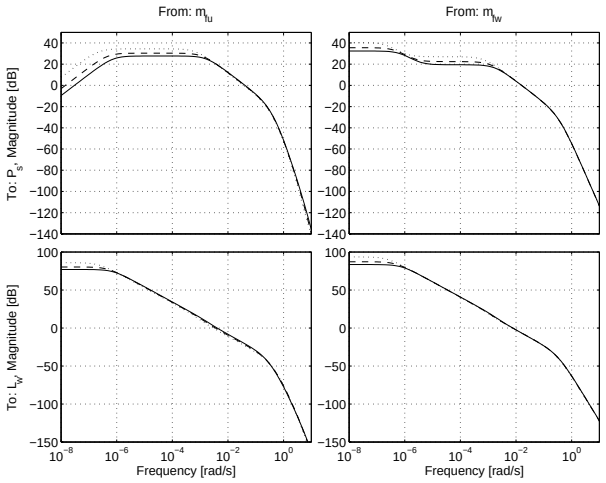

Figure 3: Magnitude plots of transfer functions in $\mathbf{G}(s)$ at three different loads; 100% solid, 70% dashed and 40% dotted.

The actual differences in model dynamics are not well visualised in these plots. In figure 4 magnitude plots

of $G_{ij,40}/G_{ij,100}$, the ratios between the transfer functions at 40% load and 100% load are shown.

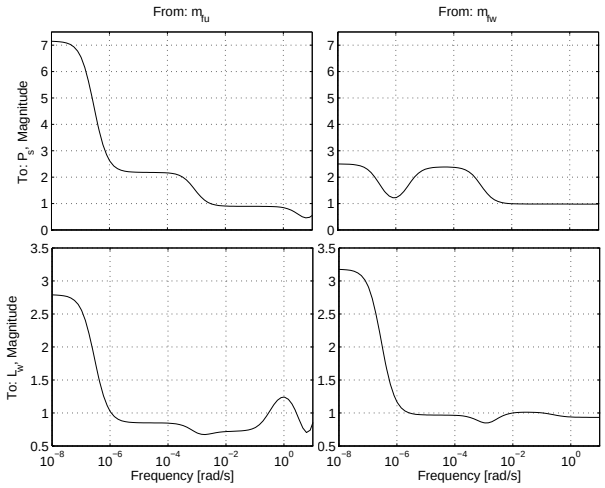

Figure 4: Magnitude plot of $G_{ij,40}/G_{ij,100}$.

From the plots it can be seen that the main differences between the model dynamics at the different operating points are at low frequencies where gain increases at lower load. On the other hand at frequencies above 10^{-3} rad/s for output one, P_s, and above 10^{-6} rad/s for output two, L_w, the behaviours are similar at least up to about 10 rad/s where the ratios associated with the fuel flow input break off. It is of interest to find out whether these differences have any practical implication in a controller design and furthermore whether interactions in the system should be handled by a MIMO control strategy.

It is obvious from the magnitude plots that they do not give any useful information regarding gains and time constants as both quantities are unreasonable high due to a pole in the left half plane close to the origin. Furthermore it can be seen that the steady state gain of $G_{11}(s)$ is zero indicating a zero in the origin.

Instead of looking at gains at steady state and at the usual definition of time constants another approach is taken. Focus is put at the crossover frequency ω_c. Assuming knowledge of this quantity at the operating point of 100% a suitable controller for this specific load can be designed. Now the system gain variations can be defined as the variations at the crossover frequency when the operating point is changed but the same controller is applied. Furthermore instead of considering the actual time constants the variations of the crossover frequency when the operating point is changed are investigated.

This approach gives insight to the stability properties of the nonlinear boiler system.

Decentralised Control

The controller designed is a simple decentralised controller using SISO PI controllers. An estimate of the bandwidth requirements without taking MIMO interaction into account are investigated from a plot of the magnitudes of the transfer functions from the disturbances to the output, $G_d(s)$, shown in figure 5.

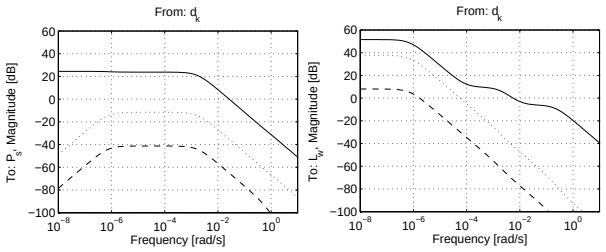

Figure 5: The left plot shows the magnitude plot from $\mathbf{d}$ to y_1 and the right plot the magnitude plot from $\mathbf{d}$ to y_2. The solid line is associated with d_1, the dashed line with d_2 and the dotted line with d_3.

Control is needed at frequencies where $|G_{dik}(j\omega)| > 1$, $|G_{dik}|$ being the disturbance gain from disturbance k to output i. From the plots it can be seen that for both the pressure, y_1 and water level, y_2, the worst disturbance is the change in the steam flow; disturbance d_1. The two temperature disturbances have proved to play a minor role in a closed loop configuration and will not be addressed further in this paper. G_{d11} cross the zero axis at $\omega_{b1} \approx 0.027$ rad/s and G_{d21} cross the zero axis at $\omega_{b2} \approx 0.006$ rad/s, setting an estimated bandwidth requirement for the pressure and level loop, respectively.

Stability conditions imposed by interaction

Of interest when performing model analysis and designing decentralised controllers are the stability conditions imposed by interactions in the MIMO model when using the diagonal controller.
Let $\mathbf{P}$ be a square $n \times n$ plant and let $\tilde{\mathbf{P}}$ ("nominal plant") be given as:

$$\tilde{\mathbf{P}} = \begin{bmatrix} P_{11} & 0 & \\ 0 & \ddots & 0 \\ & 0 & P_{nn} \end{bmatrix}$$

Then the closed loop system can be presented as in figure 6.
$\mathbf{K}$ is diagonal and $\mathbf{E}$ is an output multiplicative perturbation given as:

$$\mathbf{E} = (\mathbf{P} - \tilde{\mathbf{P}})\tilde{\mathbf{P}}^{-1}$$

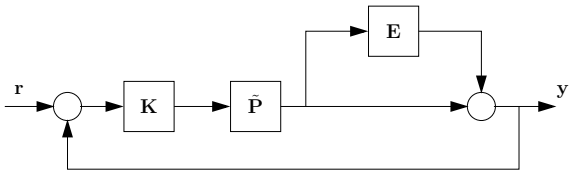

Figure 6: Block diagram of closed loop with $\mathbf{P}$ represented as the diagonal plant $\tilde{\mathbf{P}}$ and an output multiplicative perturbation $\mathbf{E}$.

By Skogestad [3] the overall output sensitivity function for this system can be factorised as:

$$\mathbf{S} = \tilde{\mathbf{S}}(\mathbf{I} + \mathbf{E}\tilde{\mathbf{T}})^{-1}$$

where $\tilde{\mathbf{S}} = (\mathbf{I} + \tilde{\mathbf{P}}\mathbf{K})^{-1}$ is the sensitivity function of the nominal system and $\tilde{\mathbf{T}} = \mathbf{I} - \tilde{\mathbf{S}}$.
Now assume that $\mathbf{P}$ is stable and furthermore that the individual loops are stable ($\tilde{\mathbf{S}}$ and $\tilde{\mathbf{T}}$ stable), then for stability of the overall system it suffices to look at

$$\det(\mathbf{I} + \mathbf{E}\tilde{\mathbf{T}}(s)) \tag{6}$$

as s traverses the Nyquist D-contour and make sure it does not encircle the origin. This follows from lemma A.5 in [3]. The spectral radius stability condition then yields stability of the overall system if:

$$\rho(\mathbf{E}\tilde{\mathbf{T}}(j\omega)) < 1 \ \forall\, \omega$$

2×2 **systems:** For these systems the condition becomes especially simple. This will be illustrated with the system addressed in this paper.

$$\mathbf{E} = \begin{bmatrix} 0 & \frac{G_{12}}{G_{22}} \\ \frac{G_{21}}{G_{11}} & 0 \end{bmatrix}, \quad \tilde{\mathbf{T}} = \begin{bmatrix} \tilde{T}_{11} & 0 \\ 0 & \tilde{T}_{22} \end{bmatrix}$$

The spectral radius of $\mathbf{E}\tilde{\mathbf{T}}(j\omega)$ is given by:

$$\rho(\mathbf{E}\tilde{\mathbf{T}}(j\omega)) = \left|\sqrt{\tilde{T}_{11}\tilde{T}_{22}\kappa(j\omega)}\right|$$

where $\kappa = \frac{G_{12}G_{21}}{G_{11}G_{22}}$ is the RIM (Rijnsdorp interaction measure) introduced by Rijnsdorp [4]. Now the sufficient condition for stability of the overall system is:

$$|\tilde{T}_{11}\tilde{T}_{22}(j\omega)| < \frac{1}{|\kappa(j\omega)|} \ \forall\, \omega$$

or the more conservative condition:

$$|\tilde{T}_{ii}(j\omega)| < \frac{1}{\sqrt{|\kappa(j\omega)|}} \ \forall\, \omega, i \in [1,2]$$

Bounds can be set on the sizes of $\tilde{T}_{11}(j\omega)$ and $\tilde{T}_{22}(j\omega)$ according to their resonant peaks which again are related to the stability margins of the individual loops. This gives the more conservative condition:

$$\|\tilde{T}_{ii}\|_\infty < \frac{1}{\sqrt{|\kappa(j\omega)|}} \ \forall\, \omega, i \in [1,2] \tag{7}$$

Hence to ensure stability of a system with offset-free tracking ($T_{ii}(0) = 1$) assuming no resonant peaks the condition becomes $1 < 1/|\kappa(j\omega)| \ \forall\, \omega$. From equation 7 it follows that the interactions in the system pose no limit on the achievable closed loop system bandwidth if $\kappa < 1$.
It is obvious that systems with $|\kappa(j\omega)| \ll 1 \ \forall\, \omega$ are preferable. One could interpret the degree to which $\kappa < 1$ as an insurance of a good stability margin. This also relates to another measure of interaction; the relative gain array (RGA), first introduced by Bristol [5], which is given as

$$\mathbf{\Lambda}(\mathbf{G}(s)) = \mathbf{G}(s) \circ (\mathbf{G}^{-1}(s))^T$$

where $\circ$ is the element wise product (also known as the Schur or Hadamard product). In the following shortened to $\mathbf{\Lambda}(\mathbf{s})$. An element of the RGA, $\Lambda_{ij}(s)$, is the ratio between the gain of G_{ij} assuming all other loops open and the gain of G_{ij} assuming all other loops closed by perfect control. Both the RIM and the RGA are independent of the particular plant input and output scaling. For 2×2 systems the RGA can be expressed as:

$$\mathbf{\Lambda}(s) = \begin{bmatrix} \frac{1}{1-\kappa(s)} & \frac{-\kappa(s)}{1-\kappa(s)} \\ \frac{-\kappa(s)}{1-\kappa(s)} & \frac{1}{1-\kappa(s)} \end{bmatrix}$$

In most cases for stability of the overall system using diagonal decentralised control it is sufficient to require $\mathbf{\Lambda}(j\omega_c) \approx \mathbf{I}$ at the crossover frequencies [3], which is the same as requiring $|\kappa(j\omega_c)| \ll 1$. $\mathbf{\Lambda}(j\omega_c) = \mathbf{I}$ imply that the individual loops are independent of the closing of the other loops meaning that the stability margins from the individual loops are preserved. Furthermore a unity RGA implies that there are zero or only one way interaction. One way interaction can be interpret and treated as a disturbance.
In figure 7 $1/|\kappa(j\omega)|$ for $\mathbf{G}$ is plotted.

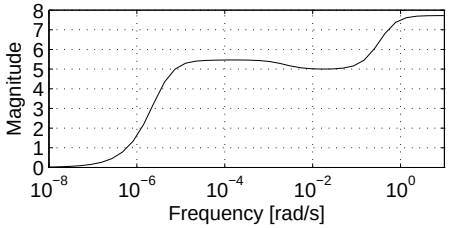

Figure 7: Plot of $1/|\kappa(j\omega)|$.

Now assume that $\tilde{T}_{ii}$ for all i is designed with no resonant peak such that $\|\tilde{T}_{ii}\|_\infty \leq 1$ given the sufficient

condition for stability: $1 < 1/|\kappa(j\omega)| \; \forall \omega$ then it is obvious from the figure 7 that stability is not ensured in the low frequency band. This is due to the zero in the origin of G_{11}. However the spectral radius stability condition is conservative meaning that this does not necessarily imply that the system is unstable.
To investigate whether the conditions in the low frequency band cause any stability problems for the overall loop again look at equation 6. Notice that at low frequencies $\tilde{\mathbf{T}} \approx \mathbf{I}$. This means that for overall stability it suffices to ensure that $\det(\mathbf{I} + \mathbf{E}(j\omega))$ behaves well at low frequencies (does not encircle the origin). Given this overall stability is ensured by (7) for $\|\tilde{T}_{ii}\|_\infty$ small enough. The Nyquist plot of $\det(\mathbf{I} + \mathbf{E}(j\omega))$ is shown in figure 8.

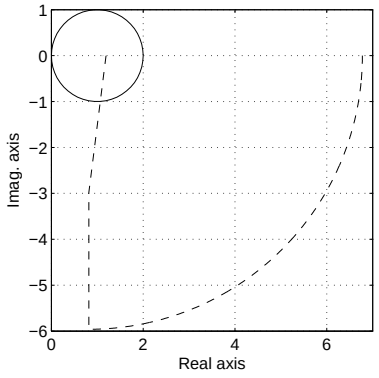

Figure 8: Nyquist plot of $\det(\mathbf{I} + \mathbf{E}(j\omega))$.

As can be seen the curve indeed behaves well at low frequencies and there are no encirclements of the origin. From the analysis it can be concluded looking at figure 7 (assuming $\tilde{\mathbf{T}}(j\omega) \approx \mathbf{I} \; \forall \omega < 10^{-5}$ for the previous analysis to hold) that to ensure stability of the overall system the condition is according to (7); $\|\tilde{T}_{ii}\|_\infty < \sqrt{5}$ that is a resonant peak less than $\sqrt{5}$. If $\tilde{T}_{ii}$ is assumed to have second order characteristics the resonant peak requirement can be related directly to the phase margins of $\tilde{T}_{ii}$ [6]. E.g. a resonant peak of $\sqrt{5}$ corresponds to a phase margin of approximately 26°.

Pairing

The RGA is often used as a measure for pairing control inputs to outputs as the structure of the RGA is dependent on this pairing. Recalling from the last section that to ensure stability one often requires that $\mathbf{\Lambda}(j\omega_c) \approx \mathbf{I}$, similar to requiring $1 \ll 1/|\kappa(j\omega_c)|$. From the discussion regarding the required bandwidth the crossover frequencies can be expected to be $\omega_{c1} > 0.027$ rad/s and $\omega_{c2} > 0.006$ rad/s. It can be seen from figure 7 that the current pairing (controlling pressure with fuel flow and water level with feed water flow) is the best choice, as would be expected. Intuitively pairing inputs and outputs for which $\Lambda_{ij} = 1$ also makes sense as this means that the gain seen from input j to output i is unaffected by the closing of the other loops.
However focusing on the low frequency range figure 7 shows that the chosen pairing results in small RGA elements indicating control problems if one loop breaks. The problem here is a zero in the origin of the transfer function $G_{11}(s)$ from fuel to pressure discussed below.

RHP-zeros

In SISO controller design and for process understanding it is of interest to determine possible non-minimum phase zeros in the process. Furthermore as discussed above zeros in the origin play a dominant role in the controller design.
A list of the transfer functions with either a RHP-zero or a zero in the origin (ORG-zero) is shown below.

RHP − zero	G_{12}	G_{21}	G_{d21}	G_{d22}	G_{d23}
ORG − zero	G_{11}	G_{d12}	G_{d13}		

In the following only the zeros most important to the analysis will be discussed.
The zero in the origin of $G_{11}(s)$ arises from the fact that with the boiler in steady state an increase in fuel input, keeping feed water flow constant, causes the steam flow to increase and the water level to drop. But as the water level drops efficiency drops. At some point the water level has dropped so much that the efficiency is so poor that the steam outlet is equal to the feed water input and a new equilibrium is found at the same pressure. In reality this new equilibrium will not appear due to the large system steady state gains meaning that the boiler will dry out. The zero may be removed by closing the water level loop. This means that if for some reason the level loop should break then difficulties in controlling the pressure could be expected. This was also the conclusion from the RGA analysis in the previous section.
Regarding the RHP-zeros the most interesting are the ones in the cross connections G_{12} and G_{21} and the one from steam flow to water level in G_{d21} which describes the shrink-and-swell phenomenon in the process. In fact the zero in G_{21} is closer to the origin than the zero in G_{d21} and furthermore it is associated with a larger gain.
Common for the RHP-zeros are that as the operating load drops the zeros move closer to the origin. Together with the increasing gain this makes the effect of these zeros most pronounced at low loads.
Seen from a control point of view the RHP-zeros do not pose any limits on performance as they are not present in $G_{11}(s)$ and $G_{22}(s)$. However it should

be mentioned that a RHP-zero was expected in the transfer function $G_{22}(s)$ from feed water to water level but so far no measurement have indicated this.

Loop Closing

As was noted previously the transfer function $G_{11}(s)$ has a zero in the origin, indicating that u_1, fuel flow, can not be used to control y_1, the pressure. However the RGA analysis showed a different result which calls for design via sequential loop closing. This technique also has the advantage of ensuring stability, though the performance of the inner loop might be disturbed when closing the outer loop [3].
PI controllers are used in both loops. These are designed to achieve the largest possible bandwidth in both loops having a phase margin of 45° well above the limit found previously.
First the level loop is closed using K_{22} as illustrated in figure 9. The new transfer function from u_1 to y_1 is given as:

$$y_1 = G_{11}\left(1 - \frac{\kappa}{\frac{1}{G_{22}K_{22}} + 1}\right) u_1 = G'_{11}u_1 \qquad (8)$$

Inspecting this equation it can be seen that at low frequencies: $G'_{11} \approx G_{11}(1-\kappa)$, as $G_{22}K_{22}$ is large at frequencies where feedback is effective. At high frequencies κ is small indicating that $G'_{11} \approx G_{11}$. As the controller design focuses on relatively high frequencies a design using G_{11} should be adequate though (8) is used to design K_{11}, due to slight phase differences between this and the approximation.

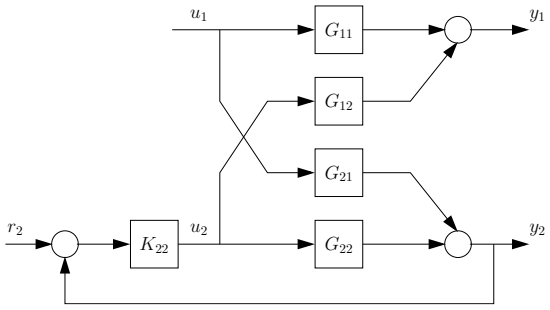

Figure 9: Level loop closed in the sequential design strategy.

Load dependency

Having determined two SISO controllers and thereby found the crossover frequency for both loops ($\omega_{c1} = 0.08$ rad/s $> \omega_{b1}$ and $\omega_{c2} = 0.13$ rad/s $> \omega_{b2}$) the load dependency of gains at the crossover frequencies and the variation of these crossover frequencies can be determined applying the controllers found for the 100% load at the remaining two operating points considered, 70% and 40%.
In the following it is assumed that the level loop is closed meaning that $G'_{11}(s)$ and not $G_{11}(s)$ is in focus. In figure 10 the mentioned variations as function of load are plotted. Included in the figure are also the variations of the stability margins.

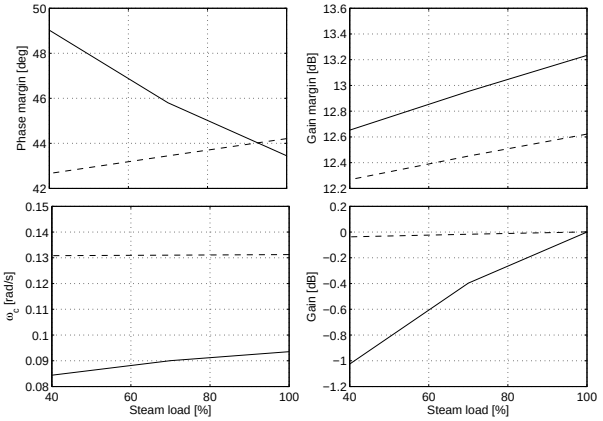

Figure 10: Plots of phase margin variations (top left), gain margin variations (top right), crossover frequency variations (bottom left) and variations of gain at the crossover frequencies for the loop at 100% load (bottom right) all as function of load. The solid line represents the loop associated with G'_{11} (pressure loop) and the dashed line the loop corresponding to G_{22} (level loop).

It is clear from the figure that nonlinearities in the model have most effect on the pressure loop. Nevertheless neither stability margins nor gains and crossover frequency vary remarkably over the load range considered.
To illustrate that the cross terms in the model do not cause the system to become unstable and to illustrate the little influence nonlinearities have on stability a Nyquist plot of $\det(\mathbf{I} - \mathbf{GK}(s))$ is shown in figure 11. The plot is shown for the three operating points under consideration given the same controller. From the right plot, focusing around the unit circle, it can be seen that stability is not effected by cross terms and nor by nonlinearities as the three curves cross the unit circle at the same point.

Model Nonlinearity

From figure 3 and the results above it is clear that the nonlinearities are mainly pronounced in the low frequency band as function of load. To investigate whether these low frequency variations should have any influence on the choice of control strategy (linear/nonlinear) the two SISO controllers developed in

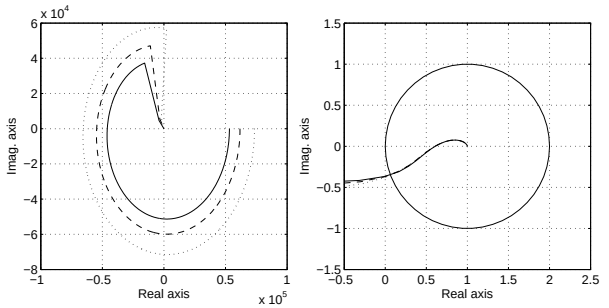

Figure 11: Nyquist plot of open loop system with controller base on sequential loop closing. Left: full plot, right: zoom around the unit circle. The solid line represents a linear model at 100% load, the dashed line a model at 70% load and the dotted line a model at 40% load.

the last section are simulated together with the nonlinear model. Steps in the steam flow disturbance, k, of different sizes are made starting from different operating points. To compare the responses the outputs are normed with the size of the disturbance step. The result is shown in figure 12.

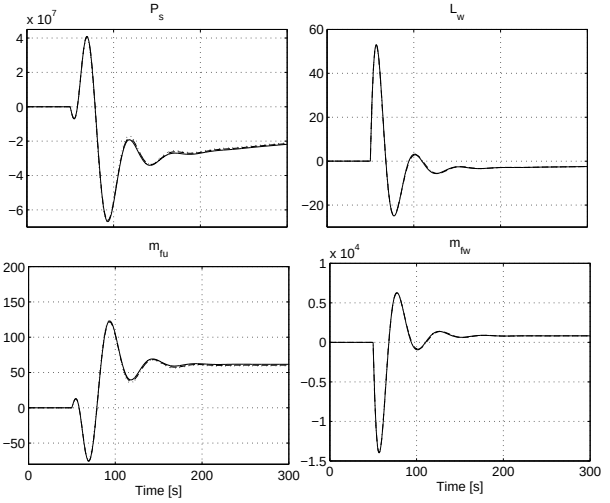

Figure 12: Closed loop response to step disturbance on nonlinear model. Three different step responses are shown; 50% → 75%, solid, 50% → 100%, dashed and 75% → 100%, dotted.

From the plots it can be seen that the transient behaviour for each step made is approximately the same. The largest differences in the plots are on pressure and fuel flow. This is illustrated in figure 13 where only the last 200 s of figure 12 is shown. Referring to figure 4 this makes sense as the largest gain variations over load are associated with the pressure.

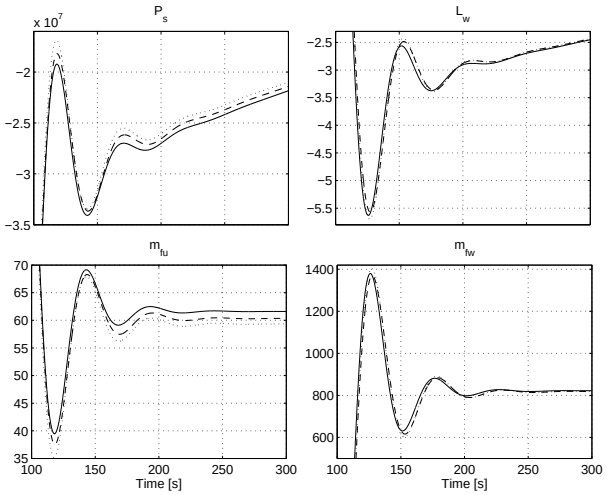

Figure 13: Figure 12 repeated with reduced axes.

Influence of interaction on performance

Having a MIMO system it is of interest to investigate the potential benefit from a MIMO controller design. This can be evaluated by inspecting the influence of the interactions in the model on the achievable controller performance, hereby meaning the ability of the controller to reject the disturbances.
The effect of the cross terms might be positive causing damping of the disturbances but amplification is also a possibility. To investigate this the performance of the previously designed controller will be compared to that of a controller designed after decoupling the interactions in the model. The decoupled system is illustrated in figure 14 assuming perfect decoupling.

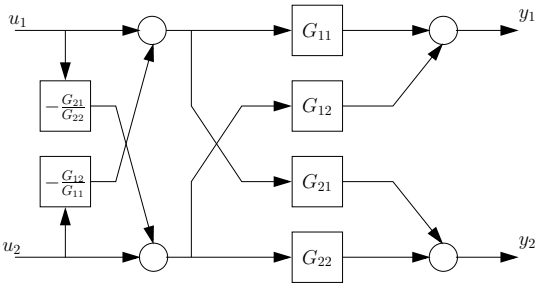

Figure 14: Decoupled system.

This system can be described as:

$$\mathbf{y} = \mathbf{G}^*\mathbf{u} = \mathbf{GWu}$$

where

$$\mathbf{W} = \begin{bmatrix} 1 & -\frac{G_{12}}{G_{11}} \\ -\frac{G_{21}}{G_{22}} & 1 \end{bmatrix}$$

giving the new system:

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} G_{11}(1-\kappa) & 0 \\ 0 & G_{22}(1-\kappa) \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} \quad (9)$$

Note that at low frequencies the transfer function from fuel to pressure is approximately the same as when designing using sequential loop closing, see equation 8. Furthermore at high frequencies $\mathbf{G}^* \approx \text{diag}(G_{11}, G_{22})$.
In practice perfect decoupling is not possible due to model uncertainties. Decoupling controllers requires accurate process models and are sensitive to modelling errors, particularly when the RGA elements are large [3]. However theoretically the decoupling from u_1 (fuel flow) to y_2 (water level) can be assumed perfect. Regarding decoupling the other way problems arise in realizing $-\frac{G_{12}}{G_{11}}$ due to an improper system and the zero in the origin of G_{11}. In the frequency range of interest around the crossover frequency $-\frac{G_{12}}{G_{11}}$ is nearly constant with zero phase. For this reason $-\frac{G_{12}}{G_{11}}$ is substituted with a constant. The decoupled system is compared with the original system in the magnitude plot in figure 15.

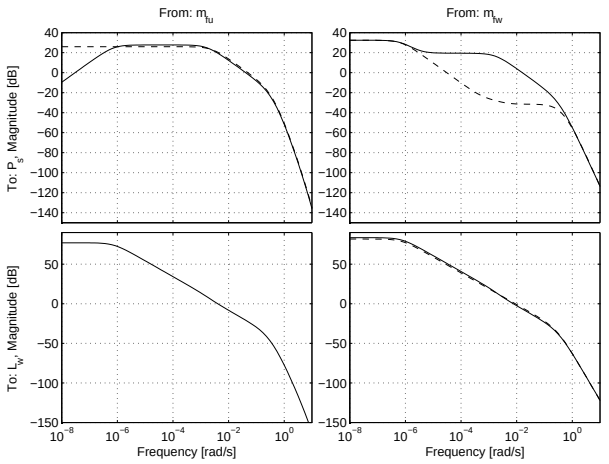

Figure 15: Comparison of open loop model without decoupling, $\mathbf{G}(s)$, solid and with decoupling, $\mathbf{G}^*(s)$, dashed.

From the figure it can be seen that for G_{11}^* the zero in the origin has disappeared. Furthermore the non perfect decoupling from u_2 to y_1 has damped the interaction at frequencies from well below the crossover frequency.
Now PI controllers are designed based on the diagonal elements in the new transfer matrix. Again these are designed to achieve the largest possible bandwidth in both loops having a phase margin of 45°. It should be mentioned that controllers with and without decoupling become very much alike, even though equation 9 is not valid, as the design focuses on the frequency band where figure 15 shows little difference between the graphs of the paired inputs and outputs. This also means that the only thing that influences whether a decoupling has any positive effect is whether the interaction amplifies the disturbance effect or not.
Bode plots of the output sensitivity functions achieved using the decoupling controller and that of the controller designed using sequential loop closing are compared in figure 16.

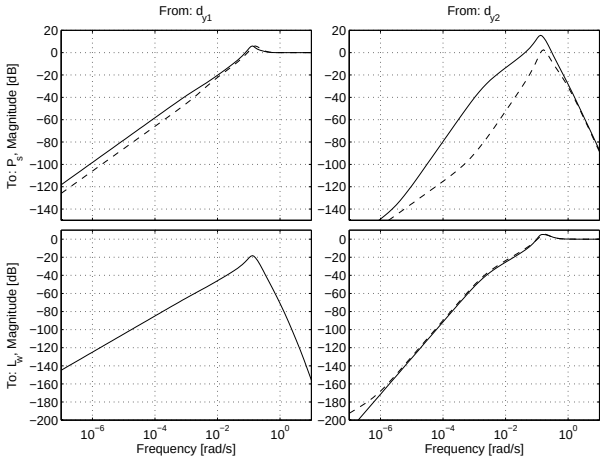

Figure 16: Comparison of sensitivity functions using sequential loop closing, solid, and decoupling design, dashed.

As the figure shows the individual sensitivities of the system based on decoupling are more damped than those based on sequential loop closing. The influence of the interactions can now be evaluated from evaluating the two controllers ability to reject disturbances on the output noting that from the specification of the normed system the objective of the controller is:

$$\|\mathbf{S}_o \mathbf{G}_{dk}\|_\infty \leq 1 \ \forall k$$

where $\mathbf{S}_o$ is the output sensitivity transfer matrix. $|\mathbf{S}_o \mathbf{G}_{d1}(j\omega)|$ is plotted in figure 17, that is only from the steam flow disturbance.
The plots show that decoupling has had a positive effect on the controller performance especially regarding the pressure loop. Here the resonant top using sequential loop closing is avoided at 10^{-1} rad/s and furthermore the controller actually complies with the demands.

Input Constraints

An important issue in controller design is whether input constraints cause any limit on the achievable performance. Constraints can be a problem when rejecting the transients in the disturbance.

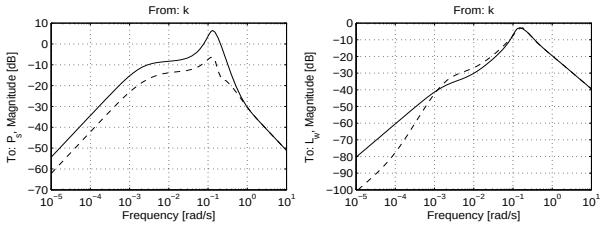

Figure 17: Illustration of effect of interaction. $|\mathbf{S}_o\mathbf{G}_{d1}(j\omega)|$ is plotted for two control strategies. Solid line is sequential loop closing and dashed line is design by decoupling.

Previous results showed that nonlinearities were concentrated in the low frequency band for which reason constraint problems as a consequence of rejecting transients in the disturbances can be carried out using linear model analysis.
This analysis can be carried out by introducing the control sensitivity $\mathbf{M} = (\mathbf{I} + \mathbf{GK})^{-1}\mathbf{K}$, describing the effect of the disturbances on the control signals. Checking whether the constraints become active can be seen from the inequality:

$$\|\mathbf{MG}_{dk}\|_\infty \leq 1 \ \forall\, k$$

If this inequality is violated there is not enough control signal to reject the disturbances. This reasoning of course requires a scaling of the inputs that reflects the constraints as was done previously. Again focus is limited to the steam flow disturbance. In figure 18 a plot of $|\mathbf{MG}_{d1}(j\omega)|$ is shown.

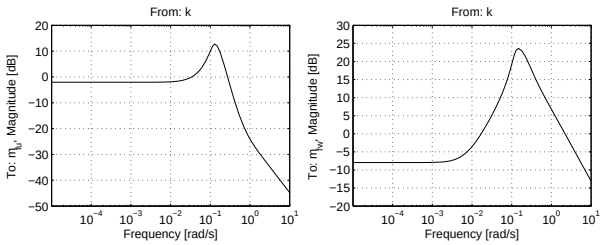

Figure 18: Plot of $|\mathbf{MG}_{d1}(j\omega)|$. The top plot represents the fuel flow and the bottom plot the feed water flow.

From this plot it is easy to see that input constraints become active for both the fuel and feed water supply.

CONCLUSIONS

This paper has shown that benefit of MIMO control can be achieved in a control strategy for the boiler system. This was a result of improved performance when decoupling the system prior to a SISO controller design.

The boiler model proved to have nonlinear behaviour mainly in the low frequency band below the crossover frequency. It was shown that one linear controller suffices leaving out gain scheduling or another nonlinear control strategy. This was manifested inspecting the performance of one linear controller to steps in the steam flow disturbance.
Input constraints showed to be a problem when controlling the boiler. This also means that the controller performance will be limited, however it is not a practical problem. The controller could be detuned to be less aggressive if the performance demands can be loosened.

Future Work

The fact that input constraints pose limitations on achievable performance, and that hard constraints for level variations are present, urge to include constraints in the controller design through an MPC strategy.
Furthermore it is of Aalborg Industries A/S' interest to introduce controllers for their boilers that do not require manual tuning and these controllers should work for a whole family of boilers. For this reason work remains in developing a strategy for making the control system self tuning. Also possible problems with model scaling should be investigated as the degree of nonlinearity and interactions in the model for scaled versions of the boiler concerned in this paper are not yet known.

ABSTRACT

A turbulent combustion simulation to predict the fluid flow, temperature and chemical species concentrations in a jet burner that generates a jet of high temperature and high speed is carried out. Conservative equations of mass, momentum and energy in the turbulent flow field are solved in conjunction with a k-ε turbulence model. A radiative heat transfer model that considers the radiative properties of soot, water and CO_2 are included in the simulation. The validity of the numerical model is presented by comparing with the experimental data. The effect of soot on the combustion is also examined.

The calculated temperature without considering the soot is higher than the experimental data. However, with considering the soot, the differences between calculated and experimental results become small. The peak temperature is in good agreement with the experimental data. This is because that the soot greatly affects the radiative heat transfer in the burner.

Moreover, to improve combustion behavior in the jet burner, a numerical simulation considering a baffle plate that causes recirculation flows is also carried out. As a result, a suitable baffle plate shifts the high temperature region to upstream.

INTRODUCTION

A jet burner, in which a fuel and an oxidizing agent burn under high-pressure conditions, generates a jet of high temperature and high speed, is mainly used for grinding and drying of processed products. The jet has the advantage that it can crush caking processed products and has a

[1] Corresponding author: Phone: +81-22-795-7251 Fax: +81-22-795-6165
E-mail: hiro@tranpo.che.tohoku.ac.jp

large heat transfer coefficient. In constructing a new jet burner efficiently, we need to understand the combustion behavior in the jet burner. Experiments are usually considered to be better for the prediction of combustion behavior, however, it is difficult to measure combustion characteristics such as temperature and chemical species concentrations. In addition, the data include unavoidable errors because the combustion characteristics are complicated under high-temperature conditions.

Thus, a numerical simulation of combustion behavior have attracted much attention for many years because it is easy and safe to understand combustion behavior in detail. In recent years, many researchers carried out a combustion simulation for gas turbine combustor[1], utility boiler[2] and spray combustion furnace[3]. However, combustion simulation is used as a complement of the experimental value because the reliability of calculated result is insufficient. Moreover, there is no research of the application of combustion simulation to the jet burner. To improve the reliability of combustion simulation, it is necessary to compare the calculated data with experiments and examine how individual factors in the simulation contribute to the combustion behavior. Especially, the radiation from soot is much stronger than that from combustion gas, and greatly contributes to the heat transfer in the burner. However, it is sometimes neglected in combustion simulation of practical combustion furnaces[1][3].

In this paper, we carry out a turbulent combustion simulation of the jet burner considering soot. The effect of soot on combustion and the validity of the numerical model are investigated. Then, we investigate combustion behavior with a baffle plate that is easy to equip the jet burner.

2. MATHEMATICAL MODEL

2.1. Governing equation

The standard k-ε turbulence model is widely used in turbulent combustion simulation[2][3]. So, in this simulation, this model is used to describe the turbulent flow. Transport equations used in this study can be expressed in cylindrical three-dimensional geometry is expressed as Eq. (1),

$$\frac{\partial}{\partial x}(\rho U\phi)+\frac{1}{r}\frac{\partial}{\partial r}(r\rho V\phi)+\frac{1}{r}\frac{\partial}{\partial \theta}(\rho W\phi) = \frac{\partial}{\partial x}\left(\Gamma_\phi\frac{\partial \phi}{\partial x}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(r\Gamma_\phi\frac{\partial \phi}{\partial r}\right)+\frac{1}{r}\frac{\partial}{\partial \theta}\left(\Gamma_\phi\frac{\partial \phi}{r\partial \theta}\right)+S_\phi+S_{d\phi}, \quad (1)$$

where ϕ represents the dependent variables, which denote mass (1), momentum (U, V, W), turbulence energy(k), dissipation rate of turbulence energy(ε), enthalpy (h) and mass fraction(m_i; i = $C_{12}H_{24}$, O_2, CO_2, H_2O, N_2, CO, H_2 and C(soot)), Γ_ϕ is the diffusion coefficient, S_ϕ is the source term in gas phase, $S_{d\phi}$ is the source term arising from droplet phase which is calculated by PSI-CELL model[4], ρ is the density and x, r, θ are axial, radial and tangential coordinates, respectively. This governing equations are solved using the original code(DRAGON) developed in our laboratory. Density is obtained from the equation of state. The gas flow characteristics at the wall boundary are estimated using the wall function model.

2.2. Reaction model

In this study, $C_{12}H_{24}$ is used to represent kerosene[5]. So, a four-step global reaction mechanism to express kerosene-air combustion reaction is used as

$$C_{12}H_{24} + 6O_2 \rightarrow 12\ CO + 12\ H_2,$$
$$CO + 1/2O_2 \rightarrow CO_2,$$
$$H_2 + 1/2O_2 \rightarrow H_2O,$$
$$CO + H_2O \Leftrightarrow CO_2 + H_2,$$

Reaction rate R_i is expressed by Eq. (2) considering both the eddy motion(EDC model, Eq. (3)) and the chemical reaction(Eq. 4),

$$R_i = -\min(R_{eddy}, R_{Arr}), \quad (2)$$

$$R_{eddy} = 4.0\frac{\varepsilon}{k}\min\left(\frac{m_{ox}}{r_{fu}}, m_{fu}\right), \quad (3)$$

$$R_{Arr} = A[fuel]^a[oxygen]^b \exp(-E/RT), \quad (4)$$

where r_{fu} is a stoichiometric oxidant requirement to burn 1 kg of fuel, A is a pre-exponential factor of rate constant, E is an activation energy and T is the temperature. The values of coefficients A, E, a and b are referred from Jones and Lindstedt[6] and Westbrook and Dryer[7].

The effect of soot on combustion is discussed in this study. Modeling of soot formation in practical combustion systems is an extremely challenging problem. Although some detailed

kinetic models of soot inception, growth and oxidation have been derived[8], it is still very difficult and time consuming to implement the detailed kinetic model to the simulations of multi-dimensional combustion systems. So, in this study, single step global reaction that produces soot directly from $C_{12}H_{24}$ and the oxidation of soot are used as follows

$$C_{12}H_{24} \rightarrow 12C(soot) + 12H_2,$$
$$C(soot) + 1/2O_2 \rightarrow CO,$$

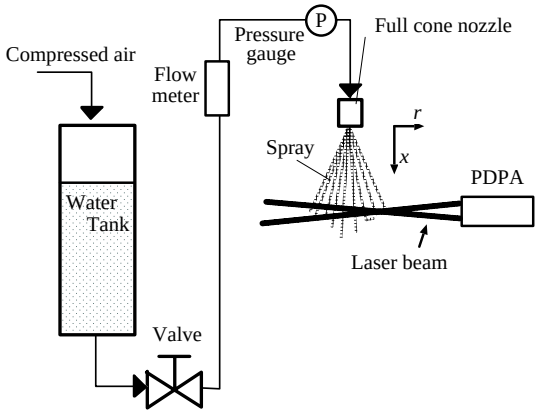

Fig. 1 Schematic diagram of experimental apparatus for examining spray properties

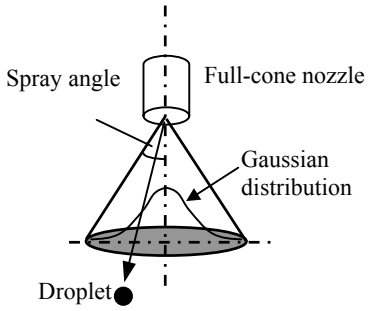

Fig. 2 Modeling of full-cone spray pattern

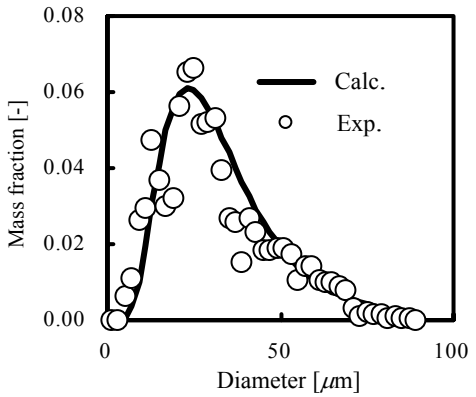
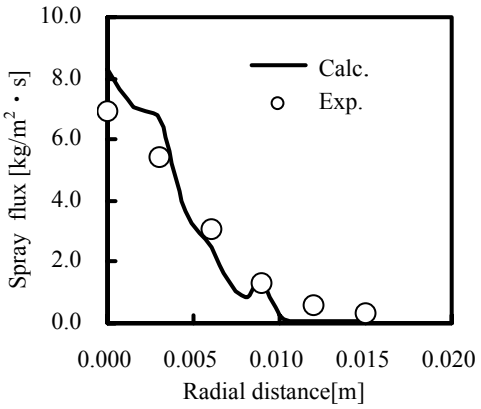
where pseudo-gas graphite carbon C(s) is used to represent soot. The formulation of the soot formation follows the previous study[9] where the soot formation is assumed to be a function of temperature, oxygen and soot building block concentration(Eq. (4)). In the oxidation model,

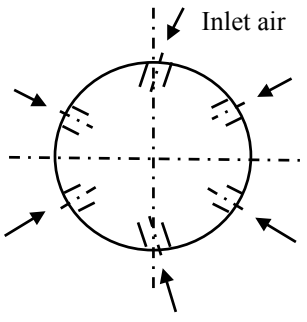


(a) Diameter distribution

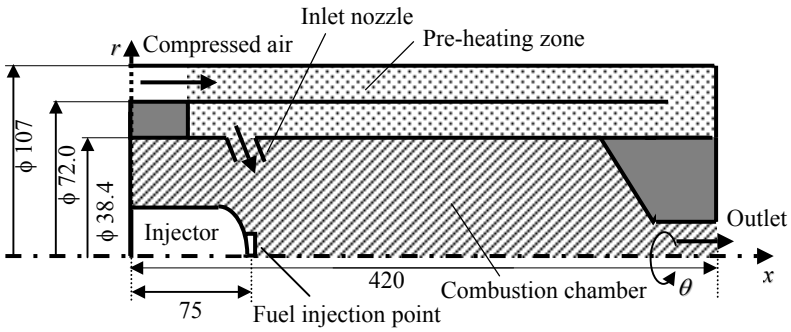


(b) Spray flux distribution

Fig. 3 Full-cone spray properties



(a) r-θ plane(at inlet nozzle)



(b) x-r plane(at inlet nozzle)

Fig. 4 Schematic diagram of jet burner

$$R_{eddy,soot} = \min[4.0\, m_s \frac{\varepsilon}{k}, \frac{4.0\, m_{o_2}}{r_s} \frac{\varepsilon}{k} \frac{m_s r_s}{m_s r_s + m_f r_f}]. \quad (5)$$

considering both the eddy motion(Eq. (5)) and chemical reaction(Eq. (4)), the reaction rate is expressed as Eq. (2). The value of coefficients *A*, *E*, *a*, and *b* in the soot formation is referred from Wang[5] and those in the soot oxidation is referred from Nagle[10]

2.3. Radiation model

Radiative heat transfer is calculated using a 6-flux method coupled with a WSGGM(Weighted-Sum-of-Gray-Gases Model). Beer's model [11] is used when soot is considered in the simulation, whereas Smith's model [12] is used in case of gas radiation without soot.

2.4. Spray model

2.4.1 model

The motions of fuel droplets in the turbulent combustion flow field are calculated using a Lagrangian method. It is assumed that the fuel is injected into the combustor as a fully atomized spray which consists of spherical droplets with various size. The Lagrangian equations for the change of droplet velocity, mass and temperature are solved simultaneously. The effect of turbulence fluctuation of gas flow on the droplet motions is considered in the droplet velocity calculation.

2.4.2 Inlet condition

A schematic diagram of experimental setup for examining spray flow inlet conditions is shown in Fig. 1. At *x*=30mm, the diameter of the droplets and the spray flux distribution is measured with PDPA. Water is used as a working fluid, pressure drop defined as the difference between injection pressure and discharged back pressure is corresponds to the combustion operation condition.

In this simulation, the diameter distribution expressed as a log-normal distribution from 0 to 90μm is divided into 45 ranges and each range has 100 computational droplets. The injection angle of a droplet is chosen randomly from a Gaussian distribution to represent the full-cone spray pattern of the nozzle used in the jet burner (Fig. 2).

Table 1 Inlet condition

	AFR 3	AFR 2
Air flow rate[Nm^3/hr]	122	81.6
Fuel flow rate[kg/hr]	3.60	3.60

To obtain the initial average velocity of droplet and injection-angle, we carry out spray calculations as to agree with the measured data for the diameter distribution and spray flux [13].

Fig. 3 shows full-cone spray nozzle properties. Calculated data express a typical characteristic of a full-cone nozzle and is in good agreement with the experiments. So these parameters can reproduce the spray pattern of the full-cone nozzle.

3. NUMERICAL SOLUTION

The governing equations are discretized using a control volume method. The discretized governing equations are solved employing the SIMPLER algorithm. Bi-CGSTAB method is used for solving linear systems. A schematic diagram of the computational domain is shown in Fig. 4. The jet burner is composed of a burner and a preheating zone. The dimension of the burner is 38.4mm in inner diameter and 420mm in length. The inlet air nozzle diameter in the burner is ϕ8mm. The burner wall is cooled by air. In this calculation, the burner and the preheating zone are separately calculated. Considering only the heat transfer between wall surfaces of combustion chamber and pre-heating zone, calculation is carried out as follows;

Overall Solution procedure

1) The calculation in the burner is carried out until a convergence is reached without considering pre-heating zone.
2) The calculated inner wall temperature is set as boundary conditions, and the calculation in the pre-heating zone is carried out.
3) The calculated outer wall temperature is set as boundary conditions, the calculation in the burner is carried out again.
4) Steps 1 through 3 are repeated until the convergence is reached and wall temperature is fixed.

Numbers of computational grid in the axial, radial and tangential directions are 122×41×30 for the simulation of a 1/6 circumference of a jet

burner and 122 × 21 × 30 for that of the combustion chamber, respectively. It assures grid-independency of the solution. The convergence criterion is that normalized residuals in all conservation equations are less than 0.015. The inlet conditions are shown in Table 1.

4. RESULTS

4.1 Combustion behavior in the burner

In this section, we discuss the combustion behavior in the burner, the effect of soot on combustion and the validity of the numerical model. Inlet condition AFR 2 is preferable in the burner. However, the experimental data under AFR 2 is insufficient because of the high temperature. So, in this section, computations are carried out under the condition AFR 3.

Fig. 5 shows the time-mean velocity vectors of the combustion gas flow. The zero-axial velocity contour is plotted in Fig. 5. In Figs. 5(a) and 5(b), the flow fields have little differences, though the velocity of the gas flow without considering soot is higher than that with considering soot.

Fig. 6 shows the time-mean temperature distribution. High temperature region exists near the injector where fuel and air are well mixed. In Figs. 6(a) and 6(b), the high temperature region above 2200K in the case without considering soot is a little larger than that with considering soot,

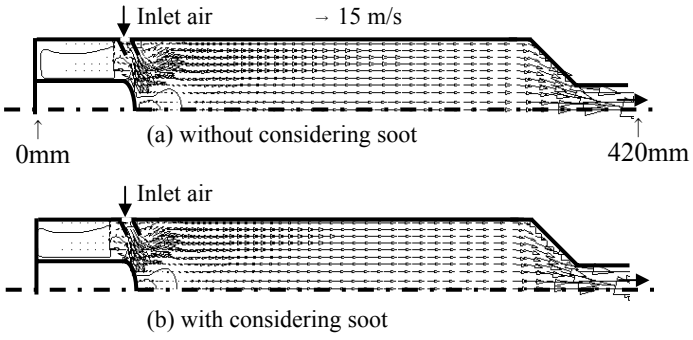


Fig. 5 Predicted combustion gas flow(AFR 3)

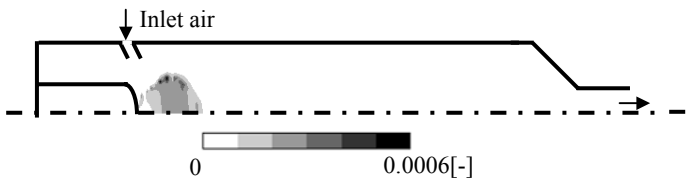

Fig. 7 Predicted soot mass fraction distribution

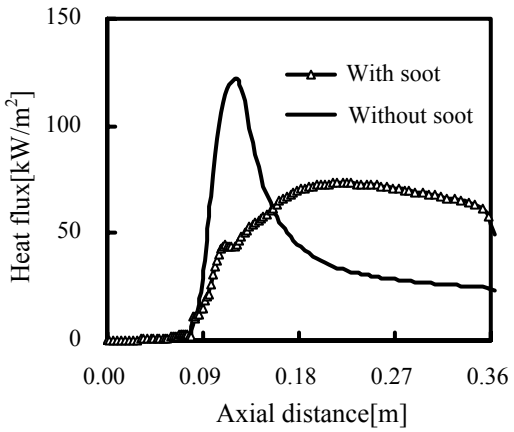

Fig. 8 Net radiative wall heat flux

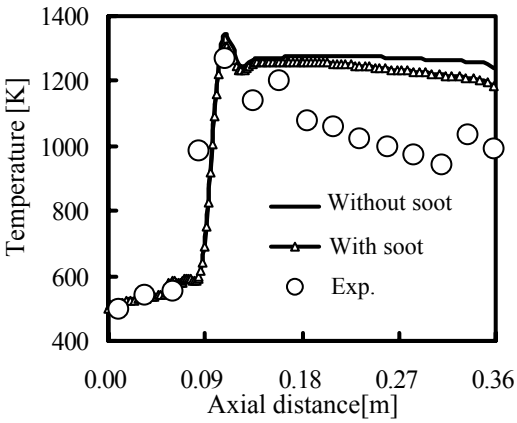

Fig. 9 Axial distribution of temperature (r=0.015m)

Fig. 10 Predicted temperature contour(AFR 2)

since the radiation intensity is increased by soot.

Fig. 7 shows the time-mean soot mass fraction distribution. In the high temperature region above 2000K, the soot is formed.

Fig. 8 shows the profile of the net radiative wall heat flux under different soot loadings. In the upstream region of the burner, net radiative wall heat flux without considering soot is higher than that with considering soot. Because of the radiation from soot, temperature of the upstream region decreases greatly. In the downstream region, the heat flux with considering soot is about twice as much as that without considering soot.

Fig. 9 shows the axial distribution of temperature at r=0.015m. The axial temperature profiles are measured with a thermocouple. The measured temperature is not accurated by the radiation loss to surrounding. So, the predicted temperatures are corrected. In the downstream region, the calculated temperature without considering soot is higher than the experimental data. With considering soot, the differences between the calculated and experimental results become small, and the peak temperature is in good agreement with the experimental data. However, the difference between measured and calculated temperature increases in the downstream, because, the thermocouple is inserted from upper part of that burner and is deviated from the correct position during the experiment. In addition, the thermocouple may be bended to the wall side by thermal stress, therefore the measured temperature is lower than the calculated one.

Baffle plate C	12	28	36

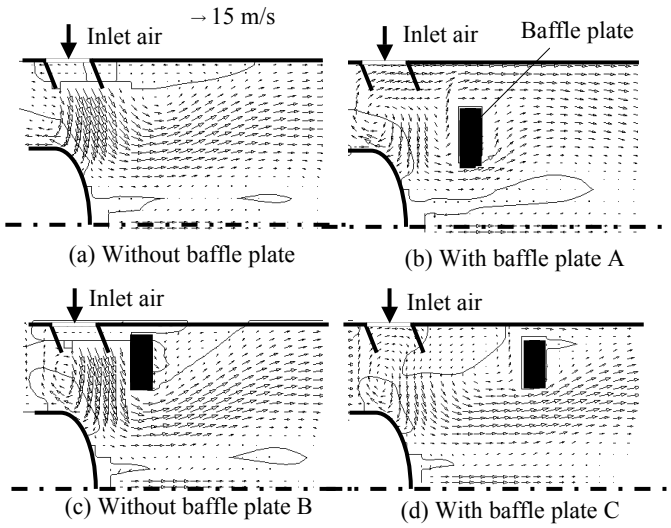

Fig. 13 Combustion gas flow near injector

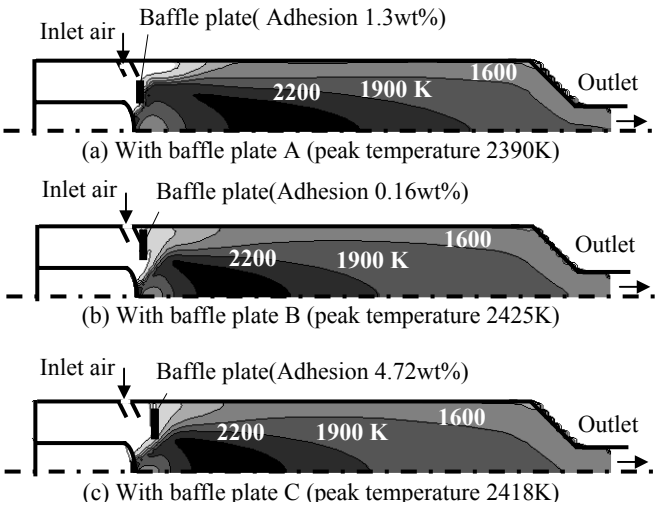

Fig. 14 Predicted temperature contour(AFR 2)

4.2 Development of the jet burner using baffle plate

Fig. 10 shows the predicted temperature distribution under AFR 2 with considering soot. In Fig. 6(b)(AFR 3) and Fig. 10(AFR2), the differences between the predicted temperature distributions are particularly noticeable. In AFR 3, a high temperature region near the injector is

small and the combustion reaction finishes in the upstream near the injector. However, under AFR 2, the high temperature region extends to downstream because the mixing of spray and air deteriorates. To shorten the flame length, a baffle plate is applied since it is easy and reasonable to equip that in the jet burner. Moreover, it does not require drastic changes of the burner shape. In this section, the effect of the baffle plate on combustion behavior is numerically investigated.

Combustion simulation is carried out under the different baffle plate size and location as shown in Fig. 11 and Table 2, where l_b is the distance between spray injector and baffle plate, $d_{b,i}$ and $d_{b,o}$ are the inside and outside diameter of baffle plate, respectively. The schematically baffle plate used in this study is shown in Fig. 12 schematically.

Fig. 13 shows the time-mean velocity vectors of the combustion gas flow near the baffle plate. The zero-axial velocity contour is also plotted in Fig. 13. The size and position of the baffle plate have a strong influence on the gas flow. Fig. 14 shows the predicted temperature contours and the ratio of the predicted adhesion of droplets to the baffle plate to the total amount of injected fuel. Fig. 15 shows predicted soot mass fraction.

Temperature and soot concentration distribution with baffle plate compare with those without baffle plate. When baffle plate A is set in the chamber, the high temperature region above 2200K is extended to downstream as shown in Fig. 14(a) compared with Fig. 10 and the soot mass fraction increases as shown in Fig. 15(b) compared with Fig. 15(a). This is because the distance between the spray injector and the baffle plate is too narrow to provide air sufficiently near the injector as shown in Fig. 13(b).

When the inner diameter of the baffle plate increases, the high temperature region becomes narrow and shifts toward the upstream as shown in Fig. 14(b) compared with Fig. 14(a), and the soot concentration decreases as shown in Fig. 15(b) compared with Fig. 15(a). This is because the mixing of spray and air is improved and the air is sufficiently supplied to the vicinity of the injector by increasing the inner diameter of baffle plate as shown in Fig. 13(c).

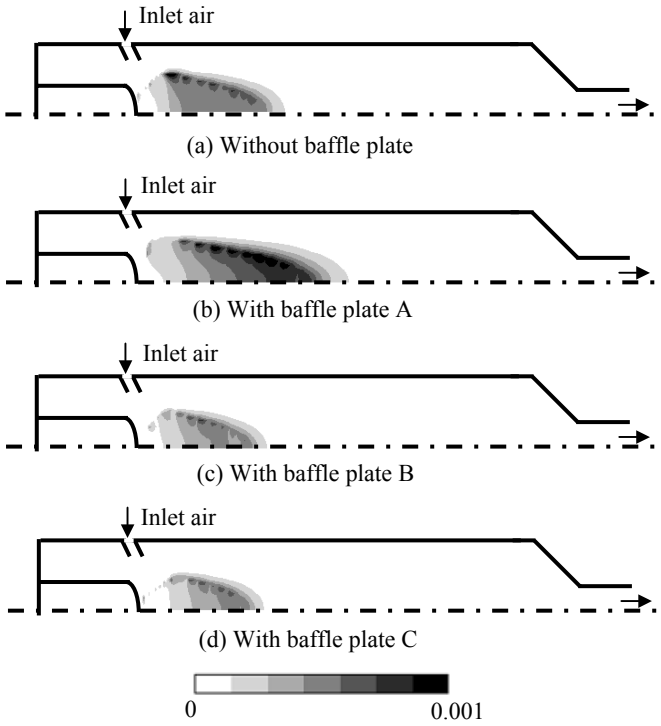

Fig. 15 Predicted soot mass fraction

When the distance between the spray injector and the baffle plate increases, temperature and soot concentration distribution have a little difference as shown in Fig. 14(b), (c) and Fig. 15(c), (d). However, adhesion of droplets to the baffle plate increases greatly.

In each case, the peak temperature is not so difference. So, NO_x formation is not so dependent on the peak temperature but dependent on high temperature region in this case. If the high temperature region becomes narrow and shifts toward upstream, NO_x reduction can be expected because of shortening of the residence time in the high temperature region. The more soot decreases, the more thermal efficiency increases. The more adhesion of droplets to baffle plate increase, the more it is difficult to carry out the stabilized continuous running to carbon deposit. Comparing the temperature distribution and the soot concentration without baffle plate (Fig. 10, Fig. 15(a)) with those with baffle plate B (Fig. 14(b), Fig. 15(c)), the combustion behavior is improved using baffle plate B. Consequently, baffle plate B has the better position of the baffle plate.

5. CONCLUSION

A turbulent combustion simulation in the jet burner is carried out. The effect of soot on the combustion behavior and the validity of the numerical model are investigated.

With considering soot, a high temperature region become small and then the prediction is improved. The soot greatly affects the heat transfer in the burner. So, it is important to develop a suitable soot formation model for practical combustion simulation.

A numerical combustion simulation with a baffle plate is also carried out. When using a baffle plate in the burner, the distance between the injector and baffle plate is important parameter. As a result, the high temperature region becomes narrow and shifts towards the upstream and soot in the burner decreases when the suitable baffle plate is used.

DYNAMIC MODELLING OF THE STEAM POWER PLANTS

Maryam Younessi-Sinaki[1], Siamak Farhad and M. Saffar-Avval
Amirkabir University of Technology
Mechanical Engineering Department
Iran

ABSTRACT

The operation of steam power plants varies from steady state to dynamic state by means of several factors; one of the most important of these factors is load variation. The practices used to control load, cause changes in working fluid properties in the cycle. Some of these properties have significant effects on the efficiency and appropriate operation of the cycle components; therefore, it is necessary to keep their variations in a suitable range. The controllers are used to perform this task and guaranty the correct operation of the steam power plant. The study of the dynamic behavior of the steam power plant is necessary for the selection and regulation of controllers.

In this paper, an object oriented and flexible simulator is presented which gives the ability to investigate the dynamic behavior of any steam power plant. The results of this simulator can be used to determine the type of controllers required in steam power plants and their regulating coefficients.

INTRODUCTION

Many controllers are used in steam power plants; these devices apply changes in adjustable variables in order to guaranty the proper operation of a power plant during dynamic conditions and lead the plant toward steady state conditions. Load variation is one of the most probable reasons causing dynamic conditions in power plants and is investigated in this paper. In order to design and regulate the controllers, it is necessary to study the dynamic behavior of a plant, provided by changes in control variables. This investigation is performed by theoretical simulation instead of experiments, which are in general expensive,

#

difficult, risky, and may prevent the normal operation of the plant.

The work of Chien et al [1] in 1958 on modelling a boiler is considered a pioneer work in the dynamic simulation of power plants. Since then, modelling power plant components have been discussed in several papers. Dynamic simulation may be used in designing plant components, training the operators and also designing and regulating controllers. In simulators applied in components design, like the RETRAN software [2], accurate models are necessary. A real time response is required in training simulators; where, simple mathematical models shall therefore be used. In simulators used in control field, the results shall reasonably represent the plant real behavior, but high accuracy is not necessary.

The purpose of the present simulation is to develop a modular and object-oriented simulator by using simple mathematical models of steam power plant components, which correctly represents the dynamic response of these plants when changes are applied to control variables.

MODELLING OF STEAM POWER PLANT COMPONENTS

In order to simulate the behavior of steam power plants, steam turbine, condenser, condensate and boiler feed pumps, feedwater heater and boiler are modeled using conservation laws and experimental heat transfer and thermodynamic equations. Assumptions are made to simplify these equations, with considering the purpose of simulation.

Boiler

Boilers have a significant effect on the dynamic behavior of power plants. In the boiler modeled in this paper, the flue gas in the furnace radiates heat to the risers and superheater tubes, passes through the superheater, reheater and economizer and leaves the boiler. In the water side, water supplied by the feedwater system is heated while passing through the economizer. It is then mixed with some saturated liquid in the drum and passes through the downcomers and risers with a constant volumetric flow rate regulated by a pump, changing into two-phase fluid. Saturated steam is separated from the saturated liquid in the drum and sent to the superheater, where it is heated. Then the steam leaves the boiler, and after passing the high-pressure turbine, enters the reheater and continues its course with a higher temperature.

The boiler is composed of different surface heat exchangers; to model the boiler, each of these heat exchangers is divided into two control volumes, the fluid inside the tubes and flue gas; the equations describing the behavior of these volumes are then derived. The fluid inside risers tubes is two-phase, while single phase fluid flows through reheater, superheater and economizer tubes; thus, both single and two phase fluid shall be modeled.

In order to simplify equations and solve partial differential equations in modelling one phase fluid (water or flue gas), the fluid volume is divided into segments in which fluid properties are considered lumped. For example, the furnace flue gas may be segmented to dimensionless, one-dimensional and three-dimensional models. In the dimensionless model, which is used in this simulation, flue gas properties are independent of the coordinate and are considered uniform all over the furnace [3]. In the one-dimensional model, the furnace is divided into horizontal layers, and several three-dimensional elements form the furnace in the three dimensional model. It is noted that the application of the three dimensional model is very complex and is only used in furnace design.

A dimensionless lumped parameter model is considered for the single-phase fluid in each heat exchanger, where the flue gas and single-phase water properties are respectively considered equal to the heater inlet gas and outlet water properties. It should be noticed that the tubes metal temperature of each heat exchanger is assumed uniform all over the heater. The lumped parameter model is only suitable in high velocities and may cause a considerable error in modelling the economizer. Considering the fact that the accuracy of the economizer model has a negligible effect on the simulation results at high loads, the application of the lumped parameter model is acceptable.

Homogeneous or quasi-homogeneous models are used to model two-phase fluid flow. In high-pressure flows, like the flow of water inside the risers, the slip velocity is negligible; thus, the homogeneous model is used, where the fluid is considered as a single-phase fluid which properties are calculated using the fluid quality. Other assumptions used to model the boiler are as follow:

- Flue gas flow rate is proportional to furnace pressure [4].
- Superheater and reheater steam are ideal gases with constant specific heats.
- Flow rate variation in the reheater is modeled with a first order lag [4].

- The pressure drop takes place at the inlet of the superheater and steam compressibility is negligible; therefore:

$$p_{si} - p_{so} = f_s \frac{w_{si}^2}{\rho_{si}} \qquad (1)\#$$

- Water pressure difference in the downcomers and risers path is about 1% of the drum absolute pressure, which can be neglected. Therefore, the fluid pressure over this path is considered equal to the drum pressure.
- Water inside drum, downcomers and risers is modeled using the following assumptions [5]:
  - Saturated liquid and vapor in the drum are in equilibrium.
  - There is no mass storage in the downcomers and risers tubes.
  - Heat is uniformly transferred to the risers.

The models used in this simulation lead to the following equations for calculating the rate of heat transfer in each heat exchanger.

- Rate of convective heat transfer from gas to tubes and from tubes to single-phase fluid inside tubes:

$$\dot{Q}_{cong} = k_{cong} w_g^{0.6} \left(T_g - T_t\right) \qquad (2)$$

$$\dot{Q}_{conw} = k_{conw} w_w^{0.8} \left(T_t - T_w\right) \qquad (3)$$

- Rate of heat transfer to boiling fluid and radiative heat transfer from furnace flue gas:

$$\dot{Q}_{rtw} = k_r \left(T_{rt} - T_{rw}\right)^3 \qquad (4)$$

$$\dot{Q}_{rad} = k_{rad} V_G \sigma T_G^4 \qquad (5)$$

It is noticed that k_{cong}, k_{conw}, k_{rad} and k_r are coefficients that are constant for each plant [3 , 6].

The law of energy conservation is presented in equation 6.

$$\frac{dx}{dt} = \frac{1}{V}\left(\dot{Q} + w_i h_i - w_o h_o\right) \qquad (6)$$

Where $x = \rho u$ is a state variable. It should be noticed that the flue gas response in dynamic state is faster than the water response; therefore, steady sate equations are used to model this gas, except in the furnace. Dynamic relations are only used when furnace pressure control or flame stability problems are to be studied.

Steam Turbine

In order to simplify the modelling of steam turbines in dynamic simulations, the turbine is divided into steady and dynamic sections [4]. A lumped parameter model is chosen for the dynamic section, where steam properties are set equal to the outlet fluid properties. The flow rate variation of the dynamic section is modeled with a first order lag. The steady state section is a simple turbine that expands steam in a polytropic process. The generated power is calculated considering the steady state section enthalpy change. Steam is assumed ideal gas with constant specific heat, and the low-pressure turbine outlet fluid is assumed saturated vapor. The efficiencies of all stages of a turbine are assumed equal and constant [7], except in the low-pressure turbine where the total efficiency is considered constant [8].

In governing control, the throttle steam pressure and flow rate are proportional [5]. The steam pressure and flow rate at the inlet of the reheater [7] and each turbine stage [9] are also proportional in this condition.

Condenser

A shell and tube condenser is modeled in this simulation. A very complex model shall be used when the inlet steam is superheated and some of the condensate remains inside the shell. To avoid this complexity, the fluid at the shell inlet and inside it are assumed saturated vapor, while the outlet condensate is considered saturated liquid.

Distributed and lumped parameter models can be applied to solve condenser differential equations. A lumped parameter model, which validity has been approved by experimental tests [10], is applied in this simulation. In this model, the cooling water is divided into several sections in the axial direction, and the properties of the shell, tubes, steam and cooling water in each section are assumed lumped.

Pump

Several pumps are used in a steam power plant but only condensate pump and boiler feed pump are considered in this paper. The condensate pump increases the water pressure to the deaerator pressure and the boiler feed pump provides the drum pressure and regulates the feedwater flow rate. The pressure of the water leaving condensate and boiler feed pumps are assumed equal to the deaerator and drum pressures respectively. Steady state equations are generally used when modelling pumps in dynamic behavior studies of power plants [7]. In this simulation, a variable speed

#

pump is modeled, which efficiency is assumed constant with regard to the range of variations investigated.

Feedwater Heaters

Models used to study the dynamic behavior of feedwater heaters are very complex. Studies have shown that it is not necessary to apply these complex models in simulations where the objective is to design, study or regulate main controllers of steam power plants. A model, in which the variations in properties of the fluid leaving the feedwater system and saturated liquid at the pressure of the steam entering the heater are estimated to be similar, is suitable in this simulation [7]. In modelling closed feedwater heaters, mass storage is ignored and the initial and terminal temperature differences are assumed constant. In modelling the deaerator, it is assumed that the liquid leaving this heater is saturated and that variation of water level is negligible.

CONTROL VARIABLES

Before developing the simulator, control variables causing the dynamic behavior of the plant, and variables affecting its proper operation shall be specified. In order to control the power output, the rate of boiler steam generation and throttle flow are regulated. The governing valve opening is used in regulating the throttle flow, and is therefore a control variable. The rate of steam generation is adjusted by applying changes to the fuel flow, burner tilt angle and air temperature; the fuel flow is considered a control variable while other mentioned factors are assumed constant. In order to perform a complete combustion, air flow must vary along with the fuel flow and is thus considered a control variable.

Fuel flow variations cause changes in throttle and reheat temperature. Decrease in these temperatures reduces the cycle efficiency, and increase of these values reduces components life; therefore, the temperature variations shall be controlled in a safe range which is about ±5˚C [11].

Drum water level is also affected by throttle flow variations. The decrease of this value causes the risers tube to overheat and its increase prevents the proper operation of the steam and liquid separator. The allowable range of variations of drum water level is about ±2.5 cm [11]. Feedwater flow is the control variable for the drum water level adjustment.

It is noticed that throttle and drum pressure shall also be maintained in a safe range, which for the throttle pressure is ±1 percent of the design pressure [11].

THE SIMULATION SOFTWARE

The aforementioned modelling was applied to develop a modular and object-oriented software with DELPHI, which can simulate the dynamic behavior of steam power plants due to step or ramp changes in air and fuel flow, feedwater flow and throttle valve opening. The software is executed in consecutive steps shown in figure 1 and the results are accessed and displayed in the form of plots and tables.

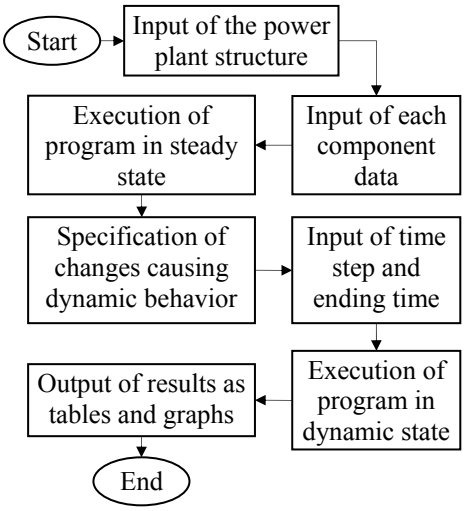

Figure 1: Consecutive steps in running the simulator

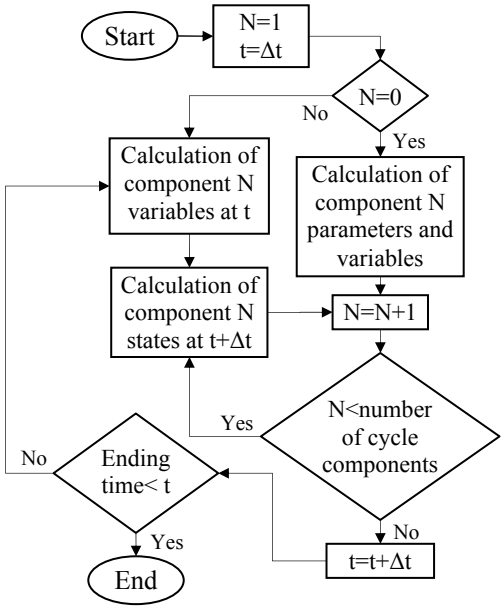

Figure 2: Calculation design of the software

The design of figure 1 shows that steady state calculations are performed before dynamic calculations, which purpose is to derive some parameters used in dynamic equations, like the constant coefficients of equations 2 to 5, and thus minimize the data entry. The dynamic and steady state calculations are realized as shown in figure 2. It should be noted that IFC experimental formulation [12] is used in calculating thermodynamic properties of water and the Euler's method is applied to solve differential equations.

VALIDATION

Before simulating a plant, the mathematical modelling used in the simulator shall be validated and the results must be shown to reasonably represent the plant response.

The steady state results of the simulator were validated using the manufacturer data of the Shahid Rajaei steam power plant. This plant has been commissioned in 1990 with 4×250 MWe steam units. The main steam pressure and temperature are 137.3 bar_g and 538 °C, while the condenser pressure is 0.19 bar_g. Each unit has a sub-critical single-reheat boiler with five close feedwater heaters and a deaerator included in the steam cycle. Tables 1 and 2 show the comparison of some actual quantities of the mentioned plant with simulation results at full load.

Table 2: Comparison of steady state results in feedwater heaters

Operational data needed for validation of the dynamic response of the simulator cannot be obtained by experiments because of the regular operation of power plant controllers. Thus, the dynamic response is validated by comparison of simulator results and data extracted from others' papers. Due to lack of information about power plants discussed in the papers, qualitative comparison is made between the simulation results of Shahid Rajaei steam power plant and these data.

In figure 3, the dynamic response of Jack McDonough power plant [5] is compared with the simulator results, due to a 2% step increase in throttle valve opening at full load. These plots validate throttle pressure, drum pressure and throttle flow variations obtained by the simulator. Comparison between the dynamic response of Fusina power plant [13] and the simulator results, due to a step increase in throttle valve opening is shown in figure 4. According to these plots, the trend of throttle temperature, drum water level and generated power variations obtained from the simulator are similar to the results of the mentioned paper, but the response of Shahid Rajaei steam power plant is approximately 10 times faster than Fusina. This can be explained by the differences in components properties of these plants. One of theses differences is the size of the

#

boiler and consequently the tubes metal mass of surface heat exchangers in the boiler. In order to show the effect of tubes metal mass on the dynamic response of the plant, the simulation of Shahid Rajaei steam power plant is performed while replacing the tubes mass of the boiler with the power plant studied by M.E. Flynn and M.J. O'Malley [14]. The trend of variations obtained by this simulation are similar to figure 4 plots, but the response is approximately 5 times slower than Shahid Rajaei simulation results, which shows the significant effect of heat exchangers tubes metal mass on the dynamic response. This can justify the difference in response times of figure 4, and the throttle temperature, generated power and drum water level variations obtained by the simulator are therefore validated. It can also be concluded that the temperature control system shall be faster in modern power plants with lighter boiler tubes.

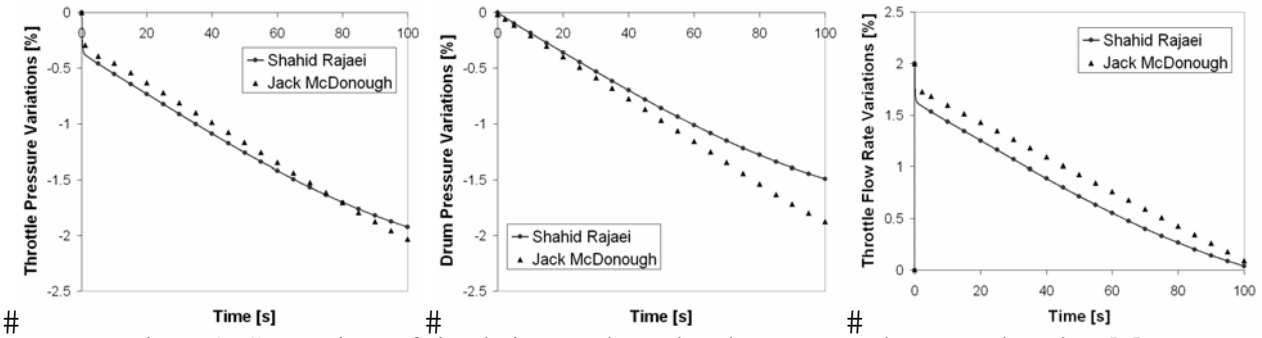

Figure 3: Comparison of simulation results and Jack McDonough power plant data [5].

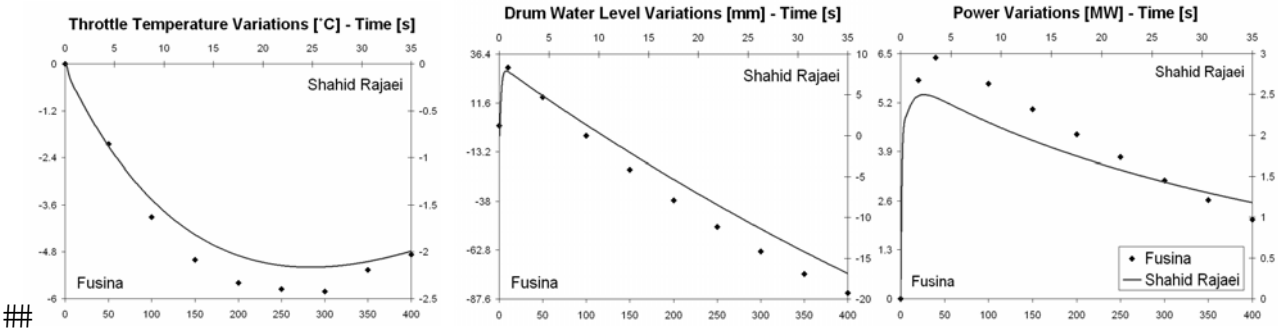

Figure 4: Comparison of simulation results (right and top axis), and Fusina power plant data (left and bottom axis) [13].

SIMULATION RESULTS

After verification of the models, the simulator is used to simulate the Shahid Rajaei steam power plant operating with natural gas at full load. The data needed to simulate this plant are obtained from the plant design documents.

At first, the effect of each control variable is separately investigated on Shahid Rajaei steam power plant. Figure 5 shows the dynamic response of this plant due to 2 percent ramp increase in feedwater flow, fuel and air flow and governing valve area, during 2 seconds. The following observations are made from these plots.

Increase of throttle valve opening - An increase in throttle flow results when the governing valve area increases. This change causes the drum pressure and consequently the throttle pressure to decrease. When the valve opening is constant, throttle flow rate is proportional to the throttle pressure; thus, the throttle flow rate decreases after 2 seconds, which leads to a decrease in generated power. The throttle pressure shall therefore be controlled while increasing governing valve opening in order to control generated power. It is also noticed that the change in valve opening has a considerable effect on drum water level, which shall be controlled.

Increase of fuel and air flow- Drum pressure, throttle pressure, throttle flow and generated power increase due to fuel and air flow raise. This change provides a raise in the flue gas temperature, therefore heat transfer to the superheater and reheater, and consequently steam temperature at the outlet of these heaters are increased; but after a short period, these temperatures fall due to the

increase in steam flow rate and temperature difference decrease. These temperature variations have the effect of reducing the rate of power variations.

The aforementioned variations are in accordance with simultaneous application of fuel and air flow and throttle valve opening in controlling the power output with turbine or boiler follow mode.

Increase of feedwater flow- The feedwater flow mainly affects the drum water level and has negligible effect on other values. It is therefore suitable for controlling the drum water level.

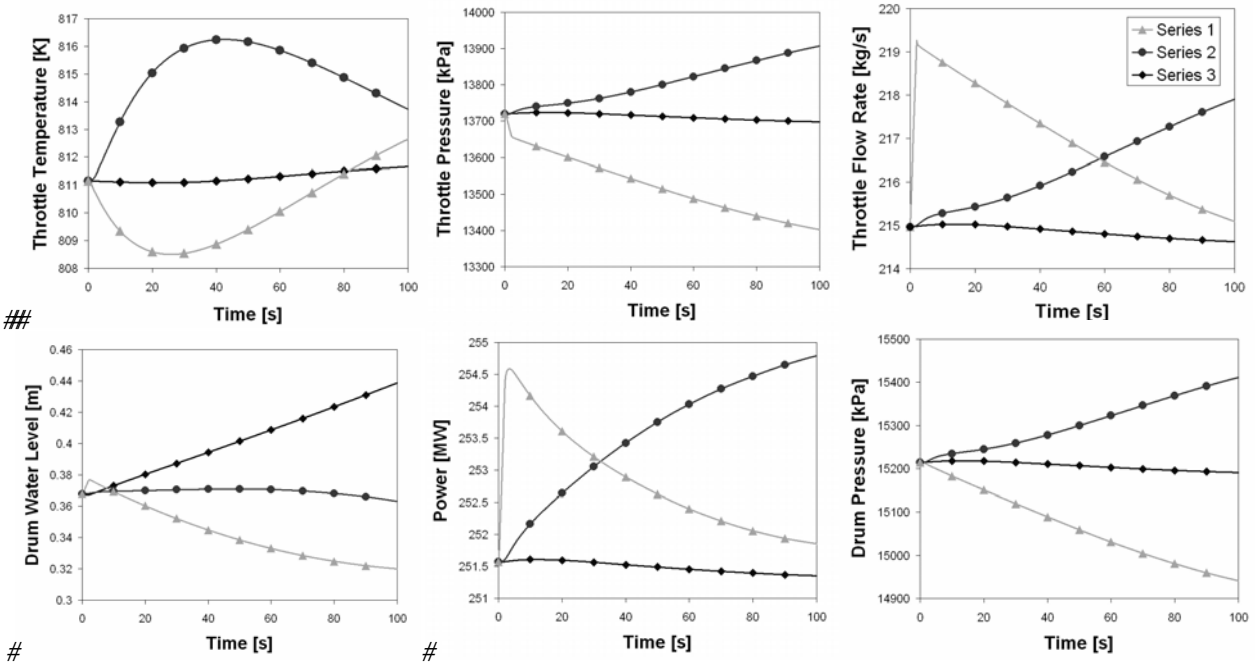

Figure 5: Simulation results of Shahid Rajaei steam power plant due to 2% ramp increase in throttle valve opening (Series1), air and fuel flow (Series 2), and feedwater flow (Series 3), during 2 seconds.

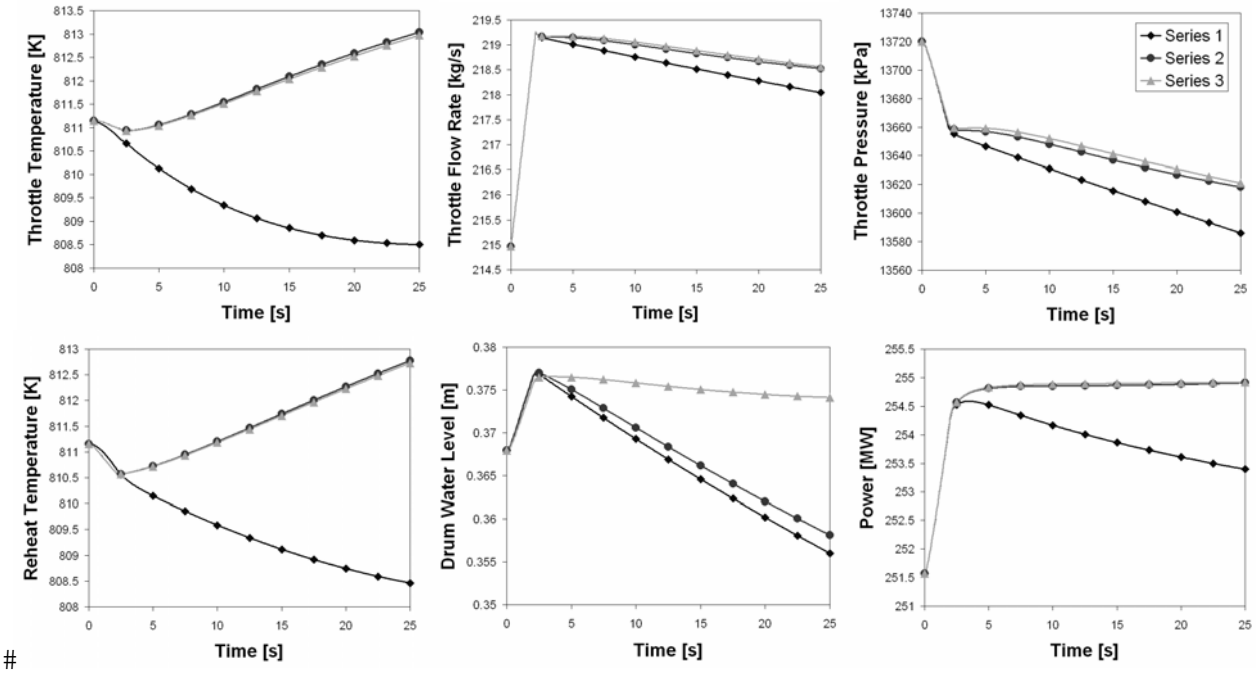

Figure 6: Simulation results of Shahid Rajaei steam power plant due to 2% ramp increase in throttle valve opening (Series1), air and fuel flow and throttle valve opening (Series 2), feedwater flow, and air and fuel flow and throttle valve opening (Series 3), during 2 seconds.

The next step in this study is to apply simultaneous changes to different control variables in the Shahid Rajaei steam power plant simulation. Therefore, the air and fuel flow are raised while the throttle valve opening increases, and the results are compared with the effect of throttle valve opening increase in figure 6. The effect of increasing all control variables simultaneously is also shown in this figure. All the changes are 2 percent ramp increase with 2 seconds durations. The following observations are made for each case.

Increase of air and fuel flow and throttle valve opening- The throttle flow rate, throttle temperature, throttle pressure and generated power variations are reduced when a raise in air and fuel is superposed to the throttle valve opening increase. In this case, the power variations are less than throttle flow variations, which is due to the temperature raise of the boiler outlet steam, that shall be controlled. The drum water level decreases considerably and shall be controlled either.

Increase of air and fuel flow, throttle valve opening and feedwater flow- This change has approximately the same effect as the previous case, but also reduces the drum water level variations. Figure 6 shows that the throttle and reheat temperature variations due to this change have considerable values and shall therefore be controlled. Variables used to control temperature are not considered in this study.

It should be emphasized that the purpose of this study is not to control the variables affecting proper function of the power plant, but is rather to show the ability of the models in representing the plant response when applying control variables separately or simultaneously.

CONCLUSION

Simple models were presented for steam power plant components and a flexible and object-oriented software was developed for multivariable control and dynamic studies. The simulator was validated in dynamic and steady state and applied to model the Shahid Rajaei steam power plant dynamic behavior due to changes in control variables. The control variables included in the simulation are air and fuel flow, feedwater flow and throttle valve opening.

The simulator displays variations of plant main variables due to changes in the aforementioned control variables, and thus can be applied to derive their beginning time, duration and rate, in order to guaranty the proper operation of the plant during change of load. These data are valuable in the design of generated power, throttle pressure and drum water level controllers.

A TEST TO CLARIFY INTERNAL FEATURES OF A FOSSIL SIMULATOR

Alexander S. Rubashkin, Vladimir A. Rubashkin,
"Power Plants Simulators", Russia, Moscow, Semenovsky per., 15, 224,
pps@edunet.ru, www.fpps.ru

ABSTRACT

Any simulator vendor always praises its simulators no matter how good they are. His past customer could praise its simulator too. It doesn't for sure mean that the simulator is really good – it could mean anything, for example that the customer just didn't see anything better. In the past when mainly black-and-white TV sets were available a lot of people who didn't see color TV sets were satisfied with black-and-white ones – they didn't see anything better.
How a potential customer could choose a vendor for his simulator development if he has no objective information he could rely upon? To give the objective information about our simulation technology we conducted on an our simulator a set of tests that could disclose for experts the internal features of our simulation technology. The paper presents one of such test.
Keywords: Fossil power unit, simulation, criteria heat exchange equations.

INTRODUCTION

At present an average price of an average simulator for a fossil power unit is a few times less then the price of an average simulator for a nuclear power unit. If so the fossil simulator vendors promote an idea that customers of fossil simulators ought to humble with numerous simulation simplifications that a lot of modern simulators have. All the simplifications lead to the fact that many modern simulators could be characterized with the following features:

- they are able to implement with an acceptable error margin a few static working modes of the simulated power unit only
- during simulation of complicated transient processes (start-ups, shut-downs and so on) the simulators implement for many important parameters a tendency only but not a full-fledged transient curve

The mentioned features of the simulators could be acceptable if such a simulator is going to be used to train people how to run the power unit in accordance with the operation instruction of the unit only.
But what to do if a trainee needs some more deep understanding of how a fossil power unit works? Let us assume that you are going to illustrate for high students in a university the fundamental principals of heat exchange or the fundamentals of once-through fossil power unit behavior. Or an engineer needs an information how the power unit is going to work as a result of the forethought reconstruction.
In such the cases a simulator with an advanced simulation technology needs to be used.
The paper illustrates some of the internal features of a simulation technology used by Russian company "Power plant simulators". The features allow the simulation technology to be publicly recognized as a very advanced one, and simulators developed on the base of the technology could be recognized as to be suitable to obtain the deep knowledge of fundamentals of fossil power units.
To illustrate the above mentioned internal features we made a number of tests on one of our simulator. The complete test results with colored pictures could be found on our web-site www.fpps.ru. In the paper we present a one test only.

WHICH SIMULATOR WAS TESTED?

For testing we used 200 MW oil fired drum boiler at a drum pressure of 14 MPa with natural circulation and at a pressure before the turbine of 13 Mpa.
The oil fuel is pumped into the boiler furnace through 16 burners. From the furnace the flue gases pass into the horizontal gas duct and first encounter the platen superheater. Then the gases pass the 1st stage convective superheater (CSS-1). After the

CSS-1 the flue gases pass into the 2nd stage convective superheater (CSS-2), which serves as an exit superheater of the live steam. After the CSS-2 along the gas duct the heating surfaces of the intermediate steam reheating, economizer and regenerative air heater (RAH) are situated.

UNIT TRIP, SAFEGUARDING AND START_UP

The objective of this test is to show how the gas route of the boiler is modeled. The parameters of the flue gases and metal in the CSS-1 were examined.
Plots display trends of the following variables:
BMAZSC – oil fuel flow to the boiler (kg/sec)
OXIG – oxygen content in the effluent gases (%)
FDI14M – live steam flow, leg A (ton/hour)
RA11T2 – temperature of live steam in the live steam pipeline after the boiler (°C)
TGMKH1 – gas temperature in the CSS-1 (°C)
KH1Tma – average temperature of the metal of heat exchangers in the CSS-1 area (°C)
TZMKH1 – average temperature at the soiled wall of heat exchangers in the CSS-1 area (°C)
WGKH1 – gas flow velocity in the CSS-1 (m/sec)
ALKKH1 – convective heat transfer coefficient from flue gases toward clean metal (kcal/(m^2·h·°C))
KH1Nu – kinematic viscosity coefficient of the gases in the CSS-1 ($\nu \cdot 10^6$, m^2/sec)
KH1Li – thermal conductivity coefficient for gases in the CSS-1 ($\lambda \cdot 10^2$, kcal/(m·h·°C)
KH1Pr – Prandtl criterion for gases in the CSS-1
BLKH1 – gas flow "blackness" degree in the CSS-1
ALLKH1 – coefficient of the heat irradiation toward the clean metal (kcal/(m^2·h·°C))
ALGKH1 – net heat transfer coefficient from the gases toward soiled metal (kcal/(m^2·h·°C))
The test was run as follows. Immediately after the beginning of the test a unit protection was activated. It stopped the boiler and the turbine. The operator ventilated the furnace after the shutdown, which took about 10 minutes. After this operation the unit was safeguarded in order to conserve heat for the subsequent start-up.
One hour after the shutting down the operator began the power unit start-up. At 1 hour 3 minutes the furnace ventilation before start-up was initiated. At 1 hour 20 minutes the boiler was ignited. The test took about four hours, although the plots show only the first three hours.
The results of the test are shown in three pairs of plots. Each plot contains five variables. The plots with the index a) show the evolution of the chosen variables during the first 90 minutes of the test. The plots with the index b) show the evolution of the same variables during the next 90 minutes.
What was the evolution of the chosen variables?

During the furnace ventilation after the shutdown (the first ten minutes) a relatively large amount of air necessary for the ventilation was passing through the boiler. The mass flow of air was even slightly more than the air flow in the nominal state. However, the gas flow velocity in the region of the CSS-1 (WGKH1) diminished considerably in comparison with the nominal value. During the furnace ventilation the gas flow velocity in the region of the CSS-1 (WGKH1) was about 2.6 m/sec (fig. 1-b), while the velocity was 8.8 m/sec for the nominal load of the boiler. This phenomenon is explained by the fact that gas temperature in the CSS-1 (TGMKH1) during ventilation was considerably lower than at the nominal loading.
At the same time the following was happening:

- the gases T in the CSS-1 (TGMKH1) dropped from the nominal value 1000°C to approximately 220°C and stabilized at this level (fig.1-a);
- the average metal T of the heat exchangers at the CSS-1 (KH1Tma) was dropping smoothly from the nominal value 490°C to 370°C (fig.2-a);
- the average temperature at the soiled wall of the heat exchangers (TZMKH1) was dropping as well and was all the time lower than the temperature of the clean metal (KH1Tma) – fig.2-a
- the kinematic viscosity coefficient of the gases at CSS-1 (KH1Nu) dropped from the nominal value 172.5 to 34 and stabilized at this value (fig.2-a);
- the thermal conductivity coefficient for gases at the CSS-1 (KH1Li) dropped from nominal value 9.6 to 3.6 and stabilized at this value (fig.3-a);
- the Prandtl criterion for gases at the CSS-1 (KH1Pr) increased from the nominal value 0.58 to the value 0.66 (fig.3-a);
- the convective heat transfer coefficient (ALKKH1) dropped from the nominal value 57 to the value 32;
- the gas flow "blackness" degree (BLKH1) dropped from the nominal value 0.14 to the value 0.06, which corresponds to the absence of combustion products at T 200-250°C (fig.3-a);
- the coefficient of the heat irradiation (ALLKH1) practically dropped to zero from the nominal value 33
- the net heat transfer coefficient from the gases toward soiled metal (ALGKH1) dropped from the nominal value 57 to the value 20 (fig.3-a)

The convective heat transfer coefficient linearly depends on the thermal conductivity coefficient and on the quotient of the gas velocity over the kinematic viscosity coefficient to the 0.65 power. The convective heat transfer coefficient depends on the Prandtl criterion to the 0.33 power.

Given our plots let us verify that in the tested simulator the convective heat transfer coefficient fulfils the formula:

$$\mathbf{Alfa = k\cdot\lambda\cdot(w/\nu)^{0.65}\cdot Pr^{0.33}}$$

where k – constant coefficient which depends on the structure of the gas duct at the CSS-1,

λ - thermal conductivity coefficient

w – gas velocity

ν - kinematic viscosity coefficient for gases

Pr - Prandtl criterion for gases

In the nominal state we have:

$$\mathbf{\lambda\cdot(w/\nu)^{0.65}\cdot Pr^{0.33}=9.6\cdot(8.8/172.5)^{0.65}\cdot 0.58^{0.33}=1.16}$$

The nominal value of the convective heat transfer coefficient (ALKKH1) is equal to 57. If our assumption is correct, then k=57/1.1593=49.2

So our assumption could be formulated like that: in the simulator under test the convective heat transfer coefficient is calculated according to the following formula:

$$\mathbf{Alfa = 49.2\cdot\lambda\cdot(w/\nu)^{0.65}\cdot Pr^{0.33}}$$

Given the data from the figures 1-3 we have the following for the moment of time seven minutes:

$$\mathbf{49.2\cdot\lambda\cdot(w/\nu)^{0.65}\cdot Pr^{0.33}=49.2\cdot 3.7\cdot(2.7/33)^{0.65}\cdot 0.665^{0.33}=31.3}$$

According to the plot 2-a the convective heat transfer coefficient (ALKKH1) for the moment of time seven minutes is approximately equal to 32. This means our assumption is fulfilled.

Let us continue to study the test.

An operator completed the ventilation and safeguarded the boiler in order to conserve heat for the subsequent start-up. The process of natural cooling down started.

The average temperature of the metal of the heat exchangers in the CSS-1 area (KH1Tma) began to drop very slowly (fig.1-a). The reason for this slow decrease in temperature is the fact that the region under consideration is situated inside the hermetically closed at the moment boiler. At the same time the temperature of live steam in the steam pipeline at the boiler outlet (RA11T2) was dropping much faster (fig.1-a). The reason for this process is the heat loss through the isolation in the pipeline.

Let us point out that at the same time average temperature at the soiled wall of the heat exchangers in CSS-1 (TZMKH1) evened up with the temperature of the metal itself (KH1Tma) (fig.2-a).

The gas flow velocity at the CSS-1 (WGKH1) dropped practically to zero (fig.1-a). As a result the convective heat transfer coefficient toward the clean metal (ALKKH1) dropped considerably as well (fig.2-a). The T of the gases (TGMKH1) rose to 345°C (fig.1-a) while the metal T (KH1Tma) reached 350°C (fig.2-a). You know that if there is no gas flow, the temperature of the gases has to reach the same value as the metal temperature.

The kinematic viscosity coefficient of the gases (KH1Nu) stabilized at a new value slightly less than 50. This corresponds also to the new gas T of 350°C. Following the increase in the temperature of the gases:

- the thermal conductivity coefficient for the gases (KH1Li) increased as well to the new value equal to 4.5 (fig.3-a);
- the Prandtl criterion (KH1Pr) dropped to 0.65 (fig.3-a)

One hour after the beginning of the test the operator began the power unit start-up.

In the period between 1 hour 5 minutes and 1 hour 15 minutes the boiler was ventilated before the ignition. This ventilation was performed with less air flow in comparison with the ventilation, which took place between the first and tenth minutes after the unit shutdown. As a result of this new ventilation:

- the gas flow velocity in CSS-1 (WGKH1) rose to 1.6 m/sec, while during the first ventilation it was 2.6 m/sec (fig.2-a);
- the T of the gases at CSS-1 (TGMKH1) dropped to 250°C. This value is higher than for the first ventilation because the air flow during the second ventilation was smaller (fig.1-a);
- the live steam T in the live steam pipeline (RA11T2) started a faster dropping. This was due to the fact that the process of natural cooling was coupled with the process of pressure dropping in the steam route as a result of the ventilation (fig.1-a);
- the CSS-1 metal T (KH1Tma) was dropping more actively due to the consumption of relatively cool air in the gas duct at the CSS-1 (fig.2-a);
- the average temperature at the soiled wall of the heat exchangers (TZMKH1) in the CSS-1 became lower than the temperature of the clean metal in the CSS-1 (KH1Tma) (fig.2-a);
- all other variables reacted realistically as well

At 1 hour 20 minutes the boiler was ignited. The oil fuel consumption to the furnace (BMAZSC) could be seen; the oxygen content (OXIG) reached 12 percent. A steam flow from the boiler appeared. Let us remember that, in the first part of the test, on one hand the ventilation of the furnace was performed twice, on the other hand, there was no steam flow from the boiler because it was sealed. As a result of these factors the metal inside the heated zones of the boiler cooled considerably more than the metal of the unheated steam headers and pipelines since the steam headers and pipelines cooled only due to a natural cooling. Therefore, before the ignition of the boiler the steam in the unheated steam headers and pipelines was considerably hotter than the steam inside the boiler. Thus, after the boiler ignition, as soon as the relatively cool steam started to flow into

the live steam pipeline, the temperature of the steam in the live steam pipeline dropped considerably. All these phenomena are shown in figure 2-a.
In addition, the following were happening:

- as a result of a fuel burning the T of the gases at CSS-1 (TGMKH1) rose till 600 °C (fig 2-b);
- as a consequence of the gas temperature rise as well as the increase in the quantity of gases the velocity of the gases (WGKH1) rose (fig 2-b);
- the convective heat transfer coefficient (ALKKH1) rose mainly due to the increase in the gas velocity (fig 2-b);
- the clean metal temperature (KH1Tma) was rising and the temperature at the soiled wall of the heat exchangers (TZMKH1) became bigger than the clean metal temperature (fig 2-b);
- the kinematic viscosity coefficient of the gases (KH1Nu) increased due to the gas T rise (fig 2-b);
- the gas flow "blackness" degree (BLKH1) changed due to the appearance of combustion products in the flue gases (fig.3-b);
- the coefficient of the heat irradiation (ALLKH1) increased mainly due to the rise of the gas temperature (TGMKH1) (fig.3-b);
- the thermal conductivity coefficient (KH1Li) and the Prandtl criterion (KH1Pr) for gases reacted adequately too (fig.3-b)

Let us by plots calculate the following expression for the moment of time 1 hour 30 minutes:

$$49.2 \cdot \lambda \cdot (w/\nu)^{0.65} \cdot Pr^{0.33} = 49.2 \cdot 6.4 \cdot (2.2/90)^{0.65} \cdot 0.61^{0.33} = 23.96$$

According to the plot in figure 2-b, for this moment of time the value of the convective heat transfer coefficient (ALKKH1) is equal about to 24. Thus, we can conclude that in the tested simulator the convective heat transfer coefficient from the gases to the metal under any conditions fulfils the formula:

$$k \cdot \lambda \cdot (w/\nu)^{0.65} \cdot Pr^{0.33}$$

It is worth mentioning that, while developing the simulator under test, the coefficient k was determined not from the observation of the real object but from the constructive parameters of the boiler. There is a special method for determining the coefficient k for a superheater of any type and for a boiler of any type. The Russian firm "Power Plants Simulators" masters this method.

CONCLUSIONS

The tested simulator has at least the following features:

- it simulates the heat flow from the flue gases to the metal based on the criteria heat exchange equations;
- in convective heaters it takes into account not convective heat exchange only but the radiant heat exchange too;
- it calculates independently heat transfer from gases to metal and from metal to steam/water but not the direct heat transfer from gases to steam
- the heated surfaces of the boiler and the unheated surfaces are simulated independently without merging them – parameters of the heat exchangers are taken from power unit construction data;
- the soiling of the metal by burning products is taken into consideration
- to achieve the precise implementation of transient curves the simulator has a deep fragmentation of gas and steam ducts along the spatial coordinate

A one could ask us why in your simulator do you take into account, for example, the soiling of the metal by burning products? Why don't you make it simple? In Russia there is a well-known method for static calculation of boilers on the base of constructive data. In the former Soviet Union all the boilers had to be calculated in accordance with the method. Numerous comparisons of parameters taken from real power unit with calculated ones had proved the method is very precise. We have applied the method for dynamic simulation of fossil power units in the frame of our simulation technology. The method includes not only equations that has to be used for calculation but in addition the comprehensive recommendations how to calculate numerous coefficients in the equations too. The method requires to take into consideration the soiling of the metal by burning products and we do it like that. As soon as we make any simplifications to the method we ought to change procedures for calculation of coefficients but we don't know how to do it. Just thanks to an implementation of the method in the frame of our simulation technology our simulators are really able to reproduce with a tiny error margin any static working mode of the simulated power unit.
The simulator allows to trace the details of the heat exchange in furnace, in all the convective gas ducts, in pipe lines, inside the turbine, in the regeneration system and so on during any complicated transient process of the simulated power unit. In the furnace the simulator takes into consideration air suctions both to lower and upper part of the furnace, the fuel description, recirculation of flue gases, steam for oil fuel atomization and so on.
All the mentioned features of the simulator really allow to obtain a deep understanding of power unit fundamentals.

FEASIBILITY STUDY OF CO_2 REMOVAL FROM PRESSURIZED FLUE GAS IN A FULLY FIRED COMBINED CYCLE - THE SARGAS PROJECT

Mårten Bryngelsson[*] and Mats Westermark
KTH – Royal Institute of Technology
Dept. of Chemical Engineering and Technology
SE-100 44 Stockholm
Sweden

ABSTRACT

In this article a novel concept for CO_2 removal from power plants is discussed from a systems perspective. The main advantage of the process is that the investment cost and the power penalty for CO_2 removal can be substantially reduced compared to conventional combined cycles. The proposed technical solution comprises fully fired combined cycle, which minimizes the amount of flue gas. Furthermore, the CO_2 absorption is performed at pressurized conditions prior to the expansion, which further enhances the CO_2 removal. The modification of the power cycle and integration of absorption stages makes CO_2 removal equipment much more compact and allows the use of CO_2 absorbents with lower heat demand for the regeneration. The partial pressure of CO_2 is above atmospheric pressure and removal efficiencies above 95% can be obtained with potassium carbonate absorption (the Benfield process). The treated flue gas is then reheated and re-humidified before the expansion in the gas turbine.

A Norwegian consortium has developed the concept and feasibility studies have been performed for 100 MW and 400 MW power plants based on natural gas in Norway. The produced carbon dioxide is intended for storage in the Norwegian oil and gas fields in order to enhance the oil recovery. The suggested localizations of the power plants have been chosen accordingly. The design study is based on the same gas turbine and steam cycle as used in the commercial Pressurized Fluidized Bed Combustion (PFBC) cycle. PFBC plants are presently fired with coal but the fluid bed combustor for coal will be replaced by a gas combustor if natural gas is used. A key advantage is that the process can be built solely from commercially available components.

This report is an assessment of the features, capabilities, advantages and future possibilities of the suggested power cycle with integrated CO_2 removal. A power plant for 100 MW power output and based on natural gas is considered suitable as a first demonstration plant to be built in Hammerfest, Norway. A permit application has been turned in. For such a demonstration plant the process simulations have indicated that an efficiency of about 40 % can be obtained, including the penalties from CO_2 capture and compression. Further improvements, e.g. supercritical steam cycle or more advanced gas turbine increases the efficiency and for a 400 MW power cycle a net efficiency of about 44-48% has been simulated (including CO_2 capture and compression). The cycle may also be suitable for CO_2 removal from coal-fired plants.

INTRODUCTION

Norway has been blessed with an abundance of natural resources in the form of oil and gas. Ever since the 1980s Norway has harvested these resources, which has made them the seventh and eighth largest producer of oil and natural gas respectively in the world [1].

[*] Corresponding author: Phone: +46 8 7908285 Fax: +46 8 7230858 E-mail: mrtn@kth.se

Norway does not use the natural gas for power production, even though the building of natural gas fired power plants have been proposed for a long time. The question about power plants has become an important political question though, and more specifically the question of the CO_2 emissions, that among other things made the Prime Minister Bondevik step down from his post in 2000. Today however, the building of a gas-fired power plant in Norway seems closer to realization than ever before. Several concepts are competing to become the first one built. Sargas AS is one of the competing companies with a promising concept. In cooperation with the company Hammerfest Energi they have turned in a permit application for the building of a 100 MW natural gas fired power plant with CO_2 capture [2]. Their proposed novel process (patent no EP 037 567 64.1) is the topic of this paper.

The demand for CO_2 for enhanced oil recovery, as well as high CO_2 taxes in Norway are important driving forces that needs to be discussed in order to put this development into a systems perspective. As explained in the following section, these forces are tightly linked with Norway's declining oil production and climate change.

DRIVING FORCES

The global demand for oil increases rapidly. The consumption has now reached a stunning 78 million barrels (bbl) per day [3]. At the same time oil reserves are stagnating, not only in Norway, which affects the oil price and makes competition about existing oil fierce. At the present time price is over $50 per bbl. At this high oil price, oil companies consider using sophisticated methods such as Enhanced Oil Recovery (EOR) with CO_2 to increase oil production.

Enhanced oil recovery

When the rate of recovery declines in an oil field, there are several available methods for maintaining a high production rate. After primary production comes pressure maintenance and water flooding, but an even larger amount of oil can be recovered by using Enhanced Oil Recovery (EOR). The number of EOR projects has increased rapidly over the last few decades, and among them EOR projects based on CO_2, CO2-EOR.

CO_2 -EOR is an example of a miscible recovery method where CO_2 is injected into the oil field. The CO_2 mixes with the oil and displaces it, which increases the rate of production. One region that could have use for EOR to boost production in the near future is the North Sea and especially Norway. In the United States CO_2 has been injected into oil wells for around three decades, it is a common and well-understood practice. In the year 2000 they had 66 CO_2-EOR projects running producing 216 000 barrels per day (bpd), 4 % of US oil production [4].

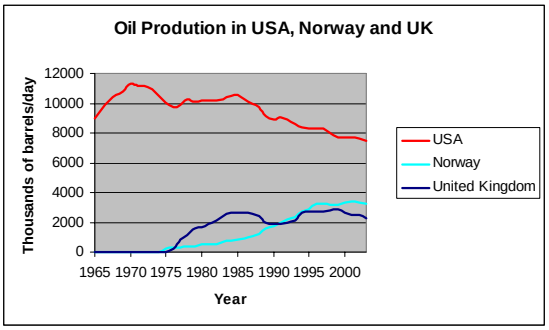

Figure 1: Oil production in the United States, Norway and the United Kingdom, 1960-2003 [3].

Figure 1 shows that the North Sea is entering its declining phase, similar to that which occurred in the United States around 1980. Previous studies of CO_2 -EOR have shown that an additional 6-15 % of the original oil in place (OOIP) can be recovered. This corresponds to a total of 10-30 % more oil for a given field [5]. For the North Sea region up to 2 billion barrels of incremental oil could be produced in a 25-year span [5].

There are alternatives for EOR, other than using CO_2-injection, which means that the availability of CO_2 and the cost of getting it to the injection site might become important factors for the future roll of CO_2-EOR in the North Sea. But if CO_2 might be hard to get at an affordable price, why not use other methods? The most appealing thing about CO_2-EOR is that it gives an opportunity to increase oil production while mitigating the effects of climate change, creating a win-win situation.

Climate change and CO2 storage

The United Nations Framework Convention on Climate Change [6] together with the later added Kyoto Protocol (KP) state that the Annex 1 countries to the protocol should reduce their overall emissions of greenhouse gasses by 5 % below 1990 level during the first commitment period 2008-2012. The KP has now entered into

force as Russia signed the protocol in late 2004. Carbon dioxide has been pointed out as the most significant greenhouse gas since it contributes to the largest radiative forcing, and three quarters of the CO_2 comes from the burning of fossil fuels [7].

Suggestions on how to mitigate the CO_2 emissions flourish. Efficiency improvement, fuel switch and the use of renewable energy are a few of them, but lately yet another one has been introduced, i.e. carbon capture and storage (CCS). The idea is to capture CO_2 from different point sources, ship it to storage sites where the CO_2 is compressed and injected into reservoirs such as oil wells (as discussed above) and sedimentary basins. If it works, CCS makes it possible to continue burning fossil fuel with minor effects on the climate. Oil wells are suitable storage sites, and the CO_2 will most likely be trapped indefinitely since oil has been trapped in there for millions of years.

One of the main problems with CCS is the efficiency penalty when capturing CO_2. In a power plant the penalty is expected to be in the order of 10 %, which makes the technology costly. In the long run however, CCS is expected to play an important roll since it can contribute a lot to the long term goal that e.g. EU has of a 70 % reduction in greenhouse gas emissions compared to 1990 levels [8]. Riahi et al predict that CCS might penetrate the market around 2040, and at the turn of the century all fossil fueled power plants could be equipped with CCS technology [9].

Whether CCS will become a reality on a global scale or not, does not only depend on cost, but also on the development of international policy. Today it is not even clear how CCS is going to be handled under the KP. However, CCS may still become a reality in the North Sea since the oil companies might need CO_2 for EOR, and the economical benefits of EOR may offset costs for CO_2 capture.

The economy of CO_2-EOR

When it comes to the economy of CO_2-EOR projects, three fundamental indicators have been identified [5]:

1. The value of the incremental oil
2. The price of delivered CO_2 at the oilfield.
3. The value of permanently stored CO_2 as a greenhouse gas.

The first two factors are connected so that a higher price of oil makes the oil companies willing to pay more for CO_2 delivered at the oilfield. Historically, the oil industry in the United States has paid \$10-\$15/t CO_2 delivered to an EOR site [10], but that figure might increase if the high oil price remains. The value of permanently stored CO_2 as a greenhouse gas sink might also become important. In the future CCS might get tradable credits, for example in trading systems like the recently adopted European Union Emissions Trading System (EU-ETS). The value of CO_2 under the EU-ETS is at the present time 15 euro per tonne. There is also a relevant tax relief in Norway when storing CO_2, which has been one of the major driving forces behind the SACS project [11].

So far most of the CO_2 used for EOR has come from natural CO_2 accumulations. In the future, and in the North Sea region however the CO_2 has to be extracted from anthropogenic industrial sources. Above all to contribute to the mitigation of climate change, but also because there are no natural CO_2 accumulations around the North Sea. CO_2 from industrial sources is more expensive though, and a lot of research is currently being done on the development of power plants with CCS. Both coal- and gas-fired power plants have been proposed, but in the case of Norway it seems logical to suggest a gas-fired plants. If a gas-fired power plant with CO_2 capture were built in Norway, it would hopefully be able to deliver CO_2 to oilfields at an acceptable cost for the oil companies. The power production, would also give a contribution to the Nordic electricity system. The plant proposed in this paper is introduced in the following section, and it is based on the PFBC-technology.

PROCESS DESCRIPTION

Pressurized Fluidized Bed Combustion (PFBC) is an advanced clean-coal power production system with low emissions of both sulphur dioxide (SO_2) and nitrogen oxides (NO_x). It has also fairly good efficiency, especially compared with conventional coal fired plants. The main part of the system consists of a pressurized fluidized bed where combustion takes place at 12-16 bars. At that pressure the combustion process is very efficient and requires very little residual oxygen. That means that the CO_2 in the flue gas is fairly concentrated. Apart from low emissions of SO_2 and NO_x, the PFBC plant has the advantage of being compact in size.

In this application the process is based on PFBC technology but the fluidized bed is replaced by a gas combustor. The process is called "Fully Fired Combined Cycle with CO_2 removal from pressurized flue gas" and is described below. An overview of the process is shown in figure 2.

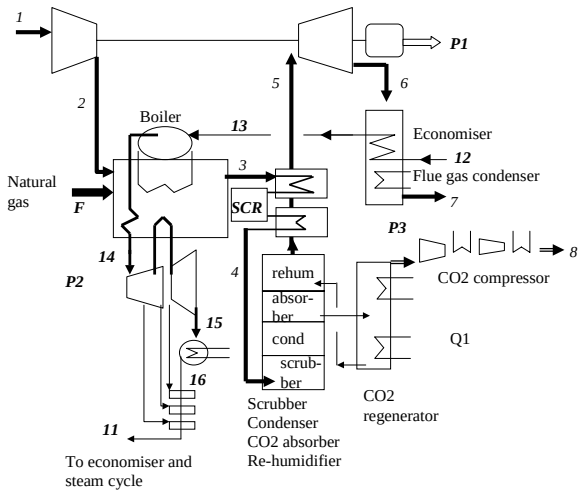

Figure 2: Process scheme. For further details see table 1.

First of all air is compressed in the compressor part of a gas turbine (1). The air is then fed to an external pressurized combustion system (2), a combination of a boiler and a gas heater where hot gas to drive the expander is produced. After the combustion the gas with a high partial pressure of CO_2 is cooled down to a temperature suitable for NO_x reduction and CO_2 capture.

Most of the NO_x is removed in a selective catalytic reduction unit, SCR. This is not only for environmental reasons but also to prevent the potassium carbonate from parasitic side reactions. The absorption of CO_2 is then performed by potassium carbonate, flowing counter current with the sour flue gas absorbing mainly CO_2 (4). CO_2 lean flue gas is then rehumidified, reheated and expanded, which produces power P1 (5, 6). Finally, the gas delivers heat to a heat recovery steam generator, HRSG (6, 7).

The CO_2 rich solution from the absorption column is fed to a regeneration column where CO_2 is released by desorption with steam. The CO_2 is then compressed using power P3 to a pressure suitable for transport (8). The regeneration process is driven by low-pressure steam taken from the steam turbine (Q1).

Steam is produced in a HRSG with the pressure vessel working as a super-heater (11,12, 13, 14). The steam is fed to a steam turbine that produces 80-85 % of the total power output P2 (14, 15). The table below displays the most important cycle data:

Table 1: Process data

No		Flow kg/s	Pressure bar	Temp ºC
1	Air inlet	400	1.0	15
2	Comp outlet	400	16.0	300
3	Flue gas	420	16.0	850
4	Cooled flue gas	420	15.5	200
5	CO_2 lean flue gas	380	14.6	837.5

P2	Power ; steam turbine	420		
P3	CO_2 compressor	20		
Q1	Regeneration heat	100		

Stream number 8 is 54 kg/s liquefied CO_2 stream from the process at 30°C and 100 bars. 98 % of the original CO_2 is captured.

Main process advantages

The main process advantages are the following:

- The investment cost for the removal plant and the power penalty for CO_2 removal can be substantially reduced compared to conventional combined cycles.
- The "fully firing" means low excess of combustion air, which minimizes the amount of flue gas.
- The CO_2 absorption is performed at pressurized conditions prior to the expansion, which further enhances the CO_2 removal. However, the decrease of flue gas volume due to CO_2 absorption will give some power loss in the turbine.
- The combination of fully firing and pressurized absorption makes CO_2 removal equipment much more compact and less expensive. As an example the volume flow is reduced by a factor of 40 if the air demand is reduced by a factor of 4 and the pressure is increased to 10 bars. The power demand to

overcome pressure losses are small due to the low volumetric flow of flue gas

- The Benfield process, which is a commercially available technology, can be used for the CO_2 absorption at high partial pressure of CO_2. This process uses potassium carbonate as an absorbent and is less sensitive to oxidation than amines. The CO_2 absorption in potassium carbonate can run at e.g. 90°C (the absorbent is not volatile) and still reach CO_2 removal efficiencies as high as 98%.
- High partial pressure of CO_2 will lower the heat demand for the regeneration.
- The reliability of the proposed power cycle is predicted to be better than for a conventional combined cycle. The gas turbine is a non-cooled machine and the steam cycle also has excellent reliability. The downtime is estimated to 2 %.

PROCESS PERFORMANCE

The calculations of the performance for a full-scale power plant have been simulated using the HYSYS Process (Aspentech) software. The efficiency of the process without CO_2 capture is around 47,5 %, which is lower than e.g. a conventional NGCC. Capture and compression of CO_2 then incur some efficiency penalties. The results from the simulations show that the total net efficiency after capturing CO_2 is 44 %

Performance of competing processes

Other proposed methods of capturing CO_2, have been compared e.g. by Göttlicher [12], Audus [13] and Bolland [14]. They show figures in the same range as the above 44 %, i.e. a thermal efficiency between 42 and 50 %. These processes are a) separation of CO_2 after combustion, b) oxy-fuel combustion, and c) separation before combustion.

Table 2: Process performance for three different CO_2 capture concepts

Technology	Göttlicher		Audus		Bolland	
	η_{th} [%]	ref. sys. [%]	η_{th} [%]	ref. sys. [%]	η_{th} [%]	ref. sys. [%]
a	50		47		49,6	
b	48	57,5	48	58	47,2	58
c	42		48		45,3	

The three types of processes are described in the following sections.

Separation of CO_2 after combustion

Technologies for separation of CO_2 from conventional gas turbines after combustion include the use of chemical absorption. The first step in a CO_2 capture plant is flue gas cooling and a booster fan to overcome the exhaust gas pressure drop in the CO_2 absorption. The next step is absorption of CO_2 by an absorbent (usually monoethanolamine, MEA) and steam stripping of CO_2 from the absorbent. Low-pressure steam extracted from the steam turbine in the CC is used to cover the heat demand in the stripping process. Finally, CO_2 compression is used to obtain liquid CO_2.

However, the integration of CO_2 removal with conventional gas turbines suffers from the low concentration of CO_2 in the flue gas (due to the high excess of air). Therefore, a powerful absorbent with strong binding to CO_2 must be used. The most suitable absorbent is MEA but the use of such a strong CO_2 absorbent increases the heat demand for regeneration.

Furthermore, MEA is rather volatile and the emission of MEA gives losses, at least above temperatures of 30-40 °C. Another problem is the oxidation of MEA by air, which also give losses of absorbent. Flue gas re-circulation has been suggested in order to obtain higher partial pressure of CO_2, which eases the absorption [13]. However, present gas turbines have to be modified before this method can be available.

Oxy-fuel combustion

The alternative is based on a combined cycle with a near stochiometric combustion using pure oxygen from an air separation unit (ASU) to oxidize the natural gas in an atmosphere of re-circulated flue gases. CO_2 and steam are produced in the combustion and the working medium in the gas turbine is mainly CO_2. The CO_2 can be concentrated by simply condensing the water [15]. Oxy-fuel combustion is not yet commercially available since it needs the development of new gas turbines adapted to compression of CO_2 and combustion in low excess of air. The gas turbine also has to be modified both in the compressor and the turbine due to different density for the working medium compared to existing gas turbines.

Separation before combustion

Separation before combustion is not yet commercially available for combined cycles since

it needs the development of new gas turbines that are modified for combustion of hydrogen. Separation before combustion includes steam reforming, partial oxidation or auto-thermal reforming plus a CO/H2 shift reactor and a high pressure CO_2 capture unit to produce a hydrogen rich (H2++) fuel gas. When using auto-thermal reforming some portion of the compressed air and steam are extracted from the combined cycle and used for the reforming. Some high-pressure steam is transferred back into the combined cycle [14]. The production of hydrogen is commercially available but new combustors must be developed for the combustion of hydrogen in the gas turbine.

Future technologies

One future technology is based on mixed conducting membranes (MCM). The basic principle is that MCM separates a part of the compressed air into oxygen and nitrogen. Fuel is then combusted in pure oxygen making the technology similar to oxy-fuel combustion discussed above. A process based on MCM called Advanced Zero Emission Power plant (AZEP) has been proposed to have an efficiency penalty of 2 % [16].

Chemical looping is yet another novel concept that uses metal-oxides instead of air for oxidizing fuel. Thus the combustion is performed in a nitrogen-free environment, leaving a flue gas consisting mainly of water vapor and CO_2 [17].

Future processes will hopefully be more efficient than today's due to technological progress and learning. However, climate change and the demand for enhanced oil recovery is a strong incentive to start CO_2 capture as soon as possible with present available technology.

DEVELOPMENT POTENTIAL

One improvement that would increase the thermal efficiency and CO_2 capture of the fully fired combined cycle is serial coupled gas turbines. The first turbine's exhaust is used in the steam cycle and then further cooled in a flue gas condenser before entering the process shown in figure 2. The net efficiency can be improved to about 48% (including CO_2 capture and compression).

PROCESS ECONOMY

The economical benefits with Sargas' proposed power plant is shown in this section by comparing it to a NGCC plant with post combustion CO_2 capture. The Sargas technology is not primarily advantageous because of higher thermal efficiency but for easier integration with CO_2 capture. Those reasons are underlined again and backed up by figures. First table 3 shows a comparison between the two concepts without CO_2 capture:

Table 3: Economical comparison between NGCC and Sargas technology without CO_2 capture

	NGCC	Sargas
Capital cost [Euro/kW e]	660	750
Operation and maintenance cost [Euro/MWh e]	2,6	1,5
Efficiency [%]	55	47,5
Down time [%]	8%	2%
Power [MWe]	400	400

Sargas can compete with lower operating costs and lower down time, but the technology without CO_2 capture has disadvantages when it comes to capital expenditure, which is higher, and a lower thermal efficiency. On the other hand, when the CO_2 capture plant is added, things look better, as seen in table 4.

Table 4: Economical comparison between NGCC and Sargas technology with CO_2 capture

	NGCC	Sargas
Capital cost [Euro/kW e]	1300	940
Operation and maintenance cost [Euro/MWh e]	5,0	2,1
Efficiency [%]	45%	44%
Down time [%]	10%	2%
CO_2 capture efficiency [%]	85%	98%
Power [MW e]	330	370

A more compact and efficient CO_2 capture plant leads to lower capital expenditure and lower efficiency penalties for Sargas.

An additional benefit is the higher CO_2 capture efficiency as shown below in table 5, which means lower emissions (lower emission factor) and as a result lower CO_2 tax costs. The NGCC plant emits 7,3 times more CO_2 per kWh than the Sargas process. Higher capture efficiency also means more CO_2 to e.g. CO_2-EOR projects, which improves income from selling CO_2.

Table 5: Emitted and captured CO_2.

	NGCC	Sargas
Emission factor [kg CO_2/kWh]	0,067	0,0092
CO_2 captured [kg/kWh e]	0,38	0,45

Cost of electricity and natural gas price
The cost of electricity is made up of the cost of capital, operating and maintenance cost and fuel cost. With a current high natural gas price, fuel cost is the largest expenditure.

The market for natural gas is not like the market for oil where the price is set on a global market. For natural gas the regional markets set the price, primarily because gas is expensive to transport. Sargas therefore seek to locate the power plant in Hammerfest, Norway, which improves the chance of getting a good price on gas. However, the market price is hard to predict, especially when considering the whole plant life cycle, and since regional price differences on the natural gas market are expected to converge within three decades [18].

In the following figure, cost of electricity for the two CO_2 capturing plants is calculated using different gas prices. The capital charge rate is 11% based on a 10% discount rate and a 25-year lifetime.

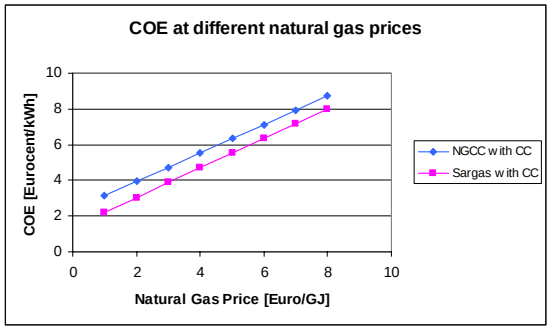

Figure 3: COE at different natural gas prices

The figure shows that Sargas has lower COE than NGCC when considering CO_2 capture. The steep slope of the COE underlines the importance of a low natural gas price that a plant location close to the source might help secure.

Mitigation cost
It has been shown earlier in this paper that both the emission factor and the cost of electricity is lower for the Sargas technology, and those are the factors that make up the mitigation cost (MC).

$$MC = \frac{COE_{cap} - COE_{ref}}{E_{ref} - E_{cap}} \qquad [19]$$

The MC for the two CO_2 capture concepts (cap) is in figure 4 calculated using the NGCC plant without CC as a reference (ref), again with a varying natural gas price.

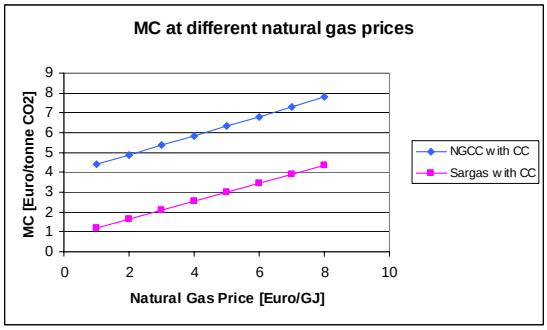

Figure 4: MC at different natural gas prices

Again we see that the Sargas process is predicted to be most cost effective with a MC of less than half of its' competitors.

CONCLUSIONS
The concept that Sargas AS has introduced has clear advantages. It is first of all based on commercial technology, which cannot be said about all previously proposed concepts. It also has a very efficient handling of flue gases under pressurized conditions that enables low penalties, compact capture plant and low capture cost.

Many studies focus primarily on comparing the thermal efficiencies of CO_2 capturing concepts, while this paper also tries to quantify other features. The thermal efficiency is not better for Sargas than for the competing NGCC with post combustion CO_2 capture. However, the Sargas process makes up by its' low emissions, low downtime, low capital cost for the capture plant and low operating and maintenance cost. With the input parameters used in this paper, the result is both lower cost of electricity and lower mitigation cost.

Because of technical difficulties realizing competing concepts, the Sargas process might be one of the better concepts for CCS that is feasible today. In combination with the high oil price and the increasing need for EOR in Norway, it might be commercially successful, and even more so if the capturing of CO_2 is somehow credited.

ABSTRACT

Phage are the most abundant biological entities in the biosphere, with an estimated 10^{31} particles on the planet. They also play a major role in carbon cycling; at least 25% of fixed carbon passes through phage. Their roles as predators of bacteria have important implications for possible marine CO_2 sequestration. Metagenomic analyses show that the rank-abundance curve for marine phage communities follows a power law distribution. This distribution is consistent with a proposed, modified version of Lotka-Volterra predator-prey dynamics, where blooms of a specific microbial species lead to blooms of their corresponding phage and a subsequent decrease in abundance. The model predicts that the majority of phage genotypes in a population will be rare and it is unlikely that the most abundant phage genotype will be the same at different time points. The model is based on spatial-temporal heterogeneity and a power law phage decay, which are both supported by empirical data.

INTRODUCTION

The marine microbial food web (MMFW) is the consortium of heterotrophic and autotrophic prokaryotes and their predators which inhabit the world oceans. The MMWF controls the transfer of nutrients and energy to higher trophic levels and thereby greatly influences global carbon cycling. Dissolved organic matter (DOM) and particulate organic matter (POM) are the largest biogenic sinks of carbon in the ocean. The concentration is so high that the bacterial populations feeding on them are controlled by predation rather than by nutrient availability. The two predator guilds that keep bacterial populations in check are protozoa and phages with about equal shares of the biomass passing through each guild. When bacteria are eaten by protozoa, their biomass can be transferred to higher trophic levels; when bacteria are eaten by phage, the biomass returns to the POM pool. How much of this POM sinks to the deep oceans for sequestration is largely dependent on whether bacterial growth digests these particles and

converts them to DOM. Understanding and controlling marine phage populations would therefore provide a route to increasing CO_2 sequestration. The paper below is a step in that direction.

A POWER LAW BEST DESCRIBES THE RANK-ABUNDANCE DISTRIBUTION OF MARINE PHAGE COMMUNITIES

Six different standard mathematical and ecological distributions (reviewed in [1]) were tested for their goodness of fit to marine phage metagenomic data described in Breitbart et al. [2]. An overlap between sequences from different clones of a shotgun library (i.e., a contig) means that the same phage genotype has been re-sampled. This information was used to predict the population structure of the phage communities based on a modified Lander-Waterman equation [3]. To determine which distribution best described the metagenomic data, the error between the predicted and the observed contig spectrum was used in a quasi-log-likelihood function using a weighted sum of squared errors (Table 1). In both marine phage populations, the data were best described by a power law distribution (error for Scripps Pier (SP) = 1.8 and Mission Bay (MB) = 2.1), followed by the lognormal distribution (error for SP = 1.9 and MB = 2.3). In contrast, classical niche-based ecological models like Broken Stick (error for SP = 11 and MB = 15) and Niche Preemption (error for SP = 12 and MB = 16) were a very poor fit to the data.

There was a major difference between the number of phage genotypes predicted by the different distributions. For example, the lognormal distribution predicted 3 to 5 times more phage genotypes in the samples than did the power law (Table 1). This is important because recent estimations of global microbial diversity have assumed lognormal distributions and may have significantly overestimated species richness [4].

Model	Error	Predicted # of Phage Genotypes
Scripps Pier (SP) [1021 17 2 0]		
Power Law	1.8	3400
Lognormal	1.9	13000
Logarithmic	2.5	1400
Broken Stick	11	1200
Exponential	12	10000
Niche Preemption	12	9100
Mission Bay (MB) [841 13 2 0]		
Power Law	2.1	7400
Lognormal	2.3	43000
Logarithmic	2.8	1600
Broken Stick	15	960
Exponential Law	16	7500
Niche Preemption	16	8200

Table 1. Goodness of fit for six different models to the observed contig spectra of two marine phage metagenomes. The error was calculated as the variance weighted sum squared deviation from predicted contig spectra, which gives the value of the log pseudo likelihood function as described in ref 2. The models are listed in order of increasing error for each sample. The observed contig spectra are shown in square brackets next to each of the samples, where a contig spectrum of [A, B, C, …] represents A one contigs, B two contigs, etc.. The exponential and logarithmic models were named according to their analytic form in the frequency-rank relationship, viz. frequency proportional exp(k*rank)) or frequency

A GENERALIZED VERSION OF LOTKA-VOLTERRA DYNAMICS PREDICTS THE POWER LAW DISTRIBUTION

Determining the population structure of marine phage communities also suggests ecological models to explain how phage and their microbial hosts interact. It is assumed that different hosts interact through competition for food. This interaction is very weak because food is not a limiting resource for microbes in the marine ecosystem [5, 6]. The second assumption is that there is a strong and specific interaction between a microbial host and its phage predators, where the most abundant microbes are killed. This relationship has been termed "kill the winner" and predicts that specific predator-prey pairs oscillate in time as blooms of a particular

microbe are followed closely by blooms of its phage predator [7]. Using these assumptions, the problem becomes a system of many non-interacting predator-prey systems. The simplest model matching the assumptions is classical Lotka-Volterra (LV; Equation 1):

$$\frac{dB}{dt} = \alpha B - \beta B\Phi$$
$$\frac{d\Phi}{dt} = -\gamma\Phi + \delta B\Phi \qquad (1)$$

where B denotes the size of the microbial population for a single genotype, Φ denotes the population size of the corresponding phage predator, and where α, β, γ, and δ are positive constants that describe microbial growth, microbial death, phage decay and phage production, respectively. For simplicity it was assumed that all phage-host pairs follow identical dynamics[1], but bloom at independent times (i.e., they are randomly distributed along a common cycle). Note that in order to match the observed population structure, blooms must alternate with comparatively long periods of "hiding out" at concentrations several orders of magnitude lower than the bloom titers (see Fig 4 in [8]). For a Lotka-Volterra model such cycles can be found by using initial states near the origin.

Figure 1a-d show the results of adopting Lotka-Volterra dynamics for a population of non-interacting phage-host pairs. Transformation of this data to a log-log plot (Fig 1d) shows a mediocre fit to the power law (R^2=0.83). The relatively poor fit occurs because the high abundance phage are over-represented on the log-log plot (i.e., too many ranks correspond to these values and destroy the linearity). The dynamics would fit the data much better if the blooms were shorter and more intense. Mathematically this can be accomplished by using a generalized version of Lotka-Volterra (GLV), where an exponent (n>1) is added to the predator populations to account for cooperativity [9]. A GLV model with an exponent of 2 produced an almost perfect fit to the power law distribution (R^2=0.99; Figure 1e-h).

$$\frac{dB}{dt} = \alpha B - \beta B\Phi^2$$
$$\frac{d\Phi}{dt} = -\gamma\Phi^2 + \delta B\Phi^2 \qquad (2)$$

We propose that in the marine environment, the cooperativity between phage in the lysis event ($\delta B\Phi^2$) and microbial death ($\beta B\Phi^2$) reflects spatial-temporal heterogeneity. The ocean is a gel made up of particles ranging from colloids to marine snow[10-12]. These particles represent higher, local concentrations of nutrients than are necessary for microbial growth [13]. Microbes are known to chemotax to these particles [14]. Phage lysis of microbes on particles would create locally high concentrations of both predators and prey (i.e., a local change in mass action). This would lead to an apparent cooperativity in the predation.

One consequence of adding the cooperativity function to the lysis event ($\delta B\Phi^2$) is that the decay exponent on Φ must match the exponent in the mass action terms to keep the populations oscillating (i.e., to maintain neutral stability of the orbits). This feature of the proposed model matches data on phage decay, which shows that phage particles display rapid initial decay rates, which then decrease over time [15,16]. Environmental factors such as local entanglement of phage particles in microbial debris would account for this observation.

The "kill the winner" hypothesis, as interpreted through the proposed model, predicts that typical phage-host cycles involve long periods of hiding from the predators at very low numbers alternating with brief spurts of dominance. Therefore, it is unlikely that the most abundant phage genotype will be the same at different time points and there should be several orders of magnitude difference in the numbers of a specific phage present at different times. Limit cycles traversing approximately the same orbit would make similar predictions and represent a viable alternative to the proposed model. In addition to making several predictions that match empirical data, the proposed model represents a new mechanism for how a system can display power-law behavior.

[1] This feature of the model is for simplicity alone – the real dynamics surely varies among the types. In this neutral evolution hypothesis, our hope is that the qualitative features are captured by replacing the full complexity of the problem by one "average" type. In fact, a comparable calculation using a distribution of parameter values also gives a close fit to the power law.

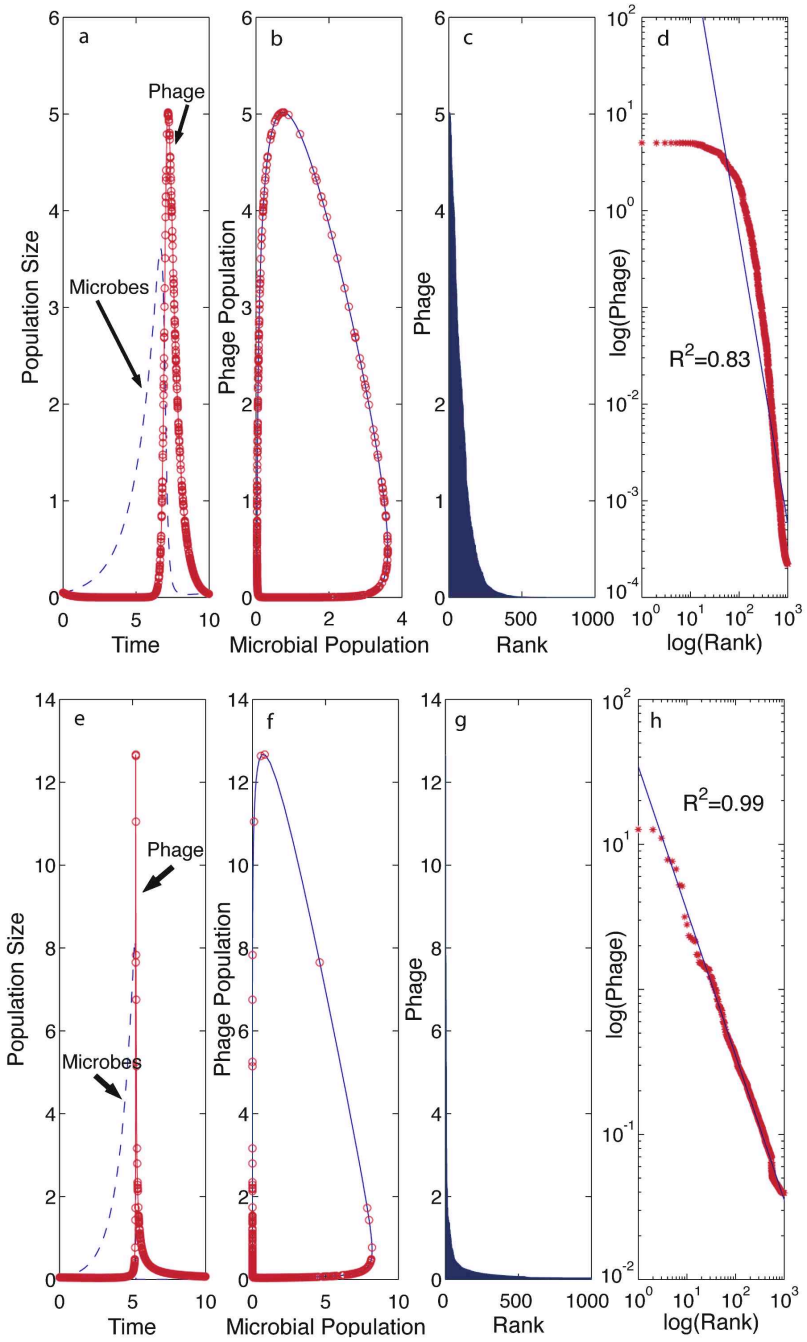

Figure 1. Comparison of phage population structure predicted by Classical Lotka-Volterra (a-d) and the proposed Generalized Lotka-Volterra (e-h) dynamics. All population sizes and time are in arbitrary units. a) Populations of microbes (dashed blue line) and phage (solid red line) as a function of time. Red circles show 1000 random samples along the cycle. b) The relationship between the sizes of the microbial and phage populations (solid blue line). Red circles show the same 1000 random samples along the cycle. c) Rank abundance plot of the 1000 random phage samples. d) Log-log version of panel c. The solid blue line is the least-squares fit to the ranked phage populations (red asterisks). Panels e-h show the same relationships for the Generalized Lotka-Volterra dynamics. The R^2 is the coefficient of determination

ABSTRACT

The purpose of the work presented in this paper is to examine and evaluate the state of the art in technological concepts for the retrofit of low-quality coal-fired power plants for CO_2 capture and sequestration. The discussion will be based on the evaluation of the most promising options in technological and economical terms, taking into account the technical and operational requirements and characteristics of existing power plants. The work will be mainly focused on oxyfuel combustion and flue gases treatment by amine scrubbing. Results from thermodynamic simulations of the retrofit power plants will be used to demonstrate the potential for emissions reduction and evaluate the associated power output and efficiency penalties. These data, coupled with the investment costs, will provide an insight on the economics associated to CO_2 retrofit sequestration options and the viability of the power plants within the framework of the application of a CO_2 economic penalty, in an electricity generation system based on low-quality coal.

INTRODUCTION

In analysing measures for reducing CO_2 emissions, the Intergovernmental Panel on Climate Change (IPCC) [1] concludes that none of the following measures alone would be sufficient to stabilise atmospheric CO_2 concentrations: demand reductions and/or efficiency improvements; substitution among fossil fuels; switching to renewables or nuclear energy; CO_2 sequestration; or afforestation. Thus, in identifying strategies for climate change mitigation, combinations of multiple technologies in all sectors must be considered.

At present, fossil fuels are the dominant source of the global primary energy demand, and will likely remain so for the rest of the century. Fossil fuels supply over 85% of all primary energy; the rest is produced by nuclear, hydro-electricity and renewable energy (commercial

biomass, geothermal, wind and solar energy). Currently, renewable energy supplies less than 1% of the global energy demand. While great efforts and investments are made by many nations [1] to increase the share of renewable energy to the primary energy demand and to foster conservation and efficiency improvements of fossil fuel usage, addressing climate change concerns during the coming decades will likely require significant contributions from carbon sequestration in thermal power plants.

Carbon sequestration can be defined as the capture and secure storage of carbon that would otherwise be emitted to the atmosphere. This is called carbon capture and storage (CCS). The rationale for carbon capture and storage is to enable the use of fossil fuels while reducing the emissions of CO_2 into the atmosphere, and thereby mitigating global climate change. The commercial or under development CO_2 sequestration technologies for coal-fired power plants can be divided into three broad categories [2]:

- Separation of CO_2 from waste gas
- Combustion in O_2 instead of air
- Production of a carbon free fuel

A detailed presentation of these technologies has been provided in [3]. The present study focuses on the application of the oxyfuel process and the MEA scrubbing process which are applicable to all fossil fuelled power plants and are considered as the two most promising CO_2 sequestration technological options for the retrofit of low-quality coal fired power plants.

RETROFIT OF A TYPICAL POWER PLANT UTILISING GREEK LOW QUALITY COAL WITH CO_2 SEQUESTRATION

The present study has focused on the application of two CO_2 sequestration technological options based on the examination of operating characteristics of a typical low-quality coal fired power plant. The simulations of the power plant and the CO_2 sequestration retrofit options were performed with the thermodynamic cycle calculation software ENBIPRO (**EN**ergie-**BI**llanz-**PRO**gram) [4], a tool for heat and mass balance solving of complex thermodynamic circuits, calculation of efficiency and exergetic and exergoeconomic analysis of power plants. The software code models all pieces of equipment that usually appear in power plant installations for both full load and part load operation and can accurately calculate all thermodynamic properties (temperature, pressure, enthalpy) at each node of the thermodynamic circuit, power consumption of each component, flue gas composition etc. The code has proven its validity by accurately simulating a large number of power plants and through comparison of the results with other commercial software, such as IPSEPRO [5].

The 330 MW_{el} gross power output power plant under examination has a supercritical boiler, a HP-MP-LP steam turbine and 8 preheating stages and represents a typical Greek low-quality coal fired power plant with flue gas desulphurisation. Table 1 presents the basic operating data of the power plant under examination compared to the simulation data. The auxiliary power consumption used to calculate the net power output includes the consumptions of FD fan, ID fan, lignite mills, LUVO, water pumps and the desulphurization plant.

		Existing Plant	**Simu-lation**
Fuel input	MW_{th}	830	830
Flue gas temperature after air preheater	°C	152.0	149.5
Steam flow at HP ST inlet	kg/s	265.4	265.4
Steam pressure at HP ST inlet	bar a	235.4	235.4
Steam temperature at HP ST inlet	°C	540	540
Steam flow at IP ST inlet	kg/s	227.4	227.4
Steam pressure at IP ST inlet	bar a	38.2	38.2
Steam temperature at IP ST inlet	°C	539.7	539.7
Steam pressure at IP ST outlet	bar a	2.22	2.22
Water flow at the boiler inlet	kg/s	265.4	265.4
Pressure after feedwater pump	bar a	292.5	292.5
Flue gas CO_2 concentration	w. %	20.7	20.7
CO_2 emissions	kg/s	-	87.7
Specific CO_2 emissions	kg CO_2/ kWh	-	1.075
Net power output	MW	294.2	293.7
Net efficiency	%	35.4	35.38

Table 1: Basic operating data of the conventional power plant

In the examined retrofit test cases, the following general assumptions have been made:

- The fuel consumption remains the same
- The water/steam cycle remains as much as possible unchanged
- The final product (CO_2-rich stream) is compressed in a multi-stage compressor to 110 bar, in order to facilitate transportation and sequestration
- The final CO_2 stream purity is 98%

O_2/CO_2 recycle combustion (oxyfuel)

According to the oxyfuel concept, presented schematically in Fig. 1, combustion is achieved with high-purity oxygen. Cryogenic air separation by an Air Separation Unit (ASU) is the most efficient commercially available technique [6] and has been used in the current study. The oxygen purity chosen is 95%, the majority of the rest 5% being Argon, and all oxygen contained in the air is used. The air entering the ASU has a pressure of 5.5 bar and air compression occurs in four stages, with an isentropic efficiency of 0.83. After each compression step, the air is cooled to 20ºC in order to decrease the compression energy demand. The compression steps are 1.013-1.53 bar, 1.53-2.35 bar, 2.35- 3.6 bar and 3.6-5.5 bar [7].

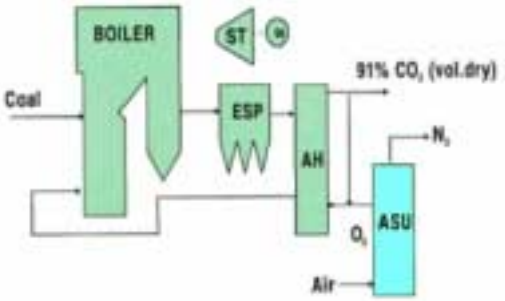

Figure 1: Oxyfuel process (IEA)

When applying the O_2/CO_2 recycle combustion concept in a coal-fired power plant, the air preheaters are not used. As a result, in the case studied, the flue gas exit temperature is increased to ca. 310 ºC. Another energy demanding process regarding air separation is air cleaning. Before air enters the distillation column, water vapour, CO_2 and any other impurities are removed, utilising adsorption with molecular sieves. For the regeneration of the molecular sieves, dry nitrogen that is produced from the ASU is used [7]. The temperature of the air nitrogen is about 180ºC and, consequently, heaters are required to heat the air nitrogen. In the current case study, the flue gases exiting the boiler at ca. 310ºC provide the heat required for nitrogen heating. Air leakage in the boiler as well as the oxygen purity play a significant role in the CO_2 concentration of the flue gases. Under the assumptions of 95% oxygen purity and 3% boiler air infiltration, the O_2/CO_2 recycle combustion process can capture 79% of the CO_2 that is produced from coal combustion [8], the rest being vented to the atmosphere during the purification process for removal of non-condensable gases. This is the value used in the current study, a lower CO_2 recovery rate compared to the recovery with the amine scrubbing process. It should, nevertheless, be mentioned that in a greenfield application, where improved sealing can be incorporated from the design and the air infiltration rate can be lower, the CO_2 recovery rate can be comparable to the amine scrubbing process.

Excess oxygen applied for the simulation is 1.5% [9]. On the other hand, the flue gas recirculation is chosen so as to maintain the flue gas flow and temperature inside the boiler at the same level as in the conventional power plant.

To conclude, the main energy requirements for the O_2/CO_2 recycle combustion are:

- Air compression for the ASU (5.5 bar)
- Compression of the final product for transportation and sequestration (110 bar)
- Cooling water pumps consumption for flue gas cooling and air inter-cooling at the ASU

Table 2 presents the simulation results of the power plant retrofit to oxyfuel operation, demonstrating the high efficiency and power output loss and the significant reduction in CO_2 emissions compared to the conventional power plant.

The current study focuses on the retrofit application of the oxyfuel process for CO_2 capture in an existing coal-fired power plant. However, considerations for a greenfield application include the optimisation of the water/ steam cycle through the integration of the heat produced during the air compression before the ASU and the compression of the CO_2, as well as the integration of the heat content of the flue gas at the boiler exit. The heat

of the above mentioned sources could partly replace some of the feedwater heating stages with steam extraction. Consequently, in a greenfield application of the oxyfuel technology, the net efficiency is expected to be increased compared to the net efficiency of the retrofit application.

Air mass flow in ASU	kg/s	315.6
O_2 mass flow	kg/s	72.78
Flue gas mass flow at boiler's exit	kg/s	416.5
Recirculated flue gas mass flow	kg/s	270.0
CO_2 concentration (wet) CO_2 concentration (dry)	w. %	58.84 96.97
ASU power consumption (n_{is}= 0.83)	MW	58.1
CO_2 compression power consumption (n_{is}= 0.85)	MW	22.4
Cooling water pumps, flue gas cooling and air inter-cooling at the ASU	MW	1.5
CO_2 emissions	kg/s	18.11
Specific CO_2 emissions	kg CO_2/ kWh	0.31
Net power output	MW	211.0
Net efficiency	%	25.42

Table 2: Oxyfuel power plant simulation results

Amine scrubbing

The present study has focused on the commercially available MEA process (Fig.2). In the amine gas processing operation, CO_2 is absorbed from the flue gas by the liquid solvent in an absorption tower, where the gas stream and the liquid solvent are contacted in counter-current flow. In the stripper (regeneration stage) the charged amine solution is heated with steam, in order to strip off the CO_2.The energy requirements of MEA scrubbing are:

- Heat consumption for regeneration of the reach solution: this low-grade heat is provided from the power plant in the form of low-pressure steam extraction at about 5 bars. The stripper column thermal consumption, according to the state of the art commercially available solutions, is about 3.25 MJ/kg of CO_2 removed, which equals to about 1.4 kg steam/kg CO_2.
- Electricity consumption: the most energy-consuming process is the flue gas blower, which is used for the flue gas pressure elevation in order to overcome the system pressure drop. This category also includes the energy required for the pumping of the amine solution and the pumping of the absorber wash water.
- Compression of the final product to 110 bar for transportation and sequestration.

The flue gases at the outlet of the boiler are cooled down to 40ºC in order to condense the water vapour and then compressed up to about 1.3 bar [10]. CO_2 recovery from the flue gases is assumed to be 90%. The heat required for regeneration of the rich solvent is provided by low-pressure steam, which is extracted from the low-pressure steam turbine at 5.96 bar and 285ºC. The steam provides its latent heat for the regeneration of the solvent and the condensate is compressed and returned to the feed-water tank.

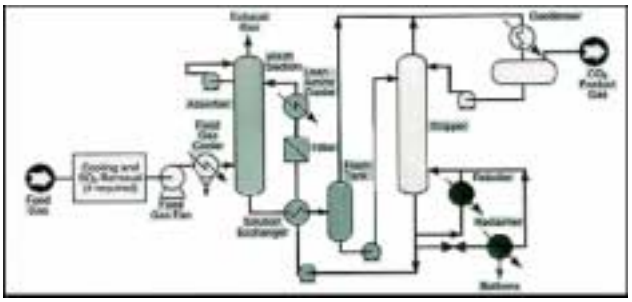

Figure 2: Amine flue gas processing operation (IEA)

Table 3 presents the simulation results of the power plant retrofit to amine scrubbing operation, demonstrating the high efficiency and power output loss, as well as the higher CO_2 emission reduction potential, compared to the conventional power plant. The loss in this case is higher than with the oxyfuel retrofit option.

Steam extraction	kg/s	109.6
Thermal consumption for solvent regeneration	MWth	256.5
CO_2 compression power consumption (n_{is}= 0.85)	MW	20.5
CO_2 absorption unit power consumption (flue gas fan, solution pumps)	MW	8.7
Cooling water pumps for flue gas cooling	MW	0.7
CO_2 emissions	kg/s	8.76
Specific CO_2 emissions	kg CO_2/ kWh	0.17
Net power output	MW	200.5
Net efficiency	%	24.16

Table 3: Power Plant with amine scrubbing simulation results

GLOBAL EMISSION REDUCTION POTENTIAL AND CO_2 CAPTURE COST

The simulations presented in the previous section have demonstrated the effect of two CO_2 sequestration retrofit options on the power output, efficiency and emissions of a typical coal fired power plant utilising low-quality brown coal. Both options demonstrate a significant reduction in the emitted CO_2, at the expense of reduced net power output and efficiency. This in its turn means that the actual emissions reduction achieved by application of a retrofit technology and the capture cost per ton CO_2 avoided, in the context of a power grid, can be assessed by making a global calculation of emissions, taking into account that the electricity generation deficit to the grid should be compensated by operation of another power plant. In the current study, three different options for covering the electricity generation deficit have been evaluated:

- operation of a conventional power plant of the same type as the retrofit plant
- operation of an advanced CCT 330 MWel low-quality brown coal fired power plant with an electric efficiency of 44%
- operation of a fourth-generation 400 MWel natural gas fired Combined Cycle with an efficiency of 56.5%.

In all cases, the power plant covering the electricity generation deficit of the retrofitted plant operates at base load for 7000 hours. The electricity generation cost has been calculated in all cases using literature data on capital costs [2], life of investment, fixed and variable operating and maintenance costs, inflation rate and company rate of return. The capital costs of the retrofit plants have been calculated on the basis of literature data.

Operating hours per year	Emissions (tons)
3000	947,183
4000	1,262,910
5000	1,578,638
6000	1,894,365
7000	2,210,093
8000	2,525,820
8760	2,765,773

Table 4: Reference CO_2 emissions of power plant

Table 4 presents the reference annual CO_2 emissions of the power plant under study, for varying annual operating hours. By applying the oxyfuel and amine retrofit technologies and covering the deficit electricity generation by each one of the three options mentioned above, the annual emissions are reduced considerably, as shown in Fig. 3. The largest emissions reduction potential is achieved when the deficit electricity generation is covered by a natural gas fired combined cycle, since this power plant type has the lowest specific CO_2 emissions.

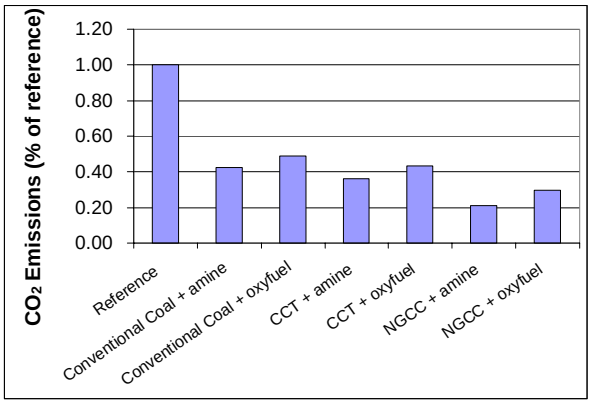

Figure 3: Global emissions from retrofit power plant and coverage of deficit electricity generation by additional power plant

Figures 4 and 5 present the overall grid CO_2 reduction cost per ton of CO_2 avoided, for two different fuel prices for low-quality coal. The transportation and storage costs are not included

here. As it is illustrated in figures 4 and 5, the CO_2 reduction cost for the amine retrofit case is always higher that the oxyfuel case, due to the increased efficiency penalty associated with this technology. In terms of global treatment of the cost, it can be seen that the CCT power plant can be competitive to the natural gas fired combined cycle for base load operation. Nevertheless, the emissions reduction is larger for the combined cycle, therefore the final decision should be taken by considering a multitude of factors such as the required cut in emissions, security of supply and economic considerations.

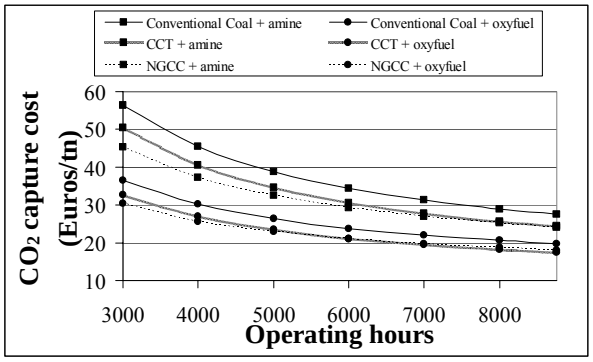

Figure 4: CO_2 reduction costs for different retrofit technologies and coverage of deficit electricity generation (coal cost: 1.8 Euros/GJ)

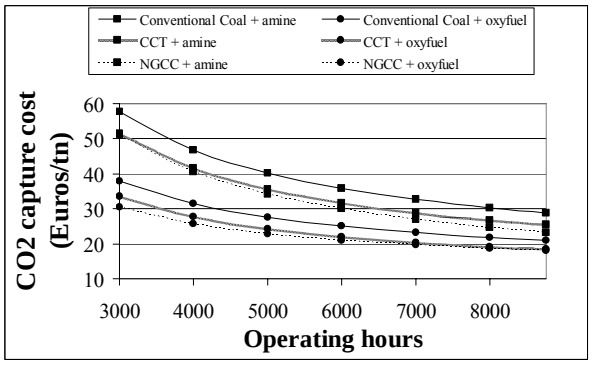

Figure 5: CO_2 reduction costs for different retrofit technologies and coverage of deficit electricity generation (coal cost: 2.4 Euros/GJ)

CONCLUSIONS

The purpose of the work presented in this paper was to examine and evaluate the state of the art in technological concepts for the retrofit of low-quality coal-fired power plants for CO_2 capture and sequestration. The present study focused on the application of the two most promising CO_2 sequestration technological options, namely the oxyfuel process and the MEA scrubbing process.

Results from thermodynamic simulations of the retrofit power plant were presented, demonstrating the potential for emissions reduction of 79% and 90% for the cases of oxyfuel and amine scrubbing respectively. The associated energy penalties are 82.7 MWel for the power output and 10 percentage points for efficiency concerning the oxyfuel retrofit and 93.2 MWel and 11.2 percentage points for the amine scrubbing option.

The case of supplementary energy supply by conventional, CCT or NGCC plants in order to cover the deficit electricity generation was examined and the overall CO_2 emissions and CO_2 reduction cost were assessed taking into account only CO_2 capture costs. The case of additional CCT use proves competitive to the NGCC option in the cases of oxyfuel or amine scrubbing retrofit power plant under base load operating conditions.

COMPARATIVE ANALYSIS OF ENERGY REQUIREMENTS OF CO_2 REMOVAL FROM METALLURGICAL FUEL GASES

Krzysztof Lampert* and Andrzej Ziebik
Institute of Thermal Technology
Silesian University of Technology
Konarskiego 22, 44-101 Gliwice
Poland

ABSTRACT

The paper presents preliminary results of the analysis of CO_2 removal process, applied to metallurgical fuel gases: blast-furnace gas and Corex gas. The CO_2 removal is realized by the physical absorption process with the Selexol solvent as the absorbing liquid. The analysis is focused on the energy consumption in the case of such installations, when blast-furnace gas or Corex gas are supposed to be treated. The CO_2 removal from metallurgical gases can be attractive from both technological and environmental points of view. Decreased CO_2 content in the gases and increased LHV results in better conditions for its utilization e.g. in a gas turbine-based CHP plant or direct utilization within the process, e.g. as an auxiliary fuel or reducing gas in a blast furnace. As the composition, flow rate and LHV of the raw blast-furnace and Corex gases differ strongly, the physical absorption installation has different requirements and operation parameters in both cases. The optimisation leads to minimal energy consumption with the assumed CO_2 removal efficiency. The results indicate which technology of pig-iron production has greater potential in the field of mitigation of greenhouse gas emissions, with respect to the technological possibilities of utilisation the treated fuel gases.
Keywords: CO_2 removal, physical absorption, Corex process, blast furnace

NOMENCLATURE

BF	Blast furnace,
C	Compressor,
CL	Cooler,
DH	Dehydrator,
DRI	Direct Reduced Iron,
f	Fuel,
FD	Flash drum,
GC	Fuel gas compressor,
GCL	Fuel gas cooler,
GT	Gas Turbine,
LHV	Lower Heating Value, kJ/kg,
$\dot{m}$	Mass flow rate, kg/s,
M	Electric Motor,
N	Power, kW, MW,
RC	Recycle gas compressor,
RCL	Recycle gas cooler,
SCL	Solvent cooler,
SP	Specific power consumption, kJ/kg,
SR	Specific amount of removed CO_2,
STP	Standard temperature and pressure.

INTRODUCTION

The best known technology of pig iron production is the blast-furnace process, commonly applied all over the world. Although some development has been made in blast-furnace technology, the process still has some important drawbacks, as the necessity of using coke and sinter, previously prepared in separate processes. In recent decades a few alternative processes of pig iron production have been developed. However, the Corex process is practically the only technology, which has been applied industrially.

Both blast-furnace and Corex processes are accompanied by the production of gaseous fuels, but the composition and LHV of these gases are different. However, both fuels contain large

amounts of CO (as the main combustible component) and CO_2. Therefore, the utilisation of such gases is connected with a relatively high CO_2 emission to the atmosphere, if compared with other hydrocarbon fuels, e.g. natural gas. CO_2 contained in the off-gas may be removed and sent for further utilisation or storage. The removal of CO_2 from the gas results in a wider range of possibilities of utilizing the purified gas. Some of the most often considered possibilities are also presented in the paper.

A number of technologies has been described in literature concerning CO_2 removal. These technologies base on different chemical and physical processes. However, special emphasis has been put on the power production sector – metallurgical processes have received little attention so far, although CO_2 removal processes are applied in a few installations, where reducing gas is needed, e.g. for iron ore reduction (DRI processes). Among different CO_2 removal technologies, physical absorption with the Selexol solvent has been chosen for this analysis as the most often considered solution for such an application, i.e. in the case of gas containing more than 10 % of CO_2 [4,6].

AN OUTLINE OF THE COREX PROCESS

The Corex process of obtaining pig iron is a modern technology, considered as more friendly for the natural environment than blast-furnace, because non-coking coal is used as a source of energy and reducing agents. In this way the harmful effects of cokeries are eliminated. The Corex installation realizes the blast-furnace function in two separate reactors (Fig. 1)[3]. The reduction of iron ore to sponge-iron takes place in a shaft furnace and the production of reducing gases and the melting of the sponge-iron are carried out in a smelting gasifier. Pig iron and slag obtained from the Corex process are nearly identical in their composition and properties to the blast-furnace technological products. In comparison with blast-furnace technology, the Corex process requires less energy due to the fact that coal is coked within the process. In this way the loss of energy due to cooling of the coke and heating it up again is eliminated. The Corex process eliminates also the consumption of energy for sintering and production of the hot blast. In this way the production of harmful substances is also eliminated.

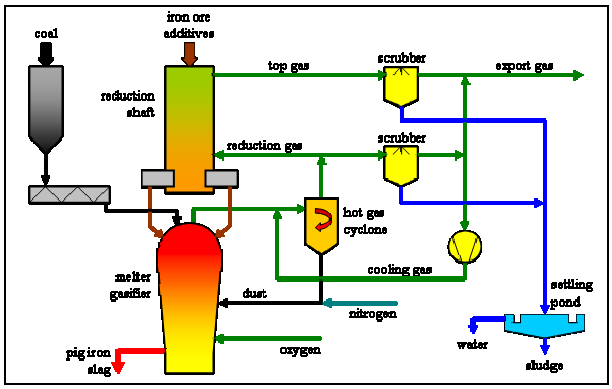

Fig. 1: Schematic diagram of the Corex process

Besides the production of pig iron, medium-LHV Corex gas is produced as the by-product. Its lower calorific value (LHV) is about two times greater than the LHV of blast-furnace gas (Table 1).

Property		Unit	Corex gas	Blast furnace gas
Gas comp. (molar)	CO	%	38 - 45	18 - 38
	CO_2	%	30 - 35	5 - 17
	H_2	%	15 - 23	1,4 - 7
	CH_4	%	1 - 2	0,1 - 1
	N_2	%	Balance	50 - 61
	H_2O, O_2	%	Balance	Balance
LHV		kJ/m^3 (STP)	7500 - 8000	3400 - 5300

Table 1: Typical analysis of the Corex export gas and blast-furnace gas [3,9,10]

The biggest difference in the off-gas composition appears when the content of nitrogen is taken into consideration. Blast-furnace gas contains at least 50% of N_2, as the process itself is supplied with a blast containing air only little enriched with oxygen. Such a ballast amount results in high costs of purification technologies. Relatively low LHV of the gas implies some difficulties with its utilization in a combustion chamber of the gas turbine, thus causing a significant decrease in the efficiency of a gas-turbine-based CHP plant. As the Corex process uses oxygen, the main ballast substance in the Corex gas is carbon dioxide.

The composition of both blast-furnace and Corex gases may be changed in specified limits. The injection of auxiliary fuels into the blast furnace influences the concentration of the main components in the blast-furnace gas. The Corex

process provides even more possibilities of changing the gas flow rate and composition, as the process is carried out in two separate reactors. A high flexibility in the Corex process is achieved by exceeding the amount of coal required for the smelting and reduction processes and increasing the amount of gas supplied directly from the gasifier to the scrubbers and for further utilization [1,8].

THE PHYSICAL ABSORPTION PROCESS

In the physical absorption process a non-reactive fluid is used as the absorbing liquid. The most frequently encountered solvent in CO_2 removal applications is Selexol, which is basically a dimethylether of polyethyleneglycol. Stripping of the solvent is realised only by pressure change and thus the process is more energy-effective than e.g. chemical absorption in many applications [6]. However, high pressure required in the absorption column leads to limited applications of the Selexol process. The necessity of compressing the gas is not a problem if the gas is supposed to be burnt in a gas turbine combustion chamber, but it is a barrier if the Selexol process should be considered in other cases, e.g. for flue gas purification.

A general flow sheet of the Selexol absorption process is shown in Fig. 2 [2]. The raw gas is compressed by means of a double-body compressor (GC1 and GC2) with an intercooler (GCL1). The compressed gas is afterwards cooled (GCL2), in order to keep the temperature in the absorber at a low level (30°C). The efficiency of the absorption process decreases with rising temperature. Therefore, cooling all the streams entering the absorber is recommended. Before entering the absorber, the raw gas is mixed with the recycling gas, coming from the first flash drum (after compressing and cooling).

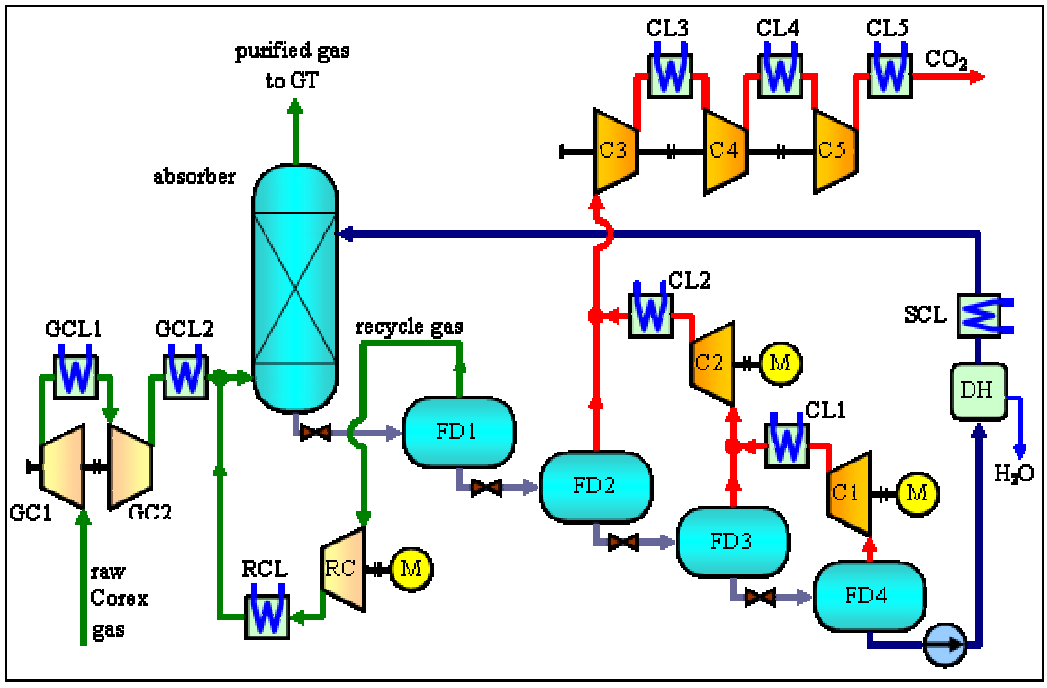

Fig. 2: Flow sheet of the analysed Selexol installation

Gas absorption is commonly realized in packed towers filled with an inert packing that provides a large interface area between the gas and the absorbing liquid. The gas rises through the tower, the solvent trickles counter-currently downward [4]. The flow rate of the Selexol solvent depends on the following parameters:

- the amount of carbon dioxide supposed to be removed from the gas (in this analysis the CO_2 removal efficiency is assumed as 90%, referred to the raw fuel gas composition),
- the CO_2 partial pressure in the gas, which depends on the overall gas pressure and composition,
- the absorption process temperature.

The purified gas leaves the absorber at the top. The carbon dioxide-rich solution leaves the absorber at the bottom and its pressure is then reduced to a value slightly lower than the solvent equilibrium pressure. Then the solvent enters the first flash drum (FD1). Apart from the absorbed CO_2, the solvent leaving the absorber contains also small amounts of CO, H_2 and water. In the first drum practically the whole amount of CO and H_2 absorbed by the solvent is released, together with some part of the CO_2. Therefore, the gas from the first flash drum is sent to the recycle gas compressor (RC), then cooled by a water cooler (RCL) and mixed with the raw gas. The solvent leaving the first flash drum is further depressurised and flows through the next flash drums (FD2…FD4), each one with a lower pressure level. Part of the carbon dioxide contained in the solvent is released at every stage of the stripping process. The CO_2 lean solvent leaving the last drum flows to the pump, where its pressure is raised to the value adequate to the pressure in the absorber. The carbon dioxide streams, previously released at different pressure levels in the flash drums (FD2, FD3, FD4), are delivered for final compression. The CO_2 delivery pressure is assumed as 8 MPa, which is higher than the critical pressure of carbon dioxide (7.39 MPa), so that CO_2 is obtained as a liquid [7].

The optimisation leads to the minimization of power consumption by the compressors, which is achieved by setting pressure levels in the flash drums and thus the pressure between the compressors.

RESULTS OF THE SIMULATION

Calculations concerning the physical absorption process have been carried out using the *EES* software [5]. The Corex unit C-2000 has been taken as reference. Such a unit is designed to produce 0.6 – 0.8 mln tons of pig iron per year (daily production 2000 tons). The average flow rate of the export gas is 50 kg/s [3]. In this analysis the average composition has been taken into consideration (Table 2) giving the LHV about 7600 kJ/m^3 (STP) (6000 kJ/kg). In the case of blast-furnace gas also the average composition has been assumed. Its LHV amounts to about 4000 kJ/m^3 (STP) (3000 kJ/kg). The following tables show the most important results obtained from the calculations.

Parameter		Unit	Raw gas		Gas entering the absorber (after mixing)		Recycle gas		Purified gas	
			COREX	BF	COREX	BF	COREX	BF	COREX	BF
Gas flow rate		kg/s	50	98,6	53,83	102,9	3,83	4,3	25,46	76,7
		kmol/s	1,75	3,35	1,85	3,47	0,10	0,12	1,18	2,84
Gas comp. (molar)	CO_2	%	35,0	16,0	37,0	17,8	70,9	71,0	5,2	1,9
	CO	%	42,0	27,0	40,8	26,8	19,9	19,8	62,2	31,9
	H_2	%	18,0	3,5	17,5	3,7	9,2	9,2	26,7	4,1
	CH_4	%	1,0	0,5	0,9	0,5	-	-	1,5	0,6
	N_2	%	2,0	51,0	1,9	49,3	-	-	3,0	60,3
	H_2O	%	2,0	2,0	1,9	1,9	-	-	1,5	1,2

Table 2: Parameters of gas in different stages of the process

To have a good comparison between both gases, it has been assumed that the flow rate of blast-furnace gas is such that it gives approximately the same flux of chemical energy delivered with the fuel as the Corex gas. The pressure level in the absorption column has been set at 1.8 MPa, allowing the direct utilization of the purified gas in the combustion chamber of a modern gas turbine.

As it is seen in Table 3, the LHV of both gases has risen because of removing 90% of carbon dioxide. However, this increase is higher in the case of Corex export gas, due to the higher CO_2 concentration in the raw gas. The higher CO_2

concentration (and thus partial pressure in the raw gas) affects also in higher pressure levels in the flash drums and a lower flow rate of the solvent (Table 4). Such a difference in the solvent flow rate obviously results in the energy demand of the solvent pump (1626 kW in the case of Corex gas and 3770 kW in the blast-furnace case). Also the size of all the equipment depends on the solvent flow rate, causing higher investment costs in the case of the blast-furnace gas.

The main power consumers in the analysed installation are the compressors, especially those for raw gas compression (Table 5). The overall power consumption concerning the raw gas compression and the whole absorption installation amounts to 26.3 MW in the case of Corex gas and 46.0 MW in the blast-furnace case. These values seem to be very high, however it must be mentioned that the major part of power is consumed to increase the fuel gas pressure, which would be realized anyway, if the gas is supposed to be the fuel for the gas-turbine-based CHP plant.

Parameter	Unit	COREX gas		BF gas	
		Raw gas	CO_2 lean gas	Raw gas	CO_2 lean gas
LHV	kJ/kg	5 960	11 700	3 020	3 880
	kJ/m^3 (STP)	7 600	11 260	3 960	4 680
	kJ/kmol	170 400	252 440	88 880	105 000
Density	kg/m^3 (STP)	1,28	0,96	1,31	1,21

Table 3: Changes of the fuel gas parameters

Parameter	Unit	COREX gas				BF gas

Table 5: Parameters of the compressors

In such a case the power consumption connected with the absorption process itself (omitting the energy demand of raw gas compressors) amounts to 8.1 MW in the case of Corex gas and 10.7 MW in the blast-furnace case. Based on these values, the following factors have been calculated:

- specific power consumption per kg of removed CO_2:

$$SP_{CO_2} = \frac{\Delta N}{\dot{m}_{CO_2}}, \text{ kJ/kg } CO_2 \qquad (1)$$

- specific amount of removed CO_2 per kg of the fuel gas:

$$SR_f = \frac{\dot{m}_{CO_2}}{\dot{m}_f}, \text{ kg } CO_2\text{/kg fuel} \qquad (2)$$

where: ΔN – power consumption in the absorption process, kW,

$\dot{m}_{CO_2}, \dot{m}_f$ - mass flow rate of the removed CO_2 and fuel gas, kg/s.

The calculated values are presented in Table 6. These values allow to estimate the consequences of applying the CO_2 removal for the treatment of metallurgical gases and to facilitate the comparison between gases with different compositions, like blast-furnace gas and Corex gas.

Parameter	Unit	COREX gas	BF gas
specific power consumption	kJ/kg CO_2	335	505
specific amount of removed CO_2	kg CO_2/kg$_{fuel}$	0,484	0,215

Table 6: Values of specific factors

The specific power consumption, as well as specific amount of removed CO_2 differ strongly, depending on the kind of gas. CO_2 removal from blast-furnace gas requires more energy due to the lower CO_2 content in the raw gas.

POSSIBILITIES OF IMPROVEMENTS

Combustion in the gas-turbine-based CHP plant is not the only way of utilization of metallurgical fuel gases. Therefore, the purified gas may have different requirements concerning its pressure. Specifically, there are many metallurgical processes, where it is enough to deliver the fuel at nearly atmospheric pressure. It concerns mostly blast-furnace gas, which is commonly used for firing hot-blast stoves, coke-ovens and metallurgical furnaces. However, also Corex gas may replace other fuels in many applications.

The removal of carbon dioxide from the blast-furnace or Corex gas provides another interesting option. As the purified gas has a relatively high content of reducing agents (carbon monoxide and hydrogen), it may be used as the reducing gas improving the blast-furnace process. Such an option brings many positive aspects from the environmental point of view, as the consumption of coke may be in this way limited.

Further analysis has been focused on the absorption process at different pressure levels. It is obvious that increasing the pressure in the absorber results in a higher power consumption by the raw gas compressors. Keeping a constant pressure of the raw gas coming from the metallurgical installation (here assumed as 0.1 MPa) it is recommended to have also a constant reference pressure level of the purified gas. This is achieved by adding an expansion turbine at the absorber outlet. The gas expands to about 0.1 MPa. As the gas leaving the absorber has a relatively low temperature (about 30°C) and contains a large amount of vapour, heating of the gas has been applied in order to limit the condensation of water inside the expansion turbine. Heating may be realized by the partial burning of the gas or in a separate heat exchanger. Here the second possibility has been taken into consideration. The purified gas transfers heat from the compressed raw gas. The following figures show the influence of absorption pressure on the main parameters of the process and overall power demand, including raw gas compressors and power recovery in the expansion turbine (with an isentropic efficiency of 80%).

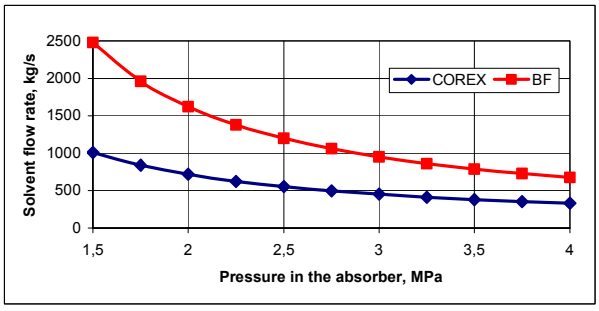

Fig. 3: Influence of pressure in the absorber on solvent flow rate

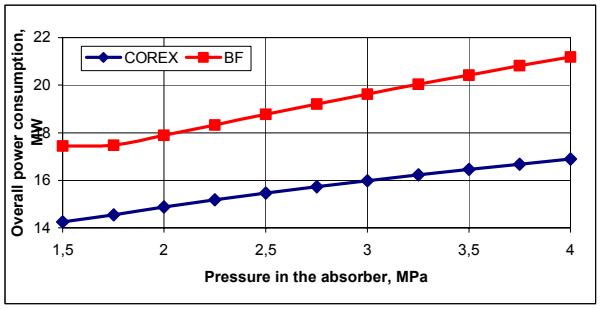

Fig. 4: Influence of pressure in the absorber on overall power consumption

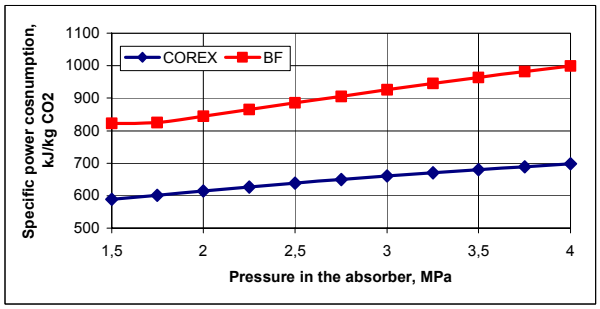

Fig. 5: Influence of pressure in the absorber on specific power consumption per kg of removed CO_2

CONCLUSIONS

The results of calculations indicate that the physical absorption process may be useful method of CO_2 removal from metallurgical fuel gases on a large industrial scale. However, such a process is always accompanied by a high power consumption. The optimisation of parameters concerning the absorption process is necessary to keep the energy demand at a minimum level.

Different CO_2 contents in Corex and blast-furnace gases result in a higher power consumption in the case of blast-furnace gas treatment. Changing the pressure level in the absorber is possible within specified limits; however this should be connected with an economical analysis which has not been applied in the paper.

A further increase of CO_2 removal effectiveness would require a shift reactor to convert some part of CO into CO_2 and simultaneously increase the H_2 content in the gas.

ABSTRACT

Mitigation technologies including CO_2 capture and storage in various energy conversion systems have been intensively developed in recent years. However, it is of importance to develop an equation of state (EOS) with simple structure and reasonable accuracy for engineering application for both pure CO_2 and CO_2 mixtures. In this paper, Redlich-Kwong equation of state was modified for gaseous CO_2. In the new modification, parameter 'a' was correlated as a function of temperature and pressure from reliable experimental data in the range: 220K to 750K and 0.1MPa to 400MPa. To verify the accuracy of the new parameters, densities were calculated and compared with experimental data. The average error is 1.68 %. Other thermodynamic properties of CO_2, such as enthalpy and heat capacities, were also calculated; results fit experimental data well except critical region. This method can be further developed for CO_2 mixture systems.

INTRODUCTION

Due to increased importance of climate change mitigation, R&D on capture and storage of CO_2 associated with cleaner fossil fuel plants have been intensively carried out worldwide.

However, thermodynamic properties of CO_2 and its mixtures play an important role in the development and design of the processes of CO_2 capture and storage. A reasonably accurate and easy-to-use equation of state (EOS) to calculate properties such as enthalpy and specific heat capacities of CO_2 and its mixtures which encountered in the related process is necessary. In this paper, it is first step to develop a suitable equation of state for gaseous CO_2.

There are many kinds of EOSs, which can be used to describe properties of CO_2. However, it is often that EOSs with simple structures result in poor

* Corresponding author: Email: hailong@ket.kth.se, Phone +46-8-7906527, Fax +46 8 7230858

calculation accuracy; and ones with good calculation accuracy are too complicated for engineering applications. From an engineering point of view, an EOS with simple structure and reasonable accuracy is preferable.

RK EOS [1] is a kind of cubic equation in molar volume, which has simple structure and can represent vapor and liquid behaviors relatively effectively. It was proposed in 1949 as:

$$P = \frac{RT}{v-b} - \frac{a}{v(v+b)T^{1/2}} \tag{1}$$

Where 'a' and 'b' are parameters. Parameter 'a' reflects intermolecular attraction, and parameters 'b' reflects molecular size (repulsive forces). For simple non-polar gases, they can be calculated from critical data.

$$a = \frac{0.42748R^2T_c^{2.5}}{P_c}$$
$$b = \frac{0.08664RT_c}{P_c} \tag{2}$$

RK EOS can get good results for many non-polar substances. But if both 'a' and 'b' with the consistent values calculated from Equation 2 even though in different conditions, RK EOS is not appropriate for the polar gases, such as CO_2.

Since 1980s, many new experiments (referring to Table 1) on gaseous CO_2 have been carried out, but little work on EOSs with simple structure for gaseous CO_2 was done. Therefore, new modification with the consideration of new experimental data for EOS is necessary. In this paper, based on more precisely measured PVT

Table 1 Summary of the experimental data used for correlation

properties, RK EOS will be modified for better precision for gaseous CO_2.

MODIFICATION ON RK EOS

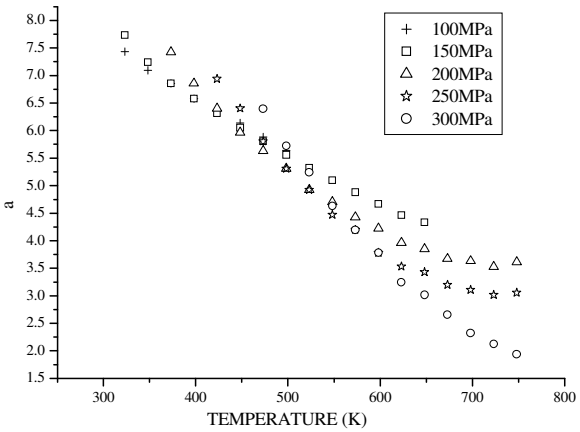

Fig. 1 Values of 'a' at different temperatures and certain pressures

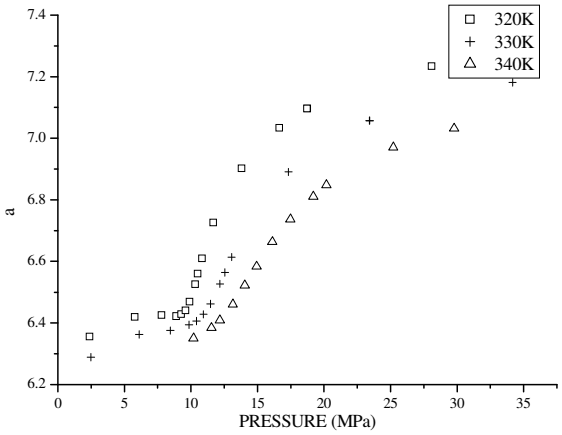

Fig. 2 Values of 'a' at different pressures and certain temperatures

It has been verified that if the parameters 'a' and 'b' in RK EOS were not constants, but functions, RK EOS can be used to describe properties of polar gases [11, 12]. Based on this conclusion, we studied the relationship between temperature and pressure and parameters 'a' and 'b'.

Compared with intermolecular attraction, repulsive forces impact gas's volume less. So here; 'b' is kept unchanged; and only 'a' will be correlated as a function. If parameter 'b' is still calculated from Equation 2, with PVT data, parameter 'a' can be calculated from Equation 1 for each point by the Newton method. Fig. 1 shows values of 'a' at different temperatures and certain pressures. Obviously, parameter 'a' depends on both temperature and pressure.

In former studies [11, 12, 13], for simplicity, 'a' was usually assumed to be dependent only on temperature; however from Fig. 2, which shows values of 'a' at different pressures and certain temperatures, it is easy to find that pressure has great effects on 'a' as well as temperature. So to get more accurate results, effects of pressure can't be ignored. With further inspection on Fig. 2, it can be found that at different temperatures, the curves 'a' versus pressure have similar trends. Thus, this may indicate that 'a' can be regressed as a function of temperature and pressure, a=(T, P).
Finally we derived Equation 3 to describe the temperature and pressure effects on 'a' for gaseous CO_2.

$$a = a_1 + a_2 P$$

$$a_1 = \frac{2.3457\times10^{5}}{T^{2}} - \frac{1.3612\times10^{3}}{T} - 4.8365\times10^{-3}T + 9.9191 \quad (3)$$

$$a_2 = \frac{1.9141\times10^{-2}}{T^{2}} - \frac{1.0132\times10^{-4}}{T} - 1.3654\times10^{-10}T + 0.1934\times10^{-6}$$

Chorng [14] pointed out that according to the temperature behavior of attractive force, 'a' should be finite and positive at any temperature. So Equation 3 can't be extrapolated to extremely high temperature cases.

RESULTS:

To verify the reliability of new correlation, density, enthalpy, and heat capacities were calculated and compared with measured values.

Calculation on density of gaseous CO_2

Fig. 3 shows the comparisons of the calculated densities of gaseous CO_2 at some temperatures and pressures with experimental data. Obviously, the calculated results in this paper agree well with experimental data throughout those comparison temperature and pressure ranges. In Fig. 4, calculated densities of gaseous CO_2 were compared with measured values in the whole experimental range. The maximum deviation is

97.52%, which occurs at the critical point; and the average deviation is 1.68%. Moreover at high pressures (400MPa) deviations are also large, up to 5-10%.

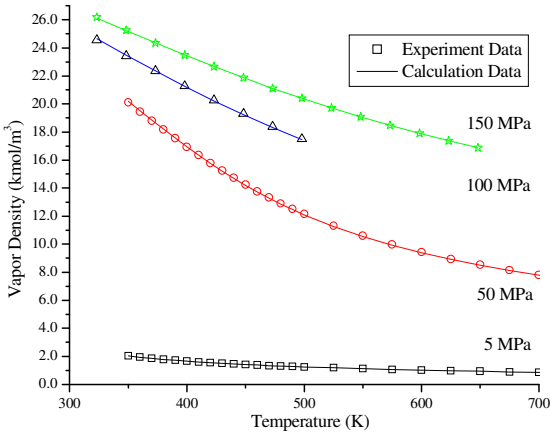

Fig. 3 Calculated densities of gaseous CO_2 at some temperatures and pressures

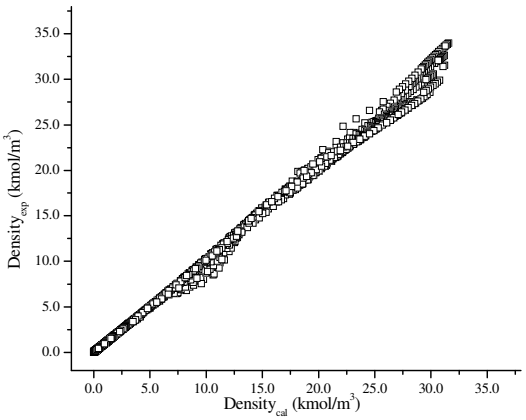

Fig. 4 Calculated densities of gaseous CO_2 versus experimental data in whole experiment range

Because the intermolecular potential energy function for CO_2, from which 'a' and 'b' should be derived, is not well understood; based on RK EOS, there are still some other empirical modifications. Santis et al [11] proposed that parameter 'a' should be a function of temperature. Later, Holloway [13], according to Santis's conclusion, regressed 'a' to a polynomial on temperature. However Bottinga et al [12] developed another set of expressions to describe the parameters 'a' and 'b', which are functions of volume. Moreover Kerrick et al [15] also regressed the parameters 'a' and 'b' as functions of volume, but they are more complex. In addition, Nakamura et al [16] proposed an EOS with simple structure in a new way to describe the properties of gaseous CO_2.

In this paper, all of these models were used to calculate molar densities and results were compared with the experimental data throughout the whole experimental data range except critical area. The comparison is listed in Table 2. The model with the parameter regressed in this paper is the best; both the standard and average errors are much lower than others. The models of Kerrick and Bottinga's are better than model proposed by de Santis and Holloway; which may be due to that functions of volume can be regarded as functions of temperature and pressure as well.

Model	STANDARD.Err*	AVERAGE.Err** %
New Model	1.031	1.6843
RK	1.433	6.1972
Holloway	1.518	5.2485
Bottinga	1.408	3.4154
Kerrick	1.291	2.9834
Nakamura	1.427	3.6527

Table 2 Comparison results of density among different models

$$^{*}STANDARD.Err = \left(\frac{\sum \left(v_{\exp} - v_{cal} \right)^2}{N} \right)^{1/2} \; kmol/m^3$$

$$^{**}AVERAGE.Err = \frac{\sum abs\left(\frac{v_{\exp} - v_{cal}}{v_{\exp}} \right)}{N}$$

Enthalpy and heat capacities

In this paper, residual method is used to calculate enthalpy, heat capacities and other properties.

As we know, residual properties can be calculated from the following equation:

$$\Delta m(T,P) = \int_0^P \left[\left(\frac{\partial m^{ig}}{\partial P} \right)_T - \left(\frac{\partial m}{\partial P} \right)_T \right] dP \qquad (4)$$

Thus enthalpy, and heat capacities can be calculated by:

$$m(T,P) = m^{ig} - \Delta m(T,P) \quad (5)$$

To solve the integration terms in Equation 4, numerical method can be employed. The rule of integration is like this: first we set an integration interval, thus the whole integration area can be divided into many segments. We regard these segments as trapeziums and calculate their areas until their values are less than 10^{-6}. Consequently, the sum of those segments' areas is the integration value.

Enthalpy

Möller [17] measured the enthalpy differences at two different temperatures. We also used RK EOS with the new correlated parameter to calculate enthalpy differences under the same conditions. Comparisons between them were shown in Fig. 5. From it, it is clear that the calculated results agree with experimental data.

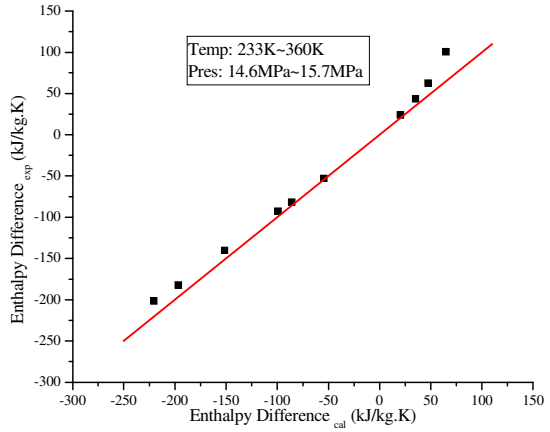

Fig. 5 Comparisons on enthalpy differences with experimental data

Heat capacities

Ernst et al [18, 19] have done a lot of work on isobaric heat capacity (C_p) measurement. Here we compared our calculated results with their experimental data on CO_2. In Fig. 6, scatters are experimental data and lines are calculation results. It is obvious that in the area close to critical point, calculation accuracy is poor; while in other areas, it is acceptable; disagreements are usually smaller than 5%.

Since only few experimental data on isochoric heat capacities are available, to test our model, we compared our results with Span's [20] in temperature range: 220K~1100K and pressure range: 0.1MPa~200MPa, which uncertainty is among ±2%. Results were shown in Fig. 7. It can be seen that at high pressure and low temperature (especially close to critical temperature), difference is big. Actually uncertainty of Span's data becomes bigger when pressure rises and temperature descends. Generally, our average deviation is less than 5%.

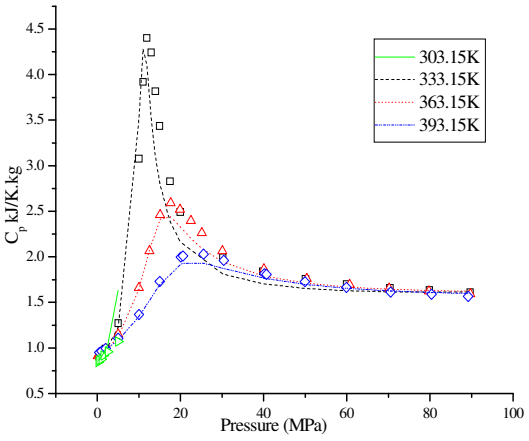

Fig. 6 Isobaric heat capacities at different temperatures and pressures

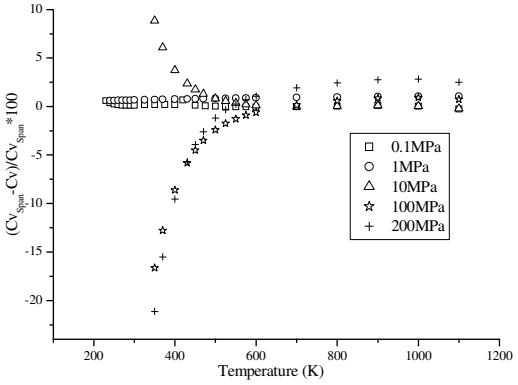

Fig. 7 Comparison on isochoric heat capacities with Span's calculation results

CONCLUSIONS

Based on some new updated experiments on CO_2, RK equation of state was modified. Compared with other EOSs, which have simple structures as well, the new model has better calculation accuracy on densities of gaseous CO_2 in temperature range: 220K~700K and pressure range: 0.1MPa~400MPa, except critical region 295~315 K and 6.5~9.5MPa. For other thermodynamic properties, such as enthalpy and

specific heat capacities, this model also predicts them well if the critical region is excluded.

ABSTRACT

This work focuses on the experimental determination and thermodynamic modeling of the solubility of carbon dioxide (CO_2) in aqueous solution of 30 mass % AEEA, AEEA being a potentially new solvent for post–combustion CO_2 capture. The vapor–liquid equilibrium (VLE) experiments were performed over a range of temperatures from (40 to 120) °C and for partial pressures ranging from (0.01 to 220) kPa. The results obtained were then modeled by use of the Deshmukh–Mather thermodynamic model. The model provides a good representation of the experimental data over the whole temperature range. In addition to modeling the experimental VLE data, ^{1}H and ^{13}C 1D NMR spectra were acquired for species identification. Quantitative analysis of the speciation from NMR data was found to be in reasonable agreement with model predictions.

INTRODUCTION

Removal of acidic gases, in particular CO_2, is an important industrial operation. Carbon dioxide is produced in large quantities by fossil–fuel–fired power plants, in steel production, in the production of petrochemicals, in cement production, and in natural gas purification. The global climate change, where CO_2 is found to be a major contributor, is one of the most important and challenging environmental issues facing the world community. This has motivated intensive research on CO_2 capture and storage.

Carbon Dioxide capture by absorption is the most common industrial technology today and recent economic studies show that the process will remain competitive also in the future. One of the key improvements that is under development is new, faster and more energy efficient absorbents. A chemical to be used as a commercial absorbent must have high net cyclic capacity, high reaction rate for CO_2, and good chemical stability. Alkanolamines, e.g. monoethanolamine ($H_2NCH_2CH_2OH$, MEA), are the most commonly used chemical absorbents for the removal of acidic gases today.

From previous work on screening tests for a large number of solvents [1], focusing on the absorption rate and capacity of the amines, it has been found that 2–(2–aminoethyl–amino)ethanol ($H_2N(CH_2)_2NH(CH_2)_2OH$, AEEA) as a diamine may be a potentially very good absorbent for capturing CO_2 from post–combustion exhaust gases. It offers high absorption rate combined with high net cyclic capacity. The net cyclic capacity of AEEA is significantly higher than that of MEA and it maintains its absorption power at higher loadings.

The objective of this work is experimental characterization and thermodynamic modeling of the absorbent, AEEA. It focuses on the experimental determination and thermodynamic modeling of the vapor–liquid equilibria (VLE) of CO_2 in aqueous solution of 30 mass % AEEA. Equilibrium experiments have been performed at temperatures ranging from (40 to 120) °C. The results obtained were modeled by use of the Deshmukh–Mather model [2]. In addition to the VLE experiments, NMR analyses have also been performed to determine the species existing in the liquid phase as function of CO_2 loading.

EXPERIMENTAL APPARATUSES AND PROCEDURES

The experimental apparatuses and procedures have been described by Ma'mun et al. [1, 3]. All the equilibrium measurements for AEEA were carried out in the VLE apparatuses designed for atmospheric and medium pressures, as shown in Figures 1 and 2.

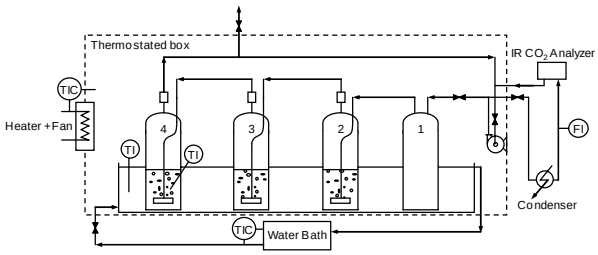

Figure 1: Vapor–liquid equilibrium apparatus for atmospheric pressure.

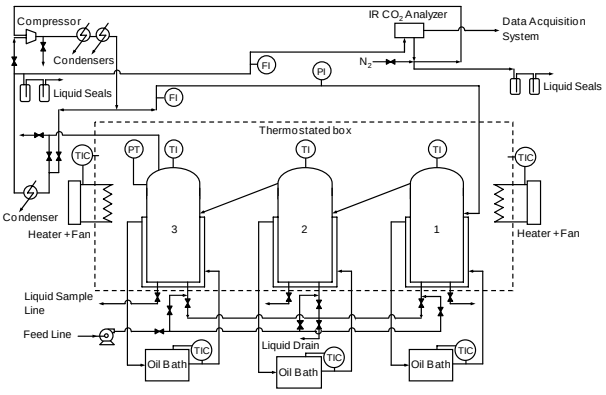

Figure 2: Vapor–liquid equilibrium apparatus for medium pressure.

The VLE apparatus for atmospheric pressure is designed to operate at temperatures up to 80 °C and consists of four 360–cm^3 glass flasks. A preloaded AEEA solution of 150 cm^3 was fed into flask 2. The same amount was also fed into flasks 3 and 4 while flask 1 was used as a gas stabilizer. The flasks were heated by water and placed in a thermostated box with temperature measured to within ±0.1 °C. The gas phase was circulated as the temperature reached the desired level and equilibrium was obtained when the analyzer showed a constant value. After the equilibrium reached in (30 to 60) min, a liquid sample was then withdrawn from the flask 4 to be analyzed.

In addition, the VLE apparatus for medium pressure consists of three 300 cm^3 stainless steel cylinders (the equilibrium cells 1, 2, and 3) designed to operate at pressures up to 700 kPa and temperatures up to 130 °C with recirculation of the gas phase. Before starting the experiment, N_2 was flushed through the apparatus to purge out the air within the cells. A 30 mass % AEEA solution of 200 cm^3, preloaded with CO_2, was then fed into the cell 1 while cells 2 and 3 held 150 cm^3 each of the same solution. The cells, placed in a thermostated box, were heated by individual oil baths and the temperatures were measured to within ±0.1 °C. Typically, temperature variations during an experiment would be within ±0.5 °C. To prevent boiling and vaporization of the solvent during the heating up, the minimum initial pressure in the cells was set to 300 kPa. As the temperature reached the desired value the compressor increased the pressure up to 700 kPa and circulated the vapor. A back-pressure valve was used to maintain the pressure at 700 kPa. Equilibrium was obtained when the temperature was established at a constant value and the CO_2 concentration in the vapor phase was constant. This took about (2 to 3) h including the heating–up period. After equilibrium was obtained, a liquid sample was withdrawn from cell 3 into a 75 cm^3 evacuated sampling cylinder such that the cylinder was completely filled by the liquid sample and then cooled to ambient temperature. The temperatures and pressures were automatically collected by the FieldPoint™ data acquisition system.

Liquid samples containing all bound CO_2 for both experiments were analyzed by the barium chloride ($BaCO_3$) method. The amount of hydrogen chloride (HCl) not used to dissolve $BaCO_3$ was titrated with 0.1 $mol.L^{-1}$ sodium hydroxide (NaOH) carried out with an automatic titrator (Metrohm 702 SM Titrino) with end point pH 5.2. Due to solvent losses during the process at high operating temperature, the AEEA concentrations were then determined by titration. A liquid sample of 0.5 cm^3 was diluted into deionized water of 75 cm^3 and titrated with 0.1 $mol.L^{-1}$ sulfuric acid (H_2SO_4) using Metrohm 702 SM Titrino. The end point was obtained at pH 4 to 5.

pKa measurements

Protonation constants (pKa) of AEEA were measured over a range of temperatures from (20 to 60) °C. An aqueous solution of 30 mass % AEEA, heated in a water bath, was neutralized by use of 5 M HCl solution. Due to the increase of temperature during titration, the HCl solution was discretely added in to the AEEA solution and the pH was measured by use of pH meter at a constant temperature.

PHASE AND CHEMICAL EQUILIBRIA

The AEEA–CO_2–H_2O system is very complex as AEEA is a diamine containing one secondary and one primary amine group. This gives rise to a large number of possible species and the following 14 species are considered to exist: AEEA, $AEEAH^+$, $^+HAEEAH^+$, $AEEACOO^-_p$, $AEEACOO^-_s$, $^+HAEEACOO^-_p$, $^+HAEEACOO^-_s$, $^-OOCAEEACOO^-$, CO_2, HCO_3^-, $CO_3^=$, H_2O, H_3O^+, and OH^- with the chemical equilibria written as follows:

Dissociation of water

$$2H_2O \rightleftharpoons H_3O^+ + OH^- \quad (1)$$

Dissociation of carbon dioxide

$$CO_2 + 2H_2O \rightleftharpoons HCO_3^- + H_3O^+ \quad (2)$$

Dissociation of bicarbonate ion:

$$HCO_3^- + H_2O \rightleftharpoons CO_3^= + H_3O^+ \quad (3)$$

Dissociation of protonated AEEA:

$$AEEAH^+ + H_2O \rightleftharpoons AEEA + H_3O^+ \quad (4)$$

Dissociation of diprotonated AEEA:

$$^+HAEEAH^+ + H_2O \rightleftharpoons AEEAH^+ + H_3O^+ \quad (5)$$

Formation of carbamates:

$$AEEA + CO_2 + H_2O \rightleftharpoons AEEACOO^-_p + H_3O^+ \quad (6)$$

$$AEEA + CO_2 + H_2O \rightleftharpoons AEEACOO^-_s + H_3O^+ \quad (7)$$

Dissociation of protonated carbamates:

$$^{+}\text{HAEEACOO}^{-}_{p} + \text{H}_2\text{O} \rightleftharpoons \text{AEEACOO}^{-}_{p} + \text{H}_3\text{O}^{+} \quad (8)$$

$$^{+}\text{HAEEACOO}^{-}_{s} + \text{H}_2\text{O} \rightleftharpoons \text{AEEACOO}^{-}_{s} + \text{H}_3\text{O}^{+} \quad (9)$$

Formation of dicarbamate:

$$\begin{aligned}&\text{AEEACOO}^{-}_{p} + \text{AEEACOO}^{-}_{s} + 2\text{CO}_2 \\ &+ 2\text{H}_2\text{O} \rightleftharpoons {}^{2-}\text{OOCAEEACOO}^{-} + 2\text{H}_3\text{O}^{+}\end{aligned} \quad (10)$$

The corresponding equilibrium constants are mathematically defined in term of activity coefficients γ_i and mole fractions x_i:

$$K = \prod_i a_i^{v_{ij}} = \prod_i \left(x_i \gamma_i\right)^{v_{ij}} \quad j = 1, 2, ..., R \quad (11)$$

where v_{ij} is the stoichiometric coefficient for component i in reaction j and R is the number of chemical reactions.

The balance equations for the reacting species include total mass balance expressed in term of mole fraction x,

$$\sum_i x_i = 1.0 \quad (12)$$

mass balance for AEEA,

$$\begin{aligned}x^{o}_{\text{AEEA}} = {} & x_{\text{AEEA}} + x_{\text{AEEAH}^+} + x_{{}^{+}\text{HAEEAH}^+} + x_{\text{AEEACOO}^-_p} \\ & + x_{\text{AEEACOO}^-_s} + x_{{}^{+}\text{HAEEACOO}^-_p} + x_{{}^{+}\text{HAEEACOO}^-_s} \\ & + x_{{}^{-}\text{OOCAEEACOO}^-}\end{aligned} \quad (13)$$

mass balance for carbon dioxide,

$$\begin{aligned}x^{o}_{\text{CO}_2} = {} & x_{\text{CO}_2} + x_{\text{HCO}^-_3} + x_{\text{CO}^{=}_3} + x_{\text{AEEACOO}^-_p} \\ & + x_{\text{AEEACOO}^-_s} + x_{{}^{+}\text{HAEEACOO}^-_p} + x_{{}^{+}\text{HAEEACOO}^-_s} \\ & + 2x_{{}^{-}\text{OOCAEEACOO}^-}\end{aligned} \quad (14)$$

and electroneutrality.

$$\begin{aligned}x_{\text{H}_3\text{O}^+} + x_{\text{AEEAH}^+} + 2x_{{}^{+}\text{HAEEAH}^+} = {} & x_{\text{OH}^-} + x_{\text{HCO}^-_3} \\ & + 2x_{\text{CO}^{=}_3} + x_{\text{AEEACOO}^-_p} + x_{\text{AEEACOO}^-_s} \\ & + 2x_{{}^{-}\text{OOCAEEACOO}^-}\end{aligned} \quad (15)$$

Equations 11–15 represent a system of 10 chemical equilibria for the reactions 1–10 together with 3 mass balances and the electroneutrality. These equations are solved simultaneously to determine the equilibrium composition of the liquid phase.

At equilibrium, the fugacities of each volatile component are equal in the vapor and liquid phase and the equilibrium is defined by

$$\phi_i y_i P = \gamma_i x_i H_i^{\infty} \exp\left\{\bar{v}_i^{\infty}\left(P - P_s^{o}\right)/RT\right\} \quad (16)$$

where H_i^{∞} and $\bar{v}_i^{\infty}$ are the Henry's law constant and partial molar volume for molecular solute i at infinite dilution in the solvent, respectively. The Henry's law constant for CO_2 at infinite dilution in water was taken from Chen et al. [4] and the partial molar volume of CO_2 was substituted by molar volume and taken form Brelvi and O'Connel [5].

For the volatile solvent (water), the vapor–liquid equilibrium is given by

$$\phi_s y_s P = \gamma_s x_s P_s^{o} \phi_s^{o} \exp\left\{v_s\left(P - P_s^{o}\right)/RT\right\} \quad (17)$$

The fugacity coefficients ϕ_i for all volatile components were calculated by the Peng–Robinson equation of state [6].

ACTIVITY COEFFICIENT MODEL

The data obtained in this work were correlated using an adaptation of the Deshmukh–Mather [2] model. This model has been chosen because it is more rigorous than the simple approaches e.g. Kent and Eisenberg [7] and is capable of producing reasonable species concentrations. Yet algebraically it is simple enough to be computationally efficient for column and plant calculations. More complex models like the electrolyte–NRTL and the MSA models are more expensive computationally [8] without seeming to offer any better fit to VLE data or species concentrations. In the Deshmukh–Mather model, the activity coefficients of the species in the liquid phase are calculated using the extended Debye–Hückel equation. The equation is described as:

$$\ln \gamma_i = \frac{-2.303 A_\gamma z_i^2 I^{1/2}}{1 + BaI^{1/2}} + 2\sum_j \beta_{ij} m_j \quad (18)$$

The first term of this equation represents the electrostatic forces and the second term represents the short–range van der Waals forces. A_γ (the Debye–Hückel limiting slope) and B are functions of temperature and the dielectric constant of the solvent. I is the ionic strength and is defined as function of the charge number on the ion z_j and molality.

$$I = \frac{1}{2}\sum_j m_j z_j^2 \quad (19)$$

The values for the quantity *a* represent the effective diameter of the ions and were taken from Weiland et al. [8] and treated as constants independent of the ionic strength. AEEA is considered a solute and the reference state is infinite dilution in water. The activity coefficients obtained by equation (18) are molality based and have to be transformed to the molar fraction concentration scale on which the equilibrium constants were defined.

Simplifications were made for the Deshmukh–Mather model in which the value of the Debye–Hückel limiting slope at 25 °C in water was used (A_γ = 0.509) and B was set equal to 1. In addition, the second term of the extended Debye–Hückel equation representing the short–range van der Waals forces was disregarded at this stage of the work. This implies that the activity coefficient model as used in this work does not contain any parameters for regression.

THERMODYNAMIC PARAMETERS

The thermodynamic parameters needed for the model are such as equilibrium constants for all chemical reactions, parameters in the activity coefficient model, and Henry's law constant for CO_2 in pure water.

The temperature dependency of the equilibrium constants and the Henry's law constant can be expressed in the form

$$\ln K = C_1 + C_2/T + C_3 \ln T + C_4 T \qquad (20)$$

Coefficients C_1–C_4 for reactions 6–10 were determined by regression of the VLE data with the model and are summarized in Table 1. The protonation constants for reaction 4 and 5 were determined from separate titration experiments. For reaction 1, the equilibrium constant of water is given by Olofsson [9], and for reactions 2 and 3, the equilibrium constants were taken from Edward et al. [10].

PARAMETER REGRESSION

The parameters regressed in this model are those contained in the equilibrium constants for reactions 6–10. The regression was performed by using Modfit, an in–house MATLAB computer program for parameter estimation. The regression method used was the Levenberg–Marquardt minimization with the normalized objective function as given by

$$F = \sum_{i=1}^{n} \left(\frac{100\left(p_{CO_2}^{exp.} - p_{CO_2}^{cal.} \right)}{p_{CO_2}^{exp.}} \right)^2 \qquad (21)$$

The criterion used was the relative error between the calculated and experimental values of the CO_2 partial pressures.

RESULTS AND DISCUSSION

The vapor–liquid equilibrium experiments were performed at temperatures ranging from (40 to 120) °C. The results are given in Figure 3 together with the predictions obtained by the model. As shown in the figure the representation of the data by the model agrees well with the experimental data. However, this should only be taken as a preliminary result. The only parameters fitted were the parameters involved in the temperature dependency of the chemical equilibrium constants. It is very unlikely that a model based only on equilibrium constants should be able to describe the complex AEEA–CO_2–H_2O system perfectly, especially with regard to the species distribution, as will be discussed later.

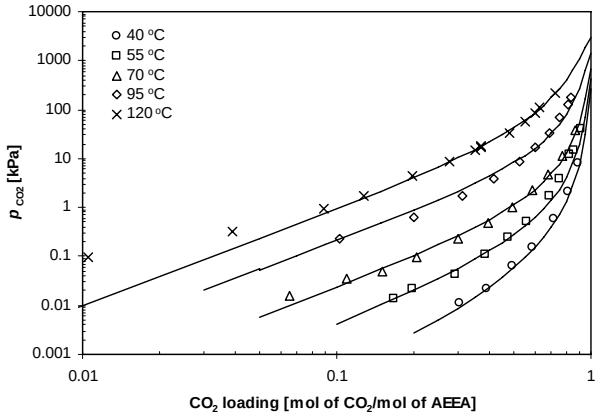

Figure 3: Equilibrium solubility of CO_2 in aqueous solution of 30 mass % AEEA. All data points were measured in this work. Curves were calculated by the VLE model.

A more advanced activity coefficient model will certainly be needed. Including the short range term of the Deshmukh–Mather model might make the model more flexible and regression of the interaction parameters might improve the fit. However we do not have enough experimental information on the system to be able to reliably determine both the equilibrium constant parameters and the parameters of the activity coefficient model. So in

Table 1: Temperature dependence of the equilibrium constants for reactions 2–10 and Henry's law constant for CO_2.

this work, the liquid phase non–idealities were lumped into the obtained equilibrium constant parameters. On the other hand, the done here regression was based on data that are typically used for such a procedure. Very often VLE data of the kind presented in this work are the only data available. The findings here thus also highlight the need for a variety of data for developing equilibrium models for complex absorption systems, and not only VLE data. As a first estimate, however, the regressed equilibrium constant parameters given in Table 1 should be satisfactory.

pKa determinations

Protonation constants of AEEA were measured over a range of temperatures from (20 to 60) °C. The results are given in Figure 4 and Table 2. AEEA is a diamine with one primary and one seconddary amine group and will therefore have two equilibrium points (EPs). In the first EP, the protons will associate with both the primary and secondary amine groups with a certain ratio which cannot be determined from the experiment, but probably 80–90% with the primary group. The first protonation constant (K_{AEEAH+}) is therefore the constant for the total of the first protonated AEEA ($AEEAH^+$) from both primary and secondary amine groups. In addition, dissociation of the second protonated AEEA ($^+HAEEAH^+$) will then form primary and secondary protonated AEEA ($AEEAH^+_p$ and $AEEAH^+_s$). The second protonation constant ($K_{+HAEEAH+}$) is therefore the constant for the total of the second protonated AEEA ($^+HAEEAH^+$). The temperature dependency of the protonation constants are given in Table 1.

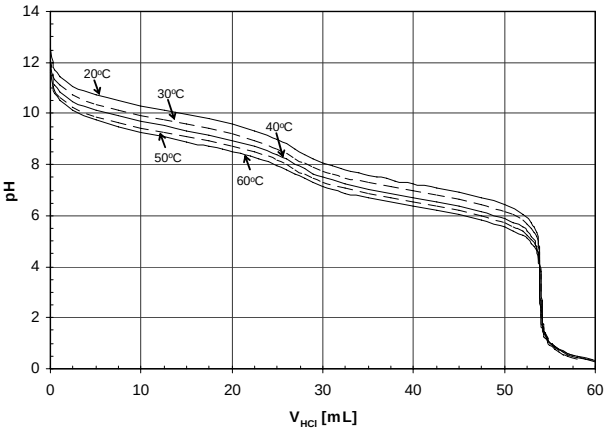

Figure 4: pH curves of aqueous solution of 30 mass % AEEA for several temperatures.

20	10.05	7.21
30	9.70	6.94
40	9.44	6.67
50	9.20	6.49
60	9.00	6.31

Table 2: pKa values of aqueous solution of 30 mass % AEEA for several temperatures.

Speciation and NMR analysis data

In order to identify the species existing in the liquid phase in the AEEA–CO_2–H_2O system, an NMR study was performed. CO_2–loaded 30 mass % AEEA solutions were investigated at 20 °C and loadings of 0.20, 0.50, and 0.80 mol of CO_2/mol of AEEA, respectively. Both ^1H and ^{13}C 1D NMR

spectra were acquired. Three types of amine species were identified; amine, primary carbamate, and secondary carbamate and the peaks were assigned to particular proton/carbon types with help of 2D NMR spectra. The different types of proton/carbon atoms are shown for AEEA molecule in Figure 5. An example of a ^{13}C spectrum is given in Figure 6. There were observed 4×3 peaks representing the four carbon types for each of the three AEEA species in the spectra. On the spectrum in Figure 6, the peaks of highest intensity correspond to primary carbamate, the middle intensity peaks to AEEA, and the lowest intensity peaks to secondary carbamate.

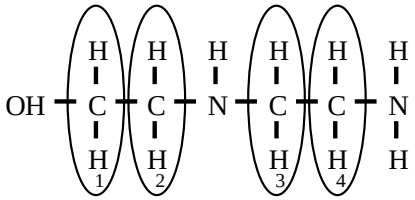

Figure 5: The four different carbon atoms in AEEA molecule.

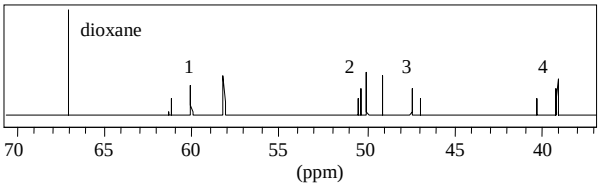

Figure 6: ^{13}C spectra of aqueous solution of 30 mass % AEEA at a loading of 0.80 mol of CO_2/mol of AEEA.

Since the peak intensities correspond to the species concentrations, the NMR spectra were also used for a quantitative investigation of the species distribution as function of CO_2 loading. The relative species concentrations were evaluated based on the area integrals. The detailed procedure can be found in Jakobsen et al. [11]. Because of the fast proton exchange with water, the data obtained actually represent the sum of the free and protonated AEEA, the sum of the primary and protonated primary carbamates, and the sum of the secondary and protonated secondary carbamates. In Figure 7, the NMR data are compared to the concentrations predicted by the model.

The VLE model was fitted to experimental data down to 40 °C and an extrapolation to 20 °C was deemed to be uncertain. Therefore 40 °C model data were compared to 20 °C data from the NMR experiments. This is the main reason for the discrepancies observed in Figure 7. Qualitatively, however, the model predictions are in good agreement with the NMR data. It should be noted that the given loadings are weighed in loadings and that these were not in total accordance with the material balances calculated from the NMR data.

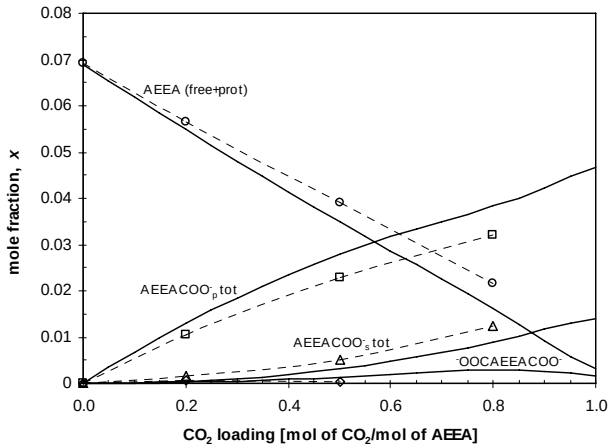

Figure 7: Liquid–phase concentrations of a CO_2–loaded 30 mass % AEEA at 40 °C in comparison to those analyzed using NMR at 20 °C. Solid lines are calculated by the model and points from NMR data. {AEEA (free+prot) = AEEA + $AEEAH^+$ + $^+HAEEAH^+$; $AEEACOO^-_p$ tot = $AEEACOO^-_p$ + $^+HAEEACOO^-_p$; $AEEACOO^-_s$ tot = $AEEACOO^-_s$ + $^+HAEEACOO^-_s$}.

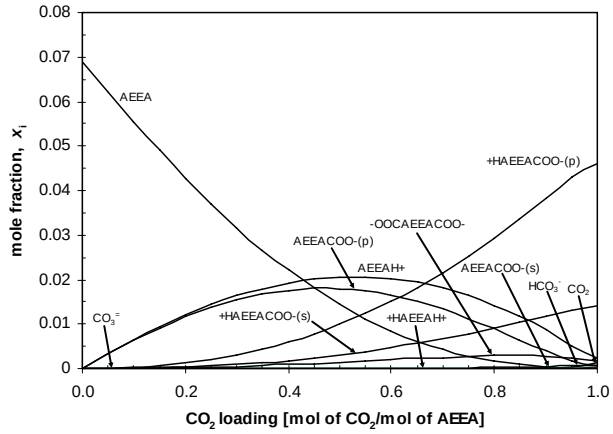

Figure 8: Distribution of species in aqueous solution of 30 mass % AEEA at 40 °C.

Figure 8 shows the distribution of species predicted by the model as a function of loading for 40 °C. As CO_2 is added to a fresh AEEA solution, the dominant product is the carbamate formed by the primary amine group ($AEEACOO^-_p$). At a loading of approximately 0.6 mol of CO_2/mol of AEEA, the

primary carbamate is progressively replaced by protonated primary carbamate ($^{+}HAEEACOO^{-}_{p}$). As the loading increases, pH decreases so that it is low enough to protonate the carbamates. In addition, secondary carbamate ($AEEACOO^{-}_{s}$) starts forming but still exists in very small amounts, approximately 0.03% of the primary carbamate. It is also clear that the dicarbamate only exists in small concentrations in the whole loading range. As expected, the formation of bicarbonate increases somewhat at high loadings, but the protonated carabamates are the main constituents in this region.

CONCLUSIONS

The vapor–liquid equilibrium data of CO_2 in aqueous solution of 30 mass % AEEA were measured over a range of temperatures from (40 to 120) °C for partial pressures ranging from (0.01 to 220) kPa. The Deshmukh–Mather model was fitted to the data and was shown to provide a good representation of the experimental points. ^{1}H and ^{13}C 1D NMR spectra were acquired for the system and used for identification of the system species. In addition, quantitative information on the species concentrations could be obtained and was shown to be in reasonable agreement with model predictions.

CO-UTILIZATION OF CO_2 AND CALCIUM SILICATE-RICH SLAGS FOR PRECIPITATED CALCIUM CARBONATE PRODUCTION (PART I)

Sebastian Teir[1], Sanni Eloneva and Ron Zevenhoven

ABSTRACT

A promising option for long-term storage of CO_2 is to fixate carbon dioxide as carbonates in minerals. Slag from iron and steel works is a potential raw material for carbonation due to its high content of calcium silicates. Carbonation of calcium silicates produces calcium carbonate ($CaCO_3$), which is used as filler and coating materials in paper. Precipitated calcium carbonate (PCC) is currently produced by carbonating burned lime. If calcium silicate-rich slag materials are used instead of limestone for producing PCC, considerable energy savings and carbon dioxide emissions reductions could be achieved. A suitable process utilizing acetic acid for producing calcium carbonates from calcium silicates was identified. The option for fixating carbon dioxide with calcium silicate-rich slag using acetic acid as reaction intermediate and solvent was investigated using process modeling and laboratory-scale batch experiments. Using this process, 0.24 t of CO_2 could theoretically be captured and stored per ton of iron and steel slag products carbonated, while the world-wide CO_2 storage potential was estimated to be 62 – 83 Mt/a. The experiments showed that the calcium in iron and steel slags easily dissolve in acetic acid.
Keywords: mineral carbonation, CO_2 storage, CO_2 utilization, slag, calcium carbonate, calcium silicate

INTRODUCTION

The increasing carbon dioxide, CO_2, content in the atmosphere and its long-term effect on the climate has led to increasing interest and research in options for capture, utilization and long-term storage of carbon dioxide. Oil refineries, coal-fired power plants, iron and steel works, cement, lime and natural gas production are the largest producers of anthropogenic CO_2 emissions. However, the potential to reuse CO_2 in industry is limited, so the captured CO_2 has to be stored. Although CO_2 can be stored in aquifers and utilized in depleted oil and gas fields, the distances to the CO_2 producer site can be thousands of kilometers, which raise the storage cost significantly.

The disposal of CO_2 as solid carbonates is another potential option for long-term storage of CO_2. This method accelerates the natural weathering of silicate minerals, where these minerals react with CO_2 and form carbonate minerals and silica [1]. Suitable carbonates for storing CO_2 are magnesium- and calcium-based carbonates, since they are hard to dissolve in water. While magnesium- and calcium oxides and hydroxides carbonate faster, the availability of magnesium- and calcium silicates is much better [2]. Although calcium silicate has been successfully carbonated at temperatures and pressures relevant for industrial processes [3], natural calcium silicate resources are far too small and expensive to be of practical interest [2, 4]. Therefore, current research activities focus mostly on carbonation of magnesium silicates [5].

However, industrial by-products, such as iron and steel slags and cement-based materials, can have

[1] Corresponding author: Phone: +358 9 4513631 Fax: +358 9 4513418 E-mail: sebastian.teir@hut.fi

very high contents of calcium- and magnesium oxides, and could therefore be carbonated for CO_2 storage and hazardous waste neutralization [6, 7]. At the same time, calcium carbonate ($CaCO_3$) and precipitated calcium carbonate (PCC) has currently far more industrial uses than magnesium carbonate. Currently, PCC is manufactured by first calcinating limestone (natural calcium carbonate), and then carbonating the produced calcium oxide (CaO).
In this paper, we investigate the potential to use calcium silicate-rich slag products as raw material for PCC production, and explore the possibility to dissolve iron and steel slags in acetic acid for carbonation. A future paper will focus on the carbonation process step.

BACKGROUND

Precipitated calcium carbonate (PCC)

Calcium carbonate is mined and crushed to be mainly used as a concrete or bituminous aggregate and roadstone, as well as for manufacturing Portland cement. Lime (calcium oxide) is also calcinated from calcium carbonate for steelmaking, glassmaking, soil stabilization and neutralization, treating water, flue gas desulphurization, and PCC production. Ground and precipitated calcium carbonates are used as fillers in paints, rubbers, plastics and papers.
PCC is used as an alternative filler and coating material for changing physical and chemical properties of paper. It improves paper bulk, brightness, light scattering, fiber coverage and printability. In 2002, the world's PCC consumption was approximately 6 Mt, of which approximately 4 Mt was consumed by the paper industry [8], and approximately 425 kt produced in Finland [9].
Most PCC is currently produced from lime, which has been manufactured by calcining limestone in a lime kiln at temperatures over 900 °C:

$$CaCO_3 \rightarrow CaO + CO_2 \quad (1)$$

The lime is hydrated with water into a calcium hydroxide slurry:

$$CaO + H_2O \rightarrow Ca(OH)_2 \quad (2)$$

CO_2 is injected into the slurry, where it reacts with calcium hydroxide and forms calcium carbonate, which precipitates out:

$$Ca(OH)_2(aq) + CO_2 \rightarrow CaCO_3 \downarrow + H_2O \quad (3)$$

Although CO_2 is bound during the PCC production process, a larger amount of CO_2 is released from the lime production, due to the fuel combusted to provide heat to the endothermic calcination reaction (Equation 1).
According to Miner and Upton [10], almost all of the PCC in paper eventually ends up in landfills. Although significant amounts of inorganic carbon are removed from recovered paper in the recycling process, this material is disposed of in the landfills of recycled paper mills. In both cases, the carbon in PCC becomes eventually sequestered in landfills.
If PCC could be produced from a carbonate-free calcium mineral, such as calcium silicate, the calcination process could be abandoned and less CO_2 would be released. While the natural calcium silicate reserves are too few and too expensive to be used for manufacturing PCC [2, 4], the price, composition and availability of industrial slag products makes slag a more suitable material for carbonation.

Iron and steel slags

Slags are nonmetallic by-products of many metallurgical operations and consist primarily of calcium, magnesium, and aluminum silicates in various combinations. Iron and steel slags are co-products of iron and steel manufacturing.
Pig iron is produced by heating iron ore, coke and limestone in a blast furnace. Since silicon dioxide is a common impurity in iron ore and does not melt, limestone is needed. In the blast furnace, limestone calcinates to lime (CaO) (see Equation 1) and reacts with the silicon dioxide in the iron ore forming a molten calcium silicate slag:

$$CaO_x + (SiO_2)_y \rightarrow (CaO)_x \cdot (SiO_2)_y \quad (4)$$

The molten silicate slag is less dense than the molten iron and accumulates at the top of the reactor, where it can be drawn off. Different blast furnace slag types are produced depending on cooling technique used: air-cooled, expanded or foamed, granulated, or palletized slag.

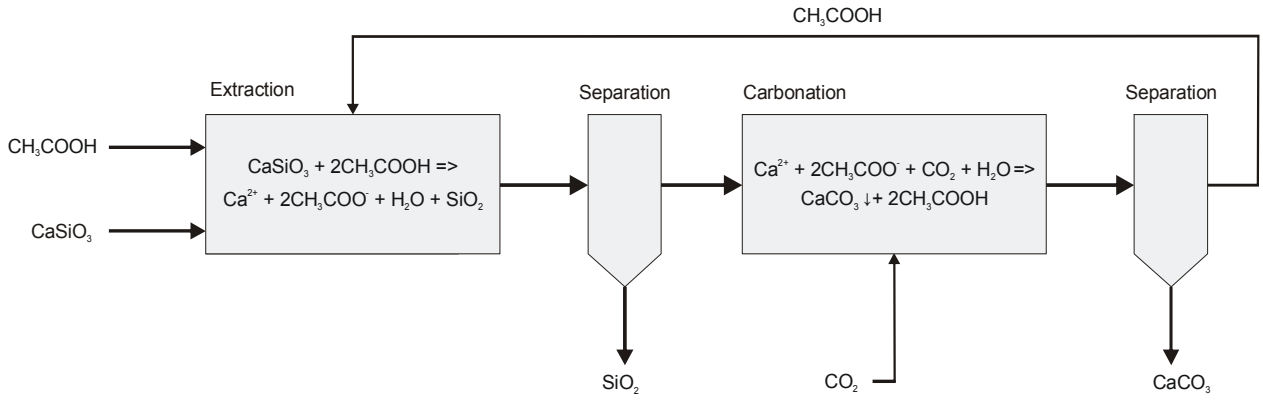

Figure 1: Acetic acid process

Element	Blast furnace slag	Steel slag
CaO	39.9 %	44.2 %
SiO_2	34.4 %	13.5 %
MgO	10.8 %	1.93 %
Al_2O_3	9.07 %	1.80 %
S	1.74 %	0.09 %
Fe	0.95 %	16.9 %
K_2O	0.71 %	0.12 %
Na_2O	0.50 %	-
Mn	0.35 %	2.35 %
P	0.002 %	0.33 %
Ti	-	0.50 %
Cr	-	0.21 %
Other	1.58 %	18.1%

Table 1: Annual average composition of slag products [12]

Steel slag is produced as lime reacts with molten iron ore, scrap metal, or other ingredients charged into the steel furnace. During this process, part of the liquid metal becomes entrapped in the slag.
This molten slag flows from the furnace into the pit area where it solidifies, after which it is transferred to cooling ponds and metals are removed by magnetic separation. Steel slags are highly variable with respect to their composition, even for the same plant and furnace.
The amount of slag produced is largely related to the overall chemistry of the raw material. For a blast furnace using high grade iron ore, about 0.25 – 0.30 t of blast furnace slag will be produced per ton of crude iron. Lower grade ores can yield as much as 1.0 – 1.2 t of slag per ton of crude iron. Steel slag output is also variable and depends on both the feed chemistry and the type of furnace used. Since 50 % of the molten steel slag is recycled inside the process, the slag remaining after entrained steel removal is usually equivalent to about 10 – 15 % of the crude steel output. It has been estimated that the world output was in 2003 160 – 200 Mt of iron slag and 96 – 145 Mt of steel slag [11]. Examples of the elemental composition of iron and steel slags can be found in Table 1.

Carbonation of calcium silicate

The most promising option for producing precipitated calcium carbonate from calcium silicates seems to be the acetic acid carbonation process suggested and studied by Kakizawa *et al.* [3]. The process consists of two main steps, where the reactions occur (Figure 1). First, calcium ions are extracted from a natural calcium silicate mineral by acetic acid (CH_3COOH):

$$CaSiO_3 + 2CH_3COOH \rightarrow Ca^{2+} + 2CH_3COO^- + H_2O + SiO_2 \quad (5)$$

After filtrating silica out of the solution, CO_2 is pumped into the solution, forming calcium carbonate that precipitates from the solution:

$$Ca^{2+} + 2CH_3COO^- + CO_2 + H_2O \rightarrow CaCO_3 \downarrow + 2CH_3COOH \quad (6)$$

Acetic acid is recovered in this step and recycled for use in the extraction step. According to Kakizawa *et al.*, the Gibbs free energy change of each step is negative, and should therefore not require large amounts of energy input. However,

the second step may require pressurized CO_2 in order to achieve a high carbonation efficiency.
The process was studied with batch experiments. Using an aqueous solution of acetic acid (27 % acid and 72 % water at 60 °C) to extract calcium ions from natural calcium silicate, an extraction ratio of 48 % was achieved in 250 min. Using CO_2 pressures of 5 – 50 bar and temperatures of 40 – 80 °C, a carbonation ratio of 20 % of a calcium acetate solution was achieved in approximately 1 h [3].

PROCESS COMPARISON

We have studied the feasibility of PCC production from calcium silicates using process modeling, and compared it with the current PCC production route from limestone [4]. The processes were modeled using Aspen Plus 12.1® and HSC 4.0 software. Both processes were modeled using a gas supply of 100 % CO_2 at room temperature, and at the pressure level needed for the process (assuming CO_2 is provided from a CO_2 capture facility).
The net CO_2 emissions from the current PCC production method were according to our model 0.21 kg CO_2/kg $CaCO_3$ produced, with the CO_2 bound in the carbonation process accounted for, and the energy need for the calcination facility included.
The PCC production from calcium silicates was modeled using an extraction efficiency of 100 % and 10 % carbonation ratio, in order to be comparable with available modeling results [3]. The model assumed that all acetic acid could be regenerated and recycled with the calcium ions that had not carbonated, so that the process has no other output streams than $CaCO_3$ and SiO_2. This model captures CO_2 and produces none, since the heat for the endothermic carbonation step was supplied by the exothermic extraction reactor. When the total power demand of the process was taken into account the fixation of CO_2 was calculated to be 0.34 kg/kg $CaCO_3$ produced [4]. If this process would replace existing PCC production facilities, the net reduction would be 0.55 kg CO_2/kg $CaCO_3$ produced.

Potential

According to our acetic acid process model, roughly 0.24 kg of CO_2 could be stored per kg of slag (with an average CaO content of 40 %) carbonated. The world-wide iron and steel slag carbonation potential can be estimated using these numbers at 62 – 83 Mt CO_2/a.
Production of PCC from carbonation of iron and steel slag could also be a profitable refining method for the slag products, if the purity required for commercial PCC could be achieved. In Finland, granulated blast furnace slag can be purchased for 10 €/t, which is approximately the same price as limestone lumps used for producing lime for PCC manufacturing (11 €/t), while the cheapest available PCC type has a price tag of 120 €/t [13].
For example, in 2003 Raahe steel works produced 2.80 Mt steel slabs, 899 kt slag products, and 4.84 Mt CO_2 emissions [14]. If all the slag products could be carbonated, 642 kt/a of PCC would be produced, reducing the CO_2 emissions of the plant with 218 kt/a (4.5 %), and possibly increasing the value of the slag product ten-fold. If this PCC produced from slag would replace conventional PCC manufactured from limestone on the filler market, an additional 135 kt/a of CO_2 emissions from lime kilns currently producing lime for PCC manufacture could be avoided. This would also annually save more than 642 kt of natural limestone mineral resources.
However, if the PCC purity specifications cannot be met, the carbonates could still possibly be used e.g. for soil neutralization and stabilization.

EXTRACTION EXPERIMENTS

In order to investigate the possibility to carbonate slag products instead of natural calcium silicates, the extraction of calcium ions from iron and steel slags in acetic acid was investigated using batch experiments.

Materials and methods

The iron and steel slags used in the experiment were provided by Ruukki Production, Co-products, from Raahe steel works in Finland. The experiment setup is displayed in Figure 2.
A solution of 200 g distilled water and 100 g acetic acid was heated to a specified temperature in a decanter glass. Depending on the temperature of the solution, its pH ranged from 0.74 to 1.7, prior to the addition of slag. The decanter glass was surrounded by a water bath, which was

heated using a magnetic stirrer with an integrated heater. Each slag was tested at solution temperatures of 30 °C, 50 °C and 70 °C. The solution was stirred at 650 min^{-1}. Nitrogen was continuously fed to the container at 6 l/min to prevent carbonation of atmospheric CO_2, and the container was sealed with a cork.

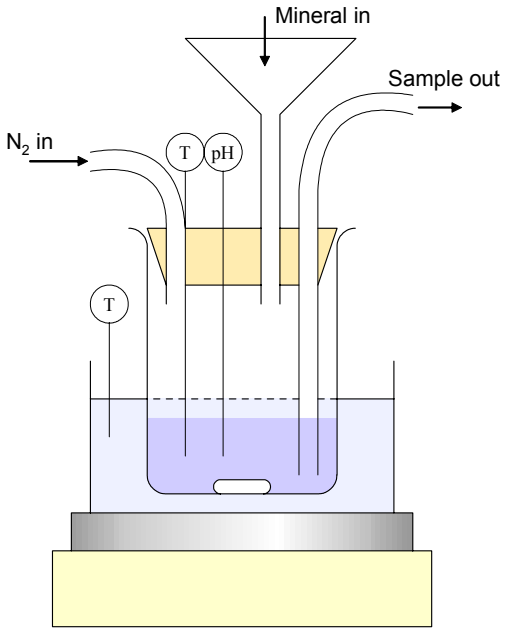

Figure 2: Experiment setup

When the temperature for the solution had stabilized after heat-up to the desired temperature, 5.0 g of slag, sieved to a particle size of 125 – 350 µm, was added to the solution. The temperature and pH of the solution were recorded with electrodes in real time, and were not regulated after the addition of the batch. The solution was stirred for 2 h, and four samples of 15 ml each were extracted during the course of the experiment using a syringe. The samples were immediately filtered through a syringe membrane filter of 0.45 µm pore size and stored for analysis. A few samples blocked the membrane filters immediately. These samples were filtered using other methods and are marked in the result figures. The Si, Fe, Al, Ca and Mg concentrations in the solution samples were measured after the tests using Inductively Coupled Plasma-Atomic Emission Spectrometry (ICP-AES) and Atomic Absorption Spectrophotometry (AAS), since these are the main species of the slag. The solution was assumed to be free from these species prior to the addition of the batch of slag, being prepared from only distilled water and pure acetic acid.

Results

The results from the AAS and ICP-AES analyses of the experiments made with steel slag are shown in Figure 3, Figure 4, and Figure 5. The corresponding results from the experiments with iron slag are shown in Figure 6, Figure 7 and Figure 8. Samples of the solution were extracted for each test at 15 min, 30 min, 1 h, and 2 h after the batch had been added, with one exception: sample extraction for the iron slag solution at 50 °C were performed at 15 min, 45 min, 1 h and 15 min, and 2 h after the addition of slag. Due to substantial weight loss at 50 °C and 70 °C as a result of solution evaporation, the concentration values have been corrected by assuming a constant evaporation rate, which was calculated using the initial mass of the container, the final mass of the container, sample volumes extracted and the time between measurements. The

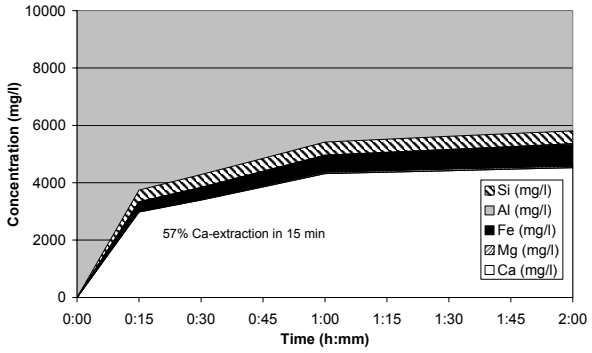

Figure 3: Steel slag in solution at 30 °C

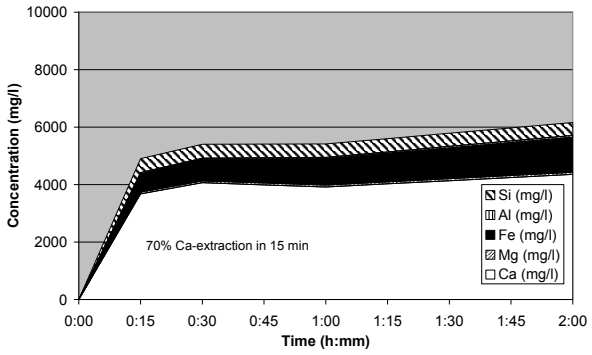

Figure 4: Steel slag in solution at 50 °C

mass/solution ratio was assumed not to be affected by the sample extraction, since the solution was continuously stirred.

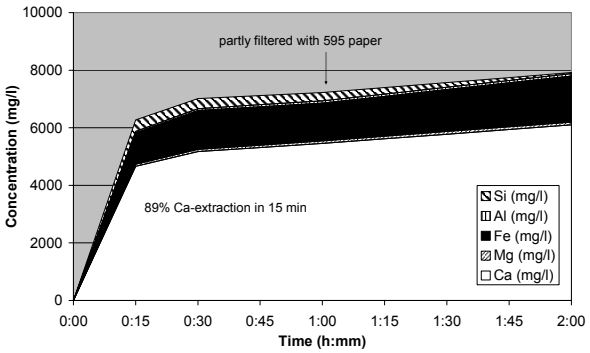

Figure 5: Steel slag in solution at 70 °C

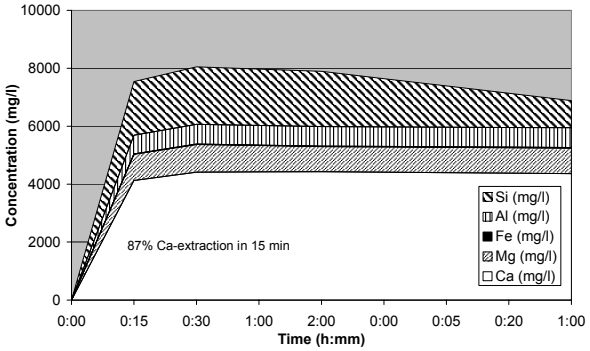

Figure 6: Iron slag in solution at 30 °C

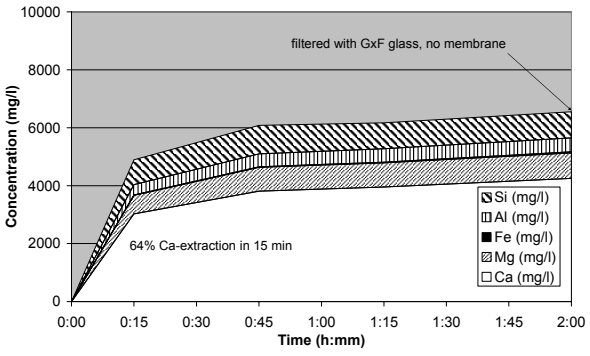

Figure 7: Iron slag in solution at 50 °C

In order to estimate the dissolution rate, the pH curve was plotted into the same graph as the Ca extraction rate, calculated from the Ca analyses (Figure 9 and Figure 10). The same scale was used for both experiments. Peaks in pH data have been filtered out, since the signal suffered from some interference in the data logger card. Only solutions at 30 °C were compared, since the evaporation loss made the comparison less reliable for solutions at higher temperatures.

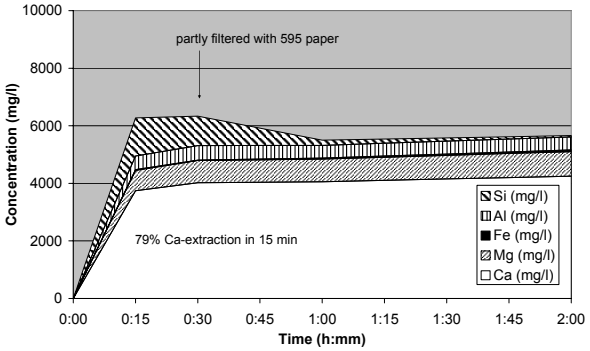

Figure 8: Iron slag in solution at 70 °C

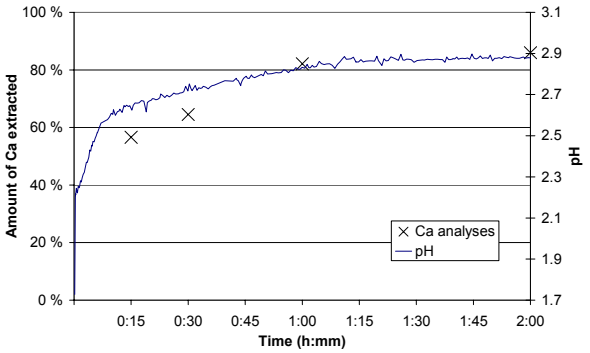

Figure 9: Steel slag in solution at 30 °C

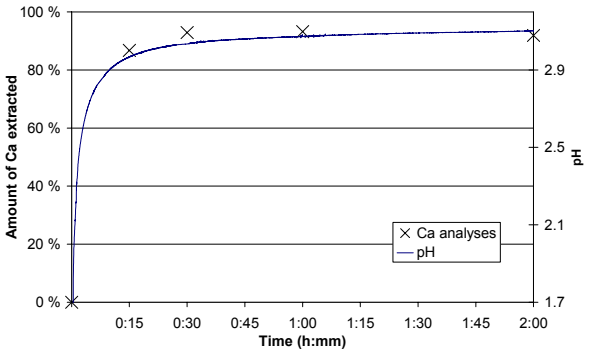

Figure 10: Iron slag in solution at 30 °C

Discussion

When the batch of slag was added to the solution, the solution temperature was raised immediately with a few degrees, verifying a reaction occurring and the exothermic nature of the reaction. The

results from the experiments (Figure 3 – Figure 8) show that Ca from iron and steel slag dissolves readily in acetic acid. While higher temperature allows more calcium to be dissolved from steel slag, temperature does not seem to have an effect on the calcium extraction from iron slag. In most experiments performed here, approximately 70 % of the calcium in the slag has been dissolved within 15 minutes. According to the estimates in Figure 9 and Figure 10, over 50 % was dissolved from both iron and steel slag within 5 minutes. This is much faster than the values reported by Kakizawa *et al.* The reason for this is still unclear, but indicates that calcium is much easier to extract from iron and steel slags than from natural calcium silicates. However, a much smaller batch load was used in the experiments presented here (16.7 g slag/kg acid, in comparison to 208 g calcium silicate/kg acid used by Kakizawa *et al.*). Since acid will continuously be regenerated in the subsequent carbonation process step, allowing more slag to dissolve, the achieved extraction ratio should be enough for a continuous process.

However, other elements of the slag, such as Si, dissolve as well. Extracting Ca from steel slag also dissolves Fe, while Ca extraction from iron slag dissolves Mg and Al. Both experiments performed at 70 °C show a gradual decline in dissolved Si content with residence time of the filtered samples. The filtration residue in both experiments was a gel, indicating that silica may be separated as a gel at temperatures > 70 °C using centrifugal separation technology. More research is needed to verify this.

FUTURE WORK

While the experimental work presented here only investigates the possibility to extract calcium from calcium silicate-rich slag, future work will investigate the carbonation of acetic acid solutions containing calcium. Experiments with precipitation of carbonate from these solutions will determine the purity of CO_2 required for carbonation, and the type of separation methods needed to eliminate impurities. The quality of the produced PCC will also be analyzed.

The extraction experiments will continue as well, by exploring the influence of higher solution temperatures, larger particle sizes, and the concentration of acetic acid on the extraction efficiency. The regeneration of acetic acid requires also investigation.

The results from that work will be submitted and hopefully accepted for presentation at ECOS 2006 as part II of this paper.

CONCLUSION

Carbonation of calcium silicate-rich slags is an interesting option for simultaneously reducing CO_2 emissions and refining by-products from the industry. If the produced calcium carbonate could reach the purity specifications of PCC, the processing of slags could increase its value ten-fold, while also reducing CO_2 emissions and preserving natural mineral resources. Although the global CO_2 storage potential by carbonating slags is low in comparison with other CO_2 storage options, it can reduce the annual CO_2 emissions for an individual steel plant with several hundreds of kilotons.

Using an acetic acid process 0.24 t of CO_2 could theoretically be captured and stored per ton of slag carbonated. The results from the experiments show that calcium ions can rapidly be extracted at an average 70 % efficiency from iron and steel slags in an acetic acid solution. However, filtration of the solution may be required to remove silica and other impurities.

ACKNOWLEDGEMENTS

We thank the people working at the Laboratory of Energy Engineering and Environmental Protection and the Laboratory of Applied Thermodynamics for facilitating this work. We also thank Hannu Revitzer at the Chemical Analysis Centre of the university for his technical support, and we thank the Nordic Energy Research, the National Technology Agency of Finland (TEKES) and the Finnish Recovery Boiler Committee for financial support. We also thank Prof. Mikhail Gasik for giving us the idea to investigate whether iron and steel slag could be carbonated.

ABSTRACT

In this paper, two methods are proposed to assess the efficiency of Carbon Capture and Sequestration schemes (CCS) involving back-leakage of CO2 from geological storage reservoirs to the atmosphere. In other words, we develop criteria to quantify the marginal benefit of non-permanent carbon storage. The first method is a physical approach based on radiative forcing. It leads to a criterion that assesses whether a given technology of CCS is physically beneficial compared to a reference technology without CCS. The second method is an economic approach based on the classical framework of Net Present Value. It leads to an economic feasibility condition that assesses whether a given CCS technology is economically beneficial compared to a reference technology. The two models are compared with respect to their parametric dependence. Under general assumptions, the economic criterion is stricter than the physical criterion when the leakage coefficient is small, and the opposite is true when the leakage coefficient is large.

Keywords: Carbon sequestration, Carbon dioxide, Efficiency assessment, leakage.

NOMENCLATURE

a_g	Radiative efficiency
CR	Capture rate of CCS technology
EF	Emission factor of fuel employed [tCO_2/GJ]
EF_C	Emission factor of generation in capture plant [tCO_2/kWhe]
EF_r	Emission factor of generation in reference plant [tCO_2/kWh]
$f^C(t)$	Time dependent decay function of CO_2
$f^g(t)$	Time dependent decay function of gas
GWP(η)	Global warming potential of carbon storage with a constant leakage coefficient η.
HR_c	Heat rate of captured plant [GJ/kWhe]
HR_r	Heat rate of reference plant [GJ/kWhe]
$L(t)$	Leakage rate [ton/year]
$l(t)$	Specific leakage rate [$year^{-1}$]
P_C	Carbon price at time 0 [$/$tCO_2$]
P_e	Electricity price in wholesale market [$/kWhe]
P_F	Fuel price at time 0 [$/GJ]
r	Discount rate
$S(t)$	Carbon stock in reservoir at time t [ton]
S_0	Amount of carbon sequestered at time 0 [ton]
β	Expectation of increase of carbon price
η	Leakage coefficient
λ	Energy penalty of Capture technology

INTRODUCTION

In line with the Kyoto Protocol [1], there is currently a great interest in carbon sequestration as a complemental option for carbon mitigation. The Intergovernmental Panel on Climate Change (IPCC) defines sequestration as an increase in carbon stock in some reservoir other than the atmosphere. Several kinds of reservoirs have been considered for carbon sequestration, such as bio-

*Corresponding author: Phone: +0033 383 17 5280
Fax:+0033 383 32 2975 Email: fei.teng@ensic.inpl-nancy.fr

logical carbon sinks including forests and soil; onshore geological reservoirs such as deep coal seams, depleted hydrocarbon reservoirs, deep saline aquifers; and deep ocean.

For geological reservoirs, greenhouse gas will be captured at the places of fossil fuel combustion and then transported and injected into these reservoirs. Such activities are often called CCS (Carbon Capture and Storage).

A particular feature of carbon sequestration is that the carbon sequestrated (stored in plantation or underground) is always at risk of leaking back to the atmosphere. In contrast, carbon mitigation caused by a reduction of fossil fuel consumption will result in a risk-free reduction in atmospheric CO_2 level. This is the issue of permanence which has been hotly debated in the literature [2, 3]. Existing approaches are mainly economical [4-6], and based on a Net Present Value (NPV) model. By contrast, the present paper firstly uses a physical approach, comparing the cumulative radiative forcing of the CCS plant with its reference plant. Then focusing on the economic efficiency, a more detailed NPV model is employed for the same comparison. At last, these two approaches are compared and conclusions are given.

BACKGROUND

The core problem of the permanence issue is the following: compared with carbon avoided from fossil fuel usage, what is the value of temporary sequestrated carbon? As Chomitz [7] suggested, two possible approaches can be used to address this issue: (1) To assess the environmental and economic benefit of commitments to limited-term sequestration agreements. (2) To devise mechanisms that provides reasonable assurance of indefinite sequestration. The first approach leads to researches for a numerical index comparing the contribution to global warming of temporary sequestration on one hand and permanent fossil fuel avoided on the other hand.

Radiative forcing or concentration are often used as proxy for climate change [8,9] because they can be specified with better accuracy, and most global carbon models (GCMs) suggest that global mean surface temperature response is related to radiative forcing by a linear relation.

Radiative forcing and global warming potential

The impact of GHGs upon the atmosphere is not only related to radiative properties, but also to their lifetime which controls the time-scale of their influence on the thermal budget. That means, the radiative property should be integrated over a selected time period to account for the cumulative effects of the gas during that period. Then, an absolute (rather than relative) global warming potential (AGWP) of a given GHG symbolized by "g" can be defined as:

$$AGWP(g) = \int_0^{TH} a_g f^g(t)dt, \qquad (1)$$

where *TH* is the time scale selected for the calculation[1], a_g is the radiative efficiency due to a unit increase in atmospheric abundance of the substance in question (i.e., $Wm^{-2}kg^{-1}$), $f^g(t)$ is the time-dependent decay function (sometimes called impulse response function). $f^g(t)$ is equal to the fraction of the initially added carbon at time t=0 which is still found in the atmosphere at any later time t. For the purpose of comparing various GHGs, a relative rather than absolute index is preferred, and CO2 is often selected as a reference gas. Then GWP can be defined as the ratio of the time-integrated radiative forcing from instantaneous release of 1 kg of a given GHG relative to that of 1 kg of CO2 (reference gas). This definition can be presented by the following formula:

$$GWP_C^g = \frac{AGWP(g)}{AGWP(CO_2)} = \frac{\int_0^{TH} a_g f^g(t)dt}{\int_0^{TH} a_C f^C(t)dt}, \qquad (2)$$

GWP of some typical GHGs are listed in Table 1.

	Radiative Efficiency ($Wm^{-2}ppb^{-1}$)	Global Warming Potential		
		20 years	100 years	500 years
CO_2	1.55×10^{-5}	1	1	1
CH_4	3.7×10^{-4}	62	23	7
N_2O	3.1×10^{-3}	275	296	156
SF_6	0.52	15100	22200	32400

Table 1: GWP of several typical GHGs.

Currently the best known CO_2 impulse response function is the function described in Bern's carbon cycle model [10]. In the literature, a simplified parameter version is often used [10], which doesn't take into account the concentration level, and is represented by equation (3):

$$f^C(t) = 0.30036 \bullet e^{-t/6.6993} + 0.34278 \bullet e^{-t/71.109} + 0.3568 \bullet e^{-t/815.727}, \qquad (3)$$

EFFICIENCY OF CCS

Based on the first approach suggested by Chomitz [7], two possible ways have been identified in the preceding context to evaluate the efficiency of temporary storage: one from an environmental point of view and the other from an economical point of view.

[1] The Kyoto Protocol uses 100 years as selected time scale, but it is based on a political negotiation rather than a scientific argument.

Radiative forcing efficiency of CCS

The impact of CO2 leakage from storage depends on volumes stored and leakage rate. However it is difficult to know how much carbon will be sequestered in the future because it will depend on the trade off among different mitigation options, and in addition there is still not sufficient experience to estimate leakage rate. To account for the first problem, we take a marginal point of view where only an additional unit of sequestered carbon is considered. To account for the second problem, we start from a conservation equation of CO_2 over the storage, assuming the leakage rate $L(t)$ is proportional to the stock.

$$L(t) = \frac{dS(t)}{dt} = -\eta \bullet S(t)\,, \tag{4}$$

where S is the carbon stock (ton) and the proportionality coefficient η (year^{-1}) is called the leakage coefficient and assumed constant in the following discussion. The product $L(t)=-\eta S(t)$ is the leakage rate with units of tons per year. Equation (4) is integrated over time into equation (5):

$$S(t) = S_0 e^{-\eta t}\,, \tag{5}$$

Where S_0 is the amount of carbon sequestered at time 0. Substituting equation (5) into equation (4) and dividing by the initial value S_0, we get:

$$l(t) = \frac{L(t)}{S_0} = \eta \bullet e^{-\eta t} \tag{6}$$

This "specific leakage rate" tells us that when one unit of CO_2 was sequestered at time 0, the amount $l(t)$ will have leaked from the stock at time t. This function is illustrated in Figure 1 for different leakage coefficients.

The leaked carbon will get into the atmosphere and the carbon cycle, so the cumulative decay function caused by the former leakage curve can be expressed from the following integral:

$$f^S(t) = \int_0^t f^C(t-\tau) l(\tau) d\tau\,, \tag{7}$$

that is illustrated in Figure 2.

If we treat sequestered carbon with leakage as a kind of "GHG", the corresponding "GWP" can be calculated from the above defined formulation, where the radiative efficiency is that of CO2. Hence the "GWP" of the sequestered carbon with leakage is calculated by the following formula:

$$GWP_{TH}^S = \frac{\int_0^{TH} a_C f^S(t) dt}{\int_0^{TH} a_C f^C(t) dt}\,, \tag{8}$$

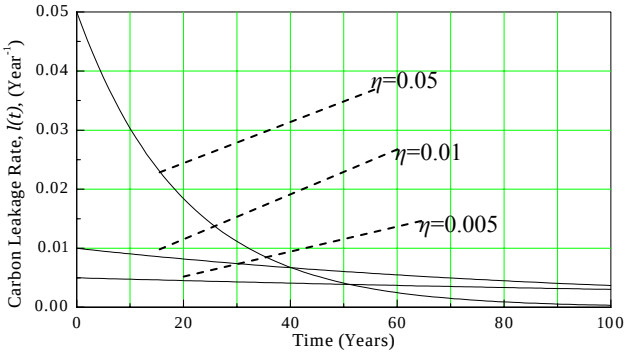

Figure 1: Leakage curve of carbon sequestration under different leakage coefficients

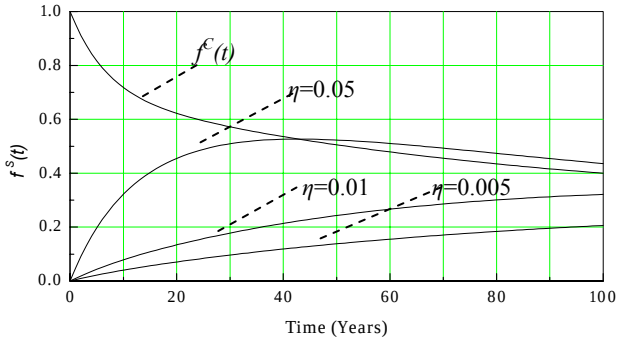

Figure 2: Decay function corresponding to different leakage coefficients

Assuming a constant radiative efficiency, we get a simplified version as follows:

$$GWP_{TH}^S = \frac{\int_0^{TH}\int_0^{TH} f^C(t-\tau) l(\tau) d\tau dt}{\int_0^{TH} f^C(t) dt}\,, \tag{9}$$

Given the leakage curve f^C of sequestrated carbon, its "GWP" compared with carbon avoided or with perfect sequestration can be calculated from the above formula using a numerical method. The following table gives some results for a series of constant leakage coefficients for the given time scale TH of 100 years.

Leakage coefficient (η)	0.001	0.005	0.01	0.02	0.05
GWP	0.054	0.237	0.404	0.613	0.839
Efficiency (1-GWP)	0.946	0.763	0.596	0.387	0.161

Table 2: "GWP" and efficiency factors of sequestered carbon under different leakage coefficient

The quantity of 1-GWP can be considered as an index of "efficiency" which translates one unit of temporary carbon storage into some unit of carbon reduction without leakage risk. For example, given η=0.01, one additional ton of carbon se-

questered has the same cumulated radiative forcing effect as 0.404 (Table 2) ton of carbon emitted at the same time (time 0). Thus it may be considered to be equivalent to 0.596 ton carbon avoided. Figure 3 illustrates the dependence of this efficiency on the leakage coefficient.

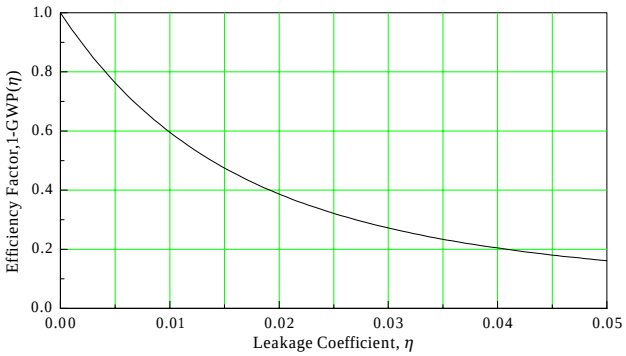

Figure 3: Function relationship between leakage coefficient and efficiency

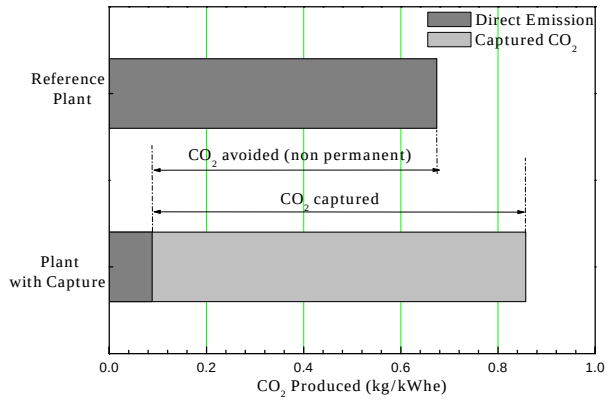

Figure 4: Difference between CO_2 "avoided" and CO_2 captured[2]

Energy penalty issue and carbon accounting

Even if there is no leak risk for carbon storage, it is still wrong to account all of the carbon captured and sequestered as carbon credits. We still have no idea how much carbon will be emitted into the atmosphere if carbon sequestration is not put into force. A benchmark needs to be defined for calculating how much carbon is offset compared with a business-as-usual scenario.

In the literature focused on CCS in power plants, a reference plant is often defined as a power plant without carbon capture facilities while other characteristics are the same as a plant with capture. Given this definition, a plant with capture will consume more fuel than a reference plant when generating the same output, because of the energy requirement for separating and compressing the carbon dioxide from the flue gas.[3] That is, not all of the carbon captured and sequestrated should be considered as a kind of carbon reduction, because the additional energy needed for carbon capture and compressing will also cause CO_2 emission but without contribution to energy output, and such emission should be removed from carbon credit. The difference between CO_2 captured and CO_2 non-permanent avoided is illustrated in Figure 4 [11].

Energy penalty λ is defined as the reduction in net power output of the capture plant compared to the reference plant for equal fuel inputs, thus:

$$\lambda = 1 - \frac{HR_r}{HR_C}, \qquad (10)$$

where HR is the so-called "heat rate", a measure of a power plant thermal efficiency.

For the reference plant, the CO_2 emission factor of electricity generation (in $kgCO_2/kWhe$) is:

$$EF_r = HR_r \cdot EF, \qquad (11)$$

while the emission factor of electricity generation in the plant with capture may be defined as :

$$EF_c = HR_c \cdot EF \cdot (1-CR) + HR_c \cdot EF \cdot CR \cdot GWP(\eta). \qquad (12)$$

The first term of equation (12) is related to direct emission of non-captured CO_2, and the second term is related to the captured and sequestered carbon with a leakage coefficient η. Recall that one unit of CO_2 stored is equivalent to GWP(η) unit of CO_2 emission based on cumulative radiative forcing. If we use equation(10) to rewrite equation(12), we get:

$$EF_c = [(1-CR) + CR \cdot GWP(\eta)] \cdot HR_r \cdot \frac{EF}{1-\lambda}. \qquad (13)$$

Comparing equation (11) and equation (13), we can establish the sufficient and necessary condition for the emission of the plant with capture to be smaller than that of the reference plant, that is $EF_c < EF_r$:

$$1-GWP(\eta) > \lambda/CR. \qquad (14)$$

This formulation means that carbon sequestration in a power plant MAY cause a LARGER global warming effect than in a reference plant, if the capture rate is too low, energy penalty is too high or leakage coefficient is too large. Generally speaking, if the criterion (14) is not satisfied, the CCS project should be rejected because it will increase cumulative radiative forcing instead of decreasing it. For this reason, equation(14) can be

[2] This figure and corresponding data came from Herzog [11] Figure 2.

[3] The energy used for carbon transportation and injection was not included here.

considered as an **efficiency criterion** for a carbon sequestration project in the power sector.

The ratio λ/CR can be looked at as an index representing characteristics of different capture technologies, while the characteristics of geological reservoir are represented by η. When given a specific λ/CR, we define a **maximum permissible leakage coefficient** η_m as the solution of the following equation:

$$1\text{-GWP}(\eta_m) = \lambda/\text{CR}. \qquad (15)$$

The equation (15) is illustrated in Figure 6 and shows the relationship between different capture technologies, characterized by their index λ/CR, and the corresponding maximum permissible leakage rate. Characteristics of different capture technologies are collected in Table 3; original data come from IEA [12].

Note that the graph of Figure 5 is identical to that of Figure 3, because of equation (15), but they have different interpretations.

Table 3:λ/CR of different capture technology with different reference plant

For example, a typical PC (Pulverized Coal) capture plant has an energy penalty λ of about 27%, while the capture ratio CR is assumed 90% for most research works [12]. According to condition(14), the efficiency of temporary carbon storage 1-GWP(η) should be larger than 0.30, which is equivalent to a leakage coefficient η smaller than 0.027. As another example, an energy penalty of 35% and a capture ratio of 80% require that the corresponding efficiency of temporary carbon storage be larger than 0.44, which is equivalent to a leakage coefficient smaller than 0.017.

The preceding simple analytical model shows that the trade-off between capture plant and non-capture plant is affected by two factors: (1) the capture technology characteristics defined as energy penalty divided by the capture ratio; (2) the leakage of stored carbon.

As a conclusion of the physical approach, it appears that CCS doesn't always prevent from global warming. Under certain conditions, for example high energy penalty and/or low capture ratio and/or high leakage, CCS can be ineffective and even worsen the warming effect.

ECONOMICS EFFICIENCY OF CCS

Differing from the above approach, some researchers suggested to treat emissions and removal separately [6], thus the sequestration will not be different from permanent carbon avoided. In other words, when one removes a ton of carbon, one gets credits for its removal; when the sequestered carbon leaks back to the atmosphere, one must buy credits from somewhere for offsetting its "emission", we call it "Pay When Leak". The essential feature of this approach is that sequestered carbon implies a permanent liability for the "owner". With this permanent liability, a potential investor in a sequestration project will face an investment decision problem based on a cash flow caused by leakage from reservoirs and carbon credits price in the future. The classical approach for such decision problems is based on the so-called Net Present Value (NPV), which calculates the discounted present value of project cash flow. It can be expressed as follows:

$$NPV = \int_0^\infty p(t)A(t)e^{-rt}dt\,. \qquad (16)$$

where t is the time, $p(t)$ is the carbon price or carbon tax at time t, $A(t)$ is the carbon credits acquired (positive) or needed (negative) at time t, r is the discount rate. This framework is widely employed for discussion of economic efficiency of sequestration [4-6]. But the definition of economic efficiency in literature is not consistent. Some researchers define it from a point of view of potential investors [4, 6], framing it as an industrial economics problem, while others define it on the basis of carbon tax path [5]. Such definition can give a more macroscopic measure for CCS

because carbon tax is often a shadow price of carbon emission coming from a complicated economy-environment model.

The difference between these two definitions is clear: the former is based on expectation about future carbon price and discount rate of specific investors, and can be used for explaining decision making of an individual; the latter is based on carbon tax path and social discount rate, and can be used for aggregation analysis. For the latter way, it can be considered as a partial equilibrium model if carbon tax path and social discount rate are exogenously given; it can also be integrated with some economy-environment model to make these variables endogenous, making it then a general equilibrium analysis.

As Keller et al [5] argued, in a simple NPV framework, the tradeoff between CO_2 abatement and CO_2 sequestration is affected by four factors: (1) energy penalty; (2) leakage rate; (3) future carbon tax path; (4) discount rate. We follow this simple analytical framework, from the view point of an investor, with the aim of determining whether or not CCS should be employed in a power plant. For linking this section and the former discussion, a fifth factor is added into this framework: the capture ratio.

For the reference plant, the marginal benefit for 1kWh electricity output is:

$$\text{Profit}_r = P_e - EF \cdot HR_r \cdot P_c - P_F \cdot HR_r. \quad (17)$$

While for the plant with capture, the marginal benefit for 1kWh electricity output is:

$$\text{Profit}_c = P_e - EF \cdot HR_c \cdot (1-CR) \cdot P_c - P_F \cdot HR_c - \int_0^\infty EF \cdot HR_C \cdot CR \cdot \eta e^{-\eta t} \cdot P_C \cdot e^{\beta t} \cdot e^{-rt} dt \quad (18)$$

The integral of the preceeding equation[4] can be calculated analytically, assuming $r+\eta-\beta>0$ [5] and the solution can be written as follows:

$$\text{Profit}_C = P_e - EF \cdot HR_c \cdot (1-CR) \cdot P_c - P_F \cdot HR_c - \frac{EF \cdot HR_C \cdot CR \cdot P_C \cdot \eta}{r+\eta-\beta}. \quad (19)$$

The criterion for the plant with capture to be preferred over a reference plant is $\text{Profit}_c > \text{Profit}_r$. Using equations(10), (17) and(19), this condition can be expressed as:

$$\left(1+\frac{P_F}{EF \cdot P_C}\right)\frac{\lambda}{CR} < 1 - \frac{\eta}{r+\eta-\beta}. \quad (20)$$

Letting

$$\alpha = \left(1+\frac{P_F}{EF \cdot P_C}\right)\frac{\lambda}{CR} \quad (21)$$

Equation 21 is equivalent to the following condition: [6]

$$\eta < \frac{(1-\alpha)(r-\beta)}{\alpha} \quad (22)$$

A necessary condition (but not sufficient) for formulation (22) is $\alpha<1$, otherwise the capture plant will be dominated by the reference plant no matter how small is the leakage rate, because it can't be negative. We call this condition **economical feasibility condition**.

When the economical feasibility condition stands, a **maximum permissible leakage coefficient** can be given by:

$$\eta_m = \frac{(1-\alpha)(r-\beta)}{\alpha}, \quad (23)$$

For illustration, the following parameters set are selected:

P_F=1.5\$/GJ[7], P_C=24\$/tCO_2[8], EF=90kg CO_2/GJ[9] for coal burning.

With the above parameter set for coal, the economic feasibility condition is: $\lambda/CR<0.59$, with a capture ratio of 90%; the above condition is equivalent to $\lambda<0.53$. Almost all of capture technologies listed in Table 3 are economically feasible.

COMPARISON AMONG DIFFERENT FACTORS

As we have discussed earlier, for a physical analysis based on a cumulative radiative forcing calculation, the maximum permissible leakage coefficient η_m^{I} is only related to the technological characteristics of capture technology, which is qualified as λ/CR. When we change to the economical viewpoint, η_m^{II} is affected not only by technological characteristics, but also by economical characteristics ($1+P_F/(EF \cdot P_C)$) and by the expectation term ($r-\beta$). The economical characteristics will determine whether or not a kind of capture technology is economically feasible (not considering the leakage issue), while the expectation term gives the individual expectation about future carbon price path and discount rate.

[4] For simplicity, we use an infinite time scale here instead of a finite one. This simplicity will not do harm to our subsequent conclusion because $\text{Profit}_C > \text{Profit}_r$ is a sufficient condition (but not necessary) for $\text{Profit}_C^{TH} > \text{Profit}_r$ with any given finite time scale.

[5] If this condition fails, the sum of (18) will be firmly negative so that the CCS project is financially unbeneficial.

[6] Note that $\alpha>0$ and $r+\eta-\beta>0$.

[7] Data came from World Energy Outlook [13].

[8] Data from [14], the carbon tax adopted by Norway government in 1999 for coal burning.

[9] Data came from Emission Factor Database ,http://www.ipcc-nggip.iges.or.jp/EFDB/main.php.

$$1\text{-GWP}(\eta_m^{\mathrm{I}}) = \lambda/\mathrm{CR}. \qquad (15)$$

$$\eta_m^{\mathrm{II}} = \frac{(1-\alpha)(r-\beta)}{\alpha}, \qquad (23)$$

Corresponding with criterion (14) coming from a radiative forcing approach, formulation (22) gives a criterion based on a financial analysis. If this latter criterion is not satisfied, a CCS project should be rejected economically, but it may still be acceptable physically, that means the criterion (14) still stands and vice versa. In other words, the radiative forcing criterion (15) is inconsistent with the economical one (23). In addition, the criterion based on radiative forcing is an objective criterion which doesn't change according to any subjective conclusion while the economical criterion will vary with different subjective expectation and economical characteristics.

These differences between radiative forcing criterion and economical criterion are illustrated in Figure 6 and Figure 7 under different expectation and different carbon price[10].

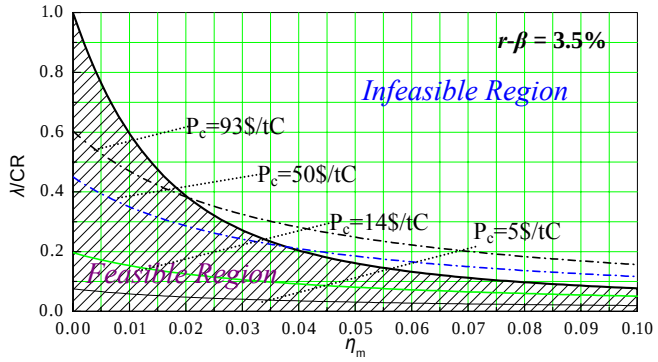

Figure 6: Physically and economically maximal permissible leakage rate under different carbon price.[11]

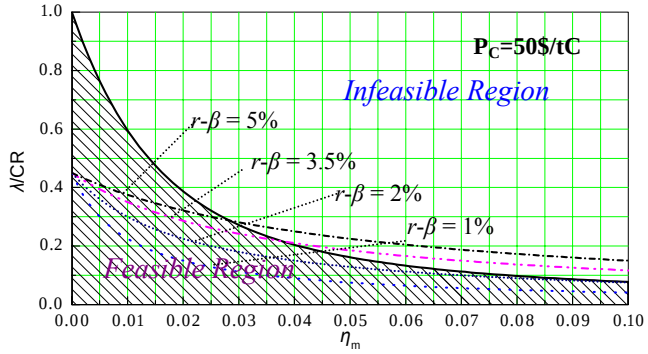

Figure 7: Physically and economically maximal permissible leakage rate under different future expectation.

The relationship between physical criterion and economic criterion is complex; none of them is simply dominated by the other. Generally speaking, for lower leakage coefficient, the economic criterion is stronger than the physical one while for higher leakage coefficient, it is just the opposite. As we discussed above, the economic criterion relaxes further and further when carbon price and/or expectation term become higher and higher, while the physical one doesn't vary. Under high carbon price and high expectation, some CCS technologies will be economically worthwhile but physically non-beneficial.

When using the economic approach, as Herzog argued [6], the potential investor of a sequestration project must make careful estimation about future carbon price and calculate the rate of return which will be compared with other alternatives. Once he decides to put such project into force, he must cover the leakage when it happens. But the "Pay When Leak" approach relies on individual expectation term (r-β), not on social aggregation one. If an individual investor underestimates the risk and uses a physically inefficient storage location, the whole society has to suffer because the permanent liability can't be really unlimited [15]: at one point the investor will chose bankruptcy to avoid further losses. Most important, if such risk are correlated, then they cannot be averaged through insurance mechanisms, then we have no way to average such risk, and the damage caused by such failure is difficult to be measured with monetary value. Just as Baer argued [15] "If we are to proceed with the use of sequestration, we need to regulate it in a way that establishes a precautionary limit on storage today based on the long-term rate of leakage and the plausible failure of liability".

When they underestimate the "expectation term", some physically feasible CCS project will be pending because of economical consideration, some other mitigation strategy with higher cost will be employed. There will be an efficiency loss.

CONCLUSION

This paper examined carbon capture and sequestration technology with leakage under different aspects: a physical aspect based on radiative forcing, and an economical aspect based on discounted net present value. The former approach can be interpreted as a systemic point of view, while the latter can be interpreted as a cost-benefit assessment from the viewpoint of individual investors.

The analysis based on the GWP concept confirms that a leakage coefficient of 0.001 is nearly the same as perfect storage, meaning storage without any leakage or carbon avoided. The same conclu-

[10] But the fuel price is assumed fixed here.
[11] (r-β)=3.5% is based on estimation of [5].

sion has been reached by several other researchers through different approaches [16]. A comparison analysis shows that for high leakage rates CCS may cause larger global warming effect than a reference plant, at least for CCS in power plants.

Although the economical approach is straightforward for CCS, it is strongly affected by "individual expectation" about the future, which is an expectation for future carbon price path. When the carbon price path is overestimated, it will lead to a "moral hazard" problem, and some high leakage reservoirs may be employed and cause higher radiative forcing in the future. When it is underestimated, some CCS project that ought to be good will be rejected, thus an efficiency loss.

Of course the radiative forcing approach also has some shortcomings. Firstly, it doesn't consider the economic terms and gives no idea on cost considerations and investors incentives. Secondly, the marginal treatment we used in this paper only gives an insight for comparative static analysis. But it is useful for being a benchmark case.

There is no simple relationship between the physical criterion and the economic criterion. Generally speaking, the economic criterion is more strict, more selective, than the physical one when the leakage coefficient of the reservoir is small, but it is just the opposite when this coefficient is large.

Finally, our models are based on a set of assumptions, some of which are strong and restrictive. The results should therefore be used carefully and checked under some more realistic assumptions. A fully comprehensive analysis requires more realistic numerical models to be developed in the future.

MODELING OF THE REGENERATION UNITS FOR AMINE BASED CO_2 ABSORPTION PLANTS: INTRODUCTION OF AN ORGANIC STRIPPING MEDIUM

Finn Andrew Tobiesen and Hallvard F. Svendsen*
Norwegian University of Science and Technology
Department of Chemical Engineering,

ABSTRACT

A computational model for the regeneration unit of a monoethanolamine (MEA) based absorption plant for CO_2 removal has been developed. The model simulates a three phase process in order to investigate the effects of adding an immiscible organic component to the units to control reboiler temperature. The results show that the desorption process using MEA is very sensitive to the reboiler temperature. There is a significant increase in reboiler duty as hydrocarbon is added to the system. However, the reboiler- and desorber column temperatures are reduced significantly. The driving force for desorption is lowered even though the acid gas is diluted throughout the column. This is due to the strong temperature dependency of the CO_2 partial pressure over the MEA.

INTRODUCTION

The removal of carbon dioxide (CO_2) from gas streams, such as natural gas and flue gas, is an essential step in their purification process. This, as well as the desire to alleviate the problem of global warming has resulted in an increased emphasis towards designing more economically efficient technologies for removing CO_2 from natural- and industrial flue gases. Based on the technologies available today, post-combustion removal of CO_2 by use of absorption with chemical solvents is considered to be the most cost-effective and viable option. For CO_2 removal from natural gas and refinery gases, amine based absorption systems have been the most used alternative and is a well proven commercial technology [1, 2, 3]. Despite their extensive usage, the cost of removing CO_2 using traditional amino-compounds is still high, in particular when considering this as a cost penalty on electricity from the power producing industry. On the other hand, the earlier lack of incentive to really minimize the energy requirements in typical post-combustion situations with very large gas flows and low CO_2 partial pressures, does leave room for significant improvements to these processes

* Corresponding author: Phone: +47-735 94100, Fax: +47-735 94080
Email: hallvard.svendsen@chemeng.ntnu.no

For these reasons, there is a strong interest in new developments for both reducing the energy required and for improving the environmental impact of these processes.
In a typical post-combustion CO_2 removal process more than 90% of the energy requirement stems from regeneration of the loaded liquid in the desorber. This, in addition to solvent losses and financial costs, is a dominating contributor to the operational costs of the overall gas cleaning process.
Despite this, the available literature in the area of detailed desorber operation is relatively scarce as compared to the extensive work done on the absorption side.

The costs incurred are mainly due to the large amount of steam required by the indirectly heated desorber reboiler. This steam is needed mainly for three purposes:

1. To provide sufficient energy to reverse the exothermic amine-acid gas reaction.

2. For diluting the CO_2 gas throughout the desorber and thereby work as stripping gas.

3. To provide sufficient sensible heat to warm up the rich amine liquid feed.

The three above mentioned energy sinks are about equally important. This paper is mainly aimed at investigating the effects of providing an additional low cost stripping gas to the regeneration column, thereby reducing the second sink term in the list above. This is suggested done by introducing an organic solvent to the traditional aqueous MEA absorption process, providing a three-phase system, containing two liquid phases, one organic and one aqueous, as well as the vapor phase. The principle is that the organic stripping gas medium is immiscible with the aqueous phase. After being evaporated in the desorber reboiler, it dilutes the CO_2 in the regenerator and is subsequently fully recovered as an organic immiscible liquid in the condenser. The organic liquid is then separated from the condensed water and piped directly back to the reboiler while maintaining its full vapor pressure. Since the two liquid phases are immiscible, the organic phase is not a part of the lean solution and is thereby contained only in the regeneration part of the gas cleaning process and will not circulate to the absorber via the cross-flow heat exchanger.

PROCESS DESCRIPTION AND THEORY

The fundamental nature of adding a volatile organic immiscible component to the regeneration process is to increase the degrees of freedom and give room for an increased number of ways of operating the desorber.
Firstly it enables the aqueous phase components, mainly water and CO_2, as well as the volatile organic solvent, to be evaporated, and subsequently recovered, at a temperature substantially below that of the boiling point of the aqueous phase alone. Since there are two immiscible liquid phases present in the reboiler, each more or less unaffected by the presence of the other (as long as they are agitated so that the lighter liquid does not form an impenetrable layer over the heavier), they both vaporize to an extent determined only by their individual volatilities. The phases will behave as distinct entities and there will be no dependence on how much of each species is present as long as the amount to be vaporized is balanced by the reboiler steam input. Therefore, such a mixture always boils at a temperature lower than that of either constituent alone. In this way, by keeping the pressure constant, the reboiler temperature can be gradually decreased by adding more third component to the desorber cycle. Secondly, one may wish to operate the reboiler at a certain temperature. For instance since MEA is prone to corroding steel as well as degrading at elevated temperatures, it might be advantageous to keep an upper limit for the reboiler temperature. The reboiler temperature can be controlled by adding a certain amount of an organic component, while the total pressure is increased. The water/CO_2 ratio remains for all practical purposes unchanged, while the third component creates the pressure increase. Earlier studies show that an increased pressure in the regenerator system can have a positive effect on the desorber performance [4, 5], as well as decreasing possible recompression costs for CO_2 if this is to be recompressed for further piping and storage.
Finally, one may utilize a combination of the above two effects and increase both the reboiler temperature and pressure. If the CO_2 product pressure can be increased to about 6 bar, then one may do away with the compressor for recompression altogether and liquefy the CO_2 directly for storage.

MODEL DEVELOPMENT

Introduction of an organic immiscible stripping medium to the desorber cycle introduces some new complications in the process simulations.

An earlier developed two-phase model for CO_2 regeneration with MEA was modified to accommodate for three phases. The general code for the mass and energy transfer in the desorber column including reboiler, desorber and condenser, as well as the equilibrium and interfacial mass transfer models, were written in FORTRAN 90. The details of the complete two-phase model, including model assumptions, are addressed in a separate paper [5]. A discussion of the choice of interfacial mass transfer model and thermodynamic model for the aqueous phase is also found in this paper.

In order to minimize the complications associated with the introduction of a second liquid phase, the following simplifying assumptions were made:

- It is assumed that the two liquid phases are completely immiscible. An effect not accounted for in this study is the non-ideal nature of this aqueous-organic system.
- When present, the organic component is at its saturation point throughout the system.
- The aqueous phase yields its own equilibrium partial pressures given by an explicit activity coefficient based thermodynamic model.
- The organic phase yields its equilibrium partial pressure given by an Antoine relationship.
- Daltons law is applicable eg.; the total equilibrium partial pressure of the liquid phases is the sum of the vapor pressures of the two phases.
- For the liquid phase, in terms of mass and energy balances, the new component is included as an additional molar fraction in the overall sum of components. Therefore, the model does not separate the two liquid phases at the overall level in terms of balances. However, a separate phase will give, in terms of thermodynamics and gas phase driving forces, an organic phase with its full partial pressure obtained throughout the system, which is described for one organic component:

Aqueous phase components:

$$x'_{i,aq} = \frac{x_{i,aq}}{\sum(x_{i,aq}) - x_{1,org}}$$ where

$$\sum x_{i,aq} = 1 \text{ and } \sum x'_{i,aq} = 1$$

Organic phase component:

$$x'_{1,org} = 1$$

- The reboiler is calculated as two temperature-pressure (TP) flashes, one for each phase (aqueous and organic). A schematic diagram is shown in figure 1. Since there are three phases (one vapor and two liquids) and four components, the phase rule shows that the reboiler has three degrees of freedom. Therefore, an inner loop iteration is used to obtain the total partial pressures of each phase at an initial given temperature and total pressure, while the inlet stream is fully defined. To ensure that the vapor flow generated from the reboiler is stable for overall code stability, an outer loop can be used to iterate to a given reboiler vapor fraction using the reboiler temperature as the iteration variable.

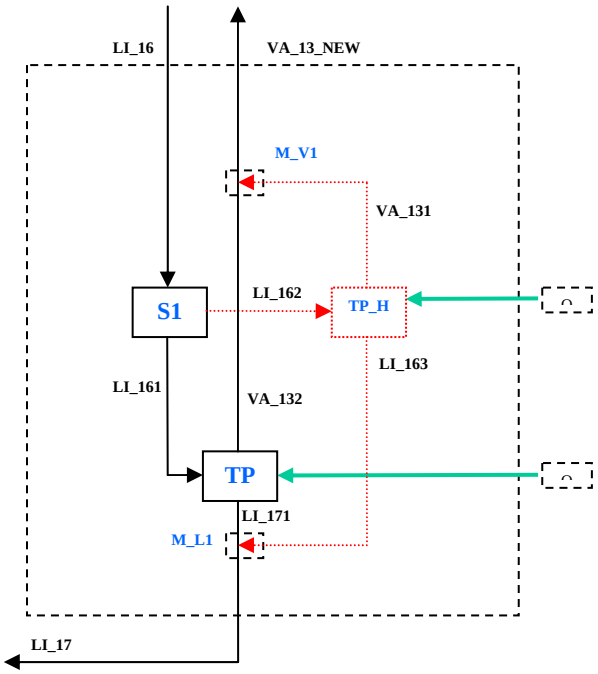

Figure 1: Schematic diagram of the three-phase reboiler model. Dotted lines indicate organic streams.

- The condenser is modelled in a similar manner but here the temperature is always fixed and an outer iteration loop is not necessary.
- The organic component is taken from the condenser and piped directly to the reboiler.
- Since the temperature in the reboiler is higher than the organic component boiling point, all of it will vaporize.

The overall flow sheet is shown in figure 2.

BASE CASE

The base case is a conceptual MEA pilot plant intended to recover CO_2 from flue gas at atmospheric pressure with parameters and dimensions identical to a pilot plant available in our laboratories. It should be noted that the regeneration unit does not necessarily depend on whether the absorption unit is for flue gas or natural gas since the units in both cases are usually operated at low pressure and elevated temperature.

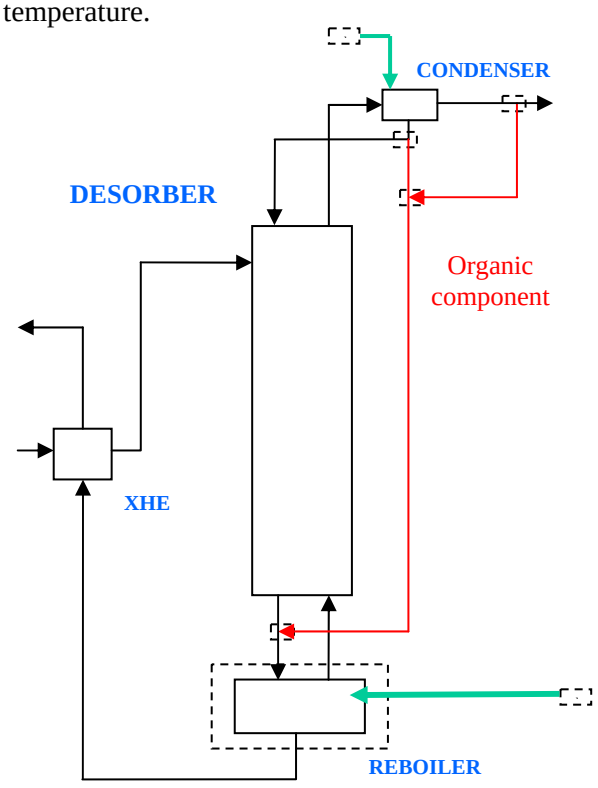

Figure 2. Schematic diagram of the modified flow sheet.

The MEA concentration has been set to 30wt% and initially there is no added organic component. This high MEA concentration is not uncommon today and standard for the Fluor Econamine Process [2]. With the higher amine concentration in the circulating liquid, including corrosion inhibitors, a higher CO_2 pickup is possible without the extensive corrosive effects normally associated with MEA solutions. For this to be applicable, however, the temperature must be closely controlled. The desorber column characteristics and the operating conditions used in the simulations are all given in table 1. All other details about the two-phase model are described elsewhere [6].

Table 1: Column characteristics and operational parameters for the base case

Column characteristics	Value
Column internal diameter (m)	0.10
Main packing height (m)	4.0
Wash section packing (m)	0
Desorber height (m)	4.0
Packing (Structured):	Sulzer Mellapak 250Y

Parameter:	Value
Liquid circulation rate (kmol/h)	12.0
MEA concentration wt% (15 C)	30.2
Rich solution loading (kmol CO_2/ kmol amine)	0.48
Lean solution loading (kmol/kmol)	0.16
Reboiler pressure (kPa)	200.0
Condenser temperature (C)	60.0
Percent to equilibrium reboiler* (%)	70.0

* Percentage reduction of the equilibrium value of CO_2 with the ideally mixed aqueous phase in the reboiler

SIMULATION RESULTS AND DISCUSSION

Base case

Results from the base cases without addition of hexane are given in table 2 and 3. A cyclic capacity of 0.32 mol CO_2/mol, using 0.48 mol CO_2/mol as rich loading and 0.16 mol CO_2/mol as lean amine loading, has been used for all simulations. It should be noted that in table 2 and 3 the column giving “loading after flash” is the actual loading of the solvent entering the desorber packing. For the base case at 180 kPa, which is a little lower than the more conventional 200-220 kPa, the simulation yields a steam consumption of 4.01 MJ/kg CO_2 removed. This number is very comparable to the numbers reported to be attainable in the industry today, 3.24-4.20 MJ/kg CO_2 [2, 3]. At 240 kPa the reboiler temperature is raised to 129^{o}C. It is evident that this has a significant positive effect on the steam consumption. The energy required for stripping decreases from 4.01 to 2.93 MJ/kg CO_2 recovered. This temperature is too high for the MEA process, but it does indicate the potential that lies in optimising the reboiler temperature.

The added bonus is the reduced recompression costs. It should be kept in mind that the recompression costs can be reduced significantly when going from 1.2 to 2.4 bar CO_2 condenser outlet pressure.
Although the heat duty figures given here are reasonable, they are not intended to be accurate as absolute optimized numbers. Ideally, by maximizing the loading obtainable from the absorber and at the same time avoiding the pinch region in the desorber during stripping, it is possible to lower steam usage substantially. Also, the model flow sheet does not consider split flow configurations. For the purpose of studying desorber performance characteristics for an MEA plant with given operating conditions, the specific steam consumption parameter should therefore be regarded as a relative number only, and the purpose of the present paper is to study variations in this.

Addition of Hexane to the regeneration unit

The organic component to serve as a stripper gas could basically be a fictitious compound. However, to have something to relate to, a real component has been chosen, in this case hexane. This does not imply that hexane is an ideal component. Hexane does not dissolve to any significant extent in the aqueous phase and it is significantly more volatile than water with a normal boiling point of 68.7 ºC, and a boiling point of 92.4 ºC at 200 kPa. This will ensure that the hexane is liquid phase in the condenser while it is evaporated after being piped to the reboiler.
Table 2 and 3 show the effects of increasing the amount of hexane in the reboiler at 180 kPa and 240 kPa respectively. In both cases the total pressure is kept constant. As more hexane is added to the reboiler providing more dilution agent to the column, a lower reboiler temperature results. From table 2 it is seen that at a 23 mole% hexane concentration in the vapour from the reboiler, the reboiler temperature is reduced with 8ºC compared to the base case. Conversely, the steam consumption increases significantly, from 4.05 to 6.49 MJ/kg CO_2 removed. The same trends are seen in table 3 where the pressure is increased to 240 kPa. The base case simulation at 240 kPa shows a reboiler temperature of 129 ºC, and an energy requirement of 3.27 MJ/kg CO_2 removed, while as the hexane is added to a molar fraction of 26%, the temperature is reduced to 120 ºC and the energy duty is raised to 5.7 MJ/kg CO_2 removed. The reboiler temperature in the last case is very close to the temperature of the base case for 180 kPa pressure. It is from this clear that one may not expect energy savings by only keeping the reboiler temperature constant and adding a third immiscible component to raise the pressure.

It is clear from the simulations that there are mainly two competing effects causing the significant change in reboiler heat duty as more hydrocarbons are added to the system. At constant total pressure, the partial pressure of CO_2 throughout the desorber decreases significantly due to the added dilution agent, thus providing a larger driving force for desorbption of CO_2. This should make the desorber more efficient. The second and counteracting effect is due to the reduced temperature in the reboiler which reduces both the water and CO_2 partial pressures. If the P_{CO2} / P_{Water} ratio increases with decreasing temperature, a possible positive effect of the reboiler temperature decrease would result. If the opposite is true, then the effect would be negative. The degree to which this second non-favorable effect affects the desorption process is governed by the thermodynamic properties of the amine and it is clear that for MEA this effect is negative and large.
Figure 3 shows the effects on the CO_2 content in the vapor and on the equilibrium partial pressures in the liquid throughout the tower as hexane is added. The dotted lines represent the liquid phase equilibrium pressure of CO_2 while the plain lines indicate the actual vapor CO_2 partial pressure. As more hydrocarbon is added, the driving force (area between the same color dotted and plain lines) decreases, which signifies that the temperature effect is greater than the CO_2 dilution effect for MEA.

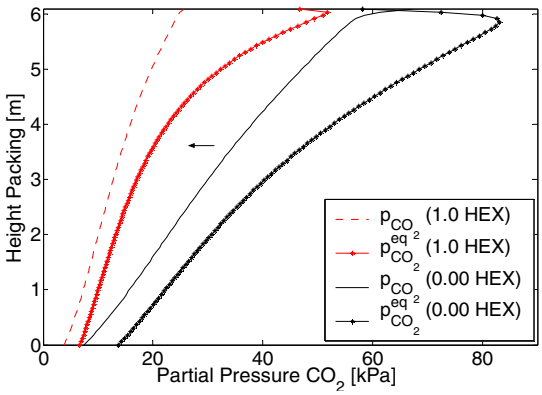

Figure 3: Partial pressures in the tower.
Rich loading, 0.48. Lean loading, 0.16. Reboiler temperature, 120 ºC.

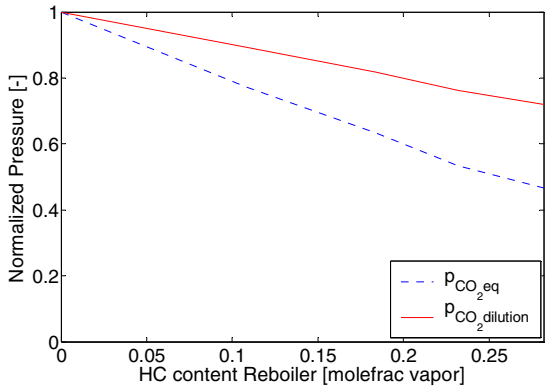

Figure 4: The CO_2 dilution vs. temperature effect.

These competing effects are more clearly shown in figure 4. The line named $P_{CO2\ dilution}$ is a function of the dilution effect from the added hydrocarbon, while the line named $P_{CO2\ eq}$ is a function solely of temperature and composition in the liquid phase. For a favourable steam consumption effect, $P_{CO2\ dilution}$ should change more rapidly than the $P_{CO2\ eq}$ line as hexane is added, or:

$$-\frac{dp_{CO_2}^{Dilution}}{dHC_{content}} \geq -\frac{dp_{CO_2}^{Eq.}}{dHC_{content}}$$

which is clearly not the case for MEA.

Increasing reboiler pressure at constant temperature

Table 4 shows simulations where the pressure is increased while the temperature is kept constant by adding hexane. The cost of recycling the added hexane causes the specific steam consumption ratio to increase significantly as pressure throughout the units increase. The favourable effects by increasing pressure found earlier [4, 5], is found to be almost exclusively due to the increased temperature in the reboiler/desorber. Increasing the pressure requires progressively larger amounts of hexane to maintain constant temperature, which in terms leads to more expenses associated with evaporation and to keep the organic solvent in circulation. The same can be seen in table 5, where the base temperature is 129 ºC. The raised temperature leads to a significant enhancement in desorber performance.

This suggests that the temperature should be maximized in the reboiler to yield a high liquid partial pressure of acid gas as the pressure effect caused by the dilution with hexane is less prominent compared to the temperature effect in the case for chemical desorption with MEA.

It should be noted that the rich amine entering the packing has the full rich amine loading of 0.48 mol CO_2/mol. At this pressure no stripping in the desorber feed lines will take place (see column "loading after flash" in figures 2 and 3) and no problems with two phase flow in the cross flow heat exchanger (XHE) will occur. One problem that may arise if the amine entering the desorber packing is stripped too low, e.g. by lowering the temperature approach of the XHE too much, or by operating the desorber at low pressure, is that absorption and not stripping takes place at the top of the packing. This occurs because the equilibrium partial pressure of the inlet feed is lower than the desorber section CO_2 partial pressure, which will yield a driving force for absorption at the top of the column. This absorption effect is more pronounced at lower feed pressures and will occur until enough sensible heat is provided from the steam for the liquid to reach equilibrium. A part of the upper packing might therefore not be utilized. This can easily happen and indicates an over-sizing of either desorber or XHE. It is therefore important to realize the combined interactions between these units and that their sizes should be chosen depending on the other unit's size and efficiency.

Cost of CO_2 compression

The usual parameters for transportation in pipelines are pressure of about 140 bar and ambient temperature. For liquefaction and transport in ships, the optimal pressure is 6 bar. In any case, if compression is required, increased pressure in the desorber will reduce compression work for subsequent transportation process. It can be omitted completely if pressure approaches 6 bar in the desorber and liquefaction is required. Table 6 shows an estimation of the energy requirement for a simple compressor. The ideal compressor work is calculated from the change in enthalpy of the stream, by holding the stream entropy constant. Here it is assumed that the outlet stream from the condenser contains pure CO_2. The values show that the compression work required

is small for a pressure raise to 400 kPa. The gain by increasing pressure in the desorber in terms of compression work saved is therefore only marginal.

A comparison between the investigated method introducing a third immiscible component to the stripper, and the conventional stripper needs to be done where all effects are included. The following items should be considered in the overall evaluation, starting with the favourable effects

Possible advantages

- Reduced compression work, although only small gains.
- Reduced temperatures in reboiler, reduced steel corrosion, (lower quality steel can be used), less amine degradation.
- Larger driving forces for desorption at the same temperature.
- Decreased desorber diameter due to the pressure increase.
- If pressures increases up to 6 bar, the entire recompression prior to liquefaction might be avoided.

Disadvantages:

- Somewhat thicker steel to account for higher pressures.
- Added reboiler duties associated with the inclusion of the organic component. A factor that seems to be the decisive factor when using MEA.

In conclusion, the principle point that probably surpasses the advantageous points regarding the addition of an organic immiscible stripping medium, is that the incurred costs associated with the increased reboiler duty as more hydrocarbon is added to the reboiler, increase too rapidly when MEA solvent is used. Therefore, addition of hexane to the regeneration process is most probably not favourable using MEA, due to the strong temperature dependence of the equilibrium CO_2 pressure. A thorough cost investigation must be carried out. However, since this effect is specific for each amine there might be, and probably are, amines with more favourable properties. Also, there are certainly organic solvents that have better properties, lower heats of vaporization and lower heat capacities.

CONCLUSION

A computational model for the regeneration unit of a monoethanolamine (MEA) based absorption plant for CO_2 removal has been developed. The model simulates a three phase process in order to understand the effects of adding an immiscible organic component to the units to control reboiler temperature. The results show that the desorption process using MEA is very sensitive to the reboiler temperature. There is a significant increase in reboiler duty as hydrocarbon is added to the system. However, the reboiler- and desorber column temperatures are reduced significantly. The driving force for desorption is lowered even though the acid gas is diluted throughout the desorber tower. This is due to the strong temperature dependency of the CO_2 partial pressure over the MEA. It is thus probably not feasible to increase pressure in the desorber to the extent such that a CO_2 recompression unit can be avoided. The amount of hexane that must be added causes the reboiler duty to increase excessively. However, an increased desorber pressure can reduce compression costs.

If a reduction in reboiler temperature is required because of excessive corrosion or solvent degradation, the addition of an organic component can greatly reduce tower temperatures, however, at the expense of increased reboiler duties.

ABSTRACT

Thermo-economic modelling techniques are well known techniques to optimise power plant designs. These methods are usually based on the definition of a superstructure that includes the major options of the design. If this approach has proved to be appropriate for the optimisation of several conventional NGCC (Natural Gas Combined Cycles), it reveals some weaknesses when dealing with particularly complex systems where heat integration leads to a lot of possible heat exchange configuration. This is for example the case in advanced cycles in zero emission plants where numerous heat exchanges between the gas turbines, the steam network and the CO_2 capture units can be considered. In this situation, the superstructure approach is not anymore practical and new modelling techniques are needed. In this paper, we present a new modelling technique developed to be used in the context of a multi-objective optimisation framework. This method uses a thermodynamic model of the energy flows of the energy conversion units. The results of the model allow the calculation of the hot and cold streams to be considered in the heat exchanger network. A heat cascade model using the ΔT_{min} concept is used to compute the optimal integration of the heat exchange in order to maximise the energy conversion. In this model, a special steam cycle model has been developed to represent all the possible heat exchange interactions and to compute the optimal flowrates in the system with a minimum of structural information. The third part of the model is the thermo-economic estimation of the system cost to deduce the performances of the system. An optimisation method, based on a multi-objective evolutionary algorithm is then used to identify the most important system configurations. The method is illustrated on an AZEP (Advanced Zero Emission Plant) combined cycle design.

BACKGROUND

The conventional process simulation approach [8], [15] is based on the idea of scenario: a model is built according to a given structure, in order to meet mass and energy balance. All the elements of the process are connected together to form a superstructure. For each heat exchange, one has to choose between which units it is performed. From here the idea of scenario: each heat exchangers network design corresponds to a well defined structure. When the network is not trivial, i.e. when there is more than one way to exchange heat between units, it is necessary to build several scenarios in order to evaluate the performance of all the possible combinations. When modelling a very complex superstructure composed by several units, the possible scenarios for heat exchangers network become too large to be entirely taken into account. At this point, it is necessary to eliminate some possible solutions and to select only the most interesting ones. The major drawback of this approach is that, when handling with non-linear models, the optimal solution is not known a priori. So, eliminating some possible solutions could lead to the loss of some good solutions. The same topological problem is met when analysing several technological alternatives for a given process. For each unit it is necessary to create the streams and energy connections with the rest of the model, which means creating a scenario. The pinch technology [9] has been widely used in industrial processes to encompass the difficult task of the optimal heat exchanger network design. The method has been adapted to consider streams with unknown flowrates [10] and optimise the combined production of heat and power in a process. It has been demonstrated that the method may be adapted to tackle the optimal integration of steam cycles in power plants [11].

A NEW APPROACH FOR COMPLEX SYSTEMS

The approach developed combines the use of thermo-economic modelling and process integration concepts. In the first step, the process is divided into subunits according to the material flows. Each subunit of the process is modelled independently from the others using a thermo-modelling package. The heat exchanges between the units considered as hot or cold sources. In a second step, an energy integration is performed to model the heat exchange contribution to the final layout of the superstructure. By this way, all the units are correctly sized according to the thermodynamic of heat exchanges, as shown in Figure 1. With this approach the heat exchangers network is a part of the solution of the optimisation problem. The main advantage is that it is possible to build a model without taking care of the heat exchangers network layout, avoiding therefore the creation of scenarios. The same reasoning can be applied to the choice of process alternatives: in the process modelling all the alternatives are programmed; the energy integration will choose the one which best satisfies the objective functions. Alternatively, the use of integer variables allows the direct control of the alternatives during the optimisation. After the application of the energy flows and the process integration model, all the necessary data for computing the system cost estimation is available.

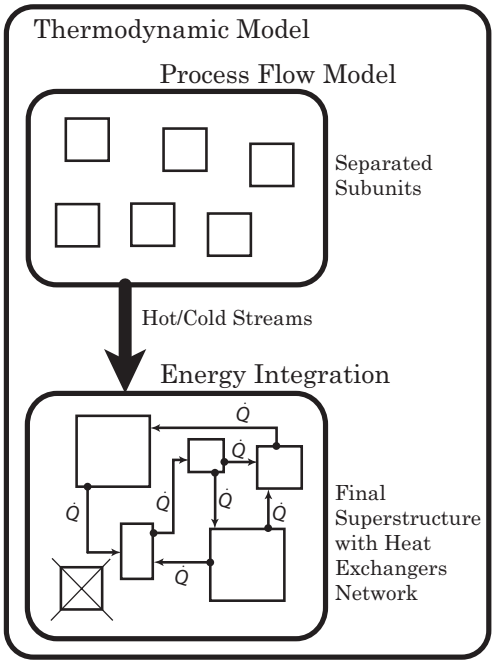

Figure 1: Detail of the thermodynamic model

HOW IT WORKS

The approach can be split into two parts: modelling and optimisation. As shown in figure 2, the optimiser sends the values of the decision variables to the model. Its performance is then evaluated and the values of the objective functions are returned to the optimiser. Decision variables can be sent to all

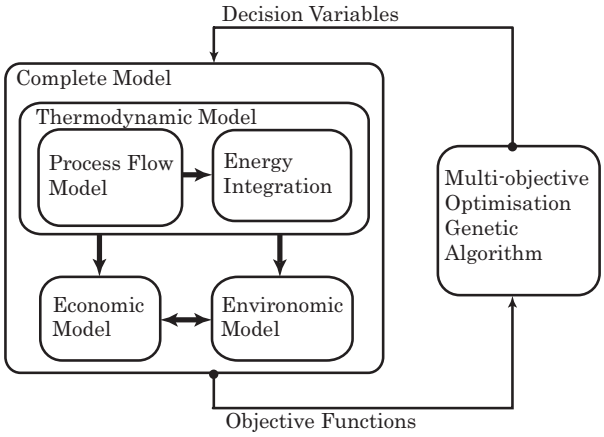

Figure 2: Schematic view of the process integration approach

subparts of the model, in particular, to the process flow, to the energy integration model, to the economic model, to the environomic model or to any sub-model developed for the simulation.

Integrating models

The Laboratoire d'Energétique Industrielle (LENI) is developing a MATLAB® routine called OSMOSE allowing to apply the approach presented in this paper. The details of the modelling and energy integration software called by OSMOSE can be found in [12]. The first sub-model to be run is the process flow. Here the thermodynamics of the material and energy transformation for each sub-unit in the process is computed. Then, the table of cold and hot streams is established. The list can be completed with some units which can be entirely defined in the energy integration model, like the steam network, described later. The process is then perfectly integrated and sized by solving the energy integration as an optimisation [10]. The information coming from the thermodynamic model are then passed to the thermo-economic performance evaluation model in order to compute the objective functions of the global optimisation. At this stage, the values of the objective functions are returned to the optimiser, and the cycle can restart.

Process Flow Model

The process flow model is built with a process modelling software, BELSIM [2]. Each sub-unit of the process is modelled as if it was energetically independent from the others. All the heat exchanges are performed between streams and imaginary sources, assumed to be available at the required temperature. Two types of units are defined: process units and utilities. First ones are the units with fixed flow, which will be used to compute the Minimum Energy Requirement (MER) of the process. Utilities are units with a well defined structure (temperature levels, pressures,...), but with unknown level of utilisation. They are built in the process flow model with a nominal size and the best size is defined to reach the optimal energy integration.

Energy integration - pinch technology

The list of the hot and cold streams of the process is built. Other units can be added to complete the model. The energy integration of the process allows to build the composite curves, in order to determine the MER and to integrate the utilities. The steam network model is embedded in the approach allowing the calculation of the optimal flows in the steam cycle that maximises the power production using the exergy delivered or required by in the process streams. Heat exchanges are computed according to the pinch technology [10], allowing the design of the heat exchangers network, which becomes a solution of the optimisation problem,

Thermo-economic model

Thermo-economic modelling allows predicting the cost of the units used in the process. The thermo-economic costing model used in this paper is using the concepts proposed by Turton [16]:

$$C_x = C_{x,r}(\frac{V}{V_{ref}})^n$$

where V is the sizing variable representing a technical characteristic of the process unit treated. It can be an area (typically for heat exchangers), a mechanical power, a pressure ratio or a temperature.

Hybrid Multi-objective optimisation method

The approach presented in this paper can use both genetic (GA) and conventional semi-Newton optimisation algorithms. GA's are very useful to explore an extremely large solution space, since they can

easily handle first degree discontinuities and multiple local minimums. Their weakness is that they ask a lot of computational time and they can't ensure convergence, since they don't compute objective function's first derivative. Conventional optimisation methods based on semi-Newton algorithm offer the guarantee of convergence (if there is one) with a limited number of iterations. Unfortunately, these algorithms are extremely sensitive to the slope of the objective and they are limited to the research of local minima.
Coupling GA with conventional optimisation allows reducing computational time and ensures convergence. In our work we used advanced GA developed at LENI (MOO) [7],[13] exploiting clustering and multi-objective functions. The usage of integer variables allows studying several technological alternatives leading to the creation of different solution's families. The optimisation of several objectives functions like exergetic efficiency, cost, environmental impacts, leads to the generation of a Pareto curve which is a powerful information support for decision making considering mature and new technologies. In the hybrid approach, the members of the Pareto curve are optimised along the two objectives (the other being considered as a constraint) so that the Pareto curve is pushed to its frontier.

CASE STUDY - ADVANCED NGCC WITH CO_2 CAPTURE

For demonstration purposes, we choose to study the performance of an advanced natural gas combined cycle based on the zero-emission gas turbine (AZEP) developed by Alstom [6]. This cycle combines a conventional 3-stage steam turbine with reheat and a modified gas turbine allowing CO_2 capture. Modifications concern the combustor: the conventional combustion chamber has been substituted with a system composed of two heat exchangers and an oxygen separation membrane (OTM) [6]. Figure 3 shows the concept. After compression, air is preheated to the membrane working temperature (between 800 and 900°C) and oxygen is partially captured. The remaining air is then heated and finally expanded in the turbine. Since depleted air does not participate in the combustion, there is no additional water in the flue gases and therefore it can be cooled down to the ambient temperature. The separated

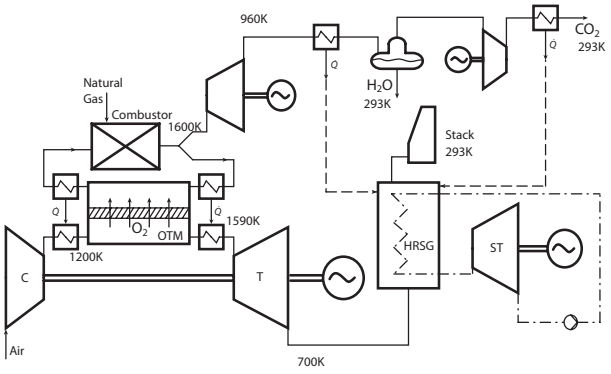

Figure 3: AZEP combined cycle layout

oxygen is recovered in a recirculation loop containing CO_2 and steam and burned with methane. The combustion in the absence of N_2 eliminates concerns about NO_x formation. Combustion gases are partially recycled in the loop and partially sent to the CO_2 capture system. The latter flow is expanded in a turbine down to ambient pressure and then cooled down in order to almost completely condense water. Since the gas phase is composed of CO_2 and water, it is possible to separate the CO_2 by condensation and recover it by pressurising it to about 100 bars and cooling it down to 25°C in order to be transported to its storage place [1].
This cycle is very interesting from the point of view of energy integration, because there are several hot streams that can be used to heat up steam in the heat recovery steam generator (HRSG). Since the network structure is not known a priori, energy integration allows creating the optimal one.

Advanced zero-emission power plant (AZEP) gas turbine

The AZEP gas turbine developed for this study is extremely simplified (Figure 3): the compressor has an isentropic efficiency of 88%, the turbine 93%, combustion is assumed complete, natural gas is composed by pure methane and air is 78%N_2 and 22%O_2. Heat exchangers have a global heat exchange coefficient of 1 kW/°C/m^2. The oxygen separation membrane is assumed ideal, i.e. it is possible to separate as much oxygen as needed; membrane area and cost are backward calculated. Stack temperature is fixed at 25°C. Heat exchanges performed in the membrane zone are directly computed in the process flow model, i.e they are not considered for

energy integration.

CO_2 capture system

Combustion gases which are not recycled are expanded in a turbine and then cooled down to 25°C in order to condense water, which is separated in a liquid/gas separator. The gas phase, composed by more than 99% of CO_2 is then pressurized with a compressor up to 100 bar, and then cooled down to 25°C in order to be liquified. Turbine efficiency is 90% and compressor efficiency is 80%.

Steam network

The steam network model is entirely developed in the energy integration model, using the technique explained in [11]. The concept is related to the definition of a superstructure made by combining Rankine cycles that define one hot stream, one cold stream, one mechanical power by steam expansion and one mechanical power consumption for liquid pumping. Both counter pressure and condensing pressure turbines are considered. Knowing the temperature and pressure levels, the thermodynamic state of the hot and cold streams are computed as well as the mechanical power productions and consumptions. There are two types of streams: steam production and steam condensation. The former can be represented as cold streams by choosing steam pressure and starting/ending temperature. the latter are modelled in the same way as headers, but they are hot streams, since they need to be cooled down. Finally, a steam network can be modelled in the energy integration software by using an assembly of three elements: steam headers (for collecting and distributing steam), extraction ports (to extract steam form the turbines) and one condensation level (representing the return to the deaerator), each one being associated with an integer variable. The superstructure being built to represent all the possible interconnections between the headers.
The main advantage of this way of modelling the steam network is that it is possible to build a very complex steam network by assembling the base elements and to let the software choose the optimal configuration. At each model evaluation, the software performs a MILP (Mixed Integer Linear Programming) optimisation over all the streams appearing in the process and will choose the configuration that best fits the objective function. In this way, the optimal flowrate of each stream of the steam network is computed and some of the headers or extraction ports will be turned off (flowrate equal to zero) and the complex initial configuration will be simplified. The mathematical modelling of the steam network is based on the definition of one or more steam headers and one or more condensate headers. Steam headers can receive steam from four different sources: from an external source (e.g. from the process), from a previous steam header (i.e. from an header with higher pressure), from a condensate header or from an expansion turbine placed between the actual header and a previous one. Symmetrically, a steam header can distribute steam to four kinds of outlets: the exterior of the steam network (e.g to the process), to one of the downstream steam headers, to one of the following condensate headers or to an expansion turbine. Since an header is defined by a pressure and a temperature, it is possible that an expansion from a header A to the pressure of a header B will not provide the corresponding temperature defined for the header B. In order to maintain consistency in the steam network model and to valorize the expansion (which allows extraction of mechanical power from the turbine), the temperature difference is compensated by injecting into header steam coming from either the previous steam header or the condensate header which follows. with this procedure the solution of the MILP optimisation consist in the choice of the headers to be used (integer variables) and their flowrates. The steam network developed for the model presented in this paper is composed by three steam headers, and five steam condensing levels. Steam can be extracted from one of the steam headers, superheated and re-injected in the steam network. This is equivalent to a reheat system. The corresponding steam turbine is a three-stage turbine with one reheat and four extractions. This is the most complex configuration that the energy integration software can select.

Thermo-economic model

The thermo-economic model is based on the investment cost functions of the following equipment: air compressor and turbine, combustion chamber, combustor heat exchangers, oxygen transport membrane, CO_2 compressor and turbine, HRGS heat exchangers and steam turbines system.

Compressors [14]:

$$C_C = \frac{f_{M\&S}}{1069.9}\frac{C_{C,r}}{0.95-\eta_C}\dot{m}_{C,r}\left(\frac{\dot{m}_C}{\dot{m}_{C,r}}\right)^{0.7}\pi_{C,r}\ln(\pi_C)$$

Turbines [14]:

$$C_T = \frac{f_{M\&S}}{1069.9}\frac{C_{T,r}}{0.94-\eta_T}\dot{m}_{T,r}\left(\frac{\dot{m}_T}{\dot{m}_{T,r}}\right)^{0.7} \cdot \ln(\pi_T)\left(1+e^{0.025(T_T-1570)}\right)$$

Combustion Chamber [14]:

$$C_{CC} = \frac{f_{M\&S}}{1069.9}\frac{C_{CC,r}}{|0.995-\pi_{CC}|}\dot{m}_{CC,r}\left(\frac{\dot{m}_{CC}}{\dot{m}_{CC,r}}\right)^{0.7} \cdot \left(1+e^{0.015(T_{CC}-1540)}\right)$$

Heat exchangers [3]:

$$C_{HX} = \frac{f_{M\&S}}{1069.9}\cdot C_{HX}(A_{HX})^{0.7948}$$

The energy integration of the process computes the overall area of the heat exchangers network and gives the minimum number of heat exchangers to respect the minimum energy requirements. With these two values it is possible to estimate the average area and the minimum number of the heat exchangers. The cost of the heat exchangers is then estimated by assuming identical heat exchangers.
Oxygen Transport Membrane [5],[4]:

$$C_{OTM} = \frac{C_{OTM,r}\cdot\dot{\tilde{m}}_{O_2}}{0.0022(P_{O_2})^{0.25}e^{-72000/RT}}$$

The membrane cost (c_{OTM}) is estimated on the basis of a guest future commercial price. For this reason $f_{M\&S}$ is not used.

Steam Turbine with alternator [14]:

$$C_{ST} = \frac{f_{M\&S}}{1069.9}1.15\dot{E}_{ST}\cdot C_{ST,r}\left(\frac{\dot{E}_{ST}}{\dot{E}_{ST,r}}\right)^{0.7}$$

Multi-objective optimisation

The optimiser used for this case study is MOO (Multi-objective Optimiser, [7], [13]), developed at LENI. Two objectives are defined for the problem: maximising the efficiency of the combined cycle and minimising the specific cost of the installation ($\$/kWe$). Twenty decision variables have been defined. They are resumed in Table 1.

Decision variable	Range
Gas turbine press. ratio	15 - 45
OTM inlet temp.[1]	1050 - 1200 K
Oxygen sep. ratio[2]	0.2 - 0.6
OTM outlet HX ΔT[3]	30 - 100 K
Combustor outlet temp.	1500 - 1600 K
Steam head. press.	1 - 100, 1 - 50
	100 - 160 bar
Steam head. superheating	0 - 400, 0 - 500
	100 - 400 K
Condensate head. press.	2x 1 - 10, 1x 1 - 100
	1x 0.020 - 0.025, 1x 0.020 - 1
ΔT multiplication factor[4]	1 - 3

[1] Inlet temperature of the air entering the OTM's heat exchanger

[2] Ratio of of oxygen molar flowrate captured by the OTM

[3] Temperature difference between air entering the OTM heat exchanger and recycling gases entering the combustor (See fig. 3)

[4] ΔT is defined for each stream depending on its thermodynamic state (liquid, gas,two-phase). The multiplication factor optimised here allows amplifying the ΔT_{min} defined by default.

Table 1: Definition of the decision variables and their range

Results

Pareto curve

The Pareto curve allows showing the relationship between the two objectives of the optimisation. It represents the frontier of the solution space, separating feasible and infeasible solutions. In the application, it defines the best specific cost for a given efficiency or, symmetrically, the best efficiency which can be obtained for a given specific cost. The Pareto curve obtained for the optimisation of the AZEP combined cycle is shown in Figure 4. Since clustering has been used to keep local minima alive, the different markers in Figure 4 represent the different families of solutions obtained. It is possible to see that the cluster represented by the square marker is performing a little bit worse in terms of efficiency than the other clusters.
The best performance that can be obtained with the AZEP combined cycle is about 62%, which puts the cycle in direct competition with the best conventional combined cycles and with the new CC's, like gas turbines with fuel cells.

Solutions analysis

Two solutions are detailed in Table 2 : solution A represents the lower specific cost configuration; solution B is the one which gives the best efficiency.

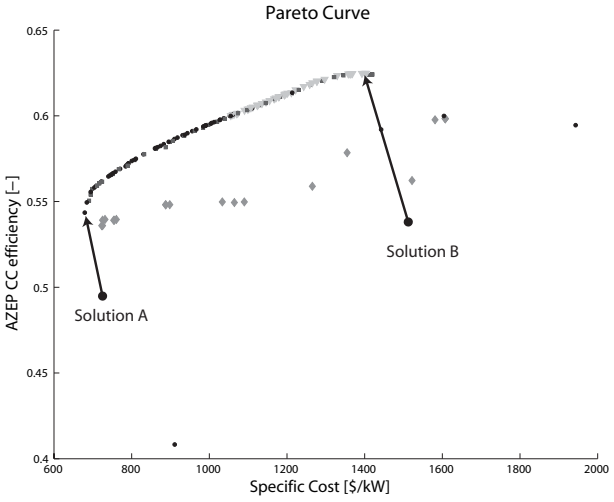

Figure 4: Pareto curve of the multi-objective optimisation

	Solution A	Solution B
Gas Turb. press. ratio	18	41
OTM inlet temp.	1200 K	1200 K
Oxygen sep. ratio	21.8%	31.2%
OTM outlet HX ΔT	100 K	97 K
Combustor out. temp.	1600 K	1600 K
Steam head. press.	101 bar	102 bar
	14 bar	13 bar
	2 bar	1 bar
Steam head. superh.	357 K	365 K
	311 K	214 K
	283 K	290 K
Condensate head. press.	0.021 bar	0.020 bar
ΔT multiplication factor	1	1
Specific Cost	690 US$/kW	1404 US$/kW
Efficiency	55.1%	62.5%

Table 2: Best solution of the optimisation

The layout of the two solutions is extremely similar. The only consistent difference is given by the gas turbine pressure ratio and the oxygen separation rate. Higher ratios lead to better performances but also to higher specific cost. A comparison between Table 1 and Table 2 shows that some variables (OTM inlet temperature, OTM outlet heat exchanger ΔT and combustor outlet temperature) are pushed to their upper bounds, which means that performances will increase when the ceramic technology will accept higher temperatures. The steam network resulting from the optimisation is very simple: 3-stage steam turbine. Reheat is not selected. Compared to conventional steam network, where several steam extractions and reheat are necessary to ensure a good performance, this simplified configuration allows money saving, which compensate the cost of the OTM. Figure 5 shows the integrated composite curve of the steam network. The slope change of process streams at high temperature (around 700 K) is due to the difference of temperature between the expanded CO_2-steam stream and the depleted air from the turbine (the first temperature is 260K higher). It is ideal to integrate steam superheating and to minimize exergy losses. Cooling down streams to 25°C ensures heat availability to preheat water and avoids low pressure steam extractions. From the figure, it can be seen that heat remains available from 75°C to 25°C for district heating, if necessary.

It should be noted that the excellent efficiencies obtained with our model can be partly explained with the following assumptions: the default ΔT_{min} defined for the HRSG (16K for gas-gas heat exchanges, 8K for liquid-gas and 4K for liquid-liquid) allows to increase the efficiency of the plant by 1-2%; the steam superheating of 365K for the high pressure steam header is also critical for conventional HRSG.

The method presented in this paper shows nevertheless that the integration of the hot streams of condensing water are extremely useful to improve the combined cycle performances: taking Solution B as reference, we obtain 62.5% of efficiency. If the temperature at stack is limited to 120°C, the performances are limited to 61.9%. If the heat recovery of the CO_2 separation system is limited to 120°C, the efficiency goes down to 60.9%, because it becomes necessary to introduce steam extraction in the cycle. Finally, if the CO_2 separation system is not integrated in the HRSG, performances fall to 56%. If the steam network is not implemented, the efficiency of the AZEP gas turbine plus the CO_2 system is 46%, and the efficiency of the AZEP gas turbine alone is 37%. The latter value is similar to the results published in [6], where the CO_2 capture system is not considered for power production.

CONCLUSIONS

The optimisation framework based on the coupling of process flow modelling and energy integration, is extremely useful to study complex superstructures and identify promising process configuration at early stage of design. The multi-objective optimisation performed with genetic algorithms combined

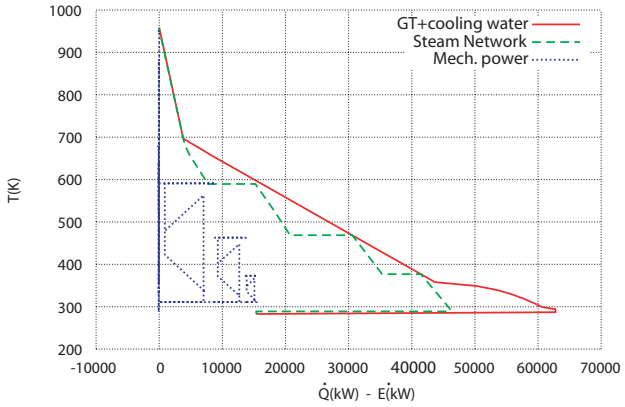

Figure 5: Optimal steam network for the AZEP combined cycle

with conventional optimisation method is ideal to handle multiple decision variables generating non-linear objective functions. Clustering techniques allow the simultaneous study of several promising solutions. The approach is very useful to explore new energy conversion technologies and combined cycles and to generate complex superstructures with unknown heat exchangers network. This is the case of fuel cells, thermal solar energy, organic Rankine cycles, biomass conversion or hydrogen production, to cite a few examples. In this approach, the heat exchangers network is a solution of the optimisation and its structure can be optimally designed thanks to energy integration when optimised configuration and operation of the other energy conversion units are decided.

In the application, the CO_2 capture, which represents a cost increase for conventional NGCC, becomes an interesting option for AZEP combined cycles: the availability of heat down to the ambient temperature allows an significant simplification of the steam network with an increase of performance of the combined cycle. When OTM technology will be mature enough to be commercially competitive, AZEP combined cycles will become a valid alternative in the energy conversion market.

ABSTRACT

In the paper are presented the results of calculations regarding effectiveness of operation of binary power station fed by low-temperature waste heat/geothermal water. Analysed are possibilities of application of various working media with a view of the most effective utilization of energy. Apart from fundamental thermophysical properties of a working medium such as temperature of thermal disintegration, normal boiling temperature, medium specific heat in liquid and vapour state, considered is the influence of properties such as critical temperature, latent heat of evaporation with a particular attention paid ecological indicators of assessment of low-boiling fluids.
Keywords: natural working fluid, power plant, low-temperature Rankine cycle, geothermal heat exhanger

INTRODUCTION

Electricity production based on a low temperature Clausius-Rankine cycle has been known for over 100 years now. First binary power plant producing electricity for a large industrial scale, which formed a part of Paratunsky Power Plant (Russia), with geothermal water as the upper heat reservoir, was built in the years 1965-67 [1]. At that time R-12 has been used as a working fluid. The Montreal Protocol, however, seriously postulates the issue of reduction of production and consumption of substances from the CFC and HCFC group, which are regarded as harmful to the ozone layer. Technologies of production of electricity using the geothermal waters or a low-temperature waste energy are continuously intensively developing, particularly in the direction of substitution of popular freons with natural or new synthetic fluids offered by the chemical industry. Due to the fact that geological conditions of existence of geothermal waters in Poland together with potential resources of contained there thermal energy form significant possibilities of its utilization in production of electricity the authors of the present work strive to search for optimal design for Polish conditions. On the territory of Poland there is approximately 6600 km^3 of geothermal waters with temperature ranging from 25°C to 150°C. The resources are more or less evenly distributed across Poland in specified geothermal basins and sub-basins belonging to selected provinces and geothermal periods [2].

A SYSTEM OF INSTALLATIONS UTILISING GEOTHERMAL ENERGY/ LOW-TEMPERATURE WASTE ENERGY IN PRODUCTION OF ELECTRICITY

Development of power plant installations practically is independent from the way in which energy is acquired, but temperature and properties of water or other medium being the heat carrier of geothermal/waste heat. In fig. 1 presented is a schema of binary power plant operating according to the Rankine cycle [3]. The working medium in such types of installations are low boiling point fluids, usually refrigerants.

GENERAL CHARACTERISTIC OF LOW BOILING POINT FLUIDS WITH THE VIEW OF THEIR UTILISATION IN POWER CYCLES

The molecular mass, normal boiling temperature, critical temperature, latent heat of evaporation, specific heat in the liquid and vapour state belong to the fundamental thermophysical properties of working fluids. These quantities influence the shape of saturation curves. Due to the shape of saturation lines all low boiling point fluids can be divided into two groups (fig. 2 and 3). To the first group belong all these which feature the fact that the isentropic expansion starting on the saturated vapor line continues in the superheated vapour region. To the second group belong all these low boiling point fluids, which must be superheated before directing it into the turbine, if the decompression process in turbine must be realized in the region of superheated steam. Schematic diagram of geothermal power plant operating according to the above cycle of processes and the temperature field in heat exchangers have been presented in fig. 4. In the case of fluids from group I there is no necessity of using the superheater.

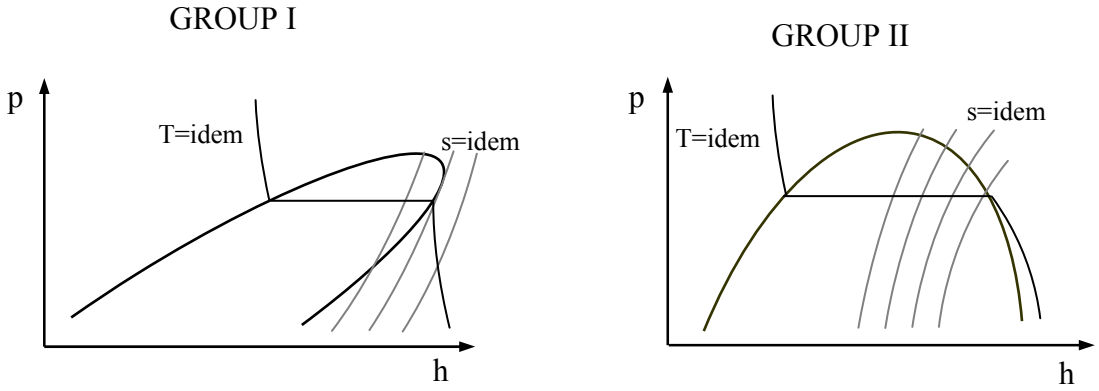

Figure 2: Shape of saturation curves in the pressure-enthalpy diagram

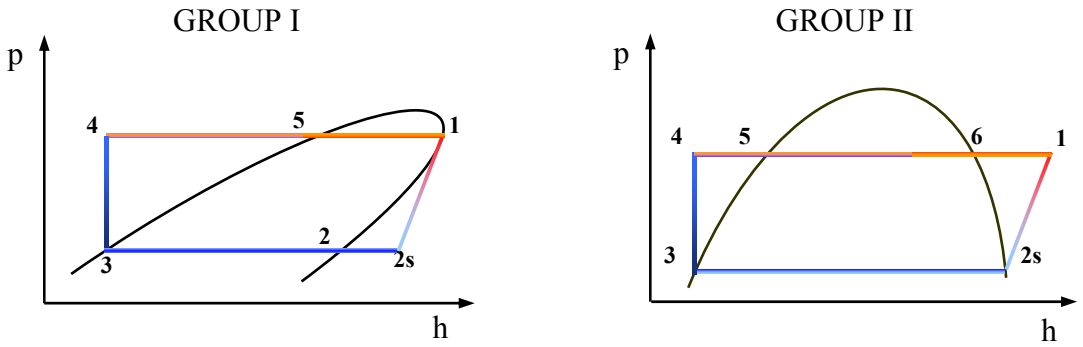

Figure 3: A cycle of thermodynamic processes of the working mediumk in the C-R cycle realised in the region of superheated vapour

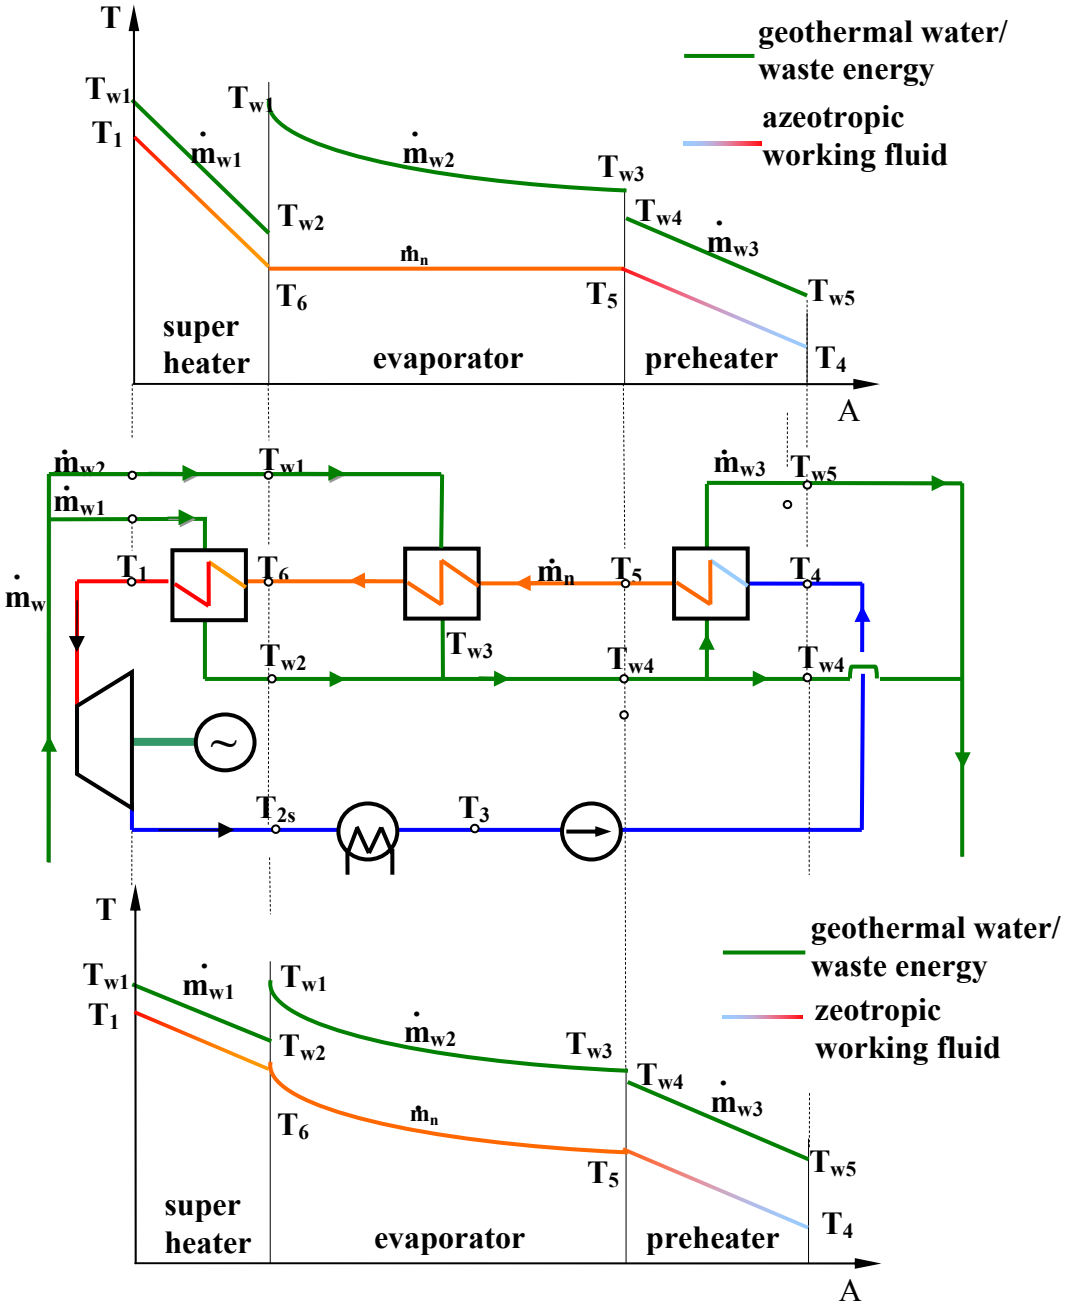

Figure 4: Schema of geothermal power plant operating according to the above cycle of processes and the temperature field in heat exchangers

CHARACTERISTICS OF ZEOTROPIC WORKING MEDIA

Transition of the two-component solution from one state of the matter to another takes place in a completely different way than in the case of single-component media [4]. Implementation of multi-component fluids in the Clausius-Rankine cycle requires knowledge of their behaviour during processes occurring in the evaporator and condenser [5]. In figure 5 presented have been thermodynamic processes of working fluid in the Clausius-Rankine cycle. On the other hand the schematic presenting the binary power station operating according to such cycle in the superheated vapor region together with the temperature field in the heat exchanger is shown in figure 6.

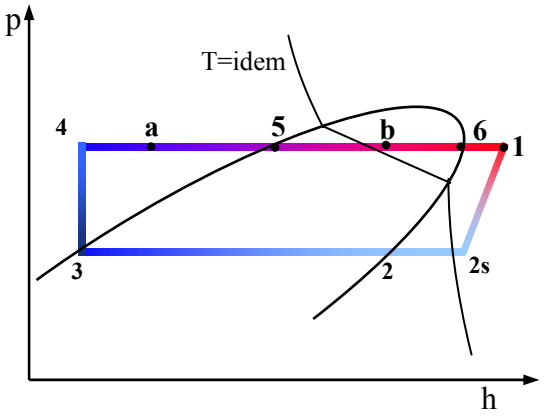

Figure 6: A cycle of thermodynamic processes of two-component working fluid in the Clausius-Rankine cycle

BASIC ASSUMPTIONS

In the paper presented are the results of calculations of the C-R cycle efficiency and turbine power in line with the fig. 4. Carried out have been calculations for the fluids presented in table 1. Thermodynamic parameters of fluids have been taken from the code Refprop 7.0 [6].
Assumptions:
- flowrate of water being the heat carrier of geothermal/waste heat $\dot{m}_w$ =30kg/s;
- temperature of water flowrate $\dot{m}_w$ T_{w1}=80-115°C;
- temperature of evaporation of single component fluids $T_5=T_6=T_{w1}$-15K, for zeotropic mixtures the mean arithmetic evaporation temperature in the beginning and final states $T_e=(T_5+T_6)/2=T_{w1}$-15K;
- temperature of condensation of working medium T_c=25°C, for zeotropic mixtures arithmetic mean of condensation temperatures in the beginning and final states $T_c=(T_2+T_3)/2$=25°C;
- process of isentropic expansion in turbine takes place in the superheated vapour region, which means that for the fluids from the second group considered have been additional energy required to superheat the fluid prior to the turbine (6-1).

Name of fluid	Critical temp. °C	Remarks
propylene	92,4	Single-component natural fluid
propane	96,7	Single-component natural fluid
ibutane	134,7	Single-component natural fluid
ethane	32,2	Single-component natural fluid
water	373,9	Single-component natural fluid
0.9 propane/ 0.1 ethane	90,7	Two-component zeotropic mixture (mass fraction)
0.8 propane/ 0.2 ethane	84,6	
0.7 propane/ 0.3 ethane	78,4	
0.6 propane/ 0.4 ethane	72,1	
0.5 propane/ 0.5 ethane	65,7	
R227ae	101,7	Single-component synthetic fluid
R236fa	124,9	Single-component synthetic fluid
RC 318	115,2	Single-component synthetic fluid
R407C	86,0	Zeotropic mixture of synthetic fluids

Table 1: Tabulation of fluids used in calculations

RESULTS OF CALCULATIONS

On the basis of obtained results of calculations constructed have been relevant diagrams illustrating the influence of temperature of geothermal water on efficiency and power of

binary geothermal power station for selected low boiling point fluids.

In fig. 7 compared have been values of thermal efficiency of the C-R cycle for different fluids, which have been obtained for water with temperature 90-115°C (upper heat reservoir) and condensation temperature of working fluid 25 °C.

In fig. 8 presented has been turbine internal power in the C-R cycle for different fluids, obtained for condensation temperature 25°C in function of feeding water temperature.

In fig. 9 and 10 presented has been enthalpy of fluid evaporation and flowrate of working fluid in the C-R cycle for different fluids, obtained for condensation temperature 25°C in function of feeding water temperature.

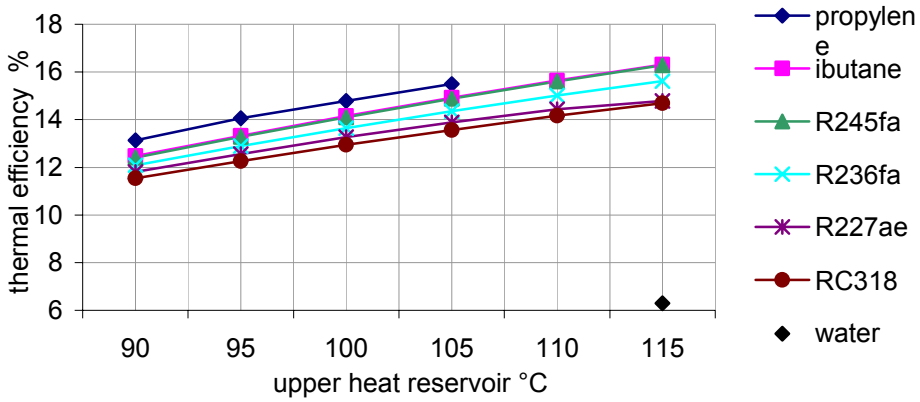

Figure 7: Efficiency of C-R cycle for different fluids obtained for the condensation temperature t_2=25°C

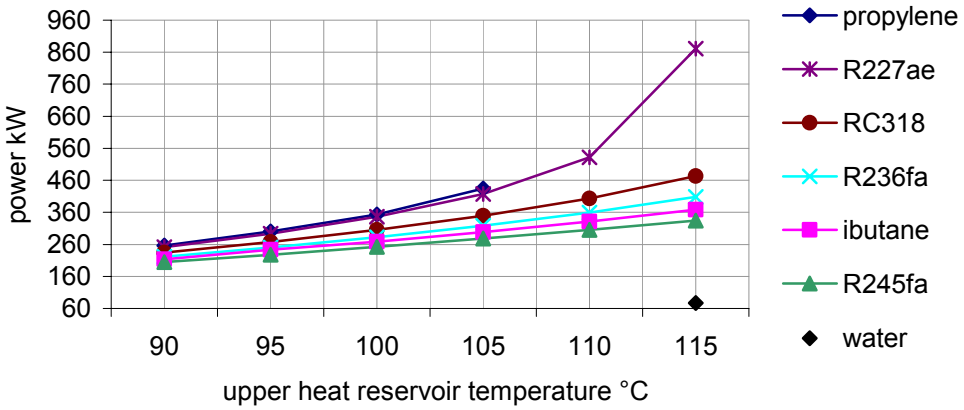

Figure 8: C-R cycle power (temperature of supply water t_1=80-100°C, flowrate of feeding water 100 m^3/h, fluid condensation temperature t_2=25°C

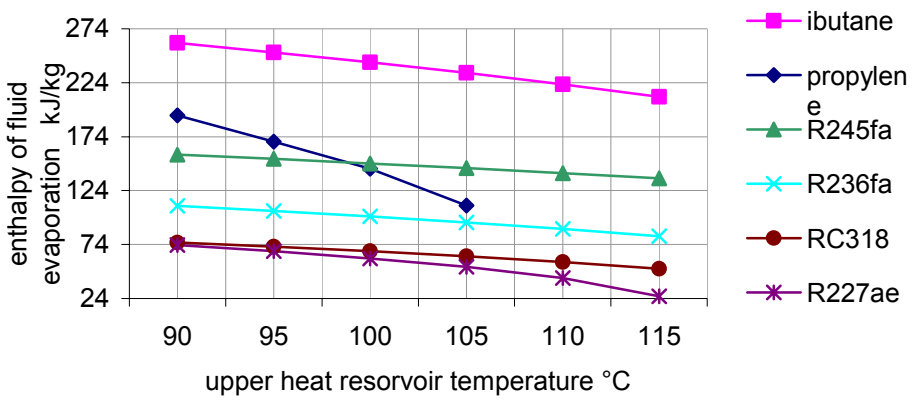

Figure 9: Enthalpy of fluid evaporation in function of feeding water temperature

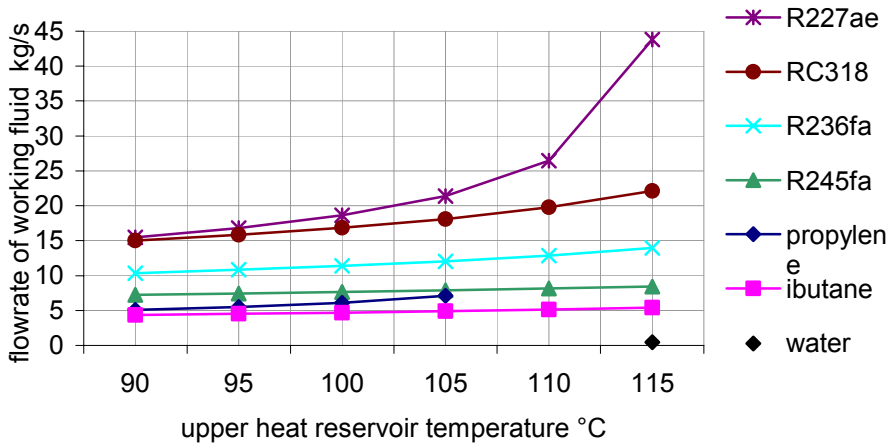

Figure 10: Flowrate of working fluid in function of feeding water temperature

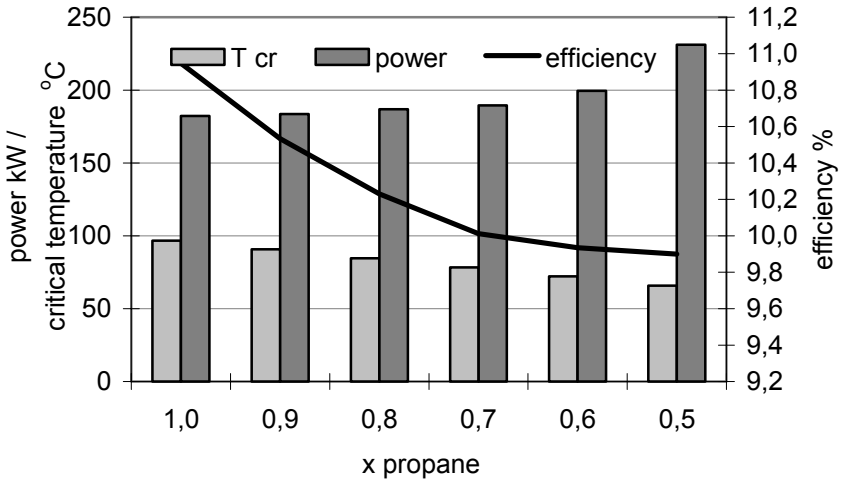

Fig. 11. Power of C-R cycle and thermal efficiency for the propane-ethane mixtur

In the figure 11 tabulated have been the results of calculations of efficiency and power of C-R cycle in the case of propane - ethane mixture (with five different mass fractions) obtained for the temperature of feeding water t_{w1}=80°C, feeding water flowrate 30 kg/s, fluids condensation temperature t_2=25°C. Propane-ethane form a zeotropic mixture (the temperature slip is present).
Analysing the above diagram it can be noticed that the highest cycle efficiency has been obtained for the pure propane and that it decreases with the increase of the share of ethane in the mixture. A different relation is observed when we focus our attention on the function of the cycle power in function of the working fluid composition. The highest value of power has been obtained in the case of a 50/50 propane/ethane mixture. A tendency of power increase with decrease of the critical fluid temperature has also been noticed. That can be explained due to the fact that the enthalpy of fluid evaporation decreases with increase of pressure (a temperature) to achieve a value of zero in the critical point. The lower the latent heat of evaporation the more of it can be introduced to the cycle at a constant flowrate of geothermal water (fig. 12 and 13).

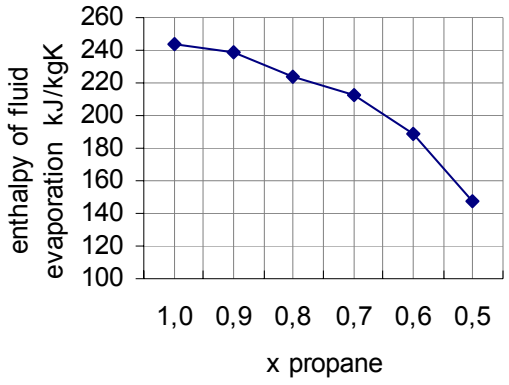

Figure 12: Enthalpy of fluid evaporation in function of composition of working fluid

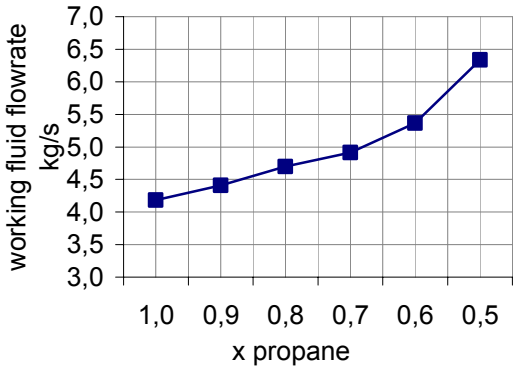

Figure 13: Cycle fluid flowrate in function of composition of working fluid

CONCLUSIONS

In the paper presented have been the results of calculation of theoretical efficiency and power of Clausius-Rankine cycle for different refrigerants and a zeotropic mixture propane-ethane of different mass composition.
On the basis of analysis of obtained results of calculations there can be formulated the following final conclusions:

- determination of efficiency of C-R cycle operating with the low boiling point fluid as a working fluid is insufficient in the energetical assessment of the fluid; for similar efficiencies for different fluids obtained have been different powers in both groups of fluids;
- highest values of power of C-R cycle are obtained for the fluid, which critical temperature is mostly approaching the temperature of the upper heat reservoir;
- usually low value of fluid evaporation enthalpy is desirable property in low-temperature Rankine cycle;
- highest values of power obtained have been for the natural working fluid – propylene and single-component synthetic fluid R227ae;
- highest values of efficiency obtained have been for the natural working fluid – propylene and single-component synthetic fluid R245fa;
- for similar efficiencies (10.9 - 9.9%) for different mass compositions of propane-ethane mixture obtained have been different values of power (182.3 - 231.2 kW).

DEVELOPMENT OF A BIOMASS SLOW PYROLYSIS ROTARY KILN MODEL

D.Chiaramonti, M.Berti, D.Fiaschi
Department of Energy Engineering "S.Stecco"
University of Florence, Via S.Marta 3 I-50139 Florence
d.chiaramonti@ing.unifi.it

ABSTRACT

A model for the simulation of biomass slow pyrolysis in rotary kilns is necessary for preliminary sizing bioenergy plants based on this process. In order to develop this kind of model, the thermochemical conversion process as well as the solid motion within the reactor have to be modelled.
As regards the thermochemical process, the conversion of each component (cellulose, hemicellulose and lignin) has been considered, and literature data implemented. The impact of ash composition (inorganics) on product yields has been taken into account, together with other relevant parameters, such as reactor temperature and heating rate.
The analysis of the possible solid motion in the reactor identified the so-called "rolling motion" as the appropriate one for the process under study. The geometrical dimensioning model has then been coupled to the heat balance of the rotary kiln.
Pyrogas (tar and gases) is used as fuel in a boiler of a small scale steam power plant, while char is used to thermally sustain the slow pyrolysis process. In addition, assuming 9-10 % d.a.f. moisture content of the biomass input, only 10 % of the energy in the biomass fed to the reactor is needed to sustain the process: therefore, 70 % of the char yield can be used for additional energy production or for other uses (as a co-product). In this last case, the final energy efficiency of the plant is comparable to the values typical of small scale bioenergy plants.

Fr	Froude number
g	acceleration due to gravity (m^2/s);
h_0	bed depth at kiln inlet (m)
h_{ex}	bed depth at kiln outlet (m)
L	reactor length (m)
MRT	mean residence time (min)
MVF	material volumetric flow (m^3/min)
n	kiln rotational speed (rpm)
PBR	Packed Bed Reactor
R, R_{Ti}, r	internal radius of kiln (m)
RC, f	fill ratio
TGA	Thermogravimetric analysis
X_a	initial silica-free ash fractional content (%wt daf)
X_C	initial fraction of cellulose (% wt daf)
X_l	initial fraction of lignin (%wt daf)
X_{si}	initial silica fraction (% wt daf)
$Y_{b,i}$	Y is the product yield (% wtdaf); subscript "b" denotes biomass, subscript "i" denotes char (c), liquid (l) or gas (g) accordingly.
Y_C	producted char yield (%wt daf)
α	kiln slope (deg)
β	bed slope (rad)
ε	filling angle: it corresponds to the half bed angle of the circular segment occupied with solids
ε_f	correctional coefficient (ε_f=1.03)
ε_t	correctional coefficient (ε_t=1.04)
θ, θ_d	dynamic angle of repose (deg)
μ_W	frictional coefficient of bed material – wall.
μ_{W,C_max}	maximum frictional coefficient of bed material – wall.
ρ_B	bulk density (kg/m^3)
ρ_C	char density (kg/m^3)
ω	kiln rotational speed (rad s^{-1})

INTRODUCTION

The development of a mathematical model able to preliminary design a small scale bioenergy plant based on slow pyrolysis in a rotary kiln reactor requires the simulation of several aspects of the energy conversion process, such as the kinetic of the pyrolysis process, the solid motion in the reactor, the exchange of the heat inside and outside the reactor.
The rotary kiln reactor is an interesting technology for bioenergy units, thanks to its ability to deal with heterogeneous materials (as regards particle

dimensions and characteristics), and process parameters can be modified in a relatively simple way to meet the process requirement.
Slow pyrolysis is a reliable and well know method for biomass conversion: products (char, gas and tar) can be used to generate electrical energy in steam cycle, and to provide the heat necessary to the process.
As regards pyrolysis-based plants, a wide number of researches and reviews have been published on the issue of biomass pyrolysis: modelling allows for the estimation of the interactions between process parameters and end-products. In fact, a biomass pyrolysis model should:

1. Estimate the link between process conditions (e.g. heat of pyrolysis, moisture content, biomass particle size, etc) and product yields
2. Allows for process optimisation by modifying the above mentioned process parameters
3. Represent a first instrument for preliminary reactor selection, sizing and dimensioning

KINETIC MODELLING

A large number of homogeneous and heterogeneous reactions occur during the biomass pyrolysis process, in a simultaneous as well in a consecutive way. Reactor conditions govern these reactions.
The attempt of kinetic modelling is therefore to simulate the process as a whole (by using Arrhenius type equations to model pyrolysis reaction rates), being individual reaction pathways very difficult to be described.
Di Blasi [1] reviewed modelling of biomass pyrolysis kinetics distinguishing among: (1) one step global reaction (which cannot predict the relationship between products yields and reaction conditions), where a constant ratio between volatiles and char is assumed; (2) multi-reaction models (which cannot be generalized, as they are based on different and distinct reactions that correlate specific experimental data); (3) semi-global models (kinetic pathways here consider primary and secondary reactions, and three main products – tar, gas and char –).
Semi-global models seem the most appropriate choice for developing engineering tools aimed at preliminary reactor design and optimisation, as they take into account competitive chemical pathways, estimate product yields on the basis of reactor conditions, but also limit the complexity of the model itself and the data needed for running the model, and allows for coupling chemistry and transport processes.
Most of the first semi-global models which have been developed were focused on pyrolysis of cellulose, while only few works examined hemicellulose and lignin pyrolysis.
Semi-global models considering the biomass degradation rate as the sum of cellulose, hemicellulose and lignin pyrolysis were then proposed: they represented a first rough attempt to describe the entire biomass pyrolysis process in a relatively simple way, as it is not possible to determine accurate correlations among the various components and process conditions which are valid on a general basis. This was probably due to the presence of inorganic matter in the biomass fuel: inorganics behave as a catalytic/inhibitor component, which therefore significantly modify the process of thermal degradation of raw biomass. Also the purity and the characteristics of cellulose play a role in this problem. It was then concluded that the specific biomass type has an influence on the pyrolysis process iself.
In the '90s Raveendran *et al* [2, 3, 4] carried out a number of studies and experimental works focused on the estimation of the impact of inorganic components contained in biomass ash on the pyrolysis process. Thirteen different biomass types have been investigated in a packed bed reactor (PBR) and in a TGA experiment: the TGA analysis examined a temperature range between the environment temperature and 1273 K, at a linear heating rate of 50 $Kmin^{-1}$, while the packed bed reactor was operated at a temperature of 773 K. These research activities developed correlations able to reasonably estimate the product yields (char, tar, gas) in slow pyrolysis processes (TGA or PBR) through the weighted sum of the partial contributions of biomass components.
In addition, correlations taking into account the impact of inorganic components on the thermal conversion process were developed and experimentally verified by the authors.

Among the correlations reported in the previously mentioned studies, the simplified overall correlation (valid for the PBR case) has been selected for the present work. The necessary input are the cellulose, lignin, silica-free ash and silica content in biomass.

$$Y_{b,i} = \left[A \left(\frac{X_c}{X_l} \right)^{n_1} X_a^{n_2} X_{Si}^{n_3} \right] \qquad \text{eq. 1}$$

A, n_1, n_2, n_3 are constant obtained by experimental analysis and different for char, tar and gas products (tab. 1).

Table 1 *Constant for eq. 1*

	A	n_1	n_2	n_3
char	49,9	-0,0258	0,258	-0,044
tar	102,86	0,7028	0,335	0,033
gas	13,93	-0,4168	-0,337	-0,002

Being the aim of this work the preliminary design of a bioenergy system based on slow pyrolysis of biomass, the use of the given above equation seemed reasonable because:

1. a Packed Bed Reactor is a good approximation for a rotating kiln slow pyrolyser of biomass. In fact, heating rates are rather similar, even if the PBR is operated in the batch mode and the rotating kiln in the continuous one.
2. the final process temperature adopted for the present work is very similar to the one used for the PBR case.

ROTARY KILN MODELLING

The use of rotary kiln systems as heterogeneous noncatalytic gas-solid reactors is very wide in some industrial sectors, as the metallurgical and the chemical ones. Among other uses, drying or heating of wet solids, mixing or grinding of powders, calcining of limestone, clinckering of cementitious materials, reducing of iron ore or ilmenite are well known applications: other recent applications are related to the thermochemical conversion of wastes. Even if new and more recent reactors (such as Fluidized Bed Reactors, FBRs) have been developed in the recent years and achieved commercial maturity, rotary kiln are still playing an important role.

Biomass pyrolysis can be efficiently implemented in rotary kilns: the slow rotational motion of the reactor, which can be varied in its inclination and speed, can be well coupled to slow pyrolysis processes, as it facilitates mixing of solids and can be well adopted with heterogeneous fuels, which are different not only in terms of biomass type, but also in terms of physical aspects. In fact, the production of biofuels of constant physico-chemical quality is a major issue in the bioenergy field, and the costs associated to this action can be significant for the whole process economy.

Even if a large number of studies have been published on the modelling and design of this type of thermochemical conversion technology, few of them describe the pyrolysis process keeping at the same time into consideration the simultaneous mass transfer and heat transfer in the reactor. These are instead essential elements of a model designed for this type of endothermic process.

The present work was therefore focused on coupling selected results from various research works [5] where the solid motion into the reactor is described and modelled, with other studies which examined the heat transfer process and, in particular, defined the heat exchange coefficients.

Possibile motions in a rotating kiln

Mellmann [6] reviewed the forms and the transition behavior of the transverse motion of free-flowing bed materials in rotantig cylinders. He distinguished among the following possible alternatives: sliding, surging, slumping, rolling, cascading, cataracting and centrifuging. All these motions have different and distinct mixing characteristics, and therefore different effects on the heat transfer in the bed of solids.

Boateng [7] observed that the heat transfer process in a rotary kiln is carried out in the same way as the PBR. Radiation and conduction occur between solid particles, and convection between solids and gas. There is also an advective component, which has the capability of regulating the overall process.

All these types of motion mainly depend on rotational speed, filling degree and rheology properties of solids, which has a deep influence on the bed rotational motion and therefore on mixing.

Also the roughness characteristics of the material used in the internal walls of the reactor are very important in dimensioning the system.

The most used motion type for these kind of technologies is the rolling motion, which allows for a fast transfer of solid particles between the upper and lower surfaces of the bed. The rolling motion is in fact characterised by two different regions, as regard the particle motion: the Active Layer, which is very thin and where most of the mass and heat transfer occur, and a larger part, the Plug Flow region, where the solid is pushed by the rotational motion towards the upper surface of the bed.

The best mixing, and therefore the most appropriate, heat transfer conditions are achieved through the rolling motion: Mellmann [6] provides the equation needed to identify the boundary conditions among different motion regimes. The parameters which play the most important roles in this process are the following:

1. The Froude number, Fr, i.e. the ratio between centrifugal forces and gravity:

$$Fr = \frac{\omega^2 * R}{g} \qquad \text{eq. 2}$$

In the case of rolling motion it has to stay in the range $10^{-4}<Fr<10^{-2}$;

2. The filling degree, which is the part of the transver section of the cylinder which is occupied by the solid bed:

$$f = \frac{(\varepsilon - \sin\varepsilon * \cos\varepsilon)}{\pi} \qquad \text{eq. 3}$$

It has to be in the range $0,1< f < 0,2$ in order to have a rolling motion regime;

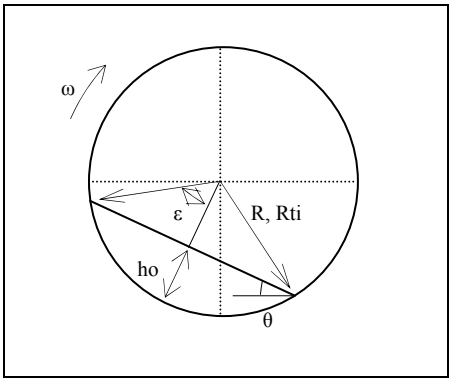
3. The friction coefficient between inner wall of the reactor and solid bed. In the rolling motion it has to be greater than the maximum friction coefficient at wall, which can be expressed as a function of the dinamic angle of repose θ:

$$\mu_W > \mu_{W,C\_\max} = sen\theta \qquad \text{eq. 4}$$

4. The size of the solid particles, which in the rolling regime must be:

$$d > F_r * D \qquad \text{eq. 5}$$

fig. 1 Section of the reactor



Geometrical dimensioning of the reactor

Given the conditions to establish a rolling motion regime in the reactor, a geometrical dimensioning model has been developed to define the geometry of the rotating kiln, in terms of both length and diameter. The fill ratio has been varied between 0.1-0.2, which correspond to a range of 93° - 121° of filling angle (2ε). Equations 2, 4 and 5 have been used for the verification of the rolling motion regime.

The system consists of two equations which links the residence time and the mass flowrate of solids with the geometrical characteristics of the rotating kiln reactor.

The equations are the following:

$$MRT = \varepsilon_t * \frac{L * \sin\theta_d}{2 * \pi * r * n * (\tan\alpha + \cos\theta_d * \tan\beta) * \cos^2\beta} \qquad \text{eq. 6}$$

$$MVF = \varepsilon_f * \frac{4}{3} * n * \pi * \cos^2\beta * \left(\frac{\tan\alpha}{\sin\theta_d} + \frac{\tan\beta}{\tan\theta_d}\right) \qquad \text{eq. 7}$$

$$* \left(2 * R * h_0 - h_0^2\right)^{3/2}$$

$$\tan\beta = \frac{h_0 - h_{ex}}{L} \qquad \text{eq. 8}$$

$$RC = \frac{1}{\pi}\cos^{-1}\left(\frac{R_{Ti} - h_0}{R_{Ti}}\right) - \frac{(R_{Ti} - h_0)\sqrt{\left(2R_{Ti}h_0 - h_0^2\right)}}{\pi R_{Ti}^2} \qquad \text{eq. 9}$$

where eq. 9 is the same as eq. 3 in different terms.

A further equation is needed, which links the initial and final height of the solid bed (h_0 and h_{ex}):

$$h_{ex} = \frac{\left(Y_C \frac{M_B}{\rho_C}\right) h_0}{\frac{M_{tot}}{\rho_B}} \qquad \text{eq. 10}$$

This equation is proportional to the amount of solids entering and leaving the rotary kiln: these are estimated on the basis of the previously mentioned pyrolysis model developed by Ravendran *et al* [2, 3, 4].

Thermal dimensioning of the reactor

Preliminary dimensioning in terms of heat exchange was developed considering the kiln as a heat exchanger: flue gases from char combustion heat the cylinder and therefore the biomass in that (fig.2).

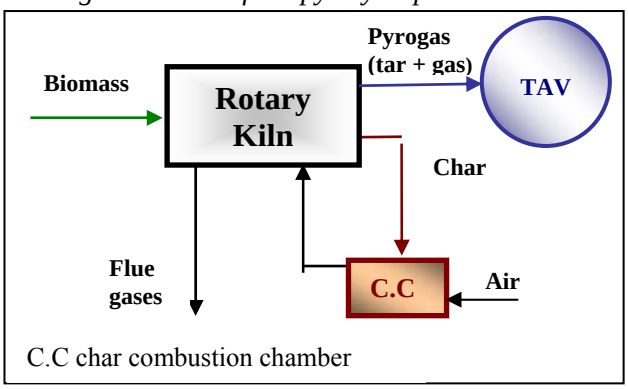
The heat exchange process is therefore defined by:

- Convection, between flue gases from char combustion and external wall of the reactor;
- Conduction, between outer and inner wall of the cylinder;
- Conduction, between inner reactor wall and solid biomass/char;
- Convection, between inner reactor wall and pyrogas.

No heat sources are located in the internal part of the rotary kiln, being pyrolysis and endothermal process.

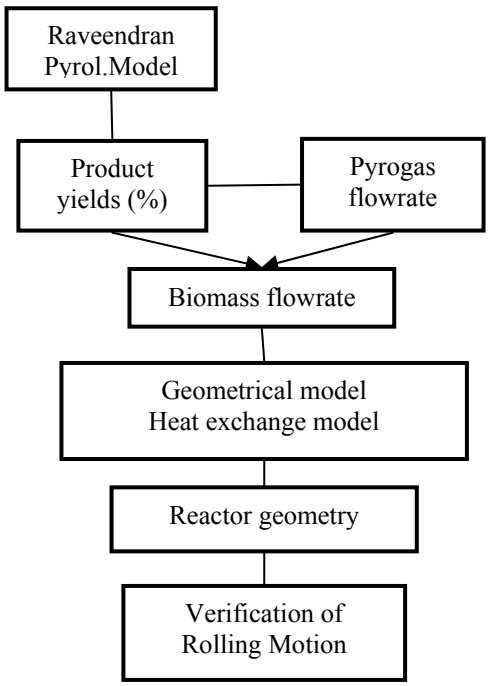
Heat exchange coefficient have been taken from literature [8].

Fig. 2 Scheme of the pyrolysis plant



The model has been integrated with the thermodynamic analysis of the steam cycle for power generation and the balance in the char combustion chamber.
The initial biomass flowrate has been derived by considering the percentage distribution of pyrolysis products as a function of the pyrogas flow necessary to supply the heat to the steam boiler of a given steam power cycle.

Summarising, the overall model is structured as described in the following figure:



MODEL APPLICATION

The rotating kiln reactor model has been used to preliminary dimensioning of two small scale steam power plants, the first using a steam engine (155 kWe power output) and the second one a steam turbine (225 kWe).

Biomass pyrolysis product yields

The selected feedstock is straw biomass, which composition is given in tab.2. It has been derived from literature data on straw composition analysis [9, 2,10],

Table 2 Composition of straw (wt% daf)

Cell.	Hemicell.	Lign.	Extractt.	Ash	Si
33,56	31,80	18,05	14,75	10,05	3,48

By applying the pyrolysis model, this biomass is expected to generate the following distribution of pyrolysis products, expressed as percentage of the initial biomass amount:

- char: 28,2 % wt, daf;
- tar: 44,69 % wt daf;
- gas: 27,11 %wt daf.

These results, obtained by applying the Ravendran correlations, are in good agreement with other data available in literature for this type of process [10, 11, 12, 13].

155 kWe bioenergy plant

The plant has been preliminary dimensioned on the basis of the following main input:

- biomass flowrate: 0,297 kg/s;
- Pyrolysis temperature: 823 K;
- Reactor inclination: $\alpha = 2°$;
- Reactor rotational speed: n = 5 rpm;
- Dinamic angle of repose: $\theta = \theta_d = 48,5°$.

The calculation has been performed by changing the fill ratio RC (eq. 9) between 0,1 and 0,2:

Table 3 Results and verification of rolling motion conditions (155 kWe plant)

RC	MRT	L_T	R_{Ti}	Fr	d_p
	[min]	[m]	[m]		[mm]
0.1	11.54	12.1	0.8559	$3.8\ 10^{-3}$	6.5
0.11	11.9	12.24	0.8306	$3.7\ 10^{-3}$	6.1
0.12	12.23	12.36	0.8083	$3.6\ 10^{-3}$	5.8
0.13	12.53	12.47	0.7884	$3.5\ 10^{-3}$	5.5
0.14	12.81	12.57	0.7707	$3.4\ 10^{-3}$	5.3
0.15	13.05	12.66	0.7547	$3.37\ 10^{-3}$	5.1
0.16	13.27	12.74	0.7401	$3.3\ 10^{-3}$	4.9
0.17	13.48	12.81	0.7268	$3.25\ 10^{-3}$	4.7
0.18	13.66	12.87	0.7146	$3.19\ 10^{-3}$	4.5
0.19	13.82	12.93	0.7033	$3.14\ 10^{-3}$	4.4
0.2	13.96	12.98	0.6929	3.110^{-3}	4.2

The analysis of results given in Table 3 indicates that: (1) the solid residence time is in agreement with typical values of slow pyrolysis processes, which requires slow residence times in order to limit secondary reactions; (2) rolling motion conditions - being the Froude number in the specified range of $10^{-4}<Fr<10^{-2}$ - are met if biomass dimension at reactor inlet are above the values indicated in the table and in the case the material which constitutes the inner wall has roughness within the range that guarantee a friction coefficient above the critical-conditions friction coefficient ($\mu_{wc;max}$ = sen θ = 0,749).

The application of the model also shows that the thermal power required by the biomass pyrolysis process (in order to heat the biomass from 293 K to 823 K) is approximately 405 kW, assuming a 1156 kJ the necessary energy for pyrolysing 1 kg of biomass. This last figure is a slightly lower value than the one given by Jensen [14], 1359 kJ/kg, for a similar process but different biomass conditions at inlet: in fact, this difference is probably due to the feedstock moisture content, which is higher for Jensen than for the case studied in the present work.

255 kWe bioenergy plant

Similar calculations have also been performed for a different bioenergy plant, having a greater capaicity but still in the range of very small unit (255 kWe). The same critera have therefore been applied, the main difference being a lower biomass flowrate (0,136 kg/s), thanks to a greater efficiency of the steam turbine compared to steam engine at nominal conditions.

Results are shown in table 4:

Table 4 Results and verification of rolling motion conditions (255 kWe plant)

RC	MRT	L_T	R_{Ti}	Fr	d_p
	[min]	[m]	[m]	$exp10^{-3}$	[mm]
0.1	7.747	6.811	0.6334	2,8	3,6
0.11	7.982	6.888	0.6143	2,8	3,4
0.12	8.193	6.956	0.5975	2,7	3,2
0.13	8.383	7.016	0.5826	2,6	3,0
0.14	8.555	7.07	0.5692	2,5	2,9
0.15	8.71	7.119	0.5572	2,5	2,8
0.16	8.849	7.162	0.5462	2,4	2,7
0.17	8.974	7.2	0.5361	2,4	2,6
0.18	9.085	7.234	0.5269	2,4	2,5
0.19	9.183	7.263	0.5184	2,3	2,4
0.2	9.269	7.289	0.5106	2,3	2,3

Similar considerations apply to this case.

CONCLUSIONS

The goal of the present work was to develop a mathematical model simulating biomass slow pyrolysis process in a rotary kiln reactor: the overall scope of the model is to provide a useful tool for the design of pyrolysis-based bioenergy unit.

In order to achieve this objective, three different aspects have been considered, and the relative models coupled:

- Slow pyrolysis process;
- Reactor geometrical design;
- Thermal dimensioning of the reactor.

The model which has been developer has been applied to simulate two different biomass microgeneration unit, where pyrolysis products are used not only to generate power in a bottom steam cycle, but also to provide the necessary heat to the pyrolsysis process itself.

The considered biomass flowrates at the reactor inlet where 0,297 kg/s and 0,136 kg/s, for a power generation of 155 kWe and 255 kWe respectively.

Results are in agreement with those available in literature for similar plants

ABSTRACT

This paper is a case study of thermodynamics and economics related analyses applied to an existing gas/steam combined cycle cogeneration plant. Basic thermodynamic properties of the plant are determined by energy analysis utilizing main operation conditions. Exergy destruction and losses within the plant are investigated to determine thermodynamic inefficiencies in the system and to assist for guiding future improvements in the plant. Cost balances are applied to several subsystems in the plant, hence, cost formation in the plant is observed. Besides, cost of each product of the system is calculated.

INTRODUCTION

There is a range of technologies that can be applied to cogenerate electricity and heat. Among these technologies, gas/steam combined cycle cogeneration systems are currently in widespread use. These systems can be quite complex as there are different configurations that can be selected and optimized to provide the desired flexibility, reliability and rate of return for the owner [10]. Main configuration differences arise due to using different kinds of steam turbines (i.e. back pressure, condensing) and HRSG (differ in number of pressure levels, circulation type, supplementary firing). The configuration of the plant chosen in this study is explained in detail in the following sections.

Thermodynamic analysis and improvement of plants are meaningful via exergy analysis. There are many papers and books that explain the exergy analysis method and its importance [1,2,7]. Unlike energy analysis, this analysis takes into account the quality of the energy.

Thermoeconomic analysis combines exergy and economics principles. There are different approaches in literature. In this study, specific exergy costing method (SPECO method) [3] is used to analyze the plant.

DESCRIPTION OF THE PLANT

General Description

Bilkent combined cycle cogeneration plant is located in Bilkent University complex, Ankara, Turkey. The plant produces electrical energy and steam for the adjacent paper mill and the nearby Bilkent University complex; the electrical surplus is sold. Besides, there is also an old system next to this plant, consisting of a gas turbine and a waste heat recovery boiler which is used only to produce process steam. However, this system is not taken into account in this study.

The plant consists of a gas turbine package, a heat recovery steam generator (HRSG), a steam turbine with relevant generator and a main steam condenser. Furthermore, auxiliary systems common to the combined cycle are provided. The schematic drawing of the plant is shown in Figure 1. Besides, there is a dump steam condenser, which is needed during start-up and shut-down of the unit, or in case of steam turbine outage.

Fuel of the plant is natural gas supplied by local supplier Botaş. Natural gas is seperated from oil and humidity in dedicated seperators and compressed by the electrically driven natural gas compressors.

Raw water is supplied by municipality. It is used as the make-up of the condensate return from the process. Also, it is supplied to the cooling tower basin.

Steam export is either only steam from the intermediate pressure steam generator (in case of no extraction from the steam turbine) or a mixture of steam from the intermediate pressure steam generator and steam from the controlled extraction of the steam turbine.

Process Description and Operation Conditions

In this paper, the performance of the plant is investigated at ISO day condition (15°C, 101.325 kPa, 60% relative humidity). The conditions of natural gas supplied at plant battery limit are 16 bar and 15°C. It is compressed by the fuel compressor to 40 bar. After cooling to 35°C and throttling, it enters the combustion chamber.

The aeroderivative gas turbine consists of a gas generator, a power turbine and an electrical generator. The exhaust gas of the power turbine is used as the waste heat source of the HRSG which is an unfired, natural circulation, three pressure level type. The superheated high pressure steam is delivered to the steam turbine which produces power. Some of that steam is extracted to IP level according to the process steam demand and mixed with steam produced in IP steam drum, the remaining steam is diverted to the condenser. The return condensate from the paper mill has very low quality, hence it is sent to the old system. The return condensate from university (60°C) and raw water enters the demineralisation unit to be treated. It is accepted that approximately 70% of the steam export from combined cycle cogeneration plant returns as condensate. These streams are mixed with the condensate from condenser and the mixture enters the deaerator where it is heated up to the saturation temperature corresponding to the pressure of the LP steam drum and degassed by

means of the saturated steam produced in the LP evaporator. The heated feedwater in the LP drum is removed by the feedpumps and sent to relevant economizers.
In addition to the descriptions above, the plant data used in this study are given in Table 1.

Operation data at ISO ambient conditions	
Gas turbine	
Gas Generator[1]	
Exhaust Temperature	1006.75 K
Exhaust Pressure	359.21 kPa
Power Turbine Isentropic Eff.[2]	0.91
Electric Generator Efficiency	0.98
HRSG[3]

IP Steam Drum Pressure	16 bar
LP Steam Drum Pressure	1.7 bar
HP Pinch Point	11 °C
HP Evaporator Approach Temp.	9 °C
IP Pinch Point	11 °C
IP Evaporator Approach Temp.	9 °C
Steam Turbine	
Inlet Temperature	450 °C
Isentropic Efficiency of Stages	0.70
Electric Generator Efficiency	0.98
Condenser Pressure	0.07 bar
Pumps Isentropic Efficiency [2]	0.80
Steam Export Pressure (Sat. Vap.)	13 bar
Raw Water Temperature	15 °C
Make-up Tank Outlet Temperature	32 °C

[1] Data is obtained from a performance test of the gas generator at ISO ambient conditions.
[2] The values that are assumed.
[3] Pressure drop across HRSG is assumed to be 5%, heat loss to environment is assumed to be 2% of heat absorbed and blow down requirements are not taken into account.

Table1: Operation data of the plant at ISO ambient conditions

ENERGY ANALYSIS

The aim of the energy analysis in this study is to determine the thermodynamic properties of the plant such as; electrical output of the plant, enthalpy difference of process, mass flow rate of steam generated at steam drums and stack gas temperature, etc. Besides, performance assessment parameters related to energy analysis are investigated for different steam demands.
For ideal gases, formulations in [1] is used which takes into account the variation of enthalpy and absolute entropy with temperature for various substances. For water, steam tables at [9] are used.
In this paper, gas generator is treated as a single unit. The exhaust gas composition is calculated by using the available data which gives mass flow rates at several points including the bleeding and cooling mass flow rates which are represented by the dashed lines in Figure 1 under the gas generator and using the combustion equation. Fuel (natural gas) is taken as methane in the combustion equation.
Ambient air molar analysis, considering relative humidity, is taken as: 78.18% N_2, 20.78% O_2, 1.01% $H_2O_{(g)}$, 0.03% CO_2. Exhaust gas composition of the gas turbine is found as: 75.85% N_2, 14.19% O_2, 6.95% $H_2O_{(g)}$, 3.01% CO_2.

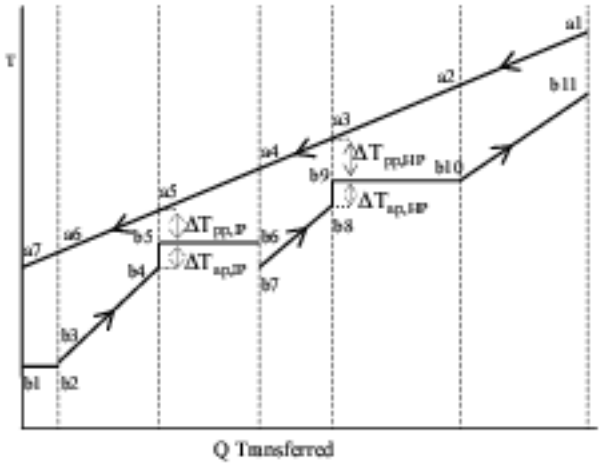

Figure 2: HRSG temperature profile

Mass flow rate of the steam generated at the HP steam drum is calculated by applying an energy balance around the HP evaporator and the HP superheater stages.

$$\dot{m}_1 = \dot{m}_E \cdot [(1-hl)\cdot(h_{a1}-h_{a3})/(h_{b11}-h_{b8})] \quad (1)$$

Mass flow rate of saturated steam generated at the IP steam drum is calculated by using an energy balance around the IP evaporator.

$$\dot{m}_6 = \dot{m}_E \cdot [(1-hl)\cdot(h_{a4}-h_{a5})/(h_{b6}-h_{b4})] \quad (2)$$

where h_{a4} is calculated from an energy balance around the HP 2nd economizer:

$$h_{a4} = h_{a3} - [\dot{m}_1 \cdot (h_{b8}-h_{b7})] / [(1-hl)\cdot \dot{m}_E] \quad (3)$$

Stack gas should be calculated due to corrosion considerations. From the energy balance in the LP evaporator, we have

$$h_{a7} = h_{a6} - \left[\dot{m}_{l5} \cdot (h_{b2} - h_{b1})\right] / \left[(1 - hl) \cdot \dot{m}_E\right] \quad (4)$$

where h_{a6} is calculated from the energy balance around the HP 1st economizer and the IP economizer, $\dot{m}_{l5}$ may be calculated from an energy balance around the deaerator as follows.

$$h_{a6} = h_{a5} - \left[(\dot{m}_1 + \dot{m}_6) \cdot (h_{b4} - h_{b3})\right] / \left[(1 - hl) \cdot \dot{m}_E\right] \quad (5)$$

and

$$\dot{m}_{l5} = \dot{m}_{l4} \cdot (h_{b1} - h_{l4}) / (h_{b2} - h_{b1}) \quad (6)$$

After calculating h_{a7}, T_{a7} is calculated by iteration. It should be checked whether stack gas temperature is greater than 400 K.

Electrical output of the plant may be given as

$$(\dot{W}_{el})_{plant} = (\dot{W}_{el})_{GT} + (\dot{W}_{el})_{ST} - (\dot{W}_{el})_{consum.} \quad (7)$$

Enthalpy difference of the process may be given as

$$\Delta\dot{H}_{process} = \dot{m}_9 \cdot h_9 - \dot{m}_{10} \cdot h_{10} - \dot{m}_{11} \cdot h_{11} \quad (8)$$

Performance assessment parameters for cogeneration systems are described in [6]. Among these parameters, fuel utilization efficiency is the most widely used one. However, power-to-heat-ratio and exergetic efficiency are the most useful parameters. Moreover, exergetic efficiency is the most meaningful and logical parameter which is discussed in the exergy analysis section.

Results of energy analysis

Although kinetic and potential energy effects are ignored and some assumptions are done, the results are compared with that of the monitoring system of the plant which gives mass flow rate, temperature, electrical output, etc. of some key points and it is found that the results are in good agreement. Stack temperature is about 130°C and this does not vary significantly with the steam demand. Also, this is a safe value when corrosion effects are considered. Other results are given in Figure 3 and Figure 4.

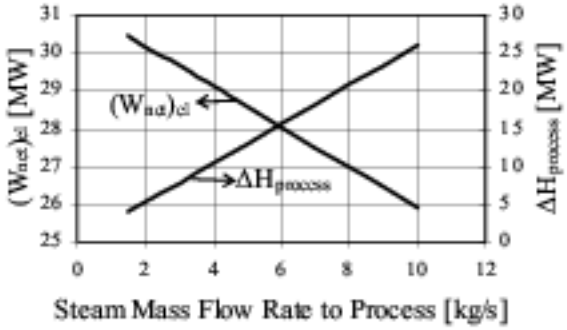

Figure 3 : Variation of outputs of the system with the process steam mass flow rate

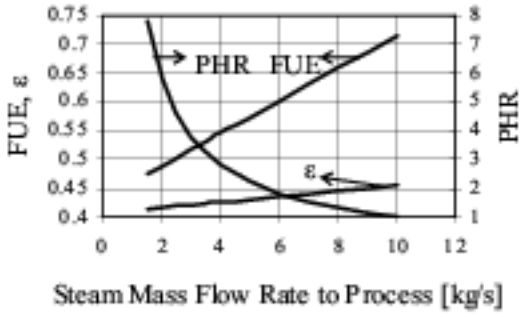

Figure 4 : Variation of system performance parameters with process steam mass flow rate

EXERGY ANALYSIS

For exergy analysis, a complex system is seperated into several subsystems. Exergy inflows and outflows to these subsystems, exergy destruction in these subsystems and exergy losses to the environment are calculated.

The steady state form of control volume exergy balance is

$$0 = \sum_j \left(1 - \frac{T_o}{T_j}\right) \cdot \dot{Q}_j - \dot{W}_{cv} + \sum_i \dot{m}_i \cdot e_i - \sum_e \dot{m}_e \cdot e_e - \dot{E}_{DEST} \quad (9)$$

Specific exergy consists of physical specific exergy and chemical specific exergy. Formulations of these terms may be found in [1,2].

Exergy balances applied to control volumes (subsystems) in this study are given in Table 6.

Exergetic efficiency of the plant may be given as

$$\varepsilon_{plant} = \frac{(\dot{W}_{net})_{el} + (\dot{E}_9 - \dot{E}_{10} - \dot{E}_{11})}{\dot{E}_A + \dot{E}_{11} + \dot{E}_{23}} \quad (10)$$

Results of exergy analysis

Exergy destructions in the subsystems shown in Table 6 are given in Table 2 for 15 t/h process steam. Exergy flow rates are given in Table 5. Process steam demand change does not affect significantly the exergy destruction ratios except steam turbine. To illustrate, y_D^* decreases from 7.8% to 2.7% as steam flow to process changes from 1.5 kg/s to 10 kg/s.

Exergy losses due to heat losses in the gas generator and the HRSG, and exergy losses due to the cooling tower and the natural gas cooler exit streams are considered as zero by taking the control volumes large enough so that the heat losses occur at the ambient temperature and the exit streams mix with the ambient air. Hence, the only exergy loss is due to the HRSG exit. It is found as 3054 kW which is 3.96% of the exergy supplied to the plant.

Control Volume#	$\dot{E}_{DEST}$ [kW]	y_D [%]	y_D^* [%]
1	307	0.40	0.75
2	30590	39.74	74.53
3	1394	1.81	3.40
4	3390	4.40	8.26
5	2574	3.34	6.27
6	2549	3.31	6.21
7	167	0.22	0.41
8	30	0.04	0.07
9	2	0.00	0.01
10	41	0.05	0.10

Table 2: Exergy destruction and relevant ratios at 15 t/h steam flow to process

It is seen from Table 2 that the largest portion of exergy destruction occurs in control volume 2 (gas generator), mainly because of combustion process. Exergy destructions in control volume 4 (HRSG); control volume 5 (steam turbine), control volume 6 (condenser + cooling tower + condensate pump), control volume 3 (power turbine) and others follow it, respectively.

From Figure 2, it can be observed that exergetic efficiency varies a little with the steam demand.

ECONOMIC ANALYSIS

The aim of economic analysis in this study is to provide necessary inputs to be used in the thermoeconomic analysis. These inputs are the levelized cost rates associated with capital and operation and maintenance expenses for components of the plant and the levelized cost rates of the expenditures (i.e. fuel costs, raw water costs) supplied to the overall system. Although fuel costs and raw water costs may be seen as a part of O&M costs, they should be treated seperately.

If money transactions occur at the end of each year within the plant economic life, for any cost component, X (i.e.carrying charges, fuel cost, etc.), levelized cost can be shown as [4]

$$X_L = CRF \cdot \sum_{j=1}^{n} \frac{X_j}{(1+i_{eff})^j} \qquad (11)$$

$$CRF = \frac{i_{eff} \cdot (1+i_{eff})^n}{(1+i_{eff})^n - 1} \qquad (12)$$

Cost rate associated with the capital and operation and maintenance expenses for the kth component:

$$\dot{Z}_k = \frac{CC_L}{\tau} \cdot \frac{PEC_k}{\sum_k PEC_k} + \frac{OMC_L}{\tau} \cdot \frac{PEC_k}{\sum_k PEC_k} \qquad (13)$$

The first term in (13) gives $\dot{Z}_k^{CI}$ and the second term gives $\dot{Z}_k^{OM}$.

Levelized cost rate of an expenditure (fuel, raw water) supplied to the overall system is

$$\dot{C}_{EX} = \frac{EXC_L}{\tau} \qquad (14)$$

The economical data needed to calculate cost rates are obtained from Bilenerji A.S., the company that operates the plant. The plant is started its commercial operation at the beginning of 2000. For its entire economic life, 25 years, year by year data for carrying charges prepared by the company is obtained. Operating and maintenance, fuel and raw water costs for the past years are obtained from company, local natural gas and raw water suppliers. For the future years; these expenditure costs are escalated using average nominal escalation rates of costs. In this study, these escalation rates of costs are taken as the estimated average general inflation within the plant economic life, which is 3% in U.S. Dollars. Besides, for operating and maintenance costs, there is an extra overhaul cost which is 0.85 M$ in the third year and 1.75 M$ in the sixth year of every six year periods. Effective annual cost-of-money rate is taken as 10%. Total number of hours of system operating at full load is taken as 8200 hours. Total capital investment of the plant is 27.8 M$.

Results of economic analysis

Levelized costs are calculated by using purchased equipment costs and year-by-year analysis. Results are given in Table 3 and Table 4, respectively.

Levelized Costs	CC_L	OMC_L	FC_L	RWC_L
$10^3 \times \$$	4139	2826	13362	1023

Table 3: Levelized costs of cost components

Other Comp.	2.10	56	38	94

Table 4: Purchased equipment costs and levelized costs for the components of the plant.

Gas turbine system is sold as one unit, and prices of its subcomponents are not available. However, to obtain more accurate results from thermoeconomic analysis, gas generator and power turbine are considered seperately. Hence, it is assumed that power turbine and its electricity generator has a price of 2 M$ and gas generator 7 M$, respectively. Levelized costs are shared according to this assumption.

Levelized cost rate of fuel is calculated as 1629 $/h and that of raw water as 119 $/h.

THERMOECONOMIC ANALYSIS

The objective of the thermoeconomic analysis in this study is to understand the cost formation process and to calculate the cost of each product generated by the plant.

Aggregation level influences the accuracy of the results, hence it is taken low enough. Discussions on aggregation level may be found in [1,8].

Cost balance is applied to each subsystem. Auxiliary equations are applied by using fuel and product rules[3]. Hence, a set of linear equations are formed and solved.

The steady-state form of control volume cost balance is

$$\sum_{j=1}^{n} \dot{C}_{j,k,in} + \dot{Z}_k = \sum_{j=1}^{m} \dot{C}_{j,k,out} \qquad (15)$$

$$\dot{C}_j = c_j \cdot \dot{E}_j \qquad (16)$$

Results of thermoeconomic analysis

Cost formation in the plant for 15 t/h process steam flow is given in Table 5. It can be observed that the highest cost is achieved at state F, which is the exit of gas generator. Costs of states D, A, and others follow it, respectively. On the other hand, the highest cost per unit exergy is seen at state 5.

Cost rate of products, $\dot{C}_9$ and $\dot{C}_{Wast}$ are calculated by cost balances. Then, cost rate associated with other plant equipment and exergy loss in the plant should be apportioned between products as discussed in [1]. Figure 5 shows the final cost rates of products for different process steam flows.

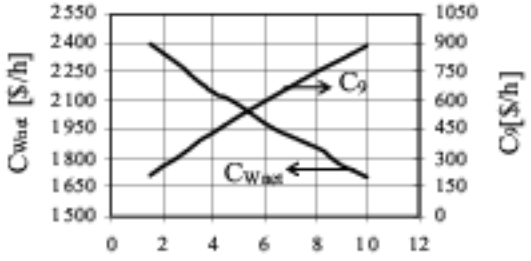

Fig. 5: Variation of cost rate of products with steam mass flow rate to process

CONCLUSIONS

This study points out the thermodynamic inefficiencies, cost formation and cost of products of the plant. The plant owner may maintain an opinion for future improvements of the plant and check the plant's economic policy. Besides, the methodology and results of this paper can be beneficial in the analysis and design of similar systems.

The results of the thermoeconomic analysis can be improved if seperate forms of total exergy of streams (e.g., physical and chemical exergies) are used. However; this increases the number of equations significantly and it is not very useful for the purpose of this study.
The results of the present study can be used as a basis for thermoeconomic optimization.

ON THE OFF-DESIGN OF A NATURAL GAS-FIRED COMBINED CYCLE WITH CO_2 CAPTURE

Björn Fredriksson Möller*, Magnus Genrup, Mohsen Assadi
Lund Institute of Technology
Department of Heat and Power Engineering
P.O. Box 118, SE-221 00 Lund, SWEDEN

ABSTRACT

During the last 15 years cycles with CO_2 capture have been in focus, due to the growing concern over our climate. Often a natural-gas fired combined cycle with a chemical absorption plant for CO_2 capture from the flue gases have been used as a reference in comparisons between cycles. The integration of the steam production in the cycle to minimise the drop in efficiency have not been extensively studied. Neither have there been any studies on the off-design behaviour of such a plant if it should be built.

In this paper the integration of steam production for regeneration of the amines is modelled at design load and studied in off-design conditions for a combined cycle. Different ambient conditions and part-load strategies and their influence on the cycle performance are also examined. Of particular interest is a novel strategy with the possibility of longer life of gas turbine blading, with marginal loss in efficiency.

The off-design performance of the combined cycle is modelled in a rigorous way, using a gas turbine performance deck to calculate the performance of the gas turbine. The boiler is calculated using simplified correlations for off-design heat transfer and pressure drop. The steam turbine calculation is based on verified models for the flow – pressure – efficiency relations, whilst the steam condenser is based on the HEI (Heat Exchange Institute) method.

INTRODUCTION

Fossil fuels are the dominant source of global energy demand and will most likely remain so for another century [1]. Recent statistics by International Energy Agency show that 87% of the worlds energy supply originates from fossil fuels [2]. The interest in combined cycles with high efficiency, especially those with CO_2 capture, is therefore understandable. Numerous studies and research projects are either ongoing or finished in the large research field of CO_2 capture [3], but still only small applications where the CO_2 is needed anyhow has been built. Few reports have been made on the integration of capture in the power plant, and there seem to be little to gain in terms of heat recovery from the capture plant to a combined cycle [4].

Part-load behaviour of these cycles have to the authors knowledge not been studied at all, but they are likely to behave like a normal combined cycle. These have been modelled in part-load with different control strategies by Kim [5], and dynamic studies have been performed by Shin et al. [6].

CYCLE LAYOUT

As a reference basis a combined cycle based on the gas turbine GE PG9351FA has been chosen. This will also simplify comparisons with other concepts as a benchmarking study has previously been performed by SINTEF/NTNU on different gas turbine cycles using this gas turbine [7]. The combined cycle is a triple-pressure reheat steam cycle with steam pressure levels chosen at 111/27/3.2 bar, where the lowest pressure corresponds to a condensation temperature of 135°C in the reboiler section of the CO_2 capture plant. Steam is extracted from the LP section of the steam turbine and returned to the high pressure feedwater circuit. A schematic process layout of the cycle with the MEA-based CO_2 capture system is shown in Figure 6. The post-combustion capture plant is based on the calculation model by Kohl and Nielsen [8] with the heat requirement for regeneration of MEA set to 4.9 MJ/kg CO_2, a figure representative for an optimised MEA plant with 3% CO_2 in the exhaust gas [9]. The CO_2 compressor work in kJ/kg is approximated by equation (1) [10].

$$W_{CO_2} = -120 \ln\left(p_{CO_2}\right) + 369 \qquad (1)$$

The design case input data can be seen in Table 1.

Parameter	Value	Unit
Steam turbine efficiency HP/IP	0.92	-
Steam turbine efficiency LP	0.89	-
Condenser pressure	0.04	bar
Deaerator pressure	1.2	bar
Fan pressure increase	0.06	bar
HRSG pressure drop	0.04	bar
Evaporator pinchpoint	10	°C
Economiser pinchpoint	20	°C
Approach point	5	°C
Steam superheating temperature (SHT)	560	°C
Steam reheat temperature	560	°C
Stator outlet temperature (SOT)	1328	°C
Pressure ratio	15.4	-
Air mass flow	611	kg/s
Exhaust gas temperarure (EGT)	617	°C
MEA heat demand	4.9	MJ/kg CO_2
Amine regeneration temperature	120	°C

OFF DESIGN MODELLING

The basic off-design modeling of a combined cycle comprises three models. The first one is the gas turbine off-design model or "performance deck", the second one is the heat recovery steam generator (HRSG) and the third one is the steam turbine model. In this work, all three are combined into a single model. The used platform is the commercially available heat- & mass balance software IPSEpro. The basic "built in" models were changed to a set of models developed at Lund University [11] and [12]. In this paper, however, the models will be described separately for clarity.

Gas turbine

The gas turbine model or performance deck is based on component matching. The standard approach is to use component characteristics, and solve the matching equilibrium. The matching equilibrium is, loosely stated, when the operational point is fulfilling e.g. geometry, speed and work balance. The calculation is highly iterative and the necessary loops are numerous. Therefore, the use of a matrix type equation solver speeds up the solution procedure. The model contains additional advanced features like a bellmouth condensation model in connection to the bellmouth pressure drop.

The modeled gas turbine is the GE Power System PG9351FA. The model was adapted to open literature performance data and details regarding e.g. secondary air system and component performance, was estimated. The exact details of the unit are proprietary and not known to the authors. The estimates are, however, in the range that can be expected for a heavy frame unit of this size. The overall performance at design load is the one found in the open literature. One further limitation in the model is the use of a generic compressor and turbine characteristics.

The compressor is modeled with a non-dimensional compressor map. This approach gives the possibility to use the same compressor behavior regardless of compressor. Providing design levels parameterizes the map, where values of unity represent design values of: normalized flow, efficiency, pressure ratio and aerodynamic speed. Variable geometry (e.g. IGV and VSV's) is introduced by the use of influence coefficients.

$$\dot{m}^*_{rel} = \dot{m}^*_{rel,CHIC}\left(1+\frac{a_{IGV}}{100}\Delta\xi\right),\ a_{IGV} = \frac{\delta\left(\dot{m}^*_{rel}\right)}{\delta\left(\Delta\xi\right)} \qquad (2)$$

$$\pi_{rel} = \pi_{rel,CHIC}\left(1+\frac{b_{IGV}}{100}\Delta\xi\right),\ b_{IGV} = \frac{\delta\left(\pi_{rel}\right)}{\delta\left(\Delta\xi\right)} \qquad (3)$$

$$\eta_{rel} = \eta_{rel,CHIC}\left(1+\frac{c_{IGV}}{100}\left[\Delta\xi\right]^2\right),\ c_{IGV} = \frac{\delta(\eta_{rel})}{\left\{\delta(\Delta\xi)\right\}^2} \quad (4)$$

The used compressor characteristic (CHIC) is based on a published industrial compressor map [13]. The compressor bellmouth- and diffuser pressure drop is modeled as a standard fix geometry pressure drop:

$$\frac{\Delta p_0}{p_0} = \alpha \cdot \left(\frac{\dot{m}\sqrt{T_0}}{p_0}\right)^2 \quad (5)$$

A thermodynamic bellmouth condensation model is included into the model. Bellmouth condensation is due to the depression in the bellmouth and the normal ambient humidity. This model is based on a thermodynamic equilibrium, with an influence factor of one half. The effect of bellmouth condensation is release of latent heat and a corresponding increase in total temperature before the compressor. The loss in output is mainly due to lost flow, and to some extent increased work input to the first stage.

The combustor section is modeled with custom methods. The pressure drop is divided into a cold (friction and dump) and the hot or fundamental:

$$\frac{\Delta p_{0,cc}}{p_{0,in}} = \left(\frac{\dot{m}_{in}\sqrt{T_{0,in}}}{A_{cc}\ p_{0,in}}\right)^2 \left[K_C + K_H\left(\frac{T_{0,out}}{T_{0,in}} - 1\right)\right] \quad (6)$$

The combustor heat leak is assumed to be a fix fraction of the fired heat. This loss also includes heat leakage from all hot section. The reason for lumping all heat leaks into a single source is to simplify e.g. the turbine efficiency.

Heat recovery steam generator

The heat recovery steam generator (HRSG) is modelled in components rather than e.g. individual tubes in different boiler sections. This approach simplifies the HRSG calculation to: (a) convective heat transfer correlations for sections and (b) section pressure drop characteristics. The details of the methods are not presented here and the reader is referred to standard textbooks for further information [14].

Steam turbine

The steam turbine model is based on a part turbine methodology. In this approach, a number of turbine stages are lumped to a group or part turbine. Each of these turbines is principally described by two parameters: efficiency and swallowing capacity. The efficiency (isentropic) is defined as:

$$\eta_s = \frac{\Delta h_0}{\Delta h_{0,s}} = \frac{h_{0,in} - h_{0,out}}{h_{0,in} - h_{0,s,out}} \quad (7)$$

For a group of stages, the efficiency is normally correlated against the Parson number. The Parson number normally replaces the isentropic velocity ratio, used for single stages, when dealing with part turbines. The Parson number is normally defined as:

$$\mathrm{X} = \frac{\sum u^2}{\Delta h_s} \quad (8)$$

It is very convenient to correlate the relative efficiency versus relative Parson number [15]. A further simplification is then evident; the sum of the blade speeds squared cancels out, since the rotation speed is unchanged. This gives a correlation for turbine section dry efficiency[†] versus isentropic heat drop only:

$$\eta_{s,act}^{dry} = \eta_{s,des}^{dry} \cdot f\left(\frac{\Delta h_{s,des}}{\Delta h_{s,act}}\right) \quad (9)$$

A *caveat* is in order, the use of standard parabolic efficiency correlations, may result in erroneous results. One typical reason for this is supersonic flow in e.g. control stages below some 50 percent load. Normally, all part turbines, except for an eventual control stage (partial arc admission) and the last stage or last partial turbine, are operated with more or less the same isentropic heat drop.

The swallowing capacity or flow – pressure – relation is used to calculate the node pressures. The pressure at each node sets the heat drop distribution through the turbine train. The probably most widely used model is the one evolved from Stodola's "cone law":

$$\dot{m}_{i-j} = C_{T,i\to j}\sqrt{\frac{p_i^2 - p_j^2}{p_i\ v_i}} = C_{T,i\to j}\sqrt{\frac{p_i}{v_i}}\sqrt{1 - \frac{1}{\left(p_i/p_j\right)^2}} \quad (10)$$

The equation above shows that the flow is directly proportional to the pressure and inversely proportional to the temperature. The model derived from Stodola is, however, known to be quite

[†]Wet efficiency is calculated according to the standard Baumann approach: $\eta_{wet} = \eta_{dry}\left(1 - a\bar{y}\right)$

erroneous on choked highly loaded sections (e.g. control stages) [16]. Instead, in this work, the model by Beckmann is used. The Beckmann correlation is more intricate and the reader is referred to the original source [17] for comprehensive information. A comparison between the models is shown in Figures 2 and 3.

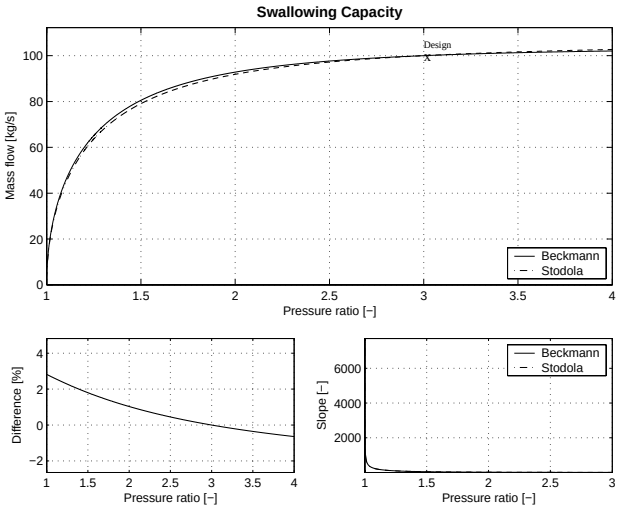

Figure 2: Comparison between the Stodola cone law and the more advanced Beckmann model for modest loaded blades (stage pressure ratio approx. 1.25)

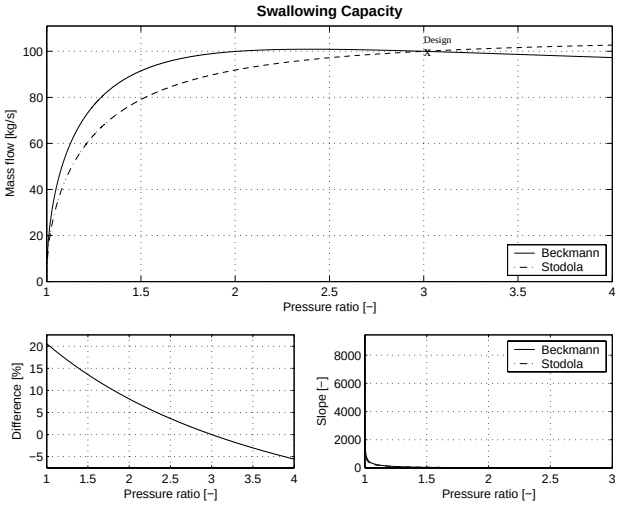

Figure 3: Comparison between the Stodola cone law and the more advanced Beckmann model for highly loaded blades (stage pressure ratio approx. 3)

This type of correlations results in a numerical problem, when transforming and using the Jacobi-matrix in the solving procedure. If one, assume constant inlet condition to the section, then the partial derivate of the expression above yields:

$$\dot{m} \propto \sqrt{1-\frac{1}{\pi^2}} \quad \rightarrow \quad \frac{d\dot{m}}{d\pi} \propto \frac{1}{\pi^2\sqrt{\pi^2-1}} \qquad (11)$$

Hence, a singularity when the pressure ratio is close to unity. This problem is solved by abandoning the equation from the system, when the section pressure ratio is below 1.001.

The exhaust loss is calculated according to the procedure in DIN 1943 [18].

The condenser performance/heat transfer coefficient is calculated according to the method developed by Heat Exchange Institute (HEI) [19].

The model has been evaluated against two real power plants and the results are well within the expectations. In both cases, the model has been calibrated against the full load cases (test code performance tests). The comparison has been done at part load cases [11]. Both plants were condensing units and the precision in calculation of e.g. the final feed water temperature was in the order of 1°C/2°F. Additional tests were carried out and the model was used to e.g. calculate the impact of removing the top heater out of service with its resulting decrease in admission flow.

CO_2 capture system

The part-load model of the CO_2 capture system is in this work limited to pressure drop correlations scaling the pressure drop to changes in massflow and velocity squared through the absorber and desorber, simulating constant geometry. The regeneration temperature and the MEA heat demand is kept constant (proportional to the moleflow of captured CO_2), while the amine overcirculation rate is varied.

OPERATIONAL STRATEGIES

Three different operational strategies have been tested for the cycle configuration. The first strategy includes a simple decrease in firing temperature which in the model corresponds to a decreasing Stator Outlet Temperature (SOT), called '*SOT decrease'* strategy. The second strategy, called '*High EGT'* strategy is a bit more complicated because it includes three different steps. In the first regime the Inlet Guide Vanes is closed with unchanged SOT. This proceeds until the Exhaust Gas Temperature (EGT) reaches 630°C, when the second regime starts. In the second regime the IGVs continue to close and the SOT is decreased with unchanged EGT. When the IGVs are fully

closed (-25°), a continued decrease in SOT also causes a decrease in EGT. Finally as a third strategy, a novel strategy called *'Constant SHT'* is introduced. Here the second regime is dictated by a constant steam superheating temperature (SHT) of maximum 565°C. This would avoid unnecessary temperature stress on the gas turbine blading and non-optimal spray cooling of steam in the superheater/reheater. The difference between the two last strategies can be seen in Figure 4 where the dotted area is cooled in the '*High EGT'* strategy.

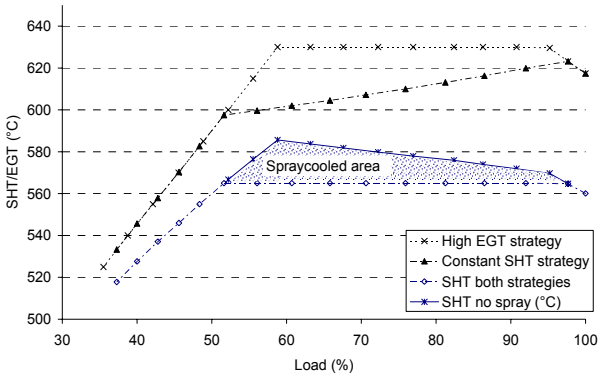

Figure 4: Difference between '*High EGT'* and '*Constant SHT'* strategies

The lowest steam pressure level is kept constant during part-load operation with variable guide vane stagger varying the swallowing capacity of that part turbine. The use of variable stagger is a powerful means to achieve a controlled extraction and one degree re-stagger typically results in five percent change in capacity. This is introduced to keep the temperature level in the regeneration part of the CO_2 capture plant high enough for efficient operation.

Two different ambient conditions have also been evaluated; a 'cold' condition with an ambient temperature set to -5°C and a 'hot' condition set to 35°C.

RESULTS AND DISCUSSION

Design case

The modelled cycle shows a design electrical efficiency of 48.6% and a gross power output of 346.5 MW, slightly higher than the SINTEF/ NTNU study which showed an efficiency of 48.1% [7]. The difference lies probably within the different assumptions for CO_2 compression and amine regeneration heat demand. Auxiliary power losses sum up to 19.2 MW in this study, more than half of it originating from the CO_2 compression.

If one wants to further improve the models using steam turbine data from GE, additional information is available in the excellent textbook by Ken Cotton "Evaluation and Improving Steam Turbine Performance" [20]. This source gives exhaustive information about General Electric's steam units. The presented material in this book is still valid with proper vintage corrections.

Part-load behaviour

The electrical efficiency resulting from the three different part-load strategies can be seen in Figure 5. The '*High EGT'* and *'Constant SHT'* show as expected the same efficiency in the first and third regime, both approximately three percentage point higher than the '*SOT decrease'* strategy below 50% load. However, the difference between the two high temperature strategies in the second regime is very small, at maximum 0.3 percentage points. It should be possible to avoid using the exergetically non-optimal spraying with only small losses in efficiency.

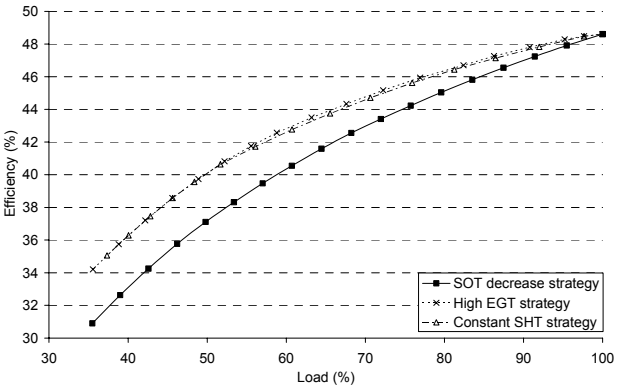

Figure 5: Electrical efficiency with different operational strategies at part-load

Furthermore, if looking into Figure 6 it is apparent that the decrease in SOT between the *'High EGT'* strategy and the *'Constant SHT'* strategy will result in longer life for the gas turbine blading.

The difference in SOT is about 20°C at 75% load and 30°C at 60% load which could be translated into terms of lifing by using the Larson-Miller parameter [21]. It is difficult to estimate the difference in lifing without details of the specific

gas turbine and its flow path. In order to get a better value it is nessecary to perform a detailed blade-to-blade analysis or 3-D CFD together with the blade cooling model [21]. However, with the use of the Larson-Miller parameter the mentioned reductions can be translated to more than a factor two in terms of lifing. This figure is conservative and a more exact evaluation should probably render in a higher figure.

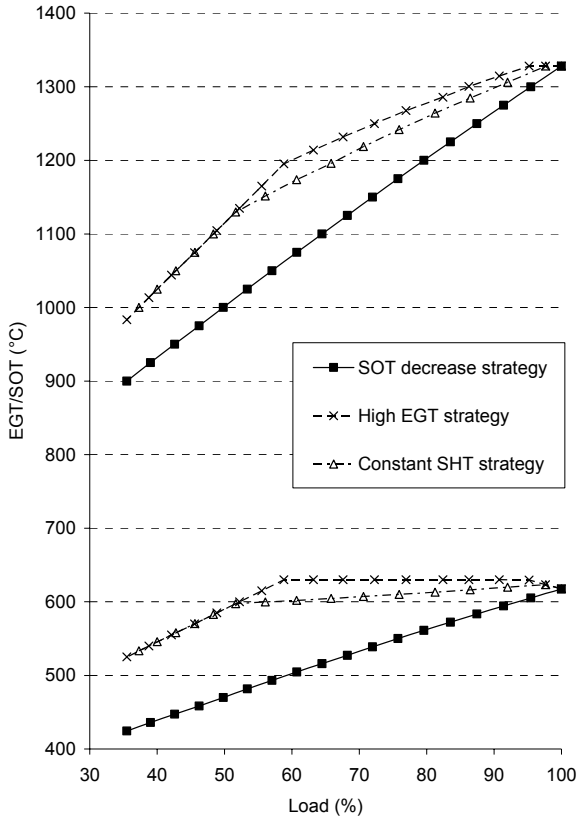

Figure 6: Difference in EGT and SOT with different operational strategies at part-load

Ambient conditions

The performance of the combined cycle at different ambient conditions behaves as expected, see Table 2. Cold ambient conditions are beneficial for power output and results in a modest increase in efficiency, whereas warmer conditions cause large decrease in both power output and efficiency. The two hot off-design strategies can be applied also to the warm ambient conditions, and in this case the '*Constant SHT'* strategy seems less attractive. The '*High EGT'* strategy shows both higher power output and efficiency at the given condition. This suggests that the novel '*Constant SHT*' strategy is more beneficial further away from the design point than close.

	'Cold'	'Hot'		Unit
Strategy		**High EGT**	**Constant SHT**	
Gross power	374.1	305.5	292.9	MW
Auxiliary power loss	20.9	17.1	16.7	MW
Net power	353.2	288.4	280.0	MW
Efficiency	48.59	47.87	47.28	%
EGT	604.3	630	618.6	°C
SOT	1328	1308	1283	°C
SHT	550.2	565	565	°C

Table 2: The influence of ambient conditions on cycle performance

CO_2 capture at off-design operation

With the assumed variable geometry in the low pressure section of the steam turbine no difficulties were experienced with the CO_2 capture plant model used. The lower CO_2 concentration in the exhaust gas flow was not reflected with higher energy demand in the capture plant, as probably would be the case [9]. This could possibly be out-weighed by changes in the heat transfer conditions in the reboiler section of the capture plant, with decreased pinchpoint etc. A more refined model of the CO_2 plant in off-design is probably needed to further evaluate this section of the power plant, and should be the subject of future work.

CONCLUSIONS

The off-design performance of a triple-pressure reheat combined cycle with post-combustion CO_2 capture has been evaluated. Three different strategies for part-load operation were tested, one of them being proposed by the authors as the '*Constant SHT*' strategy. All results presented are also relevant for a conventional combined cycle without CO_2 capture, although at a higher level of electrical efficiency.

The proposed strategy has a potential of significantly reducing the firing temperature with a marginal efficiency penalty. In order to make a "ball park" estimate, the Larson-Miller parameter can be used to give a quantitative estimation. The gain for a fix-speed unit with constant centrifugal loading is, with a conservative estimation, in the order of two. It should however be mentioned that

the discussed lifing is the first rotor creep and does not take into account e.g. oxidation of blades.

The results reveal no problem with the CO_2 capture system at part-load. During the calculations the low-pressure steam pressure was held constant, by means of a standard controlled extraction.

ACKNOWLEDGMENTS

The work presented in this paper is the result of many parallel research projects. The off-design model for gas turbines was developed as a general in-house calculation tool; the work was funded by Swedish Gas Center. Most of the actual programming was performed by Marco Lorentz. The steam cycle model was developed in the framework of the "GTX100 Helsingborg evaluation project." This work was also funded by Swedish Gas Center. The authors acknowledge Markus Truedsson for his work in programming and validation of the steam cycle models. The financial support from Sydkraft on CO_2 capture is also gratefully acknowledged.

ABSTRACT

Conventional power plants based on fossil fuel without CO_2 capture produce flue gas streams with concentrations of CO_2 between 3% and 15%, contributing to the threat of increasing global warming. Existing capture technologies such as post-combustion flue gas treatment using chemical absorption or pre-combustion carbon removal suffer from significant efficiency penalties as well as major increase in investment costs. Alternatively, combustion in O_2/CO_2 atmospheres also requires expensive and energy-consuming oxygen supplies.

A less energy intensive concept for oxygen production is a Mixed Conducting Membrane (MCM) reactor which produces pure oxygen from compressed air. The MCM reactor is best integrated into a conventional gas turbine combined cycle, called Advanced Zero Emissions Plant (AZEP), to provide an efficient and cost-effective power plant altogether.

In this paper the economic performance of four different combined cycle alternatives in two different gas turbine sizes are evaluated; a 50 MW_e size based on the Siemens SGT800 gas turbine and a 400 MW_e size based on the Siemens SGT5-4000F gas turbine. The evaluated combined cycles are one conventional combined cycle, one combined cycle with post-combustion CO_2 capture and two optimised AZEP cases from a previous thermodynamic study. One AZEP alternative provides 100% CO_2 capture and is thus a true zero emissions alternative, whereas the second alternative uses a sequential combustion system which enables 85% of the CO_2 to be captured, making a comparison with traditional post-combustion treatment easier. The results show that the AZEP concept presents a more competitive system in terms of efficiency and economy compared to traditional capture systems.

O&M	Operation and Maintenance

INTRODUCTION

Carbon dioxide has been identified as a major green house gas responsible for a large part of the enhancement of global warming. Combustion of fossil fuels for power generation is one of the main contributors to CO_2 emissions, where flue gas streams contain from 3% (natural gas fired combined cycle) to around 15% (conventional coal fired condensing plant) carbon dioxide by volume.

*Corresponding author: Phone: +46-46-222 4770 Fax: +46-46-222 4717 E-mail: bjorn.fredriksson@vok.lth.se

Capture of CO_2 can be done in several ways, often divided in three main groups as follows.

- The post-treatment of flue gases, which separates the carbon dioxide from the flue gas by means of chemical absorption (most common), membranes, distillation or other techniques [1], [2], [3], [4], [5].
- The second group includes pre-treatment of the fuel, most often seen in coal gasification plants where synthesis gas from the gasification is enriched in hydrogen through the shift reaction. The CO_2 is then removed by physical or chemical absorption [1], [6], [7].
- The third group involves nitrogen-free oxidation, also called oxy-fuel processes, as combustion with pure oxygen in semi-closed systems [8], chemical looping combustion [9], electrochemical reactions in fuel cells [10], [11], [12] or new concepts like AZEP [13], all able of producing an exhaust gas consisting of only water and CO_2.

In none of the groups above the capture is done without great effort. The post-combustion treatment, being the most mature technology, needs a significant part of the energy input to regenerate chemicals used in the process, while in pre-combustion treatment some of the fuel heating value is lost in the decarbonisation. Oxy-fuel processes are also very energy demanding if the oxygen comes from conventional air separation units.

THE AZEP CONCEPT

A less energy intensive proposition is the Mixed Conducting Membrane (MCM) which produces pure oxygen from air. The transport mechanism through the membrane is surface adsorption followed by decomposition into ions. Oxygen ions are then transported by occupying vacancies in the membrane structure. The driving force is partial pressure differences between the air and a sweep stream of recirculated exhaust gas, see Figure 1. Previous work [14] has indicated that the most efficient and cost-effective utilisation of the MCM reactor is its integration into a conventional gas turbine system to produce an Advanced Zero Emissions Power Plant, the AZEP concept.

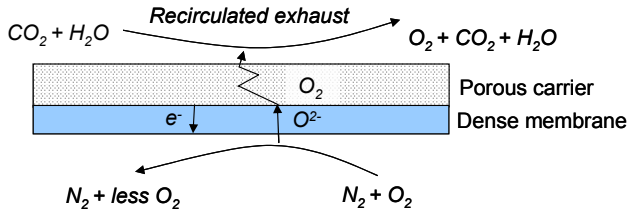

Figure 1: Schematic drawing of the MCM-membrane [14]

The combustion chamber in an ordinary gas turbine is here replaced by the MCM-reactor, which includes a combustor, sections with 'low' temperature heat exchanger (LTHX), MCM membrane and high temperature heat exchanger (HTHX) as well as a bleed gas heat exchanger, see Figure 2.

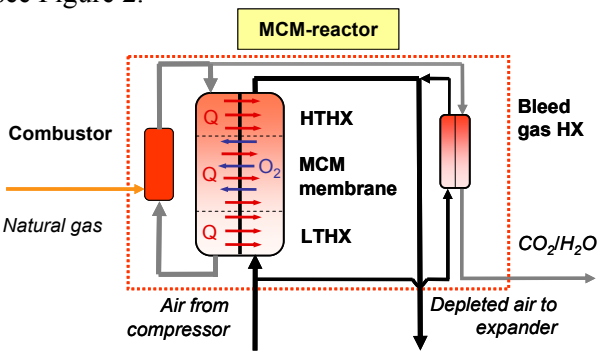

Figure 2: MCM-reactor build-up

SYSTEM BOUNDARIES

The scope of this study is to evaluate the optimal AZEP solutions [15] from a thermo-economic point of view and to compare them to alternative low emission solutions. The comparison must be as fair and transparent as possible, meaning that system boundaries should be identical in all cases. The product CO_2 will be delivered at liquid state at 100 bar for all the modelled cases. No district heating is considered from the different exhaust gas condensers present in some cases. The economic viewpoint is the CCGT plant supplier's, meaning that so called "owner's costs" are not included. Costs like these vary greatly from site to site and are difficult to model without knowledge of the specific site. For CO_2 there is not accounted for any transport or end storage cost, nor is any value assigned to the product CO_2, except the "value" of avoided CO_2 taxation.

SYSTEMS MODELLED

Two sizes of CCGT power plants are studied: a nominal 50 MW_e size based on a Siemens SGT800 (former GTX100) gas turbine and a nominal 400 MW_e size based on a Siemens SGT5-4000F (former V94.3A) gas turbine. The different systems are modelled in the commercial software IPSEpro [16], using model libraries developed within GTPOM; a European Community research project [17].

CCGT based on reference gas turbine

The first system design modelled is a reference system. As such a traditional CCGT power plant is chosen, see Figure 3. Data from such plants are in abundance, both in terms of thermo-dynamical performance used as a base in the modelling, and to some extent also cost data.

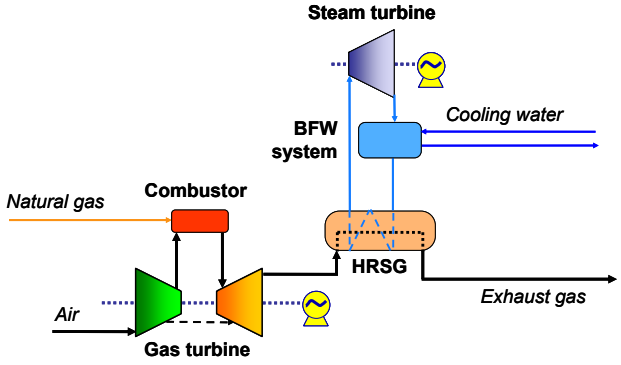

Figure 3: The reference CCGT cycle

The cost models can therefore be calibrated to Siemens CCGT power plant prices and from there extrapolated to all cases, making comparisons fair and objective. For the 50 MW_e case, a dual-pressure HSRG is chosen with live steam at 80 bar(a) and 510°C for the HP steam turbine and for the 400 MW_e case a triple-pressure cycle with reheat is chosen. In this case the live steam data is ~130/30/5 bar(a) and ~560/545/240°C.

The AZEP 100% case

This is a "traditional" type of combined cycle arrangement, but with an MCM-reactor system replacing the traditional combustion chamber. Air is compressed in the gas turbine and is then heated in the MCM-reactor. Due to MCM material and reactor design limitations the MCM-reactor outlet temperature has been restricted to 1200°C, which is considerably lower than the reference CCGT. A percentage of the oxygen contained in the air is transferred through the membrane and is carried along by the CO_2/H_2O sweep gas. The oxygen containing sweep gas is then reacted with natural gas to generate heat in a combustion chamber. A share of the sweep gas is bled off to keep the sweep gas mass flow constant in the MCM-reactor. The heat contained in the bleed gas is recovered in a separate CO_2/H_2O HRSG providing extra steam for the steam cycle and preheating of the natural gas fuel. The heat recovery has to be terminated at a higher temperature than in the ordinary HRSG due to the high water content in the bleed gas. After the HRSG the water is condensed and the remaining CO_2 is compressed from the MCM-reactor pressure at around 20 bar to delivery pressure at 100 bar. A layout of the AZEP 100% cycle is shown in Figure 4.

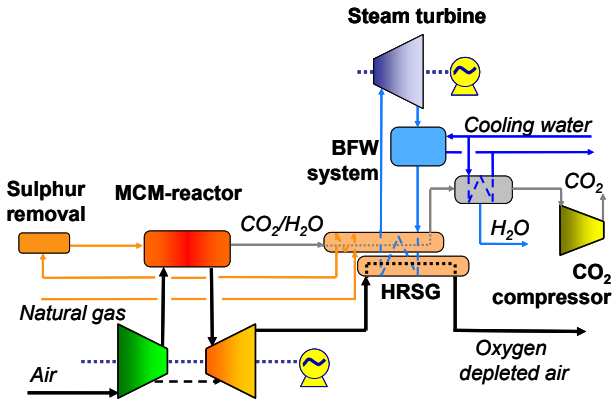

Figure 4: The AZEP 100% case

Compared to the reference system the power output is significantly reduced due to the lower turbine inlet temperature reducing gas turbine output, but also due to the lower exhaust gas temperature reducing steam production in the steam cycle. In the 400 MW_e case it is not feasible to sustain the triple-pressure reheat steam cycle from the reference case due to the low exhaust gas temperature. A dual-pressure steam cycle is therefore considered both for the 50 MW_e and the 400 MW_e case in the AZEP 100% case.

The AZEP 85% case

The third alternative, the AZEP 85% case, includes a sequential combustion chamber to increase the turbine inlet temperature. This is to improve the thermal performance of the MCM based power plant. Figure 5 shows a power plant including a sequential burner increasing the

turbine inlet temperature to 1327ºC on the air-side using natural gas as fuel.

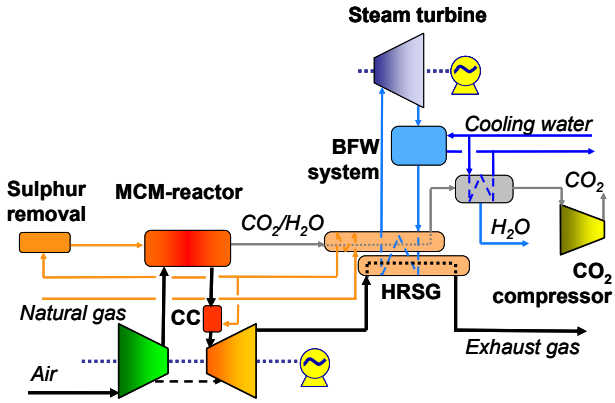

Figure 5: The AZEP 85% case

This concept is not a "pure" AZEP concept since the sequential burner will add CO_2 to the exhaust gas stream and thereby reduce the degree of CO_2 capture to 85%; a figure comparable to what is achievable in traditional amine-based CO_2 capture systems. Power plant efficiency and power output will however increase due to the higher temperature level. In this case the 50 MW_e case is modelled with a dual-pressure steam cycle with a HP steam temperature of ~500°C. The 400 MW_e alternative is modelled with a triple-pressure steam cycle with live steam data at ~130/30/5 bar(a) and ~510/485/240°C.

CCGT with CO_2 capture using MEA

The last system design modelled is the reference system with a traditional amine-based CO_2 capture system. In this case steam data is the same as for the reference system, although steam is extracted from the LP steam turbine to provide the energy needed to regenerate the amines. This steam is condensed in the reboiler section of the CO_2 capture plant and then pumped back to the steam cycle. A schematic process layout of the CCGT with an amine-based CO_2 capture system is shown in Figure 6, hereafter called the MEA 85% case. Assumptions for the CO_2 capture plant can be seen in Table 1.

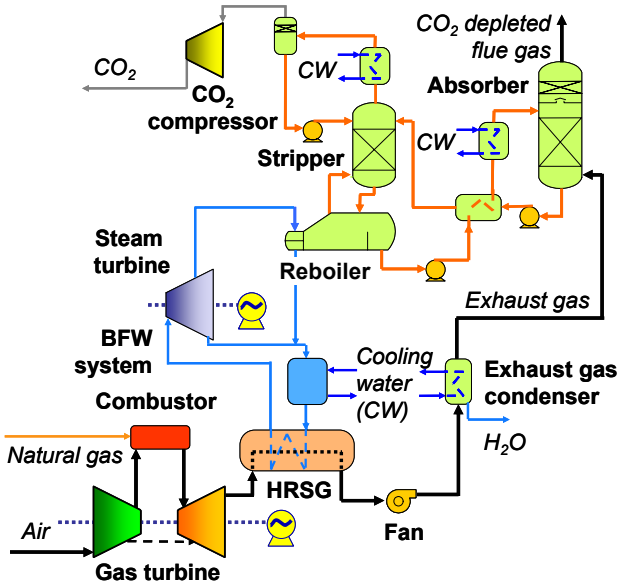

Figure 6: CCGT with post-combustion CO_2 capture

Parameter	Unit	Value
Regeneration temperature	°C	120
Regeneration heat consumtion	MJ/kg CO_2	4.5
Fan pressure increase	bar	0.06
Reboiler pinchpoint	°C	15

Table 1: Assumptions for the CO_2 capture

ECONOMIC ANALYSIS

A detailed economic model for an AZEP power plant delivery covering both main equipment, auxiliary equipment and engineering has been developed for one economic reference case; the AZEP 100% case in the 50 MW_e size. The scope is based on the vendor's scope of supply and does therefore not include the client's costs for preparing the site with connections to the main grid, to the fuel supply line etc. [18]. The scope is divided into different cost groups as follows:

- Gas turbine/genset
- Steam turbine including condenser and feed water system
- HSRG including drums, stack and ancillaries
- MEA/AZEP specific components and installation
- Buildings and civil works
- Auxiliary systems including electricals and instrumentation not included in the main component groups

- Project management, erection costs, commissioning, engineering, etc

The reference case, based on the experience of several delivery projects for CCGT plants using the SGT800 gas turbine, determines specific cost factors based on total capital cost for each of the three last groups. Auxiliary systems and project cost factors is for example considered to have approximately the same ***cost*** for an AZEP plant as for a CCGT plant of similar size (the specific AZEP equipment cost group includes both engineering and system costs), while the MEA case is considered to have a similar ***cost share*** for auxiliary systems and project costs as an AZEP plant. Buildings and civil works are treated in a special way, assuming they are based on HRSG cost, total plant power output and AZEP/MEA specific costs. The specific cost factors for project and auxiliary systems are tuned to match the reference case, while inhouse rules-of-thumb and literature data are used to determine AZEP/MEA specific costs, see Table 2. In a similar way the operation & maintenance (O&M) cost is divided into gas turbine, steam turbine, HRSG and AZEP/MEA O&M-costs. Cost of electricity for each of the cases can then be calculated as the sum of capital cost, fuel cost, O&M-costs and, if applicable, cost for CO_2 taxes.

	MEA/AZEP cases	**CCGT case**
Proj. cost 50MW_e	18%	23%
Aux. cost 50MW_e	11%	14%
Proj. cost 400MW_e	8%	10%
Aux. cost 400MW_e	9%	12%
MEA plant	6.25 k€/kg/s flue gas + 32.5 k€/kg/s CO_2	
CO_2 compressors	800 €/kW_e	
MCM reactor 50MW_e	54 k€/MW_{th} @ 1200°C[†]	
MCM reactor 400MW_e	45 k€/MW_{th} @ 1200°C[†]	

Table 2: Specific cost data used in the economic analysis [19]

[†] Includes reactor with pressure vessel and support structures

In order to determine the economic parameters having the greatest impact on the thermo-economic performance of the compared power plant concepts, a sensitivity study is performed. Apart from the ordinary parameters like discount rate and fuel price, the cost and life of the MCM reactor and CO_2-tax is also included, see Table 3.

Parameter	**Unit**	**Lower cost**	**Base case**	**Higher cost**
Discount rate	%	7.5	**10**	15
Fuel price	€/GJ	3	**4.5**	6
CO_2-tax	€/ton CO_2	-	**0**	40
MCM reactor cost	%	-25	**±0**	+25
MCM exchange period	years	2.5	**5**	7.5

Table 3: Sensitivity analysis parameters used in the study and their variation range

RESULTS AND DISCUSSION

Thermodynamic evaluation

The thermodynamic performance of the different concepts varies very little from the results presented in the preceding study [15], and is summarized in Table 4 and Table 5. Efficiencies decrease from less than 3 percentage points (AZEP 85%, 50MW_e) to over 8 percentage points (AZEP 100%, 400MW_e) in the low CO_2 emission alternatives, compared to the reference CCGT plants. Power output also decreases in all cases, most for the AZEP 100% case and least for the CCGT-MEA case, with the AZEP 85% case in between. For the AZEP cases the decrease in power output is less significant using the smaller gas turbine, due to smaller difference in COT between the unmodified gas turbine and the AZEP concept. The efficiency decrease for the MEA 85% case, around 7.5 percentage points, is at the lower end of the range previously found in literature [2],[20],[21].

Plant data 50 MW_e power plants	**CCGT**	**AZEP 100%**	**AZEP 85%**	**MEA 85%**
Net power output (MW)	63.8	46.2	53.8	55.0
Plant fired heat (MJ/s)	120.5	95.4	107.1	120.5
Net plant efficiency (LHV) (%)	**53.0**	**48.4**	**50.3**	**45.6**
CO_2 compression power (MW)	-	0.49	0.47	1.63
Plant total auxiliary power (MW)	0.7	1.1	1.1	4.0

Table 4: Process simulation results of the 50 MW_e cases

Plant data 400 MW_e power plants	CCGT	AZEP 100%	AZEP 85%	MEA 85%
Net power output (MW)	400.9	248.1	300.4	346.9
Plant fired heat (MJ/s)	692.4	500.5	562.5	692.4
Net plant efficiency (LHV) (%)	**57.9**	**49.6**	**53.4**	**50.1**
CO_2 compression power (MW)	-	2.95	2.85	9.2
Plant total auxiliary power (MW)	4.9	5.5	7.5	22.5

Table 5: Process simulation results of the 400 MW_e cases

Assumptions for the MEA case have on purpose been rather optimistic, due to the comparison between a MEA power plant, available more or less today, and AZEP power plants available some years into the future.

Thermo-economic evaluation

The results of the thermo-economic evaluation of the 50 MW_e system models are compared in Table 6. It can be seen that all of the CO_2 reduced cases suffer from large increases in cost of electricity. The lowest cost of electricity of the low CO_2 emission alternatives is shown by the AZEP 85% case with 20% increase in cost of electricity. Then comes the AZEP 100% case with 28% increase and worst is the MEA 85% case with an increase of 36% in cost of electricity. It can also be seen that the fuel price, apart from CO_2 taxation for the CCGT case, is the single variation factor that has the largest impact on the cost of electricity. Furthermore is the influence from MCM reactor cost and exchange period rather small. For all variations in MCM reactor cost and exchange period the AZEP 85% is clearly superior to the AZEP 100% which in turn is superior to the MEA 85% case.

If a CO_2-tax set to 40 €/ton is applied the results will be very different, with the AZEP 85% case showing the best economy followed by the AZEP 100% case and the reference case. The MEA 85% case is still the worst from an economic point of view. From Figure 7 a breakeven CO_2-tax can be expected at 31 €/ton for the AZEP 85% case and at 37 €/ton for the AZEP 100% case compared to the reference CCGT.

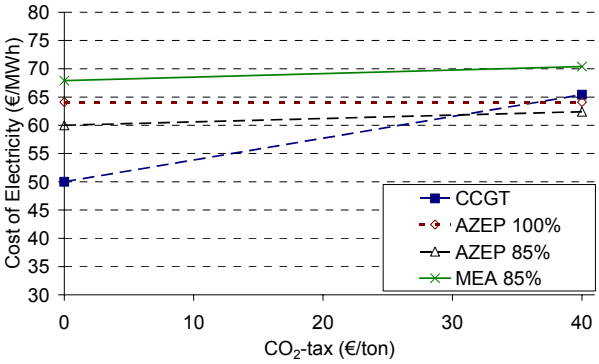

Figure 7: Influence of CO_2-tax on cost of electricity, 50 MW_e cases

The results of the thermo-economic evaluation of the 400 MW_e system models are compared in Table 7. As for the 50 MW_e cases, all of the CO_2 reduced cases suffer from large increases in cost of electricity. For the 400 MW_e systems it is again the AZEP 85% case showing the best results of the low CO_2 emission alternatives with 26% increase in cost of electricity.

Cost of Electricity (€/MWh)	CCGT	AZEP 100%	AZEP 85%	MEA 85%
Base Case	**50.0**	**64.1**	**60.0**	**67.9**
Discount rate – low	47.8	60.4	56.8	64.1
Discount rate – high	54.6	71.9	67.0	76.2
Fuel price – high	60.2	75.2	70.7	79.7
Fuel price – low	39.8	52.9	49.2	56.0
CO_2-tax – high	65.4	64.1	62.4	70.4
MCM reactor cost – high	-	65.1	60.8	-
MCM reactor cost – low	-	63.0	59.1	-
MCM exchange period – long	-	63.6	59.6	-
MCM exchange period – short	-	65.4	61.1	-

Table 6: Cost of electricity for the 50 MW_e cases

Cost of Electricity (€/MWh)	CCGT	AZEP 100%	AZEP 85%	MEA 85%
Base Case	**39.5**	**53.9**	**49.7**	**52.9**
Discount rate – low	38.4	51.6	47.7	50.6
Discount rate – high	41.9	59.1	54.1	57.8
Fuel price – high	48.8	64.8	59.8	63.7
Fuel price – low	30.2	43.0	39.6	42.1
CO_2-tax – high	51.7	53.9	52.1	55.2
MCM reactor cost – high	-	54.6	50.3	-
MCM reactor cost – low	-	53.2	49.1	-
MCM exchange period – long	-	53.5	49.3	-
MCM exchange period – short	-	55.3	51.0	-

Table 7: Cost of electricity for the 400 MW_e cases

The MEA 85% case and the AZEP 100% case show similar economic performance with the MEA case having a somewhat lower cost of electricity for all cases, except when a CO_2-tax is applied. The increase in COE for the base case is 34% for the MEA 85% case and 36% for the AZEP 100% case. Similar to the 50MW_e cases, it is the fuel price that is the single variation factor having the largest impact on the cost of electricity. The impact from uncertainties in the MCM reactor cost and exchange period is rather small also in the 400 MW_e cases. From Figure 8 a breakeven CO_2-tax can be expected at 40 €/ton for the AZEP 85% case. It can also be seen that the AZEP 100% case becomes more economical than the MEA 85% case at about 20 €/ton.

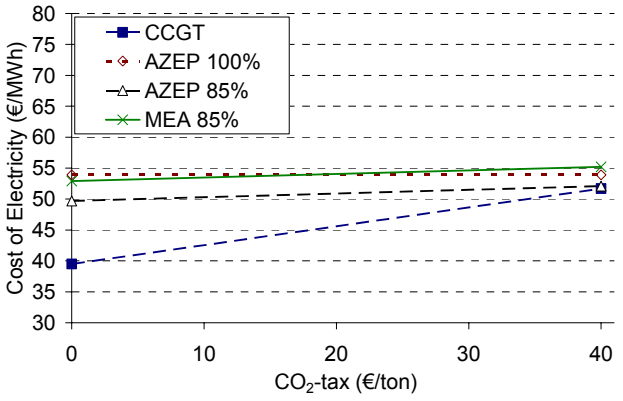

Figure 8: Influence of CO_2-tax on cost of electricity, 400 MW_e cases

CONCLUSIONS

With the economic assumptions made in this study it has been shown that the two optimal AZEP cycles (AZEP 85% and AZEP 100%) are more economical than one comparable alternative (MEA 85%) using a medium sized gas turbine, SGT800. Using a larger industrial gas turbine, SGT5-4000F, the AZEP 85% alternative is still more economical than the alternative (MEA 85%), while the AZEP 100% case needs support from CO_2 taxation to compensate for the lower emission level. With an assumed CO_2-tax of 40 €/ton the two AZEP alternatives show better economic performance than a conventional CCGT at the smaller size.

It has also been shown that uncertainties in MCM reactor cost and the life expectancy of MCM reactor ceramics do not have a big influence on the cost of electricity. It should be emphasized that the current study does not include so called "owner's costs", due to the inherent difficulties in modelling these. However, they could be expected to be bigger for a post-combustion capture plant due to the much larger footprint of that plant.

ACKNOWLEDGMENTS

The authors want to thank all partners in the AZEP project for their contributions to the results in the project. The AZEP project is partly funded by the European Commission in FP5, contract number ENK5-CT-2001-00514, and the Swiss Government (BBW 01.0054-1), the support of which is gratefully acknowledged.

ABSTRACT
This paper presents off-design evaluation of a natural gas-fired Chemical Looping Combustion (CLC) Combined Cycle with CO_2 capture. The unconventional combined cycle employs an air-based gas turbine, a CO_2 turbine and a steam turbine cycle. The proposed combined cycle has a net plant efficiency of 52.15% at full-load. At 50 % load the efficiency drops by 3.6 %-points. The efficiency drop at part-load is higher when compared to a conventional combined cycle. The pressure in CLC-reduction and -oxidation reactors is balanced by airflow reduction, using a compressor equipped with variable guide vanes. A combination of control strategies are discussed for plant start-up and part-load below 56 % when airflow reduction is not practically possible with current generation of compressors.

Keywords: power generation, natural gas, CO_2 capture, circulating fluidised bed, solids internal recirculation, metal oxide reduction, metal oxidation, combined cycle, variable guide vanes.

INTRODUCTION

Carbon dioxide is the most prevalent of man-made emissions of greenhouse gases. Power plants combusting fossil fuels are a major source of CO_2 release. Natural gas is the cleanest of fossil fuels and combustion of natural gas in power plants results in CO_2 emissions per kWh electricity below half of that compared to coal combustion. This paper presents off-design evaluation of a natural gas fired combined cycle power plant with CO_2 capture. The plant is based on Chemical Looping Combustion instead of a conventional combustor.

Chemical Looping Combustion (CLC), proposed by Richter and Knoche[1] in 1983, is a novel concept of power production with inherent CO_2 capture. In CLC, unlike a conventional combustion process, combustion takes place without direct contact between air and fuel. Combustion is split up into intermediate oxidation and reduction reactions. This goal is achieved by introducing a certain metal oxide as oxygen carrier that circulates between the two reactors, as depicted in fig. (1).

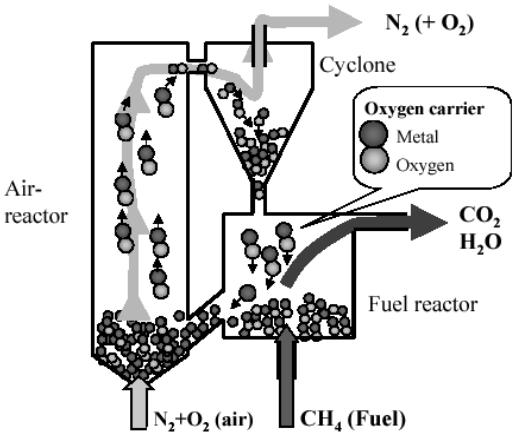

Fig. 1: The CLC Principle

In a reduction reactor, fuel reacts with oxygen in the metal oxide in a stoichiometric ratio thereby reducing the metal oxide.

The reduction reaction is given by eq. (1).

$$C_nH_{2n+2} + mMeO \rightarrow nCO_2 + [n+1]H_2O + mMe \quad (1)$$

The reduced metal oxide circulates to the oxidation reactor, carrying with it the chemical energy in the fuel. In the oxidation reactor, oxygen in the air oxidises the metal to metal oxide.

The oxidation reaction is given by eq. (2).

$$mMe + \left(\frac{m}{2}\right)O_2 \rightarrow mMeO \quad (2)$$

The metal oxide circulates back into the reduction reactor, transports oxygen to the fuel through reduction as well as provides heat for the endothermic reduction reaction. Equation (3) gives the net exothermic reaction.

$$C_nH_{2n+2} + [n+1]O_2 \rightarrow nCO_2 + [n+1]H_2O + Heat \quad (3)$$

In eq. (1), (2) and (3) MeO is metal oxide, Me is a reduced metal, C_nH_{2n+2} is a fuel (hydrocarbon), while n and m are stoichiometric factors.

The oxidation of the metal is exothermic and the oxygen depleted air is available at high temperature and pressure (in case of a pressurised reactor) and can be utilised for power production. The hot CO_2-rich exhaust stream can also be utilised for power generation, either by expansion or steam generation. The CO_2-rich exhaust stream can afterwards be condensed to separate water and CO_2 is compressed. In this way the energy penalty for CO_2 separation and compression is lower than a conventional power plant where CO_2 is diluted with other combustion products.

The metal oxide performance is vital to the process. The metal oxide should be mixed with an inert stabiliser to provide adequate mechanical stability and improved chemical reactivity. So far, investigations have been made for Iron Oxide[2] and various other metal oxides[3] (Ni, Cu, Mn, Co). Out of all, Nickel Oxide (NiO) exhibits the most promising properties[4] and the present work uses NiO supported on $NiAl_2O_4$ (60% NiO by mass).

CYCLE DESCRIPTION

Figure 2 presents the proposed CLC-combined cycle with CO_2 capture. The cycle has a unique feature that it operates two turbines on Brayton cycle i.e. an air-based gas turbine and a CO_2-turbine. The high temperature/pressure oxygen-depleted air at the air reactor (Ox) exit enters the air turbine where it mixes with the coolant bleed drawn from the compressor. The air turbine exhaust generates steam in a heat recovery steam generator. The CO_2-rich stream from the fuel reactor (Red) expands in the CO_2-turbine. The CO_2-turbine exhaust is used to pre-heat the fuel in the fuel recuperator. The exhaust is then fed to the CO_2 dehydration and recompression plant. The power plant is configured to give large power outputs (>300 MW) under varying conditions to achieve a reasonable thermodynamic design which can further be analysed under off-design mode. The computational assumptions used in the present work are given in appendix.

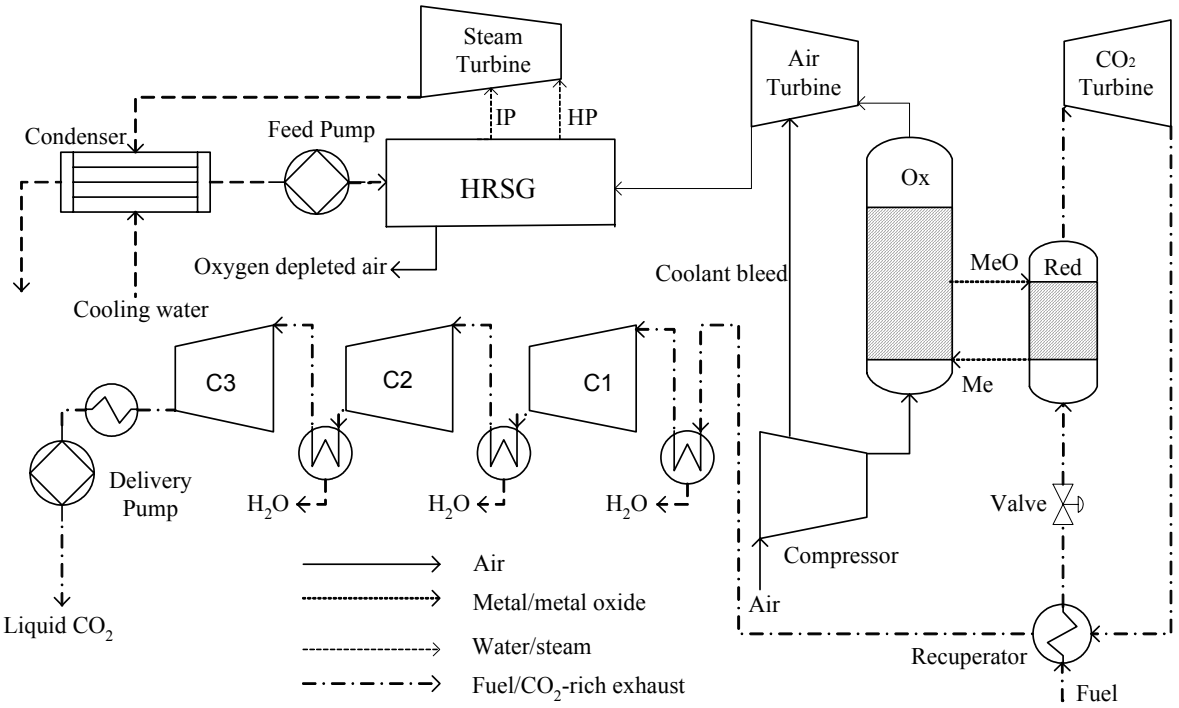

Fig. 2: Schematics of the proposed CLC-combined cycle with CO_2 capture

MODELLING BACKGROUND

The steady-state generic models of the air compressor, fuel recuperator, reactor system, air turbine and the CO_2-turbine were developed and implemented in the simulation tool gPROMS[5]. The cooling penalty for the air turbine was determined by incorporating a cooling model[6] into the air turbine model. The CO_2-turbine works at relatively lower temperatures and was assumed to be uncooled. The steam cycle was simulated in GTPRO/GTMASTER[7]. The CO_2 compression plant was simulated in PRO/II[8]. The reactor system model is based on two sub-models; a heat and mass balance model[9] and a model considering the hydrodynamic behaviour of the reactors by involving reactors geometry. In off-design mode, the compressor and the air turbine are assumed to operate according to the characteristic maps of a large axial compressor and a large axial turbine, respectively. The off-design behaviour of the CO_2-turbine is governed according to the standard choked nozzle equation.

Reactor System

The reactors should be capable of not only transporting the required amount of solids but also providing necessary solids conversion rate. The concept of circulating fluidised bed reactor (CFBR) was proposed by Lyngfelt[10] and the present work employs the same. Figure 3 presents the schematic sketch of the reactor system.

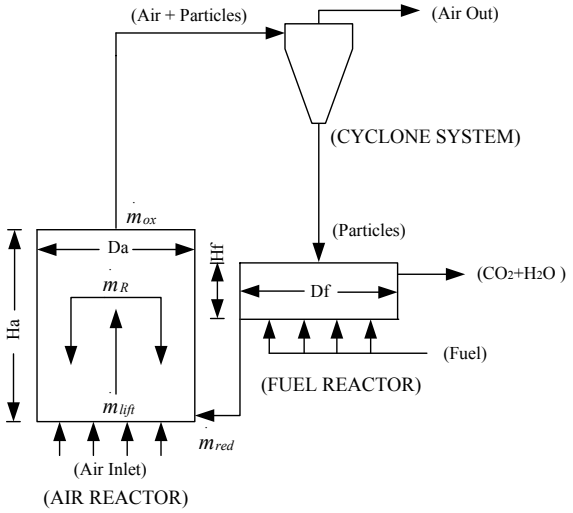

Fig. 3: Schematic sketch of CFBR System

In this work, the CLC-reactor system design is based on certain simplifications and assumptions yet sufficient details have been maintained to predict its behaviour under load-varying conditions. It is assumed that the solids leaving the air reactor are fully oxidised, homogenously mixed and in thermal equilibrium with the air leaving the reactor. The

solids at the fuel reactor exit are also in thermal equilibrium with the exhaust (CO_2/H_2O) stream. With a given air reactor diameter resulting in a certain superficial air velocity, flowrate of particles lifted from bottom of the air reactor can be calculated by eq. (4).

$$\dot{m}_{lift} = A_a \cdot \rho_s \cdot \varepsilon \cdot (u_0 - u_T) \quad (4)$$

In eq. (4) A_a is cross-sectional area of the air reactor, ρ_s is average density of particles and ε is average solids fraction in the air reactor. u_0 and u_T are superficial air velocity and terminal falling velocity of particles, respectively. Terminal falling velocity of particles is calculated as;

$$u_T = \left[\frac{4 \cdot g \cdot d_p}{3 \cdot C_D} \cdot \left(\frac{\rho_s}{\rho_{air}} - 1 \right) \right]^{1/2} \quad (5)$$

In eq. (5) g is acceleration due to gravity, d_P is average diameter of particles and C_D is drag coefficient, which is calculated by eq. (6).

$$C_D = \frac{a_1}{Re_T^{\,b}} \quad (6)$$

The constants a_1 and b were calculated according to Howard[11]. In eq. (6) Re_T is Reynolds Number of particles at terminal falling velocity given by eq. (7).

$$Re_T = \frac{u_T \cdot d_p \cdot \rho_{air}}{\mu} \quad (7)$$

In eq. (7), μ is kinematic viscosity of air. In the riser (air reactor), there is a certain internal recirculation of the solids. The internal recirculation ratio (I) is given by eq. (8).

$$I = 1 - R \quad (8)$$

In eq. (8) R is the entrainment ratio defined as:

$$R = \frac{\dot{m}_{ox}}{\dot{m}_{lift}} \quad (9)$$

From eq. (8) and (9) it can be seen that internal recirculation of particles increases with decrease in the entrainment of particles out of the reactor. Internal recirculation of particles results in an increased overall solid fraction (ε in eq. 4) in the air reactor. The overall solids fraction is calculated as:

$$\varepsilon = \frac{(2 - R) \cdot \varepsilon_{se}}{R} \quad (10)$$

In eq. (10), ε_{se} is solid fraction at exit of a pneumatic transport reactor. This is typically in the range of 0.001-0.003 and is assumed to be 0.0015. In eq. (9) $\dot{m}_{ox}$ is flowrate of fully oxidised solids (pure NiO) and inert stabiliser. According to eq. (9), at R=0, there is no particle entrainment and hence the reactor behaves as a steady-state fluidised bed. And when R=1, all the particles are entrained i.e. transported out of the reactor in a single pass and hence there is no internal recirculation of particles. The entrainment ratio, R is a function of the difference in superficial velocity and particles terminal velocity, say; $\Delta u = u_0 - u_T$. Entrainment ratio increases with an increase in superficial velocity until a threshold point is reached where all the particles are blown out of the reactor without any internal recirculation. The difference in the two velocities at the threshold point is denoted as Δu_{TH} and is assumed to be 2.5, which is fairly realistic for a pneumatic transport reactor. After the threshold point, an increase in superficial air velocity has no effect on internal recirculation and a continuous pneumatic transport prevails. This phenomenon is expressed in the form of eq. (11) and fig. 4.

$$R = \begin{cases} \dfrac{1}{\Delta u_{TH}} \cdot \Delta u & \Delta u - \Delta u_{TH} < 0 \\ 1 & \Delta u \geq \Delta u_{TH} \end{cases} \quad (11)$$

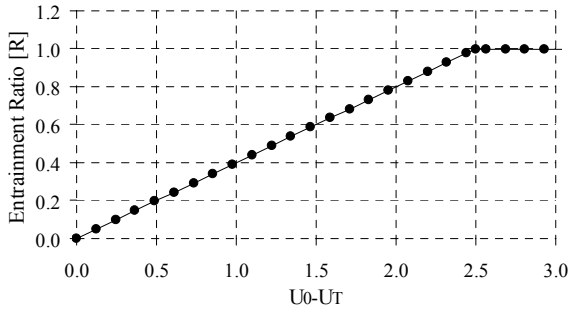

Fig. 4: Entrainment ratio vs. Δu

The air reactor hold up of solids is calculated as:

$$M_a = A_a \cdot H_a \cdot \rho_s \cdot \varepsilon \quad (12)$$

Mean residence time of the solids in the air reactor is then calculated by eq. (13).

$$\tau_a = \frac{M_a}{\dot{m}_{lift}} \quad (13)$$

Mean residence time of particles in the fuel reactor is calculated on the basis of average flowrate of particles, given by eq. (14).

$$\tau_f = \frac{2 \cdot M_f}{\dot{m}_{red} + \dot{m}_{ox}} \quad (14)$$

Where M_f is solids mass in fuel reactor given as:

$$M_f = A_f \cdot H_f \cdot \rho_s \cdot \varepsilon_f \quad (15)$$

In eq. (14) $\dot{m}_{red}$ is flowrate of solids leaving the fuel reactor and is calculated as:

$$\dot{m}_{red} = A_f \cdot \rho_s \cdot \varepsilon_f \cdot \left(u_{0,f} - u_{T,f}\right) \quad (16)$$

In eq. (15) and (16) ε_f is the solids fraction at the fuel reactor exit and is assumed to be 0.4 which is typical for a fluidised bed reactor. The present work is based on a constant ε_f under various load and flow conditions. Pressure drop in the air and fuel reactor is calculated by eq. (17).

$$\Delta P = \Delta P_B + \Delta P_D \quad (17)$$

ΔP_B and ΔP_D is pressure drop in the fluidised bed and pressure drop caused by gas distributors, respectively. The pressure drop over the fluidised bed (ΔP_B) is calculated by using eq. (18) which is derived from the hydrodynamics described by Carberry and Varma[12] & Kunii and Levenspiel[13].

$$\Delta P_B = 1.2 \cdot \frac{M \cdot g}{A} \quad (18)$$

In Equation (18), M is the hold up of the solids in air or fuel reactor, g is acceleration due to gravity and A is cross-sectional area of the reactor. Pressure drop due to the gas distributors is given as:

$$\Delta P_D = 0.4 \cdot \Delta P_B \quad (19)$$

The pressure drop in cyclones is assumed to be 20 mbar.

RESULTS AND DISCUSSION

Thermodynamic Analysis

In order to analyse a power cycle under off-design mode, it is essential to have a reasonable thermodynamic design. A sensitivity study of the key cycle parameters was carried out to thermodynamically analyse the combined cycle and a design point was established. Under the thermodynamic analysis, the reactor system was based on certain assumptions. Pressure drop in both the reactors was calculated in accordance with eq. (17) for oxidation temperature 1200 °C and compressor pressure ratio 18. The same pressure drop percentage was used during the thermodynamic analysis under all conditions. It was also assumed that the internal of both the reactors is well-mixed and the exiting solid streams are in thermal equilibrium with the corresponding exiting gaseous stream. It was assumed that 100 % of the solids entering the air reactor are converted (oxidised) while only 70 % of the solids entering the fuel reactor are converted (reduced). Experimental studies by Lyngfelt[5] show that the thermodynamic limit of NiO to convert fuel is 99.5 %. However, 100% fuel conversion was assumed for the present work. The net plant efficiency includes CO_2 compression penalty and losses (mechanical, generator, auxiliaries). The definitions of net plant efficiency and specific work used in the present work are given by eq. (20) and (21), respectively.

$$\eta_{net} = \frac{\left(\left(\dot{W}_{GT} + \dot{W}_{CO_2-T} + \dot{W}_{ST} - \dot{W}_{comp}\right) \cdot \eta_{m+g+aux}\right) - \dot{W}_{CO_2-comp}}{\dot{m}_{fuel} \cdot LHV} \quad (20)$$

$$w = \frac{\left(\left(\dot{W}_{GT} + \dot{W}_{CO_2-T} + \dot{W}_{ST} - \dot{W}_{comp}\right) \cdot \eta_{m+g+aux}\right) - \dot{W}_{CO_2-comp}}{\dot{m}_{air}} \quad (21)$$

Figure 5 presents the net plant efficiency as a function of specific work for different values of compressor pressure ratio (PR) and TIT values. The term TIT refers to the air reactor exit temperature.

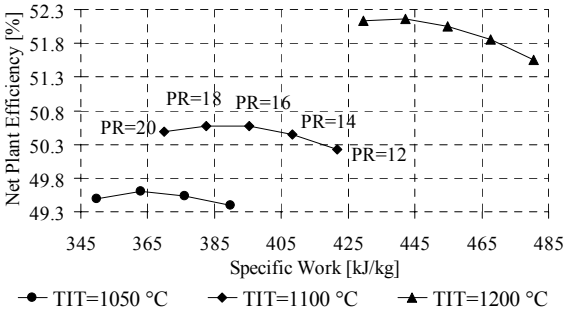

Fig. 5: Net plant Efficiency vs. specific work

The simulation results showed that the proposed CLC-combined cycle can achieve a net plant efficiency of 52.15 % at TIT=1200 °C and compressor pressure ratio (PR) of 18. The reactors were dimensioned for TIT=1200 °C and PR=18 for the full-load condition. The design is based on assumption that all the solids leaving the air reactor are fully oxidised. The air reactor (D=14m,

H=25m, ΔP=153 mbar, τ=47 s) supplies the required amount of pure NiO (and inert stabiliser) to the fuel reactor under all load conditions. At full-load, 74.6 % of the particles are internally recirculated. The fuel reactor (D=8m, H=2m, ΔP=316 mbar, τ=156 s) can convert 70 % of the NiO supplied to the fuel at full-load.

Off-design Strategy

In the off-design mode, the combined cycle was analysed under load-varying conditions. The air turbine is the key component in the cycle and drives the compressor. The compressor pressure ratio and inlet flow are determined from the choked air turbine at part load. Pressure in the fuel reactor is determined by the choked CO_2-turbine. The coolant fraction at different load conditions also varies. There are two major strategies for determining the coolant fraction (% of flow at compressor inlet). It can either be assumed as the same as at full-load; or it can be assumed that the coolant flow is choked. The latter approach has been adopted for the present work. The steam turbine work is dependent on the air turbine exhaust temperature and varies accordingly. The CO_2-turbine determines pressure at the fuel reactor entry and its work also varies at reduced fuel flowrate (part-load). The control strategy for the present work focuses on two major issues: fuel cut at part load in order to meet the load requirements; and use of variable guide vane angles at the compressor inlet (VGVs) in order to reduce the air flowrate, influencing the pressure through the system thereby achieving the same pressure at the two reactors exits.

Pressure at Reactors Exit

It is important to achieve the same pressure at the exit of both reactors. If there is a pressure difference between the two reactors, the gas from the reactor at higher pressure will tend to flow into the other reactor. With the proposed reactor system, the air reactor has a lower pressure drop than the fuel reactor. The power plant is configured such that the streams leaving the air and the fuel reactor are at the same pressure at full-load. As soon as the load is reduced, a pressure gradient occurs at the reactors exit because the two turbines require different inlet pressures. Under such a condition, an uncontrolled (in terms of pressure) system will result in a higher pressure at the air reactor exit. The consequence will be air entrapment into the fuel reactor, coming in direct contact with the fuel, thereby upsetting the stoichiometric reactions and resulting in undesired combustion products. The present work employs a compressor with variable inlet guide vanes to cope with this problem.

Part-load Performance

The presented part-load analysis uses the following definition of Load Factor (LF).

$$LF = \dot{W} / \dot{W}_0 \qquad (22)$$

In eq. (22) $\dot{W}$ and $\dot{W}_0$ are the net plant output at part-load and full-load, respectively. Figure 6 compares the relative net plant efficiency of the proposed cycle with two conventional combined cycles at various values of load factor. The part-load results for the conventional cycles were obtained by simulations in GTMASTER[7].

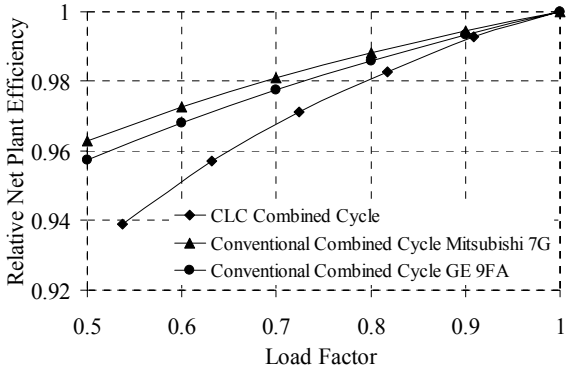

Fig. 6: Relative net plant efficiency at varying load

The results show that by reducing the load down to 50 % the net plant efficiency drops by 3.65 %-points. The relative net plant efficiency of CLC-combined cycle at part-load decreases more rapidly in comparison with a conventional combined cycle. This effect is a consequence of the presence of the CO_2-turbine. Under part-load, the plant is controlled by reducing the airflow at the compressor inlet which results in pressure reduction at the air turbine inlet. This strategy is adopted for controlling the plant in order to match with the lowest pressure occurring in the air and the fuel reactors. Therefore, the pressure at the air turbine inlet is controlled according to the pressure at the CO_2-turbine inlet which is the lower of the two. The pressure reduction results in a reduced pressure ratio across the air turbine. The net effect is an additional work reduction and efficiency drop at part-load compared to a conventional combined cycle. The airflow reduction at part-load, by means of variable guide vanes, is of interest as regards the plant control

strategy. Figure 7 presents airflow reduction as a function of varying load.

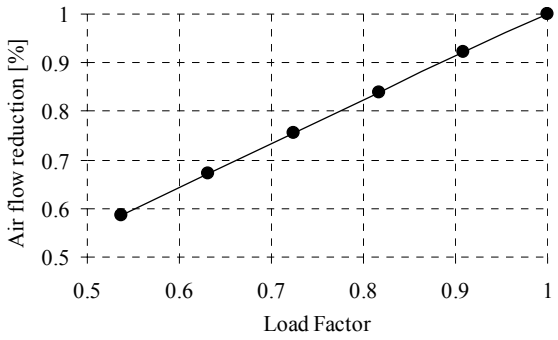

Fig. 7: Air flow reduction vs. Load Factor

It is seen in fig. 7 that decreasing the load down to 56 % results in 60 % air flow reduction. Modern compressors are equipped with VGVs that can reduce the flowrate from 100 % to typically 60 %. Therefore, according to fig. 7, the plant can not be controlled with the proposed control strategy under a load factor of 0.56 when air flow reduction is 60 %. This implies that this strategy is not valid for the plant start-up as well. This conclusion calls for the need to investigate the alternative control strategies. There is a range of diverse control strategies which can be employed in combination with one another at different load conditions. The system can also be controlled from the start-up to the 56 % load by using VGVs as well as taking extra bleeds from the compressor thereby reducing the flowrate through the air reactor and regulating the pressure. Another interesting scheme is to throttle the air after the compressor exit. While the major focus of the afore-mentioned schemes is controlling the air-side of the plant, there is certain degree of freedom to manipulate with the fuel/exhaust-side. Exhaust from the fuel reactor can be throttled and an innovative solution to the problem is to introduce VGVs at CO_2-turbine inlet.

The system can also be simplified by not employing any CO_2-turbine and generate steam in a condenser via heat recovery from the exhaust stream. This is beneficial in the terms that it is easier to control the pressure in a condenser as compared to that at turbine inlet. The system can also utilise the exhaust stream as air recuperator after the compressor prior to its entry into the air reactor.

The results concerning the reactor system behaviour at part-load are of interest. The results show that the solids conversion in the fuel reactor decreases by 20% at 50 % load compared to full-load. The internal recirculation of solids in the air reactor increases from 74.6% at full-load to 81 % at 50 % load. Residence time of particles in air reactor increases from 47 sec at full-load to 64 sec at 50 % load. In this work, the reduction rate (solids conversion) is a function of the fuel supplied and results show that despite an increase in the residence time, reduction rate decreases down to 50.6 % at 50 % load. Also, the fuel reactor is assumed to remain fluidised no matter what the load and eventually flow conditions may be. This is due to the assumption of a constant overall solids fraction. In reality, the solids fraction will change according to the flow conditions and must be accounted for the changes and determined at different conditions. This fact does imply that during the operation a condition may occur when the bed tends to defluidise. This means that the reactor will start behaving like a fixed bed and there will be no more transport of solids out of the reactor. In other words, the system will collapse. This problem can be dealt with by adopting control techniques at the fuel/exhaust side. The solids conversion in the reactors is in principle function of the solids residence time. In the air reactor with fixed geometry, air flowrate reduction results in lesser particles lifted by air. The consequence is an increased internal recirculation and decreased solids transport. This altogether has an effect of increased residence time of solids. The solids internal recirculation has been assumed to be a linear function of the relative velocity between the air and the solids. This should be determined on the basis of empirical formulations for a pressurised circulating fluidised bed system. There is, however, a different scenario in the fuel reactor. The solids conversion rates in air and fuel reactor need to be determined on the basis of residence times of particles. The solids fraction in the fuel reactor needs also to be determined by taking into account the fuel flowrate together with residence time of particles. Reactor system and oxygen carrier performance should be investigated experimentally for long-term operations at high pressure and temperature.

CONCLUSIONS

This work has been the very first attempt to analyse a CLC-combined cycle in off-design mode. At full-load the plant has an efficiency of 52.15% which is promising. The efficiency drops by 3.6 %-points when reducing the load down to 50 %. The efficiency reduction is higher at part-load as compared to a conventional combined cycle. This work suggests airflow reduction at compressor inlet

in order to balance reactors exit pressure at part-load. Other strategies have also been indicated when airflow reduction alone is not applicable under 56 % load. The results show that a CLC-combined cycle has promising efficiency at full-load yet it exhibits some operational problems at part-load which are indicated and solutions suggested.

ABSTRACT

Power production from biomass can occur through external combustion (e.g. steam cycles, Organic Rankine Cycles, Stirling engines), or internal combustion after gasification or pyrolysis (e.g. gas engines, IGCC). External combustion has the disadvantage of delivering limited conversion efficiencies (max 30-35%). Internal combustion has the potential of high efficiencies, but it always needs a severe and mostly problematic gas cleaning.

The present article proposes an alternative route where advantages of external firing are combined with the potential high efficiency of combined cycles through co-utilization of natural gas and biomass. Biomass is burned to provide heat for partial reforming of the natural gas feed. In this way, biomass energy is converted into chemical energy contained in the produced syngas. Waste heat from the reformer and from the biomass combustor are recovered through a waste heat recovery system. It is shown that in this way biomass can replace up to 5% of the natural feed. It is also shown that in the case of combined cycles, this alternative route allows for external firing of biomass without important drop in cycle efficiency.

NOMENCLATURE

LHV	Lower heating value (J/kg)

CC	Steam and Gas turbine combined cycles

KEYWORDS

Biomass, methane-steam reforming, Combined Cycle, high efficiency

INTRODUCTION

The system proposed in the present paper combines the advantages of external combustion (no gas cleaning) with the advantages of internal combustion (higher efficiencies). This is realised by using the heat from the external combustion of biomass for partial primary reforming of natural gas into mainly hydrogen and carbon monoxide (see Figure 1). In this way, the biomass energy is transferred into the syngas as chemical energy and the biomass exhaust gases are kept separate from the syngas and the internal parts of the gas turbine.

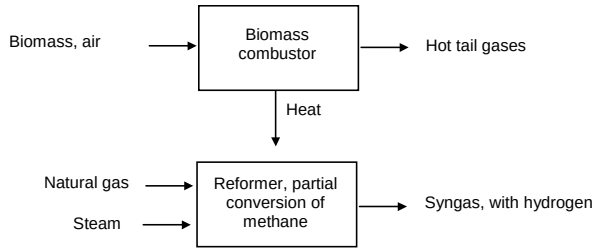

Figure 1 : Concept of steam reforming based on external combustion of biomass

The principles of combining the external biomass firing with a gas turbine cycle are further detailed in Figure 2, as follows:

- Biomass (1) is burnt in a furnace (3).
- The reforming reaction takes place in the tubes surrounding the furnace and containing the catalyst (7). The combustion air (2) needs to be preheated up to at least 600°C and the amount must yield +/- 6% O2 in the exhaust gases (4). Preheating will occur in a designated Heat Exchanger Network (HEN).
- The exhaust gases (4) with a temperature of 700°C, will feed the HEN.
- Natural gas, after desulphurisation, is mixed with steam (6) and preheated to +/- 650°C before entering the reformer (7). The required heat for natural gas and steam will be drawn from the HEN.
- Heat from the biomass furnace (3) feeds the reformer reactions (7):

$CH_4 + H_2O <\!\!\longrightarrow CO + 3H_2$ $\quad \Delta H^0_{298} = 206$ kJ.mol^{-1}

$CO + H_2O <\!\!\longrightarrow CO_2 + H_2$ $\quad \Delta H^0_{298} = -41$ kJ.mol^{-1}

Biomass energy is in this way partially converted into chemical energy in the syngas (10).
- To avoid coking in the reformer, a sufficient excess of steam is added. If appropriate, excess water is condensed and recycled (8) after the reformer.
- The obtained syngas (10) is cooled to a temperature specified by the gas turbine supplier (<300°C). The heat will be used in the HEN (9).
- The heat of the exhaust gases is recuperated in the HEN (11). This recuperation consists of the (existing) bottom cycle feed and a surplus to close the cycle energy balance.

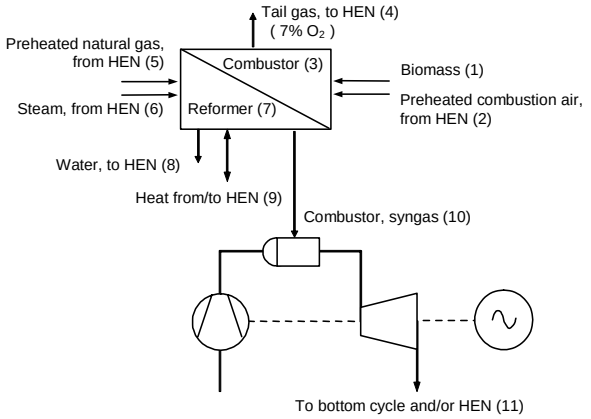

Figure 2 : Overall concept of the replacement of some natural gas by biomass through reforming (HEN = Heat Exchanger Network)

The idea of using methane-steam reforming in gas turbine cycles is not new. Two relevant papers describing the use of methane-steam reforming for heat recovery purposes are Adelman et al [1] and more recently Fiaschi et al [2]. Such 'Chemically Recuperated Cycles' use a methane-steam reformer in order to extract heat from the full gas turbine exhaust stream, and transform this heat into chemical energy in the syngas [1]. Temperatures in the gas turbine exhausts are however too low to achieve a high amount of reforming, and the obtained energy recovery is therefore too limited for practical application. Fiaschi et al [2] propose to overcome this problem by adding post-combustion of natural gas in the full exhaust of the gas turbine. They use the reforming not for purposes of heat recovery, but to capture CO2 from the fuel feed prior to the combustion process.

Another application of reforming is patented by Mittricker [3]. In this patent a reforming process is proposed to enrich fuels with low methane concentration with hydrogen. The syngas is dried in order to deliver a syngas suitable for use in gas turbines. The process integration is not further detailed.

APPLICATION TO COMBINED STEAM AND GAS TURBINE CYCLES

In the following it is shown that in the case of combined steam and gas cycles (CC) the cycle efficiency can remain unaffected when replacing a limited amount of natural gas by biomass through the proposed reforming. This proof is based on a 'black box' approach developed by the authors and applied successfully in the past [4-6]. The black box approach occurs in four steps as follows:

In a first step an adiabatic control volume is chosen around all the reference CC components, with exclusion of the compressor, the expander (Figure 3) and the steam turbine(s). The corresponding boundary conditions are given in Table 1. Assuming a Steam and Gas Turbine a certain amount of water is evaporated and preheated in the black box before feeding it to the external steam turbines. This amount is calculated from the adiabatic condition of the black box. The amount of fuel flow is adjusted to reach 1200°C at turbine inlet (turbine inlet temperature or TIT). Once the boundary conditions of the system are determined, the performance of the cycle is independent of what happens inside this 'black box heat recovery system' or BBHRS (principles of the first and second law of thermodynamics).

During the second step, the minimal amount of physical connections is made inside the BBHRS, and each connection between inlet and outlet is equipped with the necessary heaters and/or coolers. Figure 4 is drawn for the reference Steam and Gas Turbine case. The water is preheated, evaporated and superheated to 350°C before feeding it to the external steam turbine(s) (1). Methane is injected into the combustion chamber with a temperature of 150°C (2). The sole available heat source is the stack (3). Fuel and compressed air are injected in the combustor (4) where 1200°C is imposed as exit temperature.

In the third step, 'Composite Curves' of the BBHRS are drawn (Figure 5). Composite curves show at which temperatures heat is exchanged between components that require heat ('cold curve'), and components that provide heat ('hot curve'). Crossing hot and cold curves corresponds to a violation of the second law of thermodynamics. From Figure 5 it appears that the chosen boundary conditions do not lead to a second law violation. Boundary conditions can be adjusted to meet the optimal pinch point in the composite curves.

Eventually the BBHRS synthesis can be designed in the last step by means of a pinch analysis.

BASE CASE WITH REFORMING

The second to fourth steps can be repeated assuming a reforming reactor. The resulting cycle will be referred to as the 'adapted' cycle with 5% biomass input. Figure 6 shows the minimum physical connections to be made to achieve the proposed reforming step. Components 1 to 4 are as before. Part of the fuel and water is diverted and preheated (5,11). The diverted preheated fuel is then partially mixed in an isothermic way with enough water to reach a steam-methane ratio of 2 before entering the reforming reactor (8). The requested water is diverted from the steam cycle water supply, thus reducing the steam turbine flow rate (13). The residual diverted fuel is fed to the combustor (7) to deliver the required heat for the reforming process (8). For coherence in this proof, this fuel is assumed to be methane whereas in reality it has to be replaced by biomass. The comburant air is taken from the turbine exhaust gas (6). Its flow rate is adjusted to yield 6% of excess oxygen in the combustor. The heat in the combustion tail gas is to be used as a heat source in the black box (9). The syngas is cooled (10) down to the same temperature as the undiverted preheated fuel, a temperature suitable for the nozzle and combustion chamber. The amount of diverted fuel (e.g. biomass) is such that the biomass energy input into the cycle reaches 5%. According to the assumed reformer temperature, the syngas at exit of the reformer can be considered as in equilibrium : it contains 35.7% of hydrogen, 3.4% CO, 6.4% CO2, 12% methane and 42.5% water (in mole fraction).

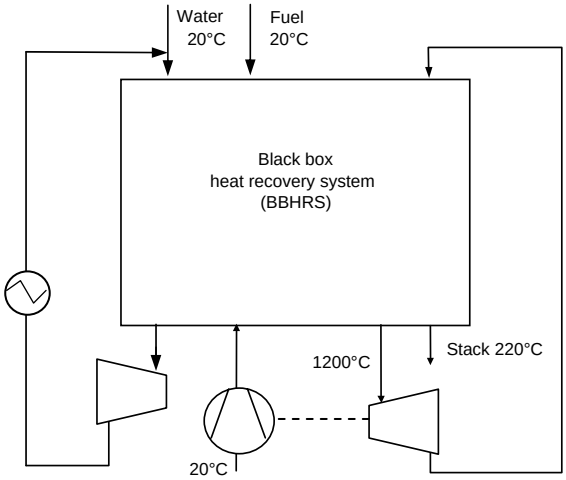

Figure 3: Black box heat recovery system(BBHRS)

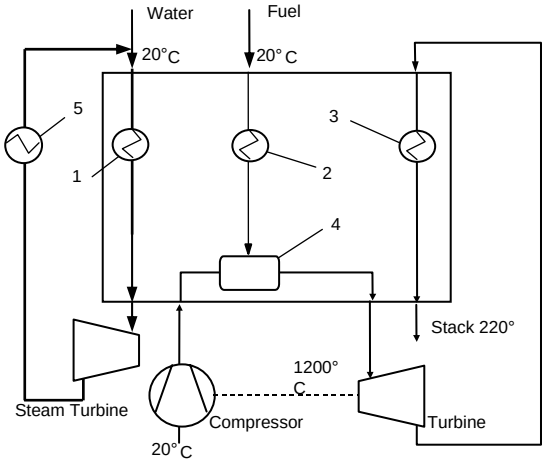

Figure 4: BBHRS with minimal amount of connections

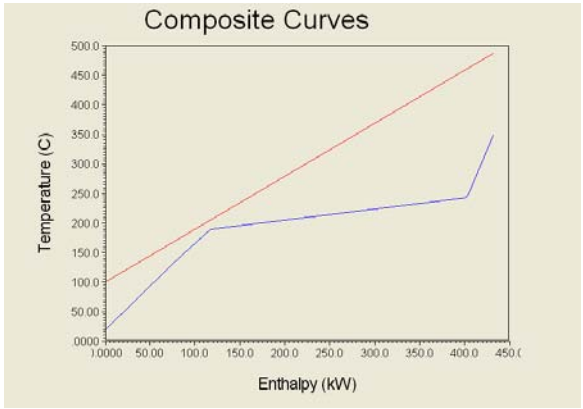

Figure 5: Composite curves of the 'original' CC cycle

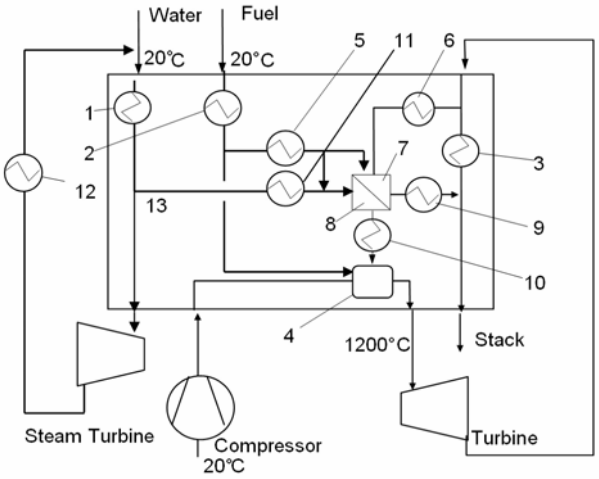

Figure 6: Minimal connections when introducing biomass through reforming

Table 1 summarises all the relevant boundary conditions of both systems, without and with reforming. Small differences are observed, due to

- the fact that part of the fuel is diverted to a different route through the combustor and next to the stack, without being expanded in the turbine.
- The diversion of part of the water from the steam cycle, lowering the flow rate of the steam turbine

The total water flow rate however, remains constant. After superheating an equal amount of steam, the residual heat must be rerouted inside the black box, where the sole appropriate heat sink is the syngas. The loss in mass flow and power in the steam turbine can thus be compensated by the increased mass flow through the main turbine and elevated methane and syngas injection temperatures. A marginal LHV efficiency of the diverted fuel η^{mar} can be defined as follows

$$\eta^{mar} = \frac{\dot{W} - \eta^{ref}\dot{m}^{meth}LHV^{ref}}{\dot{m}^{bio}\ LHV^{bio}} \qquad \eta^{ref} = \frac{\dot{W}^{ref}}{\dot{m}^{ref}LHV^{ref}}$$

In these formulas, $\dot{m}^{meth}$ stands for the remaining methane mass flow in the adapted gas turbine cycle and $\dot{m}^{bio}$ stands for the diverted 'biomass' fuel.

		Refcase	*5% Bio*

	°C	100	100
	atm	1	1

Table 1: Boundary conditions of the reference case (refcase) and base 5% biomass case

The reference LHV efficiency η^{ref} is determined for the original cycle in which all the energy input is methane. By means of η^{ref} , the remaining fossil fuel in the adapted cycle would provide a power output equal to $\eta^{ref}\dot{m}^{meth}LHV^{ref}$ and the surplus work can be attributed to the diverted methane (or biomass).

As indicated in Table 2a, the adiabatic condition of the black box needs the combustor injection temperature to be forced up to 470°C, delivering a marginal efficiency of over 60%. Although this may seem very interesting in theory, in practice such an injection temperatures is too high. If the residual heat is appointed to the bottom cycle to produce more superheated steam instead of heating the syngas, Table 2b shows a 20% drop in marginal efficiency compared to the reference cycle. This can be explained as follows: The amount of water rerouted to the reformer, is calculated to obtain a 100% surplus of water to methane in the reactor. After the reforming reactions, a lot of the unreformed water remains in the syngas and is injected into the combustion chamber further down the road. The unreformed water is therefore consumed according to the definition of a Steam-injection cycle, instead of the more efficient combined steam and gas cycle. In order to elevate the adapted cycle efficiency, a condenser is therefore needed to separate the unreformed water from the syngas and feed it to the bottom cycle.

REFORMING CYCLE WITH CONDENSER

When introducing a condenser in the BBHRS at a temperature of 50°C into the adapted cycle, the major part of the 42.5% water (mol fraction) can be recuperated and routed to in the bottom cycle at 20 atm. This condensation raises the marginal efficiency by ten percent and compensates half of the loss found when no condenser was used (Table 2c).

For the results shown in table 2c, all the residual heat was used in the bottom cycle, resulting in an increase in water flow rate from 0.1323 in the reference case to 0.137 in

		Reference	a	b	c	d

- *b) 5% biomass, no constant water flow, all heat assigned to the bottom cycle, no condenser or saturation tower*
- *c) 5% biomass, constant water flow, addition of a condenser*
- *d) 5% biomass, constant water flow, condenser, addition of a saturation tower*

the adapted case. For comparison purposes however, it is better to keep the water flow rate constant as it is a boundary condition of the black box. After preheating, evaporating and superheating a 0.1323 kg/s water flow rate to 350°C, the remaining heat is used to increase the syngas injection temperature, making the box adiabatic. The resulting marginal efficiency surpasses the reference cycle efficiency and the injection temperature of 360 °C is more realistic for current injection nozzles (Table 2d).

Figure 7 shows the corresponding composite curves. The composite curves show that hot and cold are in balance in the adapted cycle. However at the level of evaporating water, a cross-pinch or second law violation occurs, rendering the BBHRS unfeasible. This problem can be solved by the more gradual evaporation within a saturation tower. This saturation tower mixes water and methane before entering the reforming reactor rather than evaporating water at a constant temperature in a conventional boiler.

REFORMING CYCLE WITH CONDENSER AND SATURATION TOWER

Figure 9 shows a final arrangement of the HEN, with inclusion of a saturation tower. Methane and liquid water are preheated and fed to the counter stream saturation tower, where water is evaporated at a variable temperature. In order to reach a steam-methane ratio of three, the inlet temperature of water and (to a lesser extent) methane must be sufficiently high so the desired amount of water is mixed into the methane. Before entering the reformer, the mixture is further preheated to 650°C.

Figure 8 shows the corresponding composite curves. Both curves are kept on a comfortable temperature difference from each other, in contrast to the curves without saturation tower in Figure 7.

Table 2d and table 3 confirm that while keeping the boundary conditions (nearly) constant, the adapted cycle is capable of maintaining and even surpassing the reference cycle efficiency. It is apparent that the unavoidable loss in efficiency due to the nature of biomass can be compensated by the increase in injection temperature of the syngas.

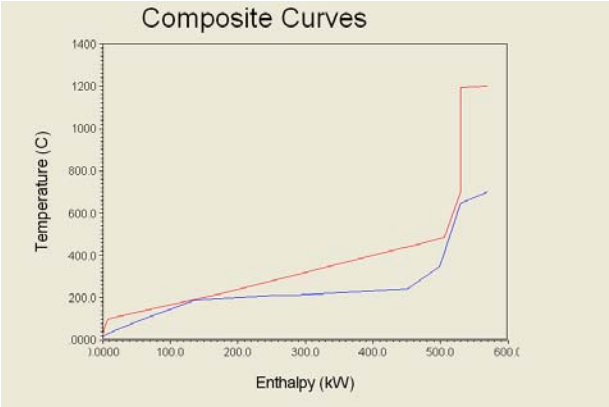

Figure 7: Composite Curves of the adapted case (5% biomass, condenser included)

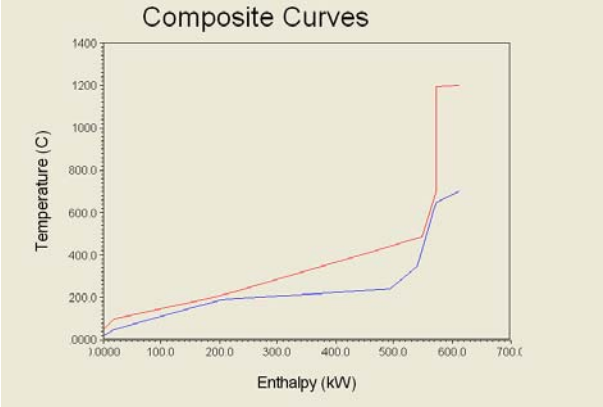

*Figure 8: Composite Curves of the adapted case **with** the introduction of a saturation tower*

To conclude the simulation, pinch analysis helped designing the BBHRS synthesis as shown in Figure 9.

The implementation of a saturation tower yields a second advantage, as the high quality requirements of the consumed water can also be reduced considerably and high priced purifications can be avoided: experimentally [6] salts and sulfur tend to lag behind in the recirculating surplus of water, ruling out expensive purification systems.

CONCLUSIONS

The present paper demonstrates that it is possible to combine the advantages of external and internal firing of biomass without a significant drop in efficiency by means of (partial) steam reforming of natural gas. In retrospect, the adapted cycle had to satisfy three conditions to be competitive with the reference cycle:

- While maintaining a constant stack temperature, all available heat must be appointed adequately
- After the reforming reactions take place, redundant water must be condensed and expanded in the bottom cycle
- A saturation tower is necessary to avoid a second law violation when keeping the water flow constant

Table 3: Boundary conditions of the reference case (refcase) and the adapted, 5% biomass case, saturation tower and condenser included

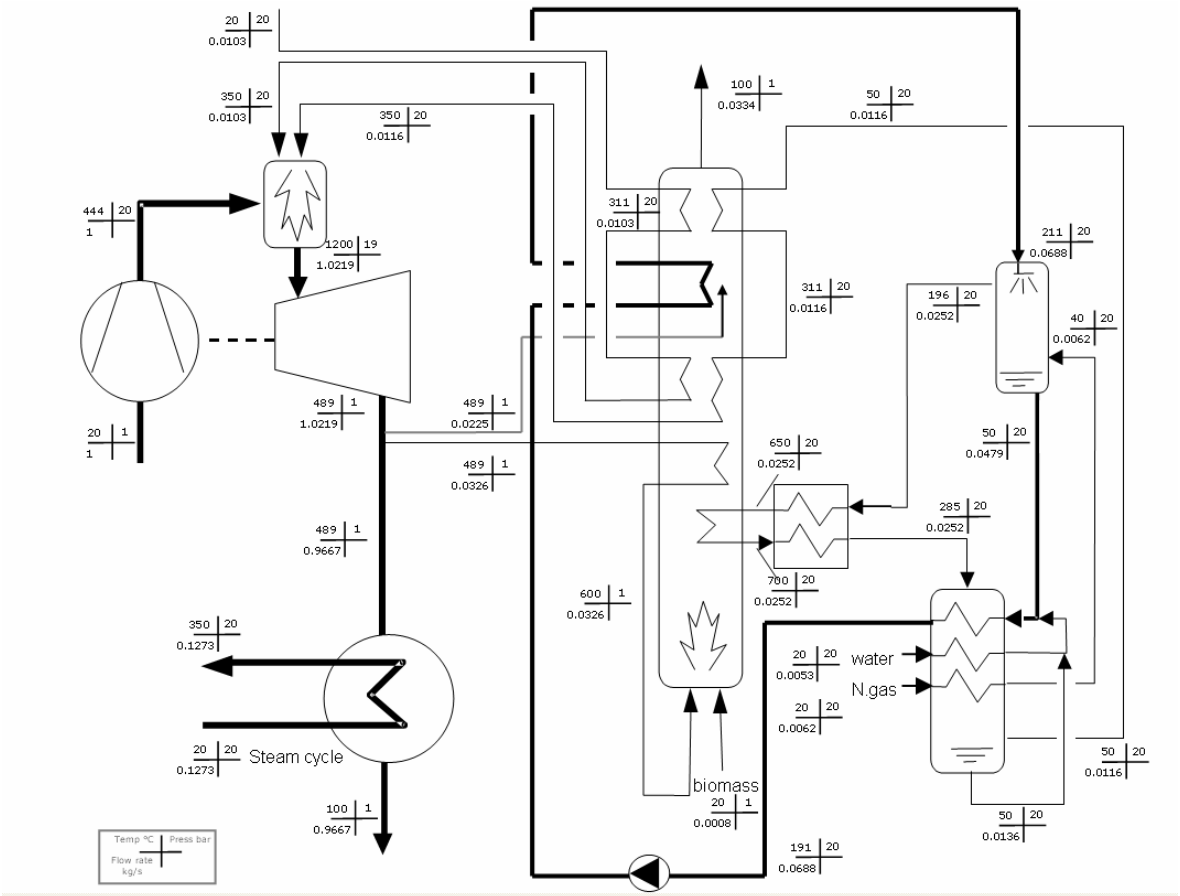

Figure 9: Synthesis of the reforming case including condenser and saturation tower (5% biomass)

The suggested alternative route has minimal interference with the reference cycle and allows a bio-input of 5% to result in a 51.7% cycle-efficiency compared to the reference cycle-efficiency of 50.4 %. In other words, biomass is converted at a marginal efficiency of 51.7%, which is a very high conversion efficiency for an external combustion route. Constant overall efficiencies can be obtained by routing some stack heat to the syngas, leading however to increased gas temperatures in the combustor nozzles. It is to be observed that the volume flow in the combustor nozzles is nearly doubled in the adapted case.

The next logical step will be the simulation of an existing power plant, with a comparison between the reference and the adapted cycle. This simulation will deliver the final theoretical proof of the capabilities of the suggested biomass process. If no significant drop in efficiency is noted for a 5% biomass energy input, this alternative route is worth to be tested in practice. In the current cycle, methane is used instead of natural gas and even though no problems are likely to turn up, this simplification needs to be validated.

ABSTRACT

Good air circulation within the storage room is essential to maintain proper product temperature and relative humidity. At present, the transportation of refrigerated cargo, by sea, land and air, is increasing rapidly due to economic growth. In addition to fruits, fresh vegetables, and marine products, semiconductors and precision instruments are also conveyed as constant temperature transportation products.

Little published data are available to predict supply air volumes for optimum cooling of the products. In order to improve and establish the storage and transportation technology, studies are necessary on the cold air circulation systems.

In this study, the velocity distributions of airflow and pressure drop in the loading space are measured at various supply air velocities under various geometrical conditions of clearance area, aperture area, packing factor and carton stage. The results of this study can be summarized as follows: Steep changes are observed in the air velocity and pressure drop with the change of clearance area of the aisle. The pressure drop increases with the decrease of aperture area. The effect of the packing factor on the pressure drop is comparatively small. The pressure loss coefficient is nearly proportional to the number of carton stage, but it increases a little with the decrease of airflow.

INTRODUCTION

The most popular refrigerated transportation systems at present are marine cargo containers and stores. As the mechanism of the systems is to maintain a controlled atmosphere around the products by circulating cold air, they are called "cold air circulation systems". In the case of the marine container, the cold air intake is located at the bottom of the container. So the cold air passes through the products from bottom to top of the container. Then it returns to the refrigeration unit from the ceiling duct and enters into the bottom intake again. In refrigerated transport, maintaining regular temperature throughout the cargo is essential to preserve quality, safety and shelf life of perishable foods. In the refrigerated enclosure, the control of temperature and temperature homogeneity is directly governed by airflow patterns [1]. A uniform cooling and cold storage of fresh produce are difficult to obtain in industrial cooling rooms because of an uneven distribution of the airflow [2,3].

It is considered that the cooling rate of this system is largely governed by the characteristics of airflow passing through the products and the airflow is affected by the geometrical conditions of the products and the loading space.

Recent investigation showed that little research on the characterization of air velocities has been performed. Van Gerwen et al. applied PHOENICS to simulate the velocity and temperature distribution in a refrigerated room. The validation was done for the airflow velocity, airflow patterns, static pressure and temperature of the air and the product. However, no data were given. Furthermore no information was reported about how the boundary conditions were applied [4,5]. More recently, Hoang et al. used the CFX CFD package code to predict the airflow pattern in empty and loaded cold stores [6].

In this study, the influences are examined experimentally of clearance factor, aperture factor, packing factor and carton stage (i.e., the number of piled cartons) on the velocity distribution and pressure drop.

EXPERIMENT

Experimental apparatus

A schematic view of the experimental apparatus is shown in Figure 1.

An inverter control fan (3.7kW) is used to supply air into the test section. In order to set the air volume, total and static pressures are measured with a composite Pitot tube sensor at a location between fan outlet and test section inlet [7]. To make airflow distribution as uniform as possible at both entering and leaving sides of the test sections, two wire nets of 30 meshes are fitted across the passage, 350 mm apart. A stainless steel honeycomb frame is also fitted to support the upper wire net.

Some boxes made of transparent acrylic resin panels of 5 mm thickness are used as model cartons. All faces of the boxes have holes of 10 mm inside

diameter with a square pitch of 15 mm. The dimension of the carton is $280^{L}\times180^{W}\times120^{H}$ mm and its cross-sectional area $A = 6.05\times10^{-3}$ m^2. The upper face of the carton can be opened, for it is fastened with bolts.

Plastic balls of 66.7 mm outside diameter are used as imitation loads. The packing factor is changed with the number of balls inside the carton, while the aperture factor is changed by sealing some holes [8]. The clearance factor is changed by filling partly or wholly the aisle open section between the carton and the test section sidewall with foamed polystyrene blocks.

Velocity and pressure drop measurement

Airflow velocities in the test section are measured with a three-dimensional ultrasonic anemometer and recorded in a personal computer. Figure 2 shows a block diagram of the anemometer.

In order to measure the air velocity distribution, whole cross-sectional area of the test section is divided into 6×4 meshes of 100 mm×100 mm square. The anemometer probe is moved to the center of each mesh to measure local air velocity.

Pressures are measured at each of the suction nozzle, the composite Pitot tube section, and the test section, under the various conditions of fan speed, clearance factor, aperture factor, packing factor and carton stage. Pressure drops in the test section are measured with digital vacuum manometers through the measuring holes on the test section sidewall.

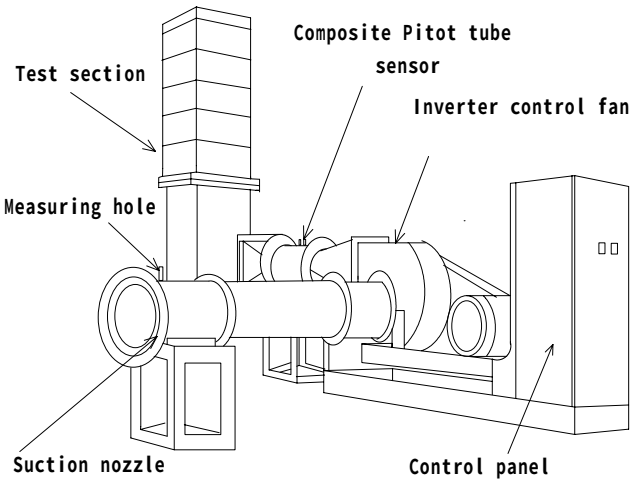

Figure 1: Schematic view of the experimental apparatus

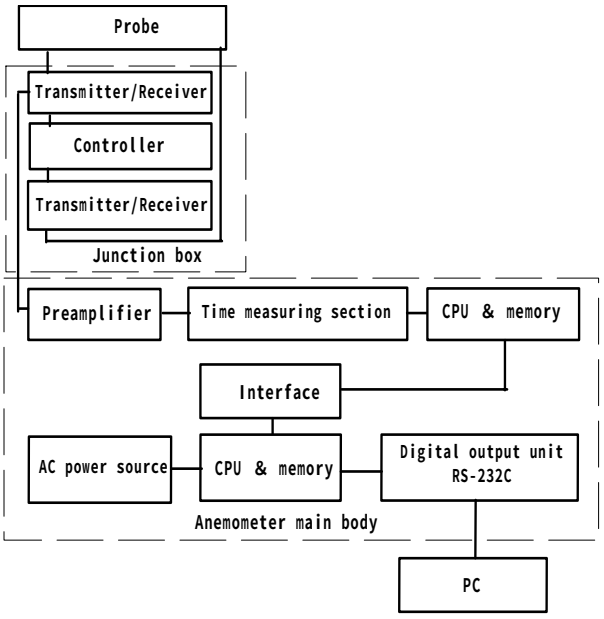

Figure 2: Block diagram of ultrasonic anemometer

DISCUSSION AND RESULTS

Figure 3 shows the relationship between the local mean air velocity and total flow rate Q in relation to clearance factor γ and the number of carton stage N, at an aperture factor α = 8.1% and a

packing factor β = 43.1%. Effect of clearance factor γ on velocity distribution is shown in Figure 3. In this figure, solid symbols represent the data for the aisle open section between carton and the sidewall, while the other symbols represent the data for the carton section. The total flow rate means the intake air volume per second.

Figure 4 shows the relationship between pressure loss coefficient ζ and Reynolds number *Re* in relation to clearance factor γ, for α = 8.1%, β = 43.1%, and the number of carton stage *N* =1 and 7. Figure 5 shows the relationship between the pressure loss coefficient ζ and clearance factor γ at *Re* = 50000. As is evident from these figures, a combination of the smallest clearance area, γ = 0, and the largest number of carton stage, *N* = 7, has the largest effect on the pressure loss coefficient ζ. In the case where γ = 0 and *N* = 7 the pressure loss coefficient ζ increases with the decrease of Reynolds number *Re*, while in the other cases the pressure loss coefficients ζ are far smaller and nearly constants.

In the same manner as Figure 3, Figure 6 shows the relationship between the arithmetic mean air velocity of 24 mesh points and total flow rate *Q* under the condition of no clearance, γ = 0. Needless to say, the air velocity and the flow rate are directly proportional regardless of aperture factor α and the number of carton stage *N*, for the air volume through the area other than carton section can be neglected.

Figure 7 and 8 show the effect of aperture factor α and the number of carton stage *N* on pressure loss coefficient ζ under the condition of no clearance, γ = 0. The aperture factor α has a significant effect on the pressure loss coefficient ζ especially in the case where *N* =7.

Figure 9 shows that the relationship between the mean air velocity and total flow rate is not affected by packing factor β in the case where γ = 0 for the same reason as above.

Figure 10 show the effect of packing factor β and the number of carton stage *N* on pressure loss coefficient ζ under the condition of no clearance, γ = 0, and the largest aperture factor α =16.2%.

Figure 11 shows the relationship between the mean air velocity and total flow rate for various number of carton stages, *N* =1 to 7, under the condition of no clearance, γ = 0.

Figure 12 shows that the pressure loss coefficient ζ increases with the increase of the number of carton stage *N* and is affected to some extent by Reynolds number *Re* and the number of carton stage *N* in the case of small *Re* and large *N*.

As shown in Figure 13, the pressure loss coefficient ζ is directly proportional to the number of carton stage in the case where γ = 0.

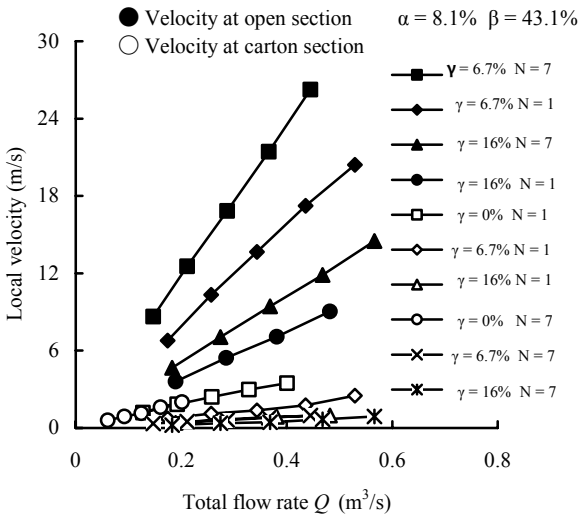

Figure 3: Relationship between local velocity and total flow rate *Q* for various clearance factor γ and number of carton stage *N* =1 and 7

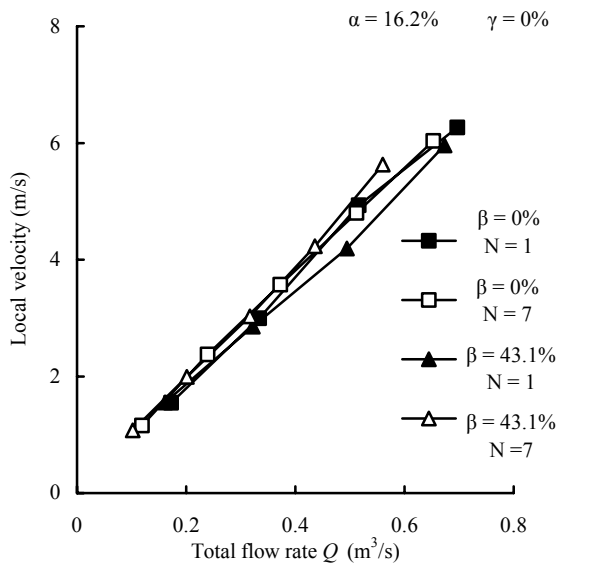

Figure 9: Relationship between the mean air velocity and total flow rate Q under the condition of no clearance, $\gamma = 0$, for packing factor $\beta = 0$ and 43.1% and the number of carton stage $N = 1$ and 7

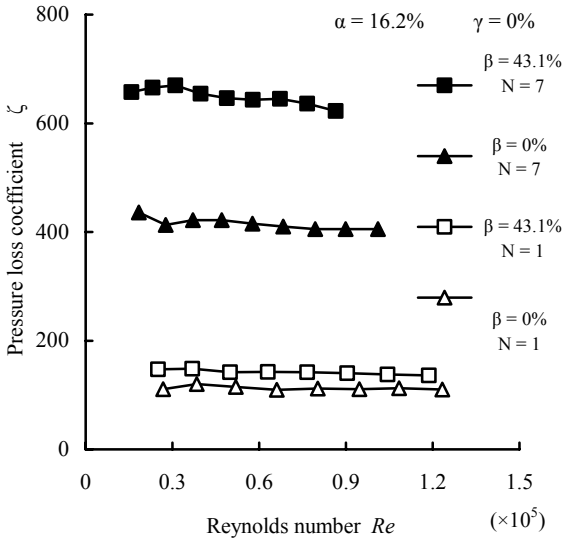

Figure 10: Relationship between pressure loss coefficient ζ and Reynolds number Re under the condition of no clearance, $\gamma = 0$, for packing factor $\beta = 0$ and 43.1% and the number of carton stage $N = 1$ and 7

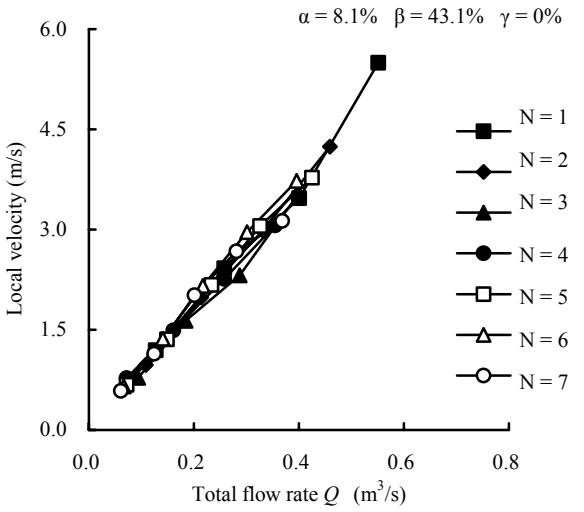

Figure 11: Relationship between the mean air velocity and total flow rate for various number of carton stages, $N = 1$ to 7, under the condition of no clearance, $\gamma = 0$

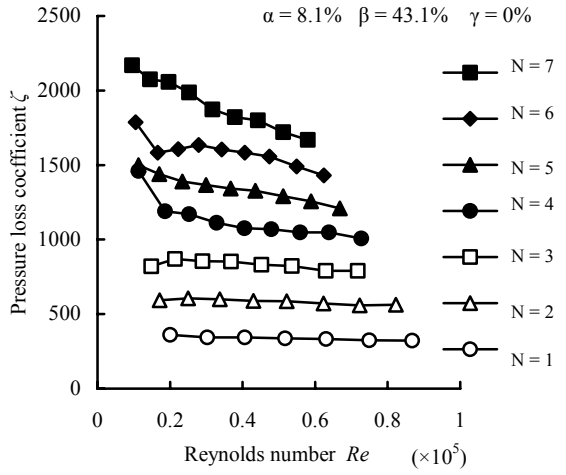

Figure 12: Relationship between pressure loss coefficient ζ and Reynolds number Re under the condition of no clearance, $\gamma = 0$, for various number of carton stage N =1 to 7

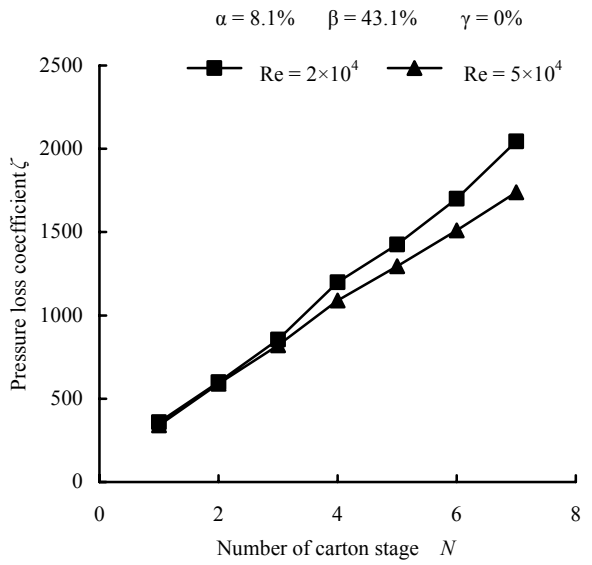

Figure 13: Effect of the number of carton stage N on pressure loss coefficient ζ under the condition of no clearance, $\gamma = 0$

CONCLUSIONS

From the experimental result on the velocity distribution of airflow and pressure drop in the model loading space, the following conclusions are obtained:

1) The velocity in the aisle, open section, becomes steeply higher with the decrease of clearance factor and the pressure loss coefficient suddenly increases near 0 clearance factor.
2) The pressure loss coefficient increases with the decrease of aperture factor and with the increase of packing factor and the number of carton stage.
3) The effect of packing factor on the pressure loss coefficient is relatively smaller than the other factors.
4) The pressure loss coefficient at 0 clearance factor is nearly proportional to the number of carton stage, although it increases a little with the decrease of Reynolds number.

Space Research Institute
Riyadh KSA

CHARLES GARRIS
The George Washington University
Washington DC, USA

ABSTRACT

The work to be presented herein is a Computational Fluid Dynamics investigation of the complex fluid mechanisms that occur inside a non-steady, three-dimensional, supersonic pressure exchange ejector, specifically with regard to the pressure exchange mechanisms and the induction processes between a primary fluid and a secondary fluid using steam as working fluid. It is the purpose of this research to study from the computational perspective the complex non-steady flow processes and induction mechanisms within a supersonic pressure-exchange ejector, how they relate to overall ejector performance, and to obtain geometrical parameters such as primary inlet area, rotor length, cone angle, and spin angle which would allow this technology to be utilized in many applications such as in ejector refrigeration systems. Results utilizing velocity vectors, contour plots of total enthalpy and static pressure showing the actual behavior of the steam supersonic pressure exchange ejector are presented. In this research, computational study is used to show how the aerodynamics flow is managed to provide the desirable flow induction characteristics of steam supersonic pressure exchange ejector. The geometry of this steam ejector is as follows: a 20-degree spin angle, 20-degree half angle cone, 1.80 inches rotor length and a 0.30 inlet area ratio. This research shows that the adiabatic efficiency is as high as 23% for this steam ejector.

If this new concept in ejector technology based on non-steady flow processes can be shown to be viable, the impact on refrigeration and air conditioning in the commercial, automotive, and residential sectors would be enormous and would enable environmentally benign refrigerants such as water to replace the harmful CFC's, and reduce the effluence of greenhouse gases by reducing fuel consumption through the use of waste heat and improved efficiency.

INTRODUCTION

All the attempts to improve the ejector performance have involved variations on the conventional design of the steady-flow ejector. The physical principle upon which this ejector operates is that of entrainment of a secondary

[1] Khaled alhussan: Phone +9661 481 4508 Fax +9661 481 3845 P.O. Box 6086 Riyadh 11442, KSA, alhussan@kacst.edu.sa

flow by an energetic primary flow by virtue of the work of turbulent shear stresses. Thus, the relatively low-energy secondary flow is dragged by the relatively high-energy primary flow through tangential shear stresses acting at the interface between the two contacting streams. These turbulent stresses are a result of mixing that occurs between primary and secondary streams and the consequent exchange of momentum.

While this mechanism is quite effective and has been widely adopted in many applications, an inherent characteristic of the mixing process is the dissipation of valuable mechanical energy. This results in a substantial entropy rise, which is intimately connected with ejector performance and consequently, refrigeration system performance [1-4].

On the other hand, the pressure-exchange ejector offers the possibility of attaining a breakthrough in the level of performance of ejectors by means of utilizing non-dissipative non-steady flow mechanisms [5-6].

Unlike the steady flow conventional ejector, the non-steady pressure exchange ejector is designed to utilize an entirely different physical principle, which is based on the pressure exchange phenomenon. Pressure exchange utilizes the reversible work of interface pressure forces, which exist only in non-steady flows. This mode of energy exchange is inherently non-dissipative. The utilization of this mode of energy-transfer is of interest, because of its potential to produce high efficiency [7-10]. The overarching goal is to create a flow induction machine which utilizes the work of interface pressure forces available in non-steady flows through direct contact of two fluids.

Pressure exchange is a designation applied to any process whereby contiguous fluid bodies or flows exchange mechanical energy through the work of mutually exerted pressure forces at their interfaces [11]. Pressure exchange cannot take place in steady flow, because no work is done by pressure forces acting on a stationary interface [12]. Therefore, pressure exchange is always a non-steady process.

An ejector is a direct contact flow induction device, which exchanges mechanical energy and momentum between a high-energy primary fluid and a relatively low-energy secondary fluid to produce a discharge of an intermediate specific energy level. The transfer of momentum gives rise to an increase in the stagnation enthalpy of the secondary fluid and enables the ejector to function as a compressor [13-15].

The work to be presented herein is a Computational Fluid Dynamics investigation of the complex fluid mechanisms that occur inside a non-steady, three-dimensional, supersonic pressure exchange ejector, specifically with regard to the pressure exchange mechanisms and the induction processes between primary fluid and secondary fluid [16-19].

This research is based upon utilizing a non-steady flow field resulting in the work of pressure forces acting at a fluid interface between primary fluid and secondary fluid. These interfaces are produced through the aerodynamic design of a flow field, non-steady in the laboratory frame of reference, consisting of rotating oblique shock waves and expansion fans. Minimizing the possible losses from the oblique shocks and boundary layers offer the potential of achieving adiabatic efficiencies approaching those of turbo-machines[5-6 and 16-20].

Study of the actual flow configuration inside the complex three dimensional supersonic pressure exchange ejector offers some insight into the complex flow phenomena that occur inside the ejector. This paper shows some geometrical parameters that produce the right environment for pressure exchange to take place, for the steam supersonic pressure exchange ejector that generates a high adiabatic efficiency about 23% [18]. Adiabatic efficiency is related to both the ratio of mass flow rate and the ratio of temperature of secondary fluid to primary fluid [2 & 21]. The efficiency of the energy exchange is increased if it is made to take place, at least in part, through the non-dissipative work of interface pressure forces.

COMPUTATIONAL FLUID DYNAMICS ANALYSIS

The flow induction in the supersonic pressure exchange ejector is so complex that there exist direct fluid-fluid interactions, oblique shock waves, expansion fans, slip surfaces, and shock wave interactions and reflections. The flow is

non-steady, viscous, compressible, and high-speed supersonic.

The governing equations are a set of coupled nonlinear, partial differential equations. In order to formulate or approximate a valid solution for these equations they must be solved using computational fluid dynamics techniques. To solve the equations numerically they must be discretized. That is, the continuous control volume equations must be applied to each discrete control volume that is formed by the computational grid. The integral equations are replaced with a set of linear algebraic equations solved at a discrete set of points.

CFX is used in the current research to model the flow in the supersonic pressure exchange ejector. The code uses block-structured, non-orthogonal grids with grid embedding and grid attaching to discretize the domain. CFX is a finite volume method, but is based on a finite element approach of representing the geometry. Thus, the method used here possesses much of the geometric flexibility of finite element methods as well as the important conservation properties of the finite volume method.

It should be possible to model the interaction of the shock waves and expansion fans around the rotating vanes and describe how the secondary flow is drawn into the interstices. It should be possible to study the mutual deflection and pressure exchange processes between primary and secondary flows using the CFD analysis [16].

A numerical analysis must start with breaking the computational domain into discrete sub-domains, which is the grid generation process. A grid must be provided in terms of the spatial coordinates of grid nodes distributed throughout the computational domain. At each node in the domain, the numerical analysis will determine values for all dependent variables such as pressure and velocity components.

Creating the grid is the first step in calculating a flow. A 180-deg sector was chosen to model the flow. The grid is refined near the surface of the vanes in order to model the large gradient in that region. For computation, a Mach number of 3.0 is used as the Nozzle Exit Mach number. Solution parameters and fluid properties are defined in the parameter file. For the steady-state solution, the time step is selected equal to 0.00001. The advection discretization scheme selected is the Modified Linear Profile Skew scheme with the Physical Correction. The convergence criterion is 10E+04 and the maximum number if iteration is 300. The maximum number of iteration is increased form 300 to 1000 to allow the solver to run until a converged solution is found.

A computational model that illustrates the physics of flow induction through non-steady shock waves and expansion fans was developed. This provides strong insight into the mechanisms through which the supersonic pressure exchange ejector operates.

Through this computational analysis, a better interpretation of the physical phenomenon of the non-steady pressure exchange ejector can be achieved. The results from the numerical analysis are used to study the flow structure inside the complex geometry of the pressure exchange ejector and to develop a design methodology so as to predict optimal ejector performance.

DISCUSSIONS

Water is an excellent refrigerant, which has a high latent heat of vaporization, a high specific heat, good heat transfer characteristics, non-corrosive, and is totally in harmony with the environment. However, for normal air conditioning applications, the specific volume of water vapor under operating conditions must be hundreds of times larger than that of a system using CFC's under comparable environmental conditions and design requirements. Water as a refrigerant, when used with a positive displacement type compressor, requires a much larger compressor displacement volume. The need for a much larger compressor, and the associated increased cost, has rendered water less desirable as a refrigerant for conventional air conditioning. However, this problem can be resolved by the use of an ejector, which is capable of transporting large volumes of vapor within a relatively small space and at a low cost [6].

It is an objective of this research to provide an ejector refrigeration system with a Coefficient of Performance considerably higher than that of the conventional steady flow ejector and approaching that of the ideal turbo-machinery standard. The

pressure-exchange ejector utilizes a non-steady flow principle to obtain higher adiabatic efficiencies than conventional ejector while retaining much of the simplicity of construction and the low manufacturing cost of a conventional ejector [5-8].

Advantages of the Pressure-Exchange Ejector in Refrigeration Systems:

1) The pressure-exchange ejector could benefit the environment by reducing pollutants at their source.
2) The pressure-exchange ejector retains much of the mechanical simplicity of conventional steady flow ejector.
3) The pressure-exchange ejector could be amenable to the utilization of environmentally benign refrigerants such as water instead of chlorofluorocarbons.
4) This ejector is capable of compressing high specific volume vaporized refrigerants with an ejector of reasonable size and cost.
5) Since this ejector refrigeration system uses a boiler, which could be energized by waste heat instead of a compressor, the emissions of undesirable greenhouse gases, i.e., carbon dioxide (CO_2), nitrous oxide (N_2O), methane (CH_4), etc., could be reduced considerably.

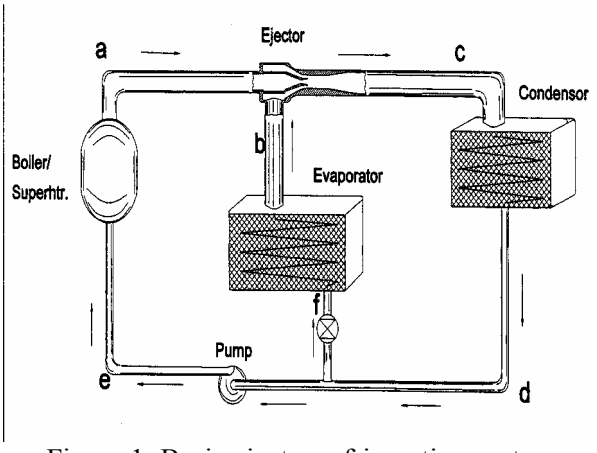

Figure 1: Basic ejector refrigeration system

A basic ejector refrigeration system is shown in figure 1. A pump discharges condensate to a boiler/superheater that releases energetic primary vapor to the ejector. The ejector draws secondary vapor from the evaporator and discharges it to the condenser. The condensate from the condenser is divided between the pump inlet and the expansion means that supplies cool vapor/liquid to the evaporator. A high-energy primary fluid compresses a lower energy secondary fluid through direct fluid-fluid momentum exchange.

It can be shown [1-2], that the COP for a basic ejector refrigeration system is given by:

$$COP = \mu \frac{h_b - h_f}{h_a - h_d} \qquad (1)$$

where COP is the Coefficient of Performance, the ratio of energy extracted from the evaporator to the energy provided in the boiler/superheater and the pump; μ is the ratio of secondary mass flow rate to primary mass flow rate; h_a, h_b, h_d, h_f are the specific enthalpies at points a, b, d, and f in the system as indicated in figure 1.

Equation 1 shows that with the system operating at prescribed evaporator, condenser, and superheater conditions the COP is directly proportional to the ratio of the ejector secondary mass flow rate to the ejector primary mass flow rate. This ratio is commonly known as a fundamental figure of merit for the flow induction efficiency of an ejector. Hence, the higher the ratio of secondary to primary mass flow rates, the higher the COP [22].

The performance of the ejector is a controlling factor in determining the performance of the refrigeration system. This has been recognized in the literature with many attempts at improving the ejector performance [6].

The efficiency of an ejector is closely connected with the entropy generation processes occurring within it. The operating principles of a conventional steady-flow ejector result in two major sources of entropy generation: turbulent mixing and strong normal shock waves. By means of the pressure-exchange ejector that utilizes physical mechanisms which produces modest entropy rises, a substantial improvement over conventional technology is possible.

The advantage of the pressure exchange process is that, even accounting for shock losses, the entropy rise can be small. Post-pressure-exchange mixing will incur a much smaller entropy rise than would have occurred with primary-secondary mixing in a conventional ejector, since the energy levels in the former are nearly equalized by pressure exchange.

It can be shown [2& 21] that the ejector efficiency is defined as:

$$\eta_d = \mu \frac{(T_{ts})}{(T_{tp})} \left[\frac{\left(\frac{p_e}{p_{ts}}\right)^{\frac{\gamma-1}{\gamma}} - 1}{1 - \left(\frac{p_e}{p_{tp}}\right)^{\frac{\gamma-1}{\gamma}}} \right] \qquad (2)$$

From this equation, one can see that increasing the mass flow ratio,μ, of the ejector will result in increasing the overall adiabatic efficiency η_d. Remember that increasing the ratio of the mass flow rate of the ejector also will result in increasing the COP of the refrigeration cycle. Thus one can conclude that the higher the adiabatic efficiency, the higher the COP.

RESULTS

The domain of interest is a complex, three-dimensional, bounded conical shape. The flow is non-steady and compressible. In this situation, one should expect oblique shock waves, expansion fans, shock wave interactions, and slip surface generation.

The previous discussion demonstrated that steam makes an excellent working fluid for the pressure exchange ejector. In this paper a numerical analysis was conducted to study the actual behavior of the steam supersonic pressure exchange ejector.

Figure 2 depicts the shape of the rotor vane. The geometry of this steam ejector is as follows: a 20-degree spin angle, 20-degree half angle cone, 1.80 inches rotor length and a 0.30 inlet area ratio. Inlet area ratio is defined as primary inlet area to the secondary inlet area. Figure 3 shows three-dimensional schematic view of the aerodynamic shroud surface.

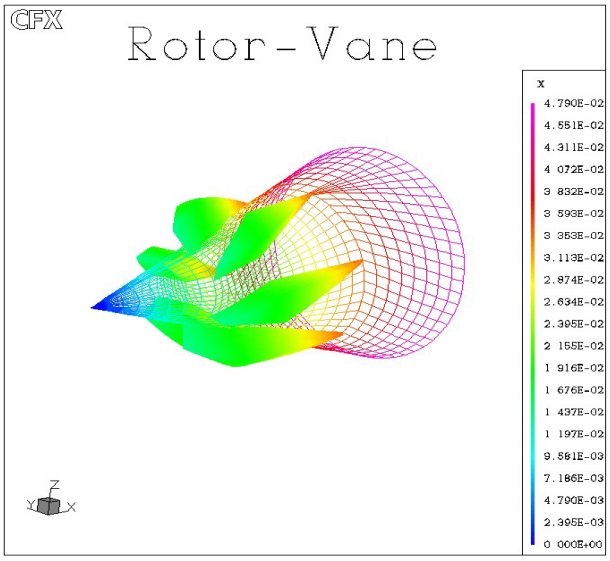

Figure 2: Partial sketch of the geometry for 20-degree spin angle, 20-degree cone half angle, steam ejector

The vane configuration plays a very important role in the design analysis of the supersonic pressure exchange ejector. The best vane configuration was chosen based on a previous study [20].

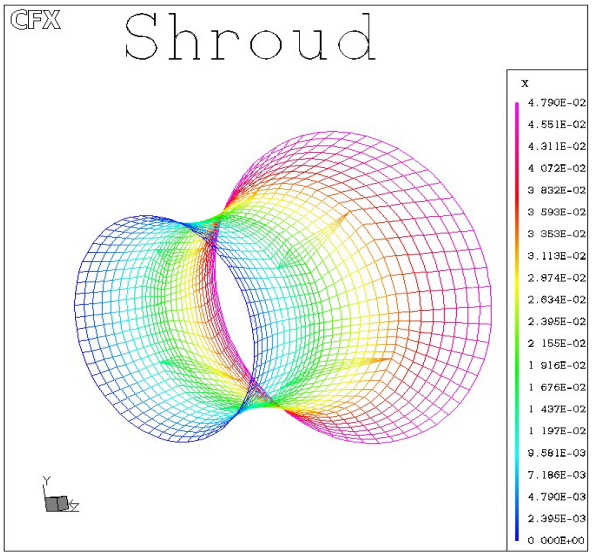

Figure 3: Partial sketch of the geometry (shroud) of steam ejector, 0.30 inlet area ratio, steam ejector

In order to see the flow pattern between the vanes and on the vanes, contour plots are shown projected on the surfaces defined in figure 4.

Figure 4 shows two surfaces, one surface is on the vanes and the other surface is between the vanes. Figure 4 shows a sketch of the planes that will be used in this analysis. In this figure one should notice that the planes over the vanes and between them are not simple colinear with the longitudinal axis. Rather they are a series of planes, which show the flow path through the vanes. The reason is to show the three-dimensionality of the problem and the construction of the grid.

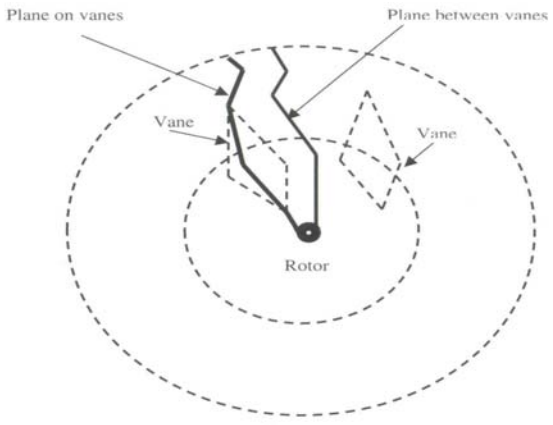

Figure 4: Sketch to show the surfaces of side view planes between and on the vanes

Figure 5 shows velocity vectors for steam ejector. By analyzing this figure, one can observe the existence of expansion fans over the vanes and the direction of the velocity vectors when they pass over the vanes. One can see the primary fluid expanding and pulling the secondary fluid with it. This is represented by the direction and the magnitude of the velocity vectors of the entrained secondary fluid. In the same figure, one can see that the velocity vectors of the secondary fluid are growing and curved in this steam ejector. Also, from figure 5, one can notice that at the surface of each vane, a three-dimensional expansion fan develops. This expansion draws secondary fluid down into the interstices of the primary flow behind the vanes and initiates the pressure-exchange process between the primary and secondary flows. One can also see the presence of the attached oblique shock wave at the apex of the cone. One can conclude from this figure that the primary fluid expands rapidly and the secondary fluid finds itself accelerating and is being drawn with the driving stream. The velocity vectors show the entrainment of the secondary fluid. From the same figure one sees the deflection of the secondary fluid near the expansion fan.

The velocity vectors in planes passing between the vanes are plotted in figure 6. In this figure one should only see the primary flow filling up the passage and this is accomplished for the design.

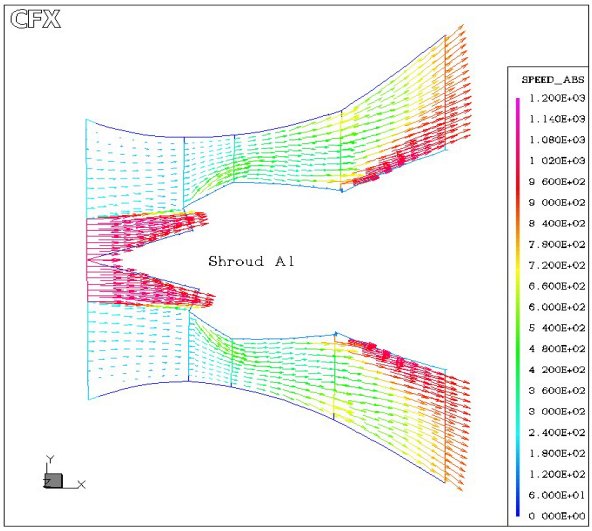

Figure 5: Velocity vectors, planes passing over the vanes, side view, steam ejector

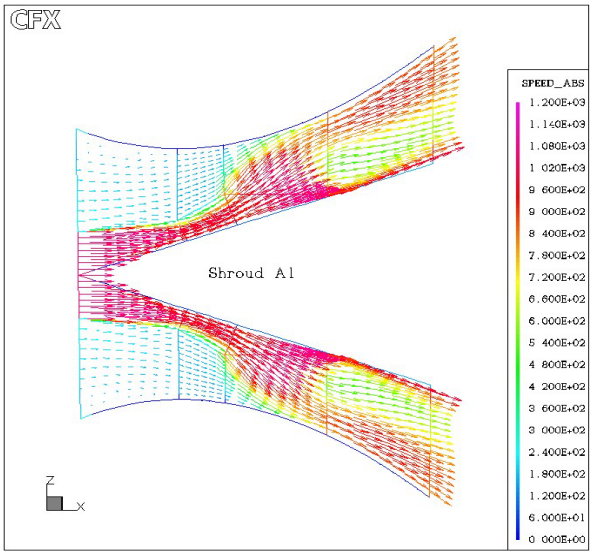

Figure 6: Velocity vectors, planes between the vanes, side view, steam ejector

Figure 7 shows the side view (see figure 4) of static pressure for of the entire ejector. Analyzing this figure, one should see that the expansion fan is causing the suction of the secondary fluid. Also this figure shows that the pressure exchange zone is indeed very short and that the compression is completed. Figure 7 also, shows the static pressure for steam as working fluid for planes passing over the vanes. In this figure one can notice the shape of the shock wave over the fore-body and in this figure the expansion fan is also clear. The oblique shock wave was designed to be a weak one that extends to touch the top surface of the leading edge of the vane. This is accomplished, as seen in figure 7.

In the pressure-exchange ejector system, the interaction of primary fluid and secondary fluid is completed in two consecutive processes: the deflection phase and the mixing phase. During this flow induction process, energy transfers from the primary flow to the secondary flow and the energy level of the secondary flow is increased [16]. The basic principle of the energy exchange between two fluids in the non-steady flow induction is that one should optimize the total enthalpy rise of the secondary fluid. This is shown in figure 8 where the total enthalpy for steam ejector is plotted. This figure shows the top view of the entire ejector near the shroud surface. This figure shows that indeed the total enthalpy of the secondary fluid is increased as it flows inside the ejector. This figure shows also the formation of the pseudo-blade and how this is related to the increase of the total enthalpy (in the absolute frame of reference) of the secondary fluid as it passes through these pseudo-blades. This can be seen, also, from the side view of the steam ejector, namely figure 9 the total enthalpy.

Figure 9 shows the total enthalpy in planes on the vanes. In this figure one can see that the primary fluid and the secondary fluid enter the ejector with different levels of energy. Then as they pass over the vanes the level of energy of the secondary fluid increases, and this is represented by the increase of the total enthalpy as seen from the absolute frame of reference.

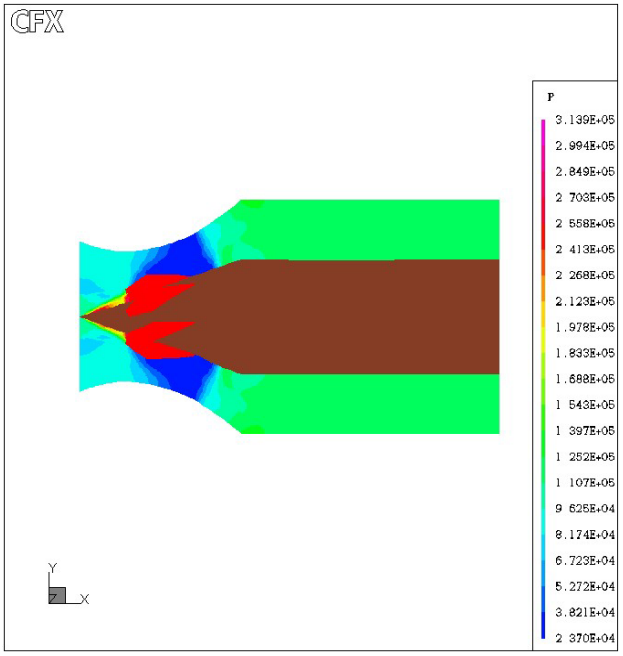

Figure 7 Contour plot of static pressure planes passing over the vanes, steam ejector

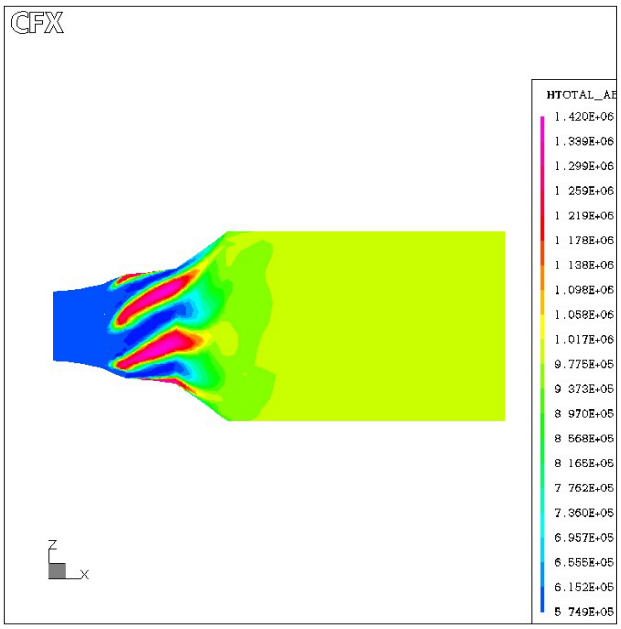

Figure 8: Contour plot of total enthalpy, absolute frame of reference, for steam ejector, top view, steam ejector

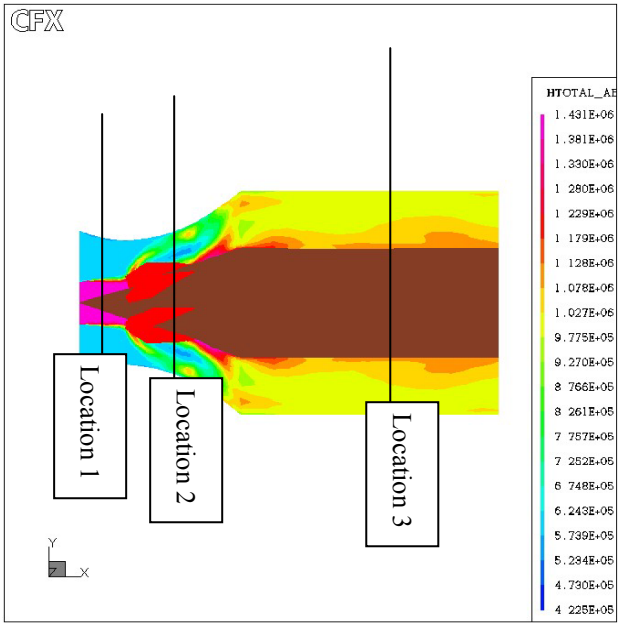

Figure 9: Contour plot of total enthalpy, absolute frame of reference, planes passing over the vanes, steam ejector

One should notice that at location 1, in figure 9, there are two fluids; namely, the primary represented by red color, and the secondary represented by blue color, and both have different total enthalpy. At location 2 the primary stream impinging on the canted-vanes causes the rotor to free spin. At location 2 one should observe the initiation of the expansion fan in between the vanes. From the same figure the secondary fluid is being drawn into the interstices of the primary flow where they are permitted to exchange their energy. At the same location, one should notice the structure of the flow where the secondary flow is co-rotating and the primary fluid is counter rotating. The exchange of pressure energy between the primary and the secondary fluids start in region 2. Finally at location 3, the total enthalpy of the secondary fluid is increased as it is shown in figure 9.

The adiabatic efficiency of the steam ejector is important, and this research shows that for $T_{\Re}$ of 1.125 the calculated adiabatic efficiency is as high as 23% and the mass flow ratio is 1.164. It should be noted that this adiabatic efficiency is calculated on the basis of the assumptions that perfect expansion in the primary nozzle is achieved, the total pressure at the exit as an average value over the flow cross section, and the ideal gas assumption is used. The main purpose of calculating this adiabatic efficiency is to use it in this analysis of determining the flow requirements of the supersonic pressure exchange ejectors [16-19].

The results suggest two points in regard to the calculation of the adiabatic efficiency: mass flow ratio and the temperature ratio. From analyzing the mass ratio one can conclude that the higher the mass flow ratio the lower the entropy production. The lower the entropy rise the higher the COP for the refrigeration system.

CONCLUSION

This research showed how to utilize the pressure exchange principle to overcome the shortcomings of conventional steady-flow ejectors. This pressure exchange ejector can be used in a refrigeration system. The ejector can utilize refrigerants such as water instead of environmentally harmful chlorofluorocarbons (CFCs) and can utilize waste heat as an energy source.

The results showed increase in total enthalpy. The increase in the total enthalpy confirmed the advantage in energy transfer by work of interface pressure forces in the non-steady ejector over the viscous shear forces in the steady flow ejector.

A high mass flow ratio was achieved. This parameter is an important characteristic of the steam ejector, since the higher the mass flow ratio the lower the entropy production. This results in a higher COP for the system.

The geometry of this steam ejector is as follows: a 20-degree spin angle, 20-degree half angle cone, 1.80 inches rotor length and a 0.30 inlet area ratio. The adiabatic efficiency was calculated for this ejector using steam as working fluid, and it was shown that the adiabatic efficiency is related to both the ratio of mass flow rate and the ratio of temperature. A high adiabatic efficiency of 23% of the steam ejector was calculated with this simulation.

This pressure-exchange ejector could positively contribute to the environment by reducing the production of hazardous effluents at the source.

ABSTRACT

Due to the overwhelming concern of global warming and ozone depletion, the replacement of many currently used refrigerants is a pressing matter within all sectors of refrigeration. When deciding to replace a refrigerant worldwide, many factors are taken under consideration. The benefits and necessary changes that occur when using carbon dioxide (CO_2) as the working fluid are explored. One important aspect of using CO_2 as a replacement refrigerant in automotive air conditioning (AC) systems lies in diagnosing refrigerant leakage within a faulty system. A reliable refrigerant leakage detection and diagnosis system is a necessity for the automotive industry. In current research at Rochester Institute of Technology (RIT), advanced thermodynamics is being used to develop a detailed simulation model as well as a fault detection and diagnosis system specifically for the future CO_2 automotive AC systems.

INTRODUCTION

Refrigeration systems are a common technology in today's world, being used in everyday activities, such as food preservation and air conditioning (AC) applications. Presently, the hydroflourocarbon HFC-134a, the working fluid of automotive air conditioning systems, greatly contributes to global warming. Natural refrigerants have gained worldwide attention as the logical replacement for HFCs. Carbon dioxide (CO_2) is the natural refrigerant receiving the most attention due to its abundance in nature.

In order to better understand the operation of an automotive AC system which utilizes CO_2 as its working fluid, a simulation model is created by the authors using the software program Engineering Equation Solver (EES) [www.fchart.com]. The model simulates normal operation as well as faulty operation due to refrigerant loss within an automotive AC system using CO_2. The First and Second Laws of Thermodynamics are used to verify normal operational data and performance parameters obtained from past experimental and analytical work described within this paper. Using the EES model, refrigerant losses are simulated throughout the system one at a time at locations prone to leaks and the model produces a faulty operating data library. Analyzing the simulated fault data for possible trends or patterns is done in order to detect future system faults and to diagnose the faults accordingly.

Each of the different types of refrigeration systems can be modeled thermodynamically in order to find the system's overall efficiency. Both a first law based (energetic) efficiency as well as a second law based (exergetic) efficiency can be found in order to evaluate the system's performance. The concept exergy comes from using the Second Law of Thermodynamics in conjunction with the conservation of energy laws. The idea of exergy better enables the examiner to further understand the location, types, and true magnitudes of waste and loss. An exergy loss or destruction can reflect an inefficient use of fuel or a location of major irreversibilities within the system. With exergetic efficiency, the examiner can gauge the potential for improvement in the performance of a system [1].

Throughout the history of refrigeration, the working fluid (refrigerant) used for applications has changed based on economical, safety and environmental reasons. Major contributors to the evolution of refrigerants are system efficiency as well as emission issues. Balancing the amount of hazardous emissions released to the atmosphere with the financial burden of increasing the system's efficiency is essential in designing an automotive air conditioning system.

The Montreal Protocol, an international treaty that controls the production of ozone-depleting substances, disallowed the production of chlorofluorocarbons (CFCs), such as R-12, by the year 1996. R-22, a hydrochloroflourocarbon (HCFC), is to cease production by 2030 [2]. In addition, HFC-134a will not be produced in Europe after 2017. On October 14, 2004, the Environment Ministers of the European Union agreed that a ban will apply to all new vehicles being produced beginning in 2011. By 2017, every new vehicle produced must utilize a refrigerant that has a global warming potential (GWP) of less than 150 [4]. Thus, new environmental regulations have lead to an increased interest from the AC automotive industry to explore the use of CO_2 as a refrigerant.

Carbon dioxide as a refrigerant has been used in past air conditioning systems. It was originally used for cold storage refrigerators in food markets and for comfort cooling in motion picture theaters in the 1900s [3]. Within automotive applications, more investigations are necessary to design an automatic or manual leak detection and diagnosis system for use during troubleshooting and maintenance. All CO_2 cycles are transcritical, which means they move between sub and supercritical pressures during the cycle, due to a low critical temperature of 31.1°C. Also, segments of the system are under extremely large pressures which can contribute to refrigerant loss.

RESEARCH OBJECTIVE

The objective of research currently underway at Rochester Institute of Technology (RIT) is to effectively detect and diagnose leaks for automotive carbon dioxide air conditioning (AC) systems using a technique that incorporates exergetic analysis. Before designing the experimental setup which will be used to validate the proposed technique, a computer simulation of a CO_2 automotive AC system is developed. First, a normal operating AC system is simulated in order to better understand the operating condition of a normal system. When the experimental setup is completed it will be utilized to verify the accuracy of the EES simulation model under normal operating conditions.

Developing a simulation model for refrigerant loss is enhanced through the identification of probable leak locations within the system. Based on the fleet of prototype vehicles in Europe that currently use CO_2 AC systems, leaks typically occur around

the compressor and between connections of hoses and lines. A major change that must be made to a current air conditioning system is that the lines of the system are no longer hoses, but a combination of metal lines and hoses. Metal lines are incorporated because the CO_2 cycle is transcritical and therefore the CO_2 remains as a superheated vapor or liquid-vapor mixture throughout the cycle. The metal lines include hoses in order to dampen the vibrations that would occur otherwise. The connections between the metal lines and the hoses are considered one probable area for refrigerant loss. Any time there is a connection made between components, the chance for leakage increases. Another probable location for leaks is within the compressor. The compressor used in most automotive CO_2 AC systems is non-hermetically sealed. It incorporates an open configuration with a sealed rotating shaft which is a significant contributor to potential leakage.

Using an EES refrigerant loss simulation model, the typical fault areas are reproduced by inflicting mass flow rate losses upon the system in order to replicate refrigerant losses. Losses must be varied in order to accurately replicate an actual leak. Some leaks can be slow if they are steady and constant, but some leaks may be large if a seal erratically breaks open. The refrigerant loss simulation model will be validated using the experimental setup. Currently, the refrigerant loss simulation model provides insights into locations and types of sensors required to detect and diagnose CO_2 losses within the system.

Within this paper, a more detailed description of the EES simulation model and proposed sensor locations is provided. The objective of this ongoing research is to develop an inexpensive, effective, and automatic leak detection and diagnosis methodology for automotive CO_2 AC systems. The work is performed in conjunction with industry in order to add to its relevance and to ease potential market transfer in the future.

CURRENT LEAK DETECTION METHODS

Technically, every system has leaks, because all equipment leaks to some degree. According to Tomczyk [5], a leak is "a physical path or hole, usually of irregular dimensions, that may be the tail end of a well fracture, a speck of dirt on a gasket, or a micro-groove between fittings." Leaks can be classified by a number of factors: pressure dependent, temperature dependent, vibration dependent, etc. Reducing the likelihood and detecting leaks is a significant challenge in developing refrigeration systems.

Within many research, development, and testing facilities, gas analysis is used in order to detect leaks within HFC-134a AC systems. This method is used for experimental purposes in order to identify faulty equipment before it is used in manufacturing. Components (all or some) of an air conditioning system are placed inside a closed test chamber of a known volume. This test chamber is calibrated using a correlation factor determined through a known leakage rate of refrigerant. The components are placed in the chamber and operated, allowing for refrigerant to leak. The HFC-134a gas concentration is determined by measuring the level of sound created by the expansion of the gas following absorption of infrared light at a specific wavelength. Gas sensitivity is achieved using optical filters capable of detecting concentrations in the parts per billion (ppb) range. To ensure the accuracy of the equipment, the analyzer compensates for temperature, pressure, and water vapor interference.

For on-sight maintenance, automotive repair technicians utilize a refrigerant detecting gun like the one shown in Figure 1 [6]. On-sight maintenance refers to testing components which have been installed on the vehicle. The refrigerant detection gun can detect leaks only as small as 500 parts per million (ppm), which is highly ineffective for smaller leaks.

Figure 1: Example Leak Detection Gun

CARBON DIOXIDE AS A REFRIGERANT

In the past, research has been conducted in using carbon dioxide as the refrigerant for many different types of refrigeration cycles. More recently, automotive air conditioning applications that utilize CO_2 are investigated as well. Currently, HFC-134a is used as the automotive AC working fluid. As compared with carbon dioxide, it has a much higher GWP. The GWP for a substance is calculated as the ratio of the radiative forcing impact that results from the emissions of one kilogram of the substance to that from emissions of one kilogram of carbon dioxide over a period of time (usually 100 years) [7].

The GWP of HFC-134a is approximately 1300; therefore it has 1300 times the GWP of CO_2. If one unit of HFC-134a is released into the atmosphere, it will take 1300 units of CO_2 to create the same amount of damage. Table 1 [7] shows how the GWP value for HFC-134a has been adjusted by scientists since 1990 due to improved understanding of effects on global warming. An increase in the adjustments regarding the GWP value is anticipated to continue into the future.

	Year	
Refrigerant	**1990**	**1996**
CO_2	1	1
R-134a	1200	1300
R-22	1400	1400
R-12	7300	7300

Table 1: Global Warming Potential (GWP) of Various Refrigerants in 1990 and 1996

Carbon dioxide appears to be a logical replacement for chemical based refrigerants because of its natural occurrence in the atmosphere. Also it is non-flammable and involves a high operational pressure for effective performance which results in a reduction in required compressor size. The required compressor volume is inversely proportional to the suction pressure. The volumetric capacity of carbon dioxide is eight times higher than conventional refrigerants, which allows for a smaller compressor compared to conventional ones [8]. A major disadvantage of CO_2 as a refrigerant is that it is not self-alarming and therefore leak detection is difficult. This is a major concern for system manufacturers. The term 'self-alarming' means that one cannot detect (smell or taste) small amounts of CO_2 in the air.

The basic design of an AC system is typically affected by its refrigerant selection. Fartaj et al. [8] used a CO_2 AC system developed by Lorentzen and Pettersen [9] that incorporates a few changes to the typical AC system configuration (shown in Figure 2) to take the transcritical properties of the CO_2 refrigerant into account. The condensation process within the CO_2 AC cycle is changed. The purpose of the condenser is to transfer heat from the refrigerant to the cooler surroundings. Because the critical temperature of carbon dioxide is so low (of 31.1°C), it is normally below the typical ambient temperature. The condenser is replaced with a gas cooler and the condensation process is further enhanced with an internal heat exchanger as shown in Figure 3.

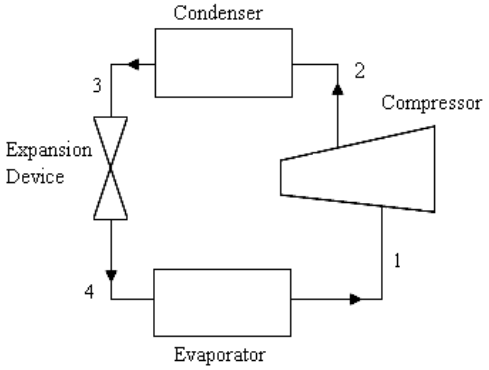

Figure 2: Basic HFC-134a Refrigeration System Schematic

Figure 4 is the representation of the temperature-entropy diagram for a CO_2 refrigeration cycle superimposed on the vapor dome for this substance [8]. High temperature supercritical CO_2 exiting the compressor (state point 2 in Figures 3 and 4) is cooled in the gas cooler to a lower temperature (state point 3) and then enters the internal heat exchanger where the high pressure refrigerant is further cooled by the low pressure CO_2 coming off of the evaporator (state point 6). This cooled carbon dioxide (state point 4) passes through an expansion valve where it is throttled to a lower pressure and temperature (state point 5). Finally, the refrigerant absorbs heat from the air within the car's interior while flowing through the evaporator and exiting as a high quality mixture (state point 6). The AC system's evaporator is the part of the system attached near the inside of the vehicle.

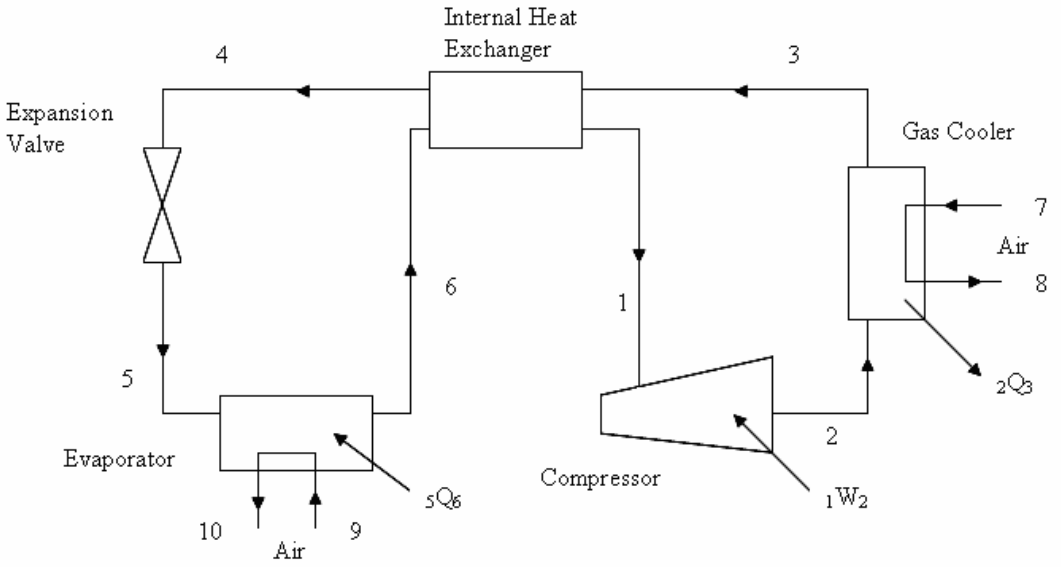

Figure 3: CO_2 Refrigeration System Schematic

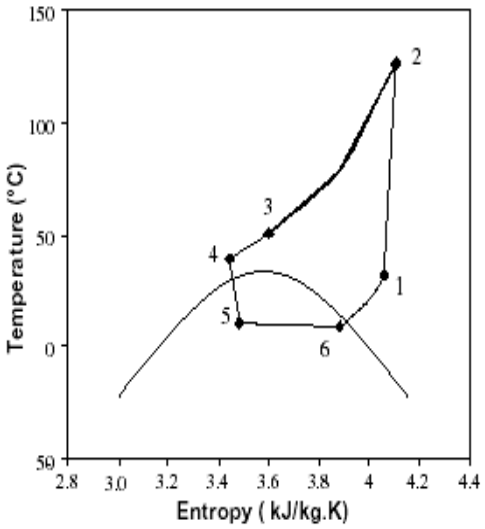

Figure 4: Temperature vs. Entropy Diagram for CO_2 Refrigeration Cycle

SIMULATION MODEL DEVELOPMENT

The EES simulation model developed considers the CO_2 AC system shown in Figure 3. The simulation model assumes steady state operation and thus transient operation such as at initial start up of the system is neglected. This assumption is made to reflect the data provided by Fartaj et al [8]. The heat exchangers, expansion device and compressor are considered adiabatic. Constant pressure drops across the system's heat exchangers are assumed and based on past published experimental work. In addition, the isentropic efficiency of the compressor and heat exchanger effectiveness are assumed to remain constant during both normal and refrigerant loss scenarios. When modeling refrigerant loss, three potential refrigerant loss areas are investigated, however simultaneous losses at more than one location are not considered. Compressor power consumption during loss scenarios is also considered constant.

The simulation program provides pressure, temperature, enthalpy, and internal energy of state points around the system. It uses these values to also determine exergetic efficiency of system components. Exergy can be defined as the maximum theoretical work obtainable as a system and its reference environment interact to equilibrium [1]. The use of exergy in thermodynamic analysis provides more meaningful results that simply using the first law of thermodynamics. An exergy analysis can

determine where and how losses occur in the system so that energy can be used more effectively and efficiently.

The exergy of a pure substance is given by Equation 1.

$$e = (h - h_0) - T_0(s - s_0) \quad (1)$$

where the enthalpy (h) and entropy (s) of the given state is compared to the reference, or dead state (depicted by subscripts of '0'). An environment is assumed to be a simple compressible system that is large in extent and uniform in both temperature and pressure. This reference state is typically the ambient temperature and pressure for the system, such as 298 K and 101.325 kPa, respectively. The exergy loss (Δe) is calculated using Equation 2 [1].

$$\Delta e = \text{exergy supplied} - \text{exergy recovered} \quad (2)$$

By calculating the exergy loss, components of the system can be ranked based upon their contribution to the overall exergy destruction of the system. An energy balance and an exergy balance are done around every component of the system (gas cooler, compressor, evaporator, internal heat exchanger, and expansion valve). The energy balances produce the total coefficient of performance for the system, and the exergy balances produce the corresponding exergetic efficiency of each component of the system. The exergetic efficiency of each component is given by Equation 3 [1].

$$x = \textit{exergy recovered / exergy supplied} \quad (3)$$

With the knowledge of the locations prone to leaking, mass flow rate losses are applied across the compressor and across the evaporator. The mass flow rate loss across the compressor is applied after the compressor (state 2 in Figure 3), because if leaking is to occur, it would do so across the seal of the compressor. Both the mass flow entering and leaving the evaporator are adjusted to simulate joint leaks between metal tubing and hoses. The refrigerant flowing into and out of the evaporator (states 5 and 6) is the portion of the cycle that is subcritical, which means the refrigerant is a liquid-vapor mixture. With this mixture, manufacturers can place the hoses in between metal lines and components in order to reduce vibrations. Also, the evaporator is the portion of the system closest to the passengers, which is where vibrations need to be dampened the most.

Vargaftik [10] provides a detailed table of carbon dioxide properties based on temperature and pressure. Fartaj et al [8] used these tables in order to calculate the corresponding exergy losses for each component. The developed simulation model verifies this published normal operation data. EES utilizes a set of databases that have been organized by various published works for properties of a substance.

Table 2 is a list of the temperatures and pressures for each state point used in analyzing the AC system assuming a constant mass flow rate of 2.64 kg/min thus under normal operation (no leakage).

State	T (K)	P (kPa)
1	305.05	4259
2	399.75	11410
3	323.55	11279
4	312.55	11129
5	283.45	4540
6	282.35	4409

Table 2: Properties of State Points in the Normal Mode CO_2 Refrigeration System

Using the normal operation simulation model, mass flow rate loss is incorporated in the locations described earlier. For each of the leaks experienced by the system, a loss of 0.005 kg/min is applied at the location of the leak and at each subsequent state point. Only discrete values of the mass flow rate are considered.

For each loss, a new simulation is performed around the cycle in order to calculate the new state points based on the new mass flow rates. State points 7 through 10 remain constant with every leak scenario, by assuming that the vehicle is under constant load and is operating under steady state conditions. The mass flow rate of the air through the evaporator and gas cooler are also held constant. The initial refrigerant loss is considered after the available charge in the receiver (at State 4) is emptied and the system is operating at normal conditions with the minimum amount of charge (~500g). In order to calculate the new temperatures and pressures along the system,

multiple assumptions are made as discussed previously. The gas cooler and the evaporator are modeled as non-mixing cross flow heat exchangers and the internal heat exchanger includes a counter flow configuration. Table 3 compares exergy loss across each component under normal operation and during a refrigerant loss where the three probable leak locations are considered. It also shows the differences of the exergetic efficiency of each component in the system. For simplicity, only one change of mass flow rate is applied and reported in Table 3.

PROPOSED CO_2 LEAK DETECTION METHODOLOGY AND FUTURE WORK

As shown in the development of the simulation model under normal and refrigerant loss scenarios, if the temperature and pressure is known at each point in the cycle, the performance of the cycle can be determined based on both the first and second laws of thermodynamics. When comparing the results of the normal and leakage models based on exergy losses, differences can be seen. When a leak is applied to the compressor (state 2), the exergy loss of the expansion device and heat exchanger decreases. On the other hand, the exergy loss for the compressor and gas cooler increases.

For the leak applied before the evaporator (state 5), the heat exchanger, compressor, and expansion device decrease in exergy loss, while the gas cooler experiences an increase in exergy destroyed. For the leak applied after the evaporator (State 6), the heat exchanger's exergy destroyed increases while the other comparisons remain the same.

When looking at the efficiency differences between normal operation and leakage conditions, one can see an opposite change compared to the exergy loss. By looking at Table 3, the efficiency decreases when the exergy loss increases across the gas cooler. The opposite occurs for the evaporator; the exergy loss decreases and therefore the exergetic efficiency increases. The correlation between exergy loss and efficiency is expected. If a component has greater exergy destroyed, the efficiency should go down, because the component is not functioning to its maximum capability.

The premise behind the proposed leak detection system is that these differences will be used to detect a refrigerant loss within the system. Data collected from sensors embedded within the system will be used to determine system performance characteristics. An on-board system will collect the data and periodically determined the system's performance profile. This will occur during steady state operation of the system. Over time, if the system develops a refrigerant leak, deviations in performance characteristics will be determined by the on-board system and a fault condition will be detected.

	Normal Operation		**Leak at State 2**		**Leak at State 5**		**Leak at State 6**	
Component	**Exergy Loss (kW)**	x (%)	**Exergy Loss (kW)**	x (%)	**Exergy Loss (kW)**	x (%)	**Exergy Loss (kW)**	x (%)
Compressor	0.5572	81.11	0.5598	81.02	0.5058	82.85	0.5243	82.23
Gas Cooler	0.5579	67.85	0.5780	67.84	0.6089	66.70	0.5951	67.20
Heat Exchanger	0.2646	20.22	0.2533	23.57	0.2533	24.83	0.2689	23.59
Expansion Valve	0.6054	--	0.4875	--	0.5090	--	0.4892	--

Table 3: Exergy Loss and Exergetic Efficiency for the CO_2 Refrigeration System

Ongoing and future research includes developing an experimental carbon dioxide air conditioning system which will be used to verify the simulation models described within this paper. In addition, the experimental setup will be used to validate the feasibility and viability of the proposed leak detection methodology based on operational and economical consideration.

CONCLUSIONS

An EES simulation model of a carbon dioxide air conditioning refrigeration system is developed. The simulation is based upon the Second Law of Thermodynamics or exergetic analysis of the system. Refrigerant leaks simulated as mass flow rate losses are applied to three areas prone to leaking in the system. From the simulations, it is concluded that differences exist in exergetic efficiencies and exergy destroyed within each component during the different operating scenarios. Future work includes developing an experimental set-up to validate the simulation model. In addition, a fault detection and diagnosis system will be developed which will use differences in thermodynamic behavior to classify the system's operation.

ACKNOWLEDGEMENTS

The authors extend their gratitude to Mr. Prasad Kadle and Edward Wolfe from Delphi-Harris Corporation for their guidance and continuing support of this ongoing research. In addition, to the Gleason Foundation and Rochester Institute of Technology for the financial support required to conduct this research.

ABSTRACT

Energy-efficient adsorption systems which utilize water as a working fluid, such as adsorption heat pump, desiccant cooling, humidity control system, thermal energy storage etc., have attracted much attention, because they have an advantage of energy saving and environmental acceptance. Since the water adsorption properties required to such system depend on the temperature level of generation, environment and recovery, it is necessary to design and synthesize new adsorbent which have large heat storage capacity for each systems. Zeolites are one of the most commonly used adsorbents; however, the adsorption of water by zeolite saturates at low relative pressures because of its small pore size of around 1 nm and its strong affinity with water molecules, making them unsuitable as a heat storage material for the low-temperature recovery. It has been reported metal doped mesoporous silicas show a suitable water adsorption properties (a steep increase of adsorption amount at a certain relative humidity) for the low-temperature recovery and enough stability toward water vapor. However, there are no systematic studies on the mesoporous silica as useful adsorbents for energy-efficient adsorption systems. In this work, we synthesized metal doped mesoporous silica by a solvent evaporation method and examined their water adsorption properties. In the synthesis, hexadecyl trimethyl ammonium chloride was used as a structure directing agent and $ZrO(NO_3)_2$, $Al(NO_3)_3$, titanium diisopropoxide bisacetylacetonate and $Fe(NO_3)_3$ was used as the metal source. The possibility/applicability of them for various energy-efficient adsorption systems are also discussed.

Keywords: Energy-efficient adsorption system, Metal doped mesoporous silica, Solvent evaporation, Water vapor stability

INTRODUCTION

Thermal energy conversion systems, such as adsorption heat pumps, desiccant cooling systems, humidity control systems, thermal energy storage devices, etc., are increasingly expected to function as decentralized energy systems for reducing energy consumption based on their ability to utilize low temperature exhaust heat. When porous materials are used for water adsorption in these systems, the primary performance of these systems is dictated by the capacity and the rate of water vapor adsorption/desorption under the relative humidity conditions specific to their practical operation. Since the water adsorption properties required by these systems depend on the temperature level of generation, environment and recovery, the design and synthesis of new adsorbents that have large heat storage capacities is an ongoing process.

Silica gel and zeolite are commonly used adsorbents in the systems listed above. Silica gel has a low adsorption/desorption capacity in the specific relative humidity regions of these systems due to its disordered porous structure. Although zeolites have ordered porous structures, zeolites saturate with water at low relative humidities because of their small pore size

*Corresponding author. Phone: +81-29-861-4653 Fax: +81-29-861-4660 E-mail: endo-akira@aist.go.jp

(around 1 nm) and their strong affinity with water, making them unsuitable as heat storage materials for low-temperature utilization.

The synthesis of ordered mesoporous silicas (MPSs) with pore diameters of 2 ~ 3 nm, e.g. MCM-41 [1, 2] and FSM-16 [3], have potential applications in many various fields, including as adsorbents of water vapor. MPSs posses a large adsorption/desorption capacity in a range of specific relative humidities due to the capillary condensation of water in the mesopores, making them potentially applicable as new adsorbents that can be recovered by low temperature exhaust heat. After MPSs were discovered in the early 90's, studies were conducted on the water vapor adsorption properties of MPSs from the viewpoint of stability in the presence of water vapor and humidity. Initially, MPSs did poorly as adsorbents of water vapor, as the pore structure of MPSs was easily destroyed by humidity, directly resulting in a decreased adsorption capacity [4]. The introduction of metallic elements into the silica network was performed in order to modify the silica surface, and to introduce catalytic activity onto the surfaces [5]. These metal-doped mesoporous silicas have been reported to have higher stabilities compared with non-doped MPSs. For example, Ohashi *et al.* reported the synthesis of a Ti-doped mesoporous silica prepared under hydrothermal conditions [4]. The stability of this material towards water vapor increased, and a potential application as a humidity control material was demonstrated. Park *et al.* reported the synthesis of a zirconium-doped MCM with a high alkaline resistance [6]. Specifically, Zr-MCM-41 and Zr-MCM-48 showed a high structural stability in alkaline solutions of pH 10-11.5. The structures of pure silica samples were destroyed in the solution of pH 10. Yano *et al.* reported a super-microporous aluminosilicate having a water vapor adsorption capacity of 0.2 ml/g at a relative vapor pressure of 0.2 [7]. They suggested that if were to be utilized as an adsorbent for an adsorption heat pump, it would be possible to produce a coolant with a lower temperature than could be produced with an adsorbent that does not incorporate Al. Aika *et al.* published a study of the water sorption/desorption behavior $CaCl_2$-doped materials [8]. This study reported that the heat storage capacity of FSM-16 with 33 wt% $CaCl_2$ (1200 MJm^{-3}) was higher than that of zeolite (Na-Y, 345 MJm^{-3}) and FSM-16 (731 MJm^{-3}). Based on this, $CaCl_2$-doped materials are more suitable as chemical heat storage media for water adsorption than zeolite. These studies suggest metal-doped mesoporous silicas do have a sufficient stability towards humidity and water vapor to be applied in this way. Though it has been reported that metal-doped mesoporous silicas have been applied to adsorption heat pumps, desiccant cooling systems, humidity control systems, thermal energy storage devices, etc. as described above, there are no systematic studies focused on the specific metal elements that increase the stability of these materials towards water vapor and their potential applicability as energy-efficient adsorbents. The focus of this study is the synthesis and properties of four ordered, metal-doped mesoporous silicas and pure silica using a solvent evaporation method. The water adsorption properties and stability in steam of these silicas, as well as the energy storage capacity of these materials, are reported.

EXPERIMENTAL

Synthesis

Metal-doped mesoporous silicas and pure silica were prepared according to Endo's procedure [9]. Hexadecyltrimethylammonium chloride (C_{16}TAC) was used as a structure-directing agent. For the introduction of metal, salts of zirconium, aluminum, iron and titanium were chosen and used at a fixed quantity of 5 mol% relative to the silica source.

Zirconium oxynitrate dihydrate [$ZrO(NO_3)_2$ $2H_2O$], aluminum nitrate nonahydrate [$Al(NO_3)_3$ $9H_2O$], titanium diisopropoxide bisacetyl acetonate and iron(III) nitrate enneahydrate [$Fe(NO_3)_3$ $9H_2O$] were used as the metal sources. The starting solution, a mixture of

tetraethylorthosilicate (TEOS) as a silica source, the metal source, C_{16}TAC, hydrochloric acid, water and ethanol, was stirred for 1 hour at room temperature. The typical molar ratio of the starting solution was 1 TEOS : 1 metal source : 0.2 C_{16}TAC : 10 EtOH : 1.8×10^{-4} HCl : 10 H_2O. The reaction mixture was then transferred to a round-bottom flask and evaporated using a vacuum rotary evaporator for 1 hour. The base temperature was kept at 298 K during the solvent evaporation. After the solution reached a paste-like consistency, the pressure was reduced and the solvent was again evaporated for 2 hours. This resulted in the viscous, paste-like liquid changing to a wet solid with some bubbling. The temperature was then increased to 333 K to evaporate the remaining solvent. 1 hour later, the obtained silica-surfactant composite was calcined at 873 K for 5 hours in air to remove the surfactant, resulting in a porous solid. It should be noted that the total synthetic time was almost the same for all of the metal sources except Al-doped MPS. (The solvent evaporation in the synthesis of Al-doped MPS was longer than for the others.)

Characterization

XRD and nitrogen adsorption/desorption measurements were carried out for the characterization of the metal-doped mesoporous silicas. XRD measurements were performed using a Rigaku Miniflex diffractometer (Cu/Ka radiation, operated at 40 kV and 30 mA). The nitrogen adsorption isotherm was measured using Belsorp-mini, fully automatic adsorption isotherm measuring equipment (manufactured by BEL Japan, Inc.). The measurements were carried out at 77 K. The pre-treatment was carried out at 573 K for 5 hours under a nitrogen atmosphere.

Water vapor adsorption properties

The water adsorption isotherms were measured using a Belsorp 18 plus and a Belsorp 18-3, both of which are fully automatic adsorption isotherm measurement instruments (manufactured by BEL Japan, Inc.). The measurements were carried out at 298 K. The pre-treatment was carried out at 573 K for the first measurement and 413 K for the second measurement for 8 hours under a pressure of 2 Pa. The stability of pure silica and the obtained metal-doped mesoporous silica samples towards water vapor was evaluated based on the nitrogen and water adsorption/desorption measurements before and after steam treatments at 373 K for 24 hours.

RESULTS AND DISCUSSION

Synthesis

The metal source is very important when metal is introduced into a silica network. Metal alkoxides are generally used in the synthesis of metal-doped mesoporous silicas. However, the reactivity of metal alkoxides is much higher in comparison with silica alkoxides, namely TEOS. Metal alkoxides are easily hydrolyzed by atmospheric moisture, leading to polymerization. For this reason it was necessary to select a metal salt with a low reactivity. In terms of the metal sources described in the experimental section, all of the starting solutions were transparent and precipitation was not observed.

The synthesis was completed in two days, including the calcination. This synthetic method that makes use of a vacuum rotary evaporator is very simple compared with conventional methods, such as a hydrothermal synthesis or a sol-gel synthesis. It can be performed in a relatively short time and is suitable for large-scale synthesis.

The pH was measured after the hydrolysis reaction, and the metal-doped mesoporous silica products were much more acidic than pure silica, as shown in Table 1.

The yields of the calcined samples, defined here as the proportion of the obtained silica to the supplied TEOS and metal source, were over 95% for all of the syntheses, indicating that only the ethanol and water were removed during the vacuum evaporation. The obtained metal-doped mesoporous silicas are herein referred to as Zr-MPS, Al-MPS, Ti-MPS and Fe-MPS.

X-ray diffraction

Figure 1 shows the X-ray diffraction patterns of (a) pure silica, (b) Zr-MPS, (c) Al-MPS, (d) Ti-MPS and (e) Fe-MPS after calcination. The XRD data of the metallic-MPSs (b-e) had a characteristic peak of mesoporous silicas, also present in (a) pure silica. As a result of the introduction of the metals into the silica network, the peak intensity of d_{100} in (b) Zr-MPS, (d) Ti-MPS and (e) Fe-MPS was reduced, whereas the intensity of (c) Al-MPS increased and sharpened, even more so than (a) pure silica. With regard to the d_{100} peak position, it shifted a greater distance as a result of metal doping in all of the samples (Table 1).

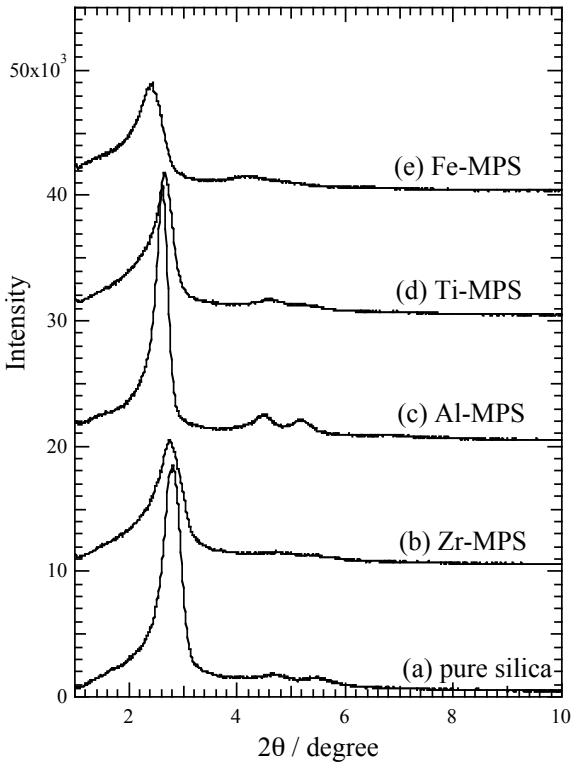

Figure 1: XRD patterns of pure silica and metal doped mesoporous silicas

N_2 adsorption/desorption isotherms

The porous structure of the obtained metal-doped mesoporous silicas was evaluated by nitrogen adsorption measurements at 77 K. The adsorption/desorption isotherms are shown in Figure 2. The porous properties obtained from these experiments are summarized in Table 1. The isotherms were similar to type IV in terms of an IUPAC classification, clearly indicating a mesoporous structure. The pore size distribution curves (PSD) were calculated using the Broekhoff and de Boer equation [10] with the D-H algorithm. The amount of adsorbed nitrogen at $P/P_0=1$, which is almost identical to the total pore volume, was higher with the introducing of a metal with the exception Zr-MPS. The most common pore size for the metal-doped mesoporous silicas was larger than that of pure silica, again with the exception of Zr-MPS. It was reported that the pore size of mesoporous silicas could be decreased by incorporating aluminum into the skeleton of the silica [7, 11-13]. The results of these experiments, however, indicated a pore size of 2.95 nm for Al-MPS, which is clearly larger than that of pure silica. The thickness of the silica wall did not depend on the metal used, remaining around 1 nm for all of the samples.

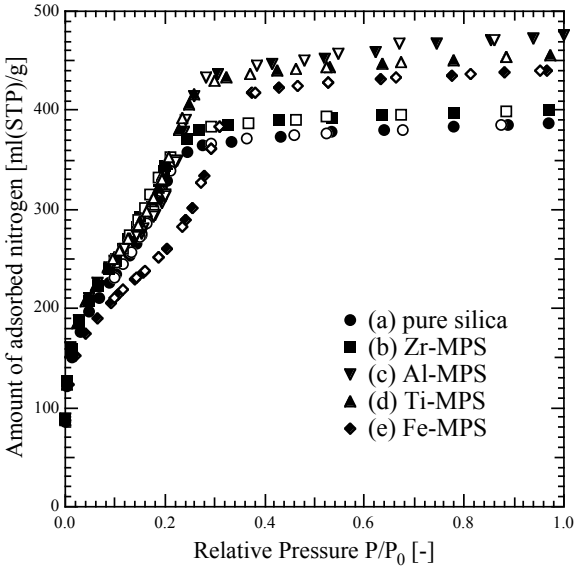

Figure 2: Adsorption isotherms of nitrogen on (a) pure silica, (b) Zr-MPS, (c) Al-MPS, (d) Ti-MPS and (e) Fe-MPS.

Table 1: Characterized porous properties of the obtained pure silica and the metal-doped mesoporous silicas.

Sample	pH	d_{100} [nm]	d_P [nm]	d_W [nm]	V_P [ml/g]	S_{BET} [m^2/g]
Pure silica	3.43	3.12	2.66	0.94	0.60	1155
Zr-MPS	1.44	3.14	2.63	1.00	0.62	1238
Al-MPS	1.77	3.36	2.95	0.92	0.73	1098
Ti-MPS	2.61	3.31	2.76	1.06	0.70	1168
Fe-MPS	1.87	3.63	3.28	0.92	0.68	935

Water vapor adsorption properties

The water vapor adsorption/desorption isotherm of pure silica is shown in Figure 3(a), and those of the metal-doped mesoporous silicas are shown in Figure 4(b-e). The amount of water vapor adsorbed increased with the introducing of all of the metals in this study. The absorbed amount in low relative humidity (P/P_0<~0.3) increased such that the hydrophilicity of the pore surface of the silica increased after the first measurement due to the rehydrorization of water molecules on the pore surface. The position of the steep increase in the water vapor adsorption isotherm shifts to the lower relative pressure side in the second measurement (Figures 3 and 4). In terms of the four metal-doped mesoporous silicas, the lowest amount of saturated adsorption was observed in Zr-MPS (Figure 4(b)), but there was little change in the capillary condensation position or in the amount of saturated adsorption between the first and second measurement.

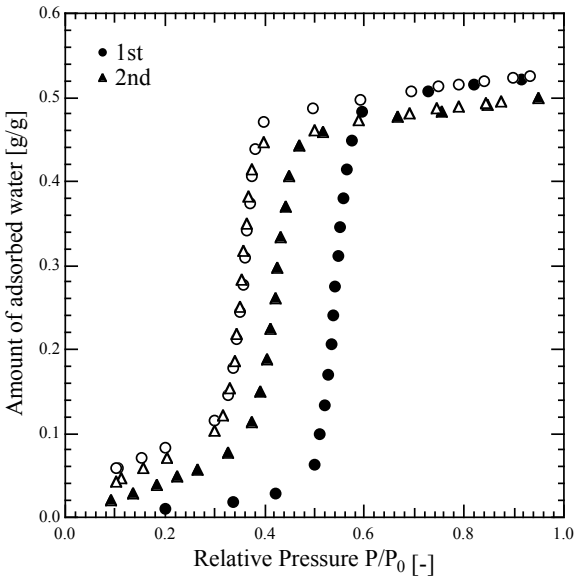

Figure 3: Adsorption isotherms of water vapor on (a) pure silica at 298 K. The pre-treatment temperature was 573 K for the first measurement and 413 K for the second measurement for 8 hr in vacuum.

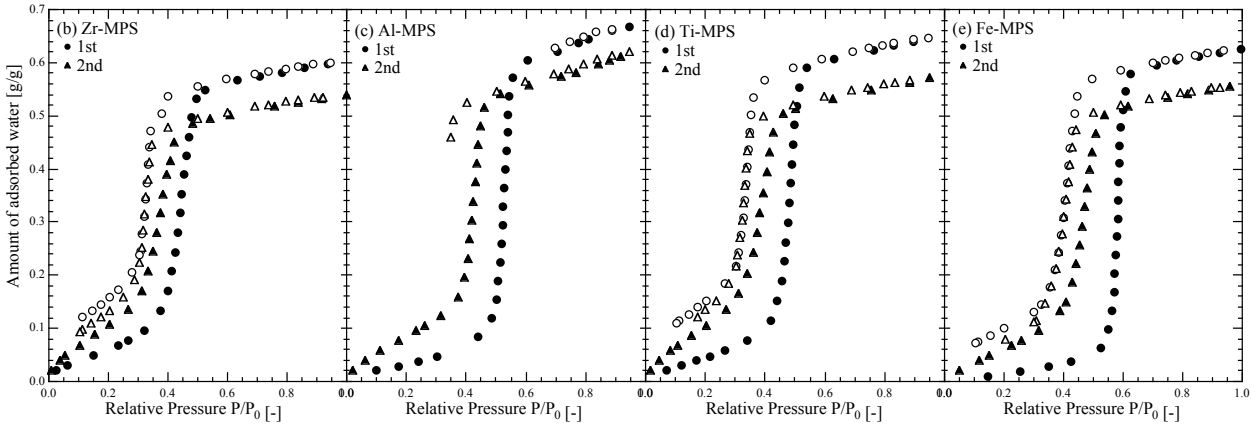

Figure 4: Adsorption isotherms of water vapor on (b) Zr-MPS, (c) Al-MPS, (d) Ti-MPS and (e) Fe-MPS at 298 K. The pre-treatment temperature was 573 K for the first measurement and 413 K for the second measurement for 8 hr in vacuum.

Water vapor stability

Figure 5 shows the nitrogen adsorption/desorption isotherms, and the porous properties obtained from these experiments are shown in Table 2. The water adsorption/desorption isotherms before and after the steam treatment are shown in Figure 6 and 7, respectively. The pore structure of pure silica (Figure 6(a)) collapsed during the steam treatment, decreasing the BET surface area. The capillary condensation previously observed disappeared (Figure 6). On the other hand, no significant change was observed in the shape of adsorption isotherms of the metal-doped mesoporous silicas after the steam treatment, indicating an increase in the stability of these materials in the presence of water vapor. In particular, (b) Zr-MPS and (e) Fe-MPS showed the highest stability.

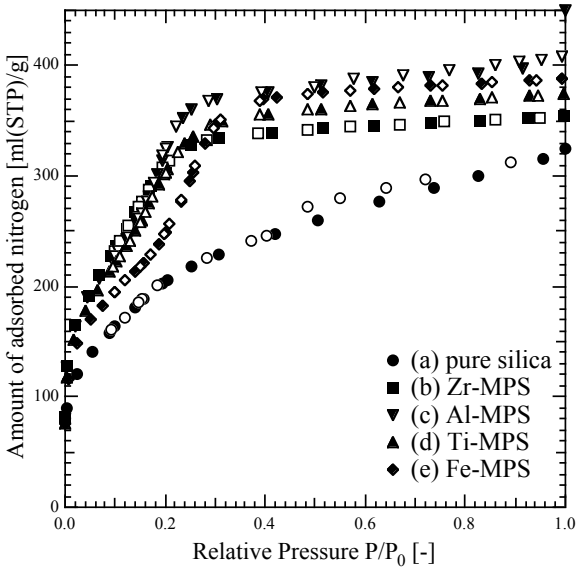

Figure 5: The nitrogen adsorption isotherms of (a) pure silica, (b) Zr-MPS, (c) Al-MPS, (d) Ti-MPS and (e) Fe-MPS after the steam treatment.

Table 2: Characterized porous properties of (a) pure silica, (b) Zr-MPS, (c) Al-MPS, (d) Ti-MPS and (e) Fe-MPS after the steam treatment.

Sample	d_P [nm]	V_P [ml/g]	S_{BET} [m^2/g]
Pure silica	2.45	0.48	764
Zr-MPS	2.45	0.55	1140
Al-MPS	2.67	0.63	1035
Ti-MPS	2.56	0.58	1023
Fe-MPS	3.04	0.60	869

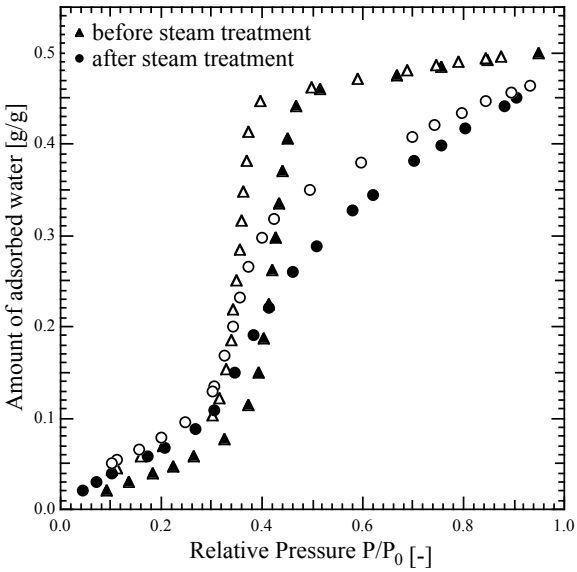

Figure 6: The water adsorption isotherm of (a) pure silica before and after the steam treatment.

CONCLUSION

Highly ordered, metal-doped mesoporous silicas, Zr-MPS, Al-MPS, Ti-MPS and Fe-MPS, were synthesized by a rapid solvent evaporation method using a vacuum rotary evaporator. In this synthesis, $ZrO(NO_3)_2$, $Al(NO_3)_3$, titanium diisopropoxide bisacetylacetonate and $Fe(NO_3)_3$ were used as metal sources based on their lower reactivity. The introduction of these metals into silica network effectively enhanced the water vapor stability. The water vapor stability of (b) Zr-MPS, (c) Al-MPS and (e) Fe-MPS was enhanced based on the results of the nitrogen and water vapor adsorption/desorption isotherms

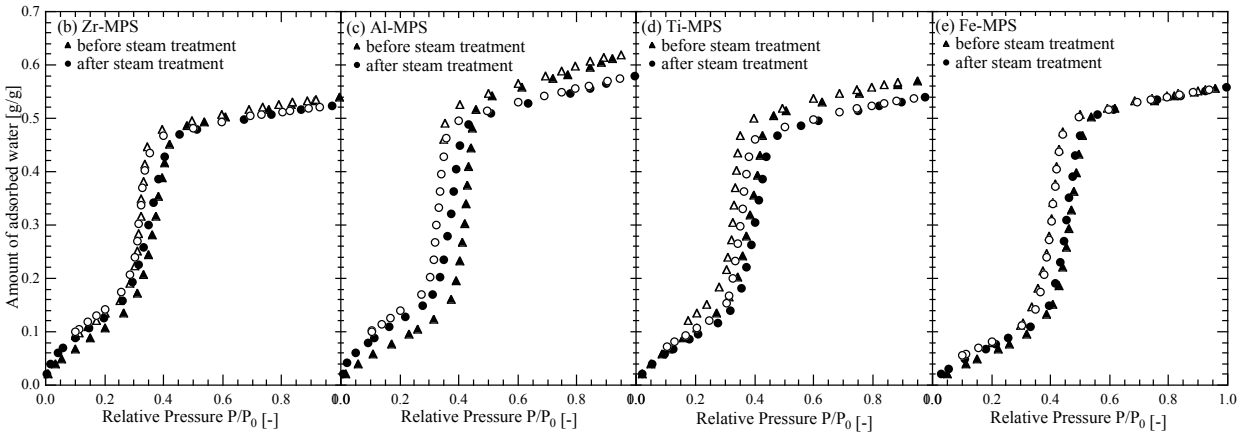

Figure 7: The water adsorption isotherms of the metal-doped mesoporous silicas (b-e) before and after the steam treatment.

before and after the steam treatment. In terms of the practicality of the syntheses of these materials, it took a longer time to synthesize Al-MPS uniformly compared with the synthesis of pure silica, making it unsuitable for large-scale synthesis. This was not the case for Zr-MPS and Fe-MPS, making them more suitable adsorbents for energy-efficent adsorption systems from the vewpoint of practial demands such as stability and mass productivity.

ABSTRACT

Desiccant cooling is one of the most attractive air-conditioning systems, not only owing to their high energy efficiency but also due to environmental acceptance. A typical adsorptive desiccant cooling process is an open heat driven cycle consisting of a rotary dehumidifier and a sensible heat exchanger and the most popular adsorbents are zeolite and silica-gel. A desiccant (adsorbent) removes moisture from the air, and then the adsorbed water removed using thermal energy supplied by electricity, waste heat or solar heat. From the perspective of energy saving, the recovery of adsorbents should be carried out at low temperature, which can utilize the waste heat. Ordered mesoporous silica (MPS) templated by self-assembly of surfactant molecules is one of the most prominent adsorbent because of their characteristic adsorption properties as reported in many literatures. The water adsorption isotherm of MPS shows steep increase at a certain relative humidity region, depending on the pore size thus it is possible to reproduce at low temperature as low as 50-80℃. In particular, metal-doped MPSs have high stability toward water vapor, making it suitable as an adsorbent for desiccant cooling systems.

In this work, we report the water adsorption/desorption properties and stability toward water vapor of Zr-doped MPS. The synthesis of MPS was carried out by a solvent evaporation method. The preparation of honeycomb rotary dehumidifier using Zr-doped MPS and their performance is also discussed.

Keywords: desiccant cooling, mesoporous silica, adsorption, water vapor

INTRODUCTION

Energy efficient adsorption systems such as desiccant cooling systems, heat pumps, humidity control systems, etc. using low temperature exhaust heat have attracted recent attention due to the increasing interest in the global environmental problems. The desiccant cooling process is based on an open heat driven cycle consisting of a combination of a dehumidifier and sensible heat exchanger.

Desiccants are materials that adsorb moisture and can be dried, and thus regenerated, by adding heat supplied by waste heat. In most systems, a turning rotor that contains a desiccant picks up humidity from incoming air and discharges that humidity outdoors. The most popular adsorbents for these systems are zeolites and silica gels [1, 2]. These materials have been used because of their low cost and ease of acquisition, although their adsorption/desorption properties regarding water vapor are not optimal from the viewpoint of system performance.

Zeolites are microporous materials with pores

smaller than 1.5 nm with a water vapor adsorption isotherm typical of Type I in IUPAC classification. A relatively high temperature (as high as 473 K in most cases) is necessary for their recovery. Silica gels have a disordered pore structure from the microporous to the mesoporous or macroporous region. Their adsorption capacity increases gradually with increasing relative humidity.

In recent years, highly ordered mesoporous silicas templated by surfactant micelles, such as MCM-41, FSM-16, etc. formed by a hydrothermal synthesis or a sol-gel based synthesis has attracted increased attention. These ordered mesoporous materials have potential applications in catalysis, adsorbents, membranes, sensors, etc., based on their orderly and uniform mesopores, large specific surface area and pore volume. Moreover, it is possible to control the pore diameter of these materials by changing the alkyl chain length of the surfactant. In considering the application of highly ordered MPSs as adsorbents of water vapor, control of the pore size is very important for effective adsorption. That is, materials that have a high adsorption capacity at the humidity present during practical operation are preferable as heat storage materials for desiccant cooling that exploit low temperature exhaust heat [3].

Unfortunately, MPS materials tend to dissolve in water and alkaline solutions, which decreases the possibility of their practical use as adsorbents of water vapor. Recently, some researchers have reported a porous glass containing zirconium with a high resistance to water and alkaline solutions [4]. Furthermore, an additional study reported that while the structures of pure silica samples were destroyed in a solution of pH 10, zirconium-doped MCM-41 and MCM-48 had a high structural stability in alkaline solutions ranging from pH 10 to pH 11.5 [5].

In the present study, zirconium-doped MPSs with hexagonal arrays of cylindrical pores were synthesized using a solvent evaporation method, and their water adsorption/desorption properties and stability in the presence of water vapor were investigated. Blocks of zirconium doped MPS were ground up into a fine powder for the preparation of a honeycomb rotary dehumidifier, of which the performance is also reported.

EXPERIMENTAL PROCEDURES

Tetraethoxysilane (TEOS), HCl aqueous solution (10^{-3}M), $ZrO(NO_3)_2$ and C_nTAC (n = 10 - 18) were added into ethanol, where n represents the number of carbon atoms composing the alkyl chain of alkyltrimethylammonium chloride (C_nTAC). The starting solution was stirred at room temperature for 1 hour to hydrolyze the TEOS. The typical molar ratio of the starting solution was 1 - 0.95 TEOS : 0 - 0.05 $ZrO(NO_3)_2$: 0.2 C_nTAC : 10 EtOH : 1.8×10^{-4} HCl : 10 H_2O. The solvent was then transferred to a round-bottom flask and evaporated using a vacuum rotary evaporator at 70 hPa. After the solution reached a paste-like consistency, the pressure was reduced to 20 hPa. After the paste-like liquid changed to a white solid, the temperature was increased to 333 K to evaporate the remaining solvent. The resulting solid, a silica-surfactant composite, was calcined at 873 K for 5 hours to remove the surfactant.

The powder X-ray diffraction measurements for the obtained solids were carried out using a Rigaku MiniFlex (CuK α, 40 kV, 30 mA).

The nitrogen adsorption isotherms were measured to investigate the pore structure of the obtained MPSs using a BELSORP-mini instrument (BEL Japan, Inc.) after outgassing the samples at 573 K for 5 h. The BET surface areas of the MPSs were calculated, and the pore size distributions (PSD) were calculated using the

BdB method with the DH algorithm [6]. The water vapor adsorption isotherms were measured using a BELSORP 18PLUS instrument.

For evaluating the durability of the samples, the synthesized silicas were not exposed to water directly, but rather were exposed to water vapor in an autoclave at 373 K for 24 hours. After this water vapor treatment, the adsorption characteristics of the samples were examined.

The obtained zirconium-doped MPS solid was ground to a fine powder. The honeycomb rotor dehumidifier used in this study was designed to have a thin wall of zirconium-doped MPS-based sheet adsorbent.

RESULTS AND DISCUSSION

Characterization of MPSs

Figure 1 and 2 show XRD patterns of pure silica and zirconium-doped mesoporous silicas. The XRD patterns for the synthesized silicas exhibit a strong (100) reflection peak with two small peaks in the higher 2 θ region. The diffraction peaks indicate that the samples have a periodic mesostructure in a hexagonal array.

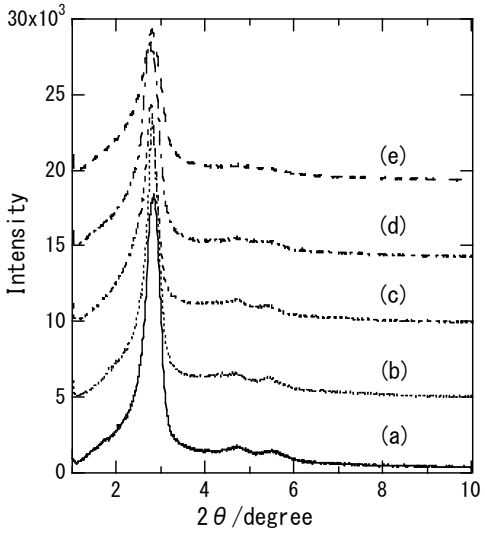

Figure 1: XRD patterns of pure silica and zirconium-doped silica; (a) pure silica, (b) 0.5% Zr-doped silica, (c) 1% Zr-doped silica, (d) 3% Zr-doped silica, (e) 5% Zr-doped silica

The XRD patterns of silicas with varying quantities of zirconium are shown in Figure 1 (b) - (d). The peak intensity of the (100) peak decreased as the zirconium content increased.

Figure 2 shows the XRD pattern of the zirconium-doped C_{10} - C_{18}TAC templated silicas. These MPSs have a different (100) peak. As the alkyl chain length of the template increases, the (100) peak shifts to a lower angle.

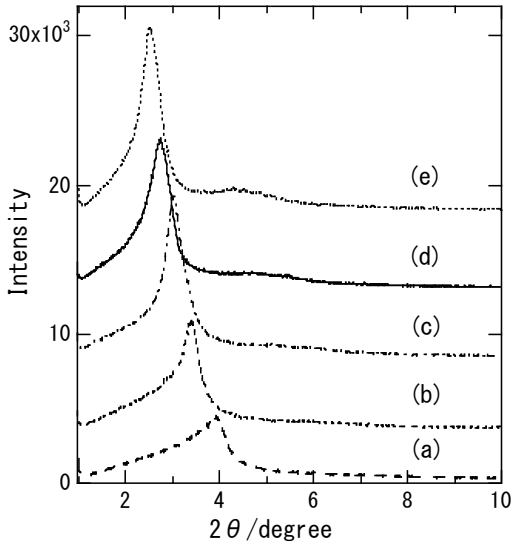

Figure 2: XRD patterns of zirconium-doped silica; (a) C_{10} TAC templated silica, (b) C_{12} TAC templated silica, (c) C_{14} TAC templated silica, (d) C_{16} TAC templ ated silica, (e) C_{18}TAC templated silica

The nitrogen adsorption isotherms measured at 77 K are shown in Figures 3 and 4. In the zirconium-doped samples, the absorption quantity and pore size were generally higher than in the pure silica. However, the pore characteristics of the 5% zirconium-doped MPS were almost equal the same as those of pure silica.

Table 1 lists the structural parameters of the samples. The pore diameters of the 0.5 - 3% zirconium-doped samples were 2.76 - 2.77 nm, whereas the 5% zirconium-doped sample was 2.66 nm, which is the same as that of the pure

silica. A similar result was observed in the pore volume values. The BET surface areas of the zirconium-doped MPSs were all higher than that of the pure silica.

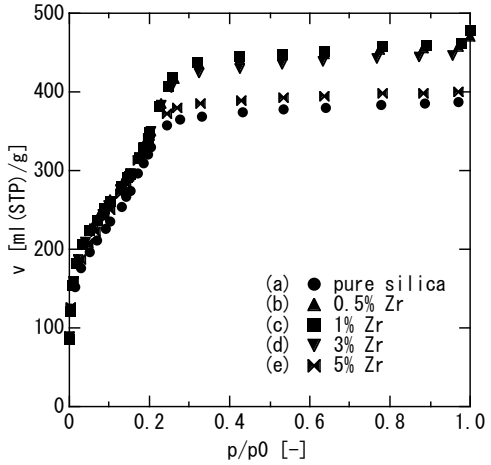

Figure 3: Adsorption isotherm of nitrogen; (a) pure silica, (b) 0.5% Zr-doped silica, (c) 1% Zr-doped silica, (d) 3% Zr-doped silica, (e) 5% Zr-doped silica

Table 1: Pore diameter, pore volume and surface area of pure silica and Zr-doped silicas

Sample	**d_{100} [nm]**	**d_p [nm]**	**d_w [nm]**	**V_p [ml/g]**	**S_{BET} [m^2/g]**
Pure silica	3.12	2.66	0.94	0.60	1155
0.5%Zr	3.18	2.76	0.91	0.71	1201
1%Zr	3.20	2.77	0.92	0.71	1196
3%Zr	3.23	2.77	0.96	0.69	1202
5%Zr	3.19	2.66	1.02	0.61	1220

Figure 4 shows the nitrogen adsorption isotherms of the zirconium-doped C_{10} - C_{18}TAC templated silicas. All of the samples had a small pore size distribution, from 1.6 nm to 3.0 nm, due to the differences in the template surfactant. As the *n* value of the template decreased, the adsorption isotherms changed from Type IV to Type I in the IUPAC classification due to the decrease in the pore size.

Table 2 lists the pore structural parameters of the zirconium-doped C_{10} - C_{18}TAC templated silicas.

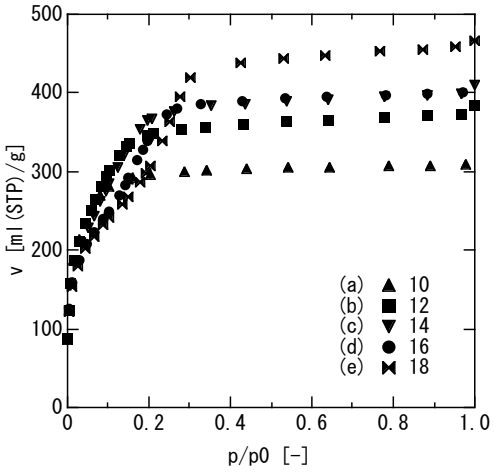

Figure 4: Adsorption isotherm of nitrogen; (a) C_{10} TAC templated silica, (b) C_{12} TAC templated silica, (c) C_{14} TAC templated silica, (d) C_{16} TAC templ ated silica, (e) C_{18}TAC templated silica

Water vapor adsorption properties of MPSs

Figures 5 and 6 show the second water vapor adsorption/desorption isotherms at 298 K for the zirconium-doped silicas. After the first measurement, the surfaces of the silica walls were rehydrorized, and the isotherms for later measurements were shifted to a lower relative pressure region. The shapes of the isotherms indicated a class of Type V with a hysteresis loop.

Figure 5 shows the water vapor adsorption isotherms of pure silica and the zirconium doped silicas. The zirconium-doped samples adsorbed more water and the relative pressure where the steep increase in the amount of adsorbed water

occurred was shifted to a lower region. This indicates the zirconium doped samples posses a stronger hydrophilic nature than the pure silica.

Figure 6 shows the adsorption isotherms of the zirconium-doped samples with different pore sizes (different *n* values). The relative humidity where the steep increase in the adsorption occurred for all of the samples was shifted to a lower relative humidity with decreasing pore diameter.

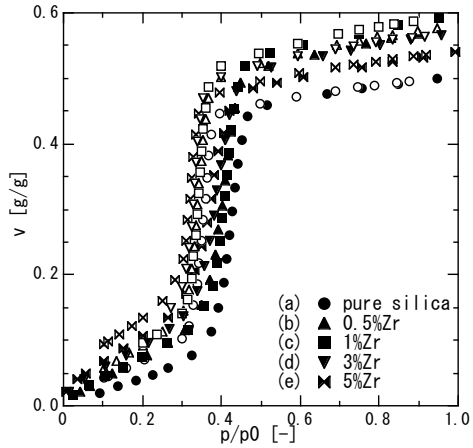

Figure 5: The second adsorption isotherm of water vapor (a) pure silica, (b) 0.5% Zr-doped silica, (c) 1% Zr-doped silica, (d) 3% Zr-doped silica, (e) 5% Zr-doped silica

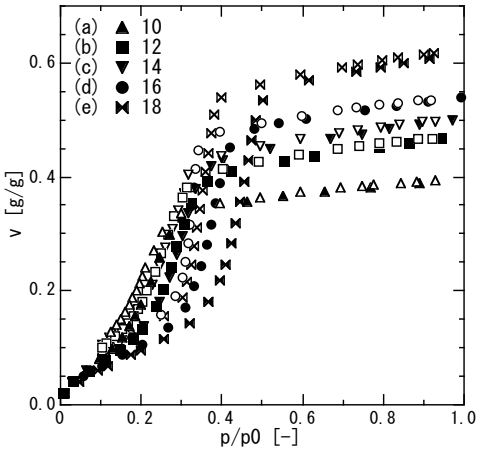

Figure 6: The second adsorption isotherm of water vapor (a) C_{10} TAC templated silica, (b) C_{12} TAC templated silica, (c) C_{14} TAC templated silica, (d) C_{16} TAC templ ated silica, (e) C_{18}TAC templated silica

For ordered mesoporous materials such as MCM-41 and FSM-16, in which the pore size is between about 3 nm and 10 nm, the adsorption of water vapor occurs at a relative humidity of over 40% [7, 8]. These MPSs can be used as adsorbents in humidity control systems in a relatively high humidity region. The adsorption of water vapor on zeolite, however, saturates at a low relative humidity because of its small pore size (less than 1.5 nm) and strong interaction with water molecules. The amount of adsorption and desorption in the operating pressure region is very small, and the recovery temperature for zeolite is higher than 473K [9]. Thus, zeolite can be used for systems that tolerate high temperatures, or for systems that require the humidity to be controlled at a very low level.

As shown in Figure 6, the second adsorption of the variable pore sized MPSs showed a steep increase in adsorption in the relative pressure region of 0.1 - 0.4, which is the intermediate between the zeolites and conventional MPSs (namely, MCM-41 and FSM-16 etc.).

Stability of MPS in the presence of water vapor

Figure 7 shows the water vapor adsorption isotherms.

In the case of the pure silica, the adsorbed amount of water vapor greatly decreased after the steam treatment, indicating the porous structure was considerably collapsed. The results of the isotherms of the zirconium-doped samples, however, showed only a slight decrease, indicating the structure was maintained. This suggests the durability of these samples was increased by the addition of zirconium. From the water vapor isotherms, it is clear that an increase in durability can be achieved from as little as the addition of 0.5% zirconium.

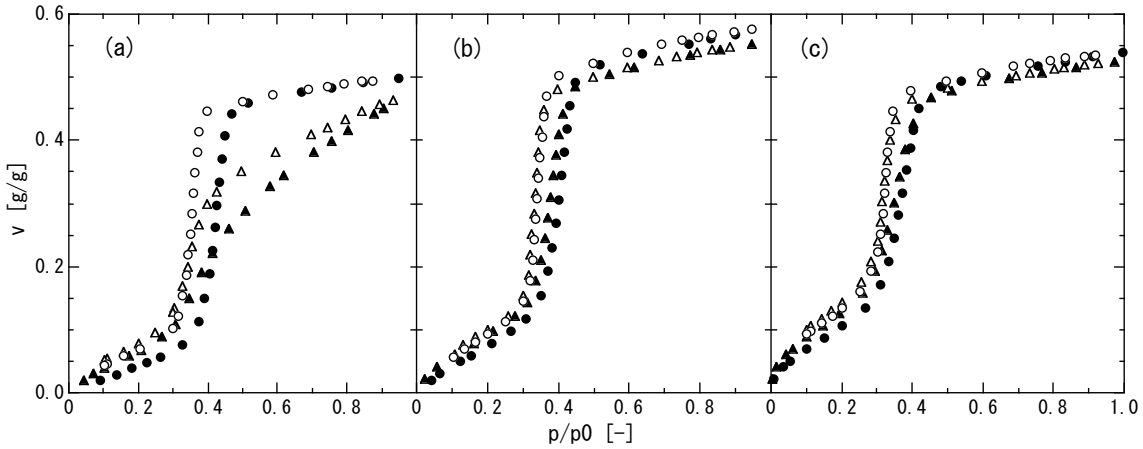

Figure 7: Adsorption isotherm of water vapor (a) pure silica, (b) 0.5% Zr-doped silica, (c) 5% Zr-doped silica; ● original (2nd ads.), ▲ after the water vapor treatment

These results suggest that the introduction of zirconium into the silica structure does not deteriorate the porous properties and maintains the quality of the ordered structure.

As an application, the synthesized zirconium doped MPSs were ground up into a fine powder, and a honeycomb rotary dehumidifier was manufactured with a slurrying sample. The adsorption/desorption capacity of this rotor was investigated, and it was confirmed that the primary properties of the zirconium-doped MPS were maintained after this preparation. This honeycomb rotor adsorber could be used as part of a high-efficiency desiccant cooling process driven by lower temperature (as low as 323 K) waste heat.

CONCLUSION

Ordered, zirconium-doped mesoporous silicas were synthesized through a solvent evaporation method with controllable pore diameters in the region from 1.6 nm to 3.0 nm. This synthetic method can easily introduce metals into silica materials such as these, in comparison with a hydrothermal synthesis, and can be scaled-up as required. These zirconium-doped MPSs have a large adsorption capacity than conventional materials at a relative humidity between 0.2 and 0.4, which is suitable as adsorbents for desiccant cooling systems.

The zirconium-doped samples possess a high structural stability in the presence of water vapor compared with pure silica. The introduction of only a small amount of zirconium into MPSs effectively enhances water vapor resistance, showing the potential possibility for their practical use in energy-efficient adsorption systems.

ABSTRACT

Engineering calculation of the thermodynamic properties for cycle simulation and design requires simple but reliable models. This has been proved to be of importance for the research and development on humidified gas turbines, such as humid air turbine (HAT) cycles and compressed air energy storage (CAES). This paper has made a comprehensive review and comparison among different models for calculating thermodynamic properties of the humid air mixtures, including ideal gas model (IG), ideal mixing model (IM), and real gas model (RG); and based on temperature and pressure range, gave quantitative evaluations on saturated water vapor composition and enthalpy. Based on performance conditions of an HAT cycle, several suggestions were given for the use of the today's available models for engineering cycle calculations, which can provide accurate results for cycle performance analysis and design while keeping the methods straightforward.

SH	Superheated Humid Air

INTRODUCTION:

The basic idea of gas turbine humidification is that the injected water or steam increases the mass flow rate through the turbine. This augments the specific power output, since the compressor work remains constant (i.e., if water is injected after the compressor) and much less work is required to increase the pressure of a liquid than a gas. When energy in the gas turbine exhaust is recovered by preheating water or generating steam for injection

* Corresponding author: Email: hailong@ket.kth.se, Phone +46-8-7906527, Fax +46 8 7230858

or preheating the combustion air in a recuperator, the cycle efficiency is raised. An additional advantage of humidifying the gas turbine working fluid is a reduced formation of NO_x in the combustion process [1, 2]. Advanced gas turbines integrated with humidification have been comprehensively reviewed by Jonsson and Yan [3]. The options for water or steam addition to a gas turbine are shown schematically in Figure 1.

The technology of water or steam addition can also be used in the process of compressed air energy storage (CAES) [4], including the recuperated adiabatic process, and the adiabatic process with humidification. Figure 2 illustrates schematically the adiabatic CAES process.

The addition of water or steam to the air changes the thermophysical properties (i.e., thermodynamic properties and transport properties) of the working fluid. So far several models are available to calculate the properties of air-water mixtures. It has been verified in our previous paper [5] that to model the processes for cycle performance estimations and component sizing and design reliably, the impact of the changes of thermodynamic properties on simulation should not be ignored. In this paper, we made further quantitative evaluations on different models for the difference of thermodynamic properties including density and enthalpy. Moreover we discussed the impacts on cycle performance analysis due to the choices of calculation methods; several suggestions were given at the end.

SUMMARY OF DIFFERENT MODELS

In this paper, three types of models, which are used to calculate thermodynamic properties for the air-water mixtures, have been included for the comparison. They are ideal gas model, ideal mixing model and real gas model.

Ideal gas model (IG)

An easy approximation for the air-water mixture is the assumption that it is a mixture of the ideal air and ideal water vapour. The calculation of property m (heat capacity, enthalpy and molar volume) except entropy s is:

$$m = y_a m_a^0 + y_w m_w^0 = (1 - y_w) m_a^0 + y_w m_w^0 \qquad (1)$$

where m^0 is the properties in the ideal-gas state at temperature T and standard pressure P^0.

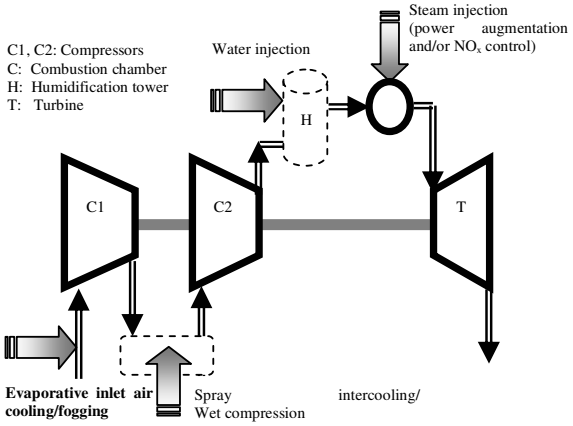

Figure 1. Options for water or steam addition in simple cycle gas turbines

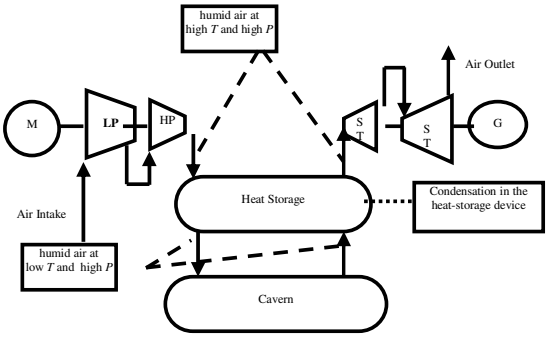

Figure 2. Adiabatic CAES process

The calculation of the property entropy s in the ideal gas model is:

$$s = (1 - y_w) s_a^0(T, P^0) + y_w s_w^0(T, P^0) - R \ln\left(\frac{P}{P^0}\right) - R[(1 - y_w)\ln y_a + y_w \ln y_w] \qquad (2)$$

The saturated composition is related to the temperature in the ideal gas model and is calculated with the following equation.

$$y_{ws} = \frac{P_w^s(T)}{P} \qquad (3)$$

where P_w^s is the saturation pressure of water at the corresponding temperature T, and P is the system pressure.

Ideal mixing model (IM)

The properties of water vapour and the dry air have been studied extensively [6, 7]. In engineering calculations, it is often assumed that each property of the air-water mixture is an ideal mixture of the properties of real gaseous air and water vapour [6]. The calculation of property *m* (heat capacity, enthalpy and molar volume) except entropy *s* is:

$$m = (1 - y_w) m_a(T, P) + y_w m_w(T, P) \quad (4)$$

where *m* is the properties of a real gas at temperature *T* and pressure *P*.

The calculation of the property entropy *s* is:

$$s = (1 - y_w) s_a(T, P) + y_w s_w(T, P) - R[(1 - y_w) \ln y_a + y_w \ln y_w] \quad (5)$$

The calculation of the saturated composition wasn't described in previous studies [8]. In this paper, y_{ws} can be calculated with two methods. In method one y_{ws} is estimated with Equation (3) (noted as IMG model). In method two, y_{ws} is calculated from the real gas model (real gas model 2) (noted as IMR)

.

Real gas model (RG)

Both the ideal gas model and ideal mixing model are suitable at low pressures. The calculation of the properties for the humid air at high pressures is performed with real gas models. The calculation of property *m* (heat capacity, enthalpy, molar volume) except entropy *s* is:

$$m = (1 - y_w) m_a^0(T, P) + y_w m_w^0(T, P) + m^E(T, P) \quad (6)$$

The calculation of the property entropy *s* is:

$$s = (1 - y_w) s_a^0(T, P^0) + y_w s_w^0(T, P^0) - R \ln(P / P^0) + s^E(T, P) \quad (7)$$

The saturated composition is calculated from phase equilibrium.

In this paper, two real gas models were included for comparison, one is the model proposed by Hyland and Wexler [9, 10] (real gas model 1); the other is the model proposed in our previous paper (real gas model 2). Real gas model 1 is based on the virial equation of state (EOS) with the assumption that the dry air is a homogeneous pure component. The reliable application range is stated to be 273.15-372.15 K and up to 50 bar. Their calculated results have been collected in the handbook as standard data [11]. Recently, the commercial software, MOISTAIR TAB [12], was developed based on this model, and the calculation was extended to 473.15 K and 50 bar. Real gas model 2 proposed in our previous papers [13-15] is based on the modified Redlich-Kwong (RK) EOS. The dissolved gas in the liquid phase follows Henry's law in order to calculate the saturated composition. The dry air was assumed to be the mixture of nitrogen and oxygen with a fixed mole ratio. It is stated that the application range can be up to 573 K and 200 bar for the humid nitrogen, oxygen, air and the nitrogen-oxygen mixture. This model is mainly used to calculate the saturated vapour composition in our previous work.

COMPARISON OF MODELS

The comparison of different models with experimental data

Experimental data for the air-water mixture in the vapor phase have been determined [16-20] and all of them are related to enhancement factors, from which saturated vapor composition in humid air can be derived. The PvT experimental data and excess enthalpy are not available in the literature. Therefore, the comparison of the calculated results of different models with the available experimental data can only be performed in composition under saturated conditions.

Among the available experimental data, several groups were determined at the pressure higher than 1atm [16, 18-20]. However, Hyland and Wexler [18] stated that the experimental data of Pollitzer and Strebel [16] were not accurately enough. In our previous work [15], it is found that the experimental data of Hyland [19] were not consistent with others. It is likely that best available experimental data are those of Hyland and Wexler [18] and Wylie and Fisher [20], which have been used for comparing with the calculated results of each model. Part of comparison is shown in Figure 3.

It is clear that the calculated results of these two real gas models are accurate, and the average deviation from the experimental data is less than 0.4% in the whole experimental temperature and pressure ranges. While for the ideal gas model and IMG model, the calculations of the saturated vapor composition are the same; and the deviations are

much larger than those of two real gas models. The highest deviation is up to 34%; and the lower the temperature and the higher the pressure, the lager the deviation. We may conclude that real gas models are more suitable for calculating saturated vapor composition than ideal gas model and IMG model in the experiment range.

Moreover Figure 3 also indicates real gas model 2 can be used in much wider pressure range (up to 140 bar) than real gas model 1 (up to 50 bar).

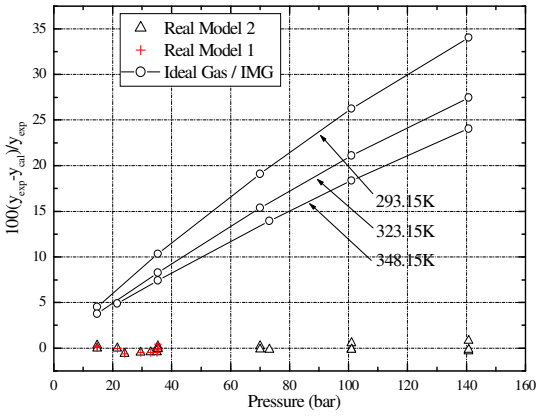

Figure 3 Comparison on saturated vapor composition of different models with experimental data

Comparison among different models

In this section, calculated results of real gas model 2 were used as reference; and deviation was defined as:

$$Deviation = \frac{Calculation_{RG2} - Calculation}{Calculation_{RG2}} \times 100\% \qquad (8)$$

Saturated properties

Water vapor composition, enthalpy and entropy of saturated humid air were calculated with different models from 273.15 to 623.15 K and 5 to 200 bar for comparison.

To calculate saturated vapor composition, three models, i.e. ideal gas model, real gas model 1, and real gas model 2, are available. The comparison between ideal gas model and real gas model 2 was shown in Figure 4. The largest deviation is up to 48.6% at 273.15 K and 200 bar; and the average deviation is 16.32%. It is clear that at the same temperature, deviations increase with pressure; and at the same pressure, deviations decrease with temperature. It can be concluded that the lower the temperature and the higher the pressure, the larger the deviation. Figure 5 shows the distribution of deviations of the saturated water vapor composition calculated by the ideal gas model. It indicates that ideal gas model is not suitable for calculating saturated water vapor composition in those cases above the line illustrated in Figure 5.

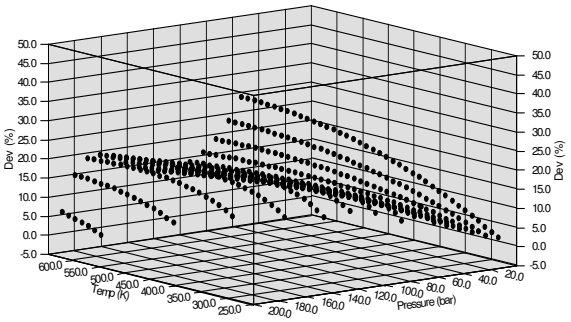

Figure 4 Comparison of the saturated water vapor composition calculated by the ideal gas model, and real gas model 2 from 273.15 to 623.15 K and 5 to 200 bar

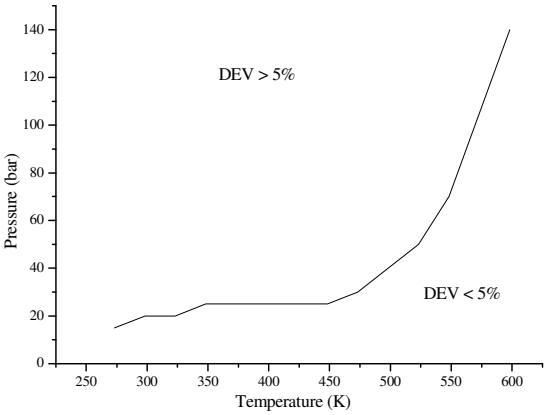

Figure 5 Distribution of deviations of the saturated water vapor composition calculated by the ideal gas model.

In Figure 6, two real gas models were compared. They agree well with each other except in the temperature range close to 473.15 K. The reason might be that the original model of Hyland and Wexler was applied only up to temperature 373.15 K. It may be questionable, when it is extrapolated to 473.15 K. However the calculation range of real gas model 2 is much wider in pressure than that of real gas model 1, so real gas model 2 is better than real gas model 2

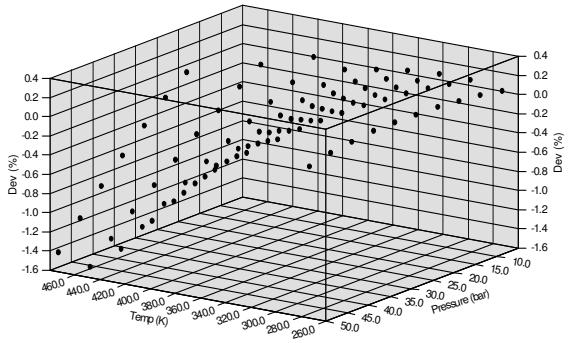

Figure 6. Comparison of the saturated water vapor composition calculated by the real gas model 1 and real gas model 2 from 273.15 to 473.15 K and 5 to 50 bar.

The deviation in the compositions calculated by various models may result in even larger differences in other saturated properties, e.g. enthalpy and entropy. However for enthalpy, the calculated results of ideal mixing model are closed to those of real gas model 2 when the temperature is low (<423.15 K), even though the saturated water vapor composition is far away from those of real gas model 2. This may be explained that in this temperature range, water composition in the vapor phase is so low so that the composition of water vapor has little impacts on enthalpies of moist air. The comparison of entropy is not the same as that of enthalpy. If temperature is lower than 550 K, average deviations among different models are always larger than 5%.

Properties in temperature range 273.15-1773.15 K and pressure range up to 200 bar

Superheated properties and properties at supercritical temperature of water were also calculated and compared among different models. The considered range in this paper is 273.15-1773.15 K and up to 200 bar. Because the only difference between IMG and IMR model is how to calculate y_{water}, if enthalpy and entropy are calculated at given temperature, pressure, and y_{water}; they have the same results. Therefore in the following discussion, only ideal gas model, IM model, real gas model 1 and real gas model 2 are compared. In the area out of the application range of real gas model 1, the comparison was performed between the ideal gas model, ideal mixing model and real gas model 2.

In Figure 7, comparison results of enthalpy between IM and real gas model 2 are comprehensively illustrated with information of deviations under considered pressure and temperature. From Figure 7, it is easy to see that at low temperature, temperature close to water's critical point, and high pressure, deviations are large. The deviations of enthalpy between ideal gas model and real gas model 2 in the temperature range less than 647 K were shown in Figure 8. The maximum deviation is up to 500%, and the average deviation is 73.5%; and the deviations decrease with temperature and increase with pressure. As to the part in the temperature range higher than 647 K, because in this range the deviations between IG and IM are less than 1%, ideal gas model can be regarded having the same accuracy as IM model. Thus the right part of Figure 7 can be used to illustrate IG model as well. Moreover the deviations between real gas model 1 and real gas model 2, in 273.15-473.15 K and 0-50 bar are less than 1%. This figure can be divided into two parts by temperature 647 K which is water's critical temperature.

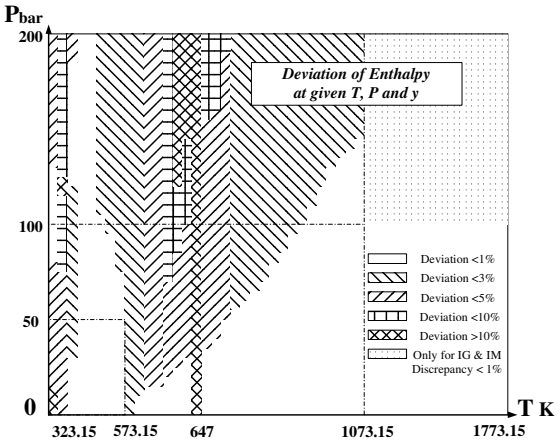

Figure 7 Comparison on enthalpy among ID, IM and real model 2 at given T, P and y_{water}

With Figure 7 and 8, generally we can get such results that when temperature is lower than 623.15 K, if not at very low temperature and high pressure, ideal mixing model is suitable to calculate enthalpy of humid air with an average error less than 3%; while when temperature is higher than 673.15, ideal gas model can be used.

Calculated results of entropy with different models were compared in Figure 9. It shows that deviations of entropy among those models are very

large and much more complicated than deviations of enthalpy. Only when temperature is higher than 1073.15 K they become less than 50%. So it is difficult to evaluate different models. In practical application, choosing a model should depend on other properties.

IMPACTS ON HAT CYCLE

Component	Saturated humid air		Superheated humid air	
	T (K)	P (bar)	T (K)	P (bar)
Heat exchanger	432.9	35.3	505.1	35.3
Compressor	288.2	1.01	-	-
Humidificati on tower	373.2-393.2	35.3	505.1 -720	35.3

Table 1 Parameters in a HAT cycle [20, 21]

Advanced humidified gas turbines have been studied and developed in the past [3]. For example, Ågren and Westermark [21, 22] simulated an HAT cycle. Some parameters of several main components in their simulation, such as heat exchanger, compressor, and humidification tower, were summarized in Table 1. Based on these parameters, we can analyze the impacts of different models on every component.

Referring to Figure 5 and 7, it is clear that to these components, different models have large discrepancies on calculated results of saturated water vapor composition, especially in humidification tower, up to 7% (both IG and IMG model). Moreover, discrepancies of different models on enthalpy are comparatively small, usually less than 3%. Therefore we have such suggestions that real gas models are preferred to calculate saturated water vapor composition; after getting $y_{s,w}$, ideal gas model might be applied to calculate enthalpy at given temperature, pressure in this HAT cycle.

CONCLUSIONS

In this paper different models were used to calculate thermodynamic properties of humid air to investigate their impacts on the simulation results of wet cycles. The comparison results of the saturated water vapor composition of different models with the reliable experimental data show that the deviations of the ideal model and ideal mixing model are larger, especially at low temperature and high pressure; and the highest deviation is up to 34 % at 293.15 K and 140 bar.

The comparison of other properties (enthalpy and entropy) up to 1773.15 K and 200 bar of different models reveals that at given temperature, pressure and y_{water}, discrepancies of enthalpy may be large at low temperature, while small at high temperature; and discrepancies of entropy always exist among different models. Finally we have such a conclusion that to calculate saturated water vapor composition, real gas model should be chosen except at low pressure or high temperature; to calculate enthalpy from given temperature, pressure and y_{water}, if T<623.15 K, except very low temperature and high pressure, ideal mixing model can be used with an average discrepancy less than 3% compared with real gas model, if T>673.15 K, ideal gas model is available and its average discrepancy with other model is less than 3%; to calculate entropy from given temperature, pressure and y_{water}, real gas models may be preferred according to their accuracy on other properties.

Moreover based on running conditions of an HAT cycle, today's available models for engineering cycle calculations were analyzed. We recommend using real models to calculate saturated water vapor composition, then using ideal gas model to calculate enthalpy.

ABSTRACT

The experiments on the flow boiling heat transfer of HCFC22 and HCFC123 were performed using a horizontal spirally grooved STB-340-S-C steel tube with 12mm in average inner diameter. The test tube was developed as a evaporator tube of an air-conditioner using an ammonia refrigerant. The circumferentially averaged heat transfer coefficients and wall temperature distributions were presented and discussed by comparison with the predicted values by available correlations for ordinary grooved copper tubes. The empirical correlation was proposed for the heat transfer coefficients in the region where the wall surface is completely covered by liquid.

INTRODUCTION

Internally spirally grooved tubes have been widely used as heat transfer enhancement tubes for evaporator/condenser of heat pumps, refrigerators and air-conditioners. Many researches have been performed on the forced convective boiling heat transfer inside these grooved tubes, and so far some correlation equations have been proposed[e.g. 1-5]. Most of these tubes are made of copper which may be the best material for fluorocarbon refrigerants, and

can not be applied to an ammonia refrigerant due to its corrosion behavior against copper. Ammonia has attracted the attention again as a working fluid of refrigerators owing to its extremely small GWP(Global Warming Potential). The internally spirally grooved tube used in the present study was made of STB-340-S-C steel and originally developed as a heat transfer enhancement tube for air conditioning applications using an ammonia refrigerant. Most of above mentioned correlations for the flow boiling heat transfer have been obtained with the experimental results for ordinary grooved copper tubes. The present STB-340-S-C steel tube has much different surface roughness and groove configuration from those of ordinary copper tubes, mainly due to the difference of hardness. These parameters are expected to affect on the flow boiling heat transfer. In order to investigate the difference of heat transfer characteristics between the present steel tube and ordinary copper tubes the experimental investigation were carried out on the flow boiling heat transfer inside this steel tube using two fluorocarbon refrigerants HCFC22 and HCFC123, which makes experiments easier than ammonia.

EXPERIMENTAL APPARATUS AND PROCEDURE

The experimental apparatus is made up of a closed refrigerant loop and a brine loop to supply cooling fluid to condensers. The refrigerant loop mainly consists of a magnet drive gear pump, three preheaters, a test evaporator and two condensers. The pump was used for the circulation of refrigerant in order to exclude an effect of compressor lubricating oil, which is required in practical vapor compression refrigeration systems.

Figure 1 indicates the scheme of the test evaporator and the arrangements of the sensors. The refrigerant flowing inside the tube is heated directly by alternative current and the supplied heat rate was obtained by measuring the electric power input. The wall temperatures of the tube were measured at three locations of 1350, 2150 and 2950mm apart from the inlet with six T-type thermocouples, which were soldered on the outer surface at every 60° point in circumferential direction from the top of the tube. The pressure at the outlet of the test section and the pressure drop for the whole of the test tube were measured with an absolute pressure transducer and differential pressure transducer, respectively.

The internally grooved tube used in the present study is made of STB-340-S-C steel and configured by 3.5m in length, 15mm in outside diameter, 12mm in average inside diameter, 32 in number of fins, 0.4mm in fin height, 15 degree in helix angle, and 1.34 in area expansion ratio. The expanded cross sectional drawings are shown in the Figure 2 for the test tube and internal fins.

The average heat flux, the wall temperature and the refrigerant temperature required to calculate the axially local heat transfer coefficient(circumferentially averaged), α, are defined as follows, respectively. (1)The heat flux, q, is defined based on the average inner diameter, (2)the circumferentially averaged inner surface temperature, T_{wi}, is computed by using the one dimensional heat conduction equation in radial direction with internal heat source and the circumferentially averaged value of the measured outer surface temperatures, and (3)the saturation temperature corresponding to the measured pressure is used as the refrigerant temperature, T_{b}. The uncertainity in heat flux due to errors in power meter is estimated at most 4%. The error in wall temperature measurement is 0.1 K judged from the calibration of thermocouples. The uncertainity in the saturation temperature depends on the accuracy of the absolute pressure measurement, the pressure drop estimation and the thermophysical tables, and those are estimated to be 0.2 to 0.3 K. From these uncertainities the accuracies of the heat transfer coefficients are determined to be 10 to 24%.

A series of experiments listed in the table 1 were carried out with HCFC22 and HCFC123. All data were

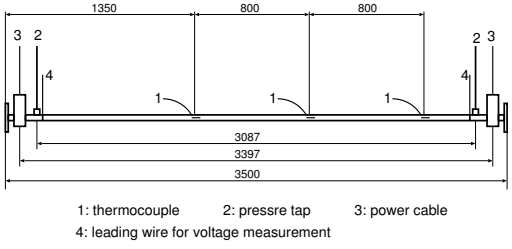

Figure 1: Scheme of test section

Heat flux, q [kW/(m^2)]	5 ~ 25	
Vapor quality, x [-]	0.2 ~ 0.8	

taken under steady state conditions. The present experimental conditions are different from those of ordinary ammonia refrigerator and similar to those of the dataset which were used in the developing process of some available correlations for ordinary grooved copper tubes, in order to investigate the effect of larger inner grooves and surface roughness by comparing with these correlations.

EXPERIMENTAL RESULTS

The heat transfer characteristics of the evaporating refrigerant inside the present steel tube would be discussed here using the Figures 3 and 4, which indicates the measured heat transfer coefficients and the temperature differences, ΔT, between the saturated refrigerant and the arithmetic mean of the measured values at the outer surface for the upper and lower halves of the tube, against the vapor qualities. These two temperature differences are plotted in order to estimate the condition of the liquid film on the inner surface of the tube, which affects strongly on the flow boiling heat transfer.

The present steel tube has much larger surface roughness and groove depth and pitch than those of ordinary spirally grooved copper tubes widely used for fluorocarbon refrigerants, and somewhat different flow regimes are supposed to be appeared. Thus, in order to investigate the peculiarity of the present steel tube about the flow boiling heat transfer against ordinary grooved copper tubes, the predicted values by the two available correlations, Mori *et al.*[5] and Murata[1] equations, are plotted in the figures as the estimated values for an ordinary grooved copper tube under the same experimental conditions. The Mori *et al.* correlation is one of the most recommendable equation in Japan for ordinary grooved copper tubes, which was developed using a large dataset of experimental results. Mori *et al.* also showed that all of Murata, Kandlikar-Raykoff[2], Thome *et al.*[3], Cavallini *et al.*[4] correlations gave nearly same accuracies in about 30 to 35% mean deviation against their dataset. The Murata correlation was chosen because this equation showed better agreement with the present result than other correlations assessed in our research so far. It should be noted that the inner diameter of the tube used in developing the Murata correlation is 10.7mm and nearly equal to 12.5mm of the present tube, and also that its experimental conditions are similar to those for HCFC123 in the present study.

Heat transfer at low heat flux condition

Figure 3 shows the heat transfer coefficients and wall temperatures at the upper and lower part of the tube against vapor qualities at the low heat flux condition, q=5kW/m^2, where the contribution of nucleate boiling is supposed to be relatively small.

Figures 3(a)-1 to (a)-3 present the results for the refrigerant HCFC123 in the condition of mass velocity, G= 100, 200 and 250 kg/(m^{2}s), respectively. The pressure range of the data shown in these figures is 0.2 to 0.3MPa. Except for the high quality region with G=100kg/(m^{2}s) the measured heat transfer coefficients of HCFC123 agree well in the low heat flux condition with the estimated values by the Murata[1] correlation.

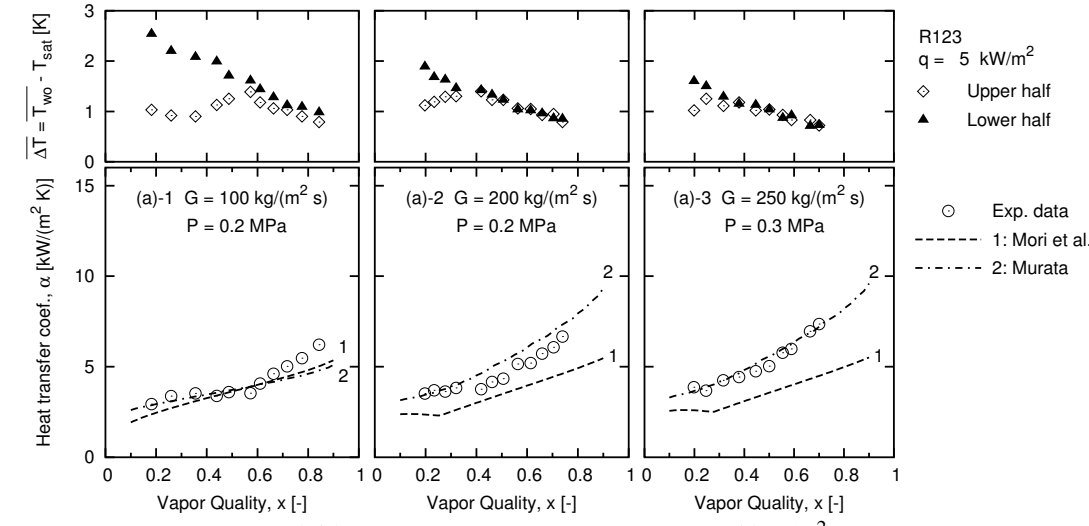
In the case of low mass velocity, G=100kg/(m^{2}s), the heat transfer coefficient is nearly constant when the vapor quality is less than about 0.6 as shown in the Figure 3(a)-1. In this region of $x < 0.6$ the wall temperatures at the upper half are about 1 to 1.5K lower than those at the lower half. The difference in wall temperatures and the constant heat transfer coefficient suggest the separated flow regime where the most of liquid flows in the lower part of the tube. Also, from the lower wall temperatures at the upper half the wall surface of the upper part is considered to be covered by the thin liquid meniscus which has fine heat transfer characters. On the other hand, the typical trends of the annular flow on the flow boiling heat transfer inside a tube, increasing heat transfer coefficients with larger vapor quality and circumferentially constant wall temperatures, are observed in the region where the vapor quality is larger than about 0.6. Nevertheless the both Mori *et al.*[5] and Murata[1] correlations estimate the flow pattern to be a separated flow in this region of $x > 0.6$ and underpredict the heat transfer coefficient for the present steel tube. It is to be noted that the equations for the angle of the wetted perimeter used in these two correlations were developed based on the same equation, the Yoshida *et al.*[6] correlation.

Similar trends to the case of G=100kg/(m^{2}s) were

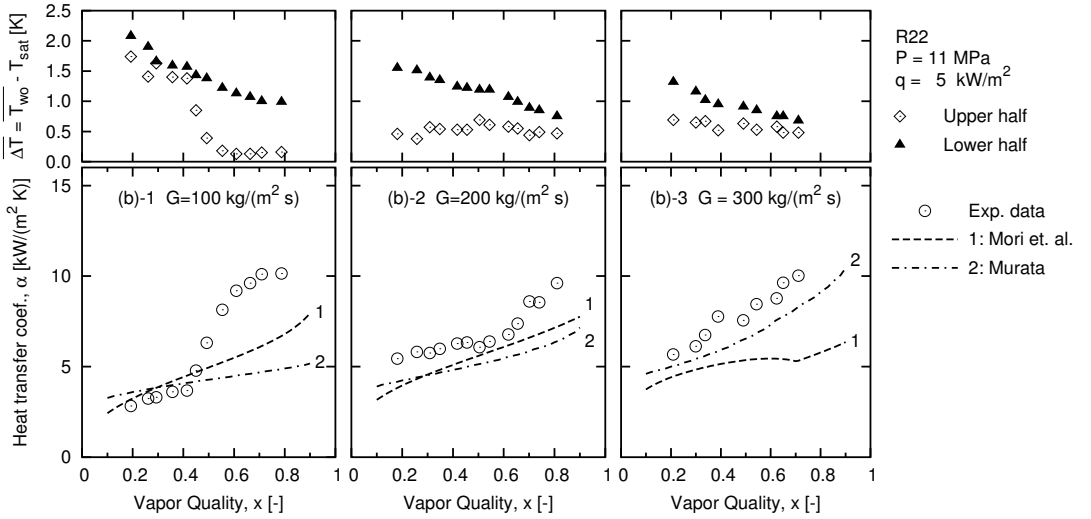
obtained for the case of 200 and 250 kg/(m^{2}s), except for the vapor quality at the transition point between the separated and annular flow regimes, as shown in the Figures 3(a)-2 and (a)-3. The qualities at the transition point are about 0.3 and 0.15 for the case of G=200 and 250kg/(m^{2}s), respectively, and much smaller than that of 100kg/(m^{2}s), 0.6. While this transition point is not correlated by the either Mori *et al.*[5] or Murata[1] equation in the low mass velocity condition, G=100kg/(m^{2}s), the both equations predict well in the higher mass velocity conditions, G=200 and 250kg/(m^{2}s).

Figures 3(b)-1 to (b)-3 indicate the results for the refrigerant HCFC22. The pressure of these data is 1.1MPa that is more than five times higher than 0.2MPa of the results for HCFC123 shown in the Figures 3(a). Therefore the velocity of HCFC22 is much slower than that of HCFC123, and the contribution of nucleate boiling on flow boiling heat transfer is supposed to be much larger as a result of this higher pressure.

The heat transfer coefficient of HCFC22 with mass velocity, G=100kg/(m^{2}s), shown in the Figure 3(b)-1 increases moderately with larger vapor quality in the region of $x < 0.4$, rises abruptly near the point with the vapor quality, x=0.5, and keeps a quite high value at $0.6 < x < 0.8$. The degrees of the wall superheat at the upper half of the tube are rather smaller than those at the lower half in the region of $x < 0.4$. This trend of wall temperatures and the nearly constant heat transfer coefficient against vapor quality suggest that the flow pattern is a sep-



(a) Fluid: HCFC123, P = 0.2 – 0.3 MPa, q = 5 kW/m^2



(b) Fluid: HCFC22, P = 1.1 MPa, q = 5 kW/m^2

Figure 3: Heat transfer coefficient vs. vapor quality at low heat flux condition, q = 5 kW/m^2

arated flow at $x < 0.4$. Compared with the result of HCFC123 in the low quality region plotted in the Figure 3(a)-1, the wall temperatures at the lower half are almost same, and those at the upper half are about two times higher. From this higher wall temperature at the upper half, small area near the top of the tube are supposed to be dried, where the heat transfer coefficient is extremely smaller. The liquid film on the tube surface usually rises toward the top with increasing the vapor quality, and the dried area around the top may become covered by the liquid meniscus at $x \approx 0.5$. Therefore the cause of the rapid increasing of heat transfer coefficients and decreasing of wall temperatures at the upper half at $x \approx 0.5$ is considered to be this covering of the extremely thin liquid meniscus, which has excellent heat transfer characters.

In the Figures3(b)-2 and (b)-3, which presents the experimental results for HCFC22 with the mass velocity, G=200 and 300kg/(m^{2}s), respectively, the lower temperatures at the upper half and the gradually increasing of the heat transfer coefficient are observed in the whole region of the vapor quality. These trends agree with the typical characteristics of the separated flow expect for the rather steep gradient of heat transfer coefficients in the high quality region, which might be caused by the relatively high vapor velocity. The measured heat transfer coefficients of HCFC22 are about 20% higher than the predicted values by the Murata[1] correlation that predicts those of HCFC123 in the low heat flux condition with enough accuracy. The heat transfer coefficients at the lower half, $q/\overline{\Delta T}$, agree well to the predicted value by the relevant term in the Murata correlation(not shown). So the discrepancy of the circumferentially average heat transfer coefficient may be caused by the thinner liquid meniscus around the top of the tube generated by the relatively large inner diameter and groove width of the present tube.

Heat transfer at high heat flux condition

Figure 4 indicates the heat transfer coefficients and wall temperatures at the upper and lower halves of the tube at the high heat flux condition, q=15kW/m^2, in the same manner with the Figure 3. The combination of the higher heat flux and large surface roughness of the present tube usually produce the much larger ratio of the nucleate boiling contribution against the whole heat transfer than that in the low heat flux condition.

Figures 4(a)-1 to (a)-3 present the experimental results for HCFC123. The measured heat transfer coefficients are higher than predicted values by the Murata[1] correlation in the high vapor quality region with G=100kg/(m^{2}s) and the low vapor quality region with G=200 or 250kg/(m^{2}s), where the contribution of nucleate boiling is supposed to be dominant. The low quality region with G=100kg/(m^{2}s) is the domain where the contribution of the nucleate boiling should be largest. However, in this region the some area around the top of the tube seems to be dried out because of the too high heat flux and heat transfer coefficient against the expected thin liquid film, and this dry area reduces the circumferential average heat transfer coefficient.

The trend of the wall temperature at the lower half in the case of HCFC123 with G=100kg/(m^{2}s), shown in the Figure 4(a)-1, is almost same in the low quality region with that shown in the Figure 3(a)-1 for the low heat flux condition. In the high quality region the wall temperatures at the lower half are nearly constant against the vapor quality and identical to those at the upper half. Thus, the flow condition in the high quality region is considered to be an annular flow with a relatively large contribution of nucleate boiling due to the high heat flux.

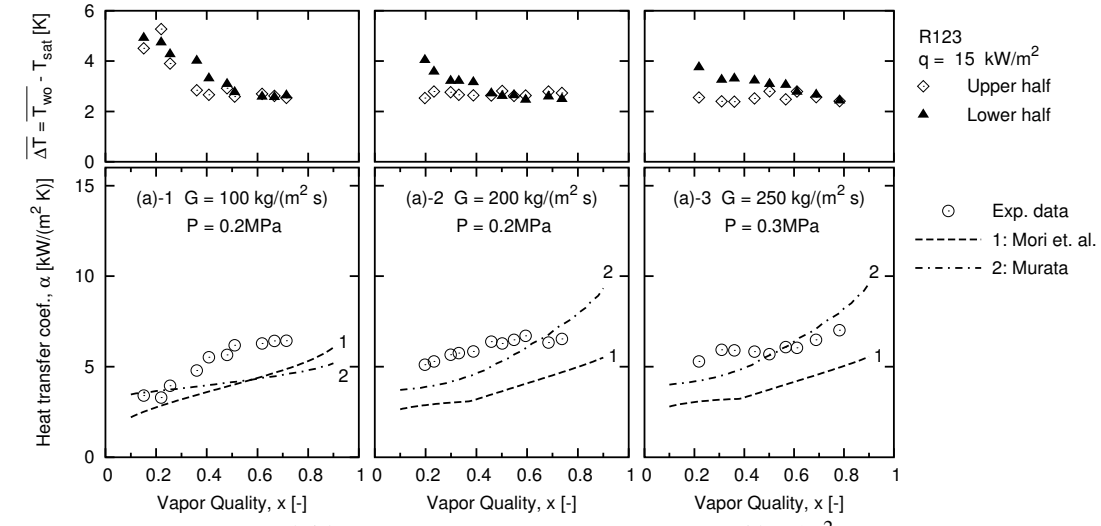
For the case of G=200 and 250kg/(m^{2}s), the Figures 4(a)-2 and (a)-3 indicate the similar trends of wall temperatures against the vapor qualities to those in the low heat flux condition plotted in the Figures 3(a)-2 and (a)-3, except for the the wall temperatures at the upper half near x=0.4. In this region the temperatures at the upper half are slightly lower than those at the lower half, and the temperature difference between the upper and lower halves is smaller than those in the low heat flux condition. The small area near the top of the tube may be covered by the very thin liquid meniscus that is thinned by the higher heat flux in this case, and the cause of the lower temperatures at the upper part is considered to be the higher heat transfer coefficient of this thin liquid meniscus.

The Figures 4(b)-1 to (b)-3 show the experimental results for HCFC22 with the pressure, P=1.1MPa. The wall temperatures of the upper and lower halves are different each other in most of the present data for HCFC22. So the flow pattern of these data is considered to be a separated flow. The dominance

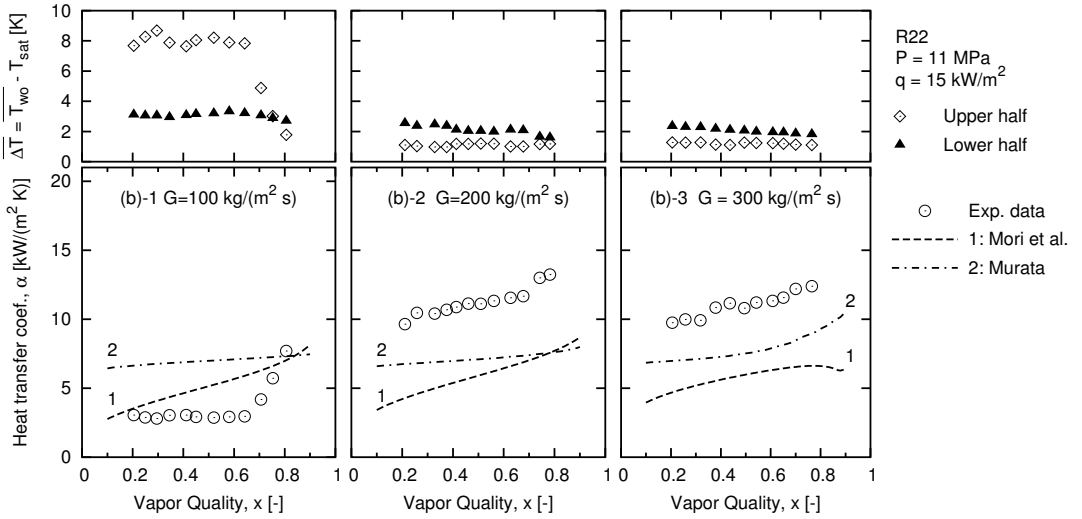
of the separated flow is caused by the relatively large inner diameter and the low velocity as a result of the high pressure condition of HCFC22.

The wall surface at the upper part of the tube is completely dry in the most case of HCFC22 with the mass velocity, G=100kg/(m^{2}s), judging from much higher temperatures at upper half than those at lower half, as shown in the Figure 4(b)-1. The heat transfer coefficients of the data with dry surface are extremely low. It should be noted that for ordinary grooved copper tubes the wall surface near the top of the tube is covered by the thin liquid meniscus and that the largest heat transfer enhancement performance by the grooves of the tube is usually obtained in the case of $G \approx$ 100kg/(m^{2}s).

On the other hand, the relatively low wall temperatures at the upper half are indicated in the Figures 4(b)-2 and (b)-3 for the HCFC22 with G=200 and 300kg/(m^{2}s). The low temperatures signify the excellent heat transfer at the upper half and suggest that the heat transfer surface is covered by the very thin liquid meniscus. The average heat transfer coefficients, $q/\overline{\Delta T}$, at the upper half in the high heat flux condition are slightly larger than those in the low heat flux condition, which is shown in the Figures 3(b)-2 and (b)-3. The heat transfer coefficients at the lower half are smaller than those at the upper half, but still fine compared with the results in other experimental conditions in the present work. The present steel tube has much rougher surface than ordinary copper tube as above mentioned. Therefore this fine heat transfer coefficients at the lower



(a) Fluid: HCFC123, P = 0.2 – 0.3 MPa, q = 15 kW/m^2



(b) Fluid: HCFC22, P = 1.1 MPa, q = 15 kW/m^2

Figure 4: Heat transfer coefficient vs. vapor quality at high heat flux condition, q = 15 kW/m^2

half are caused by the excellent nucleate boiling heat transfer due to the high heat flux and pressure.

CORRELATION FOR HEAT TRANSFER COEFFICIENT

The correlation for the heat transfer coefficient is obtained for the region where the wall surface is completely covered by liquid (film or thin meniscus) in the present study. Circumferentially averaged heat transfer coefficient is expressed using the three correlation equations for the heat transfer coefficient at the well-wetted wall surface, α_{ww}, and at the surface covered by the thin liquid meniscus, α_{tl}, and the degree of the well-wetted perimeter, ϕ_s.

Heat transfer coefficient at the well-wetted surface, α_{ww}

Based on the Takamatsu *et al.*[7] correlation for the heat transfer coefficient inside a smooth tube in the annular flow regime, the following equations are obtained for the heat transfer coefficient at the well-wetted surface, α_{ww}.

$$\alpha_{ww} = \alpha_{cv} + \alpha_{nb} \tag{1}$$

where

$$\alpha_{cv} = 0.040\,F\cdot Re_{lo}^{0.8}\,Pr_l^{0.4} \tag{2}$$

$$Re_{lo} = G(1-x)d_i/\mu_l \tag{3}$$

$$F = 1+2.0X_{tt}^{-0.8}+0.13X_{tt}^{-1.6} \tag{4}$$

$$X_{tt} = \{(1-x)/x\}^{0.9}(\rho_v/\rho_l)^{0.5}(\mu_l/\mu_v)^{0.1} \tag{5}$$

$$\alpha_{nb} = K^{0.745}\cdot S\cdot\alpha_{pb} \tag{6}$$

$$K = (1+0.768\eta+0.351\eta^2 +0.347\eta^3+0.131\eta^4)^{\frac{-1}{0.745}} \tag{7}$$

$$\eta = \alpha_{cv}/(\alpha_{pb}S) \tag{8}$$

$$\alpha_{pb} = 1.6\,\alpha_{SA} \tag{9}$$

$$\alpha_{SA} = 246(\lambda_l/La)^{0.255}(q/T_{sat})^{0.745} \times(\rho_v/\rho_l)^{0.581}\,Pr_l^{0.533} \tag{10}$$

$$S = (1-e^{-\xi})/\xi \tag{11}$$

$$\xi = 1.2\times10^{-5}\,Ja^{*1.25}\,La\,\alpha_{cv}/\lambda_l \tag{12}$$

$$Ja^* = (\rho_l/\rho_v)(Cp_l T_{sat})/h_{fg} \tag{13}$$

$$La = \sqrt{2\sigma/\{g(\rho_l-\rho_v)\}}. \tag{14}$$

In this correlation the total heat transfer coefficient is expressed as the sum of the forced convective and nucleate boiling heat transfer coefficients, and the nucleate boiling heat transfer coefficient based on the degree of wall superheat is obtained using the total heat flux q and the parameter $K \equiv q_{nb}/q$. The detail of the physical base of this correlation is stated in the reference [7], and therefore omitted here. Empirical constants in the present equations are 0.040 in the equation(2), all constants in the equation(4), 1.6 in the equation(9), and 1.2×10^{-5} in the equation(12). These were determined through the assesment with assumed values, whose parameter ranges had been arbitrary settled refereeing to the Takamatsu *et al.* correlation. It is to be noted that the equation (7) for K was modified to become more suitable to the model used in the developing process of the Takamatsu *et al.* correlation.

Heat transfer coefficient at the surface covered by the thin liquid meniscus, α_{tl}

Using the boiling number, Bo, Froude number, Fr, and the Reynolds number of the vapor, Re_v, The α_{tl} is correlated empirically by the following equation.

$$\alpha_{tl} = 5.62\times10^3\,(Re_{vo}\times10^{-4})^{0.16}(Bo\times10^4)^{0.45} \times Fr^{0.8}\,(\rho_v/\rho_l)^{0.85}\,\lambda_l/d_i\,. \tag{15}$$

The definitions of Re_{vo}, Bo and Fr are $Re_{vo}=G\,x\,d_i/\mu_v$, $Bo = q/(G\,\Delta h_{fg})$ and $Fr = G/\sqrt{g\,d_i\rho_v(\rho_l-\rho_v)}$, respectively.

Degree of well-wetted perimeter, ϕ_s

Assuming that the boundary between the well-wetted surface and the area covered by the thin liquid meniscus is almost equal to the boundary between the wetted and dried surfaces in the flow boiling inside a smooth tube, the following Mori *et al.*[8] correlation for the degree of the wetted perimeter in a smooth tube is applied for the degree of well-wetted perimeter, ϕ_s.

$$\frac{\phi_s}{\phi_0} = 1+0.75\left[\frac{x}{1-x}\left(\frac{\rho_l}{\rho_v}\right)^{0.5}\right]^n e^{1.06-23.8\left(\frac{\rho_l}{\rho_v}\right)}, \tag{16}$$

where

$$n = 0.26\,Fr^{0.84}\,(Bo\times10^4)^{-0.16} \tag{17}$$

$$\frac{1}{1+\{(1-x)/x\}(\rho_v/\rho_l)} = 1-\frac{\phi_0-\sin\phi_0\cos\phi_0}{\pi} \tag{18}$$

Comparison with measured values

The circumferentially averaged heat transfer coefficient is estimated in the present correlation by solving the one dimensional heat conduction problem in circumferential direction assuming that the temperature difference between the outer and inner surfaces of the tube can be neglected. The method to solve this problem is not explained here due to the limited space, and the detail of the procedure may be referred, for example, to the appendix B of the reference [6]. It is noted that the circumferential distribu-

Table 2: Percentage deviations of the present correlation in the region where the wall surface is completely covered by liquid

Heat flux	HCFC22			HCFC123		
[kW/m^2]	N	AD	MD	N	AD	MD
5	49	-11.8	14.2	33	-20.9	21.7
15	39	-8.0	10.6	30	-23.6	24.0
25	24	-8.8	9.6	21	-31.3	31.3

tion of the temperature difference between the inner and outer surfaces can be considered smaller than the circumferential temperature distribution due to the small ratio of thickness and circumference of the tube. Therefore, the circumferencial heat conduction was treated as a dominant factor in this problem even though the temperature difference in the radial direction of the steel tube may not be neglected.

Table 2 lists the comparison result on the measured and predicted circumferentially averaged heat transfer coefficients. The N, AD and MD in the table are the number of the data and the average and mean deviations between the measured and predicted values, respectively, and the definitions of AD and MD are $AD=\sum(\alpha_{\mathrm{cal}}/\alpha_{\mathrm{exp}}-1)/N\times 100[\%]$ and $MD=\sum\left|\alpha_{\mathrm{cal}}/\alpha_{\mathrm{exp}}-1\right|/N\times 100[\%]$. The present correlation predicts the experimental data with good accuracy, about 10 to 15% for HCFC22 and 20 to 30% for HCFC123 in mean deviations. However, the experimental data with the dry surface, such as shown in the Figure 4(b)-1, were eliminated in the comparison because the present correlation is applicable only to the region in which the wall surface is completely covered by liquid. In order to extend the applicable region of the present correlation, the prediction method is to be established for the border of this dry surface.

CONCLUSION

The experiment was carried out on the flow boiling heat transfer of refrigerants HCFC22 and HCFC123 inside a horizontal, spirally grooved steel tube with the 12mm average inner diameter. The conclusions are as follows:

1. In the case of HCFC123 with P=0.2MPa the annular flow seems to be formed even in the low mass velocity, G=100kg/(m^{2}s), condition.
2. In the case of HCFC22 with P=11MPa the wall surface at the upper part of the tube appears to be completely dry in the low mass velocity, G=100kg/(m^{2}s), condition with the high heat flux, 15kW/m^2.
3. The measured heat transfer coefficients at high heat flux condition, q=15kW/m^2, are higher than the predicted values by both Murata and Mori *et al.*[5] correlations except for the case with some dry area around the top of the tube.
4. A set of correlation equations is proposed for circumferentially averaged heat transfer coefficients in the region where the wall surface is completely covered by liquid.

ABSTRACT

The desiccant cooling system coupled with low temperature sources less than 323K has been attracted from the view point of effective energy utilization. It has been desired to enhance the performance of the adsorber containing the adsorbent in commercial and industrial uses. We have developed a thermo-sensitive gel - silica gel composite adsorbent bed column equipped with the recycle flow system for increasing the capacity of adsorbing water vapor and regenerating the thermo-sensitive gel-silica gel composite adsorbent quickly at low temperatures. The numerical study on heat and mass transfer (water vapor) in the thermo-sensitive adsorbent packed within a bed column was carried out. A part of dehumidified air was recycled through a heat exchanger into the entrance of the packed bed column. The rise of temperature within the packed bed column during adsorption of water vapor was reduced by introducing the recycle process, so that the amount of adsorbed water vapor increased remarkably. The adsorption – desorption cycle operation was simulated to investigate the regeneration property of the thermo-sensitive adsorbent. The thermo-sensitive adsorbent packed within the bed column was almost regenerated at low temperature of 323K. This is why the thermo-sensitive adsorbent changes in hydrophobic state when it is heated at somewhat higher temperatures than a specific one which is called phase transition temperature of the thermo-sensitive adsorbent. The desorption of adsorbed water took place quickly. As a result, the thermo-sensitive adsorbent was regenerated reversibly at such low temperatures. The performance of the desiccant cooling system can be improved by the introduction of both the recycle flow system and the use of the thermo-sensitive gel – silica gel composite adsorbent

INTRODUCTION

Desiccant air conditioning system has been paid much attention to an energy saving cooling method, which can utilize effectively the waste heat sources at temperatures less than 333K. For enhancement of the efficiency of desiccant air conditioning system, it will be an important item

to improve both the ad-and desorption properties of water vapor adsorbent and heat transfer during ad-and desorption.

The performance of adsorbents is mainly governed by their surface properties and sizes. Silica gel and zeolite have been commonly used as the water vapor adsorbents for open-cycle desiccant cooling system [1-4]. Zeolite has a large capacity for water vapor adsorption at low relative vapor pressure. However, for regeneration, the high temperature heat source is required. On the other hand, silica gel is a favorable material for regeneration because the heat of adsorption of water vapor is equivalent to the heat of condensation of water. To improve the regeneration property of the water vapor adsorbent, thermo-sensitive gel was immobilized onto the silica gel [5-9]. Thermo-sensitive gel shows the changes of its physical property (hydrophobic-hydrophilic balance) depending on surrounding temperature. We tried to evaluate the isotherms of thermo-sensitive water vapor adsorbent using an adsorption apparatus.

For using the thermo-sensitive water vapor adsorbent effectively, the adsorption process should be modified for reducing a rise in temperature accompanied by adsorption of water vapor below the phase transition temperature of the thermo-sensitive water vapor adsorbent. A part of the dehumidified air is introduced into the adsorbent bed unit after removing the heat of adsorption through a heat exchanger unit, so that a temperature rise within the unit is reduced to increase the capacity of adsorbing water vapor.

The aim of our investigation is to evaluate the dehumidified and regenerated properties of silica gel adsorbent and the thermo-sensitive gel - silica gel adsorbent by a numerical calculation of simultaneous water vapor mass transfer and heat transfer in the adsorbent bed unit equipped with the recycle flow system.

MATHEMATICAL MODEL

Figure 1 shows a schematic diagram of the desiccant cooling system. This system is composed of an adsorbent bed unit, a recycle flow path of a dehumidified air and a heat exchanger unit. The heat generated with adsorption in the adsorbent bed unit is transferred to the dehumidified air that is recycled through the heat exchanger. To predict this system by mathematical modeling, it is assumed that

(1) Adsorption of water vapor is performed under an adiabatic condition.
(2) Adsorption equilibrium exists at the surface of the adsorbent.
(3) The temperature distribution inside the adsorbent particle is uniform
(4) The dehumidified air exhausted from the adsorbent bed is immediately cooled to a room temperature by heat exchanger.

A set of equations describing the mathematical model of the combined water vapor mass transfer and heat transfer in the adsorbent bed unit can be written as follows:

(Water vapor mass transfer balance)

Mass transfer in the packed bed

$$\frac{\partial H}{\partial t} = -\frac{u}{\varepsilon}\frac{\partial H}{\partial z} - \frac{(1-\varepsilon)\rho_{ads} M_{H2O}}{\varepsilon \rho_{gas}}\frac{\partial q}{\partial t} \quad (1)$$

Mass transfer in a silica gel adsorbent particle

$$\frac{\partial q}{\partial t} = D_P\left(\frac{\partial^2 q}{\partial r^2} + \frac{2}{r}\frac{\partial q}{\partial r}\right) \quad (2)$$

(Heat transfer balance)

Heat transfer in the gas phase

$$\frac{\partial T_{gas}}{\partial t} = -\frac{u}{\varepsilon}\frac{\partial T_{gas}}{\partial z} + \frac{(1-\varepsilon)hS}{\varepsilon \rho_{gas} Cp_{gas}}(T_{ads} - T_{gas}) \quad (3)$$

Heat transfer in the adsorbent phase

$$\frac{\partial T_{ads}}{\partial t} = \frac{k_e}{\rho_{ads}(Cp_{ads} + qM_{H2O}Cp_w)}\frac{\partial^2 T_{ads}}{\partial z^2} - \frac{\varepsilon hS}{(1-\varepsilon)\rho_{ads}(Cp_{ads} + qM_{H2O}Cp_w)}(T_{ads} - T_{gas}) + \frac{\Delta H}{Cp_{ads} + qM_{H2O}Cp_w}\frac{\partial q}{\partial t} \quad (4)$$

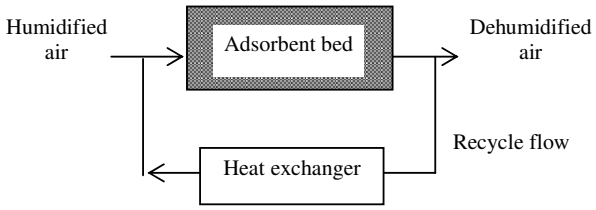

Fig. 1 Schematic diagram of the adsorbent bed unit equipped with recycle flow system

The calculation is performed for the particle radius of 2.0×10^{-3} m and for D_P of 5.0×10^{-10} m^2 s^{-1}. To investigate the effect of the recycle flow on the water vapor adsorption, the recycle ratio, R, is defined as:

$$R = \frac{G_{re}}{G} = \frac{G_{re}}{G_{re} + G_{exh}} \quad (5)$$

where G_{re} is the mass flow circulated in the desiccant system, and G_{exh} is the mass flow of dehumidified air exhausted from the desiccant system. The value of G_{exh} (=0.503 kg s^{-1}) is fixed in this study. Therefore, for R = 0.5, the mass flow rate in the adsorbent bed unit, G, is twice the mass flow rate of G_{exh}.

THERMO-SENSITIVE ADSORBENT

N-isoprolylacrilamide gel (NIPA gel) is known as a thermo-sensitive polymer. This polymer shows the changes of its physical property (hydrophobic-hydrophilic balance) depending on surrounding temperature. NIPA gel was immobilized onto silica gel particles. In Figure 2, the adsorption amount of water vapor on the thermo-NIPA-silica gel adsorbent is shown as a function of relative vapor pressure. The isotherm of water vapor onto the NIPA-silica gel adsorbent depended on the adsorption temperature. NIPA-silica gel shows the hydrophobic property above 306K in the NIPA-water system. As a result, the amount of water adsorbed onto the NIPA-silica gel adsorbent was reduced drastically at high temperature (308K) [5-8]. On the basis of the adsorption isotherms of water vapor for the NIPA-silica gel adsorbent, the numerical study on heat and mass transfer (water vapor) within the adsorbent bed unit packed with the thermo-sensitive NIPA-silica gel particles was carried out, as described in the following section.

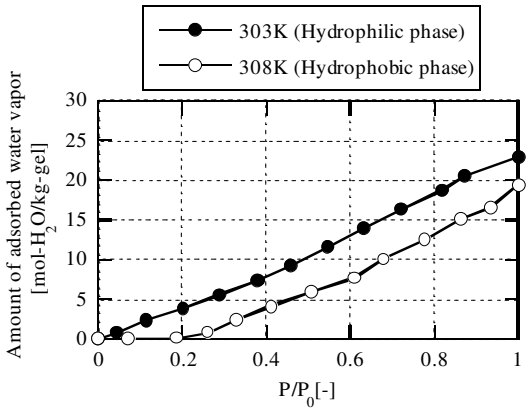

Fig.2 Adsorption isotherms of the thermo-sensitive NIPA-silicagel adsorbent for water vapor

RESULTS AND DISCUSSION

Adsorption

In the adsorption process, only silica gel was used as a water vapor adsorbent whose adsorption isotherm was almost the same as that of NIPA-silica gel adsorbent at 303K. The time history of the absolute humidity of humidified air and the temperature were calculated numerically using Eqs.1-4. The height of the adsorbent bed is 5cm. The mass flow rate of the dehumidified air exhausted from the adsorbent bed unit is 0.503kg s^{-1}. The absolute humidity of humidified air supplied into the unit is 0.012 kg-H_2O/kg-air. Figure 3 shows the temperature rise of dehumidified air at the exit of adsorbed bed unit packed with silica gel adsorbent. For R=0, the temperature reached 318K. On the other hand, the temperature rise decreased by introducing the mixture of humidified air and part of dehumidified air through recycle process. When R was 0.8, the maximum temperature at the exit of the unit was 306K which was lower 12K than that of R=0.

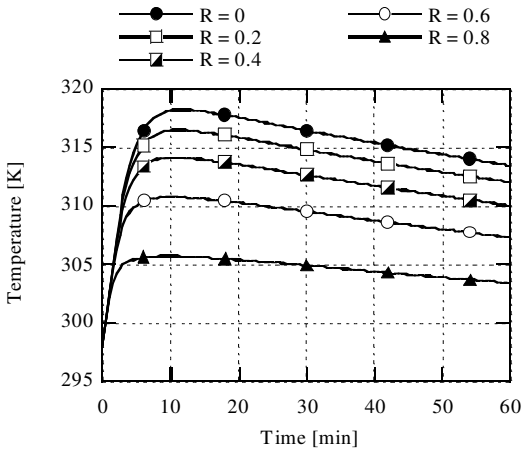

Fig.3 Effect of the recycle ratio on temperature rise of defumidified air at the exit of adsorbent bed unit

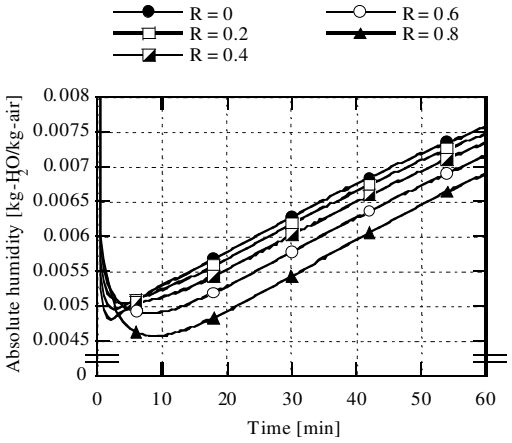

Fig.4 Effect of the recycle ratio on absolute humidity of dehumidified air at the exit of adsorbent unit

Figure 4 shows the time history of the absolute humidity of dehumidified air at the exit of adsorbent bed unit. The absolute humidity was lowered with increasing the recycle ratio. Although the mass flow rate of the humidified air passing through the unit increased with increasing the recycle ratio so that the residence time became short, adsorptivity of water vapor adsorbent became high due to the reduction of temperature rise within the adsorbent bed. As a result, the volume of dehumidified air which was treated less than 0.0055, 0.006 or 0.007 kg-H_2O/kg-air increased with an increase in recycle ratio, as shown in Fig.5.

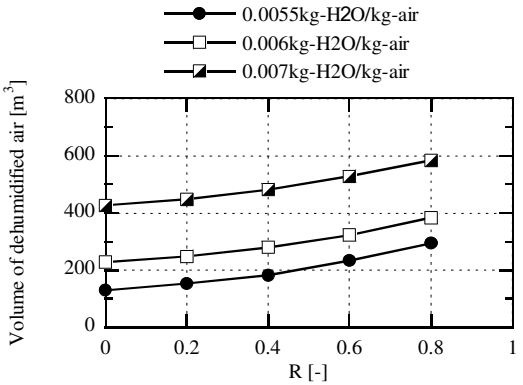

Fig.5 Relationship between the volume of defumidified air treated less than 0.0055, 0.006 or 0.007 kg-H2O/kg-air and the recycle ratio, R

Regeneration

To investigate the regeneration property of the NIPA-silica gel adsorbent bed, the adsorption-desorption cycle operation was simulated. Following the adsorption operation for 60 min, the regeneration operation was performed for 300 min. The humidified air heated at 323 or 353K (AH=0.012 kg-H_2O/kg-air) was used as the regeneration gas.

Figure 6(A) shows the time history of the amount of water vapor adsorbed onto the NIPA-silica gel adsorbent during the adsorption and desorption cycle. When the regeneration temperature was as high as 353K, the NIPA-silica gel adsorbent was regenerated quickly and completely, while the silica gel adsorbent was not regenerated completely. The regeneration property of the NIPA-silica gel adsorbent at a lower temperature level (323K) is shown in Fig. 6(B). Although the silica gel adsorbent was not regenerated at 323K, the NIPA-silica gel adsorbent was almost regenerated completely. This elucidates that the NIPA-silica gel became hydrophobic because the regeneration temperature was higher than the phase transition temperature (306K) of the NIPA-silica gel. So, the amount of water vapor adsorbed onto the NIPA-silica gel adsorbent dropped drastically, as shown in Fig.6(B). It was found that NIPA-silica gel adsorbent can be regenerated easily at even a lower temperature level. Although the thermo-sensitive gel - silica gel that has a somewhat lower phase transition temperature is used in this simulation, it can be said that the water vapor adsorbents with such thermo-sensitive properties

are extremely useful for developing a new desiccant air conditioning system.

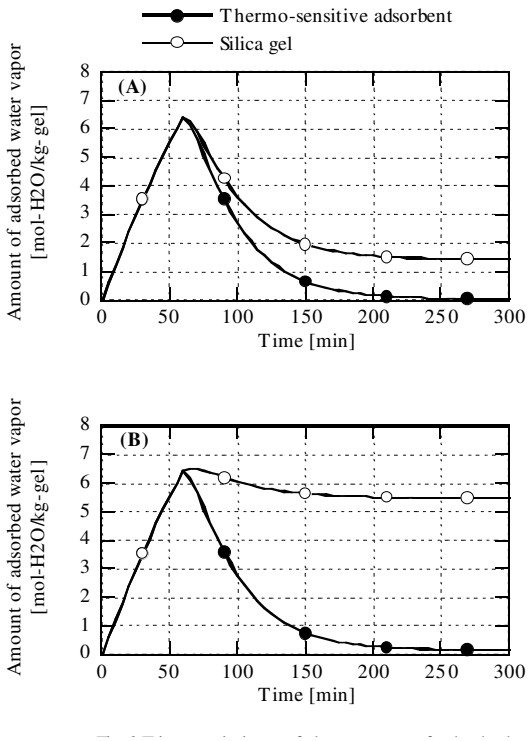

Fig.6 Time histories of the amounts of adsorbed water vapor onto the thermo-sensitive water vapor adsorbent and silica gel adsorbent
(A) Regeneration temperature: 353K
(B) Regeneration temperature: 323K

CONCLUSION

The dehumidified and regeneration properties of the thermo-sensitive gel – silica gel adsorbent were investigated by the numerical calculation of simultaneous heat and water vapor transfer in the adsorbent bed unit equipped with the recycle flow system. In the adsorption process, the recycle flow of the dehumidified air was effective to increase adsorptivity of water vapor adsorption by reducing the temperature rise of the adsorbent bed and the dehumidified air. In the regeneration process, the thermo-sensitive gel - silica gel adsorbent was regenerated quickly and reversibly by heating beyond the phase transition temperature of the immobilized thermo-sensitive gel. The performance of the desiccant cooling system can be improved by the introduction of the recycle flow system and by the use of the thermo-sensitive gel - silica gel adsorbent.

Department of Thermal Engineering
9 Iroon Polytechniou Str., Zografou 15780, Athens, Greece

ABSTRACT

In the present paper, an attempt has been made to estimate the energy consumption in Greek buildings. This is a subject of great interest due to the upcoming building certification that will take place in Greece after the application of the European directive concerning the energy performance of buildings. Our purpose is to examine the energy consumption throughout Greece by simulating the thermal behaviour of typical buildings. In order to achieve this we are founded on the philosophy of the computer programme EnerWin. Information with sketches of buildings showing the thermal zones, Greek climatic data, properties of the various construction assemblies, type of heating and cooling systems, the occupancy of the building in question, as well as hot water, lighting and ventilation profiles are fully outlined in the code.

The annual energy needs of a Greek residential and an office building, as well as the breakdown of energy use are presented. The results of such a simulation can give us a first indication on which end uses are the most energy consuming, the "weaknesses" of a building and thus urge the owner or engineer to take conservation energy measures.

The article focuses on the thermal comfort conditions of the occupants. Thermal comfort is an important issue which should not be overlooked. In the present article we will attempt to examine whether comfort conditions in typical Greek buildings comply with international standards and discuss the particularities of Greek people as far as thermal comfort, energy use and behaviour is concerned.

INTRODUCTION

In Greece the building sector accounts for the 36% of the country's total energy consumption [1]. Given the importance of buildings on the country's energy balance, an attempt has been made to study their energy behaviour and thermal comfort in three Greek cities, namely, Athens, Thessaloniki and Heraklion. Our primary purpose is to provide an estimation of the buildings' energy consumption and examine how this affects the comfort conditions. We cannot underestimate the value of

* Corresponding author: Phone: +30 210 7721255 Fax: +31 210 7723976 Email: asagia@central.ntua.gr

real measurements and observations of the buildings' energy systems, but such data are not always available.
The use of a computer programme, such as EnerWin, can offer an indication of the building's performance. EnerWin is a simulation tool, which consists of the user interface and the computer code. After the user has inserted the input data describing the building, the program can perform the thermal simulation.

METHODOLOGY

Two types of buildings were simulated, a residential and a commercial building. On the one hand residencies dominate as a building type in Greece (75% of the total number of buildings are residencies [2]). On the other hand, office buildings consume large amounts of energy within the commercial sector and as they have specific and homogeneous energy needs, it is easier to study and apply conservation measures.
Real building layouts were used.

Residential building

A typical Greek urban building is defined. Buildings used as residencies in the Athens area and the rest of the big cities in Greece have 4 to 6 floors with 1 to 5 apartments on each floor [3,4]. The building that was simulated has 4 floors with 2 apartments on each floor. The area of each floor is 172m^2, with the ground floor being a garage.

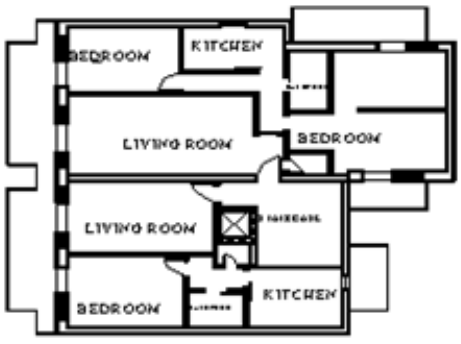

Figure 1: Layout of typical floor, Residential building

Office building

The building has three floors; the area of each is 390m^2. Window openings represent 20% of the total wall area.

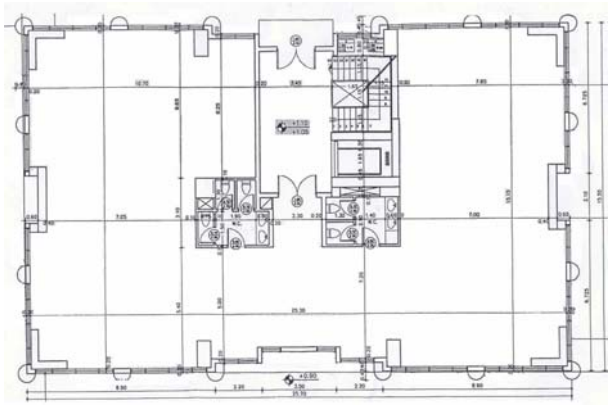

Figure 2: Layout of ground floor, Office building

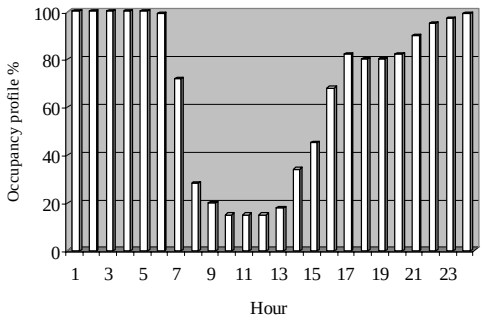
The basic parameters to be inserted in order to conduct the thermal simulation are:

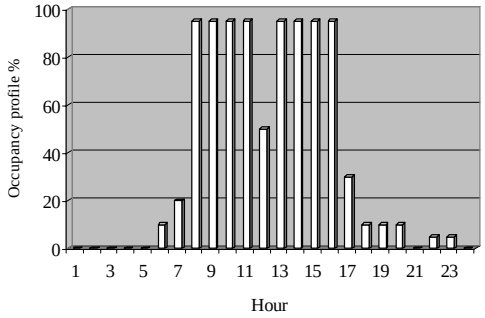
- The climatic data of the region. They include ambient temperatures, solar radiation data as well as wind speed [5-8].
- Geometry and building orientation. Zones are specified, that is spaces where similar conditions dominate.
- Wall, floor and roof materials and properties. The typical external wall of a Greek multi-storey building is 26cm thick and has the following properties: thermal transmittance U=0.66 W/m^{2}C, solar absorptivity α=0.75 [3,4]. Accordingly, the roof has U=0.397 W/m^{2}K, α=0.80 and the floor U=0.568 W/m^{2}K, α=0 [8].
- External shading. The effect of balconies, which is a very common feature in Greek residential buildings, is taken into consideration.
- Window properties. As far as the residential building is concerned, windows are double-glazed (25mm), transparent with U=2.839 W/m^{2}K, solar heating gain coefficient SHGC=0.75, emissivity ε=0.60, daylight transmissivity τ=0.77. The office building has grey tinted double-glazed windows, with properties U=2.839 W/m^{2}K, SHGC=0.47, ε=0.84, τ=0.39 [8,9]. It is noted that the SHGC is the percentage of the incident

solar radiation which turns into heat gain inside the space and is defined as $SHGC = \tau + \sum_{k=1}^{n} N_k a_k$, with N being the inward-flowing fraction of absorbed radiation in the k*th* layer.

- Heating system. Both the residential as well as the office building are assumed to use central heating system with oil as fuel. This is very common in Greek multi-storey buildings. The efficiency of the heating system is 85% [10].
- Air conditioning system. Residencies usually have direct expansion split units for air conditioning purposes. The coefficient of performance is 2.50, but its value is adjusted, according to the ambient temperature and humidity. It is noted that according to the philosophy of the program, all the spaces of the building are air conditioned. In reality, there is only a limited number of cooling units, usually in bedrooms or sitting rooms. The office building has a central VAV (Variable Air Volume) air conditioning system. Its coefficient of performance is 2.60.
- The maximum number of people expected to occupy the zone, as well as the occupancy profile of the zone. Each profile contains 24 hourly values that describe the average daily occupancy pattern.



(a)

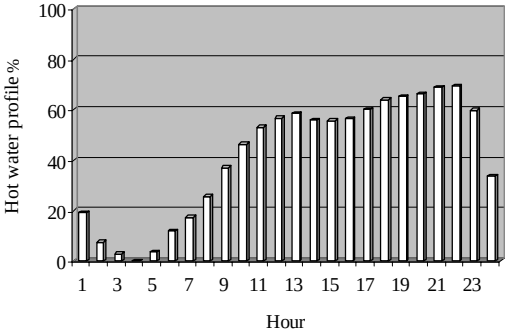


(b)

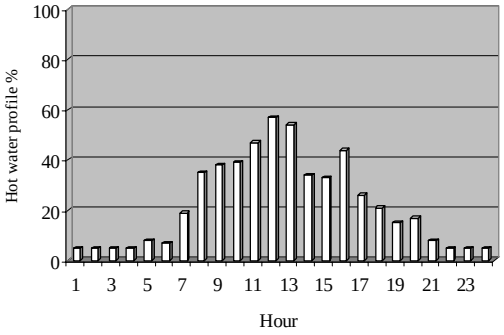
Figure 3: Occupancy profiles (%) for (a) the residential [11] and (b) office building [8].

The profiles have resulted after processing the available data [8,11]. The residential building is assumed to be occupied by four member families, while for the office building an estimation has been made according to the guide of the Greek Technical Chamber [13]. The guide indicates an occupancy of 10 persons/100 m^2 for an office building.

- The average number of volume units of hot water used per person per occupied day, which is 35 lt/day/person for the residential and 3.8 lt/day/person for the office building. The hot water profiles that describe the use by the occupants are a product of process of the available data [8,12]. Values represent the hourly percentage of total daily use.



(a)



(b)

Figure 4: Hot water profiles (%) for (a) the residential [12] and (b) office building [8].

- Natural ventilation. This parameter simulates the opening of windows from the occupants, when the space is too warm. While this is common practice in residencies, natural ventilation is not assumed for the office building.
- Lighting and electrical equipment [8,14]. In the residence incandescent lamps are used, while in the office building fluorescent lighting sources are assumed. The equipment refers to any kind of electrical device, for example refrigerators, television sets, computers but no space conditioning equipment is included here.
- Space temperature. Temperature is allowed to float between set limits. Temperatures are those that exist in a building and are nor the desired ones neither the design temperatures. This is for simulating the real situation, and allows seeing what the comfort conditions are. The temperature range is set to be 20 to 29^{o}C.

It is stressed that the program sizes both the heating and cooling systems according to the existing load, the thermostat settings and the system efficiency. By setting the temperature to float in a range representing the real temperatures in the interior [16] we can estimate the actual energy consumption and examine what comfort conditions are achieved.

RESULTS

Three Greek cities were selected, in order to examine the effect of the climate on the building's energy consumption. The cities are representative of the three climatic zones in which the country is divided [9].
The results obtained for the two types of buildings are:

Residential building

	Total annual energy consumption
Athens	586.2 MJ/m^2
Thessaloniki	614.5 MJ/m^2
Heraklion	530.4 MJ/m^2

CONCLUSIONS

Energy consumption

End uses differ with the building type. Space heating and hot water heating are the most important end uses for the residential building, whereas lighting and space cooling for the office building.

Although an attempt was made to estimate the needs of a typical building, the results indicate a relative small demand in heating energy in comparison to common experience. This is because there is a great number of existing buildings with little or no insulation and single glazed windows. The building used, has on the contrary, double-glazed windows and good insulation, as the Greek regulation (1979) indicates [9].

It is important to stress that the energy behaviour of the occupants has been considered as a parameter. Occupancy and hot water use profiles have been used. Moreover, the use of natural ventilation is allowed, as means of controlling indoor climate.

The effect of the climate on both energy consumption and breakdown is decisive. This is to be taken into consideration in the case of application of energy conservation measures. In northern climate (Thessaloniki) it is clear that heating energy is the most energy consuming sector. Nevertheless, it is harder to achieve thermal comfort during the winter months in comparison with the other two cities.

The fact that the urban climate has specialties must not be overlooked. Temperatures in densely populated cities are higher than in the surrounding areas. This mostly affects the cooling load, thus the electricity demand.

Thermal comfort

The conditions proposed from ASHRAE have been used as the comfort zone [15]. The problem of thermal discomfort is concentrated on the summer months, as it is observed even up to 70% of the occupancy time. During winter months the problem is not so intense.

International comfort standards are based on energy balance models (static models). ASHRAE defines that the comfort conditions in terms of operative temperature values range from 20 to 27^{o}C.

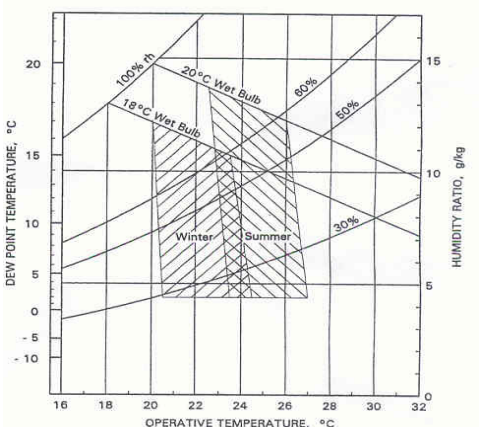

Figure 9: ASHRAE Comfort Zone

According to the standards, it seems that for a large percentage of time on yearly basis, there is discomfort inside Greek buildings. This is only partially true. On the one hand, there is room for better use of energy as well as improvement of thermal comfort in Greek residencies. On the other hand, a number of factors concerning the occupants' behaviour [17] indicate that the results regarding thermal comfort are overestimated:

- In various cases there may exist the possibility of improving comfort, but reasons such as financial, cause the occupant to take measures other than using available control mechanisms. It is very common for example to adjust clothing according indoor conditions so as to avoid turning on a heating or cooling apparatus.
- The thermal sensation is subjective. This consists of an important factor which can affect energy consumption, but cannot be easily measured or taken into consideration in case of thermal simulation, designing, etc. International standards can act as guiding lines, cannot, however, be approached globally. Especially in the case of the Mediterranean climate, the tolerance in higher temperatures is given. While, for example the standard indicates that 28^{o}C are outside the comfort zone, a resident in Greece would find the conditions acceptable.
- When it comes to residential buildings, an important factor influencing thermal comfort is the long stay in a space, which causes the adaptation of settings of the physiological thermoregulation system. In other words, the occupant is acclimatized and responds to expected conditions.
- Another parameter has to do with perceived control of the occupants. That is, in cases when a person has, or think (s/)he has some control over the indoor environment, the person is more tolerant against climatic changes.

Energy use and thermal comfort interact, and with careful designing comfort can be provided using rational amounts of energy.

In Greece the problem of comfort is focused on summertime, mostly due to the climate, but also because the majority of building designers do not lay importance on cooling. Moreover, there are no regulations concerning air-conditioning or cooling, as there are for heating systems. In all, action has to be taken so that both comfort and energy conservation is achieved.

ABSTRACT

This paper reports an energy conservation project implemented on a packaged air cooled air conditioning (PAC) system at an office within Nanyang Technological University campus. The PAC system is serving an office with a built up floor area of 1,664 m^2. Before the implementation of the project, the average monthly energy consumption of the PAC system was 10,236 kWh with average operating time of 60 hours per week. After the implementation of the BeONE automatic switching control system for 6 months, average saving on power consumption recorded was 956.7 kWh per month. Based on the prevailing electricity cost of S$0.1354/kWh, a payback period of 19.3 months is achieved for installing the BeONE system. Similar application of BeONE controller in a manufacturing plant with 24-hours operation of PAC achieved a much shorter pay back period of 6 months. With the large number of PAC systems installed in offices, retail and commercial properties in Singapore, the wide spread use of such automatic switching control systems will have significant contribution to building energy saving.
Keywords: Energy conservation, air conditioning, compressor switching control

INTRODUCTION

Electricity used for air conditioning accounts for a significant portion of total electricity consumption in tropical cities. In Singapore, this portion is relatively high at 24% according to a study done by Energy Market Authority of Singapore [1].The results were based on a series of survey done during the period from late eighties to early nineties. There are reasons to believe that this figure is much higher at around 30% now. Packaged air cooled air conditioning units are popular with small and medium sized commercial properties. The low cooling load prohibits the use

of higher capacity and more efficient central air conditioning systems. PAC systems are easy to install and lower in initial investment. However, PAC systems suffer from inefficient cut in/cut off of compressor using thermostat temperature set point control.

A project to investigate the effectiveness of an automatic programmed switching controller BeONE developed by Toyo Standard Co., Ltd of Japan was jointly under taken by Nanyang Technological University (NTU) and Toyo Standard Asia Pte Ltd. Two sites employing PAC systems for their air conditioning need were selected concurrently for the study; one at an office of 1,664 m^2 built up floor area at NTU Campus and the other a manufacturing plant of Matsushita Electronic components of Singapore.

The objectives of the study were to quantify energy saving, obtain field data on thermal comfort and evaluate payback of installing the controller under various operating conditions. It is hoped that the study will establish some useful criteria to help building owners in decision making of using such controllers.

PAC AIR CONDITIONING SYSTEM

The PAC air conditioning system in NTU Office of Facilities Planning and Management is a Daikin system consists of one indoor unit and two outdoor units. The indoor unit model FRJ1120P as shown in Figure 1 consists of two compressors and two evaporators arranged in parallel with rated cooling capacity of 107.6kW. The refrigerant used is R22 with compressor operating at suction pressure of 0.5 MPa and discharge pressure of 1.55 MPa. The outdoor unit is an air cooled condenser model CRJ560 (Figure 2). Thermostat temperature settings are used to switch on/off of compressors at 23.5^{o}C ON and 22^{o}C OFF based on return air. Fan motors are controlled by main switch which will be on whenever the PAC system is switched on.

Figure 1 Indoor unit of PAC

Figure 2 Outdoor unit of PAC

During a typical working day operation, the PAC system is switched on at about 07:30 and switched off at 18:00. For a typical 5½-day work week, total operating hours of the PAC system is about 60 hours. The average power consumption of the indoor unit (compressors and circulating fans) was measured to be 40.77 kW over a four days period in June 2004. Power by compressors alone was measured to be 33.76 kW.

BeONE COMPRESSOR SWITCHING CONTROLLER

The BeONE controller was developed by Toyo Standard of Japan. The heart of the system consists of a power monitoring device (Figure 3) and an automatic switching control system (Figure 4) which can be programmed to switch on and off of the refrigerant compressor and its driving motor. The system differs from other demand controllers with a patented compressor protection system which can automatically protect the compressor from excessive and inappropriate switching. Another unique feature is the time-zoning capability available with the system such that day and night periods can be programmed by the time-zoning system.

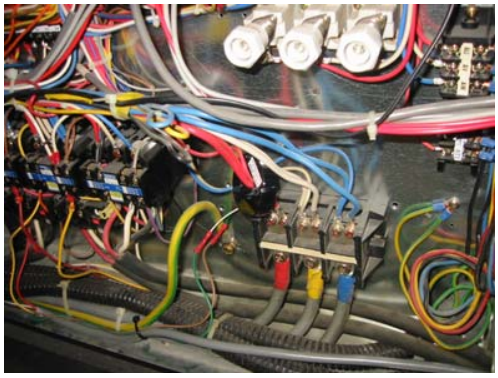

Figure 3 Power monitored by CT connection

Figure 4 BeONE controller

The controller uses a 30-minute interval as a standard session for switching control. Users only need to key in the seconds that users want to stop and save (between 10%/180s to 50%/900s) and the built-in program of the controller will do the rest. A 10% control means that the compressor will cut off for 3 minutes over a 30-minute session. Figure 5 explains the basic functions of the cut out/cut in control of a single unit at 15% and 20% control and a multi-unit PAC at 15% control. The fundamental strategy of BeONE controller is based on the assumption that PAC system with traditional thermostat control can be further exploited for energy saving by switching off the compressor for a few minutes in a 30-minute interval. With the circulating fan remains working, indoor air conditions should still maintain at comfort level.

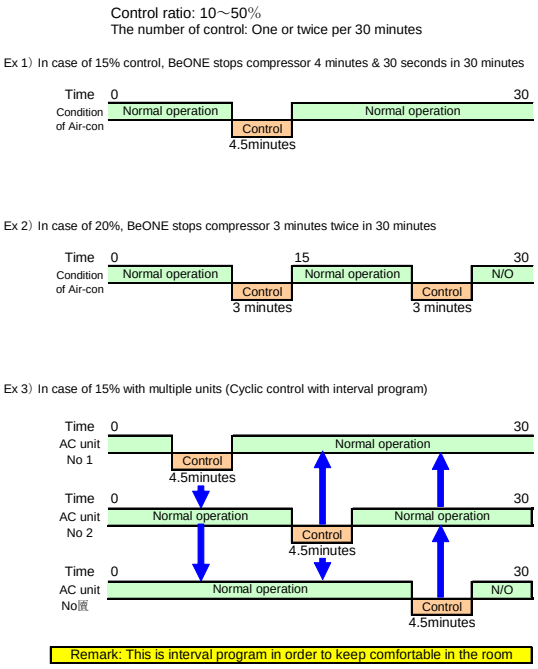

Figure 5 Basic function of BeONE control

The BeONE controller incorporate a built-in timer and program such that compressors being controlled are protected from excessive cut out when working together with thermostat controller.

TEST PROGRAM AT NTU

The objectives of the test program at NTU is to use the PAC air conditioning system at the Office of Facilities Planning and Management to quantify the power saving, evaluate the effect on indoor comfort level and to perform the cost/benefit analysis of installing the BeONE controller.

The BeONE controller was installed on 15 June 2004 but did not activate the control function. The power consumption and indoor air temperature and relative humidity data were collected for the one week under the usual thermostat control. The control function was then activated for 15% control but some part of the office had recorded temperature higher than 25^{o}C. Control level was set to 10% on 23 June 2004 and the power consumption, room temperature and humidity were monitored continuously at hourly interval. The temperature and humidity monitoring stopped on 2 July 2004 but the BeONE controller continues to operate at 10% control level to monitor the long term power saving.

TEST RESULTS OF NTU PROGRAM

Power Saving

The hourly electrical power consumption of the PAC system using the usual thermostat control and BeONE is shown in Figure 6. The data displayed cover the period from 15 June to 30 June. Average hourly electricity consumption reduces from 40.77 kWh with thermostat control to 36.56 kWh, a saving of 10.3%. At an independent test conducted by a certifying agency in Singapore, the saving in compressor power alone for a single 30-min period was 8.83% [2]. The daily power consumed and controlled for the month of July 2004 is shown in Figure 7. The total electrical power saved for the month is 935.8 kWh which represents 8.6 % of saving. For the six months period from July 2004 to December 2004, monthly saving in electricity is shown in Table 1 with average saving of 956.7 kWh/month. It is believed that the saving can be further exploited if the time-zoning option is used.

Month	**Jul04**	**Aug04**	**Sep04**
Power Saved (kWh)	935.8	962.8	1000.2
Month	**Oct04**	**Nov04**	**Dec04**
Power Saved (kWh)	991.2	863.0	987.2

Table 1 Monthly power saved from BeONE control

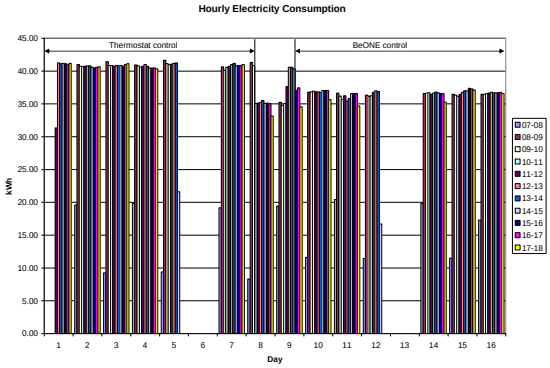

Figure 6 Hourly electrical power consumption

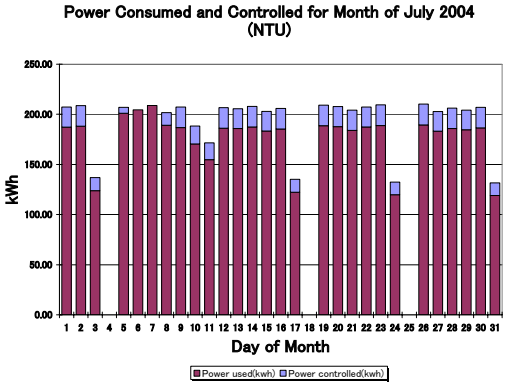

Figure 7 Daily power consumed and controlled for one compressor

Thermal Comfort

Energy saving devices used for air conditioning system must be evaluated against the effects on

thermal comfort of the indoor environment. The present study monitors the indoor air temperature and relative humidity before and after using the BeONE control. Figure 8 shows the upper and lower room temperatures and relative humidity of the office served by the PAC system before and after the use of BeONE controller. It is obvious that no noticeable effects can be observed with the activation of BeONE controller when control level was set to 10%. However when the control level was originally set to 15%, the upper temperature reaches 25^{o}C with complaint from occupants and the controller was re-set to 10% control level.

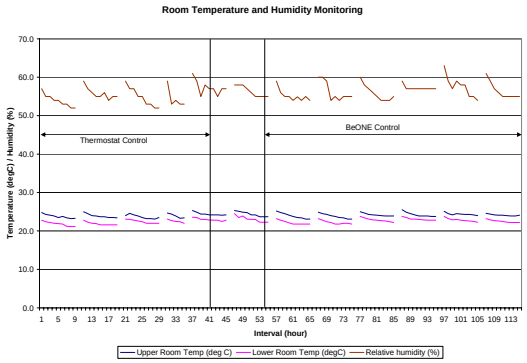

Figure 8 Temperature and relative humidity

The closer comparison of the average room temperatures with the usual thermostat control and BeONE control is shown in Figure 9. The use of BeONE control did not adversely affect the room temperature over the operating hours.

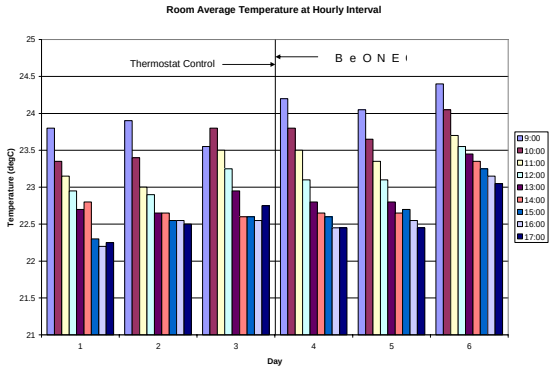

Figure 9 Average room temperature with thermostat and BeONE control

Cost and Benefit Analysis

Any energy saving device must be evaluated for its economic viability. As energy conservation projects are competing for financial resources of organization with other project, a short pay back period can ensure its acceptance to decision makers. The application of the BeONE controller to a typical office PAC system like the one at NTU Facilities Office is of representative significance. Based on the average monthly saving of 956.7 kWh for the six months tested and the prevailing electricity tariff of S$0.1354/kWh, saving per month is S$129.50. With the cost of BeONE system at S$2,500.00, the pay back period is 19.3 months or 1.6 years. The following simplified method of analysis can be applied to other PAC systems for first order evaluation.

Analysis of NTU PAC system using BeONE controller

- PAC usual compressor power consumption = *33.76 kW*
- Usual operating hours per week = *60 h/week*
- Annual power consumption without BeONE control = *33.76x60x52 =105,331 kWh/yea*r
- Control level = *10%*
- Annual electricity saving = *0.1x105331 = 10533 kWh*
- Electricity Tariff = *S$0.1354/kWh*
- Annual cost saving = *0.1354x10533 = S$1426/year*
- Cost of BeONE controller = *S$2500*
- Simple pay back period = *2500/1426 = 1.75 years.*

The pay back period of 1.75 years from the analysis is close to the actual pay back period of 1.6 years based on 6 months data.

It is observed that the most important parameters affecting the payback of installing BeONE controller or similar energy saving devices are:

Compressor power (kW)
Average weekly operating hours

Control level (%)
Local electricity tariff

BeONE CONTROLLER APPLIED TO MANUFACTURING PLANT

Air conditioning systems installed at manufacturing plants operate for longer hours. Many electronics plants are running continuously for 24 hours a day. Such plants provide good opportunities for installing energy saving devices like BeONE controller.

A case study on a BeONE controller installed at Matsushita Electronic Components in Singapore delivered the following results:

- PAC model: Hitachi/RP60-WSY
- Motor capacity: 60 HP
- Operating hours: 24 hours/day
- Control level: 20%/360s
- Power consumption without controller in December 2004 = 32,403 kWh
- Power saved in December 2004 = 6434 kWh
- Electricity tariff = S$0.1354/kWh
- Cost saved in December 2004 = S$671
- Cost of BeONE controller = S$2500
- Payback period using December 2004 as average monthly cost saving = 2.87 months.

The daily power consumed and controlled for December 2004 is shown in Figure 10. With a bigger PAC system running at longer hours in a factory environment, the pay back period is shortened to less than 3 months. As December is usually a rainy month with lower ambient temperature, power consumption in air conditioning is lower than other months. It is therefore safe to use December consumption as the average monthly consumption.

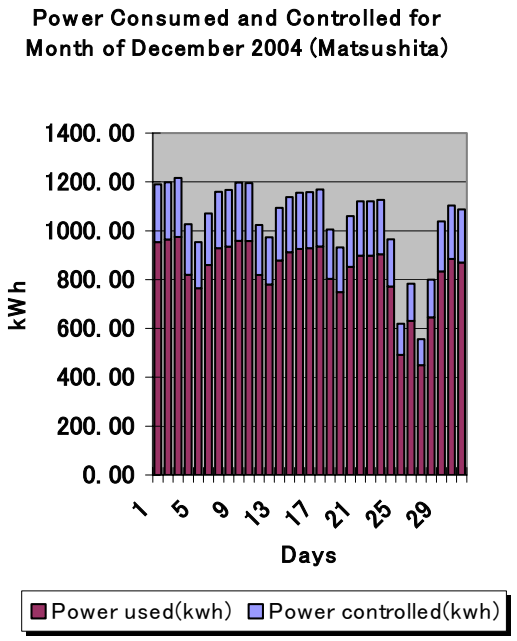

Figure 10 Daily power consumed and controlled for Matsushita PAC plant

MONITORING OF PAC SYSTEM

As half-hourly loading and unloading of compressors were recorded within the controller's memory system, any malfunction of compressor and its motor can be detected when data is downloaded to a computer for examination. It is also an added advantage that the BeONE controller can be doubled up as an equipment surveillance system for fault diagnosis and human malpractice.

CONCLUSIONS

In conclusion, the projects on saving power consumptions of packaged air cooled air conditioning systems have proven to be successful. Typical pay back period for medium sized office space of 1700 m^2 with power capacity of 40-kW is less than 2 years. In manufacturing plants where air conditioning is needed for 24 hours, pack back period will be shortened to a few months.

No damage on compressors or motors was observed for 6 months test running. The room temperature and humidity were maintained at the comfort zone for its occupants.

ACKNOWLEDGEMENTS

MODELLING OF LOW ENERGY COOLING STRATEGIES FOR UNDERGROUND RAILWAYS

Thompson J.A.[1], Maidment G.G., Karayiannis T.G. and Missenden J.F.
Department of Engineering Systems, London South Bank University,
103 Borough Road, London SE1 0AA

ABSTRACT

Underground railways often experience high temperatures during the summer months. It is not practical to install conventional cooling systems on the older underground systems because of increased heat rejection. Sustainable and low energy cooling systems have been developed for use in conventional building services applications but have not been used on underground railways because of an inability to effectively model them in this type of environment. This paper introduces a novel mathematical model, which has been used to investigate low energy cooling strategies on underground railways.

INTRODUCTION

Underground railway systems can generate enough heat from their operations to raise tunnel and station temperatures as much as 8 to 12 K above outdoor temperatures, the greatest differences being at night and in the early morning hours [1]. Passenger discomfort will result in warm weather conditions if the underground railway environment is not cooled.

Ventilating techniques for an underground railway environment in which there is to be heavy traffic of electrically propelled rapid transit trains differ from those normally encountered in air-conditioning work. The heat generated by the train motors and electric lighting, together with body heat from passengers, is so great that excessive temperatures would prevail in the summer when limited cooling is available [1]. The installation of in car air-conditioning units adds another major heat source in the tunnel. This heat must be rejected to make in car air-conditioning units worthwhile.

The need in modern society to provide sustainable and low energy solutions to engineering problems is recognised through national and international legislation, [2]. This has produced an expansion in the use of low energy cooling strategies in buildings. Low energy is defined for the purposes of this paper as solutions, which provide substantial cooling power with minimal net energy input required. This could involve the use of ground cooling, thermal storage, nighttime and seasonal ventilation and phase change materials [3][4].

However, few low energy strategies have been used on an operational underground railway. This is largely due to the lack of a dedicated mathematical model to simulate their application in the thermal environment of underground railways, [1]. The mathematical models that are designed for use in underground railways do not currently take proper account of the capacitance, storage and heat sink issues which are associated with low energy cooling systems and are used for assessing peak summertime conditions in systems employing conventional technology, [1].

An initial proposal by Maidment and Missenden [5], suggested the use of a groundwater based cooling system to operate on an underground railway. The work included a mathematical model, which was used to evaluate the system. The model did not use fully crowded loading of passengers and as such was not investigating a worst-case scenario. This could lead to incorrect sizing of the system. The model also did not deal with the tunnel geometry and conditions in detail. The model was developed under steady state conditions and as such cannot model time varying effects. The preliminary work of [5] was continued by Ampofo et al. in [6]. This model corrected the passenger loading section to be under maximum crush loading. The model also extended the analysis to include the tunnel and provide it with specific geometry. It specifies a value of the far field radius taken from the earlier work [7]. The value given there though contains little justification of distance given as the far field radius. Also the concept of far field radius is still poorly reported in the literature.

This paper builds on the work of Maidment, Missenden and Ampofo et al. [5], [6] and describes the mathematical model that has been designed to provide an overview of the thermal environment of underground railways. The model uses steady state theory to show the inter-relationship between the various heat loads present in an underground railway. Whilst the model is unable to simulate the exact nature of the time dependence of low energy systems it can be used to provide an initial sizing of these systems. This model forms the basis of a transient simulation, which is being developed and will be published later.

OVERVIEW OF THE MODEL

The mathematical model has been written in EES (Engineering Equation Solver) created by f-Chart software [8]. This package was used for development of the model because EES will automatically determine the correct order to solve the equations entered. It allows each section of the model to be individually packaged without interdependence problems. EES allows easy parametric analysis for all variables in the system. Also EES has built in psychometric functions, which allows the easy calculation of humidity and thermal comfort for both the train and tunnel.

The model solves 143 equations iteratively to reach the solution. It has been designed to operate on a generic deep line underground railway tunnel section. The model uses the geometric and thermofluid properties of the railway under

investigation to determine its solutions. It predicts temperatures, humidities and thermal comfort parameters under summer worst-case scenario steady state conditions. It uses average peak loads and normal train running conditions. While the model has been constructed to be very general in nature the investigations were all performed using London Underground data and as such certain material and geometric constraints were modeled for the London system.

The tunnel is considered to be a control volume with the following loads considered and analysed.

- Internal heat generation
  - Train carriage heat loads
  - Heat generated by the braking mechanism
  - Heat generated by the tunnel lighting
- Ground heat sink load
- Ventilation heat due to air entering through the ventilation shafts

The tunnel is assumed to be cylindrical in cross-section having an internal diameter equal to 2R. The tunnel is formed from a hollow concrete lining which is also cylindrical. The final boundary is located at the far field radius (FFR). This is the distance away from the tunnel where there is no longer heat transfer occurring. While this point is theoretically located at infinity, for the purposes of this model the FFR has been varied to investigate the effect that this parameter has on the temperature of the system. If this variable is to be fixed then the value chosen was taken from the work of Cockram and Birnie [7] as 6.825 m. This is shown as distance b in Figure 1.

Internal Heat Load

Train Carriage load

The train carriage load is the heat load that is generated within the train carriage. The latent and sensible gains as a result of the passengers and operation of the train carriage are included in this section. The various loads are shown in Figure 2.

The solution is calculated by balancing the energy and mass transfer between the various components and the global system. The two global equations for latent and sensible heat gain are given in equations (1) and (2).

$$Q_{sen} = Q_r + Q_w + Q_g + Q_f + Q_{ps} + Q_{tl} \quad (1)$$

$$Q_{lat} = Q_{pl} \quad (2)$$

The train carriage construction for the roof, walls and floor are assumed to be made with an external and internal skin with mineral wool insulation in between. The external heat transfer coefficient was assumed to be mainly convective and to depend on the velocity of the surrounding air. The internal surface heat transfer coefficient was assumed to be constant. The heat transfer for the roof, walls and floor are all evaluated using the following conductive equation.

$$Q = UA(T_t - T_{tr}) \quad (3)$$

Where

$$UA = \sum AR_i^{-1} \quad (4)$$

Which is summed across all surfaces.

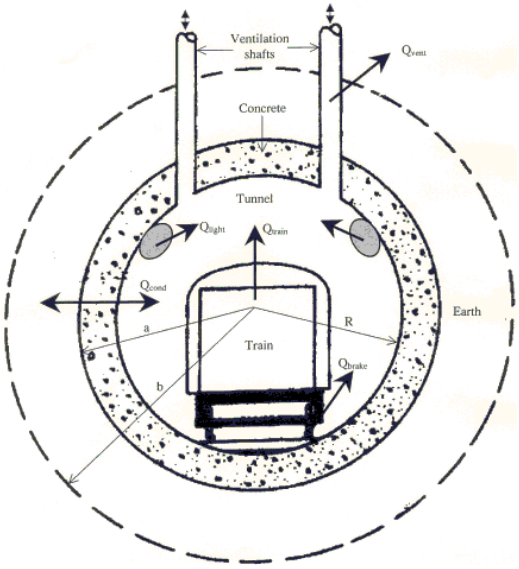

Figure 1 – Model representation of the tunnel control volume

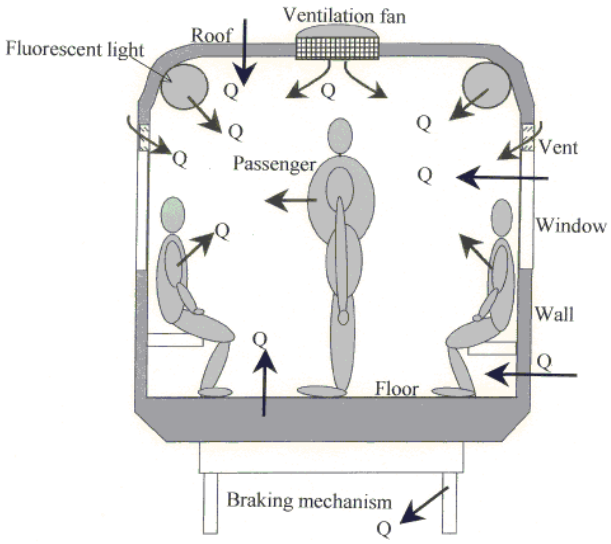

Figure 2 – Heat Loads in the train

The passenger load was assumed to be 90 people per carriage. This is a realistic average that could be expected on the London underground system during rush hour conditions in the center of London. The latent and sensible passenger heat gains were calculated according to equations (5) and (6).

$$Q_{ps} = -3.6517 \cdot T_{tr} + 168.15 \quad (5)$$

$$Q_{pl} = 3.6517 \cdot T_{tr} - 28.146 \quad (6)$$

Equations (5) and (6) were obtained by fitting trend lines to heat emission data for occupants involved in light activity, [9]. The train lighting was assumed to be 1400W per carriage.

The latent and sensible loads for the carriage can now be balanced with that produced from the ventilation air. The latent and sensible loads produced in this way are given in equations (7) and (8).

$$Q_{sens} = \dot{m}_{tuair} C_p \left(T_{tr} - T_t\right) \quad (7)$$

$$Q_{lat} = \dot{m}_{tuair} h_{evap} \left(g_{tr} - g_t\right) \quad (8)$$

Braking Mechanism

The heat load developed by the traction motor can be broken into three parts. The aerodynamic drag due to airflow generated within the tunnel; the mechanical friction losses due to the wheel, flange and other moving parts and the resistor losses due to electrical energy produced by the generators, [6]. The aerodynamic drag resistance is defined in equation (9).

$$Q_{aero} = \tfrac{1}{2} \rho V_{ave}^2 A C_D \cdot L_{stop} \cdot n \quad (9)$$

The mechanical friction is defined using equation (10). The weight in this equation is the equivalent weight taken from the combined weight of the train, the passengers and the rotational inertia.

$$Q_{mech} = F L_{stop} W_e N n \quad (10)$$

$$F = 0.0058 + \frac{516}{W_e} + 0.00045 \cdot V_{ave} \quad (11)$$

The final heat load in this section is the load due to the resistor losses. This parameter is defined in equation (12).

$$Q_{res} = \frac{KE}{e} \quad (12)$$

Here the kinetic energy is calculated with respect to the mass and velocity of the train as a whole.

Tunnel Lighting

The tunnel is assumed to have 100 fluorescent tubes per km each of which have an output of 50W. The lighting is assumed to be on at all times, although some subway systems only use tunnel lighting during 'engineering hours'.

Ventilation Heat Loads

The sensible and latent heat gains to the tunnel are in balance with the sensible and latent heat loads produced by the ventilation air entering the tunnel through the ventilation shafts. The heat gains to the tunnel are in equations (13) and (14).

$$Q_{tsen} = Q_{sens} + Q_{aero} + Q_{mech} + Q_{res} + Q_{tul} + Q_{gr} \quad (13)$$

$$Q_{tlat} = Q_{lat} \quad (14)$$

These heat loads are then balanced with equations (15) and (16).

$$Q_{tsen} = \dot{m}_{air} C_p \left(T_t - T_{amb}\right) \quad (15)$$

$$Q_{tlat} = \dot{m}_{air} h_{fg} \left(g_t - g_{amb}\right) \quad (16)$$

It should be noted that both C_p and h_{fg} both vary with changes in temperature. These two values are then not constant and are calculated by EES using the inbuilt psychometric functions.

Energy Balance

The heat loads in the system are then balanced using the following logic; In the summer, a cold air stream is continuously flowing into the tunnel through the ventilation shafts. Warmer air of the same mass flow rate is also flowing out of the ventilation shafts. The tunnel (control volume) is losing heat to the surrounding soil while the train, braking mechanism and tunnel lighting are heating the tunnel air. The conservation of energy principle is then applied to the underground railway system in the model.

Ground Heat Transfer

The heat transfer in the ground involves both steady and transient functions. Previous models had purely considered the steady state without considering the implications of the transient effects of heat. This investigation considers the implications of this on system performance.

The ground heat transfer load is the heat conducted through the tunnel walls and surrounding earth. Soil is a poor conductor and at depths beyond 5m the temperature is approximately constant. This temperature is the mean annual temperature and therefore during the summer months heat is

transferred from the tunnel to the surrounding soil. The simplest steady state theory for the calculation is that based on the thermal resistances. However CIBSE buried pipe equations could also be applicable in this situation, [10]. This coupled with the imprecise location of the FFR mean that this area of the model was investigated extensively. The two approaches are shown respectively in equations (17) and (18).

$$Q_{gr} = \frac{-(T_t - T_{FFR})}{R_{total}} \quad (17)$$

Where R_{total} is defined as the total thermal resistance to heat. In this case this comprises of three parts, resistance to heat in the tunnel, thermal resistance to heat through the tunnel walls and the thermal resistance to heat through the earth beyond the tunnel walls.

$$Q_{gr} = \pi 2RU(T_{surface} - T_{FFR})L_{tunnel} \quad (18)$$

Where U is the overall thermal transmittance and is given as

$$U = \frac{1}{R_{in} + R_{earth}} \quad (19)$$

R_{in} is the thermal resistance due to the tunnel liner and R_{earth} is given by equation (20), [10]

$$R_{earth} = \frac{a}{K_{Earth}} \ln\left[\frac{2D}{2R}\left(1+\left(1-\left(\frac{2R}{2D}\right)^2\right)^{0.5}\right)\right] \quad (20)$$

The results of the comparison of these models are shown in figures 3, 4 and 5. From figure 3 it can be seen that the train and tunnel temperature is approximately 2 K higher when using simple resistance theory than using the CIBSE buried pipe equations. The gradients using both solution methods are similar. Figure 4 shows that the simple resistance approach is strongly dependent on the position of the FFR. This figure shows the temperatures within the tunnel and trains against different FFR values for both the simple resistance and the CIBSE models for a given ambient temperature. It can be clearly seen that the CIBSE buried pipe model does not depend on far field radius but only on the depth of the pipe or in this case the tunnel. The depth of the tunnel is a known factor for an underground railway and therefore the CIBSE equations require only known information. In contrast the far field radius is not strongly reported and must be found either experimentally or by assumption.

Figure 5 shows the temperature variation through the tunnel lining and surrounding ground for the CIBSE model and the simple resistance model with a range of FFR values. The models have been using a given ambient temperature and have been compared against real data taken from Cockram

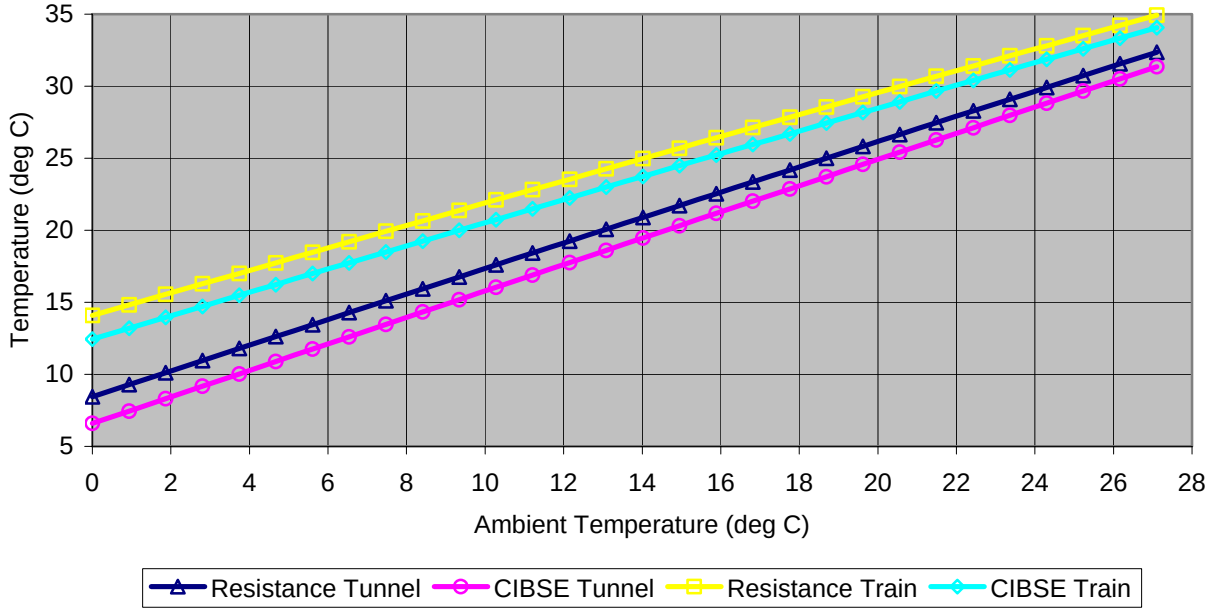

Figure 3 – Comparison of CIBSE buried pipe theory with thermal resistance theory

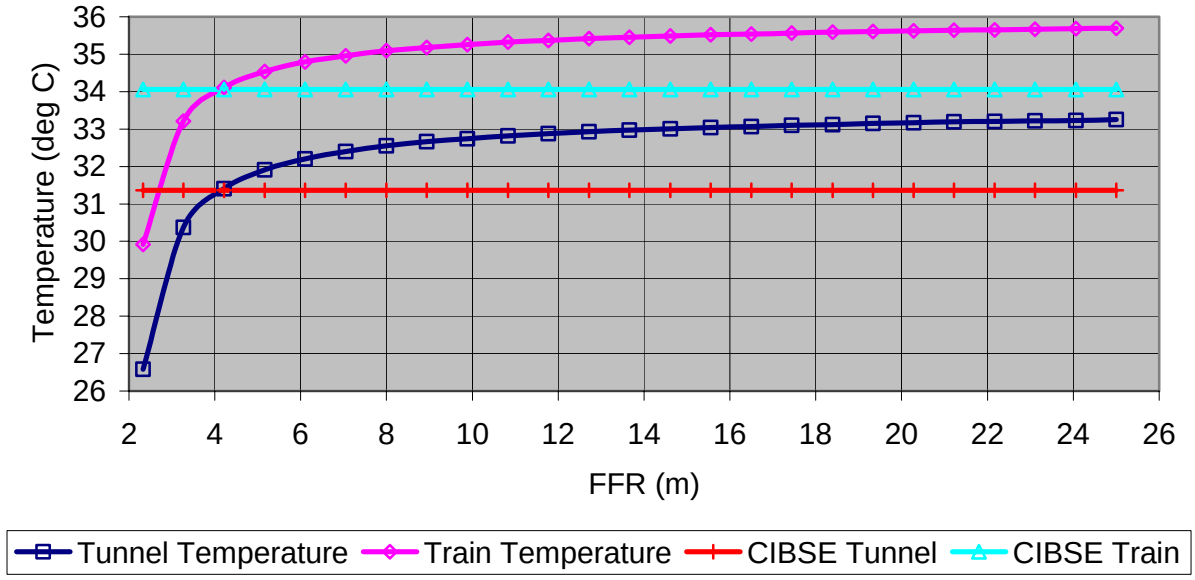

Figure 4 – Variation of FFR and its effect on temperature

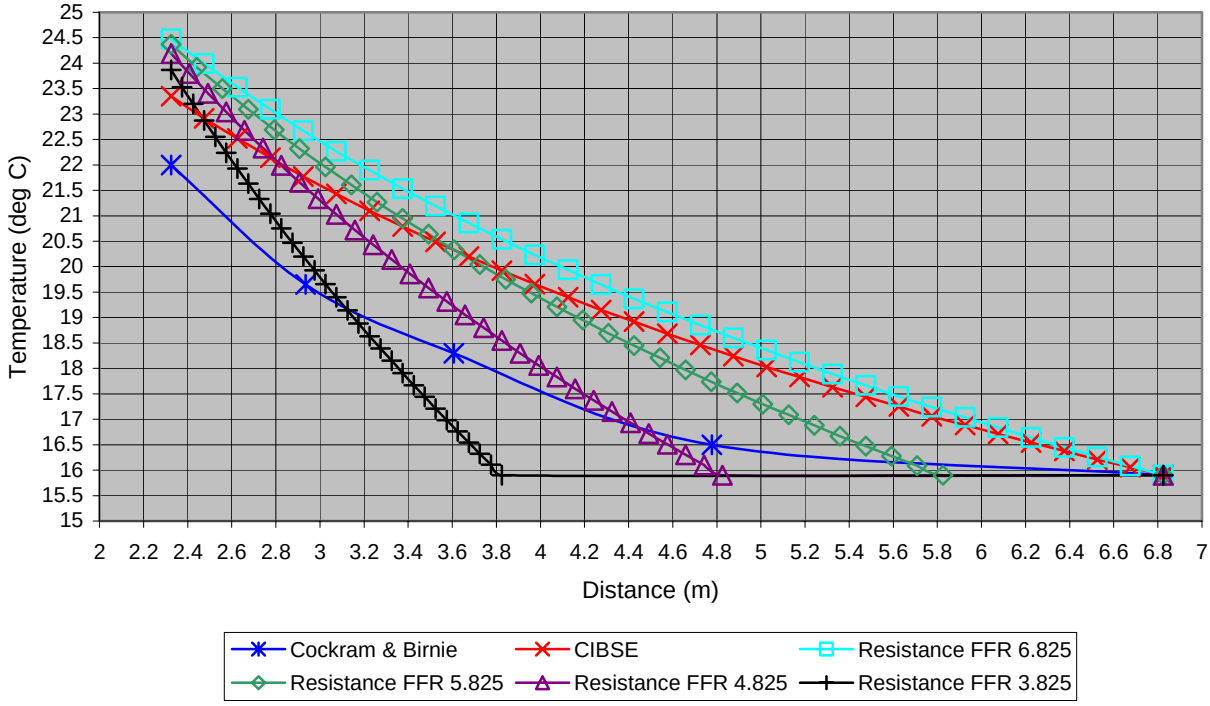

Figure 5 – Variation of temperature in the ground surrounding a railway tunnel

and Birnie [7]. From the results in Figure 5 it can be seen that all approaches produce similar temperature profiles to the Cockram and Birnie data. The main difference is that the surface and ground temperatures are colder than those predicted by the models. This is probably due to capacitance effects partly because the Birnie and Cockram data was obtained soon after the Victoria line was opened and partly due to diurnal variations.

Tunnel Wall Surface Temperature

It is assumed that there is no variation in temperature around the surface of the tunnel wall. Surface temperature can therefore be calculated at one point only and extended around the surface. It

was calculated using the surface finite differences equation taken from [11].

It can be observed that with all models the temperature of the bulk air is very close to the tunnel lining surface temperature. For both calculation methods the difference is very small and is approximately 0.15 K. This implies that the ground controls the heat transfer. The results also clearly show that whilst a FFR of 6.825 m is needed to simulate the deep ground temperature distribution accurately, the FFR value has much less of an effect on the lining surface temperature. The first 3 meters of tunnel lining therefore appear to control heat transfer.

Validation of the Mathematical Model

The model was shown to respond similarly to experimental data obtained from the London Underground. The experiment measured the train and tunnel temperature concurrently. The relative humidity of the train was also measured together with passenger loading and train position. As can be seen in Figure 6 the model has a similar gradient but is shifted to higher train temperatures. This is a consequence of trying to model a constantly transient system using steady state theory. Figure 7 shows the capacitance issues and coupling between train and tunnel temperatures. The variation in tunnel temperature is very large compared to the temperature variation in the train. Also the two temperatures do not peak at the same time. This shows that for complete understanding the ground heat transfer should be modeled using full transient analysis methods.

CONCLUSIONS

Current thermal modeling of underground railways does not allow for the successful modeling of sustainable cooling systems. This is because of poor modeling of the heat sink effect, thermal storage and other capacitance issues. This has led to a need to improve the modeling of these effects under the complex environment of an underground railway tunnel.

This paper has presented a mathematical model that provides an initial overview of the heat transfer in an underground railway. This model is used to provide an overview of the thermal environment and focus the research on the areas that require full transient modeling. The model now needs revising to allow for transient effects to be evaluated in conjunction with the sustainable cooling schemes.

The ground heat sink effect will require full transient modeling because of the potential for heat transfer both to and from the ground depending on how the remainder of the environment reacts to the heat loads in the system. This will enable the full use of geothermal cooling in underground railway systems.

ACKNOWLEGMENTS

London Underground has supplied both data and documentation to assist with this project. They have also allowed the authors to conduct experiments on the underground railway. This PhD is funded by the Engineering and Physical Sciences Research Council and their support is gratefully acknowledged.

ABSTRACT
The main obstacles of the aqua-ammonia vapour-absorption refrigeration (VAR) systems for getting the market acceptance are their higher investment cost and lower first law efficiency when driven by high exergy input. In this paper, the thermoeconomic concept is applied to the optimization of an aqua-ammonia VAR system—aimed at minimizing its overall product cost. Thermoeconomic concept based simplified cost minimization methodology calculates the economic costs of all the internal flows and products of the system by formulating thermoeconomic cost balances. The system is then thermoeconomically evaluated to identify the effects of design variables on costs and thereby enables to suggest values of design variables that would make the overall system cost-effective. Finally, the optimization of the system is carried out using evolutionary programming. The optimized result shows that the performance of the system can be improved significantly without any additional capital investment.

Keywords: thermoeconomic analysis; aqua-ammonia; exergy; optimization.

NOMENCLATURE

c = Cost per exergy unit (Rs kJ^{-1})
COP = Coefficient of performance
$\dot{C}$ = Cost flow rate (Rs hr^{-1})
e = Specific exergy (kJ kg^{-1})
$\dot{E}$ = Exergy flow rate (kW)
f = Thermoeconomic factor (%)
h = Specific enthalpy (kJ kg^{-1})
i_r = interest rate (Rs yr^{-1})
$\dot{m}$ = Mass flow rate (kg s^{-1})
N_y = years
r = Relative cost difference (%)
s = Specific entropy (kJ kg^{-1} K^{-1})
t = Temperature on Centigrade scale (C)
T = Temperature on Kelvin scale (K)
Y = Ratio of exergy destruction (or loss) to total exergy supplied to the system
z = Concentration
Z =Investment cost of the system components (Rs)
$\dot{Z}$ = Levelized (annual) investment cost of the system components (Rs s^{-1})

Greek letters

c = Effectiveness of the heat exchangers
e = Exergetic efficiency (%)
h = Isentropic or mechanical efficiency
t = Annual number of hours of system operations
x = Capital recovery factor

Superscripts

Ch = Chemical component
Ph = Physical component

Subscripts

0 = Environmental state

INTRODUCTION

Ammonia absorption refrigeration is one of the oldest known refrigeration technologies. The vapour-compression technology invented later almost ousted the absorption systems because of poor efficiency and higher cost of absorption systems. Vapour-compression systems use electricity, which has poor conversion efficiency. Presently, the energy and environmental norms regarding the ozone layer depletion and global warming are becoming more and more stringent in almost all countries [1]. In this challenging scenario, the binary mixture of ammonia and water has once again become a research topic in the past few years. The natural character of this mixture and its excellent thermodynamic properties equal out its negative aspects.

The oil embargoes of the 1970s focused attention on the efficient use of energy. Attention refocused on the concept of exergy, because it allows a uniform basis to compare between disparate processes. Since the exergy analysis (i.e. the second law analysis) gives a clear picture about the losses of a system quantitatively as well as qualitatively, the use of exergy in the thermodynamic analysis and optimization becomes obvious choice [2]. However, the thermodynamic optimization, which aims at achieving the maximum thermodynamic efficiency, does not guarantee a cost-effective design. It is because the cost of a component/system generally increases with the increase in its efficiency. This calls for multi-disciplinary analysis and optimization. In this respect, the thermoeconomic concept has emerged to be a better tool as it addresses this multi-disciplinary analysis by blending the exergy analysis with economic analysis. The most significant advantage of the thermoeconomic optimization method lies in its capacity to solve complex practical problems without using sophisticated numerical analysis.

The recent developments by Tsatsaronis and his coworkers [3], Valero and his coworkers [4,5], Frangopoulos [6], von Spakovsky [7], d'Accadia and de Rossi [8] adequately represent the different directions of development. The major fields of application of these developments are mainly in the field of large cogeneration and combined power plants, chemical plants, etc. [3-7], whereas the domains of refrigeration and air-conditioning are still limited. Application of thermoeconomics to refrigeration systems can be found in references [8-11]. It is because the industrial utilities are probably considered with great interest, as they are capital intensive. Refrigeration systems, particularly absorption systems, require improvement in theirs performance to be competitive with conventional vapour compression systems.

In this work, a heat-operated aqua-ammonia VAR system is analyzed using thermoeconomic principles and optimized using evolutionary programming.

ASSUMPTIONS USED IN THE ANALYSIS

Figure 1 shows the schematic diagram of an aqua-ammonia VAR system, which uses ammonia as refrigerant and water as absorbent. For the purpose of analysis the following assumptions are made:

- The system is in steady state.
- The temperatures of the condenser, evaporator, absorber, generator, and rectifier are constant and uniform throughout the components.
- The condenser and evaporator pressures are the equilibrium pressures corresponding to the temperatures and concentrations in the condenser and evaporator respectively.
- The pressure loss in pipes between the rectifier and the condenser, and between the RHE and the absorber, respectively, are taken as $\Delta p/p_{out}$ =0.05 and $\Delta p/p_{out}$ =0.05 [12].
- Strong solution leaving the absorber and the weak solution leaving the generator are in equilibrium at their respective temperature and pressure.
- The refrigerant vapour concentration at the rectifier exit is equal to 0.999 [12].

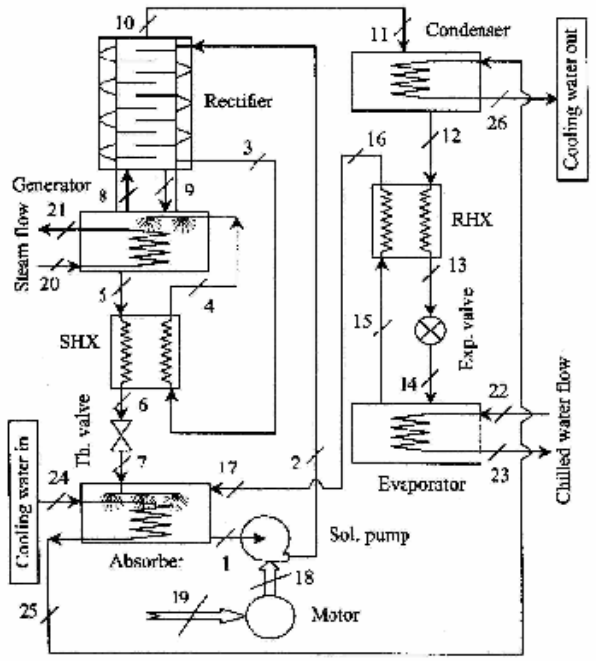

Figure 1. Schematic diagram of the Aqua-ammonia vapour absorption system.

- The generator temperature and pressure determine the vapour concentration at State 8, while the rectifier temperature and pressure determine liquid concentration at State 9.
- Refrigerant vapour at the rectifier and evaporator exit is equivalent to the vapour state at their respective temperature and pressure, while refrigerant liquid at the condenser exit is equivalent to the liquid state at the condenser temperature and pressure.
- The rectifier temperature is equal to the average temperature between the generator and the condenser temperature.
- The reference environmental state for the system is water at an environment temperature (T_0) of 25^0C and 1 atmospheric pressure(p_0).
- The system uses high-pressure steam to drive the generator.
- Cooling water first enters the absorber at 27^0C, then is passed through the condenser, and finally is rejected by the system at 35^0C.
- The chilled water enters the evaporator at 20^0C and leaves at 10^0C.

Based on these assumptions, a workable initial design, referred to as the base case, is conceptualized for the VAR system shown in Fig. 1 with the following data: t_g = 150^0C, t_c = 40.3^0C, t_e = -10^0C, t_a = 39.4^0C, c_{rhx} = 60 %, c_{shx} = 60 %, h_p = 75%, h_m = 90%, t_{21} = 170^0C, t_{22} = 170^0C. Thermodynamic properties of the aqua-ammonia mixture in liquid and gas phase are taken from the work of Ziegler and Trepp [13]. The property data for the water/steam are taken from the correlations provided by Irvine and Liley[14].

EXERGY ANALYSIS

The second law analysis, i.e. the exergy analysis, calculates the system performance based on exergy, which is defined as the maximum possible reversible work obtainable in bringing the state of the system to equilibrium with that of environment [2]. In the absence of magnetic, electrical, nuclear, surface tension effects, and considering the system is at rest relative to the environment, the total exergy of a system can be divided into two components: physical exergy and chemical exergy;

$$\dot{E} = \dot{E}^{Ph} + \dot{E}^{Ch} \quad (1)$$

The physical exergy component is calculated using the following relation:

$$\dot{E}^{Ph} = \dot{m}\left[(h - h_0) - T_0(s - s_0)\right] \quad (2)$$

The calculation procedure of the chemical exergy of various substances based on standard chemical exergy values of respective species is widely discussed by Bejan et al. [2], Ahrendts [15], and Szargut et al. [16]. Chemical exergy of the flows is calculated using the following equation:

$$\dot{E}_i^{CH} = \dot{m}_i\left[\left(\frac{z_i}{M_{NH_3}}\right)e^0_{CH,NH_3} + \left(\frac{1-z_i}{M_{H_2O}}\right)e^0_{CH,H_2O}\right] \quad (3)$$

where, e^0_{Ch,NH_3} and e^0_{Ch,H_2O} are the standard chemical exergy of ammonia and water, respectively, and their values are taken from Ahrendts [15].

A detailed exergy analysis includes calculation of exergy destruction, exergy loss, exergetic efficiency, exergy destruction ratio, and exergy loss ratio in each component of the system along with the overall system. Mathematically, these are expressed as follows [2]:

$$\dot{E}_{D,k} = \dot{E}_{F,k} - \dot{E}_{P,k} - \dot{E}_{L,k} \quad (4)$$

$$e_k = \dot{E}_{P,k} / \dot{E}_{F,k} = 1 - \left[\left(\dot{E}_{D,k} + \dot{E}_{L,k}\right) / \dot{E}_{F,k}\right] \quad (5)$$

$$Y_{D,k} = \dot{E}_{D,k} / \dot{E}_{F,total} \quad (6)$$

$$Y_{L,k} = \dot{E}_{L,k} / \dot{E}_{in,tot} \quad (7)$$

The exergy analysis of the system and its components are carried out using fuel-product relationships and Eqs. (4-7). The results are

summarized in Table 1. Low exergetic efficiency of the system suggests the designer to find means for the improvement of the overall exergetic efficiency to maximum possible value. However, the thermodynamic optimum, so obtained, does not guarantee a cost-optimal design. A cost-optimal design can be obtained through thermoeconomic analysis and optimization of the system, which is discussed in the following sections.

Table 1. Exergy analysis of the system - base case.

Compo-nents	$E_{F,k}$ (kW)	$E_{P,k}$ (kW)	$E_{D,k}$ (kW)	$E_{L,k}$ (kW)	$Y_{D,k}$ (%)	$Y_{L,k}$ (%)	e_k (%)

Overall system	76.0	3.49	66.1	6.42	87.0	8.45	4.59

THERMOECONOMIC ANALYSIS

The prerequisite for the thermoeconomic analysis is a proper 'Fuel-Product-Loss' definition of the system to show the real production purpose of its subsystems by attributing a well defined role, i.e. fuel, product or loss, to each physical flow entering or leaving them [2]. In the case of aqua-ammonia system, this is quite easy for the generator, rectifier, evaporator, pump, solution heat exchanger (SHX), and refrigerant heat exchanger (RHX), where exergy of the product stream is increased. However, in the case of heat dissipative devices, e.g. the condenser, expansion valve, absorber, and the throttling valve, the product cannot be readily defined. Therefore, they are considered as a single virtual component, named as evaporator assembly, together with the component(s) they serve, i.e. the evaporator in this case. The 'Fuel-Product-Loss' (F-P-L) structure of the system is shown in Fig. 2. Thus, the system can be considered to be composed of six productive components, namely, generator, rectifier, evaporator assembly, solution pump, RHX, and SHX.

The thermoeconomic costs of all the flows that appear in the system's F-P-L definition are

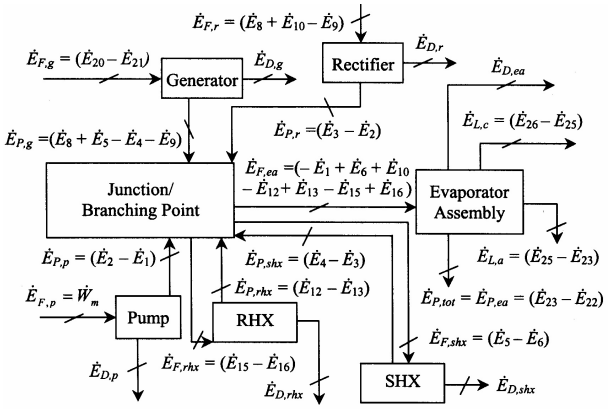

Figure 2. Fuel-Product-Loss structure of the system

obtained through exergy costing principles, discussed by Bejan et al. [2]. Exergy costing involves formulation of cost balances for each component. One can write six equations for the six subsystems shown in the productive structure. The number of unknowns is more than the number of subsystems and one needs auxiliary equations to have a close form solution. The cost balance equations along with auxiliary equations for each of the subsystems are given below:

Generator: The purpose of the generator is to provide a stream of ammonia vapour (stream 8) and a weak solution of refrigerant (stream 5). This purpose is achieved by supplying the exergy of steam to it. Hence, streams 8 and 5 are charged with all costs associated with owning and operating the generator. Thus, the following equations are developed:

$$\dot{C}_H + \dot{C}_4 - \dot{C}_5 - \dot{C}_8 + \dot{C}_9 = -\dot{Z}_g \tag{8}$$

$$\frac{\dot{m}_8(c_8 e_8 - c_4 e_4)}{\dot{m}_8(e_8 - c_4)} = \frac{\dot{m}_5(c_5 e_5 - c_4 e_4)}{\dot{m}_5(e_5 - c_4)}$$

$$\Rightarrow \frac{(e_8 - e_5)\dot{C}_4}{\dot{m}_4(e_8 - e_4)(e_5 - e_4)} - \frac{\dot{C}_5}{\dot{m}_5(e_5 - e_4)} + \frac{\dot{C}_8}{\dot{m}_8(e_8 - e_4)} = 0 \tag{9}$$

$$\frac{\dot{m}_8(c_8 e_8 - c_9 e_9)}{\dot{m}_8(e_8 - c_9)} = \frac{\dot{m}_5(c_5 e_5 - c_9 e_9)}{\dot{m}_5(e_5 - c_9)}$$

$$\Rightarrow -\frac{\dot{C}_5}{\dot{m}_5(e_5 - e_9)} + \frac{\dot{C}_8}{\dot{m}_8(e_8 - e_9)} + \frac{(e_8 - e_5)\dot{C}_9}{\dot{m}_9(e_8 - e_9)(e_5 - e_9)} = 0 \tag{10}$$

Rectifier: The purpose of the rectifier is to drag the possible amount of unwanted water vapour from the ammonia vapour leaving the generator (stream 10) by cooling it. The condensed water is returned to the generator (stream 9). The cooling is done by the strong solution leaving the pump. Hence, streams 10 and 9 are charged with all costs associated with owning and operating the generator. Thus, the following equations are developed:

$$\dot{C}_2 - \dot{C}_3 + \dot{C}_8 - \dot{C}_9 - \dot{C}_{10} = -\dot{Z}_r \tag{11}$$

$$\frac{\dot{m}_9(c_9 e_9 - c_8 e_8)}{\dot{m}_9(e_9 - c_8)} = \frac{\dot{m}_{10}(c_{10} e_{10} - c_8 e_8)}{\dot{m}_{10}(e_{10} - c_8)}$$

$$\Rightarrow \frac{(e_{10} - e_9)\dot{C}_8}{\dot{m}_8(e_9 - e_8)(e_{10} - e_8)} - \frac{\dot{C}_9}{\dot{m}_9(e_9 - e_8)} + \frac{\dot{C}_{10}}{\dot{m}_{10}(e_{10} - e_8)} = 0 \tag{12}$$

RHX: The purpose of the RHX is to subcool the liquid refrigerant leaving the condenser (stream 12) by the refrigerant vapour (stream 15) leaving the evaporator. Therefore, stream 13 is charged with all costs associated with owning and operating the RHX. Accordingly, the cost equations become,

$$\dot{C}_{12} - \dot{C}_{13} + \dot{C}_{15} - \dot{C}_{16} = -\dot{Z}_{rhx} \tag{13}$$

$$\dot{C}_{15} - (\dot{E}_{15}/\dot{E}_{16})\dot{C}_{16} = 0 \tag{14}$$

Solution pump: The purpose of the pump is to raise the pressure of the strong solution leaving the absorber (stream 2) to the generator pressure with the help of external work. Thus, stream 2 is charged with all costs associated with purchasing and operating the pump (with motor). Accordingly, the cost equation becomes

$$\dot{C}_m + \dot{C}_1 - \dot{C}_2 = -(\dot{Z}_p + \dot{Z}_m) \tag{15}$$

SHX: The purpose of SHX is to transfer the exergy of weak solution (stream 5) coming from the generator to the strong solution moving towards the generator (stream 4). Therefore, stream 4 is charged with all costs associated with owning and operating the SHX. Accordingly, the cost equations become

$$\dot{C}_3 - \dot{C}_4 + \dot{C}_5 - \dot{C}_6 = -\dot{Z}_{shx} \tag{16}$$

$$\dot{C}_5 - (\dot{E}_5/\dot{E}_6)\dot{C}_6 = 0 \tag{17}$$

Evaporator assembly: The evaporator and heat dissipative components—condenser, expansion valve, absorber, and throttling valve—are combined in the evaporator assembly. The cost rates associated with the capital investment for these components and the cost rates associated with the exergy losses are charged to the final product. The cost rates associated with the exergy losses in condenser and absorber are given by the following two equations

$$\dot{C}_{11} - \dot{C}_{12} - \dot{C}_{L,c} = -\dot{Z}_c \tag{18}$$

$$-\dot{C}_1 + \dot{C}_7 + \dot{C}_{17} - \dot{C}_{L,a} = -\dot{Z}_a \tag{19}$$

For the dissipative components and the evaporator, following auxiliary equations are developed:

$$\dot{C}_6 - (\dot{E}_6/\dot{E}_7)\dot{C}_7 = 0 \tag{20}$$

$$\dot{C}_{10} - (\dot{E}_{10}/\dot{E}_{11})\dot{C}_{11} = 0 \tag{21}$$

$$\dot{C}_{11} - (\dot{E}_{11}/\dot{E}_{12})\dot{C}_{12} = 0 \tag{22}$$

$$\dot{C}_{13} - (\dot{E}_{13}/\dot{E}_{14})\dot{C}_{14} = 0 \tag{23}$$

$$\dot{C}_{14} - (\dot{E}_{14}/\dot{E}_{15})\dot{C}_{15} = 0 \tag{24}$$

$$\frac{\dot{C}_1}{\dot{E}_1} - \frac{\dot{C}_7 + \dot{C}_{17}}{\dot{E}_7 + \dot{E}_{17}} = 0 \tag{25}$$

$$\dot{C}_{16} - (\dot{E}_{16}/\dot{E}_{17})\dot{C}_{17} = 0 \tag{26}$$

Since the purpose of the evaporator is to transfer exergy from stream 14 to the product stream 23, therefore, all costs associated with the owning and operation of the evaporator is charged to stream 23. Considering all these points the following cost equations are developed:

$$-\dot{C}_1 + \dot{C}_6 + \dot{C}_{10} - \dot{C}_{12} + \dot{C}_{13} - \dot{C}_{15} + \dot{C}_{16} - \dot{C}_{L,c} - \dot{C}_{P,tot} - \dot{C}_{L,a} = -(\dot{Z}_c + \dot{Z}_{ex} + \dot{Z}_e + \dot{Z}_a + \dot{Z}_v) \tag{27}$$

In the above formulations cost of equipment are calculated using relations provided in references [17,18]. The cost per exergy unit of the product of the system is given by,

$$c_{P,tot} = \frac{\dot{C}_{P,tot}}{\dot{E}_{P,tot}} = \frac{\dot{C}_{23} - \dot{C}_{22}}{\dot{E}_{23} - \dot{E}_{22}} \tag{28}$$

Out of these 22 variables used for system analysis $[X] = \{\dot{C}_1, ..., \dot{C}_{17}, \dot{C}_{L,c}, \dot{C}_{L,a}, \dot{C}_{P,tot}, \dot{C}_H, \text{and } \dot{C}_m\}$, the last two are known parameters. They are the costs of steam used to energize the generator $(\dot{C}_H)$ and the electrical energy input to the solution pump through the motor $(\dot{C}_m)$, and their values are Rs. 300.0 per 1000 kg of steam and Rs. 5.00/kWh espectively. These are the existing market price in

India. The remaining 20 unknowns are calculated by solving the linear system of equations ($[A][X]=[Y]$), where the coefficient matrix $[A]$ contains the terms on the LHS and $[Y]$ contains the terms on the RHS of Eqs. (8-27).

THERMOECONOMIC EVALUATION

In this section, the system is evaluated with the help of the following thermoeconomic variables, namely, the average unit cost of fuel ($c_{F,k}$), the average unit cost of product ($c_{P,k}$), the cost rate of exergy destruction ($\dot{C}_{D,k}$), the cost rate of exergy loss ($\dot{C}_{L,k}$), and the thermoeconomic factor (f_k). These are calculated using the following relations [2]:

$$c_{F,k} = \dot{C}_{F,k} / \dot{E}_{F,k} \quad (29)$$

$$c_{P,k} = \dot{C}_{P,k} / \dot{E}_{P,k} \quad (30)$$

$$\dot{C}_{D,k} = c_{F,k} \dot{E}_{D,k} \quad (\dot{E}_{P,k} \text{ is constant}) \quad (31)$$

$$\dot{C}_{L,k} = c_{F,k} \dot{E}_{L,k} \quad (\dot{E}_{P,k} \text{ is constant}) \quad (32)$$

$$f_k = \frac{\dot{Z}_k}{\dot{Z}_k + \left(\dot{C}_{D,k} + \dot{C}_{L,k}\right)} \quad (33)$$

The guidelines for the thermoeconomic evaluation are presented in details by Bejan et al. [2]. The thermoeconomic analysis results for the base case operating conditions of the system are presented in Table 2. It is seen that the evaporator assembly has the maximum value of $(\dot{C}_{D,k} + \dot{C}_{L,k} + \dot{Z}_k)$ with higher value of r_k and a lower value of f_k. Therefore, improvement of the exergetic efficiency of this unit should be considered at the cost of capital investment. The generator has the second largest value of $(\dot{C}_{D,k} + \dot{C}_{L,k} + \dot{Z}_k)$ with slightly lower values of f_k, suggesting the possibility of increasing the generator temperature. The third next component in that order is the SHX, where the lower value of f_k suggests improvement in exergetic efficiency through increase in its effectiveness. Next comes the rectifier, where there is no direct decision variable controlling the exergetic efficiency or the investment cost for this component, rather it is controlled mainly by the generator and condenser temperatures. Therefore, the effect of these two variables on rectifier is seen globally. As far as RHX is concerned, there is a slight scope for improvement in the exergetic efficiency of the system by increasing its effectiveness. The solution pump, on the other hand, shows a very high value of thermoeconomic factor f_k. The logical conclusion would be to try to decrease the investment cost of pump at the cost of its exergetic efficiency. This information for each component is extremely helpful to the designer for the improvement of the system.

OPTIMIZATION OF THE SYSTEM USING EVOLUTIONARY PROGRAMMING

Theoretically, the system optimization requires a compromise between two conflicting objectives; one is the increase in the exergetic efficiency and the other is a decrease in the product cost. The first objective is governed by thermodynamic requirements and the second by economic constraints. The maximization of exergetic efficiency means minimization of exergy destruction costs and exergy loss costs. Thus, the objective function becomes a minimization problem. Cammarata et al. [19] demonstrated the use of this technique in optimizing district heating networks using GA. The objective function for this problem is defined as to minimize a total cost function $\dot{C}_S$, which can be modeled as:

$$\dot{C}_S = \dot{C}_{P,total} + \dot{C}_{L,total} \quad (34)$$

$$\text{where, } \dot{C}_{P,total} = \dot{C}_{F,total} + x\, Z_{total} \quad (35)$$

The cost of exergy destruction is a hidden cost and is charged to the product cost. The capital recovery

factor x is calculated using the following relation

$$x = \left(\frac{i_r.(1+i_r)^{N_y}}{(1+i_r)^{N_y}-1} \right) \text{ yr}^{-1} \qquad (36)$$

The system is subject to the following constraints:

- minimum approach temperature for the condenser and absorber $\geq 2^0$C
- minimum approach temperature for the evaporator $\geq 2.5^0$C
- minimum approach temperature for the generator $\geq 10^0$C
- $70 \leq h_p \leq 90$ %
- $50 \leq c_{rhx} \leq 90$ %
- $50 \leq c_{shx} \leq 90$ %

The main steps of the optimization procedure are as follows:

Initialization: The i[th] trial vector that represents the decision variables of this system to be optimized can be written as $\overline{p}_i = [t_{g,i}, t_{c,i}, t_{e,i}, t_{a,i}, c_{rhx,i}, c_{shx,i}, h_{p,i}]$. Selecting each decision variable randomly from their allowable range creates each trial vector. For each trial, the objective function is evaluated through the thermoeconomic formulations after satisfying the constraints mentioned above.

***Fitness Evaluation*:** As shown in Fig.3, in the first part, the program evaluates fitness of the parent individuals (N_p) capable for producing offspring from a randomly generated large population. The value of the objective function, $\dot{C}_S$, is used as the fitness function for evaluating the fitness value of the total available individuals and the first N_p populations are selected by sorting the population generated in ascending order of the $\dot{C}_S$ values. These populations are allowed for producing offspring through mutation.

Mutation: Each of the decision variables $\overline{p}_i = [t_{g,i}, t_{c,i}, t_{e,i}, t_{a,i}, c_{rhx,i}, c_{shx,i}, h_{p,i}]$ of the i[th] parent individual is mutated to a new variable $\overline{p}_i^{/} = [t_{g,i}^{/}, t_{c,i}^{/}, t_{e,i}^{/}, t_{a,i}^{/}, c_{rhx,i}^{/}, c_{shx,i}^{/}, h_{p,i}^{/}]$, by adding a Gaussian random variable with zero mean and a standard deviation to each of them as, i.e., the generator temperature is evaluated as

$$t_{g,i}^{/} = t_{g,i} + N(0, s_{i,g}^{2}) \qquad (37)$$

In the above equations, N is a Gaussian distribution with zero mean and standard deviation of s. The standard deviations for the generator temperature is

$$s_{i,g}^{2} = f \times \frac{\dot{C}_{S,i}}{(\dot{C}_S)_{\min,p}} (t_{g,i,\max} - t_{g,i,\min}) \qquad (38)$$

where f is the scaling factor, $\dot{C}_{S,i}$ is the cost function of the i[th] parent going for producing offspring and $(\dot{C}_S)_{\min,p}$ is the minimum value of the cost function of the population selected for offspring production. In this work, the value for the scaling factor, f, is taken as 0.01. The other variables are similarly modified.

Competition & Selection: The offspring produced and the parent individuals, thus, form a set of $2\times Np$ populations. As shown in Fig. 3, they are placed in a competition pool, where a stochastic competition for survival of these individuals is carried out by assigning appropriate score to each of them. The score for each trial vector after a stochastic competition is calculated by the following relation given by Yang et al.[20].

$$w_{pi} = \sum_{t=1}^{N_p} w_t \qquad (39)$$

where, $w_t = 1, \quad \text{if } u_1 > \dfrac{f(p_i)}{f(p_r)+f(p_i)}$

$= 0, \quad \text{otherwise}$

where the competitor p_r is selected at random from among the $2N_p$ trial solutions based on $r = [2\ N_p u_2 + 1]$ and u_1 and u_2 are the random numbers ranging over [0,1].

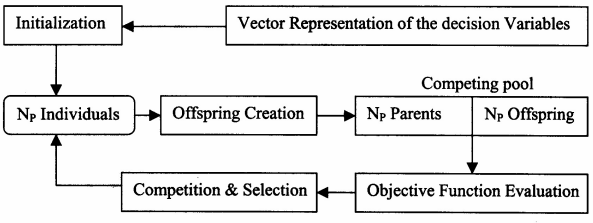

Figure 3. Schematic diagram of the evolutionary programming algorithm

After the competition, the $2\times N_p$ individuals are arranged in descending order of the score obtained by them. The first *Np* trial solutions are considered to be the survivors, and are transcribed along with their objective function value and other related values into a new survivor set of individuals. Thus,

they become the parent individuals for the next generation. For a particular iteration, the individual (trial solution) that gives the minimum value of the objective function is the best individual in that lot.

Termination/Stopping Rule: The above-mentioned process of generating offspring and competition for survival, i.e. iterations, continues till the solution converses within a predefined tolerance limit or a predefined maximum number of iteration is reached.

RESULTS AND DISCUSSIONS

The following admissible range of the decision variables, which form the trial vectors, are considered for both industrial steam and natural gas driven systems:

$140 \le t_g \le 160^0$C, $33 \le t_c \le 45^0$C,

$-15 \le t_e \le 7.5^0$C, $33 \le t_a \le 42^0$C,

$50 \le c_{rhx} \le 90\%$, $50 \le c_{shx} \le 90\%$,

$50 \le h_P \le 90\%$.

The fitness (objective function of the best trial vector in a given population) curve against the number of iterations is shown in Fig. 4, which clearly shows the rapid convergence of the objective function. It is seen that after about 65 iterations the objective function stabilizes to the value of Rs. 385.2 hr^{-1}. The optimized variables of the system are as follows: t_g = 157.55^{0}C, t_c = 37.65^{0}C, t_e = 7.4^{0}C, t_a = 34.2^{0}C, c_{rhx} = 77 %, c_{shx} = 90%, h_P = 69%.

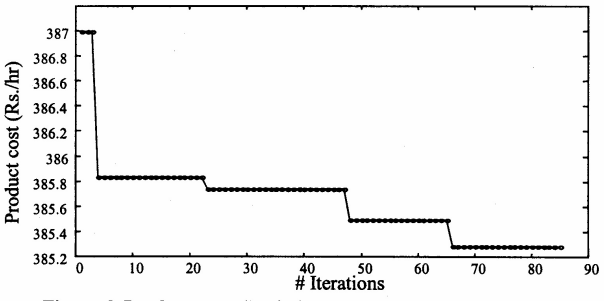

Figure 4. Product cost (Rs./hr) versus iterations for optimization of the aqua-ammonia system

The final results of the optimized system are summarized in Table 3. The value of the objective function, i.e. the product cost is reduced by 10.0% and the fuel cost is reduced by 29.9%. The exergy destruction cost and the exergy loss cost also are decreased by 32.4% and 20.7% respectively. The exergetic efficiency and the COP of the system are increased by 42.7% and 42.2% respectively. Incidentally, the overall investment cost of the system is decreased by 1.5% in comparison to the Base Case. This is because, on one hand the investment costs of the evaporator assembly and the RHX are increased by about 17.6%, and 61.5% respectively, on the other hand the investment costs of the generator, the rectifier, and the SHX are decreased by about 58.4%, 66.4%, and 22.4% respectively.

Table 3. Comparative results between the Base Case and the Optimum Case of the system.

Properties	Base Case	Optimum Case	%-Variation
OBF ($C_{P,tot}$ Rs./hr)	428.12	385.20	-10.03

Z_{shx} (Rs./hr)	5.10	3.96	-22.38

CONCLUSIONS

The thermoeconomic optimization using EP is found to be a powerful and systematic tool in optimizing the design of thermal systems. However, the designer should pay adequate attention to the following points:

- Proper definition of fuel-product-loss of the system.
- Proper selection of local decision variables for various subsystems.
- Reliability of the cost information available and how to relate these with thermodynamic parameters

OPTIMAL PERFORMANCE ANALYSIS OF A SMALL-SIZE GAS-FIRED AIR-COOLED AIR CONDITIONER

L. Wang*, G.M. Chen and Q. Wang,
Zhejiang University
Institute of Refrigeration and Cryogenics
Hangzhou 310027
P. R. China

ABSTRACT

Absorption refrigeration cycle using lithium bromide-water solutions as a working fluid has been increasingly considered one of the most desirable alternatives for electricity-powered compression refrigeration cycle in China. A small size gas-fired air-cooled air-conditioner is developed. The system has two new features of waste heat recovery of condensed water from high-pressure generator and an adiabatic absorber with an air cooler. It helps solve the problems, for example, boost of pressure, temperature and concentration in the generators, increase of risk of crystallization and acceleration of corrosion occurring in the conventional air-cooled falling film absorption refrigeration system. Optimal performance of the device is simulated. The results indicated that the system conserved energy. And COP with heat recovery was 0.058 higher than that without heat recovery. Optimal solution distribution ratio into HG made it achieve the maximum COP.

Keywords: adiabatic absorption; heat recovery; heat transfer; mass transfer; COP

1. INTRODUCTION

The problems of power supply and potential environmental destruction have become momentums of developing air-cooled gas fired air conditioner using lithium bromide-water solutions as a working fluid. In the last ten years, rapid expansion in the use of electricity-powered air conditioning system in Chinese big cities partially has caused occurrence of electricity demand peaks in the summer and winter seasons. Chinese government has done something to change the adverse situation by encouraging customers into using heat-driven absorption refrigeration devices. It is promising in China. Firstly, it uses natural working fluids and helps to protect environment. Secondly, there are plentiful natural gas resources in China. In addition, the Project of the Western Natural Gas Transported Into the East Area has been fulfilled. It is popular that water-cooled absorption heat pumps supply cooling and heat for large buildings, but it is advisable to develop air-cooled absorption refrigeration systems for small building such as villa. The

air-cooled absorption refrigeration has great advantages such as low construction, installation and operation cost, outdoor installation, no special machine rooms, increased ease of handing and enhanced level of reliability [1]. On the other hands, the advantages in human health and application in areas lack of water source are remarkable. However, the higher temperature in the condenser and absorber causes boost of pressure, temperature and concentration in the generators, increase of risk of crystallization and acceleration of corrosion [2]. In order to solve these problems, some theoretical or experimental studies are devoted to invention of new cycle modes, selection of new working fluids and enhancement of heat and mass transfer process in the absorber [3-6]. In view of the facts that the above questions caused by the traditional air-cooled falling film absorption aren't really solved in terms of practical application, in this paper, based on previous works, an air-cooled adiabatic absorption refrigeration air conditioner are developed. To ensure the optimal control and reliability of operation in extremely hot climates, in this study, its operation performance is evaluated.

2. DEVELOPMENT OF AIR CONDITIONER

Fig.1 shows schematically the gas-fired air-cooled double-effect absorption refrigeration device with an adiabatic absorber. The system has two generators. The refrigerant vapor generated from the high-pressure generator (HG) supplies heat energy for the low-pressure generator (LG) to increase the efficiency of the cycle. It uses outdoor air as a cooling source for an air-cooler and a condenser. The weak solution leaving the absorber is split into two parts that flow in parallel. One part flows into the high-pressure generator (HG) after passing through the high temperature heat exchanger (HX), and the other one flows into the low-pressure generator (LG) after passing through the low temperature heat exchanger (LX). When weak solution flowing into the high-pressure generator (HG) is concentrated into the strong solution, the strong solution passes back through the high temperature heat exchanger (HX) and its heat is transferred to the weak solution stream going to the high-pressure generator (HG). Similarly, when weak solution flowing into the low-pressure generator (LG) is concentrated into the strong solution, the strong solution passes back through the low temperature heat exchanger (LX) and its heat is transferred to the weak solution stream going to the low-pressure generator (LG). Finally, the two parts of strong solutions are mixed and return to the absorber.

Fig.1: Schematic diagram of a small size air-cooled air-conditioner

The system has two new features of waste heat recovery of condensed water from generator and an adiabatic absorber with an air cooler, and contributes to solving the problems occurring in

the conventional air-cooled absorption refrigeration system Owing to different mechanics of heat and mass transfer, it is difficult to enhance heat and mass transfer in air-cooled falling film absorber simultaneously. However, Heat and mass transfer process is separated in adiabatic absorber with an air-cooler. In this way, heat is rejected effectively in an air-cooler while the mass transfer occurs subsequently in an adiabatic absorber. There is a packed bed to enhance the mass transfer in adiabatic absorber. The pack bed augments interface between vapor and spray solution, and provides enough space and time for mass transfer process.

2. SIMULATION MODEL

The simulation models involves mathematical model of governing equations for each component making up the cycle system. The governing equations are developed based on conversation of mass and conversation of energy. For the purpose of simplification of the models and steady state simulation, the following assumptions are made:

1. After the superheated vapor from the high-pressure generator supplies heat for low pressure generator, the coolant leaving the low pressure generator is in the saturated water state.
2. Thermophysical properties of subcooled water are treated as that of saturated water at the same temperature conditions. Subcooled water temperature from the low temperature heat exchanger is 15 ℃ higher than weak solution temperature leaving the absorber.
3. After the superheated vapor from the low-pressure generator is condensed in the condenser, the coolant leaving the condenser is in the saturated water state.
4. The pressure drop in the absorber is considered.
5. Flow in the heat exchangers is regarded as the counterflow.
6. Heat loss to the environment is negligible, and pressure drop in the system except the absorber is neglected.
7. Thermophysical properties of air are constant.

According to conversion of mass, total mass balance equation and solution mass balance equation is shown as follows respectively

$$\sum G_i - \sum G_o = 0 \qquad (1)$$

$$\sum G_i X_i - \sum G_o X_o = 0 \qquad (2)$$

where G_i, G_o is mass flow rate of solution (or refrigerant) flowing into and leaving each component respectively, kg/s; X_i, X_o is concentration of solution flowing into and leaving each component respectively, %(wt).

According to conversion of energy, energy balance equation for each component is written as follows

$$Q + \sum G_i h_i - \sum G_o h_o = 0 \qquad (3)$$

where Q is heat capacity, W, and it is equal to zero, for the other component except high pressure generator; h_i, h_o is enthalpy of solution (or refrigerant) flowing into and leaving each component respectively, J/kg.

Coefficient of preference (*COP*) is defined as ratio of the cooling capacity output from the system to the sum of heat input from the gas-fired heater and power input from pump, fan and other electric component, which is shown as follows:

$$COP = Q_{EV} / (Q_{HG} + P) \qquad (4)$$

To solve the set of governing equations, several specific model details incorporated into the model for each component must be addressed. The model details involve the empirical relations and the thermophysical properties of lithium bromide-water solutions, water and steam. The nucleate boiling heat transfer coefficient of lithium bromide-water solutions is derived from Charters' correlations [7]. The convection heat transfer coefficient of water is evaluated according to the equation given by Dittius and Bolter [8]. The

evaporation heat transfer coefficient outside horizontal tubes is calculated using the correlation by Lorenz et al [9]. The convective condensation heat transfer in tubes is obtained from the correlation employed by Sarma et al [10]. Thermophysical property values of lithium bromide-water solution, water and steam required by the model in solving the governing equations were evaluated from Reference [11-16]. Based on the thermodynamic property and transport property equations in the literatures, a subroutine is made. Thermophysical properties values are calculated when the subroutine is called from the main program.

In addition, the model involves heat transfer area of each component. According to optimization design results, Solution distribution ratio (SDR) into HG is 0.483, which is defined as the ratio of the solution mass flow rate into the high pressure generator to total solution mass flow rate leaving the absorber, and power input from pump, and fan and other component is equal to 1.486 kW. Table 1 shows the optimization design results of heat transfer surface area for LG, HX, LX, air-cooler, condenser and evaporator.

Component	Area (m^2)
Coolant side of LG	1.189
Strong solution side of HX	8.842
Strong solution side of LX	7.939
Coolant side of LX	0.249
Air side of air cooler	118.202
Air side of condenser	48.099
Water-cooled side of evaporator	1.949

Tab1: Results of heat transfer area obtained from optimization design for the normal system

4. RESULTS AND DISCUSSION

The influences of SDR into HG, outdoor air temperature and cooled water inlet temperature to evaporator on cycle performances are investigated.

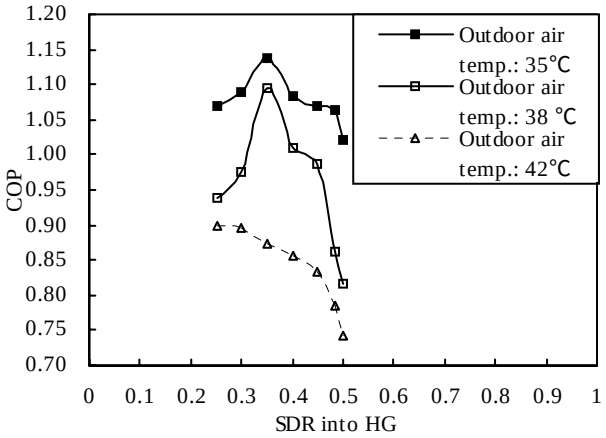

Fig.2: Effects of SDR into HG on COP

Fig.2 shows the effects of SDR into HG on COP at outdoor air temperature of 35℃, 38℃ and 42℃. It is seen that the maximum of COP appears as SDR into HG varies. So at different outdoor air temperature, optimal SDR into HG makes the cycle the most efficient.

SDR	Solution crystal-zation temp	Outdoor air temp. with crystallization
0.25	55.2	39.0
0.30	51.8	36.0
0.35	47.7	32.0
0.40	43.2	28.0

Tab.2 Solution crystallization temp in HX and outdoor air temp with crystallization

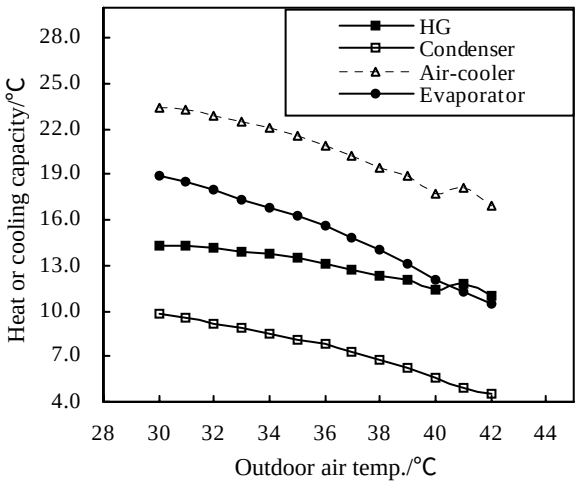

Fig.3: Effects of outdoor air temp. on heat or cooling capacity

Tab.2 illustrates both solution crystallization temperature in HX and outdoor air temperature with crystallization decrease with SDR into HG rise. It results from the increase of solution leaving the HG as SDR decreases.

Fig.3 shows the influences of outdoor air temperature on heat capacity of three components (HG, condenser and air-cooler) and cooing capacity of evaporator. It is seen that both heat capacity and cooling capacity decrease in steps with air temperature increase. However, the slope of heat input into HG is the smallest of all.

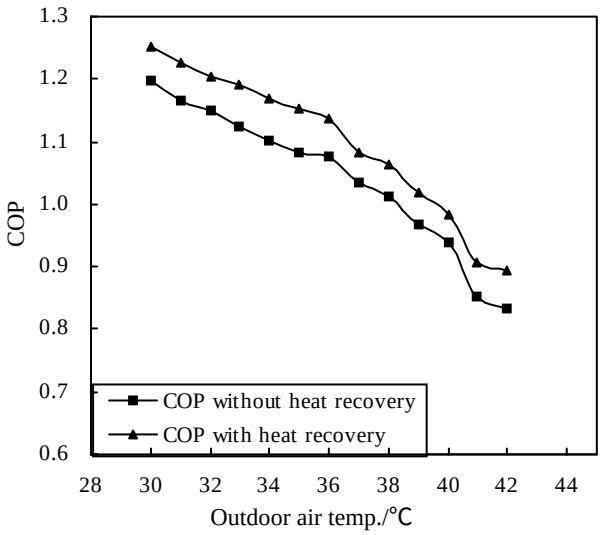

Fig.4: Effects of outdoor air temp on COP

Fig.4 shows the trends of variation of COP with outdoor air temperature increase when SDR into HG is 0.35. It is seen that COP decreases as air temperature rises. Especially at extremely hot climates, when air temperature reaches 43℃, COP reduces significantly 1. At the same air temperature, COP with heat recovery is higher than that without heat recovery. On the average, COP with heat recovery increases 0.058.

Fig.5 shows the effects of cooled water inlet temperature to evaporator on COP and cooling capacity at SDR of 0.483. It is seen that COP and cooling capacity increases linearly with cooled water inlet temperature rise. It indicates that, at the extremely hot climates, cooled water inlet temperature to evaporator is properly boosted so as to improve COP and cooling capacity.

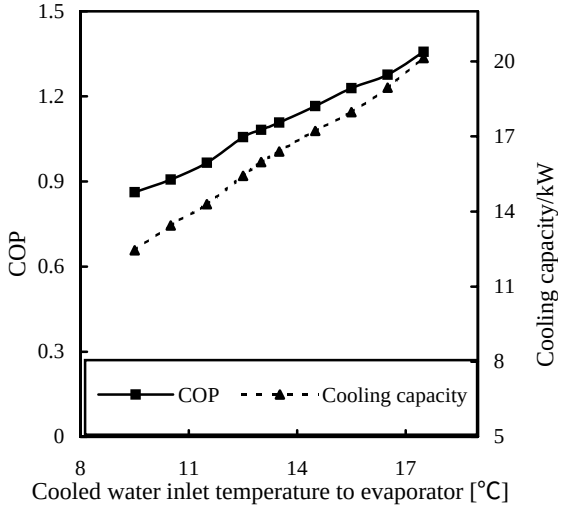

Fig.5: Effects of cooled water inlet temperature to evaporator on COP and cooling capacity

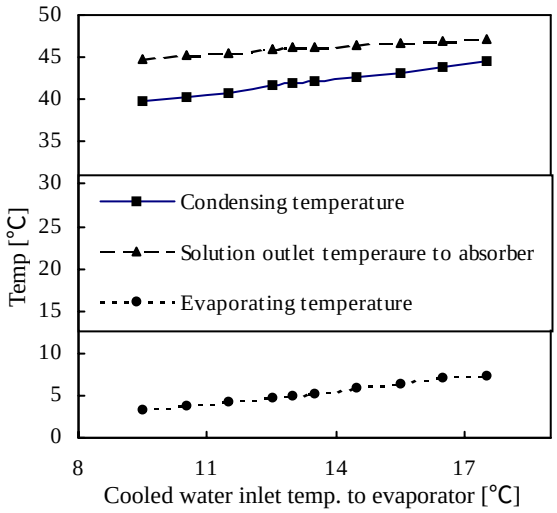

Fig.6: Effects of cooled water inlet temp to evaporator on solution outlet temp to absorber, condensing temp and evaporating temp

Fig.6 shows the effects of cooled water inlet temperature to evaporator on solution outlet temperature to absorber, condensing temperature and evaporating temperature at SDR of 0.483. As cooled water inlet temperature to evaporator rises, condensing temperature, evaporating temperature and solution outlet temperature to absorber increase in steps. However, the rate of increase of solution outlet temperature to absorber is not obvious. When cooled water inlet temperature to

evaporator varies between 9.5 ℃and 17.5℃, solution outlet temperature to absorber ranges from 44.8 ℃ to 47.2 ℃, but condensing temperature ranges from 39.7 ℃ to 44.5℃ and evaporating temperature from 3.3 ℃ to 7.4 ℃.

Fig.7 shows the effects of cooled water inlet temperature to evaporator on circulation solution flowrate, recirculation solution flowrate, subcooling of spray solution, which is defined as temperature difference between solution from absorber and spray solution from air cooler, at SDR of 0.483. It is seen that, recirculation solution flowrate linearly rises as cooled water inlet temperature to evaporator, but circulation solution flowrate decreases in steps. Recirculation solution flowrate has a strong effect on power input from circulation pump, but circulation solution flowrate has a small effect on power input from solution pump because circulation solution flowrate is too small compared with recirculation solution flowrate. The figure illustrates that subcooling temperature has small variations when cooled water inlet temperature to evaporator varies. Although Subcooling is almost kept constant, absorption effects of solution are still enhanced owing to increase of evaporating pressure.

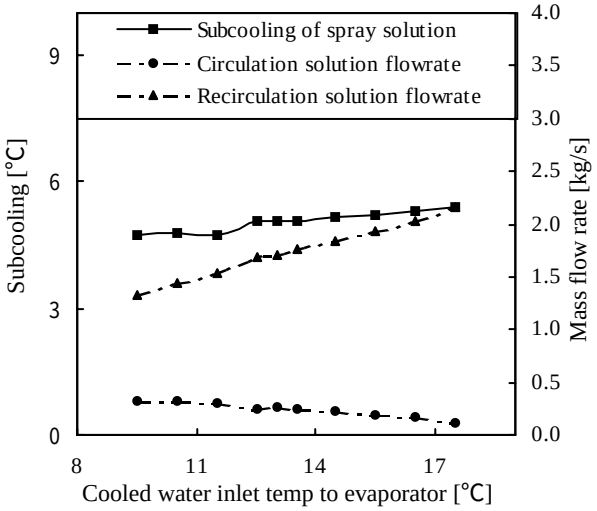

Fig.7 Effects of cooled water inlet temp to evaporator on subcooling of spray solution, circulation flowrate and recirculation flowrate

4. CONCLUSIONS

Small size gas-fired air-cooled adiabatic absorption air conditioner is developed. Heat is recovered from coolant-saturated water in the low temperature heat exchanger. It contributes to energy-conservation and COP boost. Adiabatic absorber with air-cooler separates mass transfer process with heat transfer process. It is feasible to enhance mass transfer in adiabatic absorber and heat transfer in air cooler effectively. Based on performance simulation and characteristic analysis, the optimal control and mode of reliable operation in extremely hot climates are obtained. It indicated that the device resolved some problems occurring in air-cooled falling film absorption refrigeration systems and helped save energy. At extremely hot climates, boost of cooled water inlet temperature to evaporator contributes to increase of cooling capacity and COP, but it causes increase of condensing temperature. Solution outlet temperature to absorber is insensitive to cooled water inlet temperature to evaporator.

ACKNOWLEGEMENT

The authors would like to express the appreciation to Air conditioner Technology Research Institute, Air Conditioning Company, Changhong Electric Co., Ltd., who gives the support to the research work of this paper.

ABSTRACT

In this paper, ammonia-water systems are analyzed for the cogeneration of refrigeration and power. Some general principles for the system integration are summarized, for better recovery of both the external and internal heat and pressure exergy, and reduction of the exergy destruction in the condensation process. Based on these principles, three ammonia-water systems are proposed and analyzed. The plants operate in combined cycle mode with ammonia-water Rankine cycle(s) and an ammonia refrigeration cycle, interconnected by absorption, separation and heat transfer processes. It is found that the cogeneration systems have good thermal performances, with energy and exergy efficiencies of ~28% and 55~60%, respectively, for the base-case studied (at maximum heat input temperature of 450°C). That efficiency is, by itself, excellent for cycles using heat sources at these temperatures, and comparable to that of nuclear power plants. When using the waste heat from topping gas turbine power plants, the total plant energy efficiency can rise to the remarkable value of about 57%. The hardware proposed for use is conventional and commercially available, no hardware additional to that needed in conventional power and absorption cycles is needed.

1. INTRODUCTION

An approach to reduce the exergy loss in the heat transfer process from a variable temperature heat source is to concurrently also vary the temperature of the heat sink and thus make the temperature difference between the heat source and sink more uniform along the heat exchanger (cf. [1]). This can be accomplished in a number of ways, one is using binary-component working fluids that exhibit a variable boiling temperature during the boiling process. The ammonia/water mixture is one of the most widely used working fluids in refrigeration

machines. Maloney and Robertson [2] proposed the use of an ammonia/water mixture as the working fluid in an absorption power cycle. In the combined power cycle proposed by Kalina [3], an ammonia/water mixture was employed as the working fluid in the bottoming cycle. Both systems have power as their only usable output. Refrigeration, however, is also a very valuable product in many circumstances.

Cogeneration is a highly efficient energy utilization method [4]. Goswami et al [5] proposed a combined power/refrigeration cycle using mixed working fluids and investigated its performance [6, 7]. In their system, the ammonia rich vapor from a rectifier unit, which is about 20% of the total mass flow, first expands in a turbine to generate power and then the cold turbine exhaust provides cooling by transferring only sensible heat to the chilled water. The amount of produced cooling is relatively small, and none would be produced for high turbine inlet temperature; hence the system was mainly intended to be operated with low temperature heat sources including geothermal or solar. Zheng et al [8] also proposed an absorption power and cooling (APC) combined cycle based on the Kalina cycle. To produce almost pure ammonia, a rectifier was used to replace the flash tank in the Kalina cycle. The outflow from the top of the rectifier is throttled by a valve and then produces refrigeration before mixing with the main stream. An energy efficiency of 24.2% and an exergy efficiency of 37.3% were reported with the turbine inlet parameters of 350°C/50bar.

In integrated refrigeration/power combined cycles, driven by the same external heat source, such as the one proposed and analyzed here, the integration can be accomplished via several configurations. Such configurations are studied and compared here, with an attempt to also develop and demonstrate a basic general methodology for the system integration.

2. THE MAIN PRINCIPLES FOR SYSTEM INTEGRATION

The power and refrigeration cycles generally operate in different temperature regions. They are complementary to each other in some way: for example, in the power cycle, there are some middle/low temperature waste heats, which are impractical for generating additional power because of their low temperatures, but might be a suitable heat source for an absorption refrigeration cycle. Similarly, in the cooling cycle, some cooling capacity may exist that is not cold enough for refrigeration, but could be an appropriate heat sink to the power cycle. Their integration thus has the potential for becoming a new combined cycle or cogeneration system that may have a higher efficiency.

In the cogeneration systems proposed in this paper, there are two sub-cycles: a Rankine power cycle and an absorption refrigeration cycle, interconnected by the absorption, separation, and heat transfer processes. They use the same working fluid, a mixture of ammonia and water, but with different concentrations, and they are supplied with heat by one external heating fluid. The energy input to the system is via several heat exchangers, and to obtain high efficiency they should be arranged in a cascade according to their temperature level. Within each heat exchanger, small temperature difference should be maintained to allow for a good thermal match between the hot and cold streams.

Binary component mixtures exhibit a boiling temperature that varies during the boiling process, and their employment as working fluids thus allows maintenance of a more constant temperature difference between them and variable temperature heat sources, and consequently reduces exergy losses in the heat addition process. To have an increasing temperature during the evaporation process, the working fluid concentration should be neither too high nor too low, to be able to produce the necessary glide.

To produce more power, the turbine back-pressure should be as low as possible. Condensation of the binary working fluid is a temperature varying process too. To attain complete condensation, the fluid bubble point temperature should be higher than the cooling water inlet temperature by at least the minimal heat transfer temperature difference that allows use of practical heat exchanger sizes. Since ammonia has a lower saturation temperature than water for a given pressure, completing the condensation of ammonia/ water mixtures at the same temperature results in a higher pressure than that for pure water. A binary working fluid in the power turbine must thus expand to a higher back-pressure, which is unfavorable for power generation. In the Kalina cycle, this problem is addressed by an absorption condensation process, in which a weaker stream from the bottom of the flash tank dilutes the turbine exhaust so that the latter can be condensed at a lower pressure [3].

For better efficiency, the physical exergy of any pressure differences in the system, needed for the process, should also be recovered properly.

3. THE EFFICIENCIES AND MAIN ASSUMPTIONS

This analyzed system has two useful outputs: power and refrigeration. In this paper, the heat source fluid

is chosen to be air (79% N_2 and 21% O_2 by volume), entering at the hot end of the Boiler.

The most commonly used energy efficiency and exergy efficiency definitions are adopted for the system performance evaluation. Since the heating fluid is finally exhausted to the environment, the calculation of the efficiencies is based on its initial state. The energy efficiency is defined as:

$$\eta_1 = (W + Q_{EVA}) / Q_{in} \quad (1)$$

where $$Q_{in} = m_{hs} \cdot (h_{hs,i} - h_{hs,a}) \quad (2)$$

Since the energy efficiency weighs the power and refrigeration outputs, as well as the heat input, equally, even though the quality of these energies is rather different, exergy efficiency is a more proper evaluation criterion in this case, and in the evaluation of cogeneration systems with more than one kind of energy output or input in general.

The exergy efficiency is defined as the exergy output divided by the exergy input to the cycle:

$$\eta_2 = (W + E_{EVA}) / E_{in} \quad (3)$$

where the exergy of the heating fluid, E_{in}, is given as:

$$E_{in} = m_{hs} \cdot [(h_{hs,i} - h_{hs,a}) - T_a (s_{hs,i} - s_{hs,a})] \quad (4)$$

The exergy of refrigeration, E_{EVA}, is calculated as the working fluid exergy difference across the evaporator *EVA*.

Table 1. Main assumptions for the calculation

Evaporator *EVA*	Pressure p_{EVA} [bar]	1.6
	Pressure loss [%]	3.0
	Outlet temperature [°C]	-15
(High pressure) Absorber $ABS_{(H)}$	Absorption pressure [bar]	1.55
	Pressure loss [%]	3.0
	Outflow vapor fraction	0
Ambient state	Temperature t_a [°C]	25.0
	Pressure p_a [bar]	1.013
Turbine *T*	Inlet temperature t_7 [°C]	450.0
	Isentropic efficiency [%]	87
Rectifier *REC*	Theoretical stage number	6
	Molar reflux ratio *RR*	0.3
	Operation pressure p_{REC} [bar]	14
	Pressure loss [%]	3.0
	Feed stream vapor fraction	0
Reboiler *REB*	Outlet temperature t_{REB} [°C]	165
Heat exchangers (*B*, *REB*, *HEX*, *CON*, *C*, *ABS*)	Pinch point temperature difference ΔT_P [K]*	5 or 15
	Pressure loss [%]	1.0~3.0
Pumps *P*	Efficiency [%]	75

*ΔT_P is 15 K when one side is air

It is assumed that the system operates at steady state. The simulations were carried out using the commercial Aspen Plus [9] code, with the thermal property method of the Electrolyte NRTL model or the SR-Polar model for high temperatures (>246°C) and pressures (>100 bar) application.

The proposed cogeneration systems could be used as a bottom cycle in a combined cycle system, with a gas turbine as the topping cycle. Since the flue gas temperature of common gas turbines of small size or middle size is about 500°C, the binary turbine inlet temperature is chosen to be 450°C in this study, because ammonia starts dissociating at higher temperatures to nitrogen and hydrogen, although some past studies (cf. [3]) have assumed its use in power cycles up to 532°C. In the condensers *CON* and the absorbers *ABS*, the working fluid is cooled by 30°C water.

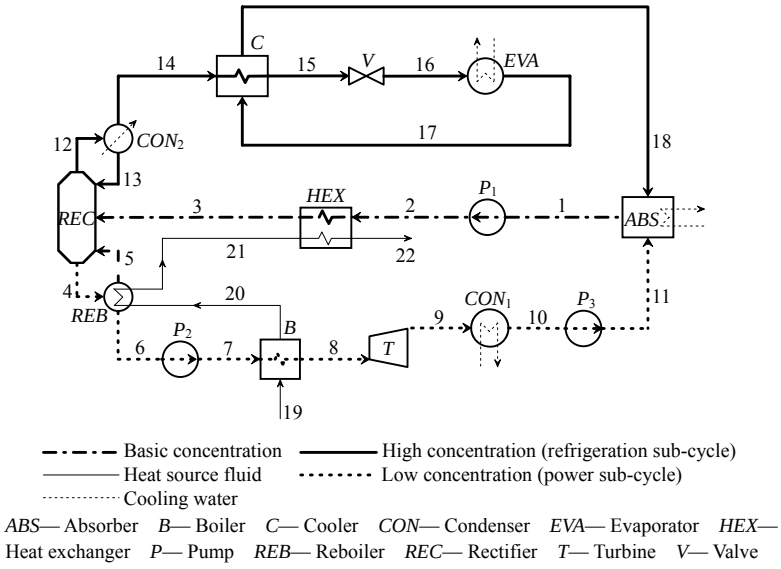
Three cogeneration cycle configurations are studied below.

4. THE PARALLEL POWER/REFRIGERATION COMBINED CYCLE

This plant combines an ammonia-water Rankine cycle and an ammonia refrigeration cycle in parallel, as shown in Fig. 1. The power cycle can be identified as 6-7-8-9-10-11-1 and the refrigeration cycle as 14-15-16-17-18-1. They connect together in the process 1-2-3-4/12-…6/14. Correspondingly, the working fluid has 3 primary concentration levels: the basic concentration solution in the process 1-2-3; the weak concentration solution in the power cycle 6-7-8-9-10-11, and the high concentration solution in the refrigeration cycle 14-15-16-17-18. The combined cycle also has 4 pressure levels.

The main motivation in the development of this cycle was the recognition that proper operation of the absorption cooling cycle requires the generator to be at a significantly higher pressure than the absorber (here the pressure ratio is ~9), and that the weak solution flow (which is about 80% of total work fluid mass flow rate) from the generator to the absorber is just throttled for creating this pressure drop, with the accompanying large exergy destruction. Introduction of a steam-driven power generation system in lieu of the throttling valve, with heat addition to vaporize the weak solution, allows generation of power alongside with the refrigeration produced by the absorption system.

The calculations are based on a unit mass flow rate (1.0 kg/s) of the basic working fluid fed to the rectifier. The system performances are reported in Table 2; good performance is obtained with the energy efficiency and exergy efficiency being 28 and 56%, respectively. Incidentally, the exergy efficiency is much higher than the energy efficiency because the



ABS— Absorber *B*— Boiler *C*— Cooler *CON*— Condenser *EVA*— Evaporator *HEX*— Heat exchanger *P*— Pump *REB*— Reboiler *REC*— Rectifier *T*— Turbine *V*— Valve

Fig. 1 The flow sheet of the combined power/cooling cycle

external heat source fluid is at a relatively low temperature and its exergy content is hence much lower than its energy content.

Table 2. The performance summary for the parallel cogeneration system

Turbine *T* work [kW]		726.9
Pump work [KW]	P_1	2.2
	P_2	5.6
	P_3	0.15
Refrigeration output Q_{EVA} [kW]		266.2
Condenser CON_1 load [kW]		1732.7
Rectifier condenser CON_2 load [kW]		381.0
Cooler *C* load [kW]		59.4
Absorber *ABS* heat load [kW]		427.9
Boiler *B* heat input [kW]		1947.1
Reboiler *REB* heat input [kW]		585.4
Heat exchanger *HEX* heat input [kW]		462.11
Net power output *W* [kW]		719.0
Refrigeration/power ratio *R*		0.37
Heat input Q_{in} [kW]		3496.0
Exergy input E_{in} [kW]		1379.6
Energy efficiency η_1 [%]		28.2
Exergy efficiency η_2 [%]		55.8

Figure 2 is the *t*-*Q* diagrams of the cycle heat addition process. The heat duty *Q* is normalized by the cycle energy input Q_{in} (eq. 2), to show more clearly the fraction of heating fluid energy utilized in the system. To get a better temperature match with the heat source fluid, the positions of the boiler *B*, the reboiler *REB*, and the heat exchanger *HEX*, are arranged (cascaded) in the plant according to their temperature levels.

In this cycle, the working fluid in the power sub-cycle is a weak solution from the reboiler; its physical exergy of pressure is recovered for power generation. The working fluid has a low ammonia concentration (0.098) in both the heat addition and condensation processes; this has both advantages and disadvantages. The power turbine has a relatively low back-pressure, but the temperature in the evaporation process does not change very much, leading to a poor match with the heating fluid variable temperature in the evaporation process.

5. THE SERIES-CONNECTED COGENERATION CYCLE

In the parallel system, the working fluid in the refrigeration sub-cycle has the highest concentration, and in the power sub-cycle the lowest. Consequently, the desired temperature glide in the power sub-cycle boiling process does not occur. In the series-connected system proposed in this Section, the power sub-cycle is downstream of the refrigeration cycle, thus allowing the use of a relatively strong solution, with a consequent desirable temperature glide, in its heat addition process. At the same time there are also some impairments: the working fluid is brought into the power cycle at a lower temperature and pressure than in the parallel cycle, and it is hard to lower the turbine backpressure because of the relatively high working fluid concentration.

The cycle layout is shown in Fig. 3. The refrigeration cycle can be identified as 15-16-17-18-19, followed by the power cycle: 20-21-22-23-24. 1-2-3-4-5/13-…7/15 is the preheat and rectification process. The weak solution from the reboiler is split into two streams in the splitter *SP*: one stream merges with stream 19 to accomplish the absorption process in the high pressure absorber ABS_H and form the

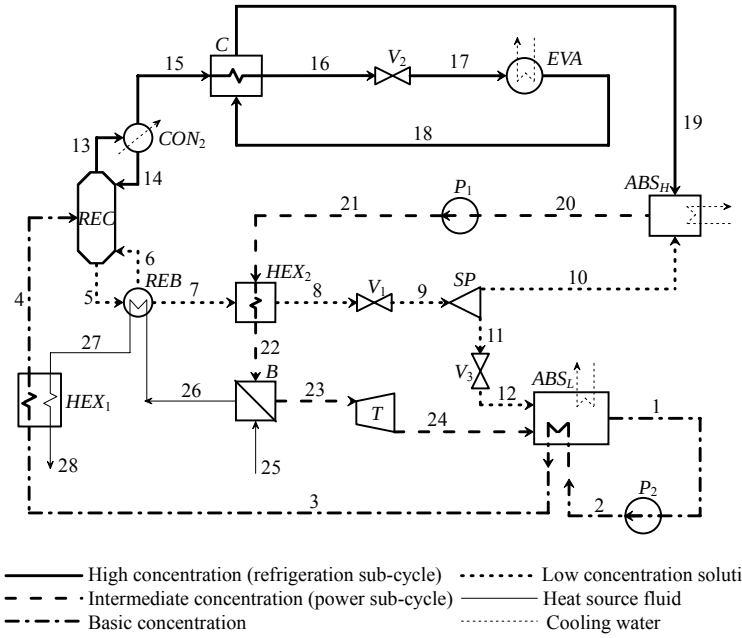

Fig. 3 The flow sheet of the series connected power/refrigeration cycle

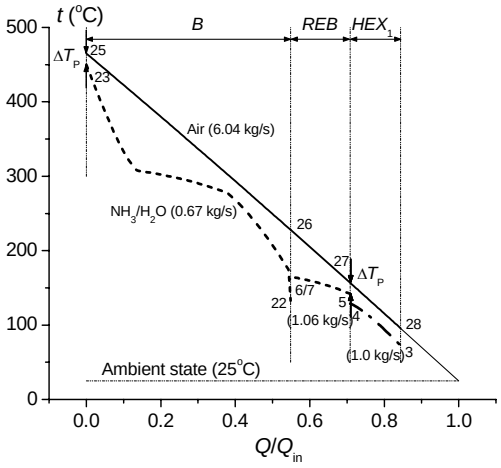

Fig. 4 the heat exchange *t*-*Q* diagram in the series-connected cogeneration system

turbine working fluid with the intermediate concentration; and the remainder is sent to the power sub-cycle and mixes with the turbine exhaust in the low pressure absorber ABS_L. This has two advantages: (1) the working fluid concentration in the power cycle boiling process can be adjusted to match the variable temperature heat source fluid, and (2) the turbine exhaust fluid is diluted in the low pressure absorber ABS_L by a part of the weak solution (12), bringing its concentration back to the basic value (1), thus reducing the condensation pressure somewhat and increasing the turbine power output. Consequently, the working fluid has 4 ammonia concentration levels and also has 4 main pressure levels. The heating fluid follows the path of 25-26-27-28. The calculation was based on 1 kg/s basic working fluid feed to the rectifier. The computed cycle performance is reported in Table 3.

The *SP* split fraction SF_1 (= m_{11} / m_9) is a key parameter to the cycle performance. When the split fraction is 0, the low-pressure absorber ABS_L is eliminated, replaced by a common condenser. As the split fraction increases, more of the dilute working fluid bypasses the high-pressure absorber and the turbine and is sent to the low-pressure absorber (ABS_L) directly. On the one hand, this raises the concentration of turbine working fluid, but on the other hand, the turbine inlet working fluid mass flow rate decreases, and leads to less power generation, but the boiler *B* heat demand decreases too. It is found that there exist values of SF_1, which maximize the thermal or exergy efficiencies.

Figure 4 is the *t*-*Q* diagram of the cycle heat addition process for SF_1=0.4, the tubine inlet pressure is 153 bar. The amount of heat needed in the evaporation process is only a small portion of the total heat demand, leading to a better thermal match in the boiler heat transfer process.

Table 3. Cycle performance summary for the series-connected cogeneration system

Split Fraction SF_1		**0.4**
Basic solution concentration		0.25
Intermediated solution concentration		0.32
Turbine working fluid mass flow rate [kg/s]		0.67
Turbine inlet pressure [bar]		152.5
Turbine backpressure [bar]		0.85
Turbine power output [kW]		581.0
Pump work [KW]	P_1	2.2
	P_2	17.2
Cycle input [kW]	Reboiler	443.9
	Boiler	1522.4
	Heat exchanger HEX_1	376.2
Cycle output [kW]	Cooling capacity Q_{EVA}	171.8
	Net power output *W*	561.6
Refrigeration/power ratio *R*		0.31
Heat source fluid	mass fluid rate [kg/s]	6.04
	Inlet temperature [°C]	465.0
Energy input Q_{in} [kW]		2776.24
Exergy input E_{in} [kW]		1095.55
Energy efficiency η_1 [%]		26.42
Exergy efficiency η_2 [%]		54.12

The efficiencies are somewhat lower than those of the parallel cycle despite the higher turbine inlet pressure. The variation of SF_1 has no effect on the turbine backpressure. The turbine backpressure (0.853 bar) is much higher than that in the previous parallel congeneration system. The comparatively big exergy loss in the condensation process is the cause for the modest efficiencies of this cycle.

6. THE COMPOUND COGENERATION CYCLE

In the parallel system, the working fluid in the power sub-cycle has a fairly low concentration, so it is hard to achieve the best temperature glide and consequent thermal match in the boiling process with the heating fluid, but, on the other hand, the turbine may have a desirable low backpressure. The opposite happens in the series-connected cycle. The ideal system should have low exergy losses in both the heat addition and condensation processes. To address an improvement in this direction, we now propose and analyze, a more complex cycle configuration, based on the parallel cogeneration cycle of Section 4. The major difference is the addition of another power route 5-14-15-16 as shown in Fig. 5, to reduce the irreversibility in the cycle heat addition process.

Now the working fluid with the basic ammonia concentration (3) is divided by the splitter *SP* into two streams (4) and (5). Stream 5 is directly brought into one power cycle by being pumped and heated, and then expands in turbine T_2, so it is possible to have a stronger solution at least in this power cycle heat addition process. The other (stream 4) is sent to the rectifier *REC*, where it is separated into ammonia-rich vapor (19) and ammonia weak solution (6). The weak solution is further weakened to state (8) in the reboiler by boiling off ammonia-rich vapor (7), and then is sent to the boiler *B* and a second turbine T_1, for power generation.

There are two power routes in this system: 8-9-10-11-12-13 and 5-14-15-16. The ammonia concentrations of the two turbine working fluids are also different. The exhausts of the two turbines merge in the low pressure absorber ABS_L to form an intermediate concentration solution (17). In that way the stream 16 is diluted and therefore turbine T_2 may have a lower backpressure.

It adopts the Kalina cycle concept of varying working fluid concentration to reduce the turbine backpressure. The working fluid (8) in the first power route is not only used for power generation, but also as the absorbent in the low pressure absorber, therefore the condensation process for the second power route is eliminated and replaced with a absorption process.

The cycle performance is calculated and the results are reported in Table 4. Similar to the former sections, the calculation was based on 1 kg/s basic working fluid feed to the rectifier.

In addition to the advantages of the absorption condensation, it is found that the heat transfer process in the boiler is improved too.

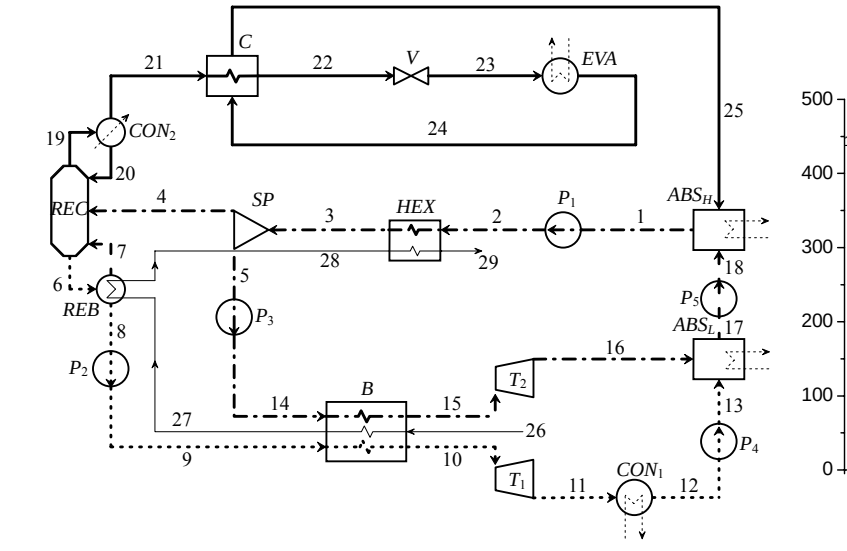

Fig. 5 The flow sheet of the combined power/cooling cycle

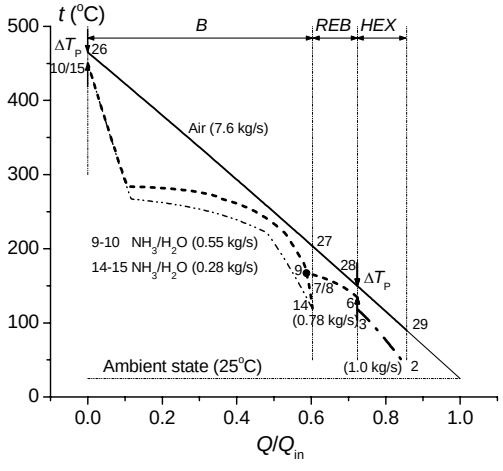

Fig. 6 the heat exchange *t*-*Q* diagram in the compound cogeneration system

Figure 6 shows the *t*-*Q* diagram of the heat addition process. The two cold streams in the boiler have concentrations of 0.3 and 0.098 respectively; they neither have high ammonia concentrations nor high pressures. The thinner dash-dot-dot line shows a temperature curve of a single cold stream with the ammonia mass fraction of 0.3, heated by the same heating fluid. It can be seen that the combination of the two cold streams has a much better temperature match with the heating fluid, thus reducing the irreversibility of the heat transfer process.

Table 4. Cycle performance summary for compound cogeneration cycle

Split Fraction SF_2		**0.72**
Turbine *T* work [kW]	T_1	540.78
	T_2	255.61
Pump work [KW]	P_1	2.18
	P_2	6.74
	P_3	3.56
	P_4	0.017
	P_5	0.15
Refrigeration output Q_{EVA} [kW]		191.66
Condenser CON_1 load [kW]		1209.28
Rectifier condenser CON_2 load [kW]		274.37
Cooler *C* load [kW]		42.75
Absorber heat load [kW]	ABS_H	628.85
	ABS_L	287.6
Boiler *B* heat input [kW]		2108.64
Reboiler *REB* heat input [kW]		421.43
Heat exchanger *HEX* heat input [kW]		462.12
Net power output *W* [kW]		783.75
Refrigeration/power ratio *R*		0.245
Heat input Q_{in} [kW]		3493.26
Exergy input E_{in} [kW]		1378.51
Energy efficiency η_1 [%]		27.92
Exergy efficiency η_2 [%]		59.5

Similar to the series-connected system, the split ratio in the splitter, defined as $SF_2 = G_4/G_3$, is also a key parameter for this cycle. It is easy to see that when SF_2=1 the cycle becomes the parallel one described in Section 4.

As SF_2 increases, more basic concentration working solution is sent to the rectifier, leading to the increase of the refrigeration output. When SF_2 increases, the concentration of the mixture (state 17) at the two turbine exhausts decreases, leading to the decrease of the backpressure of turbine T_2. It is found that there are SF_2 that maximizes the exergy efficiency and the energy efficiency.

The base case compound cogeneration cycle has very good thermal performance with the energy efficiency and exergy efficiency of 28% and near 60% respectively, as reported in Table 4. The good thermal match in the boiler is obtained by the arrangement of two cold streams with different low ammonia concentrations, rather than one high concentration cold stream; and the backpressures of both turbines can be maintained at a lower level because of the low ammonia concentration and the adoption of absorption condensation. The irreversibility in both the power cycle heat addition process and condensation process can thereby be reduced.

We note that all three analyzed systems have power as the main output, the parallel one has the highest refrigeration/power ratio *R* of 0.37, and the compound one has the lowest *R* of 0.25. For the same heating fluid mass flow rate, the compound cycle can produce 9% and 11% more power and 28% and 11% less refrigeration, respectively, than the parallel and series-connected systems. Its exergy efficiency is 4 and 5 percentage points higher, respectively, than those of the parallel and series connected systems.

7. CONCLUDING REMARKS

This paper shows the implementation of some general principles for power and refrigeration cogeneration system design and synthesis, with ammonia/water mixture as the working fluid. The well-known principles, and the way they were implemented in this development, are:

1) Both the external heat input and heat exchanged within the cycle components should be used/recovered properly and thoroughly: an important way for that is to cascade the heat exchange according to the temperature of both hot and cold streams.

This principle was followed here by creating a component configuration cascaded, heat source to sink, by their temperatures. To generate more power, the turbine working fluid needs to be heated to as high a temperature as possible in the boiler. The reboiler at the bottom of the rectifier needs mid-temperature heat to boil off the ammonia-rich vapor. Therefore, to match with the heating fluid, the boiler was placed at the highest temperature region, followed by the reboiler. Lower in the cascade, the heating fluid at the outlet of the reboiler was used to preheat the working fluid feed to the rectifier, helping to reduce the reboiler load.

2) To obtain a good temperature match with the sensible heat source, the working fluid must exhibit an appropriate temperature glide in the boiler, that was accomplished here by ensuring that its concentration in the evaporation process is neither too high nor too low.

3) The turbine backpressure should be as low as

possible to generate more power output and reduce as much as possible the exergy loss in the condensation process.

Principles 2 and 3 are not always easy to satisfy at the same time in the ammonia/water system. For example, in the evaporation process, accomplishment of a working fluid temperature glide that produces a good thermal match with the sensible heat source requires an ammonia concentration of about 50%. That, however, creates a high turbine backpressure and thus reduces power production if this solution is used as the turbine working fluid. The ideal system should have low exergy losses in both the heat addition and condensation processes, which requires that different ammonia concentration be maintained in these processes.

To accomplish that, a splitting and absorption unit is employed to adjust some stream mass flow rates and thus maintain the desired ammonia concentrations in both the heat addition process and the absorption process, in the series-connected and the compound cogeneration systems. That unit brings a stronger solution into the power sub-cycle heat addition process, thus making a better temperature match with the heating fluid. It also dilutes at the same time the turbine exhaust in the absorption-condensation process, leading to a drop of the turbine back-pressure and improvement of the temperature match in the condensation process.

4) The exergy loss associated with pressure drops needed for the process should be minimized, for example by substituting a throttling process with a power generation one.

That was accomplished in the parallel and compound systems by recovering the pressure exergy of the reboiler weak outflow, by introduction of a steam-driven power generation system instead of the throttling valve. This increased the power output significantly. Other means for pressure exergy recovery are under investigation.

In the three cycle configurations analyzed, the energy and exergy efficiencies were found to be 26~28% and 55~60%, respectively, in the base case when the top heat input temperature is 450°C. That efficiency is, by itself, excellent for cycles using heat sources of ≤450ºC, and comparable to that of nuclear power plants. When using the waste heat from topping gas turbine power plants, which, if used independently, typically have efficiencies of about 40%, the total plant energy efficiency rises to the remarkable value of about 57%. The hardware used is conventional and commercially available, no hardware additional to that needed in conventional power and absorption cycles is needed, and the use of mixtures results in a smaller total required heat exchanger area than the conventional separate cycles.

It is of course of interest to compare the performance and capital investment of the proposed cogeneration system with separate conventional steam Rankine power cycles and absorption refrigeration cycles that produce the same power and refrigeration outputs. Such comparison was made by the authors [10], where it was demonstrated that a somewhat similar cogeneration system operates at better efficiency than the separate cycles, with no penalty in capital equipment.

ABSTRACT

This paper presents experimental local heat transfer coefficient and pressure drop results obtained during the evaporation of the zeotropic mixture R407C (R32-R125-R134a, 23/25/52 % in weight). The test section was a smooth, horizontal, stainless steel tube (6 mm ID, 6 m length) uniformly heated by Joule effect. The effects of mass flux, heat flux and evaporating pressure on the heat transfer coefficients have been investigated. The experimental tests have been performed with a refrigerant mass flux of 200 and 355 kg/m^{2}s varying the heat flux within the range 8.0-16.9 kW/m^2 and the evaporating pressure from 3.5 up to 10.0 bar.
Keywords: R407C, heat transfer coefficient, pressure drop, experimental results, convective boiling.

INTRODUCTION

Following global climate changes, the environmental impact of technology systems need to be investigated. Refrigeration systems contribute to both global warming and ozone layer depletion. As known a new family of substances harmless towards the ozone layer is hydro-fluorocarbons, HFCs. Nevertheless, these fluids are greenhouse gases and may be subjected to limitations on their use in the future. The refrigerant fluids with long atmospheric lifetimes and high numbers of carbon-fluorine bonds have been identified as greenhouse gases (direct contribution).
The vapour compression air conditioners, heat pumps and refrigeration plants that use refrigerants also use energy. Therefore they contribute to global warming both by release of refrigerants and by emission of carbon dioxide and other greenhouse gases, in powering the devices

E-mail address: wmauro@unina.it

(indirect contribution). If the proposed replacements for CFCs and HCFCs are characterized by a lower performance coefficient, higher amounts of electrical energy must be supplied to the machine. In turn, this implies higher amounts of primary fossil energy and higher carbon dioxide emissions.

Therefore the choice of vapour compression machine operating fluids must be governed by both the absence of chlorine and bromine atoms in the molecule and a low direct and indirect contribution to the greenhouse effect.

Experimental tests carried out with these new refrigerants have pointed out a reduction of the energetic performances of the systems that means a larger environmental impact in terms of green house effect. Accurate investigations highlighted how these performances are influenced from the functioning of the heat exchangers (evaporator and condenser). For this reason the knowledge of two-phase characteristics is of prime importance to design heat exchangers for refrigeration and air-conditioning applications. In this paper the results about the experimental evaluation of heat transfer coefficients and pressure drops for the zeotropic mixture R407C (R32-R125-R134a, 23/25/52% in weight) are presented.

EXPERIMENTAL APPARATUS

An experimental apparatus schematic view is provided in Fig.1. It consists of different loops: the main loop and two auxiliary ones. The main loop is not a classic compression vapour plant to keep the refrigerant free by lubricant. Along the main loop a gear pump drives the liquid refrigerant coming from a boiler and by means of a hydrodynamic speed variator allows the refrigerant to flow at different flow rates. The mass flux can be varied continuously within the range 200–1100 kg/m^{2}s.

At the test section inlet, saturated liquid conditions are ensured by a thermally controlled electric ribbon wound around the tube upstream from the test section.

The test section is a 6 m stainless steel horizontal

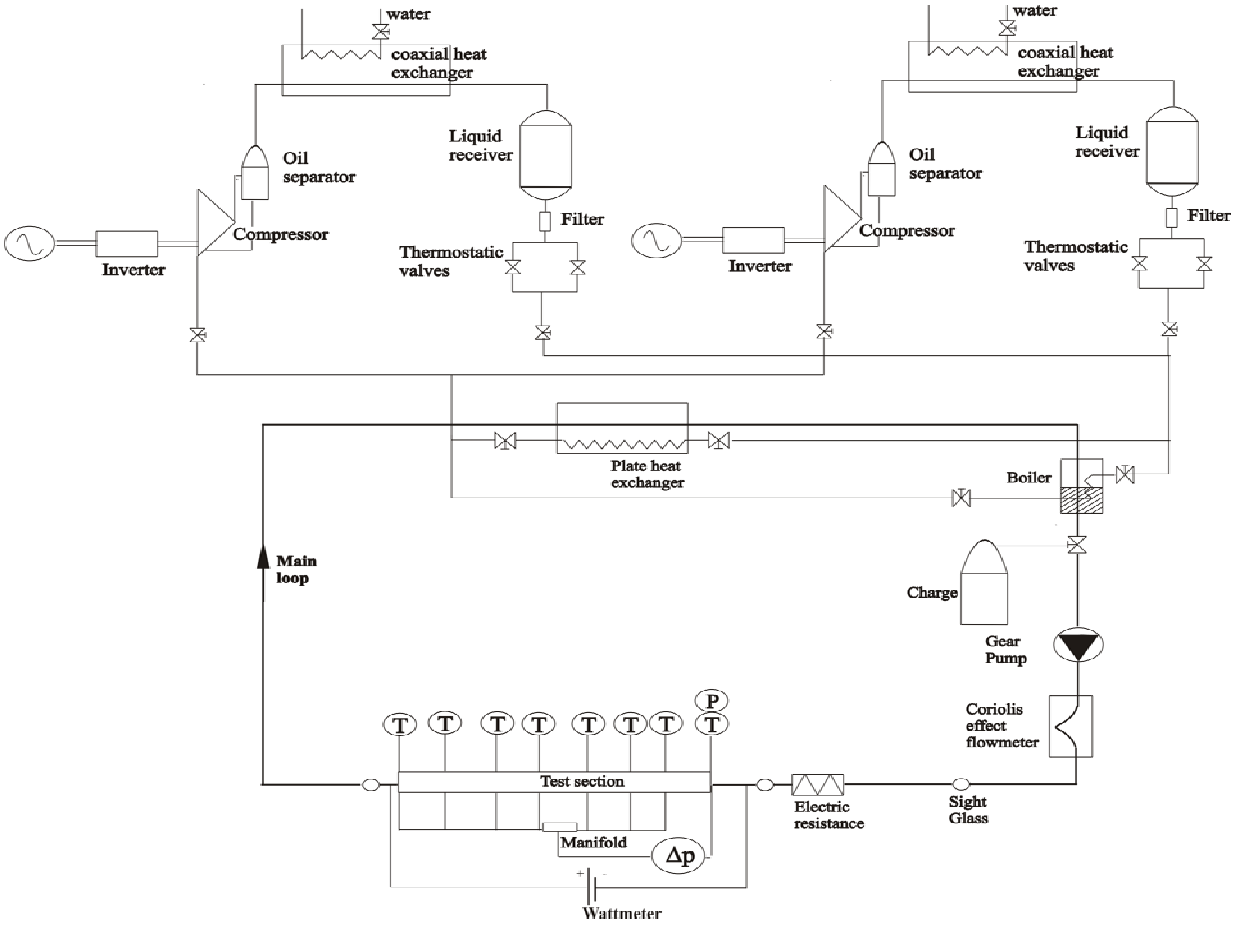

Fig. 1 Experimental apparatus

tube with inside diameter 6 mm and wall thickness 1 mm in which the refrigerant evaporates. The tube is electrically heated by Joule effect and insulated by means of PFA connections at its headers. A direct electrical current supplied by a feed current device circulates on the surface of the tube. Varying the direct electrical current, it is possible to have heat fluxes within the range of 8–70 kW/m^2.The heat flux supplied along the tube can be safely considered constant. Two sight glasses are installed at the inlet and outlet of the test section to check the refrigerant flow patterns. The refrigerant condenses in a plate heat exchanger. This heat exchanger may be the evaporator of two different vapour compression plants, alternately working as auxiliary. R507a is the working fluid for each auxiliary loop, which is composed by a semi-hermetic bi-cylindrical compressor, a coaxial condenser, two thermostatic valves and a plate evaporator.

In order to separately analyse the influence of several operating parameters on the evaporating heat transfer characteristics, the experimental apparatus has to be able to carry out tests in which it is possible to control independently the evaporating temperature, the mass flow rate of the circuiting refrigerant and the heat flux in the test section. To this aim a vapour compression plant with a classic design cannot be utilized, otherwise only one evaporating temperature corresponds to an evaporating power.

For this reason the components of the two auxiliary loops are sized differently, in particular one is sized to work at higher evaporating temperature and the other one to work at lower evaporating temperature. Moreover the compressor of each loop is connected to an inverter, which enables to vary its revolution speed, and each loop has two thermostatic expansion valves to permit a correct lamination in different operating conditions. Using all systems it can be varied the evaporating temperature within the range of -30°C to 20 °C.

Finally the test apparatus has been heavily insulated with a 32 mm layer of cellular insulate for the heat exchangers and with a coaxial tube of armflex insulate for tubes and tube fittings.

MEASUREMENTS AND DATA REDUCTION

Locations of sensors in the test section are shown in Fig.1.

Since the test section is thermally insulated the heat transferred to the refrigerant can be evaluated as the electric power supplied by the feed current device. The voltage and the current are monitored by means of a voltmeter and an amperometer. The voltmeter has an accuracy of ±0.2% in the range 0-30 V and the amperometer has an accuracy of ±0.2% in the range of 0-220 A.

A four wire 100 Ω platinum resistance thermometers are inserted in the refrigerant flow stream at the inlet of the test section. Such type of resistance thermometers is located in other key-points of the test circuit.

Along the tube there are eight test stations. Each test station is placed according to the qualitative diagram relating the evaporative heat transfer coefficient to vapour quality. For each station there are four four-wire 100 Ω platinum resistance thermometers. These thermometers are located on the top, bottom and both sides of the outside tube wall. All the resistance thermometers are calibrated in the proper operating range and they have an accuracy of ±0.03°C.

An absolute piezoelectric pressure transducer measures the pressure at the inlet of the test section. It has an accuracy of 0.1% F.S. in the range 0-14 bar. Pressure drops between the inlet and each test station are directly measured. In fact each station is shunted one by one to a manifold and by means of a pressure gauge the pressure drop between the inlet and the manifold can be measured. This piezoelectric pressure gauge has an accuracy of 0.1% F.S. in the range 0-1 bar.

Refrigerant mass flow-rate is measured by a Coriolis effect mass flow-meter, inserted after the gear pump, where sub-cooled liquid conditions have been achieved. This device has an accuracy of ±0.2% in the range 0-2 kg/min. Since the measurement could be affected by mechanical vibrations, it has been mounted on a 5 kg steel plate separated from plant.

In each station the heat transfer coefficient is calculated four times for the four wall temperature measurements by the following equation:

$$h_{ev} = \frac{\dot{Q}}{A_{tot}\left(T_w - T_{bulk}\right)} \qquad (1)$$

where $\dot{Q}$ is the power supplied to the refrigerant, A_{tot} the total area of the tube, T_w the temperature of the inner wall, T_{bulk} the fluid bulk temperature. Than their mean value is held and stored as the local heat transfer for that station.

According to the previous equation also the fluid bulk and the inner wall temperatures have to be known. The bulk fluid temperature along the tube

is calculated rather than measured directly, because an in-stream thermometer considerably perturbs the two phase flow pattern. Since R407C is a zeotropic mixture, to evaluate the fluid bulk temperature (i.e. saturation temperature, during evaporation) the local pressure and the local specific enthalpy must be known. The local pressure is derived from the inlet pressure and the pressure drop between the inlet and each test station.

The local specific enthalpy is derived from an energy balance between the generic test station and the inlet:

$$h = h_{in} + \frac{\dot{q} A}{\dot{m}} \qquad (2)$$

where h_{in} the enthalpy at the inlet section, $\dot{q}$ is the heat flux along the test section, A is the inner tube area between the generic test station and the inlet and $\dot{m}$ is the mass flow rate. By measuring the inlet pressure and the inlet temperature the specific enthalpy at the inlet is known.

All the thermodynamic properties of the refrigerant fluid are evaluated using a computer program [1].

The inner wall temperature along the test section is estimated from the measured outside wall temperature by applying the one-dimensional, radial, steady-state heat conduction equation for a hollow cylinder assuming uniform heat generation within the tube wall and an adiabatic condition on the outside of the tube.

DATA ACQUISITION AND UNCERTEAINTIES ESTIMATION

The data acquisition starts when steady-state conditions have been achieved. A personal computer connected to a data-acquisition system, consisting in a controller, a 48-channel scanner and a multimeter, performs data collection. To control the achievement of the steady-state conditions temperature and pressure values in key points of the plant are continuously monitored. Preliminarily it is fixed a deviation value and the steady-state conditions are assumed to hold when the deviations of the controlled variables from their corresponding mean value are lower than the fixed deviation.

If steady-state conditions have been achieved, the test starts and the data logging with a 1 Hz sampling rate is performed on all channels for 1000 s. For the channels corresponding to the gauges of the test section, the 1000 samples recorded are averaged. Each sample is checked against the corresponding mean value and it is rejected if it does not lay within the fixed range. If more than 5% of the samples are rejected, the whole test is discharged.

Uncertainties in the experimental data are calculated using the analysis suggested by Moffat [2]. The uncertainty of each measured quantity consists mainly of uncertainties of the measurement device and of the data-acquisition system.

For the heat transfer coefficient the error analysis is carried out with the following equation:

$$\frac{\partial h_{ev}}{h_{ev}} = \sqrt{\left(\frac{\partial \dot{Q}}{\dot{Q}}\right)^2 + \left(\frac{\partial A}{A}\right)^2 + \left(\frac{\partial T_w}{T_w - T_{sat}}\right)^2 + \left(\frac{\partial T_{sat}}{T_w - T_{sat}}\right)^2} \qquad (3)$$

The total error depends on the uncertainties in measurements and on the operating conditions. Under the employed operating conditions for the zeotropic mixture R407C the inaccuracy of the heat transfer coefficients are ranged between 1.8% and 8.5%.

EXPERIMENTAL RESULTS AND DISCUSSION

The flow boiling tests in the present paper are carried out for the zeotropic mixture R407C (R32-R125-R134a, 23/25/52 % in weight).

In the present paper the heat transfer coefficients and pressure drops are measured varying the evaporating pressure, keeping the refrigerant mass flux almost constant.

The test conditions are performed in the refrigerant mass flux range 200-355 kg/m^{2}s, varying the heat flux between 8.0-16.9 kW/m^2 and the evaporating pressure within the range 3.5-10.0 bar.

The experimental conditions are summarized in Table 1. Refrigerant mass-flux, evaporating pressure at the inlet of the test section, the corresponding saturation temperature, and heat flux are specified for each test.

Because the heat-transfer process depends on the flow regime, first the flow patterns have to be identified in order to calculate the heat transfer coefficients and pressure drops. Numerous flow pattern maps have been proposed over the years for the prediction of two-phase flow regime transitions in horizontal tubes. In this paper, the latest version of the Kattan-Thome-Favrat map [3, 4] is used. An intermittent flow pattern is observed from the inlet

G [kg/m^{2}s]	P_{ev} [bar]	T_{ev} [°C]	q [kW/m^2]

355	9.02	15.1	15.5
352	9.84	18.1	16.8

Table 1 The operating conditions

section to the part of the test section with vapor qualities between 30 – 40 %, depending on the test conditions. The intermittent flow covers both plug and slug flow regimes (it is essentially a stratified–wavy flow pattern with large amplitude waves that wash the tube top). With increasing vapor qualities, an annular flow is achieved. At higher vapor qualities (>76 % in dependence of the heat flux values) the liquid film in the upper part of the tube disappears and the flow became annular with a partial dry-out.

The experimental heat transfer coefficients obtained during the evaporation of R407C are depicted in Fig. 2 as a function of vapour quality obtained by varying the evaporation pressure at the almost constant refrigerant mass flux of 200 kg/m^{2}s.

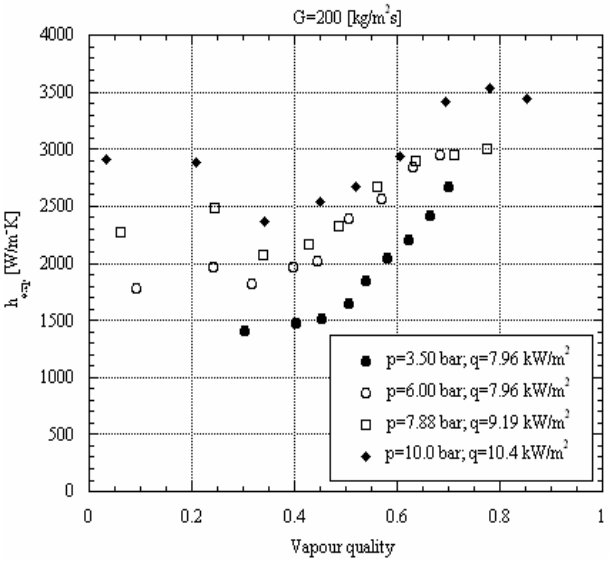

Fig.2 Local heat transfer coefficients as a function of the vapor quality at a fixed refrigerant mass flux varying the evaporating pressure.

The heat transfer coefficients present distinct behavior depending upon the quality range. The heat transfer coefficients first decrease with increasing vapor quality and then increases again. The local minimum corresponds to the transition from intermittent flow to the annular flow regime. The experimental test corresponding to the evaporating pressure of 3.5 bar does not present this local minimum, though the transition quality occurs outside the range considered in the present study (x < 30%).

In the experimental tests reported in this figure, corresponding to low mass velocities, there were observed two distinct heat transfer regions during evaporation. In the first one, occurred at low vapour qualities, nucleate boiling (characterized by the formation of bubbles on the heated wall of the tube) was dominant. In this region, the heat-transfer coefficients decreased as the effect of nucleate boiling diminished. Indeed, with increasing vapor qualities, the wall-to-interface temperature difference needed to drive the heat flux was reduced.

The decrease in the wall superheat reduced the number of active nucleation sites for bubble formation. Furthermore, in flow boiling the wall shear stress causes the bubbles to depart early from the wall, and reduce the bubble size compared with pool boiling. This effect leads to a reduction in the nucleate boiling component with increasing shear stress. Both effects lead to a reduction in the effectiveness of nucleate boiling with increasing vapour quality. The second region corresponded to convective evaporation. It is characterized by the

increase of the heat transfer coefficients with increasing vapour qualities. In an annular regime, heat-transfer is dominated by evaporation at the interface between the liquid (located at the wall) and the vapour (in the tube core). As vaporization proceeds, the thickness of the liquid film on the tube wall decreases together with its thermal resistance thereby enhancing the heat-transfer effectiveness. The ensuing increase of the heat transfer coefficient proceeds until the liquid film disappears, leaving the tube-wall partially or totally dry. In this region, the heat transfer coefficient decreases because of the low thermal conductivity of the vapour.

It is clearly highlighted from the experimental results that the heat transfer coefficients increase together with the pressure and the heat flux.

With increasing pressure, the nucleate boiling contribution to the heat transfer coefficients increased mainly due to the corresponding decrease in the bubble radius for a given wall superheat. Assuming spherical nuclei, the required bubble radius at which the bubble is in equilibrium with the liquid follows from the well-known equilibrium conditions for a small bubble (Thomson equation) and the linearized Clausius-Clapeyron equation and it depends on physical properties (surface tension, enthalpy of vaporization, vapour-phase density). With increasing pressure the vapour density strongly increases and the surface tension decreases.

The decrease of the average departure diameter of vapour bubbles with increasing pressure implies the activation of the additional new small cavities on the heated surface, and therefore the increase of the nucleate boiling contribution to the heat transfer coefficient. For lower values of the refrigerant mass-fluxes, the dependence of the heat-transfer coefficients from pressure was stronger, since nucleate boiling contribution became increasingly more important and there is no bubble suppression in the whole quality range.

The experimental heat transfer coefficients of R407C are depicted in Fig. 3 as a function of vapour quality obtained by varying the evaporation pressure at the almost constant refrigerant mass flux of 355 kg/m^{2}s.

The experimental tests reported in this figure correspond to higher mass velocities and the convective contribution to heat-transfer predominates in the whole quality range. Indeed, as the flow proceeds downstream and vaporization takes place, the void fraction increases, thus

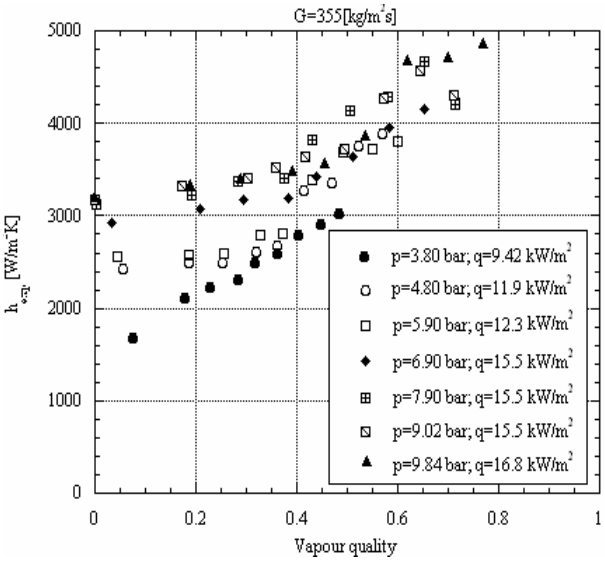

Fig.3 Local heat transfer coefficients as a function of the vapor quality at a fixed refrigerant mass flux varying the evaporating pressure.

decreasing the density of the liquid-vapour mixture. As a result, the flow accelerates enhancing convective transport from the heated wall of the tube.

For these higher refrigerant mass fluxes, the convective contribution was predominant and therefore the dependence on the evaporating pressure became weaker. The heat transfer coefficients increased with pressure, but only for low vapour qualities. For higher qualities, the effect of the evaporating temperature became weaker and the heat-transfer coefficients merged together.

The local pressure drops of R407C as a function of the vapour quality varying the evaporative pressure at the almost constant refrigerant mass fluxes of 200 and 350 kg/m^{2}s are reported in Fig.4 and 5, respectively. The pressure drop is evaluated as the pressure drop per unit length between the pressure taps. As seen in both the figures, the pressure drop increases with the quality. The total pressure drop is mainly caused by the frictional pressure drop. It involves not only the transfer of momentum between fluid and wall, but also the transfer of momentum between the individual phases. This contribution increases with the vapour quality to a maximum between 70-90% and then decreases to the pressure drop of the vapour flow. Indeed, increasing the vapour quality, the void fraction increases, thus decreasing the density of the liquid-vapour mixture. As a result, the flow accelerates increasing the frictional pressure drop.

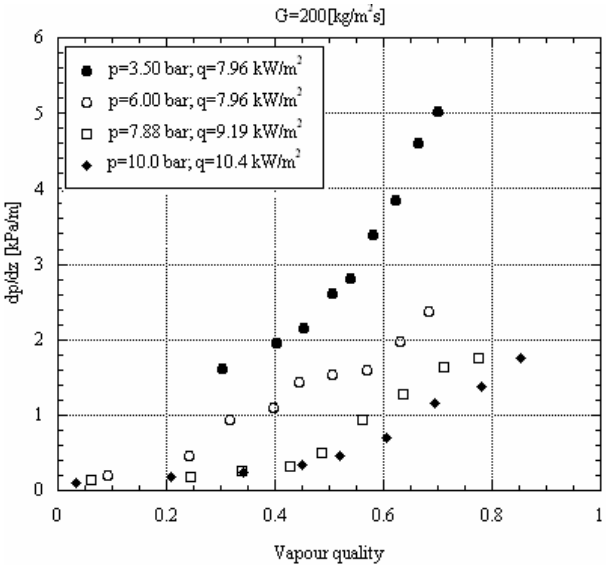

Fig.4 Local pressure drops as a function of the vapor quality at a fixed refrigerant mass flux varying the evaporating pressure.

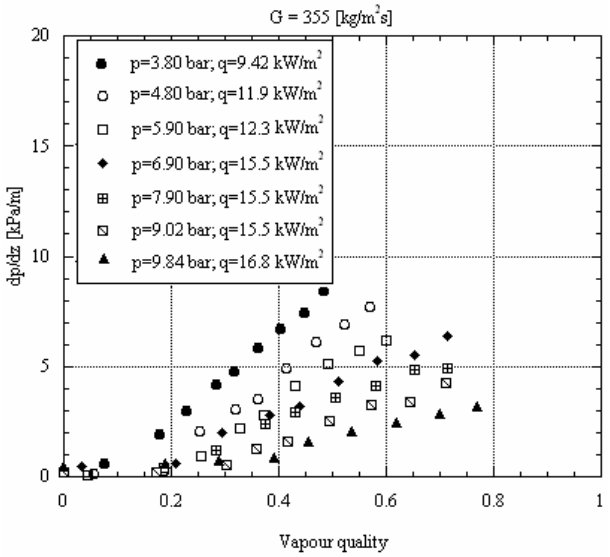

Fig.5 Local pressure drops as a function of the vapor quality at a fixed refrigerant mass flux varying the evaporating pressure.

The pressure drop decreases strongly with the increase of the evaporating pressure. Indeed, as the evaporating temperature increases, the decrease of the liquid viscosity and of the specific volume of the vaporized refrigerant leads to the decrease of refrigerant velocity and pressure drop.

CONCLUSIONS

An experimental apparatus has been set up at the University of Naples for evaluating the heat transfer characteristics of pure and mixed refrigerants. This paper presents the experimental results for evaluating the local heat transfer coefficients and the pressure drops for the zeotropic mixture R407C (R32-R125-R134a, 23/25/52 % in weight) during convective boiling in a horizontal tube. The experimental tests have been performed with a refrigerant mass flux of 200 and 355 kg/m^{2}s varying the heat flux within the range 8.0-16.9 kW/m^2 and the evaporating pressure from 3.5 up to 10.0 bar.

It is highlighted from the experimental results that the heat transfer coefficients increase with increasing the saturation pressure for a constant refrigerant mass flux. With increasing pressure, the nucleate boiling contribution to the heat transfer coefficients increases mainly due to the corresponding decrease in the bubble radius for a given wall superheat. For the higher refrigerant mass flux, the convective contribution is predominant and the dependence on the evaporating pressure becomes weaker.

The total pressure drop is mainly caused by the frictional pressure drop. The pressure drop decreases strongly with the increase of the evaporating pressure.

NATURAL GAS HEATING BOILERS EMISSIONS A RESIDENTIAL BUILDING STUDY

C. Balocco, A. Gagliardi, G. Grazzini[1], M. Sarti
Università di Firenze
Dipartimento di Energetica "S. Stecco"
Via Santa Marta 3 - 50139 Firenze
Italy

ABSTRACT

This work shows evaluation of emissions from natural gas heating systems applied to a residential building and its flats located in Firenze. Two building designs have been considered: the reference residential house proposed as standard by the AICARR and its flats, and the same but with higher insulation. The operating response of different boilers due to the hourly heating power demand of building has been studied. The CO and NO_X emissions have been evaluated during the heating season and also for each month. Results show that the centralized boiler is more suitable to the building heating demand and it has lower emissions impact.
Key words: domestic burner; natural gas combustion; emissions; control.

INTRODUCTION

High ozone levels, summer smog in cities, forest depletion and the threat of irreversible changes in climate provide the only answer of drastic reduction of air pollution. The White Paper [1] has introduced emissions standards in the European Communities Countries focusing high attention on the fact that a third of our energy consumption and the resulting emissions can be ascribed to domestic heating and hot water production. The Kyoto Protocol for greenhouse gases and the introduction of emission standards rouse several studies, researches and technologies for low NO_X emission of small-scale combustion equipment.

There are many measures adopted in building design and there are also many laws in each European Country about energy saving and integrated energy use with particular attention to sustainable development and environmental pollution [2,3,4,5,6]. So recent developments in materials and technologies for the energy conservation, have opened new possibilities for reducing the total energy consumption in

[1] Correspondig author: Phone +390554796242 Fax:+390554796342 E-mail:ggrazzini@ing.unifi.it

residential buildings and for lowering the NO_X and CO_X emissions, while maintaining acceptable comfort levels.
There are many certification schemes to identify products with different degrees of energy efficiency. Some are specifically oriented to environmental effects taking into account emissions from the use of appliances and the life-cycle sustainability of the product. There is abundant literature [7,8,9,10,11,12,13,14,15,16, 17] concerning greenhouse gas emissions reduction, but not so ample [18,19,20,21] on the emissions from domestic heating systems for different buildings.
The introduction of new gas burner technology by using the V-shaped flame stabilised at the centre of the burner blade [3,20,21,23,24], the modulating fan powered premixed low NO_X burners [16,24], and the new catalytic combustion technology for different applications for condensing boilers and water heaters [25], needs a flexible and critical approach. Looking at the many existing heating old systems in buildings, not all of them are able to meet these new combustion techniques. The V-shaped flame technique bases on an extended bladed combustion front with low mean temperatures and low NO_X, CO_X, HC emissions [17,06]; fully aerated premixed burner technology provides the lowest NO_X emission values and low CO_X and other air borne pollutants [3,19]; flameless catalytic combustion applied to domestic heating systems, then catalytically stabilised and completely catalytic radiation boiler are recently studied but not so adopted and diffuse in the real plant systems [22,23,25].
In particular there are not studies in transient conditions of domestic and centralised natural gas boiler applications.
The aim of this work is to investigate the performances in transient conditions of different gas heating systems for a typical residential building.
CO_X and NO_X emissions related to the heating systems working hours at different load have been analysed for the heating season by using experimental data and the climatic data of the standard year in Firenze.

THE METHOD

Building and its plant for heating and domestic hot water production have been considered as an integrated system. Three kinds of heating boilers and different regulations of gas burners have been considered:

- a wall mounted boiler with room sealed, 25 kW nominal power and modulating low NO_X burner with drawing up fan;
- a base boiler with open chamber, low NO_X burner with on-off regulation and 35 kW nominal power;
- a wall mounted boiler with conventional burner, on-off regulation and 25 kW nominal power.

Experimental results from direct measurements of CO, CO_2 and NO_X emissions for the considered boilers, reported by Sarti [26, 27], have been used. The studied building is the residential house proposed as standard by the AICARR (Italian Air Conditioning Association) in the '60's. Four similar flats located on two levels compose it. To evaluate the heating needs for the whole building and for each flat, the Italian Standard UNI EN832 and UNI EN ISO13789 have been used [28,29,30]. An appropriate computational tool was built by using interactive spreadsheets. The method is based on a steady state energy balance for each zone with an allowance for external temperature variation, and an utilisation factor taking into account the effect of thermal internal and solar gains. The hourly climatic data have been used [31].
The gain utilisation factor is evaluated as a function of the gain to load ratio and of a thermal inertia parameter expressed by the time constant of the zones for each flat. The same was made for the building. Each flat and the whole building have been evaluated separately because of different heating systems and related to different burners considered. Heating energy need for the building agrees to the imposed value due to DPR 412/93 Italian Standard [28], considering a fixed internal temperature value of 20 °C with a tolerance of ± 2 °C.
To compare the performances of the studied boilers, working with modulating or intermittent regulation, also the same building, with higher

insulated envelope, has been considered. New building data and comparison between the two thermal peak load are shown in table 1.

Thermal transmittance [W/m^2 K]	**Reference**	**High insulated**
Glass wall	2.9	2.3
Opaque wall	1.22	0.5
Roof	1.52	0.51
Floor	1.4	0.34
Nominal peak load [kW]		
Building	30.49	19.85
Flat	7.94	4.78

Table 1: Thermal characteristics of reference and high insulated building.

The nominal power of the studied boilers is higher than the maximum thermal load calculated for building and flats. On the other hand, only transient condition emissions of these boilers are available.
Hot water demand has been calculated separately from heating demand. A correlation equation that relates the water needs per day W has been built with reference data [32,33,34,35] as a function of users N:

$$W = 0.0639\ N + 65.995 \ ; \ R^2 = 0.1129 \qquad (1)$$

R is the R-squared value used to evaluate the reliability of the regression line.
Regression equations reported in some reference models [36,37] are comparable to the above calculated. The hourly typical domestic hot water trend, for a 3 persons average family, built by experimental data [32,33,34,35], is reported in figure 1.
Considering for each flat that a tap opening duration of about six minutes, hot water demand controls the power supply. For a water mass flow of 0.2 kg/s with a rise temperature of 30 °C, the requested power is 25 kW, which meets the boiler's one. Total hot water consumption evaluated considering same taps opening, is greater than that shown in figure 1.

The 35 kW boiler alone doesn't satisfy hot water power demand for the whole building; then a water storage tank has been considered. By taking four delivering taps for each flat, results a

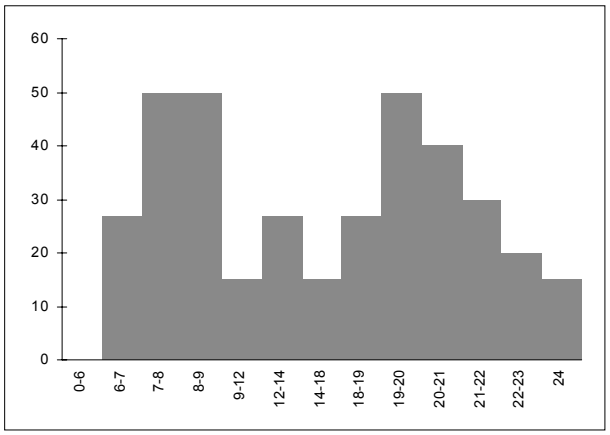

Fig.1: Typical domestic hot water load - 3 persons average family.

contemporary factor of 30% [38]. In table 2 the considered water flow rates for the different sanitary equipments are given.

Sanitary equipments	**Flow rate [l/s]**
1 bath sink	0.10
1 bidet	0.10
1 kitchen sink	0.20
1 shower	0.15

Table 2: Sanitary equipments flow rate for a flat.

In these conditions a 300 litres hot water storage tank is sufficient for the whole building.
The 35 kW boiler can easily provide the needed water also with a 50 °C rise temperature.
For an on-off burner regulation, the heat capacity of the building has been calculated for a temperature variation of 4 K, to estimate the working and turning off period of the boiler, as a function of temperature difference. Those periods are given by:

$$\tau_{on} = (C\ \Delta T) / (P - H_{tot}) \qquad (2)$$

$$\tau_{off} = (C\ \Delta T) / H_{tot} \qquad (3)$$

Daily emissions due to heating and to hot water demand have been evaluated by:

$$E_{tot\,CO} = \sum E_{CO}\ \varepsilon\, P\, \tau_{on} + \sum E_{CO}\ P\, \tau_{H_2O} \qquad (4)$$

$$E_{tot\,NO_X} = \sum E_{NO_X} \varepsilon\, P\, \tau_{on} + \sum E_{NO_X}\ P\, \tau_{H_2O} \qquad (5)$$

where E concerns the daily CO and NO_X emissions due to heating and hot water demand; P is the boiler's power; ε is the percentage of the nominal power, always 1 for the on-off boiler. The experimental results [26, 27] have been used to evaluate CO and NO_X emissions of different boilers for domestic hot water production and heating. This calculus has been done during the legal heating season in Firenze and from 6 a.m. to 10 p.m. of each day.

RESULTS

Hourly heating load and hourly hot water demand have been calculated for flats and building. Results have been obtained for each month of the heating season. Firenze heating season is 151 days long (starting from 15 November). Heating and hot water CO and NO_X emissions for the six months have been evaluated for the low NO_X burner with on-off regulation on 35 kW nominal power boiler, for the 25 kW boiler with modulating low NO_X burner, and for the 25 kW boiler with on-off regulation conventional burner (Bunsen flame). The 35 kW nominal power boiler has been used for the building; the last two kinds of boiler have been used for each flat. Building and flats have been also considered with high-insulated envelope and the new emissions results have been compared.

The 35 kW boiler considered for the insulated building produces lower CO and NO_X emissions values, for all the heating season and also for each month, than the corresponding values calculated for the other two kinds of boiler considered for the four insulated flats (figg.2,3). Comparing monthly and seasonal CO and NO_X emissions obtained for the reference building and four flats, with the corresponding values obtained for insulated building and flats (figg.4,5), the 35 kW boiler always provides lower values than the 25 kW on-off and modulating ones. Moreover, the same

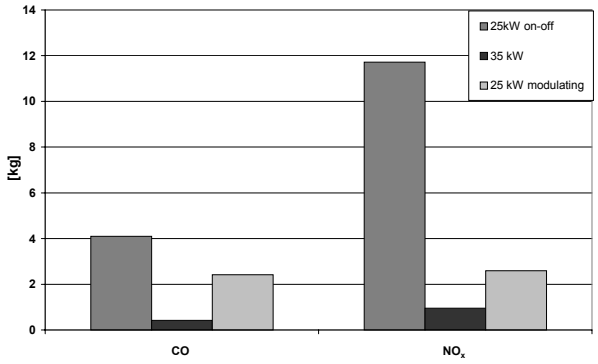

Fig.2: CO and NO_X emissions for the heating season – Building and four high insulated flats.

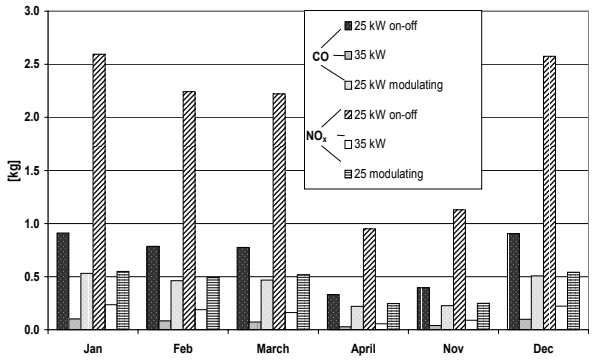

Fig.3: Monthly CO and NO_X emissions – Building and four high insulated flats.

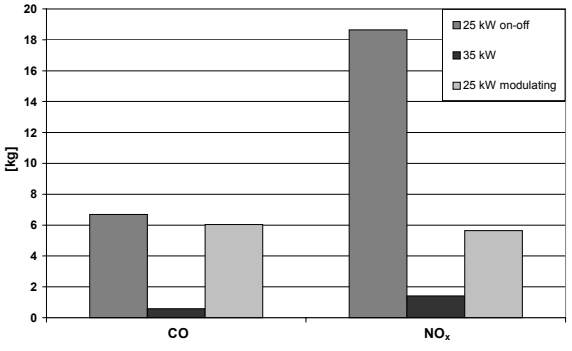

Fig.4: CO and NO_X emissions for the heating season – Reference building and four flats.

comparison between 25 kW on-off boiler with the modulating one shows that the CO and NO_X

monthly and seasonal emissions for this last kind of boiler are lower than the first one.

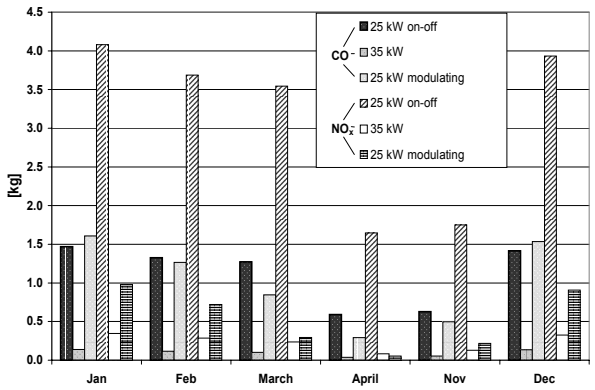

Fig.5: Monthly CO and NO_X emissions – Reference building and four flats.

A day of the whole season, when the outside air temperature value is 0°C, that is the 13th January, corresponding to the design building peak load due to the difference between inside and outside temperature of 20°C, has been considered as an example of this analysis. Figure 6 shows that modulating boiler for the reference flat works at about 30% nominal load from 6 a.m. to 22 p.m. If the insulated flat is considered, it modulates on 20% nominal load only from 6 a.m. to 12 a.m..

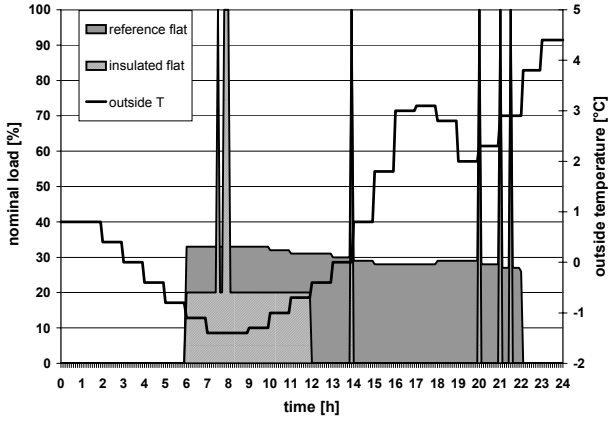

Fig.6: Rate of nominal load for the modulating boiler – Insulated and reference flat – 13th January.

In fact each flat has a boiler with a power higher than heating peak demand due to instant sanitary hot water power demand. Load peaks on the graph are due to hot water demand.

As it can be seen by comparisons at specific climatic conditions and in presence of high insulated building, it can be more convenient by energy, economic and also environmental impact point of view to use the centralised base boilers with low NO_X burner. From this study, centralised base boiler results indicated for high-insulated buildings' applications compared to modulating boilers single flats' applications.

By comparison, it can be deduced that our 35 kW nominal power base boiler provides lower emissions for all the heating season and for each month.

Transient condition emissions data for a condensing boiler of the same power and with modulating gas burner are not available, but the Authors believe they'll be lower.

CONCLUSIONS

Natural gas domestic boilers with different burners have been compared for building and household applications. In particular a reference building and its flats with two different envelope insulations, supplied by different boilers, have been considered. CO and NO_X emissions for the heating season and for each month have been calculated using experimental transient conditions results [26]. The more reliable domestic boiler application depends on the local climatic conditions and the connected building heating energy demand, but also on its operating conditions during defined daily heating time. Existing and new centralised base boilers are more suitable for buildings energy retrofitting especially if they are connected to the actual gas and temperature sensors [12]. The analysis was limited to data available to the Authors, so a centralised modulating boiler was not considered.

INTRODUCTION

This paper deals with "on site power production", namely based on small size co-generative (CHP) plants.
Distributed electricity generation allows to catch many more opportunities of energy savings, arising from the use of heat released by mechanical work producing processes [3,4,6].
Main issues are control flexibility, investment cost containment, and the pursuit of lower operation and maintenance costs [9].
Distributed generation means producing energy on site, where it is required, thus reducing electric power flowing along transmission lines. In order to be competitive with the electricity produced by larger plants, which is available from the mains, it will be required to control "clusters" of small plants, large enough (in terms of both number of units and total installed power) to be economic [8]. Any single small plant, so far as it works independently (though connected to the electrical grid), produces more costly energy: scale economy can be recovered by means of a great number of small units rather than of a restricted number of large plants.
The best results can be achieved with highly standardised units, suited to be grouped in batteries, preferably coupling units of different size (e.g. a CHP plant could reach 600kW with 2x100kW and 2x200kW modules).
Suitable control logics will allow to reach the best thermodynamic efficiency in any load condition, as well as to yield to renewable energy units whenever they are available, thus balancing undesired effects of small size [7,10].
The presence of a large number of small units gives rise to the question as to whether all the units should better be modulated their load together, or should advantages be obtained by cascading, i.e. starting the units in sequence on increasing load, while keeping running plants mostly at a steady state.
The problem was set down quite early in the history of CHP plants (see e.g. [1]), but outcomes were fairly against cascading, the main issue being the slow start up of steam units, the only kind of prime movers suitable for cogeneration at that time.
In this work a convenient control logic is developed, that pursues technical-economical optima: a case study of a modular system applied to a CHP plant for hospitals is presented, and the suitability is demonstrated by comparing cascaded to uniformly shared load control. The same electric and heat loads vs. time (functions extracted from real cases) are imposed on both cases, for which the price sensitivity among energy vectors (fuels, electricity, biomass, etc.) is given parametrically [9].

UNEVENLY SHARED LOADS

In order to find out suitable conditions as to whether the load must be shared in equal or different amounts among plants in a cluster, the simplest cluster is analysed, i.e. a plant consisting of two equal units.

Power plants

Let a case where only work production is present be first considered. The Willans (or consumption) line ($\dot{F}$ vs. $\dot{W}$) for one unit is plotted in fig. 1.

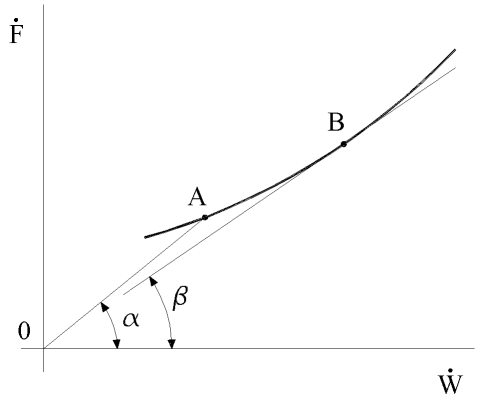

Fig. 1: Properties of Willans line

For any given point on the curve, A, the slope of the straight line ($\tan\alpha$) connecting to the origin O, represents the heat rate, while the efficiency is

$$\eta = \frac{\dot{W}}{\dot{F}} = \operatorname{cotg}\alpha$$

The best efficiency is easily found, and it is remarked that, where the projecting straight ($\overline{OB}$) is tangent to the Willans line, efficiency may show an optimum ($\operatorname{cotg}\beta$) at a lower than maximum load.

Passing to the set of two units (fig. 2), the Willans line is plotted for one unit, which is also representative of the behaviour of the set, provided that values are read on the scales ($2\dot{W}_1$,$2\dot{F}_1$), as far as the load is evenly shared between the units.

A given load $\dot{W}^*$ (scale $2\dot{W}_1$) can be either satisfied by running both sets at E, or by running one at a lower (G) and the other at a higher (H) than E power output, the only condition being

$$\dot{W}_A + \dot{W}_B = \dot{W}^*$$

that, passing from ($\dot{W}_1$,$\dot{F}_1$) to ($2\dot{W}_1$,$2\dot{F}_1$) scales, is represented by point K, i.e. the arithmetic average on the graph for both work and fuel energy rate.

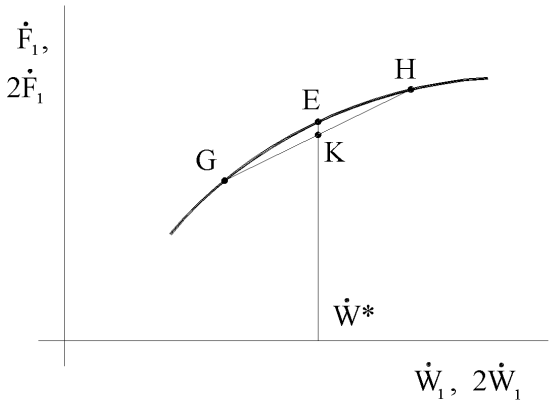

Fig. 2: Conditions for uneven load sharing

Point K yields a lower or higher value of $\dot{F}$ than point E depending on the curvature of the Willans line, thus determining a condition for uneven load sharing to be convenient from an energy saving viewpoint. If the consumption line is convex upward, then K lies beneath E, and fuel energy saved is given by

$$\Delta(2\dot{F}_1) = \dot{F}_{=} - \dot{F}_{\neq} = 2(\overline{KE})$$

In this case the best efficiency is sought by so choosing G and H as to maximise $\overline{KE}$. Of course benefits from cascading can be expected in terms of fuel savings, in the circumstances outlined for the convenience of non uniform load sharing.

CHP plants

When a CHP plant is considered, conditions can be identified in which electrical (work) and heat loads can be conveniently split, in a similar way as described above. Lines analogous to Willans' can be drawn, namely ($\dot{F}$,$\dot{W}$) at $\dot{Q}$ = const, ($\dot{F}$,$\dot{Q}$) at $\dot{W}$ = const, where, of course, the energy input $\dot{F}$ represents the whole fuel consumption of the CHP unit.

When plant features include the possibility to supply heat independently - to a certain extent - of work, at least one control device exists which determines how much of energy is diverted from work to heat production (e.g. a by-pass flap in a GT exhaust duct). Let z be the position of this control device, such as to have maximum heat yield for z = 1, minimum at z = 0. It is sometimes easier to plot ($\dot{F}$,$\dot{W}$) and ($\dot{F}$,$\dot{Q}$) lines at z = const.

Limiting the number of devices controlling λ in any single unit to one, for a CHP plant consisting of two units, called to match assigned electrical $\dot{W}^*$ and thermal $\dot{Q}^*$ loads, four are the control variables, namely $\dot{F}_A$, $\dot{F}_B$, z_A, z_B ; therefore, assuming no energy storage, i.e. loads are met at any time, there are two degrees of freedom in plant control. There may be chances for optimisation, if an objective function is identified, suitably dependent on the parameters remaining free.

In the following an energy conservation criterion is assumed, as to minimise fuel cost, on the basis of a quasi-steady approximation.

In the more general case of a cluster made of many CHP plants, each comprising several units for a total number N of units, as far as the couple ($\dot{W}^*$,$\dot{Q}^*$) can be considered assigned to the whole cluster, the degrees of freedom are easily recognised to be (2 N – 2). The problem becomes hard to solve on a rational basis.

Hence a simple case will be analysed, in order to throw some light on the subject.

APPLICATION TO A SAMPLE CASE

A sample case is introduced, which consists of two small co-generative gas turbine units (350 kW rated electrical power), grouped into a CHP plant.

Brief description of the unit

The unit is a regenerative GT, compressor and expander are radial, single stage machines, the regenerative heat exchanger (RHX) is of the plate-fin type. A co-generative heat exchanger (QHX) is installed downstream RHX; a diverter allows

part of the exhaust gas flow rate to bypass RHX, thus increasing $\dot{Q}$ through QHX. In this application only hot water (possibly superheated) is produced by QHX.
The flap diverter is the device in charge of controlling λ, so that z represents its position in a dimensionless fashion.

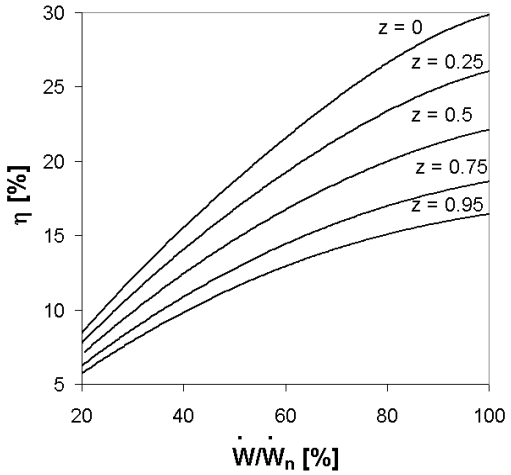

Fig 3: Electric efficiency of the GT unit

The performance of the GT unit, in its standard, regenerative setup, and the effect of the RHX bypass are shown in fig. 3, in terms of overall efficiency vs. electrical load.

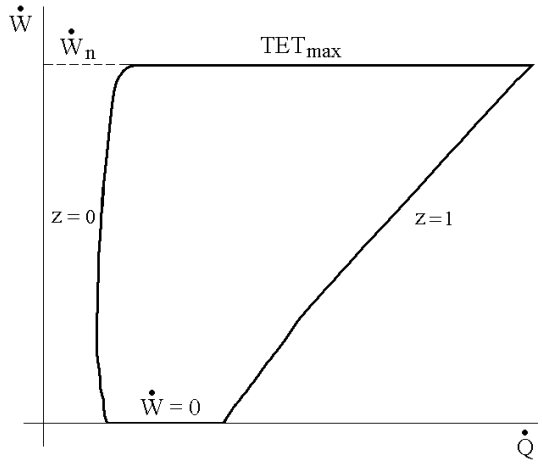

Fig 4: CHP unit operating range

The operating range of this CHP unit is shown in fig. 4 [7], where the boundaries are determined (clockwise, starting from the bottom) by:

- idling ($\dot{W} = 0$)
- bypass closed ($z = 0$)
- maximum *TET*
- bypass fully open ($z = 1$)

Constant z lines are significant, at least because they fix the left and right ends of the working field, and also:

- $z = 0$ means minimum (in the example) $\dot{Q}$ and describes how the unit behaves in its non-CHP set-up
- $z = 1$ shows what can be done in case heat is supplied at the highest possible rate.

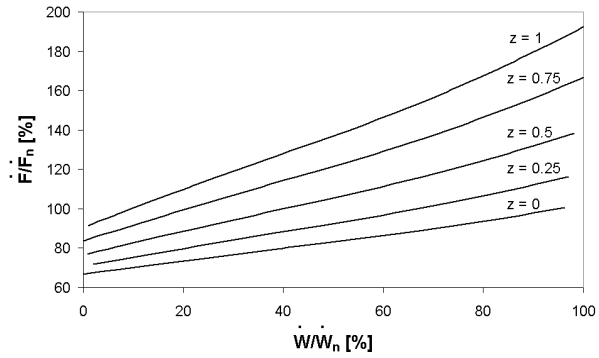

Fig 5: constant z lines, fuel consumption vs. electric power

In fig. 5 fuel energy rate is reported against electric power at z = const: the lower is a true Willans line, the others are akin. The curvature (slightly convex downward) of the $z = 0$ line, demonstrates that this kind of GT unit, when used in a non-CHP mode, should not experience energy savings from a cascaded control. This holds only in steady operating conditions.

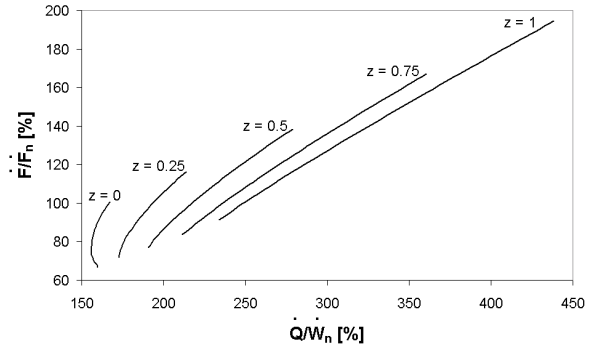

Fig. 6: constant z lines, fuel consumption vs. heat load

Fig. 6 reports fuel energy versus heat (rate terms) at constant bypass flap position. It is remarkable that also at $z = 0$ a significant rate of useful heat can be supplied. This is because the exhaust gas temperature at RHX exit is well above compressor

outlet temperature, i.e. enough to transfer heat to hot water (probably a worse result would be obtained if steam generation were required).

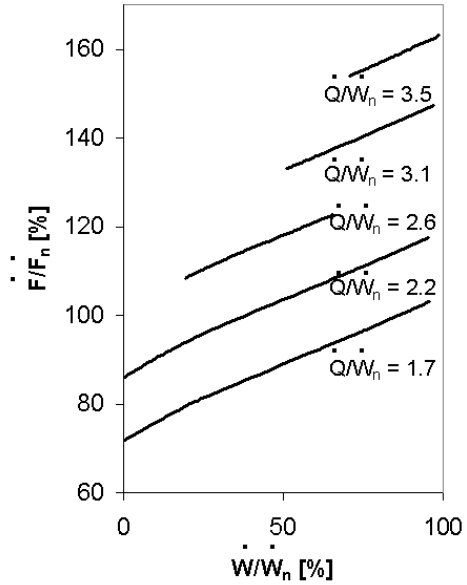

Fig. 7: constant heat load lines

The curvature of z = const lines suggests that uneven heat load sharing is convenient, at least in the lower range of thermal output.

For assessment purposes constant $\dot{Q}$ (fig. 7) and constant $\dot{W}$ (fig. 8) lines are introduced.

In fig. 7 a range is recognized where

$$\left.\frac{\partial^2 \dot{F}}{\partial \dot{W}^2}\right|_{QQ} < 0$$

while in fig. 8 it is found that

$$\left.\frac{\partial^2 \dot{F}}{\partial \dot{Q}^2}\right|_{WW} \cong 0$$

actually throughout the operating field.

Hence conditions exist for electric load cascading to be beneficial: uneven distributions of thermal load might also be found consequently necessary, because of the shape of the operating range. It is noteworthy that by introducing heat exploitation, what was not convenient beforehand, has now become beneficial.

It is necessary to further investigate on the suitability of cascaded control by means of simulation [10], bearing in mind that both conclusions hitherto, and results from the next point, are valid for the particular CHP arrangement considered [7].

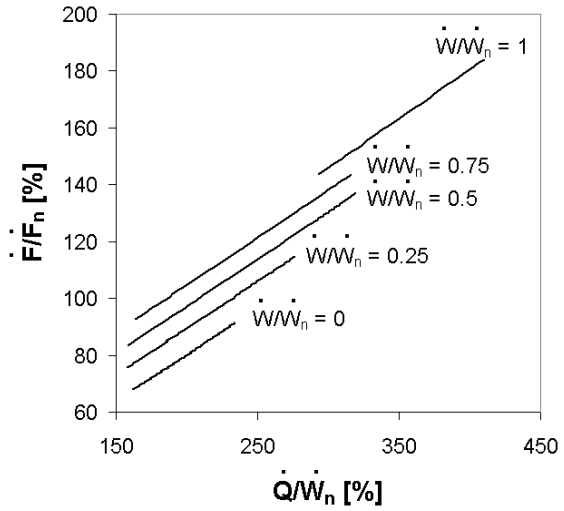

Fig. 8: constant electrical power lines

Method of analysis

To find the optimum combination of parameters (sharing heat and electrical load between the two plants) a numerical procedure has been employed, consisting of a minimum search algorithm linked to a GT and heat exchangers thermodynamic model. The objective function was the total fuel consumption in steady conditions.

An algorithm was first tested, based upon the aforementioned criterion of the second derivatives of fuel flow rate.

Later a different criterion prevailed, that requires the same model to be used for optimising both design and control/management during operation: for this reason a thorough search throughout the operating field is adopted, which permits deterioration of performance to be taken into account, when coupled to a self-learning monitoring system.

Results highlighted that the best conditions are obtained with uneven load distribution, one unit being called to supply both more work and more heat than the other.

Simulation results

A simulation has been carried out throughout one year [10], starting from meteorological records for heat request, and from typical load courses for the particular application: figs. 9 and 10 show control parameters vs. time, for part of the simulated time.

Two control modes are compared, load cascading and even sharing. In both modes a control system

is envisaged, performing functions that a dispatcher will be committed in a larger cluster.

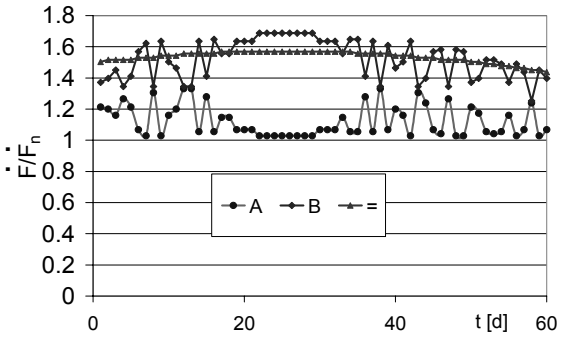

Fig. 9: simulated fuel energy rate vs. time

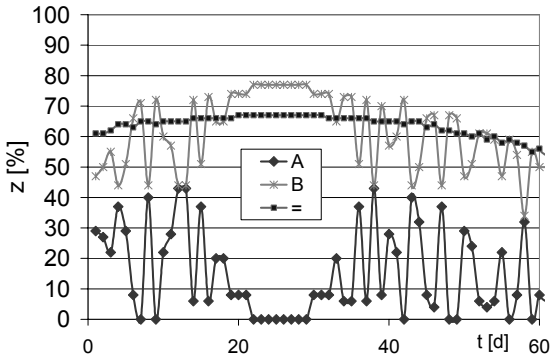

Fig. 10: simulated diverter flap position vs. time

This device automatically forces the total heat produced by the plant to match heat users' requests, while the electrical power is so controlled as to maximise cash flow, mismatches to internal requests being compensated by the mains. In this process the dispatcher-controller utilises predictive-self learning algorithms [8,10] committed to assure the target *FESR* value to be reached on an annual basis, which entitles the plant to be granted CHP benefits.

In order to give an idea of how cascaded control affects the operating points of the two units in the simulated plant, in fig. 11 an outlook at typical load unevenness is given through a couple of samples, each representing an instant situation: a high total electrical and a high total thermal load case are reported.

Economic analysis

The results of the thermo-economic analysis[2] are summarised in tab.1, in terms of *FESR* and of *NPV* per unit installed electrical power, $\dot{W}_n$. During simulations the same electric and heat loads vs. time are assigned to both cases, and the price sensitivity among energy vectors is given parametrically [9]. *NPV* is evaluated for a 10 years lifetime.

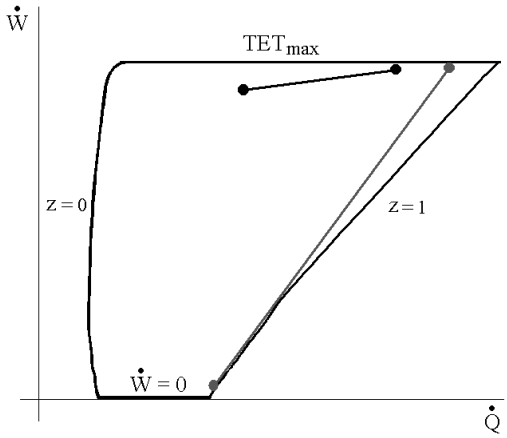

Fig. 11: split operating points for cascaded control

Operation has been simulated by applying both control/monitoring strategies to the same request for electric and thermal load, e.g. a given hospital unit in the same climate conditions.

Steady state performance of the cogeneration unit, as a function of control parameters and of environmental conditions, has been represented by matrices, obtained from mass and energy balances, matching of GT components and heat exchangers, on design as well as off-design conditions of the CHP plant.

The data supplied by the model (fig. 12, *FESR* map as a function of $\dot{Q}$ and $\dot{W}$) highlight an increasing irreversibility as *z* increases, just like what happens in "duct burner" plants when raising the afterburning ratio; because in both cases the energy of added fuel is utilised at similar, fairly low temperature values.(250 – 650°C).

For low *z* values, the above solution is however more efficient than afterburning and it looks sim-

[2] See Appendix for definitions of economic and performance criteria

pler and more compact: it is obviously more effective than the utilization of donkey boilers.

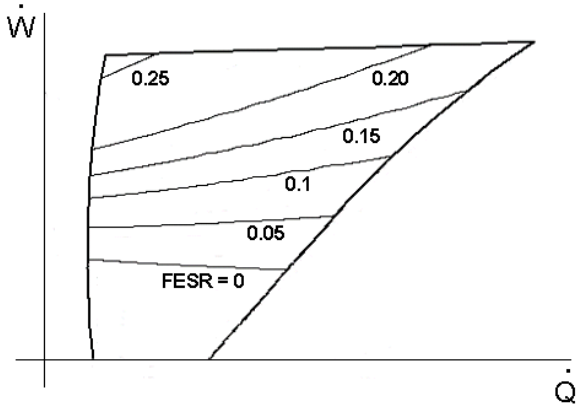

Fig. 12: *FESR* map of the single unit

The model was obtained by using Matlab-Simulink and validated through comparison with data supplied by the manufacturer in full regenerated as well as in many by-pass conditions. *FESR* was calculated by reference – for separate generation – to the average efficiency of Italian thermoelectric power plants (i.e. 0.38) and to the reference efficiency of civil boilers (taken as 0.8) according to the Italian rules in force. Start up, load connection and stop transients, which cannot be represented by the steady state model, have been assessed by the simulator according to suitable algorithms. The same tariffs for natural gas and electric energy (taken in or supplied by the plant) has been used to assess the cash-flow while taking the same operation and maintenance costs into account, although "even" and "uneven" control modes may cause small, but hardly to assess, differences.

The investment profitability for is assumed 5% net of the inflation drift of electric/gas energy carriers and present costs.

Parameterization in this simulation model of elasticity between fuel cost and electric energy value (Y_f/Y_w) is possible and shows in all cases an improvement of economic as well as of thermodynamic results when this ratio is reduced.

This and further aspects cannot be discussed in this Paper because of lacking space.

Improvements from uneven load sharing exist, but they are tiny comparatively to the complexity of cascaded dispatching, which is significantly increasing with the number of units in a cluster.

The results strictly depend on the particular type of GT employed and on CHP arrangement. It is believed that different kinds of prime movers showing more suitable features to cascaded control may give better figures: it is therefore worthwhile to account for possible benefits of uneven load sharing.

		load sharing	
		even	uneven
FESR		0.151	0.159
$NPV/\dot{W}_n$	[€/kW]	210	350

Tab.1 Thermo-economic results

Anyhow considerations other than energy based, e.g. transient behaviour of both GTs and heat exchangers, thermal stresses, components ageing, maintenance, suggest to minimise the number of units following load variations, while taking advantage of the quick start time of small GTs.

In a cluster any single module will be shifted his function periodically, from base to peak load supplier and vice versa.

Environmental issues

From the environmental point of view, CO_2 savings can be achieved through converting to cogeneration a number of heat users that otherwise produce heat (either SWH or process) separately. Passing to DER, which is cheaper thanks to a modular approach, makes the range larger of applications for which CHP plants are cost effective. This corresponds to the exploitation of *heat quarries*, i.e. thermal users not yet converted to cogeneration, as explained in [9].

CONCLUSIONS

A modular arrangement of CHP plants belonging to an independently controlled DER cluster allows to better follow instant loads, and to increase the fraction of electricity produced through cogeneration.

Modules can easily be standardised, thus improving reliability and availability, and reducing operation costs.

In this scenario, while the load is shared among several modules, units work out to be better utilised if a cascaded control is applied. Appropriate dispatcher logics, together with a suitable choice of components, can lead to energy savings, by seeking at any time the best set of control parameters.

APPENDIX

The parameters described in this appendix comply with the criteria assumed in [2].

FESR is a performance criterion developed for CHP plants, that involves comparison between the fuel required to meet the given electricity and heat loads with that required in separate conventional plants to meet the same loads, say in a conventional electric power station of overall efficiency $(\eta_0)_c$ and a "heat only" boiler of efficiency $(\eta_b)_{th}$. Then the fuel energy saved is

$$\Delta F = \frac{Q_u}{(\eta_b)_{th}} + \frac{W}{(\eta_o)_c} - F,$$

and the fuel energy saving ratio is defined as the ratio of the saving (ΔF) to the fuel energy required in the conventional plant

$$FESR = \frac{\Delta F}{\left(\frac{Q_u}{(\eta_b)_{th}} + \frac{W}{(\eta_o)_c}\right)} = 1 - \frac{(\eta_o)_c / (\eta_o)_{CHP}}{\left[1 + \left(\lambda_{CHP}(\eta_o)_c / (\eta_b)_{th}\right)\right]}$$

where $\lambda_{CHP} = \frac{Q_u}{W}$ is the useful heat to work ratio of the CHP plant, and $(\eta_o)_{CHP}$ is its overall efficiency.

The net present value derived from a change type of analysis (from an existing conventional scheme to a new CHP scheme), balances extra capital cost (ΔC) against the rate of savings which arises (ΔM), mainly from the reduced use of fuel.

If the extra capital ΔC invested at time zero leads to immediate annual money saving ΔM in the first year, and this money is invested at the end of that year, subsequent years lead to identical savings and investment. These savings may be discounted back to time zero and lead to a net present value of

$$(NPV)_{(i)} = \frac{\Delta M}{({}_N f_{AP})} - \Delta C$$

where $({}_N f_{AP})$ is the annuity present worth factor, for an interest rate i over a period of N years, i.e. the life of the project,

$$({}_N f_{AP}) = \frac{i(1+i)^N}{\left[(1+i)^N - 1\right]}$$

The interest rate (*i*) can be chosen to make (*NPV*) zero after a chosen number of years, N. This value of *i*, given by

$$NPV = \sum_{K=1}^{n} \frac{CF}{(1+i)^k} = 0$$

is known as the internal rate return (*IRR*)

Donghua University, 1882 West-yan'an Road, Shanghai 200051, China

ABSTRACT

Industrial boiler plants play an important role in energy conservation, for there is huge amount of energy consumed by a great number of industrial boilers. Optimal operation of an industrial boiler plant through optimal load assignment to boilers in the boiler plant is one of the major effective methods to improve the real efficiency of the plant. It is especially convenient for industrial boiler plants to carry out optimal load assignment in practice when the boiler plants are assisted by thermal energy storage (TES) that stabilizes the load levels of boiler plants. To accomplish this, accurate load forecast is a prerequisite. Based on the analysis of recorded load data the error back propagation (BP) neural networks are used to perform the forecast of daily load curves. Combined with the segmentation of the daily load curve, the minimum-departure model (MDM) that is newly developed is used to optimally assign the plant load, which is invariant due to TES during a time segment, to various boilers in the plant, so that the boiler plant can achieve the minimum daily fuel cost. A computer program was completed and used in an example. The results show that the fuel costs of the boiler plant are reduced.

Keywords: Optimal operation, boiler plant, thermal energy storage, load forecast, load assignment

NOMENCLATURE

A	lower limit of the departure of boiler load rate
B	upper limit of the departure of boiler load rate
C	fuel cost, kg/hr
d	date
E	error function
k	ordinal number of network training epoch
L	load of boiler plant, MW
n	maximum number of time segments of a day, or boiler number in a boiler plant
n	day(s)
m	hour(s)
Q	capacity of a TES, or thermal energy stored in TES, MJ
q	output rate of a boiler, MW
R	load rate vector
R	coefficient of correlation
r	load rate of a boiler
s	length of a time segment, hr
T	vector of beginning or end time of a segment
t	time, hr
W	connection weight vector
X	vector of departure of load rates from economical load rates
x	input to neural network, or departure of load rate from economical load rate
Y	expected output of neural network in training
y	output of neural network in training
α	momentum term
Δ	incremental
η	learning rate of neural network
$\boldsymbol{\theta}$	bias vector
τ	time (o'clock), or beginning or end time pitches of a segment
¥	Chinese monetary unit

SUBSCRIPT

0	initial, or beginning of a segment, or no-load
AV	average
d	day
f	fuel
k	ordinal number of network training epoch
M	maximum
m	economical load condition
n	maximum number of time segments of a day, or boiler number in a boiler plant
rt	rated condition
w	times of load recording per hour

INTRODUCTION

When boiler plants adopt thermal energy storage (TES), usually their real energetic efficiencies increase because of stabilized load levels for the boilers in the plants. However, for a boiler plant having 2 or more boilers there is still a task to guarantee the plant to perform best in efficiency. The task is to guarantee every boiler working at its appropriate load rate so as to enable the

plant as a whole to perform best. Compared with the cases without TES, the boiler plants in question here are easier to achieve this goal thanks to the function of TES in stabilizing plant loads. Usually, boiler plants equipped with TES often adopt an operation mode of segmenting a whole workday into several time intervals (segments) with different lengths, and work at different stable load levels during the various intervals. This is helpful for the controls of a boiler plant to assign the plant loads to separate boilers in the plant optimally so that the boiler plant works with the efficiencies as high as possible, consuming the least amount of fuel. To accomplish the segmentation of a whole day, the precondition is just the accurate forecast of the load curve of that day.

In the paper a new method of optimal load assignment to working boilers is developed and combined with optimal segmentation of a workday to carry out the optimal operation of the boiler plant with TES based on the forecast of load curve of the plant.

FORECAST OF LOAD CURVE OF A BOILER PANT USING ARTIFICIAL NEURAL NETWORKS

There are load forecast techniques for industrial boiler plants[1,2], e.g., the method using cascaded neural networks (CNN) can perform load forecasts with the average errors of lower than 3%[1]. However when a boiler plant is equipped with TES, it allows the forecast error to increase to some extent. It is because when the forecasted load curve is averaged for a period by TES the positive and negative errors cancel out each other, and then the error of the averaged load level is actually much smaller than those of the forecasted load curve. For this reason, the relatively simple BP network (see Fig.1) instead of CNN, which usually forecasts the loads for boiler plants with errors smaller than that BP network does, can be applied in this paper to forecast the load curves of the boiler plants. Relatively simple algorithm for BP network results in shorter computer time, and it makes sense for operation control of boiler plants.

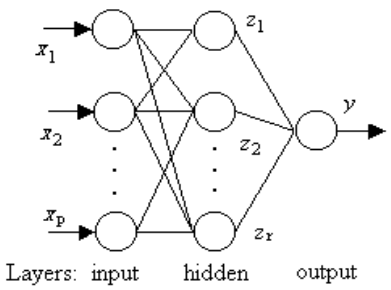

Fig.1 Structure of BP network

Usually, there are only historical load data available as a data bank for load forecasting by neural networks. For BP networks, proper preprocess of the data bank is necessary for the improvement of load forecast in accuracy. Ref.1 introduced an effective data procession by estimating the coefficients of correlation between the data in data set according to three correlation directions of "vertical", "horizontal" and "oblique" in the matrix of the data set (see Fig.2). Then select input data among the data set as the input pattern according to the coefficients of correlation that are higher enough.

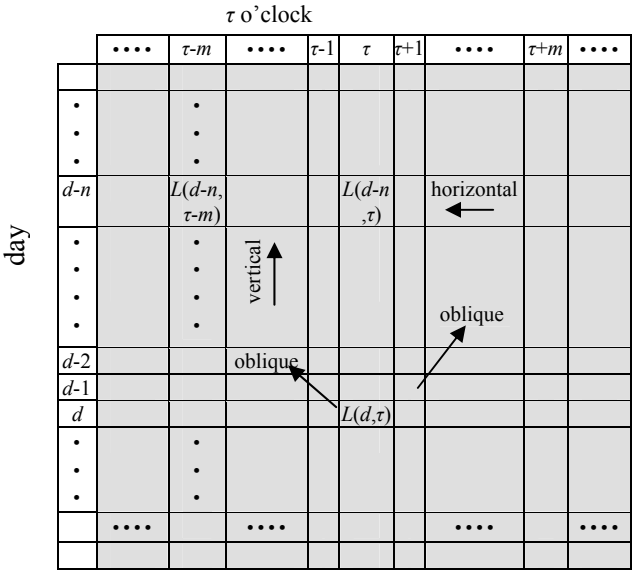

Fig.2 Matrix of data bank of hourly thermal load

A row of the data matrix that constitutes the training set for the BP network contains the load records in a whole day. As a computation example, a series of hourly load data of successive 28 workdays (excluding the weekends) from March 19 to April 27, 2004 is plotted against time as shown in Fig.3, which was recorded by a steam plant in Shanghai and now constitutes the data bank for use.

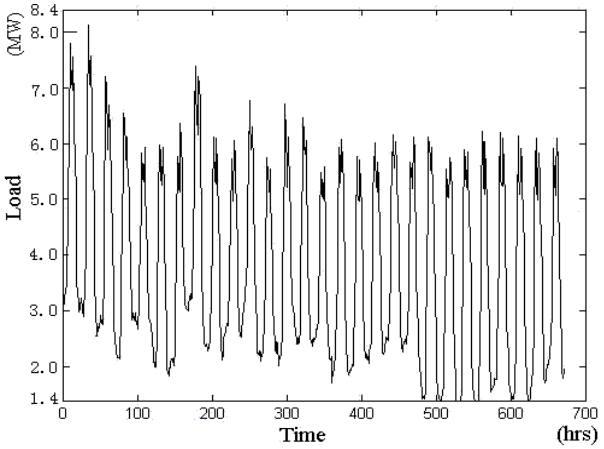

Fig.3 Data bank containing load records of 28 workdays

Similar to the method introduced in Ref.1, if $L(d,\tau)$ denotes the hourly load of the boiler plant at τ o'clock on the day of d, coefficient of correlation $R_d(n)$, which is called "vertical" (Fig.2), represents the relationship of the loads $L(d,\tau)$ on the day of d to the loads $L(d\text{-}n,\tau)$ (n=1,2,⋯ [days]) that are n days ahead of the day of d. Then $R_{d,\mathrm{AV}}(n)$ (see Table 1), representing the mean coefficient of correlation of all such $R_d(n)$s, can be easily calculated. Coefficient of correlation $R_\tau(m)$, which is called "horizontal" (Fig.2), represents the relationship of the loads $L(d,\tau)$ at τ o'clock to the loads $L(d,\tau\text{-}m)$ (m=1,2,⋯ [hours]) that are of m hours before τ o'clock. Thus $R_{\tau,\mathrm{AV}}(m)$ (see Table 1), representing the mean coefficient of correlation of all such $R_\tau(m)$s, can be calculated in a similar way horizontally.

Table 1: Mean vertical and horizontal coefficients of correlation for different n and m

Vertical		Horizontal	
n [days]	$R_{d,\mathrm{AV}}(n)$	m [hours]	$R_{\tau,\mathrm{AV}}(m)$
1	0.9739	1	0.9230
2	0.9675	2	0.8252
3	0.9730	3	0.7410
4	0.9683	4	0.6754
5	0.9668	5	0.6190
6	0.9575		
7	0.9649		

The "oblique" correlation of a load to other loads that are of the previous days and are not in vertical or horizontal directions in the data bank (Fig.2) may be useful to see if there is close relationship between them. In other words, the oblique coefficient of correlation $R_{d\tau}(n,m)$ represents the correlation of the load $L(d,\tau)$ to the load $L(d\text{-}n,\tau\text{+}m)$ (n=1,2,⋯; m=±1, ±2,⋯) and can be calculated in an analogous way. Therefore, the mean oblique coefficient of correlation $R_{d\tau,\mathrm{AV}}(n,m)$ is obtained in the same way (see Table 2)

Table 2 Mean oblique correlation coefficients for n=1 and different m

m [hours]	$R_{d\tau,\mathrm{AV}}(n,m)$
-2	0.4655
-1	0.4912
+1	0.4887
+2	0.4599

Obviously, it is reasonable that the load data with higher correlation to the future loads that are to be tested in training or to be forecasted could be selected as the input to the BP network. According to this principle, two kinds of 3-layer BP networks have been constructed, and correspondingly there are two groups of the networks including totally 24 BP networks, each serving a single hourly load of a day to be tested in training or to be forecasted. For the first group of networks, the input layer has 10 neurons for the input of 4 "vertical" records (n=1,2,⋯,4), 4 "horizontal" records (m=1,2,⋯,4), and 2 "oblique" records (n=1, m=±1), and the hidden layer has 7 neurons, which has been determined through trial-and-error method. The second group including 8 networks is used for testing or forecasting the loads of 7-10 o'clock and 20-23 o'clock, to which the coefficients of horizontal correlation are lower than average values. Therefore the number of "horizontal" records as the input to the network of the 2nd group should decrease to 2 and some other factors should be considered as the input so that the forecast errors do not increase at all. As a result of many calculation trials, the input layer of the network of the 2nd group can have 11 neurons for the input of 4 "vertical" records (n=1,2,⋯4), 2 "horizontal" records (m=1,2), 2 "oblique" records (n=1, m=±1), and the records of the average, maximum and minimum loads of the day before the day to be tested in training or to be forecasted. The hidden layer of the 2nd group has 9 neurons also determined by trial-and-error method. The output layer of the network in both groups has only one neuron for output. In brief, the BP network structures can be expressed as 10-7-1 and 11-9-1 for the 2 network groups respectively.

A total of 648 records (from March 19 to April 26) were used as the training set. After the data in the training set had been normalized[1] totally (from then on all the load records $L(d,\tau)$ represented the normalized ones), the BP networks could be trained in the following way. Take the load records of the first 5 days as the first data group for the first training epoch. For the τ-th network of the 1st network group, use 10 records in "vertical", "horizontal", and "oblique" directions to the load of τ o'clock on the 5-th day as the input to the network (see Table 3). Then the iteration of training through the network could be carried out according to the epoch sequence in Table 3 and was repeated from the beginning of Table 3. The iteration did not stop until any stop condition reached. The 16 networks of the 1st network group could be trained in the same way. The 8 networks of the 2nd group could be trained similarly, while the difference was only in the different input sets, which was mentioned in previous paragraph.

Table 3 Scheme for training the 1st network group

Epoch No.	Day ordinal in the sample: d	Input (x_i) of BP network
1	5	$L(1,\tau)$,⋯,$L(4,\tau)$; $L(5,\tau\text{-}1)$,⋯,$L(5,\tau\text{-}4)$; $L(4,\tau\text{-}1)$,$L(4,\tau\text{+}1)$*
2	6	$L(2,\tau)$,⋯,$L(5,\tau)$; $L(6,\tau\text{-}1)$,⋯,$L(6,\tau\text{-}4)$; $L(5,\tau\text{-}1)$,$L(5,\tau\text{+}1)$*
⋮	⋮	⋮
25	29	$L(25,\tau)$,⋯,$L(28,\tau)$; $L(29,\tau\text{-}1)$,⋯, $L(29,\tau\text{-}4)$; $L(28,\tau\text{-}1)$,$L(28,\tau\text{+}1)$*

*If $\tau\text{-}n \le 0$, $\tau\text{-}n$ should be substituted by $24 - (\tau\text{-}n)$. If $\tau\text{+}n \ge 24$, $\tau\text{+}n$ should be substituted by $\tau\text{+}n\text{-}24$.

In the training, the error function E, the weight vector $\mathbf{W}$, and the bias vector $\boldsymbol{\theta}$ are calculated by the BP networks. The adaptive variable learning rate method with momentum terms is adopted to improve the learning efficiency and calculation convergence of networks. The incremental vectors $\Delta\mathbf{W}$ and $\Delta\boldsymbol{\theta}$ are introduced for updating the weights and biases. Equations 1 to 5 describe the calculation of what mentioned above.

$$E = \frac{1}{2}\sum_{k}(y_k - Y_k)^2 \tag{1}$$

$$\mathbf{W}(k+1) = \mathbf{W}(k) + \eta(k)\frac{\partial \mathbf{E}}{\partial \mathbf{W}(k)} + \alpha\Delta\mathbf{W}(k) \tag{2}$$

$$\boldsymbol{\theta}(k+1) = \boldsymbol{\theta}(k) + \eta(k)\frac{\partial \mathbf{E}}{\partial \boldsymbol{\theta}(k)} + \alpha\Delta\boldsymbol{\theta}(k) \tag{3}$$

$$\Delta\mathbf{W}(k) = \mathbf{W}(k) - \mathbf{W}(k-1) \tag{4}$$

$$\Delta\boldsymbol{\theta}(k) = \boldsymbol{\theta}(k) - \boldsymbol{\theta}(k-1) \tag{5}$$

where Y_k denotes the expected outputs in training, viz., the corresponding load records in the data sample, and y_k denotes the forecasted outputs in training, viz., the outputs produced by the network calculation. k is the ordinal number of network training epoch. η is the learning rate and α the momentum term.

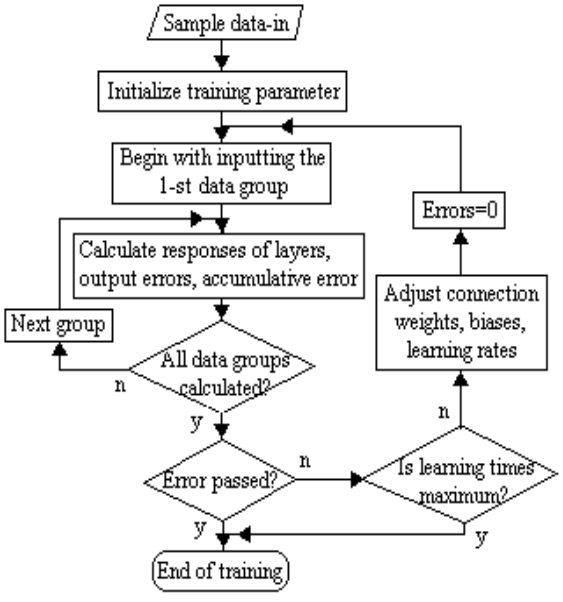

Fig.4 Flow chart of network training

For the training and later for the forecasting, values should be set to some factors as follows. The momentum term α = 0.90, and the learning rates: the initial η_0 was set 0.01, while the increasing rate of η was set 1.05 and the decreasing rate of η was set 0.70. Finally, 0.01 was set to the training errors, which was one of the stop conditions of training.

Fig.4 shows the process of the BP network training. When the training finished, use 120 load records (from April 20 to April 26, 2004 excluding the weekend April 24 and 25) in the data bank as the testing set. The trained BP networks gave the testing results as shown in Fig.5 and Fig.6. The mean relative error of the hourly tested loads on April 26 was 6.07%. The properly trained BP networks could be used to perform the load forecast through computer simulation for the boiler plant. Fig.7 shows the forecasted hourly loads on April 28 and the corresponding relative errors are plotted out versus time on Fig.8. The mean relative error was 7.28%.

In fact there are a number of other types of neural networks can forecast the load curves with higher accuracies. It is on purpose, however, to use BP network here to prove later in the text that BP network is applicable in the case when TES exists in boiler plants.

SEGMENTATION PATTERN OF A WORKDAY FOR THE OPERATION OF TES

When a boiler plant is assisted by TES, it works at stabled load levels in several segments in a workday. The number, the lengths and the starting moments of the segments depend upon the daily load curve. In other words, the segmentation of a day should satisfy the daily load curve. Suppose a thermal storage tank has a storage capacity of Q (MJ) and the daily load curve of the boiler house is denoted by $Q'= f(t)$. A segmentation pattern could be described as the following. A whole day is divided into n time intervals (segments). The i-th interval is from moment t_{0i} to moment t_i, s_i denoting the length of the i-th segment. The average load, Q_{AVi}, during the i-th segment is expressed below.

$$Q_{AVi} = \frac{\int_{t_{01}}^{ti} f(t)dt}{s_i} \qquad (6)$$

Equation 7 defines the average load function, Q_{AV}, when $t \in [t_{01}, t_n]$. In fact, t_n is just t_{01} after 24 hours.

$$Q_{AV} = Q_{AVi} \qquad t \in [t_{01}, t_n],\ i = 1,2,\cdots,n \qquad (7)$$

The thermal energy stored in the storage tank at moment t could be calculated by the integral of the difference of Q_{AV}–Q' against t between the limits of t_{01} and t.

$$Q_i(t, \mathbf{T}_0, \mathbf{T}) = \int_{t_{01}}^{t} (Q_{AV} - Q')dt$$

$$i=1,2,\cdots,n; \quad t \in [t_{01}, t_n] \qquad (8)$$

where

$$\mathbf{T}_0 = (t_{01}, t_{02}, \cdots, t_{0n})^T, \qquad \mathbf{T} = (t_1, t_2, \cdots, t_n)^T \qquad (9)$$

The difference between the values at the highest point and the lowest point of the integral curve, viz. $Q_i(t,\mathbf{T}_0,\mathbf{T})$, is the maximum amount of thermal energy Q_M that need be stored in the storage tank. The segmentation pattern can satisfy the load curve if Q_M does not surpass the storage capacity Q. It follows that

$$Q_M = \max Q_i(t,\mathbf{T}_0,\mathbf{T}) - \min Q_i(t,\mathbf{T}_0,\mathbf{T}) \le Q \qquad (10)$$

It is obvious that because the starting moment of a segment is just the ending moment of the previous segment, a set of n and $\mathbf{T}_0$ determines a segmentation pattern and Q_M as well. Generally speaking, there may be a lot of segmentation patterns can meet Eq.10 and they as a whole constitute a feasible domain of segmentation patterns.

Take a segmentation pattern arbitrarily from the domain. There are n segments and each has an averaged load on which the boiler plant works. By using MDM method of optimal load assignment that is going to be introduced in next section of the paper, the average load in every segment can be assigned to separate working boilers in the plant optimally. Then an optimized operation mode for the boiler plant is obtained corresponding to the segmentation pattern and the daily total fuel costs can be easily calculated for the operation mode. This calculation continues until the whole domain is covered. The calculations constitute a set of daily total fuel costs, among which the segmentation pattern called optimal segmentation with the least daily total fuel costs could be picked out by comparing the values of the total fuel costs.

In order to be convenient for computer programming Eq.8 can be descretized as Eq.11 (see Ref.[3] for detail).

$$Q_i(j, \tau_{0i}, \tau_i) = \frac{1}{w}\left[\frac{j-\tau_{0i}+1}{\tau_i-\tau_{0i}+1}\sum_{j=\tau 0i}^{\tau i} f(j) - \sum_{j=\tau 0i}^{j} f(j)\right]$$

$$i = 1,2,\cdots,n \qquad j = 1,2,\cdots,24w \qquad (11)$$

OPTIMAL OPERATION OF BOILER PLANTS

Model of optimization of load assignment

Almost all the sections or accessories of a boiler plant system involve with the optimization of plant operation. However, optimal assignment of plant load to various boilers is one of the most effective approaches to the optimal operation of boiler plants.

The optimization of load assignment among different units in a public utility system has been a long-lasted subject since the middle of the 20-th century when E.E. George, H.W. Page, and J.B. Ward raised the principle of coordination of incremental fuel costs[4] and L.K. Kirchmayer contributed to the complete of it[5]. From then on, this principle has been cited in a lot of papers. It is noticed that recently there were still authors who applied the method of coordination of incremental fuel costs to solve the problem of optimal load assignment for boiler plants[6]. However, for all practical purposes, the coordination of incremental fuel costs could take effect mainly in principle because of complexity in many real cases. As it is, optimal load assignment for boiler plants is even more difficult than for public utility systems in a way, for industrial boiler plants are much smaller in size than utility systems and their load fluctuation is usually more vigorous. This is one of the major reasons why there are quite a few reports on successful work on optimal load assignment to boilers in a boiler plant. Establishing stable load levels in several segments, TES makes it easier to perform load assignment in a boiler plant. In this section the method of minimum-departure model (MDM) is developed for this task. The method of MDM, as an applicable method to boiler plant practice, takes some considerations into account, such as the allowable limits of load rate for each boiler, the strategy of determining in advance how many and which boilers going to work, etc.

As a matter of fact, almost all the existed methods of optimal load assignment reported so far rely on fuel cost curves of boilers. It is well known that fuel cost curves of industrial boilers present a form of polynomial, and in most cases they can be considered as quadratic curves (Eq.12).

$$C_{\mathrm{f}} = a_0 + a_1 r + a_2 r^2 \tag{12}$$

$$r = \frac{q}{q_{rt}} \tag{13}$$

where C_{f} is the fuel cost per hour, q denotes boiler output rate and q_{rt} the rated output of the boiler.

However, for most industrial boiler plants, it is not easy and is expensive to obtain accurately the complete fuel cost curves for every boiler through tests on the spot, especially for coal-fired boilers. It is well worth pointing out that the method of MDM is such a one that needs, instead of complete fuel cost curves, only a few data that are originally available or ready-made and accurate.

From Eq.12 it is easy to find out following relationships (see Eq.14) through simple development if special behavior of the first derivative of the equation is considered at the economical load rate r_{m}.

$$a_1 = \frac{C_{\mathrm{f\,m}} - 2C_{\mathrm{f}\,0}}{r_{\mathrm{m}}}, \qquad a_2 = \frac{C_{\mathrm{f}\,0}}{r_{\mathrm{m}}^2} \tag{14}$$

where subscripts 0 denotes no-load conditions. Since the data on such two typical load conditions can be easily obtained from daily records of boiler operation or from the master data manufacturer supplied and thus are more accurate than the data on other non-typical load conditions, coefficients a_1 and a_2 are relatively reliable.

The development of MDM can be explained in brief as follows.

The objective function of optimal load assignment takes the form as the following (Eq.15) in the case that there are n working boilers in the industrial boiler plant under consideration.

$$\min\ C(\mathbf{R}) = \sum_{i=1}^{\mathrm{n}} C_{\mathrm{f}i}\ , \quad \mathbf{R} \in \mathbf{E}^{\mathrm{n}} \tag{15}$$

where $$\mathbf{R} = (r_1, r_2, \cdots, r_{\mathrm{n}})^{\mathrm{T}} \tag{16}$$

Equation 15 can be transformed equivalently into Eq.17.

$$\min\ \Delta C = C(\mathbf{R}) - C(\mathbf{R}_{\mathrm{m}}), \quad \mathbf{R} \in \mathbf{E}^{\mathrm{n}} \tag{17}$$

where $\mathbf{R}_{\mathrm{m}}$ is the condition on which every boiler in the boiler plant works at its economical load rate $r_{\mathrm{m}i}$. Namely,

$$\mathbf{R}_{\mathrm{m}} = (r_{\mathrm{m}1}, r_{\mathrm{m}2}, \cdots, r_{\mathrm{mn}})^{\mathrm{T}} \tag{18}$$

Expand $C(\mathbf{R})$ around $\mathbf{R}_{\mathrm{m}}$ into Taylor series, while considering the fact that $C(\mathbf{R})$ is a quadratic function and therefore the n-th nablaes of $C(\mathbf{R})$ equal zero when $\mathrm{n} \geqslant 3$. Therefore $C(\mathbf{R})$ becomes Eq.19 accurately.

$$\begin{aligned} C(\mathbf{R}) &= C(\mathbf{R}_{\mathrm{m}}) + [\nabla C(\mathbf{R}_{\mathrm{m}})]^{\mathrm{T}} (\mathbf{R} - \mathbf{R}_{\mathrm{m}}) \\ &\quad + \frac{1}{2} (\mathbf{R} - \mathbf{R}_{\mathrm{m}})^{\mathrm{T}} \mathbf{H}_{\mathrm{m}} (\mathbf{R} - \mathbf{R}_{\mathrm{m}}) \end{aligned} \tag{19}$$

The terms in the right hand of Eq.19 are developed as Eqs.20 to 24.

$$\begin{aligned} [\nabla C(\mathbf{R}_{\mathrm{m}})]^{\mathrm{T}} (\mathbf{R} - \mathbf{R}_{\mathrm{m}}) &= \sum_{i=1}^{\mathrm{n}} (a_{1i} + 2a_{2i})(r_i - r_{\mathrm{m}i}) \\ &= \sum_{i=1}^{\mathrm{n}} (a_{1i} + 2a_{2i}) x_i = \sum_{i=1}^{\mathrm{n}} \frac{C_{\mathrm{fm}i}}{r_{\mathrm{m}i}} x_i \end{aligned} \tag{20}$$

where $x_i = r_i - r_{mi}$ (21)

or $\mathbf{X} = \mathbf{R} - \mathbf{R}_m = (r_1 - r_{m1}, r_2 - r_{m2}, \cdots, r_n - r_{mn})^T$ (22)

As to Hessian matrix $\mathbf{H}_m$,

$$\mathbf{H}_m = \begin{pmatrix} \frac{\partial^2 C}{\partial r_1^2}, \frac{\partial^2 C}{\partial r_1 \partial r_2}, \cdots, \frac{\partial^2 C}{\partial r_1 \partial r_n} \\ \frac{\partial^2 C}{\partial r_2 \partial r_1}, \frac{\partial^2 C}{\partial r_2^2}, \cdots, \frac{\partial^2 C}{\partial r_2 \partial r_n} \\ \cdots \quad \cdots \\ \frac{\partial^2 C}{\partial r_n \partial r_1}, \frac{\partial^2 C}{\partial r_n \partial r_2}, \cdots, \frac{\partial^2 C}{\partial r_n^2} \end{pmatrix} = 2 \begin{pmatrix} a_{21} & & & \\ & a_{22} & & \\ & & \cdots\cdots & \\ & & & a_{2n} \end{pmatrix} \quad (23)$$

It follows that

$$\frac{1}{2}\mathbf{X}^T \mathbf{H}_m \mathbf{X} = \sum_{i=1}^{n} a_{2i} x_i^2 = \sum_{i=1}^{n} \frac{C_{f0i}}{r_{mi}^2} x_i^2 \quad (24)$$

In combination of Eqs.17, 19, 20 and 24, the objective function of MDM for load assignment of industrial boiler plants can be expressed as Eq.25, while Eq.26 is the constraint conditions of the problem.

$$\min \Delta C = \sum_{i=1}^{n} \left(\frac{C_{fmi}}{r_{mi}} x_i + \frac{C_{f0i}}{r_{mi}^2} x_i^2 \right), \quad i = 1, 2, \cdots, n \quad (25)$$

subject to

$$h(\mathbf{X}) = \sum_{i=1}^{n} q_{rt,i} (x_i + r_{mi}) - L = 0 \quad i = 1, 2, \cdots, n \quad (26)$$
$$-A_i \le x_i \le B_i$$

Equations 25 and 26 constitute the model referred to as minimum-departure model (MDM), which needs only the fuel cost data at two typical load rates: no-load and economical load rates instead of complete fuel cost curves, and thus this model is more accurate than other models.

Two steps for the algorithm of MDM

So far the first phase, i.e., to determine in advance how many and which boilers are going to work, has not yet been discussed. In performing the task, set 0 and 1.2 to A_i and B_i in Eq.26 respectively, and then run the computer program to solve the problem equations (Eqs.25 and 26). According to the solutions in this phase, if there were a boiler assigned with a load rate less than a preset critical value, say 0.2, it would be assigned automatically a zero load rate or even rejected from use. Computation trials proved that the boilers to be rejected from use tend to have the worst characteristic curves.

Then comes the 2nd phase—to solve the problem equations (Eqs.25 and 26) again, while the values of A_i and B_i are re-assigned according to the actual requirements of working boilers, to which the load of the boiler plant is going to be assigned. The computer program proves robust enough, for it is almost impossible for the fuel cost curves of industrial boilers in the form of quadratic functions to be ill-conditioned when iteration is going on.

Programming of optimal operation of boiler plants with TES

On the basis of 3 major modules, i.e., Module 1: the forecast of a daily load curve by BP neural networks, Module 2: the optimal segmentation of the curve, and Module 3: the optimal assignment of loads to boilers in a boiler plant, the modeling of a comprehensive program can be accomplished. The program is finished based on the platform of MATLAB6.5.

AN EXAMPLE

As an example, the load data (see Fig.3) that were used in the section of "Forecast of load curve of a boiler pant using artificial neural networks" are to be used again. The related boiler plant is equipped with a TES, a steam (latent heat) accumulator of 130 m^3, and some original data of the boiler plant are listed in Table 4.

A sub-program for selecting working boilers, which determines in advance how many and which boilers in the boiler plant to work at a particular load level, is added as the first phase in Module 3, this also helps the load assignment by MDM to be more preferable than by other reported models.

Table 4 Some data of the boilers in the boiler plant

Boiler No.	Rated capacity, q_{rt} [MW]	Economic capacity, q_m [MW]	Fuel consumption, C_{f0} on no-load, [kg/hr]	Fuel consumption, C_{fm} at economical load rate, [kg/hr]
1	2.2	1.0	10.2	110.1
2	6.63	3.4	45.7	365.6
3	2.2	1.0	10.2	110.1

Table 5 Optimal operation condition on April 28 based on forecasted load curve

Segmentation pattern	Load level [MW]	Assigned load rate		
		Boiler 1	Boiler 2	Boiler 3
8:00~12:00	5.281	0.4336	0.5092	0.4344
13:00~16:00	5.462	0.4523	0.5244	0.4524
17:00~7:00	2.515	0	0.3795	0

Table 6 Optimal operation condition on April 28 based on actually recorded load curve

Segmentation pattern	Load level [MW]	Assigned load rate		
		Boiler 1	Boiler 2	Boiler 3
8:00~12:00	4.998	0.4045	0.4855	0.4064
13:00~16:00	5.520	0.4581	0.5292	0.4582
17:00~7:00	2.510	0	0.3784	0

It took several minutes for the computer to complete calculation of the load curves forecasted on April 27 and 28, the optimal segmentation patterns for the operation of the 2 whole days, the preferable schemes of working boilers, and the calculated least fuel costs of the boiler plant of the two days respectively. The major computation results are listed in Table 5, which were resulted from the forecasted load curves. Based on the actually recorded load curve of the boiler plant, instead of the forecasted load curve, on April 28, similar results are listed in Table 6. Comparing Table 5 with Table 6, one can see that there is trivial difference in optimal segmentation patterns and the preferable schemes of working boilers between the two cases. This proves that BP network can meet the requirement of optimal segmentation in the case when TES exists in boiler plants, though the forecast accuracy using BP network is somewhat lower than those using some other types of neural networks. Table 7 gives the comparison in daily fuel cost of the boiler plant between the cases with and without optimal load assignment. The difference between the two cases means savings about ¥4.4×10^5 (5.3×10^4 USD) per year, which sometimes makes sense for an industrial boiler plant that is often not big in size. The difference may be much bigger if there is not optimization of segmentation (thanks to the successful load forecast) for daily operation of the boiler plant.

Table 7 Daily fuel costs with and without optimization of load assignment

Date	Fuel cost with optimization of load assignment, [kg]	Fuel cost without optimization of load assignment, [kg]
April 27	9198.715	9459.543
April 28	9579.968	9827.254

CONCLUSIONS

- The method of optimal operation of industrial boiler plants introduced in the paper is effective on saving energy in the case of the assistance of TES.
- When boiler plants are equipped with TES, the forecast carried out simply by BP networks is accurate enough for optimal load assignment to boilers in an industrial boiler plant.
- The minimum-departure model (MDM) is more practicable to use in optimal load assignment for boiler plants than most existing methods.
- The method and the computer program can be applied to the online control of optimal operation of boiler plants with TES.

ABSTRACT

A useful numerical code for energetic design of a co-generation system and its economic optimal operation is presented. In the planning phase, the numerical model allows to match different configurations of the system, finding the best one in the econimic point of view. The plant scheme is as general as possibile, in fact is possible to choice among the following elements: gas turbine, steam turbine, diesel engine, absorption heat pump and electrical and mechanical heat pumps, boilers and storage system of thermal energy, heat recovery steam generators with in-duct burners system. Once assigned the electrical and thermal demand, the code examines alternative solutions from the general scheme, with respect to the traditional one (boilers, electrical and mechanical heat pumps and electricity national distributor). Aim of the numerical code is finding all the maximum energetic power of the elements and, hour per hour, the optimal operation conditions. In the usual situation of contemporary demand of hot and/or cold thermal and electric energy, priority is given to the energy with higher cost, considering the energetic rates, hour per hour, meanwhile the satisfaction of the demands would have however to happen with not cogenerative systems. In the numerical code is considered the possibility to sell the electric energy surplus and to storage the thermal one.

In particolar the benefit of using a thermal storage unit has been highlighted in this paper, by reporting results of numerical simulation carried out varying electrical and thermal load of CHP plant.

Keywords: heat storage, optimisation

INTRODUCTION

The rising diffusion of CHP plants has been led to develop design and operation models able to indicate, in every single case, which is the best plant configuration among all possible, giving the lowest cost for the best performances.

Such a model has been built up in this work, searching for the optimum operation parameters of a tri-generation plant, for any assigned electrical, thermal and cooling load. The numerical model which has been developed by authors is quite general and has two specific application phases: the design phase ant the operation one.

In the first type of approach (the design one) the model indicates the best plant solution for a given

[1] corresponding author: giulange@unina.it

energy demand, making a comparison among all technologically available and choosing the most efficient in terms of cost/benefit ratio.
The chance to cheaply and fast foresee economic performance of such a plant , which is often a big plant, has led to a very detailed numerical model, comprehensive of all technological solutions
A very important reliability characteristic of the model is the capability to foresee the plant performances not only in steady regime but also in transitory phases according with thermal and electrical demand fluctuation.

THE MODEL

For given daily curves of thermal, cooling and electric demand, both for holiday and working days, summer and winter, the numerical code computes the optimum load curve (from a money saving point of view), hour per hour, of the single components of the plant (main engine, integrative boilers, post combustion systems, absorbption chillers etc), varying engine load within the allowed range
In order to keep the model as general as possible, it is possible to evaluate the advantage of the contemporary installation of different engines, such as steam turbines, gas turbines, internal combustion engines, specifying their performances depending on weather condition and load variation.
For example, the variation of electrical efficiency of a gas turbine has been taken into account, depending on environment temperature.
The model takes into account the different heat recovery systems of above mentioned engines according with temperature levels required for thermal vectors: in case of gas turbine, for example, heat is recovered only at high temperature, while internal combustion engines allows two different temperature levels of recovery (heat from lubricating and jackets cooling systems and heat from exhaust gas); for steam turbines besides, heat recovery has temperature constrains coming from backpressure circuit. Another comparison can be made about post combustion: for gas turbines it is easy to install such a system downstream the machine, for ICE instead it is possible to do it only when they work in very lean condition, for environmental demands, and installation and operation are more complex.
A basic requirement of a CHP system is the chance of using heat recovery in summer: in this case the energetic recovery index is higher than traditional or electrical heat pump cooling systems: for this reason the use of absorbption chillers is strongly recommended, even if these machines appear less efficient than traditional.
The model takes into account also the situation of underproduction and overproduction of electricity with respect to the instantaneous demand: the economic evaluation of such situation is carried out on the basis of national rates and their variability hour per hour.
The model is structured in order to estimate the influence of delay between heat recovery from the plant and thermal demand within the day, considering the chance to storage surplus thermal energy.
The generalized scheme of the whole plant is sketched in fig.1.
As remarked, the thermoeconomic model can be easily used both in design and in operation phase.
In design phase it matches the layout which gives the best economic and energetic performances, with respects to energy demands. In operation phase, for the given layout, it determines the load level of the components, according with energy demands, hour per hour, and giving the best efficiency.
Economic analysis is based on comparison between the investment costs and the money saving feedback, during plant lifetime. Discounted Pay-Back period (DPB), Internal Rate of Return and Net Present Value methods have been adopted.
The concept the model is based on is the comparison of the different money value of energy available in a given point of the plant, depending on destination to electric, thermal or cooling demand, in the case that this energy can be utilized by different components of the system.

In a preliminary phase plant layout is defined, specifying machines with their efficiency, load limits, regulation facilities, possible absorbption system and relative COP, post-combustion burners and heat storage systems with their maximum capacities.

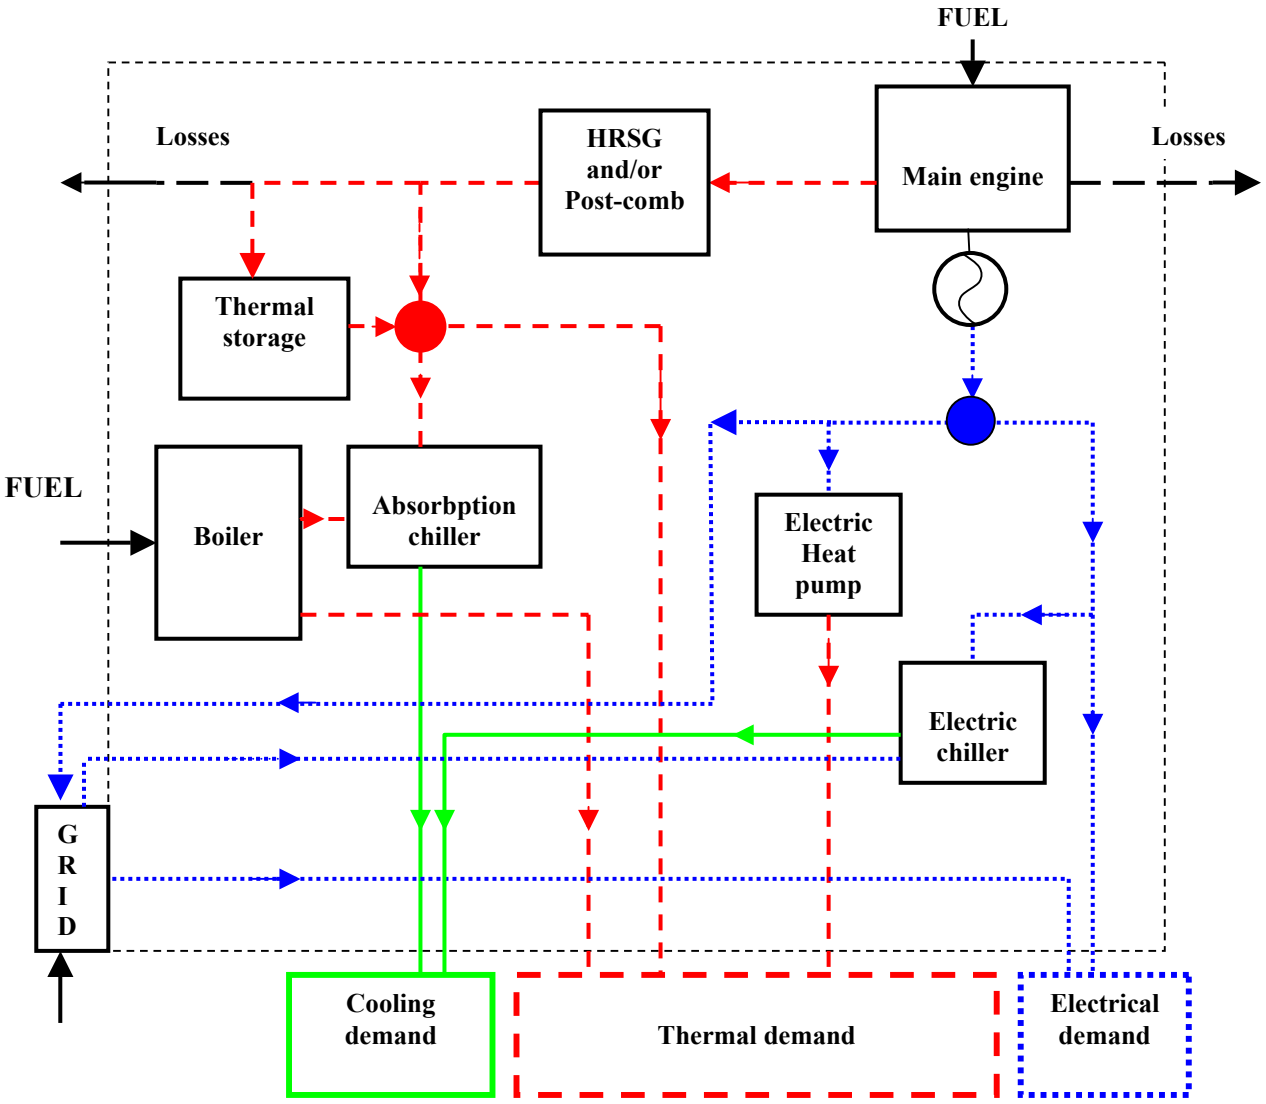

Fig.1: generalised scheme of the plant

Within the economic parameters, fuel rates, electricity tariffs, machine costs, production taxes, possible tax discount, maintenance costs are the most relevant.

After computation, the routine gives the economic indexes, optimum load curve of the components along the day, load curves for integrative systems, the electricity given to the grid and the thermal energy stored. At this point, calculation are repeated for different layout configuration, evaluating the most convenient one.

The general scheme of the plant is made of different sections of energy production:

1. mechanical-electric energy production
2. thermal energy production

3. cooling energy production

In section 1 it's possible to insert one or more different engines, depending on energy user requirement, in terms of size, electric load variability and temperature of heat recovery.
In section 2 heat recovery steam generator is positioned, together with post-combustion system, when possible, heat storage system and integrative boilers.
In section 3 absorbption chillers and/or heat pumps or electrically driven chillers are considered; the first ones can be fed by heat recovered and/or by integrative boilers and /or by post combustion system, while the second ones can be fed by electricity produced by the plant or taken from the grid.
In section 2 the maximum size of each component can be assigned, together with efficiency variation diagram vs partial load; in a different way the size of the component can be considered as a variable parameter to be computed by the model as optimum value together with the number of components, depending on the minimum and the maximum power given to the user by the single component.
The whole plant, sketched in fig.2, can be considered as a number of energy transformers, closed in control volumes, crossed by energy fluxes, changing from primary energy to end user energy with some energy loss, related to the specific process.
For a given plant configuration, the best and cheapest path for energy fluxes can be identified, when different choices are available. The analysis is performing making a comparison with traditional energy solutions like grid supply , boilers and electrical cooling systems. By simple and rational consideration based on specific efficiencies and standard tariffs for electricity and gas, the best configuration can be identified.
By the fig. 1 it can be highlighted that a generic energy flux can be transferred directly to the end user or to another "energy box" downstream it. We indicate as "joints" these intersection points.

SIMULATIONS

The characteristics and potentialities of the code have been already described in previous works [1]. The parameters and functions the code is based on are the following:

- daily curves of electrical, thermal and cooling demand for holyday and working, summer and winter days
- electrical efficiency of main engine varying the engine typology, load level and weather condition
- thermal efficiency of boilers, Heat Recovery Steam Generators (HRSG), post-combustion systems and heat pumps and their dependence on load level
- cooling efficiency of absorbption systems and electrical chillers and their dependence on load level
- heat storage capacity
- electricity tariffs also for selling case
- fuel costs
- maintenance costs
- cost for engine and auxiliary installation

In this paper the benefit of installing a heat storage system, when electrical and thermal load have specific characteristics is analysed. In a special way it's very interesting when thermal and electrical demand are not coherent and shifted from each other during the day, or when thermal load arises and decreases continuously with respect to a mean value.
In the first case, the absence of a thermal storage unit, should lead to switch off the engine when only thermal energy is required: but in this case we should have a less operation time in a year and a longer pay-back period. In the second case, it should be necessary to operate the engine at partial load when heat recovery should be greater than demand and to integrate with auxiliary boilers when recovery is less than demand: partial load operation reduces system efficiency and money saving.
Thermal storage modules allow to separate load curves from demand ones , for a better and more convenient technical management of the plant.

Obviously, thermal storage capacity must be optimised with demand characteristics: this can be better understood by a simulation on a case study.
Let's consider a factory user with daily electrical and thermal demand as shown in fig 2-3.
Let's search for the optimal set up when a 3 MWe gas turbine is installed with a heat recovery steam generator, without heat storage system. Italian tariffs for gas and electricity have been considered for simulation.
Two cases have been analysed:

1. operation load electrical demand-dependent
2. operation load thermal demand-dependent

The first case is reported in fig. 4-5 by diagrams of electrical end thermal output of the system.
The second case is reported in fig 7-8.by similar diagrams.
In the first case gas turbine runs continuously at maximum load: this causes thermal recovery not to be utilized for a certain number of hours along the day, as shown in fig.6.
In the second case, referring to thermal demand, the gas turbine runs for a number of hours at partial load, needing an integration from electrical national grid.

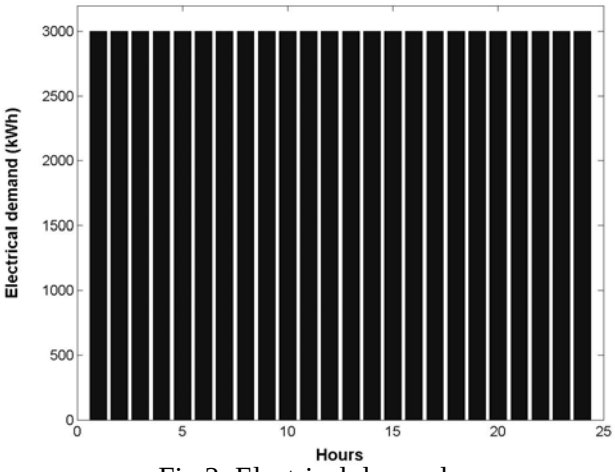

Fig.2: Electrical demand

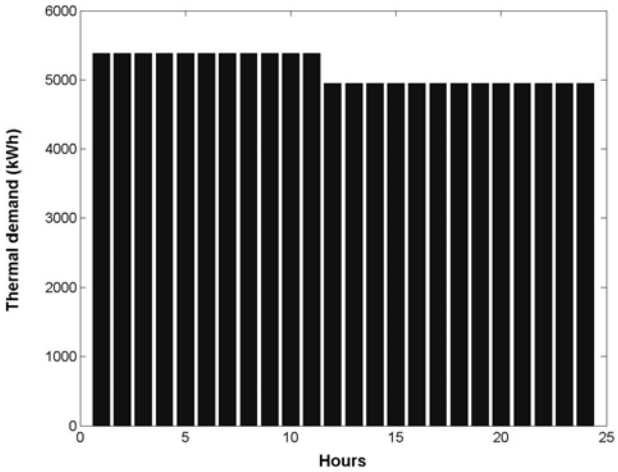

Fig.3: Thermal demand

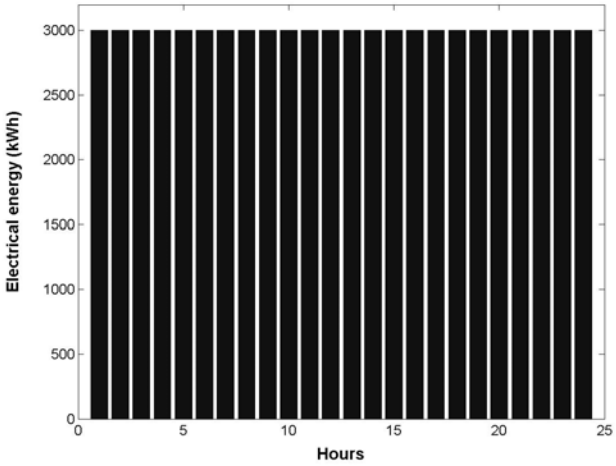

Fig.4: Electric output (case 1)

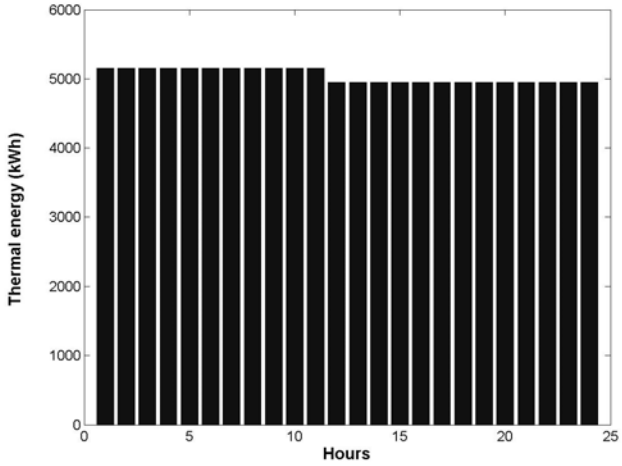

Fig.5: Thermal output (case 1)

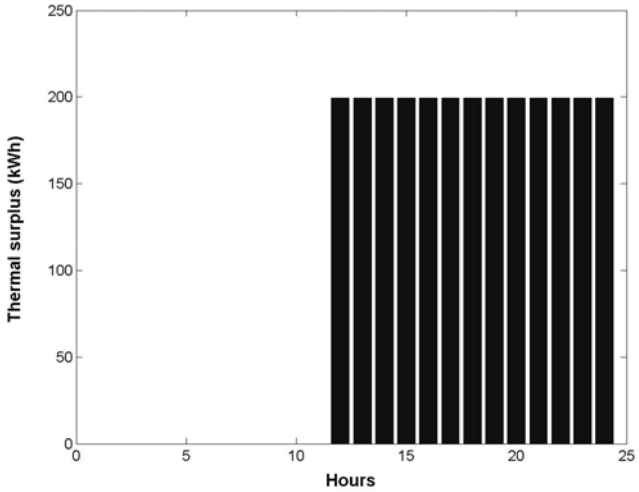

Fig.6: Thermal surplus (case 1)

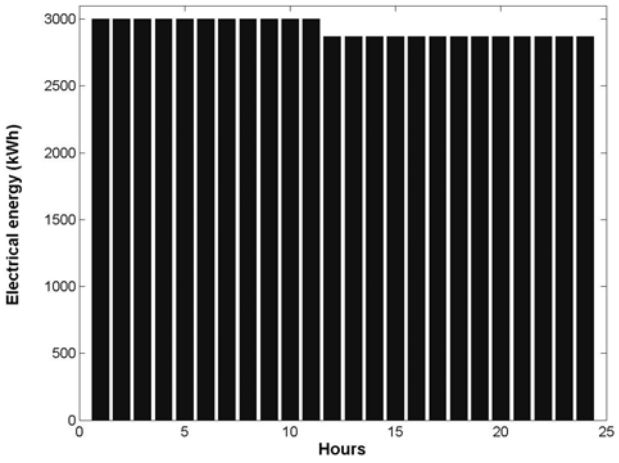

Fig.7: Electric output (case 2)

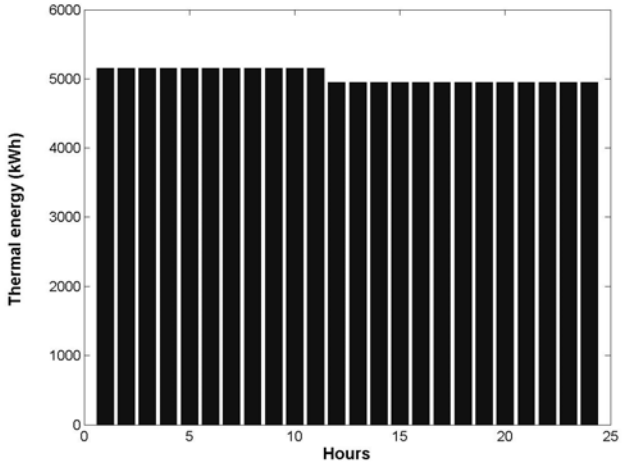

Fig. 8. Thermal output (case 2).

Let's consider now the same situation but with a thermal storage unit (case 3): this facility allows to storage hot water at 130 °C, with a return temperature of water at 80 °C. According with these values, an optimum capacity for storage tank should be 50 m^3 .

Energetic losses have been neglected, also because energy is stored for a few hours. The storage system allows to store all thermal surplus, which is given to the users at first hours of the day, when demand is higher than thermal output of the system (fig.9).

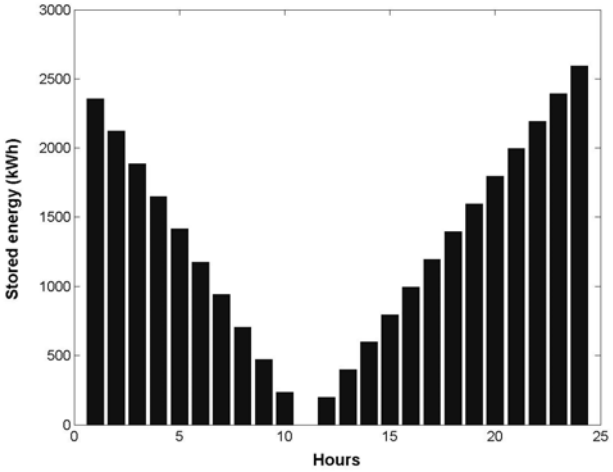

Fig.9 : stored energy per hour (case 3)

Finally the heat given to the end user by thermal storage is represented in fig.10

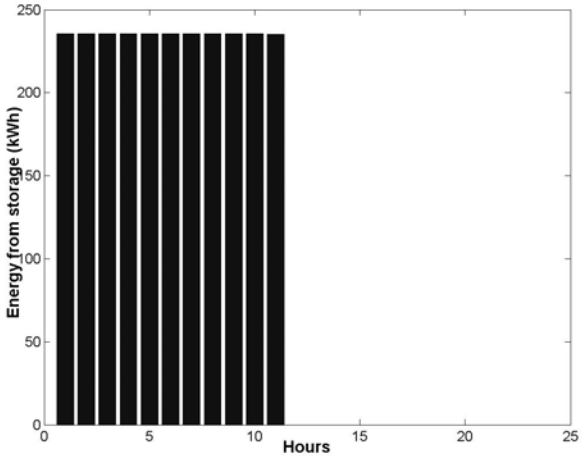

Fig.10: heat from storage (case 3)

Allowed benefits of such a system can be easily understood in the following table

Case	Money saving €/y	Electric **η**	Thermal **η**	Exergetic **η**
1	1.067.400	30.27	50.87	44.51
2	1.048.700	30.19	51.96	44.73
3	1.107.900	30.27	51.96	44.82

Tab 1: Comparison datasheet

η is the symbol adopted for efficiency.
Money saving is calculated with respect to a traditional plant which has the following energetic characteristic:

- Electricity from the grid
- Heat from gas fired boilers
- Cooling from electric chillers

The storage system increases money saving with respect to the traditional situation, allowing to save 40.000 € more (2% of the costs in a year) in the first case and 60.000 € more (3%) in the second. Considering the cost of a storage system with auxiliary equipment, it can be recovered in a couple of years.

CONCLUSIONS

The model built up by authors is quite general and the simulation reported in this paper is only a single application of it.
In design phase for example it can be very useful for the sizing of the main engine or other components of the plant, starting from daily energetic demands for all the year and from their efficiency at the different load levels.
The capacity oh thermal storage system can be optimised too.
From the operation point of view, it can be investigated the best regime from the main engine, if is better to follow the electric demand or to run the machine at constant load, taking benefit from thermal storage and from a constant load set on best efficiency level.
The convenience of selling electricity can be also evaluated, depending on the different tariffs of different electricity providers in the free electric market.
The operation with thermal storage can be integrated with weather forecast, storing more heat when a very cold day is going to come, for example.
The adoption of a heat storage system gives a big management flexibility of the plant. The chance to run the main engine at full load also when thermal demand is lower than production allows best efficiencies to be reached for the system. Money saving is often very interesting and justifies the investment with a short pay-back period.

ABSTRACT

This paper reports a research of behavior of second law performance parameters of a 1 MW Diesel plant cogeneration system under variable power load. An engine simulation model is used as well as a cogeneration cycle simulation model which permits to foresee the system performance with varying load. The adoption of second law viewpoint allows to perform the analysis according to a more realistic physical nature than first law analysis does, as heat and work have different qualities in heat-to-work conversions. For such a case, plus than enthalpy, heat and work, flux exergies are taking into account. The second law performance parameters used in this paper are the second law efficiency, and the relative irreversibility ratio. These factors are plotted in function of the engine power load.
Key-words: Exergy, simulation, cogeneration, Diesel engine, Second law, thermal analysis.

INTRODUCTION

Northern Brazilian power grid has a huge potential for cogeneration, due to that the electric generation is made through the use of Diesel engine in a decentralized grid. The uniquely generation of electric energy by the system is the cause of its unprofitable economic performance.
An advantageous way to perform the analysis of such cogeneration system is by searching how its second law efficiencies respond to the variation of the load of its power engine. For the daily engineering purposes, it is not easy to get such an engine simulation, but it can easily be done on Diesel engines through their performance parameters.

EXERGETIC PARAMETERS

The first parameter is the *rational efficiency*, for what the cogeneration system is divided into its subunits creating a *productive structure* as in Figure 3. The rational efficiency is defined as:

$$\eta_i^B \equiv \frac{\dot{P}_i}{\dot{F}_i} \quad (i = 1, ..., m) \qquad (1)$$

In this definition, by fuel we consider not only the inlet flux exergy but the net inflow of exergy to the subunit. As a consequence, product is the exergy outflow from the subunit (Table 3). An implicit result in Equation (1) is that $\dot{F}_i > \dot{P}_i$, as the exergy balances is expressed by:

$$\dot{F}_i = \dot{P}_i + (\dot{I}_i + \dot{L}_i) \quad (i = 1, ..., m) \qquad (2)$$

in which $\dot{I}_i$ are losses inside the bulk control volume evolving the whole plant, but $\dot{L}_i$ are losses in the form of fluxes that go outside the plant. Part of the summation inside parenthesis in Equation (2), usually denoted as *destroyed exergy* ([1], [2]), can be recovered by the cogeneration system, e.g. the combustion products and the heat loss to cooling fluid of Diesel engine. Figure 1 illustrates the whole idea behind Equation (2).

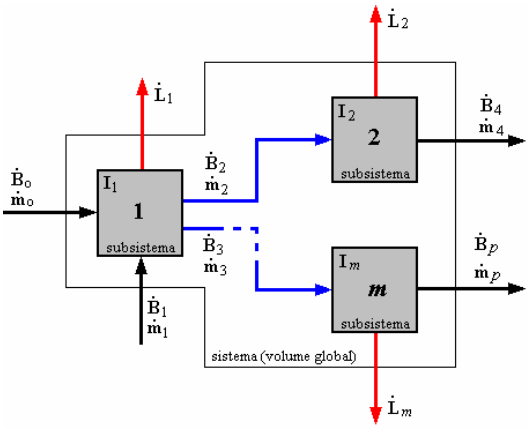

Figure 1: A general productive structure.

Besides the rational efficiencies of the subunits, one can define the *relative irreversibility* of each subunit as:

$$\zeta_i \equiv \frac{\dot{I}_i}{\sum \dot{I}_i} \quad (i = 1, ..., m) \qquad (3)$$

In general, any exergy flow of the plant may be calculated by:

$$\dot{B}_j = \dot{m}_j \left(b_j^{\text{fís.}} + b_j^{\text{quím.}} \right) \quad (4)$$

where the physical part of exergy is:

$$b_j^{\text{fís.}} = \left(h_j - h_{0.j} \right) - T_0 \left(s_j - s_{0.j} \right) \quad (5)$$

$$s_j = \sum_e X_e s(T_j, Y_e p_j) \quad (6)$$

$$h_j = \sum_e X_e h(T_j) \ (e = CO_2, H_2O, O_2, N_2) \quad (7)$$

In (6) and (7), s_j, h_j and h_0 are given by the JANAF tables, at $T_0 = 298.15\,[\text{K}]$ (25 [C]) and $p_0 = 101.325\,[\text{kPa}]$ (1 [atm]).
And for the chemical term of Equation (4):

$$b_j^{\text{quím.}} = \tilde{R} T_0 \sum_e \left(\frac{Y_e}{M_e} \right) \ln \left(\frac{y_{0.e}^j}{y_{00.e}} \right) \quad (8)$$

Usually for the heat flux exergies we do:

$$\dot{B}_j^Q \equiv \dot{Q}_j \left(1 - \frac{T_0}{T_j} \right) = \dot{Q}_j \eta_{C\,j} \quad (9)$$

where $\eta_{C,i} \equiv 1 - (T_0 / T_i)$ (i = 1, ..., *m*) is the *Carnot efficiency*.
For power/work exergy:

$$\dot{B}_j^W = \dot{W}_j \quad (10)$$

In all these equations, j = 1, ..., *p*. For water as a working fluid it is assumed the Szargut, Morris and Steward [3] standard environment, for what these authors define the concept of *standard chemical exergy*. For water in liquid phase [3], $\tilde{b}_{H_2O}^{\text{quím.}} = 0.9$ [kJ/mol]; and for the Diesel oil, the following correlation is enough [3]:

$$b_{DO}^{\text{quím.}} = Q_{LHV} \left[1.046 + 0.0144 (H/C) \right] \quad (10)$$

For the gases composing the combustion products mixture, Table 1 shows the molar fractions considering the Szargut, Morris and Steward [3] standard environment.

Substance	$y_{00.e}$ **(in dry air)**	**Standard pressure[5] [kPa]**
CO_2	0.000 345	0.033 5
H_2O_{gas}	—	2.2
O_2	0.209 9	20.39
$N_{2atmosf.}$[6]	0.7898	76.705

Table 1: Fractions of some gases in the standard atmosphere [3].

SYSTEM CONCEPTION

In this section we show the conceived cogeneration system intended to produce electric energy, low temperature cooling flux for food conservation (RAA-1 at -25 [C]) and ice for fishing conservation (RAA-2 at -3 [C]), as shown in Figure 2. On Figure 3 we show the productive structure defined for the system of Figure 2.
The most important characteristic of the plant in Figure 2 is that we defined the low temperature cooling flux as being generated by the high temperature energy of the exhausted gases of the Diesel engine, and the production of ice being generated by the low temperature energy contained in the cooling water of the Diesel engine. We assume that the absorption systems belonging to the refrigeration units may be properly designed to get these purposes.

[6] It is considered the gas N_2 plus the rest of the gases and the dust which compose the actual atmosphere, except O_2.

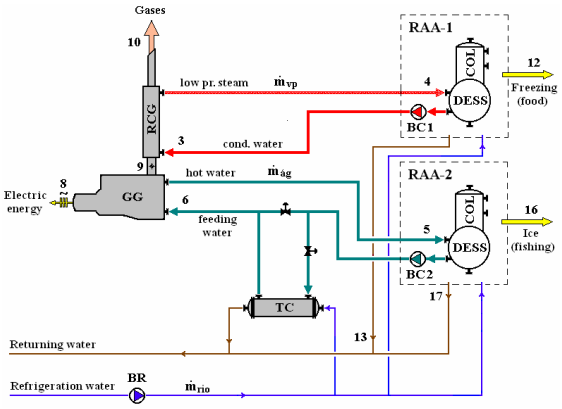

Figure 2: Cogeneration system conceived [4].

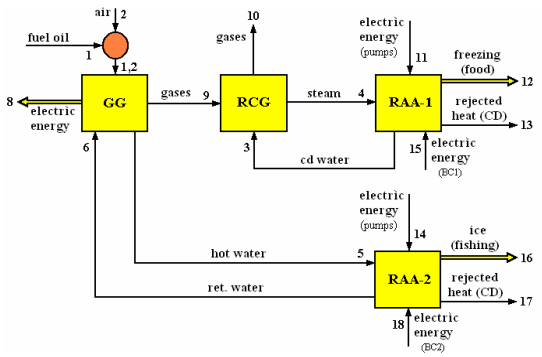

Figure 3: Structural diagram for the system of Figure 2 [4].

Technical Characteristics of the System

The RAA-1 and RAA-2 subunits are the 'clients' of the cogeneration system. These subunits adopt the aqua-ammonia absorption refrigeration cycle. The heat to RAA-1 is furnished by low pressure steam and the heat to RAA-2 is transported by hot water, which main data are shown on Table 1, assumed constant with the varying power load. This assumption does not imply that the cogeneration system must supply constant heat, but determined electric power, defined as mandatory.

The electric generator is powered by a commercial supercharged Diesel engine which main technical data are reported in Table 3 [5] at four discrete power loads ($q \equiv \dot{W}_{lq} / \dot{W}_{l100}$).

Stations	T [K] (C)	p [kPa]
3 (sat. liq.)	403.15 (130)	—

q	10^{-8} *bsfc*	AF
25	6 841	89.92
50	6 034	50.97
75	5 688	36.05
100	5 592	27.50

Table 3: Main Diesel engine data [5].

A simple simulation model of the energy balance of the Diesel engine may be found in Reference [4], or on a related paper submitted to ECOS 2005, from the authors of this work. Figure 4 shows the results of the simulated energy balance of the Diesel engine of Table 3 obtained by that model [4].

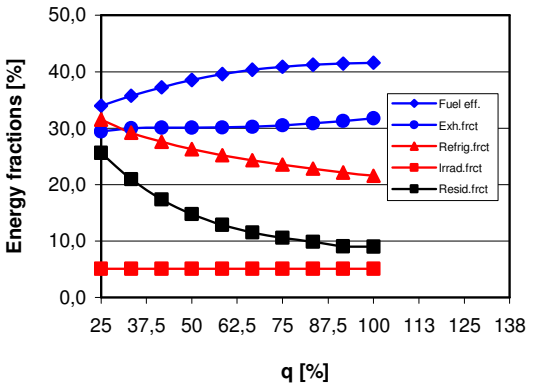

Figure 4: Simulated energy fractions for the Diesel engine [4].

Exergy Balances for the Subunits

On Table 4 we show the exergy balances for the subunits of Figure 3, written in obedience to Equation (2). In this sense, we firstly had to

discuss the philosophy to follow for the F-P-L structure of the cogeneration plant under analysis.

Subunit	Flow	Balance
GG	F	$\dot{B}_1 - \dot{B}_9 - (\dot{B}_5 - \dot{B}_6)$
	P	$\dot{B}_8$
	L	—
RCG	F	$\dot{B}_9$
	P	$(\dot{B}_4 - \dot{B}_3)$
	L	$\dot{B}_{10}$
RAA-1	F	$(\dot{B}_4 - \dot{B}_3) + \dot{B}_{11} + \dot{B}_{15}$
	P	$\dot{B}_{12}$ (freezing)
	L	$\dot{B}_{13}$ (heat rejection)
RAA-2	F	$(\dot{B}_5 - \dot{B}_6) + \dot{B}_{14} + \dot{B}_{18}$
	P	$\dot{B}_{16}$ (ice)
	L	$\dot{B}_{17}$ (heat rejection)

Table 4: Exergy balances of the subunits [4].

So, when defining the F-P-L structure for the structural diagram of Figure 3 we took into account:

1. RAA-1 and RAA-2 are closed control volumes for what only the bulk losses will be computed.
2. Flow $\dot{B}_8$ (electric power) is considered the unique product of the Diesel power generator (GG). This assumption was adopted by various authors, see for instance, Frangopoulos [6], Lozano and Valero [7], Silveira and Nogueira [8]. Nevertheless we decided to adopt this criterion by analyzing the hypothesis of taking as GG products also the flows $(\dot{B}_5 - \dot{B}_6)$ (Diesel engine cooling water) and $\dot{B}_9$ (combustion gases). In this last case the GG irreversibilities should be equally partitioned among these three products, as done by Tozer and Capilla [9][7]. However, it has no sense considering that the engine irreversibilities must be equally "loaded" to the principal product, e.g. electric energy, and the fluids that transport the thermal rejects.
3. The RCG recover is assumed as a subunit apart from the subunit GG. In this way, the flow $\dot{B}_9$ (combustion products exiting GG) and $(\dot{B}_5 - \dot{B}_6)$ (hot water feeding RAA-1) result to be by products of the subunit GG.

[7] In this case the working fluid is the exhaust gases from a gas turbine.

SIMULATION RESULTS

Figure 5 shows the rational efficiency and the relative irreversibility of the subunits varying discretely, at the power load values of 25 [%], 50 [%], 75 [%] and 100 [%]. Intending to furnish more information, we detached figures from Figure 5 for the η_i^B and the ζ_i, as shown on Table 5, at the power load values of 25 [%] and 100 [%].

As one can see both on Figure 5 and Table 5, the power generator GG is the major producer of irreversibility of whole cogeneration system. This subunit is the most rationally efficient too, closely followed by RAA-1 efficiency and by the efficiency of whole system.

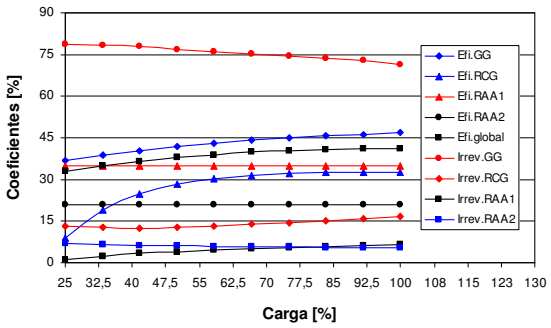

Figure 5: Second law parameters for the cogeneration system [4].

It is interesting to mention that the irreversibilities generated by the heat transfer between the combustion products and the steam and the exhaust gas flux are 'loaded' to heat recover RCG and not to the RAA-1 aqua-ammonia refrigeration subunit, as it would be if the heat fed to RAA-1 were carried directly by the combustion products (in a system without the RCG). Despite its low rational efficiency performance, RCG subunit

irreversibility diminishes with increasing load, what reflects the part that subunit plays in lowering the system entropy generation.

Subunit	25 [%]		100 [%]	
	η_i^B	ζ_i	η_i^B	ζ_i
GG	36.7	78.9	46.9	71.5
RCG	8.9	13.2	32.7	16.7
RAA-1	35.0	1.0	35.0	6.5
RAA-2	21.0	6.8	21.0	5.3
Bulk	32.9	—	41.3	—

Table 5: Second law parameters for the cogeneration system [4].

Figure 5 and Table 5 show that the refrigeration subunits RAA-1 and RAA-2 perform constant values in the 'efficiency game' of the cogeneration system. This result was already expected, as the heats fed to these subunits keep a constant relation to the heat transferred by the Diesel engine on its combustion products and water refrigeration, what can be seen on the balance of Figure 4.

CONCLUSIONS

The present methodology shows to be useful for application on the analysis of energy planning of cogeneration systems; however, it depends on the performance simulation method for the energy balance of the system power engine. In particular, that adopted on this paper shows no difficulties for the daily engineering.

On Figure 5 and Table 5, we could see that the GG subunit is which generates the greatest irreversibility. An important result should be detached from those figures, which is the fact that the refrigeration subunits RAA-1 and RAA-2 perform constant efficiencies all over the power load range.

Figure 5 and Table 5 show too the important part the RCG subunit play on lowering the entropy generated in the combustion process performed in the Diesel engine. That is why the efficiency of the RAA-1 subunit is quite close to that of the GG subunit.

ABSTRACT

The first law parameters are commonly used in cogeneration system analysis, mainly because of their practical meaning despite the fact that those factors neglect any considerations about energy quality (availability) during heat-to-work conversions. In this paper, the first law efficiency of each subunit of the plant, the heat to power ratio, the fuel utilization factor, the fuel saving factor, and the artificial efficiency factor are the first law parameters that are used to characterize a Diesel plant cogeneration system performance under variable power load.
Key-words: Simulation, Diesel plant cogeneration, First law parameters for cogeneration systems.

INTRODUCTION

The methodology developed by the authors in this paper is intended to be used in energy planning studies for autonomous power stations being upgraded towards cogeneration. Northern Brazilian power grid is such a case, in which the power stations presently generate only electricity on an unprofitable basis.

FIRST LAW PARAMETERS

First law analyses usually consider the system embodied in a closed control volume. Such an approach is suitable for a plant producing even more than just electric energy, as in cogeneration systems.

However, first law analysis is allowable too for analyzing systems divided into subunits, what generates a *productive structure* as in Figure 3.

Given a disaggregated plant the *first law efficiencies* of its subunits may be defined as:

$$\eta_i^E \equiv \frac{\dot{P}_i}{\dot{F}_i} \qquad (i = 1, ..., m) \qquad (1)$$

It should be noted that the fuel is not the inlet energy flow but the net energy inflow to the subunit, and the product is a net energy outflow (see Table 3).

For the bulk control volume Horlock [1] gives suitable coefficients. The *heat-to-power ratio* measures the magnitude of one product of the plant relative to the other, for what Silvia Nebra [2] and Lozano Serrano [3] suggest values ranging from 2 to 0.5. So:

$$RCP \equiv \frac{\dot{E}_{coger.}}{\dot{W}_{el.}} \qquad (2)$$

The *energy utilization factor* is an extension of the common bulk first law efficiency of the system:

$$FUE \equiv \frac{\dot{E}_{coger.} + \dot{W}_{el.}}{\dot{E}_{comb.}} \qquad (3)$$

Another way to visualize the whole system is by the *fuel saving factor*, defined as:

$$IPE \equiv \frac{\left(\frac{\dot{E}_{coger.}}{\eta_Q} + \frac{\dot{W}_{el.}}{\eta_W}\right) - \dot{E}_{comb.}}{\left(\frac{\dot{E}_{coger.}}{\eta_Q} + \frac{\dot{W}_{el.}}{\eta_W}\right)} \qquad (4)$$

IPE demands previous definition of the two *reference virtual efficiencies* η_W and η_Q, showed in Figure 1, in which the cogeneration is 'substituted' by a virtual system consisting of a thermo machine and a heater.

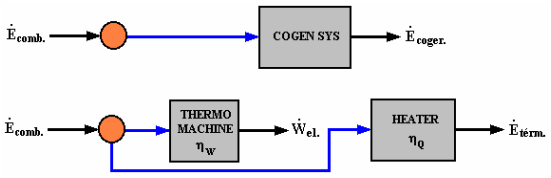

Figure 1: Cogeneration system and its virtual references [4].

Finally, the *artificial mechanical efficiency* is a trial to measure the fraction of the fuel inflow to the plant that attempts the mechanical product of the plant:

$$\eta_{art.} \equiv \frac{\dot{W}_{el.}}{\dot{E}_{comb.} - \left(\frac{\dot{E}_{coger.}}{\eta_Q} \right)} \qquad (5)$$

Any energy flow of the plant may be given by:

$$\dot{E}_j = \dot{m}_j \left(h_j - h_0 \right) \quad (j = 1, ..., p) \qquad (6)$$

For gas mixtures, the following equation should be accessed as well:

$$h_j = \sum_e X_e h(T_j) \quad (e = CO_2, H_2O, N_2, O_2) \; (7)$$

In these equations h_j and h_o are given by the JANAF tables at $T_0 = 298.15$ [K] (25 [C]) and $p_0 = 101.325$ [kPa] (1 [atm]).

SYSTEM CONCEPTION

In this section we show the conceived cogeneration system intended to produce electric energy, low temperature freezing for food conservation (at -25 [C]) and ice for fishing conservation (at -3 [C]), as shown in Figure 2.

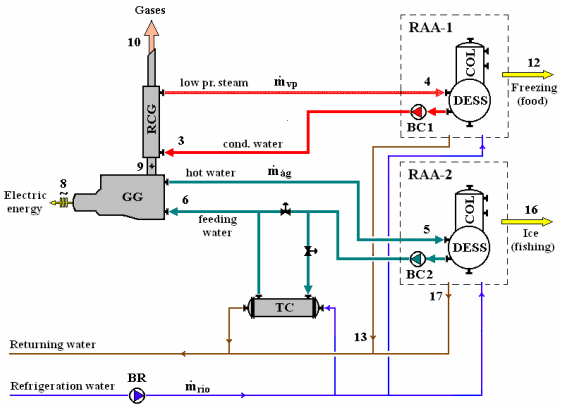

Figure 2: Cogeneration system conceived [4].

The system in Figure 2 has a productive structure associated to it, as shown in Fig. 3.

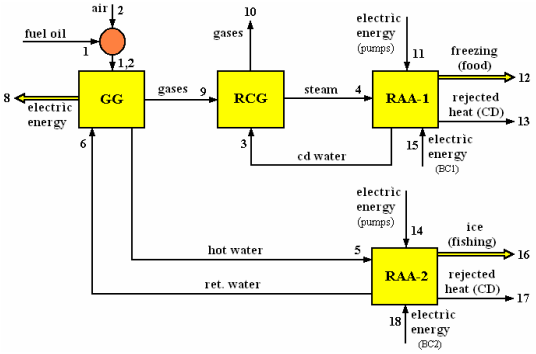

Figure 3: Structural diagram for the system of Figure 2 [4].

Technical Characteristics of the System

The RAA-1 and RAA-2 subunits are the 'clients' of the cogeneration system, which adopt the aqua-ammonia absorption refrigeration cycle, and for what the data shown on Table 1 are chosen assuming water properties constant with the varying power load.

The assumption for constant thermodynamic states for water at the cycle points of Table 1 does not imply that the cogeneration system must supply constant heat, but instead, determined electric power defined as mandatory.

Stations	T [K] (C)	p [kPa]
3 (sat. liq.)	403.15 (130)	—
4 (sat. steam)	403.15 (130)	270
5 (comp. liq.)	363.15 (90)	250
6 (comp. liq.)	348.15 (75)	—

Table 1: Water at the stations of the system.

In order to attempt to the heat surplus, the electric generator is powered by a supercharged Diesel engine which main technical data is reported on Table 2 [5] at four discrete power loads ($q \equiv \dot{W}_{lq} / \dot{W}_{l100}$).

A simulation model attempting to the energy balance of the Diesel engine under its variable power charge may be found in Reference [4], or on a related paper submitted to ECOS 2005, from the authors of this work. On Figure 4, one can find the simulated energy balance varying with

the power load of the Diesel engine of Table 2, obtained by the mentioned model ([4]).

q	10^{-8} *bsfc*	AF
25	6 841	89.92

75	5 688	36.05
100	5 592	27.50

Table 2: Main Diesel engine data [5].

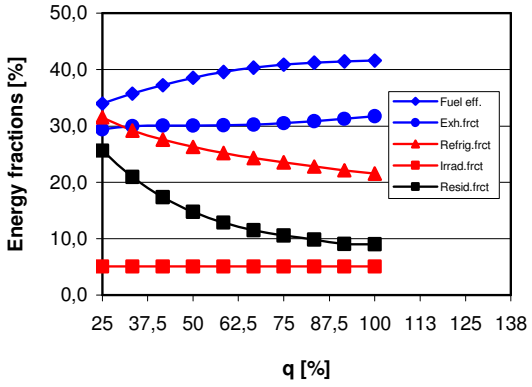

Figure 4: Simulated balance of energy fractions for the Diesel engine.

Energy Balances for the Subunits

Equations given on Table 3 compile the balances of energy flows through the subunits of Figure 3.

Subunit	Flow	Balance
GG	F	$\dot{E}_{1,2}$
	P	$\dot{E}_8 + \dot{E}_9 + (\dot{E}_5 - \dot{E}_6)$
RCG	F	$\dot{E}_9$
	P	$(\dot{E}_4 - \dot{E}_3)$
RAA-1	F	$(\dot{E}_4 - \dot{E}_3) + \dot{E}_{11} + \dot{E}_{15}$
	P	$\dot{E}_{12}$ (freezing)
RAA-2	F	$(\dot{E}_5 - \dot{E}_6) + \dot{E}_{14} + \dot{E}_{18}$
	P	$\dot{E}_{16}$ (ice)

Table 3: Energy balances of the subunits.

And for those equations on Table 3, the following equations show their correlative energy terms:

$$\dot{E}_{1,2} = \dot{m}_{comb.} Q_{LHV} \equiv \dot{E}_{comb.} \quad (8)$$

$$(\dot{E}_5 - \dot{E}_6) \equiv \dot{E}_{refr.} \quad (9)$$

$$\dot{E}_8 \equiv \dot{W}_{el} \quad (10)$$

$$\dot{E}_9 = \dot{m}_{exaus.}(h_9 - h_o) \equiv \dot{E}_{exaus.} \quad (11)$$

$$(\dot{E}_4 - \dot{E}_3) + (\dot{E}_5 - \dot{E}_6) \equiv \dot{E}_{coger.} \quad (12)$$

$$\dot{E}_x \equiv \eta_{BR} \lambda_z \dot{W}_{BR} + \eta_{BS} \dot{W}_{BS} \quad (13)$$

$$\dot{E}_y \equiv \eta_{BC} \dot{W}_{BC} \quad (14)$$

$$\lambda_z = \frac{\dot{m}_z}{\dot{m}_{rio}} \quad (15)$$

The subscripts x, y and z on these equations are referred to the stations as follow: x, to 11 and 14; y, to 15 and 18; and z, to 13 and 17.

As a consequence of the previous balances, it may be determined the first law parameters given by equations (1) to (5). By the way, it may be noted that if neglected the electric power demanded by water and solution pumps of the system, the first law efficiencies η^E_{RAA-1} and η^E_{RAA-2} equal the *performance coefficients* of the RAA-1 and RAA-2 subunits. Particularly, the bulk Horlock's coefficients [1] may be written as:

$$RCP = \frac{(\dot{E}_4 - \dot{E}_3) + (\dot{E}_5 - \dot{E}_6)}{\dot{E}_8} \quad (16)$$

$$FUE = \frac{(\dot{E}_4 - \dot{E}_3) + (\dot{E}_5 - \dot{E}_6) + \dot{E}_8}{\dot{E}_{1,2}} \quad (17)$$

$$IPE = 1 - \left\{ \frac{\eta_Q \eta_W \dot{E}_{1,2}}{\eta_W [(\dot{E}_4 - \dot{E}_3) + (\dot{E}_5 - \dot{E}_6)] + \eta_Q \dot{E}_8} \right\} \quad (18)$$

$$\eta_{art.} = \frac{\eta_Q \dot{E}_8}{\eta_Q \dot{E}_{1,2} - \left[(\dot{E}_4 - \dot{E}_3) + (\dot{E}_5 - \dot{E}_6)\right]} \quad (19)$$

For IPE and $\eta_{art.}$, we defined the constant values for the reference virtual efficiencies, η_Q = 0.95 and η_W = 0.40, which are usual figures for steam generators and Diesel engines [2], [3].

SIMULATION RESULTS

It can be seen on Figures 5 the plots of the simulation of the first law parameters. We have plotted on Figure 5 an efficiency curve for the power generator producing only electric energy $\eta_{el.}$ (power plant without cogeneration), to suit comparisons. It was accomplished by permuting the term relative to thermal energy at the numerator of the above FUE equation by Equation (10); i.e. the unique product is $\dot{W}_{el}$.

For the purpose of conciseness, the constant first law efficiencies η^E_{RAA-1} = 37.1 % and η^E_{RAA-2} = 36.2 % were not plotted on Figure 5, as their curves over-plot another ones. It should be emphasized that these efficiencies are constant by the reasons discussed after Table 1.

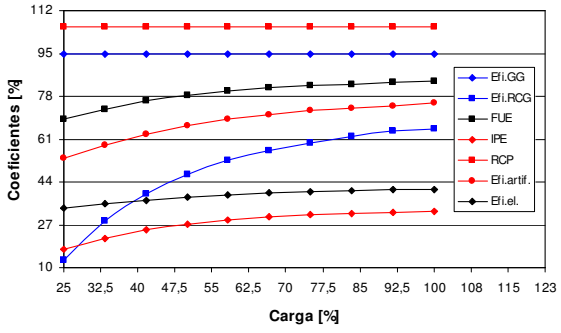

Figure 5: Simulated first law parameters.

On Figure 5, η^E_{GG} is constant and high (94.9%) for every value of the power load. This high figure denotes the enormous energy losses rescued by cogeneration. That can be seen noticing on Figure 5 that the low electric power generator efficiency ranges from $\eta_{el.}$ = 33.5 % (q = 25 [%]) to $\eta_{el.}$ = 41.0 % (q = 100 [%]).

The reason for the behavior of η^E_{GG} can be explained by noticing on Table 3 that η^E_{GG} is the summation of the *fuel conversion efficiency*, $\eta_f = 1/(bsfc\, Q_{LHV})$, the *energy fraction of the exhaust gases* $f_{exaus.} = \dot{E}_{exaus.lq} / (\dot{m}_f Q_{LHV})$ an the *energy fraction of the refrigerant* $f_{refr.} = \dot{E}_{refr.lq} / (\dot{m}_f Q_{LHV})$, where both fractions are related to the energy of the Diesel oil fuelled to the engine. As so, one can see on Figure 4, η_f grows, while $f_{refr.lq}$ decreases and $f_{exaus.lq}$ is kept quite constant.

Another constant parameter on figure 5 is RCP, set on 105.5, a value that rests in the range recommended by Silvia Nebra [2] and Lozano Serrano [3]. That behavior can be justified by noticing on Equation (2) that $\dot{W}_{el}$ (Equation (10)) responds quite faster than $\dot{E}_{coger.}$ (Equation (12)) to the power charge increases.

The rest of the first law parameters on Figure 5, i.e. FUE, $\eta_{art.}$, η^E_{RCG}, and IPE, present a general growth that is related to the behavior of the energetic terms by which these first law parameters are defined. It may be noticed that most of those energetic terms show their behavior relative to the variable power load on Figure 4.

It is import to emphasize that IPE and $\eta_{art.}$ were determined under the hypothesis of constant values for the reference virtual efficiencies η_Q and η_W, as it is difficult to find figures for these coefficients varying with the power load on the literature.

However, for the purpose of analysis, we issued a sensitivity analysis of IPE and $\eta_{art.}$ to η_Q and η_W, while these efficiencies vary ±2.5 % and ±5.0 % around their assumed values. By the plot on Figure 6, we show that IPE senses the variations of η_Q and η_W on a quite higher basis than $\eta_{art.}$ in the previously defined range of variation. Nevertheless, it can be seen that both IPE and $\eta_{art.}$ do not vary so highly as η_Q and

η_W vary from -5% to +5%, what gives confidence to the assumption of constant value for these reference efficiencies.

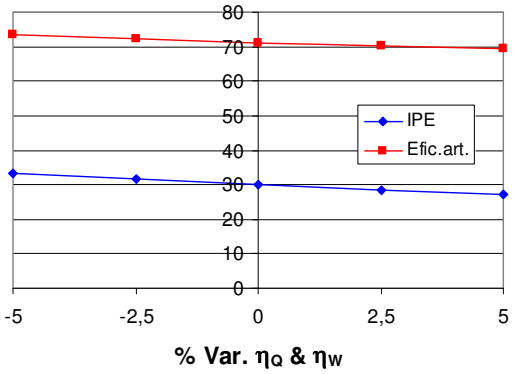

Figure 6: Sensitivity of IPE and $\eta_{art.}$.

CONCLUSIONS

The methodology presented in this work is suitable and reliable for energy analysis on a structural basis, despite it is not usual to perform such an analysis in energy planning studies. The effectiveness of the methodology, however, depends on the method for the simulation of the energy balance of the engine.

The simulation showed that the two most important first law efficiency parameters are constant along the range of the power load, to say, η_{GG}^{E} and RCP.

It is a very interesting result, as these parameters assume an important row on the definition of the part work and heat share in the performance of a cogeneration plant. In other words, work and heat shall ride side by side in terms of their relative magnitudes in the cogeneration system behavior. It means that the only effort a designer has to perform in his project is on defining the *share* of work and heat, as it depends mainly on the purpose of the cogeneration plant.

ABSTRACT

A simulation of a cogeneration system was performed. The systems consisted of a Diesel engine with two different refrigeration system, one of which working with steam generated using the engine exhaust gases and the other working with the engine cooling water. The first one produced cold water and the other one, ice. Afterwards, a thermoeconomic structure was defined for the system to perform a thermoeconomic costs analysis which gave information about every system flow on a monetary basis. The methodology used was the Exergetic Cost Theory (ECT). The costs obtained differed from that from got the first law point of view, by the fact that the later loses information about the quality of energy, which is taken into account in a second law approach. Unit costs and exergetic and exergoeconomic costs are plotted as the engine power load varies.
Key-words: thermoeconomics, costs, cogeneration, Diesel power plant, variable load.

NOMENCLATURE

$\mathbf{A}$	Leontieff's incidence matrix
$\dot{\mathbf{B}}^*$	Flow exergetic cost vector
$\dot{\mathbf{B}}$	Exergy flux vector
$\dot{\mathrm{B}}$	Exergy flux [kW]
bsfc	Brake specific fuel consumption [kg/kJ]
$\dot{\mathbf{C}}$	Exergoeconomic cost time-rate vector
$\dot{\mathrm{C}}$	Exergoeconomic cost time-rate [US$/s]
C	Capital cost of a subunit [US$]
$\dot{\mathrm{F}}^*$	Exergoeconomic cost of fuel [US$/s]
$\dot{\mathrm{F}}$	Fuel flux to a subunit [kW]
FA	Amortization factor
FK	Capitalization factor
k	Flows number
f_{IS}	Auxiliary additive factor
$f_{\mathrm{O\&M}}$	O&M factor
f_{RP}	Diesel power set refurbishment factor
$\dot{\mathrm{I}}$	Irreversibility time-rate of a subunit [kW]
i	Discount rate [%]
$\dot{\mathrm{L}}$	Exergy loss flux of a subunit [kW]
m	Number of subunits
$\dot{\mathrm{P}}^*$	Exergoeconomic product cost vector [US$/s]
$\dot{\mathrm{P}}$	Product flux of a subunit [kW]
p	Energy flow number
p	Price [US$/kW]
q	Power load [%]

INTRODUCTION

The potential to upgrade the Northern Brazilian power grid up to cogeneration is determined by both its high social importance and poor profitability. The electric energy generation by autonomous Diesel power plants, under a great number of logistic and maintenance problems, is particularly trouble-some in Brazilian Amazon. This was the motivation to perform simulations and then extract thermoeconomic costs for a Diesel cogeneration plant under varying power load. A simple engineering method, explained in other paper presented at this congress, was used to simulate Diesel engines.

THERMOECONOMIC MODELING

Exergetic Costs Balance

To any productive structure, as the one illustrated on Figure 1, it can be assigned a *F-P-L structure*, what defines the exergy balance [1]:

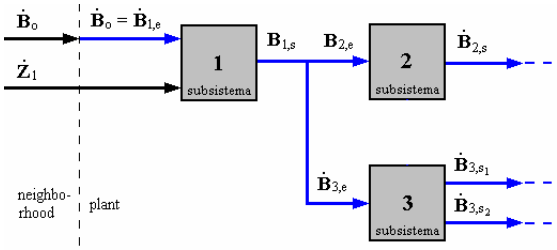

Figure 1: Exergy flows through a productive structure [3].

$$\dot{F}_i = \dot{P}_i + \left(\dot{I}_i + \dot{L}_i\right) \leq \dot{P}_i \quad (\mathrm{i} = 1, ..., m) \qquad (1)$$

In general, for the defined productive structure, the following matrix exergetic cost balance can be written:

$$\mathbf{A}\,\dot{\mathbf{B}}^{*} = \mathbf{A}\left(\mathbf{k}\,\dot{\mathbf{B}}\right) = \mathbf{0} \qquad (2)$$

in which $\dot{\mathbf{B}}^{*}$ and $\dot{\mathbf{B}}$ are $m \times 1$ column-vectors, $\mathbf{A}$ is a $m \times k$ matrix (which elements are +1 to inflows and -1 to outflows), and $\mathbf{k}$ is the vector of the *unit exergetic costs*, which are defined as [1], [2]:

$$k_j \equiv \frac{\dot{B}_j^{*}}{\dot{B}_j} \quad (j = 0, 1, ..., p) \qquad (3)$$

For the flow exergies in Equation (3), we took into account its physic and chemic parts. Detailed description about the formulation for those figures can be found in [3]. Moreover, it was considered, for work and heat:

$$\dot{B}_j^{Q} \equiv \dot{Q}_j \left(1 - \frac{T_0}{T_j}\right) = \dot{Q}_j\,\eta_{Cj} \qquad (4)$$

$$\dot{B}_j^{W} = \dot{W}_j \qquad (5)$$

As an extension of Equation (3), for the fuel and the product of any subunit, it is possible to define unit exergetic costs to fuel and product of each subunit as well:

$$k_{F,i} \equiv \frac{\dot{F}_i^{*}}{\dot{F}_i} \qquad (6)$$

$$k_{P.i} \equiv \frac{\dot{P}_i^*}{\dot{P}_i} \qquad (7)$$

In Equations (6) and (7), i = 1, ..., *m*.
Once Equation (2) is written for the system, it can easily be seen that it demands $k - m$ additional equations for the matrix system to be solved, while $k > m$. One set of additional equations can be satisfactorily defined by the propositions postulated by Valero et al.[1]. So the whole matrix exergetic cost balance plus the additional equations can be written as:

$$[\mathbf{A} \ \vdots \ \mathbf{a}]^t \dot{\mathbf{B}}^* = (\mathbf{0} \ \vdots \ \mathbf{w})^t \qquad (8)$$

Or, in a more concise form, as:

$$[\boldsymbol{A}]\dot{\mathbf{B}}^* = (\mathbf{Y}) \qquad (9)$$

In Equation (9), matrix $[\boldsymbol{A}]$ contains matrix **A** and vectors **a** and **w**, which respectively contain the first member and the second member of the Valero et al. [1] propositions.

Exergoeconomic Cost Balance

Defining *unit exergoeconomic costs* similarly to the exergetic unit costs, Equation (3), as:

$$c_j \equiv \frac{\dot{C}_j}{\dot{B}_j} \quad (j = 0, 1, ..., p) \qquad (10)$$

And taking into account the same discussion issued to write Equation (8), a matrix exergoeconomic cost balance results too:

$$[\boldsymbol{A}]\dot{\mathbf{C}} = (\boldsymbol{Z}) \qquad (11)$$

Equation (11) requires information about the flow of capital cost to the subunits of the plant, embodied in vector $(\boldsymbol{Z})$. Each element in this vector may be obtained by:

$$\dot{Z}_i = \frac{C_i\left(f_{O\&M} + FK \cdot FA\right)}{\tau} \qquad (12)$$

for what i = 1, ..., *m*. The factor $FK = 1 + f_{IS} + f_{RP}\sum_{j=1}^{p}(1+i)^{-3j}$ contemplates the cost of the generator set and its maintenance. The $FA = i(1+i)^t\left[(1+i)^t - 1\right]^{-1}$ isthe cost of auxiliary equipment.. These figures can be found in [3].

SYSTEM CONCEPTION AND THE COSTS STRUCTURE

The cogeneration Diesel plant is rated as 1 [MW] electric power, planned to generate electric energy, low temperature freezing for food conservation and ice for fishing conservation, as shown in Figure 2. Detached from Figure 2, on Figure 3 we show the productive structure defined to guide the thermoeconomic discussion.
On Figure 2, subunit RAA-1 is powered by the high temperature exhaust gases from the Diesel engine. And subunit RAA-2 is powered by the low temperature cooling water from the Diesel engine. Both units are aqua-ammonia absorption systems.
Thermoeconomic costs are appropriate monetary expressions for cogeneration plants. The exergetic costs and the exergoeconomic costs are interpreted as *average costs* in economy, i.e. costs developed by the economic system, 'measured' after a time period has past. Similarly, the *marginal cost*, defined in economy as the addition to the unit cost a growth of the production factor imputes to the product (it is the derivative of a production function relative to its productive factors), has its correlative in thermoeconomics. This approach was not taken into account in our analysis.

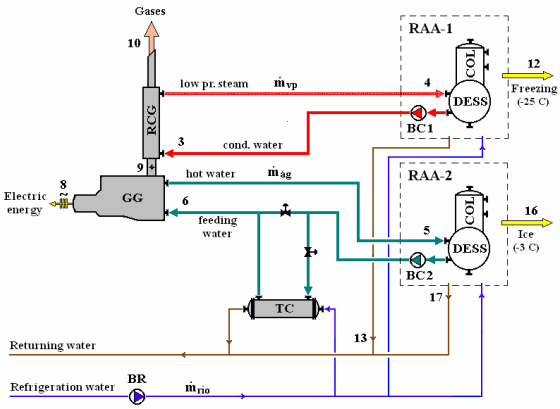

Figure 2: Cogeneration system conceived [3].

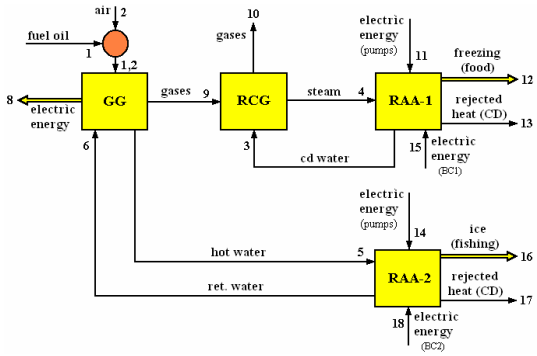

Figure 3: Structural diagram for the system of Figure 2 [3].

Technical Characteristics of the System

Heat for RAA-1 is furnished by low pressure steam, and for RAA-2 it is done by hot water. For the water data in Table 1 we assumed constant temperature and pressure while the engine power load varies, noticing that this assumption does not imply a constant heat supplement by the cogeneration system. This results from the fact that the plant generates primarily electric energy, which is the product that must be privileged.
The electric generator of the plant is powered by a supercharged Diesel engine from an international manufacturer, which main technical data are shown in Table 3, at four discrete power loads ($q \equiv \dot{W}_{lq} / \dot{W}_{l100}$).

System Points	T [K] (C)	p [kPa]

100	5 592	27.50

Table 3: Main Diesel engine data [4].

In accordance to the purposes exposed in previous sections, a simple simulation model of the engine energy balance is mandatory, in order to allow the thermoeconomic analysis of the autonomous Diesel cogeneration plant at the actual economic, social and technical conditions of Amazon. Defeating sophisticated modeling procedures, simple simulations can be done by means of *performance parameters* of internal combustion engines, as that one found in [3] for discrete simulation, or on a related paper submitted to ECOS 2005, from the authors of this work.
Adopting such a simple model [3], we obtained Figure 4, as illustration of the simulated energy balance of the Diesel engine of Table 3.

F-P-L Structure for the Cogeneration Plant

It was assumed that flow $\dot{B}_8$ (electric power) is the unique product of the Diesel power generator (GG), as referred on [5], [6], [7]. We considered subunit RCG apart from GG. Table 4 shows the exergy balances written with the aid of Equation (1). As a consequence, flows $\dot{B}_5$ (hot water input to RAA-2), $\dot{B}_6$ (hot water exiting RAA-2) and $\dot{B}_9$ (gases exiting GG) are *sub products* of GG.

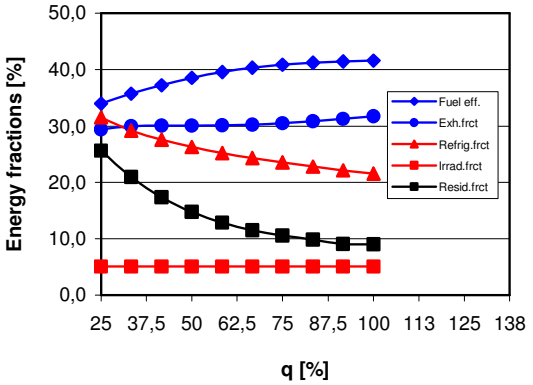

Figure 4: Simulated energy fractions for the Diesel engine [3].

Subunit	Flow	Balance
GG	F	$\dot{B}_1 - \dot{B}_9 - (\dot{B}_5 - \dot{B}_6)$
	P	$\dot{B}_8$
	L	—
RCG	F	$\dot{B}_9$
	P	$(\dot{B}_4 - \dot{B}_3)$
	L	$\dot{B}_{10}$
RAA-1	F	$(\dot{B}_4 - \dot{B}_3) + \dot{B}_{11} + \dot{B}_{15}$
	P	$\dot{B}_{12}$ (freezing)
	L	$\dot{B}_{13}$ (heat rejection)
RAA-2	F	$(\dot{B}_5 - \dot{B}_6) + \dot{B}_{14} + \dot{B}_{18}$
	P	$\dot{B}_{16}$ (ice)
	L	$\dot{B}_{17}$ (heat rejection)

Table 4: Exergy balances of the subunits [3].

The Cost Equations of the Cogeneration Plant

When the matrix exergetic cost Equation (9) is written for the plant, it generates a set of 4 linear equations, one for each subunit. Then, as for the productive structure of Figure 3 there are 17 unknown exergetic cost flows, so 13 additional equations must be defined to the system to be solved, what can be done with the aid of the propositions of Valero et al. [1]. On Table 5, additional equations were listed, written in terms of unit costs, and following the previous discussion about the parts that flows $\dot{B}_5$, $\dot{B}_6$, $\dot{B}_8$ and $\dot{B}_9$ play as sub products.

$k_1 = 1$	$k_{11} = k_8$
$k_2 = 0$	$k_{13} = 0$
$k_3 = k_4$	$k_{14} = k_8$
$k_5 = k_6$	$k_{15} = k_8$
$k_6 = k_9 = k_1$	$k_{17} = 0$
$k_{10} = 0$	$k_{18} = k_8$

Table 5: Set of additional equations for the solution of the exergetic cost equation.

Equation (11) can be written to obtain the exergoeconomic costs $\dot{C}_j = c_j \dot{B}_j$ (j = 0, 1, ..., *p*), in this case also additional equations are required. Such additional equations are those in Table 5, however on a monetary basis, i.e. written as unit exergoeconomic costs. For flow 1 (Diesel oil feeding the plant), the unit cost equals the price of Diesel oil per exergy unit.

Analyzing the Cost Formation of the Two Products of the Cogeneration Plant

Besides proceeding to the solution of the exergetic and exergoeconomic equations, it seems interesting to go deeper into the analysis of how the unit costs c_8 (electric energy) and c_4 (low pressure steam) of the cogeneration system become formed. It must be noticed that both the unit costs related to the engine cooling hot water flows (c_5 and c_6) are equal to the Diesel fuel oil price, in such a way these flows are not 'charged' with any cost relative to the Diesel engine.
The analysis was performed by extracting from the matrix equations written for the productive structure of Figure 3 the following equations; i.e. from the exergoeconomic cost equation obtained from Equation (11) and the exergetic equation obtained from Equation (9):

• GG:
$$c_1\dot{B}_1 + c_6\dot{B}_6 - c_5\dot{B}_5 - c_8\dot{B}_8 - c_9\dot{B}_9 + \dot{Z}_{GG} = 0 \quad (13)$$

$$\dot{B}_1 + \dot{B}_6 - (\dot{B}_5 + \dot{B}_8 + \dot{B}_9) - \dot{I}_{GG} = 0 \quad (14)$$

• RCG:
$$c_3\dot{B}_3 + c_9\dot{B}_9 - c_4\dot{B}_4 + \dot{Z}_{RCG} = 0 \quad (15)$$

$$\dot{B}_3 + \dot{B}_9 - \dot{B}_{10} - \dot{B}_4 - \dot{I}_{RCG} = 0 \quad (16)$$

Equation (13), aided by the additional equation $c_1 = p_{DO}$, can be solved for the unit cost of the cogeneration electric energy:

$$c_8 = \frac{p_{DO}[\dot{B}_1 - (\dot{B}_9 + \dot{B}_5 - \dot{B}_6)] + \dot{Z}_{GG}}{\dot{B}_8} \quad (17)$$

This solution shows the expected result that the unit cost of the electric energy partly derives from the cost of the Diesel fuel oil associated to the exergetic fuel to the subunit GG (see Table 4), and partly from the capital cost of the plant

(Diesel power set plus building, and equipments, etc.). Another form of viewing unit cost c_8 is by changing the term $\left(\dot{B}_9 + \dot{B}_5 - \dot{B}_6\right)$ in Equation (17) for its correlative term obtained from Equation (14), resulting:

$$c_8 = \frac{p_{DO}\left(\dot{B}_8 + \dot{I}_{GG}\right) + \dot{Z}_{GG}}{\dot{B}_8} \qquad (18)$$

What corroborates the previous hypothesis that the irreversibilities of the Diesel power set GG are 'carried' by the cost flow $\dot{B}_8^*$; fact that, by its turn, justifies the hypothesis of considering subunit RCG apart from subunit GG.

Besides, it can be noticed that in the case the plant generates only electricity (without cogeneration), the term $\left(\dot{B}_9 + \dot{B}_5 - \dot{B}_6\right)$ in Equation (17) equals zero, as this term of 'sub products' (in the cogeneration case) turns into lost exergies. In such a case, Equation (18) simplifies to $c_{8,WC} = \left(p_{DO}\dot{B}_1 + \dot{Z}_{GG}\right)/\dot{B}_8$, expression which reflects the fact that as the electricity becomes the unique product, it 'charges' all the costs, Diesel fuel oil and capital cost. Finally, we can say: $c_{8,WC} < c_8$, which means that cogeneration works towards contributing to lower the cost of the generation of electric energy.

Solving Equation (15), the cost of the product of the subunit RCG is obtained:

$$c_4 = \frac{p_{DO}\dot{B}_9 + \dot{Z}_{RCG}}{(\dot{B}_4 - \dot{B}_3)} \qquad (19)$$

As done for the unit cost c_8, we changed $\dot{B}_9$ in Equation (19) by its expression gotten from Equation (16):

$$c_4 = p_{DO} + \frac{p_{DO}\left(\dot{I}_{RCG} + \dot{B}_{10}\right)}{(\dot{B}_4 - \dot{B}_3)} + \frac{\dot{Z}_{RCG}}{(\dot{B}_4 - \dot{B}_3)} =$$

$$= p_{DO} + \frac{p_{DO}\dot{D}_{RCG}}{(\dot{B}_4 - \dot{B}_3)} + \frac{\dot{Z}_{RCG}}{(\dot{B}_4 - \dot{B}_3)} \qquad (20)$$

In other words, the unit cost of the low pressure steam is generated by the price of the Diesel fuel oil, adding the cost of the exergy destroyed by the subunit RCG and the capital cost.

SIMULATION RESULTS

The equations and simulations were solved with the aid of the software EES®, whose property data bank for many substances suffices.

Exergetic Costs Results

Figures 5 and 6 show the results of the unit exergetic costs and the exergetic costs, respectively, along the engine power load range.

It is interesting to discuss the two distinct behaviors presented in Figure 5.

On the one hand, flows 12 (freezing from RAA-1), 4 (low pressure steam) and 3 (condensed steam) have decreasing unit exergetic cost as the power load increases, what in economy is visualized as the *scale effect* of the production factor (its 'elasticity' is positive). At a load of 37.5 [%] the curves diminish notably its slope, denoting the increasing temperature of the exhaust gases, while its energy is kept quite constant; while the power load decreases (see Figure 4) – i.e. as the quality of the energy fed decreases, the unit cost of subunit RAA-1 increases.

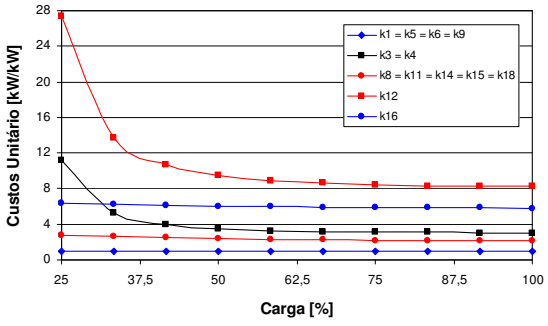

Figure 5: Unit exergetic costs of the flows of the cogeneration system [3].

On the other hand, the rest of the flows do not present a scale effect, meaning that their unit costs are constant (called 'economically inelastic').

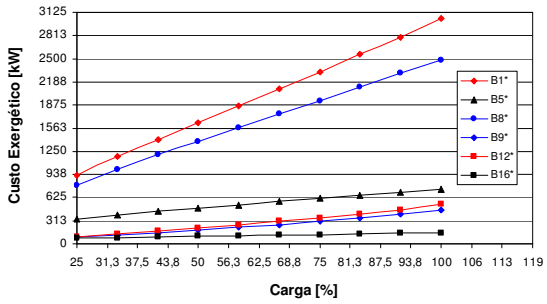

Figure 6: Exergetic Costs of the flows of the cogeneration system [3].

In Figure 7, the total exergetic cost of the *fuel* (F) of each subunit was plotted in function of the engine load. It may be noted that the figures in Figure 7 are the same for the total exergetic costs of the *product* (P) of each subunit, in accordance to what Valero et al. [1] have shown. It does not mean that the unit exergetic costs of fuels and products are the same, as each product carries the irreversibilities generated into the subunit from which it comes from. Figure 7 denotes also the importance of the subunit GG ('Grupo-gerador'), by both its departure from the other lines to a higher cost level, and by its bigger slope meaning higher fuel consumption. Figure 7 shows that the total exergetic costs of subunits RCG and RAA-1 are quite coincident and increasing along the power load range.

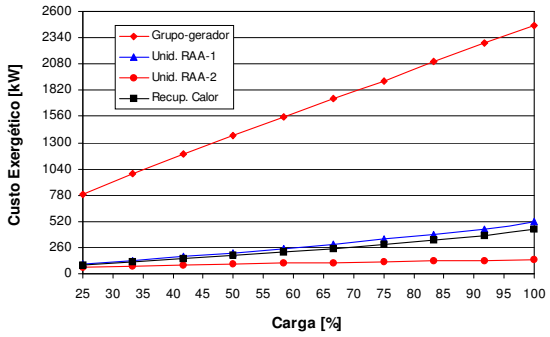

Figure 7: Total Fuel and Product Exergetic costs in the cogeneration plant [3].

Simulations of the Exergoeconomic Costs

Comparing Equation (9) to Equation (11), it can be noticed that the exergetic costs and the exergoeconomic costs of the flows behave in the same way. So we restricted our analysis to the exergoeconomic costs of the products of the 'economic' subunits, e.g. GG, RAA-1 and RAA-2, plotted at Figures 8 and 9.

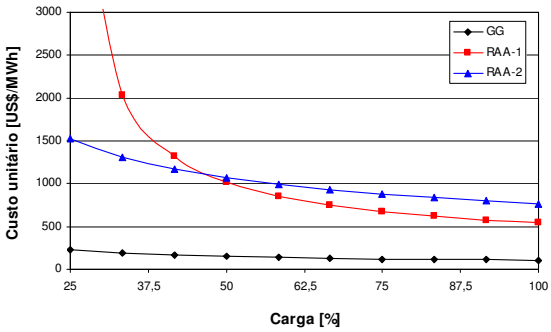

Figure 8: Exergoeconomic unit costs of the three principal products of the cogeneration plant [3].

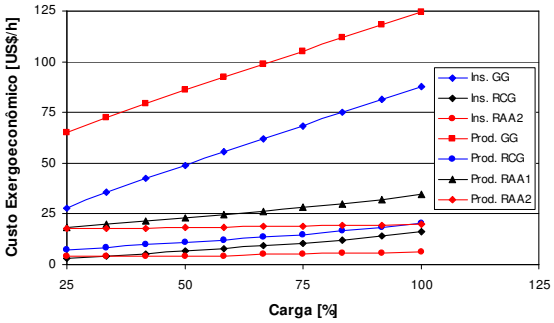

Figure 9: Exergoeconomic costs of F and P of the subunits of the cogeneration plant [3].

It can be seen, on Figure 8, that subunit RAA-1 has the highest cogeneration unit cost at a power load of 25 [%], and drops fast from that point. Such behavior denotes that the cost of its fuel – heat flux exergy – is inversely dependent of its 'quality' (temperature), particularly for power load bellow 50 [%].

By the exergoeconomic costs side, Figure 9 shows the quick answer of subunit GG to the power load, while the rest of the subunits do not.
The total exergetic and the exergoeconomic costs of fuel and product of the subunits behave similarly, but despite the exergetic cost of F and P are equal, the exergoeconomic are not, as can be seen at Figures 7 and 9.

CONCLUSIONS

The analysis performed in this work is useful for deepening energy planning studies about Diesel cogeneration systems, which, so, may go beyond the usual engineering practice. Some subsidiary analysis could be performed, but the main goal of simulating the behavior of the thermoeconomic costs of the plant, as its power load varies, was achieved.
On emphasizing a special result from all the conclusions we got, we would like to emphasize the corresponding established between the engineering thermoeconomics and the economy points of view, once we found that the economic scale effect explains the relationship among the unit costs and the engine power load. The importance this result embodies is the fact that it adds well to the behavior of the 'quality' of the heat flux fueled by the cogeneration system, i.e. it grows when the Diesel engine power load goes toward its maximum, as it was expected to be.

ACKNOWLEDGEMENTS

The authors wish to thank Cummins do Brasil S.A. for the kind permission for utilization of their engine data sheets and costs information; as well as FUCAPI Foundation in Amazon, State University of Amazon (UEA) and National Bureau for Scientific and Technologic Development (CNPq), for their financial support.

ABSTRACT

This paper focuses on the single-shaft microturbine in combined heat and power generation. In the application, the microturbine is operated by the heat demand and it replaces purchased electricity and produced heat in an existing boiler. The objective of the study is to analyze the effect of recuperation and different load control methods on the overall economy of the operation. The control parameters include the turbine inlet temperature and the rotational speed of the shaft. As a basis for the analysis, a steady state performance model using realistic component descriptions has been constructed for the microturbine. The operating values of the microturbine are obtained by solving the system of non-linear equations formed by the governing relations. The economy of the operation is determined by combining the performance model with the economy model developed for the engine. The economy model uses the present value of the gain from investing in the microturbine as a criterion. As a result, the conditions are determined for the cost-effective operation of the engine. In addition to the analysis of general validity, the developed models are applied to a case with given profiles for heat and power demand. The size range with the highest economic potential is determined for the microturbine options. For the selected size, the maximum costs are determined that can be allowed for the investment. Apart from the microturbine specifications and case-specific heat and power demand, the results are strongly dependent on the economic parameters. Sensitivity analysis is presented for the main affecting factors.

INTRODUCTION

Microturbines are small gas turbines (25 - 250 kWe) with high potential for future energy systems. They are expected to have steady growth especially in distributed generation, for instance in hospitals, supermarkets, and in small industry [1]. Additional value in distributed generation is gained when the thermal energy from the exhaust gases is recovered to supply local heat.

The turbine inlet temperatures of microturbines are low (800 - 1000°C) to keep the material costs at a reasonable level. The resulting power generation efficiency is quite low, but it can be counteracted by using recuperation. As a result, microturbines typically apply a recuperated cycle and achieve power generation efficiencies as high as 30 % [2]. The use of recuperation always increases the investment costs and needs to be justified economically.

In combined heat and power (CHP) generation, the overall efficiencies of the microturbines are in the range 75 - 85 %. The total investment costs for microturbine-based CHP applications are estimated to vary from 1000 to 1700 EUR/kWe [3].

Microturbines are typically single-shaft engines. The microturbine and the generator have a common shaft that rotates at high speed. The high-frequency current from the generator is converted to grid frequency with an inverter, which enables variable-speed operation.

This paper focuses on a single-shaft microturbine in CHP use. The study includes recuperated and non-recuperated configurations and two alternative load control methods: 1) using the turbine inlet temperature as the only control parameter, and 2) using the rotational speed of the shaft together with the turbine inlet temperature. The objective of the study is to investigate the effect of different configurations and control methods on the technical and economic performance of the specified microturbine. In the analysis, the conditions for profitable operation are determined. Furthermore, the most promising size range and the maximum allowed investment costs are determined for the microturbine in a selected CHP application. The sensitivity of the results against the energy prices is studied.

CHP SYSTEM

The studied CHP system has the maximum electric power demand of 220 kW, and the heat power demand of 728 kW as hot water at 80 °C. The annual energy demand for electricity is 824 MWh and for heat 2378 MWh. Figure 1a presents the annual load profiles for heat and power, and Figure 1b the load duration curves for the case.

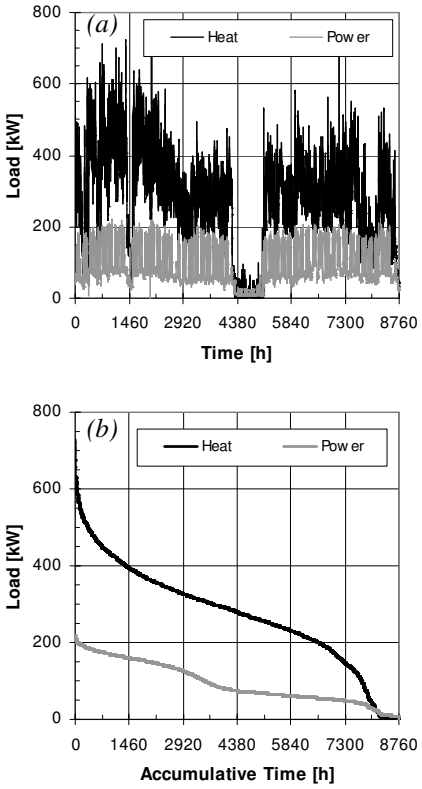

Figure 1: Load profiles *(a)* and duration curves *(b)* for heat and power demand.

In the studied case, the power and heat from the microturbine replaces purchased electricity from the network and produced heat in an existing natural gas-fired boiler. The load level of the microturbine is controlled – within the control range – by the heat demand of the system. If the demand is lower than the minimum heat output

from the microturbine, the excess heat remains unutilized. If the electric power demand is lower than the actual power output from the microturbine during the operation, the exceeding amount is exported. The microturbine is operated only when it is economical, compared to the alternative case where all the required electricity is purchased and the heat produced in the boiler.

GAS TURBINE MODEL

Model Composition

For the performance analysis, a steady state one-dimensional model has been constructed for the operation of single-shaft recuperated gas turbines at the design point and outside design conditions. The model is composed of 1) mass and heat balances, 2) process equations, for instance for compression and expansion, 3) general correlations, such as ellipse law for the mass flow through the turbine, and 4) component-specific maps. While the mass and heat balances and process equations set the universal model base to determine engine performance at reference (design) conditions, correlations and component-specific maps determine the variation of some parameters (mass flows, pressure ratios and pressure losses, for instance) in the system and, together with the other relationships, the overall operation outside design conditions. Figure 2 demonstrates the computational relationships between the equations setting the model base (DES) and the additional equations outside design-point operation (OD).

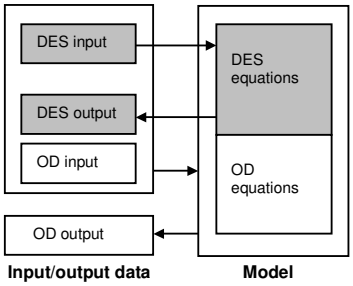

Figure 2: Computational relationships in the gas turbine model.

In the model, the assumption of perfect gas has been applied for the fluids in the cycle: fuel, air and combustion gases. The computation of the fluid properties utilizes polynomial functions for the specific heat capacities of gaseous components and the viscosity of air, a table for combustion reactions, and molecular heating values for the reactions.

The variation of the mass flow and the isentropic efficiency of the compressor outside design conditions is modeled using component-specific maps adapted from in-house design software for radial turbomachinery. For the turbine, the variation of isentropic efficiency is modeled using a map adapted from [4]. The maps are shown in Figures 3 and 4. The map parameters Π, Φ, X, and E for pressure ratio π, rotational speed N, mass flow q_m, and isentropic efficiency η_s are presented in generalized form, which makes the maps valid also outside the reference conditions (denoted with subscript 0). The inlet and outlet states for the components are referred to with subscripts α and β.

$$\Pi = \frac{\pi - 1}{\pi_0 - 1} \tag{1}$$

$$\Phi = \frac{N}{N_0}\sqrt{\frac{T_{\alpha 0}}{T_\alpha}} \tag{2}$$

$$X = \frac{q_m}{q_{m0}}\sqrt{\frac{T_\alpha}{T_{\alpha 0}}}\frac{p_{\alpha 0}}{p_\alpha} \tag{3}$$

$$E = \frac{\eta_s}{\eta_{s0}} \tag{4}$$

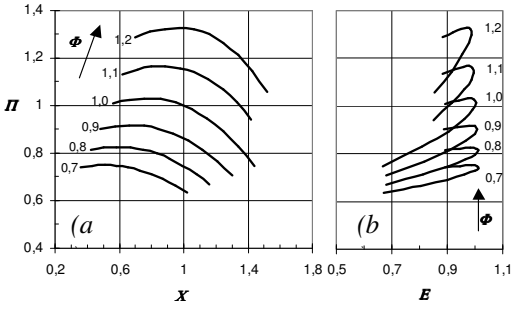

Figure 3: Compressor mass flow *(a)* and efficiency *(b)* maps.

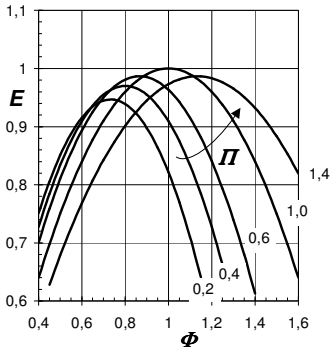

Figure 4: Turbine efficiency map.

The variation of the turbine mass flow outside design conditions is approximated using the ellipse law.

$$\frac{q_m}{q_{m0}} = \frac{p_\alpha}{p_{\alpha 0}} \sqrt{\frac{T_{\alpha 0}}{T_\alpha}} \sqrt{\frac{1-\left(\frac{p_\beta}{p_\alpha}\right)^{\frac{2.3}{1.3}}}{1-\left(\frac{p_{\beta 0}}{p_{\alpha 0}}\right)^{\frac{2.3}{1.3}}}} \tag{5}$$

For recuperator effectiveness ε, the variation is assumed to follow an equation suggested in [5] for a plate-fin recuperator of the counterflow type. In the equation, the inlet and outlet states on the airside and, correspondingly, on the combustion gas side are denoted with subscripts α, β, γ, and δ. Dynamic viscosity is referred to with μ.

$$\frac{\varepsilon}{\varepsilon_0} = \frac{q_{m0}}{q_m} \frac{\bar{\mu}_{\alpha,\beta}}{\bar{\mu}_{\alpha,\beta\,0}} \frac{T_\delta - T_\alpha + T_\gamma - T_\beta}{T_{\delta 0} - T_{\alpha 0} + T_{\gamma 0} - T_{\beta 0}} \frac{T_{\gamma 0} - T_{\alpha 0}}{T_\gamma - T_\alpha} \tag{6}$$

The variation of the mechanical losses outside design conditions is determined as proportional to the square of the rotational speed. The variation of the pressure losses Δp is given by a correlation derived from the model for tubular flows. In the correlation, constant factors for friction and minor losses are assumed.

$$\frac{\Delta p}{\Delta p_0} = \left(\frac{q_m}{q_{m0}}\right)^2 \frac{p_{\alpha 0}}{p_\alpha} \frac{T_\alpha}{T_{\alpha 0}} \tag{7}$$

Electromechanical losses for the generator and the inverter are determined on the basis of the curve presented in Figure 5. The values are presented relative to the corresponding design-point values.

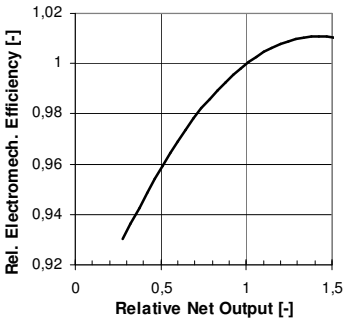

Figure 5: Electromechanical efficiency of the generator and the inverter against net power output.

The calculations are based on the ISO operating conditions (15°C, 101.325 kPa, 60 %), using Russian-type natural gas as fuel. The main components of the fuel are as follows: methane (97.9 %-vol), nitrogen (0.96 %-vol), ethane (0.82 %-vol), and propane (0.23 %-vol).

The turbine inlet temperature is 900°C, a typical value in the microturbine scale that allows the use of standard materials without cooling the hot gas-path components. The compressor pressure ratio is selected to yield the maximum net electric efficiency for the given specifications. However, the upper limit 4 is applied in the optimization. This is considered the highest possible value for a single-stage centrifugal compressor when using lower cost aluminum material [6]. The specifications for the component efficiencies and losses have been selected to reflect the typical values for the microturbine scale. The specifications are presented in Table 1.

The fuel is virtually sulfur-free, and therefore the amount of heat that can be recovered from the combustion gases is not limited by the condensation risk of sulfuric acids. The heat output is determined at design-point operation as well as outside design conditions by assuming the combustion gases to be cooled down to 70°C in the heat recovery boiler.

Compressor polytropic efficiency	84 %
Turbine polytropic efficiency	83 %
Recuperator effectiveness	90 %
Mechanical efficiency of the shaft	98 %
Electromechanical efficiency (generator and inverter)	90 %
Inlet pressure loss	1 %
Recuperator air-side pressure loss (if fitted)	3 %
Combustion chamber pressure loss	3 %
Recuperator exhaust gas-side pressure loss (if fitted)	3 %
Outlet pressure loss	1 %
Pressure loss in the heat recovery boiler	3 %

Table 1: Design-point specifications for the calculations. All pressure losses are given relative to the corresponding inlet pressure.

Computational basis

The relations defining the operation of the gas turbine form a set of non-linear equations, as shown schematically in Figure 2. This set of equations is solved to obtain the operating values for the gas turbine [5]. The selected solution method applies a modification of Newton's method to increase the convergence properties of the basic Newton method. The method requires the calculation of the Jacobian matrix, composed of partial derivatives. The derivatives are approximated using forward differences. Errors arising in finite-precision computing have been reduced by applying double precision arithmetic. The basis for the method and the source codes for the implementation have been presented in [7].

When using deterministic methods, such as Newton's method as the basis, a necessary precondition for convergence is that the starting point is sufficiently close to the root. Newton-based methods also require the Jacobian matrix to be non-singular and the partial derivatives in the matrix to be continuous [8].

For the gas turbine model, the determination of the above-mentioned starting point for the design and off-design calculations is based on simplifications in the model, so that sequential computation can be applied to the equations that set the model base.

The performance maps of the compressor and turbine have been modeled by approximating the constant parameter curves with appropriate polynomial fits and using basic bivariate interpolation schemes [9]. For any value of the curve parameter, the surrounding curves on the map are then transferred to approximate the curve that corresponds to this value, obtaining the result by a linear interpolation of these curves. Although the method does not ensure continuity of the first derivatives as the interpolating point crosses the surrounding curves, the solutions were found without exceptions.

ECONOMIC MODEL

The economic analysis is based on determining the present value C of the gain from investing in microturbine-based CHP. It uses the performance data for the microturbine options and the variation of the heat and power loads. In the analysis, the following costs are taken into account: the investment costs C_{inv} for the microturbine and the associated components, the present value C_f of the fuel costs from using it, the present value C_{ma} of the operation and maintenance costs, the present value C_{av} of the avoided costs, and the present value C_{sur} of the income from selling the surplus electricity to the network.

$$C = C_{av} + C_{sur} - C_{inv} - C_f - C_{ma} \quad (8)$$

In addition to the microturbine itself, the investment costs for the microturbine-based CHP include the heat recovery boiler, the electrical system, as well as the building and installation.

When in operation, the heat output $\Phi_{h,mt}$ from the microturbine is set to follow the heat load $\Phi_{h,load}$. If the load remains below the control range, the engine is operated at the minimum heat output level. The electric power output $P_{e,mt}$ and fuel power $\Phi_{f,mt}$ that correspond to the actual heat output are gained from the performance characteristics, determined for each configuration and control method. If the electric power demand $P_{e,load}$ remains below the actual power output from the microturbine, the exceeding amount is sold to the network.

Denoting the energy prices of purchased and sold electricity with $e_{e,buy}$ and $e_{e,sell}$, the fuel price with e_f, and the boiler efficiency with η_b, the present value of the avoided costs is given by

$$C_{av} = a \int_0^{8760h} \left[P_{e,av}(t)\, e_{e,buy} + \frac{\Phi_{h,av}(t)}{\eta_b}\, e_f \right] dt \quad (9)$$

where

$$P_{e,av}(t) = \min\left(P_{e,load}(t), P_{e,mt}(t)\right) \quad (10)$$

and

$$\Phi_{h,av}(t) = \min\left(\Phi_{h,load}(t), \Phi_{h,mt}(t)\right) \quad (11)$$

In the equation, a is the factor of the present value of periodic payments. The operation and maintenance costs of the boiler are assumed to be constant and thus have no effect on the avoided costs.

The present value of selling the excess electricity to the network is determined from

$$C_{sur} = a \int_0^{8760h} P_{e,sur}(t)\, e_{e,sell}\, dt \quad (12)$$

where

$$P_{e,sur}(t) = \max\left(0, P_{e,mt}(t) - P_{e,load}(t)\right) \quad (13)$$

The constant part of the annual operation and maintenance costs of the microturbine is determined as a fraction r of the investment costs and the variable part as relative to the produced eletricity, using the factor c_{ma} for the specific costs.

$$C_{ma} = a \left(r\, C_{inv} + \int_0^{8760h} P_{e,mt}(t)\, c_{ma}\, dt \right) \quad (14)$$

The present value of the fuel costs is determined from

$$C_f = a \int_0^{8760h} \Phi_{f,mt}(t)\, e_f\, dt \quad (15)$$

At low power levels, the use of the microturbine may not be economical when compared to the alternative case where all the required electricity is purchased and the heat produced in the boiler. On an hourly basis, a criterion for the operation of the microturbine is obtained by requiring that the energy-related total gain flow (EUR/h) from using it be positive. The gain flow includes the avoided costs from using the microturbine to generate power and heat, the income from selling any surplus electricity, the fuel costs, as well as variable maintenance costs for the microturbine. For the calculation, the gain flow is formed from the integrands in equations (9) to (15).

The maximum investment cost that can be allowed for the microturbine-based CHP to be an economically feasible investment has been determined by using the criterion for profitable operation, taking into account equations (8) to (15), and setting the present value C of the gain to equal zero. In the calculation, the integrals have been approximated numerically using discrete data points. The values for the parameters in the calculation are presented in Table 2. The price for the purchased electricity includes transmission costs, and all energy prices include taxes (excluding value added tax), fiscal charges and fees [10].

RESULTS

The pressure ratio that maximizes the net electric efficiency at design point operation is very close to 4 for the recuperated (Rec) configuration, while for the non-recuperated (No Rec) cycle the optimum would lie well above the limiting value 4, applicable for the selected compressor type. Consequently, the pressure ratio of 4 was selected for both configurations. The corresponding performance is presented in Table 3. The table certifies the established impact of the recuperator: an increase in the electric efficiency and a decrease in the heat output. In this case the electric efficiency of the non-recuperated cycle is further penalized by the limitations in the pressure ratio.

As a result of heat regeneration in the cycle, the ratio of unusable (exhaust) heat to incoming (fuel) heat is increased, which decreases the overall efficiency.

		No Rec	Rec
Power-to-heat ratio	[-]	0.220	0.659
Net electric efficiency	[%]	16.4	32.0
Overall efficiency	[%]	90.8	80.6

Table 3: Performance data for the microturbine options at design point operation.

Figure 6 presents the part load characteristics for the recuperated and non-recuperated microturbine configurations and for both control methods used in the study. The parameters are presented as relative to their design-point values. To produce the curves for the turbine inlet temperature (TIT) control, the temperature has been reduced with 25°C steps. For the combined rotational speed and turbine inlet temperature (Sp and TIT) control, first the relative speed of the shaft has been reduced with 0.05 steps until the limiting value 0.70, set by the compressor map, has been achieved. After this, the turbine inlet temperature has been reduced again with 25°C steps while the speed has remained unchanged.

The use of combined speed and turbine inlet temperature control has a strong increasing impact on the electric efficiency of the recuperated cycle, but also a strong decreasing impact on the heat output when compared to using the turbine inlet temperature as the only control method. For the non-recuperated configuration, the difference between the control methods is smaller. The variation of the overall efficiency relative to its design value is fairly small and similar in the studied microturbine options.

For the recuperated configuration, the heat output does not determine the operating point unambiguously when altering the turbine inlet temperature after the speed control. Therefore, only speed control is considered for the recuperated cycle instead of combined speed and turbine inlet temperature control.

To evaluate the economic potential of the selected microturbine options, Figure 7 presents the effect of the varying heat and power demand on the gain flow from the microturbine. The parameters in the figure are divided by the performance parameters of the microturbine at design-point operation. The load levels that exceed the design heat and power output of the microturbine have no effect on the gain flow, and hence are not shown in the figure. As a result, the presentation depends on the energy prices, but is independent of the microturbine size and the size of the CHP system.

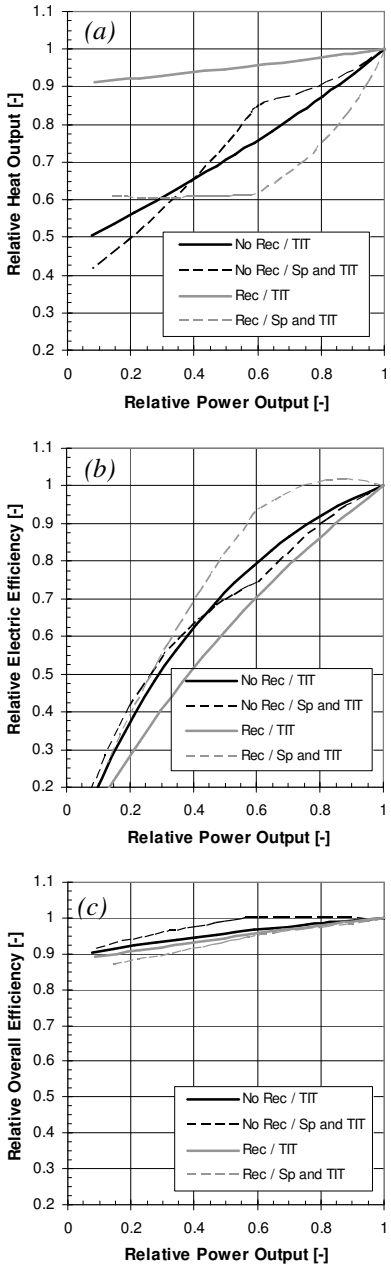

Figure 6: Heat output *(a)*, net electric efficiency *(b)*, and overall efficiency *(c)* during part-load operation for the selected microturbine options.

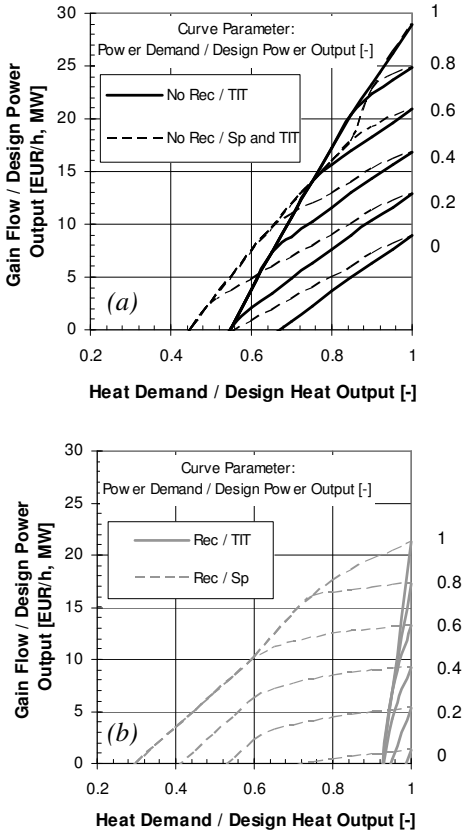

Figure 7: The gain flow from using the microturbine options at varying heat and power demand. Non-recuperated *(a)* and recuperated *(b)* configuration.

Compared to the recuperated configuration, the non-recuperated cycle has a higher maximum gain flow for a given microturbine size. Due to the high cost of the recuperator, the non-recuperated configuration is also less expensive, despite the increased size of the heat recovery boiler. As a result, the non-recuperated cycle has higher potential for feasibility at design point operation. It must be noted that in order to realize this potential, significantly higher heat load levels are required for a given power level than with the recuperated cycle. The recuperated configuration with turbine inlet temperature control suffers from a very narrow margin for profitable operation when the heat demand is decreased. The implementation of the speed control expands the range significantly. For the non-recuperated configuration, the control methods have a lesser impact on the economy of operation.

As a result of the economic analysis using the heat and power profiles from Figure 1a, Figure 8 presents the effect of the electric power output (engine size) on the maximum investment costs that can be allowed for the microturbine-based CHP. As a general rule, increase in power output increases the investment costs of the engine. Therefore, the best economy for the investment can be expected at the increasing part of the curves. Since the recuperated configurations are more expensive than the non-recuperated cycles of the same power output, the non-recuperated configurations gain the highest potential for feasibility at lower power levels while for the recuperated cycles the optimum power levels are higher.

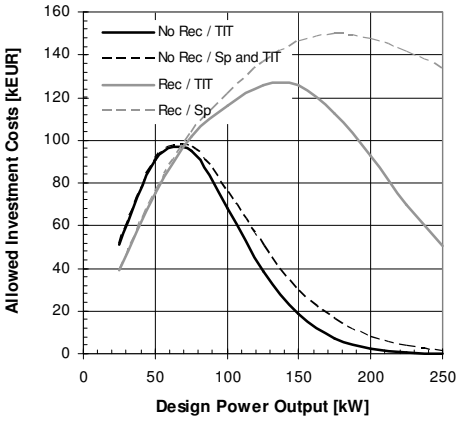

Figure 8: The effect of the engine size on the maximum investment costs that can be allowed for the microturbine-based CHP.

For further analysis, the electric power output of the recuperated configuration was selected to be 100 kW at design-point operation, and one third of this was chosen for the non-recuperated cycle. As a result of the selection, the heat output levels of the configurations are close to each other at design-point operation. Table 4 summarizes the selected sizes for the configurations.

		No Rec	Rec
Power output	[kW]	33.3	100.0
Heat output	[kW]	151.3	151.7
Air mass flow	[kg/s]	0.241	0.825

Table 4: The selected microturbine size at design point operation.

Table 5 presents the annual operating hours and the maximum specific investment costs [EUR/kWe] that can be allowed for the microturbine options of the selected size when supplying the heat and power demand from Figure 1a.

	Operating hours	Allowed specific investment costs
	[h/a]	[EUR/kWe]
No Rec / TIT	7808	2006
No Rec / Sp and TIT	7899	2007
Rec / TIT	7364	1162
Rec / Sp	7887	1218

Table 5: The annual operating hours and the maximum specific investment costs that can be allowed for the selected microturbine size.

With the selected energy prices and load profiles, the allowed specific investment costs are significantly higher for the non-recuperated cycle than for the recuperated one. However, the difference must be weighted against the different size of the engines: smaller size is typically featured with higher specific investment costs. The specific investment costs for the microturbine-based CHP applications are typically in the range of 1000 - 1700 EUR/kWe, and hence, the investment may be feasible in all the studied options.

Compared to the turbine inlet temperature control, the use of a more expensive combined turbine inlet temperature and speed control has no effect on the allowed investment costs, and is hence not justified with the non-recuperated configuration. This is also indicated in Figure 8. For the recuperated cycle, the use of speed control instead of turbine inlet temperature control yields an increase in the allowed investment costs, which may make the speed control a feasible choice.

Figure 9 presents the sensitivity of the allowed specific investment costs against energy prices. Increase in the price for the purchased electricity and decrease in the fuel price have a similar contribution for both non-recuperated and recuperated cycles. Compared to these, the price of sold electricity has a lesser effect on the recuperated cycle and no effect on the non-recuperated one.

The energy prices have only a small effect on the difference between the control methods for the recuperated cycle. For the non-recuperated cycle, the difference remains negligible.

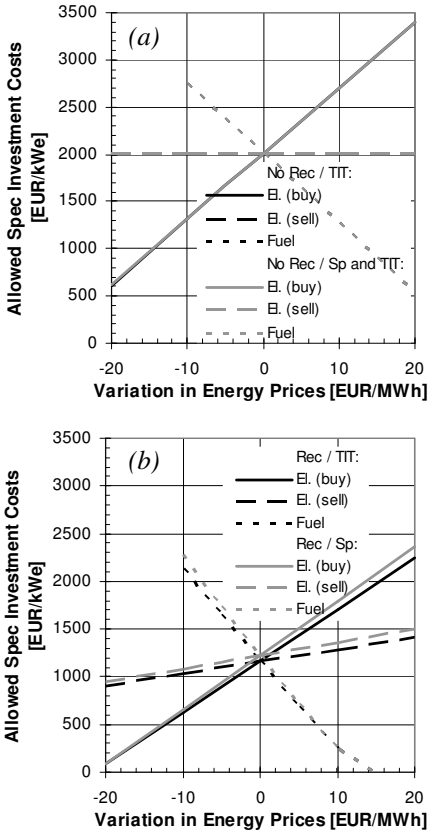

Figure 9: The sensitivity of the allowed specific investment costs against energy prices. Non-recuperated *(a)* and recuperated *(b)* configuration.

The allowed costs given in Table 5 and Figure 9 are based on the selected interest rate 5% and the operating time 10 years, the factor a of the present value of periodic payments during the operating time being 7.722. The costs are directly proportional to the factor of $a/(1+ra)$ where r is the ratio of the annual maintenance costs to the investment costs.

DISCUSSION

The use of a recuperator has a strong effect on the design-point performance of the microturbine by increasing the electric efficiency, but decreasing the heat output when compared to the non-

recuperated cycle of the same power output. This phenomenon affects the sizing of the microturbine as well.

At part load, the implementation of variable speed operation maintains the electric efficiency of the recuperated cycle significantly better than with turbine inlet temperature as the only control parameter. Again, benefits in electric efficiency are gained at the cost of reduced heat output. For the non-recuperated configuration, variable speed operation has a lesser effect on the part load characteristics.

With the selected energy prices, higher gain flows can be attained by using the non-recuperated cycle instead of the recuperated one. However, essentially higher heat demand for given power demand is required to realize this potential. The use of speed control increases significantly the economically feasible operating range of the recuperated configuration. As a result, the recuperated cycle with speed control is especially suitable for applications with a high power-to-heat ratio, and with largely varying heat and power loads.

For the selected CHP application, the engine size range has been found for each configuration where it is expected to have the highest potential for feasibility. The results for the selected microturbine sizes suggest that the investment may be feasible for all the studied microturbine options. Consequently, a non-recuperated microturbine of smaller power output and with simple turbine inlet temperature control may offer a feasible alternative to a larger recuperated cycle. However, the overall economy of the microturbine options must be thoroughly investigated using accurate cost data before any further decisions.

High prices for purchased electricity or low fuel prices contribute strongly to the economy of the microturbine-based CHP.

This study has focused on a case where the microturbine is installed parallel to an existing boiler. In case both the microturbine and the boiler are obtained simultaneously, the boiler size could be reduced compared to the stand-alone alternative. This would further increase the feasibility of the microturbine investment.

CASCADING AND RADIATOR FLOW OPTIMIZATION IN DISTRICT HEATING SUBSTATIONS AND ADVANCED CUSTOMER ACCOUNTING – IN PURSUIT OF IMPROVED COOLING

Patrick Ljunggren* and Janusz Wollerstrand
Lund Institute of Technology
Department of Heat and Power Engineering
P.O. Box 118, SE-221 00 Lund
Sweden

ABSTRACT

This paper deals with various methods of improved cooling of primary water in district heating (DH) substations and evaluates the benefit of an improved cooling from the perspective of the construction of an appropriate customer accounting method. The general benefit of an improved cooling is well-known: Less thermal stresses in pipelines, lowered heat and pumping losses and increased capacity in the network, improved efficiency of combined heat and power plants and other types of generating plants using heat pumps, waste heat and flue gas condensation.

To stimulate improved cooling in customer owned DH substations, some Swedish DH companies apply a method of customer accounting based not only on heat energy consumption but also on primary water usage and mean water cooling. This benefits customers with thermodynamically well-functioning substations, i.e. a proper cooling, at the expense of customers with less well-functioning substations. The extension of 'flow accounting' has been mapped and found to be applied for a majority of the delivered heat. It represents an important incentive for proper cooling in substations. The study has found that the size of the flow accounting generally very well reflects the benefits for the DH company from an improved cooling.

The amount of cooling of DH primary water achieved in DH substations depends on the employed connecting scheme. In a recent study, we demonstrated that adopting three-stage cascading could achieve significant improvements in this respect. The economical aspects on this subject are here further mapped out based on the results from the study of flow accounting. Optimized and properly functioning substation and secondary systems are, from an economical perspective, of at least equal interest as the choice of connection scheme. Especially if there is an existing oversizing of the radiators, considerably larger savings can be made if optimized control of the radiator circuit is employed.

Keywords: District heating, substations, cascading, customer accounting, radiator circuit

INTRODUCTION

District heating (DH) is a system connecting many buildings to one or more large heat producing plants via a network with hot water as heat-carrier. The large-scale heat production provides efficient use of primary energy and possibility to use waste heat from nearby industries or from electricity production, so-called combined heat and power (CHP) production. Figure 1 shows a schematic overview of a DH network.

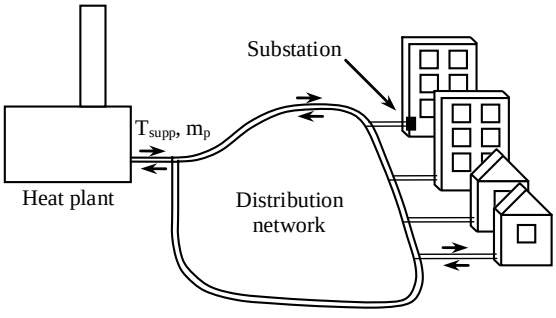

Figure 1: DH network. T_{supp} and m_p denotes supply temperature and primary mass flow respectively.

*Corresponding author: Phone +46 46 222 92 73 Fax: + 46 46 222 4717 E-mail: Patrick.Ljunggren@vok.lth.se

The substation is marked out in the figure, i.e. the equipment that transfers heat from the network to the consumer installations. The essential components of the substation are heat exchangers, temperature sensors, controller, control valves and heat meter.

A central concept concerning district heating is the thermal efficiency of consumer installations, which especially applies to cooling of primary water in substations. It is a well-known fact that low temperatures in the DH networks are beneficial. Heat losses and thermal stresses in pipes will decrease, the required flow will be smaller due to the improved cooling and will thereby require less pumping energy and increase the capacity of the network. There are also advantages for the heat plant from lower temperature levels such as improved efficiency for CHP production and other types of heat plants using heat pumps, waste heat and flue gas condensation.

This paper evaluates the economical benefits of an improved cooling, from the customer's as well as the DH company's perspective. The condition for a possible profit for a customer is, however, that an accounting based on primary water usage, so called 'flow accounting', is employed by the DH company. The paper presents an inquiry concerning the use of such an accounting.

Efforts in pursuit to improve the cooling, such as cascading in substations and certain optimizations of the hydronic system, will be evaluated using the most common flow accounting models.

THE CONCEPT OF CASCADING

In a recent study [1] we dealt with the concept of cascading in DH substations. A short summary of that work is presented here to give the reader some background.

Differences in temperature level in building side thermal requirements (space heating and hot service water) entails that cascading, i.e. dividing the cooling of DH water into two or more stages, can reduce the return temperature, i.e. improve the cooling. This is usually performed by using a two-stage connection instead of the simple parallel connection. However, in Sweden today there is a trend away from cascading mainly because most investigations so far have shown marginal return temperature gains and that the parallel connection is simpler and slightly cheaper. The first argument, however, deserves a closer examination. We have used an English translation of the Swedish nomenclature for the different connection schemes shown in figure 2:

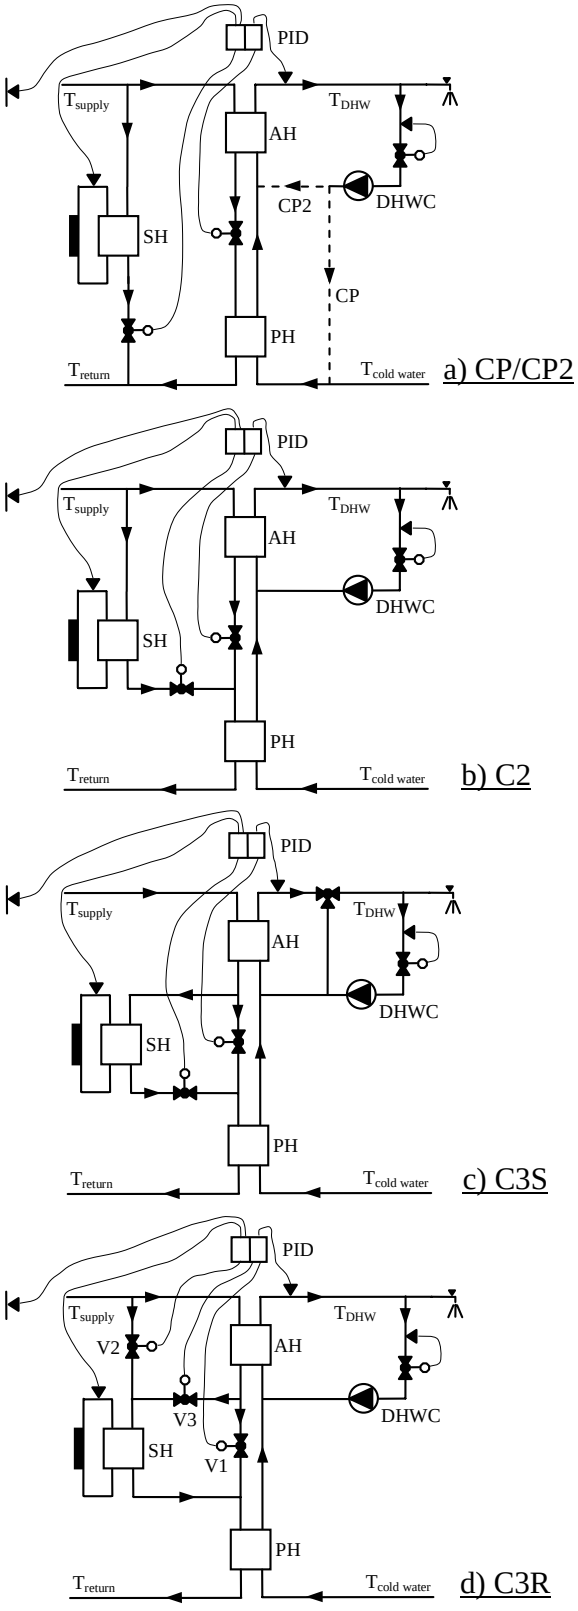

Figure 2: Various substation connection schemes

The abbreviations in figure 2 represent the following cases:

- CP is a simple parallel connection with two heat exchangers only
- CP2 is a parallel connection, where hot water heating has been split on two heat exchangers
- C2 is an example of what is termed a two-stage connection scheme
- C3S is an example of what is termed a three-stage connection scheme
- C3R is an example of another type of three-stage connection scheme

All of them, except the last one can be found in various editions of recommendations [2] issued by the Swedish DH association. Case C3R resembles a scheme found in old Russian DH literature [3]. The 'R' in the designation stands for 'Russian'.

The parallel connection scheme can be designed in two ways, illustrated by the dashed lines in figure 2a. CP is the simpler one where the re-circulated hot service water is connected to incoming cold water. This is the type usually shown by the Swedish DH association. Re-circulation is generally used in larger buildings to prevent bacterial growth (especially legionella) and to maintain a proper hot tap water comfort.

It is in fact rather obvious that when a tapping occurs, mixing incoming cold water with much warmer re-circulated hot water results in a substantial thermodynamical loss. Instead, as long as there is re-circulation, provision of hot service water should be divided in two stages with mixing of re-circulated water between them. This is done in all connection schemes except for CP.

C3S has been abandoned in Sweden due to the risk of scaling of the heat exchanger. Since all primary flow has to pass the afterheater (AH), a high space heating load may cause the hot service water to be overheated.

The Russian type of three-stage connection does not suffer from this drawback because of the use of a third valve, see figure 2d. If there is no space heating load, only valve V1 will be open. If then some space heating is demanded, valve V3 will open to a degree that will result in the required supply temperature of the radiator circuit and the valve V1 will tend to close. When V3 reaches its fully opened position, and further increase of primary water flow for space heating is required, then valve V2 will open, to supply water directly from the incoming primary supply line. At high hot water loads, when a great flowrate needs to be passed through the after-heater, the valve V1 opens again and leads the appropriate amount of flow in bypass of the radiator heat exchanger preventing overheating of water in the radiator circuit.

The dynamic simulation of the different connection schemes were performed for a number of cases, a building with 20 and 100 apartments respectively, and supply/return temperatures in the hydronic system of 60/40 ºC and 80/60 ºC respectively. Figure 3 shows an example of a simulation of one case:

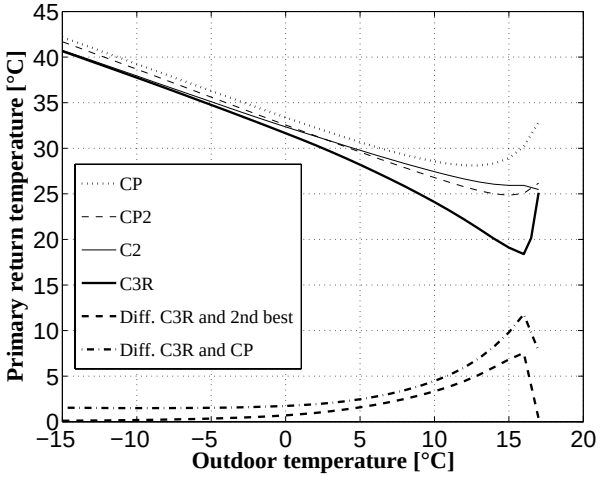

Figure 3: Building with 20 apartments, 60/40 °C space heating system design.

An average return temperature for a whole year was calculated for each case, with respect to outdoor temperature duration and the magnitude of the primary flow, see table 1:

Connection scheme/ case:	**A**	**B**	**C**	**D**
CP	32.5°	41.8°	32.8°	42.1°
CP2	31.1°	41.1°	30.8°	40.9°

Gain: C3R compared with second best alternative	1.24°	0.52°	1.05°	0.56°
Gain: C3R compared with worst alternative	2.80°	1.79°	3.30°	2.13°

A: 20 apartments, 60/40 °C space heating system
B: 20 apartments, 80/60 °C space heating system
C: 100 apartments, 60/40 °C space heating system
D: 100 apartments, 80/60 °C space heating system

Table 1: Average return temperature [°C] for various connection schemes.

As can be seen from the results connection scheme C3R can produce substantial gain, especially at modest heat loads. The opinions differ weather a

parallel or two-stage connection is to prefer. The average return temperature for CP2 and C2 is about the same, although slightly better for C2 in the case with higher temperatures in the hydronic system. The simpler parallel variant, CP, which often is claimed to be comparable to C2, shows significantly worse performance in terms of cooling.

RADIATOR FLOW OPTIMIZATION

In Sweden, up to 90 per cent of the annual heat energy demand in residential buildings is due to space heating (SH). For this reason, the cooling of DH water in properly sized and correctly operating DH substations depends mostly on the working parameters of the radiator circuit, which in turn depends on the sizing of the circuit and on how the heat output is controlled. A traditional way of controlling the heat output from the circuit is to keep the flow rate of the circulating water constant and to vary the supply temperature, depending on the outdoor temperature and on the thermal characteristics of the radiators used. As a consequence of constant flow rate the temperature drop in radiators is proportional to its heat output and has a largest value at maximum load operating point. A principal scheme of SH circuit connected to a DH network is given in Figure 4.

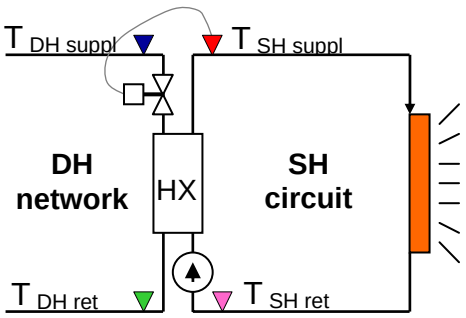

Figure 4: SH circuit in the DH substation

Given some supply and return temperatures of radiator water at sizing conditions, the space heating heat exchanger (HX) in the DH substation can be sized in such a way that least temperature difference (LTD) between DH and radiator water return respectively will fulfil the design rules [2]. Now, the DH water cooling will be optimal at full load operating point. However, this does not guarantee that the cooling will be optimal at part load. Frederiksen et al [4] proved that, to maximize DH water cooling in space heating heat exchanger at part load, the radiator water flow rate should be decreased while the radiator supply temperature should be increased until minimum LTD was achieved.

The phenomenon is exemplified in figure 5, where the calculated temperatures in HX with outdoor temperature are shown. The radiators are intended to operate at 80 °C supply and 60 °C return temperature at full load. The continuous and bold lines show the condition at constant radiator flow rate, while the dot stretched lines shows the optimal condition. The black dot stretched line at the bottom of the diagram shows how the optimum flow rate decreases with decreasing load. We can see that flow rate optimization alone does not result in large gain of DH water cooling compared to results in figure 3. However, the situation changes if we consider that both radiators and HX often are oversized.

Figure 6 shows results when the radiators sized as in previous example are in fact 100 per cent oversized (not an unusual situation until the 70's in Sweden). As we can see here, the oversized radiators are able to operate as if they were sized for about 60–40 °C at full load, and at reduced LTD, which results in substantial increase of DH water cooling (compare the green lines in figure 5 and 6 respectively). This leads to the conclusion that in practice, it is important that flow rate optimization should take possible oversizing of heat transfer areas in space heating circuit into account.

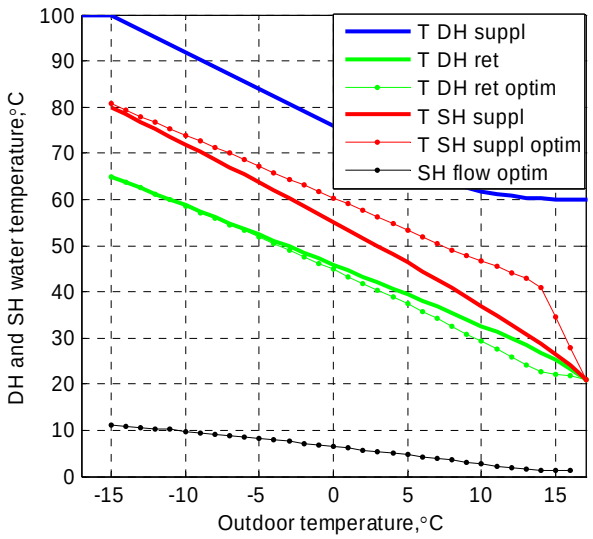

Figure 5: SH supply temperature and circulation flow rate optimisation in space heating circuit sized for 80–60 °C.

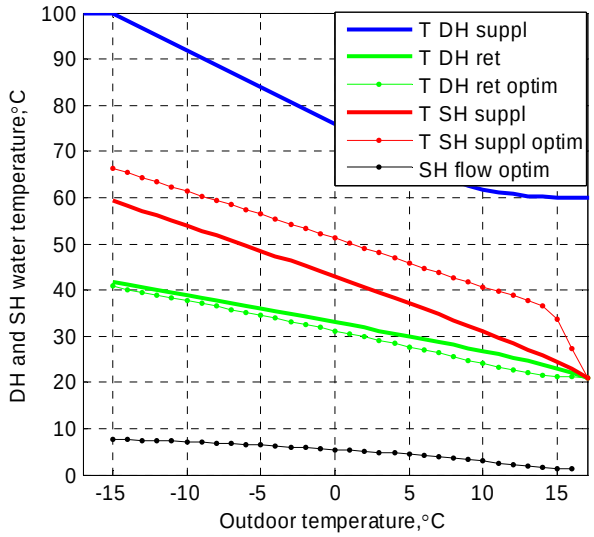

Figure 6: Optimisation as in figure 5 if the SH radiators are in fact 100 per cent oversized.

THE BENEFIT OF AN IMPROVED COOLING

Flow accounting

A DH substation will always transfer the same amount of heat energy for a specific heat load, no matter how well or poorly it is operating. This is a difference from for instance a furnace that will consume less fuel if the efficiency is better. The substation will however consume less primary water if the cooling of the flow is better. This means that with a traditional customer accounting where the customer only pays for consumed heat energy, the thermodynamical performance of the substation will not be of interest. On the other hand, if the accounting model also is based on the amount of primary flow that is used, there will be an incentive for maintaining a proper performance of the substation.

Some of the Swedish DH companies apply a customer accounting model that takes the usage of primary flow into account. Still, many companies just charge the customer for consumed heat energy. A number of questions regarding the various accounting models may be aroused, such as how common this type of accounting model is, i.e. how many of the DH companies that charge the customers for flow consumption and how much of the total amount of delivered heat that these companies correspond to. It is also essential to evaluate how much a *customer* can gain from an improved cooling.

To be able to map out the various accounting models, information was collected, mainly through the DH companies' homepages but also by telephone and email contact. However, there is a large number of companies and in order to limit the effort, the goal has been to cover most of the total delivered energy. Therefore, not all existing DH companies have been included in the survey. The objective with this work has been to create an overall picture of the extent of accounting models with flow accounting and how they are designed.

The annual delivery of DH in Sweden amounts to about 47 TWh[1]. The Swedish DH association has about 150 members, which corresponds to 99 per cent of the delivered DH. [5] The accounting models of 115 of these companies, corresponding to at least 90 per cent of the total amount of delivered heat, have been examined. A majority of the companies (62 per cent) proved to be charging the customers for heat energy only, i.e. not at all for primary flow usage. However, the companies in this category tend to be smaller than the ones charging also for flow usage. Therefore, it turned out that a majority of the delivered heat (61 per cent) corresponds to companies with some kind of flow component in their accounting model. A reservation should be made for the statement that the companies applying flow accounting are larger. Not all companies were included in the investigation and there are a quite large number of smaller companies among these.

Additional differences between the companies that apply flow accounting and those who do not, was attempted to be found. Therefore, the composition of the heat generation plants was mapped out according to the fact that, as mentioned in the beginning, certain types of heat generation are more favoured by a lower return temperature. The result was compared with statistics from the Swedish DH association [6], embracing the total average heat generation composition, see table 2. For the companies applying flow accounting the composition is presented both as an average value and as an average weighted with respect to the size of the networks.

[1] 1 Wh = 3 600 Ws = 3 600 J = 3.6 kJ

Energy source	All	Flow accounting	Flow accounting (weighted)
Bio fuels	55	64	52
Fossil fuels	16	18	23
Waste heat	12	10	7
Heat pumps	13	4	10
Electricity	2	2	6
Other	2	3	2

Table 2: Energy sources for heat generation. Comparison between all DH networks and those who apply flow accounting. All data expressed in per cent.

The conclusion from the results in table 2 is that a significant connection between the energy sources used in a DH network and the use of flow accounting in the same network does not seem to exist.

The customer's perspective

A typical accounting model consists of a number of components such as a fixed component (often based on the size of the substation), a component based on the demand for power, a flexible component based on the heat consumption and finally a possible flow component. It is not unusual that one of the first two components is omitted.

The flow component is usually designed as a cost per consumed cubic metre of primary water. Some companies use a more refined component where the customer's use of primary flow in relation to the heat consumption (which corresponds to the cooling) is compared to the average relation for the whole network. Such a variant entails a flow component that works as a charge if the customer's cooling is worse than the average for the network, or as a bonus if the cooling is better.

Many companies use flow accounting only during the colder half of the year, i.e. when the load in the network is higher and additional, more expensive heat production has to be utilized.

Price information have been collected from the companies applying flow accounting in order to evaluate an improved cooling from the customer's perspective. An average cost for a building with 20 and 100 apartments respectively could then be calculated for a number of different degrees of cooling, see figure 7. The two lines in the diagram are parallel, a fact that is rather obvious since a change in cooling only affects the flow component of the price. The offset between the lines is, however, due to the fixed price in the various accounting models, which entails a lower price per kWh for the building with 100 apartments.

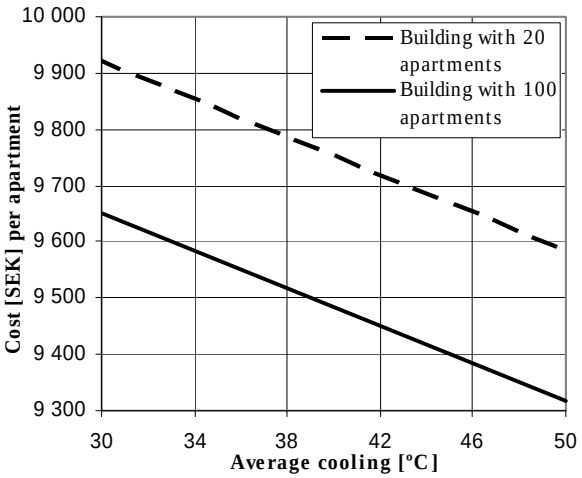

Figure 7: Annual cost for building with 20 or 100 apartments respectively depending on the cooling of primary water flow.[2]

The next diagram, figure 8, shows how much that can be gained from a certain number of degrees improved cooling.

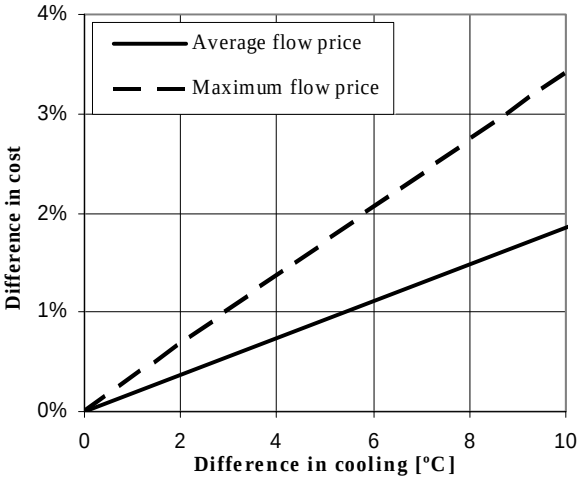

Figure 8 The difference in cost for a customer for a change in cooling, either with average flow accounting level or the maximum found.

The results from the simulations of various connection schemes, as presented in table 1, has been economically evaluated from the perspective of a customer being charged with flow accounting, see table 3. As can be seen, the economical gain from a change in connection scheme must be considered rather small. However, for a larger building, i.e.

[2] 1 SEK is equivalent to 0.1109 EUR (2005-01-19)

100 apartments or more, installing a substation of type C3R instead of the simpler substation CP, which often is the case, could be economically defensible.

Connection scheme/ case:	A	B	C	D
CP	194 652	198 357	945 728	964 298
CP2	194 410	198 112	944 238	961 587
C2	194 384	197 878	944 079	962 637
C3R	194 054	197 636	942 522	960 365
Gain: C3R compared with second best alternative	242 (0.12 %)	245 (0.12 %)	1 490 (0.16 %)	1 661 (0.17 %)
Gain: C3R compared with worst alternative	598 (0.31 %)	721 (0.36 %)	3 206 (0.34 %)	3 932 (0.41 %)

A: 20 apartments, 60/40 °C space heating system
B: 20 apartments, 80/60 °C space heating system
C: 100 apartments, 60/40 °C space heating system
D: 100 apartments, 80/60 °C space heating system

Table 3: Average cost and gain [SEK] for different connection schemes.

The possibility to utilize a possible oversizing in the space heating system can also be evaluated. As shown in the previous chapter this could, at the best, correspond to a shift from an 80/60 ºC to a 60/40 ºC space heating system design. Under these circumstances, the comparison will be made horizontally in table 3, from columns B to A and D to C respectively. The former one corresponds to a saving of about 3 600 SEK (1.8 per cent) and the latter to 18 000 SEK (1.8 per cent), thus substantially more than when comparing just connection schemes.

The district heating company's perspective

The gains from low temperature levels in a DH network are well-known. It is, however, a rather complex task to evaluate how much an improvement is worth due to the characteristics of every specific network. Still, it would be interesting to compare the benefits of an improved cooling for the customer with the benefit for the DH company. In order to accomplish this task a calculation program, accessible from the Swedish DH association's homepage has been used. The program gives the opportunity to specify numerous parameters regarding a DH network and to evaluate a specific change in supply and/or return temperature with reference to both the heat generation plant as well as the network, i.e. heat losses and pumping work. Another factor of importance for a DH company that was found in the study is the existence of bottlenecks, which, however, is not included in the program. Still, these can also be reduced by an improved cooling and produce substantial gain.

Three different cases of heat production composition were tested with the program:

a) 80 per cent bio or fossil fuel (the difference is negligible) and 20 per cent flue gas condensation
b) The same composition as the average network applying flow accounting, cf. table 2
c) 95 per cent waste heat or heat pump (the difference is negligible) and 5 per cent electricity (used as peak load)

Here it must be emphasized that default values in the program has been used regarding the production data. For instance, changing the efficiency of the flue gas condenser or the temperature levels for the waste heat or heat pump can cause large variations in the result. However, the number of possible combinations is infinite and the purpose here has been to show some demonstrative examples of how much that can be gained.

It turned out that case a) produced the smallest gain from a lowered return temperature. Case c) produced the largest gain and consequently case b) was found in between. The resulting gain from the lowered return temperature was distributed on one apartment, see figure 9.

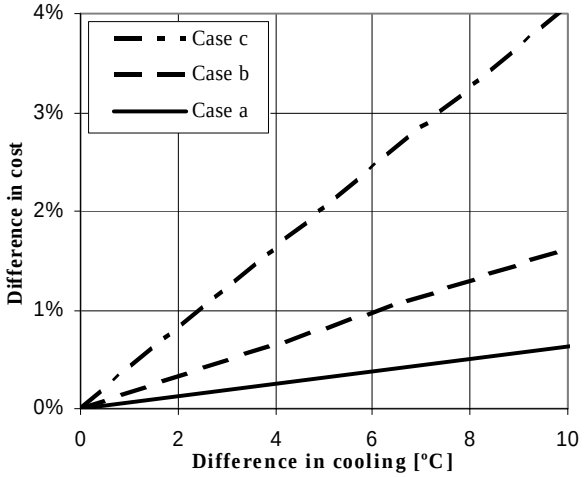

Figure 9: The difference in cost for a company for a change in cooling, distributed among the customers, either with average flow accounting level or the maximum found.

If one compare figure 9 with figure 8 it can be found that the flow accounting in general seems to reflect the size of the earnings for the DH company in case of an improved cooling.

Reflections on flow accounting

The dominating apprehension among DH companies applying flow accounting is that the flow accounting method is functioning very well. However, some companies claim that the flow accounting, although it did have effect when it was introduced, now hardly makes any difference. The companies *not* applying flow accounting are of the opinion that the customers do not understand the use of flow accounting and find it complicated. Instead they mean that a customer with extremely poor cooling is taken care of individually.

The annual Swedish survey "Nils Holgersson" [7], performed by a number of Swedish tenants' associations, examines various charges regarding DH, electricity, water, drain and waste for multi-family houses in Swedish municipalities. The DH accounting is claimed to be complicated with too many components. A simpler model, preferably with only *one* component, is inquired.

It should be pointed out that flow accounting is not applied for single-family houses. For this category, the flow accounting can be considered as complicated. In addition, single-family houses represent a very small part of the total DH.

For larger buildings, it is our opinion that flow accounting entails an important incentive for proper thermodynamical operation of substations. This especially applies when the DH company does not own the substations, which generally is the case in Sweden.

Another issue regarding flow accounting is that the supply temperature in the DH network varies, i.e. it is decreasing with increasing distance from the generating plant. With a lower supply temperature, a substation will use more primary water flow. The flow accounting is by that not entirely fair. However, if this should be considered as a problem, the flow accounting component could be adjusted depending on where in the network a customer is situated.

CONCLUSIONS

Swedish DH companies rather commonly apply flow accounting, preferably the larger ones. In general, it is considered to be functioning well. This study has found that the size of the flow accounting generally very well reflects the benefits for the DH company from an improved cooling. Still, an improved cooling in a substation in the order of a couple degrees C does not result in any larger savings. Of at least equal interest as the choice of connection scheme is, from an economical perspective, optimized and properly functioning secondary systems and substation. However, considerably larger savings could be made if there is an existing oversizing of the radiators and an optimized control of the radiator circuit is employed.

No matter how much that can be gained from an improved cooling, flow accounting is an important incentive to stimulate proper thermodynamical operation of DH substations.

Thermo-Dynamic Analysis of CHCP Microturbines

Marco Milanese, Antonio Ficarella, Domenico Laforgia
University of Lecce
Department of Engineering for Innovation
73100 Lecce (Italy)

ABSTRACT

The CHCP (combined heating, cooling and power) microturbines allow a large operational flexibility at sites with demand for energy in the form of electricity, heating and cooling. These systems are particularly relevant in those countries, where air-conditioning is a must and a variety of factories require process cooling.

An investigation on the several trigeneration systems, based on CHCP microturbines, was carried out, developing a software, called "Trigen 1.0". Trigen 1.0 analyzes the fluid-dynamic parameters, as pressure, temperature, enthalpy, and entropy, in every point of the trigeneration system; assesses the machine efficiency and the power generated in terms of electricity, heating and cooling.

The comparison between commercial CHCP microturbines has allowed to evaluate the performances of these systems under different conditions, as atmospheric air temperature, temperature of gas turbine and compression/expansion ratio. Further calculations were carried out to develop a model to evaluate the break-even point of the microturbines, under several conditions.

INTRODUCTION

In many industrial processes (food industry [1], cold storage and ice production industry [2], chemical and petrochemical industry, pharmaceutical industry [3-4]) there is a simultaneous need for electric power and refrigeration at low temperatures. In these cases, a trigeneration plant, that produces electric energy and converts the waste heat a cogeneration plant would have wasted into useful energy in the form of chilled water, is a viable and, under certain circumstances, economical option [5].

The major improvements in the economic, operational, and environmental performance of microturbines have been achieved through decades of intensive research; nowadays microturbines operate with fuels with low NOx emissions, higher reliability and energy efficiency [6, 7].

Onsite trigeneration plants are much more efficient, economically-sound and environmentally-friendly than typical (central) power plants. Because of this, their demand is growing.

There are several reasons why the market for microturbine is growing: firstly, they are less polluting than other forms of power generating devices. Secondly, thanks to the environmental legislation, the availability of gas as a fuel is possible for smaller scale industrial and cogeneration applications. Thirdly, a small microturbine is quick to install, easy to maintain and has a short payback period.

This paper presents a numerical benchmark of 5 trigeneration systems available on the market.

The performances of these systems have been examined varying their working conditions: atmospheric air temperature, temperature of gas turbine and compression/expansion ratio.

Further calculations were carried out to evaluate the break even point of the microturbines, varying the annual utilization coefficient of the microturbine and other parameters, as performances, energy price, etc.

SYSTEM DESCRIPTION

A trigeneration or combined heat, cooling and power (CHCP) system is a thermal system, often involving a turbine, in which fuel is burnt to produce hot gases to power a turbine coupled to an electric generator. The heat/thermal energy from the exhaust gases, before being discharged to the environment, is recovered to produce hot water and steam and/or to power an absorption chiller

The trigeneration systems presented in this paper comprise 4 subsystems:

1) fuel supply;
2) microturbine;
3) heat recovery system;
4) absorption chiller.

Figure 1 shows a typical scheme of the microturbine trigeneration system analyzed [6]. Exhaust gases from the microturbine were directed into a recuperator, to recover the heat from the turbine, and then in a heat recovery system coupled to an absorption chiller, that produces heat and cold, respectively.

Table 1 shows the main characteristics of the commercial microturbine analyzed in this work.

N.	Microturbine	Power (kW)	Type of lubrification	Type of recuperator	Turbine speed (rpm)	Further notes
Turbine 1	Turbec T100	100	Oil	External	70000	Only cogeneration
Turbine 2	Bowman TG80CG	80	Oil	External	68000	Trigeneration
Turbine 3	IR PowerWorks	70	Oil	External	44000	Trigeneration
Turbine 4	Capstone C30	30	Pneumatic	Internal	96000	Trigeration
Turbine 5	Elliott TA-80R	80	Pneumatic	Internal	70000	Trigeration

Table 1. Commercial microturbines analyzed

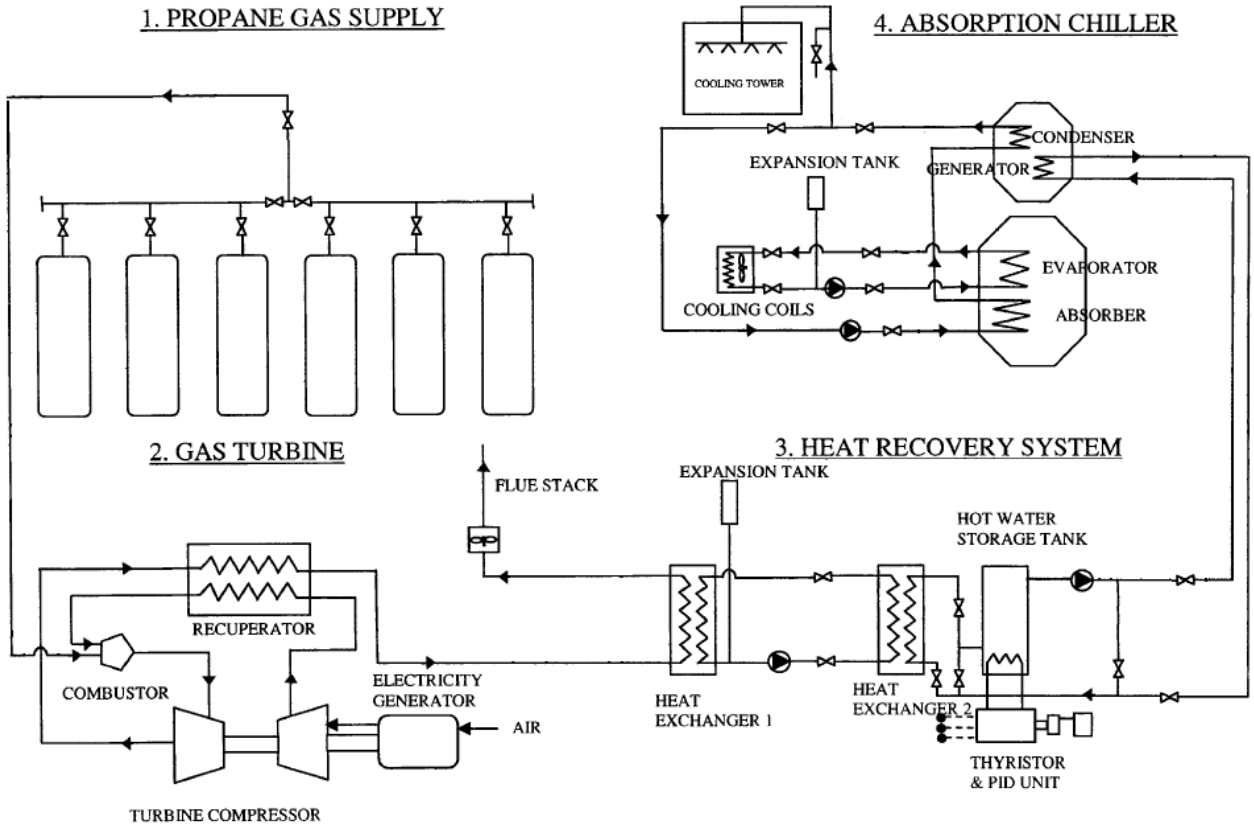

Figure 1: Schematic diagram of a typical trigeneration system

MATHEMATICAL MODEL

To investigate the commercial trigeneration systems, analyzed in this paper (see Table 1), a software, named TRIGEN 1.0, was developed. The software input parameters were the following:

- air pressure inlet;
- compression ratio;
- expansion ratio;
- air temperature inlet;
- air mass flow;
- adiabatic efficiency of the compressor;
- adiabatic efficiency of the turbine;
- generator efficiency;
- temperature of gas turbine;
- flow resistance of the recuperator;
- flow resistance of the heat exchanger;
- NTU recuperator;
- NTU heat exchanger;
- water temperature inlet in the heat recovery system;
- water mass flow inlet in the heat recovery system;
- COP refrigerator;
- net heat value of methane;
- net heat value of oil.

The software allows to calculate electric power, thermal power, cooling power, fuel consumption, electric efficiency, fuel utilization coefficient, etc, and in each point of the system, as Figure 2 shows, pressure, temperature, enthalpy, entropy, volume and density of the gas.

Mathematical model determines the compressor power, the turbine power and the electric power respectively by Equations 1, 2 and 3.

$$\dot{W}_c = \dot{m}\Delta H_c \quad (1)$$

$$\dot{W}_t = \dot{m}\Delta H_t \quad (2)$$

$$\dot{W}_{el} = \left(\dot{W}_c + \dot{W}_t\right)\eta_{gen} \quad (3)$$

To calculate air enthalpy (*Hair*) in every point of the system, the mathematical model considers the air as mixture of 8 gases (Ar, N_2, O_2, CO, CO_2, H_2O, NO, SO_2), and for each gas it calculates the enthalpy as indicated in the equations 4 and 5.

$$Hgas_i(T) = n_i\left(A_1T + A_2T^2 + ... + A_nT^n\right) \quad (4)$$

$$Hair(T) = \sum_i Hgas_i(T) \quad (5)$$

Electric efficiency, fuel utilization index, and fuel consumption were determined by equations 6, 7 and 8.

$$\eta_{el} = \frac{\dot{W}_{el}}{Q} \quad (6)$$

$$FUI = \frac{\dot{m}\Delta H_{term} + \dot{W}_{el}}{Q} \quad (7)$$

$$F_{cons} = \frac{\dot{m}\Delta H_{burner}}{SHC_{fuel}} \quad (8)$$

In Figure 2 the interface of the software Trigen 1.0 is shown.

In the second part of this work, to evaluate the break even point of the systems under investigation, several parameters were considered and calculated.

According to Campanari [8], the cost of the microturbines was calculated by Equation 9.

$$C_m = \dot{W}_{el}\left[44000\left(\frac{\dot{W}_{el}}{75}\right)^{0.66}\right] + 10000 \quad (9)$$

The break even point was evaluated as ratio between the cost of the microturbine and the investment saving (difference between the cost of the energy bought on the market and the cost of the energy self-produced) (Eq. 10, 11, 12 and 13)

$$BEP = \frac{C_m}{IS} \quad (10)$$

where:

$$IS = C_{Ener} - C_{SPE} \quad (11)$$

$$C_{Ener} = 8760UCM\left(\dot{W}_{el}P_{el} + \dot{W}_{th}P_{th} + \dot{W}_{cool}P_{cool}\right) \quad (12)$$

$$C_{SPE} = 8760F_{cons}P_{fuel}UCM \quad (13)$$

In Equations 12 and 13 the annual utilization coefficient of the microturbine (UCM) is defined as a part of the year when the microturbine is on.

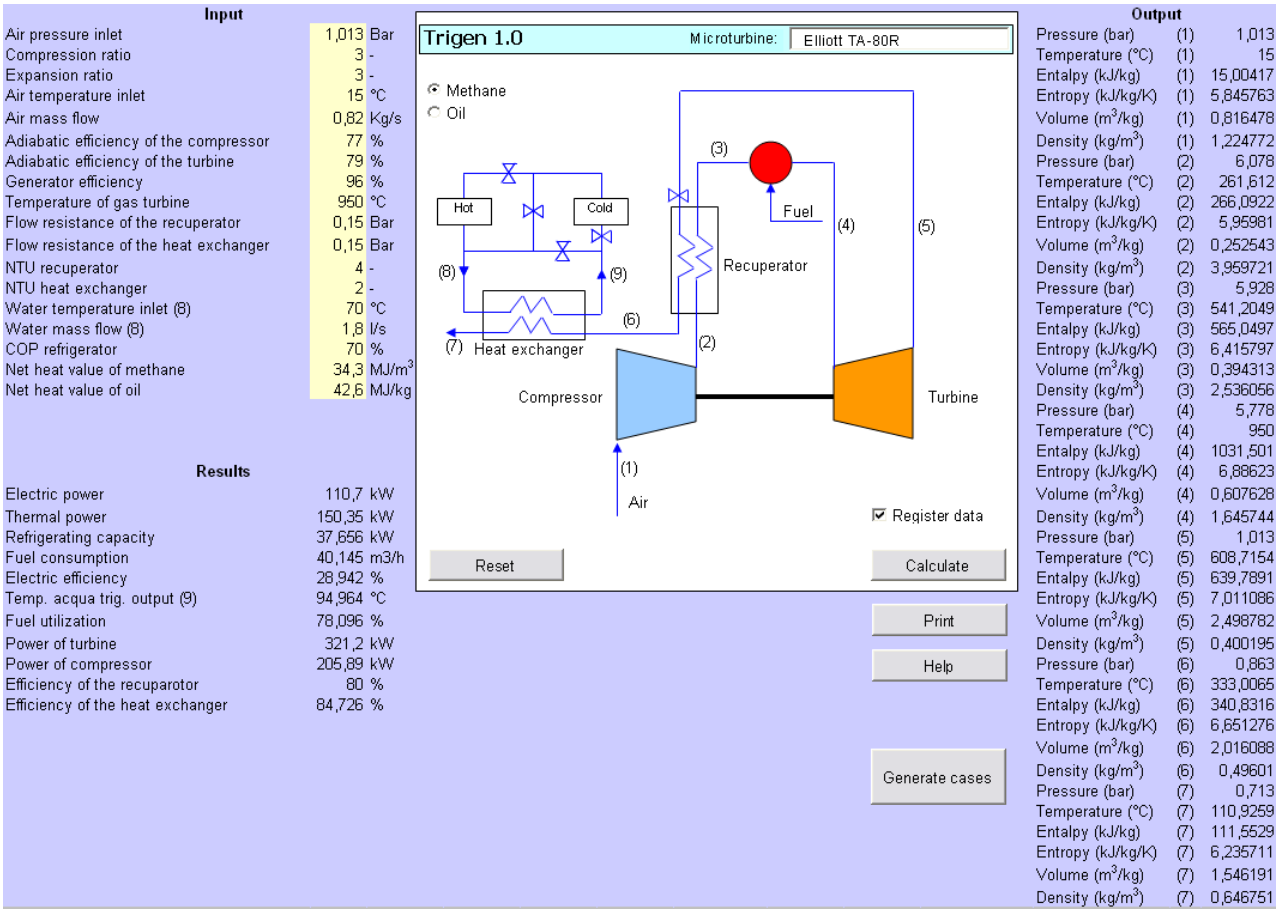

Figure 2: Software Trigen 1.0

PERFORMED SIMULATIONS

Several numerical simulations were carried out varying some parameters (air temperature inlet, compression and expansion ratio, temperature of gas turbine) to calculate possible variation in the microturbine performances (electric power, electric efficiency and fuel utilization).

Table 2 shows the cases under investigation in the present work.

In the calculations, the air pressure inlet and the air temperature inlet were varied in order to investigate the influence of the atmospheric parameters on the microturbine performances.

Air temperature inlet (K)	Compression and expansion ratio (-)	Temperature of gas turbine (K)
273	1.5	873
278	2	923
283	2.5	973
288	3	1023
293	3.5	1073
298	4	1123
303	4.5	1173
308	5	1223
313	5.5	1273
318	6	1323
323		1373

Table 2: Variation of air temperature inlet, compression/expansion ratio and temperature of gas turbine in the cases under investigation

Further simulations were carried out to examine the variation of the electric power, electric efficiency and fuel utilization of the microturbines, adapting both the compression/expansion ratio and the temperature of gas turbine.

DISCUSSION OF RESULTS

Microturbine electric power and microturbine electric efficiency are strongly influenced by atmospheric air temperature, as Figures 3 and 4 show. In particular, low atmospheric temperature is preferable than high temperature: between 0 °C and 50 °C all microturbines present an electric efficiency decrease equal to 5÷6%.

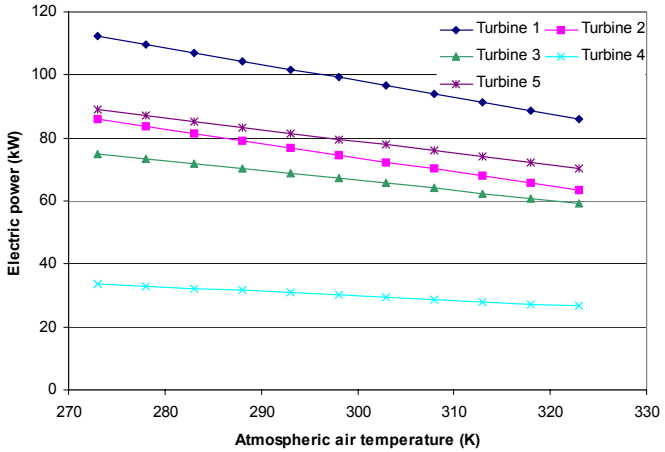

Figure 3: Electric power as a function of atmospheric air temperature

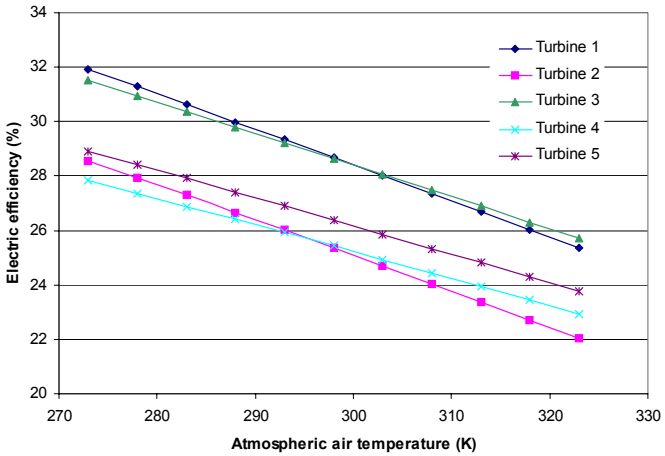

Figure 4: Electric efficiency as a function of atmospheric air temperature

The gas turbine temperature and the compression/expansion ratio are important parameters to improve the peak efficiency of a microturbine, as Figures 5, 6, 7 and 8 show.

For all microturbines, electric efficiency and generated power is almost directly proportional to the temperature of gas turbine. While, the compression/expansion ratio is a very negative working parameter at low values and in all cases a good range is equal to 3÷4.

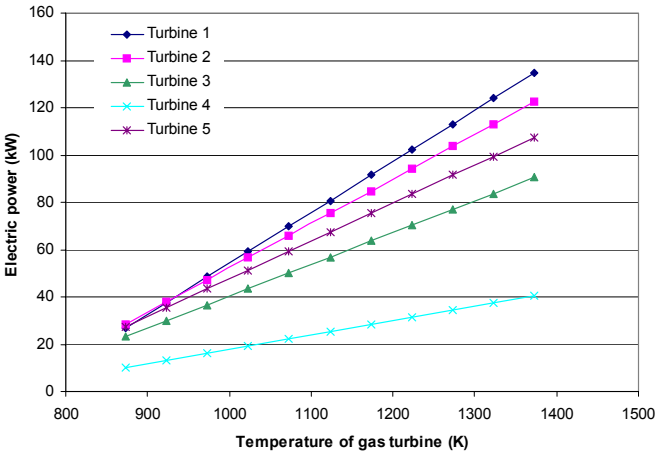

Figure 5: Electric power as a function of temperature of gas turbine

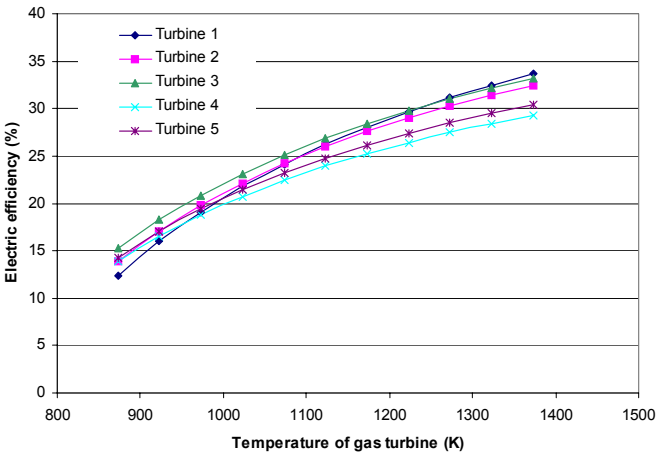

Figure 6: Electric efficiency as a function of temperature gas turbine

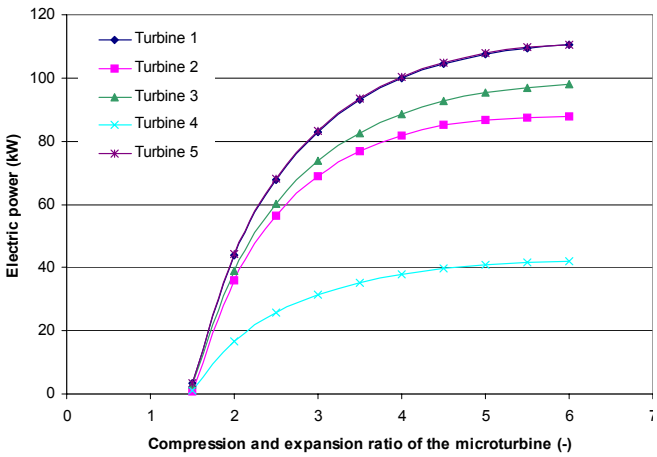

Figure 7: Electric power as a function of compression and expansion ratio of microturbine

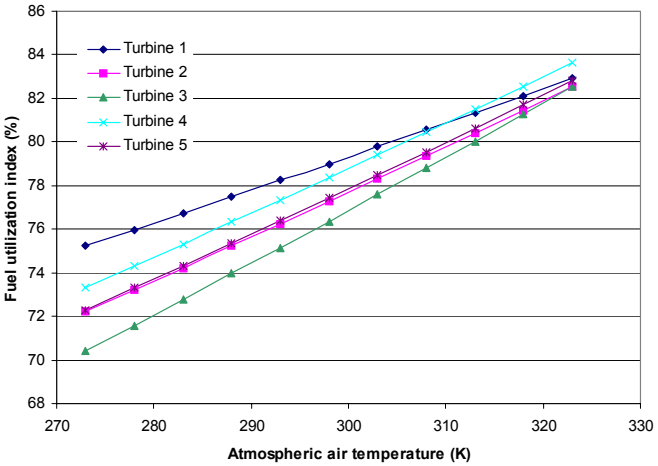

Figure 9: Fuel utilization as a function of atmospheric air temperature

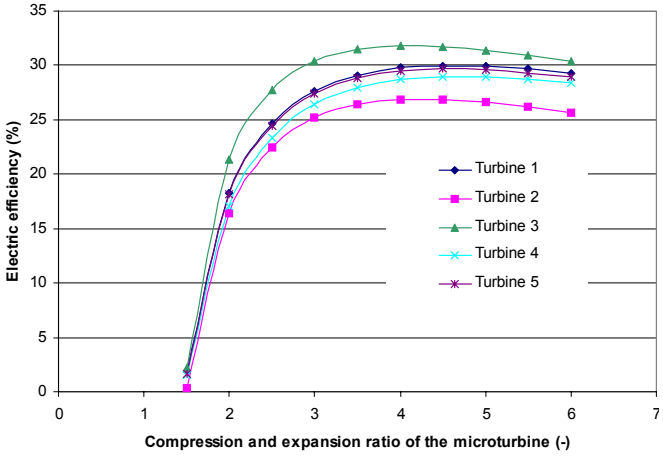

Figure 8: Electric efficiency as a function of compression and expansion ratio of microturbine

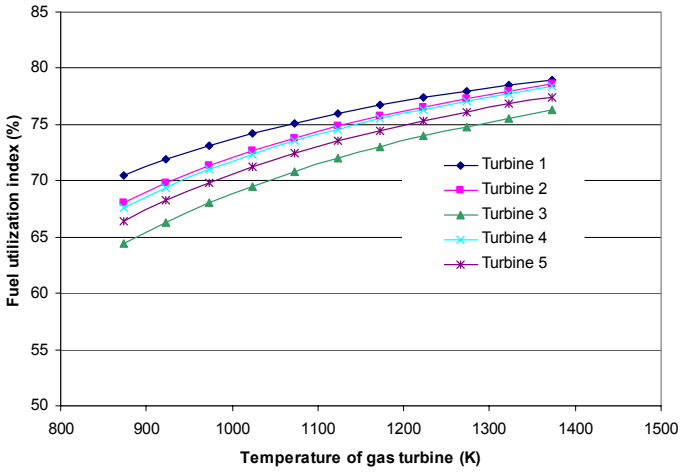

Figure 10: Fuel utilization as a function of temperature of gas turbine

Fuel utilization is a parameter used to estimate the global efficiency of the trigeneration systems, because it takes into account both electric and thermal (and/or cooling) power.

As Figure 9 shows, fuel utilization is influenced by atmospheric air temperature, but the variation of the global microturbine performances is contrary with respect to the previously examined cases: the rise of air temperature causes the increase of the total fuel utilization.

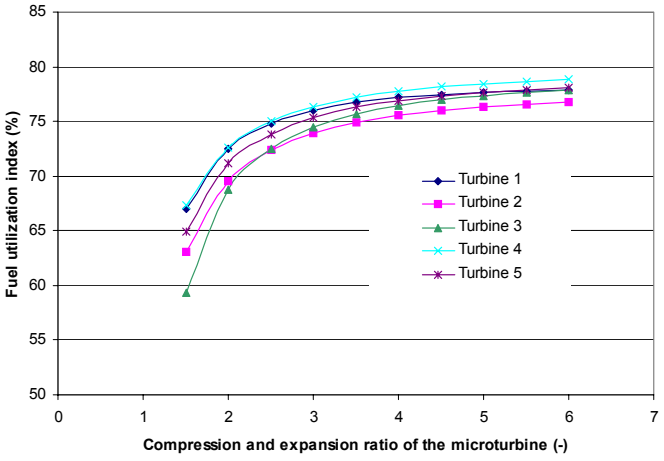

Figure 11: Fuel utilization as a function of compression and expansion ratio of microturbine

Figures 10 and 11 show the variation of the fuel utilization as a function of the gas turbine temperature and the compression/expansion ratio of the microturbine. The influence of these parameters on the microturbine fuel utilization is less important than the previously examined cases.

Considering the previous results together with the manufacturers' official data, the microturbine performances were calculated by means of TRIGEN 1.0. Figure 12 shows the results.

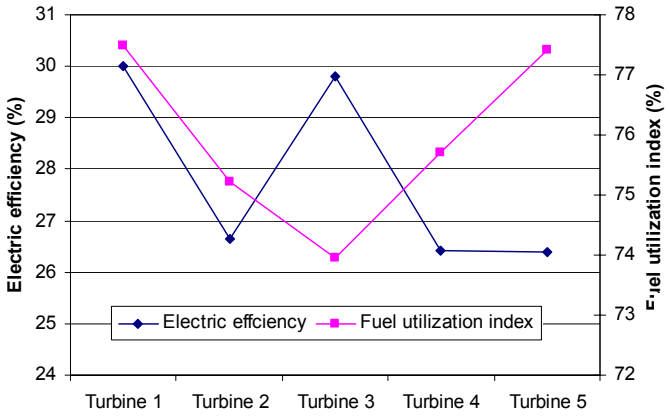

Figure 12: Performance of the microturbines

Turbine 1 is a very efficient system because it provides high electric efficiency and high fuel utilization index.

The other microturbines seem less efficient than the first one, as they show a lower electric efficiency or a lower fuel utilization coefficient.

It is important to note that the quality of a microturbine does not depend on electricity efficient and fuel utilization index only. Other features (as technical life, maintenance charges, reliability of a system, etc, not considered in this paper) are as much important as the considered parameters.

To develop this study, several parameters were considered, as the annual utilization coefficient of the microturbine, the average price of the electric, thermal and cooling energy on the market and the average price of the fuel.

The average price of the thermal and cooling energy can be expressed as a function of P_{fuel} as Equations 14 and 15 show.

$$P_{th} = \frac{P_{fuel}}{\eta_{burner} SHC_{fuel}} \quad (14)$$

$$P_{cool} = \frac{P_{th}}{COP_{hp}} \quad (15)$$

Where η_{burner}, SHC_{fuel} and COP_{hp} can be considered constants.

Taking into account Eq. 11, 12 and 13, *IS* results:

$$IS = UCM \cdot f\left(P_{el}, P_{fuel}, \dot{W}_{el}, \dot{W}_{th}, \dot{W}_{cool}\right) \quad (16)$$

As Figure 13 shows (case of turbine 1, other cases are similar) Eq. 16 can be written as Eq. 17.

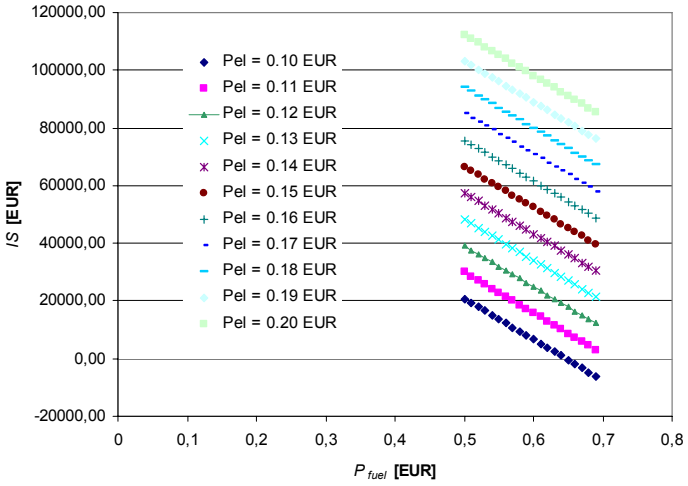

Figure 13: Investment saving (case of turbine 1)

$$IS = UCM\left[aP_{fuel} + b\right] \quad (17)$$

where:

$$a = f\left(\dot{W}_{el}, \dot{W}_{th}, \dot{W}_{cool}\right) \quad (18)$$

$$b = f\left(P_{el}, \dot{W}_{el}, \dot{W}_{th}, \dot{W}_{cool}\right) \quad (19)$$

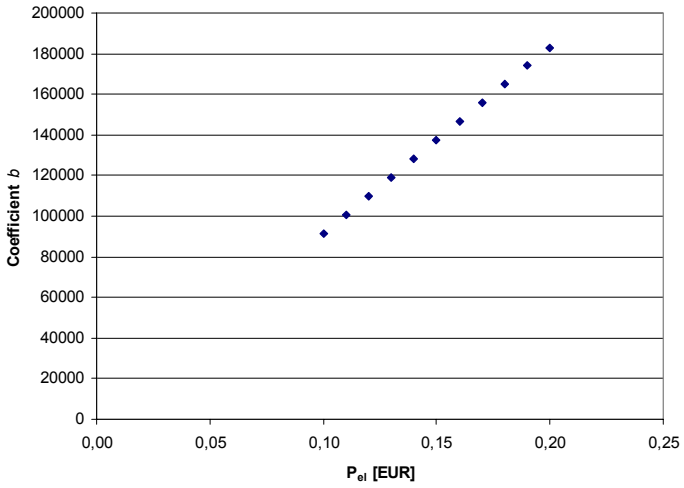

Figure 14: Coefficient *b* (case of turbine 1)

In similar manner, Figure 14 shows that Eq. 19 can be written as follows:

$$b = cP_{el} \tag{20}$$

where:

$$c = f\left(\dot{W}_{el}, \dot{W}_{th}, \dot{W}_{cool}\right) \tag{21}$$

and so:

$$IS = UCM\left[aP_{fuel} + cP_{el}\right] \tag{22}$$

Defined the power index as:

$$P_i = \dot{W}_{el}\eta_{el} + \left(\dot{W}_{el} + \dot{W}_{th} + \dot{W}_{cool}\right)FUI \tag{23}$$

the relationship between *a*, *c* and P_i is shown in the Figure 15.

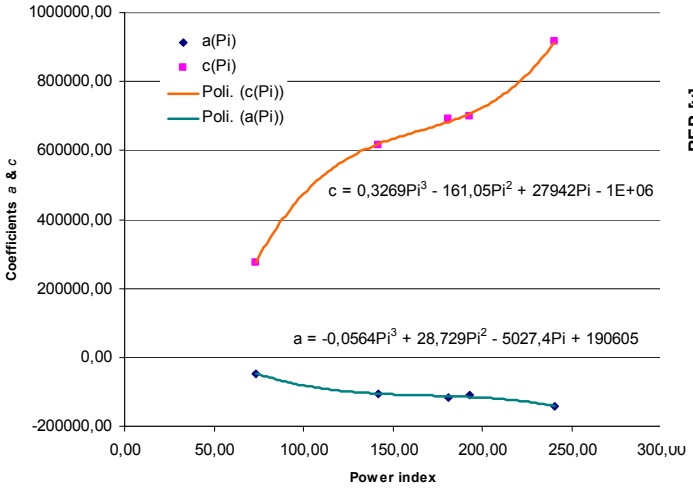

Figure 15: Coefficient *a* and *b* as a function of power index

Applying a third order polynomial regression to the coefficients *a* and *c*, Equations 24 and 25 were solved.

$$a = -0.0564P_i^3 + 28.729P_i^2 - \ldots \\ \ldots - 5027.4P_i + 190605 \tag{24}$$

$$c = 0.3269P_i^3 - 161.05P_i^2 + \ldots \\ \ldots - 27942P_i - 1037258 \tag{25}$$

Equations 10 and 22 allow to assume Equation 26.

$$BEP = \frac{C_m}{UCM\left[aP_{fuel} + cP_{el}\right]} \tag{26}$$

This mathematical model allows to calculate in a very simple way the microturbines' BEP, knowing the cost of the system (*CCA*), the efficiency of the microturbine (taking into account by coefficients *a* and *b*), the annual utilization coefficient of the microturbine (UCM), the fuel and electricity price on the market.

As example, Figure 16 shows the break even point in the case of the microturbine 1, supposing the UCM factor equal to 100% (BEP over 20 years is not shown).

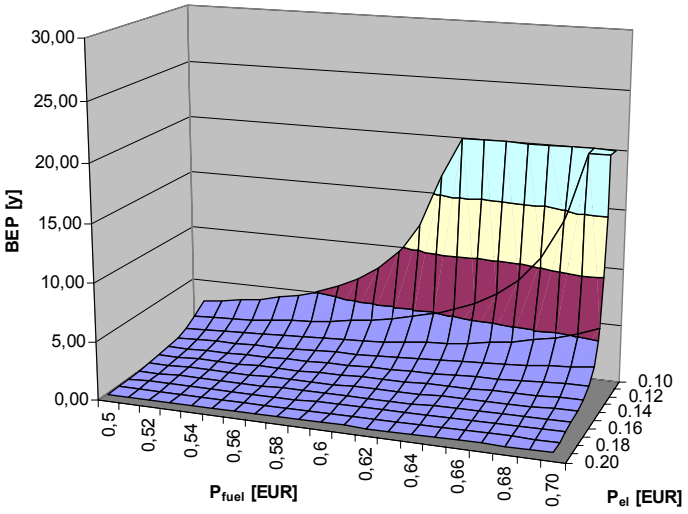

Figure 16: Break even point (case of turbine 1, UCM = 100%, BEP over 20 years is not shown)

CONCLUSIONS

A study of five commercial trigeneration systems that meet electrical, thermal and cooling demands has been carried out, examining their performance varying some working conditions, as atmospheric air temperature, temperature of gas turbine and compression and expansion ratio of microturbine.

The numerical simulations, performed by a software called TRIGEN 1.0, shown that the microturbine electric efficiency and fuel utilization are influenced in opposite manner by the atmospheric air temperature.

To improve the peak efficiency of a microturbine, temperature of gas turbine and compression/expansion ratio are parameters very important: in fact, for all examined microturbines, electric efficiency and generated power are almost directly proportional to the temperature of the gas turbine. Whereas, the compression/expansion ratio can have a very negative impact on the working parameter at low values.

As well, in the second part of this work a mathematical model was developed. This model allows to calculate in a very simple way the microturbines' BEP, knowing the cost of the system (*CCA*), the efficiency of the microturbine (taking into account by coefficients *a* and *b*), the annual utilization coefficient of the microturbine (UCM), the fuel and electricity price on the market.

The model is an efficient tool to decide, as first approach, if the CHCP Microturbines is a valid alternative respect to a more traditional solutions.

ABSTRACT

The paper describes measurements performed in three district heating (DH) substations in semi-detached houses. In all these houses more than 40 % of the domestic hot water (DHW) tappings turned out to be shorter than 10 s. The fraction of total energy used to heat this water varied between 2.4 % and 10.2 %, indicating a large influence of households' daily habits. For 60-78 % of tappings, the total amount of supplied DH water volume was below 2.5 litres, which underlines the importance of using small volume pulses for the energy metering. When analysing the off-load behaviour of the DH substations it was established that radiator circuit control valves for the most part of the studied period were working on/off. During periods when there was no radiator load, the primary supply temperature was typically 50-60 °C, which was higher than expected. The differences in supply temperature level between the substations might be caused by leaking valves or by differences in off-load set point temperature of DHW control valves. Furthermore, the measurements indicate large differences among DHW controllers regarding the characteristics of the feed-forward control. In more than 80 % of the tappings with duration of more than 10 s, an outgoing DHW temperature of at least 40 °C was obtained within a maximum of 10 s. However, depending on the house studied, in 17-55 % of those tappings the monitored DHW temperature did not reach the level of at least 50 °C, as required by the Swedish District Heating Association.

Keywords: Domestic hot water, district heating, low-heat density areas, semi-detached houses

NOMENCLATURE

Abbreviations

Secondary	Referring to the house internal system
T	Temperature, [°C]
τ	Time, [s] or [h]

Subscripts

outdoor	Outdoor conditions
ret	Return pipe
prim	Primary
sup	Supply pipe
tap	Quantity referring to a tapping

INTRODUCTION

Due to heat losses the temperature will decrease in the supply pipes of a DH system. As a consequence of the lower heat load during summertime the supply temperature in peripheral parts of the system may become so low that an acceptable DHW comfort cannot be maintained. This especially is a problem in low-heat density areas, such as single-family house areas. Of special interest is how DHW controllers in DH substations behave during off-load. In order to investigate these issues measurements were performed in three semi-detached houses. The paper is a follow-up on previous theoretical work by the authors on DHW comfort in detached houses, [1,2].

DESCRIPTION OF THE STUDIED DH SUBSTATIONS AND MEASUREMENTS

Measurements were performed during summertime in the DH substations of three semi-detached houses connected to the DH system of the town Malmö in the southern Sweden. All of the studied DH substations are furnished with instantaneous DHW heaters equipped with self-acting, proportional and flow-compensated DHW controllers termed 'AVTQ' (manufactured by Danfoss A/S). AVTQ is the most commonly used DHW controller in single-family houses connected to Swedish DH systems. A detailed description of the AVTQ controller can be found in [2].

The three houses studied are labelled "House 1", "House 2" and "House 3". The households comprise two adults two children, two adults, and one adult, respectively. The houses are located in the DH system as shown in Figure 1. With respect to DH supply temperature House 2 and House 3 are better located than House 1, which is found at the end of a branch of the network.

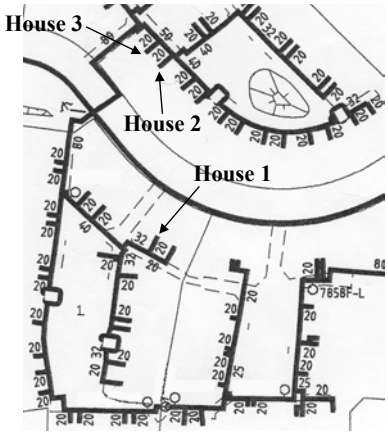

Figure 1 Location of investigated houses in the DH system

Analysed measurements were performed during months June-October of year 2004. The parameters monitored were: DH and DHW flows, DH supply and return temperatures, as well as cold water (CW) and DHW temperatures. The DH flow was measured using the existing flow meter already in place on the primary side, used for billing heat consumption. Since the measurements were performed during summertime and the study focuses on the DHW load, one flow meter on the secondary side was considered sufficient. The measurement set up is shown in Figure 2.

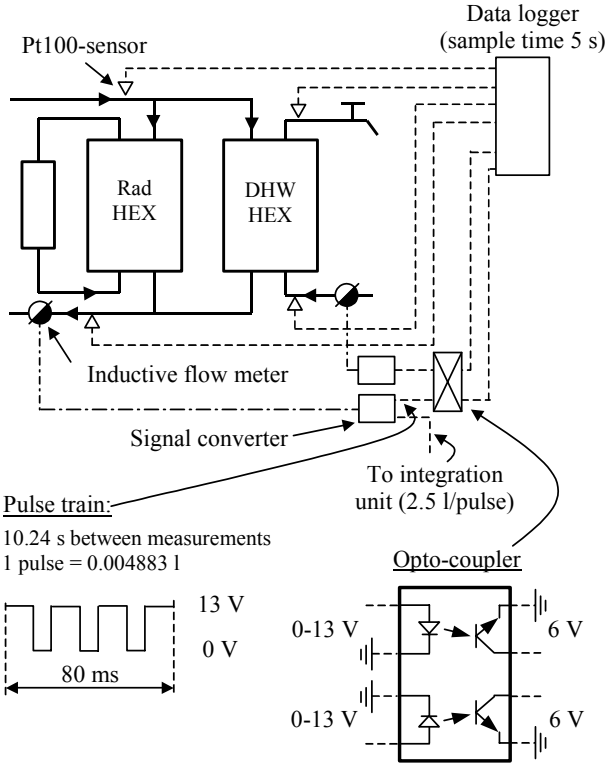

Figure 2 Measurement set up

All temperatures were measured with paired Pt100-sensors of the clamp-on type that were placed identically in all the DH substations. The DHW temperature was measured on the outside of the HEX outlet in which the AVTQ temperature sensor is installed. The Pt100-sensor was placed only a few centimetres from the HEX but not within its insulation. Both the primary side flow meter already in place and the supplementary flow meter were of the inductive type, which was found suitable for monitoring flow rates. Specifications for the flow meters are given in Table 1.

Table 1 Specifications for inductive flow meter, [3]

Property	**Value**
Start flow, q_{start}	0.003 m^3/h
Minimum flow, q_{min}	0.030 $m^3/h \pm 5$ %
Nominal flow, q_n	1.5 m^3/h
Maximum flow, q_{max}	3 m^3/h

The signal converter interprets the signal from the flow meter and sends a pulse to the integration unit at a resolution of 2.5 litres of flow volume. There is also a test pulse output that sends a pulse train every 10.24 s. Each pulse in the pulse train represents a volume of 0.004883 litres. This signal

was sent to the data logger using an opto-coupler interface. The latter provided galvanic insulation between the signal converter and the data logger, which minimised the risk of measurements causing disturbance to the signal used for energy metering.

All data were logged with a sample time of 5 s. This sample time was selected to be appropriate in relation to the response time of the temperature sensors and the limited data storage capacity. However, due to the sample time of the flow meters used, the effective sample time for the flow measurements is only 10.24 s. This relatively long sample time will introduce uncertainties when determining tapping lengths and flows. A typical result from a flow measurement during a tapping is displayed in Figure 3.

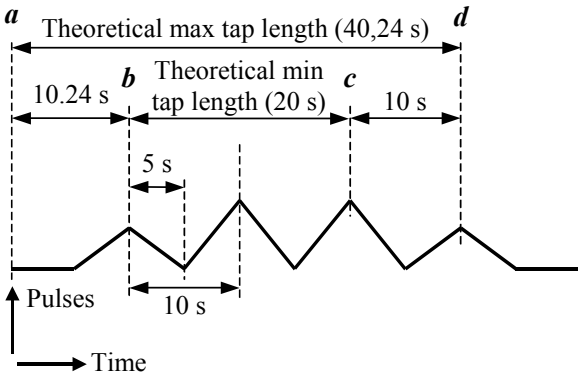

Figure 3 Illustration of typical result from a flow measurement during a tapping

To simplify the analysis the assumption was made that when two subsequent registered volumes are approximately of the same size, the flow has been constant during the studied period. Considering typical human behaviour and various aspects of system performance, such as the moderate pressure fluctuations in the CW system, the simplifying assumption made is considered to be acceptable.

For the case shown in Figure 3 it is known that no water has been drawn off prior to time ***b*** and after time ***d***. However, the tapping may have started anytime in the time interval ***a-b*** and may have ended within the time interval ***c-d***. Assuming that water is drawn off continuously during the period under consideration, the theoretical minimum and maximum tapping length can be expressed as:

$$\tau_{tap,min} = (N-2)\cdot 10 \text{ [s]}$$

$$\tau_{tap,max} = (N-2)\cdot 10 + 20.24 \text{ [s]}$$

Where: N = Number of registered values > 0 pulses

In order to limit the error caused by the sample time of the flow meter the tapping length in this work is estimated as the mean value of $\tau_{tap,min}$ and $\tau_{tap,max}$.

MEASUREMENT RESULTS

During the period studied almost 30 million data points were registered. Obviously, it is impossible to account completely for all data in the paper. In this section results derived from the measurements are analysed and discussed. The displayed results are examples of representative consumer behaviour as observed in the studied DH substations. When studying the results the reader should keep in mind how the measurements were carried out (as described in the previous section). Especially the sample times of the flow meters have a significant influence on the results.

Variation in domestic hot water consumption depending on social factors

The houses studied comprise three households with quite different composition. Consequently, it appears be of interest to investigate if there are any distinct differences between them concerning DHW use. In Figure 4 information about the DHW use in the three houses are shown.

The bars in the figure show how large part of the tappings during the studied period that are within the specified tapping lengths. Above each bar is accounted for how large part of the total energy usage these tappings represent. It should be noted that the last category contains all tappings longer than 125 s. The upper boundary for this category is determined by the longest tapping in each house. This value varies between 11-23 minutes. The DHW volume specified in Figure 4 is the water volume heated up at the DH substation. This water is mixed with fresh water at the taps and thus the volume of heated water leaving the taps will be greater than the specified DHW volume.

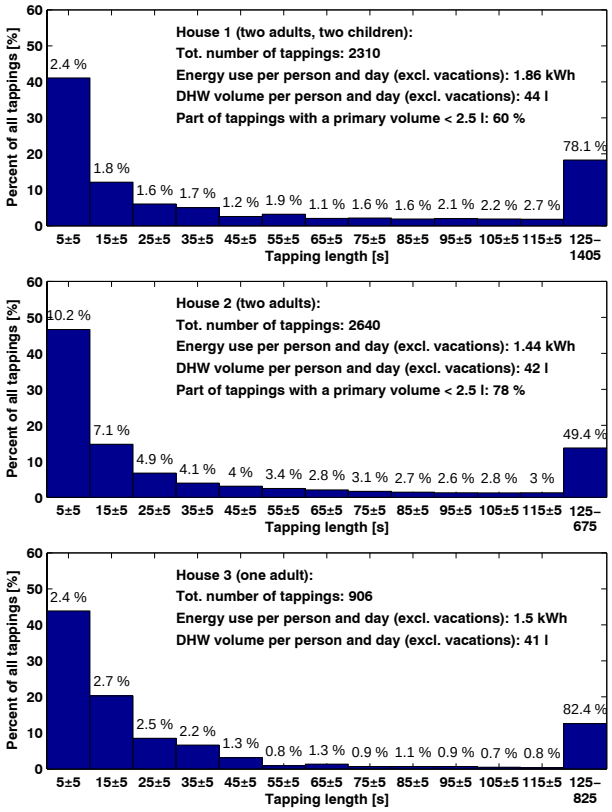

Figure 4 Characteristics for domestic hot water use in three houses

In the studied houses 41-47 % of all tappings are shorter than 10 s. In Houses 1 and 3 the part of the total energy required to heat this water is only 2.4 % while it is 10.2 % in House 2. For tappings longer than 125 s the situation is the opposite. While about 80 % of the total energy is required to heat the water at these tapping lengths in House 1 and 3, the corresponding value for House 2 is only 49 %. A possible explanation for is that on average more water is drawn off at tappings shorter than 10 s in House 2 than in the other houses (0.69 litres compared to 0.52 and 0.34 litres). This deviation may be caused by differences in habits between the households or by faucets with a larger capacity in House 2. Another possible explanation of the difference is that House 2 is only equipped with a shower while the other houses have a bathtub. This may increase the part of the energy used in long tappings since the energy required to fill up a warm bath is normally larger than the energy used when someone is taking a shower.

Excluding days when all members of a household were on vacation (= no DHW used) the energy use per person and day is greatest in House 1 (1.86 kWh) while it is approximately equal in Houses 2 and 3 (1.44 and 1.50 kWh, respectively). This could be caused by different habits and by the fact that there are children in House 1. A third possible explanation can be found by comparing the DHW volume prepared at the DH substation.

The energy used to heat each litre DHW is significantly larger in House 1 than in the other houses. This could be explained by the fact that the DHW temperature is generally higher in the substation in House 1 than in the other substations (see Figure 9). Thus, since the temperature of the fresh water entering the substations is about the same in all houses, either the household members of House 1 have a preference for warmer water than the persons in the other houses and/or they use larger amounts of hot water (note that the DHW is mixed with fresh water at the taps).

Finally, a comment should also be made regarding the accuracy of the energy metering used for billing purposes. In Houses 1 and 2 the primary flows were measured (but not in House 3). According to the measurements the total primary water volume passed during a tapping was below 2.5 litres, which is the pulse value sent to the integration unit (see Figure 2), in 60 % of the cases in House 1 and in 78 % in House 2. The energy used in these tappings corresponds to 6 % and 33 %, respectively, of the total energy used to prepare DHW in the two houses. Based on this it is obvious that the accuracy in the energy metering can be rather poor during summertime unless pulse volumes significantly smaller than 2.5 litres are used.

Domestic hot water controller behaviour during off-load

In Sweden, the heat load in residential areas with semi-detached houses, during summertime, is mainly caused by DHW preparation. If the DHW control valves only open when there is a DHW load, the DH flow in parts of the system will be very small from time to time, resulting in a low DH supply temperature. In consequence, waiting times until the DHW reaches an acceptable temperature during tappings might be long. For this reason the off-load behaviour of the DHW controller is of interest. According to the manufacturer's specification the AVTQ valve functions as a thermostatic valve with a set point

temperature of approximately 40 °C when there is no DHW load, [4].

In Figure 5 off-load behaviour in the studied sub-stations during the 14th of July is shown. All the households were on vacation on this day.

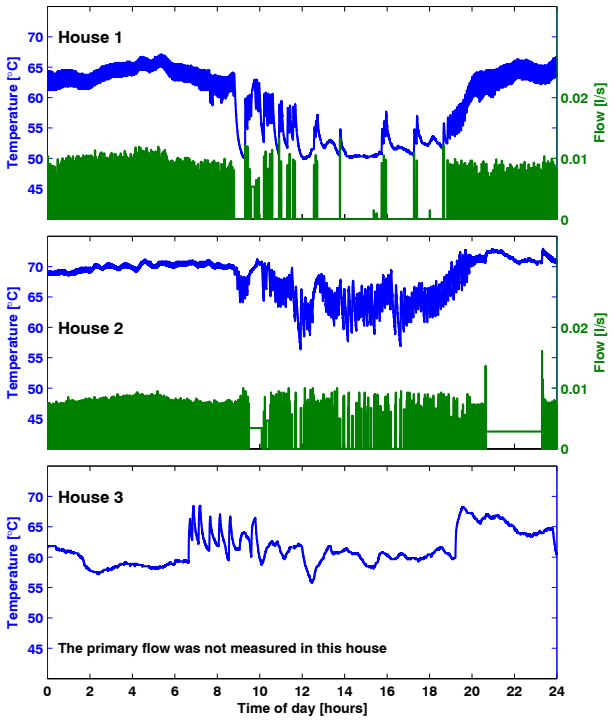

Figure 5 Off-load behaviour in three DH substations, the 14th of July. DH water supply temperature and flow are shown.

A DH supply temperature slightly above the off-load set point of 40 °C for the AVTQ should be expected. However, when studying Figure 5, three quite surprising phenomena can be observed:

1. The supply temperature is high compared to the off-load set point for the AVTQ.
2. In Houses 1 and 2 the supply temperature is 5-15 °C higher during the night than during daytime.
3. During most of the day the primary flows in Houses 1 and 2 show on-off behaviour with a rather high frequency (2-4 minute periods). When looking at the entire range of measurements, it becomes apparent that day-time flow fluctuations begin and end approxi-mately at the same time in both houses.

The explanation to these load behaviours can be found by studying the primary supply and return temperatures, and DHW and CW temperatures together with the outdoor temperature, Figure 6.

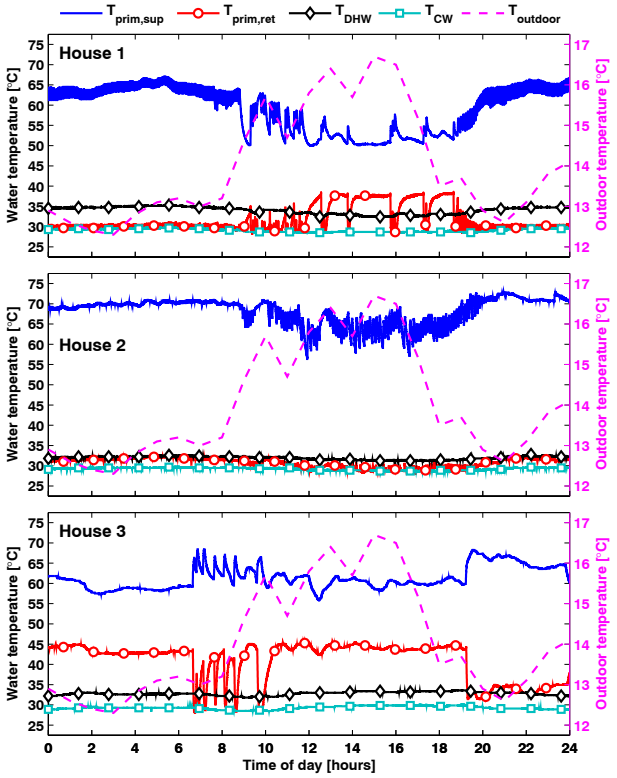

Figure 6 Outdoor temperature and primary and secondary temperatures corresponding to Figure 5

The frequency of the primary flow fluctuations in Houses 1 and 2 decreases between 9 a.m. to 7 p.m. when the outdoor temperature rises. Between 11.30 a.m. and 6.30 p.m. there is almost no primary flow at all in House 1 and the DH water supply temperature decreases, while there is still some DH flow present in House 2. According to Figure 6 these flow changes are closely correlated to changes in outdoor temperature. It is a general trend that the primary flow ceases at slightly lower outdoor temperatures in House 1 than in House 2.

Furthermore, during periods when a primary water flow is registered it is typically cooled off 35-40 °C as it passes through the substation. This is to be compared to a cooling of 10-15 °C when there is no registered flow. Apparently there is a flow in some of the secondary circuits that cools the primary water. However, the measured DHW temperature is only marginally influenced by the large changes in primary temperatures. In other words, the primary water does not pass through the DHW HEX.

The conclusion from this is that it is actually the space heating circuit that causes the observed primary flows. Unfortunately the primary flow was not measured in House 3 but the temperature variations indicate a similar behaviour in this house. Notice for instance in Figure 6 the temperature changes between 7 and 10 a.m. and the step-like temperature change at 19 p.m. in the bottom diagram. The primary temperatures also indicate that nighttime temperature set-back between 0 and 6.30 a.m. is employed in House 3.

The characteristic of the flow variations in Houses 1 and 2 proves that the radiator valves are working on/off. This causes wear of the valves and is therefore highly undesirable. The primary temperature variations in House 3 suggest that this valve to a much less degree is working on/off.

In Figure 7 off-load behaviour in the studied houses during the night between the 15th and 16th of August is shown. The outdoor temperature varied between 17 and 18 °C. During the studied period no primary or DHW flows were registered.

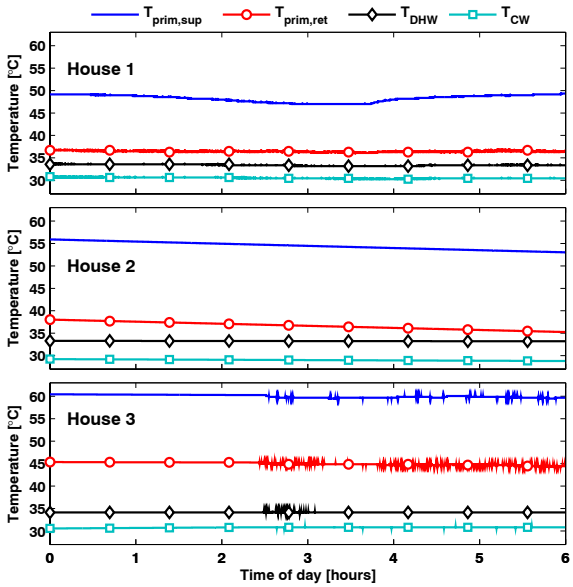

Figure 7 Off-load behaviour in House 1 and 3, the night between the 15th and 16th of August

Considering the high outdoor temperature, low supply temperatures, 47-60 °C, and a primary water cooling of 12-17 °C it can be stated that there is no space-heating load in the houses (compare with Figure 6). Notice the large differences in supply temperatures between the houses. A keyword in this context is that no primary flows were *registered*, which does not necessarily mean that there were no flows. According to Table 1 the flow meters used start to register flow at q_{start}=0.003 m^3/h. An estimation of the heat loss from new service supply pipes confirms that a primary flow lower than q_{start} can actually uphold the observed DH supply temperatures.

The registered DHW and CW temperatures only differ a few degrees among the various houses. Since there is no DHW flow the influence of the ambient temperature on the measured secondary temperatures will be large. The registered CW temperatures indicate that the air temperatures within the DH substations are approximately 30 °C. The registered DHW temperature is somewhat higher than the air temperature due to the fact that the temperature sensor is attached close to the AVTQ temperature sensor in the DHW HEX. However, due to heat losses both the AVTQ temperature sensor and the Pt100-sensor will register a DHW temperature that is lower than the temperature inside the HEX.

The real off-load set point temperatures can be estimated to be somewhere between $T_{sup,prim}$ and $T_{ret,prim}$. The differences in supply temperatures between the substations might be caused by differences in off-load set point temperatures or by leaking control valves.

Domestic hot water controller behaviour during tappings

Next, the controller behaviour during tappings will be studied. Due to the relatively large sample times of the flow meters used some details of the controller behaviours are lost. Still, some principal differences between the controllers in the studied houses can be observed. The flows have been reconstructed based on registered volumes.

Some representative controller behaviour patterns during tappings are shown in Figure 8. The temperatures before the tappings occur are seen to depend on the previously studied off-load behaviour of the controllers. Note that the uncertainty of when a tapping actually starts can introduce some obviously incorrect reconstructed flows. One example of this is that the primary flow starts 5 s before the first tapping in House 2 in Figure 8.

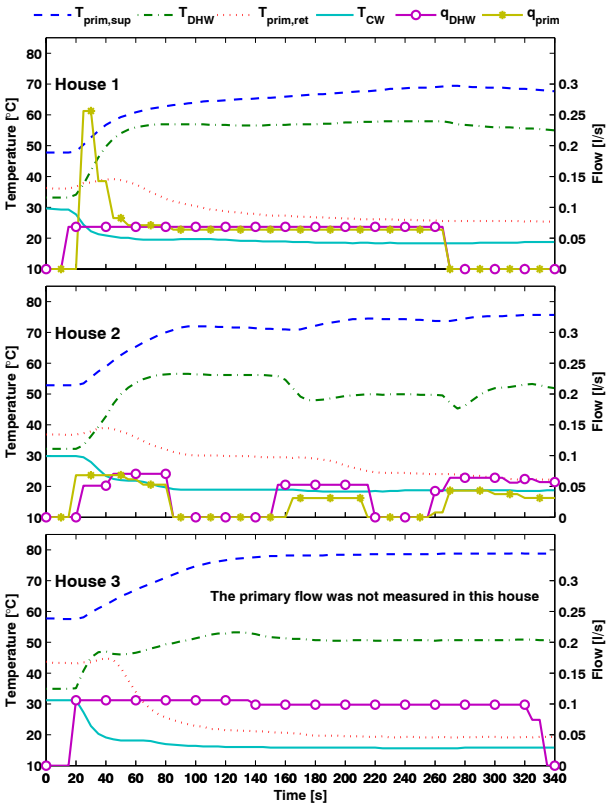

Figure 8 DHW controller behaviours during tappings, the 5th of August

In House 1 it can clearly be observed that the feed-forward control gives rise to an initially large valve opening, resulting in a large primary flow. As the DHW temperature increases the thermostatic part of the controller decreases the valve opening. In House 2 the influence of the feed-forward control cannot be noticed, and the initial primary flow is significantly lower than in House 1. This difference in controller behaviour can be observed during the whole measurement period. For instance the maximum tapping flow is 0.27 l/s in both houses while the maximum primary flow is 0.35 l/s in House 1 and only 0.17 l/s in House 2. A typical initial primary flow at a tapping is above 0.2 l/s in House 1 and below 0.1 l/s in House 2. Thus, the measurements indicate a relatively large variation in controller characteristics. This phenomenon has also been observed in laboratory testing of DH substations, [1].

According to Figure 1 it holds that Houses 2 and 3 are advantageously located in the DH system compared to House 1 with regard to supply temperature. The influence of this can be observed in Figure 8. Although the studied tapping in House 1 is 4 minutes long the supply temperature does not reach 70 °C while it in House 3 is nearly 80 °C.

It is hard to draw any definite conclusions regarding the set point of the AVTQ:s based on Figure 8. For this to become possible, the average DHW temperature at the end of tappings for the whole measurement period must be studied. The temperature partly depends on the tapping length and this has to be taken into consideration in order to make a fair comparison between the houses. In Figure 9 is shown the mean DHW temperature at the end of tappings with different lengths.

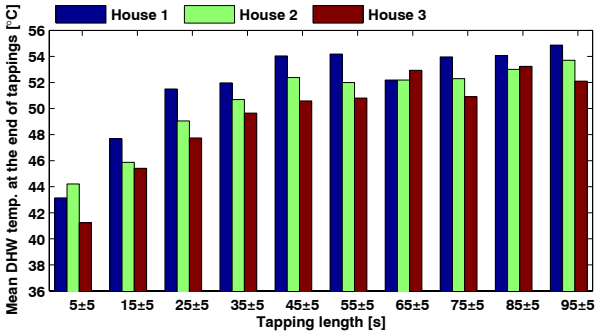

Figure 9 Average final DHW temperatures at different tapping lengths

Based on the information in Figure 9 it seems likely that the AVTQ set point is highest in House 1 and lowest in House 3.

Domestic hot water temperature at the district heating substation and DHW comfort

When opening a tap one expects water of sufficient quantity and temperature to be delivered. The purpose of the DHW controller is to secure that an acceptable temperature is obtained. Swedish authorities stipulate that the temperature at the tap in single-family houses should be above 50 °C (to secure a good DHW comfort and to avoid bacterial growth) and below 65 °C (to avoid scalds), [5]. If only temperature comfort is regarded most people find a water temperature of 40-45 °C to be sufficient, [6].

In Figure 10 is studied how long the delay is between the point when the tap is opened and when the DHW temperature at the DH substations reaches 40 °C, 45 °C and 50 °C, respectively. Note that only the temperatures at the substations, and not at the taps, are studied. Depending on the

distance between the heat source and the tap, the total time delay for the warm water to reach the tap can be significantly longer. This holds for any heat source and is not a problem related to DH. For short tappings it seems realistic to assume that the demand for a high DHW temperature is low. For this reason tappings shorter than 10 s are disregarded in the analysis in Figure 10.

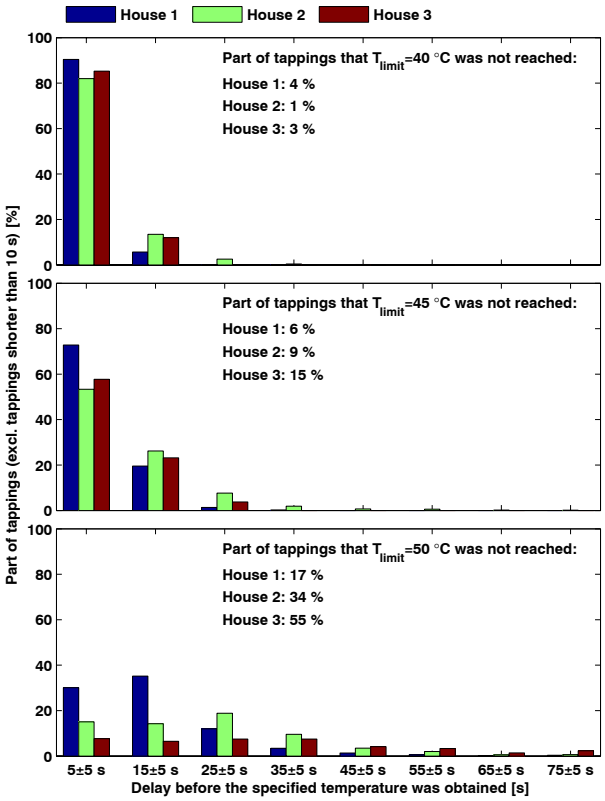

Figure 10 Waiting times before the specified DHW temperature is obtained at the substation

Considering the off-load primary supply temperatures shown in Figure 7 it is not surprising that a DHW temperature of 40 °C is obtained within 10 s in almost all tappings (the upper part of Figure 10). A DHW temperature of 45 °C is typically reached within 20 s, while the situation is considerably worse if the prescribed temperature of 50 °C is studied. This observation corresponds well to results from a theoretical investigation, [1]. In House 1 the DHW temperature reaches 50 °C within 30 s in 77 % of all tappings longer than 10 s, while in House 3 the corresponding figure is only 21 %. Furthermore, 50 °C is not at all reached in 17-55 % (depending on which house is regarded) of the studied tappings.

Next, let's study if the tappings when 50 °C is not reached have something in common that clearly distinguish them from other tappings. One possible explanation is that the DH system in itself causes the low DHW temperatures. For instance the DH parameters during some parts of the studied period may be disadvantageous considering the DHW control. A low supply temperature could potentially be the result of the low load during nighttime, causing long delays before warm primary water reaches the DH substation. However, when studying the distribution of the 'deficit' tappings in time, they do not clearly differ from other tappings.

Another explanation is that it is the characteristics of the tappings themselves that causes that 50 °C is not obtained. In Table 2 the 'deficit' tappings are compared to the average tappings regarding tapping length and volume.

Table 2 Information about tappings where 50 °C was not reached

House number	τ_{tap} = 10-20 s	Tapping vol. / Mean tapping vol.
1	84 %	0.86 l / 6.13 l
2	80 %	1.78 l / 2.55 l
3	81 %	1.16 l / 3.91 l

From Table 2 it is clear that most of the tappings have in common that they are short (shorter than 20 s) and that small volumes are drawn off. Due to this the warmer water in the DH mains simply do not reach the substation before the tapping has ended.

Finally, also the characteristics of the DHW controllers must be considered. With the large capacity of the DHW control valve in House 1 into consideration (see Figure 8) it is not surprising that the waiting times are shortest in this house despite its disadvantageous location in the system. This clearly shows the benefit with a feed-forward control that has a large influence on the initial position of the valve. The lower primary flows in House 2 causes longer waiting times. The relatively high off-load primary supply temperature in House 3 secures short waiting times if 40 °C and 45 °C are considered. However, the

low DHW controller set point (see Figure 9) causes a poor DHW comfort if 50 °C is considered.

CONCLUSIONS

The measurements proved that a large part (approximately 40 %) of all tappings are shorter than 10 s. The part of the total energy used to heat this water varied between 2.4 % and 10.2 %, indicating a large influence of the households' habits etc. The primary water volume consumed was below 2.5 litres in 60-78 % of the tappings, which illustrates the importance of using energy metering volume pulses that are significantly smaller than this value. The volume pulses in old flow meters, still installed in DH systems, are therefore often too large, resulting in inaccurate energy measurements. During periods with no DHW load, it was observed that the radiator control valves for the most part of the studied period were working on/off. This behaviour is undesirable considering wear of the valves and the increased temperature level in the return service pipe. The latter fact will result in unnecessarily high heat losses from the DH system during summertime. During periods when there was neither a DHW load nor a radiator load, the primary supply temperature was typically 50-60 °C, which is higher than expected. The differences in supply temperature might be caused by leakage or differences in off-load set point temperature of the DHW control valves. Large differences in feed-forward control behaviour were observed. For instance, at tappings the initial primary flow in the substation with the largest flow was about twice as large as in the substation with the smallest flow. The waiting time before a specified temperature is reached was typically shorter in the substation with a distinct influence of the feed-forward. This indicates that manufacturing tolerances of the valve might be improved. In general, however, feed-forward control works well when implemented in a DHW controller. When DHW is drawn off a temperature of 40 °C is typically obtained within 10 s in more than 80 % of all tappings longer than 10 s. Depending on which house that is studied, the temperature prescribed by Swedish authorities (50 °C) was not reached in 17-55 % of the tappings longer than 10 s.

ACKNOWLEDGMENTS

The authors would like to thank Mr Anders Lövdahl at Sydkraft AB who mediated the contact with the households in which the measurements were performed. Mr Lövdahl also installed the flow meters and temperature sensors. Our colleagues Peter Matsson and Per-Olof Johansson at the Department of Heat and Power Engineering assisted at the installation of the measurement equipment. The study was funded by the official Swedish district heating programme, which is cosponsored by the Swedish State and the Swedish District Heating Association.

ABSTRACT

Recently, efforts have been made to scale down some types of Combined Heat and Power (CHP) plant technology, such as fuel cells, gas turbines, Stirling engines or organic Rankine cycles, in order to adapt them for residential applications. The driving force for this is the high overall thermal efficiency and the low associated GHG emissions. Beside this, distributed power generation is expected to alleviate partially the issue related to the general rise in electricity demand. However, as micro-CHP have only modest electrical conversion efficiencies, the effective exploitation of the thermal output is critical to realising high levels of energy efficiency and the associated environmental benefits. The heat-to-power ratio of currently available micro-CHP units (in the best case approx. 2 to 1) compares poorly with the heat-to-power ratio of high-performance buildings (on average 1 to 1 according to recent construction practice).
The present paper considers the building and the heating, ventilating, and air-conditioning (HVAC) system (including the micro-CHP) and the resident's heat and power patterns as a whole, taking into account their inherent interactions. First, it describes new simulation tools which were developed to balance the production and the consumption of both heat and electricity in terms of both energy and costs. Computations based on Solid Oxide Fuel Cells (SOFC) and Stirling engines are discussed. Second, these technologies are compared in terms of primary energy consumption and costs to competing technologies such as condensing gas boilers. Third, the role of the appropriate level of thermal insulation for the building as a compromise between building heat losses and overall primary energy efficiency, including electricity supply, is discussed.

INTRODUCTION

Local and global environmental issues, the steady rise in costs for crude oil and natural gas, people's expectation of comfort, cosiness and automation and the changes in the commercial and political framework lead to the need to conceive cost-effective buildings with highly reliable, low-energy building services.

In Europe, on average, one third of the end energy is consumed in the building sector, especially for space heating. The first step taken to address this form of energy usage was to reduce the specific heating load of buildings by increasing their thermal insulation and by rendering the building envelop more air-tight to reduce heat losses by natural ventilation (due to wind pressure and cracks in the wall). New high-efficiency construction standards arose, such as the 3-litre house (3LH) with a heating load ceiling at 30 kWh/(m² a). The passive-house (PH) standard is even stricter with a ceiling at 15 kWh/(m² a). This kind of housing typically requires low-temperature heat that can be supplied in an efficient way by a compact heat pump. Heat pumps are high-performance heat suppliers because they take heat from the environment and transfer it to the house, but they generally require electric power to do their job (compression heat pumps). Therefore, running the heat pump will add to the domestic electric bill and will put even more strain on the local electric grid.

The second step was to develop supply systems able to meet energy loads of all kinds in the building. These are basically electricity, heat and, to a lesser extent, cooling. Micro-Combined Heat and Power (mCHP) systems arose from the scaling-down of reliable CHP technologies such as fuel cells, Stirling engines, reciprocating engines and micro-turbines. However, as mCHP systems have only modest electrical conversion efficiencies, effective exploitation of the thermal output is critical to realising high levels of energy efficiency and the associated environmental benefits. Designing and operating a building-integrated cogeneration system that delivers useful thermal output, however, is a complex task due to the strong coupling between the cogeneration unit, other HVAC components, and the building's thermal and electrical demands. The volume and thermal characteristics of the storage tank, the occupant's electrical usage patterns, the house's thermal characteristics, and the prevailing weather, all influence whether this thermal energy will be exploited or wasted.

This paper intends to assess the feasibility of coupling high-performance residential buildings with mCHP systems in terms of energy conservation and of costs. The scope of the work is restricted to single-family buildings and mCHP systems with an electrical output power of less than 5 kW. First, the energy requirements and load patterns of high-performance buildings will be described. Second, the specifications of mCHP for residential applications will be explained. Third, models for fuel-cell mCHP and Stirling mCHP will be detailed briefly and the results gained from whole-year simulation will be presented. Performance of mCHP will be compared to conventional heaters like condensing gas boilers (cGB) within a benchmark analysis. Finally, the issue of building thermal performance versus energy conversion technology will be addressed with regard to the simulation results.

HIGH-PERFORMANCE BUILDINGS

A new trend in construction practice arose from concerns about fuel scarcity and environmental protection: Buildings must guarantee comfort with as little energy as possible even during cold winters. This demand can be met by enhancing the thermal performance of the building envelope and by smarter usage of solar input through the windows. Heat losses through the envelope arise

when heat flows through the external walls and cold outdoor air enters the house due to wind pressure. The first issue can be alleviated by making the thermal insulation layer of the external walls thicker, while the second issue is counteracted by rendering the walls air-tight. The passive-house construction standard arose from the offset between the benefits due to lower energy bills and the additional costs due to extra thermal insulation. The optimum is found for a specific heat load of approx. 15 kWh/(m² a). Below this value, there is no longer any need for room-based heating equipment such as radiators, as the heat can be distributed by using hot air that is circulated by the central mechanical ventilation system with heat recovery (more details in [1]). The heat recovery considerably decreases the energy demand for heating. However, it adds strongly to the overall investment costs of the house and significantly prolongs the payback time of the additional equipment. In addition to this, the HVAC system requires a heat supplier with extra-low power output (the total thermal output for an average free-standing house does not exceed 1.5 kW), which prohibits the use of low-cost gas boilers. Instead, expensive small-scale exhaust air heat pumps, that are not mass products, have become a standard [2].
As a result of this dilemma, the 3-litre house construction standard, that draws on the concept of higher energy costs but lower capital costs, has become established on the marketplace. This standard puts a ceiling at a heat load of 30 kWh/(m² a). In this case, radiators or floor radiation systems are necessary, but low-cost exhaust air ventilators replace the expensive ventilation system with heat recovery. Heat is preferably provided by low-priced boilers, but compact heat pumps can also be used.

MICRO-CHP SYSTEMS FOR RESIDENTIAL APPLICATIONS

Benefits and sales expectation

In the meantime, new systems with similar output power, producing not only heat but also electricity from the same fuel, are emerging on the market place. These are known as micro-Combined Heat and Power. The concurrent production of electricity and heat from a single fuel source can reduce primary energy consumption and associated GHG emissions. Reductions in combustion by-products such as nitrogen oxides and hydrocarbons are also a possibility. The distributed generation nature of the technology also has the potential to reduce electric transmission inefficiency (the European Commission estimates that transmission and distribution losses amount to an average of 6% of the electricity transported in the EU [3]). Since the device can partly meet the power demand of the household [4], mCHP may be able to alleviate utility peak demand problems and the need for grid reinforcement caused by the general rise in electricity demand. 40 million homes in 15 countries of Europe are said to be suitable for mCHP systems [5]. Sigma Elektroteknisk of Norway estimates a yearly market potential for mCHP of some 800,000 units per annum only in Europe [6]. Leading contenders for building cogeneration include fuel cells, Stirling engines, reciprocating engines and micro-turbines.

System sizes

As a result of a statistical survey carried out in England, stating that the power consumption of an average household amounts to approx. 1 kW as a daily average, two different output power categories have become established on the marketplace so far. These are units with a nominal output power of around 1 kW for usage in free-standing houses and 5 kW output power for medium-density housing with central heating. Since the specific internal consumption of the balance-of-plant components diminishes significantly with the size of the plant, larger units ought to display better efficiency. However, issues related to heat storage and distribution may annihilate the benefits of size. One can observe that the nominal power-to-heat ratio currently varies from 1 to 10 (i.e. steam engine systems) up to approx. 1 to 2 (fuel cell system) depending upon the core technology of the mCHP plant. Since effective usage of the heat released is critical to achieving high levels of energy efficiency, the plant should be chosen judiciously to match the heat load of the building well,

bearing in mind that system costs depend strongly on the core technology inside.

Marketplace

Moreover, mCHP must compete against more traditional types of technology such as cGB, wood/oil furnaces, district heat, distributed electricity and renewable energy converters such as solar thermal energy, photovoltaics and small-scale wind mills. If mCHP wants to gain a share of the marketplace, it must show proven economical and environmental benefits. There are three main reasons why now is the right moment for mCHP. First, new commercial possibilities are arising simultaneously with the liberalisation of the European energy markets, which are stimulating radical changes to the thinking about energy production. Second, environmental pressures to minimise CO_2 emissions are mounting, accompanied by governmental financial incentives. Third, the technology is becoming available. All over Europe, energy distribution and supply companies have expressed interest in mCHP, as a way to gain new customers or retain previously captive customers. Furthermore, mCHP can be used not only in new buildings but also in old buildings that have been retrofitted according to current building thermal standards.
As a conclusion, designing and optimising a mCHP system with regard to energy and overall costs is a complex task, that requires dedicated computational tools.

SYSTEM MODELLING

The SOFC-mCHP

The SOFC generally operates between 800 and 1000 °C and belongs to the category of high-temperature fuel cells. At this temperature, the solid ceramic electrolyte is able to conduct ionised oxygen molecules. At the same time, hydrogen is oxidised at the anode, liberating electrons which flow via an external circuit to the cathode. When fuelled with natural gas, hydrogen is gained from reforming the hydrocarbons with steam. While electricity can be obtained at the cell's poles, useful heat is produced from cooling down the flue gas of the cell.
This study has been carried out by using characteristic curves presented in [7]. Dynamic features gained from the detailed model can be found in [8]. Parameters of the model are given in Table 1. Efficiency hypotheses were taken from [9]. It has been assumed that the SOFC system can be modulated in the range between 20 and 100% of the nominal electric power. Below 20%, the SOFC is led to the hot-standby mode where it produces neither electricity nor useful heat. The fuel consumption in hot standby is dictated by the heat losses of the stack at around 1000 °C. These amount to approx. 200 W fuel (lower heating value LHV).
An additional gas burner backs up the SOFC when the heat load is large.

Nominal net power output	1000 W
Warm-up time for the stack initially at room temperature	8 hr
Thermal losses of the thermal jacket of the stack	0.16 W/K
Maximal load variation rate	55 W / min
Electrical efficiency at nominal power (LHV)	29.5%
Thermal efficiency at nominal power (LHV)	50.5%

Table 1: : Parameters of SOFC characteristic-curve model

The Stirling mCHP

Stirling engines operate according to the principle that when heat is provided to a gas, it expands and when heat is removed, the gas contracts. Cyclic supply and removal of heat can put a piston into motion. The piston rod is connected to a crankshaft that drives a power generator.
The Stirling mCHP system has been described using a dynamic characteristic curve. The data intends to describe a commercial system that could be available by 2010 on the German market. The mCHP system is considered as a package with a 1 kW_{el} Stirling engine and an additional gas burner. With the German market in mind, a machine with a rather high electrical efficiency

was suggested (about 25%). The parameters used in the simulations are presented in [10]. These characteristics assume that the mCHP unit is equipped with an exhaust gas/cooling medium heat exchanger, where steam contained in the flue gas condenses. The flue gas is expected to exit the CHP unit at a temperature around 50 °C. The overall thermal efficiency was assumed to be 95%. The electrical and thermal response time at 63% of the set value is approx. 60 seconds for electrical power and 100 seconds for thermal power.

HVAC system and building model

The HVAC system consists essentially of a pressurised water heating system. It is illustrated in Fig. 1. In order to optimise the operation cycle of the mCHP, a large heat storage tank of 750 liters has been foreseen. Domestic hot water is produced from a flat-plate heat exchanger. The temperature setting is 45 °C. The seasonal variation of water inlet temperature is taken into account. The quantity for hourly consumed domestic hot water (DHW) has been derived from a statistical study. Depending on the thermal insulation of the building, hot air (PH) or radiators (3LH) have been used for heat redistribution in the room (heating loop). The setting for the room temperature is 20 °C.

The space heating load is computed using a multiple-zone building model describing the thermal behaviour of an free-standing house. Details can be found in [11]. The building is located in the Frankfurt area. Parameters of the model can be found in Table 2.

The mCHP unit is thermally controlled. If the temperature in the storage tank is below a set value, then the mCHP will be operated until the temperature rises above an offset value. When the heating load has been met, case A: the SOFC is switched to the hot stand-by mode or case B: the Stirling engine is switched off. When it is operated, the mCHP concurrently produces electricity that is intended to cover the household electricity load. At some time of the day, the mCHP may produce more electricity than consumed by the household. The surplus is sold to the grid utility. When self-generation is not enough to cover the needs, electricity can be bought from the utility.

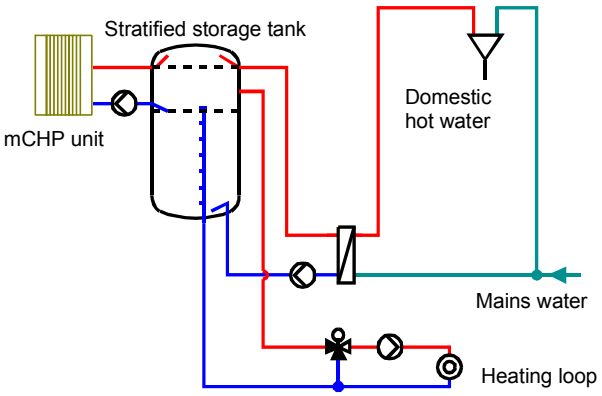

Fig. 1: Schematic diagram of the HVAC system

A two-way metering system enables separate billing according to the rates of Table 3. Costs are recovered and profit is generated by a mCHP through the electricity exported. However, electricity reaches its highest monetary value when it is used directly in the house (substituting the electricity that would have been bought from the grid) since resale of the electricity produced is at a lower price (about 8 c€/kWhe in Germany). The latter price consists of a bonus (5.11 c€/kWh$_{el}$, defined in a law) plus the price of the electricity traded on the wholesale market.

Building type		3LH	PH
Space heating load	KWh/(m²a)	29	11
Floor area	m²	118	118
Household electricity	MWh/a	5.5	5.5
Water heating	MWh/a	2.6	2.6

Table 2: Annual energy comsumption of different building services

Energy	Pricing
Natural gas	3.8 c€/kWh (LHV)
Electricity from the grid	13 c€/kWh
Electricity exported to the grid	8 c€/kWh

Table 3: Pricing of energy according to [9] (without VAT)

SIMULATION RESULTS AND PERFORMANCE BENCHMARK

In order to handle electricity and natural gas on the same basis, the consumed energy amounts have been transformed into their corresponding amount of primary energy. For natural gas, the primary energy factor equals 1.1 and for grid electricity 3 (both referring to the national average for Germany). Equation 1 illustrates the primary energy balance of the building. The total primary energy expenditure equals the sum of primary energy in the form of natural gas for the prime mover and for the auxiliary burner of the mCHP, and in the form of electricity that is imported from or exported to the grid .

$$\begin{aligned} P_{total} &= P_{NG}^{FC} + P_{NG}^{GB} + P_{el}^{Imp} - P_{el}^{Exp} \\ &= n_{NG}\left(M^{FC} + M^{GB}\right) + n_{el}\left(M_{el}^{Imp} - M_{el}^{Exp}\right) \end{aligned} \quad (1)$$

A similar balance can be established for monetary costs for energy supply to the building (see equation 2).

$$E_{total} = E_{NG}^{FC} + E_{NG}^{GB} + E_{el}^{Imp} - E_{el}^{Exp} \quad (2)$$

Whole-year simulations have been run for the 3LH and PH building with the same boundary conditions (DHW load, electricity load, geographic location). First, it turns out that the thermal power output of both mCHP systems is enough to cover the thermal needs of the building. The auxiliary gas burner has only safety-of-supply function and could easily be replaced by a low-cost electric heating element in the storage tank. Second, due to the low heating load of the building, the operation time of the mCHP's does not exceed 3000 hr/a. Therefore, a large proportion of the household electricity must be bought from the utility grid. This adds strongly to the primary energy balance and to the costs.
In order to assess the financial viability of mCHP in high-performance buildings, a conventional cGB with 7 kW thermal output and 100% overall thermal efficiency was chosen as the baseline product, while electricity is bought completely from the utility. In a further step, the cGB was coupled to solar thermal collectors with 5 m² absorber area in order to reduce the natural gas consumption without reducing comfort. Fig. 2 shows the results of the benchmark analysis in terms of primary energy expenditure.

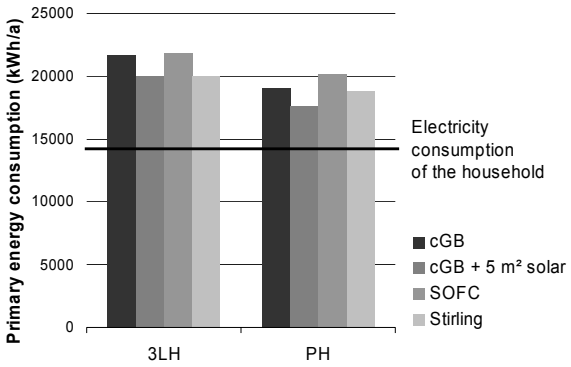

Fig. 2 : Primary energy consumption of the building vs. the thermal insulation standard and the energy conversion system

The electricity consumption of the household accounts for the major part of the energy consumption. DHW production and room heating account approx. for ¼ of the total. Fig. 2 illustrates as a result that even if the space heating load of the 3LH is more than twice as high as that of the PH, its overall primary energy consumption increases only by 10% on average.
In the case of 3LH, the lowest primary energy consumption is achieved by both the pair cGB + solar collector and by the Stirling- mCHP. The Stirling yields better results than the SOFC because it features higher thermal efficiency and no hot-standby consumption.
In the case of PH, the pair cGB + solar performs the best. The reason why the Stirling can not perform better is the lack of heat demand (i.e. short operating time). The Stirling engine is not able to compensate its comparatively poorer efficiency with electricity export to the grid. The SOFC performs worst mainly because of the hot-standby consumption.

Financial aspect

Operation and investment costs are the major issues affecting commercial success and wide market uptake of mCHP. Since mCHP technologies are in an early phase of development,

retail prices are not known yet. For most mCHP manufacturers, the allowable retail price for their product is a major concern. The allowable price is defined as the upper limit at which the mCHP can be offered in order that the customer gets the same benefit as if he used the baseline technology. The income drawn from electricity export or household electricity substitution plays the major role and helps to offset the additional costs due to the more complex technology. As shown in Fig. 3, the allowable retail price for the mCHP device is derived from the accumulated difference of annual total costs over a period of 15 years (expected lifetime of the mCHP).

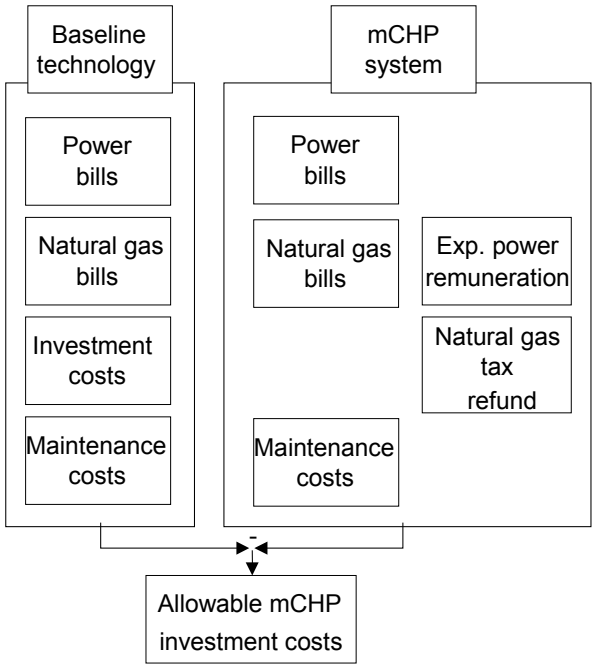

Fig. 3: The annual allowable investment costs for the mCHP are derived from the difference between the annual total costs of the baseline system and the mCHP

Simulation results such as fuel consumption, running time of the mCHP and the amount of exported or imported electricity serve as input for the operation costs. The retail price basically depends upon the technology employed and upon the specification of the building. The final computation results are found in Table 4. The computation details are documented in [4].

Considering the investment costs for a conventional cGB (on average, 3100 EUR on the German market), it makes no sense to propose SOFC-mCHP products for high-performance houses, since the allowable retail price is much too low. SOFC-mCHP units fit much better in non-refurbished houses. In the case of the Stirling-mCHP, the sales margin depends strongly on the actual production costs, especially the manufacturing costs of the complex and heavy Stirling engine unit.

	3LH	PH
SOFC-mCHP	2372	1956
Stirling-mCHP	4536	3901

Table 4: Allowable retail prices (in EUR) in comparison to the currently standard option (a split supply consisting of power taken from the local grid and heat from a condensing boiler). The higher the allowable cost, the bigger the margin for the manufacturer, while the customer's benefit remains the same.

Thermal insulation vs. overall primary energy consumption

It is straightforward to conclude that mCHP units better suit poorly insulated buildings, since more electricity can be generated. However, one should bear in mind that the primary energy bonus obtained when exporting CHP electricity to the grid depends strongly upon the local efficiency of the grid. Subsequent investigations [4] have shown that approaches like building refurbishment and use of solar-assisted cGB may lead to greater energy conservation than use of mCHP in non-refurbished building stock houses (this is even true for countries with relatively little solar radiation). Both facts, steadily rising crude oil and natural gas prices and mass production, are expected to cause a rise in the cost-effectiveness of solar thermal systems, so that they can further compete on the marketplace.

CONCLUSION

The paper presents a method to assess energy supply systems for buildings in terms of energy

conservation and monetary costs. The method was illustrated by handling the case of two innovative micro-CHP technologies together with high-performance buildings. Based on whole-year simulations involving dedicated mCHP models and a multiple-zone building model, the energy benefits have been evaluated via a benchmark analysis. Since mCHP technologies are in an early phase of development, retail prices are presently not known. The allowable retail price gives the manufacturer an indication of how expensive his product may be, in order that the customer gets the same benefit as if he used conventional technology.

Computation results indicate that mCHP roughly achieves the same degree of energy conservation as modern high-efficiency technologies such as condensing boiler and electricity taken from the modern public grid. However, the low heat load leads to reduced operating time and therefore to little generation of electricity. As a result, the allowable retail prices turn out to be rather low or even prohibitive.

In order to access the market of high-performance buildings, manufacturers must definitely improve the electrical performance of their units. One way to do this is to significantly lower the parasitic power consumption of the balance of plant. This can be achieved when the mCHP is judiciously integrated into HVAC systems especially developed for high-performance houses. Fraunhofer ISE is presently delving into that topic.

Abstract

The paper describes a new concept for controlling the supply temperature in district heating systems using stochastic modelling, prediction and control combined with physical modelling. The method is well suited for district heating systems with more than one supply point and possibly with different production costs. The new controller minimises the heating and pumping costs under the restriction that the consumer requirements to inlet temperature are fulfilled and that the flow rate in the system is kept within acceptable limits. The controller closely resembles the Model Predictive Control scheme allowing the restrictions to be incorporated directly into the control problem. At each time-step a linearisation of the system around the current operating point is derived using a physical network model to simulate the system response to changes in the supply temperatures. Based on the linearised system the optimal control sequence is then found by solving a linear programming problem defined such that the probability of violating the restrictions is fixed and small. Simulation results are presented showing that around the current operating point the system is well approximated by a linearisation as well as demonstrating the control scheme for a realistic case study.

Keywords: District Heating, Model Predictive Control, Deterministic Modelling, Stochastic Modelling.

INTRODUCTION

District heating plays an important part in covering the heating demands in the Nordic countries, hence the subject of optimal operation of district heating systems has a huge economical potential. This is by no means a trivial subject though, as district heating systems are inherently non-linear and non-stationary, and the issue is further complicated by the fact that district heating systems are very diverse with respect to production facilities, operational requirements and so forth.

A district heating system can be seen as consisting of three primary parts: one or more central heat producing units, a distribution network and finally the consumer installations for space heating and hot tap water production. The task of identifying a cost function for the operation of an entire district heating system with multiple heating plants and following that finding a feasible solution to the posed minimisation problem will in most cases be very difficult due to the size of the problem. The problem is subject to continued research though. In [1] an op-

*email: tsn@imm.dtu.dk

timisation scheme based on fairly detailed physical models of the heat production units and the distribution network is proposed, where the unit commitment problem is solved by a fuzzy logic approach. Under certain simplifications a pseudo optimal control strategy is derived for the district heating system of Malmö, but as the simplifications include disregarding power production, heat accumulators and flow restrictions the control strategy is not considered operational.

In order to make the solution of the optimisation problem feasible it is suggested to separate the optimisation of the entire system into a scheduling between the different heat (and power) producing units (long planning horizon) followed by a control problem for the distribution network (considerably shorter control horizon). The potential gains by optimal scheduling between several production units will typically eclipse the potential gains by optimal operation of the distribution network by a considerable margin. Hence it makes sense to let the operation of the distribution network be subordinate to the scheduling even at the cost of a (slightly) suboptimal solution compared to an optimisation which encompass the entire district heating system. Furthermore the heat production units and the distribution network are often owned by different utilities, hence it makes economic sense from a company point of view to optimise the operation of heat production units and distribution network separately.

This paper considers optimal operation of the distribution network. At the distribution level the controllable variable is supply temperature as the load balancing between the production units done at the plant optimisation level has determined the flow control strategy. Traditionally the supply temperature in a district heating system is determined centrally as a function of the current ambient air temperature. Thus the supply temperature control is in fact a open loop control without any feedback from the distribution network, and consequently the control curve has to be determined conservatively to ensure a sufficiently high temperature in the district heating network at all times. The proposed control scheme has two objectives. First of all it optimises the operation of the distribution network with respect to operational costs. Secondly it brings the supply temperature control into a closed loop context thereby making the control a more objective matter compared to the traditional ad hoc approach.

[8] presents a method for controlling supply temperature in district heating systems with one supply point based on stochastic models of the distribution network and an extension of the Generalised Predictive Control scheme proposed by [2]. For more complex systems with multiple supply points the stochastic black box models used in [8] will be difficult to identify reliably. A different approach is to use detailed deterministic models to describe the distribution network[1]. The computational requirements for this type of models prevents direct use in numerical optimisation algorithms, but deterministic network models can serve as a mean for deriving a linearisation of the system response around the current operation point by imposing the model a predetermined input signal for each input variable. The optimisation is then carried out using the linearised model. This is the approach which will be pursued in the following.

CONTROL PROBLEM

The objectives of the present section is to identify the main conditions under which an operational optimisation of a district heating distribution system is carried out. Optimal operation of the distribution system is here assumed to be achieved by minimising the productions cost to the extent, that it can be achieved without compromising the safe operation of the system, adversely affecting the maintenance cost of the system, or sacrificing consumer satisfaction. The operational costs are separated into heating and distribution costs.

For a time interval, $]t-1,t]$ indexed t, the integrated energy balance for the distribution network can be formulated as

$$E_t^h = E_t^l + E_t^c + \bigtriangledown E_t^n \qquad (1)$$

where E_t^h is the energy feed into the network at the supply points, E_t^l is the energy loss in the network, E_t^c is the energy delivered to the consumers, and $\bigtriangledown E_t^n$ is the energy accumulated in the network. The use of an external energy storage – a heat accumulator – is not included in (1) as heat accumulators typically are part of the production system.

[1] These models are widely used to validate the daily operation and are therefore often already available at the district heating systems utilities.

Following (1) the accumulated heating costs C^{heat} over a period T can be written as

$$C^h = \sum_T (E_t^l + E_t^c + \bigtriangledown E_t^n) * P_t^h \qquad (2)$$

where P_t^h is the cost per unit energy during time interval t. In (2) E_t^c is given whereas E_t^l and $\bigtriangledown E_t^n$ are controllable. The heat loss in the network is a (complex) function of the supply temperature, but experience shows that down to a certain limit a decrease in supply temperature implies a lower temperature in the network in general and consequently a decrease in the heat loss from the network. Below the limit the return temperature will increase with decreasing supply temperature. The energy storage in the distribution network can be useful for redistribution of heat load, e.g. smoothing of peak loads, but does normally not allow larger rescheduling of heat load. P_t^h will for some systems be fixed, but for other systems increasing levels for supply and return temperature and peak load will imply a higher price per unit energy. In systems with different production costs for the production units P_t^h will depend on the load distribution between production units.

The distribution costs are dominated by the cost of the electricity consumption by the pumps at the supply points. The supply temperature has direct impact on the pumping costs as flow rate and thus pumping costs will increase with decreasing supply temperature. For most district heating utilities in Denmark the pumping costs are an order of magnitude less than the energy costs associated with the heat loss in the distribution network.

The optimisation of production cost is carried out under restrictions imposed by the distribution network and consumer installations. The restrictions are mainly due to maximum limits on the flow rates as well as requirements to a minimum inlet temperature at the consumer installations. Both sets of restrictions can be fulfilled by maintaining a sufficiently high supply temperature.

The operation of a district heating utility has a direct impact on the maintenance costs for the network. Large and frequent variations in supply temperature will increase the maintenance costs compared to a more steady operation, hence large and frequent fluctuations in the supply temperature should be avoided. It is often a requirement from the utilities that hard restrictions are placed on rate of change as well as the absolute range for supply temperature.

Based on the above considerations the operation of the distribution network can be optimised using supply temperatures as control variables by minimising the heating and pumping costs subject to the restriction that flow rates, consumer inlet temperatures as well as range and rate of change for supply temperatures are kept within acceptable bounds.

CONTROLLER IMPLEMENTATION

Following the optimisation criteria outlined above minimisation of production costs at the distribution level requires that models describing the dynamic relationship between cost variables (heat and pumping costs), restricted variables (flow rates and consumer inlet temperatures) and the control variable (supply temperatures) are available. One possible solution could be to extend the statistical models presented in [8]. However for more complex systems this type of models will be difficult to identify reliably as many of the input variables will exhibit little variation or be closely correlated. A different approach is to use a detailed deterministic model to describe the distribution network. In the following a control scheme for minimising production costs at the distribution level based on a deterministic network model will be derived.

Costs and flow rates at the supply points of the district heating network are well defined whereas consumer inlet temperature is a distributed measure. The consumer inlet temperature requirements are therefore monitored by introducing a set of *critical points* in the distribution network. The critical points are selected so that if the temperature requirements for the critical points are satisfied then the temperature requirements for all consumers are satisfied.

Flow rates and net-point temperatures exhibit different response characteristics on changes in supply temperature with an immediate but slow dying response in flow rate[2] and a delayed but fast response in the net-point temperatures. The primary factor controlling the dynamic relationships between cost and restricted variables and supply temperatures are the time-varying heat load in the system. The heat load exhibits a diurnal as well as an annual variation caused by the diurnal cycle in consumer behaviour

[2] A change in supply temperature will affect the flow rate from the time where the introduced temperature gradient reaches the first consumers and until it has reached the most distant consumers.

and the annual cycle in climate. The optimisation must be able to handle the different time scales in the responses as well as the diurnal cycle in the responses.

An approach capable of handling these requirements is to pose the control problem as a constrained minimisation problem with receding horizon. This formulation has close resemblance to Model Predictive Control (MPC), c.f. [6], but with a non-quadratic cost function.

Prediction models relating future values of cost and restricted variables to past and future values of supply temperature have to take the future heat load into account, i.e. they will depend on heat load predictions. Introducing the vector notation

$$\mathbf{T}^{s,i}_{t+k} = (T^{s,i}_{t+1}, \ldots, T^{s,i}_{t+k})^T$$

the future heat (E^h) and pump (E^p) loads, flow rates (Q) and net-point temperatures (T^{np}) can be written as

$$\begin{aligned} E^{h,i}_{t+k} &= E^{h,i}(\mathbf{I}_t, \mathbf{T}^{s,1..r}_{t+k}, E^c_{t+k}) + \varepsilon^{E^{h,i}}_{t+k} \\ E^{p,i}_{t+k} &= E^{p,i}(\mathbf{I}_t, \mathbf{T}^{s,1..r}_{t+k}, E^c_{t+k}) + \varepsilon^{E^{p,i}}_{t+k} \\ T^{np,j}_{t+k} &= F^{T,j}(\mathbf{I}_t, \mathbf{T}^{s,1..r}_{t+k}, E^c_{t+k}) + \varepsilon^{F^{T,j}}_{t+k} \\ Q^i_{t+k} &= F^{Q,i}(\mathbf{I}_t, \mathbf{T}^{s,1..r}_{t+k}, E^c_{t+k}) + \varepsilon^{F^{Q,i}}_{t+k} \end{aligned} \quad (3)$$

where E^c_{t+k} is the future consumer load, $i \in [1;r]$ is the set of supply points, $j \in [1;s]$ is the set of critical net points, $\mathbf{I}_t$ is the information set with respect to the distribution system at time t, ε^* are independent identically distributed (iid.) white noise sequences, and $\mathbf{T}^{s,1..r}_{t+k}$ is the set of future supply temperature vectors covering all supply points.

For prediction horizons more than a few hours ahead in time the future weather situation must be taken into account when predicting the consumer heat load E^c. [7] and [1] identifies stochastic prediction models for consumer load using numerical weather predictions (NWP) from a meteorological service as input to the load predictions. The consumer heat load predictions can be written as

$$\hat{E^c}_{t+k|t} = \hat{E}^c(\mathbf{I}_t, \mathbf{W}^{NWP}_{t+k|t}, h^{24}) \quad (4)$$

where $\mathbf{W}^{NWP}_{t+k|t}$ is a set of NWP variables describing the future climate, h^{24} is time of day and $\hat{E}^c(\cdot)$ is a function to be estimated.

Substituting (4) into (3) gives

$$\begin{aligned} E^{h,i}_{t+k} &= E^{h,i}(\mathbf{I}_t, \mathbf{T}^{s,1..r}_{t+k}, \hat{E}^c_{t+k|t}) + e^{E^{h,i}}_{t+k} \\ E^{p,i}_{t+k} &= E^{p,i}(\mathbf{I}_t, \mathbf{T}^{s,1..r}_{t+k}, \hat{E}^c_{t+k|t}) + e^{E^{p,i}}_{t+k} \\ T^{np,j}_{t+k} &= F^{T,j}(\mathbf{I}_t, \mathbf{T}^{s,1..r}_{t+k}, \hat{E}^c_{t+k|t}) + e^{F^{T,j}}_{t+k} \\ Q^i_{t+k} &= F^{Q,i}(\mathbf{I}_t, \mathbf{T}^{s,1..r}_{t+k}, \hat{E}^c_{t+k|t}) + e^{F^{Q,i}}_{t+k} \end{aligned} \quad (5)$$

Following [4],[3] which considers model estimation in the presence of errors in the regressors, bias in the noise sequences e^* for the models (5) must be expected due to the inevitable errors in the predictions of consumer load. Consequently the predictions given by (5) should be filtered through a prediction error model, see [5], to obtain unbiased predictions $\hat{E}^{h,i}_{t+k|t}$, $\hat{E}^{p,i}_{t+k|t}$, $\hat{T}^{np,j}_{t+k|t}$ and $\hat{Q}^i_{t+k|t}$ of the system response.

The optimisation problem may now be formulated in more mathematical terms as

$$\min_{\mathbf{T}^{s,1..r}_{t+N_p}} \sum_{i=1}^{r} \sum_{k=1}^{N_p} \hat{E}^{h,i}_{t+k|t} \cdot P^{h,i}_{t+k} + \hat{E}^{p,i}_{t+k|t} \cdot P^{p,i}_{t+k} \quad (6)$$

subject to

$$\begin{aligned} \hat{T}^{np,j}_{t+k} &\geq T^{np,j}_{min,t+k} \\ \hat{Q}^i_{t+k} &\leq Q^i_{max,t+k} \\ T^{s,i}_{t+k} &\leq T^{s,i}_{max} \\ \bigtriangledown T^{s,i}_{t+k} &\leq \begin{cases} \bigtriangledown T^{s,i}_{max} & , k <= N_u \\ 0 & , k > N_u \end{cases} \\ \forall \quad i \in [1;r], j \in [1;s], k \in [1;N_p] \end{aligned}$$

where N_p is the prediction horizon, N_u the control horizon, $T^{np,j}_{min,t+k}$ are the minimum net-point temperatures at the critical net-points, $Q^i_{max,t+k}$ are the maximum flow rates at the supply points, and $P^{h,i}_{t+k}$ and $P^{p,i}_{t+k}$ are the price per unit energy for heat and power, respectively. $P^{h,i}_{t+k}$ and $P^{p,i}_{t+k}$ are assumed to be independent of the control actions within the prediction horizon. The subject of determining appropriate limits for the restricted model output values are referred to the following section.

In (6) it assumed that the network return temperature is not adversely affected by the optimisation

[3] In [4] it is found, that in the presence of errors in the regressors a dedicated prediction model should be estimated as use of the true system for prediction will not result in the best possible predictions.

and the return temperature is not monitored explicitly. However if necessary an additional restriction on the return temperature similar to the restrictions in flow rate and net-point temperature could easily be added.

The high level supply temperature control will typically run in an hourly cycle, hence the problem (6) needs solving once every hour. The calculation time (in the order of minutes on a 1.8 GHz PC for a medium size district heating system) prohibits direct use of a detailed deterministic network model in a numeric solution of (6). Instead it is proposed to linearise the deterministic model around its current operating point by identifying a step response model and apply the supply temperature optimisation on the linearised model.

For a MIMO system a step response model is easily derived as follows

- For each output j the system response v_t^j is recorded while maintaining the control variables at their current value.
- For each input output pair (i, j) the system response $\delta_t^{i,j}$ is recorded when applying an additional unit step at time $t+1$ for input i and maintaining the remaining input variables at their current value. The step response is calculated as $s_t^{i,j} = \delta_t^{i,j} - v_t^j$. This is repeated for each time step $t+2$ to $t+k$ to allow for the time-varying dynamics in the system.

The linearised k-step prediction for output j is given as

$$\hat{y}^j_{t+k|t} = \sum_i \sum_{l=1}^{k} s^{i,j}_{t,t+l} \bigtriangledown u^i_{t+l} + v^j_{t,t+k} \qquad (7)$$

Using matrix notation the output predictions (7) for horizons between 1 and N_p is written as

$$\hat{\mathbf{y}}^j_t = \sum_i \mathbf{S}^{i,j}_t \bigtriangledown \mathbf{u}^i_t + \mathbf{v}^j_t \qquad (8)$$

where

$$\begin{aligned}
\hat{\mathbf{y}}^j_t &= (\hat{y}^j_{t+1|t}, \ldots, \hat{y}^j_{t+N_p|t})^T \\
\bigtriangledown \mathbf{u}^i_t &= (\bigtriangledown u^i_{t+1}, \ldots, \bigtriangledown u^i_{t+N_p})^T \\
\mathbf{v}^j_t &= (v^j_{t,t+1}, \ldots, v^j_{t,t+N_p})^T \\
\mathbf{S}^{i,j}_t &= \begin{pmatrix} s^{i,j}_{t,t+1} & 0 & \cdots & 0 \\ s^{i,j}_{t,t+2} & s^{i,j}_{t+1,t+2} & \cdots & 0 \\ \vdots & \vdots & & \vdots \\ s^{i,j}_{t,t+N_p} & s^{i,j}_{t+1,t+N_p} & \cdots & s^{i,j}_{t+N_p,t+N_p} \end{pmatrix}
\end{aligned}$$

Approximating the system response functions (5) for heat and pump load, flow rate and net-point temperature by step response functions (8), i.e.

$$\begin{aligned}
\hat{\mathbf{E}}^{h,i}_t &\approx \sum_{l=1}^{r} \mathbf{S}^{E^{h,l,i}}_t \bigtriangledown \mathbf{T}^{s,l}_t + \mathbf{v}^{E^{h,i}}_t \\
\hat{\mathbf{E}}^{p,i}_t &\approx \sum_{l=1}^{r} \mathbf{S}^{E^{p,l,i}}_t \bigtriangledown \mathbf{T}^{s,l}_t + \mathbf{v}^{E^{p,i}}_t \\
\hat{\mathbf{T}}^{np,j}_t &\approx \sum_{l=1}^{r} \mathbf{S}^{F^{T,l,j}}_t \bigtriangledown \mathbf{T}^{s,l}_t + \mathbf{v}^{F^{T,j}}_t \\
\hat{\mathbf{Q}}^{i}_t &\approx \sum_{l=1}^{r} \mathbf{S}^{F^{Q,l,i}}_t \bigtriangledown \mathbf{T}^{s,l}_t + \mathbf{v}^{F^{Q,i}}_t
\end{aligned}$$

and inserting in (6) leads to

$$\min_{\mathbf{T}^{s,1..r}_t} \sum_{i=1}^{r} \left[\mathbf{P}^{h,i}_t \sum_{l=1}^{r} \mathbf{S}^{E^{h,l,i}}_t + \mathbf{P}^{p,i}_t \sum_{l=1}^{r} \mathbf{S}^{E^{p,l,i}}_t \right] \bigtriangledown \mathbf{T}^{s,l}_t + const \qquad (9)$$

subject to

$$\begin{aligned}
\sum_{l=1}^{r} \mathbf{S}^{F^{T,l,j}}_t \bigtriangledown \mathbf{T}^{s,l}_t + \mathbf{v}^{F^{T,j}}_t &\geq \mathbf{T}^{np,j}_{min,t} \\
\sum_{l=1}^{r} \mathbf{S}^{F^{Q,l,i}}_t \bigtriangledown \mathbf{T}^{s,l}_t + \mathbf{v}^{F^{Q,i}}_t &\leq \mathbf{Q}^{i}_{max,t} \\
\mathbf{T}^{s,i}_t &\leq T^{s,i}_{max} \\
\bigtriangledown \mathbf{T}^{s,i}_t &\leq \bigtriangledown \mathbf{T}^{s,i}_{max} \\
\forall \quad i \in [1;r]\,, j \in [1;s]\,,
\end{aligned}$$

where

$$\begin{aligned}
\mathbf{P}^{h,i}_t &= (P^{h,i}_{t+1}, \ldots, P^{h,i}_{t+N_p}) \\
\mathbf{P}^{p,i}_t &= (P^{p,i}_{t+1}, \ldots, P^{p,i}_{t+N_p}) \\
\mathbf{T}^{np,j}_{min,t} &= (T^{np,j}_{min,t+1}, \ldots, T^{np,j}_{min,t+N_p}) \\
\mathbf{Q}^{i}_{max,t} &= (Q^{i}_{max,t+1}, \ldots, Q^{i}_{max,t+N_p}) \\
\bigtriangledown \mathbf{T}^{s,i}_{max} &= (\underbrace{\bigtriangledown T^{s,i}_{max}}_{1 \ldots N_u}, \ldots, \underbrace{0}_{N_u+1 \ldots N_p})
\end{aligned}$$

Cost function and restrictions in (9) are linear functions of the control variables $\mathbf{T}^{s,1..r}_{t+N_p}$, hence (9) is readily solved by applying standard Linear Programming techniques.

LIMITS IN OUTPUT RESTRICTIONS

The optimisation problem (6) requires, that future output restrictions are specified. The limiting value in the restrictions may be constant over time or given

as a function of one or more explanatory variables, but in any case uncertainty in predicting system outputs and explanatory variable(s) must be taken into account, when the output limit values are determined. In the following a method for determining the output limits so that the probability of future observations violating the limit is fixed (and small) is outlined using the net-point temperature restriction as an example.

In [3] the inlet temperature requirements are investigated for a number of existing buildings and a dependency on ambient air temperature as illustraited in Figure 1 is identified. The minimum net-point temperature should to be governed by a similar function. The increasing net-point temperature with decreasing air temperature reflects the limited capacity in the consumers room heating installations, whereas the minimum is determined by the hot tap water installations.

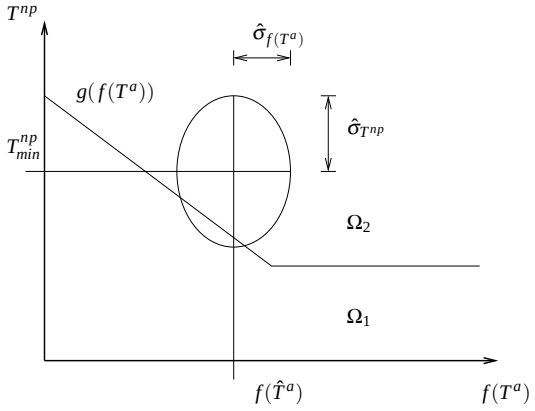

Figure 1: Minimum net-point temperature curve. The minimum curve determines the required net-point temperature as a function of the low pass filtered air temperature, $f(T^a)$.

The heat capacity of the thermal mass of the buildings acts as a low pass filter on the influence of air temperature on heat demand, hence the required net-point temperature is determined as a function of filtered air temperature. The relationship between heat demand and ambient air temperature is investigated in [7], where a physically motivated first-order filter for the ambient air temperature is proposed

$$f(T^a_t) = \frac{1-c}{1-cq^{-1}} T^a_t \ , \qquad (10)$$

and the required net-point temperature must be expected to exhibit a similar dependency on ambient air temperature. For hourly observations [7] identifies an optimal value $c = 0.94$.

Figure 1 establishes the "legal" area Ω_2 as the area above $g(f(T^a))$ as well as the "illegal" area Ω_1 below $g(f(T^a))$, where in the latter case the consumer inlet temperature restriction is violated. The minimum net-point temperature $T^{np}_{min,t+j|t}$ is determined so that

$$\begin{aligned} Prob\{\ (\ f(T^a_{t+j}), T^{np}_{t+j}\ ) \in \Omega_2 \mid \mathbf{I}_t\} &= \pi\ ,\ j>0 \\ \{(f(T^a_t), T^{np}_t) \mid T^{np}_t \geq g(f(T^a_t))\} &= \Omega_2 \qquad (11) \end{aligned}$$

where $f(T^a_{t+j})$ and T^{np}_{t+j} are future values of filtered air temperature and net-point temperature, respectively, $1-\pi$ is the probability of violating the restriction, and $\mathbf{I}_t$ is the information set at time t. Given the distribution of the prediction errors for $f(T^a_{t+j})$ and T^{np}_{t+j} and inserting

$$\begin{aligned} f(T^a_{t+j}) &= f(\hat{T}^a_{t+j|t}) + e^{f(T^a)}_{t+j|t} \\ T^{np}_{t+j} &= T^{np}_{min,t+j|t} + e^{T^{np}}_{t+j|t} \end{aligned}$$

into (11) the resulting equation is readily solved with respect to $T^{np}_{min,t+j|t}$ by numerical methods.

A PHYSICAL DISTRICT HEATING MODEL

The deterministic district heating model used is the TERMIS model of Seven Technologies. TERMIS simulates the hydraulic and thermal state of district heating systems using the fundamental physical laws as basis for modelling the various types of equipment, which constitutes a district heating system. The simulations are performed either as steady-state simulations or as dynamic simulations, where temperature tracking and heat storage are included.

One important feature of TERMIS in this context is the capability of operating in real-time mode. In real-time mode simulations of the current hydraulic and thermal state in the network are performed at a fixed frequency. The simulations are to the greatest possible extent driven by actual measurements of process variables and state indicators, which are provided via the SCADA system. In real-time mode TERMIS may also perform state forecasts, which are simulations of the future hydraulic and thermal state in the network driven by forecasts of the boundary conditions, e.g. consumer heat loads, supply temperatures or load distribution between supply points. The step responses used in the linearisation of the system are calculated as state forecasts.

SIMULATION STUDY

A feasibility study for the proposed supply temperature controller has been carried out using a TERMIS model of Randers District Heating Utility[4] – see Figure 2.

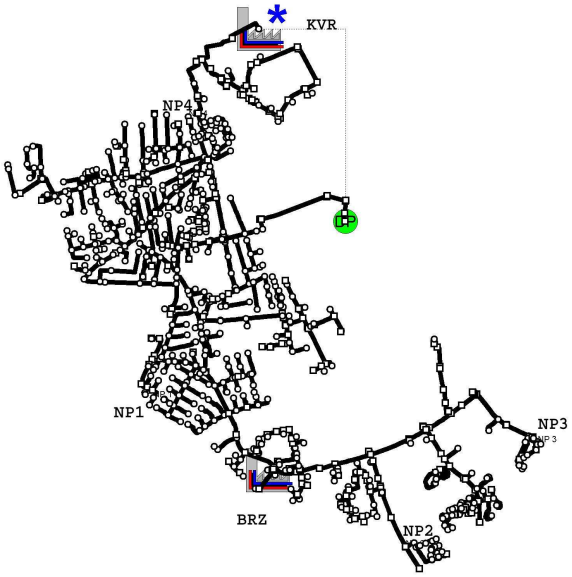

Figure 2: The case study used in the simulations. The network has two supply points (KVR and BRZ), where KVR is main station and BRZ sub-station. Four critical net-points have been identified in the network (NP1 to NP4).

The non-linearities in a district heating network are mainly related to the varying flow rate in the system, but also the different operational modes give raise to non-linearities e.g. variations in the relative flow rate between production units or differences in consumption patterns for the various types of consumers. In the following simulations the flow rate from the BRZ sub-station has been fixed at $30\frac{kg}{s}$ whereas the flow rate from the KVR main station is allowed to vary freely.

The flow rate exhibits a strong diurnal variation and as can be seen from Figure 3 diurnal differences between maximum and minimum flow of up to 40-50% of diurnal mean flow is quite common. The effect of varying the flow rate is investigated in Figure 4. From the figure it is seen that the system step responses strongly depend on flow rate. The "strange" response at NP1 is caused by the supply

[4]Randers is a mid size Danish town located in the northern part of Jutland.

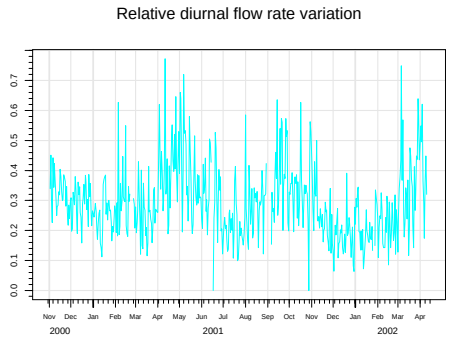

Figure 3: Observed diurnal variation in flow rate relative to diurnal mean flow for a district heating system.

of the point shifting from BRZ at low flow rates to KVR at high flow rates.

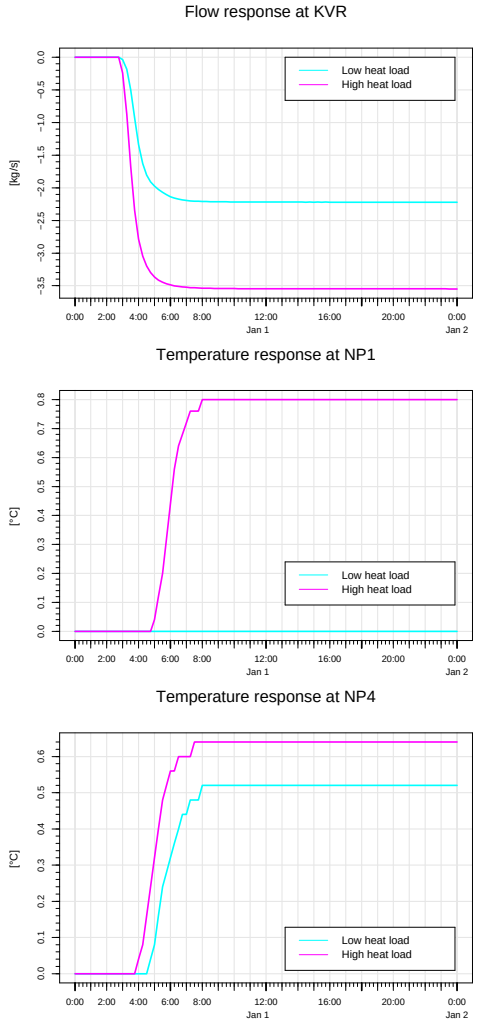

Figure 4: System responses on a unit step in supply temperature at 03:00 for the KVR main station. High and low heat load correspond to KVR flow rates of $179\frac{kg}{s}$ and $112\frac{kg}{s}$, respectively.

The validity of the linearity assumption – $F(c^1 u_t^1 +$

$c^2 u_t^2) = c^1 F(u_t^1) + c^2 F(u_t^2)$ – is investigated for a fixed heat load in Figure 5 and 6, respectively.

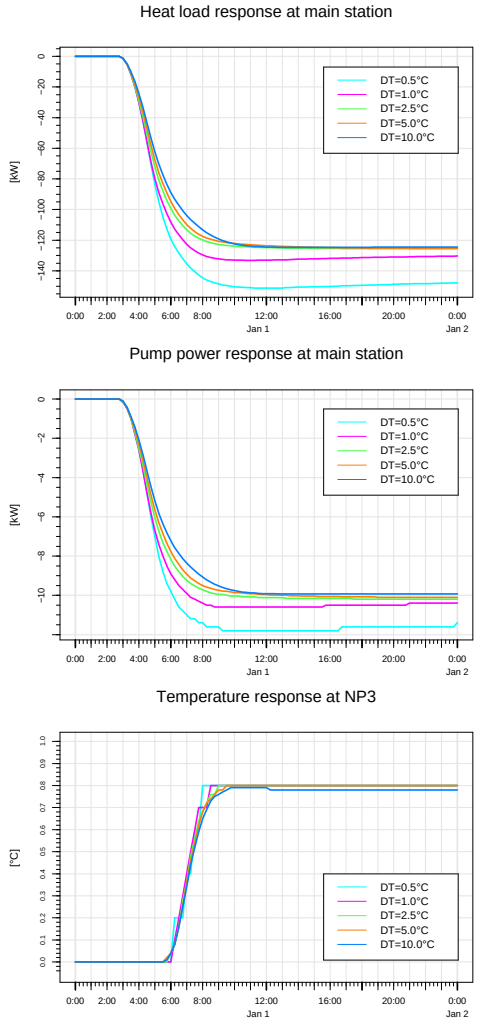

Figure 5: Normalised system response on a step in supply temperature at 03:00 for the BRZ sub-station. The response normalised with step height is shown for five different step heights ranging from 0.5 °C to 10 °C. The initial flow rate is 179 $\frac{kg}{s}$ at KVR.

The response plots indicate that for a fixed consumer load the true system as given by the TERMIS model is well approximated by a linearisation. The deviations found in Figure 5 for the pump and heat load responses to small steps in supply temperature is down to the resulting model responses being close to the modelling accuracy of the TERMIS model.

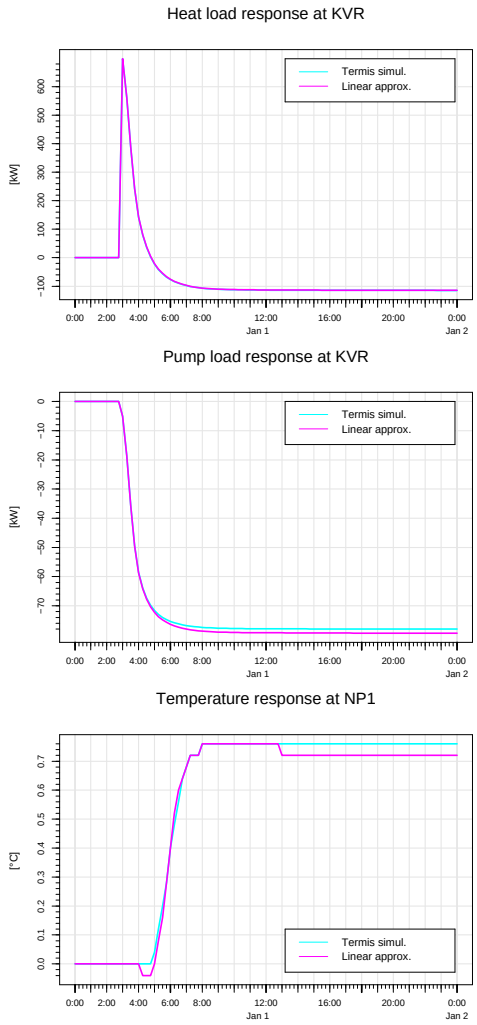

Figure 6: System response on a step response in supply temperature at 03:00 for both stations. "Linear approx." is the calculated response using the linearised step response model and "Termis simul." is the simulated response from the TERMIS model. The initial flow rate is 179 $\frac{kg}{s}$ at KVR.

The supply temperature control (9) is applied to the case study using the following conditions in the optimisation:

Heat costs:	$P^{h,KVR}$=0.3 $\frac{dkk}{kWh}$	$P^{h,BRZ}$=0.4 $\frac{dkk}{kWh}$
Pumping costs:	$P^{p,*}$=0.6 $\frac{dkk}{kWh}$	
Input restric.:	$T_{max}^{s,*}$=105 °C	$C_{max}^{\nabla T^s,*}$=1.5 °C
Output restrict.:	Q_{max}^{KVR}=150 $\frac{kg}{s}$	$T_{min}^{np,*}$=75 °C
Horizons:	N_p=24h	N_u=12h

The optimal solution w.r.t. supply temperature and corresponding system response is found in Figure 7. The changes in supply temperature over the control horizon are large and for BRZ much larger than what would happen if the system has been governed by the controller for some period. Nevertheless the sys-

tem response in Figure 7 indicates that the TERMIS model is well approximated by a linearisation over the control horizon.

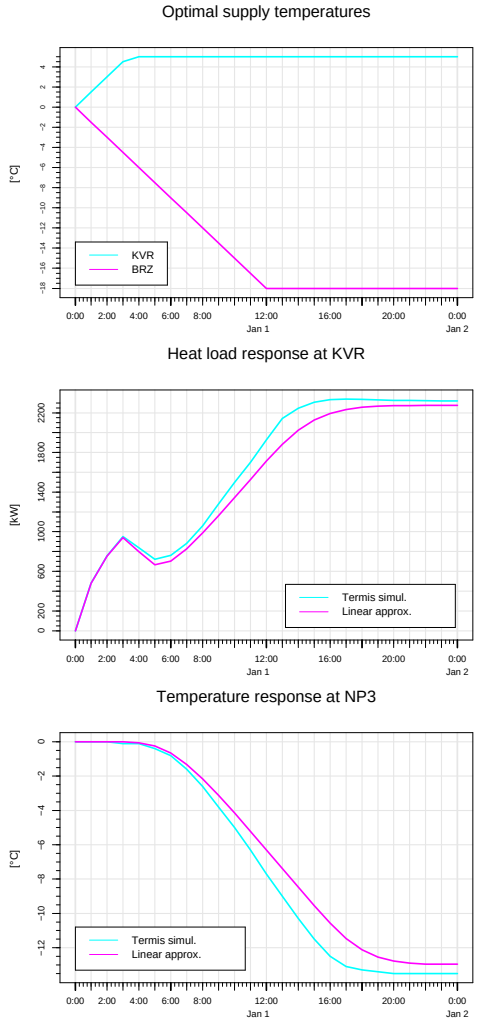

Figure 7: The optimal supply temperature trajectory and the resulting system responses. "Linear approx." is the response from the step response model and "Termis simul." is the response from the TERMIS model. The initial flow rate is $112\frac{kg}{s}$ at KVR.

The controller actions imply that heat load is moved from the BRZ sub-station to the less expensive KVR main station. As an indication of the savings potential available when optimising the operation of a district heating system it is remarked that the saving obtained in the optimisation example corresponds to an annual saving of 2.3 million ddk in steady state.

CONCLUSION

A new concept for controlling the supply temperature in a district heating system based on linearisation of readily available detailed physical system models has been presented. The control problem has been formulated as an optimisation problem with restrictions. The controller minimises the operational costs for the distribution network without compromising safety of supply or consumers temperature requirements.

Promising simulations results have been presented using a realistic case study as an example. However further work remains w.r.t. proving the controller for a longer period with simulations driven by measured data.

Eventually the controller is expected to be implemented on-line at a district heating utility.

USE OF LOCAL THERMAL STORAGE SYSTEMS IN DISTRICT HEATING NETWORKS.

Vittorio VERDA*, Michele Calì, Federica Mussa
Department of Energy Engineering
Politecnico di Torino
ITALY

ABSTRACT

District Heating is an efficient way to provide heat to residential, tertiary and industrial users. It involves the substitution of small boilers with systems such as cogenerative (CHP) plants and larger boilers. In particular, CPH plants are usually designed to provide the base thermal load (40-50% if the maximum load) while boilers provide the rest. This choice is made on the basis of economic criteria, in fact the investment cost of a CHP plant is higher than the cost of boiler, thus its use is convenient when it operates for a large number of hours.

The use of storage tanks would permit to increase the annual operating hours of CHP: heat can be produced when the request is low (for instance during the night), stored and then used when the request is high. The use of boilers results partially reduced, thus the thermal load diagram is flattered.

In this paper, the use of local storage systems, positioned in some of the buildings connected to the district heating systems, is examined. The optimal economic volume of the tanks is first calculated. A simple thermal fluid dynamic model of the tanks is considered in order to calculate the amount of energy actually provided, taking the real operating conditions into account. These considerations are applied to the Turin district heating system; the effect on the global thermal load diagram and the economic impact are determined.

S	storage system.

1. INTRODUCTION

District Heating is a rational way to provide heat to users localized in a sufficiently dense urbanization, since heat is produced by means of large, more efficient, thermal systems. These systems can be CHP units, biomass boilers, waste heat recuperators (e.g. recuperators of industrial processes) and boilers.

The thermal plant design is performed on the basis of the maximum total request. The shape of the thermal load curve is also considered. As explained hereafter, this is necessary to properly consider the economic impact of the system design. Figure 1 shows the thermal load of an urban area (the total volume of connected buildings is almost $20 \cdot 10^6$ m^3) in a typical day of January [1].

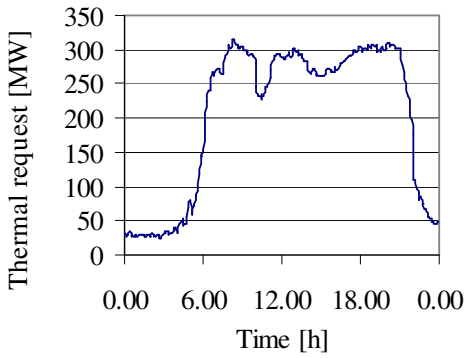

Figure 1 – Thermal request in a day of January.

This area is located in Turin and it is actually heated through a district system. The thermal plant is constituted by two cogeneration systems able to generate 167 + 63 MW. The first system is a steam turbine plant; the cogeneration is performed by condensing steam extracted from the middle pressure turbine. The second system is a gas turbine plant. A combined cycle will start operating next year in order to replace the old groups and satisfy the increasing heat demand due to the network enlargement. Some additional boilers complete the system. These boilers are mainly used for backup purpose as well as for covering pick loads.

In winter, the cogeneration systems operate at their maximum power during the day. Some of the boilers must also operate. In springs the CHPs generally operate at reduced thermal load, in particular, less steam is extracted from the MP turbine, which allows the obtainment of a larger amount of electricity. [2]

During the night, the thermal load is very low and almost constant along the year.

The use of thermal storage systems would determine a large utilization of the cogeneration plant and a consequent reduction in the use of boilers. In fact, a quote of the thermal energy could be produced during the night, stored and then used during the day. This is expected to produce some economic benefits since heat produce through a CHP generally costs less than heat produced through boilers.

In spring there are additional benefits if cogeneration is performed through steam extraction (steam power plants or combined cycles): the displacement of part of the heat production from day to night determines an increase of the electricity production during the day, when electricity has higher price. This concept is particularly important when the system is operating in the free electricity market.

In addition, thermal storage could allow one to reduce the total power installed in the thermal plant; for instance a boiler can be dismissed.

In this paper, the use of thermal storage within a district heating network is investigated by considering technical constraints as well as economic and energy impacts. In particular, local thermal storage systems, positioned in the buildings (i.e. directly at the user's side of the hydraulic circuit) are considered. Non-pressurized tanks are used. Such devices reduce the safety issues for the users, but the maximum temperature is limited to less than 100 °C in order to avoid the water evaporation.

The optimal volume of the storage tank is calculated as the function of the volume of the building where it is installed. Finally, after a discussion on the possible constraints, the impact on the thermal load diagram produced by using storage systems is determined.

A schematic of the thermal storage system is shown in figure 2.

Valve 1 controls the mass flow rate at the heat exchanger, which is a function of the ambient

temperature. The by-pass duct is used when the thermal request of the user changes. When tank charge is operated, water flows through the HE and ducts A, B, C, D. Valves 2 and 3 are closed in the verse towards the user. When tank discharge is operated, water flows to the users through ducts B, E, H and it returns to the storage tank through ducts I, F, C.
Temperature of the water flowing to the users (T_0) is controlled by mixing in valve 3 the mass flow rate extracted from the tank with some cold water flowing back from the users (duct G).

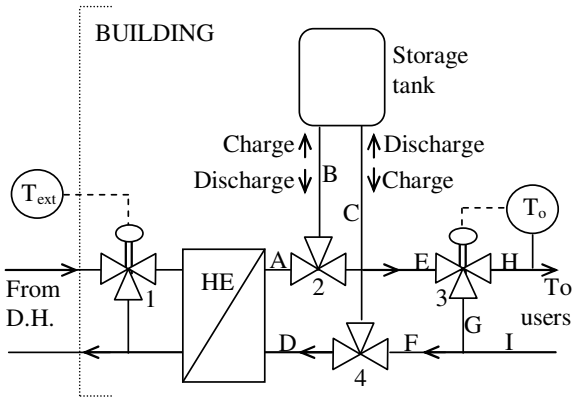

Figure 2 – Schematic of the storage tank installation

2. CHOICE OF THE STORAGE TANK VOLUME

The main design parameter for the storage system is represented by the tank volume. The optimization problem is strongly affected by some variables that are only roughly predictable, in particular the thermal request during the year. For this reason the heating season is considered as composed for the examined case, by 7 periods, each characterized by a particular value of the average ambient temperature. This means that in each period the external temperature and the daily thermal request are considered as constant.
The daily thermal request of a user can be calculated as

$$Q_{DR,i} = r \cdot V \cdot (T_{int} - T_{ext,i}) \cdot hh \cdot 3.6 \qquad (1)$$

where r is a heat transfer coefficient per unit volume of building (assumed 0.85 W/(m^{3}K) on the basis of measures conducted on several buildings), V is the total heated volume of the building, hh is the number of heating hours per day (14 h/day), T_{int} the internal temperature (20 °C) and $T_{ext,i}$ the external temperature in the i-th period. The external temperatures for the considered case are shown in Table 1.

Month	Days	T_{ext}	T_o	T_c
October	15	16	38.4	21.7
November	30	10	48	30
December	31	6	54.4	36.5
January	31	3	59.2	40
February	28	5	56	38.1
March	31	12	44.8	27
April	15	16	38.4	21.7

Table 1 – Data for the heating season.

The maximum amount of heat provided daily by the storage tank to the users Q_{DS} can be calculated:

$$Q_{DS,i} - Q_{l,i} = \Delta U_i = \rho \cdot V_S \cdot c \cdot (T_h - T_{c,i}) \qquad (2)$$

where Q_l is the heat lost during the complete process (charge and discharge of the tank), V_S is the tank volume, T_h is the temperature at which water is stored in the tank (95 °C) and T_c is the temperature of the cold water returning at the storage tank from the heating system. In table 1 the temperature T_o of the mass flow supplied to the users is also indicated.
Equation (2) is valid for an ideal tank, characterized by a volume at temperature T_h and the remaining volume at temperature T_c. The hypothesis of absence of heat conduction inside the tank is overcome by considering an efficiency η_S, defined as the ratio between the heat provided to the users and the thermal energy stored in the tank. The efficiency also accounts for the heat losses:

$$Q_{DS,i} = \eta_S \cdot \rho \cdot V_S \cdot c \cdot (T_h - T_{c,i}) \qquad (3)$$

This efficiency is calculated by using the model described in the next paragraph and it is assumed as independent on the tank volume. The average annual value is η_S=0.868.
The actual heat provided to the users Q_{DP} is the minimum between Q_{DS} and Q_{DR}.
The optimal volume for the storage tank can be calculated by using an economic criterion and by considering all the technical constraints. These constraints limit the maximum storage tank volume because of the available room and because of the time required for a complete charge. This time has been considered 7 hours, since the charge process is operated only nighttime.

The optimal volume is found by minimizing the overall annual cost for the users. The annuity includes the cost for the storage system and for heat supplied to the building by the district heating network. The unit cost of heat nighttime or daytime is different. During the night only the CHP plant is used because of the lower request while during the day also the boilers are used.
The annual cost can be calculated:

$$A = \sum_{i=1}^{7} Q_{DP,i} \cdot c_{HN} + \sum_{i=1}^{7} \left(Q_{DR,i} - Q_{DP,i}\right) \cdot c_{HD} + A_S \quad (4)$$

where c_{HN} is the unit cost of heat required during the night (3.66 €/GJ) and c_{HD} is the unit cost of heat required during the day (14.14 €/GJ) [1].
The cost of the storage tank C_S is expressed as the function of its volume [3]:

$$C_S = f \cdot C_{S,0} \cdot \left(\frac{V_S}{V_{S,0}}\right)^{0.3} \quad (5)$$

where $C_{S,0}$ is a reference cost (1356 €) for a storage tank characterized by the volume $V_{S,0}$ (0.2 m^3) and f is a factor accounting for the installation (including the insulation), piping and control system. This factor is assumed 4.33.
The annuity A_S is calculated as:

$$A_S = C_S \cdot \frac{i \cdot (1+i)^n}{(1+i)^n - 1} \quad (6)$$

where *i* is the rate of return, assumed 6% and n the expected lifetime. Alternative formulation for determining the total cost of the storage system, including owning, maintaining and operating costs can be found in [4].
Figure 3 shows the unit cost of heat to the user as the function of the storage tank volume, for two different volumes of building.

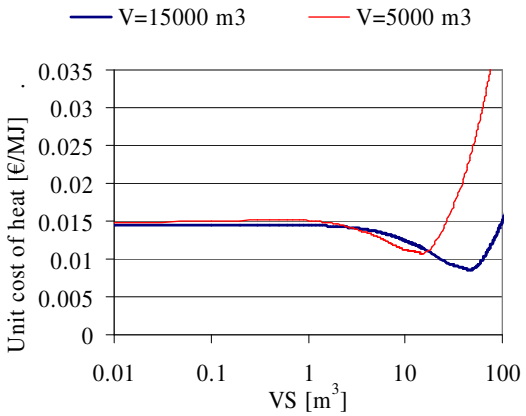

Figure 3 – Unit cost of heat as the function of the storage tank volume [€/MJ].

For small volumes of the storage tank (V_S < 2.8 m^3) the unit cost of heat is higher than the cost of heat bought daytime, thus the thermal storage does not produce any advantage. For higher volumes the unit storage system becomes convenient; the optimal volume is 14.8 m^3 in the case of a building of 5000 m^3 and 47 m^3 in the case of a building of 15000 m^3. The corresponding unit cost of heat is 10.73 €/GJ and 8.59 €/GJ, respectively. The unit cost increases for higher volumes, because the amount of heat Q_{DS} is higher than the thermal request of the users in some days.
Up to now, the constraints have not been still introduced.
The first constraint is represented by the maximum room available for the storage tank in the building. This calculation has been performed by considering existing buildings. When the building is connected to the district heating network, the old boiler is substituted by an heat exchanger. The available room for the storage tank can be evaluated by considering the boiler base surface plus an additional area for maintenance and safety reasons (assumed 1 m times the boiler perimeter). The surface required for installing the heat exchanger is subtracted; an additional area required for maintenance is subtracted as well (this area is assumed 1 m times the HE length). The available area has been assumed as squared.
The average height of a technical room is assumed 3 m, but the tank has been limited to 2 m. In table 2, the data for determining the available area for three different volumes of the buildings are shown. Nevertheless, it is expected that in most buildings the available room is larger than the limiting value determined here.

V [m^3]	5000	10000	15000
Φ[kW]	125	250	375
S_B [m^2]	3.35	3.91	4.47
S_{HE} [m^2]	0.52	0.52	0.52
V_S [m^3]	5.3	6.1	7.0

Table 2 – Data for calculating the volume constraints.

The second constraint is represented by the minimum time required for the complete charge of the tank. This time is calculated through the model presented in the next section and by considering that the initial temperature of the water is equal to T_c. This calculation is performed by considering data referred to April, which is the month

characterized by the lowest value of T_c.
The simulation of the tank charge requires to model the heat exchanger connected to the district heating network. The effectiveness-NTU method has been considered for this purpose. The water in the district heating network is available at 120 °C; the heat transfer coefficient is assumed 285 W/m^{2}K.
The charge process is stopped when the average temperature is 95 °C.
In figure 4 the time required for the complete charge of the storage tank is shown as the function of the tank volume. In the graph two cases are considered for two different values of the building volume.

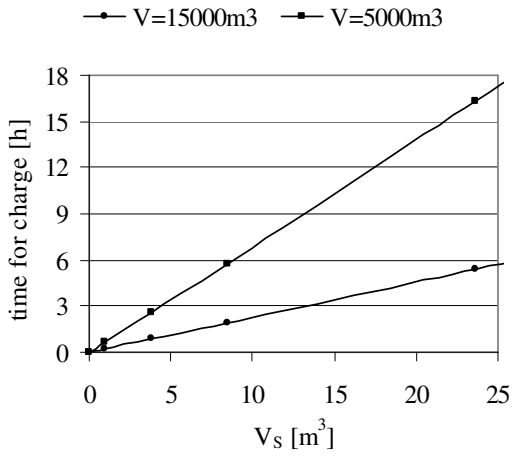

Figure 4 – Time required for the storage tank charge.

The limit for the storage tank is almost 11 m^3 for a building volume of 5000 m^3 and 27 m^3 for a building volume of 15000 m^3.
Further calculations have been performed by considering a volume for the storage tank equal to 5 m^3. Actually in most buildings in Turin there is room enough for the installation of the storage systems.

3. STORAGE SYSTEM MODEL

Numerous numerical models of storage systems are available in the literature. 2D and 3D models are mainly suitable for the design of such systems. In particular, they allows one to properly consider the hydrodynamic effects at the inlet and outlet ports, together with the fluid dynamics inside the tank [5-9].

One dimensional models are more suitable for the analysis of storage systems operation; the use of more complex model in this case involves large computational efforts. Some of the available 1D models are listed in [10, 11] and their features are presented.
A schematic of the tank is shown in Figure 5. The volume is divided into cylindrical elements, whose section is also shown.

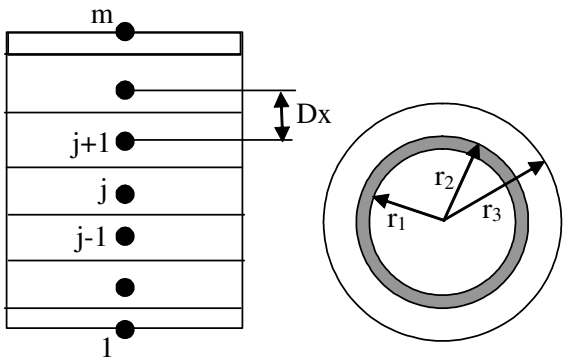

Figure 5 – Schematic of the storage tank

The energy equation applied to the general volume can be written:

$$\lambda \frac{\partial^2 T}{\partial x^2} - K \frac{\Omega}{S}\left(T - T_{int}\right) = \rho \cdot c \cdot \frac{\partial T}{\partial t} + \rho \cdot c \cdot u \cdot \frac{\partial T}{\partial x} \quad (7)$$

where the global heat transfer coefficient accounts for convective internal and external heat transfer and conductive heat transfer through the wall:

$$K = \frac{1}{\frac{1}{\alpha_i} + \frac{r_1}{\lambda_m} \cdot ln\frac{r_2}{r_1} + \frac{r_1}{\lambda_{is}} \cdot ln\frac{r_3}{r_2} + \frac{r_1}{\alpha_e \cdot r_3}} \quad (8)$$

The following assumptions have been made:
1) fluid flow in the tank is laminar (low Reynolds number; actual value is Re~50);
2) a baffle plate has been considered as located close to the inlet section in order to allow a better stratification [12]. No inlet mixing effects have been considered, which corresponds to a low Froude number [5].
The partial differential equation has been solved through a crank Nicholson finite difference scheme which allows one to rewrite it as:

$$\rho \cdot c \cdot \frac{T_j^{n+1} - T_j^n}{\Delta t} = \lambda \cdot \frac{T_{j+1}^{n+1} - 2 \cdot T_j^{n+1} + T_{j-1}^{n+1}}{\Delta x^2} - c \cdot \rho \cdot u \cdot \frac{T_{j+1}^{n+1} - T_{j-1}^{n+1}}{2 \cdot \Delta x} - K \frac{\Omega}{S}\left(T_j^{n+1} - T_{int}\right) \quad (9)$$

where n is the actual instant (all the variables are known at n-th instant) and Δt is the integration time step. The number of cylindrical elements and the integration time step must be chosen in order to avoid numerical instabilities. For further details see [13].
In the first element the boundary condition is imposed, while for the m-th element the thermal balance is written.
This model is used in order to determine the internal temperature during charge and discharge processes and, consequently, to determine the amounts of energy required for the charge and provided through the discharge.
As an example, in figure 5 the temperature profile corresponding to a possible utilization in a day of January of the storage tank in a building of 5000 m^3 is shown. The initial temperature in the tank is assumed 40 °C. The complete charge requires almost 2 hours and 30 minutes. After this time, the average temperature of 95 °C is reached. The tank is not used for 1 hour; then it covers the entire thermal request of the building. The tank utilization is stopped when the temperature of water supplied to the users becomes equal to T_0 (59.2 °C). Thermal stratification in the tank allows one to use it also if the average temperature is lower than this temperature; in particular the average temperature corresponding to this condition is about 44 °C in the specific case here considered.

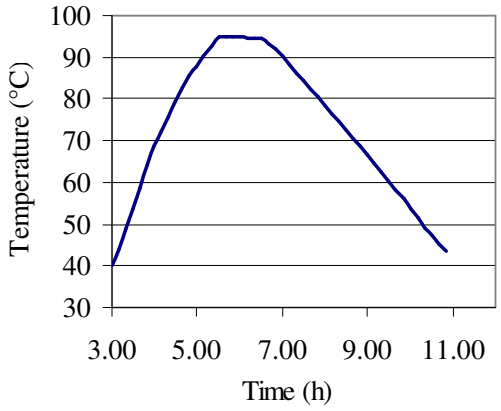

Figure 6 – Temperature profile of the storage tank during a complete process

4. USE OF THE STORAGE TANKS IN COMBINATION WITH DH.

In this section, the effect on the overall district heating system produced through massive utilization of storage tanks is determined.
For this purpose, a total volume of about $7.5 \cdot 10^6$ m^3 (almost 1/3 of the total volume of buildings connected to the D.H.) of buildings are supposed making use of storage systems. This scenario is technically feasible in the actual network configuration.

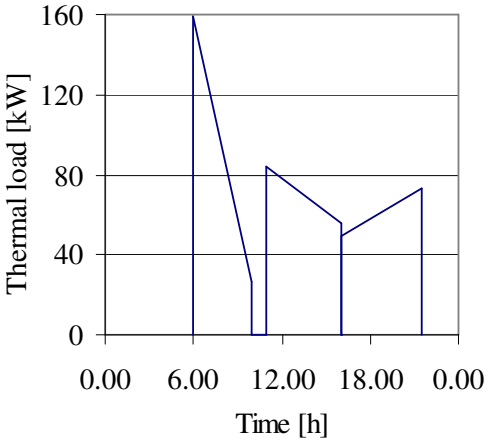

Figure 7 – Three adopted profiles for the utilization of the thermal storage systems in March

Three different utilization profiles are considered: morning (6:00-10:00), afternoon (11:00-16:00) and evening (16:00-21:30) utilization. This means that there are buildings where the storage system is used in the morning, others in the afternoon and finally others in the evening. The number of buildings for each profile is set in the model in order to determine the most effective impact on the thermal load curve. The assumed profiles are ramps. These ramps can be modified each month depending on the shape of the total load curve. As an example, Figure 7 shows three possible curves for the case of March.
For all the storage tanks the charge process has been considered as spread over a period of time of 7 hours.
In Figures 8 and 9 the comparison between the global thermal load of the D.H. network with or without storage systems is shown for two different days, one in January and one in March.
In both cases the storage systems determine a reduction in the difference between nighttime and daytime thermal load as well as a reduction in the maximum load. In January, this difference is reduced from about 250 MW to about 150 MW. The maximum load is reduced of about 30 MW.

These results suggest that a wider use of storage systems is possible.

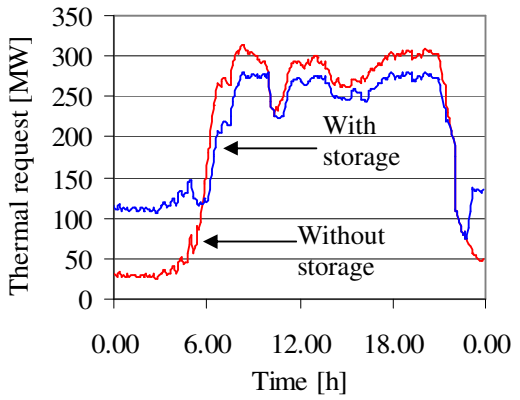

Figure 8 – Thermal load in a day of January [MW].

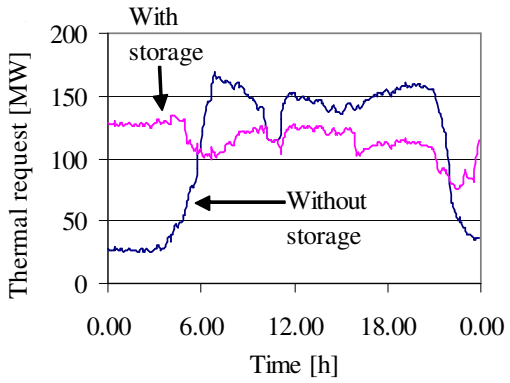

Figure 9 – Thermal load in a day of March [MW].

In March, the difference between the obtained daytime and nighttime loads becomes slightly negative. This has positive benefits since the electric production daytime can increase.
Finally the effect on the annual thermal load curve is analyzed. This curve is a typical tool for dimensioning CHP systems, since it shows the number of hours that the thermal load is over a defined value. If a CHP is dimensioned at the maximum load, it would be used for very few hours at 100%, while it would operate most of the time at partial load. Instead, if the plant it is designed in order to operate between 40-50% of the maximum load, it operates most of the time at 100%. Figure 10 shows the effects of a wide utilization of storage tanks on this curve.

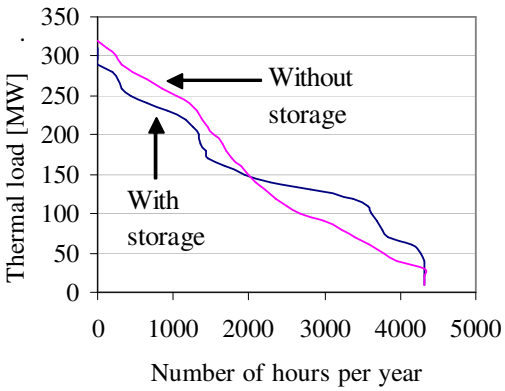

Figure 11 – Cumulate curve of the thermal load.

The use of storage tanks determines a reduction in the maximum request, as well as shift of a part of the energy request from hours characterized by a high total load to hours characterized by low total load. The diagram changes its shape, highlighting a larger utilization of the CHP system. In the case of the actual plant this benefit is not the main one, since the thermal load that can be produced in cogeneration is 230 MW. The amount of heat produced in cogeneration passes from 92.4% to 94.5%, as shown in figure 12. This last value only considers the useful energy provided to the users, i.e. it takes into account the efficiency of the storage system.
In this case, the most effective benefit is constituted by the possibility of increasing the electricity production in hours when electricity is paid more by reducing the thermal load produced in these hours.
Instead, if a CHP plant characterized by nominal thermal power of 150 MW were considered, the advantage of using storage systems would be more evident. In this case the annual amount of heat produced through the CHP plant would be 78.7%, instead of 73% obtained without storage systems.

CONCLUSION

In this paper, the effects of a wide use of storage tanks located in buildings connected to a DH system are analyzed. The economical feasibility of this system is closely related to the thermal plant configuration. If the plant is constituted by a CHP and one or more additional boilers, the use of storage systems makes increase the annual amount of heat produced through the CHP plant.

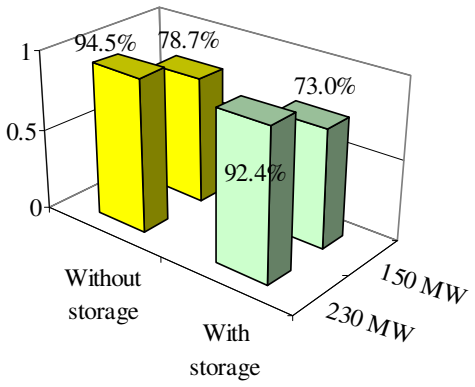

Figure 11 – Annual amount of heat produced through CHP with or without storage systems

In this way, the daily load curve results more flat.
The optimal number of local storage systems that can be usefully installed depends on the shape of the thermal load cumulate curve. The installation of any number of storage systems less or equal to this optimal number produces benefits, provided that the storage tank volume is properly chosen.
In the present paper the number of installed devices has been assumed. The optimization problem will be presented in a future paper.

ABSTRACT

Based on the latest developments of combined heat and power systems (CHP) in the range of performance of up to 30 kW electric power chosen natural gas-powered gasoline engine and Stirling engine units are discussed by means of the specific ecological and economic properties.
Detailed simulation processes for the domestic energy supply of defined model housing estates implicate the dimensioning aspects of these CHP units and the resulting ecological and economic parameters. For this purpose, different variants of dimensioning concerning the thermal CHP rate, the mode of operation and the load control are taken into consideration.
The evaluation of the CHP application in the model housing estates is realised in comparison with conventional domestic energy supply systems. Concerning the simulation results of primary energy demand and CO_2-, CO- and NO_x-emissions, the gasoline engine and the Stirling engine may be an advisable ecological option to the conventional domestic energy supply. More critical are the economic parameters of both investigated CHP units in comparison to the conventional domestic energy supply.
Keywords: cogeneration, gasoline engine, Stirling engine, domestic energy supply

INTRODUCTION

At the present time the German gross power generation is characterised by a CHP contribution of some 11 %. Concurrently CHP technologies are involved in the satisfaction of the thermal heat and the hot water demand (about 6 %) as well as the thermal demand of industrial processes below 500 °C (about 30 %) [1].
The main focus of current CHP applications within the distributed energy supply is ascertainable in industrial and communal areas. Until 2010 essential developments of the actual German CHP stock are estimated in the area of the peripheral thermal energy supply of housing estates and industrial estates [2]. In this range of application CHP units of up to 30 kW electric power such as gasoline

Table 1: Properties of CHP units related to the nominal load operating state [3], [4], [5].

engines or Stirling engines seem to be an interesting option over the medium term.
In the following different variants of dimensioning these CHP systems will be investigated in the domestic energy supply of model housing estates. Depending on the dimensioning variants ecological and economic consequences of CHP applications will be described.

GASOLINE ENGINE AND STIRLING ENGINE UNITS

These analyses are based on experimental investigations of natural gas-powered gasoline engine and Stirling engine units as mentioned in table 1. The steady state performance data of the CHP systems in table 1 are related to a consistent return temperature of 50 °C in the downstream heating system. At this operating state the utilisation of condensing technique of both CHP systems has been registered within the scope of the experimental investigations. The energy ratios heat yield α and fuel efficiency factor ω, calculated according to the definition of VDI 4661 [12], document this result explicitly.

The following sections describe the emission values and the economic parameters of the gasoline engine and Stirling engine unit.

Emission values

The emission values according to table 1 signify the direct release of pollutants during the steady nominal load operating state. The deviation from the steady nominal load operating state regarding the CO- and NO_x-emissions is illustrated in figure 1 (gasoline engine) and figure 2 (Stirling engine).

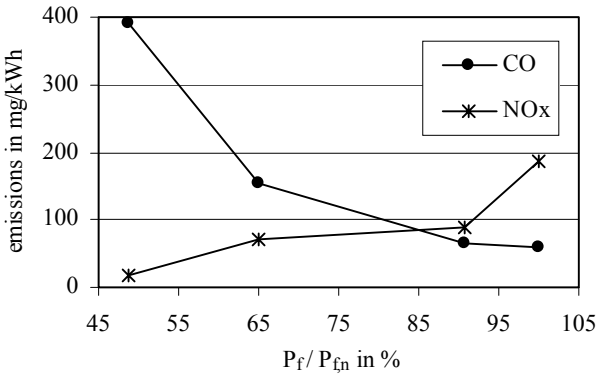

Figure 1: Gasoline engine: emission values [3].

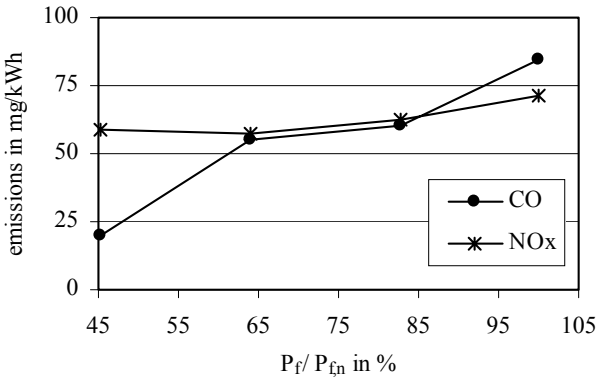

Figure 2: Stirling engine: emission values.

		low-temperature boiler	steam and gas power station
performance data and energy ratios			
performance data	MW	≤ 0.3 (P_{th})	660 (P_{el})
energy ratios	%	92.2 (α)	58.0 (β)
emission values			
carbon dioxide CO_2	kg/kWh	0.2	0.2
carbon monoxide CO	mg/kWh	100	98.2
nitrogen oxide NO_x	mg/kWh	200	343.6
economic parameters			
energy producing costs	ct/kWh	2.5 - 3.2 (net)	3.6 (net)

Table 2: Conventional systems [6], [7], [8].

Regarding to figure 1 and 2 the development of the CO-emissions of the gasoline engine is especially influenced as a result of the steady part load operating state.
A connection with the resulting CO_2-emissions in reliance on the level of load was not ascertained within the experimental investigations of the gasoline engine and the Stirling engine unit.

Comment: According to the reduction of emission values, the gasoline engine operated with a stoichiometric combustion and a three-way catalytic converter [3]. The operation of the Stirling engine was effected by means of external combustion on the basis of a FLOX-burner.

Economic parameters

Table 1 contains fundamental aspects to describe economic coherences of a CHP application.
Furthermore the following economic parameters were considered:

delivery costs (natural gas): 2.3 ct/kWh (net),
credit items (electric power): 3.6 ct/kWh (net),
interest rate: 0.08 1/a.

Thus the thermal energy producing costs k of CHP units are ascertainable concerning the definition of VDI 2067-7 [13].
Figure 3 shows the thermal energy producing costs k of the gasoline engine and the Stirling engine system with regard to the level of load, on the basis of the annual utilisation period of 4500 h/a.

Consistent tendencies of both CHP systems are certifiable with respect to the developments of the thermal energy producing costs k at a variable level of load.
Leaving taxes, subsidies, etc. out of considerations, the situation of the CHP application is represented from the point of view of political economics.

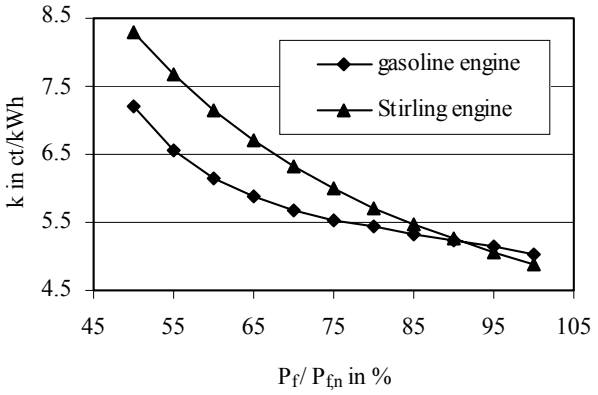

Figure 3: Example of thermal energy producing costs k of CHP systems.

The following simulation analyses the CHP integration into the domestic energy supply of the model housing estates based on these specific properties of the gasoline engine and the Stirling engine unit.
For the evaluation of the energy supply with CHP systems a comparison with the conventional energy supply is carried out. The conventional energy supply method will be considered by a natural gas-powered low-temperature boiler and a steam and gas power station according to table 2.

		model housing estate (gasoline engine)	model housing estate (Stirling engine)
annual demand (electric energy)	MWh	316.1	226.3
annual demand (thermal energy)	MWh	613.4	439.1
peak load (electric power)	kW	84.1	60.2
peak load (thermal power)	kW	184.2	131.9

Table 3: Definition of the model housing estates (example: thermal CHP rate: 20 %).

DIMENSIONING ASPECTS OF CHP SYSTEMS

The integration of cogeneration units requires a previous definition of dimensioning aspects, such as the thermal CHP rate of the objects to be supplied (model housing estates), the mode of operation or the load control of the CHP systems.

Thermal CHP rate

The thermal CHP rate describes the proportion of the nominal thermal load of the CHP unit and the maximal thermal demand of the supplied object.
At present, thermal CHP rates of up to 50 % are realised depending on the energy demand structures of the objects to be supplied [9]. Thermal CHP rates around 20 % are characteristic in domestic energy supply applications in the Federal Republic of Germany [10]. Therewith CHP systems are an essential part in the base load supply of housing estates. The remaining quota of the thermal and electric energy demand ought to be covered by the conventional energy supply.

Within the scope of the simulation processes the thermal CHP rate in the model housing estates will be analysed between 10 % and 50 %.

Mode of operation of the CHP systems

As for supply requirements, the heat oriented and electricity oriented mode of CHP operation is distinguished.
Within the heat oriented mode of operation the application of the CHP system is defined by the thermal load curves of the objects to be supplied.
On the other hand, a cogeneration unit operating in an electricity oriented mode is controlled by the electric load curves of the supplied objects.

The impact of these modes of operation to the CHP application will be verified by means of the simulation analyses.

Load control of the CHP systems

The regulations to the level of load result in the following variants of load control:

- modulating operation: The adaptation to the temporal variable demand of energy is achievable by the control of the level of load of the CHP units. A part load operation of cogeneration systems ought to be limited to 50 % of the nominal load because of the resulting economic values (thermal energy producing costs k) [11].

- intermittent operation: This kind of load control excludes any part load operation of the cogeneration systems. The adaptation to the thermal energy demand of the objects to be supplied is realised by the number of clock cycles.

By means of the simulation processes the variants of a modulating and intermittent operation of the CHP units will be discussed. The modulating operation of the cogeneration systems will be analysed with regard to different values of the lower load.

MODEL HOUSING ESTATES

The subsequent application of the gasoline engine and Stirling engine unit refer to the domestic energy supply of defined model housing estates.
These model housing estates are characterised by thermal and electric energy demand structures and values.
The modelling of the annual energy demand structures of the model housing estates results from the diurnal load characteristics of the VDI 2067-7 records. Within the scope of the following simulation processes these diurnal load characteristics were adapted to the defined model housing estates.
The description of the energy demand values in table 3 decisively factors in parameters like the nominal load data of the CHP units, the defined thermal CHP rate and the energy demand structures according to the VDI 2067-7 [13].

RESULTS OF SIMULATION ANALYSES

The present mathematical simulation of the CHP application connect the specific properties of the CHP systems, in particular the gasoline engine and the Stirling engine units, the different dimensioning aspects as well as parameters of the domestic energy supply of model housing estates.
The evaluation of the CHP application in the model housing estates is based on a relative comparison with the conventional domestic energy supply systems. The primary energy demand, the emission components CO_2, CO, NO_x and the resulting total costs describe the evaluation criteria of the energy supply variants discussed.

Analyses of the thermal CHP rate of the model housing estates

Figure 4a-e compares the simulation results with respect to the defined thermal CHP rates of the model housing estates.

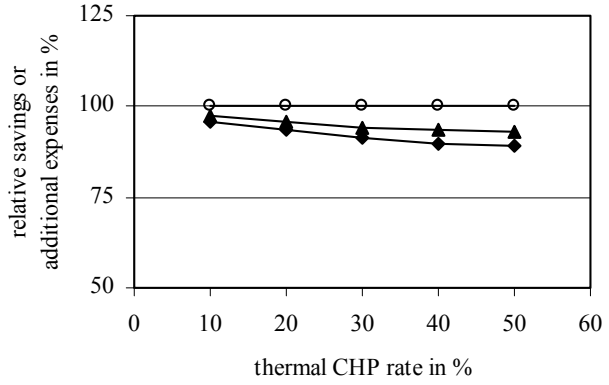

Figure 4a: Primary energy demand.

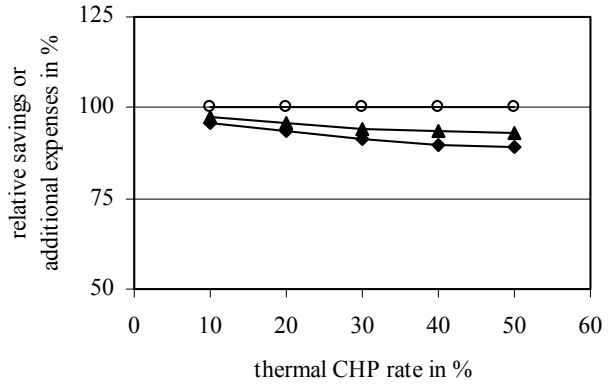

Figure 4b: Carbon dioxide.

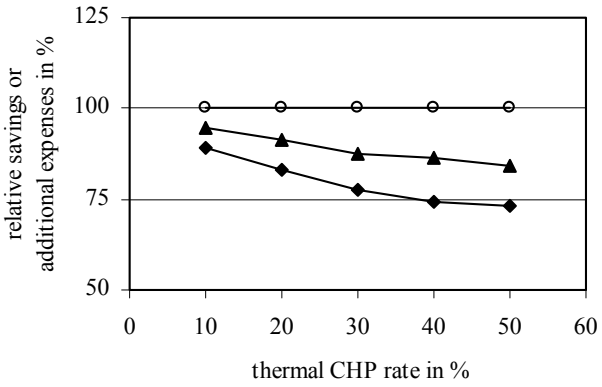

Figure 4c: Carbon monoxide.

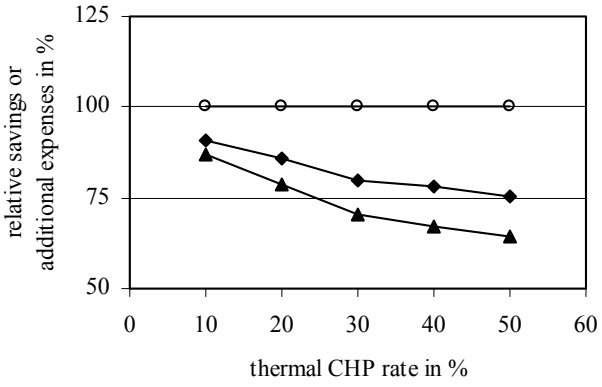

Figure 4d: Nitrogen oxide.

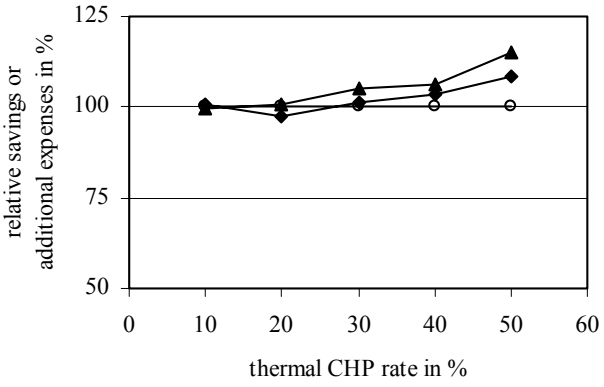

Figure 4e: Resulting total costs.

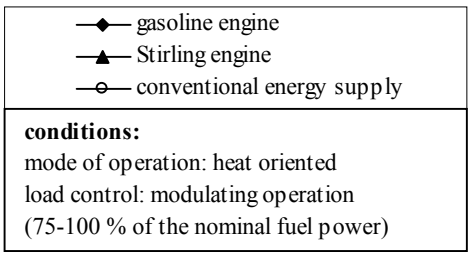

Figure 4a-e: CHP application: variation of the thermal CHP rate.

Figure 4a-e describes the following connection regarding the energy supply including CHP units: The higher the defined CHP rate of the model housing estates, the higher the achievable primary energy savings and the reduction of CO_2, CO and NO_x in comparison with the conventional energy supply. But the higher the defined CHP rate of the model housing estates, the higher the additional expenses of the resulting total costs of the energy supply based on the gasoline engine and Stirling engine unit.

Analyses of the mode of operation of the CHP systems

Figure 5a-e sums up the simulation results of the heat oriented and electricity oriented mode of operation of the gasoline engine and Stirling engine system.

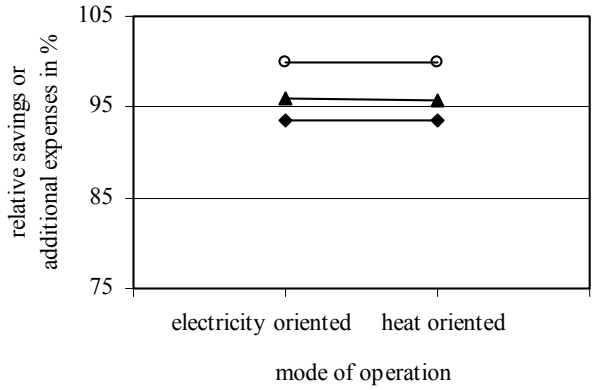

Figure 5a: Primary energy demand.

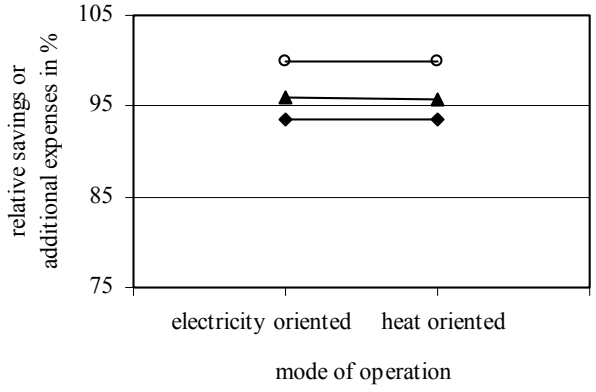

Figure 5b: Carbon dioxide.

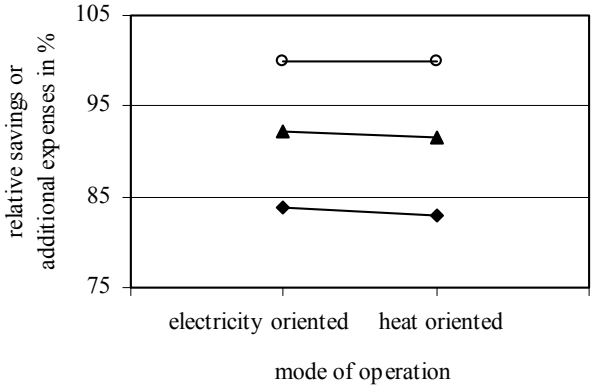

Figure 5c: Carbon monoxide.

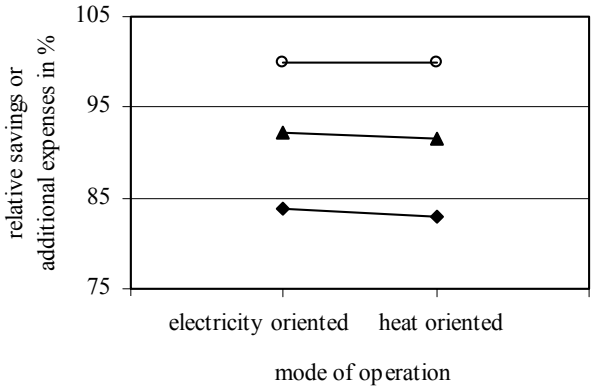

Figure 5d: Nitrogen oxide.

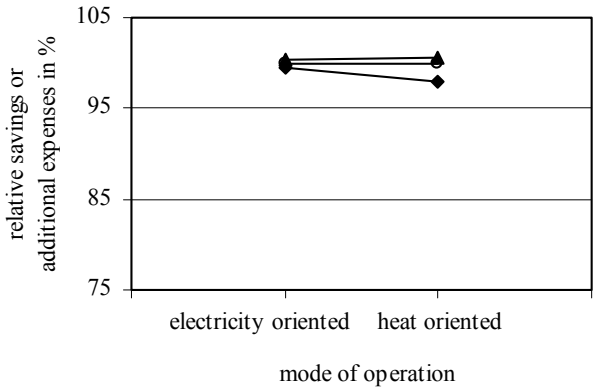

Figure 5e: Resulting total costs.

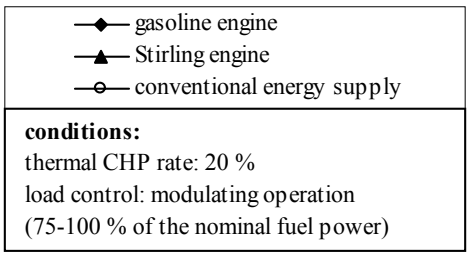

Figure 5a-e: CHP application: variation of the mode of operation.

In accordance with figure 5a-e there are no significant differences of the primary energy demand and the CO_2-emission rates regarding these modes of operation of the CHP systems discussed. Relating to the resulting CO- and NO_x-emissions and the total costs of the domestic energy supply by gasoline engine and Stirling engine units, the consideration of the mode of operation is necessary.

Analyses of the load control of the CHP systems

Figure 6a-e summarises the simulation results of the analysed variants of the load control of the gasoline engine and Stirling engine within the domestic energy supply of the model housing estates.

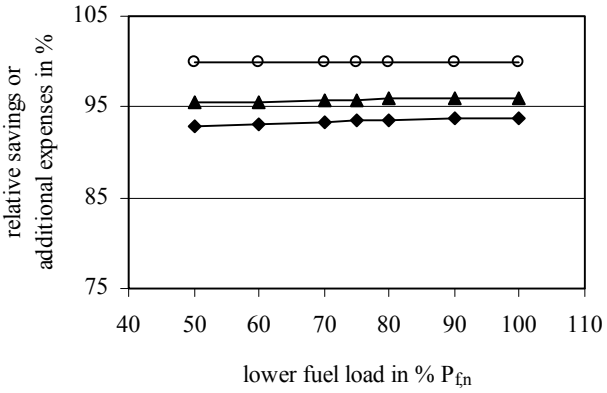

Figure 6a: Primary energy demand.

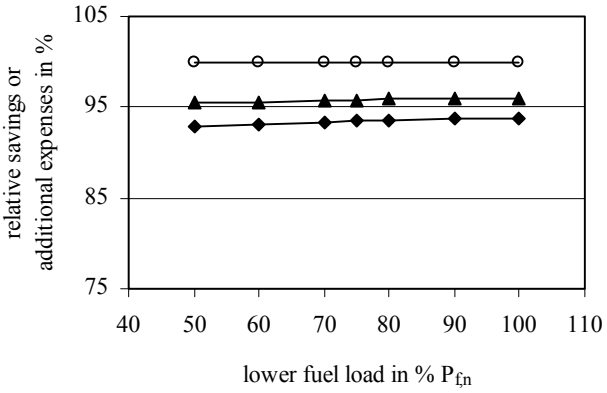

Figure 6b: Carbon dioxide.

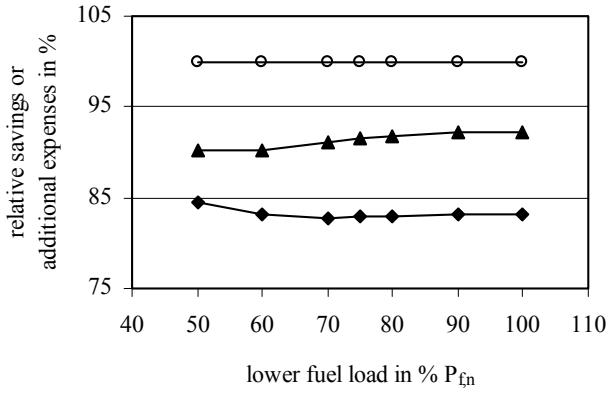

Figure 6c: Carbon monoxide.

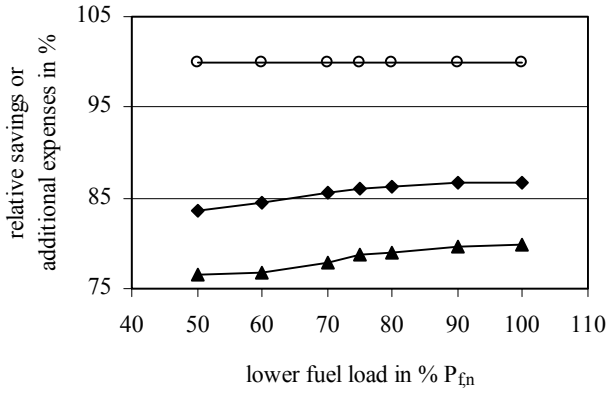

Figure 6d: Nitrogen oxide.

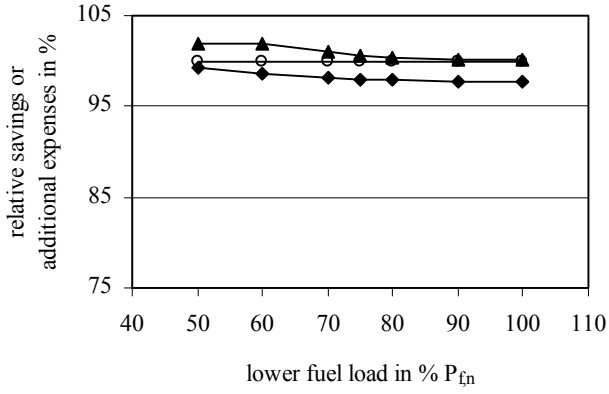

Figure 6e: Resulting total costs.

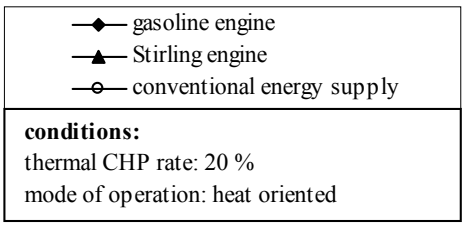

Figure 6a-e: CHP application: variation of the load control.

According to tendency, the better results of the primary energy demand and the CO_2-, CO- and NO_x- emissions in the domestic energy supply are available in a modulating operation of the gasoline engine and the Stirling engine system. But the resulting total costs of the domestic energy supply indicate the interest in an intermittent operation or an operation near the nominal load of cogeneration systems, respectively.

CONCLUSION

The focus of the preceding analyses is natural gas cogeneration systems on the basis of gasoline engine and Stirling engine units, which have been enhanced to domestic energy supply applications because of their present market potential.
The specific properties of these CHP systems, different dimensioning aspects and parameters of defined model housing estates are summarised in a mathematical simulation.
The results of the simulation analyses document the positive influence of both CHP systems on the primary energy savings and CO_2-, CO- and NO_x-reduction compared to the conventional energy supply of the model housing estates. At the same time the simulation results point out that there is no eminent economic advantage of CHP application under these terms in comparison with the conventional energy supply at present.
The simulation analyses illustrate the requirement of a system-compatible and user-specific dimensioning of cogeneration systems in objects to be supplied in order to satisfy ecological and economic demands.

For further studies referring to the application of CHP systems in the range of performance of up to 30 kW electric power the following should be mentioned:

- Based on the present simulation process of gasoline engine and Stirling engine application, fuels cells, micro turbines or steam engines need to be taken into consideration.

- The simulation processes may be enhanced by non steady state performance data while starting or load change processes of CHP systems.

- The options of further developments of the simulation processes regarding optimisation of the CHP application may be achieved.

- Considering the appropriate energy demand structures and energy demand values the simulation processes may be advanced for trigeneration applications.

ABSTRACT

In the residential application, a CO_2 heat pump is used in combination with a hot water storage tank, and the performance of this system is affected significantly not only by instantaneous air and feed water temperatures but also by hourly changes of hot water consumption and temperature distribution in the hot water storage tank. In this paper, the performance of a CO_2 heat pump water heating system is analyzed by numerical simulation. A simulation model is created based on thermodynamic equations, and the values of model parameters are estimated based on measured data on existing devices. The performance calculated is compared with that measured, and the simulation model is validated. The system performance is clarified in consideration of seasonal changes of air and feed water temperatures.
Keywords: Heat pump, Thermal storage, System performance, Thermodynamics, Cycle analysis, Numerical simulation

INTRODUCTION

Heat pumps using CO_2 as a natural refrigerant have been developed and commercialized. They are expected to contribute to energy saving in hot water supply [1].

Many theoretical and experimental studies have been conducted for the performance analysis only on CO_2 heat pumps [2–10]. However, in the residential application, a CO_2 heat pump is used in combination with a hot water storage tank. Therefore, the performance of this system is affected significantly not only by instantaneous air and feed water temperatures but also by hourly changes of hot water consumption and temperature distribution in the hot water storage tank. It takes much time to analyze the performance by experiment, and it is expected that numerical simulation enables one to analyze the performance efficiently.

The objective of this paper is to analyze the performance of a CO_2 heat pump water heating system by numerical simulation. A simulation model of the system is created based on thermodynamic equations, and the values of model parameters are estimated based on measured data on existing devices. The model results in a set of nonlinear differential algebraic equations, and it is solved by a hierarchical combination of the Runge-Kutta and Newton-Raphson methods. The performance calculated is compared with that measured, and the validity of the simulation model is investigated. In addition, the performance is analyzed in consideration of seasonal changes of air and feed water temperatures, and the influence of these ambient tem-

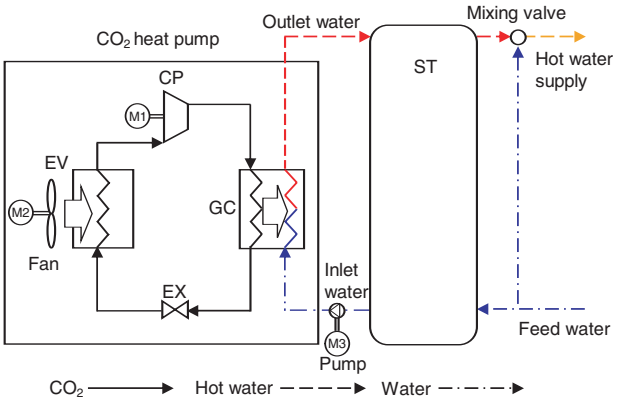

Figure 1: CO_2 heat pump water heating system

peratures on performance criteria is investigated.

CO_2 HEAT PUMP WATER HEATING SYSTEM

Figure 1 shows the configuration of the CO_2 heat pump water heating system investigated in this paper. This system is composed of a CO_2 heat pump and a hot water storage tank (ST). The CO_2 heat pump is composed of a compressor (CP), a gas cooler (GC), an expansion valve (EX), and an evaporator (EV). The system is equipped with a fan, a pump, and motors (M1~3) as auxiliary machinery. The system heats water using the refrigeration cycle of the CO_2 heat pump, stores hot water in the hot water storage tank, and supplies it to a user.

NUMERICAL SIMULATION

Summary of modeling

For each component of the system, the mass flow rates of CO_2 and water, the pressure of CO_2, and the temperatures of CO_2 and water are adopted as variables whose values are to be determined. In addition, the mass, pressure, and energy balance relationships are adopted as basic thermodynamic equations to be satisfied. If necessary, other relationships are adopted. The characteristics of the CO_2 heat pump are expressed by static equations, while those of the hot water storage tank are expressed by dynamic ones. The values of model parameters included in the equations are estimated based on measured data on existing devices commercialized initially. At the connection points between the adjacent components, connection conditions for the variables are considered. At the boundaries of the system, boundary conditions for the variables are considered. If necessary, ambient conditions are considered.

Component models

The following features are incorporated into the model of each component.

Compressor. The ideal characteristics of the compressor are expressed by an isentropic change. In addition, the adiabatic efficiency is introduced to express the real characteristics in comparison with the ideal ones. Here, the adiabatic efficiency is expressed as a function with respect to the pressure ratio.

Gas cooler. The gas cooler is regarded as a counter-flow heat exchanger. Here, it is necessary to consider a strong nonlinearity in the function of the specific enthalpy with respect to the pressure and temperature for the real CO_2 gas. For this purpose, the gas cooler is divided into multiple control volumes, in each of which the specific heat of the real CO_2 gas is assumed to be constant, and the rate of heat transfer between CO_2 and water is expressed as the product of the overall heat transfer coefficient, heat exchange area, and log-mean temperature difference. The pressure of CO_2 is assumed to be constant throughout the gas cooler.

Expansion valve. At the inlet to the expansion valve, CO_2 has only the gas phase. However, at the outlet from the expansion valve, CO_2 has both the gas and liquid phases. To express the specific enthalpy at the outlet, the quality is used instead of the temperature.

Evaporator. At the inlet to the evaporator, CO_2 has both the gas and liquid phases. However, at the outlet from the evaporator, CO_2 has only the gas phase. To evaluate the rate of heat transfer between air and CO_2, it is necessary to change equations for the two states and find the location of their boundary. Here, it is assumed that the overall heat transfer coefficient is common to the two states. In addition, the heat exchange area is divided into the ones for the two states, and they are considered as variables whose values are to be determined. For each state, the rate of heat transfer between air and CO_2 is expressed as the product of the overall heat transfer coefficient, heat exchange area, and log-mean temperature difference. Here, the air temperature is assumed to be constant. The pressure of CO_2 is assumed to be

constant throughout the evaporator.

Hot water storage tank. To consider the dynamic characteristics of temperature distribution in the hot water storage tank, the tank volume is divided into many control volumes, in each of which, the temperature is assumed to be constant. In the energy balance relationship, the heat transfer by water flow and heat conduction as well as the heat loss from the tank surface are considered. It is assumed that the temperature distribution keeps monotonic, and the mixing loss is neglected.

Control conditions

In addition to the aforementioned equations for the components, control conditions must be considered. For example, they are for the revolution of the compressor, the opening of the expansion valve, and the revolution of the pump. However, it is difficult to obtain these control conditions on existing devices. In place of the control conditions, the following equations are considered in this paper: The temperature of CO_2 at the outlet from the compressor is related with that of water at the outlet from the gas cooler; The pressure of CO_2 at the outlet from the expansion valve is related with the air temperature; The mass flow rate of CO_2 is also related with the air temperature; The mass flow rate of water is related with the temperature of water at the outlet from the gas cooler.

Ambient and boundary conditions

The air temperature is considered as the ambient condition. In analyzing the performance of the CO_2 heat pump, the temperatures of water at the inlet to and the outlet from the gas cooler are considered as the boundary conditions. In analyzing the performance of the CO_2 heat pump water heating system, the feed water temperature at the inlet to and the mass flow rate of hot water at the outlet from the hot water storage tank are considered as the boundary conditions.

Solution method

The aforementioned modeling for the performance analysis by numerical simulation is conducted by a building block approach as follows: The component models for the compressor, gas cooler, expansion valve, evaporator, and hot water storage tank, and the substance models for CO_2 and water are defined independently; The system model is composed of the component and substance models as well as the control, connection, ambient, and boundary conditions. The equations for the compressor, gas cooler, expansion valve, evaporator are static, while those for the hot water storage tank are dynamic. Therefore, the modeling results in a set of nonlinear differential algebraic equations. It is solved by the hierarchical combination of the Runge-Kutta and Newton-Raphson methods.

To calculate the properties of the real CO_2, REFPROP Ver. 7.0 is adopted [11]. However, it takes much time to calculate the properties in the iterations of the Runge-Kutta and Newton-Raphson methods. Here, the properties for each combination of many discrete values of pressure and temperature or quality are calculated in advance, and those for the combination of any values of pressure and temperature or quality are calculated by interpolation in the iterations of the Runge-Kutta and Newton-Raphson methods.

Table 1: Ambient and boundary conditions I

(Unit: ˚C)

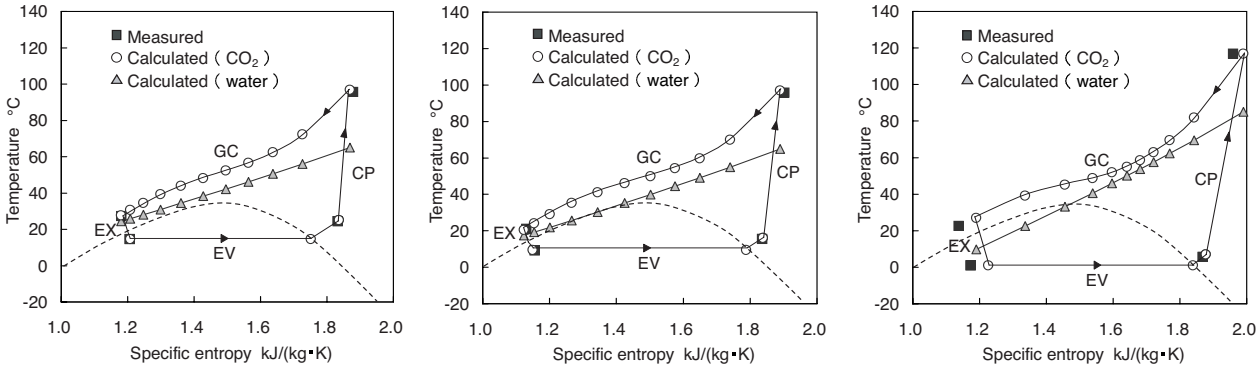
Season	Air	Inlet water	Outlet water
Summer	25.0	24.4	65.0
Mid-season	16.1	17.5	65.0
Winter	7.0	9.7	85.0

COMPARISON OF NUMERICAL SIMULATION AND EXPERIMENT

To investigate the validity of the aforementioned model, the numerical simulation and experiment are conducted for the CO_2 heat pump and overall water heating system under the same conditions, and their results are compared with each other. All the studies are conducted for a system commercialized initially. In the following, relative values are used for system performance criteria, because the system performance has been improved. The capacities of the CO_2 heat pump and hot water storage tank are set at 4.5 kW and 0.30 m^3, respectively.

CO_2 heat pump

The properties of CO_2 and water in the CO_2 heat pump are investigated. Table 1 shows the ambient and boundary conditions which correspond to summer, mid-season, and winter. Figures 2 (a) to (c) show the *T-s* diagrams with the measured and calculated values of the properties of



(a) Summer (b) Mid-season (c) Winter

Figure 2: Measured and calculated values of properties

Table 2: Ambient and boundary conditions II

(Unit: ˚C)

Case	Air	Outlet water
1	35.0	75.0
2	20.0	80.0
3	10.0	85.0

CO_2 at the inlet to and the outlet from the components for these seasons. They also show the calculated values of the properties of CO_2 and water for each control volume in the gas cooler, as well as the properties of CO_2 on the boundary between the two states of the gas and liquid phases, and the gas phase in the evaporator. According to these figures, the measured and calculated values are in good agreement. The temperature distributions of CO_2 and water in the gas cooler show some features in each season. In addition, the properties of CO_2 in the evaporator are determined rationally.

The values of heat pump COP are investigated. Table 2 shows the ambient and boundary conditions in the cases investigated. Figure 3 compares the measured and calculated values in the relationship between the inlet water temperature and heat pump COP for these cases. Here, the ratio of heat pump COP is relative to its measured value for the air, inlet water, and outlet water temperatures of 20, 15, and 85 ˚C, respectively. Figure 3 shows that the measured and calculated values are in good agreement.

From these results, it turns out that the simulation model is valid for the CO_2 heat pump.

Overall water heating system

The numerical simulation and experiment for the overall water heating system with the CO_2 heat pump are conducted for four days. This is because

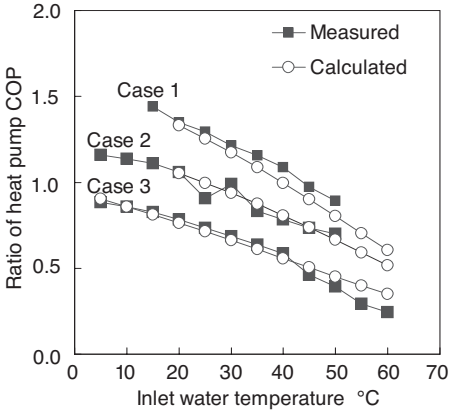


Figure 3: Measured and calculated values of relative heat pump COP

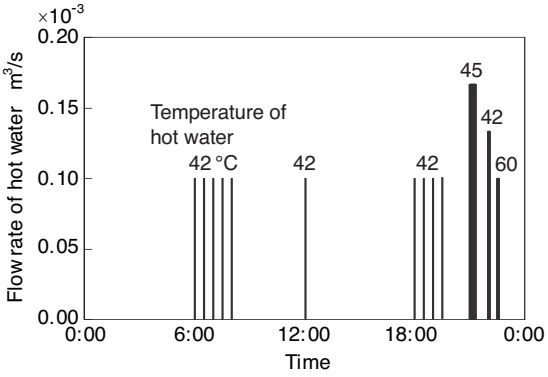

Figure 4: Hourly change of hot water demand

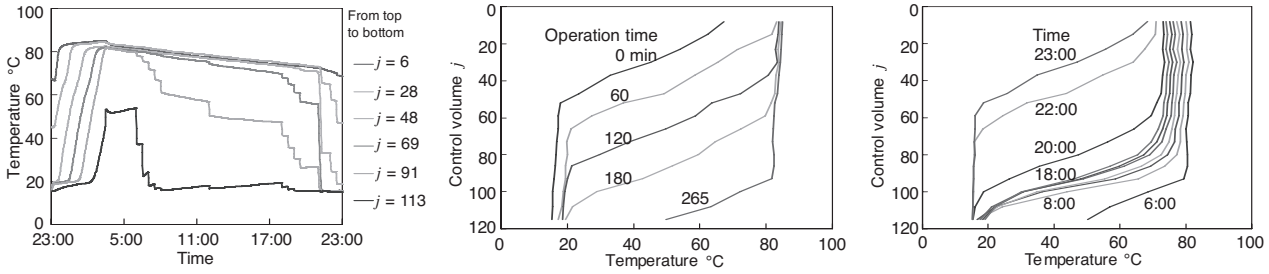
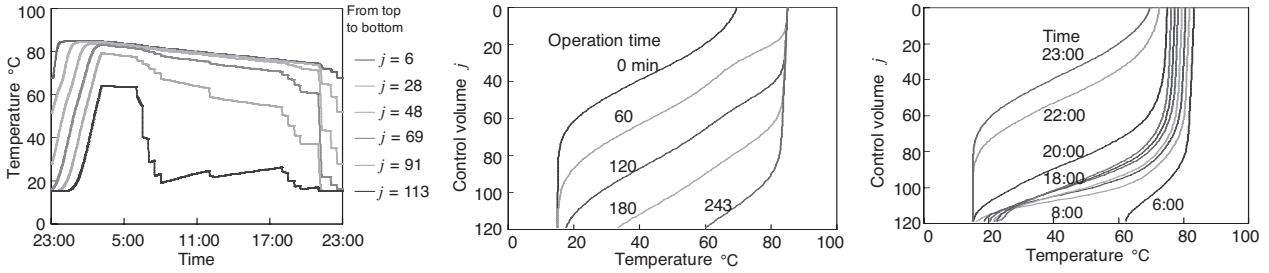
the results on the 4th day are similar to those on the 3rd day, and the periodic steady state appears.

As the ambient and boundary conditions, the air and feed water temperatures are set at 16 and 15 ˚C, respectively. The hourly change of hot water demand is given on each day as shown in Figure 4. As the initial condition, the temperature of water in the hot water storage tank is set at 15 ˚C.



(a) Hourly changes (b) Distributions in charging (c) Distributions in discharging

Figure 5: Measured values of temperatures in hot water storage tank (4th day)



(a) Hourly changes (b) Distributions in charging (c) Distributions in discharging

Figure 6: Calculated values of temperatures in hot water storage tank (4th day)

The CO_2 heat pump is operated only during the nighttime. The CO_2 heat pump is shut down with a shutdown condition satisfied at an appropriate time before 6:00, and it is started up at an appropriate time of night correspondingly. The shutdown condition is that the inlet water temperature attains 60 ˚C. In addition, the outlet water temperature is set at 85 ˚C, which is based on a standard operation mode of an existing CO_2 heat pump.

Figures 5 and 6 show the measured and calculated values of temperatures in the hot water storage tank on the 4th day, respectively. Figure (a) shows the hourly changes of temperatures at several representative positions. Figure (b) shows the temperature distributions at representative operation times in charging the hot water storage tank. Figure (c) shows the temperature distributions at representative times in discharging the hot water storage tank. Here, *j* means the vertical position of 120 control volumes of the hot water storage tank. According to these figures, the measured and calculated values are in good agreement.

Figure 7 compares the measured and calculated values of the hourly change of the heat pump COP on the 4th day. Here, the ratio of heat pump COP is relative to its calculated value for the air, inlet water, and outlet water temperatures of 16, 15, and 85 ˚C, respectively. As time passes, the heat pump COP decreases with an increase in the

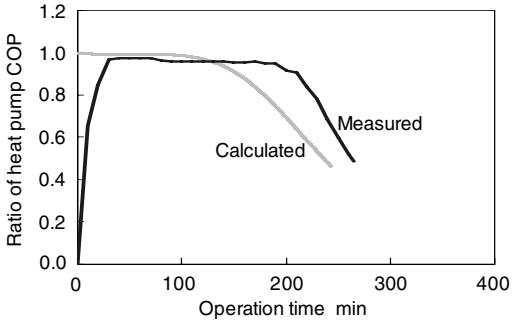


Figure 7: Measured and calculated values of hourly change of relative heat pump COP (4th day)

inlet water temperature in both the numerical simulation and experiment. In the experiment, the heat pump COP increases drastically soon after the CO_2 heat pump is started up. In the numerical simulation, however, the dynamic characteristics of the CO_2 heat pump for its startup is not considered, and the operation time is shorter than that in the experiment.

Figure 8 compares the measured and calculated values of the daily changes of the heat pump COP, and storage and system efficiencies. Here, the storage efficiency is defined as the ratio of heat output for hot water supply to heat input by the CO_2 heat pump, and the system efficiency is defined as the ratio of heat output for hot water

suppy to electric power consumption by the system. In addition, the ratio of each performance criteria is relative to its measured value on the 1st day. The daily changes in the numerical simulation and experiment are in good agreement. The errors are 0.2 to 2.1 %, –3.5 to 6.7 %, and –2.4 to 7.3 % for the heat pump COP, and storage and system efficiencies, respectively.

From these results, it turns out that the simulation model is valid not only for the CO_2 heat pump but also for the hot water storage tank. In addition, the computation time necessary to conduct the numerical simulation for four days on an AlphaStation ES47 with a CPU of 1.0 GHz is only about 1.3 hours, and the numerical simulation enables one to analyze the performance efficiently, as compared with the experiment.

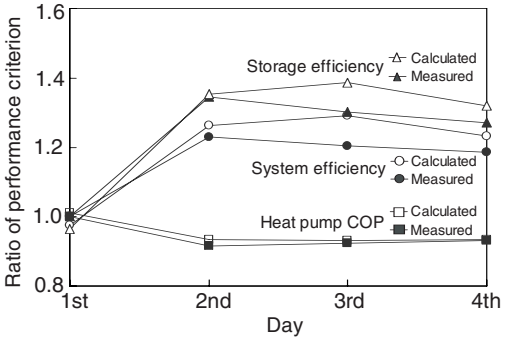

Figure 8: Measured and calculated values of daily changes of relative system performance criteria

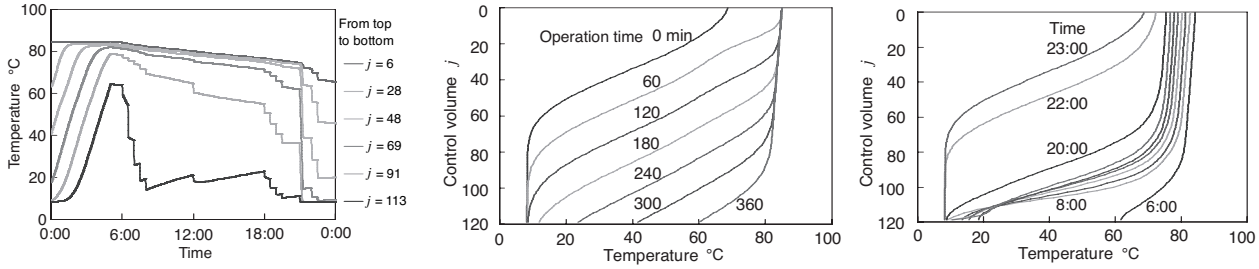
INFLUENCE OF AMBIENT TEMPERATURES ON PERFORMANCE

The numerical simulation for the overall water heating system is conducted for four days in each month of a typical year.

As the ambient condition, the hourly change of air temperature in each month is based on its monthly average observed in Osaka, Japan [12]. As the boundary condition, the feed water temperature is assumed to be constant in each month, and it is calculated from the monthly average of the differences between daily average air and feed water temperatures [13]. The hourly change of hot water demand shown in Figure 4 is adopted. As the initial condition, the temperature of water in the hot water storage tank is assumed to be equal to the instantaneous feed water temperature.

The CO_2 heat pump is started up and shut down as described previously. In addition, the outlet water temperature is set at 85, 80, and 75 ˚C for the air temperature lower than 23 ˚C, between 23 and 30 ˚C, and higher than 30 ˚C, respectively, which is based on a standard operation mode of an existing CO_2 heat pump.

Figures 9 to 11 show the calculated values of



(a) Hourly changes (b) Distributions in charging (c) Distributions in discharging

Figure 9: Calculated values of temperatures in hot water storage tank (January, 4th day)

Figure 11: Calculated values of temperatures in hot water storage tank (August, 4th day)

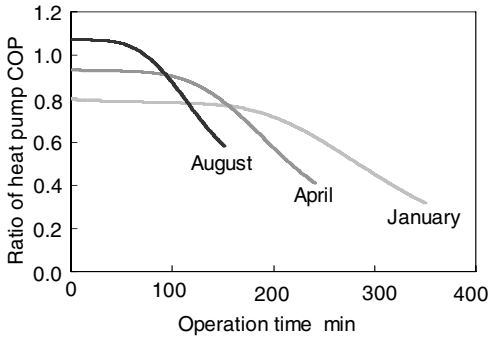

Figure 12: Calculated values of hourly change of relative heat pump COP in each month (4th day)

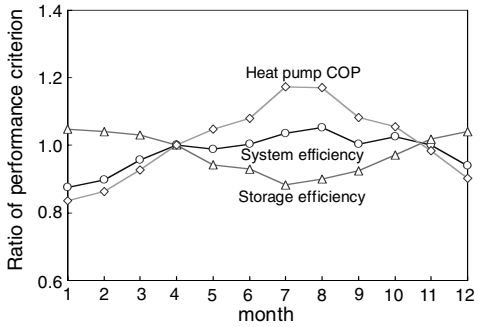
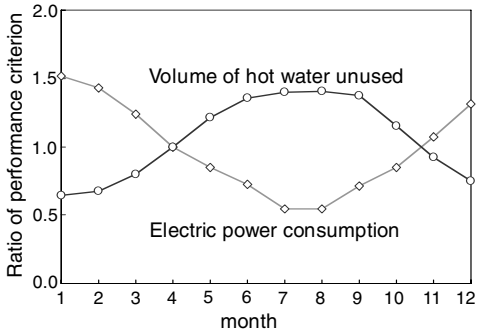


(a) Heat pump COP, and storage and system efficiencies



(b) Electric power consumption and volume of hot water unused

Figure 13: Calculated values of monthly changes of relative system performance criteria (4th day)

temperatures in the hot water storage tank on the 4th day in January, April, and August, respectively. Figures (a) to (c) are similar to those in Figure 6. Since the air and feed water temperatures in April are similar to those for the case corresponding to Figure 6, the calculated values in April are similar to those shown in Figure 6. In January, since a larger amount of hot water produced by the CO_2 heat pump is used for hot water supply, the volume of hot water unused is smaller. As a result, the gradients of the temperature distributions are larger, and the volume of hot water with middle temperatures is smaller. In August, however, since a smaller amount of hot water produced by the CO_2 heat pump is used for hot water supply, the volume of hot water unused is larger. As a result, the gradients of the temperature distributions are smaller, and the volume of hot water with middle temperatures is larger.

Figure 12 shows the calculated values of the hourly change of the heat pump COP in January, April, and August. Here, the ratio of heat pump COP is relative to its calculated value for the air, inlet water, and outlet water temperatures of 16, 15, and 85 ˚C, respectively. The operation time of the CO_2 heat pump becomes shorter with increases in the air and feed water temperatures. However, the time when the heat pump COP decreases becomes relatively longer to the operation time. This is because of the aforementioned smaller gradients of the temperature distributions in the hot water storage tank.

Figure 13 shows the calculated values of the monthly changes of the heat pump COP, storage and system efficiencies, electric power consumption, and volume of hot water unused. Here, the ratio of each performance criteria is relative to its value in April. With increases in the air and feed

water temperatures, the heat pump COP increases, but the storage efficiency decreases. This is because although the heat loss from the hot water storage tank decreases, its ratio to the heat produced by the CO_2 heat pump increases. As a result, the system efficiency does not necessarily increase with the air and feed water temperatures in summer.

CONCLUSIONS

The performance of a CO_2 heat pump water heating system has been analyzed by numerical simulation. A simulation model of the system has been created based on thermodynamic equations, and the values of model parameters have been estimated based on measured data on existing devices. The model has resulted in a set of nonlinear differential algebraic equations, and it has been solved by a hierarchical combination of the Runge-Kutta and Newton-Raphson methods.

First, the performance of the CO_2 heat pump calculated has been compared with that measured. The measured and calculated values have been in good agreement. Second, the performance of the overall water heating system calculated has been compared with that measured. The measured and calculated values have also been in good agreement. As a result, it has turned out that the simulation model has been valid. In addition, it has turned out that the numerical simulation enables one to analyze the performance efficiently, as compared with the experiment. Finally, the performance of the system has been analyzed in consideration of seasonal changes of air and feed water temperatures. The influence of these ambient temperatures on several performance criteria has been clarified quantitatively.

COMPARATIVE EVALUATION OF NATURAL GAS AND SUGAR CANE BAGASSE BASED COGENERATION SYSTEM

Leonardo Moneci Zamboni[1], Luiz Felipe Pellegrini, Silvio de Oliveira Jr. and Arlindo Tribess
Polytechnic School – University of São Paulo
Department of Mechanical Engineering
Brazil

ABSTRACT

Co-firing systems consist in burning two different fuels in the same system in order to produce power and/or heat. Following this concept, two combined cycles burning natural gas and sugar cane bagasse are proposed and evaluated, as an option for electricity generation in sugarcane mills. One system consists in Brayton cycle burning natural gas and the exhaust gases are used in burning bagasse in a Rankine Cycle. In the other, bagasse gasification is introduced and the produced gas is used together with natural gas in a Brayton cycle and the exhaust gases used in a HRSG (Heat Recovery Steam Generator). The thermoeconomic analysis developed for the systems evaluates the exergy efficiency and the production costs of steam and electricity for each system. A parametric study on the natural gas consumption is performed in order to evaluate the impacts of this fuel on costs.

Keywords: Co-firing, sugar cane bagasse, natural gas and cogeneration.

NOMENCLATURE

C	Specific cost [US$/MWh]

INTRODUCTION

The sugar and alcohol industry uses the sugar cane bagasse, by-product from the milling process, as fuel in boilers for steam production. This steam is responsible for the production of electro-mechanical energy, used in plant equipment (mills, pumps, turbo generators, etc.), and for heat supplied to the production of sugar and alcohol.

With regard to the largest efficiency and the economical and environmental advantages, gasification of sugar cane bagasse and usage of the produced gas in gas turbines may become a promising possibility for this industry. The surplus of electricity generated can be sold to the grid, thus contributing to the expansion of the Brazilian generation park [1].

Unfortunately, the generation of electricity using sugar cane bagasse is only made during the harvest (on-season), which lasts approximately seven months. Therefore, it would not be feasible to operate a thermoelectric plant that works only part of the year.

The purpose of this study is to analyze cogeneration plants that work not only with sugar cane bagasse, but also with natural gas (available the whole year), as a complement.

In this paper a comparative evaluation of two cogeneration plants based on configurations that use natural gas and sugar cane bagasse is carried out. The first configuration is a Biomass Integrated Gasification/Combined Cycle (BIG/CC) [3 and 4] and the second is a Combined Cycle with Injection of Biomass in the Boiler (CC/IB) [5].

NATURAL GAS

Natural gas is considered a clean fuel presenting the smallest indexes of pollutant emission in the atmosphere. The gas methane, containing 75% of carbon in mass, produces 2.77 kg of CO_2 and generates 55,950 kJ per kilogram of methane burned. One kilogram of a liquid hydrocarbon with 10 atoms of carbon produces 3.15 kg of $CO_2$and generates only 45,780 kJ/kg [6].

The Bolivian natural gas is composed practically by methane (CH_4) – 92% - and ethane (C_2H_6) – 6%. Its composition can be visualized in Table 1. The lower heating value of the Bolivian natural gas is 41,665 kJ/Nm^3.

Component	% molar fraction	
	Bolivian natural gas	Produced gas
C_2H_2	6.00	-
C_2H_4	6.00	-
C_2H_6	4.00	-
CH_4	80.61	3.24
CO	-	11.33
CO_2	0.52	18.38
H_2	1.00	25.09
H_2O	0.07	3.13
N_2	1.80	-
N_2	-	38.84

Table 1 – Composition of the Bolivian natural gas and the produced gas [3, 8].

SUGAR CANE BAGASSE

After the crop, sugar cane is prepared and fed to mills, where raw juice is extracted and sent to the process. From this milling process is obtained as a by-product in a proportion of 25% in weight. So, a sugar cane ton produces 250 kg sugar cane bagasse on average with 50% of humidity and lower heating value of ~7,350kJ/kg [9].

The sugar cane bagasse in excess can provide storage problems. During off-season periods (no harvest) this excess can generate expenses, even though these costs can be reduced with constant handling outdoors storage [1]. In Figure 1 surplus of sugar cane bagasse generated by a Sugar and Alcohol Mill, located in the state of São Paulo, Brazil is shown.

Figure 1 – Surplus of sugar cane bagasse generated by a sugar and alcohol mill.

Over the last years, the electricity generated by Brazilian sugar and alcohol mills has been gradually increasing.

GASIFICATION OF SUGAR CANE BAGASSE

Gasification is a thermo-chemical process in which a fuel, solid or liquid, is fragmented with the use of heat, in an oxidizer atmosphere, for the generation of a gas (mixture of gases) with low/medium heating value. This process is an alternative to the combustion of solid and liquids fuels.

The great advantage of this process is the use of the exhaust gas produced in power cycles with gas turbines, with superior efficiencies compared to the conventional Steam cycles with direct burn [3].

This work uses data generated by the model developed by Pellegrini and Oliveira [8] for biomass gasification. The model is based on the establishment of a chemical equilibrium among the main products of the gasification (CH4, CO, H2, H2O, CO2, N2, C(s)) – not considering the formation of pollutant and larger hydrocarbons. The model also makes use of correlations for the production of CH4 and C(s), as proposed by Li et al [10].

The composition of the produced gas used in this work is shown in Table 1.

THERMOECONOMY

Exergy

In the cogeneration plants, with simultaneous production of electro-mechanic energy and useful heat, there are two products whose generation costs must be calculated. In this case, it might be used thermoeconomic analysis in exergetic basis to calculate those costs.

According to Kotas [11], the exergy is a standard of the quality of the energy, that is equal to the maximum useful work that can be obtained from a given "form of energy ", using the environmental parameters (pressure, temperature, and chemical potential) as reference state.

For the purposes of this work exergy is divided in two parts: the physical exergy and the chemical exergy. The change in physical exergy can be given by the following expression:

$$ex_{ph1} - ex_{ph2} = (h_1 - h_2) - T_0(s_1 - s_2) \quad (1)$$

The chemical exergy can be obtained as a function of the heating values of the fuels [12].

Cost balance

The cost balance of a system can be given by the following expression:

$$\sum \dot{C}_P = \sum \dot{C}_I + \dot{C}_{EQ} \quad (2)$$

where:

$$\dot{C} = c \cdot \dot{E}x \quad (3)$$

COGENERATION SYSTEMS

A cogeneration system corresponds to the simultaneous production of different forms of useful energy, as electric-mechanical and thermal energies, to supply the needs of a process unit, in an industrial, agricultural or tertiary sector or an isolated system, starting from the same primary source of energy [13].

For simultaneous production of electricity and steam, a backpressure turbine or a condensing-extraction turbine, in the called process CEST - Condensing Extraction Steam Turbine - can be used. In this process, a part of the steam is extracted from the turbine in an intermediate pressure, to be used in the process; the remaining

steam expands in the turbine until the pressure of the condenser, condenses and returns to the boiler together with the condensed of the process [8].

Combined cycles based systems, composed by a gas turbine, a heat recovery steam generator and a condensation-extraction steam turbine, are used to increase the cogeneration systems efficiency.

In this paper two-cogeneration systems that use natural gas and sugar cane bagasse as inputs are studied:

1. CC/IB [5] - A Combined Cycle with Injection of Biomass in the Boiler, composed by a Gas Turbine that uses only the natural gas as input, and a Steam cycle where, in the heat recovery steam generator, bagasse is burned with the exhaust gases of the gas turbine, as represented in Figure 3.

2. BIG/CC [3] – Biomass Integrated Gasification/Combined Cycle, similar to the first cogeneration system with the differences that no bagasse is burned in the heat recovery steam generator, but is now gasified and fed to a gas turbine mixed with natural gas, as shown in Figure 4.

For the comparative evaluation of these two-cogeneration systems using natural gas and sugar cane bagasse, part of steam is extracted from the steam turbine to attend a heat demand.

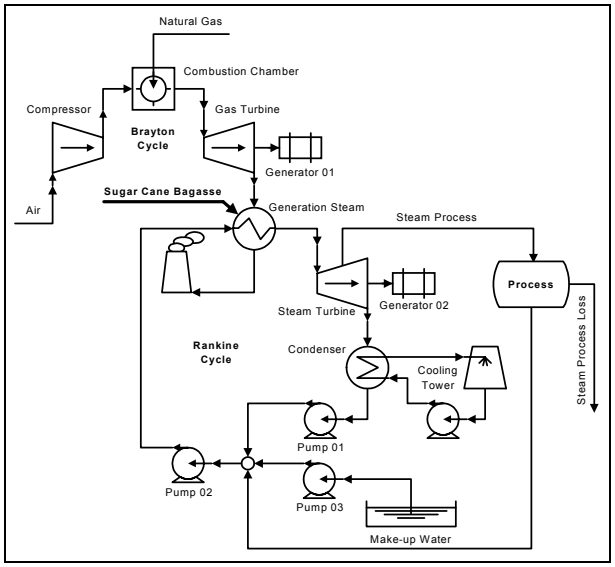

Figure 3 - Combined Cycle with Injection of Biomass in the Boiler (CC/IB).

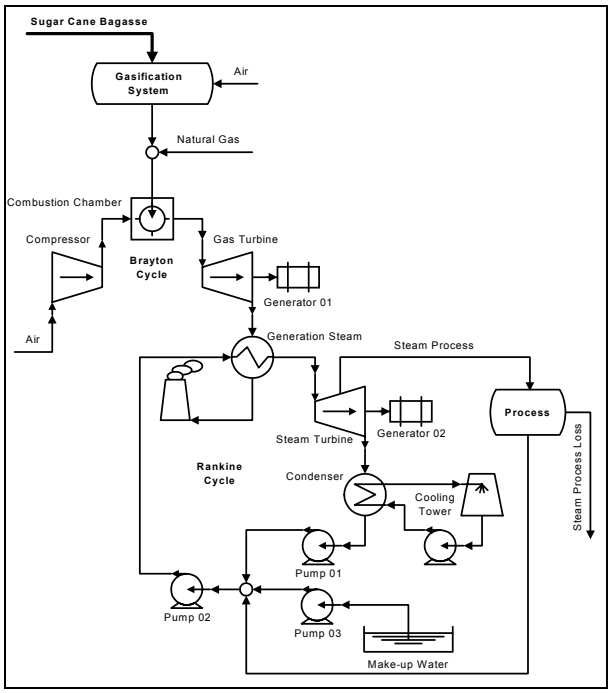

Figure 4 - Biomass Integrated Gasification/ Combined Cycle (BIG/CC).

Operational conditions

The operational conditions shown in Table 2 were adopted in the simulations. Thermodynamic properties, mass and energy rates were performed using the computational program Cycle Tempo [14].

Brayton Cycle	
Pressure ratio	16 bar
Temperature of the combustion chamber exhaust gases	1200ºC
Compressor isentropic efficiency	83%
Gas turbine isentropic efficiency	87%
Generator efficiency	95%
Produced gas mass flow rate	75.5 kg/s
Rankine Cycle	
Temperature of the steam generated	520ºC
Boiler pressure	70 bar
Temperature of the exhaust gases of the gas turbine	140ºC
Sugar cane bagasse mass flow	62 kg/s
Steam turbine isentropic efficiency	90%
Generator efficiency	95%
Pressure of the condenser	0.1 bar

Table 2 – Operational conditions.

The operational conditions regarding the steam extraction for process were:

- 77% of the turbine entrance steam mass flow is extracted for the cogeneration process at a pressure of 0.25 MPa;
- 35% of the process flow is lost in the steam form and condensed contaminated;
- Make-up water comes from an external source with environment temperature;
- The cost of the make-upt water is 0.40 US$/t.

Thermoeconomic evaluation

For the calculation of the equipment costs (I_{EQ}), the following equation was used:

$$I_{EQ} = I_r \left(\frac{S}{S_r} \right)^m \quad [US\$] \tag{4}$$

where the values of the terms of the equation are shown in Table 3.

Equip.	m	I_r	S_r	S	Ref.
Boiler	0.78	768	1	$\dot{Q}$ [kW]	[15]
Steam turbine	0.68	17082	1	$\dot{W}$ [kW]	[15]
Gas turbine	1.00	400	1	$\dot{W}$ [kW]	[1]
Condenser	0.55	3000	10	5-10[5] [kW][2]	[16]
Pumps	0.39	2500	1	1-23 [kW]	[16]

Table 3 – Values of the terms of equation (4)

It was considered a US$ 50 million cost for the gasification system.

The annual cost of the equipment (levelized), is a function of the levelized factor, f_a, annual fixed cost of operation and maintenance, f_{omf} (9%), annual variable cost of operation and maintenance. f_{omv} (1%), and of the load factor, FC (75%), is given by the following equation:

$$C_{a_{EQ}} = I_{EQ}\left(f_a + f_{omf} + FC \cdot f_{omv}\right) \left[\frac{US\$}{year} \right] \tag{5}$$

And the levelized factor f_a is given by:

$$f_a = \frac{r}{1-(1+r)^{-n}} \tag{6}$$

where *r* is the annual rate of interests (12%) and *n* is the equipment levelized period in years (20 years).

The cost of the equipment can be given by the following expression:

$$\dot{C}_{EQ} = \frac{C_{a_{EQ}}}{T_o \cdot 3\,600} \left[\frac{US\$}{s} \right] \tag{7}$$

where $C_{a_{EQ}}$ is the annual levelized equipment cost, T_0 (7000 h) is the annual operation period of the plant[h].

The cost of the natural gas is 143 US$/t and that of bagasse considered 10 US$/t.

Exergy efficiency

The exergetic efficiency of the cogeneration plants is given by:

$$\eta_{ex} = \frac{\dot{W}_{E1} + \dot{W}_{E2} - \dot{W}_P + \dot{E}x_{PS} - \dot{E}x_{RS}}{\dot{E}x_{NG} + \dot{E}x_B + \dot{E}x_W} \ [\%] \tag{8}$$

RESULTS

The simulation results can be depicted in the following graphs. The first graph (Figure 5) presents the electricity generation power by the two turbines (gas and steam) as a function of the natural gas mass flow.

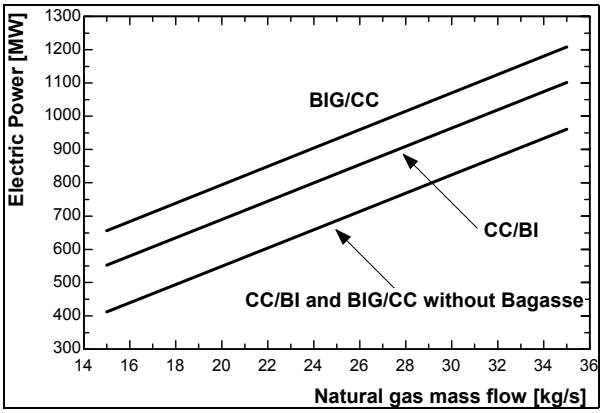

Figure 5 – Electricity generation power vs. natural gas mass flow

2 Value regarding the thermoelectric plant power.

Analyzing the results presented in Figure 5, it can be observed that the system BIG/CC, working in the sugar cane harvest, presents larger electricity generation power compared to the system CC/BI and also when the two systems work in the time between harvests (only with natural gas).

On the other hand, both systems working only with natural gas (between harvests) present the best exergetic efficiency, as shown in Figure 6. It is due to the abscenceof exergy destruction either in the gasification process (BIG/CC system) or by the temperature increasing in the HRSG - Heat Recovery Steam Generator (CC/BI system).

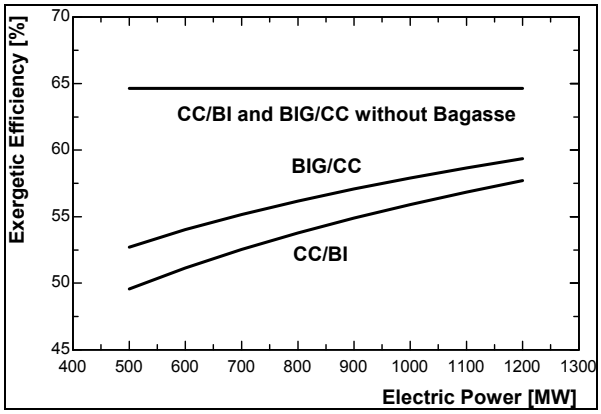

Figure 6 – Exergetic efficiency vs. electricity generation power.

In Figure 7 the average cost of electricity generated is presented. the average cost of electricity generation by the system CC/BI is smaller than the system BIG/CC. Although the BIG/CC system has higher exergetic efficiency, one of the reasons of the higher electricity generation cost is the high cost associated to the gasification system.

It can also be observed that the more natural gas is added, the lesser will be the cost of electricity generated in both cogeneration systems (Figure 7), and that the tendency of the exergetic efficiency is to be around 65% (Figure 6), corresponding to no use of sugar cane bagasse.

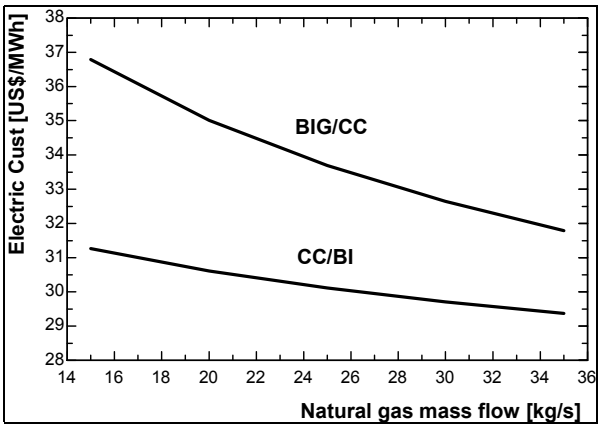

Figure 7 – Average cost of electricity generation vs. natural gas mass flow.

In Figure 8 are shown the results relative to the mass flow rate extracted for the cogeneration process (77% of the turbine inlet steam mass flow) as a function of the natural gas mass flow. the system CC/BI presents significant higher steam mass flow rates for process.

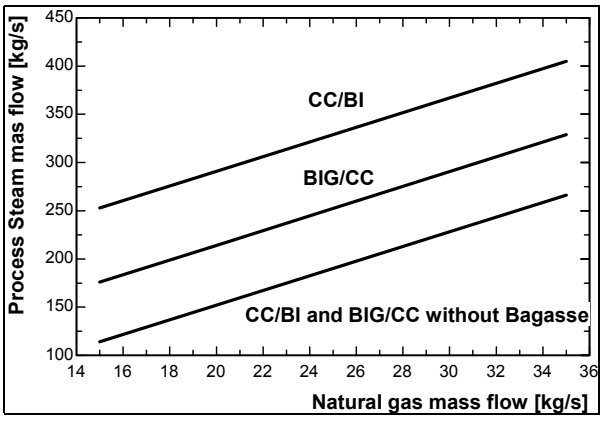

Figure 8 – Mass flow extracted for the process as a function of the natural gas mass flow.

Finally, the average cost of the steam extracted for process is shown in Figure 9. It can be observed that the average cost of the steam generated by system CC/BI is cheaper than the cycle BIG/CC. Once more, it happens due to the high cost of the gasification system.

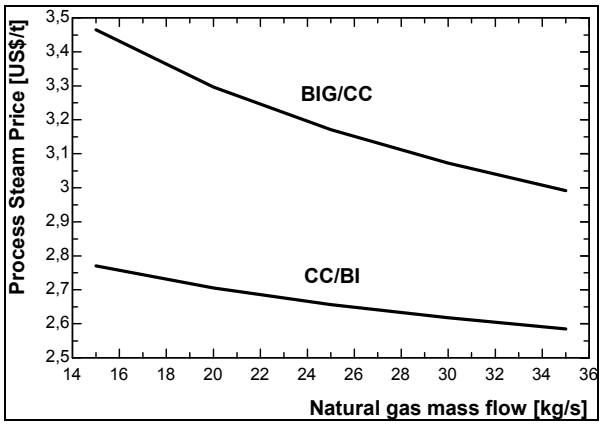

Figure 9 – Steam generation cost vs. natural gas mass flow.

CONCLUDING REMARKS

The comparative evaluation of natural gas and sugar cane bagasse based cogeneration system show that the Combined Cycle with Injection of Biomass in the Boiler (CC/IB) presents lower costs of electricity and steam generation than the Biomass Integrated Gasification/Combined Cycle (BIG/CC).

Even though these results indicate that system CC/IB is better than the BIG/CC, a closer look into the fixed costs involved (equipment costs) could bring about another idea. While the BIG/CC attains higher exergetic efficiencies, the high cost related to the gasification system more than offsets this advantage. So, gasification based cycles are still very dependent on research efforts in order to decrease its costs.

ABSTRACT

Cogeneration systems proved to be a good option for decentralized power generation in sites of coincident electrical and thermal loads. Site electrical and thermal loads demands can vary in a large range that makes cogeneration systems achieve high energy utilization factor (EUF) at hours of coincident high demands and low EUF at hours of small coincident demands. Energy availability of the prime mover must be compared with energy demands turning possible to evaluate and compare different options. Simulation of thermal systems is a powerful tool to well design power plants, helping designers evaluate several possibilities trying to turn economically feasible the cogeneration system.

INTRODUCTION

Environmental impacts, scarce and limited natural resources and a competitive electrical market are factors that turn vital the design of cogeneration systems with high energy utilization factor and that replaces costs of electricity and thermal loads at a form that turns the system economically feasible.

Evaluation of cogeneration systems involves several variables, turning the evaluation analysis a time spending process developed by an experienced engineering professional team. Energy balances, load profiles, equipments performances, operational strategies, legislation knowledge, operational costs, investment costs, environmental aspects, etc are some of the fields that must be studied.

Computational evaluation can reveal important information about the match of the loads by the system under analysis. Designing cogeneration systems sometimes lead to systems that doesn't meet all energy demands of the site, auxiliary equipments must meet particular loads and complement equipments must meet peak loads (i.e. electricity : grid). Legal aspects and tariffs structures have direct influence in the size of the cogeneration system, conducting to design of systems that attend the total electricity demand or the base of the electricity demand. Design of cogeneration systems permits several sizes for the prime mover and many systems conceptions.

CASE STUDY: HOSPITAL

To demonstrate the use of computational algorithms for the evaluation of internal combustion engines cogeneration systems, we will consider typical loads of a hospital.

The profiles weren't measured but through the analysis of electricity and gas bills and the installed equipments (chillers, boilers, water heaters, etc), it was possible to construct expected profiles for the main energy demands in the hospital. An energy monitoring system is planned to be installed.

Figure 1 shows a typical electricity demand profile. The figure was constructed with data of consumption at peak and out of peak hours, during the whole year of 2003. Figure 2 shows a typical demand profile of hot water for sanitary purpose (50^{o} C) and saturated steam demand at 6 bar. It was estimated based on the existing equipment and the gas bill. Figure 3 shows the cooling load (air conditioning) profile, based on characteristics of existing equipment, activity of the hospital and typical cooling load profiles for summer at south hemisphere. At figure 4 we can see a typical summer weather profile.

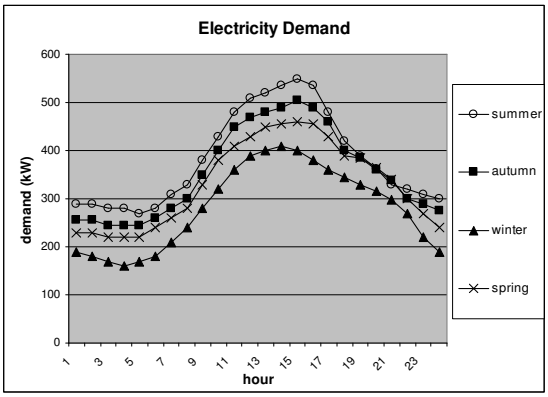

Figure 1 – Electricity demand

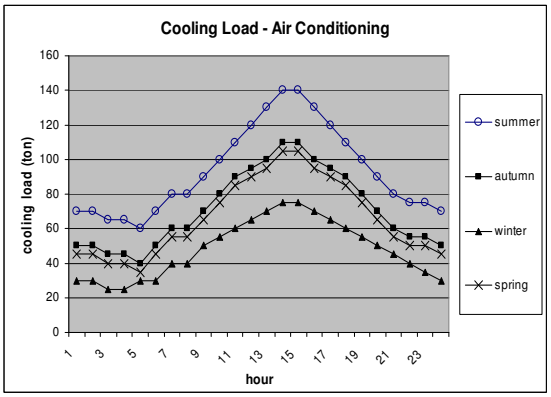

Figure 3 – Cooling load

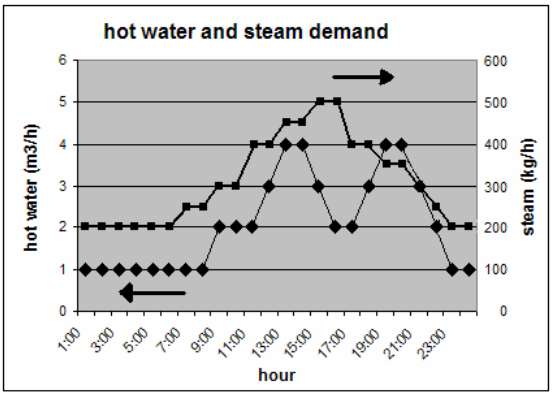

Figure 2 – Hot water and steam demand

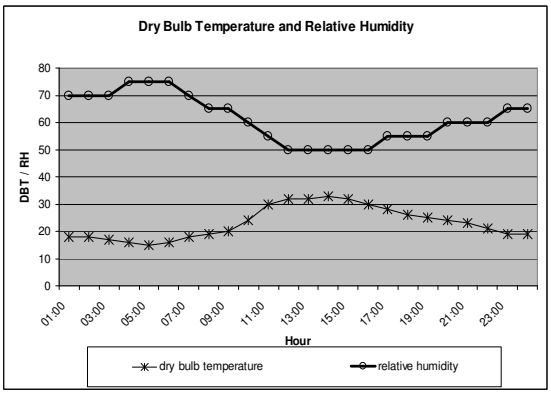

Figure 4 – local weather profiles

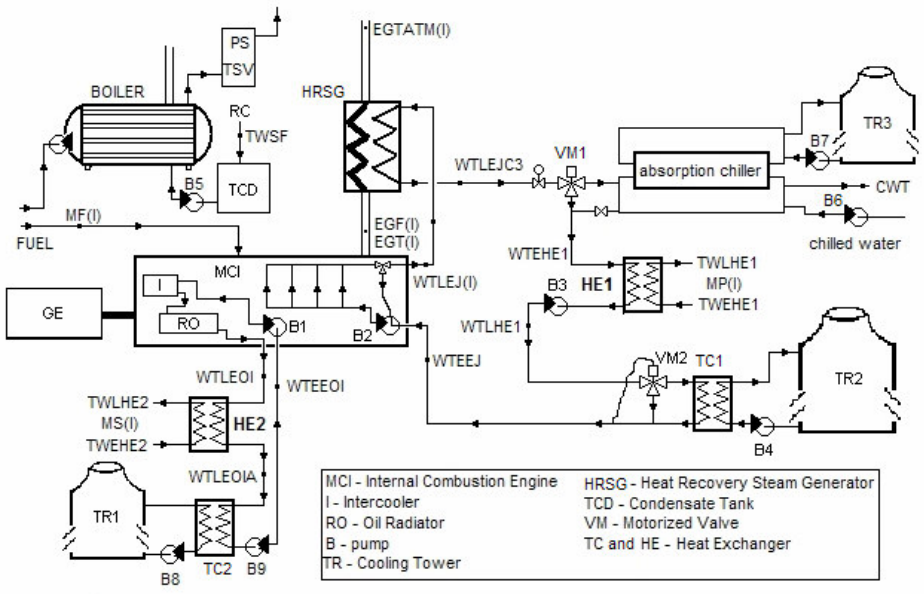

Engine + Exhaust gases heat exchanger + Hot water Absorption chiller + auxiliar heat exchangers

Figure 5 – Cogeneration Scheme

COGENERATION CONCEPTION

Figure 5 shows the cogeneration conception that will be simulated. It's composed by an internal combustion engine, primary and secondary water circuits, an exhaust gases heat exchanger, an absorption chiller and auxiliary equipments (pumps, cooling towers, heat exchangers).

Primary circuit recovery energy from the engine jacket and from the exhaust gases through an exhaust gases heat exchanger. The energy of the primary circuit is used at the absorption chiller and to warm water for sanitary purpose (after recovery at secondary circuit). Secondary circuit recovery energy from the oil radiator of the engine and utilize it to warm water for sanitary purpose.

Figure 6 reveals the energy balance of the engine at full and partial loads and figure 7 reveals the exhaust gases flow and temperature as a function of engine load. Maximum engine efficiency occur at load near 0,8 and correspond to 33%. Corrections for atmospheric pressure and dry bulb temperature are considered. No excess electricity will be sold to the grid, the engine will follow the electricity demand (electrical dispatch).

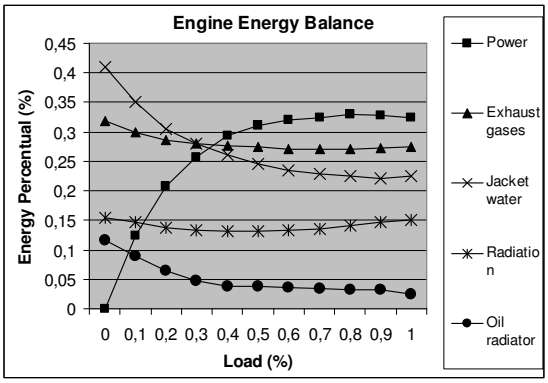

Figure 6 – Engine Energy Balance

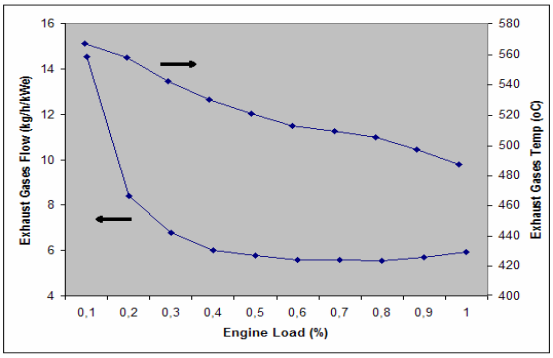

Figure 7 – Exhaust gases flow and temperature

DESIGN PARAMETERS

To compare different sizes of engines to meet the energy loads exposed, we will imagine a family of engine that has the same energy balance (figure 6) and exhaust gases flow and temperature (figure 7).

Four sizes of engines will be evaluated: 200 kW (solution 1), 300 kW (solution 2), 400 kW (solution 3) and 500 kW (solution 4).

At design condition (full load) water (primary circuit) should enter the engine (jacket) at 75° C and leave it at 95° C. After leaving engine hot water enters the exhaust gases heat exchanger.

Exhaust gases heat exchanger was designed to achieve an approach temperature of 11,1° C, with engine at full load. Approach point considers temperature difference between the gases discharged to atmosphere and hot water entering the exhaust gases heat exchanger. Exhaust gases composition are fixed and properties is calculated at mean temperature. Heat loss is equal to 1%.

At design condition water (secondary circuit) enter the engine at 35° C and leave the engine at 50° C. Water flows at primary and secondary circuit are designed considering the energy at the circuit and the design temperature difference.

Heat exchanger HE2 utilized to recovery energy from the secondary circuit (hot water for sanitary purpose) was designed to achieve an approach point of 2° C with the engine at full load.

Heat exchanger HE1 utilized to reheat the hot water for sanitary purpose was designed to achieve an approach point of 5,5°C with engine at full load.

Cooling towers and auxiliary heat exchangers are responsible to reject energy not utilized, preventing engine to operate under unsafe condition. Design of these equipments will not be developed.

Absorption chiller was designed to operate with hot water. Hot water temperature entering absorption chiller is a function of water flow at primary circuit and available energy in the exhaust gases. Absorption chiller was designed considering that hot water should leave it 8,3° C higher then the design temperature of water entering the engine. For solution 1, 2, 3 and 4 an absorption chiller of 70, 112, 148 and 200 tons was selected, respectively (nominal capacity under ARI 560). A drop of 1°C between engine and chiller is considered. Absorption chiller produce chilled water at 7°C with temperature difference of 5,5oC. Cooling water enter condenser at 29,5°C.

Total electricity produced is 3% higher then liquid engine power, taking into account the use of electricity in auxiliary equipments.

The avoided electricity due to the use of an absorption is evaluated at a rate of 1,2 kW/ton.

TECHNICAL RESULTS

Electricity

Simulating the operation of the four cogeneration systems, we have at figures 8, 9, 10 and 11 the electrical profile of the systems.

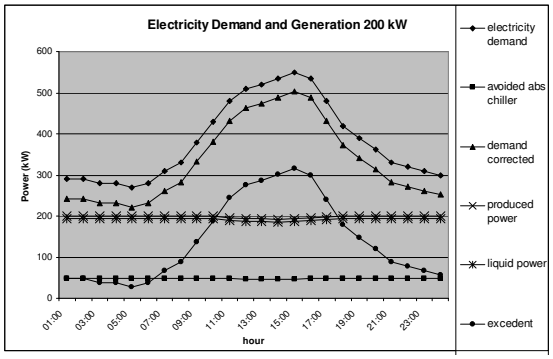

Fig. 8 – electricity demand / generation (200 kW)

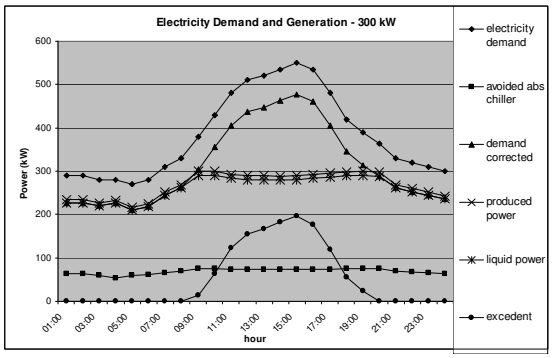

Fig. 9 – electricity demand / generation (300 kW)

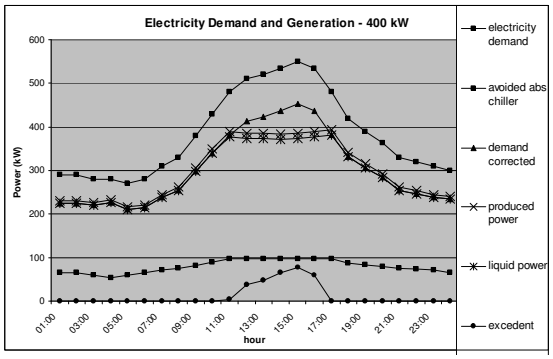

Fig. 10 – electricity demand / generation (400 kW)

Figures shows electricity demand, electricity demand with absorption chiller, total engine power, liquid available power, complement electricity (bought from the grid) and avoided electricity due to cooling load be met by the absorption chiller.

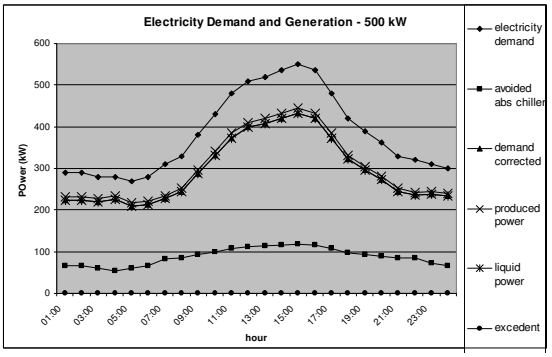

Fig. 11 – electricity demand / generation (500 kW)

It can be seen that at solution 1 the engine will operate at full load all the time, making absorption chiller produce constant capacity. At solution 2 and 3 the engine is expected to operate at full load only at electricity peak hours. At solution 4 the engine is expected to met electricity peak loads.

It's interesting to note the real capacity of the absorption chillers as a function of engine load and the surplus electricity bought from the grid as a function of engine and absorption chiller sizes. At solution 1 absorption chiller produces 40 tons and it's necessary to buy 3414,6 kWh daily. At solution 2 absorption chiller capacity ranges from 45 to 62 tons while total surplus electricity is 1277 kWh daily. For solutions 3 and 4 maximum absorption chiller capacity reaches 82 and 98 tons, respectively, while surplus electricity is equal to 293 kWh daily for solution 3.

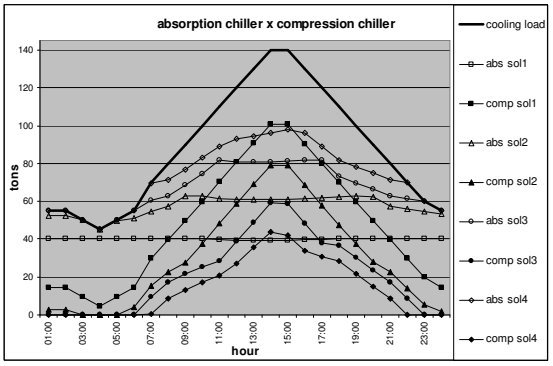

Fig. 12 – absorption and compression chiller loads

Cooling Load / Absorption Chiller

At figure 12 we see the cooling load of the hospital and the real capacity of the absorption

chiller for each solution. At solution 1 the absorption chiller operates at full load during all day. At solution 2 the absorption chiller operates at full load at all day except at hours 3 and 4 where the real capacity of the selected absorption chiller is higher then cooling load. Adopting solution 3 the absorption chiller operates at partial loads during the hours 1 to 6, 23 and 24, at the remaining hours it operates at full load. At solution 4 the absorption chiller will operate at full load between hours 7 and 21. Additional cooling load is met by a compression chiller that is expected to operate following the corresponding curve shown at figure 12.

Figure 13 shows the temperature of hot water entering the absorption chiller, the temperature of hot water leaving the absorption chiller (full load) and the hot water temperature difference at absorption chiller. Engine part load operation produces lower hot water temperature entering absorption chiller and consequent lower hot water temperature leaving absorption chiller. With engine at full load a higher difference of hot water temperature is verified, revealing a higher relation between real and nominal capacity of the absorption chiller.

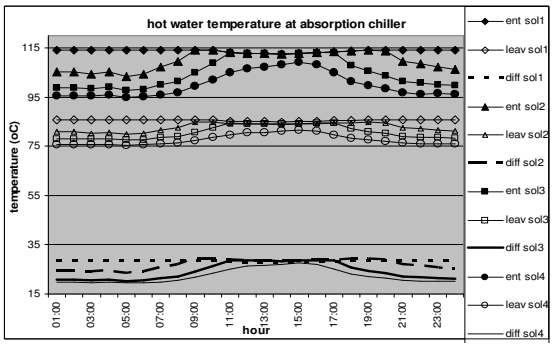

Fig 13 – hot water temperature at absorption chiller

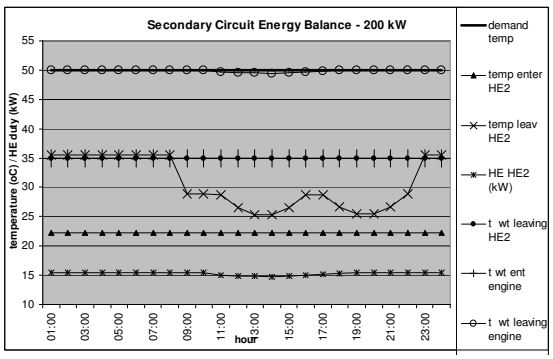

Fig 14 – Secondary circuit energy balance-200 kW

Engine Secondary Circuit (SC)

For the engine here evaluated, the secondary circuit recover energy from oil radiator. The energy at the secondary circuit is used to warm water for sanitary purpose. It can be noted that all hot water demand flow pass through heat exchanger 2 (HE2 – figure 5). Demanded hot water enter HE2 at 22° C (fixed) independent of day hour, and the demanded temperature for hot water is 50° C.

Secondary circuit hot water enter engine at 35° C (fixed) and leave engine at 50° C (full load).

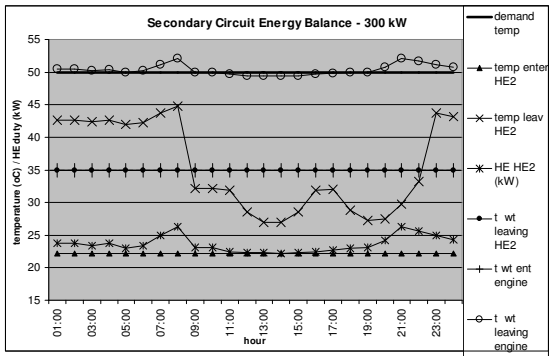

Fig 15 – Secondary circuit energy balance–300 kW

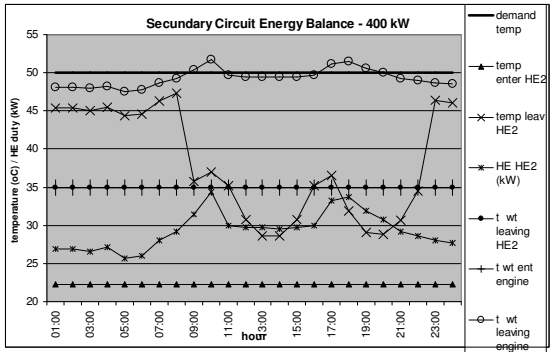

Fig 16 – Secondary circuit energy balance–400 kW

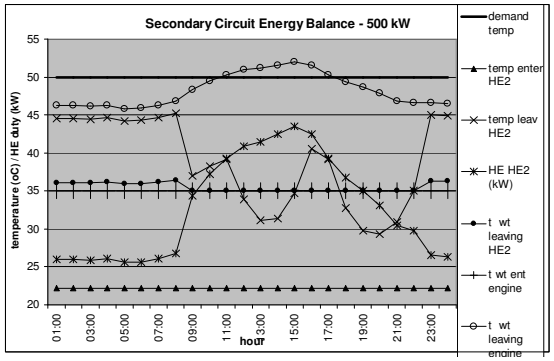

Fig 17 – Secondary circuit energy balance–500 kW

Figure 14 reveals the energy balance for SC adopting solution 1. We can note that hot water for sanitary purpose is warmed to a little more then 35° C when demand is 1 m^3/h. When hot water demand is 2, 3 and 4 m^3/h the water is warmed near to 28, 26 and 25° C, respectively.

Solutions 2, 3 and 4 have similar data, but we note that hot water temperature for sanitary purposes leaving HE2 rises as engine sizes rises.

Variation on temperature of water at secondary circuit leaving the engine is due to engine load variations for solutions 2, 3 and 4. Due to a quick rise of energy percentage at oil radiator for loads between 90 and 100%, the temperature of the water leaving engine is expected to be higher then at design condition.

All the energy of SC is used to warm hot water for sanitary purposes at solutions 1, 2 and 3 (SC hot water leaving HE2 is equal to design SC hot water entering engine). At solution 4, figure 17 reveals that not all the SC energy is used to warm water for sanitary purpose (hours 0-8 and 23-24). Design HE2 approach point is a limit for heat transfer.

Heat transferred at HE2 for all solutions are illustrated at the corresponding figures.

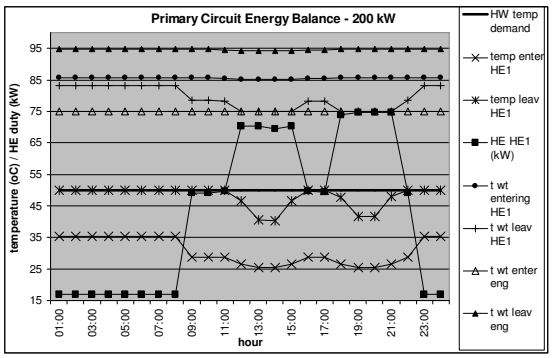

Fig 18 – Primary circuit energy balance–200 kW

Engine Primary Circuit (PC)

PC is responsible by recover energy of engine jacket and energy of the exhaust gases at exhaust gases heat exchanger (EGHE).

After leave the absorption chiller, water of the primary circuit enter HE1 that is responsible to warm hot water for sanitary purpose.

Hot water for sanitary purpose entering HE1 is at the temperature it leaves HE2. It can be seen that for solution 1 the base demand of hot water for sanitary purpose is met, while peak loads should be met by auxiliary equipments. At solutions 2, 3 and 4 a higher part of peak hot water for sanitary demand are met. Solution 3 needs less additional energy to met sanitary water demand at hours 19 to 21 than solution 4, due to part load operation of engine 4.

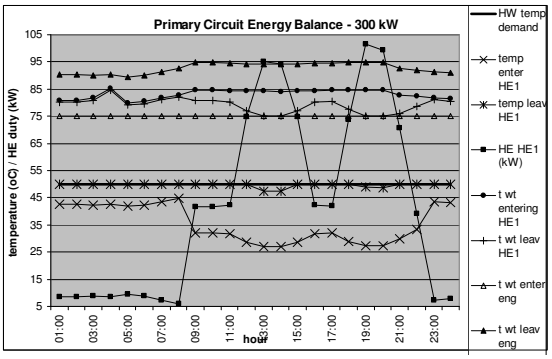

Fig 19 – Primary circuit energy balance–300 kW

Temperature of water leaving HE1 is another variable of interest, since the energy not utilized at HE1 are rejected, to return to engine at 75° C.

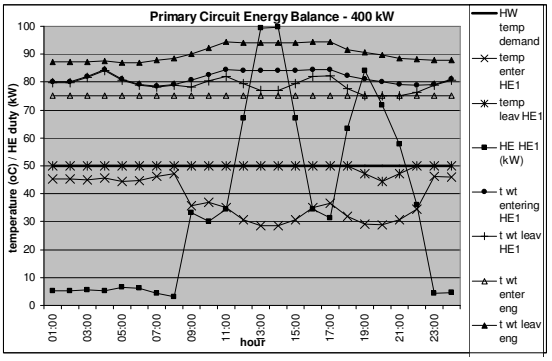

Fig 20 – Primary circuit energy balance–400 kW

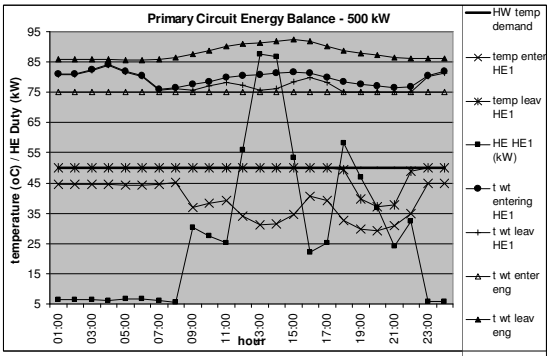

Fig 21 - Primary circuit energy balance–500 kW

It's interesting to note in figures 19, 20 and 21, that for hours 3, 4 and 5, the primary circuit water

temperature leaving absorption is higher then showed at figure 13 as a result of absorption chiller part load operation.

Exhaust Gases Heat Exchanger

Exhaust gases heat exchanger is responsible to recover energy from engine exhaust gases. Figure 22 reveals exhaust gases flow and temperature and the energy exchanged at EGHE for each solution.

Figure 23 reveals PC water temperature entering and leaving EGHE and exhaust gases temperature leaving EGHE (discharge to atmosphere).

For solution 1 PC water temperature entering and leaving EGHE remains almost constant and equal to 95 and 115°C respectively. Exhaust gases leaves EGHE near 106°C, revealing design approach temperature utilized at EGHE (11,1°C), with engine at full load this is also true for others solutions.

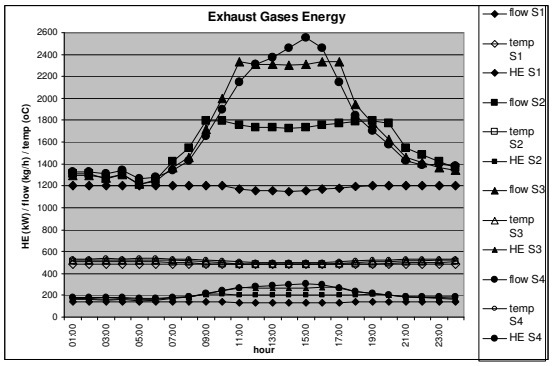

Fig 22 – Exhaust gases flow, temperature and HE.

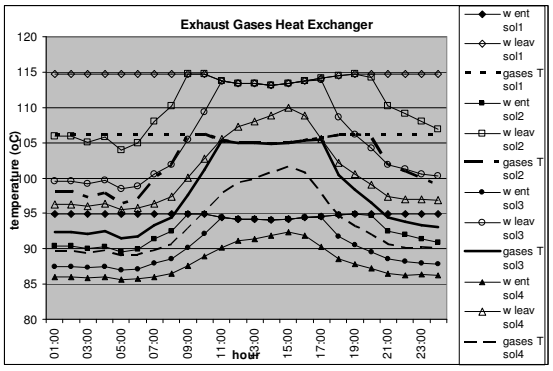

Figure 23 – Exhaust gases heat exchanger

Engine Load and Energy Utilization Factor

Figure 24 shows engines loads and figure 25 the energy utilization factor achieved on the hourly profile analysis.

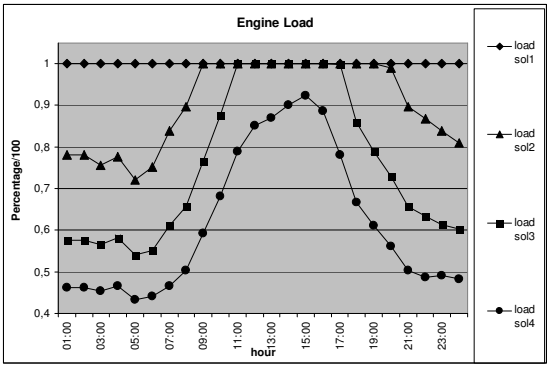

Figure 24 – Engine load

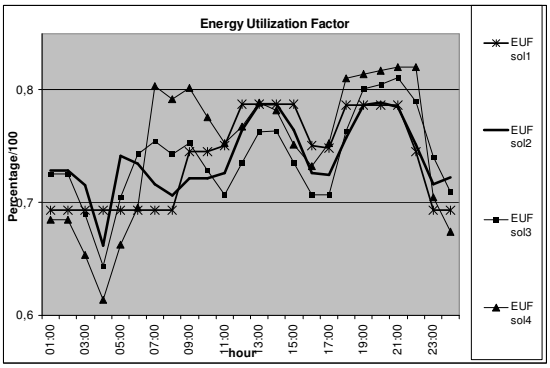

Figure 25 – Energy utilization factor

At solution 1 the engine operates at full load all the time, while for solutions 2 and 3 the engine is expected to follow electricity demand, operating at full load at high electricity demand hours. At solution 4 the engine is expected to operate with loads between 0,43 and 0,92.

Energy utilization factor is defined as the energy of the engine that is utilized by other system as a result of demands requirements, then the energy utilized at absorption chiller is computed and not the energy produced.

Energy utilization factor is a function of engine electrical efficiency (load), energy distribution at primary and secondary circuits and energy demands (electricity, cooling load and hot water).

At solution 1 EUF remains constant until hour 8, when it raises following hot water for sanitary purposes demand profile. Returning to figure 18 we can see the primary circuit water temperature leaving HE1, and justify it as the responsible by EUF rise. A medium EUF of 0,738 was found.

At solution 2 we see a quick decrease in EUF due to the operation of the absorption chiller at part load in hours 3 and 4. A medium EUF of 0,74 was found.

At solution 3 absorption chiller operate at partial load until hour 6, while the engine operate at partial loads until hour 11. A medium EUF of 0,739 was found. At solution 4 the engine operates at partial load all the time. Absorption chiller operates at full load between hours 7 and 21. Instantaneous high EUF is found at hour 22 (0.82). A medium EUF of 0,748 was found. Figure 26 reveals solution 4 engine energy balance.

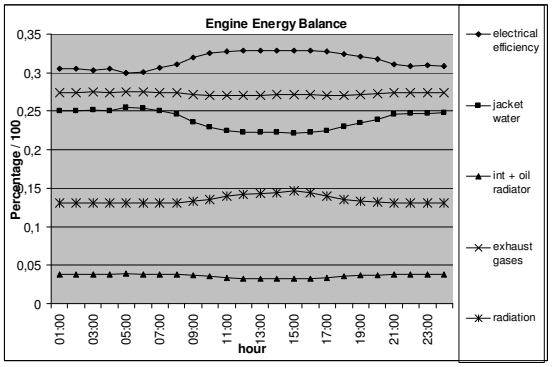

Figure 26 - 500 kW engine energy balance

CONCLUSIONS

Results here exposed were obtained through a program developed in Fortran with Delphi interface. The program is formed by one main program and more then twenty subroutines. Main program controls entrance data, report results and control all the procedures calculations. Several iterative procedures are involved, conducting results as a function of thermal loads, engine energy balance, design parameters, etc, to a converged point where all the individual equipments are expected to be in operation as a unique system.

Each solution has different nominal capacity of absorption chiller selected accordingly with design parameters and available nominal capacity on the market. Each solution has a different relation of nominal tonnage per engine nominal power.

Analysis of demand and availability can help decide to recover or not energy from secondary circuit.

High energy utilization factor was achieved for all solutions evaluated. Coincident loads profile (peak load of electricity, cooling load and hot water) contributes for these results. There is not a direct relation to evaluate EUF since we must evaluate and compare engine load, cooling load and absorption chiller load, heat exchangers simulations and hot water demand. Evaluate the variation on EUF for all the equipments individually help understand fig 25.

For the engine under evaluation radiation has a high participation on energy balance, limiting EUF for some hours.

Solution 1 has the best load factor for all the equipments involved. Justifying equipments cost acquisition, and probably a short payback period.

Considering a natural gas with low heating value of 45460 kJ/kg engines 1, 2, 3 and 4 have a daily consumption of 1159,2 kg, 1564,5 kg, 1758 kg and 1813,7 kg respectively. Solutions 1, 2, 3 and 4 produces 4756,6 kWh, 6447,1 kWh, 7187,9 kWh and 7285,7 kWh of electricity per day, respectively.

Results are particular for the engines under evaluation and are not conclusive about all possibilities. Economic analysis can reveal the better option considering costs and legal aspects.

ABSTRACT

Steam Reforming of Natural Gas is, at the moment, the most economical process for producing hydrogen. This work performs an exergetic and exergoeconomic study of this process. The main steps in hydrogen production from steam reforming are the reforming reaction, the shift reaction and the hydrogen purification. The final hydrogen has purity of about 99,999% (wt) and can be used in fuel cells. Synthesis Gas containing H_2, H_2O, CO_2, CO and residual CH_4 is formed inside the reformer; its composition depends on the Steam-CH_4 ratio and the temperature-pressure conditions. Equilibrium conditions in the synthesis gas components are considered at reformer exit. After reforming, shift reaction converts CO and H_2O into CO_2 and H_2. Absorption in diethanolamine is used to separate CO_2 from the gas stream. CO_2 can be collected and sold as a by-product. Fixed adsorption beds are used to purify the hydrogen, eliminating H_2O, CO_2 and CO and CH_4 residuals. An exergy analysis was performed in this process identifying the main sources of irreversibility. The exergy flows are disaggregated into chemical and physical exergies. The theory of exergetic cost is applied to analyse the internal cost distribution. The results are discussed.

Keywords :exergy, exergoeconomy, hydrogen production, steam reforming.

NOMENCLATURE

K - Equilibrium constant
k - Unitary exergetic cost
P - Exergetic product [kW]
F - Exergetic fuel [kW]
I - Exergetic irreversibility [kW]
Ex - Exergy
ε - Exergetic efficiency *F-P* method
ζ - Exergetic efficiency input-output method
α - Chemical coefficients of reactants
β - Chemical coefficient of products

INTRODUCTION

Light hydrocarbons, especially methane, are the main source of hydrogen because they have a low production cost associated to large reserves all over the world [1]. Reforming of natural gas is the most economical way to produce hydrogen [2]. The process is described in three main steps: reforming, a highly endothermic reaction between H_2O and CH_4, shift reaction, an exothermic reaction between CO and H_2O producing H_2, and purification of hydrogen, where highly pure H_2 is separated.

[*] Corresponding author: phone: +55-19-37883285; fax: +55-19 32893722; email: lourenco@fem.unicamp.br

During purification, a large amount of CO_2 is produced as by product. In the simulation, natural gas was assumed as simply methane.
Some authors studied this process analysing energetic ([3],[4]) and exergetic consumption ([5], [6]).
During reforming, natural gas and steam react over nickel catalyst producing H_2, CO and CO_2, synthesis gas. Some of steam and methane persist in the synthesis gas. This reaction is highly endothermic and needs a source of heat, which is, generally, the same natural gas.
Hydrogen purification is performed through absorption in amine, followed by adsorption. During absorption large amount of CO_2 is produced as by product. Adsorption is the last step of purification process.
The H_2 production process was based on Rosen proposal [5] modified to incorporate an adsorption unit to produce highly pure H_2. In the adsorption unit, gas stream passes through an adsorbent bed and exits purified. Purity up to 99,999 % H_2, (in weight), is achieved [7].

STEAM METHANE REFORMING

The global reforming reaction between methane and steam can be represented generally as Equation (1), and the partial reactions as Equation (2) and (3):

$$\alpha_1 CH_4 + \alpha_2 H_2O \rightarrow \beta_1 CH_4 + \beta_2 CO + \beta_3 CO_2 + \beta_4 H_2 + \beta_5 H_2O \quad (1)$$

$$CH_4 + H_2O \rightarrow CO + 3\,H_2 \quad (2)$$

$$CO + H_2O \rightarrow CO_2 + H_2 \quad (3)$$

Starting from inputs α_1 moles of methane and α_2 moles of steam, the β coefficients in Equation (1) are determined based upon chemical equilibrium hypothesis of (2) and (3) reactions and element balances. The SMR was performed using sthoichiometric steam to methane ratio 2:1. Figure 1 shows a scheme of the process.
The process needs material inputs, methane (30 bar) and water (101.3 bar and 25ºC), and power inputs to water pump and absorption unit.

Process description

Water enters at environmental pressure and temperature and is compressed up to 3 MPa, heated and evaporated in a boiler, HR2, and is mixed with methane previously heated in a heat exchanger, HR3. (See Figure 1).
The mixture of steam and methane go to heat recovery HR1 and to reformer, where synthesis gas is produced. Methane is burnt in the combustion chamber to provide heat to reforming that occurs over nickel catalyst at 950ºC.
Inside reformer, synthesis gas rich in H_2 and CO is formed. Synthesis gas passes through shift reactors to reduce CO producing H_2, and goes to purification.

Reforming

The reforming step is composed of a heat recovery, HR1, the reformer and a boiler, HR2. HR1 heats the methane and steam mixture before reformer. HR2 produces superheated steam. The reformer is composed of a fixed bed with nickel catalyst.

Shift Reaction

The shift reaction is a reaction between CO and H_2O to reduce CO and produce H_2. To be more efficient, this reaction occurs in two steps: high temperature shift reaction, HTSR and low temperature shift reaction, LTSR, both occur in a fixed bed with catalyst. Shift reaction is exothermic, and after each shift reactor a heat recovery is used to heat methane and air that go to combustion chamber. After HTSR, gas stream is at 238 °C and after LTSR is 182 °C. Shift reduces the amount of CO from 15,1 % to 1,7 % in the HTSR and to 0,8 % in the LTSR.

Absorption Unit

CO_2 is separated in absorption unit and sold as a by-product. In this unit, CO_2 molar ratio is reduced from 18% (71.81 % wt) to 0.62 % (6.82 % wt). After absorption unit H_2 mol ratio is of 89%.
A solution of Diethanolamine in water at 30% was used as absorbent. Absorption of CO_2 in amine is of chemical absorption type. Amine is alkaline and CO_2 is an acid gas.
Absorption was modelled based on [8] and [9]. The absorption unit was idealised based on Ruthven description[10]. Figure 2 has a scheme of the absorption unit. The phenomenon is described as:

$$RNH_3 \overset{K_1}{\longleftrightarrow} H^+ + RNH_2 \quad (4)$$

$$RNHCOO^- + H_2O \overset{K_2}{\longleftrightarrow} RNH_2 + HCO_3 \quad (5)$$

$$CO_2 + H_2O \overset{K_3}{\longleftrightarrow} H^+ + HCO_3^- \quad (6)$$

$$HCO_3^- \overset{K_4}{\longleftrightarrow} H^+ + CO_3^{2-} \quad (7)$$

$$H_2O \overset{K_5}{\longleftrightarrow} H^+ + OH^- \quad (8)$$

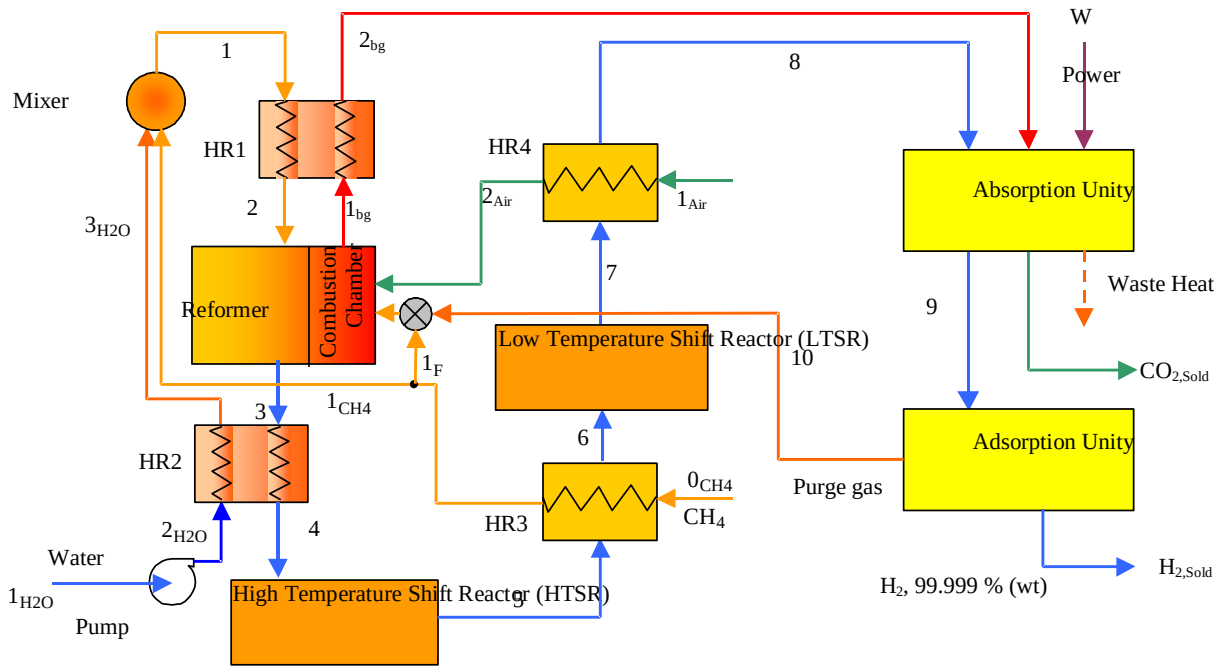

Figure 1 - Schematic of SMR process.

The equilibrium constants are:

$$K_1 = \frac{[RNH_2][H^+]}{[RNH_3^+]} \quad (9)$$

$$K_2 = \frac{[RNH_2][HCO_3^-]}{[RNHCOO^-]} \quad (10)$$

$$K_3 = \frac{[H^+][HCO_3^-]}{[CO_2]} \quad (11)$$

$$K_4 = \frac{[H^+][CO_3^{2-}]}{[HCO_3^-]} \quad (12)$$

$$K_5 = [H^+][OH^-] \quad (13)$$

Before pass through absorption column, the gas is cooled until 40ºC to promote better absorption. The absorbent and the gas flow in counter current along the absorption column, the CO_2 is carried out by the absorbent. To promote stripping, the absorbent is heated to 70 ºC and the pressure is reduced to 40 kPa.

As higher heating is, as better desorption is. The heating limit is the bubble point temperature of solution. To heat the absorbent solution, the unit has two heat exchangers

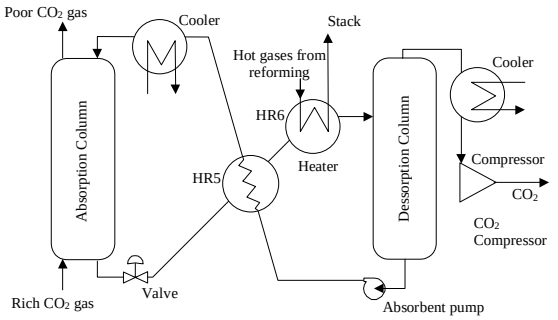

Figure 2 - Scheme of DEA absorption unit.

Adsorption unit

Adsorption is the last step in H_2 production. Its role is purifying H_2 up to 99.999 % (wt). This high purity is due to the elevated selectivity of hydrogen in the adsorbent bed related to CO_2, CO, N_2, CH4 and H_2O. Silica gel, activated carbon and zeolites compose the beds [7].

In this unit, a system of valves improves adsorption and regeneration of beds in a Pressure Swing Adsorption - PSA. At least four beds are required to improve PSA in order to establish the process near to steady state, while one bed is adsorbing, the others are regenerating, more details can be seeing at [7] and [11]. Steady state was assumed in adsorption process.

This system divides gas stream into two flows: pure hydrogen and purge gas. Purge gas is burnt in the combustion chamber. For this purge gas a Low Heat Value of 25400 kJ/kg was calculated. The purge stream saves 82 % of methane.
Due to PSA system, hydrogen exits at high pressure while purge gas at atmospheric pressure.
Recuperation factor, understood as amount of hydrogen present in the stream that is separated after adsorption cycle, was assumed as 82%. This value was based on [7] and [12].
Although adsorption process is an exothermic one it can be approximated as an isothermal process. This hypothesis is applied to cyclic process with short duration adsorption phase ([7], [11]).

EXERGETIC ANALYSIS

In order to improve exergetic analysis, the process was divided into several control volumes CV and each performance relative to its function.was determined. Some considerations were assumed:

- Environmental standard temperature and pressure conditions T0=25ºC and P0=101,3 kPa to exergy calculus. The composition was assumed as that proposed by [13].
- Efficiencies determined according to *Fuel* F, *Product* P and *Irreversibility* I concept [14], ε, or input output method, ζ, for dissipative control volumes. These efficiencies are defined as:

$$\varepsilon = \frac{P}{F} \quad (14)$$

$$I = P - F \quad (15)$$

$$\zeta = \frac{Ex_{in}}{Ex_{out}} \quad (16)$$

$$\zeta = Ex_{in} - Ex_{out} \quad (17)$$

Where Ex_{in} e Ex_{out}, are total exergies that enter and exit from CV respectively.
The exergy of a gas mixture is calculated as sum of each mixture component exergy plus the reversible isothermal work to compress (or decompress) from its partial pressure P_k to $P_{\infty,k}$ of the component in the environment [14] So, chemical exergy is calculated as:

$$\bar{e}x_{ch} = \sum_k x_k \bar{e}x_{ch,k} + RT_0 \sum_k x_k \ln(x_k) \quad (18)$$

Applying previous considerations to each CV according to figure 1:

Water pump:

$$F = \dot{W}_{pump} \quad (19)$$

$$P = Ex_{2,H_2O} - Ex_{1,H_2O} \quad (20)$$

Heat Exchanger 1 (HR1):

$$F = Ex_{1,bg} - Ex_{2,bg} \quad (21)$$

$$P = Ex_2 - Ex_1 \quad (22)$$

Heat Exchanger 2 (HR2):

$$F = Ex_3 - Ex_4 \quad (23)$$

$$P = Ex_{3;H2O} - Ex_{2;H2O} \quad (24)$$

Heat Exchanger 3 (HR3):

$$F = Ex_5 - Ex_6 \quad (25)$$

$$P = (Ex_{1;CH4} + Ex_{1;F}) - Ex_{0;CH4} \quad (26)$$

Heat Exchanger 4 (HR4):

$$F = Ex_7 - Ex_8 \quad (27)$$

$$P = Ex_{2;Ar} - Ex_{1;Ar} \quad (28)$$

Reformer:

$$F = (Ex_{1;F} + Ex_{11}) - Ex_{1,bg} \quad (29)$$

$$P = Ex_3 - Ex_2 \quad (30)$$

High Temperature Shift Reactor (HTSR):

$$F = Ex_{ch,4} - Ex_{ch,5} \quad (31)$$

$$P = Ex_{ph,5} - Ex_{ph,4} \quad (32)$$

Low Temperature Shift Reactor (LTSR):

$$F = Ex_{ch,6} - Ex_{ch,7} \quad (33)$$

$$P = Ex_{ph,5} - Ex_{ph,6} \quad (34)$$

For dissipative CV:
Mixer

$$Ex_{in} = Ex_{3,H2O} + Ex_{1,CH4} \quad (35)$$

$$Ex_{out} = Ex_1 \quad (36)$$

Absorption Unit

$$Ex_{in} = Ex_8 + Ex_{2,b} + \dot{W}_{ABS,pump} + \dot{W}_{CO2,Comp} \quad (37)$$

$$Ex_{out} = Ex_9 + Ex_{CO2,Sold} \quad (38)$$

Adsorption Unit

$$Ex_{in} = Ex_9 \quad (39)$$

$$Ex_{out} = Ex_{10} + Ex_{H2,Sold} \quad (40)$$

Where $\dot{W}_{pump}$ and $\dot{W}_{ABS,pump}$ are the power required by water and absorbent solution pumps, respectively, $\dot{W}_{CO2,Comp}$ is the power required by vacuum pump at stripping column; $Ex_{CO2,Sold}$ and $Ex_{H2,Sold}$ are the product exergies, CO_2 and H_2.
All these parameters were calculated related to 1 kmol/s of methane that enters in the reformer. These parameters are shown in Table 1.

Table 3: Exergetic Efficiency of CV

The exergetic balance identifying irreversibility along the cycle is made based on these previous values. Table 5 shows irreversibility of each CV.
It can be observed that the main source of irreversibility is the reformer (combustion chamber comprised), 52.7% of net irreversibility. This characteristic is due combustion, according discussed in [15].

EXERGOECONOMIC ANALYSIS

It was adopted the Exergetic Cost Theory proposed by [16] to perform exergoeconomic analyse of the process.
In order to apply this theory some considerations were made:

1) Input flows have unitary exergetic cost equal to one:

$k_{0,CH4} = 1$

$k_{1,H2O} = 1$

$k_{1,Ar} = 1$

$k_P = 1$

Where k_P is the power cost.

Flow	Ex_{ph} (kW)	Ex_{ch} (kW)	Ex (kW)
1_{H2O}	0	18980	18980
2_{H2O}	115,5	18980	19096
3_{H2O}	115183	18980	79249
0_{CH4}	9270	917936	927207

$H_{2,Sold}$	20078	681388	701466

Table 4: Flow exergies related to 1 kmol/s of inlet methane.

2) Streams that are fuel have same unitary exergetic cost.

$k_4 = k_5$

$k_7 = k_6$

$k_9 = k_8$

$k_{1,b} = k_{CC,In}$

$k_{1,b} = k_{2,b}$

Where $K_{CC,In}$ is the unitary exergetic cost of total exergy that enters combustion chamber and is determined as:

$$K_{CC,In} = \frac{Ex^*_{1F} + Ex^*_{13} + Ex^*_{2,Ar}}{Ex_{1F} + Ex_{13} + Ex_{2,Ar}} \qquad (41)$$

Table 5 - Irreversibility in each control volume

3) Flow division, the streams have same unitary exergetic cost:

$k_{1,CH4}=k_{1,F}$

4) Main utility of CV:

CO_2 is a by-product of a hydrogen production plant. If this concept is applied to the absorption unit, whose main objective is to concentrate H_2, the unitary exergetic cost of CO_2 separated would be the same of inlet stream in the CV. Another possible interpretation is that the main objective of the absorption unit is to produce CO_2 , in this case, the exergetic cost of the CO2 separated would be different from the inlet stream, carrying the irreversibility cost generated in the unit. In this paper, the first concept is applied. This option penalises the final cost of hydrogen.

$k_8 = k_{CO2}$

Doing analogous consideration to adsorption unit, stream of purge gas does not change the unitary exergetic cost related to stream 9.

$k_9 = k_{10}$

Based on previous considerations, exergetic cost equations can be written, whose numerical results are expressed in Table 6.

CONCLUSIONS

This work simulated SMR hydrogen production in order to apply exergoeconomic tools, the method chosen was Unitary Exergetic Cost Theory.

Some important considerations were assumed to perform the simulation: temperature of reformer, 950 ºC; recuperation factor of hydrogen in the adsorption unit as 82 %; ideal gas mixture in the flows.

The reference environment was adopted as that proposed in [13] as well as the methodology to determine chemical exergy.

Exergetic analysis showed that the main source of irreversibility is the combustion inside combustion chamber of reformer. Irreversibility of reformer is 53 % the greatest along the process. This result is according to expected. Reform methane is the main step in hydrogen production; the simulation showed that 80% of hydrogen produced along the process is in the reforming step and 20% in shift reaction.

The second biggest source of irreversibility was the absorption unit, 26 % of total irreversibility. This result is due to the heat consumption, power to absorbent and CO_2 compressor and many heat exchangers wasting exergy to improve separation of CO_2 in this unit.

Adsorption unit produces only 3 % of total irreversibility. This low irreversibility generation has some reasons: isothermal process in ideal gases, in this condition, enthalpy of ideal gas remains unchanged; so, no heat and power consumption appear in this unit. The biggest reduction of pressure, source of irreversibility,

happens in the purge gas that has lower exergy than hydrogen flow.

Considering the exergies of H_2 and CO_2 products, the net process efficiency was 75.4 %. If CO_2 can not be used, its exergy must be neglected; in this case the net efficiency diminishes to 73.6 %.

The biggest unitary exergetic cost appeared in Nr. 2_{air} flow. This flow is heated in HR4 by 7 -8 flow.

The high unitary exergetic cost of this flow is due that it carries all the irreversibilities in the balance of HR4 and also to its low total exergy,

The second biggest unitary exergetic cost was in Nr. 3_{H2O}.flow. The situation is similar to the previous case, when the exergetic cost balance is applied to heat exchanger HR2. This CV accumulates two functions: evaporating and superheating the steam flow. The high irreversibility is due to high temperature difference between hot and cold side.

The exergoeconomic analysis assumes hydrogen as the main product and CO_2 as a by-product. The exergetic cost of H_2 is not the biggest exergetic cost because the regenerating process of adsorbent beds necessitates 18% of H_2 separated to perform regeneration.

Possibilities of variations of the exergoeconomic analysis that lead to different result are:

1. Adopt CO_2 as a product of process. The plant produces H_2 as well as CO_2 to sell. This analysis makes sense only if the process has a near consumer. Even if it is possible, the noblesse of hydrogen is always superior to that of dioxide carbon.
2. Adopt CO_2 as a flow without commercial utility. In this case the cost of CO_2 flow must be zero making H_2 more expensive.

COMPARISON OF PULP-MILL INTEGRATED HYDROGEN PRODUCTION FROM GASIFIED BLACK LIQUOR WITH STAND-ALONE PRODUCTION FROM GASIFIED BIOMASS

E. Andersson* and S. Harvey
Chalmers
Department of Energy and Environment
Sweden

ABSTRACT

When gasified black liquor is used for hydrogen production at a pulp mill site, significant amounts of biomass must be imported. This paper compares two alternative options for producing hydrogen from biomass: (A) pulp mill integrated hydrogen production from gasified back liquor; and (B) stand-alone production of hydrogen from gasified biomass. The comparison assumes that the same amount of biomass that is imported in alternative A is supplied to a stand-alone hydrogen production plant and that the gasified black liquor in alternative B is used in a BLGCC (Black Liquor Gasification Combined Cycle) CHP unit. The comparison is based upon equal amounts of black liquor fed to the gasifier, and identical steam and power requirements for the pulp mill. The potential for delivering low temperature excess heat to a district heating system is considered. The two systems are compared on the basis of total CO_2 emission consequences, based upon different assumptions for the reference energy system that reflect different societal CO_2 emissions reduction target levels. If the reference energy system includes electricity production in coal-fired power plants without CO_2 sequestration and car engines that are 30% more efficient than today's , the best alternative is to use the biomass in a stand-alone hydrogen production unit. However, if electricity production has lower CO_2 emissions , hydrogen produced with gasified black liquor integrated in the pulp mill can achieve the largest CO_2 emissions reduction.

INTRODUCTION

Background

Efforts to reduce greenhouse gas emissions favor the use of renewable energy sources. Biomass is an important renewable energy resource. Assuming that only a limited supply will be available in the future, it is essential to use biomass as efficiently as possible.

EU has set a target for renewable fuel usage in the transportation sector of 5.75% by 2010 [1]. With an expanding transportation sector, this is a challenging target. Furthermore, the target is probably quite modest compared to the anticipated need for CO_2 reduction in order to meet expected demanding targets for greenhouse gas emission reduction. Another motivation for finding renewable transportation fuels to replace

oil-based fuels is to secure the supply for a sector that will be even more dependent on imported fuels in the near future. This means that there could be a large demand for locally produced, renewable transportation fuels in the future. Other important options for the transportation sector include reducing the need for transportation, enhancing public transportation and using more fuel-efficient cars.

According to Azar el al [2], conventional oil-based fuels will remain dominant for transportation for the next 50 years. Hydrogen is expected to be the preferred choice when alternative fuels are introduced. Hydrogen will be particularly attractive if CO_2 separation and sequestration becomes an available technology.

In a future Hydrogen society, fuel cell vehicles are expected to be used since they use fuel more efficiently than cars with internal combustion engines. The advantages of using locally produced hydrogen in fuel cell vehicles have been discussed by Ogden et al [3], who conclude that the hydrogen fuel cell car has the lowest projected life-cycle costs if mass-produced and if a high value for external costs is considered. External costs include costs associated with air pollution, climate change and oil supply insecurity. Ogden's calculations are based on hydrogen produced from natural gas with CO_2 sequestration.

In the industrial sector, future pulp mills are expected to have a surplus of energy [4]. Most of the energy surplus is in the black liquor, the remaining fraction of the wood after extracting fibers for papermaking. The energy content of black liquor is currently recovered through combustion in a recovery boiler. Gasification is an alternative option, producing a syngas containing H_2, CO and CO_2 that can be used to produce electricity or upgraded biofuels, such as DME, methanol or hydrogen. A third option to use the excess energy in future pulp mills is to extract lignin from the black liquor and export it as biomass fuel, as discussed in [5]. This option was however not investigated in this study.

Previous studies have evaluated energy and net CO_2 emissions consequences of integration of hydrogen production from gasified black liquor in a chemical pulp mill and compared it with other uses of black liquor, including gasification and firing in a gas turbine combined cycle CHP unit (BLGCC) [6].

Objective

When hydrogen is produced from gasified black liquor, pulp mill steam must be generated in a biofuel boiler using imported biomass fuel. This study evaluates whether production of H_2 from black liquor is advantageous, with respect to CO_2 emissions reduction, or if the same amount of biomass should rather be used for H_2 production from gasified biomass in a stand-alone unit.

Method and assumptions

The methods used are described in the next three sections. The first section defines the compared systems, the second section provides input data background and the third section explains the methodology for CO_2 emissions calculations.

Important assumptions for the evaluation are:

- biomass is CO_2 neutral
- biomass is a limited resource
- demand for electricity, heat or transportation fuel is constant
- biomass is used to a great extent in DHS. If excess heat from a process can be delivered to DHS, biomass will be released for possible use in other applications.

HYDROGEN PRODUCTION SYSTEMS

The two hydrogen production systems are defined below. The expanded systems both produce the same amounts of electricity [MJ], transportation service [km] and heat [MJ]. They both include a pulp mill with the same input of wood and the same output of pulp, black liquor and biomass (bark), and with the same electricity and heat demand.

Hydrogen production units contain process streams with high CO_2 concentrations. This facilitates CO_2 separation. This option was not however included in this study.

Systems description

System A involves hydrogen production from black liquor integrated in a pulp mill, shown by the inner circle in Figure 1. Inputs to System A are wood, biomass and electricity and the products are pulp, hydrogen and heat.

System B produces hydrogen from gasified biomass. The objective is to compare the CO_2 emissions from the two hydrogen production

systems, based on the same input of biomass. Since input of wood to the pulp mill is part of the biomass input to System A, the system boundary for System B includes a pulp mill and associated energy flows. System B is the inner circle in Figure 2. The inputs to System B are wood and biomass and the outputs are pulp, hydrogen, electricity and heat.
The pulp mills in Systems A and B are identical, with the same pulp and black liquor flows, the same biomass (bark) surplus and the same steam and power demand.

Expanded systems

To calculate the CO_2 emissions, Systems A and B are expanded to include the reference energy system, where the output of electricity, transportation service, heat service and case-dependent energy service from the systems are identical.

Fossil fuel use for production of electricity and transportation fuel is increased or decreased to maintain a constant total production of electricity and transportation services. Biomass input for hydrogen production is the same in Systems A and B (underlined). If excess process heat can be delivered to the DHS, more biomass will be available for other uses (as defined in the reference energy cases). The net amount of available biomass is assumed to be constant.
Changes of biofuel usage in Systems A and B therefore lead to changes in amounts of biomass available for the reference use (Case dependent). The amount of case-dependent energy service delivered by the expanded system is constant, which also leads to variations in amounts of fossil fuel usage and CO_2 emissions.

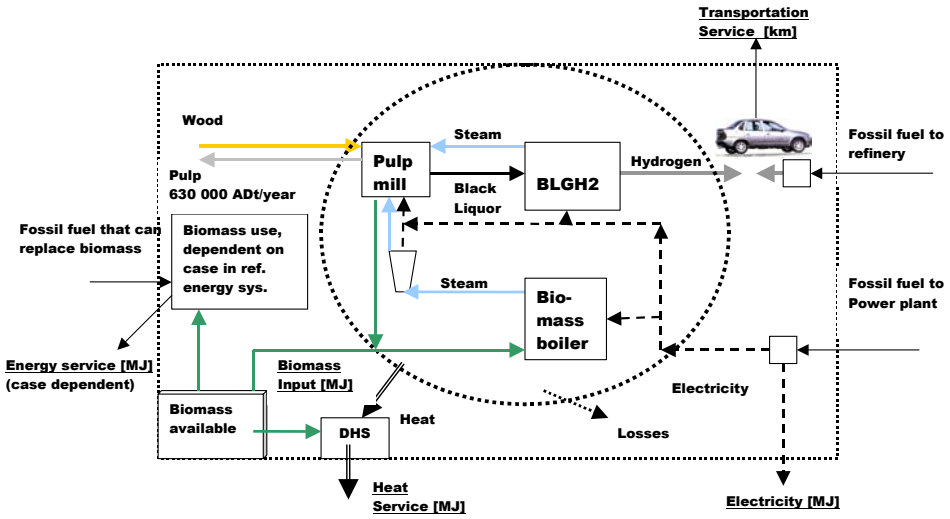

Figure 1 System A: H_2 production from gasified black liquor. The expanded system includes the reference energy system.

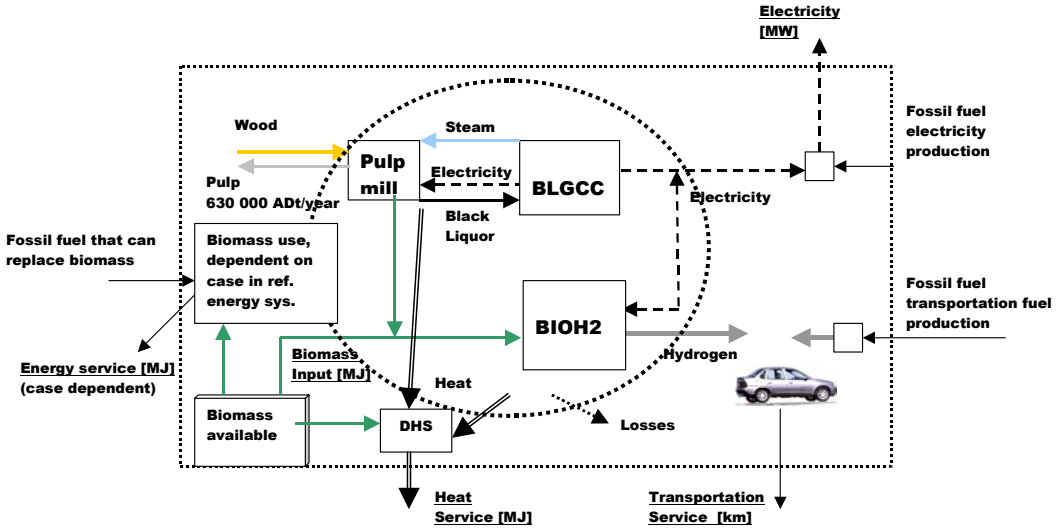

Figure 2 System B: H_2 production from gasified biomass and BLGCC. The expanded system includes the reference energy system.

INPUT DATA

Pulp Mill

The pulp mill energy flows used in the calculations are based upon results from the KAM 2 reference mill project developed within the Swedish research program KAM (Kretslopps Anpassad Massafabrik) [4]. The mill is assumed to incorporate the best available technology built and commercially used in the Swedish and Finnish pulp industry today. The pulp production is 630 000 ADt/year.

Hydrogen from gasified black liquor

The gasifier assumed for the calculations in this work has not been operated comercially, but is based on technology that has been developed since 1960. No pulp mill has yet fully replaced Tomlinson boiler technology with a black liquor gasification recovery system, but gasification plants have been introduced as booster units in parallel with existing recovery boilers to increase the plant's throughput. In these applications the performance of the gasification plant has been validated [7].

In System A, hydrogen is produced according to the process described in [8]. The possibility to deliver excess heat as district heating was evaluated and included in the energy balances for this study. Excess heat is available at the pulp mill and the hydrogen production unit. The heat is exported to a DHS, leading to biofuel savings.

Hydrogen from gasified biomass

In System B, hydrogen is produced from gasified biomass in a stand-alone production unit. The system includes a black liquor gasification combined cycle (BLGCC) unit for electricity production. The reason for selecting BLGCC is that previous studies have shown that BLGCC is an interesting alternative to a recovery boiler from a technical, economical and environmental perspective [6,9,10,11]. The excess biomass from the pulp mill is used for hydrogen production in the stand-alone facility.

Energy balances for the BLGCC plant are based on results presented in [10], in which electricity is assumed to be produced in a condensing steam turbine unit. In this paper we also evaluate the plant's energy balance assuming a back-pressure steam turbine unit delivering heat for district heating. In addition, excess heat is also available from the pulp mill.

Hydrogen production from gasified biomass has not been operated commercially. Estimated conversion efficiencies presented in the literature vary from 0.55 to 0.75 [12,13,14]. The data for a stand-alone hydrogen production unit adopted in

this work is based on the results of Hamelinck and Faaij [12], who report conversion efficiencies in the interval 0.6-0.66, which is a good average of other published studies. In addition, Hamelinck and Faaij present detailed energy balance calculations for different process configurations that produce hydrogen and electricity in different proportions with the same input of biomass. With a back-pressure turbine, excess heat can be delivered for district heating from the biomass gasification unit. To select the stand-alone facility configuration, the different configurations were assessed using the same evaluation method that was used for the final results later on (see "Evaluation of total CO_2 emissions using reference energy systems"). The configuration with the largest reduction of CO_2 emissions in each reference energy system case is retained for the stand-alone hydrogen production unit.

Limitations

CO_2 emissions associated with extraction of wood or production of chemicals used in the pulp production process are allocated to the pulp product and are not included. CO_2 emissions from construction of equipment for included processes or transportation vehicles are not included.

EVALUATION OF TOTAL CO_2 EMISSIONS USING REFERENCE ENERGY SYSTEMS

The CO_2 emissions from the expanded systems are based upon emissions associated with additional fossil fuel provided to the systems or avoided fossil fuel use. Fossil fuel is used for production of electricity and transportation fuel or to provide the same energy service that is provided by the reference use of biomass.
CO_2 emissions will depend on the technology used and the expected use of biomass. For this evaluation we assume different reference energy systems , Cases I-IVb, based on results presented by Ådahl [15]. The reference systems reflect the expected energy production technologies with increasing CO_2 emissions constraints in society. The numbers used include predictions for the future, based on qualified analysis of results from large-scale energy market models. The reference systems have been extended to also include the transportation system, see
Table 1. The alternative use of biofuel is specified for the different reference energy system cases. In Case I it is assumed to replace oil in e.g. heating applications, leading to a CO_2 emissions reduction.

Table 1 Reference energy systems with increasing CO_2 emissions reduction targets

	I	II	III	IVa	IVb
CO_2 emissions reduction target [%]	-5	-5	-25	-50	-50
Electric power production[1] (g CO_2 /MJ)	Coal (224)	Advanced coal (209)	NGCC (102)	Adv. coal with CO_2–sep (32)	Adv. coal with CO_2–sep (32)
Transportation[2] [16] (g CO_2/km)	Gasoline in today's cars (196)	Gasoline in a hybrid vehicle (140)	Gasoline in a hybrid vehicle (140)	NG-hydrogen in fuel cell vehicles (83)	NG-hydrogen in fuel cell vehicles (83)
Biomass use[1] (g CO_2 /MJ biomass)	Oil substitution (68)	Oil substitution (68)	Co-firing in coal power plant (91)	BIGCC (12)	Transporta-tion fuel (44)

[1] CO_2 emissions from extraction and transportation of biomass, coal and NG are included [17].

[2] The produced hydrogen is assumed to be used in fuel cell cars and will replace transportation fuel used for the technology described in the different cases. The functional unit when comparing transportation fuel is distance traveled. CO_2 emissions from extraction of raw materials, conversion to fuel, delivery to tank and combustion in the car engine are included in the calculations for transportation fuel.

RESULTS

Selection of stand-alone plant

As mentioned earlier, the stand-alone biomass-to-hydrogen plants presented by Hamelinck and Faaij were evaluated with the same criteria as when comparing systems A and B. The choice of stand-alone unit configuration is based on the largest reduction of CO_2 emissions. Since the different reference energy system cases yield different results for the configurations considered, the stand-alone production will vary in the different cases. Results are presented in Table 2. With reference energy system Cases I and II a stand-alone unit producing hydrogen, power and delivering heat is the best. With reference energy system Cases III, IVa and IVb, a stand-alone unit producing more hydrogen, but no power or heat gives a larger CO_2 reduction.

Table 2 Energy output from selected stand-alone hydrogen production plants [MW]

	DHS	H_2 (LHV)	Power	Heat
Case I and II	No	54	30	0
Case I and II	Yes	54	26	27
Case III, IVa, IVb	No	92	-7.9	0
Case III, IVa, IVb	Yes	92	-7.9	0[1]

[1]No excess heat available in this configuration

CO_2 emissions from extended Systems A and B

Table 3 shows the resulting energy input and output of System A and System B.

Table 3 Energy input and output from the hydrogen production units in Systems A and B. Losses are not included. See Figures 1 and 2 for definition of streams.

[MW]	Heat to DHS		No heat to DHS	
System	A	B	A	B
(Wood input – pulp output)	602	602	602	602
Biomass input	124	124	124	124
Power output[1]	-57	$108^2/74^3$	-57	$117^2/79^3$
Hydrogen output	261	$54^2/92^3$	261	$54^2/92^3$
Heat output	50	$73^2/45^3$	0	0

[1]A negative sign indicates input to system
[2] Used in Cases I and II
[3] Used in Cases III-IV

With the results in Table 3, the production (or avoided production if negative) of energy services that must be produced from fossil fuels in order to achieve a constant output from the expanded systems can be calculated. The results are shown in Table 4.

Table 4 Energy services that must be covered by fossil fuel usage to maintain constant output from the expanded systems. Operating time 315 days/year.

	Heat to DHS		No district heating	
System	A	B	A	B
Electricity[1] [PJ/year]	1.5	$-2.9^2/-2.0^3$	1.5	$-3.2^2/-2.1^3$
Transportation service [Tm/year]	-6.9	$-1.4^2/-2.4^3$	-6.9	$-1.4^2/-2.4^3$
Energy service[4] [PJ/year]	1.8	$1.2^2/2.0^3$	3.4	3.4

[1]A negative sign indicates avoided production
[2] Used in Cases I and II
[3] Used in Cases III-IV
[4] Case dependent

Using the values listed in Table 4, the CO_2 emissions are calculated based on the CO_2 emission factors from the reference energy system cases listed in. If heat can be delivered to a DHS, the reduction of CO_2 emissions will be as shown in Figure 3.

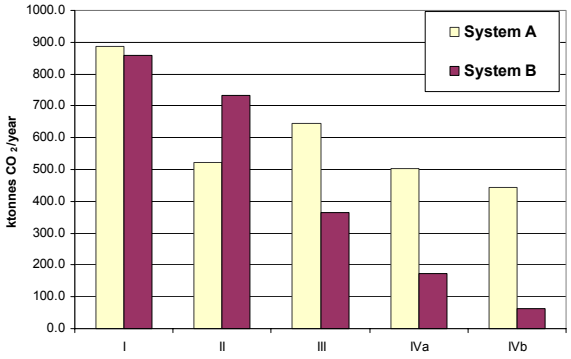

Figure 3 Reduction of CO_2 emissions for the two extended systems. Results shown for five different reference energy systems. Excess heat is used in DHS.

If heat cannot be delivered to a DHS, the total reduction of CO_2 will be less in both systems, Figure 4.

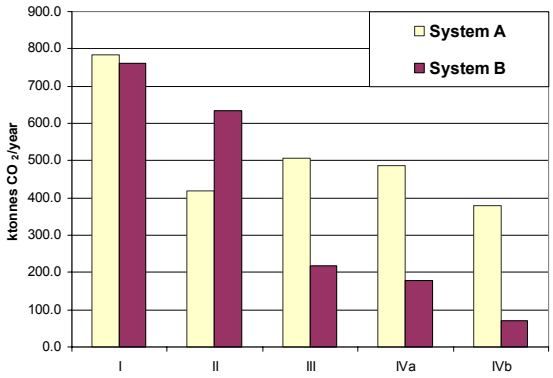

Figure 4 Reduction of CO_2 emissions for the two extended systems if excess heat cannot be used for district heating.

CONCLUSIONS

The objective was to compare hydrogen production from gasified black liquor (System A) with production in a stand-alone biomass gasification unit (System B) with respect to CO_2 emissions reduction, accounting for system consequences with an expanded system boundary. The total reduction potential is shown to be approximately the same for Systems A and B assuming reference energy system Case I. With Case II, where electricity is produced in a coal fired power plant and the reference transportation service is achieved with gasoline cars with a 30% better efficiency than today's cars, the reduction would be larger for expanded System B. In Case I, the reference transportation service is produced with gasoline in today's cars. Since the technology of fuel cell vehicles and hydrogen distribution is not widely available today, the calculated reduction would be hard to achieve in practice. In this respect, Case II probably provides a better description of the near term future.

In Cases III-IV, where reduction targets of 25 to 50 % are assumed, hydrogen from gasified black liquor achieves the largest CO_2 emissions reduction.

It is obvious that the CO_2 emissions reduction resulting from selection of a given process is very dependent on how the replaced or required energy is produced in the fossil fuel based reference energy system. The CO_2 reduction will be largest in the cases with less stringent CO_2 reduction targets.

The result show that introduction of black liquor gasification at pulp mills has benefits also when CO_2 emissions reduction targets are tougher.

Since the hydrogen production in Systems A and B is based on biomass, which is assumed to be CO_2 neutral, the reduction of CO_2 is achieved at other plants, where electricity and transportation fuel are produced. If more stringent CO_2 emission targets are adopted, this will lead to higher energy market prices. Price information for the reference energy systems must be included to evaluate the economic performance of the two hydrogen production systems.

ACKNOWLEDGEMENTS

We would like to thank Prof. Thore Berntsson for valuable comments. The work has been carried out under the auspices of The Energy Systems Programme, which is financed by the Swedish Energy Agency.

ABSTRACT

In this paper, a dynamic, lumped model of a Solide Oxide Fuel Cell (SOFC) is described, as a step towards developing control relevant models for a SOFC integrated in a gas turbine process. Several such lumped models can be aggregated to approximate the distributed nature of important variables of the SOFC. The model is evaluated against a distributed dynamic tubular SOFC model. The simulation results confirm that the simple model is able to capture the important dynamics of the SOFC. It is concluded that the simple model can be used for control and operability studies of the hybrid system.
Keywords: SOFC, control relevant, fuel cells, modeling

INTRODUCTION

Solid Oxide Fuel Cells (SOFC) integrated in Gas Turbine (GT) cycles (often denoted hybrid systems) is a promising concept for production of efficient and low-polluting electrical power. The SOFC can produce electric power at an electrical efficiency of about 55%, and when it is combined with a GT, studies show that the net electrical efficiency can be increased up to 70% [8]. The hybrid system uses natural gas as fuel and the percentage of pollutant flue gases is low compared to conventional power production from fossil fuels.

Due to the tight integration between the SOFC and the GT in a hybrid system, dynamic operability (and hence control) of the process is a challenge. It is important not only to design a good control system, but also to choose a process design that together with the appropriate control structure allows satisfying disturbance rejection and part load operation. Such a design procedure is usually called a integrated process design, see eg. van Schijndel [15]. To be able to design control structures and analyze dynamic behavior, it is very beneficial to have low complexity models of the components of the hybrid system. Such models are also valuable for online optimization. The aim of this article is to develop a low complexity mechanistic SOFC dynamic model which includes the relevant dynamics for operation in a hybrid system. There are several dynamic, distributed models reported in the literature. For example, Achenbach [1] developed a three dimensional, dynamic, distributed model for a planar SOFC stack. Chan et al. [4, 3], Thorud et al. [14], Stiller et al. [12] and Magistri et al. [10] all developed distributed, dynamic tubular SOFC models for designs similar to that of Siemens Westinghouse, for use in hybrid systems. In this paper, a simple, lumped, dynamic model of the SOFC based on mass and energy balances, with methane as fuel, is developed. The modeling approach proposed by Padulles et al. [11] for use in power systems simulation has some similarities with the approach described in this paper, however, therein hydrogen is used as fuel and only mass balances are considered.

The paper is outlined as follows: First a simple control relevant SOFC model is described with no regard to the geometric layout (tubular or planar). Extension of the simple lumped model towards capturing the distributed nature of the process by aggregating single volumes is explained next. Both SOFC models are evaluated against a distributed tubular SOFC model [14] with a considerably higher complexity. The two models are simulated for different realistic scenarios and the corresponding simulation results are presented. Applicability and shortcom-

ings of the low complexity model are discussed. A nomenclature can be found at the end of the paper.

PROCESS DESCRIPTION

The Solid Oxide Fuel Cell (SOFC) is a device which converts chemical energy of a fuel directly into electrical energy [7]. The basic components of the SOFC are anode, cathode and electrolyte (conceptually illustrated in Figure 1). The electrolyte material is zirconia stabilized with the addition of a small percentage of yttria (Y_2O_3). The anode material is a zirconia cermet. The most common cathode material is strontium-doped lanthanum manganite. Fuel is supplied to the anode and air is supplied to the cathode. At the cathode-electrolyte interface, oxygen molecules accept electrons coming from the external circuit to form oxide ions, see Table 1 for reactions. The electrolyte layer allows only oxide ions to pass through and at the anode-electrolyte interface, hydrogen molecules present in the fuel react with oxide ions to form steam and electrons get released. These electrons pass through the external circuit and reach the cathode-electrolyte layer, and thus the circuit is closed. To increase the amount of power generated, a number of cells can be connected in series/parallel. This is known as stacking of cells. Also, there are mainly two types of SOFCs depending on the geometry; tubular and planar. The operating pressure can be from one bar to 15 bars. It is found that SOFCs show enhanced performance with increasing cell pressure [7]. The operating temperature of the SOFC is around 800-1000$^\circ C$. The high temperature and pressure operating conditions of the SOFC make it advantageous to combine the SOFC with a gas turbine (GT) to get a hybrid system with an high efficiency [8]. Due to the high operating temperature, an advantage is that several types of fuels can be used. In this paper methane is used as fuel. Because of the electrochemical reactions, there is a production of steam, and partial recirculation of this steam is used to reform methane into hydrogen. Typically, one third of the fuel is reformed (for example, in a pre-reformer) before it enters the SOFC and the remaining part is reformed within the SOFC. Table 1 gives the list of reactions that take place at anode and cathode and the corresponding reaction rates notation.

MODELING

The dynamic model of a single SOFC is developed using two mass balances; one for anode volume and the other for cathode volume, and one overall energy balance. In all of the streams from/to the SOFC, the following components can be present; Nitrogen (N_2), Oxygen (O_2), Hydrogen (H_2), Methane (CH_4), Steam (H_2O), Carbonmonoxide (CO), and Carbondioxide (CO_2). A number is assigned to each of these components to simplify the notation:

i	1	2	3	4	5	6	7
comp.	N_2	O_2	H_2	CH_4	H_2O	CO	CO_2

Model assumptions

The following main assumptions are made in developing the model.

1. All the physical variables are assumed to be uniform over the SOFC, resulting in a lumped model.

2. There is sufficient turbulence and diffusion within the anode and the cathode for perfect mixing to occur (CSTR).

3. The gas temperatures within the SOFC are assumed to be the same as the solid; i.e. the thermal inertia of the gases is neglected.

4. For the energy balance, pressure changes within the SOFC are neglected.

5. All gases are assumed to be ideal.

Mass balances

Two mass balances; one for the anode volume and one for the cathode volume are used:

$$\frac{dN_i^{an}}{dt} = \dot{N}_i^{in,an} - \dot{N}_i^{out,an} + \sum_{j=1}^{n_{rx}^{an}} a_{ij}^{an} r_j^{an}, \qquad (1)$$
$$i = 1,...,7, \;\; n_{rx}^{an} = 4$$

$$\frac{dN_i^{ca}}{dt} = \dot{N}_i^{in,ca} - \dot{N}_i^{out,ca} + \sum_{j=1}^{n_{rx}^{ca}} a_{ij}^{ca} r_j^{ca}, \qquad (2)$$
$$i = 1,...,7, \;\; n_{rx}^{ca} = 1$$

The reaction rates corresponding to the electrochemical reactions (r_1^{ca}, r_1^{an}) are directly related by the current,

$$r_1^{an} = I/(2F) = r_1^{ca} \qquad (3)$$

and the reaction rates corresponding to the reforming reactions are calculated as proposed by Xu [16]

$$r_2^{an} = \frac{k_2}{p_{H_2}^{an^2.5}} \left(p_{CH_4}^{an} p_{H_2O}^{an} - \frac{p_{H_2}^{an^3} p_{CO}^{an}}{K_2} \right) / (DEN)^2$$
$$r_3^{an} = \frac{k_3}{p_{H_2}^{an}} \left(p_{CO}^{an} p_{H_2O}^{an} - \frac{p_{H_2}^{an} p_{CO_2}^{an}}{K_3} \right) / (DEN)^2 \qquad (4)$$
$$r_4^{an} = \frac{k_4}{p_{H_2}^{an^3.5}} \left(p_{CH_4}^{an} p_{H_2O}^{an^2} - \frac{p_{H_2}^{an^4} p_{CO_2}^{an}}{K_4} \right) / (DEN)^2$$

In (4), DEN is given by

$$DEN = 1 + K_{CO}^{ads} p_{CO}^{an} + K_{H_2}^{ads} p_{H_2}^{an} + K_{CH_4}^{ads} p_{CH_4}^{an} \qquad (5)$$
$$+ K_{H_2O}^{ads} p_{H_2O}^{an} / p_{H_2}^{an}$$

and k_2, k_3 and k_4, the rate coefficients for the reforming reactions, are calculated by

$$k_j = A_{kj} \exp(\frac{-E_j}{RT}), \quad j = 2,3,4 \qquad (6)$$

The equilibrium constants for the reforming reactions K_2, K_3 and K_4 are given by

$$K_2 = \exp(-26830/T + 30.114) \quad [bar^2]$$
$$K_3 = \exp(4400/T - 4.036 \quad [-] \qquad (7)$$
$$K_4 = \exp(-22430/T + 26.078) \quad [bar^2]$$

In (5), $K_{CO}^{ads}, K_{H_2}^{ads}, K_{CH_4}^{ads}$ and $K_{H_2O}^{ads}$ are the adsorption constants, which are calculated by

$$K_i^{ads} = A_{K^{ads}i} \exp(\frac{-\Delta\overline{h}_i^{ads}}{RT}), \quad i = H_2, CH_4, H_2O, CO \qquad (8)$$

It is assumed that the exhaust flows at the anode and cathode outlets can be described by the choked exhaust flow equation. This means that the mass flow rate of the exhaust flow at the anode (cathode) depends on the pressure difference between the pressure inside the anode (cathode) and the pressure at the outlet [11]:

$$\dot{m}_{out,an} = \sqrt{k_{an}(p_{an} - p_{out,an})} \qquad (9)$$
$$\dot{m}_{out,ca} = \sqrt{k_{ca}(p_{ca} - p_{out,ca})}$$

The partial pressures, volume, and temperature are assumed to be related by the ideal gas equation, for instance at the anode,

$$p_i^{an} V_{an} = N_i^{an} RT \qquad (10)$$

Energy balance

The energy balance accounts for the whole SOFC volume, and is given by [13, 9]:

$$C^s \frac{dT}{dt} = \sum_{i=1}^{N} \dot{N}_i^{in,an} (\Delta\overline{h}_i^{in,an} - \Delta\overline{h}_i)$$
$$+ \sum_{i=1}^{N} (\dot{N}_i^{in,ca} (\Delta\overline{h}_i^{in,ca} - \Delta\overline{h}_i) \qquad (11)$$
$$- \sum_{j=1}^{M} \Delta\overline{h}_j^{rx} r_j^{an} - P_{DC} - P_{rad} - P_{cond}$$

In this equation, the temperature changes of gases are neglected as they are fast compared to the temperature changes of the solid and by assuming that these fast changes of gas temperatures do not influence the dynamics of the overall process. Hence the energy balance gives a dynamic equation for the temperature changes of the SOFC solid.
In (11), P_{DC} represents the amount of DC power produced by the SOFC, P_{cond} represents the conduction heat loss from SOFC to the surroundings and P_{rad} represents the amount of radiation heat given from the SOFC. As the SOFC operating temperature is higher than that of the surroundings, there is always some loss due to radiation. It can be calculated by [6]

$$P_{rad} = A\delta\varepsilon\sigma(T^4 - T_{sur}^4) \qquad (12)$$

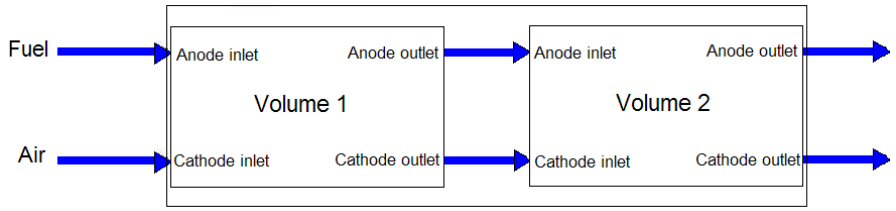

Figure 2: Aggregation mechanically

In (12), A is the surface area, δ is shaping factor, T_{sur} represents the surroundings temperature, ε is the emissivity of the SOFC surface and σ is the *Stefan-Boltzmann constant* ($\sigma = 5.67 \times 10^{-8}\text{W/(m}^2\text{.K}^4)$). The amount of DC power from the SOFC is given by

$$P_{DC} = VI \tag{13}$$

Voltage

The operating cell voltage is given by

$$V = E^{OCV} - V_{loss} \tag{14}$$

where the open circuit voltage of the cell is given by the *Nernst equation* [7],

$$E^{OCV} = E^o + \frac{RT}{2F} \ln \left(\frac{p_{H_2}^{an} p_{O_2}^{an^{0.5}}}{p_{H_2O}^{an}} \right) \tag{15}$$

where E^o is the EMF at standard pressure. V_{loss} is the voltage loss, as explained below.

Voltage loss

When the cell is operated, there are voltage losses coming from different sources; activation losses, concentration losses and ohmic losses [7]. Activation losses are caused by the limited reaction rate on the surface of the electrodes. Ohmic losses are due to the electrical resistance of the electrode material and the various interconnections, as well as the resistance of the electrolyte. The ohmic losses are responsible for the largest part of the voltage losses. The concentration losses result from the change in concentration of the reactants at the surface of the electrodes as the fuel is used. Stiller et al. [12], Thorud et al. [14], Campanari et al. [2], and Magistri et al. [10] used rather complex empirical functions to calculate the ohmic and activation losses. In this simple model the total voltage loss is approximated by a first order function of cell temperature and current. This function is obtained by curve fitting the simulated data obtained from a distributed model [14], where an active area of 834cm^2 is used to calculate the different voltage losses. Thus total voltage loss is calculated by

$$V_{loss} = f(I,T) \tag{16}$$

MODEL AGGREGATION

In a real SOFC, temperature and pressure vary over the SOFC volume. The distributed nature cannot be represented by using the ”one volume” model. By connecting many volumes in a sequential manner it is possible to approximate the distributed nature of the variables. The whole structure with all the volumes represent a single cell. So, if many volumes are connected, each volume can be represented by a scaled-down model. In principle, it is possible to connect any number of volumes, but for simplification, an example is considered where a single SOFC model is obtained by connecting two scaled-down models as shown in Figure 2. The two volumes are selected such that the first volume is represented by a scaled-down model by scaling down the ”one volume” model volume and heat capacity constants by 1/3. The second volume is represented by a scaled-down model obtained by scaling down the ”one volume” model constants by 2/3. Electrically, the two scaled-down models are connected in parallel (Figure 3). Ideally, the voltage across each of the volumes should be the same and the total current is divided between the two volumes. Then probably, most of the current will be produced from the second volume, as mainly reforming reactions take place in the first volume. In the present work it is assumed that the first volume supplies 1/3rd of the total current and the second volume supplies the remaining current. With this assumption, there is a small voltage difference between the two volumes. Developing a strategy for dividing the currents among the volumes when a SOFC is represented by many volumes is a part of further work. The basic point is

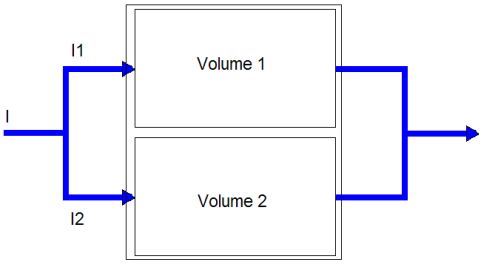

Figure 3: Electrical aggregation

to show that it is possible to approximate the distributed nature of the variables by aggregating the scaled-down models.

MODEL EVALUATION

As no experimental data is available to the authors for evaluating the simple model, the model is evaluated with an available detailed model. The detailed model [14] is a quasi two-dimensional dynamic model of a SOFC tube, similar to that of Siemens Westinghouse. It is a discretized model where gas flows are treated as 1D plug flows. The solid structures are modeled by a 2D discretization scheme in the axial and radial direction, neglecting effects in the circumferential direction. Both the simple and the detailed models are developed using gPROMS [5]. For solving the detailed model gPROMS uses about 1300 differential equations, where as for the simple model it uses 15 differential equations.

Figure 4 shows the comparison set up used for the simulation. Here the main aim is to evaluate the simple model against the detailed model [14]. The simulations are performed in such a way that the same input conditions are applied to the two SOFC models. Fuel is supplied to the pre-reformer which reforms about 30% of methane. The pre-reformer outlet gas is supplied to the anode inlet and air is supplied to the cathode inlet. Some part of the anode flue gas is recycled back to the pre-reformer to supply steam required by the reforming reactions. The other part of the anode flue gas and the cathode flue gas are supplied to a combustor where the remaining fuel is burnt and the resultant gas mixture will be the exhaust gas. The SOFC and pre-reformer are thermally connected by radiation. The details of the models of the other components used in the process shown in Figure 4 are not discussed here. The values of important parameters of the simple model are given in Table 2. The values of important variables at steady state are given in Table 3. Table 4 shows

Table 2: Model parameters

Anode volume	$1.032\times10^{-5}\mathrm{m}^3$
Cathode volume	$4.3\times10^{-5}\mathrm{m}^3$

fuel utilization	0.7

the simulation scenarios used for comparing the dynamic behavior of the two models.

SIMULATION RESULTS

Simulations are made for two comparison schemes; first, the simple SOFC model with one volume is compared to the distributed tubular SOFC model [14], and second, the simple SOFC with two volumes is compared to the distributed tubular SOFC model. SOFC mean solid temperature, cell voltage and cell power of the simple model and the detailed model are compared in each comparison scheme. Figures 5-7 show simulation results of the first comparison scheme and Figures 8-9 show simulation results of the second comparison scheme.

Table 4: Simulation details

Time(min)	Disturbance
90	fuel flow is decreased by 20%
180	fuel flow is increased back to 100%
270	air flow is decreased by 20%
360	air flow is increased back to 100%
450	current is decreased by 20%
540	current is increased back to 100%

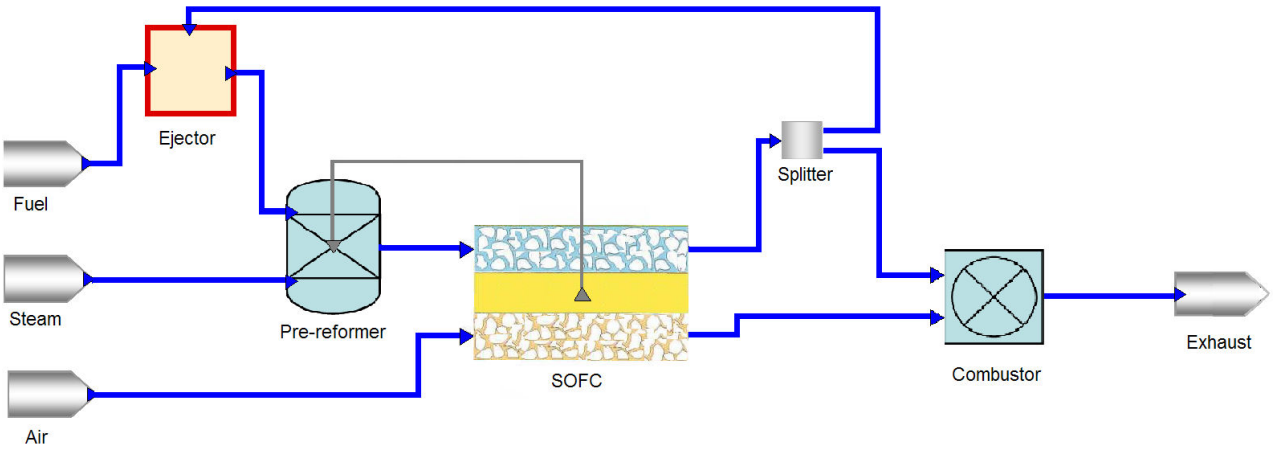

Figure 4: SOFC system

DISCUSSION

One volume SOFC model

Figure 5 shows the mean temperatures of the simple and the detailed SOFC models. At nominal steady state there is a temperature difference of about 120K between the two mean SOFC temperatures. This can be explained as follows. For both SOFC models, since inlet massflows and current are the same, the energy balance should ensure that the energy in the outlet massflow (and hence outlet temperature) is approximately[1] the same for both models. In a SOFC, the maximum temperature region is at the outlets of the anode and the cathode. Since the simple model is a bulk model, the exit temperature is equal to the mean temperature. For the detailed model, SOFC temperature is a distributed variable and the mean temperature is certainly less than the exit temperature. It is verified that the maximum temperature of the detailed model at the nominal steady state is approximately equal to the mean temperature of the simple SOFC model. From Figure 5, it is clear that both the models exhibit similar dynamics for the disturbances applied during the simulation. Figure 6 shows the voltages of the two models during the simulation. Here also both models show the same dynamic changes in the voltages for all the disturbances applied. Here the simple model has higher voltage than the detailed model which is also mainly because of the higher mean solid temperature of the simple SOFC model. Refering to (16), when temperature increases the voltage loss decreases. Hence the simple SOFC voltage given

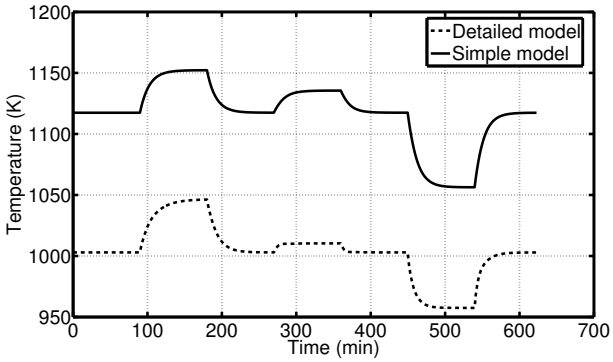

Figure 5: Comparison of mean solid temperatures of the simple model with one volume and the detailed model for different disturbances

by (14) is higher than that of the detailed SOFC model at the nominal steady state. Figure 7 shows a comparison of power production of the two models during the simulation. Since the voltage of the simple SOFC model is higher than that of the detailed model and the current is the same in both models, the power produced by the simple SOFC model is higher.

Two volume SOFC model

Figure 8 shows the comparison of the mean temperatures of the two SOFC models. Now, the simple SOFC is represented by aggregation of two volumes. The simple SOFC solid mean temperature is given by the average of the temperatures of the two volumes. The difference between the two mean temperatures at the nominal steady state is reduced to 51K as supposed to 120K. The dynamics of the two

[1] A slight difference in voltage and hence produced DC power gives a small temperature difference.

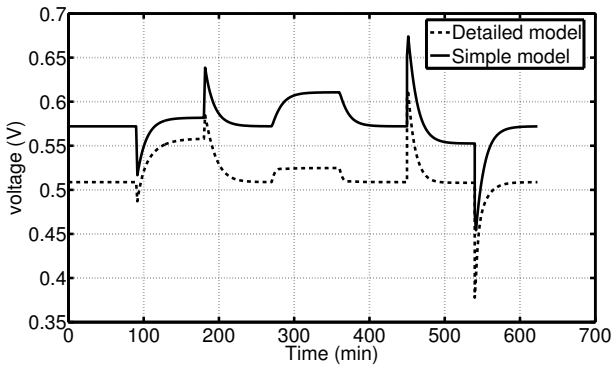

Figure 6: Comparison of voltages of the simple model with one volume and the detailed model for different disturbances

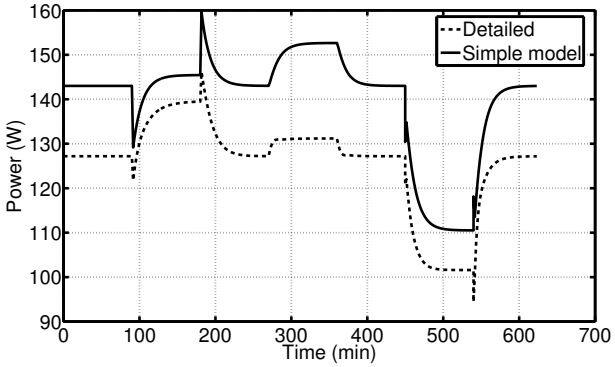

Figure 7: Comparison of power production of the simple model with one volume and the detailed model for different disturbances

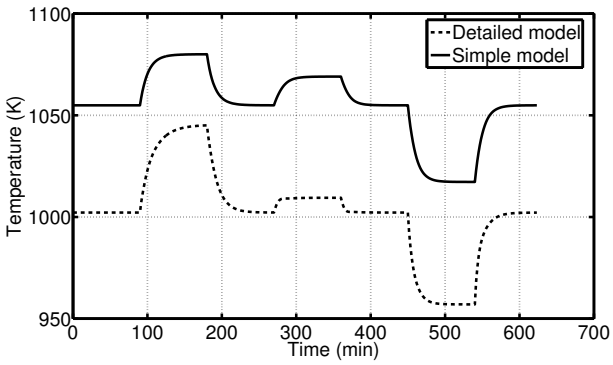

Figure 8: Comparison of mean solid temperatures of the simple model with two volumes and the detailed model for different disturbances

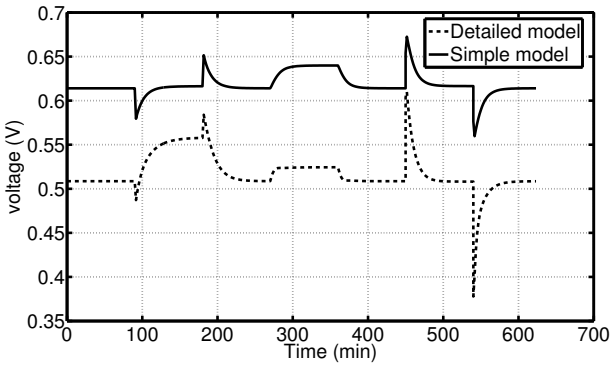

Figure 9: Comparison of voltages of the simple model with two volumes and the detailed model for different disturbances

volume model is similar to that the dynamics of the one volume model for all the disturbances. Figure 9 shows the comparison of the voltages of the two models, for the two volume model the average voltage is plotted. There is a small voltage difference of 0.1V between the two volumes and this is caused by the somewhat crude approximate distribution of currents between the two volumes. Developing a strategy for a more accurate distribution of currents between two or more volumes is a topic for future work.

CONCLUSION AND FURTHER WORK

From the simulation results, it is quite clear that even though there is some steady state offset, important variables of the simple and the detailed models show similar dynamic behavior during the simulations. It can therefore be concluded that the simple model is able to capture the overall dynamics of the SOFC. This model will hence be used for further studies on control and operability of the hybrid system, i.e. an SOFC integrated in a GT cycle.

If the one volume model is too crude, it is possible to aggregate a number of volumes. The results herein however indicate that a one volume model may suffice in many cases.

Further work includes developing the simple models of the other components in the SOFC-GT hybrid system, looking at how different design decisions affect controllability and developing an optimizing control structure for safe and part load operation.

ABSTRACT

The development of high temperature polymer fuel cell systems has gained great interest among manufacturers of automotive and combined heat and power systems due to the carbon monoxide (CO) tolerance, enhanced heat management and better mass transfer. One of the promising high temperature polymer systems is based on polybenzimidazole polymer impregnated with phosphoric acid. In order to make fuel cells with high power density the structure and morphology for the three dimensional gas diffusion electrodes (GDE) are very important. In general the electrodes consist of three layers: i) backing material, ii) micro porous layer and iii) catalytic layer. Different preparation techniques yield GDEs with very different properties. Teflon treatment of the backing material is found to be beneficial for the performance of the electrodes. In general the open circuit voltage (OCV) with PBI-based cells is very low. The performance of the fuel cells is found to increase with increasing temperature, with a typical power output of 0.3-0.4 W cm^{-2} at 0.6 V and 175 °C.

INTRODUCTION

Most membranes used as electrolyte for polymer electrolyte fuel cells, such as Nafion, relies on liquid water for protonic conductivity. Therefore, the operation temperature is limited by the boiling point of water. Cathode flooding caused by liquid water formed in the cathode is a common problem for low temperature fuel cells. This problem is not existent at higher temperatures where only water vapour can exist

Hydrogen gas produced from hydrocarbons in a reformer, for instance methanol, ethanol or diesel, will contain some CO. Fuel cell catalysts are very sensitive to CO. The CO is adsorbed on the Pt catalyst surface blocking the desired reaction. By increasing the operation temperature CO poisoning becomes much less pronounced. PBI based fuel cells operated at temperatures above 185 °C can tolerate up to 3 % CO [1, 2]. Li et al. [1] reported a CO tolerance of only 0.1 % at 125 °C, indicating a strong temperature dependence. Therefore, hydrogen produced by reforming of hydrocarbons can be used without CO removal. The membrane represents a significant cost in a fuel cell system. Compared to Nafion, PBI is considerably cheaper. The permeability of oxygen, hydrogen and methanol is very low.

At higher temperatures, the kinetics for both electrode reactions will be enhanced [3]. Operating the fuel cell at a high temperature also makes waste heat utilization more efficient. This heat can be supplied to for example a methanol reformer in order to produce hydrogen. The heat can also be utilized for desorption of hydrogen stored in metal hydrides. At temperatures below 80 °C the storage capacity in hydrides is usually limited to 1-2 wt.%. In $NaAlH_4$ at 150 °C 4-5 wt.% hydrogen can be stored more or less reversibly [3].

In addition the higher temperature results in better heat distribution within a fuel cell stack, and a smaller and cheaper cooling system is demanded.

A disadvantage by increasing the temperature, however, is longer start up time for the fuel cell.

Great efforts have recently been made to develop proton conductive membranes for fuel cell use above 100 °C. The work includes modification of perfluorosulfonic acid (PFSA), alternative sulphonated polymers and acid-base polymer membranes. The research in this field has lately been reviewed by Li et al. [4], Rozière and Jones [5] and Schuster and Meyer [6]. One of the most promising new membranes for operation above the boiling point of water is PBI doped with phosphoric acid for proton conductivity.

PBI was developed by Celanese as a fire resistant fibre for use in fire fighters clothing. PBI is an amorphous basic polymer with high thermal stability. In the pure state the conductivity is very low, about 10-12 S cm^{-1} [7, 8]. The conductivity can be substantially increased by addition of different acids. PBI has been doped with for example sulphuric acid, phosphoric acid, perchloric acid, nitric acid and hydrochloric acid [9], whereas phosphoric acid is the most promising because of its high boiling point, high thermal stability and high protonic conductivity even in anhydrous form. The idea to use phosphoric acid doped PBI as the electrolyte in fuel cells was first introduced by Wainright et al. [10].

The conductivity of phosphoric acid doped PBI increases with increasing doping level, temperature and humidification [11, 12, 13, 14, 15]. At room temperature the conductivity is unsatisfactory for normal fuel cell operations. The conductivity increase with increasing temperature following an Arrhenius equation [12].

The doping level is usually given as the mol percent of phosphoric acid per repeating unit of the polymer. Li et al. [14] suggested that two molecules of phosphoric acid per repeating unit of PBI is strongly bound to the nitrogen atoms in the imidazole ring. Exceeding the amount phosphoric acid in the membrane above two H_3PO_4 per repeating unit leads to the presence of "free acid", which contribute significantly to the ionic conductivity of doped PBI membrane. The mechanical strength of the PBI is decreasing with increasing temperature and increased level of doping. The doping level used in a fuel cell membrane is therefore a trade-off between operation temperature, membrane thickness and doping level. Li et al. [3] suggested an optimum doping level around 5 molecules of H_3PO_4 per repeating unit polymer.

The influence of the humidification of PBI is much less than for Nafion membranes. However an increase in relative humidity (RH) increase the conductivity for phosphoric acid doped PBI, especially at high temperature. This can be explained by interaction of water with excess acid [14]. For a doping level of 560 mol% a conductivity of 6.8 10^{-2} S cm^{-1} at 200 °C and 5 % RH was measured for PBI by He et al. [13]. This conductivity is close to the conductivity measured for Nafion membranes at 80 °C and 95 % RH.

For Nafion the electroosmotic drag coefficient for water has been determined to vary between 0.9 and 3.2 at room temperature. For PBI doped with phosphoric acid, an electroosmotic drag coefficient close to zero has been measured [1,15]. This may indicate that a PBI based fuel cell can be operated without any humidification, although some humidification is an advantage.

Material choice for fuel cells operating close to 200 °C with the presence of phosphoric acid, is a challenging task. For example is amorphous carbon known to be oxidized at the cathode at high voltages (low current densities). This probably indicates that traditionally used amorphous carbon can not be used as catalyst carrier in long term fuel cell operation [3].

A few works has been published about preparation of gas diffusion electrodes for PBI fuel cells. Savodogo and Xing [16] made electrodes with extremely good performance, at a cell voltage of 0.6 V the current density was 1.6 A cm^{-2} at 185 °C. Wang et al. [17] made gas diffusion electrodes in three different ways with a maximum current density at 0.2 A cm^{-2} at a cell voltage of 0.6 V and 150 °C. Li et al. [3] obtained a current density of 0.7 A cm^{-2} at 0.6 V and 200 °C.

In order to make fuel cells with high power density, gas diffusion electrodes with a large three phase area (catalyst-PBI-gas) with high electrical conductivity and high accessibility for reactants, are very important. The manufacturing of a desirable three dimensional structure is a challenging task. Many input parameters influence the performance of the final electrode. Because of the cost of the precious metals used for fuel cell catalysts, usually platinum, it is important to keep the catalyst loading low. The ob-

jective of this work has been to optimize the composition and structure of such gas diffusion electrodes.

EXPERIMENTAL

Gas diffusion electrodes (GDEs) were prepared with carbon fibre paper from Toray (TGP-H-120) as a backing material. The carbon paper was treated with PTFE(Polytetrafluoroethylene, Teflon) by immersing the electrodes into an aqueous dispersion of PTFE, and then let the electrodes dry in air, before heat treatment at 360 °C for 30 minutes.

Both the micro porous layer (MPL) and the catalyst layer were sprayed manually with an airbrush. This method allows uniform thickness of the different layers and accurate determination of the catalyst loading. Prior to the catalyst layer a MPL based on carbon black (Vulcan XC-72) was applied to the backing.

The catalytic layer was sprayed from a dispersion of platinum on carbon in PBI containing dimethylacetamide (DMAc). The electrocatalysts, 20 wt.%, 40 wt.% and 50 wt.% platinum on carbon (Pt/C) were purchased from Johnsson & Matthey. After spraying of the catalyst, the electrodes were heated at 190 °C for three hours to evaporate the remaining DMAc. In order to dope the PBI in the catalytic layer, the electrodes were sprayed with 10 wt.% phosphoric acid solution.

PBI foils with a thickness of 40 μm after hot pressing were supplied by the Department of Chemistry, Technical University of Denmark (DTU). The PBI membranes were saturated with 65 wt.% phosphoric acid before use, resulting in a doping level of approx. 560 mol%. The gas diffusion electrodes were hot pressed onto both sides of the membrane at approx. 250 N cm^{-2} at 130 °C for 25 minutes. The finished MEA was then cured for a few weeks.

The finished MEAs with an active area of 2×2 cm^2 were tested in a commercial fuel cell test rig (ElectroChem, Inc), with double serpentine flow field. The MEAs were tested in terms of their performance by recording polarization curves using pure oxygen and hydrogen at atmospheric pressure. After the MEAs were electrochemically tested, the cross section was examined in scanning electron microscope (SEM).

RESULTS AND DISCUSSION

Micro Porous Layer

The MPL was prepared in order to obtain a good electrical contact between the backing and the catalysts and prevent catalyst to penetrate into the carbon paper. The purpose of the MPL was also to provide good transport of reactants and product gases and to obtain a smooth and uniform surface for the catalytic layer. Reproducible results were first obtained after extensive study of the preparation steps involved.

Treatment in a 20 % PTFE dispersion led to reduced carbon penetration into the carbon paper during the preparation of the subsequent micro porous layer (MPL), resulting in an increase in the total porosity. It is unlikely that liquid water is present during cell operation at 175 °C, so a direct influence of PTFE on the cell performance was observed to be insignificant. The adhesion of carbon onto the carbon fibre was however found to be improved by PTFE treatment.

The properties of the MPL are strongly dependent upon the solvent used for carbon particles dispersion. During this work it was found that the drying time had a big impact on the MPL properties. By spraying carbon particles dispersed in a solution with low boiling point on a heated carbon paper, good adhesion was obtained, but the surface became uneven. Consequently, carbon particles dispersed in a solvent with a higher boiling point was sprayed on top of the layer described above. This led to a mud cracked structure with large islands and thin crevices, shown in Figure 1, due to the lengthening of the drying time.

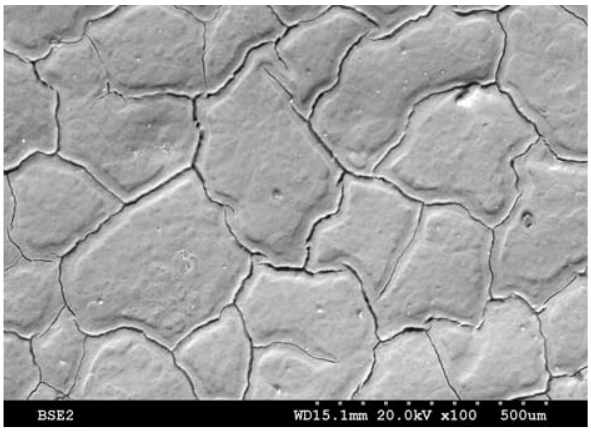

Figure 1: SEM micrograph of a complete electrode visualizing the mud cracked structure.

The catalyst eventually ending up in the crevice is far from the membrane and has a poor performance; this illustrates the importance of minimizing the total crevice volume in the support layer. A total amount of 2 mg cm^{-2} of carbon black was found to be sufficient to produce the MPL shown in Figure 1.

Catalyst Layer

The catalyst layer is a key element in a fuel cell. Because of its three-dimensional structure it can be very difficult to manufacture this layer with the desired properties. Many preparation methods for the catalytic layer have been tested. The best performing electrodes were sprayed from a dispersion of catalyst in DMAc containing PBI in solution.
The total loading on both anode and cathode was normally 1 mg Pt cm^{-2}. The overpotential for oxygen reduction is higher than for hydrogen oxidation. The performance improved when the anode loading was 0.4 mg Pt cm^{-2} and the cathode loading was 0.6 mg Pt cm^{-2} compared to a loading of 0.5 mg Pt cm^{-2} on both electrodes. SEM images of the electrodes are showing a very uniform catalytic layer made by spraying. Theoretical simulations of PEM fuel cells have shown that most of the catalytic reaction takes place within approx. 10 μm from the electrolyte membrane [18], which means that a high fraction of the catalyst in a thick layer will be inactive. In order to achieve as large three phase area as possible within the reaction zone close to the membrane 50 wt.% Pt/C was used. The best performance was obtained by first spraying a layer of 20 wt.% Pt/C and thereafter a thin layer of 50 wt.% Pt/C. This was observed both for the anode and the cathode. A cross section of a MEA is shown in Figure 2, where the different layers may easily be observed. Heavy compounds like Pt shines up in SEM backscatter mode. A polarization curve for the MEA in Figure 2 is shown in Figure 4.
The PBI loading was found to be very important. Too much PBI in the catalytic layer probably led to an electrical insulating coating around the catalytic particles. On the other hand too little PBI led to lower ionic conductivity and smaller three phase area in the catalytic layer. The experimental investigation indicates that a PBI loading in the range of 0.2 to 0.4 mg PBI cm^{-2} gave the best performing gas diffusion electrodes. Seland et al. [19] has studied this in more details.

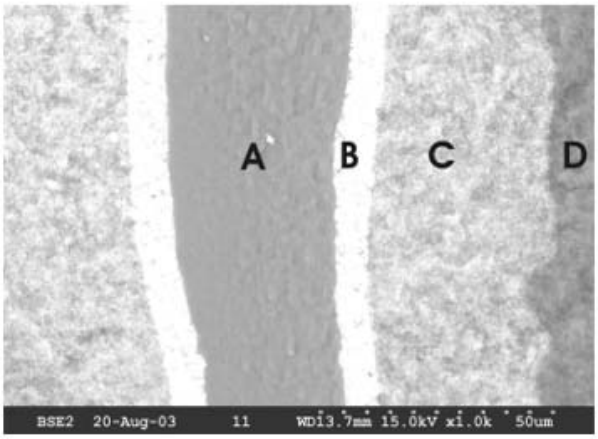

Figure 2: SEM micrograph of a cross section of an MEA, A: Membrane, B: Catalyst layer (50 wt.% Pt/C) C: Catalyst layer (20 wt.% Pt/C) and MPL. The image is taken in backscatter mode.

Open Circuit Voltage

The open circuit voltage (OCV) is the cell voltage at zero current. Commonly the OCV for fuel cells is not equal to the value calculated from thermodynamic data. This can mainly be explained by the very slow kinetics for the oxygen reduction reaction, which can easily be influenced by other parallel reactions, for instance corrosion of platinum. The thermodynamic voltage for an O2/H2 fuel cell is 1.23 V at 25 °C. The corresponding value at 175 °C is 1.10 V. The most frequently reported OCV for a Nafion based fuel cell is around 1.0 V. In this study the open circuit voltage at 175 °C varied from one MEA to another, but was typically around 0.9 V. The OCV increased with temperature above 100 °C. The variation in OCV may be explained by variation of the catalytic activity of the platinum and variations in the crossover rate caused by small variation in the membrane thickness. Carbon can be oxidized at a slow rate to carbon dioxide at high anodic voltages ($C + 2H_2O \rightarrow CO_2 + 4H^+ + 4e^-$) [20]. This may also tend to lower the OCV. The adsorption of phosphate ions on the catalyst surface may also affect the OCV value.

Testing of Single Membrane Electrode Assemblies

Figure 3 shows polarization curves as a function of temperature. In the figure the corresponding power density curves are also given. The Pt loading on the cathode was 0.6 mg cm^{-2} and 0.4 mg cm^{-2} on the anode. The PBI membrane was doped with 580 mol % phosphoric acid.

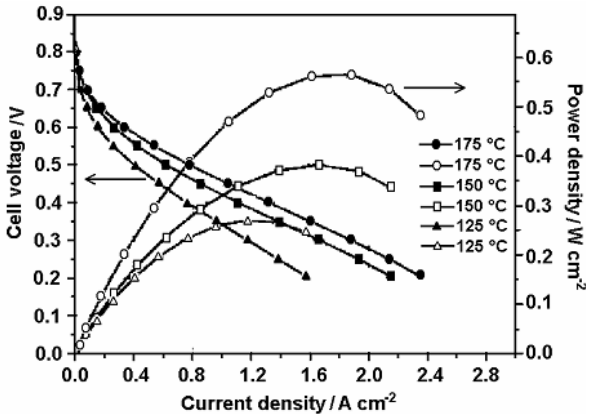

Figure 3: Cell voltage versus current density and corresponding power density versus current density for three temperatures. The cell was fed with pure H_2 and O_2 under atmospheric pressure.

Significant increase in performance by increasing the temperature was observed. This can mainly be explained by the increased membrane conductivity and enhanced reaction kinetics at elevated temperatures. When the temperature was raised above 175 °C, membrane puncturing was a common problem caused by reduced mechanical strength of the membranes. Membrane puncturing was usually observed at the edge of the GDEs.

As can be seen from Figure 4, a good MEAs prepared in house yielded a current density of 0.6 A cm^{-2} at 0.6 V. A maximum power density of 0.83 W cm^{-2} at 0.40 V was obtained for this MEA. This performance is considerably lower than the performance achieved for Nafion based fuel cells at 80 °C. This is mainly due to a lower proton conductivity of the phosphoric acid doped PBI membrane, and lower reversible voltage at high temperatures. Other explanations can also be slower reaction kinetics caused by strong adsorption of phosphate at the catalyst surface, and a substantially lower oxygen solubility in the phosphoric acid doped PBI than

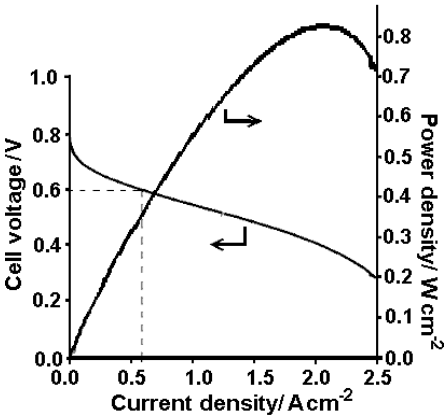

Figure 4: Cell voltage and power density versus current density at 175 °C. The cell was fed with H_2 and O_2 under atmospheric pressure.

in Nafion. This means that such fuel cells are not beneficial for pure hydrogen feed, but are superior to Nafion based cells above a certain CO level in the gas feed. Further electrode development is needed to enhance the MEA performance for the PBI based fuel cells

CONCLUSION

The well developed PEMFC is based on Nafion membranes operating at a typical temperature of 80 °C. Fuel cells operation at temperatures above 150 °C are desired for fast electrode kinetics, high CO tolerance, facilitated thermal, mass and water management and heat utilization. PBI based fuel cells are among the most promising candidates for operating at higher temperatures. Good performing MEAs have been demonstrated, but further optimization is needed both for higher performance and long term stability.

ACKNOWLEDGMENT

This work was funded by the European Commission in the 5^{th} Framework Programme (Contract no. ENK5-CT-2000-00323). The Department of Chemistry, DTU is greatly acknowledged for supplying the PBI membranes as a partner in this EU project.

ABSTRACT

A small 10-cell proton exchange membrane fuel cell (PEMFC) stack for demonstrational purposes was designed and tested. The stack was operated on pure hydrogen and ambient air without inlet gas humidification or external heating. Polarization curves for individual cells were obtained up to a current density of 0.40 A/cm^2 with a corresponding stack peak power of 41 W. The temperature distribution in the air channels of the stack was mapped showing temperature gradients of up to 10 ^{o}C. Polarization curves show very similar single cell performances despite these substantial temperature gradients. The simplicity of the PEMFC system limits the operation to low power densities. With the reactant air as the only means of stack cooling, long term operation at higher power densities was not possible due to stack overheating with subsequent risk of membrane failure.

Keywords: PEM fuel cell, polarization curves, heat distribution, water management

INTRODUCTION

Hydrogen based energy supply systems such as fuel cells are believed to play an important role in the future. Fuel cells are efficient devices for converting chemical energy into electricity, and will be able to provide energy for a broad range of applications. For automobile and portable applications the proton exchange membrane fuel cell (PEMFC) is considered the most promising candidate, due to its high power density, fast start-up capability and excellent dynamics [1, 2].

Fast start-up is facilitated by the low operating temperature and stable operation conditions are typically reached within minutes.

High power density has historically been assured by pressurised PEMFC operation [3]. However, pressurised operation requires a number of auxiliary components leading to system complexity. System complexity again leads to reduced system reliability. Furthermore, pressurised PEMFC systems typically spend 20% of stack power output for air compression [4], giving negative impact on system efficiency.

The PEMFC stack itself exhibit very fast dynamics [2], but auxiliary components (e.g., compressors, reformers etc.) typically make the system response dramatically slower. To compensate for slower system response, various buffer systems can be introduced, but these again add severely to system complexity.

Requirements for lower cost, higher PEMFC efficiency and improved reliability have, therefore, lately shifted focus on simpler PEMFC systems operating at atmospheric or close to atmospheric conditions.

However, for simpler systems with minimal use of auxiliary components, the degrees of freedom available for system control during operation are dramatically reduced. The close interrelation between the thermal- and water management is particularly challenging for PEMFC systems, and limits the possibility to control these individually.

Prototype testing of fuel cells in the laboratory is essential for identification of operation limitations and provides valuable input to improved cell and stack design.

This work focuses on identifying the operation limitations for a small 10-cell PEMFC for portable applications with an air supply fan as the only moving part. For this system, where the reactant air also is utilised for cell cooling, the air flow-rate represents the only degree of freedom for thermal as well as water management. Cell temperature constitutes the most critical factors for assuring stable and efficient system operation. Therefore, detailed exploration of the temperature distribution constitutes the main objective of this work.

THEORETICAL ASPECTS

Water management

A major disadvantage of the PTFE based membranes used in PEMFCs is that their proton conductivity depends strongly on their water content, thus making the water management one of the critical parameters during operation [5]. A key factor when controlling the water balance of a fuel cell is the temperature. Controlling the temperature is a desirable way to assure a proper water balance because it does generally not result in an increased parasitic loss in the system.

The amount of water the gases can contain ($p_{sat,T}^{H_2O}$) is exponential to the temperature. Therefore, a minor change in temperature may have a substantially influence on the membrane hydration and, hence, the ohmic resistance in the cell. A simple relationship for the water balance of a hydrogen/air fuel cell has been deduced (Eq. 1) assuming no net water transport through the membrane.

$$\text{Water excess} = \frac{iA}{2F} - \frac{iA}{4F}\left(\frac{\lambda}{0,21} - 1\right)\frac{p_{sat,T}^{H_2O}}{p_{tot}} \quad (1)$$

The first term in Equation 1 represents the water produced in the cell reaction and the latter the water leaving the cell, assuming dry gases at air inlet and water vapour saturated air exhaust gas. Back diffusion and electro-osmotic drag effects also influence the overall water balance of the fuel cell system. However, for thinner membranes, these effects counter-balance such that the overall water transport is close to zero. This assumption is in agreement with the findings reported by Mosdale et al. [6]. The water balance for a low current density system is illustrated in Figure 1 below.

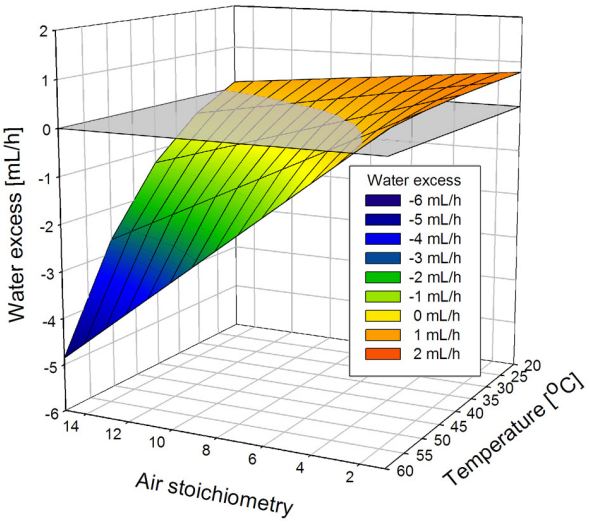

Figure 1: Simplified picture of the water balance (using Eq. 1) of a single fuel cell with a geometric area of 24 cm^2 operating at a current density of 0.10 A/cm^2, assuming atmospheric operation, no reactant gas humidification, no net membrane water transport and water vapour saturated air exhaust gas.

As expected, the water excess varies linearly with the air stoichiometry, and exponentially with respect to temperature (Figure 1). Water neutrality is indicated by the horizontal plane and its interception with the coloured surface. As can be seen from Figure 1, there is a surplus of water and hence risk of flooding at ambient stack operation temperatures for stoichiometries shown. At elevated temperatures, however, there is a water deficiency for almost any realistic set of operation conditions. For stable operation at 50 ^oC the air stoichiometry should be approximately 3.5 under these assumptions.

The simplified relationship illustrated in Figure 1 should be used with care and only serve as a guideline for water management during PEMFC operation.

Thermal management

The PEMFC is considered to be an efficient system, but still about 40-50% of the energy produced is typically dissipated as heat [6]. Heat production is mainly due to the activation overpotential of the cathode reaction, the ohmic losses and the concentration overvoltage in the fuel cell. Heat has to be removed from the fuel cell stack to prevent overheating during operation. This is usually done by means of water cooling for larger and pressurised stacks and air-cooling for smaller stacks. Active external cooling of the stack is supplemented by internal processes like water evaporation and condensation. An internal cooling effect is experienced at the cathode side where produced water is evaporated and subsequently transported out of the fuel cell by the air exhaust. Such an evaporative cooling principle has successfully been demonstrated in PEMFC stacks [4].

EXPERIMENTAL APPARATUS

The 10-cell PEMFC stack discussed in this paper is shown in Figure 2. Air was supplied by a CPU fan (Sunon) powered by an external power supply. Air flows from the transparent plastic manifold at the top and downwards through 34 straight channels (Figure 2). The four transparent 1/8 inch inlet/outlet tubes allow for counter- as well as parallel flow of hydrogen through the double serpentine anode flow field. Stack power was extracted by cables attached to gold plated copper current collectors sandwiched between graphite cell plates and aluminium end-plates. Individual cell voltages were monitored during operation.

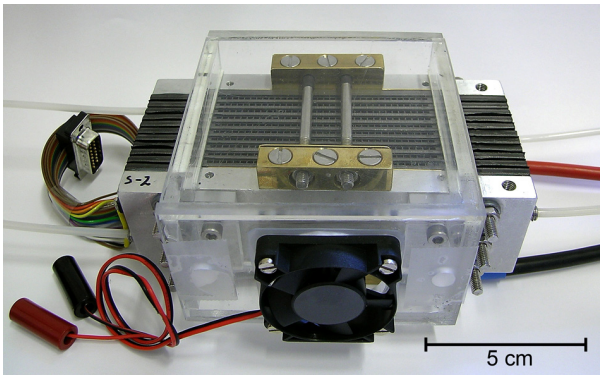

Figure 2: The PEMFC stack developed and characterized in this project.

The PEMFC stack consists of tailor made epoxy/graphite bipolar plates and commercial membrane electrode assemblies (MEAs) and gas diffusion layers (GDLs). The single cells were identical and had an individual geometric active cell area of 24 cm^2.

The MEAs were Gore Primea™ MEA Cleo Series 58 with a thickness of 18 µm, especially developed for operation with dry reactant gases. The catalyst loading was 0.4 mg Pt/cm^2 on both sides of the membrane. The GDL material used was ETEK V2 Double Sided Electrode Carbon Only with a thickness of 400 µm. The epoxy/graphite bipolar plate material was provided by SGL Carbon Group, Germany (SGL SIGRACET®, BMA5). The gas flow fields were designed and manufactured in-house using a CNC-machine. The gaskets were made from 0.5 mm silicone rubber.

The testing of the PEMFC stack was carried out at the group's test facilities with accurate control of the hydrogen gas-flow rate and logging of current, individual cell voltages and temperatures. During operation, individual cell temperature mapping was carried out by means of an array of small K-type thermocouples (Chromega/Alomega) from Omega Engineering, Inc. inserted into the air channels. The thermocouples were located at three different distances from the air outlet; bottom, middle and top position resulting in three measurement planes as indicated in Figure 3.

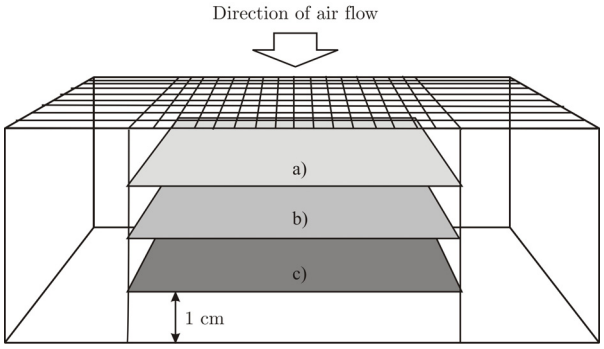

Figure 3: Sketch of the 10-cell PEMFC stack (end-plates not shown) and the three different planes a), b) and c) where the temperatures were measured by insertion of thermocouples into the air channels. Corresponding temperature contours are shown in Figure 4.

Polarization curves were obtained in a constant current mode by increasing current density from 0 to 0.40 A/cm^2 in steps of 0.05 A/cm^2.

RESULTS AND DISCUSSION

Cell performance results were obtained by generating polarization curves. Stable performance was obtained at 0.10 A/cm^2 over a period of 4 hours with less than 3 mV/h loss in single cell voltages. This small voltage decay is probably due to reversible effects such as platinum oxide formation and should not be interpreted as permanent degradation. Stack operation was limited to current densities below 0.40 A/cm^2, primarily due to uncontrollable internal temperature increase and potential risk of creating hot-spots and consequently pinholes in the membrane.

A semi-3-dimensional temperature distribution for the stack was obtained at steady state conditions. The temperature distribution (based on 300 measurement-points) is shown in Figure 4, at a current density of 0.10 A/cm^2.

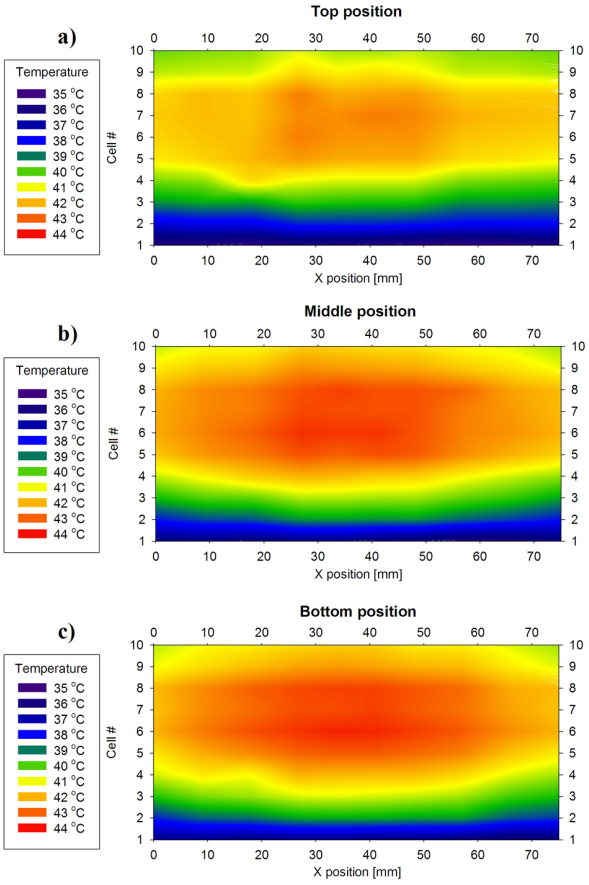

Figure 4: Temperature distribution in the air channels of the PEMFC stack at 0.10 A/cm^2, a) Top, close to air inlet, b) Middle of stack and c) Bottom, close to air outlet. H_2- and air-flow rates were 0.3 and approximately 20 L/min, respectively.

Under these operation conditions (Figure 4), the air stoichiometry is approximately 45. This high stoichiometry was chosen to keep cell temperature at approximately 40 °C. From Equation 1 it can be calculated that this corresponds to a water deficiency of approximately 5 mL/h per cell. Theoretically the cell should have dried out under these conditions. Four hours of stable operation indicates that the assumptions behind Equation 1 are not valid, and that the materials in use (MEAs and GDLs) exhibit pronounced water retention properties. Small pores in the GDLs may contribute to capillary forces and lower the water equilibrium pressure. From these results it can be concluded that the air exhaust leaving the PEMFC stack is not saturated with water vapour.

As can be seen from Figure 4, significant temperature gradients of up to 10 °C are encountered during operation. The air fan was located blowing towards one aluminium end plate to obtain a stagnant small overpressure in the air inlet manifold and a, hence, uniform air flow through all air channels. As can be seen, this contributes to substantial cooling of cells 1-3 which could have been avoided by placing the fan directly in front of the air channels. However, this may create "dead"-zones underneath the fan shaft and turbulence effects resulting in reduced stack performance.

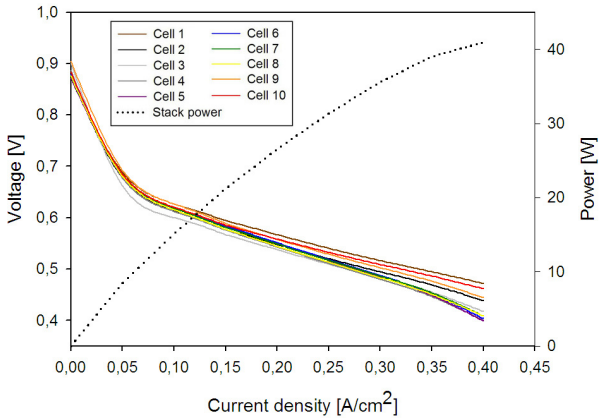

Figure 5: Cell voltages vs. current density for individual cells of the PEMFC stack up to a current density of 0.40 A/cm^2. Stack power is shown on the secondary Y-axis.

The substantial temperature gradients shown in Figure 4 may influence performance, but from Figure 5 it can be seen that all 10 cells show very similar polarization curves. However, the 2 outer most cells facing each end plate (cells 1 and 2 as well as 9 and 10) experiencing the lower operation temperatures show better performance than those closer to the middle at high current densities. This indicates that these outer most cells operate at more favourable conditions. Quantitatively, this is in agreement with the assumptions behind Equation 1 and Figure 1. The closer to water neutrality the cell operates, the better the performance. It may be concluded that although these new generation membranes which are optimised for dry reactant gases show good performance, proper water management is still of a certain importance for assuring high efficiency.

The electrical peak power output from the fuel cell stack was 41 W at 0.40 A/cm^2. Long term operation at this power density was, however, not possible due to uncontrollable temperature increase causing stack overheating with subsequent risk of membrane failure (pinholes).

Open circuit voltage (OCV) values obtained in this work were slightly lower (around 0.9 V) than OCVs measured in our laboratory for PEMFCs utilising Nafion 117 membranes (typically 0.92 to 0.98 V). This is probably due to thinner membranes (18 µm) applied in this study causing increased fuel crossover and hence a somewhat lower OCV.

The electrical efficiency, based on the lower heating value (LHV) when operating at 0.10 A/cm^2 assuming a hydrogen conversion rate of 90% ($\gamma = 0.9$), has been calculated to be 44% for the fuel cell stack and 41% for the PEMFC system, the difference due to the power consumption of the air fan.

CONCLUSIONS

An ambient pressure, self humidifying and air-cooled PEMFC stack has been designed and tested and operation limitations have been identified. Stable operation was realised at low current densities, despite temperature gradients of up to 10 ^{o}C. The stack operates well under dry conditions and provided a peak power of 41 W over short time intervals. Thermal management for this system has proven to be especially challenging and limits operation to low current densities. At high current densities, air cooling is not sufficient and the stack overheats. The water balance may be attained by proper thermal management.

Low OCV is assumed to be related to fuel crossover, typical for PEMFCs with thin MEAs. An overall electrical system efficiency (LHV) for the stack of 41% was achieved at 0.10 A/cm^2.

FURTHER WORK

A solution for more uniform cooling of the fuel cell stack is desirable. This may be obtained by placing the air-/cooling fan directly in front of the cathode air channels. However, the risk of "dead"-zones underneath the fan shaft and turbulence effects should be evaluated first. Alternatively the endplates of the stack can be thermally insulated, or dedicated cooling fans can be mounted on the stack as reported by Qi and Kaufmann [7]. However, additional fans will increase the parasitic losses in the system, and hence reduce the total efficiency of the system.

Further, since the membrane resistance gives valuable information about the humidity of the membrane, it could be interesting modifying the test facilities for online monitoring of individual cell resistivities by means of the current interrupt technique.

Recycling of hydrogen is a prerequisite for obtaining high fuel utilization and overall system efficiencies. Hence, the possibility to incorporate a pump to recycle the hydrogen should also be looked into. Even though this will add to the complexity of the system, this may increase total system efficiency.

ACKNOWLEDGEMENTS

This work was supported by The Research Council of Norway and SINTEF. IAESTE-student Feng Liu is acknowledged for carrying out the temperature measurements.

HEAT MANAGEMENT FOR HYDROGEN PRODUCTION BY HIGH TEMPERATURE STEAM ELECTROLYSIS

ABSTRACT

Many research and development projects throughout the world are devoted to sustainable hydrogen production processes. Low temperature electrolysis, when consuming electricity produced without greenhouse gas emissions, is a sustainable process, though having a limited efficiency.
It is possible to improve the performance of electrolysis processes by functioning at high temperature (High Temperature Electrolysis, HTE). This leads to a reduction in energy consumption but requires a part of the energy necessary for the dissociation of water to be in the form of thermal energy, and to be able to recover a part of the heat contained in the outlet products of the electrolysis. Heat would be brought by coupling the process either to a High Temperature Reactor (HTR) or to a geothermal source.
A technoeconomic optimisation of the upper heat exchanger network in the HTE process is carried out. The method we choose is the optimisation using genetic algorithms. The heat exchanger networks appear to be different depending on the heat source which is used.

INTRODUCTION

The use of hydrogen as a substitute to hydrocarbons, is currently the object of many research and development tasks throughout the world. To be sustainable, a hydrogen production process must be carried out without consumption of raw materials other than water and driven by energies which are produced without greenhouse gas emissions. Low temperature electrolysis carried out using sustainably produced electricity satisfies these constraints and is currently used to produce hydrogen. However, today, it is more expensive than the process of producing hydrogen by steam reforming of natural gas, which presents a double disadvantage since it consumes natural gas and rejects carbon dioxide. In the long term, methane costs should significantly increase and greenhouse gas emissions may be taxed. Therefore alternative processes should become competitive.

From a thermodynamical point of view, it is possible to improve the performance of electrolysis by functioning at high temperature (HTE). That makes it possible to reduce consumption but requires a part of the energy necessary for the dissociation of water to be in the form of thermal energy.

Recent HTE research programs have profited from new financings, mainly within the Generation IV International Forum framework for developing long term nuclear reactors [1]. The forum considers the possibilities of using nuclear energy, particularly high temperature helium cooled reactors (HTR) which include the possibility of producing hydrogen.

An interest for HTE is also expressed by a European collaboration that aims at studying and then validating the possibilities of producing hydrogen with HTE coupled with a geothermal source. One objective is the production of hydrogen by HTE coupled with a geothermal source in the Icelandic context. The goal is to build a 5 kWe prototype on the site of Nesjavellir, which is 20 km from Reykjavik [2]. The economically harnessable geothermal energy in Iceland has been estimated at approximately 200 TWh/year, of which only 1% has been harnessed up to now. Assuming the same technology as the one used in Iceland today to produce electricity from geothermal steam, the 200 TWh/year could be used for the production of 20 TWh/year of electricity, or 17 TWh/year of hydrogen.

Firstly, the communication will be devoted to the influence of the heat source temperature (HTR or geothermics) and the corresponding energy costs for both heat and electricity. Then, a technoeconomic optimisation approach will be presented in order to optimise the balance between operating costs and investment. Finally we will

detail the heat exchanger networks refering to a HTR or an Icelandic geothermal heat source [3].

HEAT SOURCES AND ENERGY COSTS

High Temperature Electrolysis (HTE) differs from the conventional electrolysis process because some of the energy required to dissociate the water is provided as heat instead of electricity, thus reducing the overall energy required and improving the process efficiency (cf. Figure 1). Because the conversion efficiency of heat to electricity is low compared to using the heat directly, the energy efficiency can be improved by providing the energy to the system in the form of heat rather than electricity.

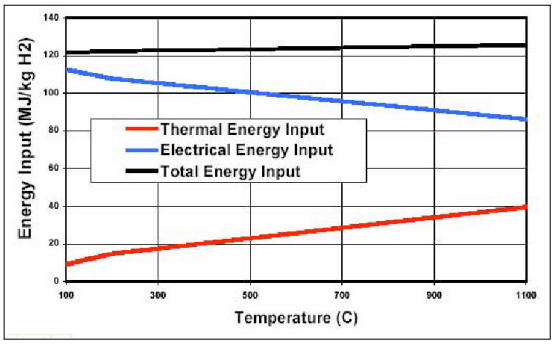

Figure 1: Thermal and electricity supply to the electrolyser

Then the economic interest of HTE will depend on both electricity and heat costs.
In Iceland the cost of extracting thermal energy from a geothermal source is only about 10% of the cost of electricity.

$$c_{kWh_{th}\,geo} = 0.1 \times c_{kWh_e\,geo} \quad (1)$$

With HTR the expected efficiency of electricity production is 50%. Hence we can assume that the price of thermal energy for HTR is 50% of the price of electricity.

$$c_{kWh_{th}\,HTR} = 0.5 \times c_{kWh_e\,HTR} \quad (2)$$

Thermal energy from a geothermal source is very inexpensive compared to thermal energy from a HTR.

In the Icelandic context steam could be supplied at 200°C. According to [3] only 3.8 kWh_e/Nm^3H_2 is needed with a thermal input of 200°C, compared with about 4.5 kWh_e/Nm^3H_2 in conventional electrolysers. Electricity price to industry in Iceland is approximately 0.014 €/kWh compared to 0.0284 €/kWh [4] for middle term electricity produced by nuclear reactors in France (cf. Table 1). The difference between producing hydrogen by HTE in Iceland or in France appears to be obvious, when regarding the cost of vaporising and heating water to the operating temperature of the electrolyser (cf. Figure 2).

c_{kWh_e} Iceland	0.014 €/kWh_e
c_{kWh_e} France	0.0284 €/kWh_e
$c_{kWh_{th}}$ Iceland	0.0013 €/kWh_{th}
$c_{kWh_{th}}$ France	0.0142 €/kWh_{th}

Table 1: Energy prices, geothermics / HTR

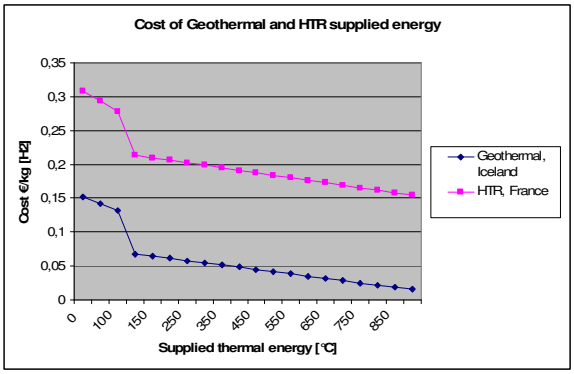

Figure 2: Cost of vaporising and heating water to the required temperature for the electrolyser

Although only 200°C of thermal output is possible today in Iceland, it could change. Recent research performed by Landsvirkjun on deep drilling in Iceland show a possibility of extracting 500-600°C steam at a depth of 4-5 km [5]. At this time deep drilling is purely experimental but could become a possibility within the next ten years. An increase of the exit temperature of the drilling well would significantly improve the economic interest of coupling HTE with a geothermal heat source.

A TECHNOECONOMIC OPTIMISATION FOR UPPER HEAT EXCHANGERS

The technoeconomic model

Method.

The technoeconomic approach we selected presupposes a heat exchanger network, also called a flow sheet. The optimisation procedure consists in minimising an objective function which takes into account operating as well as investment costs.

In the current context of sustainable development, advanced systems are being studied. These systems involve either high pressures, high temperatures, or corrosive products; sometimes several of these severe conditions. In all these cases investment costs can increase by one to two orders of magnitude when compared to classical alternative systems and consequently the interest for the technoeconomic approach should grow.

The heat exchanger network.

There are three possible operating modes for HTE depending on the energy balance at the electrolyser level: endothermal, isothermal and exothermal [6].

Endothermal. The temperature of the steam decreases from the input of the electrolyser to the output. This corresponds to the best energy efficiency but worst production cost because an endothermal electrolyser is much more expensive than an exothermal one.

Isothermal. The temperature of the steam is the same at the input as at the output. The energy efficiency is better than in the exothermal case but the electrolyser cost still outweighs better efficiency.

Exothermal. The temperature of the steam increases from the input of the electrolyser to the output. When coupling to a HTR, this corresponds to the worst energy efficiency but the best production cost because an exothermal electrolyser investment cost is the lowest of the three possibilities [6]. The exothermal mode is the only one to be considered for the geothermal context since the input temperature is only 200°C.

The heat exchanger network we optimised is the upper heat exchanger network involved in the HTE exothermal process (after the boiler, cf. Figure 3). The water entering these heat exchangers is already vaporised.

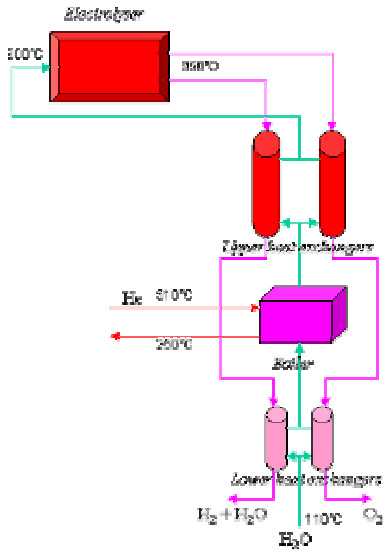

Figure 3: Heat exchanger network coupled with a HTR thermal source

The heat exchangers are supposed to be counter-current flow ones. They consist of a stack of corrugated plates. The heat exchangers characteristics are gathered in Table 2.

D_h	6.10^{-3} m
L	1 m
B	1 m

Table 2: Heat exchangers characteristics

Since we have a wide range of temperatures, we need different heat exchangers:

Low temperature (LT): < 650°C

Medium temperature (MT): 650°C < T < 850°C

High temperature (HT): > 850 °C

According to the heat source and the temperatures at the inlet and outlet of the electrolyser, either one, two or three temperature levels are involved.

The output of the electrolyser is firstly oxygen and secondly a mixture of hydrogen and water. This mixture is dependent on the recycling ratio *r*. Not all the water is electrolysed and the number *r* indicates the ratio of unelectrolysed water. The mixture of water and hydrogen is defined as follows:

$$\dot{m}_{1,H2} = (1-r)\cdot \dot{m}_{H_2 0}\cdot \frac{M_{H_2}}{M_{H_2O}} + r\cdot \dot{m}_{H_2O} \quad (3)$$

$$\dot{m}_{1,O2} = \frac{(1-r)}{2} \cdot \dot{m}_{H_2O} \cdot \frac{M_{O_2}}{M_{H_2O}} \quad (4)$$

The water flow rate used in the previous equations is the total one. This flow rate is split between the H_2/H_2O side and the O_2/H_2O side (cf. Eq. 5 et 6).

$$\dot{m}_{2,H2} = x \cdot \dot{m}_{H_20} \quad (5)$$

$$\dot{m}_{2,O2} = (1-x) \cdot \dot{m}_{H_2O} \quad (6)$$

Inlet temperatures and water outlet temperatures are fixed. Their numerical values depend on the kind of heat source and the temperatures at the inlet and outlet of the electrolyser (cf. Table 3).

The network is detailed in the Figure 4.

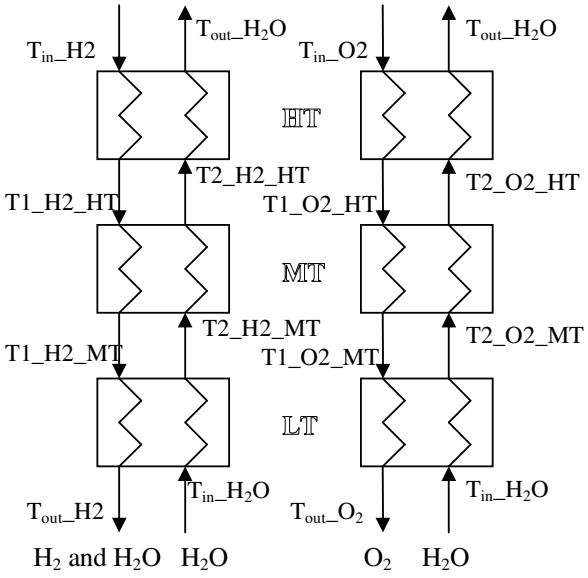

Figure 4: Upper heat exchanger network scheme

T_{in}_H2	950°C
T_{in}_O2	950°C
T_{out}_H_2O	900°C
T_{in}_H_2O (geothermics)	230°C
T_{in}_H_2O (HTR)	470°C
Pressure (geothermics)	1.5 MPa
Pressure (HTR)	3 MPa

Table 3: Fixed temperatures and pressures

The objective function.

It is the optimisation criterion, the function which is to be minimised. The objective function we chose is the discounted total unit production cost. (cf. Eq. (12)). The formula is similar to the one used in [1].

The total cost includes two parts: the investment costs (cf. Eq. (7)) and the operating costs.

$$C_i = c_i \cdot S \quad (7)$$

Investment can be done over several years (T_i). c_i depends on the heat exchanger type, materials, operating parameters. S is calculated using Equation (8).

$$S = \frac{Q}{U.\Delta T_{\log\ mean}} \quad (8)$$

The operating costs can be divided into two parts (cf. Eq. (9)): the cost of thermal energy consumption (cf. Eq. (10)) and the pumping costs (consumption of electricity, cf. Eq. (11))

$$C_o = C_e + C_{pomp} \quad (9)$$

$$C_e = c_{kWh_{th}} \frac{Q}{\eta} t_e \quad (10)$$

$$C_{pomp} = \frac{c_{Wh_e}}{\eta_{pomp}} \frac{\dot{m} \Delta P}{\rho} t_e \quad (11)$$

The discounted total unit production cost is obtained by dividing the discounted total production cost by the discounted production:

$$TC = \frac{\sum_{t=1}^{T_i+T_e} \left[\left(\sum_{n=1}^{N} (C_i)_{n,t} + \sum_{n=1}^{N} (C_o)_{n,t} \right) \cdot (1+\tau)^{-t} \right]}{\sum_{t=1}^{T_i+T_e} \left[\left(\sum_{n=1}^{N} (Pd)_{n,t} \right) \cdot (1+\tau)^{-t} \right]} \quad (12)$$

$$Pd = Q \cdot t_e \quad (13)$$

Table 4 gathers the values of the different parameters of the model.

T_i	3 yrs
T_e	30 yrs
Operating factor	80%
τ	6%
c_i	400 €/m^2 (LT) 800 €/m^2 (MT) 4000 €/m^2 (HT)
$c_{kWh_{th}}$ c_{kWh_e}	Cf. Table 1
η_{pomp}	0.80

Table 4: Model parameters

Assuming that plate heat exchangers with primary surfaces are used to insure high effectivenesses, the overall heat transfer coefficient can be derived as follows, neglecting the conduction thermal resistance:

$$U = \frac{1}{\frac{1}{h_1} + \frac{1}{h_2}} \quad (14)$$

where h_1 and h_2 are the heat transfer coefficients for the hot (*1*) and cold (*2*) side respectively.

$$h_i = \frac{Nu_i \cdot \lambda_i}{D_h}, \; i = 1, 2 \quad (15)$$

Nu_i is the Nusselt number which can be calculated for specific plates by:

$$Nu_i = 0.254 \, \mathrm{Re}_i^{0.638} \, \mathrm{Pr}_i^{1/3} \quad (16)$$

Pr_i being the Prandtl number and Re_i being the Reynolds number calculated from:

$$\mathrm{Re}_i = \frac{2 \dot{m}_i}{\mu_i \, B} \quad (17)$$

Variables and constraints.

The total mass flow rate of water $\dot{m}_{H20}$, the dividing factor x and the temperatures are the optimisation variables.

Several inequality constraints are taken into account:

- the temperatures of water are lower than the ones of the products of electrolysis;
- the velocity of the streams must not exceed 30m/s;
- the heat exchangers effectiveness must not exceed 0.9.

The optimisation software: based on genetic algorithms

The technoeconomic model was implemented in a software devoted to optimisation, called *Vizir*, which is based on genetic algorithms [7]. This software is developed at the CEA.

Genetic algorithms are a stochastic method of optimisation laying on an analogy with the Darwinist theory. They work with the same process, that is to say the evolution of a population using mutations and crossovers. The selected individuals are the ones who are adapted according to the objective function, which means for our study that the chosen values for the operating parameters are those corresponding to lower total costs.

This method has many advantages. The objective function does not need to be continuous or verify any other property. It is only needed to be able to evaluate it. Moreover, when a local optimum is found, the algorithm does not stop. Finally they are robust algorithms that allow complex systems to be studied.

HEAT EXCHANGER NETWORKS ACCORDING TO THE HEAT SOURCE: HTR OR ICELANDIC GEOTHERMICS

Icelandic geothermal heat source

The results of the optimisation are presented in Table 5, Figure 5, and Table 6.

TC	0.0033 €/kWh
Investment part	17.5 %
Part of thermal energy consumption cost	71.3 %
Part of pumping cost	11.2 %

$4690 < Re < 16540$	
0.55 kW/m^2 °C $< U < 0.65$ kW/m^2 °C	

Table 8: Heat exchangers characteristics

The dominant part is the thermal energy consumption cost.

CONCLUSION

First we can point out that genetic algorithms proved to be very effective to solve the problem of the optimisation of upper heat exchangers.

The results of the optimisation show that the heat exchanger networks strongly depend on the heat source. The investment part is very different for each case. When coupling the HTE to a HTR, the cost of thermal energy consumption clearly predominates.
Moreover, in this study, the electrolyser is supposed to work between 900°C and 950°C. Other ranges of temperature are possible. Indeed, research and development works are heading for lower ranges of temperature. This would lead to different networks, since the High Temperature level could no longer be needed.

The design of the networks for high temperature electrolysis processes will depend on the evolutions and progresses to come. In particular, in heat exchanger technology, many researches are in progress concerning materials and component assembling. It is also the case for electrolysers. It will also strongly depend on the evolutions of both heat and electricity costs.

HYDROGEN PRODUCTION BY ADVANCED PEM WATER ELECTROLYSERS - REDUCED ENERGY CONSUMPTION BY IMPROVED ELECTROCATALYSIS

A. Marshall*, B. Børresen, G. Hagen†, M. Tsypkin, R. Tunold
Department of Materials Technology, Group of Electrochemistry
NTNU, 7491 Trondheim, Norway

ABSTRACT

PEM water electrolysis systems offers several advantages over traditional technologies including greater energy efficency, higher production rates, and more compact design. Normally in these systems, the anode has the largest overpotential at typical operating current densities. By development of the electrocatalytic material used for the oxygen evolving electrode, great improvements in efficency can be made. We find that using cyclic voltammetry and steady state polarisation analysis, enables us to separate the effects of true specific electrocatalytic activity and active surface area. Understanding these two factors is critical in developing better electrocatalytic materials in order to further improve the performance of PEM water electrolysis cells. The high current performance of a PEM water electrolysis cell using these oxides as the anode electrocatalyst has also been examined by steady state polarisation measurements and electrochemical impedance spectroscopy. Overall the best cell voltage obtained is 1.567 V at 1 A cm^{-2} and 80 °C was achieved when using Nafion 115 as the electrolyte membrane.

INTRODUCTION

Carbon free hydrogen can be produced using water electrolysis. PEM water electrolysis systems offers several advantages over traditional technologies including greater energy efficency, higher production rates, and more compact design [1]. This method of hydrogen production is envisioned in a future hydrogen society whereby hydrogen as the energy carrier is incorporated in an idealised "energy cycle". In this cycle, electricity from renewable energy sources, is used to electrochemically split water into hydrogen and oxygen. The only input to this cycle is the clean renewable energy and the only output is electric power.

A basic schematic of a PEM water electrolysis cell is shown in Figure 1. The PEM water electrolysis cell consists primarily of a proton exchange membrane on which the anode and cathode are bonded. These electrodes are normally a composite of electrocatalytic particles and electrolyte polymer. Normally different electrocatalysts are utilised for the anode (eg. IrO_2) and cathode (eg. Pt). When the electrode layers are bonded to membrane, it is known as the membrane electrode assembly (MEA). The electrical contact and mechanical support is established

*Corresponding author: Phone: +47 735 94021 Fax: +47 735 94083 E-mail:aaron.marshall@material.ntnu.no

with porous backings like metallic meshes or sinters. In a PEM water electrolyser hydrogen is produced by supplying water to the anode where it is decomposed into oxygen, protons, and electrons (Equation 1). The protons are transported through the proton conductive membrane to the cathode. The electrons exit the cell via the external circuit, which supplies the driving force (i.e. cell potential) for the reaction. At the cathode the electrons and protons recombined to give hydrogen gas (Equation 2).

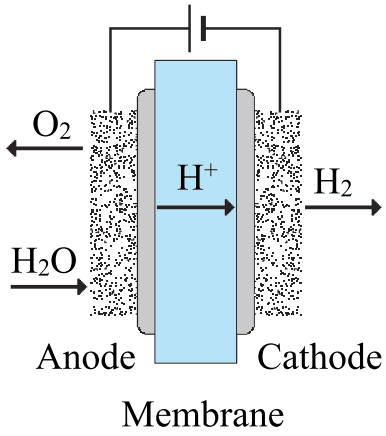

Figure 1: PEM water electrolyser schematic

$$H_2O \rightarrow \frac{1}{2}O_2 + 2H^+ + 2e^- \qquad (Anode) \qquad (1)$$

$$2H^+ + 2e^- \rightarrow H_2 \qquad (Cathode) \qquad (2)$$

$$H_2O \rightarrow \frac{1}{2}O_2 + H_2 \qquad (Cell) \qquad (3)$$

Presently there is no large scale use of PEM water electrolysis systems, with only a very few commercial systems available [2]. The restricting aspects of these systems is the high cost of the materials such as the electrolyte membrane and noble metal based electrocatalysts, as well as the complex system components to ensure safe and reliable operation.

Normally in these systems, the anode has the largest overpotential at typical operating current densities (normally around 10 kA m^{-2}) [3] with the total cell voltage required to split water given by equation 4. This is easily seen in a typical polarisation curve of a PEM water electrolysis cell (Figure 2). For this reason this work has concentrated on the anode electrocatalyst development. Recently $Ir_xSn_{1-x}O_2$ [4–7], $Ir_xRu_{0.5-x}Sn_{0.5}O_2$ [8] and $Ir_xRu_yTa_zO_2$ powders have been investigated as oxygen evolution electrocatalysts in our group.

$$E_{cell} = E^{rev} + \eta_{anode} - \eta_{cathode} + IR \qquad (4)$$

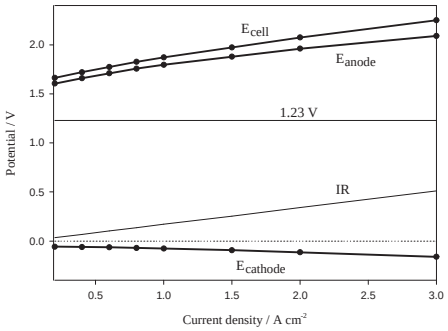

Figure 2: Polarisation curve for a PEM water electrolyser at 25 °C, IrO_2/N-105/40% Pt/C

Noble metal oxides as electrocatalysts are well established in many industrial electrochemical processes in the form of dimensionally stable anodes (DSA) as developed by Beer [9]. Ruthenium is known as the most active oxide for anodic oxygen evolution [10], however it suffers from instability and therefore should be stablised with another oxide such as IrO_2 [11] or SnO_2 [12]. Tantalum is a well known addition to DSA electrodes, and Ir-Ta oxides have been suggested as the most efficient electrocatalysts for oxygen evolution in acidic electrolytes due to the high activity and corrosion stability [13]. Although very comprehensive studies of the structural and electrochemical properties of DSA oxides have been carried out, little is known regarding the structure and electrocatalytic properties of oxide powders. This is mainly due to the prevalence of DSA electrodes in industrial processes compared with the same oxide compositions in particle form. In addition, it is well known that the a wide range of preparation conditions affect the formation and properties of DSA type oxide layers [14] as will the presence of Ti originating from the substrate (see [15]), and therefore analysis of powder based oxides gives an insight to the specific nature of noble metal oxides as electrocatalysts while providing a possible use in PEM water electrolysis applications.

In the following, we will use a range of recent results from our work to highlight the success we have had

using a muli-disciplined approach to electrocatalyst development.

EXPERIMENTAL

Electrochemical characterisation of the various electrocatalytic powders was conducted in 0.5 M H_2SO_4 (Merck, p.a) electrolyte at room temperature, by supporting the powders on titanium plates using a spraying technique. The electrocatalytic layer consisted of 95 wt% electrocatalyst and 5 wt% Nafion ionomer[1], with a total loading of 1 mg cm^{-2}. Cyclic voltammetry and polarisation measurements were performed using an IM6e electrochemical workstation from ZAHNER-elektrik GmbH & Co. KG. All potentials are quoted versus the reversible hydrogen electrode in the same electrolyte. Cyclic voltammetry is often used in DSA literature to compare the active area or number of active points of a noble metal oxide layer. This is carried out by measuring the charge (the number of electrons transferred) as a function of sweep rate. The charging / adsorption process for iridium oxide is given by the following equation [16]:

$$IrO_a(OH)_b \rightleftharpoons IrO_{a+\delta}(OH)_{b-\delta} + \delta H^+ + \delta e^- \quad (5)$$

This charging reaction allows the active surface area of the oxides to be compared assuming that the charging reaction is proportional to the total number of active sites at the oxide–electrolyte interface [17]. The outer charge represents the active area which is easily accessible, whereas the total charge includes active points within the particle structure, to which the electrolyte must diffuse, in order to be included in the electrode response.

A PEM water electrolysis cell was also used to evaluate the performance of the electrocatalysts under real conditions, by applying the oxides as the anode and 20% Pt/C[2] as the cathode. Details of the cell can be found elsewhere [6]. The membrane electrode assembly (MEA) was prepared by spraying the ink containing the electrocatalyst and Nafion ionomer directly to Nafion 115 membranes[3] at 90 °C using a custom built automated spray system. The MEA was mounted into the cell between two porous titanium sinters[4], and preheated deionised water was supplied to both the anode and cathode compartments at 5 l min^{-1}. Total cell polarisation curves were recorded by stepping the current between 1 and 2000 mA cm^{-2}, and the cell impedance was recorded at 20 mA cm^{-2} using frequencies ranging from 100 kHz to 100 mHz with an AC amplitude of 5 mV.

RESULTS AND DISCUSSION

Electrochemical Active Surface Area

In the system $Ir_xSn_{1-x}O_2$ we find that the active area is proportional to the iridium content of the oxide [6]. This is because the tin present in the oxide lattice does not contribute to the charging reaction. Small additions of tin (up to 20-30 mol%) may be considered reasonable as the total available area only decreases by 10-15% which probably results in a overall cost benefit considering the relative price of iridium and tin. Addition of ruthenium to the $Ir_xSn_{1-x}O_2$ system in order to replace the more expensive and less active iridium component with ruthenium results in a significant reduction in active surface area [8](Figure 3). The decrease is even more dramatic if the decrease in total tin content of the material and therefore higher noble metal loading on the electrode is considered. As said above mixtures of iridium and ruthenium oxide often give rise to a maximum in anodic charge at intermediate compositions [18, 19], however here we have found based on XPS and XRD results that the reduction in active surface area is explained by the shape decrease in the concentration of noble metal elements at the surface of the particles [8]. This is largely due to the synthesis method of the oxide, in which the ruthenium component clusters strongly together resulting in a heterogenous particle structure with active noble metal elements larger confined to the inner core of the particle. Since the majority of electrochemical processes occur at the surface, this noble metal core does not play a role in the charging reaction.

Similar results were obtained for the $Ir_xRu_yTa_zO_2$ system For the Ir-Ru oxides there is a slight maximum around 40 mol% Ru, whereas for the ternary

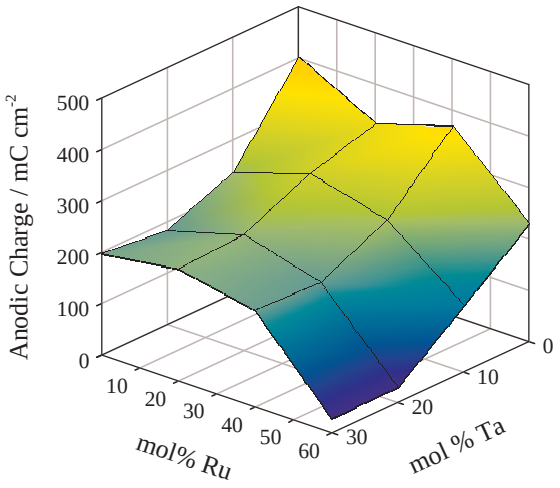

Figure 4: Total anodic charge of $Ir_xRu_yTa_zO_2$ in 0.5 M H_2SO_4

electrodes the maximums are found around 20 mol% Ru (Figure 4). The lower charge for the electrodes containing high levels of Ru, is due to the effect ruthenium has on the oxide crystallinity. Using XRD and EXAFS analysis showed that increasing the ruthenium content resulted in more ordered oxide structures which presumably have less roughness and defects. As tantalum will not take part in the charging process directly the results show the expected results with the total charge decreasing as tantalum content increases. Assuming that the charging process is similar, normally it should be expected that ruthenium oxide electrodes will have a larger anodic charge, as by weight, ruthenium oxide contains around 70 % more atoms than iridium oxide.

The choice of electrocatalyst at this stage of analysis is not straightforward. Although we know that the active area is a function of synthesis parameters and composition, we also know that specific activity, stability and cost will be effected, and thus much more analysis is required.

Steady state polarisation analysis

Low current steady state polarisation analysis is one clear method of determining an electrocatalysts ability to lower the overpotential and thus improve the efficiency the water electrolyser. A secondary result of this analysis is the ability to distinguish between various reaction mechanisms and rate determining steps for the oxygen evolution reaction [20]. Several low current polarisation curves in 0.5 M H_2SO_4 are shown in Figure 5. Data for the $Ir_xRu_{0.5-x}Sn_{0.5}O_2$ and $Ir_xRu_yTa_zO_2$ systems are shown in Table 1 and Figure 6 respectively.

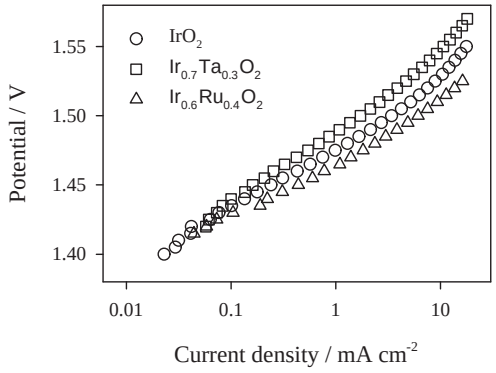

Figure 5: Polarisation curves of $Ir_xRu_yTa_zO_2$ in 0.5 M H_2SO_4

Based on this analysis and with comparison to the active area measurements, we can conclude that active surface area is not solely responsible for the electrocatalytic performance of these oxides. This is clearly due to the fact that oxide composition, particularly the type of noble metal used, effect the specific electrochemical activity, a property which is unaffected by surface area[5].

[5]This is generally true except when dealing with "nano"

Specific Electrocatalytic activity

In our work we have found that combining the active surface area measurements with the total electrocatalytic performance at low current densities can yield very useful information regarding the specific electrocatalytic activity, which is free from surface area effects [6, 8]. This best found by dividing the current density by the outer anodic charge found by the cyclic voltammetry measurements. The potentials at a normalised current density of 0.02 mA mC^{-1} can then be used to compare the materials (Figure 7). It is very clear that the specific electrocatalytic activity increases (i.e. $E_{0.02mAmC^{-1}}$ decreases) almost linearly with the ruthenium content. This is also true for $Ir_xRu_yTa_zO_2$ electrocatalysts, with tantalum having no effect of the specific activity of the material. In systems such as $Ir_xSn_{1-x}O_2$ where there is only one active element (assuming that the activity of SnO_2 is many times less than IrO_2) we find that the specific activity is constant. Therefore is systems containing multiple active elements we suggest that there is an optimum in the electrocatalytic performance of these materials, based on the active area and the specific activity. Although this finding does not directly result in any performance improvements it is important for electrocatalyst development. By carefully manipulating the synthesis procedure, it should be possible to prepare an oxide with high specific activity and high surface area, resulting in considerably increased performance.

Electrical conductivity measurements

The electrical conductivity of the active layer in a PEM water electrolyser cell is very important and contributes directly to the efficiency of the electrolyser as shown in Equation 4. This is even more critical when one considers that a main advantage of PEM water electrolysers in comparison with traditional systems is the high operating current densities which can be achieved. Due to this high operating current density, the cell (and therefore the layer) must have a low resistivity. Electrical conductivity of DSA type oxide layers has had some attention in literature [14], and as discussed in this review, the conductivity of the oxides rarely causes a signifi-

based materials, in which the small size of the particles may induce changes in the chemical and electronic properties of the material itself

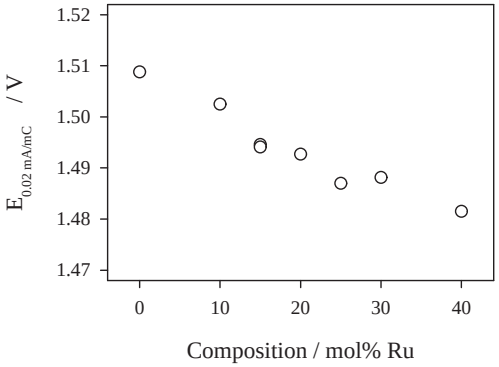

Figure 7: Specific activity of $Ir_xRu_{0.5-x}Sn_{0.5}O_2$ in 0.5 M H_2SO_4

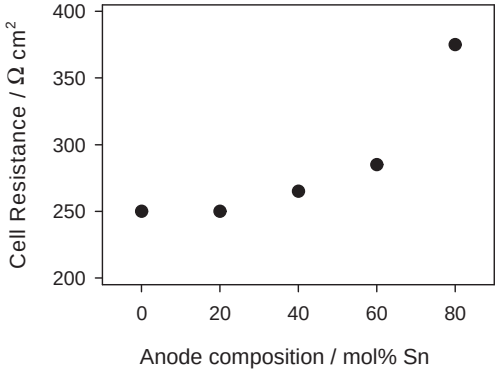

Figure 8: PEM water electrolysis cell resistance as a function of anode composition

cant performance loss as the highest resistivity reported is on the order of 10^{-2} Ω cm. Resistivities are around 3-6 x10^{-5} and 3-5 x10^{-5} Ω cm for crystalline IrO_2 and RuO_2 respectively [21]. The mechanism or cause of the resistivity is also suggested to occur primarily from the intergrain regions, and that the conductivity occurs with a "hopping" mechanism. Clearly in a layer consisting of particles, the resistance will be increased due to the large number of grain and particle boundaries. The contribution of the oxide layers resistivity to performance loss in PEM water electrolysers has been discussed previously [3, 6]. The resistivity in the MEA layer can be obtained directly by electrochemical impedance spectroscopy. From the previous work based on pressed powder measurements it was expected that the resistivity difference between the low tin and high tin content oxides should correspond to 50-100 mV at 1 A cm^{-2} [5]. The results from full cell impedance measurements show that there is an increase in the full cell resistance as the anode composition is varied (Figure 8). The maximum difference corresponds to 125 mV at 1 A cm^{-2} which is similar to that predicted by the pressed powder measurements. Clearly increasing the tin content to above 60 mol% causes unacceptable performance losses due to considerably increased ohmic resistance.

PEM water electrolysis performance

The performance of the various anode electrocatalysts were evaluated in a single PEM water electrolysis cell up to current densities of 2 A cm^{-2} with the total (anode + cathode) noble metal loadings less than 2 mg cm^{-2}. Typical polarisation curves at 80 °C are shown in Figure 9 (Anode composition indicated on Figure). The potential at 1 mA cm^{-2} is used to show the performance of the anode electrocatalysts without the influence of ohmic resistivity and high bubble formation, whereas the potential at 1 A cm^{-2} ($E_{1Acm^{-2}}$) will be affected by ohmic resistivity and bubble formation and thus gives a measure of the performance under real operating conditions.

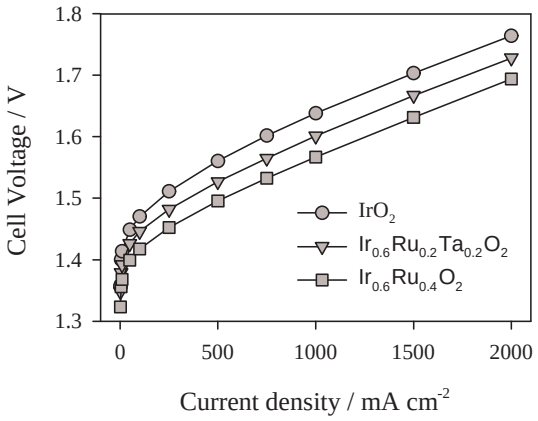

Figure 9: Polarisation curve of PEM water electrolysis cell at 80 °C

It is found that the overpotentials in 0.5 M H_2SO_4 and in the PEM environment at low current density

are highly correlated. The measurements in 0.5 M H_2SO_4 are therefore very useful in screening materials for their electrocatalytic properties. At high current densities, the relationship between the trends in low current density overpotential and high current overpotentials are complex. This is due to the influence of mass transport and electrical/ionic resistivity on the high current overpotential. Therefore using the differences between low and high current densities can yield information regarding the importance of structural aspects of the particles and catalytic layer.

Overall, by using a multi-disciplined approach to develop and characterise electrocatalysts, we have achieved significant improvements to the performance and efficency of a PEM water electrolysis cell. The best result was obtained with an $Ir_{0.6}Ru_{0.4}O_2$ anode and 20 wt% Pt/C cathode, with a cell voltage of 1.567 V at 1 A cm^{-2} and 80 °C when using Nafion 115 as the electrolyte membrane. This represents a cell efficiency based on minimum chemical work of 76 % ($\varepsilon_{\Delta G}$) and 94.4 % based on the higher heating value ($\varepsilon_{\Delta H}$), equating to an energy consumption of 3.75 kWh Nm^{-3} H_2 at 1 A cm^{-2}.

CONCLUSIONS

Hydrogen will be a part of future energy systems. By using PEM water electrolysis, this hydrogen can be produced efficiently without environmental impact if renewable energy is used as the power source. Improvements to the performance and efficiency of PEM water electrolysis cells has been studied by using electrocatalysis. Various aspects of electrocatalysis has been reviewed and it has been found that not one property should be used for characterising and understanding the electrocatalysis process. Active surface area, specific activity, electronic resistance and particle/layer structure are all important properties which need to be optimised in order to achieved high efficiency and performance. In the PEM water electrolysis, very high performance was obtained when using electrocatalysts developed following these guidelines. The best result was obtained with an $Ir_{0.6}Ru_{0.4}O_2$ anode and 20 wt% Pt/C cathode, with a cell voltage of 1.567 V at 1 A cm^{-2} and 80 °C when using Nafion 115 as the electrolyte membrane. This equates to a cell efficiency of 94.4 % ($\varepsilon_{\Delta H}$) and an energy consumption of 3.75 kWh Nm^{-3} H_2 at 1 A cm^{-2}.

ABSTRACT

This paper presents a zero-dimensional mathematical model of a planar 2^{nd} generation Solid Oxide Fuel Cell (SOFC) suitable for simulation of hybrid power systems. The model accounts for methane reforming and the water-gas shift reaction in addition to the electrochemical oxidation of hydrogen. The most novel and important part of the model is the detailed electrochemical sub-model, which is phenomenological and based on the most recent research on SOFCs. Empirical current-voltage data was obtained and used to calibrate the activation and concentration polarization parameters of the electrochemical model. This approach gives good accuracy when compared to the original data. The SOFC model was implemented in the Dynamic Network Analysis (DNA) simulation software. The result is an accurate and flexible tool suitable for simulation of SOFC-based hybrid power systems.

INTRODUCTION

The high temperature Solid Oxide Fuel Cell (SOFC) is one of the most promising types of fuel cells. Because of its high operating temperature, SOFCs can use hydrocarbons like methane and natural gas directly as fuels. In addition, the high temperature makes SOFCs usable in small stationary hybrid power systems, where the high quality heat produced in the SOFC, can be utilized in heat engines. These hybrid power systems are often complex and a flexible simulation tool is necessary to analyze the systems in detail. This paper presents a zero-dimensional mathematical model of a planar SOFC suitable for this purpose. The model accounts for methane steam-reforming and the water-gas shift reaction in addition to the electrochemical oxidation of hydrogen. This type of SOFC model is not new, however previous models were mostly based on the tubular type of SOFC with a very different geometry and thermal characteristics, see eg. (Costamagna et al 2000, [1]) or (Massardo and Lubelli 2001, [2]). Furthermore, the electrochemical model used in those models was first presented over 10 years ago and does not account for all sources of electrical polarization in the SOFC (Achenbach 1994, [3]). The model presented here offers an improvement, as it uses recent research on 2^{nd} generation SOFC electrochemistry. To facilitate the objective of hybrid power system simulation, the SOFC model has been implemented in the open source simulation software "Dynamic Network Analysis" (DNA).

THE DNA SIMULATION TOOL

DNA is a component-based simulation tool designed for both static and dynamic simulation of power plants and other energy systems (Elmegaard 1999, [11]). It is developed at the Department of Mechanical Engineering at the Technical University of Denmark and its available for download from:
`http://www.et.dtu.dk/software/dna`
DNA features:

- An extensive component library of common energy system components such as compressors, turbines, heat exchangers etc.
- Built-in routines for thermodynamic, transport and radiative properties.
- Automatic satisfaction of mass and energy conservation for all system components.
- Automatic calculation of all gas compositions.
- Warning for simulations that do not fulfil the 2^{nd} law.

By implementing the developed model in DNA, the user can utilize the existing component library which reduce the work required to develop subsequent hybrid power system simulation models.

DESCRIPTION OF THE SOFC

The SOFC is a chemical reactor that electrochemically oxidizes hydrogen into water, thereby releasing energy in the form of electrical power and heat:

$$H_2 + \frac{1}{2} \cdot O_2 \rightarrow H_2O \qquad (1)$$

A SOFC consists of three main parts, the anode, the cathode and the electrolyte. Hydrogen is supplied

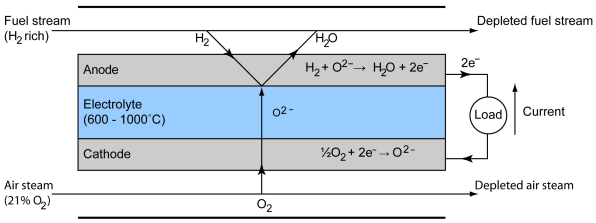

Figure 1: Solid Oxide Fuel Cell schematic (Petersen 2004, [4])

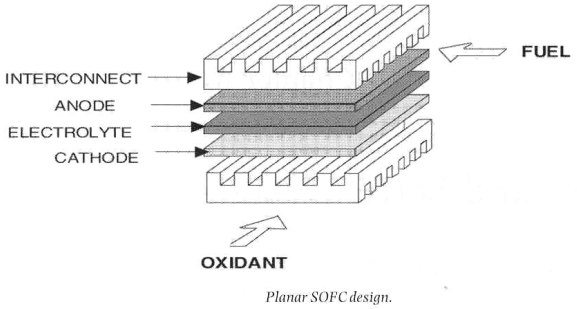

Figure 2: Planar SOFC design (Singhal and Kendall 2004, [7])

to the anode side of the SOFC, and oxygen (in air) is supplied to the cathode. A schematic of SOFC is illustrated in figure 1. The electrochemical oxidation is facilitated by the following part-reactions: Hydrogen is transported through the anode to the anode/electrolyte interface by diffusion, where it reacts with oxide ions (O^{2-}) suspended in the electrolyte. This produces water and releases two electrons:

$$H_2 + O^{2-} \rightarrow H_2O + 2e^- \tag{2}$$

The electrons are transported through an external electrical circuit to the cathode. At the cathode oxygen is transported to the cathode/electrolyte interface by diffusion, where it reacts with the electrons to produce new oxide ions:

$$\frac{1}{2} \cdot O_2 + 2e^- \rightarrow O^{2-} \tag{3}$$

The oxide ions are transported through the electrolyte to the anode, by ionic conduction, thus closing the circuit. Power is produced by inserting a load in the external circuit. The electrolyte is made from Yttria Stabilized Zirconia (YSZ), which only becomes an efficient conductor of oxide ions above approx. 650$^\circ C$. Because of this, SOFCs must operate at high temperatures (Larminie and Dicks 2003, [6]). The anode is made as a composite of metallic nickel and YSZ and is highly porous to allow for good mass transport of reagent and product gasses. The use of nickel gives the anode good electrical conductivity and it also acts as a current collector. In 2nd generation SOFCs the anode is many times thicker than the other parts as it provides mechanical strength to the entire cell. The cathode is most commonly made from Strontium-doped Lanthanum Manganite (LSM) and like the anode has a porous structure (Larminie and Dicks 2003, [6]). Interconnects are placed on both sides of the SOFC, to act as current collectors and provide effective electrical connections between the cells as illustrated in figure 2. The interconnects also provide hydrogen to the anode and oxygen to the cathode through a number of parallel channels. Interconnects are made from a stainless steel/chromium alloy provided the operating temperature is below 900$^\circ C$. The voltage of a single SOFC is in practice below one volt and to obtain higher voltages SOFCs are connected in electrical series in a SOFC stack where the number of cells depends on the required voltage. Multiple SOFC stacks can be connected in parallel in a SOFC module to provide the required power at a given voltage. Because of the high operating temperature, methane can be used directly as fuel using internal steam reforming (Larminie and Dicks 2003, [6]):

$$CH_4 + H_2O \leftrightarrow 3H_2 + CO \tag{4}$$

In addition to the reforming reaction hydrogen is produced by the water-gas shift reaction:

$$CO + H_2O \leftrightarrow H_2 + CO_2 \tag{5}$$

To avoid carbon build-up on the anode which can destroy the SOFC, more steam is supplied than required for stoichiometry. This leads to the definition of the Steam-To-Carbon-Ratio (STCR) which is the ratio between steam and combustible species (Braun 2002, [8]):

$$STCR = \frac{[H_2O]}{[CH_4] + [CO]} \tag{6}$$

The STCR is normally kept above 2 to avoid carbon deposition (Braun 2002, [8]). The reforming and the water-gas shift reactions can both be assumed to reach equilibrium because the nickel in the anode

acts as a catalyst (Larminie and Dicks 2003, [6]). Furthermore, the reforming reaction is assumed to reach completion because the high temperature and the water content result in a high equilibrium constant (Petersen 2004, [4]). Therefore, no methane is present at the SOFC outlet. There must be positive partial pressures of the reactants over the total fuel cell surface in order to generate a usable voltage. Thus, there must be un-reacted fuel and oxygen present at the exit of the fuel cell. This results in the definition of the fuel utilization which is the ratio of hydrogen consumed to hydrogen supplied, (Braun 2002, [8]). For a fuel consisting of a mixture of carbon monoxide, hydrogen and methane, fuel utilization is defined as:

$$U_f = \frac{\dot{r}_{H_2}}{4\dot{n}_{CH_4,in} + \dot{n}_{CO,in} + \dot{n}_{H_2,in}} \tag{7}$$

In eq. 7, methane and carbon monoxide are expressed as hydrogen equivalents; each methane molecule equals four hydrogen equivalents (one from reforming reaction and one from water-gas shift reaction) and each carbon monoxide is equal to one hydrogen equivalent (from the water-gas shift reaction). Air is used to supply oxygen to the reactions of the SOFC, but also to act as coolant for the SOFC. Thus the amount of oxygen supplied to the SOFC will be greater than what is required for stoichiometry. The oxygen utilization is defined as:

$$U_a = \frac{\frac{1}{2} \cdot \dot{r}_{H_2}}{\dot{n}_{O_2}} \tag{8}$$

THE ZERO-DIMENSIONAL SOFC MODEL

The approach used to model the SOFC is to split the governing equations in two categories: the conservation equations for mass, energy and momentum and the constitutive equations. The conservation equations are formulated for a control volume on a molar basis. Momentum conservation is formulated as two pressure balances; one for the anode side, and one for the cathode side (Braun 2002, [8]). The constitutive equations model the chemical and electrochemical reactions, occurring inside the SOFC. Only the constitutive equations are described in detail here, for further details see (Petersen 2004, [4]) In order to develop a simple but accurate model, a number of additional assumptions are made:

- Only steady state operation is considered.

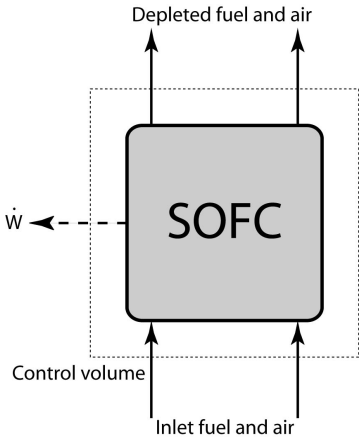

Figure 3: Control volume for the zero-dimensional SOFC model.

- Kinetic and potential energy is neglected.
- Adiabatic operating conditions.
- Outlet temperatures of air and fuel are equal to the operating temperature of the cell.
- Electrochemical oxidation, steam reforming of methane and the water-gas shift reaction are the only chemical reactions.
- Air only consists of N_2 and O_2. Fuel only consists of CH_4, CO, CO_2, H_2, H_2O and N_2. All are considered to be ideal gasses.
- There is enough water vapor present in the fuel stream to reform all the methane.
- The reforming reaction reaches completion and the water-gas shift reaction reaches equilibrium.
- Single cell performance is extrapolated to all the SOFC stacks (Braun 2002, [8]).

The control volume of the SOFC model is illustrated on figure 3, table 1 lists the user-specified inputs to the model.

The constitutive equations

The constitutive equations are split into three submodels: the first model the chemical reactions of the SOFC, the second model the cell's electrochemical behavior and the third model the pressure losses in the SOFC.

Inputs to the SOFC model
Temperature and pressure of inlet fuel and air
Chemical composition of inlet fuel and air
Fuel and air utilization
Fuel mass/molar flow
Number of cells per stack and total number of stacks

Table 1: Inputs to the SOFC model, which must be supplied by the user

Chemical reaction model

This chemical reaction model sub-model evaluates the composition fuel and air exiting the SOFC. The chemical model is based on conservation of species and chemical equilibrium, and is very commonly used in SOFC modelling (Braun 2002, [8]). The equations for conservation of species are formulated for the reactions in eq. 1, 4 and 5, and separately for the anode and cathode species:

$$\dot{n}^o_{CH_4} = \dot{n}^i_{CH_4} - \dot{r}_{ref} \tag{9}$$

$$\dot{n}^o_{CO} = \dot{n}^i_{CO} + \dot{r}_{ref} + \Delta\dot{n}^{wgs}_{CO} \tag{10}$$

$$\dot{n}^o_{CO_2} = \dot{n}^i_{CO_2} + \Delta\dot{n}^{wgs}_{CO_2} \tag{11}$$

$$\dot{n}^o_{H_2} = \dot{n}^i_{H_2} + 3\cdot\dot{r}_{ref} - \dot{r}_{H_2} + \Delta\dot{n}^{wgs}_{H_2} \tag{12}$$

$$\dot{n}^o_{H_2O} = \dot{n}^i_{H_2O} + \dot{r}_{H_2} - \dot{r}_{ref} + \Delta\dot{n}^{wgs}_{H_2O} \tag{13}$$

$$\dot{n}^o_{N_2} = \dot{n}^i_{N_2} \tag{14}$$

In the above equations $\dot{r}_{H_2}$ is the amount of hydrogen that is oxidized into water, $\dot{r}_{ref}$ is the amount of methane that is reformed, and $\Delta\dot{n}^{wgs}_i$ is the amount of species i that is consumed or produced in the water-gas shift reaction. The total molar flow of depleted fuel out of the SOFC is the sum of the individual fuel outlet flows:

$$\dot{n}^o_{tot} = \dot{n}^i_{tot} + 2\cdot\dot{r}_{ref} \tag{15}$$

The above reaction balances result in six equations with nine unknown. However, since a zero-dimensional model only describes what enters or exits the SOFC, simplifications can be made. First, the total amount of reacting hydrogen is known from eq. 7. Secondly, there is no methane present in the outlet fuel flow so $\dot{r}_{ref}$ is zero. Finally, the species involved in the water-gas shift reaction must fulfil the condition of chemical equilibrium, thus $\Delta\dot{n}^{wgs}_i$ can be determined for each species. The equilibrium constant is evaluated using the outlet temperature.
Conservation of the cathode species is expressed as:

$$\dot{n}^o_{N_2} = \dot{n}^i_{N_2} \tag{16}$$

$$\dot{n}^o_{O_2} = \dot{n}^i_{O_2} - \frac{1}{2}\cdot\dot{r}_{H_2} \tag{17}$$

As air is also used for cooling the air utilization is used to determine the total inlet flow of oxygen which, can be determined by assuming that air consists of 21% O_2 and 79% N_2.

$$\dot{n}^i_{air} = \frac{\dot{n}^i_{O_2}}{0.21} \tag{18}$$

The choice of air utilization depends on the required outlet temperature of the SOFC and is normally in the range of 15% - 25%.

Electrochemical model

The electrochemical sub-model evaluates the current density, voltage and electrical power of the SOFC. The electrochemical behavior of a given SOFC will depend on its manufacture and the materials used. The electrochemical model presented here is based on current research on 2^{nd} generation anode supported SOFCs and based on general phenomenological equations. These theoretical expressions are calibrated using empirical electrochemical data from a specific SOFC (Chick et al, 2002 [9]). In this section the general model is presented and the calibration is presented in the next section. The current density (current per unit area) through the SOFC is directly proportional to the amount of reacting hydrogen according to Faraday's law:

$$i_d = \frac{\dot{r}_{H_2}\cdot 2\cdot F}{A} \tag{19}$$

The ideal, reversible potential between the anode and cathode is determined by the Nernst equation:

$$E_{Nernst} = -\frac{\Delta G^0}{2F} - \frac{RT}{2F}\cdot ln\left(\frac{p_{H_2O}}{p_{H_2}\sqrt{p_{O_2}}}\right) \tag{20}$$

When current and power is drawn from the SOFC the reactions in the fuel cell occur irreversibly. The result is polarizations (losses) which reduce the reversible Nernst voltage to the operating voltage of the SOFC (Singhal and Kendall 2004, [7]). There are three major forms of polarizations: activation, Ohmic and concentration. A minor constant offset

polarization also contributes to the total polarization, and is the result of contact resistance, internal current and leaks. The operating voltage is found as the Nernst voltage minus the sum of the polarizations:

$$E_{fc} = E_{Nernst} - \Delta V_{act} - \Delta V_{Ohm} - \Delta V_{conc} - \Delta V_{offset} \quad (21)$$

Activation polarization is caused by that the electrodes require energy to activate and the transfer of electrons to and from the electrodes. Activation polarization is non-linear and dominates at low current densities; it can be evaluated from an approximation of the Butler-Volmer equation (Keegan 2002, [10]):

$$\Delta V_{act} = \frac{RT}{\alpha F} \sinh^{-1}\left(\frac{i_d}{2i_0}\right) \quad (22)$$

The charge transfer coefficient, α, and the exchange current density, i_0, are unknown parameters determined later.

Ohmic polarization can be described by Ohm's law and depends on the electrical conductivity of the electrodes and the ionic conductivity of the electrolyte. The contribution of the metallic interconnects is neglected since its conductivity is far greater than that of the other parts.

$$\Delta V_{Ohm} = \left(\frac{l_{an}}{\sigma_{an}} + \frac{l_{el}}{\sigma_{el}} + \frac{l_{ca}}{\sigma_{ca}}\right) \cdot i_d \quad (23)$$

The conductivity of the anode, cathode and electrolyte is evaluated from expressions previously developed for 2^{nd} generation SOFC materials, (Chick et al, 2002 [9]), presented in the following. The conductivity of a Nickel-cermets anode is assumed constant.

$$\sigma_{an} = 10^5 \quad (24)$$

The conductivity of a LSM cathode can be calculated from the following Arrhenius-type expression:

$$\sigma_{ca} = \frac{A_{ca}}{T} \cdot \exp\left(\frac{-E_{a,ca}}{k_{ca}T}\right) \quad (25)$$

The conductivity of both the anode and cathode is corrected to account for porosity:

$$\sigma_{porous} = \sigma_{solid} \cdot (1 - 1.8 \cdot \bar{V}) \quad (26)$$

The conductivity of the YSZ electrolyte is evaluated from a third-order polynomial:

$$\sigma_{el} = A_{el} \cdot \theta^3 + B_{el} \cdot \theta^2 + C_{el} \cdot \theta + D_{el} \quad (27)$$

Cathode	Electrolyte
$A_{ca} = 5.760 \cdot 10^7$	$A_{el} = 8.588 \cdot 10^{-8}$
$E_{a,ca} = 0.117$	$B_{el} = -1.101 \cdot 10^{-4}$
$k_{ca} = 8.617 \cdot 10^{-5}$	$C_{el} = 4.679 \cdot 10^{-2}$
-	$D_{el} = -6.54$

Table 2: Constants used to calculated the conductivity of the cathode and the electrolyte. Data from (Chick et al, 2002 [9])

Where θ is the SOFC outlet temperature in Celsius. Table 2 lists the constants used in eqs. 25 - 27. The concentration polarization is the result of mass transport of products and reactants to and from the interface between electrode and anode/cathode. The mass transport is accomplished by diffusion, which is associated with a resistance and thus a loss. Additionally, as the fuel is depleted, there is a decrease in the hydrogen partial pressure at the anode and in the oxygen partial pressure at the cathode. The magnitude of the depletion depends on the current density. At high current densities an insufficient amount of reactants will be transported to the electrodes and the voltage is reduced to near zero (Singhal and Kendall 2004, [7]). The current densities at which this occurs are called the anode and cathode limiting currents. Concentration polarization is therefore dominant at high current density and exhibits a non-linear behavior in the SOFC; it can be evaluated from the following equations:

$$\Delta V_{conc} = B \cdot \left(-\ln\left(1 - \frac{i_d}{i_{as}}\right) + \ln\left(1 + \frac{p_{H_2} i_d}{p_{H_2O} i_{as}}\right)\right) \quad (28)$$

In eq. 28 the cathode contribution to the concentration polarization has been neglected (Braun 2002, [8]). The anode limiting current is evaluated as:

$$i_{as} = \frac{2F p_{H_2} D_{an,(eff)}}{RT l_{an}} \qquad D_{an,(eff)} = \frac{D_{an,(bin)} \bar{V}_{an}}{\tau_{an}} \quad (29)$$

Both B and the diffusion coefficient are unknown parameters determined later.

Both the Nernst potential and the polarizations is evaluated using the outlet conditions from the SOFC. This is because the cell cannot support a voltage gradient and the lowest potential, which is found at the outlet, will dominate the entire cell (Braun 2002, [8]).

Pressure loss model

The flow in the interconnect channels can be assumed laminar and fully developed (Braun 2002, [8]). The pressure losses are mainly due to the friction between the fluid and the interconnect channels and from the fluid entering and exiting the interconnect channels (Fox 1994, [12]). The total pressure loss can be found as (Petersen 2004, [4]):

$$\Delta P = \rho \cdot f\left(\frac{L}{D_h} + 2K\right)\frac{v^2}{2} \tag{30}$$

Where f is the Blasius friction factor for laminar flow, and K is equal to 0.5 for a square edged inlets/outlet, (Fox 1994, [12]). Since the interconnect channels have a non-circular geometry the hydraulic diameter is used and the geometry of the channels and the number of interconnect channels must be known. The average of the density between inlet and outlet is used.

Calibration of of the electrochemical model

The offset polarization, the charge transfer coefficient, the exchange current density, the B parameter and the anode limiting current are unknown parameters which depend on the manufacture of a given SOFC. These parameters are normally regarded as constants and determined from reference. In this paper the above parameters are determined from experimental measurements, and nine empirical current-voltage curves were obtained for this purpose. The experimental data came from two experiments performed by the Pacific Northwest National Laboratory (PNNL) (Chick et al. 2002, [9]). The first experiments were performed with a constant fuel composition, of 7% hydrogen and 3% water vapor from 650°C to 800°C. The second experiment was performed at a constant temperature of 750°C, with a fuel composition containing from 10% to 97% hydrogen concentration, 3% water vapor concentration and nitrogen as the remainder. In both experiments the flow of fuel was 200 standard cubic centimeters per minute (sccm) and the flow of air was 300 sccm. The fuel flow was high with a low fuel utilization to keep the operating conditions almost constant over the entire cell. The performed experiments are summarized in table 3. The physical data of the anode, cathode and electrolyte used in the experiments are shown in table 4. The electroactive area of the empirical cell is 3.8cm^2, but the parameters determined in this section are assumed area independent.

T/[H_2]	10%	24%	49%	73%	97%
650°C	-	-	-	-	+
700°C	-	-	-	-	+
750°C	+	+	+	+	+
800°C	-	-	-	-	+

Table 3: : Temperature and hydrogen concentration ranges for the PNNL experiments, and a (+) denotes a performed experiment.

Part	Material	Thickness [μm]
Anode	Ni/YSZ 60	600
Cathode	LSF-20	50
Electrolyte	YSZ	10
Part	Porosity [%]	Tortuosity
Anode	30	2.5
Cathode	30	2.5
Electrolyte	-	-

Table 4: Physical characteristics of the SOFC used in the PNNL experiments

Calibration of the offset polarization

At zero current density all polarizations are zero, except for the offset polarization. It is evaluated as the difference between the measured cell voltage and the Nernst potential. This approach is used on all the current-voltage curves to determine the offset polarization for each curve. A single value of the offset polarization is then found as the average of the nine different offset polarizations, shown in eq. 31:

$$\Delta V_{offset} = 0.06 \tag{31}$$

Calibration of the activation polarization

To calibrate activation polarization, the current-voltage curves from the first experiments are used. Due to the high hydrogen concentration it can be assumed that concentration polarization is negligible (Larminie and Dicks 2003, [6]). All contributions to the total polarization are either Ohmic, activation or offset polarization. The offset polarization has been determined previously and the Ohmic polarization can be determined from eqs. 24 - 27. The activation polarization is isolated from the total polarization,

and curve fitted to eq. 22 where α and i_0 are the unknown parameters. This results in four values of α and i_0 which are expressed as functions of the temperature. The function for α is shown in equation 32, and the function for i_0 is shown in equation 33:

$$\alpha = 1.698 \cdot 10^{-3} \cdot T - 1.254 \quad (32)$$

$$i_0 = 13.087 \cdot T - 1.096 \cdot 10^4 \quad (33)$$

Calibration of the concentration polarization

To calibrate concentration polarization the current-voltage curves from the second experiment at constant temperature is used. First the concentration polarization is isolated from the total polarization using the previously developed expressions for the activation, Ohmic and offset polarization. This results in four different concentration polarization curves. These curves are fitted to eq. 28, where B and $D_{an,(bin)}$ are the only unknowns. This yields four values of the parameter B and the binary diffusion coefficient, which are expressed as functions of the hydrogen concentration. The B parameter is an inverse linear function of the hydrogen concentration. The function is modified to account for temperature, by assuming a linear dependence on temperature (Larminie and Dicks 2003, [6]). The final function is shown in eq. 34:

$$B = (8.039 \cdot 10^{-3} \cdot X_{H_2}^{-1} - 7.272 \cdot 10^{-3}) \cdot \frac{T}{T_{ref}} \quad (34)$$

Since the binary diffusion coefficient depends on both temperature and pressure, an empirical expression are used to make the fitted function pressure and temperature dependant, (Todd and Young 2002, [11]). The final function for the binary diffusion coefficient is given in eq. 35:

$$D_{a,(bin)} = (-4.107 \cdot 10^{-5} \cdot X_{H_2} + 8.704 \cdot 10^{-5}) \cdot \left(\frac{T}{T_{ref}}\right)^{1.75} \cdot \frac{P_{ref}}{P} \quad (35)$$

The calibration functions are only valid from 650°C to 800°C where supported by empirical data.

Validation of the electrochemical model

The calibrated electrochemical sub-model is validated by comparing the model's current-voltage curves to the original empirical curves used for the calibration. The comparison between model and empirical data of the first experiments are shown in figure 4. The comparison shows a good agreement

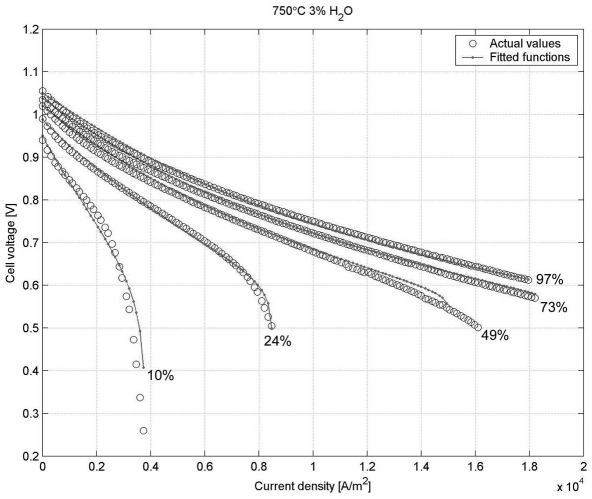

Figure 4: Comparison of empirical and model current voltage-curves from the first experiment. The line is the model results and the circles are the empirical values.

between the two sets of current-voltage curves. The maximum error between the model and the experiment set of curves is 1.05% root mean square error (rmse) at 650°C. The comparisons for the second experiments are shown on figure 5. Again the

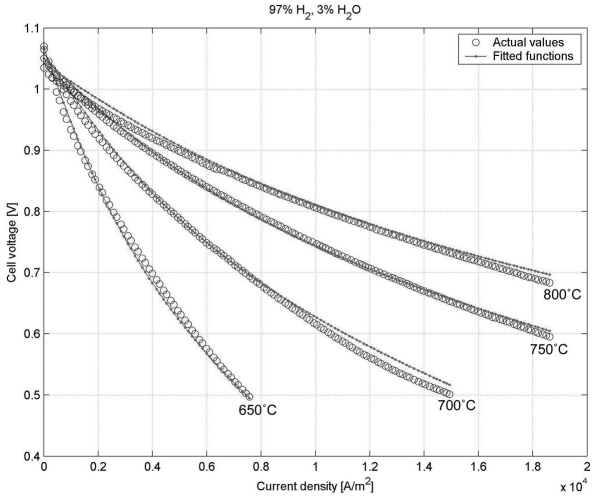

Figure 5: Comparison of empirical and model current-voltage curves from the second experiment. The line is the model results and the circles are the empirical values.

current-voltage curves show a good agreement between the two sets of current-voltage curves. The only exception is at 10% hydrogen concentration, which have the largest error of 5.21% rmse. The current-voltage curves at lower hydrogen concentrations, on figure 5, show a characteristic "tail" where the voltage is rapidly reduced at increasing current densities. This signifies the onset and the dominance of the concentration polarization, which is also the source of the greatest error. This is caused by the fact that concentration polarization dominates almost completely, which is hard to model theoretically, and eq. 28 only partly describes the concentration polarization (Larminie and Dicks 2003, [6]). This is a source of error in the SOFC model, since cell voltage is often determined at low hydrogen concentrations because of a high fuel utilization.

IMPLEMENTATION IN DNA

The SOFC model is added to the in existing DNA component library by implementing it in FORTRAN77 using a standard template for new DNA components. The additional data for the SOFC shown table 5 are used in the implementation, (Braun 2002, [8]). Note that the SOFC cell area used

Parameter	Value
Total cell area	144cm^2
Number of interconnect channels	24
Channel width	3mm
Channel height	1mm

Table 5: Physical data for the SOFC and interconnect used in the implementation of the model

in the implementation is different from the $3.8cm^2$ used in the calibration. This is because that area was for an experimental SOFC for test purposes. The area of future commercial SOFC will be as large as possible as this results in greater power. The implemented DNA SOFC model was tested thoroughly, and has subsequently been used to simulate a number of different hybrid systems. During this the model has proved robust and stable.

DISCUSSION

The chemical sub-model of the SOFC can simulate both hydrogen fuelled and methane fuelled SOFCs. However, the electrochemical sub-model is only valid for a hydrogen fuelled SOFCs because the polarization curves for a methane fuelled SOFC will be different from those of a hydrogen fuelled. This is due to the different partial pressures as well as different binary diffusion coefficients. But research has shown that the difference in diffusion coefficients are relative small, (Barfod 2004, [13]). Since the electrochemical sub-model accounts for the changes in partial pressures, the SOFC model is assumed valid for both hydrogen and methane. Calibration of general, theoretical polarization expressions was an accurate approach for the electrochemical sub-model. This was expected since in essence, a fitted function is compared to the data used for the fitting. The calibration reduces the generality of the electrochemical sub-model which cannot be expected to model any other type of SOFC accurately, since it is ”bound” to the performance a specific cell. However, the used approach is general and apply for all SOFC. The only parameters specific to the model presented here, are the charge transfer coefficient, the exchange current density, the B parameter and binary diffusion constant. When the voltage and electrical power of the SOFC are evaluated an average current density is used. But the current density varies over the cell and is lowest at the outlet (Sorrentino et al 2004, [14]). So the operating voltage is underestimated since the polarizations increases with the current density, which results in an error in the evaluated electrical power. The magnitude of this error is not clear, but assumed negligible.

CONCLUSION

A zero-dimensional model of a SOFC was developed for hybrid power system simulation. The model accounts for the oxidation of hydrogen, the reforming of methane, and the water-gas shift reaction, in a simplified but accurate manner. The electrochemical sub-model is phenomenological, and accounts for offset, activation, Ohmic and concentration polarization. It was calibrated using empirical data, and this approach has resulted in a good agreement with the original empirical data. The SOFC model can be used to obtain reliable results, for SOFC behavior within the temperature range from $650°C$ to $800°C$ where it is supported by empirical data. The model was implemented in the DNA software, which is developed specifically for energy system simulation.

ACKNOWLEDGEMENTS

The authors would like to thank Prof. Michael J. Moran from Ohio State University, Jens Paalsson and Jens Nielsen from Haldor Topsøe A/S and Rasmus Barfod from Risø National Laboratory for their invaluable help and time.

ABSTRACT

For the evaluation of potential routes for production and application of hydrogen in a future energy system, well-to-wheel methodologies provide a means of comparing overall impacts of technologies in a consistent and transparent manner. Such analysis provides important background information for decision makers when implementing political incentives for the conversion to environmentally more friendly energy production and consumption. In this study, a well-to-wheel (WtW) approach was applied in order to evaluate the energetic and environmental impacts of introducing hydrogen in the transportation sector, in terms of energy efficiency and emissions of CO_2 and NO_x, under conditions relevant for the Norwegian energy system. The hydrogen chains were compared to reference chains with conventional fuels.
Keywords: Hydrogen, transportation, well-to-wheel

TtW	Tank-to-wheel
WtT	Well-to-tank
WtW	Well-to-wheel

INTRODUCTION

It is commonly believed that hydrogen will be an important energy carrier in a future energy system based on sustainable energy conversion technologies. Hydrogen may be produced from various energy sources, and applied in a wide range of end-use technologies, and an evaluation of the environmental benefits of introducing hydrogen for certain segments thus depends on the emissions related to transport

[*] Corresponding author: Phone: +47 98230450 Fax: +47 73594083, Email: ann.m.svensson@sintef.no

and conversion of energy sources, as well as transport of hydrogen. An extensive well-to-wheel study has been conducted for the European transportation sector, comparing a wide range of technologies [1], clearly illustrating that a tank-to-wheel (TtW) analysis is not sufficient to draw conclusions of the energetic and environmental impacts on the various end-use technologies, and that WtW analysis must be applied. Another example of WtW analysis including transportation end-use, where several production technologies for hydrogen has been included, is provided in Ref. [2]. Still, WtW analysis is limited to the operational mode. For a full assessment of energy consumption and environmental impact including also production and disposal of materials and components, a LCA (life-cycle assessment) analysis is required.

A great potential for reduction of emissions in the Norwegian energy system can clearly be found in the transportation sector. Focus for this study has therefore been the possible routes for introduction of hydrogen as an energy carrier for transportation, putting emphasis on the uniqueness of the Norwegian energy system in terms of the predominantly renewable electricity production, but also on the relatively long transportation distances for the operation of filling stations.

SELECTED END-USE TECHNOLOGIES AND ENERGY CHAINS FOR PERSONAL CARS

Overviews of the chains evaluated in this study are given in Figure 1 and Table 1. The time perspective is relatively short (2010), and therefore, only electrolysis and natural gas reforming have been considered for hydrogen production, as these are the technologies considered to have reached a pre-commercial stage [3]. As hydrogen production from biomass has not reached the same state of development, biomass was not included in this study, although biofuels for combustion engines is a viable option for the future. The most promising technologies for utilization of hydrogen in private cars are fuel cells and the hydrogen combustion engine. In addition, electric cars are included for comparison, even if the application of electric vehicles at present is somewhat restricted w.r.t. range. Included are also hybridized petrol cars, i.e. cars combining a combustion engine and an electric motor.

The evaluation of the chains presented in Table 1 is based on the following assumptions:

- Efficiencies are based on lower heating value (LHV).
- Fossil fuels are assumed to be transported by trucks of ca 50 tons, with a capacity of 34 tons/40 m3, at an average distance of 50 km to the filling station. Natural gas is assumed to be transported as LNG.
- Well-to-tank efficiencies are assumed to be: 83% for refining of crude oil to petrol, 88 % for refining of crude oil to diesel, 95 % for liquefaction of natural gas, 98 % for shipping of natural gas (i.e. from north of Norway to the south)
- A loss of 6% is assumed for extraction, processing and pipeline transport of natural gas, as estimated in Ref. [1] for Norwegian gas production. No further refining of the gas is included.
- Hydrogen produced in central reformers is assumed to be stored/transported in compressed form at 700 bars. Average transportation distance is assumed to be 150 km (one way). Return of empty trucks is assumed.
- Electrolysers are assumed to deliver hydrogen at 30 bar. Additional energy loss for compression to 700 bar is included.
- An additional loss of 3% is assumed for removal of CO from hydrogen produced by reforming of NG, when PEMFC is the end-use technology.
- Efficiencies of renewable energy sources (wind, hydropower, solar energy) are not included; neither are possible efficiency reductions of electrolysers connected to the strongly fluctuating power from wind mills.
- The efficiency of gas turbines (CCGT) is assumed to be 58% wo/CO_2 cap, and 50% w/CO_2 cap.
- Efficiency of electricity transfer in the grid is assumed to be 93% for transfer from central power production units (i.e.

exergy efficiency). No losses are taken into account for distributed power generation.

- Average European electricity mixture contains: 17.4% from coal, 7.4% from natural gas, 16.4% from hydropower, 7.8% from lignite, 40.3% nuclear power, 10.7% from oil [4]. The corresponding CO_2 and NO_x emissions are: 0.428 kg/kWh and 0.92 g/kWh [4]. Average efficiency is 35% [1].
- Small scale reformers (natural gas to hydrogen) were assumed to emit the same amount of NO_x per kWh as large scale reformer (i.e. 76 % wo/CO_2 cap., and 73 % w/CO_2 cap). The efficiency of electrolysers is assumed to be 74 %.
- Catalytic removal of NO_x is assumed for the ICE H_2.
- The tank-to-wheel efficiency is assumed to be 32% for hybrid petrol vehicles, 20% for ICE H_2, 40% for PEMFC, 50% for hybrid PEMFC, 16% for ICE petrol, 17% for ICE CNG, 19% for ICE diesel, and 80% for electric cars.
- Standard European drive cycle (ECE [5]), relevant for city driving, is assumed for all the evaluated chains [5].

RESULTS AND DISCUSSION

Results for well-to wheel efficiencies and emissions for private cars (70 kW) are shown in Figures 2 and 4 for conditions typical for the Norwegian energy system (i.e. renewable energy production). Electric vehicles are therefore superior both in terms of efficiency and emissions. However, the application of electric vehicles is still limited due to their short driving range and long charging times.

On a longer time scale, utilization of hydrogen as a fuel will provide an option for eliminating emissions in the transportation sector, but this requires that the hydrogen is produced by electrolysis from renewable energy sources, or from hydrocarbon with carbon sequestration included. Fuel cell technology has a potential for high energy efficiencies, but is only expected to be commercially available in cars after the year 2010. For city driving, it is interesting to notice that hybridized petrol cars have higher efficiencies than fuel cell driven cars, regardless of how the hydrogen is produced. Similar results have been obtained in Refs. [1] and [6] This result would be different for evaluations based on highway drive cycles, as there is little benefit of hybridization at high speed. It should be noticed that both hybrid petrol cars and fuel cell driven cars have significant potentials for improvement, as opposed to engines driven by conventional liquid fuels.

It is interesting to notice that electric cars charged by electricity produced in gas turbines (NG) have efficiencies around two times higher than ICE NG cars, which is related to the fact that combustion processes have low efficiencies at part load. Similarly, the high efficiency of the hybridized petrol car is achieved because [6]: i) the engine is smaller, thus operating at higher load ii) power can be used to charge the batteries during part load operation iii) the battery can feed the electric motor for sole vehicle propulsion in urban traffic iv) energy can be recovered while braking.

There are no environmental benefits of internal combustion engines with H_2 as fuel if H_2 is produced by reforming of natural gas without CO_2 capture (for example on-board reforming, or distributed small scale reforming). The technology might, however, have the potential for creating early markets, as it is more mature than the fuel cell technology. In terms of energy efficiency, however, the fuel cell technology is superior (more than twice as efficient), and on a longer time scale, hybridization of fuel cell vehicles, or ICE H_2 could also be an interesting option for zero emission vehicles. The effect of hybridization of fuel cell vehicles is shown in Figures 3 and 5, where results for the hybridized PEMFC vehicles are included for all the chains with PEMFC as end use (5a, 7a, 9a, 12a, 15a). Although the relative improvement of efficiency is less with hybridization of fuel cell vehicles , the potential of obtaining high overall efficiencies is clearly illustrated.

From Figures 2 and 4 fuel cell driven vehicles appears to exhibit lower emissions of CO_2 and NO_x, and be more efficient than conventional ICE petrol/diesel/CNG cars, even when the

hydrogen is produced by local reforming of natural gas without CO_2 sequestration. In Ref. 7, a comparison of fuel cell cars and conventional ICE cars was made in a full LCA analysis, including both manufacturing and distribution of the vehicles. In this study, the estimated life-cycle energy consumption, as well as the life-cycle green house gas emissions are of similar magnitude for ICE vehicles and fuel cell vehicles, when the hydrogen is produced from hydrocarbons without CO_2 sequestration. The assumed drive-cycle in Ref. 7 was a mixture of urban (55 %) and highway (45 %) drive cycles.

The superiority of electric vehicles, both in terms of emissions and energy efficiency, is clearly related to the fact that the Norwegian energy system is almost entirely based on hydro power. Results for the corresponding WtW analysis based on the average European electricity mix (EU mix) are shown in Figure 3 and 5. Local/distributed power (chains 15 to 17) is assumed to be based on some kind of renewable power generation, and thus resembles the chains in Figure 2 and 3. Figure 5 clearly illustrates that hydrogen production based on electrolysis has no environmental benefits when electricity production is based on the European electricity mix. Even electric vehicles exhibit larger emissions of NO_x than petrol and CNG ICE in this case. This is related to the fact that the average European power production units emit a significant amount of NO_x per kWh. The CO_2 emissions of the electric vehicles are, however, relatively low in comparison. This is related to the large fraction of nuclear power in Europe.

It should be noticed that here, emissions are focused on CO_2 and NO_x, which are species harmful on a global and regional level. Other pollutants, such as particulate materials, hydrocarbons etc., which are released from vehicles driven on conventional liquid fuels, is a serious concern in terms of local pollution problems, which need to be solved either by a change to gaseous fuels, or by on-board cleaning of exhaust.

CONCLUSIONS

In a renewable energy system, electric vehicles are superior in terms of energy efficiency and emissions, but their application might be restricted due to the low range and high charging times.

For city driving, significant improvements of energetic and environmental impacts can be achieved by hybridization of ICE engines, and the technology is commercially available. Although the fuel cell technology is likely to exhibit even higher efficiencies and zero emissions at end-use, the WtW analysis shows that the hydrogen must be produced from renewable sources or from natural gas including CO_2 sequestration, for the fuel cell cars to be superior to the hybridized petrol/diesel cars in terms of energy consumption and emissions.

ABSTRACT

Solid Oxide Fuel Cells are a promising technology for distributed electricity generation and cogeneration. Numerous papers have been published in the last several years proposing mathematical / computational fluid dynamics (CFD) models for predicting the transient and steady state performance of such cells. In this paper, a detailed steady state CFD model of a planar anode supported SOFC is proposed, which accounts for mass, thermal, and charge transport as well as electrochemistry and the chemistry of internal fuel reforming. Its main characteristics include the use of a continuous model for the electrochemistry, allowing one to examine different three-phase boundary geometries. This is an improvement over the typical model reported in the literature, which utilizes an equivalent resistive circuit approach or a homogeneous distribution of three-phase boundaries.

The model proposed here is used to simulate the degradation of anode, cathode, and electrolyte due to instabilities (e.g., anode oxidation due to fuel depletion) or to the delamination of the electrodes from the electrolyte. Such degradations result in a drop in cell performance but are difficult to predict without the use of models which can be helpful for diagnosis. The model is applied to experimental data available in the literature both for the non-degraded and degraded cases.

Keywords: solid oxide fuel cells, computational fluid dynamics, cell performance degradation

Nomenclature

A	active surface area per unit volume [m^2/m^3];
AD	gas channel at anode side;
A_R	catalyst surface area per unit volume [m^2/m^3];
CD	gas channel at cathode side;
D_φ	general diffusion coefficient;
E	electrolyte;
E_a	activation energy [J/mol];
F	Faraday's constant [C/mol];
G	Gibbs free energy [J/mol];
i_0	exchange current density [A/m^2];
k	effective conductivity [$1/(\Omega \cdot m)$];
k_0	pre-exponential factor [$mol/(s \cdot m^2 \cdot Pa)$];
k_{TPB}	equivalent conductivity of the TPB [$1/(\Omega \cdot m)$];
K	permeability [m^2];
K	equilibrium constant;
M	molar mass [kg/kmol];
NP	number of products;
NR	number of reactants;
n	number of electrons exchanged;
p	pressure [Pa];
PA	porous anode;
PC	porous cathode;
r	rate of reaction [$mol/(s \cdot m^2)$];
R	universal gas constant [$J/(mol \cdot K)$];

Introduction

Solid Oxide Fuel Cells are a promising technology for decentralized power generation and cogeneration [1]. Some of the main advantages are the high efficiency, the low NO_x production, the possibility of directly using methane through internal reforming, and the possibility of using SOFCs in combination with bottoming cycles.

Important conditions for a large market penetration of such systems are sufficiently long operating lifetimes and minimal performance degradation. This paper deals with the problem of performance degradation and, in particular, presents a CFD model able to simulate the behavior of a SOFC under conditions of reduced efficiency. Such a model can help guide plant operations by providing information on degraded conditions in cells and stacks. Moreover, it can provide reliable information for developing diagnosis routines.

The fuel cell representation

The investigation of planar SOFC behavior is performed using a CFD model. The complete equation set is presented in this section, while its use for a 2D geometry is presented in the sections which follow. A schematic of the anode supported planar SOFC is depicted in Figure 1 where five layers are represented: the anodic and cathodic distribution channels (AD and CD), the porous anode and porous cathode, and the electrolyte.

CFD models typically rely on the hypothesis of the material within each layer being homogeneous, which is not the case for SOFC layer morphologies. In particular, the electrochemical reactions occur at the so-called triple-phase boundary (TPB), which is a surface where the ionic conductor, the electronic conductor, and the pores are simultaneously present. On this surface, the electrochemical conversion between ionic and electronic current (or vice-versa) takes place.

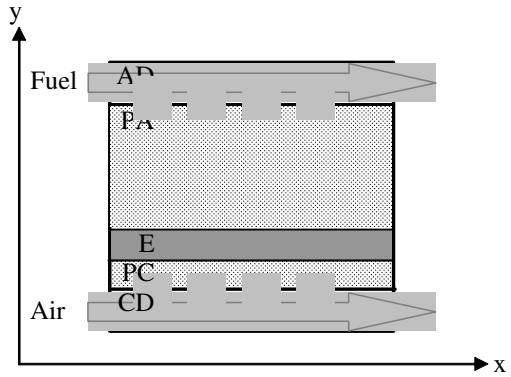

Figure 1. 2D schematic of a single cell of a planar SOFC.

The active sites where the reactions take place constitute a region which separates the ionic current thresholds and electronic current thresholds. The shape of this region generally is not regular, i.e. it is not homogeneously distributed within the electrodes. Information on this shape can come from a micro-structural analysis obtained through scanning or transmission electron microscopy. An example of a cathode reacting layer is shown in Figure 2. Larger particles are the ionic conductor, while smaller particles are the electronic conductor. The whole structure is porous so that gas can pass through.

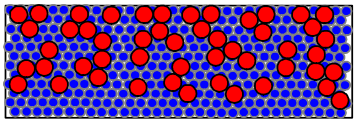

Figure 2. Example of cathode reacting layer.

Figure 3 shows the corresponding triple-phase boundary and the two regions where electronic current (areas in white) and ionic current (areas in grey) are transmitted. Two things must be highlighted: 1) the TPB is not a continuous surface, but it is interrupted by portions where only two phases are in contact. In these portions, the TPB is represented as a continuous line, but the active area is assumed zero; 2) in both regions there are non-conductive particles: ionic conductive particles within the electronic conductive region and electronic conductive particles within the ionic conductive region. These particles (areas in black) reduce drastically the conductivity in the regions since ionic conductive particles have very low electronic conductivity and vice-versa.

In addition, the area available for the electrochemical reaction at some of the active sites can decrease with time due to electrode degradation. Since the objective of the model presented here consists of simulating degraded operating conditions, the model must account for a non-homogeneous distribution of the active area.

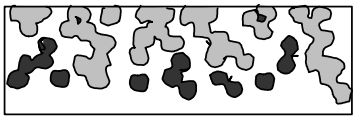

Figure 3. Shape of the triple-phase boundary.

The electrochemical reaction is a surface phenomenon but is treated in this model as if it would occur in a small volume. The domain is discretized into small cells as shown in Figure 4. For each cell, the active area per unit volume is considered. The different cells are characterized by a value of the conductivity, which is equal to the ionic conductivity for the cells in the gray region and to the electronic conductivity for the cells in the white region. The cells at the boundary are also characterized by a value of the active area, which is zero in the case of contact between just two phases. Finally, the cells in the black areas are characterized by very low values of the conductivity. This assumption is used in order to properly account for the effects of modifications in the TPB due to electrode degradation, as is explained further below.

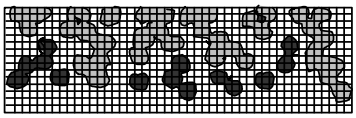

Figure 4. Example of the discretization of the region where the electrochemical reactions occur.

The fuel cell model

The fuel cell model has been developed, taking into account the following phenomena:

- fluid dynamics;
- heat transfer;
- chemical reactions;
- electrochemical reactions.

The model consists of a set of eight partial differential equations and some constitutive equations in order to model the different phenomena. The partial differential equations are: the continuity equation for the gas mixture, the momentum equation (2 components in a 2D geometry and 3 components in a 3D geometry), energy conservation, the conservation of species written for all components of the gas mixture minus one, and current conservation.

The hypotheses of steady-state conditions and incompressible fluid have been used. The partial differential equations have been solved by using a finite element code called CFDesign™ [2] modified with the help of researchers at Virginia Tech [3,4] to accommodate detailed fuel cell modeling. The general differential equation is written in the form:

$$\rho\mathbf{u}\cdot\nabla\varphi=\nabla\cdot\left(D_{\varphi}\nabla\varphi\right)+S_{\varphi} \tag{1}$$

where φ is any general transport property. The source term can be written by considering a diagonal term $S_{D\varphi}$ and a non-diagonal term $S_{ND\varphi}$, i.e.

$$S_{\varphi}=-S_{D\varphi}\cdot\varphi+S_{ND\varphi} \tag{2}$$

The general expression for the momentum equation is given by

$$\delta_1\mathbf{u}\cdot\nabla\cdot\left(\rho\mathbf{u}\right)=-\nabla p+\delta_2\mu\nabla^2\mathbf{u}+\mathbf{S_d} \tag{3}$$

where δ_1 and δ_2 are set equal to 1 in the gas channels and 0 in the porous media. For the latter case, equation (3) leads to the Darcy equation or to the Darcy-Forchheimer equation, depending on the expression assumed for the source term. Alternatively, δ_2 can be assumed to be the ratio between an effective viscosity and the fluid viscosity, namely,

$$\delta_2=\frac{\bar{\mu}}{\mu} \tag{4}$$

in order to provide Brinkman's extension to the Darcy formulation (see for example [5]).

The calculations in this paper have been performed by considering the Darcy expression in the porous media, which is obtained by writing the source term as

$$\mathbf{S_d}=\frac{\mu}{K}\cdot\mathbf{u} \tag{5}$$

where K is the permeability. The source term is null in the distribution channels.

The continuity equation is written as

$$\nabla\cdot\left(\rho\mathbf{u}\right)=S \tag{6}$$

where S is a source/sink term which accounts for the change in mass due to the electrochemical reactions.

This term is positive on the anode side and negative on the cathode side.

The conservation of species is written by considering two phases: the gas species and the mixture of gases. The species equation for the generic species A is then written as

$$\nabla \cdot (\rho \mathbf{u} w_A) = \nabla \cdot (D_A \rho \nabla w_A) + S_A \quad (7)$$

where w_A is the mass fraction of component A, D_A is the diffusion coefficient of species A in the mixture, and S_A is the source term of the species due to chemical and electrochemical reactions.

Equation (7) can be rewritten in the same form as equation (1), i.e.

$$\rho \mathbf{u} \cdot \nabla (w_A) = \nabla \cdot (D_A \rho \nabla w_A) + S_A - w_A \nabla \cdot (\rho \mathbf{u}) \quad (8)$$

so that the source term of equation (1) is given by

$$S_{wA} = S_A - w_A \nabla \cdot (\rho \mathbf{u}) \quad (9)$$

The diffusivity coefficient in this equation is calculated by considering both ordinary and Knudsen diffusion [6], the first accounting for molecular transport in the pores characterized by a large diameter in comparison to that of the mean free path, and the second for molecular transport in the pores characterized by a small diameter. For the generic species A in the gas mixture, the diffusion coefficient is expressed through the Bosanquet formula, multiplied by a term accounting for the pore characteristics [7], Thus,

$$D_A = \frac{1}{\frac{1}{D_{A,o}} + \frac{1}{D_{A,k}}} \cdot \frac{\varepsilon}{\xi} \quad (10)$$

where

$D_{A,o}$ is the ordinary diffusion coefficient
$D_{A,k}$ is the Knudsen diffusion coefficient
ε is the volume fraction of pores
ξ is the tortuosity.

The ordinary diffusion coefficient is calculated by considering the diffusivity of the species in the gas mixture, namely,

$$D_{A,o} = \frac{D_{A-m}}{1 - \alpha_{Am} \cdot y_A} \quad (11)$$

where y_A is the molar fraction of component A and

$$\alpha_{A-m} = 1 - \left(\frac{M_A}{M_m} \right)^{0.5} \quad (12)$$

In this last expression, M_A is the molar weight of species A and M_m the average mixture molar weight. The diffusivity coefficient in the mixture is calculated using the diffusion coefficient of species A in each binary system constituted by A and the other mixture contituents. A possible model is the one developed by Stefan-Maxwell which expresses this mixture diffusivity as (see for example [8])

$$D_{A-m} = \frac{1 - y_A}{\sum_{i \neq A} \frac{y_i}{D_{A-i}}} \quad (13)$$

where D_{A-i} is the diffusion coefficient for the specie A in a binary mixture constituted by the species A and i. This diffusion coefficient can be calculated by using an empirical as opposed to theoretical relation (see for example the application to a SOFC proposed by Yakabe et al. [9]). A reliable one is that suggested by Fuller, Schettler and Giddings [10]. For a mixture constituted by species A and B, the diffusion coefficient D_{A-i} is expressed as

$$D_{A-B} = \frac{101.325 \cdot T^{1.75} \cdot \sqrt{\frac{M_A + M_B}{M_A \cdot M_B}}}{p \cdot \left[\left(\sum v \right)_A^{1/3} + \left(\sum v \right)_B^{1/3} \right]^2} \quad (14)$$

where the terms Σv are the diffusion volumes. Some values of this quantity are Σv (H_2) = 7.07; Σv (N_2) 17.9; Σv (O_2) = 16.6; Σv (CO) = 18.9; Σv (CO_2) = 26.9; Σv (H_2O) = 12.7.

In case of a binary mixture, the mass concentration of species B is calculated as

$$w_B = 1.0 - w_A \quad (15)$$

When a multi-component gas mixture is considered, equation (8) must be written for n-1 species. In this case the mass fraction of the n^{th} species is calculated as

$$w_n = 1.0 - \sum_{i=1}^{n-1} w_i \quad (16)$$

The energy equation is written in the form

$$\rho \mathbf{u} \cdot \nabla T = \nabla \cdot (\lambda \nabla T) + \phi_V \quad (17)$$

where λ is the global thermal conductivity and ϕ_V the heat generated per unit volume due to chemical and electrochemical reactions. In equation (17) the hypothesis of thermal equilibrium between the porous structure and the gas is assumed so that a unique local temperature is considered.

Finally, the conservation of current equation is written as

$$k \cdot \nabla^2 V_\Delta = S_i \quad (18)$$

where k is the layer general electronic or ionic conductivity, V_Δ is the overpotential, and S_i is the current source. V_Δ accounts for the ohmic and the activation overpotentials. Other losses, such as the concentration overpotential, are considered through the boundary conditions as discussed below.

Two different approaches can be selected in order to write the resistivity (conductivity) and the source term. The choice depends mainly on the boundary conditions which one can assume for the problem. When a single electrode is considered, it is possible to treat the conversion between ionic and electronic current through a source term representing the local current density transformation. In this case, the source term assumes the form of the Butler-Volmer equation, namely,

$$S_i = A \cdot i_0 \cdot \left(e^{\frac{\alpha \cdot n \cdot F}{R \cdot T} V_\Delta} - e^{-\frac{(1-\alpha) \cdot n \cdot F}{R \cdot T} V_\Delta} \right) \quad (19)$$

This approach is used for example in [11] and [12]. The boundary conditions are imposed at the electrode surfaces, which allows one to guarantee the complete transformation of ionic current into electronic current or vice-versa, depending on the electrode analyzed.

A second approach can be used in order to avoid the need of boundary conditions at the electrode surfaces. In this case, the activation overpotential is modelled through the diffusive term, while the source term is absent. This also means that the electrochemical reaction is modelled as a volume reaction instead of a surface reaction.

The first of these approaches is used here. Furthermore, the expression for the total conductivity obtained from a one-dimensional calculation of an electrode is adopted for the model of the TPB [12]. This model is used here only for the TPB elements. These elements are described through a value of the active area in the normal direction with respect to current propagation. The conductivity (diffusive term) is:

$$k_{TPB} = \frac{\Gamma \cdot sinh(\Gamma)}{(\rho_{el} + \rho_{io})(cosh(\Gamma) + \Omega \cdot [2 + \Gamma \cdot sinh(\Gamma) - 2cosh(\Gamma)])} \quad (20)$$

where the expressions for the two dimensionless variables Γ and Ω are given by

$$\Gamma^2 = \frac{i_0 \cdot A \cdot F \cdot (\rho_{el} + \rho_{io}) \cdot a^2}{R \cdot T} \quad (21)$$

$$\Omega = \frac{\rho_{el} \cdot \rho_{io}}{(\rho_{el} + \rho_{io})^2} \quad (22)$$

All the necessary steps for deriving equation (20) are available in the reference cited. An important difference is that in the present paper, the variable a is a characteristic thickness assigned to the TPB in the normal direction with respect to the active surface available in the cell. This corresponds to the assumption of a progressive transformation between electronic and ionic currents in the element. Coherent with this assumption is A as the active area per unit volume. Note that equation (20) has been obtained by considering a linearized expression of the Butler-Volmer equation. Different approaches can be found in the literature (e.g., [13] and [14]).

The model is completed by means of a set of constitutive equations which are detailed as follow:

1) The gas mixture density is calculated through the ideal gas law. Specific heats are assumed to be dependent on the gas temperature.

2) The internal reforming is modelled by considering the methane reforming and the water-gas shift reactions only:

$$CH_4 + H_2O \leftrightarrow 3H_2 + CO \quad (23)$$

$$H_2O + CO \leftrightarrow H_2 + CO_2 \quad (24)$$

The water-gas shift reaction is usually assumed to be in equilibrium. The reaction rate depends on the gas temperature (see for example [15]). Thus,

$$K_S = \frac{K_{SF}}{K_{SB}} = \frac{y_{H_2} \cdot y_{CO_2}}{y_{H_2O} \cdot y_{CO}} \quad (25)$$

$$K_S = e^{-0.2935 \cdot z^3 + 0.6351 \cdot z^2 + 4.1788 \cdot z + 0.3169} \quad (26)$$

where

$$z = \frac{1000}{T} - 1 \quad (27)$$

The term expressing the generation of hydrogen in the water-gas shift reaction is dimensionally coherent with the conservation of species equation source term and is calculated as

$$S_S = K_{SF} \left(p_{H_2O} \cdot p_{CO} - \frac{p_{H_2} \cdot p_{CO_2}}{K_S} \right) \cdot M_{H_2} \quad (28)$$

where the forward reaction rate constant is determine by

$$K_{SF} = 0.0171 \cdot e^{-\frac{103191}{RT}} \quad (29)$$

The approach for the steam reforming is more complex. All the different approaches can be classified into two groups: a) empirical correlations and b) formal kinetic models such as the Langmuir-Hinshelwood model [16]. All the proposed relations can be implemented in the model. However, the calculations proposed in this paper have been performed using the formulation proposed by Achenback and Riensche [17], i.e.

$$r_R = k_0 \cdot p_{CH_4} \cdot \left(1 - \frac{p_{CO} \cdot {p_{H_2}}^3}{p_{CH_4} \cdot p_{H_2O} \cdot K_R} \right) \cdot e^{-\frac{E_a}{RT}} \quad (30)$$

where
$k_0 = 0.04274$ mol/(s m^2 Pa);
$E_a = 82000$ J/mol.

As to the source term in the conservation of species CH_4 equation (as reported in equation (7)), it is expressed as

$$S_{CH_4} = -r_R \cdot A_R \cdot M_{CH_4} \quad (31)$$

In the proposed calculations, the catalyst surface area A_R per unit volume has been assumed to be 0.01 m^2/m^3.

All of the other source terms for the conservation of species equations can be obtained based on reactions (23) and (24). Thus,

$$S_{H_2} = -3 \cdot S_{CH_4} \cdot \frac{M_{H_2}}{M_{CH_4}} + S_S \quad (32)$$

$$S_{CO} = -S_{CH_4} \frac{M_{CO}}{M_{CH_4}} - S_S \quad (33)$$

$$S_{CO_2} = S_S \tag{34}$$

3) The internal reforming introduces a source term in the energy equation, since the demethanization reaction (23) is endothermic (206 kJ/mol at 0 °C) while the water-gas shift reaction (24) is exothermic (-41.1 kJ/mol at 0 °C).

4) The species participating in the electrochemical reactions are CO and H_2 at the anode and O_2 at the cathode, i.e.

$$H_2 + O^{2-} \rightarrow H_2O + 2e^- \tag{35}$$

$$CO + O^{2-} \rightarrow CO_2 + 2e^- \tag{36}$$

$$\frac{1}{2}O_2 + 2e^- \rightarrow O^{2-} \tag{37}$$

A free variable in this model is the ratio between CO and H_2 participating in the electrochemical reactions. In some of the models proposed in the literature, this ratio is assumed to be 0 ([15] and [18]). Here the ratio is assumed to be dependent on the molar fraction of the two species at the TPB (see equation (42) below).

5) The relation between the local current density and the consumption of hydrogen, oxygen, and carbon monoxide as well as the generation of carbon dioxide is expressed through Faraday's law. This means that at the TPB, the source terms in the conservation of species equations are given by

$$S_{H_2} = -\frac{i_{H_2}}{a \cdot 2 \cdot F} M_{H_2} \tag{38}$$

$$S_{CO} = -\frac{i_{CO}}{a \cdot 2 \cdot F} M_{CO} \tag{39}$$

$$S_{O_2} = \frac{i}{a \cdot 4 \cdot F} M_{O_2} \tag{40}$$

where i_{H2} and i_{CO} are the current densities obtained from the two electrochemical reactions on the anode side. These currents can be obtained from the following relations:

$$i_{H_2} + i_{CO} = i \tag{41}$$

$$\frac{i_{CO}}{i_{H_2}} = \frac{y_{CO}}{y_{H_2}} \tag{42}$$

The generation of water is taken into account in the continuity equation, whose source term is written as

$$S = S_{H_2} \cdot \left(1 - \frac{M_{H_2O}}{M_{H_2}}\right) \tag{43}$$

6) The ionic and electronic resistivity are assumed to be dependent on the temperature such that

$$\rho = \frac{1}{\beta_1 \cdot e^{-\frac{\beta_2}{T}}} \tag{44}$$

The values of the selected parameters are indicated in the next section [19].

Application of the model to a 2D planar SOFC

In this section, an application of the proposed model is presented. In particular, the geometric characteristics and the boundary conditions are discussed.

A 2D model is considered for the anode supported planar SOFC shown in figure 1 above. The cell length is 20 mm. The main data are shown in table 1.

Table 1. Parameters adopted in the model.

	AD	PA	E	PC	CD
t [mm]	1	2	0.05	0.05	1
ε	-	0.45	-	0.45	-
ξ	-	4.5	-	4.5	-
β_1 [1/Ωm]	5000	7800	20500	12820	33770
β_2 [1/Ωm]	0	1290	9030	0	1130

In figure 5, the boundary conditions for the model are indicated. The values assumed in the application presented in this paper are given in table 2.

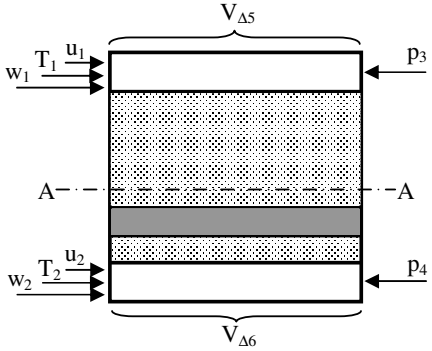

Figure 5. Boundary conditions imposed on the model.

Table 2. Values of the boundary conditions imposed in the model.

T_1	800 °C	T_2	800 °C
u_1	1.922 m/s	u_2	3.264 m/s
$w_1(CH_4)$	0.184	$w_2(CH_4)$	0
$w_1(H_2)$	0.036	$w_2(H_2)$	0
$w_1(CO)$	0.054	$w_2(CO)$	0
$w_1(CO_2)$	0.130	$w_2(CO_2)$	0
$w_1(O_2)$	0	$w_2(O_2)$	0.200
p_3	101000 Pa	p_4	101000 Pa
$V_{\Delta 5}$	Variable	$V_{\Delta 6}$	0

The boundary condition for the current conservation equation deserves a detailed explanation. As the boundary condition, the overpotential due to ohmic and activation losses is imposed in this work. Usually, the cell potential is assumed as the boundary

condition instead, especially when equivalent resistance models are adopted (see for example [20]). In the model proposed here, the cell potential could be imposed as the boundary condition provided that the other overpotentials, such as the concentration polarization, can be neglected or can be expressed through an equivalent resistivity similar to that for the activation overpotential. However, in our approach here, the cell potential is calculated once the calculation has been completed, namely,

$$V_{cell} = V_{Nernst} - (V_{\Delta 5} - V_{\Delta 6}) - \eta_{conc} \qquad (45)$$

The term $V_{Nernst} - \eta_{conc}$ can be directly calculated using

$$V_{Nernst} - \eta_{conc} = -\frac{\Delta G^0}{n \cdot F} - \frac{R \cdot T}{n \cdot F} ln\left(\frac{\prod_{i=1,NP}(p_i)^{\upsilon_i}}{\prod_{i=1,NR}(p_i)^{\upsilon_i}}\right) \qquad (46)$$

Results

The model just presented is now applied to a first case (Case 1), namely, where the TPB is homogeneously distributed at the interface between the electrodes and the electrolyte. The polarization curve is shown in figure 6.

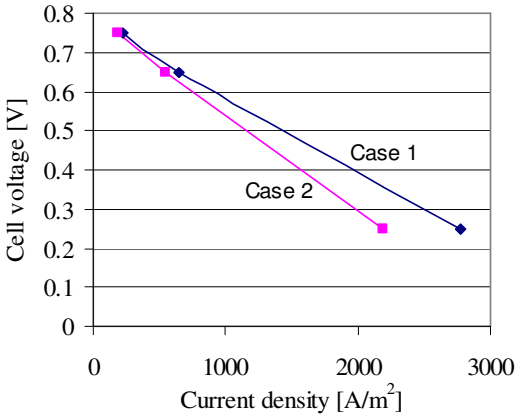

Figure 6. Polarization curves for Cases 1 and 2.

The model is then used to investigate the cell behavior when possible anomalies take place. Possible factors that determine degradation in SOFC performance are: 1) a delamination (decrease in the contact area) between the electrodes and the electrolyte, 2) an increase in the contact resistance between the electrodes and the current collector, and 3) chemical reactions between the materials constituting the electrodes, electrolyte, and interconnections [21].

The first simulation (Case 2) is performed by considering anode delamination, causing a 10% reduction in the anode active area due to a gap formed between the anode and electrolyte. This value has been assumed on the basis of some experiments conducted on a SOFC after almost 1000 h operation and available in the literature [22]. Data about the extension of the area subjected to delamination can be obtained through SEM [20].

This phenomenon has been simulated through considerable reduction of the active area for x<2.5 mm. The simulation of such an anomaly requires the use of a model able to take into consideration the shape of the TPB. The two polarization curves are shown in figure 6.

The results in figure 6 show an increase in the overvoltage. In figure 7, the current density distribution along cross-section AA in figure 5 is shown. It is evident that the reduction in the active surface area causes a significant drop in the current on the anode side of the cell.

The effects of a second anomaly (Case 3), the increase in contact resistance, are also presented in this paper. This increase in resistance was simulated by adding an electric resistance (8 mΩ·cm^2) between the cathode and gas channel, where the interconnections are located [23]. The corresponding polarization curve is shown in Figure 8.

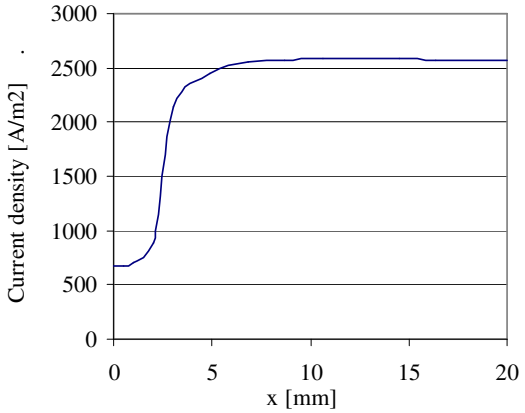

Figure 7. Current density distribution in the anode in the case of delamination (Case 2).

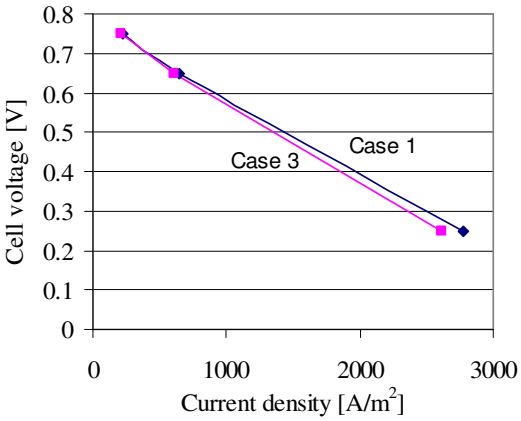

Figure 8. Polarization curves for Cases 1 and 3.

The last anomaly (Case 4) simulated in this work consists of an increase in the resistance between cathode and electrolyte due to formation of $LaZrO_7$ [21], i.e. anode oxidation. Resistance has been increased three orders of magnitude in the layer where both LSM (cathode material) and YSZ (electrolyte material) are present. The polarization curve results are not shown since they are close to those obtained for Case 3. Figure 9 shows the current density distribution in a cross section of the anode for Cases 3 and 4. As can be seen from this cross-section, the percentage difference in effect on the current density between the two cases is not great. Thus, performance in terms of the polarization curve for each case is essentially identical between the two. This also means that the effect of these two anomalies cannot be distinguished on the basis of the polarization curve only.

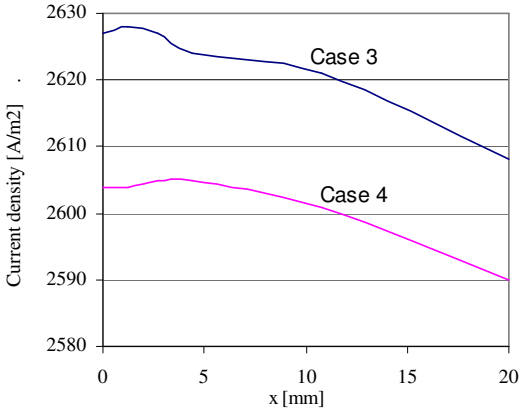

Figure 9. Current density distribution in the anode for the case of increased contact resistance.

Conclusions

In this paper a new CFD model is introduced for the analysis of SOFCs. The model was purposely developed in order to simulate possible anomalies in these devices, since it allows one to consider modifications in the shape of the TPB as well as variations in the ionic and electronic conductivity.

The model was tested by using data obtained from the literature, which deal with typical causes of performance degradation: electrode and electrolyte delamination (Case 2), increase in contact resistance (Case 3), and the formation of oxides (Case 4).

DYNAMIC MODELLING AND CONTROL OF POLYBENZIMIDAZOLE FUEL CELLS

Federico Zenith,* Sigurd Skogestad

Department of Chemical Engineering
7491 Trondheim, Norway

ABSTRACT

A dynamic fuel-cell model for high-temperature PEM fuel cells with PBI membranes has been developed in Simulink. In such models it is common to use the current density as input variable, but this model uses a different approach. The current density is regarded as an unrealistic control variable, since it cannot be controlled directly. Instead, it is possible to simulate the effect of changing the characteristic of the external circuit, a more realistic manipulated variable, with resistances or MOSFET transistors. Experimental runs have been executed to confirm the theoretical development. To measure the parameters needed for the model, impedance tests on the fuel cell are considered an effective way to extract parameters by means of parameter regression: the model has therefore been extended and reimplemented to produce simulated impedance plots, that show good agreement with experimental measurements on fuel cells.

INTRODUCTION

Research in fuel cells has shown a rapid growth. The relatively minor interest for their dynamics has recently increased as a topic in its own merit and as a prerequisite for control analysis and controller design. However, many models provided in the literature [1, 2, 3, 4, 5] were not intended for control studies, and in that context they are often "flawed" because they consider *current density* as an input to the system. This is unrealistic from a process-control perspective, because in reality the current is determined by the characteristics of the fuel cell and of its external load, and is not set directly by the control system.

Currently, most PEM fuel cells are based on electrolytes that rely on liquid water for protonic conduction, binding them to an operating temperature below 100 °C (unless pressurized). In polybenzimidazole (PBI)-based fuel cells, water is produced in gaseous form, and since the membrane relies on phosphoric acid to function, the water management issue is removed. Finally, high-temperature PEM fuel cells based on PBI electrolyte exhibit a high tolerance to carbon monoxide [6].

*Corresponding author: zenith@chemeng.ntnu.no

The parameters used in the model need to be measured appropriately. Impedance tests are measurement of the impedance of the fuel cell at various frequencies. By applying the proposed model structure to calculate the impedance of the fuel cell, a plot of clear resemblance to experimental results is obtained. The fundamental theory about impedance spectroscopy can be found in many textbooks, for example in Macdonald [7].

The objective of this paper is to show the development of a model using the external circuit's characteristic as an input, and how this model is able to explain experimental results observed on a PBI fuel cell. Another objective is making the point that dynamic models for control-design purposes should make use of proper manipulated input variables, instead of using either voltage or current as an input. Furthermore, the usefulness of impedance measurements in determining the model parameters will be demonstrated.

EXPERIMENTAL METHODS

Experiments were carried out on a PBI fuel cell, previously assembled in the laboratory of the Depart-

ment of Materials Technology at NTNU, to determine the transient response of the cell to a variable load. The load itself was assembled as a variable-resistance board, with two resistances in parallel; in series with one of these resistances, a switch could be opened and closed manually. The PBI fuel cell was kept at a constant temperature of 150 °C by an external electric heater. The fuel cell ran on industrial-grade hydrogen and oxygen at atmospheric pressure.

EXPERIMENTAL RESULTS

The results obtained switching from an initial resistance to a smaller one and back are shown in figure 1. It can be seen how the operating point moves from a resistance's characteristic to the other along parallel lines. As a reference, the steady-state polarization curve is plotted as well. Since some hysteresis was experienced in its measurement, the polarization curve is not an entirely precise reference.

Looking carefully at figure 1, it is clear that in the descent to steady-state some transients are faster than others; this can be seen by the number of markers on the trajectory in the *V*-*I* plane. It appears that the electrochemical transient to 12.88 Ω is slower than the one to 5.47 Ω, which is in turn slower than the one to 2.85 Ω.

There is therefore an indication that the electrochemical transient can have *different time constants* depending on both the start and the end point. This behavior could be related to the one observed in a Master's thesis written at NTNU [8], where the same proportional controller, applied on a PBI fuel cell, performed too aggressively in some operating ranges and too mildly in others.

MODELLING

To model the behaviour presented in the previous sections and in figure 1, we actually only need to consider a simple differential equation referred to the cathode of the cell: it is basically a charge balance of a capacitor (3). This capacitor represents what is known in electrochemistry as the *charge double layer*, but also other electrically charged species. At this point we are neglecting the anodic overvoltage and concentrating instead on the cathodic one, but this assumes we do not have any catalyst poison (as CO) on the anode side. Butler-Volmer's equation (1) is implemented with an iterative loop to find the value of the overvoltage, using Tafel's approximation as an initial value for the iterative algorithm[1]. A scheme of the model is provided in figure 2.

A preliminary analysis was run to establish the influence of diffusion transients on the response of fuel cells. The results indicated diffusion transients in the order of 0.01–0.1 seconds, which is faster than the control bandwidth of interest[2]. Furthermore, the gas concentration at the reaction sites has a significant effect only when near to the mass-transfer limit, where oxygen cannot diffuse fast enough from bulk to the reaction surface. Because of these considerations, the model will assume that diffusion transients settle instantaneously, and also that all partial-pressure profiles are linear from bulk to reaction site. The model has later been extended to incorporate the simulation of the anodic overvoltage, but this will be useful only when a reliable simulation of the dynamics of CO poisoning in PBI fuel cells has been developed; without CO poisoning, the anodic overvoltage is negligible for most practical purposes.

The activation overvoltage η of an electrode can be calculated for a given reaction current density i_r and an exchange current density i_0, according to the Butler-Volmer equation:

$$i_r = i_0 \left(\mathrm{e}^{\alpha \frac{nF}{RT} \eta} - \mathrm{e}^{-(1-\alpha) \frac{nF}{RT} \eta} \right) \qquad (1)$$

The reversible potential E^{rev} can be found with well-known thermodynamic data, and the ohmic loss is $r_{cell}\, i$. The cell voltage is then found as:

$$V = E^{rev} - \eta - r_{cell}\, i \qquad (2)$$

During transients, the reaction current density i_r is different from the current density i, which we calculate dividing the current in the circuit by the fuel cell's area. Looking at the following differential equation [1], it is obvious to see that the difference $i - i_r$ is actually the driving force of the transient behaviour of the activation overvoltage:

$$\dot{\eta} = \frac{i - i_r}{C} \qquad (3)$$

[1] Using Tafel as an initial approximation accelerates the algorithm signifi cantly.

[2] We are assuming that the bandwidth of interests begins from time constants of 0.2 seconds, as is typical for automotive applications [9].

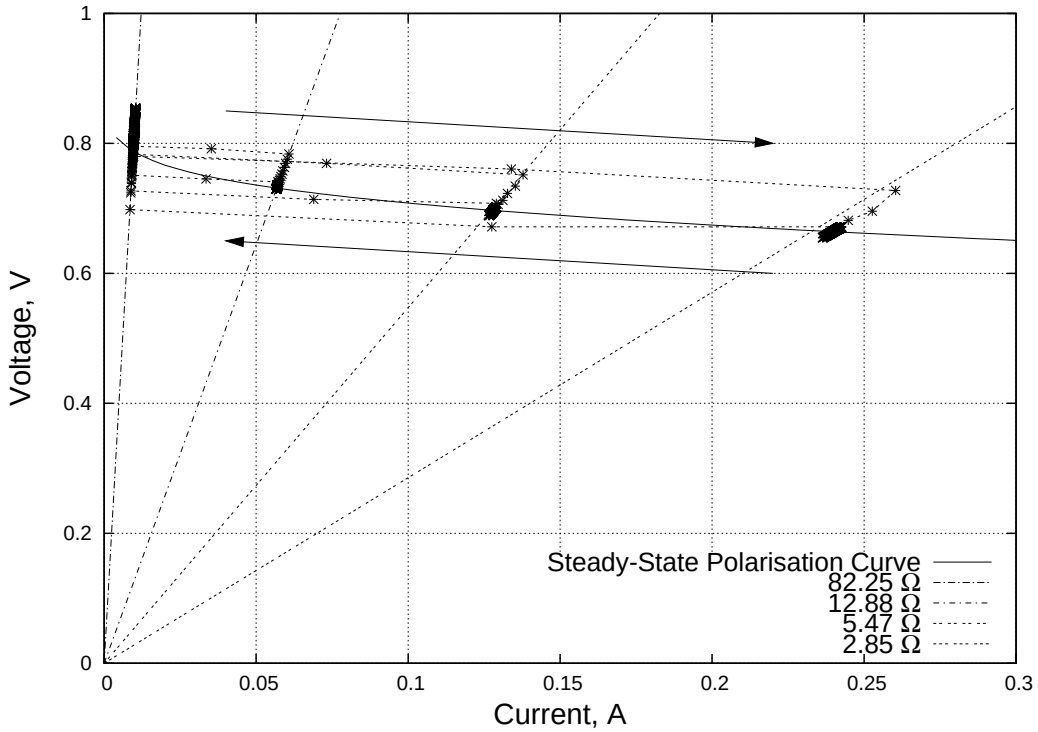

Figure 1: Operating points' path in the V-I diagram after step changes in the external circuit's resistance, starting from 82.25 Ω and switching back. The arrows indicate the path in the I-V plan.

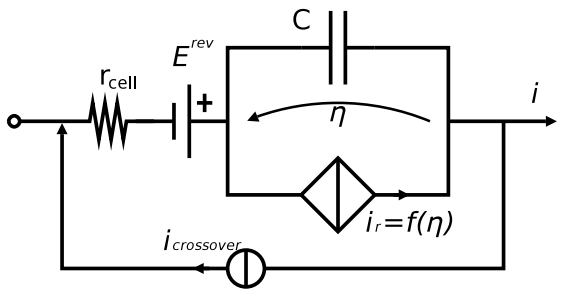

Figure 2: Diagram of the cathode-only fuel-cell model.

This is the only differential equation that we will be considering in order to compute the transient of the fuel cell. The cell's load in the model is generally allowed to vary with time, and is described by a function in the form $I = f(V,t)$.

The model can be expressed in an electrical-circuit diagram, as shown in figure 2. There, one can see the internal resistance r_{cell}, the reversible potential E^{rev}, the capacitor C and its voltage η. The bipole in parallel with the capacitor is a nonlinear voltage-controlled current generator, that enforces the Butler-Volmer law, and imposes a current i_r as a function of η (and many other parameters). This last bipole is often also modelled as a nonlinear resistance [10], or a linearized value in an area of interest. Incidentally, the ideal generator E^{rev} and the resistance r_{cell} in series with it can be viewed as a Thevenin equivalent circuit. Finally, a crossover current density (representing either electronic conductivity of the membrane or permeation of hydrogen molecules) is modelled with a current generator, and given a constant value; PBI fuel cells usually have small values for crossover current density, and a typical value is 5 A/m^2.

The actual integration of differential equation 3 is not very simple, since i_r is a function of many parameters, and also of η itself, through the Butler-Volmer equation (1). An iterative loop is therefore necessary to calculate i_r at all integration steps, and this is the major computational cost of the simulation. The resulting layout for the fuel-cell model in Simulink is shown in figure 3.

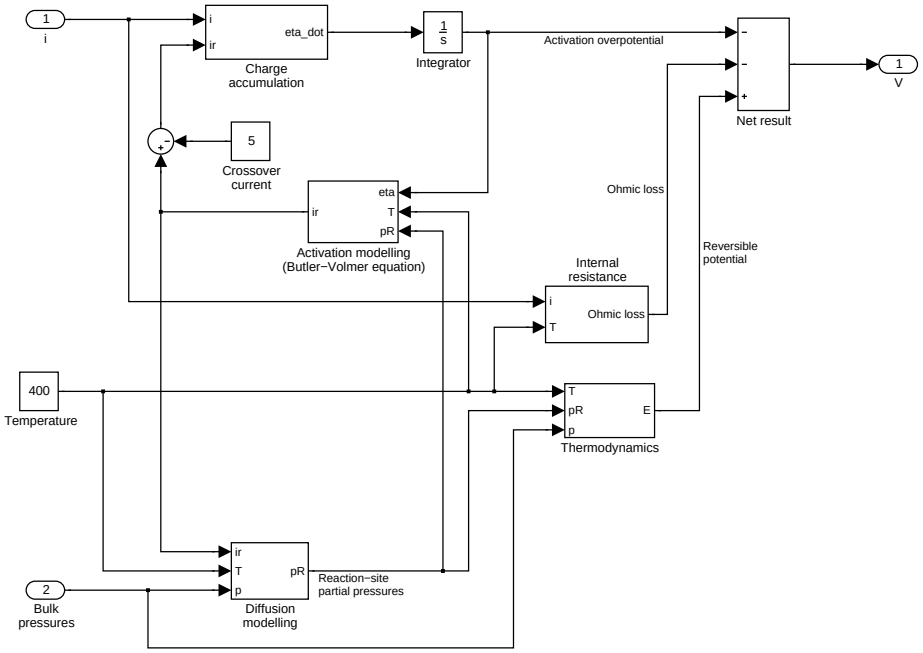

Figure 3: The Simulink implementation of the fuel-cell model, with only the cathode overvoltage being modeled.

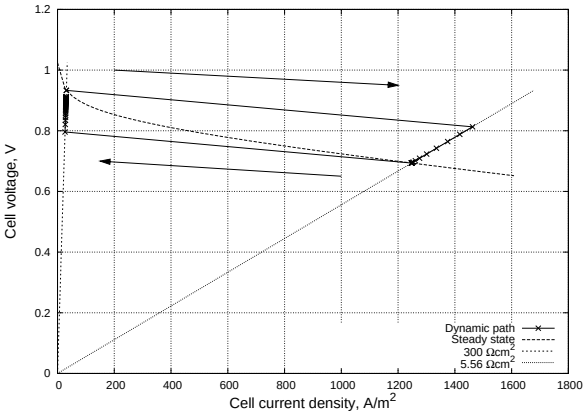

Figure 4: A typical output of the model: a simulation of a transient from a steady-state operating point to a new value of the external resistance, and back. Assumed temperature is 150 °C. The markers are spaced by 0.01 s.

MODEL RESULTS AND INSIGHTS

The cause of the sudden "kick" in the dynamic path diagram, as can be seen in the simulation in figure 4 and in experimental results in figure 1, is caused by the simple fact that the operating point *must* always lie on the load's characteristic, when the load is purely resistive. It is possible to determine to *which coordinates* on the load's characteristic the operating point will jump, considering that the activation overvoltage η varies *continuously* with time; when a step change in the outer load happens at time t_0, η will therefore be the same for times t_0^+ and t_0^-.

Using the load characteristic as the model's input has allowed to simulate real laboratory results, and has given the possibility of simulating the implementation of MOSFETs as manipulated variables in control of fuel cells. Pulse-width modulation (PWM) has also been implemented.

Looking at figure 4, it is clear that the drawn part of the polarization curve is closer to the characteristic of the higher resistance, when distance is measured along the i axis. Since $\dot{\eta}$ is proportional to the distance between the intersections of the instantaneous characteristic with the polarization curve and the external resistance along the i axis, i.e. $i - i_r$, it follows that the transient to the lower resistance will be faster than the one coming back, because of the higher val-

ues of $i - i_r$ along that path; this is confirmed by the experimental measurement shown in figure 1.

An analytic expression for the time constants has been found. Assuming that C and r_{cell} are constant, and that functions $V = \Psi(i)$ (the external load's characteristic) and $\eta(i_r, \ldots)$ are given, the time "constant" τ depends essentially on i and i_r:

$$\tau(i, i_r) = \frac{C}{\left(r_{cell} + \frac{\mathrm{d}\Psi}{\mathrm{d}i}\Big|_i\right)^{-1} + \left(\frac{\mathrm{d}\eta}{\mathrm{d}i_r}\Big|_{i_r}\right)^{-1}} \quad (4)$$

Considering the basic expression of the voltage of a fuel cell (2), and looking at figure 4, it is evident that the instantaneous characteristic at a given steady-state point stays at higher voltages than the polarization curve when moving to higher values of current density, and, conversely, at lower voltages for lower values of current density; in other words, a step change in the external resistance always results in some overshoot. Under these assumptions, a perfect step change in power output can in theory be obtained if the controller manages to steer the fuel cell properly.

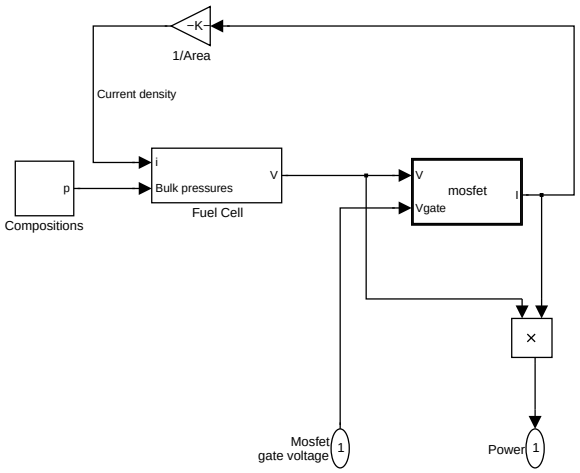

Figure 5: The structure of the fuel cell-MOSFET system in Simulink. The control input is the MOSFET's gate voltage, while the output is the power produced by the cell.

PID CONTROL

Using Skogestad's PID-tuning rules [11], a simple PI controller was devised to operate a fuel cell so that its power output would match the power necessary for an appropriately-scaled standard driving cycle. The control system operates by manipulating the gate voltage of a MOSFET transistor, which acts like a "valve" for the cell's power output. Measuring the error in watts, and using the parameters of a IRF1404 MOSFET by International Rectifier Inc., the parameters of the controller were found to be $k = 0.191$ and $\tau_I = 0.4\,\mathrm{s}$.

Several driving cycles were implemented, and in figure 6 the results for the European Urban Driving Cycle (ECE 15) are shown. It can be seen that the cell is definitely slower at following the reference signal at low power values, which correspond to high voltages and low activation overvoltages. This is consistent with the formula for time constants (4) that was found previously.

It should be remarked that this synthesis has not yet accounted for disturbances, since a satisfactory model for the main disturbance in the process, CO poisoning, is not yet available; it would therefore be

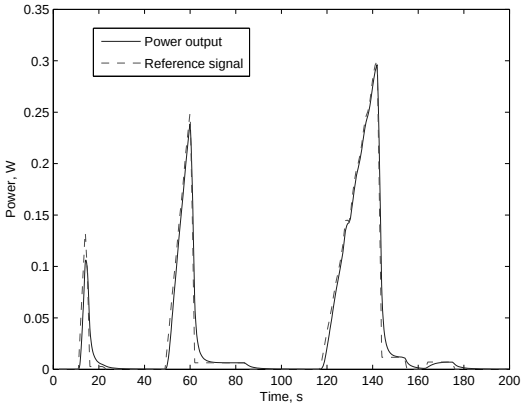

Figure 6: Simulation of a feedback-controlled fuel cell trying to deliver the power required by the ECE 15 standard driving cycle.

possible to make the cell model follow the reference almost perfectly if the proportionality constant in the controller were set to $k = \infty$. Of course this would just be a simulation trick. A more thorough synthesis will be possible when the effect of disturbances will have been estimated.

IMPEDANCE MEASUREMENTS

Given the model developed above, it is important to obtain values for its parameters. Impedance measurements are a good way to achieve this, allowing visual assessment as well as more precise techniques as nonlinear regression to estimate, among other things, the internal resistance, the overvoltages and the capacitances of both cathode and anode.

Using measurements obtained directly by logging data from transients when changing the load in a certain way is not always a good idea, since these measurements are often clouded by other transients, such as temperature variations at the reaction sites due to the different reaction rate; this is especially true for PBI fuel cells.

Impedance tests are performed by keeping the fuel cell in a known condition of voltage, temperature, partial pressures in the inlet gases, and eventually other relevant state variables, and measuring its impedance at various frequencies. The impedance values can then be plotted in a Bode diagram or, more commonly, in a Nyquist diagram[3].

Model layout

In order to estimate the model parameters, it was necessary to reformulate the model in a way that would present the user a function $Z = f(\mathbf{X}, \Theta)$, where Z is the impedance (in general a complex number), $\mathbf{X}$ is the vector of states, and Θ is the vector of parameters. The model was reimplemented in C++, and an interface function to allow its use in OCTAVE was written[4].

This time, the model was a steady-state model, but included also the anode in the description of the fuel cell. Since most impedance measurements show a "tail" at the highest frequencies, an inductance has been added in series with the fuel cell, and can be considered a parameter of the model. The model scheme is shown in figure 7.

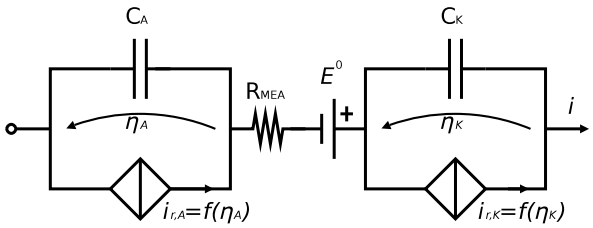

Figure 7: Diagram of the fuel-cell model used for impedance simulations.

Given this model, it is possible to develop the following formula for the impedance of the fuel cell:

$$\begin{aligned} \mathrm{Re}(Z) &= R_{cell} + \frac{R_a}{1+\omega^2 R_a^2 C_a^2} + \frac{R_c}{1+\omega^2 R_c^2 C_c^2} \\ \mathrm{Im}(Z) &= \omega L_{ext} - \frac{\omega R_a^2 C_a}{1+\omega^2 R_a^2 C_a^2} - \frac{\omega R_c^2 C_c}{1+\omega^2 R_c^2 C_c^2} \end{aligned}$$

where we have set, for ease of notation, $R_{\{a,c\}} = \eta_{\{a,c\}}/i_{r,\{a,c\}}$.

The compiled function showed excellent performance, calculating up to 4,000 values of impedance per second on a 2.4 GHz computer. Some values calculated by the function are shown in figure 8.

Assuming these equations are valid, an impedance plot can used to easily estimate some properties just by eye inspection. For instance, it is obvious that, for $\omega \to 0$, $\mathrm{Im}(Z) = 0$ and $\mathrm{Re}(Z) = R_{cell} + R_a + R_c$. When, instead, $\omega \to \infty$, $\mathrm{Re}(Z) = R_{cell}$. Fuel cells often show a similar pattern in impedance plots, with a large semicircle that represents the cathode, and a smaller one to represent the anode. The diameter of these semicircles is respectively R_c and R_a. Since we have defined these quantities to be the overvoltage divided by the reaction current at cathode and anode, and since the overvoltage has a very nonlinear dependence on the reaction current, it follows that these semicircles will vary greatly with the fuel cell's voltage. The presence of a crossover current will also be very influent, as it will cause overvoltage to be present even if there is no current moving through the outer circuit. In this latter case of open-circuit condition, the impedance plot degenerates into a vertical line (or, equivalently, a circle of infinite radius), with equations:

[3] It is common, for such Nyquist diagrams, to use an inverted ordinate axis.

[4] Writing a similar interface function to MATLAB is also possible.

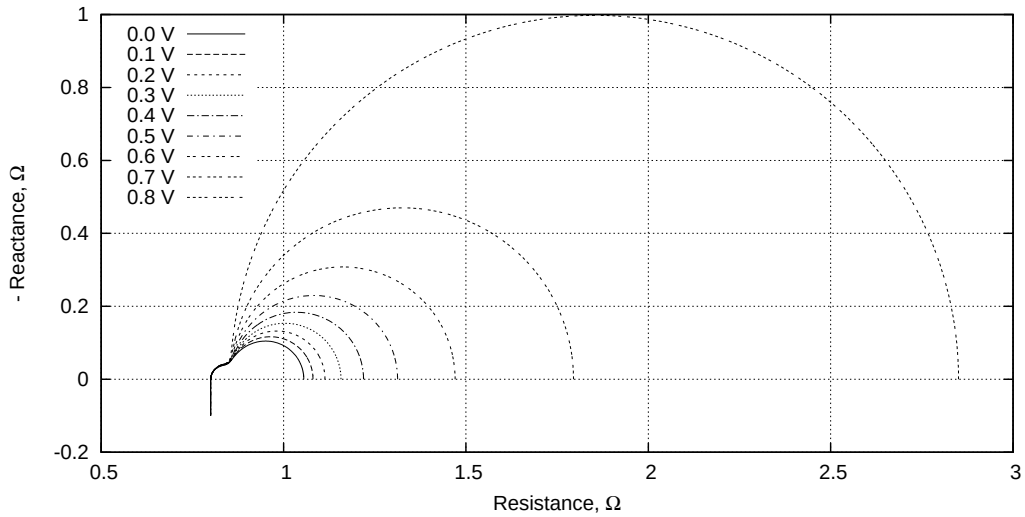

Figure 8: Nyquist plot of the impedance of a fuel cell at various voltages; the operating conditions and parameters are $p_{H_2} = 75\,\mathrm{kPa}$, $p_{O_2} = 21\,\mathrm{kPa}$, $C_a = 100\,\mathrm{F/m^2}$, $C_c = 500\,\mathrm{F/m^2}$, $T = 150\,^\circ C$, $L_{ext} = 1\,\mu\mathrm{H}$, crossover current $i_C = 300\mathrm{A/m^2}$.

$$\mathrm{Re}(Z) = R_{cell} \quad (5)$$

$$\mathrm{Im}(Z) = \omega L_{ext} - \frac{1}{\omega C_a} - \frac{1}{\omega C_c} \quad (6)$$

It should be noted that *Warburg impedance*, caused by diffusion phenomena, cannot be simulated by the model, since it was assumed for simplicity that the diffusion transient was infinitely fast. In experimental results, the Warburg impedance usually appears in the form of a small "tail" in the Nyquist plot in the lower range of frequencies, and more clearly so at high currents.

Finally, it can be demonstrated, by calculating the derivative, that the summit of the semicircles (assuming they can be isolated with reasonable precision) satisfies the equation:

$$\omega_{summit,\{a,c\}} = \frac{1}{R_{\{a,c\}} C_{\{a,c\}}} \quad (7)$$

RC has the dimensions of time, and is therefore often written τ in he literature.

These observations can be used to estimate the value of some parameters, in order to provide a more precise starting guess for a nonlinear regression algorithm for experimental values, which will be subject of further work.

Nyquist plots are also commonly used in control theory; in that context, the impedance can be viewed as the *transfer function* between current and voltage.

CONCLUSION

By using the characteristic of the circuit connected to a fuel cell as an input to a dynamic model, instead of more common inputs as current or voltage, it was possible to explain the shape of transients observed in a laboratory fuel cell, and to estimate their time constants. A simple PI controller has been synthesised, and it was observed that its performance was dependent on the power output of the fuel cell. In order to estimate the parameters of the dynamic model, the model was reimplemented in parametric form. The reimplemented model currently shows acceptable stability and good performance, and will soon be applied to data analysis.

ACKNOWLEDGEMENTS

ABSTRACT

The detailed synthesis/design optimization of a hybrid Solid Oxide Fuel Cell - Gas Turbine (SOFC-GT) power plant is presented in this paper. The plant layout consists of the following principal components: an internal reforming SOFC, a steam-methane pre-reformer, a catalytic burner, a radial gas turbine, a centrifugal air compressor, a centrifugal fuel compressor, plate-fin heat exchangers, counter-flow shell and tube heat exchangers, and mixers. In the first part of the paper, the bulk-flow model used to simulate the plant is discussed. The off-design performance of the centrifugal compressors and radial turbine is determined using maps, properly scaled in order to match required mass flow rate and pressure ratio values. Compact heat exchangers are simulated using Colburn and friction factor correlations while for the SOFC, the cell voltage versus current density curves (i.e. polarization curves) are generated on the basis of the Nernst potential and overvoltages due to activation, Ohmic, and concentration losses using the Butler-Volmer, resistivity, and limiting current density equations, respectively. A SOFC configuration with internal reforming through anode re-circulation is chosen in order to avoid the use of an external heat recovery steam generator. Validation of the SOFC polarization curves is accomplished with data available from Siemens-Westinghouse. Both the steam-methane pre-reforming and internal reforming processes are modeled assuming the water-gas shift reaction to be equilibrium controlled and the de-methanization reactions to be kinetically controlled. Finally, a thermoeconmic plant and component model is developed by introducing capital cost functions for each plant component.

The whole plant is first simulated for a fixed configuration of the most important synthesis/design parameters in order to establish a reference design configuration. Next a synthesis/design optimization of the plant is carried out using a traditional single-level approach. These results and those for the synthesis/design optimization of the plant in general are presented in this paper.

1. Introduction

Solid Oxide Fuel Cells (SOFC) are considered one of the most promising technologies for power production in stationary applications [1]. Hybrid power plants based on SOFCs are expected to reach values of net electrical efficiencies higher than 70% [2-5]. As a consequence, much research in recent years on the analysis and design optimization of such systems has shown that the best way to use a SOFC in a hybrid power plant is to introduce the cell into a traditional Brayton cycle based on the gas turbine (GT) technology [6-10]. In fact, the usual temperature of streams exiting a SOFC is perfectly suitable for the Turbine Inlet Temperature (TIT) required by state-of-the-art-turbomachinery [4]. A great number of possible

layouts for hybrid SOFC - GT plants have been proposed in the literature [1-10], which include combinations of SOFC stacks, heat exchangers, compressors, gas turbines, pre-reformers, mixers, heat recovery steam generators, and combustors in different arrangements. The performance of these plants have been investigated using a number of different techniques [11-17]. In this paper, mathematical optimization in what is called a single-level approach (e.g., see [18-20]) is used to determine the optimal synthesis/design of the configuration considered here. Detailed cost models are introduced for all components in order to establish a relationship between fuel and capital costs and the synthesis/design of the system and its components. Simulation of the system (plant), needed in order to evaluate the performance of the system and its components for given values of the synthesis/design variables, is based on a model previously developed by some of the authors [15-17]. However, a few of the simplifying assumptions used with respect to the original model are not employed here as is discussed in the following sections.

2. System Layout

Nowadays, at least four different types of SOFC are available (tubular, tubular "high power density", planar, and micro-tubular) [1-4]. In spite of the fact that such systems have been studied since the 1970s [1], until now only few prototypes have been developed and tested [1]. Siemens Westinghouse is probably one of the most important companies involved in the design and commercialization of hybrid SOFC-GT power plants [21]. This company has installed a 220 kWe hybrid tubular SOFC-GT system at the National Fuel Cell Research Center in California [1,21]. Results of a campaign of performance measurements indicate values of the design-point net electrical efficiency to be somewhat lower than the target (52% versus 57%) [1]. Furthermore, this particular system demonstrates the huge difficulties encountered in integrating a SOFC with a GT. As a result, much additional development is still required to develop this system further. Thus, an improvement of the coupling between traditional and innovative devices is not only mandatory but appears not to be necessarily straightforward [1-4]. In particular, the most stringent issue is to find a gas turbine suitable for this application [1]. On the basis of this experience, Siemens is now designing new hybrid plants in the range from 250 kWe to 1 MWe [1,21] since it is clear that the bigger the size of the plant is, the easier it is to find a GT suitable for the application [22].

In this paper, a 1.5 MWe hybrid power plant is investigated, based on an internal reforming tubular SOFC with an anode re-circulation tubular arrangement [1,2,4,10,17,22-25]. This configuration allows one to avoid the use of an expensive external heat recovery steam generator. In the present paper, the system is only analyzed at the design point. Thus, all components required for start-up and partial-load operation are not considered. Future work will also take into account partial-load operation by introducing time-dependent load curves.

The layout proposed for the hybrid plant is shown in Figure 1. It consists of a centrifugal air compressor (AC); a centrifugal fuel compressor (FC); a plate-fin, air-GT exhaust heat exchanger (HE); a plate-fin, fuel-GT exhaust heat exchanger (HE); a radial gas turbine (GT); mixers (M) for anode re-circulation, air by-pass, and pre-reforming bypass streams; a catalytic burner (C); an Internal Reforming Solid Oxide Fuel Cell (IRSOFC) Stack; a pre-reformer (PR); a counterflow air-SOFC exhaust heat exchanger (HRC); by-pass valves; an electrical generator; an inverter; and two water-exhaust gases, plate-fin heat exchangers (HE). The plant layout includes 31 streams or state points and 14 components.

The principle of operation can be summarized as follows:

- Air is compressed by the air compressor up to the fuel cell operating pressure. The air is then preheated in the plate-fin heat exchanger and brought to the cathode inlet of the SOFC stack (state point 18).
- Similarly, the fuel - natural gas - is compressed by the fuel compressor, preheated in the fuel-exhaust gas, plate-fin heat exchanger and then brought to the anode compartment of the stack (state point 1).
- Both fuel and air can by-pass the fuel cell, i.e. a certain amount of fuel flow can be brought directly to the combustor by-passing the electrochemical reaction occurring within the stack (state point 23), while excess air can be brought to the GT (state point 20).
- At the stack, fuel (state point 24) is mixed with the anode re-circulation stream (state point 5) in order to support the steam reforming reaction in the pre-reformer and in the anode compartment of the fuel cell. The mixture at state point 25 consists of methane and steam. Thus, in the pre-reformer the first step in the fuel reforming process occurs. The energy required to support the pre-reforming reaction

is derived from the hot stream at state point 26. The unreacted fuel at state point 2 is involved in the internal reforming reaction within the anode compartment of the SOFC stack. Here it is converted into the hydrogen that participates in the electrochemical reaction.

- On the cathode side, air is first preheated by a virtual counter-flow heat exchanger and then brought into the annulus (air pipe) of the SOFC where, at the three-phase boundary, the cathode electrochemical reaction occurs [1-4].
- The electrochemical reactions, occurring in the fuel cell, produce DC electrical and thermal energy [1-4]. The first of these is converted into AC current by the inverter; the latter is used by the internal reforming reaction and to heat-up the fuel cell stack.
- Anode and cathode outlet streams meet on the top of the fuel cell, entering the combustor. Un-reacted fuel and depleted air participate in the combustion reaction within the catalytic burner.
- The high energy flow rate at state point 8 is first used to preheat air in the counter-flow heat exchanger and then to supply energy to the pre-reforming reaction. This stream at state point 21 enters the gas turbine.
- The expansion in the GT supplies mechanical power and then electric power. The GT outlet stream (state point 10) energy flow rate can be used to preheat both fuel and air flows. Any residual thermal energy left over is available for cogeneration purposes, using two water-gas, plate-fin heat exchangers.

3. Plant Model

The model used to simulate the behavior of the system is a typical lumped-parameter model based on the following assumptions: one-dimensional flow; steady state; no gas leakage; negligible heat losses to the environment; negligible kinetic and gravitational terms. The model is implemented in a computer code developed by the authors and described in detail in [15-17]. However, as indicated previously, a few of the simplifying assumptions with respect to the original version are no longer employed here, and cost models are added for thermoeconomic evaluations. Finally, a genetic algorithm (GA) [26] is used for optimization purposes.

The code, including 50 subroutines, was written in MATLAB and is based on a number of built-in functions, tools and externally-developed subroutines [27-28]. When possible, equations are solved sequentially, avoiding large non-linear algebraic systems. However, in many cases, the solution of a non-linear system is necessary and is accomplished using the STRSCNE tool [24].

In the version developed for thermoeconomic optimization purposes, the model includes 19 fixed parameters (see Table 1) and 48 synthesis /design (S/D) decision variables (see Table 2). Fixed parameters, such as the net electric power production, remain constant during the optimization. The S/D decision variables can vary in a given range (usually ±30% of the starting value, or "initial" value) and represent the independent variables in the synthesis/design optimization of the system. Obviously, only some of the possible sets of values for the S/D decision variables correspond to actual feasible syntheses/designs. The others are automatically rejected by the code. For any acceptable synthesis/design, the model calculates all energy, entropy, and exergy flow rates entering and leaving each component and the capital cost of each device. In the following, the most significant aspects of the model will be described briefly as will the improvements introduced with respect to the first version of the simulation code found in [15-17].

3.1 Electrochemical Model

The modeling of the electrochemical phenomena is based on the model described in [15-17] and validated with data provided by Siemens Westinghouse [29]. The model is implemented with a number of routines for calculating the open circuit reversible voltage and activation, ohmic and concentration losses. As to the later, the model has been improved by introducing average diffusion coefficients and experimental formuli to calculate the limiting current density [30]. In order to validate the model, the polarization curves generated by the code are compared with experimental ones for different values of operating pressure, temperature, and chemical composition of the inlet streams. Results show that the lumped-parameter model achieves errors lower than 5%.

3.2. Calculation of Thermophysical and Transport Properties

As previously stated, natural gas is assumed as the input fuel with a typical Italian composition [15]. Air is assumed as the oxidant while reforming and combustion reactions occurring within several components of the plant generate four additional substances: CO, CO_2, H_2O, and

H_2. Calculation of the enthalpies, entropies, and physical and chemical exergies is based on the assumption of ideal gas, temperature-dependent specific heats and IAPWS-IF97 equations [31]. In order to calculate pressure drops, values of viscosity, conductivity, and density values are needed too. The viscosities and conductivities of each pure substance are calculated through empirical relationships [32]. Values for mixtures are calculated on the basis of Wilke's law and the inter-collision factor. Values for specific heat and density are calculated on the basis of the ideal gas model and Dalton's law.

3.3. Turbomachinery Model

Three turbomachines are included in the plant under study: an air compressor, fuel compressor, and gas turbine. These devices have been investigated in detail in order to match their requirements with those coming from the fuel cells [33]. Maps, available from the archives of the GSP software and Gasturb, are used, to describe the mass flow rate versus pressure ratio curves for different values of rotor speed. Since no map matches the values of mass flow rate and pressure ratios required by the components of the plant under investigation, all the maps are properly scaled. In particular, a centrifugal compressor (based on an ASME 95-GT-79 map) and a radial turbine (based on a NASA-CR-174646 map) are selected. Such devices show large ranges for both mass flow rate and pressure ratios so that a large number of operating points fall within the feasible region of these maps. Axial turbines, for example, can work only very close to the design mass flow rate so that it is very difficult to find a real operating point in case of a partial load.

Map scaling factors are considered as design decision variables and the code dynamically scales all the maps for each iteration of the optimization procedure. Each map is corrected on the basis of the values of inlet temperature and pressure [22,24,32]. In case of the air or fuel compressor, the inlet condition corresponds to the environmental one whereas the temperature and pressure of the GT inlet stream can vary considerably as a consequence of a change in the design and operating parameters. Consequently, once the GT corrected map is fixed, the un-corrected changes at each iteration of the procedure are updated.

The air compressor and gas turbine are assumed to be coupled on a single shaft. As a consequence they must have the same rotor speed. The speed of the fuel compressor can vary independently. The maps are used to calculate isentropic efficiencies and pressure ratios as a function of mass flow rates, rotor speed, and inlet conditions. Thus, the outlet conditions of the components are calculated as well as energy, entropy, and exergy balances. The use of maps dramatically restricts the feasible operating region of the plant. Thus, whenever the operating point of a turbomachine falls outside a map or the GT outlet pressure calculated is lower than the environmental one, the solution is rejected.

3.4. Heat Exchanger Model

In order to simulate the heat transfer between the air flowing through the fuel cell air tube and the stream coming from inside the stack (state point 8), a virtual counterflow tube-in-tube heat exchanger is implemented in the stack [1-4, 10,17,22-25]. This heat exchange is modeled on the basis of previous models [15,16], improved to take into account the dependence of thermophysical and transport properties on temperature and pressure drop models.

In general, heat exchanger (HE) performance is modeled using the ε – NTU [34,35] method, taking into account that specific heats, global heat transfer coefficients, and outlet pressures depend on temperature. The geometric model for the heat exchangers is derived from [36,37]. Pressure drops and overall heat exchange coefficients are calculated on the basis of experimental relations given for Colburn and friction factors [36]. In this calculation outlet temperatures and pressures must be calculated iteratively by embedded loops and calls to a number of routines for the evaluation of thermophysical and transport properties. As a consequence, this calculation is very time-consuming.

3.5. Pre-Reformer Model

In theory. SOFCs can be directly fed with natural gas, since the reforming process can be supported inside the stack [1-4, 10,14-17,22-25]. In practice, a pre-reforming process is always required. Two things in particular must be taken into account, namely, that i) the natural gas includes a small fraction of complex hydrocarbons that must be cracked before entering the cell; and ii) if the cell is fed directly with methane, the bottom of the SOFC tube would not be able to produce any voltage, since there would be no hydrogen available for the electrochemical reaction. A goal of the study presented here is that

of quantifying the optimum percentage of pre-reformed fuel particularly since there is a lack of clarity on this issue in literature, varying from 30% to 60%, depending on the author.

The pre-reformer unit consists of a number of tubes located inside a shell and filled with a particular catalyst [38,39]. The reformate gas flows inside these tubes. Hot gases, coming from the combustor, flow externally, supplying the thermal energy needed to support the process. In fact, the energy provided by the exothermic shift reaction is not sufficient for the endothermic demethanization or reforming process [38,39].

In order to simulate this component, the heat-exchange problem must be solved and the chemical composition of the outlet flows must be evaluated as well, taking into account both equilibrium and kinetics [40-42]. The heat-exchange problem cannot be solved with conventional techniques (log-mean or ε – NTU), since chemical reactions occur within the cold fluid. Therefore, an appropriate model is developed based on the differential form of the energy balance equation, integrated along the reformer tubes to calculate the outlet temperatures starting from a set of inlet ones and taking into account the rate at which both the reforming and shift reactions occur in the cold stream. For the shift reaction, it is assumed that chemical equilibrium is controlling whereas for the reforming reaction both equilibrium and kinetic calculations are performed in order to ascertain the actual state of the reaction[2]. The calculation of the demethanization rate is based on equations available in the literature [38-42] and can be directly related to the geometric and thermodynamic parameters of the pre-reformer [38,39]. Once the demethanization rate within the pre-reformer is known, the diameter and length of the pre-reformer tubes are calculated to match this rate. Average temperatures are used to calculate all pre-reformer kinetic and equilibrium properties.

These last set of calculations are usually very complex and time consuming, since a number of nonlinear systems of equations must be solved at each iteration. However, it can be simplified by assuming that the demethanization reaction is only ruled by the kinetics. At usual pre-reforming operating temperatures, the methane rate reaction is higher than 90%. In the present work, this value is assumed to range between 20% and 60%: in such a range, the process is ruled by kinetics [1-4].

[2] In fact in subsequent work, the authors have handled this more straightforwardly by using rate modified expressions for both reactions which incorporate the equilibrium constraints directly into the rate expressions (see [43-45]).

3.6. Internal Reforming Model

Reformate gas, coming from the pre-reformer, is rich in methane but also consists of hydrogen, carbon monoxide, carbon dioxide, some nitrogen, and steam. Usually, the CO concentration is relatively high, since the conversion rate of the shift reaction is very small and even sometimes negative. As a consequence, it is mandatory to design the fuel cell anode compartment to support both the demethanization and shift reactions within the fuel cell. To do this, it must be equipped with a proper catalyst in the same region of the SOFC stack where the anode electrochemical reaction takes place. As a consequence, three chemical reaction processes (demethanization, shift, and electrochemical) must be taken into account simultaneously. The unknowns are the methane, carbon monoxide, and hydrogen conversion rates. These variables are calculated on the basis of the shift equilibrium, kinetic/equilibrium, and electrochemical kinetics. From the solution of this strongly non-linear algebraic system of three equations, chemical compositions at both the anode and cathode outlet can be calculated. All properties and constants are evaluated at the SOFC outlet equilibrium temperature. It is assumed that temperature gradients along the cell radius are negligible as a consequence of the high conductivity and low thickness of materials used in SOFC technology [15, 16].

3.7. Combustor, Mixers, Inverter, and Electrical Generator Models

Mixers were modeled on the basis of simple energy and mass balances while the combustor reactions are assumed to be driven to completion within the catalytic burner [15, 16]. Its outlet chemical composition and energy rates are calculated by using mole, mass and energy balances. Empirical functions were introduced in order to simulate the efficiency of the inverter and the electrical generator as a function of their operational parameters.

3.8. Solution Approach

Due to the complexity of the models developed here and implemented in MATLAB™, the calculation of a single operating point is usually a very involved and time-consuming task.

Furthermore, whatever optimization approach is used, the search for an optimum set of synthesis/design decision variable values requires the calculation of a very high number of possible syntheses/designs for the plant. Thus, a great deal of effort has been spent by the authors to speed-up the calculation procedure by lightening the number of sub-functions, replacing the graphic interface, and introducing more efficient algorithms than available in MATLAB™ for the solution of integrals and non-linear systems of equations. This effort has resulted in a reduction by a factor of 4 of the computational time.

In addition, since the code is written in MATLAB™, which is not designed for the solution of strongly non-linear systems, the code has been written to the greatest extent possible using a sequential logic, which avoids having to solve a system or a set of systems of equations simultaneously. Nonetheless, in certain cases this is unavoidable and an iterative procedure is needed for some sub-systems of the plant. In particular, four main nested loops are introduced, respectively, to calculate: i) the chemical composition at state point 3; ii) the pressure and temperature at the outlet of the SOFC stack; iii) the temperature, pressure, and chemical composition at the outlet of the GT; and iv) the fuel flow rate. Since the solutions of the pre-reformer and stack subsystems require knowledge of all inputs, including the chemical composition at state point 3 and the latter depends on the characteristics and operating conditions of the stack and the GT, a guess value for chemical composition at state point 3 is fixed, starting from the value of the mass flow rate at state point 5. In other words, the re-circulation ratio is calculated in order to match the value of the steam-to-carbon ratio required to avoid carbon deposition in the anode compartment of the fuel cell. The mixer, pre-reformer, and stack are then solved followed by the anode outlet chemical composition. This is then compared with the initial guess and the iteration proceeds until the convergence criterion on the partial pressures of all the chemical constituents is satisfied.

The preceding iterative calculation requires the temperature of the stack, which must be iteratively calculated by the second loop mentioned above. Furthermore, both the preheating heat exchangers require the chemical composition, temperature, and pressure at state point 10. These can be calculated iteratively, by means of the third loop mentioned above. Finally, the fuel flow rate is iteratively calculated until the required net electrical power is achieved.

4. Cost Model

For any given set of values for the synthesis/design decision variables, corresponding to a feasible operating point of the plant, the estimated investment cost is calculated as the sum of the costs of all components provided by proper cost models. For the turbomachinery, the capital cost (C_{GT}, US$) is usually evaluated on the basis of the maximum power (P_{GT}, kW) produced. In particular, for the gas turbine, the cost function proposed by [46] is used such that

$$C_{GT} = \left(-98.328 \ln\left(P_{GT}\right) + 1318.5\right) \cdot P_{GT} \tag{1}$$

For the centrifugal compressors, the capital costs ($C_{compressor}$, US$) are calculated by interpolating data from manufacturers as a function of the maximum power ($P_{compressor}$, kW) required and using information provided in recent papers [47,48]. On this basis, the following function is employed:

$$C_{compressor} = 91562 \cdot \left(\frac{P_{compressor}}{445}\right)^{0.67} \tag{2}$$

The estimated capital costs of the compact heat exchangers (C_{HE}, US$) is related to their mass (m_{HE}, kg) [36] as described by

$$C_{HE} = 111.6\left(m_{HE}\right)^{0.95} \tag{3}$$

For the counterflow heat exchanger, the capital cost is determined on the basis of literature data [49] such that

$$C_{HEC} = 130\left(\frac{A_{HE}}{0.093}\right)^{0.78} \tag{4}$$

The cost of the SOFC stack is not calculated at present market values, since the technology is still sometime away from full commercialization. Thus, the cost is estimated with reference to market studies in which the expected cost for the case of a significant increase in production volumes is assumed. A detailed work performed by [50] relates the SOFC capital cost to the active area and the operating temperature (T_{cell}. °C). Furthermore, the electric energy produced by the SOFC must be filtered by an inverter, whose cost is not negligible and should, therefore, be taken into account. This cost depends primarily on the net power production (P_{cell}, kW) of the stack. Thus, for both of these costs, the following expressions are used:

$$C_{SOFC} = \left(n_{cells}\pi D_{cell} L_{cell}\right)\cdot\left(2{,}96\cdot t_{cell} - 1907\right) \quad (5)$$

$$C_{inverter} = 100000\cdot\left(\frac{P_{cell}}{500}\right)^{0.70} \quad (6)$$

The SOFC system also consists of a pre-reformer, whose cost is calculated on the basis of its catalyst volume (V_{PR}, m^3) and the finned exchange area ($A_{PR,fin}$, m^2) [38,39,49] which is related the number, diameter, and length of tubes. Thus, based on these references and updating the functions with literature data, the following cost functions are used.

$$C_{PR} = 130\left(\frac{A_{PR,fin}}{0.093}\right)^{0.78} + 3240\left(V_{PR}\right)^{0.4} + 21280.5\, V_{PR} \quad (7)$$

Finally, the capital costs for auxiliary devices such as combustors, mixers, and bypass valves are calculated as a fixed percentage (10%) of the stack cost. The counter-flow heat exchanger cost is given by [50].

$$C_{aux,SOFC} = 0.10 C_{SOFC} \quad (8)$$

The overall life cycle cost for owning and operating the plant is assumed as the objective function to be minimized. It is defined as the sum of the fuel and capital costs evaluated on a yearly base. The following assumptions are made: 10 year lifetime; an amortization rate of 5%; and 8760 operating hours per year. The cost avoided through the use of waste heat is also considered, assuming a reference efficiency for conventional furnaces of 90%. Thus, the objective function to be minimized is as follows:

$$f = \frac{\sum_{i}^{components} C_i}{7.72} + c_{fuel}\dot{V}_{fuel}(8760) - \frac{c_{fuel}\dot{Q}_{rec}(8760)}{9.59\,(0.90)} \quad (9)$$

5. Optimization Strategy

The optimization of the hybrid plant investigated is a very complex problem due to the non-linearity of the models, the high degree of coupling between components, the high number of synthesis/design decision variables, and the continuous and discrete nature of these variables. Furthermore, the performance maps for the compressors and turbine, introduced to develop a more realistic model, dramatically restrict the region of feasible solutions, leading to a large number of simulations with infeasible operating points. To more effectively deal with these difficulties, a Genetic Algorithm (GA) is used [26]. However, such an approach is very calculation intensive and, unlike with a gradient-based approach, is unable to mathematically establish a Kuhn-Tucker point, since it is a heuristic method. However, this can be circumvented by coupling the two types of optimization approaches together as is done in [18,20,36-38,44,45], with the former doing the general search of the optimization solution space and the latter helping narrow the search to a particular Kuhn-Tucker point or boundary. This is not done here due to software integration issues which have yet to be addressed. Nonetheless, the GA in and of itself is a very powerful tool to handle strongly non-linear, non-continuous, mixed integer optimization problems and is, thus used here.

Finally, the initial population for the GA is set at four times the number of decision variables while the number of generations is set to a very high value (700). The GA is stopped when no improvements of the objective function for a number of generations is observed.

6. Case Study: Results and Discussion

This single-level optimization strategy (i.e. as opposed to a multi-level decomposition optimization strategy) was run on PIV 3.2 GHz. 1Gb RAM and required more than a month of continuous execution to arrive at an optimum solution[3]. More than 200 generations were required to get close to the optimum design configuration.

As mentioned above, the values for the fixed parameters in this case study are summarized in Table 1 while Table 2 lists the synthesis/design decision variables, their initial guesses, their optimum values, and their ranges. In addition, Tables 3 and 4 summarize the most important thermodynamic information about plant performance for the initial and optimum syntheses/designs, respectively. By comparing the optimum and initial syntheses/designs, it can be seen that the initial configuration has been dramatically modified by the optimizer, resulting in an improvement of the objective function of about 21% (see Figure 2). This is a very remarkable result, if one takes into account how small the region of feasible solutions investigated actually is.

[3] Note that the term "optimum" is used here in an engineering sense and not a strictly mathematical sense since as already indicated the GA is unable to indicate whether or not the final point found is indeed a Kuhn-Tucker point. Nonetheless, it is the "best" or "optimum" that is found after an exhaustive search of the solution space and tens of thousands of cycle calculations.

The optimization made some important adjustments to the heat exchanger and turbomachinery syntheses/designs. The latter, in particular, is due to the complex relationship, which exists, between the turbomachinery and the fuel cell stack. Initial maps of turbomachinery are dramatically scaled, since the optimum scaling factors are found to be close to the boundary of the optimal search region. In fact, a special adjustment is made to the fuel compressor map, since a non-optimal design of this component could result in remarkable inefficiencies due to the lamination of the fuel before entering the stack. Conversely, the optimizer does not significantly change the value initially assumed for the rotor speed. This result depends on the shape of turbomachinery maps, since their design point is set very close to the minimum rotor speed. For higher rotor speeds, the code produces unfeasible points or very low values of the isentropic efficiency.

Table 2 also shows that both optimum by-pass mass flow rates are very close to the initial values. This implies that the optimum configuration corresponds to by-pass valves (state points 23 and 31) almost completely closed. Obviously, during part-load operation the management of such by-pass valves will be very useful for controlling both stack and GT inlet temperatures.

SOFC geometric parameters are also remarkably changed. The initial synthesis/design corresponds to a very low value of the current density at the design point. This allows the stack to achieve a very high potential but results in higher capital costs, since a higher number of tubes with greater length and diameters are required. The optimization procedure dramatically reduces the cell active area by decreasing the number, diameter, and length of tubes.

The optimum demethanization rate in the pre-reformer is also very low. High values of the demethanization rates are not useful, since the cell can support almost the entire reforming process internally. Higher values of the area and volume used for pre-reforming imply higher costs, which can be avoided because the same process can be realized within the fuel cell stack.

Table 2 also shows the optimum value of geometric variables of compact heat exchangers. Since no useful data in the literature for initial guesses for these variables was available, a number of values were simply picked. As can be seen from the table, the values selected are very far from the optimum. Furthermore the optimum value of the first design variable listed in Table 2 is very close to 1, as would be expected. In fact, the nominal mass flow rate was set in order to have both pre-heaters "balanced".

Finally, the optimum value of the pre-reformer demethanization rate is greater than 57% while the optimal efficiency of the plant at the design point is 67.5%, with a plant investment cost of 1.36×10^6 US$. The same plant, at the initial design point achieves a slightly greater 67.9% net electrical efficiency. However, the capital cost is 2.5×10^6 US$, which means that the optimum plant represents a 46% improvement in cost.

Figures 3, 4, and 5, respectively, show component costs, exergy destruction rates, and energy flows determined for the initial synthesis/design. For this case, the capital cost is mainly due to the fuel cell stack, as expected. The costs of the turbomachinery are much higher than those for the heat exchangers, especially for the GT. The exergy destruction rate is primarily due to the combustor, the SOFC, the GT, and the HEWA. The inefficiency of the turbomachinery (GT and compressors) is mainly caused by a non-ideal coupling so that at the initial design point, the turbomachinery does not achieve its highest values of isentropic efficiency. Finally, a very significant irreversibility is due to the heat exchange within the gas to water heat exchangers, caused by very high temperature differences.

After optimization (see Figures 6, 7, and 8), the role of the stack is reduced, since there is a greater share of the power required and produced by the turbomachinery. As a consequence, the SOFC capital cost decreases and that of the turbomachinery increases. Furthermore, in reducing the active area of the cell, its inefficiency increases remarkably. This loss in efficiency is compensated by a lower investment cost, leading to a better value of the system level objective.

8. Conclusions

The optimization described in this paper shows that the design of a hybrid SOFC-GT power plant must focus an all its components, paying special attention to their coupling. The typical mistake of optimizing only the stack as an isolated device should be avoided, since inefficiencies in the turbomachinery and in the balance of plant can be significant. Furthermore, the perspective of a full commercialization of Solid Oxide Fuel Cells is expected to lower their capital costs so that this component will not necessarily be the most expensive in the plant. This increases the importance of investigating the

plant as a whole by analyzing its behaviour at both design and part-load operation.

As a further development of this work, a decomposition strategy (multi-level optimization approach) is also being applied to this same system. It is based on the ILGO/DILGO methods proposed by Munoz and von Spakovsky [38, 39], Rancruel [44], and Rancruel and von Spakovsky [45] and is being applied in order to compare results, accuracy, and computational times to those obtained with the single-level approach used here. Results for these optimizations will be discussed in future papers.

Modular simulation and Thermoeconomic Analysis of a Multi-Effect Distillation desalination plant

P. Fiorini[1], E. Sciubba
Mechanical and Aeronautical Engineering Department
University of Roma 1 "La Sapienza"

ABSTRACT
A model for the thermodynamic and thermoeconomic simulation of a MED desalination plant has been developed. As the code is embedded in a modular simulator, CAMEL©, it is relatively easy to use it for analyses of different plant configurations. CAMEL itself had been developed by the Mechanical and Aeronautical Engineering department of the University of Roma1, "La Sapienza". In the course of the present project, a model for the MED stage was included in the code library: this allows for a stage level description of the MED plant and for a more correct detailed identification of the plant losses and inefficiencies. The model can simulate all different MED configurations: here, only the parallel flow case was investigated. The thermodynamic model of each component is based on mass and energy balance criteria, and the results have been judiciously compared with literature data. Particular attention was devoted to the development of the thermoeconomic MED stage model: due to the presence of multiple products, the cost allocation is not trivial, and its degree of arbitrariness is even more dependent on the Designer's choices than it is usually in thermoeconomic analysis. A model for cost allocation across product and by-products has been proposed. The model allows individuating different strategies for plant design and optimisation. Applications of the model are exposed referring to a possible plant solution and design constrains.

1.INTRODUCTION

The interdependence between cost and efficiency has always been recognized qualitatively. It can be quantified by correctly correlating plant investment and primary resource consumption. Basing this correlation on exergy criteria, it is possible to determine the cost of the exergy unit of the final product. This methodology commonly recognized as “thermoeconomy" accounts both for the exergy destruction of the process, which is an index of the plant efficiency, and plant capital cost. The interest in formulating this interaction quantitatively with regard to seawater distillation applications dates back to the sixties [1,2,3,4]. In the last twenty years the usefulness of this concept was acknowledged by a large number of scholars and the development is still continuing today. Thermoeconomy is able to pinpoint and quantify energy inefficiencies, the possibility of systematically generating insight towards improvement, and the ease of its application in automated optimal searches.

Such an analysis is ideally suited for the concept of a modular code: on this basis, CAMEL has been provided of proper subroutines for the thermoeconomic analysis of thermal processes. A thermoeconomic model of each component has been constructed in addition to the thermodynamic one, and the flow exergy cost has been introduced as a flow parameters.

Even if exergo-economic analysis has been originally proposed to analyze desalination plant, mainly in their combination to power plant (cogenerative configuration), it is not uniformly applied at industrial level for plant optimization, and current cost analysis procedures are based on conventional technical analyses, which do not account for the energy quality. Exergy criteria overtake this problem.

In this paper, a thermoeconomic analysis of the MED desalination process is proposed and applied to a cogenerating power plant in which the topping part is a combined cycle and the bottoming a MED desalination plant.

A sensitivity calculation was performed to assess the dependence of the desalted water cost on both the temperature and the exergy content of the feed stream of a MED desalination plant.

2. THERMO-ECONOMIC MODEL DESCRIPTION

The component library of CAMEL™ includes the elements required for the simulation of a MED desalination plant (MED stage, Pump, Heat Exchanger). The thermodynamic model is reported in the Appendix.

In this section we discuss the thermoeconomic model proposed for the MED stage. It is characterized by four inlet flows (the feed brine, the feed steam, the recycled brine and the recycle coming from the upstream stage) and 3 outlet flows (the steam produced, the recycle brine, the condensate) (fig. 1). To formulate a correct thermoeconomic model of such complex unit, it is necessary to break down the process in elementary sub-processes, which can be directly referred to elementary models [5]. With reference to fig. 1, the component has been divided into three sub-units: 1) an evaporator, 2) a flashing chamber fed by the recycle brine, 3) a flashing chamber fed by the condensate. The common objective of all the three sections is to produce steam. The stage costs can be split across component sub-units: Z1, Z2, Z3 are respectively the costs of sub-unit1 1, sub-unit 2, sub-unit 3.

Considering sub-unit 1 in isolation, the feed steam (a) is assumed as a fuel, the steam produced (c) as product, and the outlet brine (e) as by-product. The cost balance equation of this section is:

$$m_a * e_a * c_a + m_d * e_d * c_d + Z_1 = m_c * e_c * c_c + m_e * e_e * c_e + m_b * e_b * c_b \quad (1)$$

Two auxiliary equations are needed to close the system and they can be derived as follow:

1) since stream “a” is a “fuel” [5], the exergy costs of flows (a) and (b) can be assumed the same:

$$c_a = c_b \quad (2)$$

2) cost of stream (e) depends on the exergy addition it receives during the process. The increase of the exergy
cost of flow (e) must be the same of flow (c).
So that the second is:

$$\frac{(e_e * c_e - e_d * c_d)}{(e_e - e_d)} = \frac{(e_c * c_c - e_d * c_d)}{(e_c - e_d)} \qquad (3)$$

This model attributes the whole cost of sub-unit 1 to the steam produced (c).
Considering sub-unit 2, we see that it behaves as a flashing chamber [6]. There are two feed streams: the recycle brine coming from the upstream stage (f), and brine flowing downstream the evaporator section (e). There is only one product, the flashing steam (h) that has to account for the cost of section 2.
The overall cost balance of this section is:

$$m_f * e_f * c_f + m_e * e_e * c_e + Z_2 = m_h * e_h * c_h + m_g * e_g * c_g \qquad (4)$$

To determine the cost of flow (g), current thermoeconomic criteria suggest to apply the following auxiliary equation:

$$\frac{m_f * c_f * e_f + m_e * c_e * e_c}{m_e * e_c + m_f * e_f} = c_g \qquad (5)$$

In a common flashing chamber, where only one feed flow is present, the exhaust brine cost is assumed to be the same of the inlet one. When several feed streams are present, in our case (e, f), it is reasonable to assume the cost of the outlet brine, flow (g), as the weighted average of exergy cost of flow (e) and (f) (equation 5).
The thermodynamic process of sub-unit 2 characterizes also sub-unit 3 as well as the thermoeconomic model:

$$m_j * e_j * c_j + m_b * e_b * c_b + Z_3 = m_l * e_l * c_l + m_m * e_m * c_m \qquad (6)$$

$$\frac{m_j * c_j * e_j + m_b * c_b * e_b}{m_j * e_j + m_b * e_b} = c_m \qquad (7)$$

The three steam flows produced in each sub-unit are mixed in one (S_o): it is the final product of the MED stage:

$$m_{So} * e_{So} * c_{So} = m_c * e_c * c_c + m_m * e_m * c_m + m_h * e_h * c_h \qquad (8)$$

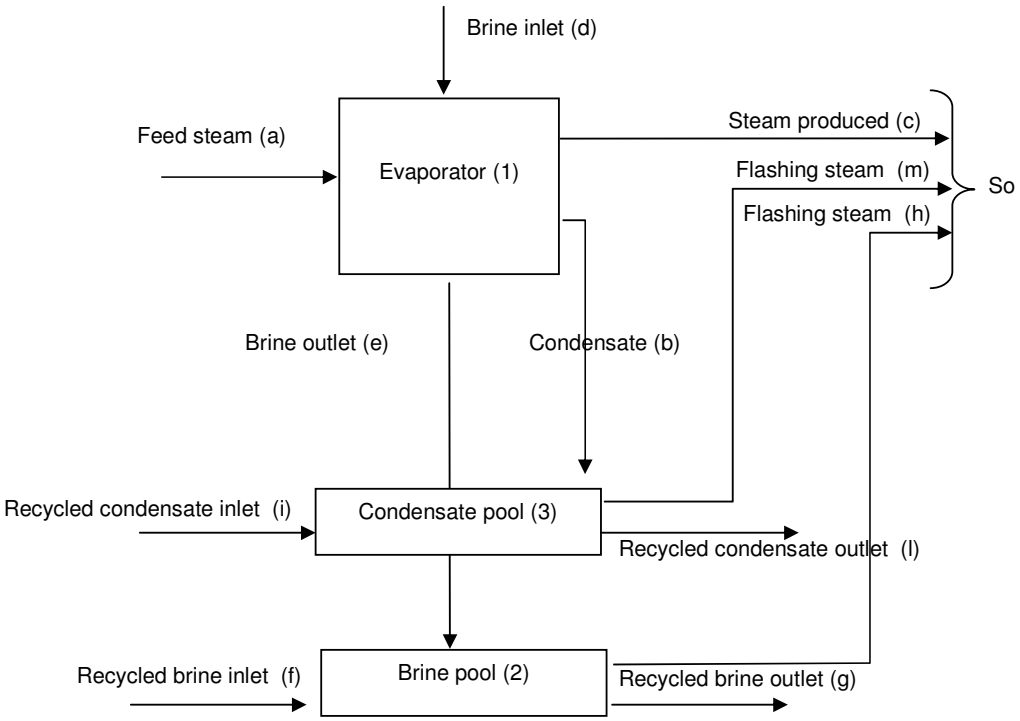

Fig. 1: MED stage scheme

The model proposed divides the MED stage in "thermoeconomic elementary units". It individuates as the main product the steam produced by the MED stage. The cost of the steam produced accounts for the cost of the exergy destroyed in the whole stage and its capital cost.

3. DESCRIPTION OF THE PROCESS CONFIGURATION TO WHICH THE MODEL WAS APPLIED

The plant chosen as benchmark of the thermoeconomic model described in section 2 consists of (fig. 2):

- A combined power plant: the bottoming section is a backpressure steam turbine. The steam extracted from plant feeds a MED desalination plant [7].
  - GT plant operates at 15 bars and 1300°C as TIT (Turbine Inlet Temperature)
  - Compressor and turbine efficiencies have been assumed respectively 85% and 88%
  - The steam power plant is characterized by a top pressure of 170 bars and throttle steam temperature of 550°C.
- A MED desalination plant: it is composed of two units. Each of them produces 15,000 m^3/day

Each unit produces 15,500 m^3/day. The plant efficiency is 9 (GOR). Table 1 displays the plant main parameters.

Tab. 1

MED Plant Parameters	
Number of Stages	14
Feed Steam Temperature (K)	348
Feed Steam Mass flow rate (kg/s)	18
Production (kg/s)	166.3247
Feed Brine (kg/s)	332.64933
Total heat exchanger (m^2)	59346
Cost (k$)	19857.7
Capital cost per m^3 of distillate ($/($m^3$d))	1.52

A thermoeconomic analysis is likely to derive a relatively low exergy cost for the steam extracted from the backpressure turbine. We would expect the distillate cost be affected more by the capital- than by the operative cost. If a different process, for example a boiler, determines a higher cost of the feed steam, we would also expect the distillate cost be more influenced by the operative than by the capital cost. These "feelings", conventionally

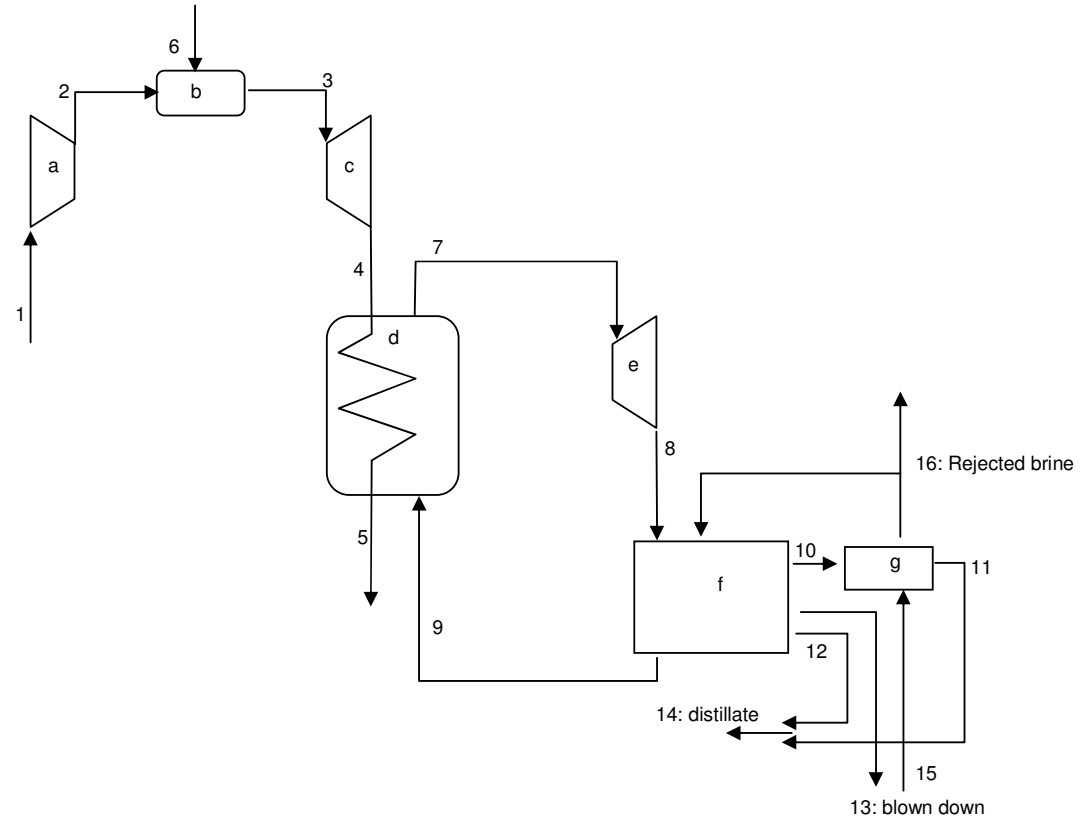

Figure 2: Scheme of the combined cogenerative power plant with MED bottoming

called "qualitative knowledge", can be now validated by a detailed thermoeconomic analysis of the process described in figure 2: it is clear from the above that the best way to proceed is to perform a sensitivity analysis to the unit cost of the steam exergy. In order to perform a thermoeconomic analysis, cost data of the plant component are required.

4.THE ANALYSIS PROCEDURE

The analysis has been divided in three separated-tasks:

1) Calculation the cost of the steam feeding the MED plant: the component cost of the topping plant have been determined using the cost function developed by El-Sayed [8]. In order to calculate the distillate cost under different operative conditions, the steam cost has been identified according to different temperature (and pressure) of the exhaust steam outgoing from the steam turbine (368 K & 348 K).

Tab 2: capital cost of MED plant configuration

Number of effects	**7**	**9**	**11**	**14**
Total production (kg/s)	**-**	**-**	**-**	166.00
Stage heat exchange surface (m^2)	8478	6594	5395	4239
Total heat exchange surface (m^2)	59346	59346	59346	59346
Brine heater heat exchange surface (m^2)	6123	6123	6123	6123
Capital cost per production capacity (k$/m3)	**-**	**-**	**-**	**1.52**
Total cost (k$)	14495.66	16492.02	18086.07	19857.78
MED stage cost (k$)	1805.49	1626.09	1475.35	1285.76
Brine heater cost (k$)	1857.20	1857.20	1857.20	1857.20

All configurations have the same total heat exchange area. As the plant cost depends on both total heat exchanger area and number of stages,

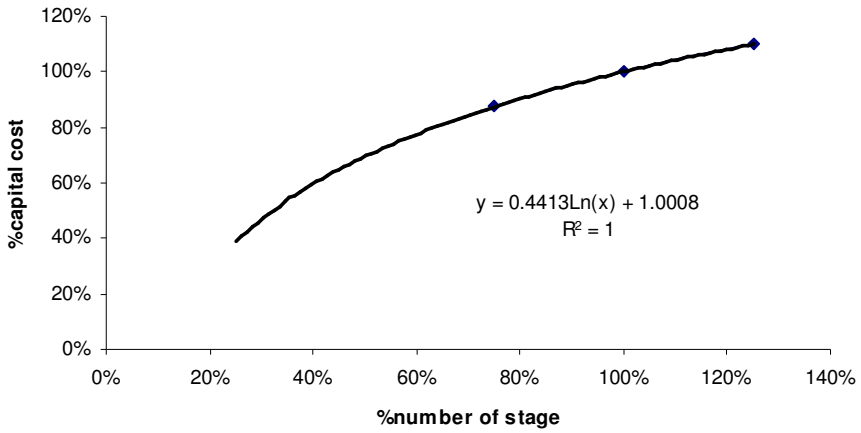

Fig. 3: Capital cost variation (%) vs. Number of stage variation (%)
Plant has supposed to have the same total heat exchange area.

2) Thermoeconomic analysis of MED desalination plant by comparing product cost vs. plant production.
3) Thermoeconomic comparison of several MED plant configurations. Each of them is characterized by a different number of stages (7, 9, 11, 14 stages, see tab. 2).

the configurations have different capital cost. Adopting an appropriate correction of the cost functions developed by El Sayed [8,10] for MSF stages, the impact of number of stage on total plant cost has been evaluated (fig. 3 and tab.3.3)
Since the number of stages affects the plant production range (the higher the number of stages, the lower the production range), the comparison has been performed considering the production rate vs. product cost.

The thermoeconomic analysis includes two sensitivity studies: the first by varying the feed steam temperature, the second by varying the feed steam mass flow rate.

5. Results

A first result has been obtained referring to the seven stages configuration and to 348 K as steam temperature. Fig 4 and 5 show the results. The procedure proposed for the MED stage thermoeconomic analysis, allows determining both the cost of product and by products. Since by-product exergy content is associated to exergy losses related to the process, by-product costs can be assumed as cost of process inefficiency. By increasing the feed steam mass flow rate, the specific exergy request of the plant increases (energy per m^3 of distillate produced). The process is less efficient and the amount of wasted exergy (and economical resources) rises up.

The main part of process cost is charged to the distillate production (fig 3). Minor costs are associated to other by-products: the main source of exergy losses is related to blow down brine flow.

Comparing MED plant configurations the whole cost of water production has to be accounted ($/$m^3$). Fig. 6 compares the water cost of different plant configurations vs. production rate. Due to thermodynamic reasons [9], different plant configurations have different production rates. High number of stages determines a high plant capital cost and high production efficiency. The configuration characterized by 14 stages has both higher capital cost and higher efficiency. Due to the high efficiency, plant-operating cost is low: if high production rates are required, the saving in operating cost balance the high investment (fig. 5).

Figure 6 shows a comparison of distillate costs according to plant configurations and distillate production rates, when the feed steam is available at 348K. Configurations characterized by a higher number of stages are convenient for higher production rates.

If the feed steam is available at higher temperature, the plant operative cost increase and the less capital intensive configuration is not the

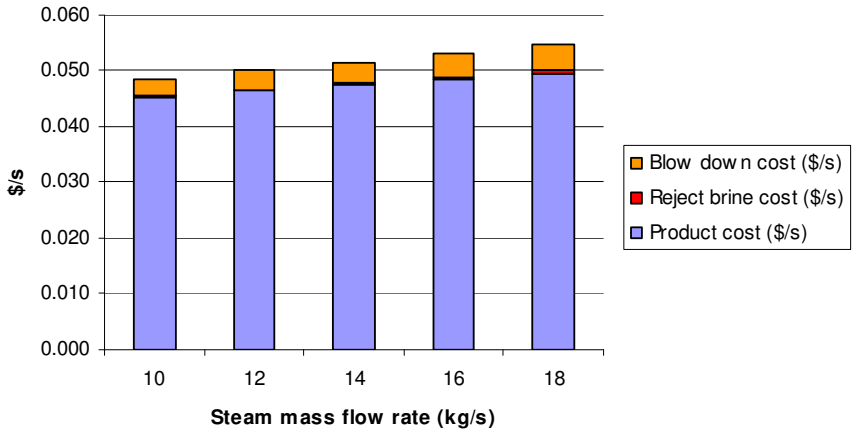

Fig. 4

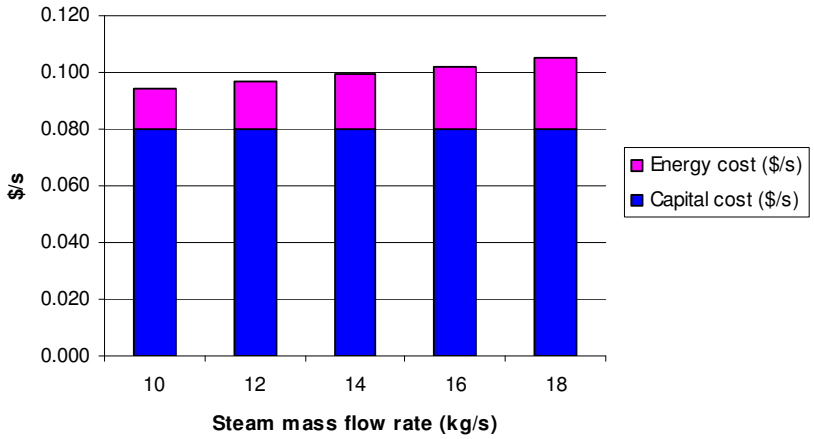

Fig. 5: inputs cost rate

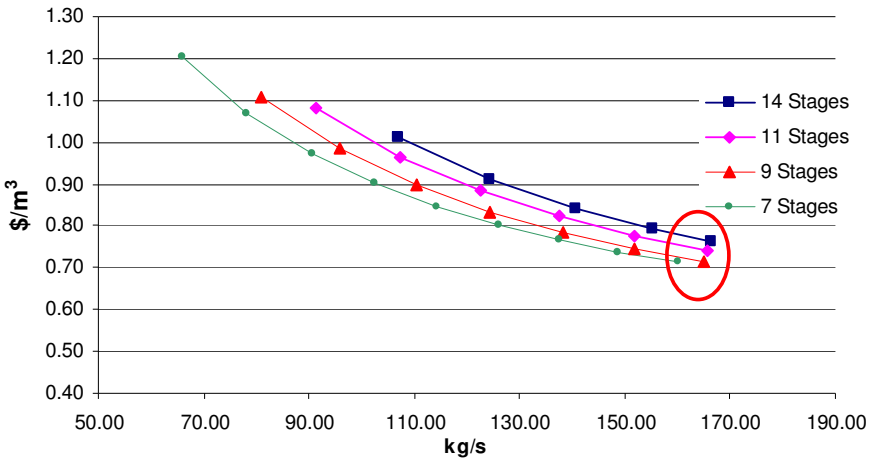

Fig. 6: Distillate cost vs. plant production for the four configurations analysed here. Feed steam temperature = 348 K

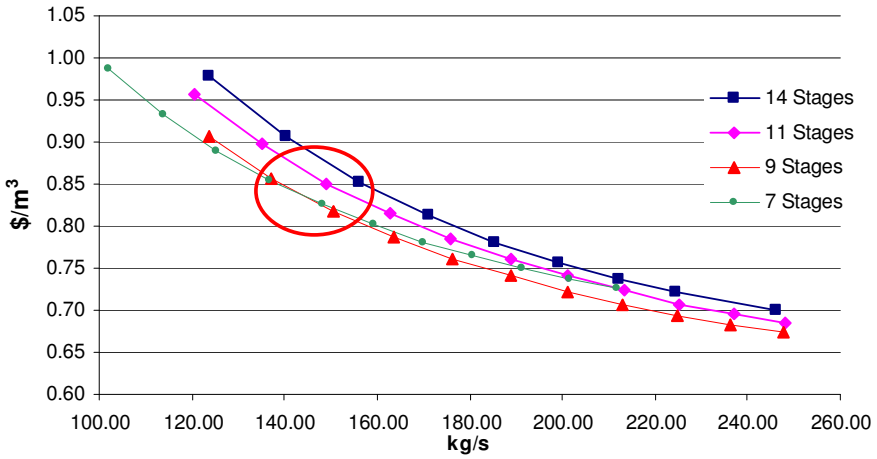

Fig. 7: Distillate cost vs. plant production Feed steam temperature = 368 K

most convenient (fig. 7). In this situation it is also possible to notice that configurations characterized by a low capital cost are convenient up to a well defined value of the production rate. Using thermoeconomic criteria, it is thus possible to optimise the plant configuration according to the plant operative conditions obtaining the lowest possible cost for the distillate. The correct number of stage that satisfies the production request and better suits the topping plant can be identified.

6. CONCLUSION

The thermoeconomic model proposed for the analysis of MED desalination processes allows both comparing and analysing different plant configurations.

Assuming a 14 stages configuration as the base case, a thermoeconomic analysis was performed considering a certain feed steam temperature (348 K). Several plant configurations, characterized by the same overall heat exchange area of the base case, but by a different number of stages, have been also investigated and compared. The feed steam is generated in a combined cycle power plant, and its cost has been assumed to be known from a previous thermoeconomic analysis. Distillate cost has been identified according to the cost of the feed steam, plant capital cost, and the plant production rate. Configurations characterized by high productions and low efficiencies values are preferable if feed steam is available at a relative low cost. If steam is available at higher cost, configurations characterized by higher capital cost (#stages) and higher efficiency values are more valuable.

According to feed steam cost, the analyses show as there are specific ranges of both distillate production where a certain configuration

(identified by a certain number of stages) is economically more convenient than another.

Appendix

In developing the MED thermodynamic model, we accounted that the first stage of the plant differs from others. In fig. 7, is represented a scheme for he first stage.

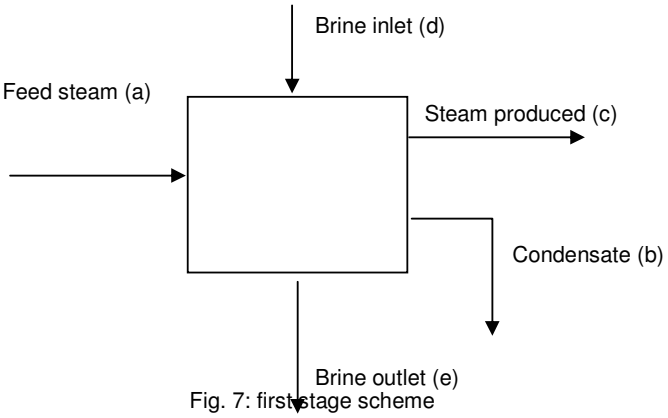

Fig. 7: first stage scheme

It is essentially a heat exchanger in which the feed steam condenses and the inlet brine is heated to the saturation temperature and evaporates. Applying the mass and energy balance equations:

$$m_a = m_b \quad (2.26)$$

$$m_d * s_d = m_e * s_e \quad (2.27)$$

$$m_d = m_e + m_c \quad (2.28)$$

$$m_a * h_a - m_b * h_b = m_e * h_e + m_c * h_c - m_d * h_d \quad (2.29)$$

The brine outlet and the steam produced have the same pressure:

$$p_c = p_e \quad (2.30)$$

The relation between the saturation pressure and temperature calculates the steam pressure:

$$p_c = PSL(T_c) \quad (2.31)$$

Brine and steam temperatures differ for the irreversibility associated with the process (NEA) [8] and the boiling point elevation (BPE) due to the brine salt concentration:

$$T_e = T_d + BPE + NEA \quad (2.32)$$

The heat exchange process takes into account the hardware characteristics, like the heat exchange area and the material properties, and the operative conditions, as required to determine the heat transfer coefficient and the temperature difference between the cold and hot side:

$$Q = U * A * LMTD \quad (2.33)$$

$$LMTD = \frac{(T_b - T_d) - (T_a - T_e)}{\ln(\frac{(T_b - T_d)}{(T_a - T_e)})} \quad (2.34)$$

The overall heat exchange coefficient depends on both the heat exchange coefficients on the steam and brine sides:

$$\frac{1}{U} = \frac{1}{U_{br}} + \frac{1}{U_{st}} + \frac{1}{U_{fouling}} + \frac{k_l}{s} \quad (2.35)$$

where the heat exchange coefficient on the brine and steam side are determined by appropriate functions. $U_{fouoling}$ is assigned as an hardware characteristics.

The model imposes the complete condensation of the inlet steam:

$$q_b = 0 \quad (2.36)$$

This assumption assumes that the component is behaving correctly. If it is not respected, energy losses are associated with the uncondensed steam. As direct consequence of this assumption;

$$T_b = TSL(p_b) \quad (2.37)$$

$$p_b = p_a - PL \quad (2.38)$$

where TSL is the steam saturation temperature as function of the pressure.

Also an option has been introduced to calculate the inlet brine mass flow rate. The heat absorbed by the inlet brine is split between the sensible heat, required to heat the brine up to the saturation temperature, and the latent heat absorbed for the steam production. The higher the stage performance, the higher the steam production, thus the inlet brine rate has to be the lowest thermodynamically allowed. The ideal optimum is obtained if all the brine evaporates. This is not possible due to scaling problems. In deep, the salt concentration cannot be higher than the maximum concentration allowed by the brine temperature inside the stage. As an option of the user, the model can automatically determine the optimal inlet brine mass flow rate by imposing the relation:

$$s_e = s_{\max} \quad (2.39)$$

s_{max} is an input defined by the user according with the stage temperature.
The model proposed for the other MED stage, is similar to that one described above, but more complex and it involves additional phenomena in order to allow the user to simulate the cross flow configuration. Figure 8 shows the scheme for the whole MED stage.

The steam produced and the outlet recycle brine have the same stage pressure imposed by the process in section 1:

$$p_b = p_l = p_m \quad (2.42)$$

Temperature are determined by the following relation:

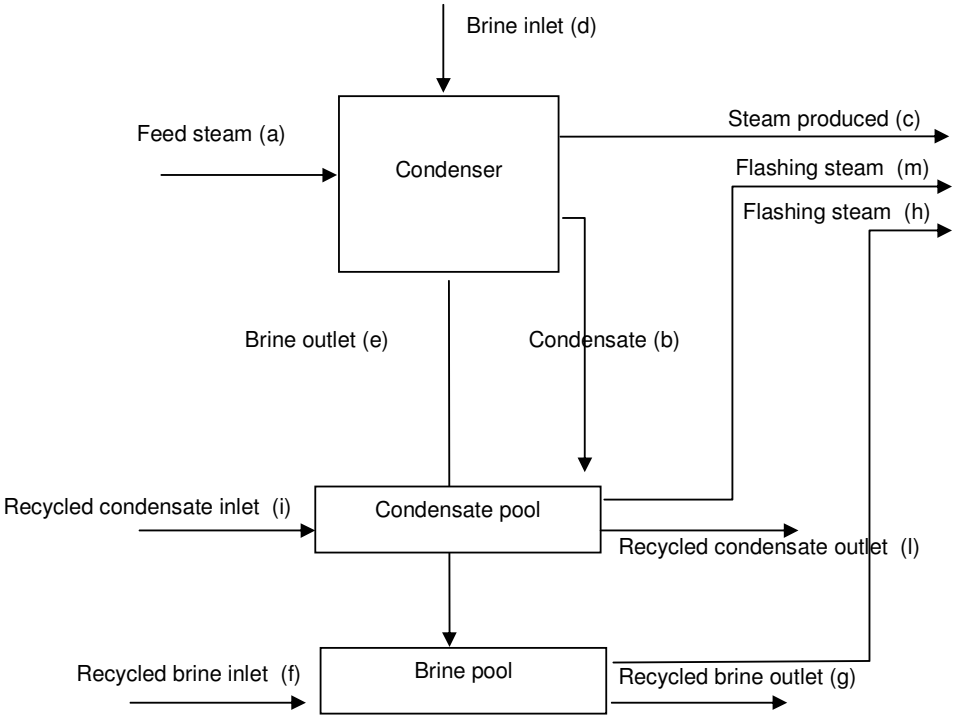

Fig. 2.9: MED stage scheme

The component is supposed to be divided in 3 main section: 1) the condenser, it heat the brine inlet producing the main fraction of the steam produced in the whole stage; 2) and 3) respectively the condensate and the brine pool, they produce additional steam by flashing the condensate and the hot brine coming from the previous stage.
Equations 26-39 describe "the condenser section". Additional equations have to be added in order to simulate the brine and condensate sections. Applying the mass and energy balances to section 2):

$$m_i + m_b = m_l + m_m \quad (2.40)$$

$$m_i * h_i + m_b * h_b = m_l * h_l + m_m * h_m \quad (2.41)$$

$$T_c = T_l = T_m + NEA \quad (43)$$

The temperature of flow *l* lowly differs from temperature of flow b. The gap is due to the different value of NEA associated to the different thermodynamic process of section 1 and 2.
In the whole stage, the main constrain is the pressure of the steam: it is imposed by section 1 and it has to be the same for both the steams produced in section 2 and 3. Section 3 is described almost by the same set of equation of section 2.
Applying mass and energy balances:

$$m_f + m_e = m_g + m_h \quad (2.44)$$

$$m_f * s_f + m_e * s_e = m_g * s_g \quad (2.45)$$

$$m_f * h_f + m_e * h_e = m_h * h_h + m_g * h_g \quad (2.46)$$

From the thermodynamic of the process, it is possible to determine pressure and temperature value.

$$p_g = p_e = p_h \quad (2.47)$$

$$T_g = T_h + BPE + NEA \quad (2.48)$$

The model proposed is able to describe all the processes that may take place inside the MED stage. Depending on the stage pressure and the brine temperature, stream "d" can firstly flash and then evaporate: equation 29 takes into account for this phenomenon.

The model completely fit the idea of a modular code: simulating all the possible plant configurations, included the MVC (MED with a vapor compressor), is possible by opportunely connecting the component flows. If a flow is not present (considering the parallel flow configuration where the recycle brine is not sent to the next stage), it is sufficient to consider the inlet recycle mass flow rate equal to zero and the flow is automatically excluded from the stage energy and mass balances.
Even this model, as the user requires, is able to calculate the inlet brine mass flow rate, imposing a value for the maximum salt concentration.

$$s_g = s_{\max}$$

ABSTRACT

The paper presents the results of a theoretical and experimental study of a new hybrid propulsion system for a passenger sedan in which the thermal engine is a small turbogas. Some preliminary results on the possibility of employing a turbogas directly in lieu of the reciprocating engine were presented and discussed in a series of papers published in the last 3 years by the same Research Group. This study presents a summary of the results of the project and constitutes an attempt to put things in a proper engineering perspective: the technical feasibility of the project is assessed via a calculation of the required mission loads, a preliminary design of the most important elements of the propulsive system and the choice of the mission control strategy. The results allow for a direct comparison between a GT-hybrid vehicle and a modern diesel car, and indicate that the GT-hybrid may actually be a successful competitor also for the FC-powered vehicle concept. Our "optimal" configuration is a combination of a 100 kg bipolar Pb-acid battery pack and two 15 kW micro turbines for urban missions and highway drives. Using commercially available data for the components, the preliminary design of a road prototype is described and briefly discussed. For practical reasons the first prototype is likely to be equipped with a sub-optimal propulsion system: the differences and their implications are discussed as well.

1. Principles of operation of a Turbogas-powered HV with an all-electric traction

A series-hybrid configuration, in which a turbogas is coupled to a high speed electrical generator, represents an interesting proposal under many points of view [1,3]. A high rotational speed turbogas coupled with a battery package is a feasible hybrid vehicle configuration: the vehicle can work in only electric mode, if requested, especially during urban missions. In our hybrid vehicle scheme the electronic VMU, vehicle management unit, controls ignition and switching off operations under a Load Following logic. The VMU determines how much energy produced by the turbogas reaches the batteries package or the electric engine directly. During the hybrid mode, the batteries provide the difference between electric engine power need and power produced by the turbogas: the current flow to- and from the batteries is controlled and maintained within a fixed range. In addition, the electric motors can also act as brakes, recovering much of the energy that is otherwise lost in braking.

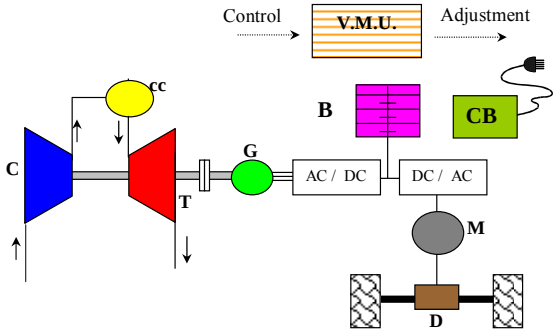

Figure 1: A scheme of the GT-hybrid propulsion system

Purpose of this study is to demonstrate the technical feasibility of the configuration in spite of some practical problems (which will briefly discussed in section 3 and 4), to identify and quantify the power requirements, to define the correct procedure for the selection of the appropriate turbogas set and to choose the most convenient energy flow control mode. In the HV scheme proposed here, a Vehicle Management Unit VMU controls the GT operating point in a *Load Following* mode: this mode has emerged as the most convenient from a series of simulations performed on a number of different configurations. The fact is, for passengers vehicles, subject to highly variable load requirements, the *On-Off* and the *Fixed Power* GT functioning modes are unsuitable (see section 2). The VMU, on the basis of a certain number of instantaneous mission parameters, determines what portion of the electrical energy generated by the GT-driven alternator ought to go -respectively- to the batteries or to the electric motor coupled with the wheels: the batteries may thus provide or absorb the difference between the energy requirements of the vehicle and the GT energy production. The generator acts as a starter for the GT as well. A continuous GT regulation is obtained via fuel flow control coupled with a variable geometry GT. Since GT power modulation is affected by a substantial efficiency penalty, the fuel flow control is coupled with a variable-stator turbine and IGV blades for the compressor: this solution is a very important aid to an effective energy flow control and regulation

strategy [9].
In the course of this study, two basic missions were analyzed: the first consisting of 10 consecutive urban cycles ECE15* (figure 2.a) and the second a "complex driving mission" (figure 2.b) composed of 4 consecutive extra-urban cycles EUDC* and 72 minutes of continuous highway drive at 120 km/hr.

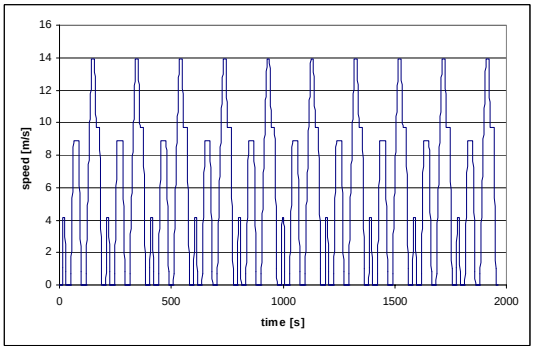

Figure 2.a: The basic mission composed of 10 consecutive ECE15 cycles.

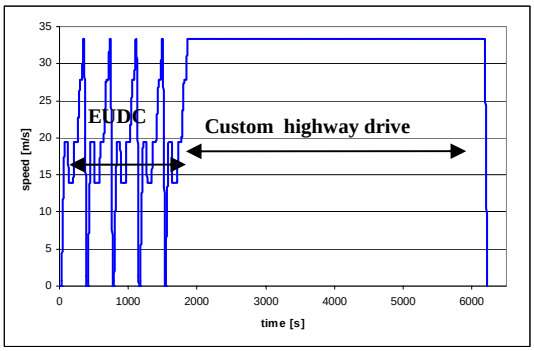

Figure 2.b: "Complex driving mission" composed of 4 consecutive extra-urban cycles EUDC and 72 minutes of continuous highway drive at 120 km/hr.

The vehicle design specifications are the same as those imposed in our previous papers [2, 4] and are reported in Table 1.

Table 1: GTHV Design Specifications

Wheel rolling radius	R = 0.265 m
Vehicle width	b = 1.7 m
Vehicle height	H = 1.4 m
Net front area	$S_f = 2.142\ m^2$
Area ratio (S_f/S_{tot})	$\alpha = 0.9$
Aerodynamic drag	$c_x = 0.25$
Tire rolling friction coefficient	$f_r = 0.015$
Vehicle mass	m = 1550 kg
Equivalent mass	$m_e = 1600$ kg
Air density	$\rho = 1.18\ kg/m^3$
Air intake temperature	T = 300 K
Minimum SOC	0.6
Maximum SOC	0.9

2. The power management protocol

There are three possible "logics" for the power management of a hybrid vehicle in a series configuration:

- I.c.e operating in a fixed mode: the GT runs constantly at its design conditions;
- I.c.e operating in a On-Off mode: the GT is alternatively run at idle ("Off ") and at its design conditions (" On ");
- I.c.e operating in a Load Following mode: the GT output is modulated conditionally between 70% and 110% of its design conditions;

In our final model, described here, we chose to adopt the load following operation mode [2]. Such a choice brings two significant advantages with respect to a simple on/off GT-management:

a) it maintains the GT within a sufficiently flat portion of the efficiency/load diagram (0.7-0.95, figure 3)
b) it allows for a "gentler" modulation of the charging and discharging of the battery, decreasing the steepness of the current/time charging curve and increasing battery life.

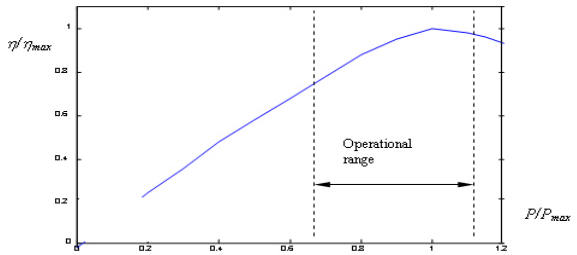

Figure 3: Efficiency/load diagram

* The EEC Directive 90/C81/01 consist of a series of Regulations that prescribes both the emissions limits (adjusted every year) and the methods for testing and certificating both passenger and commercial vehicles.

The logic of this "load following" GT management can be described as follows: The energy flows (GT-to-battery; brake-to-battery; battery-to-motor; GT-to-motor) must be exactly balanced at each instant in time;

1) The battery SOC is allowed to vary only between 0.6 (below which the GT is turned on to recharge the battery, whatever the vehicle power demand is) and 0.9 (above which the GT is turned off, whatever the vehicle power demand is).
2) In the SOC range from 0.6 and 0.9, the GT tries to provide the battery with the exact amount of instantaneous power extracted from the battery by the motor.

The logical decision matrix is shown in Table 2:

Table 2: Truth table for the GT "load following" mode

Soc, %	$(P_v - P_{bt})/P_{GTnom}$	GT load factor, % (= P_{GT}/P_{GTnom})
< 0.6	∀	100
> 0.9	∀	0
0.6 ≤ SOC ≤ 0.9	< 0 $0 \le (P_v - P_{bt})/P_{GTnom} \le 0.7$ $0.7 \le (P_v - P_{bt})/P_{GTnom} \le 1.1$ $(P_v - P_{bt})/P_{GTN} > 1.1$	0 0.7 $(P_v - P_{bt})/P_{GTnom}$ 1.1

3. Model, simulation protocol and results

The simulation program is based on an input-output model for the energy fluxes through the system, and it was implemented as an aid for configuration design. As mentioned above, the GT set is switched on when the SOC is lower than a prefixed level (0,6), and it is set to idling or to a partial load mode when the SOC reaches the maximum allowable level (0,9). Naturally, in real operation, a manual override must also be provided, but this was not considered in our calculations. In hybrid-mode operation, the batteries supply or absorb the difference between the net power demanded by the vehicle and the net power supplied by the GT. The simulation quantitatively enforced such a protocol, calculating the instantaneous power demand as a function of the assigned speed and acceleration values [2, 4]. As stated above, we have analyzed two different mission profiles: a first one consisting of 10 consecutive ECE15 cycles, and a second one composed by 4 consecutive EUDC cycles and 72 minutes of highway at a constant velocity of 120 km/h. The GT load management protocol is based on the realisation that a GT set can operate, without substantial efficiency derangements, between 70% and 110% of its nominal power. The need to compare the GT-HV with a commercial diesel sedan led us to verify several combinations of GT and batteries, to find the "optimal one": our final choice is a configuration with two 15 kW GT sets (compression ratio, inlet air conditions, TIT and rotational speed equal to those of the Elliott TA-45), and one 15 kW_e battery package .The overall constraint throughout the entire operational field (mission profile) was that of maintaining the GT Load Following operation mode while limiting the SOC variation between 0.6 and 0.9 for Pb-acid batteries (between 0,3 and 0,9 for a 41 kg Ni-Cd batteries package, considered a feasible alternate configuration). The choice of a GT-hybrid propulsion system is a heuristic balance between the relative advantages and drawbacks of the following parameters:

- A small number of moving parts;
- Compact size with the potential to be mounted within strict space limitations in the engine compartment of a sedan
- Light-weight of the micro turbines and electric engine
- Lower energy costs
- Lower emissions with multi-fuel capability
- Improved overall vehicle design due to weight and size savings
- High reliability
- Total gross weight of the battery package
- SOC trend during the mission
- Number of GT ignitions during the mission
- Instantaneous verification of the total demand power of the vehicle.

In Table 3 we report some of the considered combinations:

Table 3: GTHV configuration definition

Type	**A**		**B**	
Simulated mission profile	ECE 15	n.a.	ECE 15	EUDC + custom mission
P_{GT}	**P_{GT1}**	**P_{GT2}**	**P_{GT1}**	**P_{GT2}**
	5	0	10	25
P_{batt}	15		15	
Type	**C**		**D**	
Simulated mission profile	ECE 15	EUDC+ custom mission	ECE 15	EUDC+ custom mission
P_{GT}	**P_{GT1}**	**P_{GT2}**	**P_{GT1}**	**P_{GT2}**
	10	25	15	15
P_{batt}	25		15	

Design alternatives have to always abide the correct ratio of GT and batteries installed power, with respect to the vehicle type and missions profiles.
It turns out, that this constraint is a significant one, and limits in practice the number and type of possible configurations.
The turbogas could work at high efficiency conditions only for a low degree of hybridization (low P_{GT} , "always on" operation), but this implies a heavy battery package and leads to obvious disadvantages.
The choice of operating in a Load Following mode is in fact dictated by the need of striking a balance between a low installed battery power and a low specific fuel consumption (high average η_{GT}). We found that a small GT, operating between 70 and 110 % of its rated power, does not display a severe efficiency penalty.
Another problem is given by the fact that our simulations have shown that a 15 kW battery package and a 5 kW turbogas are suitable for urban missions, but not for high speed extra-urban missions, because the total installed power does not cover the higher vehicle power demand.
To make both urban and extra urban missions possible, the 15 kW batteries package had to be coupled with two turbogas set of 10 and 25 kW respectively: but in this case the load on the batteries (steepness of the SOC curve) increases, and the 25 kW GT is subject to an excessive number of ignitions.
Increasing batteries power up to 25 kW smooths the SOC curve and reduces the number of the ignitions, but does so at the cost of a substantial weight penalty.
The adoption of two 15 kW turbogas sets and a 15 kW battery package make both urban and extra-urban missions possible and does not seem to excessively tax either the battery and the GT life. Notice that, if Ni-Cd batteries could be used instead of the Pb-acid considered here, the same P_{GT} could be installed with a weight of the battery package of only 41 Kg.
.

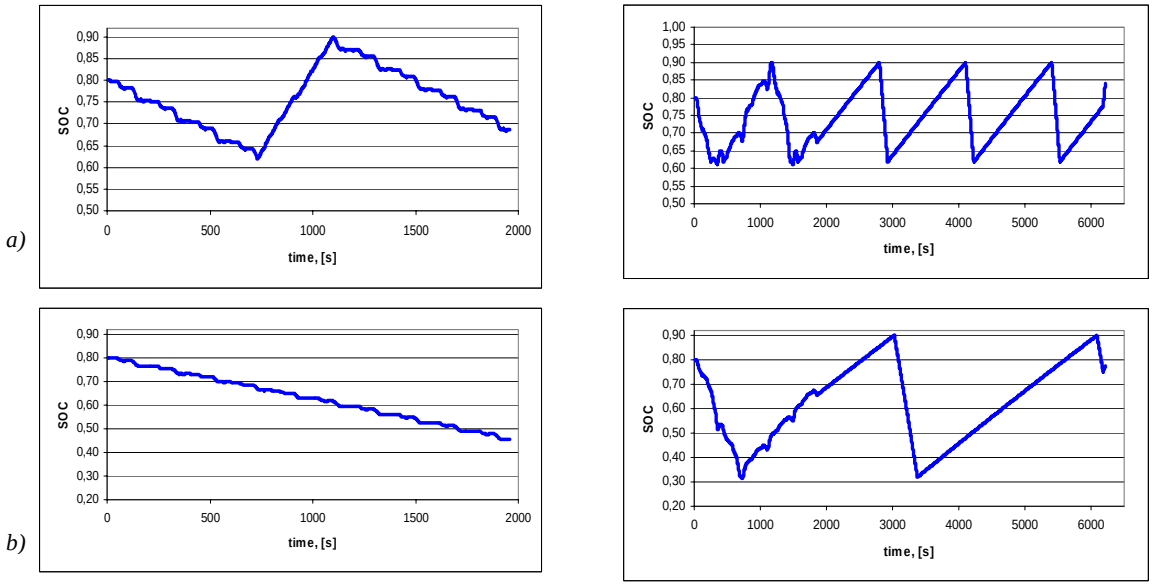

Figure 4: SOC profiles for configuration "D": a) ECE15 and "complex mission" SOC respectively with 100 kg Pb-acid battery pack b). ECE15 and "complex mission" SOC respectively with 41 kg Ni-Cd battery pack.

Table 4: Results of configuration "D"

10ECE15	GT1 "On" [s]	GT2 "On" [s]	Fuel cons.[g/km]	Km/l
Pb-acid	369	15	54	16,2
Ni-Cd	0	0	0	n.a.

Complex mission	GT1 "On" [s]	GT2 "On" [s]	Fuel cons.[g/km]	Km/l
Pb-acid	5158	4312	76,2	11,54
Ni-Cd	5045	4188	74,3	11,83

We considered the possibility of using Ni-Cd batteries because, in addition to their higher power-to-weight ratio, the operating characteristics are better suitable, for our purpose, than the usual Pb-acid batteries. Considering for example a purely urban mission, we see (figure 4.b) that the car can be propelled uniquely in an electric mode. In an extra-urban mission, the "turbine on time" is always lower with these batteries (they have a higher power density) and this implies of course less GT modulation and a lower fuel consumption. Thus, these is a double advantage in installing a Ni-Cd battery pack: first, the better specific energy density and lower weight (48% reduction w.r.t. Pb-acid) bear a direct influence on the design of the system, and lead to significant reduction of the vehicle overall dimensions and gross weight; furthermore, the improved electric characteristics (wider SOC range rechargebility from 0,3 to 0,9 and higher overload resistance) allow for the adoption of a more convenient system configuration and of a more flexible control logic. Unfortunately this kind of battery will be withdrawn from commercialisation in 2006, due to Cd related pollution problems. For future prototypes, we are thus considering the possibility of using Li-ion or Li-Mh batteries.

To obtain an experimental validation of our simulation, and to collect additional operational data, an experimental campaign was performed on an Elliott TA-45 turbine. The tests were conducted at the ENEA Casaccia Research Center: the Elliot is a 45 kW GT operating at partial load conditions (10 kW), with a rotational speed of 116.000 rpm and a cycle pressure ratio of 4.3. It appears that the system overall efficiency is quite low (≈16÷17 %): this confirms the need for an optimization of the GT operating point and control strategy.

4. Thermo-fluidodynamic optimization of the turbogas set

A simplified thermo-fluid dynamic study of the turbogas confirmed the possibility of using a one stage compressor, but indicated that a good overall efficiency requires substituting the single radial turbine stage with three-stage axial machine.

Table 5 Design Specifications for the15 kW-Turbogas Engine

Rotational speed, n	116000 rpm
Nameplate power, P	15 kW
Maximum tip velocity, U_{max}	500 m/s
Fuel Lower Heating Value, LHV	42900 kJ/kg
Inlet pressure, p_1	1 bar
Compressor delivery pressure, p_2	4.3 bar
Inlet temperature, T_1	288 °K
Maximum allowable TIT	1300 °K
Degree of regeneration, RD	0.5
Maximum allowable shaft torsion stress, τ	40 MPa
Turbine polytropic efficiency, η_{pc}	0.9
Compressor polytropic efficiency, η_{pc}	0.85
Mechanical efficiency, η_m	0.9

Figure 3 shows the final proposed turbogas configuration and the relevant thermodynamic and design data. The optimization has been carried out using the optimal n_s criterion**.** A zero-order fluid-dynamic study of the GT has confirmed the possibility of using a single stage radial compressor, but to achieve a good efficiency of the turbine set, with the imposed expansion ratio of about 4.3, the minimal number of stages of the turbine, necessarily axial, is equal to three (two in the limit). The sizing of the radial compressor has been performed by means of a quasi-one-dimensional energy balance at hub and tip, assuming a fixed law of variation of the tangential speed V_t with the radius and imposing a subsonic Mach number at the inlet (relative) and outlet (absolute) sections. The preliminary sizing of the axial turbine has been performed by the same method, but in this case the problem of the sonic phenomena is less serious except for the possible choking caused by a shock wave at the outlet rotor section (which is unlikely anyhow, since the nozzle exit is near chocking at design conditions).

The constructive outline and the calculated dimensions are shown here below.

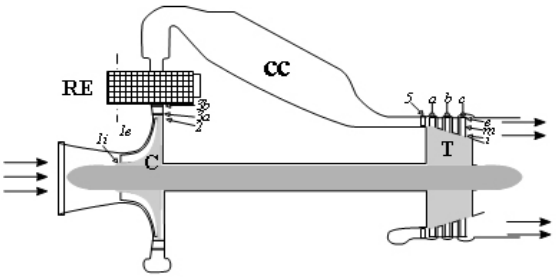

Figure 5: GT set section drawing

mm	mm	mm	mm				
41,2	3,13	4,77	8,04	15	56	50	46

We must remark that -from a thermodynamic point of view- the optimal value of β is approximately 8 and therefore the "thermodynamically optimal" TG cycle efficiency even without regeneration and intercooling results much greater than the calculated one; however we would have larger overall dimensions. In fact, the usual design procedure suggests in this case a three-stage compressor and a three-stage turbine: it is clear that the addition of an intercooler and of the regenerator lead a substantial increase of the size of the thermal power unit. Further investigations are underway to determine whether this "larger" GT set can be packaged in the trunk of a commercial passenger car.

P (kW)	β_{compr}	r_{shaft}	r_{1i}	r_{1e}	r_2
		mm	mm	mm	mm
15	8,3	6,9	9,8	20	43
r_{3a}	r_{3b}	r_{5e}	h_a	h_b	h_c
mm	mm	mm	mm	mm	mm
47	55	42	8,4	13	14

Since our main emphasis was on the possibility of assembling a working prototype using commercial existing units, we decided to adopt as a basic GT-set the supercharger of large Diesel engines, which is readily available on the market at accessible prices and has a proven record of feasibility.

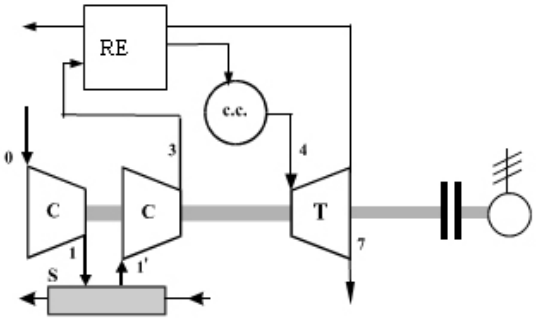

Figure. 6: Intercooled and regenerated turbogas constructive scheme

The introduction of the intercooler, even in such a simplified configuration, obviously increases turbogas efficiency, as shown in Table 7.

Table 7: Intercooled and regenerated performance values

Intercooled	β_{compr}	m_{air}	m_{fuel}	*fuel cons.*	*km/l*	η_{GT}
		g/s	*g/s*	*g/kWh*		
	4,3	0,1761	0,0029	310	18,06	0,243
Intercooled & Regenerated	β_{compr}	m_{air}	m_{fuel}	*fuel cons.*	*km/l*	η_{GT}
		g/s	*g/s*	*g/kWh*		
	4,3	0,086	0,0018	276	19,78	0,304

The constructive complexity and the higher installation costs caused by the intercooler are compensated by a real benefit obtained in terms of the specific fuel consumption. This reduced fuel consumption has a beneficial effect on another important feasibility parameter: it lowers the exhaust emissions.

7. Conclusions

Some of the most relevant issues that affect the technical feasibility of a GT-based hybrid passenger car have been discussed. Tests have confirmed that a single-stage radial-radial configuration (like the Elliott TA-45 examined here, but the results may be extended without loss of generality to other similar configurations), even if very convenient from the point of view of the installation cost, displays a rather poor efficiency. This prompted us to examine the technical feasibility of a different turbogas

configuration: a 2-stage intercooled radial CT coupled with a 2-or 3-stage axial GT. The GTHV system must be carefully designed for what the installed GT power is concerned, and the battery pack must be co-optimized with the turbogas, because the operating conditions are continuously varying. This leads to the necessity of installing a proper turbogas control unit: in simple words, the GT must operate in a "*load following"* mode, so as to maintain sufficiently high efficiency even at partial load conditions. In turn, this requires the installation of a continuous fuel flow control system, of variable turbine nozzle blades and of IGV blades at compressor inlet. We tested (i.e., simulated) several different combinations of P_{GT} and P_{BAT}. The constraints consisted in fixing the SOC variation and in "closing" the energy balance between GT, battery and wheels at $\Delta E = 0$ at each instant in time.The procedure is not yet fully systematic, but since the solution space is not connected (commercial GT sets are available only for certain power levels, i.e. 15, 30, 45 or 100 kW), such a heuristic approach was deemed convenient. Our conclusion is that, under the assumptions outlined in this paper, the "optimal" vehicle is equipped with a combination of a 100 kg Pb-acid battery pack and two turbogas sets, each rated 15 kW, to be used for both urban and highway missions drives.

Installing a Ni-Cd battery pack we could maintain the same optimal outline for urban missions or "complex missions" but we can reduce the total vehicle weight, or, conversely, increase the vehicle electric autonomy with the same weight of the battery pack (the difference between the two configurations is due to the lower specific power of Ni-Cd with respect the Pb-acid).In conclusion our preliminary results indicate that the turbogas option ought not to be discounted though: it is based on already mature technology, offers real multi-fuel characteristic, produces very low emissions and has the advantage of an extremely low installation cost.

ABSTRACT

As the quality of life increases and thus the demands for clean water, ensuring water purity and conservation became increasingly important. Water quality rules are more stringent, complex, and costly, to curb the tendency to use it irrationally. As a result, most companies have to clean their water both before and after they use it, since the harmful impact of waste streams of all types on the environment is hard to overstate. Supercritical water oxidation (SCWO) has been confirmed as a suitable technology to destroy the superior alcohols (common wastes from distilleries, especially C_3-C_5) before releasing the water to the environment. SCWO is an environmentally acceptable technology which produces disposable clean water and gases. SCWO is a process in which aqueous organic waste is rapidly oxidized at temperatures and pressures above water's critical point (647 K, 22.1 MPa). The process has conversions of about 99.999 %.

For the investigated test case, a flow-rate of about 0.8 m^3/h wastewater (containing 8% wt C_3-C_5 alcohols) from a distillery producing alcohol by fermentation is considered. Because the process is highly exothermic, the wastewater is diluted prior to entering the plug flow reactor to about 3.8 % wt, ensuring an exit reaction temperature of about 650 ^{0}C. The SCWO process was modelled using ASPEN Plus® process simulator. The thermal and energetic self-sufficiency of the process was proven, using thermal integration and power production with an Organic Rankine Cycle, using different working fluids.

INTRODUCTION

The distillery industry, which manufactures rectified spirit (plain undenatured spirit) for use both as industrial alcohol and for human consumption, is considered to be one of the most polluting industries, generating an average of 8–15 L effluent ("spentwash") per litter of alcohol produced [1, 2]. Fresh water is consumed at various stages of the alcohol manufacturing process namely yeast preparation, molasses dilution, bottle washing, adjusting the alcohol to the required strength for potable purpose and occasionally, dilution of the treated effluent, prior to discharge.

Raw spentwash (wastewater), generated from distillation of fermenter wash, is deep brown in colour, acidic in nature (low pH) with high concentrations of organic material and suspended solid. It cannot be directly discharged into rivers or on land without treatment due to its deleterious effect on human health and the environment [2].

Consequently, extensive treatment is required before the treated wastewater can meet the stipulated environmental norms.

In this context, improved water use in distilleries can contribute to:

- better operational efficiency;
- improved economic competitiveness through reduced water demand combined with savings in water and wastewater treatment costs;
- low environmental impact due to decrease in surface and subsurface withdrawals as well as less groundwater contaminant intrusion; also, such measures will mitigate the effects of water stress [1].

Monitoring of water use in industries is gaining importance due to increasing competition and stringent environment norms. Water is no longer perceived as a free commodity; further, innovative technologies, along with modification of the existing ones are commercially available to reduce process water consumption. In general, reduction in industrial wastewater can be achieved through one or a combination of the following measures:

- process modification or change in raw materials to reduce water consumption;
- direct reuse of wastewater;
- in-plant reuse of reclaimed wastewater;
- use of treated wastewater for non-industrial purposes.

The final choice of the measures adopted is dictated by the availability of substitute raw materials and technologies, nature of pollutants, purity requirement of water for reuse, competing water demands and overall treatment cost [1].

Before being disposed off or recycled, the waste water should be treated in order to decrease its pollutant content to levels that meet the increasingly stringent regulations. To reach this objective, several possible strategies may conceivably be used including concentration/ incineration, anaerobic digestion with bio-methane recovery, non-catalytic wet oxidation with steam generation followed by aerobic polishing and catalytic wet oxidation (*CWO*) using either homogeneous catalysts such as dissolved transition metal cations or solid catalysts such as supported noble metals and various metal oxides [2, 3].

In this context, supercritical water oxidation (*SCWO*) could be a solution, because appropriate water streams can be partially substituted for fresh water.

SCWO is an efficient and versatile oxidation process for the ultimate destruction of varied recalcitrant, xenobiotic or non-degradable organic wastes generating clean liquid (pure water), clean solid (metal oxides, salts), clean gas (CO_2, N_2) [4, 5, 6].

SCWO involves bringing together organic waste, water and an oxidant (such as air, oxygen, hydrogen peroxide, NO_3, etc.) to temperatures and pressures above the critical point of water. Supercritical water serves both as a reactant and as a reaction medium. In supercritical conditions, water acts as a

non-polar dense gas, and its solvation properties resemble to those of a low-polarity organic compound; as a consequence, organic compounds are soluble in supercritical water and inorganic salts are practically insoluble [4-7]. Because of the absence of mass transfer limitations due to the lack of phase-boundaries, the process rates are very high, large destruction rates being obtained inside small volumes of self contained systems.

The *SCWO* process requires temperatures higher than 400 ^{0}C and pressures above 23 MPa. During the oxidation process heteroatoms such as chlorine or other halogens, sulphur and phosphorus form acids. Because of low temperatures and low oxygen concentrations, nitrogen compounds produce mainly nitrogen gas, together with small amounts of nitrous oxides or ammonia. Organic bounded nitrogen predominately forms N_2 and small amounts of N_2O [6].

The *SCWO* process has some drawbacks related to the chemical corrosion caused by the acids formed during the oxidation and to the erosive action of the insoluble salts (which stick sometimes on the walls) already contained or formed during the neutralization process of the acids. Different reactor types and materials where proposed in order to solve the corrosion problem [4-7]. Generally, the maximum allowable temperature is 650 ^{0}C [6]. Concerning the presence of salts, this could be managed through an appropriate separation before and after the reactor, using hydrocyclone or cross microfiltration [5].

From the energetic point of view, *SCWO* is an exothermic reaction that could make the process autothermal, the heat of reaction released in the oxidation being enough to preheat the feed to operational conditions and to produce energy for the feed pump and the air compressor [5, 6]. For energy production, few solutions were proposed, namely the use of: a turbine, a Brayton Cycle or an Organic Rankine Cycle (*ORC*) [5, 6].

The use of a turbine – where a part of the reactor's effluent produces electricity is still a theoretical solution, since the extreme conditions and the presence of the salts make it hard to be practically realized, at least at this moment [6] (the turbine should be a two stage centripetal-axial engine running at speeds of 100.000 rpm – such engines are not readily available, but are technically feasible).

The Brayton Cycle is characterized by low thermal efficiencies. Because its working fluid is a gas, the presence of a compressor into the Brayton Cycle is mandatory, lowering even more its overall efficiency. Thus, the use of Brayton Cycle was disregarded, so much the more as the Brayton cycle is commercially almost unavailable.

The Organic Rankine Cycle, which works with organic vapours, is capable to recover low grade waste heat.

The *ORC* was chosen due to its advantages [6]:

- high ability in recovering waste heat at low to medium temperature;
- high (second law) cycle efficiency;
- high turbine efficiency (up to 85 %);
- low mechanical stress of the turbine, due to the low peripheral speed;
- no erosion of blades, due to the absence of moisture in the vapour nozzles;
- simple, reliable and easy operability;
- quiet operation;
- robustness (long service life, low maintenance costs).

The working fluid should have good thermodynamic properties, low toxicity, explosion and controllable flammability characteristics, and should be non-corrosive, thermally stable and cheap.

SUPERCITICAL WATER OXIDATION FOR WASTEWATER TREATMENT

The polluted water (flow rate of about 0.8 m^3/h) leaving a distillation column where the alcohols were recovered contains 8% wt C_3-C_5 alcohols (9.1% isopropyl, 19.2% isobutyl, 0.3% n-butyl, 19% amyl and 52.4% isoamyl). If the inlet feed concentration is too high for complete oxidation of the organic material to occur in one step without exceeding the reactor's design temperature, one solution may be the waste oxidization in two (or more) stages. Between stages quench water is added with the oxygen. The water cools the effluent from the previous stage enough to allow the additional oxygen to continue the oxidation reaction without exceeding the temperature limit [8].

The authors propose another solution, which uses water obtained from the *SCWO* process itself to dilute the polluted water up to 3.8 % wt. This concentration ensures that the temperature after the oxidation is as high as 647.25 ^{0}C (920.4 K), close to the limit temperature. After dilution, the flow rate of polluted water becomes about 2 m^3/h.

The simulation of a *SCWO* plant with a treatment capacity of 2 m^3/h of wastewater has been carried out using Aspen Plus© of Aspen Technology, Inc. The basic flowsheet is presented in Figure 1. For

the simulation, Peng-Robinson equation of state with modified Huron-Vidal mixing rules was used. The installation contains four parts: feedstream conditioning, reaction, effluent conditioning and heat integration.

In the first one, the polluted water is mixed with the purified one, the alcohols' concentration dropping down from 8 % to 3.8 % wt, then pumped to the operational pressure of 25 MPa and pre-heated up to 400 ^{0}C by the reactor effluent.

Oxygen, in an excess of about 6 % of the stoichiometric ratio, is compressed up to 25 MPa by a four stage compressor and has 213.55 ^{0}C at the exit, since the refrigeration is removed after the last stage. Wastewater and the oxygen are mixed and enter the plug flow reactor at 390.2 ^{0}C. Reactions take place, the pollutants' conversion being as high as 99.99 %. The kinetic used for the oxidation process was based on acetic acid as refractory compound [6]. The effluent, consisting of H_2O, CO_2 and O_2 leaves the reactor at 25 MPa (the pressure drop was neglected) and 647.25 ^{0}C.

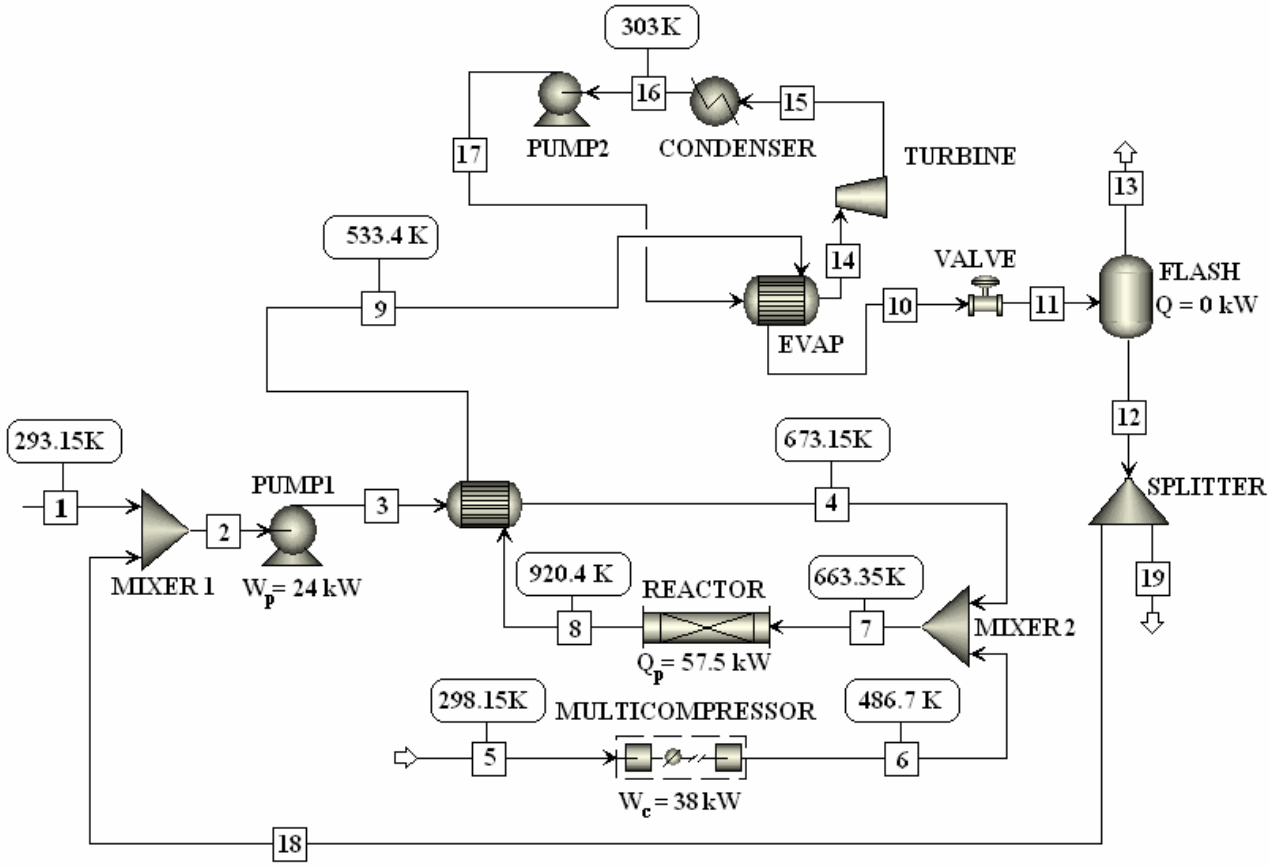

Figure 1. The flowsheet of the SCWO process for diluted wastewater treatment, with *ORC*.

The aim of the process heat integration is to achieve an autothermal operation. The energy released in the reaction is, firstly, used to preheat the liquid raw materials entering the reactor and then, the remained heat is recovered in an *ORC*, where power is produced to compensate that consumed by the pump and the oxygen compressor, ensuring, this way, at least the energetic self sufficiency of the *SCWO* process.

Several fluids were found to be able to provide the necessary electric power to cover the consumption for both pumps and the compressor. The power of the turbine is positively influenced by both higher ratios of pressures and higher inlet turbine temperatures. This is why the pressure of the organic fluids was chosen near the critical one (a little bit less than 2 MPa) and the vapours were superheated. The vapours' temperature and the flow rate were obtained after several trials and errors for different combinations, the set giving the maximum value for the turbine's power being picked up.

The turbine expands the vapours up to the condenser pressure corresponding to a saturation

temperature as high as 303 K. The organic liquid obtained in the condenser is pumped up to the working pressure, vaporized in EVAP using the heat of the purified water and the cycle repeated (see Figure 1).

The distinction between different working fluids could be done using the main performance parameters of the cycle [9]:

- the *specific work output*, *w*:

$$w = (h_{14} - h_{15}) - (h_{17} - h_{16}),\ \text{J/kg} \quad (1)$$

- the *work ratio*, r_W, defined as the ratio between the net work output and the gross work output:

$$r_W = \frac{\text{net work output}}{\text{gross work output}} = \frac{w}{h_{14} - h_{15}} \quad (2)$$

- the *cycle efficiency*, η_I, expresses the proportion of the heat transferred to the working fluid which is converted into mechanical work:

$$\eta_I = \frac{\text{heat converted into mechanical work}}{\text{heat transferred to the working fluid}} = 1 - \frac{h_{15} - h_{16}}{h_{14} - h_{17}} \quad (3)$$

- the *second law efficiency*, η_{II}, a ratio of the actual work generated and the maximum possible work:

$$\eta_{II} = \frac{\text{actual generated work}}{\text{maximum possible work}} = \frac{W_{net}}{W_{net} + I} = \frac{W_t - W_{pump2}}{W_{net} + I} \quad (4)$$

- the *irreversibility* of the *ORC* process, *I*, given by (for steady state conditions):

$$I = T_0 \cdot G_w \cdot (s_{10} - s_9) + \dot{Q}_{condenser} \quad (5)$$

The irreversibilities, as given by (5), were calculated considering the temperature of the surroundings, T_0, as high as 293 K.

The operational parameters for the *ORC*s with the working fluids used are given in Table 1, together with their enthalpies and entropies, specific to each fluid. The obtained main performance parameters are presented in Table 2.

As can be seen, all the considered working fluids used in an *ORC* produce more electrical power than that consumed in the *SCWO* process designed for the abovementioned working conditions, which is as high as 62 kW.

Regarding the performance parameters, the best of them seems to be the refrigerant R123, followed by ammonia, i-pentane and R 600.

CONCLUSIONS

Supercritical water oxidation was considered for the purification of the polluted water obtained in a distillery, containing C_3-C_5 alcohols as organic residue. The installation, used for the treatment of approximately 2 m^3/h polluted water with about 3.8% wt alcohols was modelled using ASPEN Plus®. After ensuring the thermal sufficiency – autothermal regime – the energetic sustainability of the process was investigated, for rather conservative conditions: high heat losses (of about 10% for the reactor and 3% for the heat exchangers) and low enough efficiencies (0.6 for the pumps and compressor and 0.75 for the turbine).

The Organic Rankine Cycle was the solution proposed to recover the low grade waste heat contained by the effluent of the reactor after heating the wastewater and to produce green electricity.

Six working fluids were tested and found suitable to be used in the analyzed case, the best, in terms of the main performance parameters of the *ORC*, being the refrigerant R123.

This Organic Rankine Cycle solution makes the *SCWO* process thermal and power self-sustained, being an example of efficient conversion of the reaction heat to electricity.

The power self-sufficiency implies a reduction of the power use from conventional resources, which should be associated with a lower consumption of fossil fuels and with the decreasing of the pollutant emissions.

ACKNOWLEDGEMENTS

The present paper is the result of a joint research of VITO, VUB and UPB-CTTIP developed under the auspices of the bilateral agreement between the Flemish and Romanian governments, BIL 031326 - *Application of chemical pinch technology in process industries*.

EFFECTS OF ROTARY AIR PREHEATER LEAKAGE ON STEAM POWER PLANTS PERFORMANCE

S. Farhad*, M. Younessi-Sinaki and M. Saffar-Avval
Amirkabir University of Technology
Mechanical Engineering Department,
Tehran, Iran

ABSTRACT

The effects of air leakage in the rotary air preheater on performance of steam power plants, such as fuel and power consumption, is an interesting subject in economical maintenance planning. In this paper, the analytical equations to determine the air leakage effects on the fuel consumption and consumed power of forced and induced draft fans in the steam power plants are developed. To show the rotary air preheater leakage effects, four units of 1000 MW Shahid Rajaei steam power plant were tested based on ASME PTC 4.1 and 4.3. The results show that, the air leakages average in these units have increased to 24.7% and 28.0% for natural gas and heavy oil fired fuels, respectively. According to the developed analytical equations, the fuel and power consumption increased to 850 ton/month, and 1078 kW for heavy oil and negligible variation of fuel consumption, and 834 kW for natural gas fuels firing, respectively. Therefore, higher fuel and power conservation can be obtained by proper planning to maintain the rotary air preheaters in suitable conditions.

INTRODUCTION

Efficient operation of the steam power plants in order to minimize the operation costs is very attractive subject for the plant managers. Performing periodic performance tests on different parts of the power plants are useful effort to prepare maintenance planning in order to keep energy consumption and equipments life at economic conditions [1]. One of these important equipments is the rotary air preheater for determination of the air leakage. According to the Howden Company experience in a 200 MW unit of steam power plant in Hungary, deterioration of the sealing system in the rotary air preheaters has resulted in very high levels of air leakage into the flue gas. In this plant, increasing the air leakage from 4.7% to 24%, has incurred 1.9% decrease in boiler efficiency [2]. It shows that, the air preheater leakage has important effects on the steam power plants fuel and power consumption. Therefore, diagnosing the appropriate time to repair the rotary air preheater is an economical attempt to minimize the costs. In this paper, the analytical equations to determine the air leakage effects on the steam power plants are developed. Using these equations and regarding the economical analysis, the suitable maintenance planning would be obtained for the rotary air preheaters. Figure 1, which is shown a part of steam-generating unit, can be applied as a key to numerical subscripts employed throughout this paper.

ROTARY AIR PREHEATERS

The rotary air preheater is a compact heat exchanger which was invented by Dr. Ljungstrom from Sweden. These heaters are very popular in modern steam generators. Using the air preheater improves not only the boiler efficiency by lowering the stack temperature, but also the combustion conditions by raising the combustion air temperature. The location of the air preheater in steam-generators is shown in figure 1.

The rotary air preheaters are divided into two groups concerning the arrangement of their rotors, Vertical (V) types and Horizontal (H) types. These heaters contain baskets, as extended heat transfer surfaces, which are attached to the rotor which rotates at 2 to 4 rpm. The baskets are placed in three hot-end, intermediate and cold-end zones, where the gas inlet and air outlet section is called hot-end side and the gas outlet and air inlet section is called cold-end side. In these heaters, the flue gas flows though the baskets to rise their temperature and then air is passed through the same baskets to absorb the heat, while the baskets rotate continuously. Because the pressure of the air is higher than the flue gas pressure, a high amount of air could leak into the flue gas. To limit the total air leakage under 8% of weight of exit flue gas flow, the proper seals must be used in these heaters [3]. The air leakage Percentage depends on the pressure difference between the gas and air ducts on the seals.

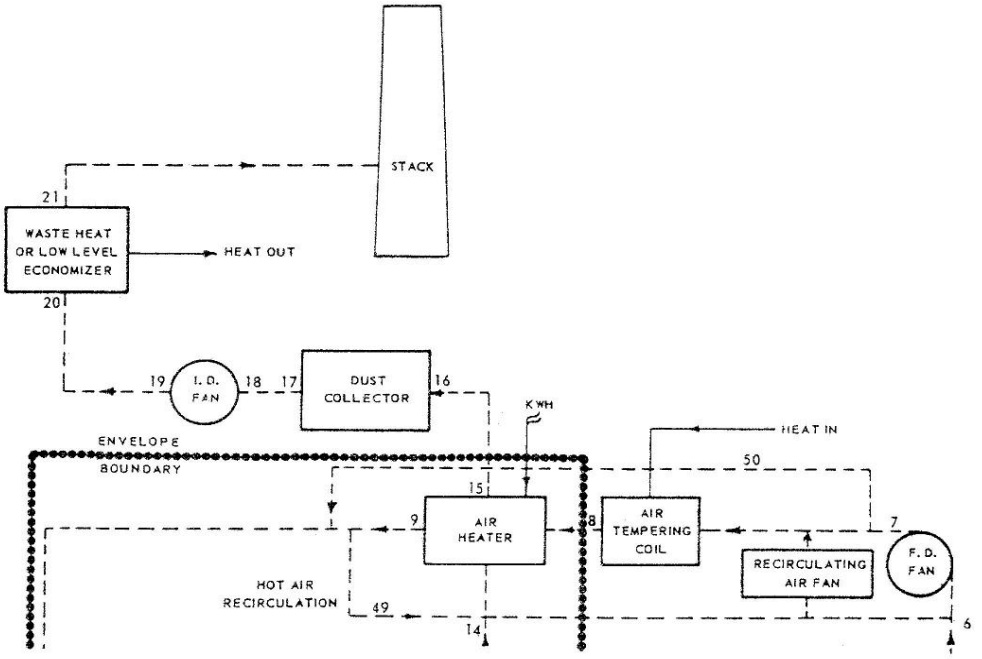

Figure 1: Steam-generating unit diagram [4]

The majority of the leakage occurs on the cold-end side, where the corrosion due to the relatively low air and gas temperatures result the larger clearances between the sealing surfaces. The amount of the air leakage per kg of as fired fuel and the air leakage percent are obtained from the equations 1 and 2, respectively [4, 5].

$$L = W_{G'15} - W_{G'14} \quad (1)$$

$$\%Leak = \frac{(W_{G'15} - W_{G'14})}{(W_{G'14} - W_{mG})} \times 100 \quad (2)$$

Whenever the metal temperature of air preheater falls bellow the dew point temperature of the flue gas, the corrosion of the metal caused by sulfuric acid is occurred. The sulfur content of the fuel and the type of firing has an important bearing on the flue gas dew point temperature. Because in most boilers the flue gas temperature decreases with boiler load, corrosion is more severe at part loads. Increasing heat transfer surfaces temperature is less possibility to cause condensation of acids from the flue gas stream. The design and operation of the air preheater control system is based on maintaining the **A**verage **C**old-**E**nd **S**ide **T**emperature (ACEST) of the rotary air preheaters in suitable limits. The ACEST is defined as equation 3 [1]:

$$ACEST = \frac{T_{G15} + T_{A8}}{2} \quad (3)$$

The air leakages can be reduced by repairing or replacing the damaged rotary air preheater baskets and seals in cold-end side of the preheater. Because this side of the rotary air preheaters is exposed to the sulfuric acid corrosion, the cold-ends zone of these heaters is designed so that the metal elements can be removed easily.

FORCED AND INDUCED DRAFT FANS

When the stack is not able to produce sufficient draft to overcome the pressure losses, the forced and induced draft fans are used. The force draft fan is required to supply sufficient static pressure to overcome the air resistance and the induced draft fan is used to overcome the flue gas resistance. It is necessary to mention that, having both forced and induced draft fans are not essential. For instance, in the pressurized steam generators, a forced draft fan overcomes all the resistances in the air and flue gas passages from the fan to the stack entrance. In this case, the furnace is under pressure and no induced draft fans are used [3]. Figure 1 shows the forced and induced draft fan locations in steam-generators.

The fans are divided into centrifugal, axial and mixed types which each one has particular advantages to another. Also the fans can be divided into straight, forward and backward blade curves. The forced draft fans ordinary use backward type and the forward or straight blades are used for induced draft fans. For any kind of the fans, the fan efficiency has similar mathematical trends in its characteristics curves. Therefore the fan efficiency can be estimated as parabolic equation versus the mass flow rate passing through the fan at constant density. In this paper, the equations 4 and 5 are applied to obtain forced and induced draft fan efficiencies, respectively.

$$\eta_{FDF} = \frac{T_{A7i} - T_{A6}}{T_{A7} - T_{A6}} = a \times [(W_A + L) \times W_{fe}]^2 + b \times [(W_A + L) \times W_{fe}] + c \quad (4)$$

$$\eta_{IDF} = \frac{T_{G16i} - T_{G15}}{T_{G16} - T_{G15}} = f \times [(W_{G'14} + W_{mG} + L) \times W_{fe}]^2 + g \times [(W_{G'14} + W_{mG} + L) \times W_{fe}] + h \quad (5)$$

QUANTIFYING THE EFFECTS OF AIR PREHEATER LEAKAGE ON STEAM POWER PLANTS

It was mentioned earlier that the leakage reduction of the rotary air preheater has an effective influence on energy consumption of steam power plants. Reduction of air leakage lead to reduce the flue gas temperature entering the stack and changes the capacity and exit temperature of the forced and induced draft fans, in the manner that the consumed power of forced and induced draft fans are decreased.

As shown in figure 1, usually three methods are used for increasing the cold-end zone metal temperature of air preheaters [3]:

1- Using the steam-air heater to increase the inlet air temperature, which is installed up-stream of the air preheater.
2- Recirculating some of the hot air from the air preheater outlet back to the inlet air, for increasing the preheater inlet temperature.
3- By-passing part of the air from the air preheater.

In the first method, the steam-air heater controls the ACEST to prevent corrosion of the rotary air preheater by increasing the air temperature at

entrance of the air preheater. In this paper, it is supposed that, the control of ACEST is performed by this method.

To show the effects of the rotary air preheater leakage on the steam power plants, the analytical equations are developed. According to PTC4.1, the energy conservation equation for steam-generators can be considered as equation 6.

$$HV\times W_{fe}+B\times W_{fe}=(BoilerOutput)+Loss\times W_{fe} \qquad (6)$$

To achieve the equation which obtains the fired fuel variations with respect to the air leakage percent, both sides of equation 6 will be differentiated. It is obvious that the differential conditions are different regarding the operating status of the steam air heater, forced and induced draft fans. These different conditions are presented in table 1. Equation 7 states the fuel consumption variation with respect to the air leakage percent for any condition of the steam air heater, forced and induced draft fans operations. Table 1 is guide key for equation 7. Notice that the dimensionless numbers of C, D, E, K, X_1, and X_2 in this equation are defined in table 2. Also the concept of the parentheses which are similar to the less than and more than sign, are specified in table 1. The variations of the forced and induced draft fan powers and the steam air heater steam consumption can be obtained with respect to the air leakage percent, from the equations 8 to 10, respectively. Also the variation of the exit flue gas temperature from the rotary air preheater which is affected from the rotary air preheater leakage can be obtained from the equation 11.

EFFECT OF THE AIR LEAKAGE IN TYPICAL STEAM POWER PLANT

To show the effects of the rotary air preheater leakage, Shahid Rajaei steam power plant is selected. This plant, which is placed in Iran, has four 250 MW units and was built in 1993. This plant operates at 3 loads of 250, 187.5 and 125 MW and has two types of burner for natural gas and heavy oil fuels firing. The rotary air preheater of this plant is the V type and the materials of its baskets are corrosion-resistant low-alloy steel for the cold-end, and cold-rolled steel for the intermediate and hot-ends zones. According to the design guideline considerations, the minimum ACEST is recommended 110°C for residual oil firing, when the excess air and fuel sulfur content are up to 5% and 2%, respectively, and 97°C, for other conditions; and this value is recommended 63°C for natural gas fuel firing, which is controlled by steam air heaters. The boilers of this plant are pressurized; therefore, the induced draft fan is not applicable in this plant. In fact, two forced draft fans and the 220 m stack are able to overcome all flow resistances. The forced draft fan efficiency of this plant can be obtained by equation 12. The other plant specifications are presented in tables 3 and 4. As presented in tables 3, the ACESTs of Shahid Rajaei's rotary air preheaters are more than the recommended temperature for the natural gas fuel firing; therefore it is not necessary to use the steam air heater to control the ACEST, while according to table 4, using this control system is essential when the heavy oil is consumed.

$$\eta_{FDF} = -1.95\times10^{-5}[(W_A+L)\times W_{fe}]^2 + 8.12\times10^{-3}[(W_A+L)\times W_{fe}] \quad (12)$$

Table4: Specification of the Shahid Rajaei steam power plant, heavy oil firing

It is necessary to note that the steam which is used to control the ACEST is provided from the last stage of the intermediate turbine extraction line.
In this study, the air heaters of four units of Shahid Rajaei steam power plant (two per boiler) were tested based on ASME PTC 4.1 and 4.3 in 2002. The obtained experimental results are shown in figure 2 [1]. The results show that the air leakage average in this plant have increased to 24.7% and 28.0%, for natural gas and heavy oil fired fuel, respectively. It must be mentioned that the Shahid Rajaei steam power plant's air preheaters had not been repaired or replaced until the tests were performed.

Regarding the test results, the effects of the air preheater leakage on the fuel and forced draft fan power consumptions can be obtained from equations 7 and 8. It is necessary to mention that, to obtain the results, the coefficients of the equations 7 and 8 are assumed constant with respect to the air leakage variations. Regarding to this assumption, the mentioned differential equations can be integrated. Although such simple approximate is quick estimate, but the studies show that the error of this assumption is less than 3.5% per each 15% of air leakage on fuel consumption. Also this assumption does not have significant error on fans power consumption. Therefore, this approximation can be accepted in the present study, while these errors can be eliminated by using the iterative methods to solve these equations.
Increasing the fuel and power consumptions of four units of Shahid Rajaei steam power plant are presented in table 5. It is obvious that repairing or replacing the damaged seals and baskets of the rotary air preheaters can decrease the additional fuel and power consumptions.

Unit No.	Natural gas firing		Heavy oil firing	
	Fuel consumption (ton/month)	FDF Power (kW)	Fuel consumption (ton/month)	FDF Power (kW)
1	-0.1	259	258	307
2	-0.3	314	314	394
3	-0.1	154	125	179
4	-0.1	107	153	198
Total	**-0.6**	**834**	**850**	**1078**

Table 5: Improving potential of fuel and power consumptions in Shahid Rajaei steam power plant

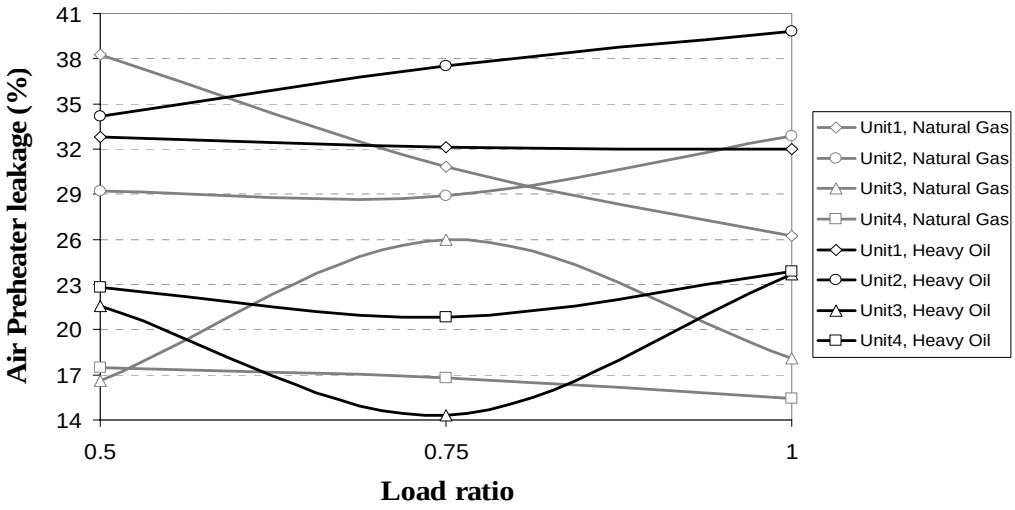

Figure 2: Air preheater leakage percent versus load ratio in Shahid Rajaei steam power plant [1]

To perform the economical analysis to determine the best planning to repair the rotary air preheaters, the additional fuel and power consumptions should be estimated with respect to the air leakage. The fuel and power consumption curves for three operating loads of Shahid Rajaei steam power plant are presented in figures 3a and 4, respectively. Because the steam-air heater is not applicable for natural gas fuel firing in Shahid Rajaei steam power plant, the variations of natural fuel consumption are negligible. By transforming the vertical axis of these graphs to the cost variations, and specifying the rotary air preheater repairing costs and detriments due to stopping the unit, the optimum rotary air preheater leakage for any steam power plants can be determined. Remember that, the optimum leakage depends on the fuel and electrical fuel prices and the repairing costs, which are different for any power plants. Thus the optimum leakage is different for any steam power plant and it is necessary to find this optimum value for each plant.

The variation of flue gas temperature with respect to the air leakage is important to estimate the ducts temperature after the air preheaters. As shown in figure 5, the air preheater flue gas exit temperature in Shahid Rajaei steam power plant reduced rapidly by increasing the air leakage. This leakage can cause the corrosion in any flue gas passage ducts after the rotary air preheater.

The variation of the consumed steam of the Shahid Rajaei's steam-air heaters with respect to the air leakage is shown in figure 3b. It seems that the air leakage has considerable influence on steam-air heater steam consumption and its influence is added by decreasing the operating load.

CONCLUSION

Generally, increasing the fuel and power consumption of operating steam power plants might be caused by various reasons like the increasing air-fuel ratio, malfunction of equipments and control devices, increasing the condenser pressure, increasing the rotary air preheater leakage, etc. Determining the effect of each item on fuel and power consumption provides a suitable opportunity to optimum maintenance planning. Obtaining the additional fuel and power consumption with respect to the rotary air preheater leakage leads to the optimum air leakage in steam power plants. This paper was intended to present the suitable analytical relations which could predict the effects of the rotary air preheater leakage on fuel and power consumption based on the plant design data in steam power plants. The results of the present study show that the increasing of fuel and power consumption due to increasing air leakage in rotary air preheaters is considerable. As shown in table 5, the fuel and power consumption of Shahid Rajaei steam power plant increased to 850 ton/month, and 1078 kW for heavy oil and, negligible fuel consumption variations, and 834 kW for natural gas fuel firing, due to the 24.7% and 28.0% air leakage average for natural gas and heavy oil fired fuel, respectively. Hence, the operation costs of this plant can save by repairing or replacing the damaged seals and baskets of rotary air preheaters.

ACKNOWLEDGMENT

The authors would like to express their appreciation to the Shahid Rajaei power plant director, and technical engineering staff.

TRANSLANG TECHNOLOGIES LTD.
Canada

ABSTRACT

Over the last ten years the TransLang Technologies Ltd Company and its main partners have undertaken considerable efforts to carry out investigations and developments and to continuously improve a new approach to the technology of natural gas conditioning and the separation of natural gas components under the general name Super Sonic Separation ("3S"). The advancement of this technology is based on the application of results achieved in aerodynamics related to aerospace engineering. Based on these developments, facilities for separation of natural gas components have been developed which have passed successful laboratory and pilot testing in Russia and Canada.
Keywords: natural gas, LPG, low temperature separation, ECOS2005

NOMENCLATURE

a - sound velocity in gas [m/s]
m - mass fraction of condensate in flow [%]
M=V/a - Mach number
P - static pressure [bar]
T - static temperature [^{0}C]
V - gas velocity [m/s]
α_0 - initial (at the facility entry) mole concentrations of components C_{3+} [%, mol.]
$\alpha_к$ - final (at the facility exit) mole concentrations of components C_{3+} [%, mol.]
$\Delta\alpha=\alpha_0-\alpha_К$ - separation effectiveness [%, mol.]

INTRODUCTION

In this presentation we will report on the overall "3S-technology" without separating it between the various variants of types of devices within this group.

* corresponding author: Phone/Fax: +7 095 1351019
E-mail: imaevsalavat@netscape.net

The 3S technology is a modern technology intended to extract target components from natural gases. The technology is based on the cooling of natural gas in a supersonic swirling gas flow. The supersonic flow is created using a convergent-divergent Laval nozzle. In such a nozzle, gas is accelerated up to velocities exceeding the sound propagation velocity in gas. Due to transformation of a part of the potential energy of flow to kinetic energy the gas is cooled to a high degree.

As an example, Figure 1 shows variations in the main flow parameters when natural gas expands in the supersonic Laval nozzle. The natural gas composition is taken to be as follows: CH4 - 80%, C2H6 – 10%, C3H8 – 6%, C4H10 – 4%. The gas pressure and temperature at the nozzle entry are assumed to be 60 bar and 5 ^{0}C, respectively. These curves are plotted proceeding from the quasi-one-dimensional isentropic approximation of gas motion in the nozzle. The vapor-liquid equilibrium is calculated by the Peng-Robinson equation. As is obvious from these curves, the natural gas expansion even up to moderate supersonic Mach numbers (M ~1.5 – 2.0) allows the gas to be cooled to temperatures sufficient for the condensation of not

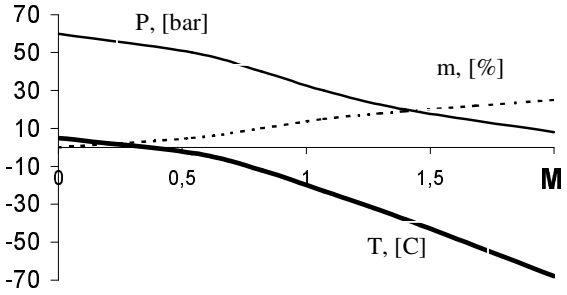

Figure 1: Main parameters of gas flow in supersonic nozzle vs Mach number

only components which are heavier than propane but also ethane. In this case, no additional cold sources, such as coolers, turboexpanders etc., are required to reach the relevant cryogenic temperatures of natural gases.

If condensed drops consisting mainly of heavy components, C3+, are separated from the gas flow in the supersonic nozzle, then the gas at the nozzle exit will primarily consist of light components, such as methane, ethane etc.

Using 3S technology, separation of condensate drops containing target components condensed in the supersonic nozzle occurs under the action of centrifugal forces. The field of centrifugal forces is created by means of flow swirling at the supersonic nozzle entry.

A schematic of the facility (hereinafter the 3S-separator) with the implemented 3S-technology is presented as Figure 2. The 3S-separator includes: 1 – swirling device, 2 – supersonic nozzle, 3 – working section, 4 – a device for the extraction of the gas-liquid mixture, 5 – diffuser.

The application of the diffuser at the 3S-separator working section exit makes it possible to transform a part of kinetic energy of the flow to potential energy to obtain the gas pressure at the diffuser exit larger than the static gas pressure in the supersonic nozzle.

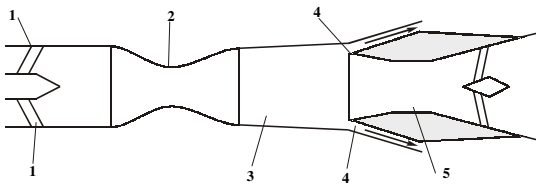

Figure 2: Schematic of 3S-separator

The international patents for the 3S-technology and the 3S-separators are the property of TransLang Technologies Ltd ([1,2] and others).

LABORATORY AND PILOT PRODUCTION TESTS OF THE 3S-TECHNOLOGY

To improve the technology and develop its commercial applications, TransLang Technologies Ltd. has developed a number of facilities. By now, the "3S"– type facilities developed are as follows:

- The test complex (Figures 3-4) at Didsbury (Calgary, Canada). The facility provides a gas flow rate of up to 12 kg/s at an initial gas pressure of 50 – 70 bar and an outlet gas pressure of not below 40 bar. The facility is designed to investigate extraction of the components C5+ from natural gas. The test facility is designed for long period tests and

Figure 3: Test bench at Didsbury

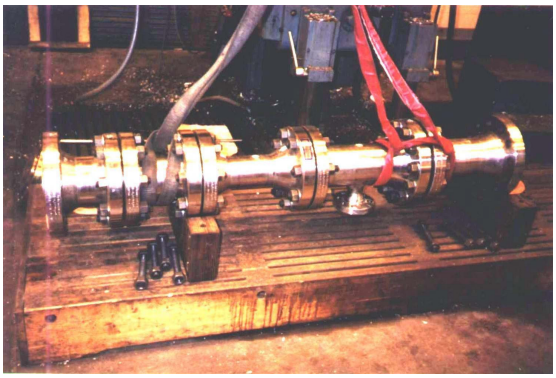

Figure 4: 3S–separator installed on the bench at Didsbury

equipped with a measuring complex to measure pressure, temperature and component concentrations in the 3S-separator elements.

- The experimental bench with the "3S"-type facility (Figure 5) in Moscow region (Russian Federation) provides a gas flow rate of 1.5 – 2.5 kg/s and

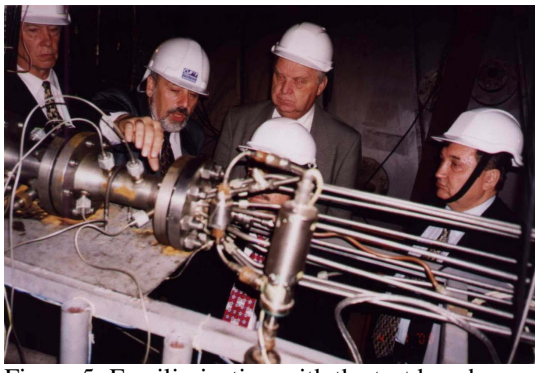

Figure 5: Familiarization with the test bench (Moscow region)

working pressures up to 150 bar. The initial temperature can be varied from –60 ^{0}C to +20 ^{0}C. The bench is equipped with special devices to specify required hydrocarbon gas mixture compositions at the 3S-separator entry.

- The pilot production facility in Western Siberia (Figure 6). In September, 2004, a complex consisting of two "3S" facilities with a capacity of above 400 mmscm per year each was successfully put into pilot production operation at one of the gas treatment plants in Western Siberia as a part of the

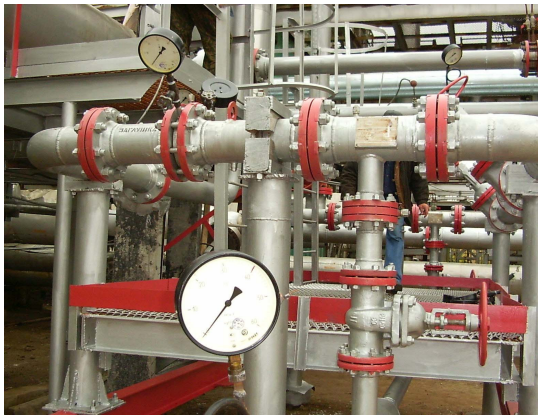

Figure 6: General view of the 3S-facility in Western Siberia

LPG complex. The initial gas pressure at the 3S-separator entry is 32 bar, the initial gas temperature is –30 ^{0}C. The 3S-separator provides extraction of components C3+ in the complex of LPG recovery.

- To investigate various fundamental physical aspects of applying the "3S" technology, two laboratory facilities are used in Moscow region. In one of them the working gas is air, while in the other the mixture of nitrogen and propane–butanes is used.

Over the last five years, more than 400 tests of "3S"-type facilities have been carried out at different temperatures, pressures and gas mixture compositions. Subsonic, transonic and supersonic separation modes have been tested. Optimal 3S-separator structures were designed to provide extraction of components C3+, C5+ from natural gas.

A range of experimental investigations were conducted under conditions up to those approaching industrial applications. Experiments confirmed the main results and conclusions made in the laboratory test facility, in particular the conclusion regarding the high level of effectiveness of the 3S-separator.

Relying on the data obtained from these test facilities, specific software was developed to calculate the 3S-separator physical components under various operating conditions.

The diagram in Figure 7 clearly demonstrates the results of a series of test runs with 3S-separator and their comparison with corresponding results for a *JT- valve*.

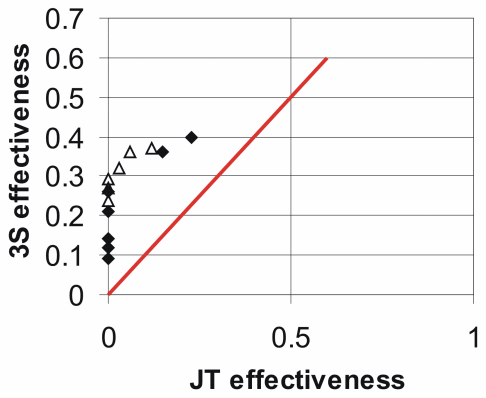

Figure 7: Comparison of 3S and JT effectiveness

Each point on the diagram corresponds to a specific experimentally achieved result. The extraction effectiveness for heavier components of natural gas (pentane, butanes+propane) in the 3S-separator is plotted on the vertical axis of the diagram and the effectiveness calculated for the facility with the JT valve for the same condition (at the same dif-

ferential pressure) is shown on the horizontal axis. The separation effectiveness is measured by $\Delta\alpha=\alpha_0-\alpha_к$, where α_0, $\alpha_к$ are the initial and final (at the facility exit) mole concentrations of components C_{3+}.

It is clear from these data that there exists a range of conditions, (especially where small initial concentrations of heavier hydrocarbons are present) when it is possible to extract such liquid components using the 3S-separator while it would be impossible if a JT valve were to be used.

In the tests, the results of which are presented on the above diagram, the initial concentrations of components, gas pressure and temperature at the 3S-separator entry, differential pressure through the facility and gas dynamic flow condition were varied. The results were obtained for conditions at Mach Number M<1.5 in the 3S-separator working section.

Comparison of the 3S-technology with *turboexpanders* shows that there exist schemes in which the 3S-technology provides better extraction of target components when compared with the schemes in which only the turboexpander is used. In some cases the 3S-separators provide extraction of target components for operating parameters when the operation of turboexpanders is impossible (see below).

ADVANTAGES OF THE 3S-TECHNOLOGY

Some advantages of the 3S-technology as compared with traditional technologies of hydrocarbons separation from natural gas are as follows:

- small size and therefore reduced space requirements, greater portability and reduced handling and installation costs,
- low capital and operating costs,
- no adverse environmental impact,
- the absence of moving parts,
- no requirement for routine maintenance,
- conservation of reservoir energy,
- superior performance capabilities compared to conventional separation equipment and configurations.

There are a wide range of potential applications for 3S-separators to solve the following problems of gas industry:

- gas conditioning (dehydration and extraction of heavy hydrocarbons);
- separation of propane-butanes (LPG);
- extraction of ethane
- production of LNG.

The calculations based on the experimental data for particular fields reveal that the application of the 3S-technology could result in an increased recovery of heavier gas components by more than 30% for the same power of requirements.

The application of 3S-separators instead of *JT-valves* on existing gas processing and extraction plants makes it possible, utilizing the same compressor power, to increase the LPG extraction by 10 – 20%. Similarly, if satisfied with the current extraction level, it would be possible to decrease the required compressor power by 10 – 20%.

At gas processing plants for LPG extraction equipped with *turboexpanders* and coolers (high LPG extraction), the application of 3S-extractors could lead to reduction in the required compressor power by 15 – 20% at the same extraction level.

These examples offer the possibility of increasing the profitability of gas processing plants by means of an inexpensive reconstruction.

APPLICATION OF THE 3S-TECHNOLOGY TO FACILITIES OF GAS CONDITIONING (HYDROCARBON DEWPOINTING)

Relying on the results of pilot production tests of the 3S-separator obtained, in particular, on the test bench at Didsbury, it is easy to show the advantages of using the 3S-technology under conditions of natural gas preparation for transportation.

The main aim of these facilities is to extract heavy components C5+ (C3+) from natural gas and to provide a required dew-point level for hydrocarbons in natural gas at the facility exit.

The process of natural gas dehydration is conducted either upstream of such a facility or water extraction is performed simultaneously with heavy components C5+ (C3+) extraction. If separation of components C5+ (C3+) and water is performed simultaneously, inhibitors of hydrate-formation, for example, ethylene glycol, are added to natural gas.

The functional diagram of the commercial facility of gas conditioning using the JT-valve is given in Figure 8. This diagram with similar parameters is typical, in particular, for various fields in Alberta (Canada).

Let us consider the operational parameters of the facility for one of the fields.

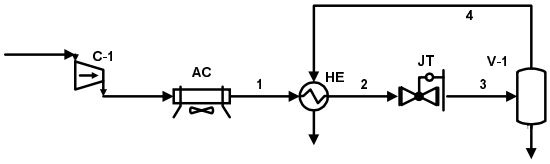

Figure 8: JT-valve LTS Process

Flow	1	2	3	4
Pressure, bar	76.3	75.6	58.8	58.8
Temperature, ^{0}C	48	-6	-15	-15
Content of Components C5+, % mass.	2.27	2.27	2.27	1.43

Table 1: Parameters of main flows for JT- valve LTS Process

Natural gas is delivered to the facility at pressure of 18.9 bar. In the compressor C-1 it is compressed up to 76.3 bar, as a result the gas temperature increases up to 140 ^{0}C. Then gas is cooled in the air cooler down to 48 ^{0}C and delivered to the recuperative heat exchanger. In the heat exchanger, gas is cooled down to -6 ^{0}C and supplied to the JT-valve entry. When the gas pressure in the JT-valve is reduced from 75.6 bar to 58.8 bar, gas is cooled down to -15 ^{0}C and there occurs condensation of heavy gas components. The condensed liquid fraction is then extracted in the three-phase separator V-1. After the separator, the gas fraction is supplied to the recuperative heat-exchanger and then to the gas main. The liquid fraction after the separator is supplied to the stabilization facility and then to the storage for condensate.

The mole composition of natural gas at the facility entry is as follows:

N2 – 1.65%, CO2 – 0.44%, CH4 – 87.49%, C2H6 – 7.00%, C3H8 – 2.07%, i – C4H10 – 0.35%, n-C4H10 – 0.46%, i – C5H12 – 0.17%, n – C5H12 – 0.14%, C6+ - 0.23%.

The parameters of main flows for Figure 8 are summarized in Table 1.

For the above process the extent of extraction of C_{5+} from natural gas flow is 38%, the dew-point for hydrocarbons being –15 ^{0}C (at gas pressure of 58 bar).

Figure 9 shows the diagram of the facility of gas conditioning using the 3S-separator. In this scheme the 3S-separator is installed instead of the JT-valve. The gas-liquid flow from the 3S-separator is delivered to the same three-phase separator V-1. Gas from the three-phase separator is mixed with purified gas from the 3S-separator and supplied to the recuperative heat exchanger.

The calculated parameters of main flows for Figure 9 are summarized in Table 2.

The calculation of the natural gas purification effectiveness in the 3S-separator is based on the results of its tests on the bench at Didsbury. For the scheme in Figure 7 the extent of extraction of C_{5+}

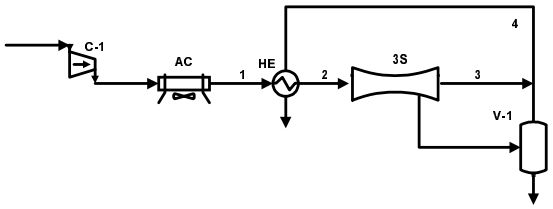

Figure 9: 3S-separator LTS Process

Flow	1	2	3	4
Pressure, bar	76.3	75.6	58.8	58.8
Temperature, ^{0}C	48	16.8	11.3	9.93
Content of Components C5+, % mass.	2.27	2.27	0.71	1.15

Table 2: Parameters of main flows for 3S-separator LTS Process

from natural gas flow at given parameters of the 3S-separator operation is 50%, while the mass fraction of gas-liquid flow delivered to the secondary gas-liquid separator from the 3S-separator is 20 – 30 % of the total flow supplied to the 3S-separator entry. Thus, simple replacement of the valve with the 3S-separator in the LTS facility of gas conditioning makes it possible to improve the C5+ extraction by a factor of 1.32. This is equivalent to reduction in the dew-point of the output gas by 4 ^{0}C.

Some modification of the scheme of using the 3S-separator, in particular, introduction of an additional recuperative heat exchanger allows the differential pressure through the facility to be decreased considerably. During the tests carried out at Didsbury it is shown that for gas pressure after

the compressor of 66.3 bar the extent of extraction of C_{5+} in the case under consideration can be 49%. Thus, with significant reduction in the compressor compression ratio and, respectively, with reduction in the compressor unit power by ~12% the application of the 3S-technology allows increase in extraction of components C5+ from natural gas by a factor of 1.3. In this case, the compressor power required for extraction of target components is halved.

APPLICATION OF THE 3S-TECHNOLOGY FOR OFFSHORE AND SUBSEA PROCESSING

Offshore Processing

It is believed that the advantages of 3S-technology listed above make the application of 3S-technology especially promising for fields in offshore locations.

The application of 3S-technology for subsea processing of gas from the fields located at sea bed is especially effective.

At the present time, the main scheme of natural gas conditioning on off-shore fields at medium and high field pressure is the scheme of low-temperature gas separation (LTS).

The purpose of such gas preparation can be provision for both the dew-point for hydrocarbons and water and, in some particular cases, achievement of required level of HV (Heat Value) of the prepared gas.

At the initial stage of operating the fields, only the Joule-Thomson effect is used in the LTS schemes for gas cooling. This effect is realized by reducing the gas pressure in the JT-valve. When the field pressure decreases with time, turboexpanders are generally used in which gas cooling is attained not only due to the Joule-Thomson effect but also due to additional work performed by the gas.

The model LTS schemes which use the JT-valve and the turboexpander are given in Figures 10 and 11.

Natural gas is cooled in the heat-exchanger by sea water or in the air cooler AC and the recuperative heat-exchanger HE and supplied to the primary separator V-1 in which the liquid fraction (water and heavy hydrocarbons) is separated from gas. Then the gas phase from the separator V-1 is delivered to the JT-valve or to the turboexpander TE. The cooled gas from the JT-valve or the turboexpander turbine is supplied to the secondary low-

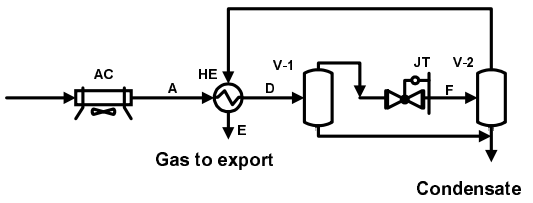

Figure 10: JT-valve LTS Process

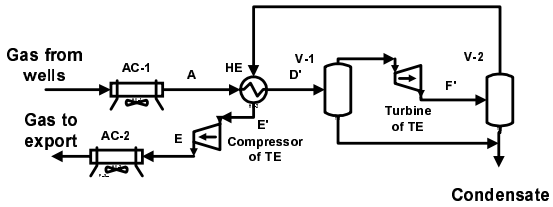

Figure 11: Turboexpander Process

temperature separator V-2, in which condensed components are separated, and then to the heat exchanger HE. Downstream of the heat exchanger gas is supplied to the gas main according to the scheme in Figure 10, but according to the scheme in Figure 11 gas is compressed in the turboexpander compressor, cooled in the air cooler and also supplied to the gas main.

The application of the 3S-separators developed by TransLang Technologies Ltd makes it possible to improve the operation of the considered schemes of gas processing.

The advantages of the 3S-separator as compared with the JT-valve are demonstrated in detail in the previous Section. Here are considered the cases when the 3S-technology offers advantages as compared with the schemes in which the turboexpander is used.

In this connection, of most interest is the case of using the 3S-technology in fields when it is necessary to maintain the pressure of the prepared gas at

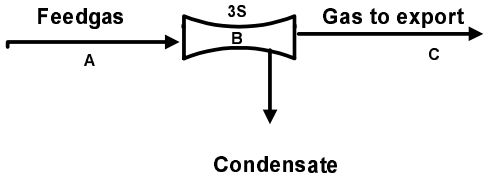

Figure 12: 3S-separator

the gas preparation facility exit at the level of ~100 bar and more. The high gas pressure level at the facility exit can be dictated by the necessity of gas transportation for long distances. This is of particular importance for versions when the prepared gas must be transported through the subsea pipe-line to the shore and then, without additional treatment, to the customer. In most cases, it is impossible to provide the natural gas conditioning using the JT-valve or the turboexpander. The reason is that in standard schemes the condensation of target components at high gas pressures is not feasible.

Figure 13 shows the phase envelope of natural gas in the "temperature –pressure" coordinates. Inside the phase envelope, natural gas represents a two-

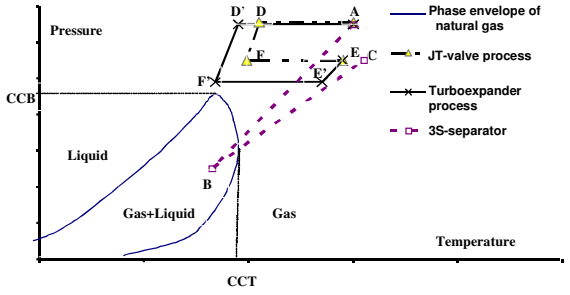

Figure 13: Diagrams of different processes of natural gas processing for high gas pressure at the facility exit

phase gas- liquid mixture. For natural gas components to be separated in the low-temperature process, it is necessary that natural gas at any process point should be in the two-phase state. At the same time, for any natural gas there are pressure Cricondenbar (CCB) and temperature Cricondentherm (CCT) above which the formation of liquid phase is impossible. For natural gases, Criconcenbar often does not exceed 100 bar, that is why at pressures above 100 bar the condensation and separation of natural gas components in the standard low-temperature processes prove to be unrealisable.

Figure 13 represents the diagrams of variations in the thermodynamic state when natural gas successively passes through different facility sections the schemes of which are shown in Figures 10–12.

The P-T diagram A-D-F-E corresponds to the scheme of the facility with the JT-valve given in Figure 10, the diagram A-D'-F'-E'-E refers to the scheme with the turboexpander (Figure 11), and the diagram A-B-C relates to the 3S-separator scheme (Figure 12). The segments A-D, A-D' and F-E, F'-E' show the gas passage through the cooling and heating channels of the recuperative heat exchanger HE, the segment D-F concerns the gas throttling in the JT-valve, the segment D'-F' reflects the gas passage through the turbine of the turboexpander TE, and the segment E'-E relates to the gas compression in the compressor of the turboexpander TE.

The diagram A-B-C corresponds to the gas passage through the 3S-separator (Figure 12). The segment A-B refers to the natural gas expansion in the 3S-separator nozzle accompanied by gas cooling, condensation of target components and separation of condensed drops of condensate, the segment B-C shows the gas compression in the 3S-separator diffuser.

In cases presented in Figure 13, neither the LTS process with the JT-valve nor the Turboexpander process provide condensation of gas components and, hence, separation of target components. While due to gas expansion up to supersonic velocities in the nozzle channel of the 3S-separator it is possible to cool gas to a sufficiently great extent and provide separation of heavy components.

Thus, the application of the 3S-technology opens up new capabilities for gas processing in offshore gas fields.

Subsea Processing

On most gas production platforms the gas pressure is limited to 100 bar. from considerations of platform and personnel safety. The gas pressure at the well-head often exceeds this by a considerable margin. This results in the necessity of installing a JT-valve at the well-head to reduce the gas pressure on the platform.

Replacement of the JT-valve with the 3S-separator will allow simultaneous solution of several problems: pressure reduction, gas dehydration, condensate (LPG) extraction together with dew-point control.

A possible scheme utilizing 3S-separator for condensate (LPG) extraction in Subsea Processing is shown in Figures 14, 15.

In these Figures, the following designations are used: 1 - Well , 2 - Well head, 3 - Condensate extraction facility, 4 - 3S-separator, 5 - Gas-liquid separator, 6 - Heat-exchanger, 7, 11 - Pipeline for condensate transportation, 8 - Gas pipeline for purified gas, 9 – offshore platform, 10 - Facility

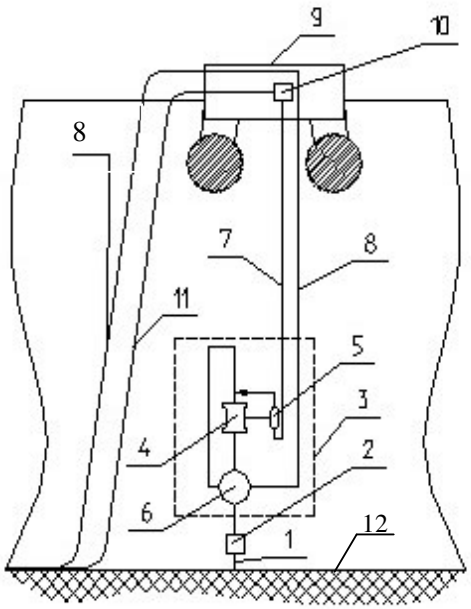

Figure 14: Application of the 3S-technology subsea

for preparing condensate for transportation, 12 – Sea land.

Gas from the well, after passing the well-head, is delivered to the processing facility with the 3S-separator mounted near the well-head located at the subsea. The facility consists of a recuperative heat-exchanger, a 3S-separator and a secondary separator for separation of the gas-liquid flow coming from the 3S-separator. The liquid mixture of hydrocarbons and water separated from the natural gas in the facility are supplied along pipelines to the platform facility to prepare condensate (LPG) for transportation.

A very important application of the 3S-separator is in a full subsea scheme. The scheme of gas preparation for transportation for this case is given in Figure 15.

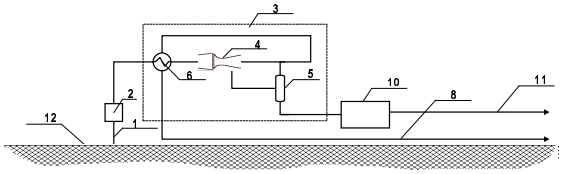

Figure 15: Fully subsea application of the 3S-technology

CONCLUSIONS

A new technology has been developed for the separation and processing of natural gas components based on the adiabatic cooling of swirling gas flow in a supersonic nozzle.

New, highly efficient, technological schemes for gas processing with 3S-separators have been designed and tested in test facilities.

There are a wide range of potential applications for 3S-separators in facilities for natural gas processing such as:

- facilities for gas conditioning;
- facilities for LPG extraction (shallow cut and deep cut);
- offshore gas separation and treatment facilities etc;
- many others (CO_2 extraction, Ethane recovery and LNG) are under extensive investigation.

In all cases considered, the technology supplied using 3S-separators makes it possible to provide a cost effective and highly efficient extraction process for C_{3+} gas components combined with a potential reduction in energy consumption.

DIABATIC TRAY DISTILLATION: EOEP AS AN APPROXIMATION TO THE STATE OF MINIMUM ENTROPY PRODUCTION

Eivind Johannessen* **and Audun Røsjorde**
Norwegian University of Science and Technology
Department of Chemistry
N-7491 Trondheim

Abstract

We show that the theorem of equipartition of entropy production is important for the understanding of the state of minimum entropy production in diabatic distillation. The theorem is not valid in a strictly mathematical sense. We explain why, when and in what sense this theorem is a good approximation to the optimal state in diabatic distillation. In order to make these predictions, we use a hypothesis for the state of minimum entropy production of an optimally controlled system, which was formulated on the basis of results of entropy production minimisation in chemical reactors. The hypothesis says that the state of minimum entropy production is characterised by approximately constant local entropy production and thermodynamic forces, given that there is sufficient freedom in the system. We present numerical results which are in agreement with the predictions. The results show that a column with constant tray entropy production in the stripping section and in the rectifying section is a good approximation to the optimal column, except when the total heat transfer area is low. The agreement between the two columns becomes better and better as the total heat transfer area and the number of trays increase. The fact that the predictions and the numerical results agree very well gives support to the validity of the hypothesis.

Keywords: Diabatic distillation, entropy production minimisation, equipartition of entropy production

NOMENCLATURE

INTRODUCTION

One way to increase the energy efficiency in traditional, adiabatic distillation is to add heat exchangers on all trays in the distillation column. This is called diabatic distillation [1]. It has been known for thirty years that diabatic distillation has a higher energy efficiency than adiabatic distillation [2, 3]. During the last ten years, minimisation of the entropy production of diabatic distillation columns has been studied extensively [4, 5, 6, 7, 8, 9, 10, 11, 12]. By minimising the entropy production of the column, the second law efficiency is maximised. The studies have shown that the potential savings of diabatic distillation are often large.

In this paper, we test a hypothesis for the state of minimum entropy production in an optimally controlled system. Based on results from entropy production minimisation in plug flow reactors, the following hypothesis was formulated [13]: "The theorem of equipartition of entropy production (EoEP, see for instance [14]), but also the theorem of equipartition of forces (EoF, see for instance [15]) are good approximations to the state of minimum entropy production in the parts of an optimally controlled system that have sufficient freedom." We want to check if the predictions contained in this hypothesis fit with the optimal state in diabatic distillation. We shall explain what the hypothesis means in diabatic distillation and test the predictions numerically.

We focus on EoEP as an approximation to the optimal state. EoEP (and EoF) was derived for models with a detailed local description of the irreversible phenomena taking place in the system [13, 14, 16]. The model which has been used in studies of entropy production minimisation in diabatic distillation does not contain such local information however (see for instance [8]). We shall therefore explain why, when and in what sense EoEP is a good approximation to the optimal state. Based on this explanation we define the "EoEP column". We shall present numerical results which show that the EoEP column is indeed a very good approximation to the optimal column, except when the total heat transfer area is low. This is in agreement with the hypothesis stated above.

Figure 1 shows a diabatic distillation column. The column has N plates, for instance sieve plates, which bring a rising stream of vapour in close contact with a descending stream of liquid. The feed stream, F, enters close to the middle of the column. The section of trays above the feed point is called the rectifying section, and the section of trays below the feed point is called the stripping section. Material leaves the column as a bottom stream, B, and as distillate, D. We consider binary distillation. The bottom stream contains thus mainly the high-boiling component and the distillate contains mainly the low-boiling component. In adiabatic distillation, heat is only added in a reboiler and only withdrawn in a condenser. In diabatic distillation, heat may also be added/withdrawn by means of heat exchangers on every tray.

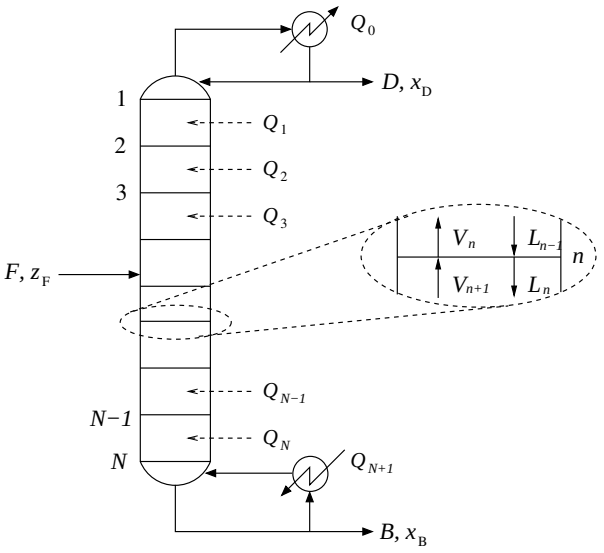

Figure 1: A diabatic tray distillation column

The studies of entropy production minimisation in diabatic distillation have focused on the optimal heating/cooling strategy along the column [4, 5, 6, 7, 8, 9, 10, 11, 12]. This strategy is represented by the heat exchanged on each tray, Q_n, in Fig. 1. In addition, the distribution of a fixed total heat transfer area, A_{total}, between all heat exchangers, has been optimised [7, 8, 12]. The optimal column with infinite heat transfer area, $A_{\text{total}} = \infty$, has been compared to the predictions of equal thermodynamic distance (ETD, see for instance [9, 10, 11]) and EoF (see for instance [4, 5]). The agreement with the true optimum was reasonably good, especially for ETD in long columns [11]. The agreement between the optimal column and EoEP has not been investigated in detail earlier, but some results suggest that parts of the optimal column have a constant entropy produc-

tion [12].

EOEP IN DIABATIC DISTILLATION

The proofs of EoEP [14, 16, 13] and EoF [15, 13], were given for processes where the total entropy production can be written as

$$\left(\frac{dS}{dt}\right)_{\text{irr}} = \int \sigma \, dz = \int \sum_i \Gamma_i J_i X_i \, dz \qquad (1)$$

Here, z is a spatial direction[1], σ is the local entropy production, Γ_i is a geometrical factor, J_i is a flux, and X_i is a thermodynamic driving force. The two most important assumptions in the proofs are that all the forces can be controlled independently and that the flux-force relations are linear (see [13] for a discussion of the assumptions needed to prove EoEP and EoF).

The model which has been used in studies of entropy production minimisation in diabatic distillation, contains very little local information, and the total entropy production can not be written in the same form as in Eq. (1), see Table 1. We shall therefore use a packed column instead of the tray column in order to explain the role of EoEP in diabatic distillation. In a packed column, condensation/evaporation at the liquid-vapour interface and heat exchange in the heat exchanger take place continuously along the rectifying and the stripping sections. At the feed point there is a mixer where the feed stream is mixed with the internal streams of the column. In addition, a condenser and a reboiler are placed at the top and at the bottom, respectively, just like in a tray column. The total entropy production of such a column can be written as

$$\left(\frac{dS}{dt}\right)_{\text{irr}} = \left(\frac{dS}{dt}\right)_{\text{irr}}^{\text{Condens.}} + \left(\frac{dS}{dt}\right)_{\text{irr}}^{\text{Reboil.}} + \left(\frac{dS}{dt}\right)_{\text{irr}}^{\text{Mix.}} + \int_0^{Z_{\text{Rectifier}}} \sigma \, dz + \int_0^{Z_{\text{Stripper}}} \sigma \, dz \qquad (2)$$

The three first terms on the right hand side of this equation are the contributions from the condenser, the reboiler and the mixer, respectively. We shall not discuss these terms in detail, but focus on the two last terms on the right. These terms give the entropy production of the rectifying and the stripping sections, respectively, and they have the same form as Eq. (1). The local entropy production, σ, has the standard form $\sum_i \Gamma_i J_i X_i$ when the local details of the processes taking place are described using irreversible thermodynamics [17]. There are four thermodynamic forces in the continuous column. Condensation/evaporation at the liquid-vapour interface involves three thermodynamic forces; the differences in chemical potential of both components across the interface and the difference in inverse temperature across the interface [18]. In addition, there is a temperature difference in the heat exchanger.

The total entropy production of the continuous column can be minimised in the following way: We fix the boundary conditions on both ends of the rectifying and the stripping sections. We then minimise the entropy production of the two sections, the condenser, the reboiler and the mixer, separately. In an outer loop, we optimise the boundary conditions on both ends of the two sections. This gives a reformulation of the optimisation problem as a combination of smaller optimisation problems. The sub-problems for the two sections are the kind of problems for which EoEP and EoF have been proved. EoEP and EoF were proved for the case when all forces in the system can be controlled independently, meaning that there are at least as many control variables as there are forces [13]. There are four forces in the column, as explain above. The controls are the heat duty along the column and the distribution of a fixed total heat transfer area. There are thus four forces and two control variables, meaning that one of the important assumptions leading to EoEP and EoF is not fulfilled [13]. This means that EoEP and EoF do not apply to the state of minimum entropy production in diabatic distillation in a strictly mathematical sense.

In order to proceed, we use the hypothesis formulated by [13]. The hypothesis says that the system will adjust to EoEP (and EoF) given that there is sufficient freedom to do so, even when there are too few control variables available. This hypothesis applies to the two sections of the distillation column, but not to the condenser, the reboiler and the mixer. The value of the local entropy production in a section of the column reflects the separation duty which is dedicated to that section. In general, the separa-

[1] Time can be used as the coordinate of the system instead of a spatial direction.

tion duty of the rectifying section and the stripping section differ, and the local entropy production will therefore be different from one section to another.

The same irreversible phenomena (condensation/evaporation and heat transfer) take place in the tray column and the packed column. The characteristics of the state of minimum entropy production in the two columns should therefore be comparable. We expect that EoEP is a good approximation to the state of minimum entropy production, also in the tray column. Based on this, we define the "EoEP column": The EoEP column is the diabatic tray column with minimum total entropy production given that the entropy production is the same on all trays in each section of the column. The condenser ($n = 0$), the reboiler ($n = N + 1$) and the tray(s) where the feed stream is mixed with the internal streams of the column, are left out in the equipartitioning[2]. The hypothesis now predicts that *the EoEP column is a good approximation to the true optimum when there is sufficient freedom in the problem*. There are many ways to change the freedom in a diabatic distillation column. In the result section, we shall discuss the effect of varying the total heat transfer area and the number of trays. The system is most free to adjust when the area and the number of trays are large. The freedom is reduced as both values decrease. The hypothesis predicts therefore that EoEP approximates the optimum best for large heat transfer areas and/or a large number of trays.

MODEL OF DIABATIC TRAY DISTILLATION

We use the standard tray distillation model that can be found in elementary textbooks on distillation (see for instance [19]). This model was also used in earlier studies of entropy production minimisation in diabatic distillation [8]. The model consists of two independent mole balances and a balance equation for the internal energy on each tray. Furthermore, the pressure drop is neglected and equilibrium is assumed between streams leaving a tray. For instance, the vapour stream V_n and the liquid stream L_n in the small frame in Fig. 1 are assumed to be in equilibrium with each other. Some minor modifications of the standard model are done in order to account for the heat exchange on each tray: A model of the heat exchangers is added and the heat added/withdrawn on each tray is taken into account in the balance equation for the internal energy. The model equations are summarised in Table 1. See [8] for details.

Table 1: Equations for binary tray distillation

Total mole balance:

$$V_{n+1} - L_n = \begin{cases} D, & n \in [0, N_\mathrm{F} - 2] \\ D - (1-q)F, & n = N_\mathrm{F} - 1 \\ D - F, & n \in [N_\mathrm{F}, N+1] \end{cases}$$

Mole balance for the light component:

$$V_{n+1} y_{n+1} - L_n x_n = D\,\kappa$$

$$\text{where } \kappa = \begin{cases} x_\mathrm{D}, & n \in [0, N_\mathrm{F} - 2] \\ x_\mathrm{D} - (1-q)F z_\mathrm{F}, & n = N_\mathrm{F} - 1, \\ x_\mathrm{D} - F z_\mathrm{F}, & n \in [N_\mathrm{F}, N+1]. \end{cases}$$

Balance equation for the internal energy:

$$Q_n = V_n H_n^\mathrm{V} + L_n H_n^\mathrm{L} - V_{n+1} H_{n+1}^\mathrm{V} - L_{n+1} H_{n+1}^\mathrm{L} - \gamma$$

$$\text{where } \gamma = \begin{cases} (1-q)\,F\,H_\mathrm{F}^\mathrm{V}, & n = N_\mathrm{F} - 1, \\ q F\,H_\mathrm{F}^\mathrm{L}, & n = N_\mathrm{F}, \\ 0, & \text{otherwise.} \end{cases}$$

Average heat exchange force:

$$X_n = \left(\delta / \lambda_n\, T_n^2\right)\, (Q_n / A_n)$$

The total entropy production:

$$\left(\tfrac{dS}{dt}\right)_\mathrm{irr} = B S^\mathrm{B} + D S^\mathrm{D} - F S^\mathrm{F} + \sum_{n=0}^{N+1} \left(Q_n X_n - \tfrac{Q_n}{T_n} \right)$$

CALCULATIONS

We have studied three tray columns: The adiabatic column, the optimal column, and the EoEP column. The results for these columns are marked with "Adiab", "Diab. opt." and "Diab. EoEP", respectively, in Figs. 2 to 9.

The adiabatic column and the optimal column were found as described by [8]. The EoEP column was found using sequential quadratic programming with the *Matlab® 6* function *fmincon*. As the initial guess of the solution, we used the optimal column.

[2]The tray(s) on which the feed is mixed with the internal streams, depends on whether the feed is a liquid ($n = N_\mathrm{F}$), a vapour ($n = N_\mathrm{F} - 1$) or a mixture of both ($n = N_\mathrm{F}$ and $N_\mathrm{F} - 1$). See the equations in Table 1.

Table 2: Parameters

P / atm	1
F / (mol/s)	1
Feed temperature / K	360
z_F	0.5
x_D	0.95
x_B	0.05
δ / m	10^{-5}
