Preface

The organising committee for "The 18th International Conference on Efficiency, Cost, Optimization, Simulation, and Environmental Impact of Energy Systems" – ECOS 2005 – welcomes you to Trondheim! The motto of ECOS 2005 is *Shaping our future energy systems*. The participants of ECOS 2005, *you*, are central for the realisation of future energy systems that our world, our ecosystem, can sustain.

ECOS 2005 features more sessions on renewable energy sources than in previous ECOS events. In particular, the session on CO_2 handling and storage is expanded. Industrial ecology and environmental issues are high on the agenda. Special activities in the Nordic regions of Europe colour the program through these sessions. Still, the core of ECOS consists of contributions showing state-of-the-art engineering methods that rest on the foundation provided by thermodynamics.

This year we honour the developers of non-equilibrium thermodynamics: Prigogine, de Groot, and Mazur. This theory, which forms a bridge between the nano-, micro-, and macroscales, may prove invaluable as engineering problems become more molecular in character.

The organising committee is grateful to the sponsors that have helped realise the meeting. Special thanks also go to our reviewers, without whom this conference could not be at its high-quality level, and to Enrico Sciubba and Noam Lior for organising panel sessions. The panel discussions together with the other formal and informal discussions at ECOS 2005 sharpen our critical thinking about energy systems and help us prepare for dealing prudently with future societal power needs.

The organising committee wishes new and old members of the ECOS family
a fruitful stay in Norway,

Signe Kjelstrup

Anne Langseth Gunhild Valsø Engdal Olav Bolland Edgar Hertwich

ABSTRACT

The three pillars of non-equilibrium thermodynamics have passed away within the last decade. Although they all followed in the footsteps of Onsager, they were able to extend the horizons beyond his contributions through their own research, students, and publications. As engineers, however, we have not been very enthusiastic or seem not to be too concerned with non-equilibrium situations; nevertheless, it seems that we have to be able to respond to new technological developments in material science and engineering as well as emerging applications to engineering processes and systems that are challenging us in today's world. To be able to do this, we at least must teach the appropriate material to our students in class and through research problems. It is only then that we will have prepared the future generation to tackle the problems at hand today and those that will appear in the future.
Keywords: De Groot, Mazur, Prigogine, Onsager, non-equilibrium thermodynamics

INTRODUCTION

In this presentation we will pay homage to three people, Sybren de Groot, Peter Mazur, and Ilya Prigogine, who have contributed so much to the use of the Onsager [1] principles in application to non-equilibrium situations in natural phenomena through their individual work, the contributions with their students, and various publications they have produced over very productive years. However, the concept of *irreversibility* started much earlier by Clausius [2] in the discussion of *non-compensated heat*, by Stokes [3] in the discussion of *energy transfer in crystals*, and by Thomson (Lord Kelvin) [4] in the discussion of *a coupled thermo-electric phenomena,* where a direct reference to non-equilibrium situations were made. Much later, Duhem [5] was able to combine the second law of thermodynamics with the three laws of conservation of mass, momentum, and energy to obtain the *local rate of entropy generation*. De Donder [6] was able to extend this by the introduction and use of *affinity* in chemical reactions for the first time. Another decade had to pass before Onsager formulated and published in two concurrent papers [1, 7] his Nobel Prize worthy seminal *reciprocal relations* which connect the coefficients of linear phenomenological laws that characterize coupled irreversible processes. About another decade later, Meixner [8], in a series of articles, followed by Prigogine [9], in his thesis presented at the l'Université Libre de Bruxelles, were able to obtain a consistent set of phenomenological coefficients for irreversible phenomena that successfully incorporated Onsager's reciprocity relations. As a result, they were able to determine the *entropy source strength* for a number of physical situations of interest thus laying the fundamental groundwork for the study of *irreversible*

thermodynamics of natural systems. Simultaneously with Prigogine in 1945, de Groot published his thesis research [10], presented at the Gemeentelijke Universiteit te Amsterdam, on the flow of matter caused by a temperature gradient, a coupled non-equilibrium situation. One of de Groot's students Mazur, who also worked with Prigogine in Brussels, published his thesis at Universiteit Utrecht [11] on the *thermodynamics of transport phenomena in liquid helium-2*, particularly the so called fountain effect, that verified the experiments performed at the Kamerlingh-Onnes Laboratory in Leiden. Now that we have seen how these three great men of non-equilibrium thermodynamics have started their careers, we can discuss the life and contributions of each.

Sybren de GROOT

Sybren de Groot was born on April 8, 1916 in Amsterdam. He studied theoretical physics at the Gemeentelijke Universiteit te Amsterdam with J. D. van der Waals. During 1942-1947 he was an assistant in the van der Waals Laboratory under the direction of A. Michels. During this time, he received his doctorate upon presentation of his thesis [10] to C. J. Gorter. The topic of the Soret effect on the macroscopic theory of thermal diffusion was very important and of interest in isotope separation. Because of this and at the invitation of Fréderic Joliot-Curie, the Haut-Commisaire à l'Energie Atomique of the Laboratoire de Chimie Nucléaire, de Groot was appointed Chef de Service at the Collège de France in Paris. He was able to continue his doctoral research making calculations on beta- and gamma-rays including angular effects as observed in the emission of oriented and polarized nuclei. A year later, he returned to Utrecht as a Lecturer and was appointed Professor of Theoretical Physics in 1949. In 1953, he moved to Leiden and was appointed Professor of Theoretical Physics following H. A. Kramers and took over the institute which would later be renamed Instituut-Lorentz. He continued, as the organizer for the famous Colloquium Ehrenfestii at Leiden that was founded by Paul Ehrenfest in 1912. He held these positions until 1964 when he went back to Amsterdam where upon his retirement he was appointed as Professor Emeritus in 1984. In 1951, at a very early age, he published his first book on the thermodynamics of irreversible processes [12]. This book contains both the statistical basis and particular topics of the macroscopic theory of irreversible processes. It contains a wide range of transport processes along with appropriate averaging procedures and effects of microscopic symmetries. It is this topic that has brought worldwide recognition to de Groot. It is also interesting to note that this book came out at the same time as his student Mazur was presenting his own thesis [11]. This actually set the stage for all developments on this topic in the Netherlands and in the scientific community for years to come and which still continues through his students and their students. In 1962, de Groot and Mazur were able to further diversify the study of irreversible processes and published their work [13]. In this book, the principles of the macroscopic derivation of Onsager [1, 7] along with the property of time reversal invariance as discussed by Casimir [14] and further remarks of Wigner [15] are all included. The macroscopic Curie principle was derived from microscopic crystal symmetries. Entropy production was also evaluated as were the statistical foundations of kinetic and fluctuation theories, the stochastic laws, and causality conditions. The applications to transport phenomena, including electromagnetic, chemical, and acoustical processes are also included. De Groot and Mazur were comprehensive and original in the proofs presented [13]. De Groot's work in Amsterdam covered the topics of micro-theory, transition from micro- to macro-theory, and macro-theory that permitted him to continue his publications of books on Maxwell's equations [16], on the fundamentals of electrodynamics with Suttorp [17], on the Weyl transformation and the Wigner function [18], and on relativistic kinetic theory principles and applications with van Leeuwen and van Weert [19], after the publication of a number of papers on relativistic transport processes. His collaborative work with Mazur that started in 1950 continued through 1966, even after he had left to go back to Amsterdam, and culminated in some twenty-six additional publications. Most of these were included in their book [13]. Through his personal initiative and those of his students, particularly Mazur, the oldest institute for theoretical physics in the Netherlands, founded in 1921, was renamed Instituut-Lorenz and became known throughout the world. Through his personal relationships, de Groot made the Lorentz Professorship an enviable position that invited persons recognized in

their fields. Among many of these visitors were Uhlenbeck who developed the theory of electron spin, Wigner who was the famous nuclear physicist and the pioneer of microscopic quantum theory, and van Vleck famous for atomic magnetism. It is interesting to note that two of the three were later selected to receive the Nobel Prize in physics, and two were awarded the Royal Netherlands Academy of Science's Lorenz Medal. De Groot was awarded an honorary doctorate by the University of Strasbourg where he was a Visiting Professor during 1958-1963. In 1958, he became a member of the Royal Netherlands Academy of Science. He was honored by the French Académie Européenne des Sciences, des Arts et des Lettres. He was made a Chevalier de la Légion d'Honneur. Upon his retirement he became an Officier and was made a Knight of the Order of the Netherlands Lion. De Groot was a special person; his lectures were exceedingly lucid, without extraneous details but mixed with subtle jokes. He was a superb physicist who freely shared his vast knowledge with his friends, students, and colleagues. His students could count on his loyalty and support and were inspired by his example. He died on May 9, 1994 leaving behind a legacy carried on by his students.

Peter MAZUR

Peter Mazur was born on December 11, 1922 in Vienna. He attended high school in Paris and The Hague. After going into hiding in the Dutch countryside for a few years during the war, Mazur started his studies in chemistry at the University of Utrecht. He did his research in theoretical physics with de Groot. His major contribution at this time was on the application of irreversible phenomena to spatially continuous systems such as superfluids. Prior to defense of his thesis research in 1951, he spent two years as a research associate with Prigogine at the Université Libre de Bruxelles. These two experiences were the start of a long and illustrious career that spanned five decades. He returned to Utrecht from Brussels as the Senior Scientific Associate in 1952 and spent the next year at the University of Maryland, the first of his many visits to the United States. In 1954 he was appointed Lecturer at the University of Leiden, a position he held until 1961 when he was promoted to Professor of Theoretical Physics. Upon Professor de Groot's departure to Amsterdam, Mazur became the Director of Instituut-Lorentz for Theoretical Physics in 1964, a position he held for a quarter of a century, before he became a Professor Emeritus in 1988. During the period of 1962 through 1991, he was appointed a Visiting Professor in France, Italy, Japan, Canada and the United States on a number of occasions, even after he had retired from Leiden. Mazur was the organizer of the Colloquium Ehrenfestii from 1964 until 1978, a tradition that was started by Ehrenfest in 1912. Like de Groot, Mazur collaborated with many people including Prigogine during early years in Brussels. In all, Mazur published one hundred fifty seven papers. He published twenty-six papers with de Groot, and twenty-nine papers with Bedeaux, a post-doctoral student and prolific collaborator of his since 1973. He published another six papers with Prigogine starting in 1951. Mazur's work started with liquid helium and its characteristics. Next he developed a microscopic basis for systems based on non-equilibrium thermodynamics within the framework of classical mechanics. This was later extended into quantum mechanics. Thermodynamics of thermo-magnetic and galvano-magnetic effects and the extension of Onsager relations to these phenomena along with relativistic thermodynamics of irreversible processes followed. In subsequent years, a great breadth of subjects within statistical physics were tackled with remarkable unity of style starting with a very clear statement of the problem followed by a detailed and complete derivation of results. In his last years, the emphasis of research was centered on Brownian motion [20] ending with the last paper on non-equilibrium thermodynamics of quantum systems [21], published after his death. Mazur was recognized by his election as member of the Royal Academy of Sciences of the Netherlands in 1970, his appointment to the Board of the International Union of Pure and Applied Physics during 1966-1984, and the Dutch Foundation for Fundamental Research of Matter during 1970-1985. He was also honored by the French Académie Européenne des Sciences, des Arts et des Lettres in 1987. Prior to his retirement in 1988, he was made a Knight of the Order of the Netherlands Lion. In 1991, he was elected to be a Member of Academia Europaea. Peter Mazur was an authoritative scientist, a superb teacher and colleague to his students and collaborators, and was an animated and flamboyant physicist. He showed his caring and interest in his students, sometimes very formally and often with a warmhearted elegance. His knowledge

and interests encompassed not only science in general and physics in particular, but also almost all fields of intellectual endeavor including literature, art, music, and history. He died on August 15, 2001 leaving behind him his students and other collaborators to carry the torch.

Ilya PRIGOGINE

Ilya Prigogine was born on January 25, 1917 in Moscow. He studied chemistry and physics earning his doctoral degree in 1941 and presenting his thesis for habilitation in 1945 [9], all at the Université Libre de Bruxelles. In 1951 he was appointed Professor in the Faculty of Sciences of the same university until his retirement in 1987. One of his first collaborators was Mazur, who came to Brussels in 1950. Prigogine and Mazur were able to publish six papers within two years. After Mazur's return to Utrecht, Prigogine and his students continued a very productive and successful path in studying many practical problems in physical chemistry and the foundations of quantum mechanics. This produced a series of sixteen authored or co-authored books along with hundreds of specialized papers with students and associates throughout the world. The great contribution of Prigogine to thermodynamic theory is his successful extension of it to systems that are far from thermodynamic equilibrium. Prigogine and his students were able to demonstrate that a new form of ordered structures can exist under such conditions. He gave them the name, *dissipative structures*. An example is Benárd instability, in which the structure is wholly dependent on the supply of energy and disappears when it ceases. Dissipative structures exist only in conjunction with their environment. Close to equilibrium, order in dissipative structures tends to be destroyed. Far from equilibrium, order can be maintained and new structures formed. Prigogine and his group's researches into irreversible thermodynamics have fundamentally transformed and revitalized the science, giving it a new relevance and creating theories to bridge the gaps between chemical, biological, and social scientific fields of inquiry with a distinguished and unequalled elegance and lucidity [22]. Under the influence of de Donder, Prigogine focused his attention on the macroscopic and microscopic aspects of the second principle of thermodynamics. He extended its validity to new situations, and other fundamental approaches to theoretical physics, such as classical and quantum dynamics. Timmermans, another teacher of his, was an experimentalist and was interested in the application of classical thermodynamics to liquid solutions of complex systems. Timmermans confronted him with the precise application of thermodynamic methods including the solutions theory, the theory of corresponding states, and isotopic effects in the condensed phase [23]. Prigogine, contrary to the standard approach which discussed degradation and *loss of useful work*, attributed to irreversible processes a constructive role. He believed that living things provided us with striking examples of systems that were highly organized and in which irreversible phenomena played an essential role. Thus, following the concepts of linear thermodynamics of irreversible processes as studied by Meixner [8] and de Groot and Mazur [13], Prigogine simultaneously published his work on non-equilibrium statistical mechanics purely from a dynamical point of view [24]. Later Prigogine and Glansdorff were able to develop a general evolution criterion valid far from equilibrium and out of the validity domain of the minimum entropy production theorem. Stability criteria that resulted led to the discovery of critical states [25]. Next he built a new kinetic model generated through diffusion-reaction processes that caused the rapid development of the study of dissipative structures. Prigogine and Nicolis were able to show that an unexpected phenomenon appeared when the fluctuation problem in nonlinear systems far from equilibrium was considered, such as chemical kinetics of non-equilibrium phase transitions [26]. Prigogine believed throughout his life that he could find a connection between the physical sciences, biology, and human science. He was able to accomplish this by many publications as stated in his Nobel Prize recognition [22]. Prigogine's last collaborations with his students led to topics of irreversibility of states in quantum mechanics [27], which appeared after his death. Starting in 1967, he was a Regental Professor and Ashbel Smith Professor of Physics and Chemical Engineering at the University of Texas-Austin and founded the Ilya Prigogine Center for Studies in Statistical Mechanics and Complex Systems. Since 1959, he was the Director of the International Solvay

Institute in Brussels. Among other awards, Prigogine was awarded the title of Viscount by the King of Belgium. Recipient of fifty three honorary degrees, he was a member of sixty four national and international professional organizations including the National Academy of Sciences and the American Academy of Arts and Sciences. He was a Special Advisor to the European Community and an Honorary Member of the World Commission of Culture and Development of UNESCO. He received various medals from Sweden, England, Italy, Russia, and France culminating in the award of Commander of the World Order "Science, Culture, Education" of the European Academy of Information in 2002. The University of Siena and the Wessex Institute of Technology in Southampton, UK have instituted two special medals and prizes in his name for best papers submitted on the topic of *ecological systems*. Prigogine died on May 28, 2003 in Brussels. There is no question that his students of the first and second generation are now working with those of the third generation throughout the world to continue his legacy.

HOW I REMEMBER PRIGOGINE, de GROOT and MAZUR

It is not too often that one gets an opportunity to meet with people of renown in their lifetimes. I personally was very fortunate and privileged to have met with each one of these three giants of irreversible thermodynamics first in the Netherlands and Belgium and then in the United States. As a Professor of Mechanical Engineering at Louisiana Sate University-Baton Rouge, I spent my sabbatical years as a Visiting Professor and Research Fellow at the Institute of Thermodynamics of the University Liége with Professor Burnay and as a Visiting Research Professor at the Institute of Heat Technology of Eindhoven University of Technology with Professor van Koppen during the two academic years, 1972-73 and 1979-80. Since my doctoral work was *on non-equilibrium thermodynamics of magneto-solid-mechanics* as applied to special power systems [28], I specifically wanted to go to Europe to have an opportunity to meet these three masters of the topic. It turned out that opportunities did present themselves in different ways. My contact with Prigogine was on personal initiative. After learning more about his personality from people at Liége, I contacted him in writing and followed up by phone. He invited me to visit him at Brussels in his university office. As is my personal custom, I arrived a little early and started looking through the corridors. When the time came, I went to his office. He was very friendly and kind although I noticed that he was very uneasy. Finally he said that we needed to get away from the university since he had told the King that he "could not meet with him that day" because he was going to be busy with me. So we left his office, rushed through the corridors, not the ones used by everyone, and got to his car. He drove away in haste to a restaurant where they knew him. Promptly and at his request we were seated at the very back, away from the crowds. We had not only a wonderful lunch but also discussed many topics for which I had questions and those that he offered on his own. I believe we stayed there about four hours. A few years later, at the invitation of the Chemical Engineering Department at Louisiana State University-Baton Rouge, Prigogine came to present a seminar. Coincidentally at the same time Professor E. P. Wigner, a Nobel Laureate himself, was spending the semester in the Physics Department. The seminar room was packed with Wigner seated at the very front. Prigogine made his presentation with no sound in the room. When he finished, a question/answer period was to follow. Before anyone had a chance, Wigner challenged Prigogine on some issues. The discussion, question-counter question went on longer than the seminar. Finally, Wigner said that it was best "to continue their agreement to disagree" which was received with a lot of laughter and applause. That evening, we went to dinner. Sitting around the table and enjoying the food and the conversation, we noticed a commotion in the restaurant. Prigogine saw immediately that a man was suffocating. Without hesitation he took off and did the appropriate things to relieve the food from the throat of the man. He returned to our table and continued his wonderful discussions into the late hours of the evening as if nothing had happened. Towards me he was most kind and generous with his thoughts. He highly encouraged my research and teaching at that time, including continuing my doctoral research work into new directions and teaching advanced courses in all fields of thermodynamics including non-equilibrium

thermodynamics. His thoughts on all these issues were most beneficial to me. During my stay at Eindhoven, Professor van Koppen gave me much latitude in my work and studies. We had decided that I would investigate the validity of two-phase correlations used in the design of heat exchangers and would determine under what conditions the second principle would be violated so as to have a string of correlations that should be used depending on flow characteristics. When I found out that de Groot was to present a seminar in the Physics Colloquium, I made arrangements to attend and asked for time to meet with him personally. My request was accepted by de Groot and, upon completion of his seminar, we spent a couple hours on the problem on which I was working. I found him to be a very generous person as well. His precise remarks as well as no nonsense attitude were what impressed me the most. He understood my point of view on the problem and made remarks that would prove to be very valuable and precise. He was not as flamboyant as Prigogine but rather reserved. A couple of months later, I found out that Mazur was coming to present a seminar. Again, as I had done with the other two, I arranged to meet with him personally after his seminar presentation. Mazur seemed to be enjoying life to the fullest. He was smiling, making remarks and jokes, and just seemed happy. After he found out who I was and what I was doing in the crowd of chemists and physicists, he became very friendly and made the remark that he "always wanted to have engineers working with him because they could do, understand, and think about situations differently." Again, we spent a few hours discussing mostly my questions. He provided different situations based on his experiences. Indeed Mazur was very kind, accommodating, and just a pleasant person. I cherish these encounters and wish that I had had more contact with each of them so that I could have expanded my understanding of nature through thermodynamics. For me, these are very fond memories of these three pillars of thermodynamics to whom we all owe much.

THERMODYNAMICS IN ENGINEERING

It is a very well known fact that thermodynamics education in the United States, in particular, is not in a healthy state. This situation starts at the undergraduate level and goes through the graduate programs in mechanical engineering. It may be the same situation in chemical engineering, but I will let those knowledgeable about that situation speak and write about it. In the last decade in the United States, most undergraduate mechanical engineering departments have reduced the required coverage of thermodynamics from an equivalent six semester credit hours to four or even three. At the same time some textbooks, written by people who did not understand the field and who have never studied it, were adopted extensively due to their "ease of reading". Since those who studied thermodynamics at the graduate level have decreased dramatically over the last two to three decades, the faculty to teach thermodynamics have been those who themselves never learned the subject. Thus, these textbooks fit the needs of the instructors very well since the students would not challenge them with questions that they could not answer. Therefore, as undergraduates were not taught complete material and graduates were not given the opportunity to study at a higher level, the quality of teaching thermodynamics has deteriorated. During my graduate years in late 1950s and early 1960s, mechanical engineering programs taught classical, statistical, and non-equilibrium thermodynamics at the graduate level. The books that taught us were those of Callen [29] and de Groot and Mazur [13] along with those in statistical thermodynamics, mostly written by physicists and chemists. When my generation started their academic careers, we continued in this mode. However, as time went on due particularly to the lack of research funding in the field, the number of graduate students has dwindled. Today in most universities, one cannot find more than one course offered at the graduate level. The numbers who take this course is way down from what it used to be making the situation even worse since we are not educating thermodynamicists. This situation perpetuates itself by having people who have not studied thermodynamics teaching those at the undergraduate level and beyond; a vicious circle. What my hope is to have this dialogue here so that we all can find an appropriate approach to resolve this problem. However, there are encouraging developments. Recently Bejan [30] has written a text that could be used at the graduate level. However, in some places, the contents are not in

sufficient depth to bring the student to a high level of understanding of thermodynamics. Demirel and Sandler [31], both chemical engineers, have written a review article on *non-equilibrium thermodynamics in engineering and science*. In this detailed study, they describe the importance of the topic in engineering, which is very encouraging indeed. I am hopeful that they are actually offering courses at their institutions which are available to mechanical engineering students as well. It would be a great pity if students are not taking advantage of these professors' interests and expertise in the field. It is really a great shame, in my opinion, that we have permitted the deterioration of the teaching of thermodynamics at all levels in universities. We have not been able to fight the faculty and administrators that make these decisions. The undergraduates are not taught why certain processes occur the way they do in thermodynamics and if a given process or system can actually exist, the use of the second principle. The graduate students are not given the chance to understand and apply thermodynamic principles within problems of research. The research that is required for materials engineering and challenges that we face in new materials by design of novel energy systems at the nano-scale, for example, definitely require innovation that can only occur if we teach the appropriate material. Even for the simplest case of linear non-equilibrium situation of thermo-electricity, the material needed has to have inverse characteristics of thermal and electrical conductivities. As long as we cannot develop this type of material, we cannot expect this energy conversion system to be successful. In other non-equilibrium situations, similar problems are faced. This is what is meant above when we discuss materials by design. I believe that intelligent study of thermodynamics will permit us to at least know what is needed so that others can develop the appropriate solutions to help us in various energy conversion schemes. In my opinion, we are not going to be successful if we do not teach the required thermodynamics at the graduate level. I am not proposing three courses; however, I am proposing the appropriate coverage of topics, not necessarily as separate courses, but as integrated topics. One such course could use the book of Callen [29] which I still believe is the best that there is and that has been written to date. This book contains not only a novel approach to classical thermodynamics but presents an exceptionally good introduction to both statistical and non-equilibrium thermodynamics. In this fashion, the student gets a good overall appreciation of what thermodynamics is and can easily expand into areas of advanced thinking and of research. We, as thermodynamicists particularly in this group of participants from throughout the world, must take control of our own destiny and make sure that we teach and research what we should. My hope is that we can actually accomplish this very soon at the undergraduate and graduate levels for the challenges of the 21st century.

ACKNOWLEDGEMENTS

I would like to acknowledge Professor Kjelstrup and Bedeaux for asking me to make this presentation at the dinner of ECOS 2003 in Copenhagen. My thanks also to Professor Eric Mazur, of Harvard University, who supplied me with information about his father and helped with the translation of the obituaries that were written in Dutch that Professor L. G. Suttorp of the University of Amsterdam sent me. Other obituaries that are in the literature about these three men were also used. Without their help, I could not have paid appropriate and personal respects to de Groot, Mazur, and Prigogine.

The views expressed herein are those of the author and do not purport to reflect the position of the United States Military Academy at West Point, the Department of the Army, or the Department of Defense.

CLIMATE CHANGE AND ENERGY POLICY: THE IMPORTANCE OF SUSTAINABILITY ARGUMENTS

Professor Roland Clift*,
Centre for Environmental Strategy,
University of Surrey, GUILDFORD,
Surrey GU2 7XH, UK

ABSTRACT

It is the stated policy of the UK government to reduce emissions of carbon dioxide by 60% by 2050. This policy, which goes far beyond commitments under the Kyoto agreement, was originally advocated by the Royal Commission on Environmental Pollution, of which the author was a member. Its acceptance was seen by many as a surprising development, possibly reflecting strength of the underlying case. The target was developed by a three-legged argument which reflects the three components of sustainability:

Environmental constraints: limits on emissions to avoid risk of major climate change;
Social equity: equal per-capita allocation of emissions;
Techno-economic: the feasibility and cost of reduction on this scale.

Assessment of techno-economic feasibility required a new evaluation of the role of different primary energy sources in the UK, including the contribution of biomass and recognising the importance of heat in the national energy balance. It also showed clearly the decisions to be made over both carbon dioxide sequestration and the future of nuclear power.

INTRODUCTION

The author was, until recently, a member of the Royal Commission on Environmental Pollution (RCEP), a uniquely UK institution appointed *to advise on matters, both national and international, concerning the pollution of the environment; on the adequacy of research in this field; and the future possibilities of danger to the environment*. The RCEP has been in continuous existence but with rotating membership since 1971. It is constituted as a body of independent experts, standing outside the political mainstream but intended to provide advice to guide long-term environmental policy. An important role for the RCEP is to present scientific evidence and its implications which may be obvious to the scientific community but politically inconvenient. Some of the RCEP's reports have had a significance which extends outside the UK; for example the concepts of Integrated Pollution Control and Best Practicable Environmental Option originated with the RCEP.

In one of its more recent reports [1], the Royal Commission addressed the issue of climate change and its relationship to energy supply. The principal recommendation of the RCEP's analysis was that carbon dioxide emissions from human activities in the UK must be reduced by 60% below 1998 levels by 2050. The year 2050 was itself chosen carefully: even the most enthusiastic advocates of nuclear fusion did not consider that it would be available before 2050, so that the target would have to be met by known energy technologies[1]. At the time, this target appeared to be too radical to be politically acceptable; for example, it goes way beyond current negotiations under the Kyoto protocol. However, it was accepted and is now UK Government policy. The present paper reviews the argument which presumably led to its acceptance and some of the implications of this policy.

[1]RCEP also recommended a decrease of 80% by 2100, but the reasons for proposing this very long-term target are not discussed in this paper.

THE CONTEXT: SUSTAINABLE DEVELOPMENT

The concept of sustainable development is now sufficiently well known that it will not be rehearsed here. However, a particular interpretation of sustainable development which has proved useful in teaching the concept to engineers and scientists [2] will be reviewed, because it happens to illustrate and support the argument developed by the RCEP [1].

The basic idea is that human activities are limited by three sets of long-term constraints, summarised by the Venn diagram in Figure 1. **Eco-centric concerns** represents the constraints imposed by the fact that the earth is, in thermodynamic terms, a closed system. Thus, energy flux is received from the sun, but the "capital" resources available to us on a global scale are finite, as is the capacity of the biosphere to absorb or adapt to the emissions from human activities. **Techno-centric concerns** represents the constraints imposed by finite human abilities: the technology which we are able to deploy and the economic system within which we deploy that technology. This lobe represents the traditional scope of engineering. **Socio-centric concerns** represents human expectations: the need to provide *a better quality of life for everyone, now and in the future* (to quote from the UK Government's interpretation of sustainable development). This lobe incorporates the principle of inter- and intra-generational equity which are central to the concept of sustainable development. Sustainability is to be found in the central area of Figure 1, which meets all the sets of constraints, while sustainable development is a process of moving towards that region. While it is recognised that Figure 1 is a simplistic representation of a very rich concept, it has nevertheless proved to be useful as an educational device.

Although not stated explicitly in the RCEP report, it is implicit that future use of fossil hydrocarbons will be constrained not by their availability but by the capacity of the biosphere to adapt to the emissions, specifically carbon dioxide. In other words, we already know the whereabouts of more fossil fuels than can be burned without risking disastrous climatic impacts. The driver for change in energy technology is therefore the effect of the emissions, not limited supply; as Sheikh Yamani famously put it, "The stone age did not end because we ran out of stones". To support this argument, current crude oil prices make it not only economic but very profitable to exploit oil sands; the quantity of "synthetic crude" available in Alberta is of the same order as the oil reserves in Saudi Arabia – a simple fact which is sometimes overlooked in discussions over the extent of remaining oil reserves. While the conventional market system can deal with scarcity of supply through rising prices which make new reserves economic, it is necessary to invent a new mechanism to deal with scarcity of "carrying capacity" to absorb emissions. It remains to be seen whether emission trading systems like that being introduced in Europe will constitute an effective market, whether the price will be sufficiently high to influence energy use and whether prices will be too unstable for effective long-term planning and restructuring.

The Royal Commission sidestepped the economic arguments over the damage costs of carbon dioxide emissions by approaching the issue of energy policy and climate change in a different way, using the approach of recognising and trying to estimate the constraints.

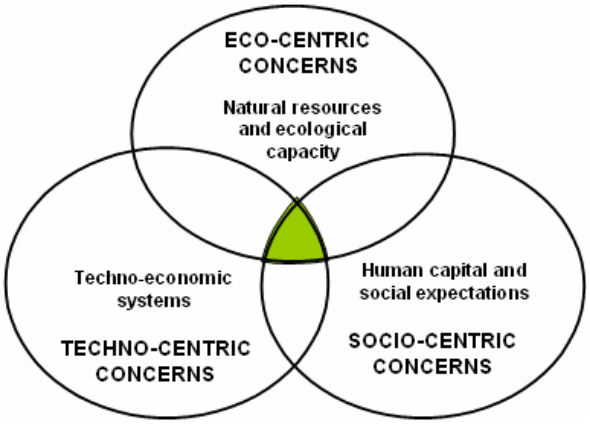

Figure 1: Sustainability expressed as long-term constraints [2]

POLICY RECOMMENDATIONS

The Royal Commission's report starts with an analysis of the evidence that emissions of climate-forcing "greenhouse gases" from human activities are causing changes in the global climate and regional weather patterns. In effect, it endorsed the conclusions of the UN Intergovernmental Panel on Climate change (IPCC). To quote the RCEP report

[1], *the world is now faced with a radical challenge of a totally new kind which requires an urgent response… By the time the effects of human activities on the global climate are clear and unambiguous it would be too late to take preventive measures*. This statement may not be news to the scientific community in Europe, but was necessary at the time of publication (2000) to underpin the Commission's recommendations; although the UK government now stresses its belief that climate change represents a real and serious threat, this commitment has emerged since publication of the RCEP report.

Of more interest here is the analysis which followed, which had three principal steps.

1. If the concentration of carbon dioxide in the atmosphere gets too high, then there will be a risk of really catastrophic climate change associated, for example, with changes in ocean circulation patterns. RCEP proposed 550ppm as the ceiling, a constraint which must not be breached. Some would prefer a lower limit – at 550ppm, the predicted rise in sea level is still bad news for low lying Pacific islands, for example – but there was also a measure of political realism behind the figure (see below).

2. Working back from the 550ppm constraint, RCEP estimated the total tolerable CO_2 emissions, and then divided them by total global population to get the *per capita* ration. Multiplying by the population of the UK gave about 40% of current emissions – hence the recommended target of a 60% reduction. This is known as the "contract-and-converge" principle. It simply ignores economists' attempts to calculate an optimal level of CO_2 emissions, on the basis that the damage cost figures mean little when the whole system is so complex and non-linear (and therefore chaotic) that detailed predictions of climate change (as distinct from estimating thresholds or constraints) are meaningless.

3. To explore the practicality of the 60% reduction target, RCEP developed representative scenarios to illustrate how it might be achieved (see below). Based on these scenarios, the cost of shifting to a low-carbon energy economy was subsequently estimated as about 2% of GDP from now to 2050. The cost is sometimes described as "enormous" but, as an economist will always ask, compared to what? The economists who produced these estimates also project 4% annual growth in GDP. So taking action to limit the potentially catastrophic effects of global climate change would merely slow down the rise in consumer spending in developed countries. Given that most forms of consumer spending lead to carbon dioxide emissions, there is a possible argument that this will in itself have some effect in constraining the growth of climate-forcing emissions.

It is interesting that, although not consciously formulated in terms of the approach to sustainability summarised in Figure 1, the three steps in the argument map exactly onto the three sets of constraints: ecological, societal and techno-economic. Perhaps this illustrates the strength of this approach to sustainability analysis. To quote the RCEP report again [1], … *the UK could cut its carbon dioxide emissions by 60% by 2050. Achieving this will require vision, leadership, and action which begins now*. Acceptance of the target of 60% reduction by 2050 has, so far at least, survived subsequent discussions over commitments under the Kyoto process and softening of UK government targets for shorter term reductions. In fact, the UK government has been advocating international acceptance of the 2050 target, and the Swedish government has also adopted it as a basis for energy policy.

ENERGY SCENARIOS

In order to explore the implications of a 60% reduction in carbon dioxide emissions, the RCEP constructed four scenarios to illustrate measures by which it might be achieved. These scenarios are only illustrations, not intended to be interpreted as predictions or projections, but they enabled rough estimates of the cost of the change (see above). They had a number of common features. They were based on known technologies, assuming that electrical generation by nuclear fusion is not available by 2050 (see above). They took as their starting point the 1998 pattern of energy use in the UK, summarised in Table 1. Figure 2 shows energy use updated to 2003, while Figure 3 shows how UK carbon dioxide emissions have changed since 1990. Compared to continental European countries at comparable latitudes, domestic energy use is high because of the relatively poor energy performance of the UK building stock and the almost complete absence of heating systems using

"low-grade" heat; the principal fuels for space and water heating are natural gas and electrical resistive heating[2]. For obvious geographical reasons, the electricity grid in the UK is separate from that of continental Europe (apart from limited imports via a cross-channel link from France). Most of the decline in carbon dioxide emissions since 1990 is attributable to replacement of coal by natural gas in electricity generation (Figure 3). However, the proportion of renewable sources in the UK electricity system is still low by European Standards: only just over 1% of total inland energy use even in 2004. These features of the UK energy sector present possible savings in carbon intensity which are not available in other European countries, and which just might enable economic growth to be decoupled from carbon dioxide emissions.

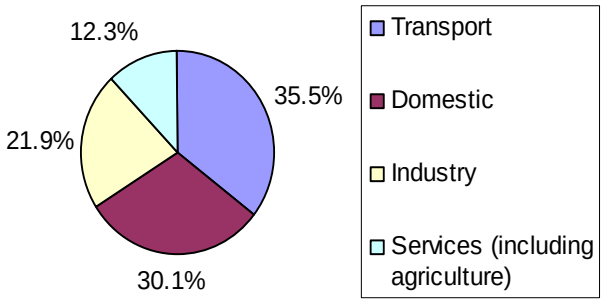

Figure 2: Final energy consumption in the UK, 2003 [3]

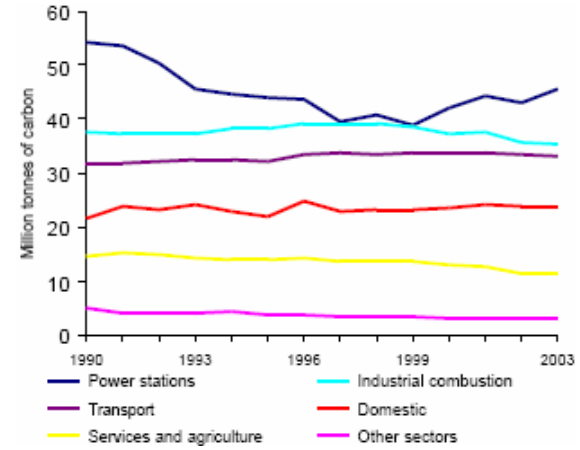

Figure 3: UK carbon dioxide emissions by source [3]

The final energy demands in the RCEP's scenarios are summarised in Table 1. They are based on a number of simplifying but not unrealistic assumptions. High-grade heat (i.e. heat for energy-intensive industrial processes) in all scenarios is supplied by natural gas. Industrial, commercial and domestic demand for electrical energy is reduced in some scenarios through improvements in the efficiency of appliances and machines – but it is recognised that any reductions in demand represent a reversal of current trends. Low grade heat is used primarily for space- and water-heating in domestic and service sectors. The reductions in some scenarios are assumed to be achieved primarily by improving the relatively inefficient UK building stock. Transport is seen as continuing to be dependent on fossil hydrocarbons, although the carbon efficiency of transport is assumed to improve through a combination of incremental technological development, larger shifts such as use of hydrogen produced from fossil fuels but with higher well-to-wheel carbon efficiency, and modal shifts (primarily from road to rail) to carry both people and goods with lower carbon dioxide emissions.[3]

End-use category	**Scenario**			
	1 (as 1998)	2	3	4
High-grade heat	87	44	44	30
Electricity	32	24	24	21
Low-grade heat	16	12	12	11
Transport	70	53	53	47
TOTAL	**205**	**132**	**132**	**109**

Table 1: Final energy consumption in 2050 by end-use (annual averages in GW) [1]

Energy supply in the four scenarios is summarised in Table 2[4]; all scenarios include the 60% reduction below 1998 emissions. Scenarios 1 and 3 assume that intermittent renewable generation of electricity is "backed up" by controllable generating stations fuelled either by nuclear fission

[2] Off-peak "night storage" heating is common in the UK. It has been argued, principally by advocates of nuclear power, that this is to be encouraged, on the basis that future energy systems will be dominated by low-carbon fixed-output electricity generation. RCEP did not subscribe to this view, rejecting its implication that new buildings should be equipped with electrical heating to fit a hypothetical energy system which might possibly exist at some future date.

[3] The role of air transport was considered in a subsequent RCEP study [4], which has also triggered an intense debate.

[4] The figures in Table 2 refer to outputs of electricity, heat and intermediate energy carriers. For the correspondence between Table 1 and 2, see [1]; it requires detailed explanation, primarily because of the use of CHP and the efficiencies assumed in the different scenarios and technologies.

Source	1998	Scenario			
		1	2	3	4
Intermittent renewables:					
On-shore wind	0.10	6.5	3.3	0.2	3.3
Off-shore wind		11.4	11.4	11.4	5.7
Photovoltaic		10.0	5.0	0.5	0.5
Wave		3.75	3.75	3.75	3.75
Tidal stream		0.25	0.25	0.25	0.25
Tidal barrage		2.2	2.2	0.0	2.2
TOTAL	**0.10**	**34.1**	**25.9**	**16.1**	**15.7**
Other renewables:					
Hydro	0.61	0.89	0.89	0.89	0.79
Energy crops	-	10.2	10.2	1.8	1.8
Bio-waste	0.04	5.7	5.7	5.7	1.2
MSW	0.15	1.9	1.9	0	0
TOTAL RENEWABLE	**0.90**	**52.8**	**44.6**	**24.5**	**19.5**
Low-C large scale electrical generation	11.4	52	0	19	0
Other fossil	266	106	106	106	106

Table 2: Outputs from energy sources in 2050 (annual averages in GW) [1]

or by fossil fuels with the carbon dioxide captured and sequestered in geological strata, primarily saline aquifers; the estimated capacity in the UK sectors of the North and Irish seas is sufficiently large to accommodate emissions way beyond 2050. Thus the scenarios illustrate that the significant technological choice, at least for the UK, is between nuclear power and fossil-fired generation with carbon sequestration. The scenarios also implicitly assume that hydrogen used in transport is produced from hydrocarbons but in dedicated reforming plants from which the carbon dioxide is sequestered. Thus the feasibility of carbon dioxide sequestration is a central concern, as is the question of how much generating capacity is needed to "back up" intermittent renewable sources. The latter depends, in turn, on the development of high-density energy storage technology; there is some pumped storage capacity in the UK, but little real prospect of significant expansion. "Other fossil" in Table 2 refers to uses from which the carbon dioxide is emitted to the atmosphere.

The use of renewables in the four scenarios is based on assessments of the cost-effective available resource in the UK [5]. There is limited hydro-electric generation capacity available, and the scenarios assume modest expansion. On-shore and off-shore wind is assumed to expand, a development which has already started in the UK. Wave generation is assumed to have developed to make a modest contribution by 2050, with a further small contribution from tidal-stream turbines. Some scenarios also assume construction of tidal barrages; there is significant technical scope for developing this resource but it may not prove to be environmentally or socially acceptable (compare with Figure 1).[5] Agricultural waste, energy crops and municipal solid waste (MSW) represent significant resources which are currently essentially unused in the UK; their significance is discussed further below.

Scenario 1 represents a "technology can fix it" approach. It is based on final demand held at the 1998 level with the maximum deployment of renewables and maximum use of electrical generation using nuclear sources or fossil fuels. In this scenario, energy crops, agricultural and

[5] One of the areas which has been considered for a tidal barrage but rejected on environmental grounds is the Bristol Channel in the South West of England. However, it is possible that this project might be revisited, on the argument that it would actually provide environmental protection against some of the effects of rising sea level.

forestry waste and municipal solid waste (MSW) are used as fuels in CHP plants or heat-only plants generating low-grade heat output.

Scenario 2 and 3 assume that energy demand can be reduced by 36% below the 1998 level. The largest reduction is in low-grade heat (see Table 1) brought about primarily by improving the energy efficiency of the building stock. In scenario 2 the reduced demand is met by a combination of renewable sources and fossil fuels, while scenario 3 is based on renewable sources plus large controllable generating plants using nuclear fission or fossil fuel with sequestration of carbon dioxide.

Scenario 4 represents the most extreme case: a very large reduction in demand (corresponding, *inter alia*, to replacing or retrofitting all the UK building stock to Nordic standards) supplied from renewable sources with no large generating stations. However, the reduction in demand means that the energy provided by renewable sources can still be less than in scenario 1.

The significance of this analysis is that, with the possible exception of scenario 4, it shows that the 60% reduction is achievable without totally novel technologies and without complete change in social and economic structures or lifestyles. As noted above, these scenarios provided the basis for assessment of the economic cost of switching to a lower-carbon economy. There is little doubt that the assessment of the cost of the transition was an important consideration leading to the political acceptance of the RCEP's "headline" recommendation of a 60% reduction in carbon dioxide emissions by 2050.

USE OF BIOFUELS

A feature of the RCEP report [1], not usual in policy documents, is frequent reference to the laws of thermodynamics. The primary reason for this is that UK energy policy has concentrated on the electricity sector, almost as if heat is not a form of energy. Results of this focus on electrical generation can be seen in the relatively slow development of the Combined Heat and Power (CHP) sector in the UK, the general resistance of local authorities and the construction sector to contemplate anything other than single-dwelling space and water heating, and cooling towers - those obvious symbols of energy waste - at electrical generating stations. The RCEP study tries to bring heat provision more centrally into energy policy.

As a further result of the policy neglect of heat, biological energy resources remain essentially untapped in the UK: agricultural wastes, energy crops and MSW[6]. A more recent RCEP report [6] examined biomass, to investigate its possible contribution to energy supply in the UK and why the sector has been so slow to develop compared to other European countries.

Austria has the most developed biomass sector in Europe. Starting from small-scale heating plants, the sector in Austria has grown over 20 years to the point where biomass provides some 15% of primary energy. This has enabled certain Austrian provinces to achieve one of the holy grails of sustainable development: decoupling economic growth from carbon to the point where GDP has increased but carbon dioxide emissions have decreased. In Denmark, biomass is now widely used, often co-fired with coal, primarily in CHP plants. These are usually built for their heat output, for example into community heating systems, with electrical output used to back-up intermittent renewables, primarily wind. In Sweden, biomass has developed more recently but rapidly, initially for community heating and then CHP plants operated, as in Denmark, over a range of heat/power ratio. But in the UK, renewables still only account for 1.1% of total inland energy use and biomass is only a small fraction of that. Why?

The RCEP diagnosed one of the reasons for this failure as the complex and confused government support for biomass, exacerbated by the focus on generating electrical power with no corresponding incentives for renewable heat production. The focus on power generation seems to have been amplified by the notion that "high technology" processes can be developed for exploitation of biomass leading to possible export markets. One result of this approach has been the conspicuous failure of the ARBRE project in South Yorkshire,

[6] For these purposes, MSW is treated as a renewable fuel, on the basis that it is available anyway but currently consigned mainly to landfill. Public resistance to recovering energy from solid waste is a UK peculiarity, not discussed here.

an electricity generating plant fuelled by short-rotation coppiced willow and using Swedish biomass gasification technology. The plant failed to progress beyond start-up to enter service – for reasons which are hotly discussed.

The RCEP argued that, rather than being seen as a possible fuel for power generation, biomass should be seen primarily as a local fuel for heating or CHP. Local supply chains must therefore be developed and, until the demand is clear, it is unreasonable to expect farmers to plant energy crops even when planting grants are available. Although credits are available to promote the development of renewable electricity generation, there has so far been a marked reluctance on the part of the UK government to extend a similar approach to renewable heat sources – a further manifestation of the neglect of heat as a significant part of the total national energy budget.

More detailed analysis of the possible availability of bio-energy broadly confirmed the earlier estimates summarised in Table 2. In fact significant quantities of biomass will become available over the next 20 years or so from forest plantations, primarily of Sitka spruce, developed to provide pulpwood based on projections of demand which now appear to have been too high. Figure 4 shows estimates by the Forestry Commission for the availability of wood in the UK. Clearly there is already a surplus of supply over demand, and the surplus becomes much larger if agricultural residues – primarily straw – are included. This persuaded the RCEP of the need to develop a market to stimulate demand before there is any point in encouraging planting of energy crops.

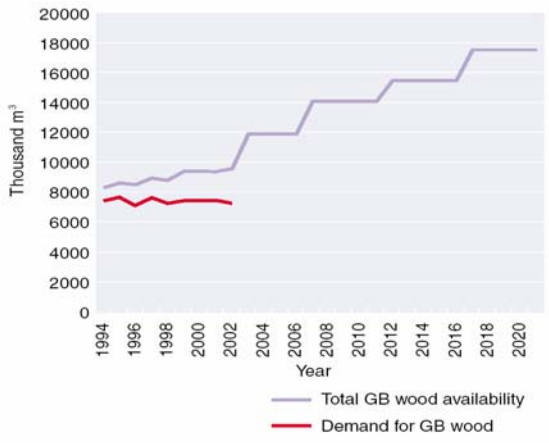

Figure 4: Supply and demand of wood in Great Britain (i.e. England, Wales and Scotland).

However, energy crops will also be needed. Based on assessments of energy yield per hectare, short-rotation coppiced (SRC) *salix* (willow) appears to be generally the highest yielding crop but other plants such as *miscanthus* may be preferred where favoured by local climate and soil conditions. Figure 5 shows the way in which the biomass sector could develop in the UK, using current supplies of wood and agricultural residues as a basis for developing the market for energy crops, up to the level of primary energy supply in 2050 needed to provide the delivered energy required by scenarios 1 and 2 in the earlier RCEP report [1]. A phased approach to the development of bioenergy in the UK was foreseen:

Phase 1 (2004 – 2012): increasing use of both agricultural and forestry resources, and of set-aside land for energy crops;

Phase 2 (2012 – 2018): area producing energy crops increases to include all set-aside land;

Phase 3 (2018 – 2025): energy crops become established as accepted main crops;

Phase 4 (2025 – 2050): the area of land under energy crops becomes a significant proportion of total available agricultural land.

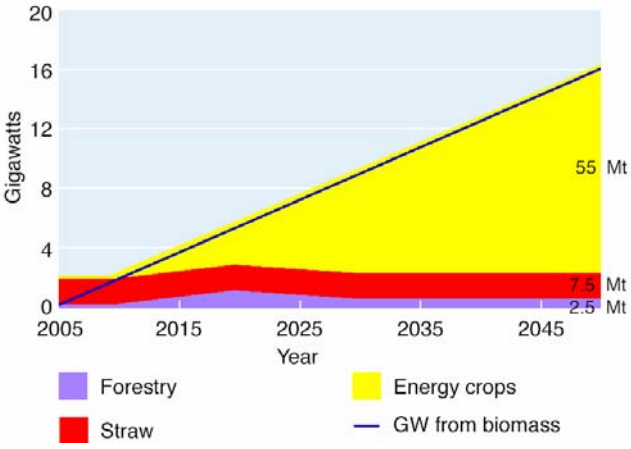

Figure 5: Scenario to achieve 16 GW of energy from forestry, straw and energy crops

It is clear that the competition for land use will be a constraint on the development of the bioenergy sector if anything like the scenario in Figure 5 develops. Contrary to current EU policy, the RCEP analysis leads to the conclusion that the focus should be on biofuels for heat or CHP rather than for transport: only if surplus land is available once the heat demand is met should transport fuels be considered, because the energy yield and carbon

reduction per hectare are lower than for *salix* or *miscanthus*. The RCEP analysis suggests that this will never be the case, providing a *post hoc* justification for the assumption in Tables 1 and 2 that transport will continue to represent the primary demand for hydrocarbons. This conclusion runs counter to the EU's policy of promoting biofuels for transport, and therefore begs the question of why transport fuels, with their less efficient use of agricultural land, have developed ahead of fuels for heat and CHP. One possible reason, which seems plausible to many involved in this sector, is that biofuels for transport have provided a way to support agricultural activities in spite of the Common Agricultural Policy, and that fuels such as biodiesel have developed because the supply chain for vegetable oils was already in place. This serves to underline the importance of developing the supply chain for other bioenergy crops.

CONCLUDING REMARKS

The work of the Royal Commission on Environmental Pollution reviewed here provides both positive and negative examples of success in using scientific analysis to underpin policy recommendations: positive in the sense that the "headline" recommendation on carbon dioxide emissions has been accepted by the UK Government; negative in the sense that more specific recommendations, such as actions to promote the development of biomass as a renewable energy source, have not been implemented. However, the overall message, that climate change is a real threat and that action to mitigate it is possible, does now appear to be widely accepted. The key question is not whether new energy technologies can be developed; on the contrary, the necessary reductions in carbon dioxide emissions could be achieved using known technology. The real question is whether the political will can be found to take the necessary action.

COMPUTATIONAL FUEL CELL ENGINEERING: CHALLENGES AND OPPORTUNITIES

N. Djilali*
University of Victoria
Institute for Integrated Energy Systems & Dept. of Mechanical Engineering
Victoria, BC Canada V8W 3P6

ABSTRACT

Fuel cell are still in early development stages, and the combination of new and optimized materials, improved product development, novel architectures, more efficient transport processes, and design optimization and integration are expected to lead to major gains in performance, efficiency, reliability, manufacturability and cost-effectiveness. Computational Fuel Cell Engineering tools that allow systematic simulation, design and optimization of fuel cell systems would be very valuable in the integration of such advances, allow less heavy reliance on hardware prototyping, and reduce development cycles.

Computational Fuel Cell Engineering (CFCE) requires the robust integration of models representing a variety of complex transport processes, and characterized by a broad spectrum of length and time scales. These processes include a fascinating, but not always well understood array of phenomena involving fluidic, ionic, electronic and thermal transport, in concert with electrochemical reactions. In this paper, we report on some progress in both fundamental modelling as well as in the development of integrated, CFD based PEM fuel cell models. A new rational model for coupled protonic and water transport in polymer electrolyte membranes, as well direct numerical simulations of two-phase flow in porous gas diffusion electrodes are discussed. Illustrative applications of CFD based simulations are presented for conventional fuel cells as well as novel micro-structured fuel cells. The paper concludes with a perspective on some of the remaining theoretical, experimental and numerical challenges to achieve truly functional CFCE tools.

INTRODUCTION

Fuel cells and hydrogen technologies hold the promise of zero emission power to meet the increasing demand for energy services such as transportation, heating, manufacturing, and communication in both developed and developing countries. Many socio-political, economic, engineering and scientific obstacles need to be surmounted before wide spread use of these technologies becomes possible. The leading contender for replacing the ubiquitous battery and internal combustion engine is proton exchange membrane fuel cell (PEMFC) technology. In addition to the important question surrounding the development of a hydrogen fuelling infrastructure discussed elsewhere [1], the main obstacles to the deployment and commercialization of PEMFCs are cost, durability, and performance [2]. In this paper we will focus on the role of computational tools in addressing some of the engineering and scientific challenges in the development of better performance and cheaper PEMFC technology.

The overall operating principle of a PEMFC is relatively simple. Hydrogen is to the cell and oxidized at the anode, and oxygen, usually carried in an air stream, is reduced at the cathode. The protons released by the oxidation of hydrogen are conducted through the proton exchange membrane (PEM) to the cathode. Since the membrane is not electronically conductive, the electrons released at the anode have to flow along an external circuit, thereby generating electric power, and eventually recombine with the protons on the cathode side to produce water. These reactions and pathways are illustrated schematically in Figure 1.

Broadly speaking, improved performance in PEMFC can be achieved by enhancing the rates of transport and/or reaction, and by increasing the surface/volume ratio of interfacial areas where reactions/transport take place. This can be achieved by, e.g., engineering the transport properties or processes in specific areas, or by introducing new materials or designs. A particularly promising avenue is the use of micro-structured features [3] as will be discussed later. In any case, it is first necessary to identify the prevailing limitations, their location and their cause. *In-situ* measurements to obtain the relevant information are exceedingly difficult due to the confined and electrochemically active

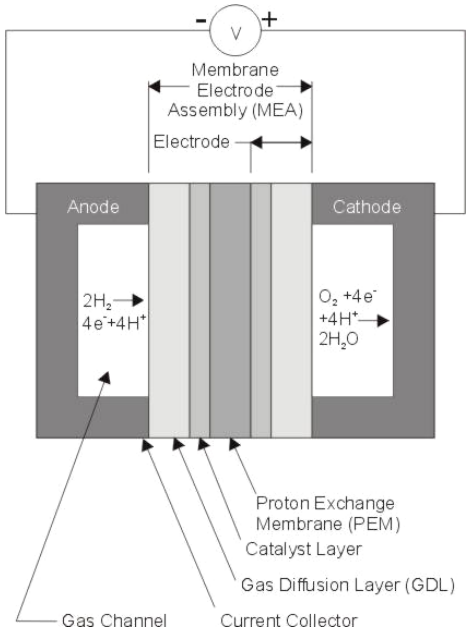

Figure 1: Schematic of a PEM fuel cell

environment of fuel cells, the complexity of the couplings, and the often transient nature of the processes. Rational models based on the fundamental physico-chemical processes together with experimental observation are thus an essential tool to gain a more complete understanding of the operation of a fuel cell. Coupling these models with modern computational fluid dynamics (CFD) and multi-disciplinary optimization methods would allow the creation of powerful Computational Fuel Cell Engineering tools that could lead to dramatic reductions in lead times and development costs, and spur innovative design.

While much progress has been made in recent years in CFD based modelling of fuel cells, truly functional and *predictive* capabilities remain a challenge due to, amongst others things:

- lack of general models for ionic and water transport in polymer membranes;
- deficient models for two phase transport in porous gas diffusion electrodes and gas flow channels;
- lack of general models for ionic and water transport in polymer membranes;

- deficient models for two phase transport in porous gas diffusion electrodes and gas flow channels;
- inadequate macroscopic modelling and resolution of catalyst layers;
- limited data for material and transport parameters; lack of *in situ* data for validation;
- wide disparity in length and time scales.

Many notable advances have been made in CFD based methods over the last few years [4]-[8]. In this paper, we provide an overview primarily focused on progress made at the University of Victoria in addressing some of the key transport phenomena issues and in the development of CFD based modelling strategies. The first part of the paper focuses on fundamental modelling of specific transport phenomena encountered in component layers of the membrane electrode assembly (MEA). In the second part, we discuss the integration of some of these models into multi-dimensional CFD codes and illustrate their application. The paper closes with a perspective on some of the remaining challenges.

TRANSPORT PHENOMENA IN PEMFCs

The cathode side of the membrane electrode assembly (MEA) provides a good illustration of the complex interplay of various transport phenomena in a PEMFC. The MEA consists of a proton exchange membrane sandwiched between catalyst and gas diffusion layers (GDL), and the latter two components essentially form the electrode. This electrode is a buffer zone that facilitates a number of transport processes:

- The conduction of electrons between the current collectors and the reaction sites.
- The conduction of protons between the membrane and catalyst layer.
- The transport of the reactants to the catalyst layer
- The transport of heat away form the reaction site primarily through the solid matrix
- condensation/evaporation and transport of liquid water and vapour.

Optimal tailoring of an effective electrode requires therefore balancing of often conflicting requirements. On the cathode side for instance, the reaction is prone to mass transport limitations at high current densities, when depletion of oxygen in the air stream becomes significant. This can be further compounded by flooding of the electrode pores by the product water and blocking of pathways for oxygen transport. Effective removal of excess water is thus essential, but must be balanced against the need to prevent drying of the proton conducting media (membrane), which causes not only deterioration in protonic conductivity (and thus higher heat generation and lower efficiency), but also impacts durability.

Computational design of fuel cells with effective reactant distribution, optimized structures and proper heat and water management, requires understanding of the various transport processes in each of the components, the development of physically representative models for these processes, and, finally, proper coupling of the models.

Polymer Electrolyte Membranes

Polymer electrolyte membranes (PEM) provide the key functions of conducting protons from anode to cathode, and of preventing reactant crossover. These membranes consist of microphase-separated structures, comprising hydrophobic polymer chains (PTFE/Teflon) and hydrophilic sulfonic acid groups.

A thorough review of transport phenomena in PEM was recently provided in [9]. The protonic conductivity characteristics of a PEM are intimately dependent on the membrane hydration given in terms of λ (number of sorbed waters per sulfonate head). Excess protons in bulk water are primarily in the form hydronium ions (H_3O^+), and higher complexes such as "Eigen" ion $(H_9O_4)^+$ may also participate.

A phenomenon closely linked to membrane conductivity is electro-osmotic drag (EOD), the process whereby a given number of water molecules associated with a proton are dragged as the proton migrates from anode to cathode. This EOD mechanism plays a major role in determining overall water balance.

The breadth of PEM transport models proposed to date ranges from molecular dynamics simulations and statistical mechanics models, to empirical macroscopic models. Our focus is on the development of macroscopic models required for computational simulations of complete fuel cells,

based on micrsoscopic insight. The most widely used model to date for determining membrane conductivity in fuel cell simulations is due to Springer, Zawodzinski and Gottesfeld [10]. This "diffusion" model has limited predictive abilities as it relies on empirical correlations obtained for Nafion membranes.

A more fundamental and general approach to modelling transport in membranes requires consideration of the dominant interactions between the aqueous system and the polymer and how they affect the conductivity and transport properties. A general model that considers such interactions based on the fundamentals of multi-component diffusion was recently derived. This new Binary Friction Membrane Model (BFM2) [11] couples the protonic flux N_p , which is proportional the ionic current i_m, and the water flux through a general constitutive law of the form:

$$\begin{bmatrix} N_p \\ N_w \end{bmatrix} = -c \begin{bmatrix} fD_{pp} & D_{pw} \\ fD_{wp} & D_{ww} \end{bmatrix} \begin{bmatrix} \nabla \Phi_m \\ \nabla \lambda \end{bmatrix} \qquad (1)$$

Where c is the molar concentration of water, $f = F/(RT)$, and Φ_m and λ are the membrane potential and water content. The coupling between the protonic and water transport is through the diagonal transport parameters D_{pw} and D_{wp} which are considered to be functions of water content λ and temperature T. A feature of the model is that all parameters can be obtained using a simplified conductivity model version of the model that represents conditions found in AC impedance conductivity measurements.

The BFM2 has a number of features that make it promising. This model:

- relies on rationally derived transport equations based on the physics of multi-component transport in the membrane;
- is not restricted by the assumption of equimolar counter diffusion;
- accounts for the effect of temperature on the sorption isotherm;
- is not restricted to Nafion, but applies to the entire family of perfluoro-sulfonated membranes.

Figure 2 illustrates the enhanced capabilities of the BFM2 model which captures the variation of

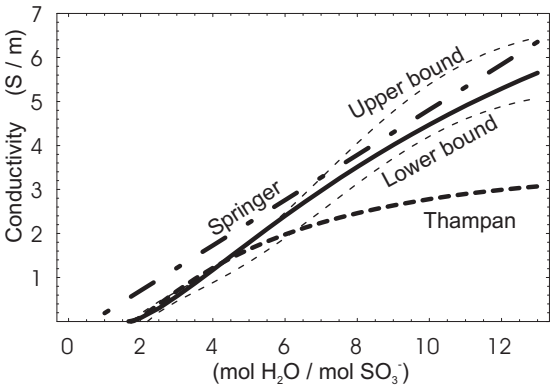

Figure 2: Calculated conductivity using BFM2 (solid) and models of Springer [10] and Thampan [12] against experimental data [13] for Nafion 117 (dashed bounds)

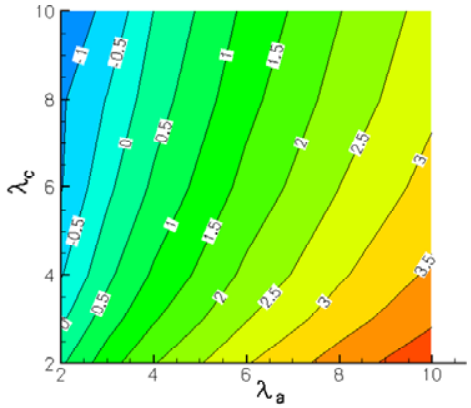

Figure 3: BFM2 computed water crossover (+ve from anode to cathode) for various cathode and anode side water content boundary conditions.

the conductivity for *all* water contents. Figure 3 illustrates the predicted water crossover coefficient $WC = N_\lambda / [I/(2F)]$. In the second part of this paper, the BFM2 is coupled to a fuel model and we will see that the resulting overpotentials and overall performance predicted by the BFM2 can, for some operating conditions, differ significantly from those obtained using the classical Springer model.

Gas Diffusion Electrodes

The gas diffusion layers (GDLs) consist of an anisotropic fibrous structure, either in the form of a "paper" or a "woven cloth", that allows distribution of reactant gases through the porous matrix and collection of current through the fibres. At higher current densities, or when local

water and heat management is inadequate, water condensation takes place leading to potential "flooding" within the GDL (and catalyst layer) as discussed earlier. In order to remedy this, GDLs are commonly treated with PTFE (Teflon) to impart hydrophobicity, and force water droplets to agglomerate at the free surface of the GDL. However, the hydrophilic Nafion in the catalyst layer will absorb and retain liquid water. Thus, liquid water produced is transported from a saturated catalyst layer to the free surface of the GDL.

A major stumbling block in the reliability of two-phase models is the necessity to rely on empirical correlations and experimental observations obtained in soil and sand samples—media with a structure that differs significantly from GDLs.

The phase distribution in a porous media is potentially the result of viscous, capillary, and gravitational forces. When modelling the diffusion layer of a PEMFC, the second (liquid) phase is taken to consist of a single component, with transfer of water only across the phase boundary through evaporation/condensation. For porous media in which the void space is occupied by two-phases, the bulk porosity ε is divided between the liquid ε_l and gas ε_g volume fractions, and the liquid saturation is defined as $s_l = \varepsilon_l / \varepsilon$. Depending on saturation, and also to some degree on wettability, two-phase flow can exist in three possible regimes [14].

Extending classical relationships for the hydrodynamics of a single-phase in porous media to each phase, and using the definition of macroscopic capillary pressure, the momentum conservation equations for the gas and liquid phases take the form [14]:

$$u_g = -\frac{k_g}{\mu_g}\nabla P_g$$
$$u_l = -\frac{k_l}{\mu_l}\nabla P_g - \frac{k_l}{\mu_l}\nabla P_c \qquad (2)$$

Where u_g and u_l are the gas and liquid phase superficial velocities, and P_g and P_c are the gas and cappliary pressures, and k_g and k_l are phase specific permeabilities, obtained by correcting the bulk permeability (k) for the effect of the reduced area open to each phase due to the presence of the other phase.

The last term in equ. (2) represents capillary diffusion. Assuming the capillary pressure gradient depends solely on the saturation gradient, the liquid phase momentum equation becomes:

$$u_l = -\frac{k_l}{\mu_l}\nabla P_g - D(s_l)\nabla s_l \qquad (3)$$

$$D(s_l) = \frac{k_l}{\mu_l}\left(\frac{dP_c}{ds_l}\right) \qquad (4)$$

And $D(s_l)$ is a capillary diffusivity

$$D(s_l) = \frac{k_l}{\mu_l}\left(\frac{dP_c}{ds_l}\right) \qquad (5)$$

Equations (2) are the basis of the most general multi-fluid formulation used so far in complete fuel cell models [15]. One of the key problems in all models of two-phase transport in GDLs is the determination of a constitutive relation for capillary pressure as a function of saturation. So far this has relied on the so-called Leverett J-function, specifically in the form proposed by Udell [16], i.e.

$$J(s) = \frac{P_c}{\sigma}\left(\frac{k}{\varepsilon}\right)^{1/2} \qquad (6)$$

with

$$J(s) = 1.417(1-s) - 2.120(1-s)^2 + 1.263(1-s)^3 \qquad (7)$$

This is then used to compute the capillary pressure, and in turn determine the capillary diffusivity.

Considering the key phenomenon of capillarity associated with interfacial tension, the microscopic capillary pressure is directly proportional to the interfacial tension (σ) and inversely proportional to the radius curvature of the interface (r), i.e. $P_c \propto \sigma / r$. A schematic illustration of capillary motion in a pore is shown in Figure 4. At the end of the pore where the liquid radius is smaller (lower local saturation), the capillary pressure is greater than at the end with the larger liquid radius (greater local saturation). Because $P_c = P_l - P_g$, the hydrodynamic pressure of the liquid is greater at the end of the pore with the smaller radius. Therefore, the bulk motion of the liquid is toward the end with the greater radius (and local saturation). This liquid water transport from low to high saturation is counter-intuitive, and illustrates the tendency for water, in *hydrophobic*

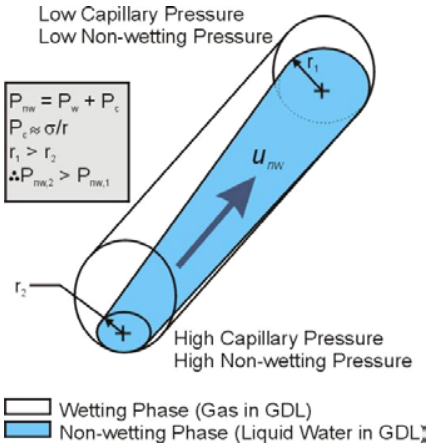

Figure 4: Schematic of capillary diffusion, in which the liquid is the non-wetting phase.

media such as those used for gas diffusion layers, to move to ever-increasing pore diameters according to the capillary pressure's inverse proportionality to the liquid radius. This analysis will be instructive in the subsequent interpretation of visualizations and simulations of flow between fibres composing a GDL.

There are a number of issues with Udell's relation [14], not the least of which is that the experimental data upon which it is based was obtained in porous samples of soils, which have a radically different structure from fibrous media used in GDLs.

The second key issue in the application of two-phase transport models is the determination of the phase specific permeabilities. These must be corrected for the volume fractions occupied by different phases. One of the approaches we have recently used is based on stochastic pore network model simulations. A more fundamental approach consists of resolving the two phase transport by performing direct numerical simulations that explicitly resolve the flow, including dynamic interface tracking, between the fibres. A Volume of fluid (VOF) technique in conjunction with sub-models for surface tension and wall adhesion is used to track the evolution of the two phase flow, including the interface. The instantaneous pressure field obtained from such simulations, Figure 5, clearly shows the two-phase interface. 2D, as well as 3D simulations provide fundamental understanding of the two-phase

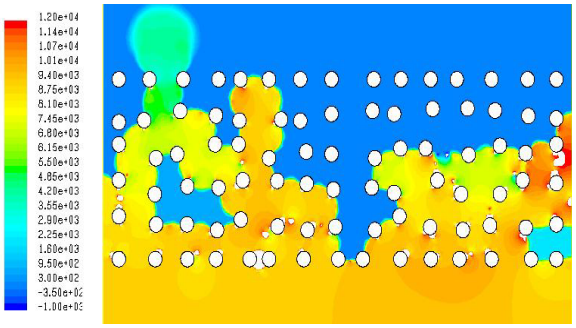

Figure 5: Two phase flow in GDL: instantaneous pressure field liquid phase (gas phase in blue).

transport, and parametric simulations that directly account for detailed features, such as degree of hydrophobicity, can yield data for determining capillary functions that are more representative of GDLs than equation (7).

In recent studies of diffusion layers and two-phase fuel cell models [17][18] it was proposed that liquid water in a GDL evolves in an "inverted tree" structure; i.e. a high number of small capillaries disperse evenly within the GDL and eventually converge into larger capillaries and eventually result in one very large capillary that reaches the surface. The VOF simulations together with quantitative visualization experiments performed at UVic using laser induced fluorescence [19] have recently revealed that transport is in fact dominated by fingering and channeling, and features numerous "dead ends" where water transport recedes when an adjacent breakthrough channel forms.

For a hydrophobically treated GDL, assuming well dispersed PTFE coating (i.e. uniform contact angle), the transport within the GDL is a process of pressure buildup and breakthrough. This process results from the fact that capillary forces provide the main resistance to the progression of the interface in the fibrous hydrophobic structure. As water is produced in the catalyst layer, the pressure in the liquid increases, the fluid surface slowly passes through the constrictions of the cross-sections generated by intersecting fibers. When the water has passed halfway through each constriction, the curvature of the surface decreases due to the expanding radius of the surface. Thus, the liquid pressure at the interface drops and induces hydrodynamic flow in the direction of the

expanding surface. Subsequently, the liquid expands rapidly above this cross-section until the fluid interface contacts the next set of fiber intersections. The process then begins again. The fluid will preferentially pass through the fiber cross-sections featuring the greatest spacing, as this reduces capillary pressure resistance.

PUTTING IT TOGETHER: INTEGRATION INTO CFD BASED FUEL CELL MODELS

One of the most challenging computational aspects is the coupling between the various transport phenomena within a PEMFC as illustrated Figure 6, where each box represents a transport equation governing a particular phenomenon, and the arrows represent the effects of the particular transport on other equations. The equations for gas species, water in liquid and solid (membrane) phases, and energy are closely coupled with all other transport equations. The transport of water, which is present in the system in both vapour and liquid forms, is central to all other coupled transport processes. Unsaturated water in the vapour phase affects local relative humidity in the vicinity of the membrane, and thus its hydration and protonic conductivity, which in turn impacts the electric potential. The liquid water transport in the GDL affects mass transport of gas species, while liquid water in the gas channels affects the pressure field and may affect the overall flow distribution in a unit cell.

Transport of water across the membrane is, as noted earlier, a key phenomenon linking the transport processes between anode and cathode sides. Polarization curves obtained using a complete fuel cell model incorporating the Binary Friction Membrane Model (BFM2) discussed earlier are presented in Figures 15. A particularly important issue here is coupling water transport within the membrane to transport of water vapor in the electrodes, in such a way that mass conservation is ensured and an experimental membrane sorption isotherm is enforced. Figure 7 compares the effects of different humidification regimes on the anode and cathode sides (25% and 75% relative humidity). The Springer model predicts similar polarization curves for both regimes, while the BFM2 predicts a substantial polarization loss for the RH = 25/75 regime (dry anode). An analysis of the source of this loss reveals that it is primarily due to larger ohmic losses predicted through the membrane as a result of drying on the anode side. In this case, there is no water to hydrate the anode CL, unlike the case of the dry cathode (RH = 75/25), where the water production from the oxygen reduction and the cathode–to–anode back-diffusion help to maintain a more uniform membrane saturation. This highlights the crucial importance of membrane modelling, particularly for fuel cell systems that rely on passive water management, such as air breathing cells considered next.

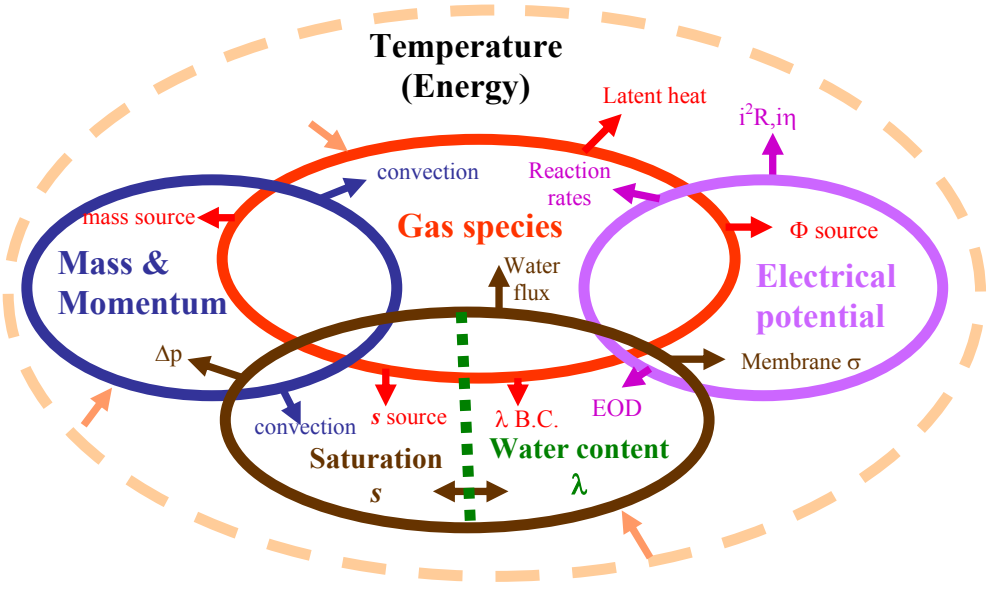

Figure 6: Coupling of Transport Phenomena in a PEMFC

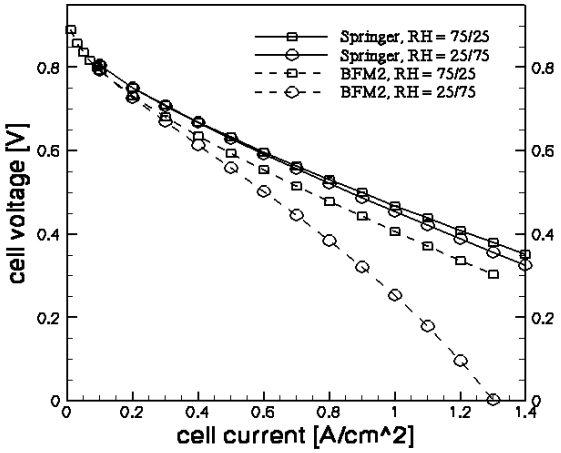

Figure 7: Polarization curve predicted using Springer's membrane model and BFM2

Adaptation of plate and frame PEM fuel cell designs for smaller applications is restricted by the macro-scale materials and manufacturing processes they utilize. Exploitation of microscale transport in conjunction with macro-manufacturing makes it possible to conceive high power density and potentially lower cost fuel cells [3]. Micro-fabrication of flow fields, current collectors, and electrical interconnects have been used in a number of designs, but these have generally relied on the traditional planar MEA architecture. Non-planar designs can achieve much higher active area to volume ratios and volumetric power densities, as was demonstrated in our waved cell topology [20]. Another approach for increasing the volumetric power density, particularly for low power applications, is passive air-breathing operation which allows elimination of manifolding and ancillaries such as fans and compressors. Mass transfer limitations are however an issue in such designs.

One of the concepts to which computational models has been applied is a novel micro-structured electrode, illustrated in Figure 8, that exploits the microscale transport principles in an air-breathing non-planar patented design. The micro-structured electrodes consist of a nano-porous GDL featuring with mean pore diameter on the order of 100nm, i.e. two order of magnitude smaller than in a typical GDLs (Figure 6). With comparable levels of porosity, the nano-porous GDL can increase the active area of the

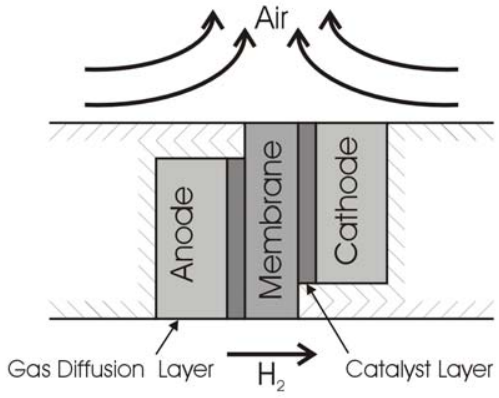

Figure 8: Schematic of micro-structured PEM electrodes.

deposited catalyst by exploiting the surface to volume ratio [3]. The higher functionality of such a GDL can be impeded by:

- the inability of nano-scale porous media to effectively transport reactant and product gases to the entire active area.
- the limited ability of natural convection to passively regulate temperature and supply adequate amounts of oxygen to the cathode.

The CFD based tools were adapted to this problem to assess the functionality of the design, determine the severity of potential transport limitations, and to identify design parameters to alleviate these. In addition to the coupled transport processes discussed earlier, two specific process that have to be accounted for in this case are natural convection in the ambient air, and Knudsen diffusion though the GDL.

Figure 9 illustrates the distribution of oxygen for a system consisting of three electrodes subjected to non-uniform convective heat and mass transport currents. The catalyst layer is located along the left hand vertical axis for each electrode. A minimum oxygen mass fraction of 0.089, a 61% drop from the ambient, is obtained in the central cathode. Though the reduction in oxygen concentration is significant, the fuel cell is still far from being oxygen starved, indicating that the GDL parameters and dimensions considered will not result in insurmountable mass transport limitations.

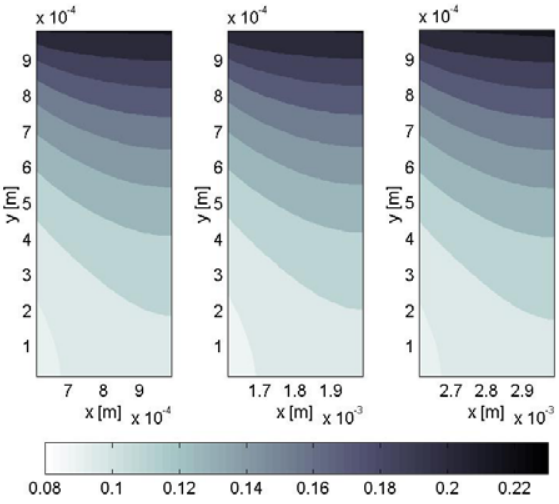

Figure 9: Mass fraction distribution of oxygen in three adjacent electrodes. The ambient oxygen mass fraction in the convective air flow (top) is 0.2303.

CONCLUDING PERSPECTIVE

Fuel cells are at the vanguard of the next generation energy technologies, but must surmount a number of key challenges in order to successfully compete against incumbent technologies such as IC engines and batteries. The availability of reliable and functional computational tools could help achieve dramatic reductions in development cycles and costs, and could spur innovative design required to surmount some of the cost and performance challenges. In this paper we have discussed the array of transport phenomena that are encountered in PEM fuel cells, and presented some of the progress made in our laboratory in addressing some of the fundamental issues that still limit the capabilities of computational fuel cell engineering (CFCE).

A new model for coupled protonic and water transport in polymer membranes was presented. This general model is based on rational and physical consideration, removes several of the limitations of the empirical models used to date, and should provide a good foundation for modelling all purfluoro-sulfonic acid membranes.

Approaches combining pore network modelling, direct numerical simulation of two phase flow in reconstructed gas diffusion layers, and quantitative visualization have been described, and sample results have been presented revealing a fundamental mechanism of liquid water transport in hydrophobic GDLs.

The important issue of integration and coupling was also discussed in the context of CFD based fuel cell models, and we have shown that used judiciously, current models and computational tools can be used in both conventional designs and in novel micro-structured fuel cells to provide detailed information and to analyze design features.

Clearly, numerous outstanding issues remain to be resolved before truly functional computational fuel cell engineering capabilities are achieved.

The broader applicability of the multi-fluid model comes at the cost of solving for an additional set of field equations and the required coupling of the phases. This makes the numerical solution much more challenging and computationally intensive. In particular, the convergence rates and the numerical stability of the model can be problematic under some operating conditions. Alternative models based on various levels of simplifications should be better assessed, and their range and regimes of validity fully established in order to allow multiple levels of modelling and practical simulations, particularly for complete cells and stacks. In any case a critical issue for all two-phase models is the determination of appropriate transport parameters for the various electrode materials (including the catalyst layer), amongst which the relative permeability and the capillary pressure function.

One of the inherent advantages of the Binary Friction Membrane Model is that it can be reduced to represent condition under which AC impedance measurements are conducted, thus allowing determination of some of the transport parameters using conductivity data. Experiments and fundamental micro/nanoscale simulations, such as molecular dynamic simulations, are required to determine the fundamental properties of specific PFSA membranes, including the diffusion and interaction coefficients, and the sorption isotherms.

PEMFC catalyst layers consist of a complex composite network structure of interconnected, microporous agglomerates surrounded by macropores. Charged species, heat, liquid water, and gas all flow through this layer. Space did not allow inclusion of recent work performed using a multiple-thin film agglomerate model for this layer, but in any case modelling and experimental characterization of this layer is one of the most

difficult problems in PEMFCs. Multi-scale modeling strategies are required to resolve the catalyst structure and guide the formulation of improved macroscopic models suitable for use in a CFCE framework.

Finally, the effective and robust integration of the various submodels in a CFCE framework, requires the development of novel algorithms that take into account the specific nature of the couplings and the large range of scales encountered in PEMFCs fuel cells.

ACKNOWLEDGEMENTS

The work presented in this paper is the result of collaboration with a number of former and current graduate students, research associates and collegues. I would like to particularly acknowledge the contributions of: Torsten Berning, Brian Carnes, Jeff Fimrite, Shawn Litster, Ged McLean, Bojan Markicevic, Børge Sivertsen, Henning Struchtrup Jay Sui, and Phong Nguyen.

Financial support from the following is also gratefully acknowledged: the MITACS Network of Centres of Excellence; the Natural Sciences and Engineering Research Council (NSERC) of Canada; Angstrom Power; and Ballard Power Systems.

ABSTRACT
The first decision to apply underground storage of carbon dioxide (CO_2) captured from natural gas - as a climate change mitigation effort - was taken by Statoil (operator) and partners in the Sleipner North Sea licence in 1990. The second such decision was taken by Statoil (operator) and partners in the Snøhvit licence in the Barents Sea in the fall of 2001. A third project of this type was put in operation in the In Salah field in Algeria. This paper presents these injection projects and possible solutions to how CO_2 can be turned into a business opportunity. The whole chain of CO_2 management will be covered, including capture, transportation, storage and end use of CO_2.

Keywords: CO_2 capture, CO_2 geological storage, Sleipner, Snøhvit, In Salah.

TERMINOLOGY

CCP	CO_2 Capture Project

IEA	International Energy Agency
R&D	Research and Development
SACS	Saline Aquifer CO_2 Storage

INTRODUCTION

Anthropogenic emissions of greenhouse gasses is widely thought to be a contributory factor to changes in the climate. The major contributor is carbon dioxide (CO_2), which arises mainly from use of fossil fuels. Recognising that about 85% of the world's commercial energy needs are met by fossil fuels, a rapid move away from oil, natural gas and coal is unlikely to be achievable without serious disruption to the global economy. Today it is starting to be recognised that emissions of CO_2 from fossil fuel combustion could be much reduced by its capture and safe storage in geological formations. The technology is called CO_2 Capture and Storage (CCS). The aim of this paper is to give an overview of the current CCS operational projects, R&D projects and concept of CO_2 value chain from an industrial perspective. Statoil is a Norwegian oil & gas company and is leading in this area. More extensive information can be found in Buller et al [1].

THE SLEIPNER CO_2-INJECTION

Since 1996 about 1 million tonnes (metric tonnes is used throughout this article) per year of CO_2 has been separated from the natural gas and stored in a saline aquifer (the Utsira formation) at the Sleipner field, see also Baklid et al [2]. Figure 1 gives its location in the North Sea.

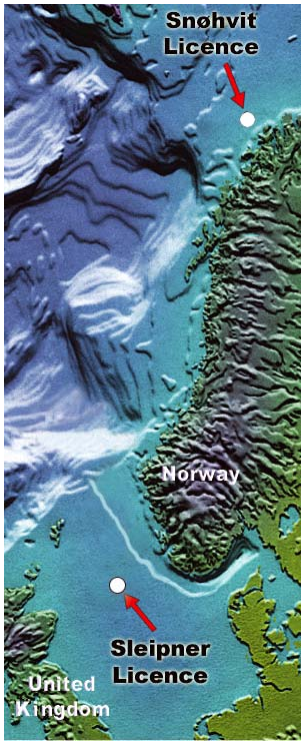

Figure 1: location of Sleipner and Snøhvit CO2 capture and storage sites

Figure 2 gives a drawing of the platform, gas reservoir and Utsira aquifer, which is the storage site. The main motivation for starting this project was an offshore CO_2 tax imposed by the Norwegian government. Valuable experience has been gained both through the operation of this project as well as from the monitoring of the injection through the so-called SACS project. The SACS project is a 4,5 million € R&D programme run under the European Union R&D 5th Framework programme, involving numerous European geological survey institutions and energy companies together with the IEA Greenhouse Gas R&D Programme, see also its website [3]. So far, the SACS programme has carried out two seismic surveys in addition to the pre-injection survey. The results revealed that the CO_2 is trapped in the aquifer and that it is not leaking.

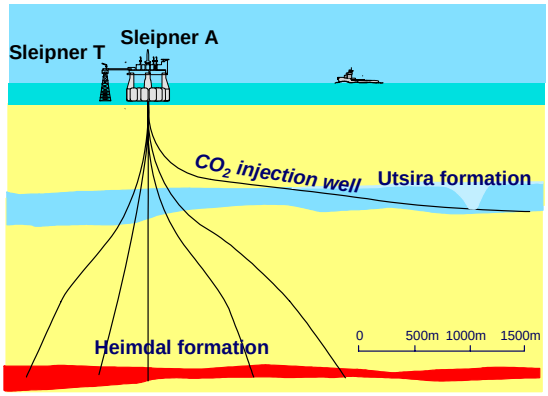

Figure 2 : Drawing of CO_2 injection captured from Sleipner natural gas into the Utsira formation.

THE SNØHVIT CO_2-INJECTION

Since Sleipner, two additional and large CO_2-injection projects of the same type as Sleipner have materialised. The Snøhvit gas field in the Barents Sea north of Norway (see Fig. 1) was the first after Sleipner to be decided for development with CCS. About 0,7 mill tonnes per year will be injected from 2006. The natural gas will flow out of the reservoir via sub-sea wells and a multi-phase pipeline to shore, see Fig. 3. CO_2 captured from the Snøhvit natural gas is captured at the LNG plant (background) and will be piped back 150 km to the field in a separate pipeline.

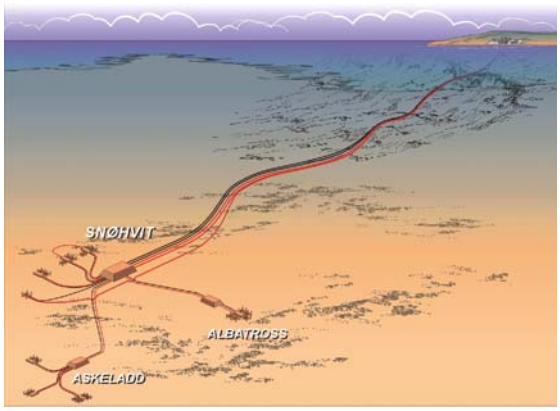

Figure 3 : Overview of offshore Snøhvit field with pipelines and onshore LNG plant in background.

THE IN SALAH CO_2-INJECTION

The In Salah gas field is jointly operated by BP, the Algerian oil & gas company Sonatrach, and Statoil. It is a natural gas field in the middle of Sahara. Like in the Sleipner and Snøhvit fields, this is also a gas field in which CO_2 naturally occurs. The CO_2 is removed, compressed and in this case injected into a remote corner of the gas field. About 1,2 mill tonnes per year of CO_2 is injected. The actual injection operation started in 2004, and will continue for the life of the field. A short comparison of the three CCS projects can be found in De Koeijer and Solbraa [4]

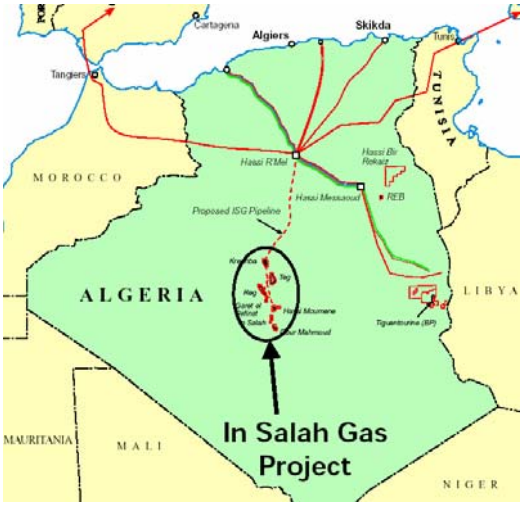

Figure 4: Map with the In Salah CO_2-injection project. The storage takes place at the Kreshba field, north of the In Salah field.

REDUCTION OF CO_2 EMISSIONS

CO_2-injection, together with energy efficiency measures and the electrification of the Troll A offshore gas platform as well as the Kollsnes gas terminal from the land grid will by 2010 have reduced Statoil's CO_2-emissions by 1/3, as is shown in Figure 5

RESEARCH AND DEVELOPMENT

From the start of the Sleipner CO_2-injection project it became clear that it was viewed globally as a demonstration project for a promising new climate technology.

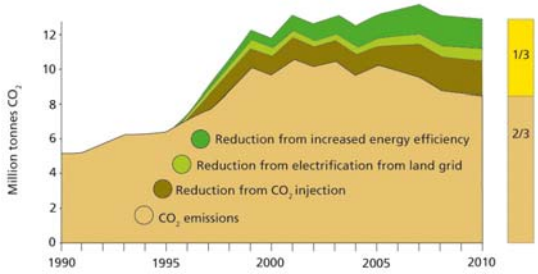

Figure 5: Reduction of CO_2-emissions from Statoil operated facilities 1990-2010.

It was also realised that if this technology were to become widespread in the years to come, questions would be asked about the long-term security of storage in general. Statoil therefore embarked on a long road of research and development with regard to storage security and low-cost CO_2 capture. In this process we realised that in order to gain the consent from the society it was important to conduct an open process (e.g. CO_2 Capture Project [5]). The method chosen was to establish R&D projects with wide participation to follow up these injections. Figure 6 illustrates how, in this case, various EU-funded projects have been established to carry out R&D within the areas of CO_2 storage and capture, see also the project websites [3, 6, 7, 8]. The possible future projects are being prepared and have no reference yet.

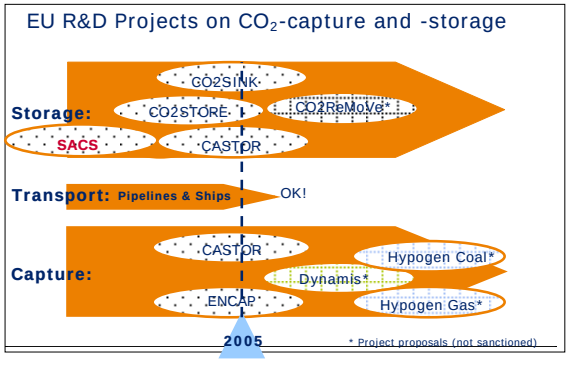

Figure 6 : R&D projects within the EU framework programmes. Dotted backgrounds are running (or already closed) projects. Backgrounds with squares are possible future projects

CO_2 FOR ENHANCED OIL RECOVERY

Carbon dioxide has such properties that it can be used for enhanced oil recovery, see Figure 7. It is extensively used in North America, primarily West Texas for enhanced oil recovery, see Figure 8.

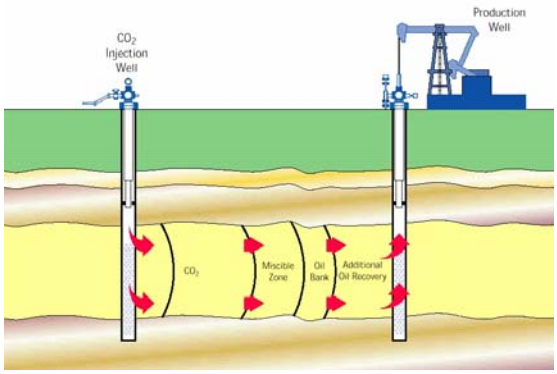

Figure 7 : The principle of using CO_2 for enhanced oil recovery.

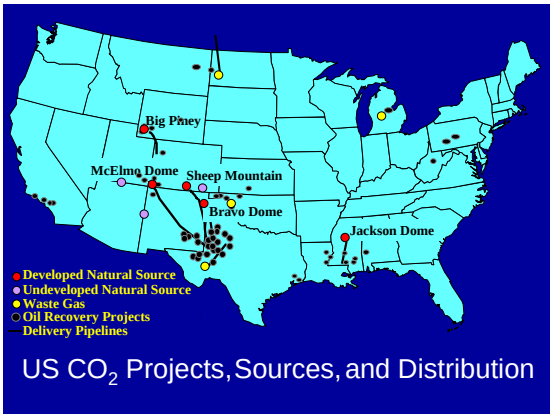

Figure 8 : CO_2 for enhanced oil recovery infrastructure in West Texas

Most of the CO_2 used for enhanced oil recovery in the United States is from naturally occurring reservoirs with nearly pure CO_2, but there is also some industrial CO_2 being used in the system. All in all over 70 oil fields are using CO_2 in this area at present even without any climate change incentive!

So far CO_2 has not been utilised for EOR purposes in the North Sea, but things may change. One thing that makes the North Sea very different from the North American situation is that we lack those large, natural CO_2-reservoirs.

Statoil and partners have carried out studies to see if the Tampen offshore area in the North Sea (North of Sleipner) can benefit from the use of CO_2. A very large amount of work was done in this connection both with respect to reservoir simulation, rebuilding of platforms, transportation of CO_2 and - not the least - in accessing the best CO_2-sources for a total need of 5 million tonnes per year, see Agustsson and Grinestad [9]. This effort identified that more oil can be produced by CO_2-injection than any other method, but the cost of CO_2 in this remote setting far from major industrial sources was shown to be too high for a commercially viable project.

THE CO_2 VALUE CHAIN CONCEPT

In most regions of the world, there are not yet any infrastructures for capturing, transporting and permanently storing large quantities of CO_2. In order to build the necessary infrastructure, large investments must be made, see also Berger et al [10]. Oil fields in the right phase of their lifespan for CO_2 flooding may improve the economics for investment in CO_2 infrastructure. In a near-term time perspective, using CO_2 for enhanced oil recovery is an option that can help us start building the sort of infrastructure needed. The total CO_2 value chain is illustrated in Figure 9.

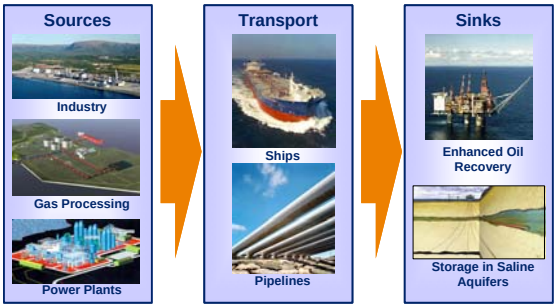

Figure 9 : The CO_2 value chain concept

In order to supply the Gullfaks field in the Tampen offshore area with sufficient amounts of CO_2 for miscible-flood EOR within the limiting time-window, Statoil has, from 2002 to 2004, performed detailed studies on such CO_2 value chain elements as:

- CO_2 sources in northern Europe

- Pure and/or small sources versus large (often dilute) sources
- Liquefaction and compression of CO_2
- Intermediate storage of CO_2
- Ship and pipeline transportation
  - Flexibility versus fixed installations and investments
  - Intermediate CO_2-storage solutions for ship-based chains
- Supply scenarios using combination of ships and pipelines.

Based on the experience from CO_2 pipeline transportation in North America and on the pipe-laying history in the North Sea area, it can be assumed that building pipelines of the lengths and dimensions required for these EOR purposes would not be a difficult undertaking. Pipelines could start at source and go directly to the oil field, or, alternatively, via an onshore CO_2 hub in Norway. For pipeline transportation of CO_2, only compression is needed. One large pipeline carrying several Mt of CO_2 per year could supply a field with all the CO_2 needed over the lifetime of the CO_2 injection. However, the costs associated with the pipeline infrastructure increase significantly when CO_2 is supplied from multiple and geographically spread sources.

Ship transport on a large scale is not as mature as pipeline transportation, but there are already some experiences to learn from Yara International (previously Hydro Agri) routinely transports CO_2 by three small ships (900-1200 tonnes capacity) for the North European market. Loading takes place at Yara's ammonia plants in the Netherlands and in Norway. The experience of Yara has been taken further in the so-called CO_2 ship-transportation project with ships having a carrying capacity of 10 000 to 30 000 m^3. Such ships are not found today, but their design is not a long stretch from an existing type of liquefied petroleum gases (LPG) ships. Ships have the advantage of introducing flexibility in the CO_2 value chain, allowing collection of concentrated CO_2 from various sources at volumes below the critical size for pipeline transportation. A disadvantage is that liquefaction plants and intermediate storage facilities would have to be built at each loading site, adding cost. If an onshore CO_2 hub were to be introduced, intermediate storage facilities matching the incoming amounts of liquefied CO_2 would also be needed there.

The results of these studies have been used to estimate the cost/price range for supplying 5 million metric tonnes (Mt) of CO_2 per year from industrial sources through a 10-year period for the Gullfaks EOR operations. As mentioned above this particular project did not turn out to be commercially viable, but others may be so in the future, in particular as the cost of emitting CO_2 to the atmosphere increases.

CONCLUSION: THE WORLD ON A LOW CARBON DIET?

Capturing and injecting CO_2 from natural gas may not seem to be terribly exciting by itself. Sense is first made when seen in a larger context of decarbonising fossil fuels (coal, oil, natural gas) from major point sources such as energy intensive industries and power plants in order to keep more massive amounts of CO_2 out of the atmosphere.

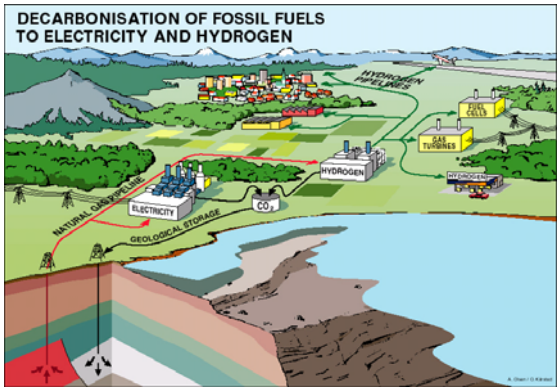

Figure 10 : A vision of a lower carbon future where electricity and hydrogen are the major energy carriers.

Figure 10 seeks to show in a simplified way how electricity and hydrogen may become the favoured energy carriers based on fossil fuels in combination with CO_2-capture and –storage. These energy carriers are essentially the only ones that do not carry the carbon with them to the point of end use. From an oil and gas company perspective this allows our main

products of oil and natural gas to be still attractive while at the same time taking a lead in climate change mitigation. As a result the world might be put on a low carbon diet [11].

PROCESS INTEGRATION: CURRENT STATUS AND FUTURE POTENTIAL

Robin Smith

Centre for Process Integration, School of Chemical Engineering and Analytical Science, University of Manchester, Manchester, UK.

ABSTRACT

Process integration as a systematic approach to the development of chemical process flow sheets, first a merged in the late 1970's. Emphasis in the earliest applications was on energy conservation. By exploiting thermodynamics and graphical techniques, methods were developed to allow designs to maximise energy recovery. These techniques have now found widespread industrial practice. In parallel with the graphical and thermodynamic techniques, approaches based on the optimization of a superstructure were developed. These allowed automation of the whole design process and allowed both economic trade-offs and complex constraints to be included in the design methods. However, it is only recently that such methods have found their way through to industrial practice. Stemming from the early interest in energy conservation, process integration techniques were extended to encompass mass exchange. Techniques were developed for minimizing water consumption and these have found industrial practice. Another area that has found industrial practice is that of hydrogen integration in petroleum refining. Even though these tools are now well established in process engineering, with commercial software available, the understanding of such tools is still very patchy around the process engineering community. Whilst academic research has forged ahead into new areas, such as reaction systems, there seems to be little attention paid to this so far in industrial applications in these new areas.

INTRODUCTION

Before systematic approaches were developed for process integration, process designers only had heuristics, experience and intuition to guide the creation of new designs. Heuristics are guidelines based on the generalization of past experience. The first attempts to develop process integration methodologies attempted to formalize the use of heuristics in a structured approach [1]. This early work achieved only a limited success in synthesizing flow sheets. The fundamental problem with using heuristics is they do not have a sound scientific basis, are often qualitative in their guidance and different heuristics can often be contradictory. However, the approaches developed required decomposing the problem into sub-problems [1]. These sub-problems (e.g. reaction system synthesis, separation system synthesis, heat exchanger network synthesis) are still the most common exploited today. Much of the research into process integration methodologies has concentrated on removing the need for heuristics to develop designs for the sub-problems and provide a sound theoretical basis.

Whilst new scientifically-based procedures have been helpful in removing the need for heuristics in process integration, heuristics nevertheless have an important role to play for the process designer. Heuristics provide the process designer with a feel for the problem and a benchmark against which to measure features of the process design. It might be that a design feature agrees well with known heuristics, or perhaps disagrees. If the design agrees, then it gives the designer some assurance that the procedure is not producing misleading answers. If the design departs significantly from the heuristics, then the designer should try to understand why.

The first scientifically-based procedures to be developed for process integration developed new thermodynamic principles to solve the heat exchanger network synthesis problem. The composite curves [2-8] are perhaps the best known tool of process integration, see Figure 1. The composite curves give in a single picture the cumulative cooling and heating requirements of a complete process. The overlap between the curves provides us with a target for the heat recovery opportunities, and the residual heating and cooling in the composite curves give us the targets for external heating and cooling requirements.

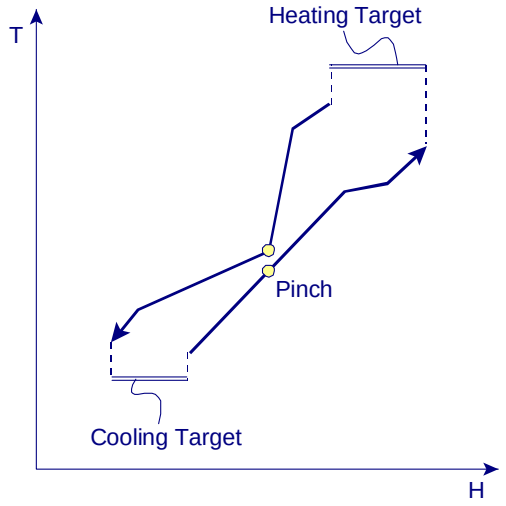

Figure 1: Composite curves allow energy targets to be set before design.

The pinch design method was then developed in order to allow the energy targets to be achieved in practice [9]. The pinch design method followed the pinch principle [4-8], which required that heat should not be transferred across the pinch by process heat recovery and that we should not make inappropriate use of utilities. Another early application was the grand composite curve [10], Figure 2. The grand composite curve presents a temperature enthalpy profile of the external heating and cooling utility requirements after heat recovery has been carried out. This gives a clear picture of the interface between the process and utility system and allows the most appropriate mix of utilities to be selected. So far, all of this relates to individual processes in isolation.

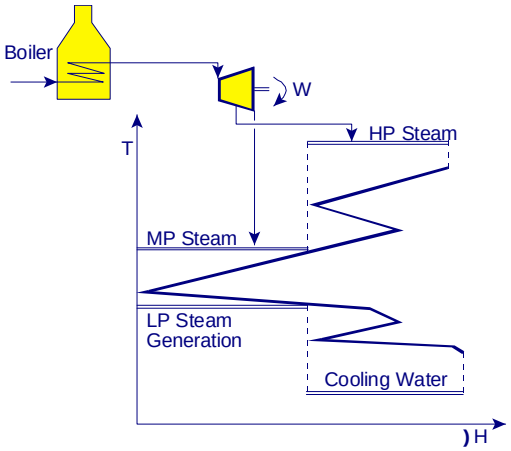

Figure 2: The grand composite curve allows us to select the utility mix before design.

The idea of the grand composite curve was found to be readily extended to total sites in which the grand composite curves of the individual processes could be combined together to produce the site composite curves and give a complete picture of the total site utility requirements as temperature enthalpy profiles [11]. These site composite curves then allow targets to be set for the utility requirements for the complete site and also allow targets for cogeneration from steam turbines to be set.

This process integration technology for energy efficiency has seen widespread application throughout the world. There have now been thousands of successful applications in a wide range of industries from petroleum, petrochemical, chemical, fine chemical, through to steel manufacture, food and drink, pulp and paper. The financial benefit has been both in terms of reduced energy costs and debottlenecking for increased throughput. In a few cases, studies have been driven by the requirement to reduce the emissions of combustion gases. Although applications for reduction in combustion

emissions have so far been few in number, it seems inevitable that this will be a major driving force for future studies as governments seek to reduce national levels of the emissions of greenhouse gasses.

In parallel with the thermodynamic approach that was developed for process integration, an alternative approach based on the optimisation of superstructures using mathematical programming was developed [12]. In this approach a structure, known as a superstructure, is first created that has embedded within it all feasible operations and all feasible interconnections that are candidates for an optimal design. The problem is formulated mathematically and the superstructure optimised in a structural and parameter optimisation. The optimisation then removes redundant features, reducing the complexity of the design and setting operating conditions. Thus, the decision-making aspects of design are carried out by automated procedures in software.

RECENT DEVELOPMENTS IN ENERGY INTEGRATION

Investigating improvements in energy integration should start by investigating the utility system that services the process. Only in this way can the true incentives to improve the energy performance of individual processes be established. Figure 3 illustrates a typical industrial utility system in which different process production units are linked to a common steam system.

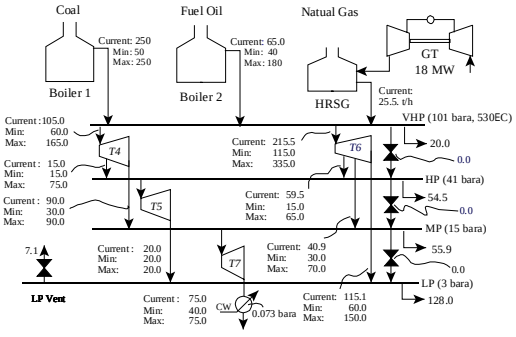

Figure 3: Existing steam system at its optimized conditions (flows in t/h).

Steam is distributed around the site at different pressures. The process units use steam from different pressures, and in some cases, generate steam from sources of waste heat at high temperatures that is fed to steam mains. High temperature heating demands within process units may require furnace heating. Power is generated in the utility system in Figure 3 in backpressure steam turbines from the expansion of steam from high to low pressures. The steam turbines in Figure 3 also feature some condensing power generation. Large sites might also feature gas turbines, Figure 3. Power might be imported to the site from centralized power generation, or in some cases, power exported from the site. On such a site, what is the true value of steam saving? The answer turns out to be not so obvious.

To analyze a utility system, it is first necessary to develop a simulation model [13]. Commercial software is available to allow such models to be developed. The simulation model should allow part-load performance of the steam system components and should provide a simulation of the complete material and energy balance around the steam system, capable of predicting the fuel, power generation, water requirements, etc. for any condition of the steam system. The model must take account of the operating constraints around the system. Once such a simulation model has been developed, it can be subjected to optimization [13]. The value of such an optimization model is that it can be used to identify the true value of energy saving from different pressure levels. The steam usage from each main can be gradually reduced and the system re-optimized at each step [14]. This sounds like a lot of work, but it is straightforward given appropriate software. Figure 4 shows a typical result. Two things need to be noted.

1. There is not a single value for steam at a given level. It depends on how much is being saved, the various costs, equipment performance and the constraints in the utility system.
2. Steam saving is limited by equipment constraints in the utility system. The

steps in Figure 4 are created by the optimization encountering constraints in the utility system.

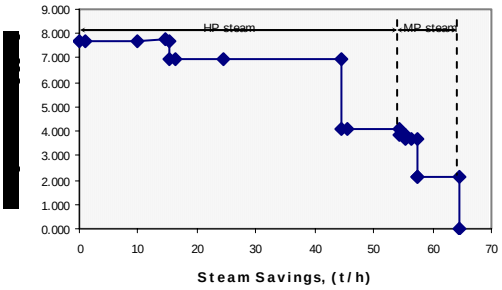

Figure 4: Steam marginal costs for a site.

Figure 4 provides the basis of a strategy for steam saving on a site, but does not show how to go about making the saving. That requires detailed analysis of heat recovery systems, etc.

Process integration techniques for heat exchanger network retrofit have improved significantly. This problem was difficult to address using the thermodynamic methods developed in the 1980's, since when they were applied to retrofit they effectively considered the problem as a pseudo new design. Heat transfer across the pinch was identified as inefficiency in the design and, where appropriate, attempts made to correct it in order to reduce the energy consumption. However, the process pinch relates to an ideal new design and not to what is existing in an existing heat exchanger network. One of the methods proposed to overcome these drawbacks is the so-called network pinch [15, 16]. The network pinch starts by identifying the bottlenecking exchangers within the existing structure. To overcome the network pinch requires a modification to the network structure. This could be relocation of an existing heat exchanger to a new duty, addition of a new exchanger, or introduction of a stream split. To identify the most appropriate structural modification is not straightforward. At this point mathematical programming can be used to identify the most beneficial structural changes, but guided by thermodynamic insights. This approach allows retrofit to be carried out one step at a time, leaving the designer in control to accept or reject options at each stage in the development of a retrofit design.

MASS INTEGRATION

The heat integration developments in the 1980's were later extended to processes involving exchange of mass. El-Halwagi and Manousiouthakis [17] took some of the fundamental ideas from the thermodynamic analysis of heat exchanger networks to create a new area of mass exchange networks. Later work took these ideas and focused on the particular problem of water networks [18, 19]. The design objective in water-using networks is to minimize the water consumption by maximizing the re-use of water. Further reduction in water use can be obtained by introducing processes for partial treatment of the wastewater, termed regeneration, allowing further re-use or recycling of water.

Various water-using processes can be combined together to give a composite curve for the entire system, allowing targets to be set for minimum water supply. Extension of the methods of energy integration to water integration is thus, in principle, quite straightforward. However, this approach rapidly runs into problems. It is possible, although very difficult, to extend this approach to deal with multiple contaminants, rather than a single contaminant [19]. It is also possible, but also difficult, to allow the introduction of the flowrate constraints which are often encountered with water-using operations. Add to this the desire to introduce cost optimization and forbidden matches, etc., and the simplistic extension of the energy integration approach to the

water minimization problem rapidly runs into problems.

However, it is possible to formulate the problem using mathematical programming that allows all of the complexities of water system design to be included [20]. Multiple contaminants, multiple water sources, flowrate constraints, forbidden matches, water costs, effluent treatment costs and piping costs can all be included in the problem.

HYDROGEN INTEGRATION IN PETROLEUM REFINING

The changes taking place in the specifications for gasoline and diesel are causing fundamental changes in petroleum refining throughout the world. When product specifications are changed in a petroleum refinery or the refinery optimized or debottlenecked, the supply of hydrogen is often a limiting factor, particularly when producing low sulphur, low aromatics products. The recovery of hydrogen from off-gases for reuse in refinery processes is a problem analogous to the recovery of process heat. Similar benefits can be achieved by developing integrated designs that make better use of available resources. The problem of hydrogen management is therefore to find a network that will allow the best overall operation of the refinery to be achieved. Sources of hydrogen include recovery from fuel gas and tail gas, dehydrogenation processes, heavy end gasification, steam reforming and outside purchase. Systematic methods of identifying hydrogen needs and available production are required in order to optimize site performance and maintain the flexibility to run different crude oil feed stocks, while maintaining maximum equipment utilization.

Graphical targeting can be used to analyse the hydrogen resources available in the refinery and suggest which off gases should be sent to hydrogen recovery processes [21]. Targets for required hydrogen plant production or off-site purchase can also be set. As with other network design problems, mathematical programming can be used to include the details of the pipework, compressors and the capital cost associated with hydrogen recovery processes. Although the methodology is new, it has already seen many successful applications. To take the best opportunities from hydrogen network design, process changes for the hydrogen consumers needs to be included in the methodology.

INTEGRATION OF DISTILLATION SYSTEMS

Turning now to distillation system design, it is first useful to distinguish between simple and complex columns. A simple column takes a single feed, produces two products with key components adjacent in volatility and the column has a reboiler and a condenser. If consideration is restricted to simple columns, then a system requiring the separation of a mixture into a number of products can be configured in a number of different ways. Although different configurations are possible when using simple columns, the problem still remains of a manageable size. Once complex distillation arrangements are introduced, each simple configuration can be evolved into many complex arrangements involving thermal coupling, side strippers, side rectifiers, pre-fractionaters and dividing wall columns. Thus, as the number of products increases for the distillation system, the number of possible complex column configurations explodes. Added to this problem, the most appropriate pressure for each separation in a complex arrangement needs to be chosen and heat integration considered simultaneously.

Whilst significant progress has been achieved in the development of process integration design methods for the synthesis of heat integrated distillation systems, there is still much work required before the full potential can be exploited commercially. Methods are available to synthesize systems of complex columns, but not heat integrated. Some progress has been made for a particular case of heat integrated refinery distillation, but further development work is required [22].

One of the most significant developments in distillation in recent years has been the application of partition, or dividing wall, distillation columns [23-26]. These allow three essentially pure products to be taken from a single column with efficiency greater than that possible with conventional designs. Such columns allow energy reductions of the order of 30%, together with capital cost reductions, when compared with the equivalent arrangement of simple distillation columns. Although the basic idea has been known since 1947, it is only in recent years that the arrangement has been exploited commercially [23, 25, 26].

The distillation systems considered so far have been restricted to non-azeotropic systems. When azeotropic systems are considered, a whole new set of problems emerge. Graphical techniques have been developed to help designers visualize the problems associated with azeotropic and extractive distillation [27]. Unfortunately, these tools are restricted largely to ternary systems. With the use of elaborate graphics, the principles can be extended to quaternary systems. However, the most complex cases cannot be considered by such simple graphical tools. Even though much progress has been made in recent years towards a better understanding of azeotropic and extractive distillation, much work is still required. Better understanding of heterogeneous systems needs to be developed in order that the potential for simple phase separations can be fully exploited.

GRAPHICAL TECHNIQUES VERSUS OPTIMIZATION

The early systematic procedures developed for process integration were based on graphical techniques. Graphical techniques were developed for energy integration, water minimization and hydrogen integration. Such techniques provide valuable insights and leave the designer under full control. However, graphical techniques also have very severe limitations. Multi-dimensional information is difficult or impossible to represent. Economic trade-offs and constraints are difficult or impossible to include. Thus, to deal with the size and complexity of industrial design problems, the trend is to increasingly exploit approaches to process integration that are based on optimization of a superstructure. This approach has a number of advantages. Many different design options can be considered at the same time. The complex multiple trade-offs usually encountered in chemical process design can be handled by this approach. Also, the entire design procedure can be automated and is capable, in principle, or producing designs quickly and efficiently. However, there are also fundamental problems associated with approaches to process integration based on the optimization of a superstructure. The engineer looses control and the intuitive feel that a graphical representation provides. There is still an incentive to provide the designer with a graphical picture that gives some indication of the physical aspects of the design, for example, in the same way as the composite curves would. In many cases, such graphical representations can be developed from the output of an optimization calculation. This combines the advantages of both the graphical and optimization approaches to process integration.

Another feature of the graphical techniques used in process integration is that they are based on a two-step approach. In the first step, targets are set to scope and screen alternatives. In the second step, a design is developed to achieve the targets set by the graphical approach. Once an approach is adopted that is based on the optimization of a superstructure, structural issues relating to the design are readily included in the process integration technique. This means that the targeting and design steps that were a feature of the early techniques are combined into a single step.

FUTURE POTENTIAL

Challenges remain in process integration, even in the established areas discussed above. Enormous challenges still lie ahead

in new areas. There are many areas of process integration that have hardly been addressed in terms of producing methods that can be exploited commercially.

Process integration of reactions systems is still in its infancy. It is desirable to be able to synthesize the design of the reaction and the associated separation systems simultaneously. This is particularly important when the separation system is extremely complex and costly, as is the case with many azeotropic systems. Reactor design is generally carried out by considering the reactor in isolation. Yet, in most cases the reactor design interacts strongly with the rest of the process. Taking this a step further, the catalyst is often designed prior to the reactor design and without too much consideration of the reactor design to follow. Yet, the catalyst design, reactor design and separation system design should only be carried out simultaneously in an integrated fashion. Biochemical reaction systems present similar, but more daunting challenges.

Besides reaction systems the process integration of separation systems other than distillation has hardly been considered. Membranes, crystallization processes, and solids processing operations in general all need further development. Hybrid separations offer potential advantages in some applications. Yet, the potential for hybrid separation has hardly begun to be exploited

It is often considered that process integration techniques only apply to large scale continuous processes. This is not the case. Whilst it is true that heat integration of batch processes is usually not worthwhile, batch processes still have significant potential for improvement through better process integration. Most batch processes are designed through scale-up. The time element in batch processes provides flexibility in the design and operation. However, the flexibility that the time dimension offers is often taken as an excuse from not doing a thorough design and optimization of the design. In these applications, data is often the biggest problem. How can we design and optimize such a process if we do have basic information, such as reaction kinetic data? Such problems require that experimental investigation (and the design of the experiments) be conducted in parallel with the design of the process and its integration. The experimental design and the process design must be integrated in a co-ordinated activity.

Lack of software for the newer areas of process integration is a bottleneck. There is plenty of commercial software available for energy integration. More recently, commercial software has become available for water system integration, hydrogen system integration and the design of distillation systems.

Unfortunately, commercial software on its own is not enough. Even with the best commercial software, process engineers need to be educated in process integration techniques. Crowded university curricula in too many cases mean that students are not exposed at all to process integration techniques. But this is where awareness must start [28]. Education and updating must continue through professional training. Otherwise, significant opportunities will be missed in process engineering.

ABSTRACT

The environmental impact produced in the residential sector is among the biggest in modern society. The energy consumption in this sector accounts for about 40 % of the total energy consumed in a country. Windows are among the main responsible of the energy losses and gains in buildings, affecting both their summer and winter energy balances, and being responsible for up to 25-50 % of the energy consumption due to thermal conditioning purposes, depending on the climate conditions. Modern technology have produced a variety of models aimed at controlling these energy transfers, like double and triple glazed windows filled with heavy inert gases, low-emittance coatings, thermal breaks in frames, etc. However, the fabrication of these new windows requires new consumptions and releases new emissions, and their real environmental and economic benefits are not always guaranteed. For instance, the production of heavy inert gasses like Ar, Kr and Xe requires huge amounts of energy, and therefore is responsible for the associated emissions of pollutants. In this paper, the environmental and economic assessment of the application of double-glazed windows filled with air, Ar, Kr and Xe in typical houses of the Andean arid region of western Argentina is performed. The methodology used for the evaluation of the environmental impact is Life Cycle Assessment, while the economic assessment is performed using the Life Cycle Costing method.
Key words: high performance windows, Life Cycle Assessment, Life Cycle Costing.

INTRODUCTION

Among the many problems arising from sustainable development connected to social, economic and environmental issues, those concerning habitat and energy become of utmost importance. Firstly –and due to its size and permanence- development of the habitat is the physical, most significant impact on natural environment. Secondly, energy is essential for the survival of present-day society. The eventual exhaustion of fossil fuels, together with the negative environmental impact produced by the massive use of such fuels, make it necessary for people to start implementing strategies to control and even undo the harmful processes which are now at work. It becomes obvious, therefore, that those sectors responsible for the production and management of habitat and energy will have to acquire further knowledge of these topics. The built environment probably has the greatest impact on ecosystems of all of society's enterprises, a phenomenon in progress due to the increasing rate of urbanization. According to data provided by the United States Green Building Council (USGBC), the construction of buildings takes up 40% of the energy and materials, 25% of the virgin wood, and 15% of the water used around the world annually [1].

Energy use in the built environment is undoubtedly one of the key issues to be addressed by planners and designers on the path towards such ambitious but elusive goal of sustainable development.

Some official figures on energy consumption in the urban domestic sector in Mendoza (Argentina) show that the domestic sector is responsible for 29.1% of the total end use energy consumed in the province. Within it, the participation in the net consumption by domestic uses is as follows: space heating 41.1%, domestic water heating 32.6%, cooking 11.3%, food conservation 6.1%, lighting 1.7%, space cooling and ventilation 0.5%, other appliances: 6.8 %. It can be seen that space heating and domestic water heating add-up to 73.7% of the total consumption and share a 90.0% of the natural gas consumed by the sector [2].

In general, factors influencing energy consumption in a building in use are as follows:

1. The influence of the building's shape and orientation on the load of heating and air-conditioning.
2. The role of building's design on the utilization of daylighting, solar energy and of natural ventilation.
3. The energy-effectiveness of the heating, cooling, lighting and domestic hot water systems.
4. The role of the users and their strategy to control the building's temperature.

If we consider the quantity of energy required to manufacture the materials and components used in the construction of a building, and the huge amount of materials involved, it becomes evident that it could be as effective to reduce the amount of energy required by buildings through a reduction of the energy consumption during their use –for instance through a bioclimatic design; as to reduce the energy content of the materials used. A study performed by Cole and coworkers shows an example for the Canadian climate [3]. The relation between the energy consumed in the energy content of the building varies according to factors concerning climate, use, tradition and social status; and is common that strategies to reduce the former are based on a higher consumption of energy to manufacture the building's materials and components. Therefore, it becomes necessary to make a deep analysis of all the stages involved in the building's lifecycle, in order to fully determine the value of the strategies at stake.

This paper will discuss the second of the above mentioned factors, focusing on one of the components: the window. Considerations will also be made about the environmental impact of the materials used to manufacture windows. Although this component takes up only 10-25% of the surface of new buildings' outer walls, it is responsible for up to 25% of the values for heating in cold climates and up to 50% of the values for air-conditioning in warm climates [4]. There exist different technologies to improve the termal behaviour of windows, all of which are tending to reduce the speed of heat flowing through the window as a consequence of the temperature difference between the interior and the exterior of the building, measured by the U-value, and the solar energy gain through the window, measured by the Solar Heat Gain Coefficient (SHGC). Among them, we can mention two and three-glazing windows, Low-emittance coatings, insulating gases between the panes, frames with thermal breaks, insulating spacers, etc. Figure 1 shows some of these strategies. This paper will discuss the effect of the reduction of the U-values through the use of a two-pane window and different gases between the panes.

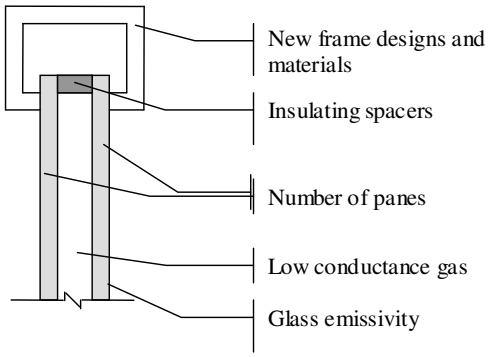

Figure 1

It is a common practice in Argentina to use single-glazing windows and only occasionally can two-glazing windows with air inside be found in sectors with a high purchase power. The second group shows a better performance than the first; yet, convective air currents form between the glazings and let heat flow through them. Using instead a less conductive, more viscous gas, such convective currents are reduced and, therefore, the transfer of heat between the interior and the exterior. There are in the current market high performance windows which make use of heavy inert gases, such as Argon, Kripton and Xenon, all of which have more insulating properties than air. As the molecular weight of the gas used increases, thermal conductivity dramatically decreases, together with cavity gap required. Therefore, high-performance windows can be manufactured with no need for increase significantly the weight of the

frames. The following picture shows the U-value for a window built with air, Ar, Kr y Xe, a low-emissivity coating on both glazings, and with a cavity gap of 20, 16, 12 and 8 mm, respectively [5].

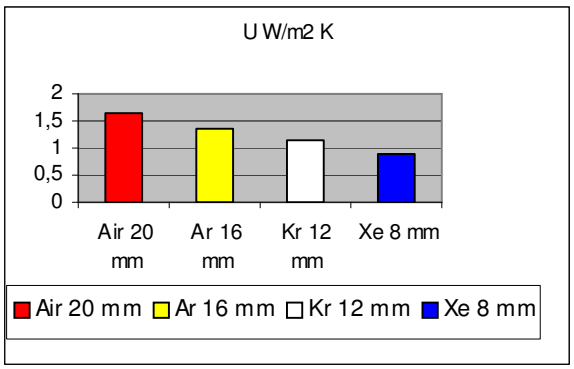

Figure 2. U values for window filled with different gases

Window sellers assure that having high performance windows at home is an intelligent investment, since they help save so much money on heating and cooling regular homes that they represent a far better investment than most available in the market today. They provide more comfort, reduce condensation on the windows, they transmit a smaller amount of UV radiation, responsible for colour fading of drapes and carpets, they reduce the amount of noise coming from outside, etc. This analysis, however, does not take into consideration the fact that to manufacture an efficient window a new set of materials and components are necessary, which, in turn, demand more energy consumption and release harmful emissions. The production of low conductive inert gases, for instance, which are natural components of the air, are obtained through a separation method which requires huge amounts of energy. According to Weir et al 1998, the specific amount of energy required to obtain these gases is 0.672; 38,500 and 511,400 kJ/lt, for Ar, Kr and Xe, respectively. The following questions arise: how is the amount of energy consumed for making a high performance window as compared with the energy saving produced by using that window in a house in normal conditions in Mendoza? How is the CO2 balance like? What about the impact of other environmental factors? Are return rates that significant? What kind of window would be best to have around the house: with air, Ar, Kr or Xe? To answer these questions, we need to know about the processes involved in the manufacturing of the materials and components of the windows, as well as about the energy consumption in the house when each type of window is installed on it. To do so, a windows maker from Mendoza is studied. Information about the processes carried out in this firm will be given later.

OBJECTIVES

This paper will discuss the following topics:

1. Environmental and energy impact of the manufacturing and use of four different types of two-glazing windows, using different types of gases between the panes: air, argon, kripton, xenon. The window discussed is built with aluminium frame, sheet and spacers. A house in Mendoza will be the location for this study case. For the use phase of the windows, only the energy consumption required for heating purposes on a house located in Mendoza will be analyzed, since according to the data given in [2] the energy consumed for cooling accounts for a small share in the region.
2. Economic advantage of each type of window, including different scenarios with different discount rates and the projection of different rates of increase in the cost of energy.

SCOPE OF THE STUDY

The utilized data account, if possible, for present technologies used in Argentina. When these data were not available, foreign values were used, taking into account the local energy mix for calculating the environmental effects associated with energy consumption. Average data have been used, except when the supplier was known and its data were available.

The environmental aspects included in this study account only for external effects, and it is assumed that the same comfort conditions are obtained in the house when the different windows are considered, thus conducing to different energy consumption in the building accordingly to their U-value.

Functional Unit: the study will be carried out based on a 1.2-m x 1.2-m window, the standard size in the local market.

INVENTORY ANALYSIS

For the energy calculations, the energy content of the main materials involved in the construction of the windows (aluminium, glass, inert gas) as well

as the energy consumed for balancing the energy losses through each type of window considered are taken into consideration.
For the other environmental categories considered, and according to the objectives and scope, the evaluation will be comparative and the inventory will only include those materials and energy flows which are different for each case studied. The only input flows to be included, therefore, are inert filling gases and the energy involved in heating the building to make it a warm, comfortable place, considering the insulating properties of each window. The aluminium frame, sheet, spacer and the glass are consequently not included in the inventory.

Making of the window

Making the window comprises many stages: obtaining filling inert gases, the aluminium, the frame, the sheets, the spacers, the glasses, the airtight double glaze (ADG) and the final assembling.
The aluminium profiles are made and painted at ALUAR plant - aprox. 1,400 km away from Mendoza, and then shipped by trucks.
The window frame and sheets are made in a plant located in Mendoza, where also the assembling process takes place. To make the window frame and sheets, the aluminium profiles must be cut properly, which requires relatively low energy consumption: 0.2 MJ per window. Out of the total 16.1 kg used, 15% (2.1 kg) is wasted and 14 kg are actually utilized. The material and processes involved at this stage are the same for all the alternatives assessed.

Assembling

There is no consumption of material or energy in this process.

ADG Manufacturing

The ADG is manufactured at a plant located 10 km away from the window manufacturer. The process includes cutting the glass, polishing its edges, washing it to prevent chips and dust from remaining inside the unit, placing the aluminium spacers, filling up with inert gas and sealing. Due to the lack of reliable information received from the company involved and the similarities found with the data published by Weir et al [6], the latter have been taken as a reference. The complete process requires an average energy consumption of 6 MJ per unit. The gap between glasses varies according to the type of gas used, thus varying the quantity of gas required: 22 l are necessary for air, 17.6 for Ar, 13.2 for Kr and 8.8 for Xe. 0.241 kg of aluminium is required for the spacers, plus 3% of waste.
The glass used is manufactured at another local company. The percentage of recycled glass is 56%. The amount of glass required for both layers is 21.2 kg. During the processes of cutting and assembling, some glass is broken and wasted, which represents 5.5% of the total. The total amount of glass required is 22.26 kg.
The quantity of inert gas consumed is the only relevant aspect at this stage, since the other materials are the same for all the alternatives.

Obtaining the inert gas

The gases involved in the study, Ar, Kr and Xe are natural components of the air and they are obtained through a process of separation, which utilizes considerable amounts of energy, depending mainly on the amount of such gas present in the air. According to data provided by Weir et al [5], the specific amount of energy required for obtaining these gases is 0.672; 38,500 and 511,400 kJ/lt for Ar, Kr and Xe, respectively.

Energy Required for Heating

The energy performance calculations were carried out in a conventional manner (Excel Worsheet) using the Solar Load Ratio method of LANL [7] for a normal 24 hr period The base temperature chosen was 18 ºC.
It is assumed that the window is placed in an outer wall with no solar gain.

LIFE CYCLE IMPACT ASSESSMENT

Classification

The following categories have been considered in the assessment of impacts:

1. Global Warming.
2. Acidification
3. Energy Consumption. All energy subsystems (heat, electricity, transport) are taken into consideration to reach a total amount of energy used. Values thus obtained are absolute and do not merely show differences between a window and a reference. In the other environment categories, instead, the results are comparative using the double-glazed window filled with air as a reference.

Characterization

The potential characterization factors of the CML [8] method have been used.

ECONOMIC ANALYSIS

The method used to carry out the economic analysis is the so-called Life Cycle Costing (LCC) [9]. LCC is used to assess alternative systems competing on the basis of cost, which requires such systems to be functionally equivalent (efficiency, safety, comfort, reliability, etc). Therefore, the system chosen can be that which, from the point of view of the cost, shows the best behaviour in the long term. It is a useful method to compare alternatives in projects which show different costs, and specially useful to determine if an alternative with a higher starting cost can later become more convenient after reducing future costs. The method adds up every cost related to the studied system's possession and operation for a certain period. Such costs are adjusted to the value of money at different times. The most cost-effective alternative will be the one whose life cycle cost –including the starting investment costs and all the expenses during its useful life- is the lowest.

For the economic analysis, several scenarios have been presented, where the discount rate and projections for rate increase of energy costs varied. The first scenario includes no increase in the real price of energy during the building's life time and a real discount rate of 2%, which is the one that the middle investor can obtain at local banks today. Considering no increase in the energy prices in this scenario does not favour conservative measures. In a second scenario it was assumed that energy prices will follow the tendencies shown in the past. Therefore, and according to data from the State Energy Department, a track record was made of natural gas prices for end-consumers in the last 15 years and then extrapolated to the future, following the minimum square method, resulting in an average increase rate in energy prices of 3%. The discount rate used is the same as the one for the previous scenario. The discount rate considered for the third scenario is nil, thus comparing the cost of investment with the non-discounted cost of the energy saved. Rate increase of energy cost is the same as in the previous case. This scenario favours investments in conservative projects, due to its nil discount rate. The last scenario considered here takes into account the present Argentinean situation concerning prices and rates, since the devaluation of the peso at the end of 2001 and the resulting modification of prices had a direct impact on companies which provided public services: the so-called "Economic Emergency Law" established that these companies' prices had to remain unchanged. Therefore, only in the initial period energy prices were around 30-55 % "backwards" – in terms of local currency- according to the inflation rates between 2001 and 2002 [10].

Businessmen in the sector are claiming since then for an increase in rates, and some official announcement are coming on the issue. The percentage of such increase, however, is still under discussion. According to an agreement between the State and the Techint group to install a gas duct in the Northwest, gas rates for domestic consumption will be gradually increasing to over 100% in a period of two years. By mid-2006, they will have reached 80% of their 2001 price in US dollars, which means a 114% overall increase from today's prices [11]. This information has caused some controversy and has even been denied. The truth is that there has been no increase yet. The last scenario suggests a relatively moderate increase: 20% during the first year; 20% after the following two years. After this initial augmentation, the increase would follow the historical tendency (3 %). The discount rate is 2%.

As regard the investment cost of the windows, and according to suppliers, the extra cost for a double-glazed window with air is 14 $/m2 with Argon, 140 $/m2 with Kripton and 556 $/m2 with Xenon [12].

RESULTS

Environmental Aspects

The figures below show the results for each of the studied categories and the influence of each stage (manufacturing and use) in the different categories of impact.

Figure 3 shows the distribution of the energy required for the fabrication of the windows filled with different gasses. It can be seen that in the case of a window filled with Ar, most of the energy consumed is due to the high energy content of aluminium. In the case of Kr and Xe the inert gas is the predominating material instead, due to the big amount of energy required for the separation of these gases from the other constituents of air. The influence of other materials and processes involved

in the fabrication of the windows as glass, transportation and cutting is irrelevant.

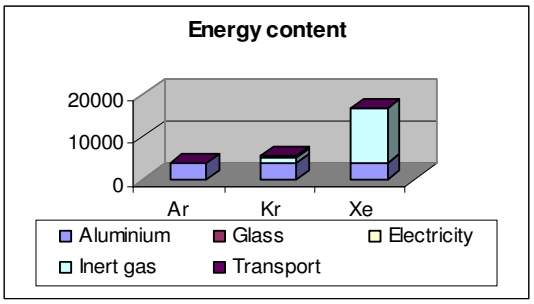

Figure 3. Energy content of the window filled with different gases

When the energy losses through the window during the heating seasons of 50 years are included into the analysis, the values shown in Figure 4 are obtained.

It can be seen that the energy content of the window represents only 25 % of the total in the Air case, and it increases progressively for the Ar, Kr and Xe until reaching up to 72 % in the latest case. Figure 4 shows that the minimum energy consumption is reached in the Argon case. This means that energy investments in inert gases are worth only up to the Ar case, but the additional investments required in terms of energy for the Kr and Xe cases are too expensive compared to the energy savings obtained during the heating seasons.

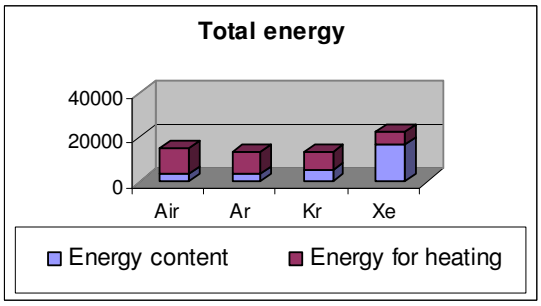

Figure 4. Energy content of the window filled with different gases

Performing now a comparative assessment, considering only the processes and materials used for the Ar, Kr and Xe windows in addition to those used in the window filled with air, and analyzing the global warming potential and acidification categories, tendencies similar to the energy analysis are obtained, as it can be seen in Figures 5 and 6. In all three categories of impact considered, Argon is the preferred alternative from the environmental point of view. These results make weighting and normalization stages of LCA unnecessary.

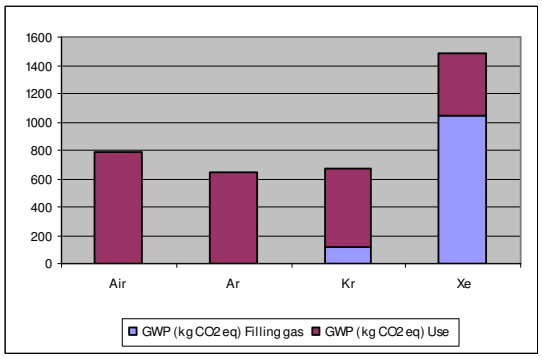

Figure 5. Global Warming Potential. Comparative analysis.

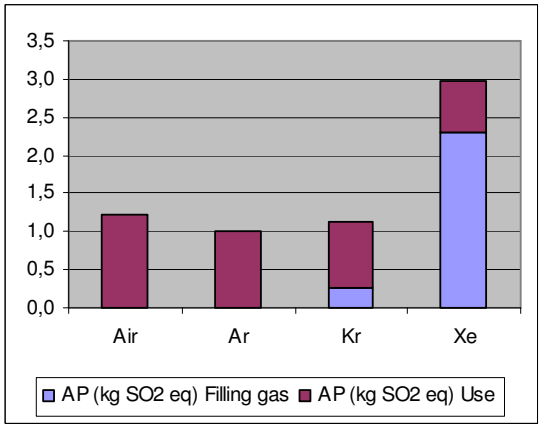

Figure 6. Acidification potential. Comparative analysis.

Economic Aspects

Table 1 shows the results, in present values, in the four considered scenarios. Scenarios 1, 2 and 4 show a preference for windows with air, which explain why this is the preferred window in Mendoza. Scenario 1 does not favour conservative measures since considers no increase in the cost of energy in the future. Neither scenario 2 gives preferentiality to conservative measures, since considers that in the coming 50 years fossil fuels prices will follow the same tendency than in the past, thus assuming that fossil fuels wells are plenty of resources and no scarcity will be in the coming future. Scenario 4 is similar to Scenario 2 with the only difference that takes into consideration initial increases in the energy costs, but the same tendency in the long term. All of these three scenarios consider a real discount rate

of 2 %. Scenario 3, on the other hand, shows that, from the economic point of view, the use of argon as filling gas in double glass windows is preferable when the discount rate is nil, even if the assumption on the increase in the energy costs is the same as in the past. Exploring for the lowest annual increase rate in energy cost that would justify the additional investment needed for the Argon window when a discount rate of 2 % is considered, a value of 5.5 % was found.

Scenario 1		
Project alternative	Initial cost	LCC
Air	0	33 (*)
Argon	20	47
Kripton	200	223
Xenon	801	819
Scenario 2		
Project alternative	Initial cost	LCC
Air	0	68 (*)
Argon	20	76
Kripton	200	247
Xenon	801	838
Scenario 3		
Project alternative	Initial cost	LCC
Air	0	121
Argon	20	120 (*)
Kripton	200	285

Air	0	79 (*)
Argon	20	85
Kripton	200	255
Xenon	801	844

Table 1. Comparative Present-Value Costs of Alternative Projects (* = Lowest LCC)

CONCLUSIONS

Results show that, although there are some environmental and energetic advantages in the use of double-glazed, argon-filled windows, the economic aspect is a disadvantage to its introduction to the market. Even in the case of the most favourable scenario (number 3), with a nil discount rate (which considers no difference between the value of money today and that to be saved in the future), economic results for the argon window and for the air window are almost identical. Kripton windows show small environmental advantages compared to air windows, but their use is not justifiable from the economic point of view. Xenon windows are the least convenient from both the environmental and the economic points of view, even though they are the most energy-effective during the use phase.

ABSTRACT

By means of a finite-time thermodynamics formalism we analyze the performance of an endoreversible power plant model (the Novikov model) under thermoeconomical criteria. This is accomplished by using the concept of the profit function defined in terms of the performing costs of the plant. Our study is based upon two optimization criteria: the maximum power regime and the so-called modified ecological regime. We show that under ecological conditions the plant dramatically reduces the rejected heat to the environment, and a lost of profits is translated in an usage of the fuels reducing the rejected heat towards the environment in 50-55% respect to that of a maximum power regime. This reduction depends on the heat transfer law used in the Novikov engine.
Keywords: thermoeconomics, endoreversible cycles, optimization.

INTRODUCTION

It is well known that due to practical and economical considerations actual power plants work under conditions which are between the maximum power (MP) regime and the point corresponding to maximum efficiency[1]. An analysis in this sense was reported by De Vos[1] by means of a thermoeconomical study of an endoreversible power-plant model, obtaining an optimum operation point in terms of relative investment costs and the fuel consumption of the plant. A similar criterion can be used for this thermoeconomical analysis by means of the so-called ecological function introduced in ref.[2], which is defined by

$$E(\tau,\eta) = W(\tau,\eta) - T_2\sigma(\tau,\eta), \qquad (1)$$

where W is the plant's power output, T_2 is the absolute temperature of the cold reservoir, τ is the temperature ratio of the cold (T_2) and hot (T_1) reservoirs of the endoreversible power plant model, η is the efficiency of the endoreversible model and σ is its total entropy production. In general, the maximization of the ecological function given by Eq. (1) leads to an engine configuration with a power output around 75% of the maximum power output and an entropy production around 25% of the entropy produced in the maximum power regime[2, 3]. Another important property of the so-called ecological regime is that at the maximum-E regime the engine's efficiency is approximately the semisum of the efficiencies corresponding to the maximum power regime, $\eta = 1-\sqrt{\tau}$, and the Carnot efficiency, $\eta = 1-\tau$, respectively[2, 3]. Recently, in ref.[3], Angulo-Brown and Arias-Hernández showed that a more suitable ecological optimization criterion must depend on the heat transfer law used to model the irreversible heat fluxes between the heat reservoirs and the working fluid, through a generalization of Eq.

(1), given by

$$E(\tau,\eta) = W(\tau,\eta) - \varepsilon(\tau) T_2 \sigma(\tau,\eta). \qquad (2)$$

This expression is called the modified ecological (EM) function, and the function $\varepsilon(\tau)$ contains the dependence on the particular heat transfer law[3]. As it was shown in [3] the function $\varepsilon(T_1, T_2)$ for the case of a linear Newtonian heat transfer law is given by

$$\varepsilon(\tau) = \sqrt{\frac{1}{\tau}}. \qquad (3)$$

If the heat transfer law is given by one of the Dulong-Petit (DP) type, then the function $\varepsilon(\tau)$ is given by[4]:

$$\varepsilon(\tau) = \frac{\sqrt{\tau(80+\tau)} - \tau}{10\tau}. \qquad (4)$$

The modified ecological criterion also leads to a good compromise between high power output ($\sim 0.75 P_{\max}$) and low entropy production ($\sim 0.25 \sigma_{P_{\max}}$) [4]. In the present work we analyze an endoreversible power plant under thermoeconomical criteria by using both a De Vos-type economical criterion and the modified ecological criterion. The paper is organized as follows: In section 2, we review the results obtained by De Vos[1] by means of a thermoeconomical study of an endoreversible model for a power plant operating under maximum power conditions, by considering both a Newton's and a Dulong-Petit's heat transfer laws. In section 3, we study the same system but using the modified ecological criterion, and we obtain an optimum efficiency in terms of the relative investment and fuel consumption costs of the power plant. We also compare these results by means of the both mentioned criteria. In section 4, we calculate the quantity of energy rejected to the environment of the power plant under the same both criteria. Finally, in section 5, we present our conclusions.

MAXIMUM POWER REGIME

The De Vos model, which was firstly introduced by Novikov[5] for a nuclear power plant, consists of two thermal reservoirs: a hot reservoir at temperature T_1 and a cold reservoir at temperature T_2, both T_1 y T_2 are taken as constants and with known values. Between the two reservoirs we have two components: A reversible Carnot engine and a thermal

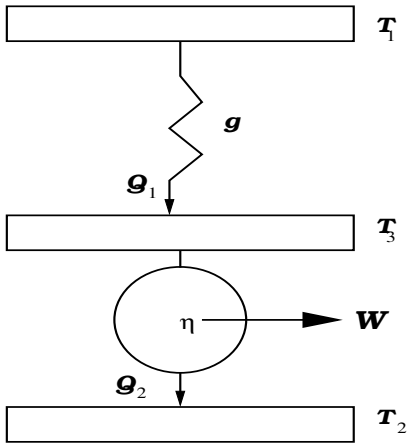

Figure 1: Scheme of the Novikov engine model.

conductor (with conductance g), which is an irreversible component (see Fig. 1). In the Novikov model, the hot side of the Carnot engine is at temperature T_3. In the De Vos thermoeconomical approach a profit function, q, is maximized, this function is given by the quotient between the power output and the costs involved in the performance of the power plant, that is,

$$q = \frac{W}{C}, \qquad (5)$$

where W is the plant's power output and C are the costs, which have two contributions: a).- the cost of the investment which is assumed as proportional to the size of the plant and b).- the cost of the fuel consumption which is assumed as proportional to the quantity of heat Q_1 (see Fig. 1).
If one takes that $Q_{\max}$ is a proper measure of the plant's size, then the costs C can be expressed by

$$C = aQ_{\max} + bQ_1, \qquad (6)$$

where the proportionality constants a and b have units of $\$/Joule$, and $Q_{\max} = g(T_1 - T_2)$.
If in Fig.1 we assume that Q_1 is given by a linear Newtonian heat transfer law, we have

$$Q_1 = g(T_1 - T_3). \qquad (7)$$

On the other hand, from the heat to work conversion in the reversible part of the model we get

$$W = \left(1 - \frac{T_2}{T_3}\right) Q_1. \qquad (8)$$

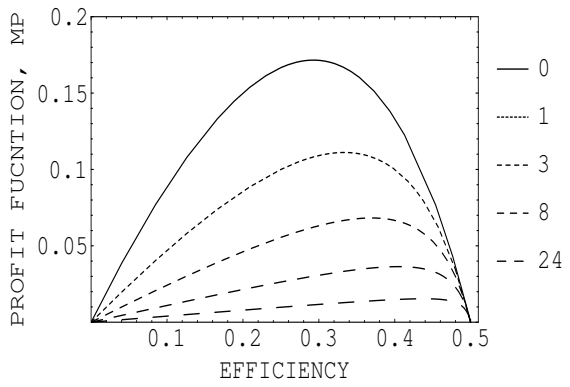

Figure 2: Profit function at maximum power versus efficiency η for several β-values.

If we use the Carnot's efficiency formula for Fig.1 and Eq.(6), the expression for the power output becomes

$$W(\tau,\eta) = gT_1\eta\left(1-\frac{\tau}{1-\eta}\right), \qquad (9)$$

where W is function of the efficiency η and thus of the temperature T_3.
From Eq.(6) the function of costs C becomes

$$C(\tau,\eta) = agT_1\left[(1-\tau)+\beta\left(1-\frac{\tau}{1-\eta}\right)\right], \quad (10)$$

where $\beta = \frac{b}{a}$. From Eqs. (5), (9) and (10), the expression for the De Vos profit function is given by

$$q_V(\tau,\eta,\beta) = \frac{1}{a}\frac{\eta\left(1-\frac{\tau}{1-\eta}\right)}{\left[(1-\tau)+\beta\left(1-\frac{\tau}{1-\eta}\right)\right]}. \quad (11)$$

Fig. 2 shows the form of $aq_V(\tau,\eta,\beta)$ for several values of β, in the case of $\beta = 0$, we have

$$q_V(\tau,\eta) = \frac{1}{a}\frac{W(\tau,\eta)}{Q_{\max}},$$

which has a maximum value at $\eta = 1-\sqrt{\tau}$, that is, the Curzon-Ahlborn efficiency [6], which is the efficiency of an endoreversible engine model working under maximum power conditions. When $\beta \to \infty$, the maximum point of the function aq_V tends to the Carnot efficiency, $\eta = 1-\tau$.

We can calculate in an explicit manner the maximum of the function given by Eq.(11) in terms of the adimensional parameter β. Nevertheless, this parameter is not easy to evaluate and it is more convenient to work in terms of the so-called fuel fractional cost f defined by [1]

$$f = \frac{bQ_1}{aQ_{\max}+bQ_1}, \qquad (12)$$

which is the ratio of the fuel cost between the total cost of the plant. The value of f for several types of fuel is shown in Table I. Therefore, the De Vos optimum efficiency[1] in terms of the fractional cost f, is given by

$$\eta_{opt}^{DV}(\tau,f) = 1-\frac{f}{2}\tau-\frac{\sqrt{4(1-f)\tau+f^2\tau^2}}{2}. \quad (13)$$

Fig. 3 shows how the optimum efficiency changes between $f = 0$ (free costs case) and $f = 1$ (the Carnot case).
Eq. (13) gives us the optimum efficiency of the Novikov's model in terms of the fractional cost of fuel f, when the power plant works in a maximum power regime and the heat exchange between the thermal reservoir and the working fluid is given by a Newton-type heat transfer law.

Fuel	f (%)
Renewable	0
Uranium	25
Coal	35
Natural Gas	50

Table 1. Relative cost of fuel for several energy resources, taken from [1].

We now consider in the Novikov engine a Dulong-Petit transfer law of the type $Q_1 = g\,(T_1-T_3)^{\frac{5}{4}}$, performing in a MP regime, then the profit function is given by[7]:

$$q_{mp}^{DP}(\tau,\eta,\beta) = \frac{1}{a}\frac{\eta(1-\frac{\tau}{1-\eta})^{\frac{5}{4}}}{\left[(1-\tau)^{\frac{5}{4}}+\beta(1-\frac{\tau}{1-\eta})^{\frac{5}{4}}\right]} \qquad (14)$$

This function has a similar behavior as that given by Eq. (11), with a maximum value at $\beta = 0$, which is the MP point, in addition, if $\beta \to \infty$, the maximum value of the curve tends to the reversible Carnot point, that is, to the point $\eta_C = 1-\tau$, see ref. [7]. From the maximization of Eq. (14) we obtain the optimal efficiency in terms of

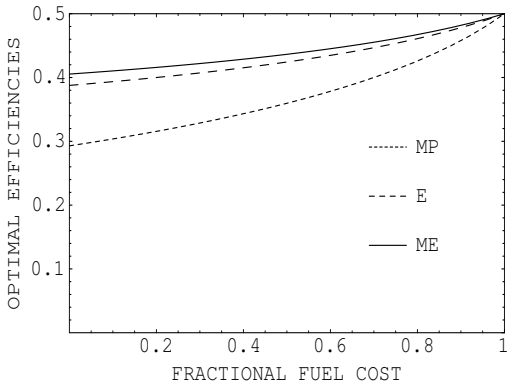

Figure 3: Comparison between η_{opt}^{DV}, η_{opt}^{EM} and η_{opt}^{E} for a Newton heat transfer law, for $\tau = \frac{1}{2}$.

the adimensional parameter β, and by using Eq. (12), we get[7]:

$$\eta_{mp}^{DP}(\tau,f) = 1+\frac{\tau(1-5f)}{8} - \frac{\sqrt{\tau^2(1+25f^2-10f)+80\tau(1-f)}}{8} \quad (15)$$

The function $\eta_{mp}^{DP}(\tau,f)$ has a similar behavior that Eq. (13). From Eq. (15), if $f=0$ (equivalently to $\beta=0$) we obtain the maximum efficiency value of the Novikov engine for a heat transfer law of the Dulong-Petit type, this efficiency is given by [7],

$$\eta_{mp}^{DP}(\tau) = \frac{8+\tau-\sqrt{\tau(\tau+80)}}{8} \quad (16)$$

This expression also was recently obtained by Arias-Hernández et al.[4].

THE ECOLOGICAL CRITERION

Following the same procedure employed in the previous section, now we calculate the optimum point of operation of the Novikov model in terms of the fractional fuel cost assuming that the power plant model works under the maximum modified ecological function (see Eq. 2). We again take the Newton's heat transfer law to describe the heat exchanges between the heat reservoir and the working fluid (see Eq. 7). By using Eqs. (2) and (3), the modified ecological function becomes[7, 8]:

$$E(\tau,\eta) = gT_1\left(1-\frac{\tau}{1-\eta}\right)\left[\eta\left(1+\sqrt{\frac{1}{\tau}}\right)+\sqrt{\tau}\left(1-\frac{1}{\tau}\right)\right], \quad (17)$$

where we also employ the mean entropy production given by $\sigma = \frac{Q_2}{T_2}-\frac{Q_1}{T_1} = \frac{Q_1-W}{T_2}-\frac{Q_1}{T_1}$, which by using Eqs. (7) and (9), becomes $\sigma = \frac{Q_1}{T_2}[1-\tau-\eta]$.

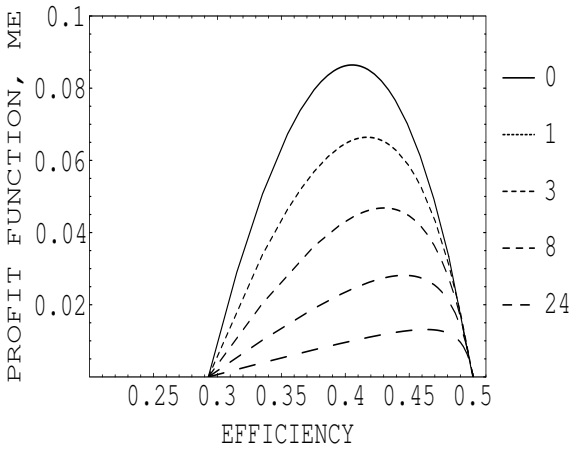

Figure 4: Profit function at maximum modified ecological function versus efficiency η for several β-values.

Thus, by means of Eqs. (10) and (17), the profit function in this case is,

$$q_E(\tau,\eta,\beta) = \frac{1}{a}\frac{\left(1-\frac{\tau}{1-\eta}\right)\left[\eta\left(1+\sqrt{\frac{1}{\tau}}\right)+\sqrt{\tau}\left(1-\frac{1}{\tau}\right)\right]}{\left[(1-\tau)+\beta\left(1-\frac{\tau}{1-\eta}\right)\right]}. \quad (18)$$

Figure 4 shows the behavior of the function $aq_E(\tau,\eta,\beta)$ for several values of β, as we can see, this function has a completely equivalent behavior to the function $aq_V(\tau,\eta,\beta)$ (see Fig. 2) based in the De Vos approach. If $\beta=0$, the profit function becomes

$$q_E(\tau,\eta,\beta) = \frac{W(\tau,\eta)-\varepsilon(\tau)T_2\sigma(\tau,\eta)}{aQ_{\max}},$$

with a maximum value at η given by

$$\eta = 1-\tau^{\frac{3}{4}}, \quad (19)$$

which is the efficiency of an endoreversible heat engine model with Newtonian heat transfer as reported in [3] and also obtained by Velasco et al. [9] by means of a different optimization criterion. If we maximize in an explicit manner Eq. (18), we obtain an expression for the optimum efficiency in terms of the adimensional parameter β and by means of the definition of the fractional fuel cost given by Eq. (11), we get[8]

$$\eta_{opt}^{EM}(\tau,f) = 1-\frac{f}{2}\tau-\frac{\sqrt{4\tau^{\frac{3}{2}}(1-f)+f^2\tau^2}}{2}, \quad (20)$$

that is, the optimum efficiency under the so-called modified ecological regime. Figure 3 shows the form of the function $\eta_{opt}^{EM}(\tau,f)$, which has the same behavior of

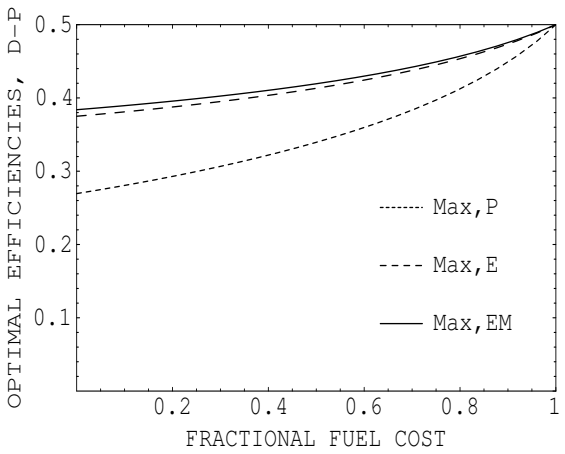

Figure 5: Comparison between η_{mp}^{DP}, η_{ME}^{DP} and η_{E}^{DP} for a DP heat transfer law, for $\tau = \frac{1}{2}$.

$\eta_{opt}^{DV}(\tau, f)$ also showed in Fig. 3. The optimum efficiency smoothly varies from the case $f = 0$ (free cost fuel) where the investment is the predominant cost until the Carnot case with $f = 1$, where the fuel cost is the predominant cost. We can see that in the case $f = 0$ (or $\beta = 0$) we obtain the ecological efficiency given by Eq. (19).
Analogously to the MP-regime, if the heat transfer law is of the Dulong-Petit type, the profit function under an ecological regime is given by[7],

$$q_E^{DP}(\tau,\eta,\beta) = \frac{1}{a}\frac{\frac{(\tau-1)(1-\frac{\tau}{1-\eta})^{\frac{5}{4}}\left[8(\eta-1)-\tau+\sqrt{\tau(8+\tau)}\right]}{\sqrt{\tau(8+\tau)}-9\tau}}{\left[(1-\tau)^{\frac{5}{4}}+\beta(1-\frac{\tau}{1-\tau})^{\frac{5}{4}}\right]}. \tag{21}$$

This function has the same behavior that the function given by Eq. (14). From the maximization of Eq. (21) we arrive to the optimal ecological efficiency in terms of f, given by

$$\eta_{EM}^{DP}(\tau,f) = 1+\frac{\tau(1-5f)}{8} - \frac{\sqrt{10\tau(1-f)\sqrt{\tau(\tau+80)}+(9-25f^2)\tau}}{8} \tag{22}$$

Fig. 5 shows the function $\eta_{EM}^{DP}(\tau, f)$ in terms of the parameter f, it is remarkable that this function has a similar behavior that Eqs. (13), (15) y (20). In Fig. 5 we compare the optimal efficiencies both under the MP and the ecological regimes by using a Dulong-Petit heat transfer law. In Fig 5 we also can observe the optimal efficiency under the former ecological function, given by Eq. (1)[7]. In additon, from the Eq. (22), if $f = 0$ (equivalently to $\beta = 0$), we obtain the maximum ecological efficiency for a Dulong-Petit heat transfer law, which is given by[7]:

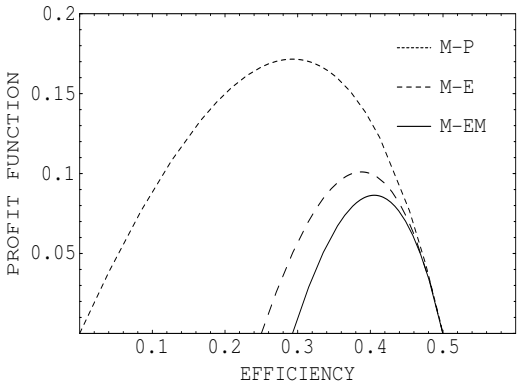

Figure 6: Comparison of the profit functions for the Newtonian case.

$$\eta_{\max}^{DP}(\tau) = \frac{8+\tau-\sqrt{10\tau\sqrt{\tau(\tau+80)}-9\tau}}{8}. \tag{23}$$

If we compare the profits both under the MP and the ecological regimes for a same value of f, it can be observed that the ecological profits are lesser than the profits at MP-regime (see Fig. 6). However, this lost of profits is concomitant whit a better efficiency for a given f (see Fig. 5). This means that the fuel consumption is better used by the power plant at maximum ecological regime.
The relationship between the mentioned optimum efficiencies is as follows,

$$\eta_{CA} < \eta_{DV} < \eta_E < \eta_C.$$

The fact of reducing the system's entropy without an important reduction of the power output has significant consequences in regard to the environmental impact.

ENVIRONMENTAL IMPACT

Nowadays, it is believed that the production of greenhouse gases, as CO_2 for example, can have an important impact over the global climate of the Earth. A great part of the atmospheric CO_2 is produced by human activities based on the combustion of fossil fuels occurring for instance in internal combustion engines. Thus, the aim of designing more efficient engines is concomitant with long-range ecological objectives. In this context, the ecological criteria seem a suitable procedure for the search of insights about an engine's performance with a less aggressive interaction with the environment. In this context, we propose the following simplified analysis. If we apply the first law of the thermodynamics to Fig. 1, we get

$$Q_2 = Q_1 - W. \tag{24}$$

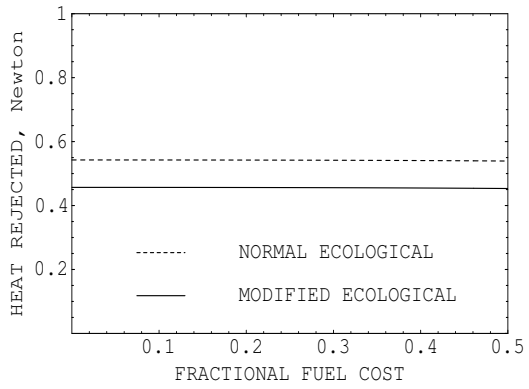

Figure 7: Quotient between the ecological rejected heat and the maximum-power rejected heat for a lineal heat transfer law.

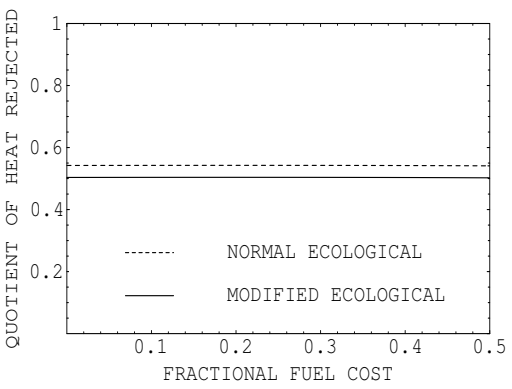

Figure 8: Quotient between the ecological regected heat and the maximum-power regected heat in the case of a DP heat transfer law.

By using Eqs. (8) and (9) in Eq. (24) we obtain

$$Q_2(\tau,\eta) = gT_1(1-\eta)\left(1-\frac{\tau}{1-\eta}\right), \qquad (25)$$

where $Q_2(\tau,\eta)$ is the heat rejected to the environment by the power plant. Therefore, if the power plant works in the maximum power regime, Q_2 becomes

$$Q_2(\tau,\eta_{opt}^{DV}) = gT_1(1-\eta_{opt}^{DV})\left(1-\frac{\tau}{1-\eta_{opt}^{DV}}\right). \qquad (26)$$

Analogously, if the power plant works under maximum modified ecological function conditions,

$$Q_2(\tau,\eta_{opt}^{EM}) = gT_1(1-\eta_{opt}^{EM})\left(1-\frac{\tau}{1-\eta_{opt}^{EM}}\right). \qquad (27)$$

From Eqs. (26) and (27), we can calculate the rejected heat to the environment for each value of f and under different manners of operation of the power plant. From Eqs. (13) and (20), the quotient between both the rejected heats in the modified ecological and maximum power cases can be expressed as

$$R_N(\tau,f) = \frac{(f-2)\tau+\sqrt{4\tau^{\frac{3}{2}}(1-f)+f^2\tau^2}}{(f-2)\tau+\sqrt{4(1-f)\tau+f^2\tau^2}}. \qquad (28)$$

Figure 7 shows the plot of $R_N(\tau,f)$ versus the parameter f for $\tau=\frac{1}{2}$. This plot shows that

$$\frac{Q_2(\tau,\eta_{opt}^{EM})}{Q_2(\tau,\eta_{opt}^{DV})} = 0.45, \qquad (29)$$

that is, the heat rejected to the environment (a river, a lake, the sea, etc.) by the plant under ecological conditions is around a half of the heat rejected under maximum power conditions. This same result was obtained by Velasco et al.[7] by means of another optimization procedure. Fig. 7 also shows the ratio between rejected heats corresponding to the former ecological regime (Eq. (1)) and the Q_2 at maximum power output.

In the same way, if we consider in the Novikov engine a Dulong-Petit heat transfer, we also calculate the quotient between both the rejected heats in the ecological and MP cases. Sustituting the Eqs. (15) and (22) in the Eqs. (26) and (27) respectively, this quotient can be expressed as,

$$\begin{aligned} R_{DP}(\tau,f) &= \frac{Q_2(\tau,\eta_{EM}^{DP})}{Q_2(\tau,\eta_{mp}^{DP})} \\ &= \frac{\sqrt{10\tau(1-f)\sqrt{\tau(\tau+80)}+(9-25f^2)\tau}}{\sqrt{\tau^2(1+25f^2-10f)+80\tau(1-f)}} \end{aligned} \qquad (30)$$

Fig. 8 shows the plot of $R_{DP}(\tau,f)$in terms of the parameter f for a $\tau=\frac{1}{2}$. This plot shows that

$$\frac{Q_2(\tau,\eta_E^{DP})}{Q_2(\tau,\eta_{mp}^{DP})} = 0.5, \qquad (31)$$

that is, the heat rejected to the environment by the plant under ecological conditions is now a half of that rejected under maximum power conditions. This fact can be used for designing some kind of ecological taxes based in the way of performance of heat engines [7, 10].

CONCLUDING REMARKS

Within a finite-time thermodynamics context we have determined an economically optimum regime for a power plant model (the Novikov model) following the De Vos procedure, but by means of an ecological-type optimization criterion. We have found that when the Novikov model maximizes the so-called modified

ecological criterion it reduces the rejected heat to the environment between 50 and 55% of the heat rejected in the case of a power plant model working under maximum power conditions. This represents a great advantage if the aim of the engine's performance is to diminish the impact on the environment.

ABSTRACT

Today decisions concerning energy systems are mainly based on economic analyses, paying minor attention to the Laws of Thermodynamics. This represents a serious conceptual drawback to the possibility of increasing thermal efficiency, reducing pollution emission and making a correct use of energy resources, because those are often subordinate to economic decisions. After a short overview of the methods present in the literature, concerning the multi-dimensional analysis of energy system, the utilization of aggregated indicators is discussed with reference to the case of "clean coal conversion technologies" analysis. The utilization of a different method based on a multi-criteria utility function is also discussed and analyzed with reference to the case of CGAM power plant.

INTRODUCTION

Beyond thermodynamic and economic, new criteria are going to influence the evolution of energy production; concepts as the depletion of resources associated with highly intensive use of energy, the

need to preserve the environment or the social issues related to investment decisions and political actions (taxes, incentives, etc.) are also significant subjects concerning the power generation. The general approach to the design of thermal energy systems is based on the idea that it has to be realized with high efficiency, low environmental impacts and acceptable costs. The design of a complex energy system represents a kind of multi-objective optimisation. In this sense the major effort of the EU energy policy is concentrated towards the direction of eco-efficiency. In general no unique solution exists that satisfy all the objectives, because some of them are in "structural" contradiction. In this sense, the problem of considering different viewpoints in the design and analysis of energy systems appears to be crucial and requires the elaboration of specific instruments. Multi-criteria assessment methods were recently proposed in the literature to compare different energy production technologies in the field of fossil fuels or renewable energy sources by the aggregation of thermodynamic, economic and environmental indicators [1-4]. First and Second Law efficiency, emissions to the atmosphere or to the water, heat rejected to the environment, cost of fuel or the specific cost of the energy produced are some of the main indicators used to compare the various energy conversion systems. The method is interesting, but it requires a careful application. First, the indicators considered are not dimensionally homogeneous and they must be recasted to a common normalized base. Second it is necessary to give to every indicator a relevance (i.e. weight) that accounts its influence. In general, it seems difficult to develop an unequivocal weight theory. Different methods for a multi-criterial analysis assessment of energy system are analyzed and discussed in detail with reference to the comparison among common and advanced technologies for the conversion of fossil fuels. The use of composed utility functions appears to be most suitable, owing to the possibility of introducing also the design variables of the system, even if open difficult questions [5-8].

MULTICRITERIA ANALYSIS OF ENERGY SYSTEMS: A CONCISE OVERVIEW

In the last years, methods of analysis and optimisation have been developed taking into account together with the technical elements related to the energy use (thermodynamic dimension), the financial resources expended (economic dimension), the correct use of physical resources and energy sources as well as any pollution and degradation of the environment resulting from the energy systems (environmental dimension). Other dimensions like sanitary, biological or social can also be directly linked to those three macro-dimensions, but they cannot be so simply related to the design of the plant. All the methods discussed in the literature to analyze the energy systems under that multi-dimensional point of view can be reconnected to a multi-objective optimisation. Some of them are based on the maximisation or the minimisation of a utility function in the form also known as "weighting function method" [9]

$$U = \sum_{i=1}^{k} U_i = -\sum_{i=1}^{k} w_i f_i(x) \qquad (1)$$

where w_i is a scalar weighting factor and $f_i(x)$ the i-th objective function. In the literature it is largely diffused the optimization of power plants and energy system basing on utility functions. The aggregation of the different dimensions has been object of the **environomic analysis** [6-7]. This analysis performs an optimisation of the plants by searching for the minimum of a utility function U

$$U = \sum_{r} Z_r + \sum_{r}\sum_{k} \Gamma_{ok,r} + \sum_{e} \Gamma_e - \sum_{r} \Gamma_{ro} \qquad (2)$$

where Z_r is the capital cost of the system associated to the r-th unit of the system, including charges and maintenance cost, $\Gamma_{ok,r}$ is the cost of resource and services, Γ_{ro} is the revenue from products or services that the system furnish (energy, steam etc.), Γ_e is the environmental costs. This term distinguish the environomic from the thermoeconomic approach and is defined as [5]

$$\Gamma_e = f_p k_e p_e \qquad (3)$$

where f_p is a penalty factor related to the pollutant, k_e is an environmental unit cost and p_e is a pollution measure [6]. The selection of the coefficients of Eq. (3) and its evaluation give place to misleading. Till now, the method was developed in a satisfactory way only with reference to some particular systems. A different method, the **aggregative utility function method**, takes into account the different feature of energy production by means of defined indicators. A multi-criteria analysis of energy system could include resource, environment, social and efficiency indicators. A selection among the

different indicators permits of including all the relevant dimensions of the system in a cumulative index. The general indices method comprises the formation of an aggregative function

$$Q(q,w)=\sum_{i=1}^{m} p_i q_i \qquad (4)$$

where p_i is weight-coefficients elements of vector w and q_i is the indicator of the specific criteria [1-2]. A rational work with indicators will confront us with two main problems, the aggregation problems and, the choice of a correct number of indicators.
In the literature some papers are present providing a selection of criteria and options for the comparison of fossil and renewable energy technologies [1-4]. But the comparison of different technologies carried out in those papers raises to a number of questions about the reliability of the method and the final result is strongly influenced by the priority given to a particular dimension or indicators.
Another approach is represented by the **Integrated environmental assessment (IEA).** The purpose of some researchers is to provide a method to evaluate the ability of a set of indicators to support decision-making and measure progress toward more sustainable systems of production. In its current state, the framework focuses on economic, environmental, health and safety aspects of energy production. [10]. The problems, induced on the environment by the pollutant emissions, and the related costs, represent an external costs of the energy systems. The economic approach has to decide how to estimate the external costs of pollutant emissions and how to internalise them into the economic evaluation of the system.
Models aiming at structuring these cross-boundary problems of an economic and environmental nature are usually called 'economic-environmental' or 'economic-ecological' models. The quantitative tradition in economics has enabled researchers to include environmental elements as costs. Nevertheless, in integrating economic and environmental models, some methodological problems are usually met, such as differences in time and spatial scales and differences in measurement levels of relevant variables. The typical approaches for the internalisation of pollution externalities are market based. The charge approach (taxes assigned to the pollutants) is the most commonly used and in this way the technical elements are considered only in a marginal way and the analysis could be very fragmented.

THE AGGREGATED COEFFICIENT OF POWER GENERATION (ACP)

Considering the methods available in the literature joining the idea of aggregative function with the integrated environmental assessment appears interesting. But doubts have been raised about the comparison among different type of power generation plants described in the literature [1-4].
A correct development of the ideas rises to compare systems of similar technologies, including indicators appreciating also some technical details. In general the indicators are not homogeneous and its aggregation to a common basis is a difficulty. This problem is object of the environomic analysis [6-7]. A possibility of aggregating the values of non-homogeneous indicators is to refer them to a normalized basis, using linear or non-linear approach. The Aggregated Coefficient of Power Generation (ACP) is obtained as sum of the different normalized indicators required in the analysis. This provides a simple method to compare different power plants belonging to a similar category depending on fuel used and size. The ACP for the j-th power system can be defined as:

$$ACP_j = \sum_{i=1}^{n} w_i NI_i \Big/ \sum_{i=1}^{n} w_i \qquad (5)$$

where NI_i is a generic normalised indicator, w_i is the weight coefficient for the i-th indicator and *n* is the number of used indicators. Once that the indicators have been defined the best power plant results the one with the highest ACP coefficient.
According to the method, the indicators can be normalized into a linear or no-linear scale [3]. A worst and a best value have to be identified for each indicator. The best value of each indicator is normalised at 1, while the value –1 identifies the worst value. An identification of a reference value (normalized value equal to 0) is also necessary, when a non-linear scale is used; these reference values are fundamental implying a preference among the various energy policies (rising the efficiency, reducing the environmental impact and the costs). In an analysis involving a lot of energy conversion systems the identification of reference values represents a key point too. An exaustive analysis can be obtained using a quite high number of indicators, causing a significant advance in the description of the different power systems, but also the risk of a very fragmented analysis. A definition of the indicators belonging to each dimension and an analysis about their meaning is given below.

The indicators used for the analysis

Among the possible indicators, thermodynamic indicators must be considered. If the comparison concern energy systems using the same input fuel First Law efficiency seems to be more appropriated, while a Second Law efficiency, permits to appreciate some peculiar differences among the technologies when the same fuel is used. For example using as reference the different values of the maximum operating temperature of the system (T_{max}). An indicator that can be introduced in the analysis is a quality index of the fuel utilization. Such an indicator can be related to intrinsic properties of the fuel, like calorific value, exergetic value or adiabatic flame temperature, but also to different data related to the fuel and its utilization in the energy system. Referring to this indicator it is possible to give a significant importance, based on a non-economic dimension, to the fuel used and the different technologies used to convert it to energy, represented for example by the maximum operating temperature of the system

$$\varepsilon = \left(1 - \frac{T_0}{T_{max}}\right) \Big/ \left(1 - \frac{T_0}{T_{ad,flame}}\right) = \eta_c / \overline{\eta}_c \qquad (6)$$

As economic indicators those based on a microeconomics analysis of the system could be used: the total capital cost of the plant for unit power, the energy unit cost, the internal rate of return of the investment related to the plant, the price of the fuel etc. More complex indicators can be defined taking into account the life cycle of the plant, but this is not argument of the present study.

The environmental indicators try to quantify all the "externalities" related to the energy system. In this sense, the pollutant and thermal emissions are considered environmental indicators, and included in the non-energetic dimension. Some typical example could be air pollution emissions (CO_2, NO_x, SO_x, etc.) and heat rejected to the atmosphere or to the water. A detailed report containing the indicators that can be considered for the analysis of energy systems that could be considered in the environmental dimension is outlined in [11].

In the definition of the ACP coefficient, the influence of each indicator is defined by a weight w_i. This underlines the relevance of each dimension considered in the analysis and of the various indicators considered. Methodological issues and data limitations complicate the perspective for the definition of a non-arbitrary weight theory. A first approach is to give an equal weight distribution to every macro-dimension and to each indicator inside the macro-dimension.

APPLICATION OF THE ACP METHOD TO COMPARE DIFFERENT POWER PLANTS

The analysis of the ACP method can be applied in the framework of various fossil fuel based conversion technologies as the advanced coal conversion ones: the Ultra Super Critical (USC), the Pressurized Fluidized Bed Combined Cycle (PFBC) and the Integrated Gasification Combined Cycle (IGCC). In order to show the reliability of the ACP method for high efficiency coal power plants, the Natural Gas Combined Cycle (NGCC) power plant, which is today the most competitive energy conversion technology, and the sub-critical pulverized coal combustion plant (PCC), are used as upper and lower border reference technologies. Values considered for various parameters of the plants are shown in Table 1 [12-15]. The analysis is carried out considering for each dimension the various indicators reported together with the reference values for their normalization in Tables 2-3. Different reference values are considered if coal generation systems are compared with technologies based on the use of a different fuel like NGCC (Table 2) or if only coal technologies are compared (Table 3). In the first case the reference values for adimensionalisation are chosen considering a larger range of variability.

INDICATORS	Power	Thermal efficiency	Total capital cost	Quality index ε	Fuel price	Heat reject factor (1-η)/η	CO_2	SO_2
Power plant type	[MW]	[%]	[€/kW]	[-]	[€/GJ]	[-]	[g/kWh]	[g/kWh]
PCC	400	40	1200	0.78	1.2	1.500	850	2.5
USC	400	47	1400	0.82	1.5	1.127	780	2.0
PFBC	350	43	1500	0.90	1.2	1.326	730	0.3

Results and discussion

The results of the comparison among the various energy systems from the perspective of the ACP method are reported in the Figures 1 and 2.

In Fig. 1 the analysis of five coal-based power plants in comparison with the NGCC is outlined in term of ACP coefficient. The cumulative indicator is obtained considering the same weight for the three dimensions (thermodynamic, economic and environmental) and for the various indicators.

Obviously the NGCC power plant has the higher ACP, due to its lower environmental impact and its higher efficiency and represents today the more advantageous option for power generation but unfortunately natural gas reserves are not infinite. Further considerations can be carried out comparing only the coal conversion options. Joining the results of Figs. 1-2, the development of USC plant appears to be not really convenient, even if, at present, they show the higher efficiency.

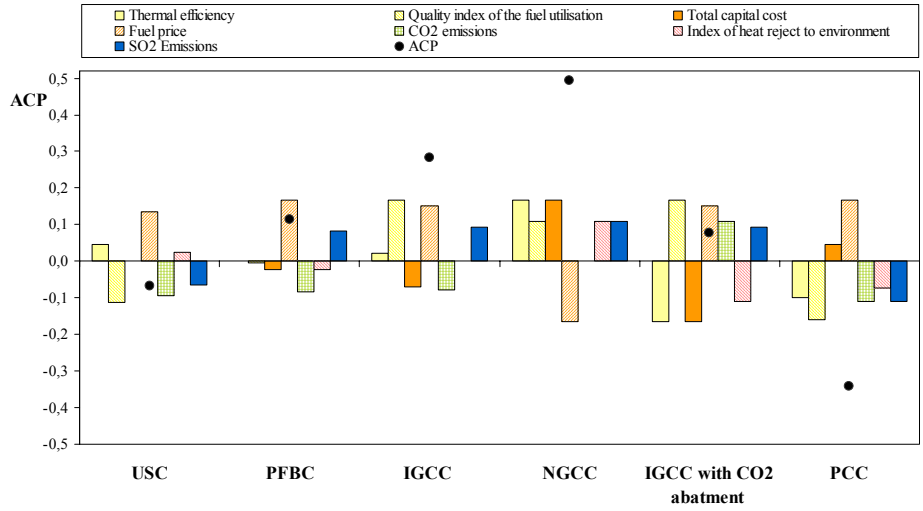

Figure 1: Comparison of coal conversion technologies and natural gas combined plants (ref. Table 2)

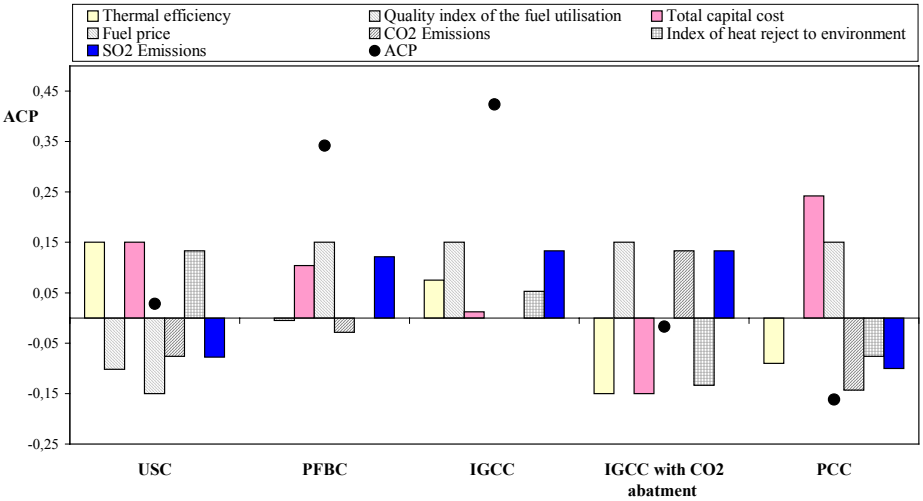

Figure 2: Comparison of coal technologies (ref. Table 3)

The increase of the efficiency and the low reduction of CO_2 emissions, with respect to a conventional PCC plant, do not compensate the increase of the costs and the technological efforts required.
Concerning to the comparison between PFBC and IGCC, a difference between the two technologies cannot be defined in absolute terms even if IGCC seems better than PFBC. The use of abatement technologies, like CO_2 capture, at present, can be considered only if a great weight is attributed to the environmental dimension. With the actual technologies, CO_2 capture seems not always a profitable option: the reduction of CO_2 emissions cannot compensate the lower thermodynamic efficiency and the increase of costs. But clearly appears the difficulty in giving indications about the correct approach to the energetic problem, the guidelines for the development of new technologies and the more efficient use of well known ones. The instrument of ACP seems to really lead towards the direction of eco-efficiency meaning the concept of making the same energetic "service" with a minor use of resources and impact on the environment.

USE OF COMPOSED UTILITY FUNCTIONS FOR POWER PLANTS ANALYSIS

The previous analysis shows that the ACP method, even if it can furnish an element for the comparison of technological solutions for energy conversion, suffers of some limitation related to:

a) the selection of the indicators;
b) the definition of the weight distribution;
c) the adimensionalisation of the indicators.

The quest is open for what concerns the selection of the correct number of the indicators; concerning both the selection of opportune reference values and the normalization (linear or non linear), in general it is simple to compare indicators of economic performance, due to the fact that all of them are referred to a common basis. The same cannot be said for thermodynamic and environmental indicators. A different approach is represented by the development of composed indicators that reconnect to common basis the three dimensions considered.
Considering a thermodynamic point of view, an index that can furnish a simplified comparison between plants using different fuels, like coal or natural gas, can be carried out making reference to the minimisation of a function that aggregate the three main elements involved in the operation of the system: power production (W_{out}), the physical (thermal and pressure) exergy losses (I_{ph}) and the power input (W_{in}). Obviously, this last term have to be weighted by attributing it a weight index to the fuel used (γ). An interesting idea can be represented by the use of the function:

$$\Psi = W_{out} - I_{ph} - \gamma \cdot W_{in} \qquad (7)$$

The Ψ function can be an interesting tool to carry out a thermodynamic optimisation of energy conversion systems, as diffusely discussed in [8].
The Ψ function, due to the consideration of the term γ, can assume an economic connotation. In general it may assume any possible value between 0 and the Carnot factor related to the fuel used ($0< \gamma < \eta_c$). More properly this coefficient γ may account the value of the power input with respect to the output basing on both the characteristics of the input fuel and on the current technological status of energy conversion. The higher is γ the higher is the value of the fuel used and of the technology used to convert it. In general a possible value of γ is a mean efficiency of the plants used to convert the fuel (e.g. natural gas can be converted in gas turbine based plants so $\gamma \approx 0.3$ or in combined plants, $\gamma \approx 0.5$).
The use of the function Ψ, examined in a previous work by the authors, seems to be particularly important due to the possibility of introducing directly the term of input energy. This represents an important conceptual goal, because it couples eco-efficiency policy with a policy aimed at reduction of energy use [8]. The Ψ function does not take directly into account environmental impact issue. In order to introduce environmental concerns, the utility function Ψ can be modified by adding a term that take into account the pollutant emission.

$$\Psi_p = W_{out} - I_{ph} - \beta_p - \gamma \cdot W_{in} \qquad (8)$$

According to the simplified description of Fig. 3 the optimum system is the one that maximize the output power (W_{out}) with the minimum amount of losses (I_{ph}), environmental damage (β_p) and energy consumption (W_{in}). A methodological problem evidenced by the application of ACP analysis was the weight given to each pollutant emissions: this can be considered as an element of inaccuracy.
In order to define the term β_p, an attempt to give a common (physical) basis to the various emissions is necessary. Significant attention has been directed towards the use of exergy analysis in the assessment of thermal systems and their environmental impacts. ([16-17]).

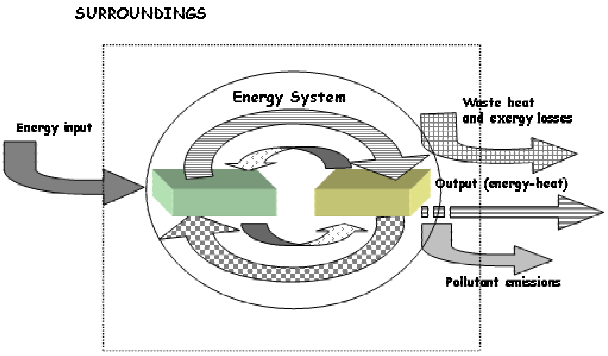

Figure 3: System definition for Ψ functions

Considering, that the exergy content of a chemical species determines the minimum amount of energy needed to construct that chemical from a soup of stable elements the chemical exergy is defined as the minimum work to be supplied if a material has to be produced from the inert reference system.
The impact of the generic pollutants, could be evaluated with reference to the energy required to re-establish the reference system environmental conditions analyzing the single chemical species. Conceptually, this means that a pollutant must be eliminated while the concentration of reference state components must be re-established. In this way the impact of the pollutant is strictly related with the minimum work required to eliminate or to restablish the concentration of the single pollutant. Basing on the definition of a reference state [18] a cumulative pollutant emissions indicator could be:

$$\beta_p = \sum_i \left| e_{ch,i} \left[c_{ip} \frac{m_p}{M_p} - c_{ia} \frac{m_a}{M_a} \right] \right| \qquad (9)$$

where i is the generic chemical species, $e_{ch,i}$ is the standard chemical exergy of the generic chemical species (pollutants as CO_2, SO_x, NO_x or substance contained in the environment as N_2, O_2 or H_2O) [19-20], and c_{ip} and c_{ia} is the concentration of the substances in the exhaust gas and in the reference state respectively. In general the values obtained by Eq. (9) furnish results substantially different from the chemical exergy of the fuel.

Application to a test case

In this section an example for the calculation of the pollutant emission factor in the form of Eq. (9) and for the total function Ψ_p is given. The system used as reference, schematically described in Fig. 4 is a cogeneration system. It operates with natural gas and produces electricity and heat in the form of saturated steam. The thermodynamic specifications are given in Table 4.

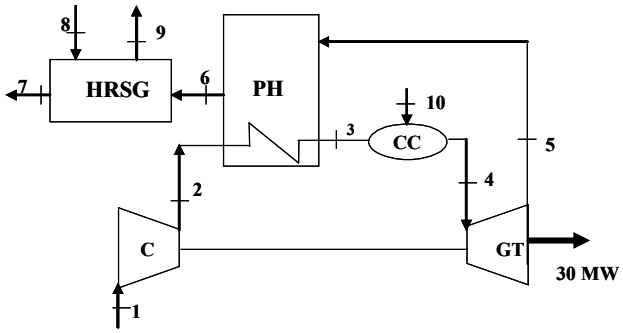

Figure 4: Flow diagram of the CGAM system

Pt.	Substance	m [kg/s]	T [K]	P [bar]	Ex [MW]
1	Air	91.2757	298.15	1.013	0.0000
2	Air	91.2757	603.7	10.130	27.5382
3	Air	91.2757	850.0	9.623	41.9384
4	Exhaust	92.9176	1520.0	9.142	101.4538
5	Exhaust	92.9176	1006.2	1.099	38.7823
6	Exhaust	92.9176	779. 8	1.066	21.7516
7	Exhaust	92.9176	426.9	1.013	2.7726
8	Water	14.0000	298.15	20.000	0.0616
9	Sat. steam	14.0000	485.6	20.000	12.8102
10	Methane	1.6419	298.15	12.000	84.9939

Air: Ma = 28.649 (%) 77.48 N_2, 20.59 O_2, 0.03 CO_2, 1.90 H_2O
Exhaust Mp = 28.254 (%) 75.07 N_2, 13.72 O_2, 3.14 CO_2, 8.07 H_2O

Table 4: Thermodynamic parameters of CGAM [5]

According to the data reported in Table 5, the pollutant emission factor is β_p = 2.65 MW; this value quite low but different from the chemical exergy of the fuel [5] ($e_{ch,}$ = 0.3665 MW). Table 6 provides all the terms of the function given by Eq. (8) considering two different values of the parameter γ and two different plant configurations (with and without HRSG). The two different values of the parameter are considered (γ=0.3 and γ=0.5).
As we can see, in all the cases the Ψ function assumes a negative value and the pollutant emission factor is rather lower than the exergy loss term (I_{ph}).

		CO_2	N_2	O_2
$e_{ch,0}$ [19]	[kJ/kmol]	14176	639	3951
c_a	[%]	0.0003	0.7748	0.2059
$c_a * e_{ch} * m_a / M_a$	[kW]	13.56	1578.38	2593.49
c_p	[%]	0.0314	0.7507	0.1372
$c_p * e_{ch} * m_p / M_p$	[kW]	1513.4	1630.9	1843.4

Table 5: Data for the calculation of β_p index

	Ψ_p [MW]	W_{out} [MW]	I_{ph} [MW]	β_p [MW]	γW_{in} [MW]
Gas Turbine γ=0.3	-51.82	30	54.99	2.65	24.18
CGAM γ=0.3	-39.07	30	42.24	2.65	24.18
Gas Turbine γ=0.5	-67.94	30	54.99	2.65	40.30
CGAM γ=0.5	-55.19	30	42.24	2.65	40.30

Table 6: Values of the terms of utility function Ψ_p

The introduction of the term β_p does not determine a sensible difference between Ψ_p and Ψ, but this is not properly the case for plants using coal where this term has a well higher weight. In this last case the methodological consideration of pollutant emission could become the opportunity to promote the high efficiency design of conventional plants and the dissemination of advanced technologies, like CO_2 capture, that have difficulties to compete in the energy market.

CONCLUSIONS

The problem of considering aspect connected to energy systems like economic, thermodynamics and impact on environment, in term of both energy use and environmental emissions is analyzed. Two approaches for the multi-dimensional analysis of energy systems are considered: the method of the aggregated indicators (ACP method), also referred in the literature and the method of the multi-criterial utility functions (Ψ_p method), originally proposed in this paper. The two methods permit to aggregate different dimensions in order to find a compromise between the increase of the benefits and the reduction of the undesirable elements, present at the energy production assessments with different targets.

The method of aggregated indicators in the form of the Aggregated Coefficient of Power Generation, represents a powerful instrument to compare different energy system of similar technology and to define the technological goal that must be pursued, but it introduces several elements of arbitrariness. An example of application to the comparison of coal technologies delineated in the paper permits to better understand its potentiality.

The second method is more interesting in perspective representing not only an instrument for analysis and comparison of energy system but a real instrument for the design and optimization of energy systems, taking into account also design variables of the system. An example of application is carried out and tested with reference to CGAM.

THERMODYNAMIC ESTIMATION OF THE ENVIRONMENTAL IMPACT OF MINERAL FERTILIZERS PRODUCTION

Zornitza Kirova - Yordanova*,
University "Prof. Assen Zlatarov"
Department of Inorganic Technology
8010 Bourgas
Bulgaria

ABSTRACT

In a previous work the cumulative exergy concept was used to estimate the environmental impact of the mineral fertilizers production on the natural resources consumption [1]. In this work an attempt is made to apply the exergy method to estimate the environmental impact of emissions from mineral fertilizers production. The environmental impact of emissions is estimated by three different approaches: by exergies of the emissions and waste flows; by the exergy of the natural resources, accumulated in waste flows; by the exergy and cumulative exergy consumption of natural resources in some processes of purification, utilisation and recycling of waste flows.
Keywords: Exergy, Cumulative exergy, Mineral fertilizers, Environment, Emissions, Pollutants

NOMENCLATURE

AN	ammonium nitrate
CExC	cumulative exergy consumption [MJ/t]
D	exergy losses [MJ/t]
E	exergy [MJ/t]
LP,MP	Low pressure, Middle pressure
TSP	triple superphosphate

INTRODUCTION

The mineral fertilizers play a critical role in the global food provision. It is estimated [2], that about 40% of the world's protein needs are derived from atmospheric nitrogen fixed by the Haber-Bosch process and its successors to produce ammonia.

In 2002/2003, the world fertilizer industry produced about 144 Million metric tonnes (Mt) of primary plant nutrients, including: 85 Mt nitrogen (N), 34 Mt phosphate (P_2O_5) and 25 Mt potash (K_2O), contained in about 380 Mt various fertilizers products [3,4].

The mineral fertilizers production and use have a versatile and specific environmental impact. As other process industries, the environmental impact of the mineral fertilizers production processes is twofold and concern the consumption of natural resources as well as the discharges to air, water and land. Besides that, the use of mineral fertilizers arises one more relation to environment, because they are introduced directly into the arable land and thus interact immediately with the environment.

Since 1960s, the production of mineral fertilizers have made enormous progress in reducing natural resources consumption as well as emissions [5-7]. As the pollutants, released into the environment from the fertilizers plants, are usually products, semi-products or feed stocks of the production processes, the recycling and recovery of the emissions leads to decreasing both the feedstocks and energy consumption.

In the last decade intensive investigations of the environmental impact of the mineral fertilizers production, distribution and use, made by some

Fax +359-56-880249 E-mail zkirova@btu.bg

fertilizers producers, are partially inspired by their international organizations in the EU and USA as EFMA, IFA, etc., as well as by FAO, UNEP and UNIDO [8-10]. The various methods and indicators are used, but in most of them some subjective or economic criteria are also used.

New methods have been developed in the last years with the intention to obtain environmental impact indicators based on both the First and Second Laws of Thermodynamics.

The exergy method and the cumulative exergy concept (Szargut et al. [11]) are useful means for evaluation of the overall consumption of all kinds of natural resources at every step of a production process. Szargut proposed also the term *ecological* costs as a measure of their depletition [11,12].

The application of exergy as a measure of the impact of the emissions and wastes is proposed from R. Ayres [13], R. Ayres et al. [14], Rosen [15], etc. As the exergy is the potential of a system with respect to the environment, the higher the exergy of the emissions or the wastes, the greater their influence on the environment. However, some problems, as lack of specifying, are still open. R Ayres [13] pointed out, that the exergy content of a waste stream could be a rough measure about its potential to causing harm, despite of its impossibility to measure the human or eco-toxicity. Szargut [12] proposed to evaluate the impact of waste products by means of their monetary index of harmfulness. Another approach is developed from Valero and Botero [16]. They regard the exergy of resources, consumed by the processes of the emissions abatement, as a measure of environmental impact of technical systems. Cornelissen [17], Gong and Wall [18], etc., use exergy method in the context of Life Cycle Analysis in order to specify a Second-Law based ecological indicator.

In a previous work [1] the cumulative exergy concept was used to estimate the environmental impact of the mineral fertilizers production on the natural resources consumption.

This work is an attempt to use the exergy method and cumulative exergy concept for estimation of environmental impact of emissions and wastes from some basic nitrogen and phosphorous fertilizers production processes.

NITROGEN AND PHOSPHOROUS FERTILIZERS PRODUCTION PROCESSES: FEATURES, INTERACTIONS, INPUTS, OUTPUTS AND DISCHARGES

Urea and fertilizer grade ammonium nitrate (AN) are the most intensive used nitrogen fertilizers, with 100 and 30 million tonnes annual world production respectively. The production and use of di- and monoammonium phosphates (DAP and MAP) rose in the last two decades to about 29 million tonnes/year. The annual world production of the triple superphosphate (TSP), the major phosphorous fertilizer in the past, now decreases down to about 5 million tonnes [3,4].

Ammonia production is a process central to the manufacture of all nitrogen fertilizers, as well as of NP and NPK fertilizers. Besides urea and various ammonium-containing fertilizers, obtained directly from ammonia, it is also used for production of nitric acid, which is the base chemical for the manufacture of ammonium nitrate and other nitrates used as fertilizers, as well as of various NP and NPK fertilizers. Two thirds of phosphate fertilizers, including DAP, MAP and TSP, are derived from phosphate rock treated with phosphoric acid; hence the production of wet-process phosphoric acid is also a base process in the fertilizers manufacture. All these fertilizers production processes are chemically interlinked and sometimes are co-located on the same site forming an integrated complex [6].

Ammonia is produced from water, air and hydrocarbons or coal. Currently about 77% of world ammonia production is based on the steam reforming of natural gas. It takes 28 - 30 GJ/te (only about 40% above the thermodynamic minimum) in modern ammonia plants to make ammonia from natural gas by the overall reaction:

$$\text{Natural gas} + \text{Water (Steam)} + \text{Air} \Rightarrow$$
$$\Rightarrow 3\,H_2 + N_2 + CO_2 \Rightarrow \text{Ammonia} + CO_2 \quad (1)$$

The production of ammonia is relatively clean compared to many other chemical processes, as well as to other production processes in fertilizer industry.

Carbon dioxide (about 99% CO_2), produced in stoichiometric ratio by the main reaction, flue gas from the steam reforming furnace and process condensate are the only discharges from natural gas based modern ammonia plants (Figs.1 and 2). If the produced ammonia is used at the same site for urea production, the carbon dioxide is completely used

and is not venting to the atmosphere. The process condensate is formed by condensation of the extra steam, after the $H_2 + N_2$ mixture is cooled, of the order of about 1 m^3 per tonne NH_3 and contains up to 0.1% ammonia and methanol. In modern ammonia plants the process condensate is treated with steam and then recovered as boiler feed water, after polishing. As the fuel in the steam reforming furnace is preferably natural gas, there is practically no SO_2 emission and CO_2 and NO_x are the only pollutants in the flue gas [6,7].

Fertilizer grade nitric acid (45 - 60%) is produced (Fig.1) by oxidation of ammonia with air to NO_x and subsequent absorption of NO_x with water by the overall reactions:

$$4NH_3 + 5O_2\,(Air) \Rightarrow 4NO + 6H_2O \quad (2)$$

$$2NO + O_2 \Rightarrow 2NO_2 \quad (3)$$

$$4NH_3 + 5O_2\,(Air) \Rightarrow 4NO + 6H_2O \quad (4)$$

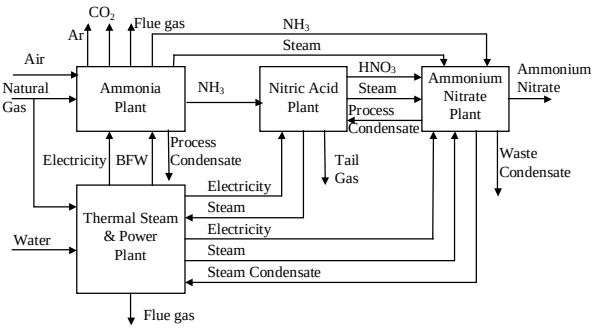

Fig. 1. Block flow diagram of nitric acid and AN production

The nitric acid production is a known source of nitrogen oxides (NO_x and N_2O) emissions into the atmosphere. The waste gas (tail gas) from nitric acid plants can contain various quantities of these pollutants, depending on the process parameters, mainly on the absorption pressure and on the waste gas treatment. The NO_x emissions are attributable to the production process, as by the third reaction one mole NO is produced for every three moles of NO_2 and then complete absorption of NO_x is impossible. The N_2O emissions are also attributable to the nitric acid production, however by another reason: N_2O is an undesirable, but unavoidable by-product of the first reaction, as a result both of the thermodynamic and kinetic features of the ammonia oxidation reaction and of the quality and condition of the catalyst used. Three methods are currently used for NO_x abatement from the tail gas from new as well from existing nitric acid plants and the NO_x emission level strongly decreased in the last decade. However, there are still not reliable commercial methods for N_2O decreasing. Excluding some occasional emissions, no continuous liquid effluents are released from a nitric acid plant [6,7].

Fertilizer grade ammonium nitrate (AN) is produced from ammonia and 45-60% nitric acid (Fig. 1) by the reaction:

$$NH_3 + HNO_3 \Rightarrow NH_4NO_3 \quad (5)$$

The main releases into atmosphere from prilling towers are AN particulate matter and ammonia. Another source of the discharges into atmosphere is the process steam formed in neutralizers and evaporators from water entering into neutralizers with the nitric acid. Two approaches are used to the emission abatement: process steam purification or steam condensation and subsequent purification of the formed condensate. In the last case the condensation heat can to be used in the process. Condensed process effluents and exhaust vapors are used in some cases in nitric acid production. However, there exist various problems and the emissions to the atmosphere as well as to water are still significant [6,7]).

The production of urea from ammonia and CO_2 (Fig.2) by the overall reaction:

$$2NH_3 + CO_2 \Rightarrow NH_2CONH_2 + H_2O \quad (6)$$

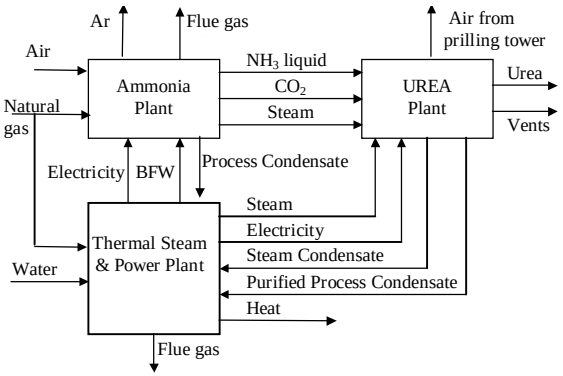

Fig. 2. Block flow diagram of urea production

achieves the most progress in the last years in minimization of both feedstocks consumption and pollutants. The ammonia consumption in the new plants is reduced down to nearly stoichiometric quantity of 567 kg/ tonne urea as a result from diminishing of ammonia and urea emissions both to air and to water.

The main problem in pollution prevention in urea production is the formation of water as a by-

product (Fig.1). The urea synthesis reaction produces process condensate water of 300 kg/tonne urea. Additional water inputs are necessary to remove ammonia from absorbers vents as well as to remove ammonia and urea dust from air, discharged from prilling towers. These sources may increase the final quantity of process water to about 500 kg/te, which has to be discharged to the environment. However, some quantities of ammonia and urea dust are still emitted into atmosphere from vents and prilling towers. The process water treatment to very low emissions limit levels is very difficult and requires big quantities of middle pressure steam [6,7].

Wet process phosphoric acid is produced by decomposition of phosphate rock with sulphuric acid. Depending on the process parameters, five process routes exist, but the dihydrate process is still the most popular one, with by-product $CaSO_4.2H_2O$ (phosphogypsum):

$$3Ca_3(PO_4)_2.CaF_2 + 10\ H_2SO_4 + 20\ H2O \Rightarrow$$
$$\Rightarrow 6\ H_3PO_4 + 10\ CaSO_4.2H_2O + 2\ HF \quad (7)$$

The phosphogypsum is a undesirable, but unavoidable by-product of the reaction. As the quantity of the formed phosphogypsum is very big (about 5500 kg/te phosphoric acid) and it contains various impurities, many problems exist about utilization or deposition of this process waste on land or into the sea. Liquid effluents, containing fluorides and phosphates are formed by the filtration of the phosphogypsum. Some emissions of phosphate dust into atmosphere are formed by handling and grinding of phosphate rock as well as of gaseous fluorides, released by the reaction [6,7].

As is clear from the Table 1, the discharges into environment from both nitrogen and phosphorous fertilizers industry, fall into three groups and therefore, various methods have to be used for treating of the discharges.

Large volume by-products from the main reactions, e.g. CO_2 from ammonia production, phospho-gypsum from wet process phosphoric acid, etc., are suitable for using as feedstocks in another processes or, if possible, as final products. The pollutants, which are by-products from some parallel reactions, usually exist in low concentrations in the emissions. If their formation is unavoidable, they have to be removed and recycled or transformed to harmless components. The pollutants, which are products, semi-products or residuals of feedstocks, have to be removed from gaseous emissions and liquid effluents and recycled into the process. This is the case in the urea and ammonium nitrate production.

DATA SOURCES AND CALCULATION PROCEDURES

Most of the data, used in this work, are collected from Bulgarian fertilizers plants in 1996-2003. In 1996 there were four nitrogen and one phosphorous fertilizers plants in Bulgaria with total capacity of about 1.2 Mt/y ammonia and about 0.1 Mt/y (as P_2O_5) wet process phosphoric acid and TSP. Urea and AN were manufactured from ammonia with a capacity of 0.8 Mt/y and 1.1 Mt/y, respectively. Currently one of the ammonia/ AN plants is closed and dismantled, also the production of ammonia and urea in another plant is temporary stopped. Within the last two years the total ammonia production in Bulgaria are converged to a stable amount at about 0.45 Mt/y. Total production of fertilizers grade AN is about 0.8 Mt/y, with half of this quantity stabilized with phosphate (2-3 % as P_2O_5). The real data about natural resources consumption and emissions in Bulgarian fertilizers plants had been collected yearly and verified by fitting the material and energy balances of all the production unit in the technological chain. Also, some of data used are from EFMA publications about emissions level in the new and existing plants [6,7].

We calculate the chemical and physical exergies of the material flows released to the environment (gaseous and liquid flows, and solid wastes) by Szargut‘s method [11]. Gaseous emissions are released at pressures close to atmospheric pressure and are treated as ideal mixtures of real gases. Liquid effluents are extremely diluted and are treated as ideal mixtures, despite off some lack of precision. The solid waste (phosphogypsum) is also treated as ideal mixture. The environment parameters are assumed as follows: P_0 = 101325 Pa, T_o = 298.15 K and relative humidity 0.301. The cumulative exergy consumption (CExC) of natural resources is also calculated by the method, proposed from Szargut [11]. In addition, we use some results about CExC of mineral fertilizers obtained in a previous work [1].

Reactions	Emission or pollutant	Discharges	Methods for utilization, removal or recycling
BY-PRODUCTS FROM MAIN REACTIONS			
Steam reforming of natural gas and shift conversion	CO_2 98,5 – 99%	Vent gas from CO_2 removal unit in ammonia plants	Urea, soda ash or pure CO_2 production, *or emission to air*
Combustion	CO_2 8-12%	Flue gas from reforming furnace in ammonia plants	Utilization for pure CO_2 production *or emission to air*
Phosphate rock decomposition with H_2SO_4	$CaSO_4.2H2O$ and contaminants	Phosphogypsum from wet process phosphoric acid production	Utilization in cement industry, road making, sulphur recycling *disposal on land or into the sea*
	HF and SiF_4	Vent gas from wet process phosphoric acid production	Fluor compounds production
BY-PRODUCTS FROM PARALLEL REACTIONS			
N_2O formation by ammonia oxydation	N_2O	Tail gas (waste gas) from nitric acid production	NSCR of N_2O *or emission to air*
CH_3OH and NH_3 synthesis in H_2-N_2 preparing units	CH_3OH 0.1% NH_3 0.1%	Process condensate from ammonia production	Condensate purification and recylcing
NOx formation from air	NOx	Flue gas from reforming furnace in ammonia plants	SCR or NSCR of NOx *or emission to air*
RESIDUALS OF PRODUCTS, SEMI-PRODUCTS OR FEEDSTOCKS OF THE PRODUCTION PROCESS			
	NH_3 and urea	Waste water and vents from urea production	Waste water purification with NH_3 and urea recycling
	NH_3 and NH_4NO_3	Waste water and vents from AN production	Waste water purification with NH_3 and NH_4NO_3 recycling
	NOx	Tail gas (waste gas) from nitric acid production	SCR or NSCR of NOx or extended absorption (recycling)
	Urea dust	Air from prilling towers from urea production	Air purification with NH_3 and urea recycling
	NH_4NO_3 dust	Air from prilling towers from AN production	Air purification with NH_3 and NH_4NO_3 recycling

Table 1. Emissions, pollutants and wastes from mineral fertilizers production processes

RESULTS AND DISCUSSION

Some of the collected data were used to calculate various Second-Law based indices:

- exergies of the emissions and waste flows;
- exergies of the natural resources, accumulated in the waste flows;
- exergy and cumulative exergy consumption of natural resources in some processes of the waste flows treatment.

Exergies of the emissions and waste flows

The exergy of the waste flows released to the environment from chemical plants account for the main fraction of the external exergy losses. In most cases the temperature and the pressure of the discharged fluids or solids are close to the environmental parameters, therefore, their physical exergy is rather small. Besides that, the potential of the emissions to damage the environment, depends on their chemical composition and especially, on the concentration and properties of the pollutions. Because of that, the chemical exergy of pollutants as well as of the flows, released to the environment, appears to be a more representative index, than their total exergy.

In Table 2 and Figs 3 and 4 are shown some results of calculation of chemical exergy of gaseous, liquid and solid flows, released to the environment, as well as the chemical exergy of the individual pollutants.

The chemical exergies of the pure pollutions (ammonia, urea, AN, etc.) are usually very high, which is in agreement with their harmfullness, at least qualitatively. The chemical exergies of the same pollutions, referred to the 1 tonne of the product, are small, because of the low contents of the pollution in the released flows. The exergies of the emitted flows as a hole, are rather high, especially in the case of the liquid effluents, higher than the exergies of all the pollutants in them. The reason is that the exergy of the pure liquid water is rather high at the specified environmental parameters.

Gaseous emissions, liquid effluents and solid wastes	Pollutant	Concen-tration of the pollutants	Chemical exergy of the pollutants		Chemical exergy of the emissions flows		Mixing exergy
			GJ/t pollutant	GJ/t product	GJ/t flow	GJ/t product	GJ/t product
Gaseous emissions to atmosphere and liquid effluents from ammonia production							
Vent gas from CO_2 removal	CO_2	98.5-99%	0.4576	0.6030	0.4945	0.6590	0.0024
Flue-gas from the primary reforming furnace	CO_2 NOx ($asNO_2$)	8 -12% <300 mg/Nm^3	0.4576 1.2192	0.2480 0.0012	0.1342	0.5399	0.0755 0.0005

Table 2. Chemical exergy of the emissions and liquid effluents from ammonia, nitric acid, ammonium nitrate, urea and wet process phosphoric acid production

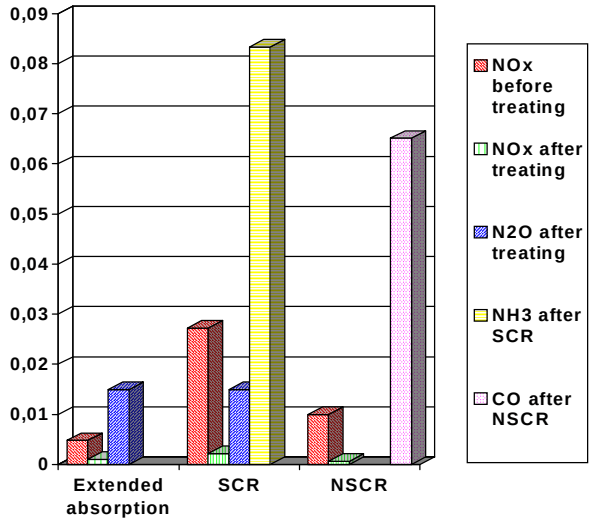

Fig. 3. Chemical exergy (GJ/t 100%HNO_3) of the gaseous pollutants from dual pressure nitric acid production plants before and after the tail gas treating: 1–MP/HP plant with extended absorption; 2–LP/MP plant with SCR; 3–MP/HP plant with NSCR.

- SCR – Selective catalytic reduction of NO_x
- NSCR – Non-selective catalytic reduction of NO_x [6,7]

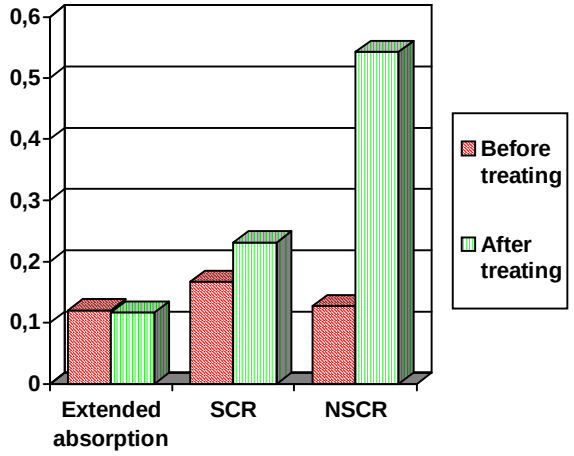

Fig.4. Chemical exergy (GJ/t 100%HNO_3) of the tail gas from nitric acid production plants before and after the tail gas treating. The rest of the explanations are as in fig. 3.

Cumulative exergy

Cumulative exergy of the gaseous pollutions from three different nitric acid production plants before and after the tail gas treating by three different methods are shown in fig.5. The cumulative exergies of ammonia after the SCR and of CO after the NSCR are higher than the cumulative exergies of NOx before treating. Fig.6 shows, that the exergy and cumulative exergy consumption are highest, if NSCR method for NO_x abatement is used. Cumulative exergy of the emissions from urea production (Fig.6) in the existing plants is higher than from AN production, but in the new plants it is lower. The cumulative exergy of the emissions from nitrogen fertilizers production in the existing plants is about 1 % from the total cumulative exergy consumption (CExC) of these fertilizers production [1].

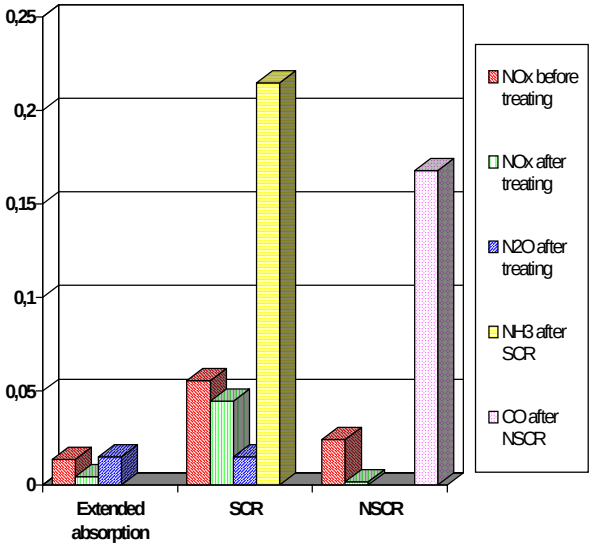

Fig.5. Cumulative exergy (GJ/t 100%HNO_3) of the gaseous pollutants from nitric acid production plants before and after the tail gas treating. The rest of the explanations are as in fig. 3.

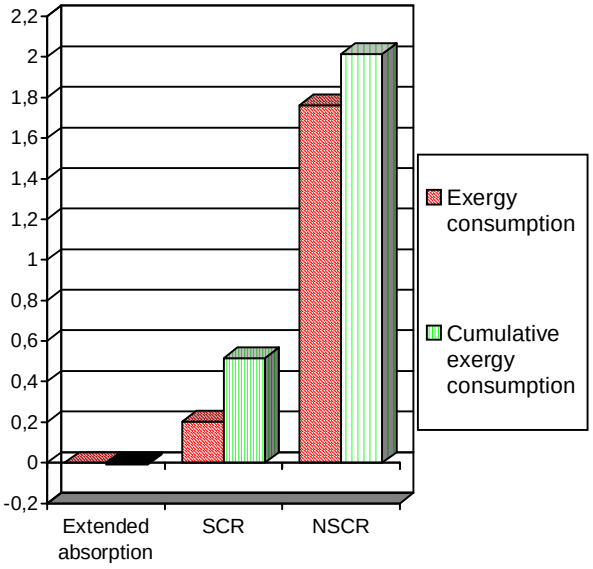

Fig.6. Exergy consumption and cumulative exergy consumption (GJ/t 100% HNO_3) for NOx abatement in nitric acid production plants before and after the tail gas treating. The rest of the explanations are as in fig. 3

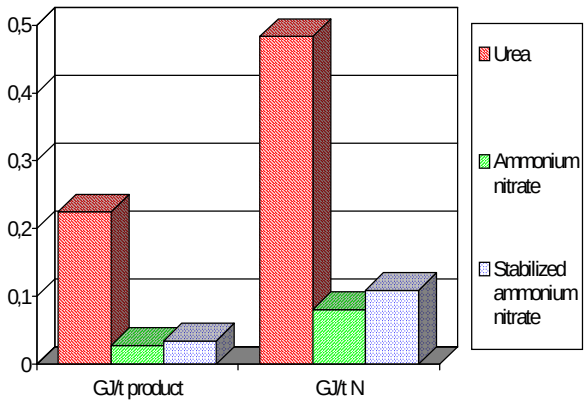

Fig.7. Cumulative exergy (GJ/t) of the emissions from nitrogen fertilizers production

CONCLUSIONS

An attempt is made to estimate the environmental impact of mineral fertilizers production by the Second-Law based indices. The chemical exergy of emissions flows and of pollutants, referred to an unit produced product or primary nutrient, as well as cumulative exergy consumption of the emissions and pollutants, appear to be the representative indices. The cumulative exergy consumption for the emissions abatement could be used to compare different methods.

ABSTRACT

Cold production processes generally use harmful refrigerants that increase ozone depletion and global warming effect and it is thus important to design new systems that are more environmentally-friendly. A major issue is to use refrigerant fluids which are neutral with respect to ozone depletion and global warming problems. Another goal is to correlate the quality of the energy used to the quality of energy produced by these processes.
The exergy analysis applied to ideal thermochemical dipoles is an efficient way to deal with these questions. Thermochemical dipoles connect two thermal processes exchanging gas with each other. The working gas can be environmentally inert, ammonia or water for example. Original couplings of the dipoles enable to design new processes, for heat or cold production at a desired temperature level.
Our work is aimed to create an original process that could use low-grade energy (produced for instance from a thermal solar collector or a geothermal drilling at around 70°C) to provide low-temperature heat (below -23°C, in order to store deep-frozen food). Indeed, existing solar cooling systems can provide cold at a temperature of around 0°C and produce ice but up to now none is able to ensure long term food conservation. Analysing several possible dipole couplings, one cycle was found to be particularly adapted to a solar heat source. The whole exergy entering this ideal system is used and no cold in excess or unused energy are produced. The ideal coefficient of performance of this system is 0.5.
A numerical simulation of the process evolution proved the feasibility of the concept and showed that its expected coefficient of performance is about 0.11, which is similar to the up-to-date solar cooling systems, but at higher cold temperatures. The system exergetic yield is expected to attain 0.4 in average over the year.
Keywords: exergetic analysis, ideal process, thermochemical dipole, deep freezing.

NOMENCLATURE

COA	coefficient of amplification of heat
COP	coefficient of performance
D	exergetic losses [J]
d	relative exergy losses =D/E’
e_w	exergy selectivity
E’	inlet exergy [J]
E'_{nu}	unused exergy [J]
E’’	outlet exergy [J]
E''_{ex}	excess produced exergy [J]
E''_{un}	untapped produced exergy [J]
E''_{u}	useful produced exergy [J]
P	pressure [Pa]
Q	heat quantity [J]
T	temperature [K]
T_0	reference temperature [K]
x_e	exergy conversion factor
η	exergy yield
θ	Carnot factor
ΔH	heat of transformation [J/mol]

INTRODUCTION

When one designs new processes, one has to take into account environmental questions and thus the type of the energy used and of the energy produced involved in this process. It is important to design new systems that are more environmentally-friendly and the utilisation of renewable energies is an interesting option. In the case of solar energy, either transformed into heat or converted into electricity, the question of the quality of the energy source is of particular importance. Indeed, the energy produced by the new process should be of the quantity and quality adapted to its use, of variable power and usable at the time when it is needed, independently from the discontinue time availability of the energy source.

In this study, focus will be directed toward the conversion of solar energy into heat. Nowadays, solar energy is only commonly used in domestic water heating systems and recent developments were made concerning solar cold production and particularly solar climatisation systems. Solar liquid-gas absorption systems were developed more than 50 years ago to transform solar heat into cold, but still present major drawbacks and constraints. Indeed, this type of process works in a continuous way, thus with a continuous heat source. For solar systems, the storage of the needed heat or of the cold produced allows a good functioning of the process, but necessitates heavy and voluminous storage capacities. Moreover, the needed temperature of the heat source is high: from 90 to 140°C [1], what imposes the use of expensive solar collectors, as parabolic concentrators or with vacuum tubes glazing. Problems are of the same kind concerning the solid-gas adsorption systems, with however a lower temperature of the heat source, around 80°C in this case [2]. Adsorption and absorption systems allow to obtain cold at a minimum temperature of about -5°C.

Sorption based on the chemical reaction between a solid and a gas also allows the production of cold at around –5 to –10°C from heat at 80° to 90°C [3], and a solar prototype proved the effectiveness of that concept as soon as 1986 [4]. The reactive gas used is ammonia. This refrigerant fluid is totally neutral with respect to ozone depletion and global warming problems. Lower temperature levels were also obtained using this thermochemical technology, but from higher temperature levels of the heat source, at about 140 to 160°C [5].

The aim of this study is to determine the possibilities to design a new process concept to produce cold at low temperature (at about -30°C for storage of frozen food) from a heat source at about 70°C compatible with the use of flat simple glazed solar collectors. This process separates the time of solar heat availability and the time of cold production.

Recent research work based on the exergetic analysis characterised classical and original processes. Studies were directed toward cold production systems with ideal coefficient of performance (COP) of 1, 2 and 3 [6], and systems producing both cold and heat at higher temperature level (with a coefficient of amplification of heat COA of 0.5) presenting the possibility of heat transport over long distances [7,8].

ANALYSIS BASIS

The first basis of the analysis comes from the definition of the exergetic efficiency, yield and effectiveness [9] based on the work of Brodyanski et al. [10]. These definitions take into account the concept of transiting exergy in the process : the ranking of ideal processes by the determination of the ideal exergy conversion factor x_e [11] allows the optimisation of the ideal and practical exergetic yields of a process, as soon as its conception.

Considering an ideal process, the inlet exergy E' leads to the production of (figure 1):
- exergy that is converted or transformed in the process $E'-E'_{nu}$,
- unused exergy E'_{nu} that only transits through the ideal system.

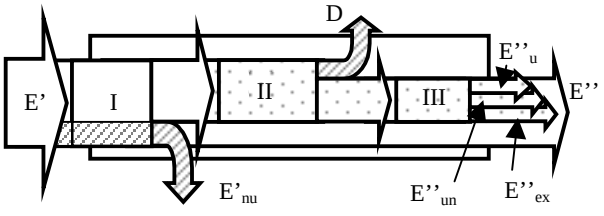

Figure 1: Exergies within (I) an ideal system, (II) a real system and (III) with the different output exergies

The ideal exergy conversion factor x_e defined as:

$$x_e = \frac{E' - E'_{nu}}{E'} \quad (1)$$

should be maximised up to 1.

In real processes, destroyed exergy D, exergy produced in excess E''_{ex} and untapped E''_{un} must be minimised, such that the useful produced exergy E''_u is maximal.

The exergetic yield η is defined as :

$$\eta = \frac{E''_u}{E'} = x_e - d - e_w \quad (2)$$

where $d = \frac{D}{E'}$

and the exergetic selectivity $e_w = \frac{E'_{ex} + E''_{un}}{E'}$

The exergetic yield applied to an ideal system (where d=0), is η_i :

$$\eta_i = x_e - e_w \quad (3)$$

η_i should be maximised, such that the ideal exergy conversion factor x_e approaches 1 and the exergetic selectivity e_w approaches 0.

The second basis of the analysis is the exergetic dipole, used for the study of heat transformation processes by Spinner et al [8]. An exergetic dipole results in the coupling, via an active gas transfer (figure 2.a), of an endothermic process such as:

- an evaporation or
- a gas-liquid or gas-solid desorption

and an exothermic process such as :

- a condensation or
- a gas-liquid or gas-solid absorption.

We will focus on the gas-solid reaction, a monovariant process, and which can be coupled to a liquid-gas phase change, also a monovariant process, or to another gas-solid reaction involving the same fluid but a different reactive solid. The representation of the thermodynamic equilibrium of these reactions in Clausius-Clapeyron diagram are linear (figure 2.b).

Thermodynamic conditions applied to each pole of a closed dipole lead either to a useful heat or cold production phase, or to a regeneration phase. The two phases are independent temporally from each other (figure 2.c). For cold production cycles, the useful cold production phase ‘b’ is followed by the regeneration phase ‘a’ of the dipole.

Transfers from a pole to the other are characterised by the quantity and quality of heat transferred. The quantity of heat transferred is proportional to the enthalpy of the involved transformation. The quality of the heat transferred depends on the temperature levels involved at each pole.

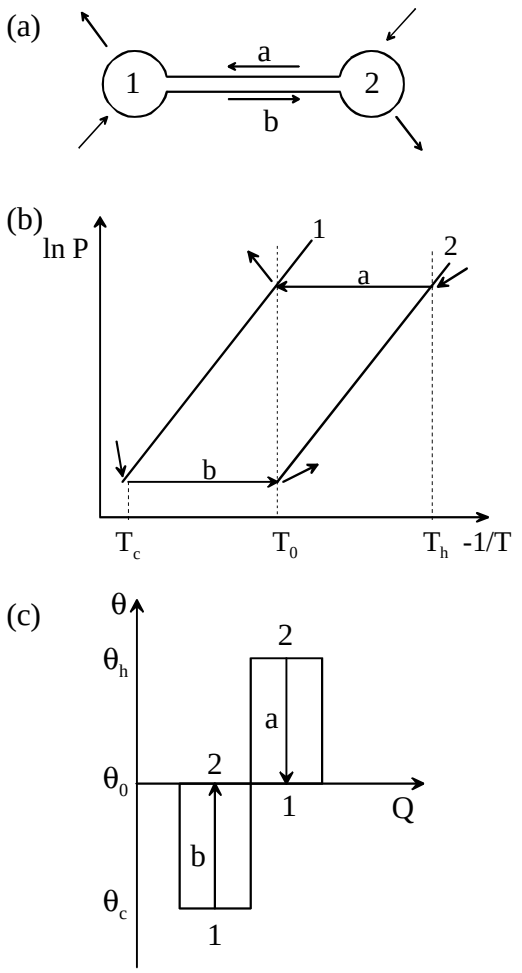

Figure 2:
(a) Dipole functioning between the physico-chemical processes (2) and (1). It is regenerated when gas flows in direction (a) and produces cold in direction (b).
(b) Thermodynamic conditions of the dipole phases in the Clausius-Clapeyron diagram.
(c) Exergies Q.θ involved in the ideal process with cold production at θ_c from heat at θ_h in the diagram $\theta = f(Q)$.

T_h is the regeneration temperature, the highest temperature level involved. T_c is the cold production temperature. T_0 is the reference or ambient temperature. If the heat released by the process is at T_0, the corresponding Carnot factor equal zero and thus the unused and untapped exergies E'_{nu} and E''_{un} equal zero. Thus, x_e equals 1 following equation (1). Moreover, if T_c is the cold temperature level which is necessary to the user, the excess exergy production E''_{ex} is zero and consequently, following equations (2) and (3) in the ideal case, the selectivity e_w equals 0 and the exergetic yield η_i is maximum.

The basic dipole COP_i is defined as :

$$COP_i = \frac{\Delta H_1}{\Delta H_2} \quad (4)$$

for the poles 1 and 2 of the basic dipole represented figure 2, where pole 1 is the one where cold production occurs and 2 is the one that has to be heated for regeneration.

In the ideal case, the COP_i is proportional to the exergetic yield η_i:

$$COP_i = \frac{\Delta H_1}{\Delta H_2} = \eta i \frac{\theta_h}{|\theta_c|} \quad (5)$$

as exergies E' and E''_u in the case of this dipole, equal respectively ΔH_2. θ_h and ΔH_1. θ_c.

In real processes, the transformation enthalpies ΔH vary with the process and the temperature. Moreover, the liquid/gas transformation heat is always smaller than the solid/gas reaction enthalpy [12]. However, in a first analysis of the ideal processes, all enthalpies are considered equal. Real values will be studied in a second step.

DEFINITION OF THE ORIGINAL PROCESS

From equation (5), we can see that, for an ideal system with an exergetic yield of 1, if the desired ideal system COP is of 1 and if the cold temperature level is at -22°C for example, the high temperature level should be at least at 79°C, for a reference temperature T_0 of 20°C. It is supposed that the process enthalpies ΔH_1 and ΔH_2 involved are equal, as precised above.

For the purpose of designing a deep-freezing process using heat at about 70°C, this necessary heat source temperature of 79°C is a lot too high, taking into account the external irreversibilities of such systems [12]. Thus, to design a deep-freezing solar system using low temperature solar heat, the ideal system COP_i has to be lower than 1. A study of ideal processes with a COP_i lower than 1 must thus be done. A particular focus can be drawn on systems with COP_i equal to 0.5. In that case, the high temperature level necessary to produce cold at -22°C is of 47°C for a reference temperature of 20°C. This is compatible with the limit temperature of 70°C for simple flat plate solar collectors. An extensive study of these systems has been lead [13]. This study uses the concept of a thermal coupling between two dipoles presenting respectively an exothermal and an endothermic process. This type of study has already been lead before [7]. A particularly interesting process concept has been extracted from the different possible dipole configurations, and is presented on figure 3.

Following equation (5), an ideal system with a COP_i of 0.5 needs the introduction of twice as much heat as the useful amount of cold produced. On figure 3.a, we can see in the $\theta = f(Q)$ diagram that the process needs twice the heat quantity ΔH at θ_h and once at θ_c. The Carnot factor $|\theta_c|$ can thus be twice as big as θ_h. In that case, the inlet and produced exergies, equal to the area $\theta.Q$ on the diagram, are equal since the exergetic yield is equal to 1. This system involves two dipoles. Both dipoles are (figure 3.c):

- without any thermal connections during the regeneration phase
- with a thermal connection between an endothermal and an exothermic process during the cold production phase.

This ideal process thus allows the production of cold at -22°C using ideally low-grade heat at 47°C from simple flat plate solar collectors. In that case, since solar radiation is the thermal energy supply, the cold production and regeneration phases correspond respectively to the natural diurnal solar radiation and nocturnal sky cooling periods. The monovariant processes chosen for this deep-freezing purpose are one solid-gas reaction coupled to a liquid/gas transformation in each dipole.

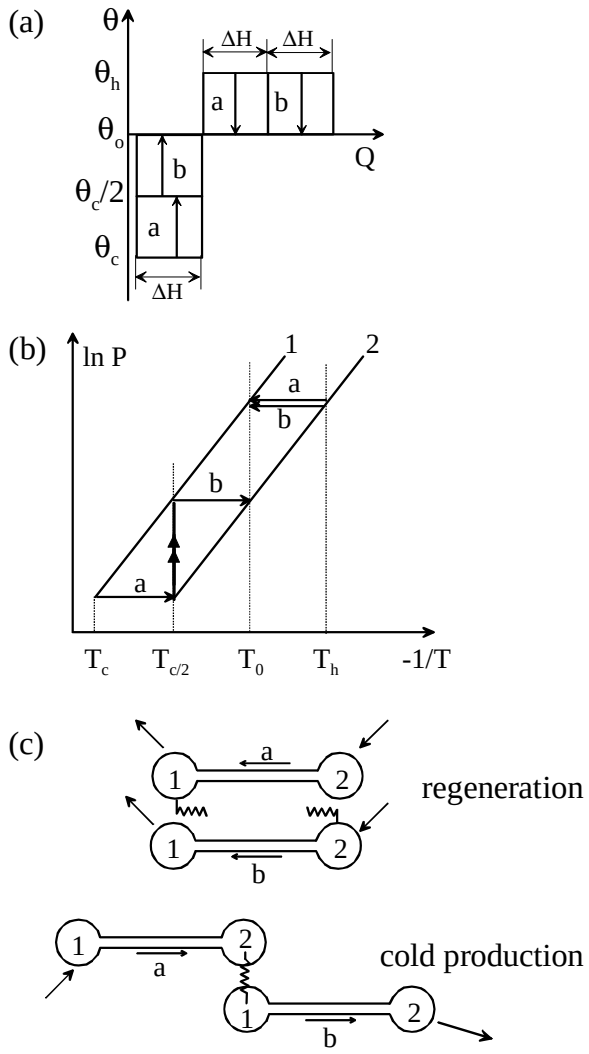

Figure 3:
(a) Exergies (Q.θ) involved in the ideal process with cold production at θ_c from heat at θ_h in the diagram $\theta = f(Q)$.
(b) Thermodynamic conditions of the two dipoles phases in the Clausius-Clapeyron diagram.
(c) Dipoles functioning without thermal connection in regeneration phase and with a thermal connection between processes 'a' and 'b' during the cold production phase.

The fixed bed solid-gas reaction poles (2) of each dipole are situated inside the solar collectors. Evaporator (1) of dipole 'a' (named pole (1a) in the following) is placed in a cold box, where cold is produced at -22°C, and the other evaporator (1b) is coupled to reactor (2) of process 'a', to insure its cooling during the night phase. As can be seen from figure 3.b and 3.c, both systems are brought to high pressure and temperature during the day phase, using the solar radiation received. Gas is desorbed from the reactor beds, and condensates at T_0 (ambient temperature) in the condensers (1). During the night phase, the reactor (2b) is brought to ambient temperature by convection with outside air and radiation to the nocturnal sky. Thus, it absorbs the gas present in dipole 'b' and that leads to the evaporation of the liquid in pole (1b). The thermal connection between system 'a' and 'b' during the night phase allows the cooling of pole (2a) through the boiling of the fluid in pole (1b) at low temperature $T_{c/2}$. Consequently, synthesis happens in the reactor (2a) and boiling at T_c of the liquid in evaporator (1a) can proceed.

This process has been studied and the reactive components have been chosen [14]. The gas used in these systems is ammonia, and the reactive salt chosen is $BaCl_2$, reacting with NH_3 to form $BaCl_2$-$8NH_3$. The reaction equilibrium lines of these components are represented on figure 4. The condensation/boiling enthalpy of NH_3 is about 23 kJ/mol, and the the reaction enthalpy of the $BaCl_2$ with NH_3 is of about 37 kJ/mol of ammonia. Thus, equilibrium lines on figure 4 are not parallel, as for ideal cases and following (4), the ideal COP of this process is 0.31.

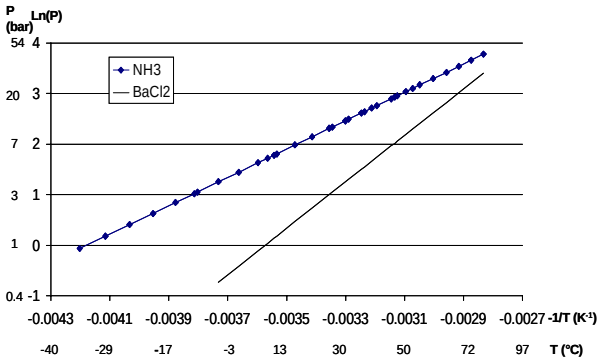

Figure 4: Clausius-Clapeyron diagram of NH_3 liquid-gas transformation and $BaCl_2$-NH_3 reaction.

NUMERICAL ANALYSIS OF THE PROCESS PERFORMANCES

Numerical simulations were performed to characterise the real process corresponding to the ideal process presented above. The development of the modelisation has already been described [14]. Simulations allowed the dimensioning of the process (table 1) and the calculation of its performances depending on the meteorological situation around the solar collectors.

Area solar collector of pole (2a)	1.8 m^2
Area solar collector of pole (2b)	3.8 m^2
Salt mass in pole (2a)	10.4 kg
Salt mass in pole (2b)	20.8 kg
Cycled NH_3 dipole a	5.4 kg
Cycled NH_3 dipole b	10.9 kg

Table 1: Dimensions of the simulated system.

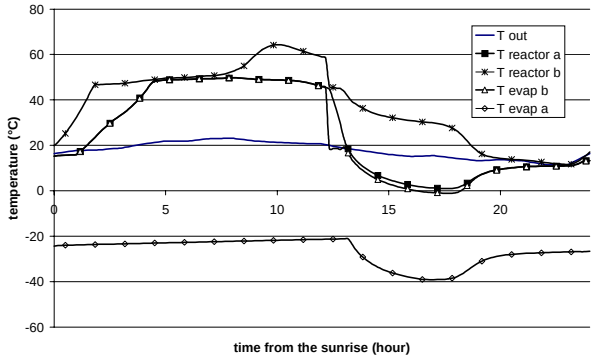

Figure 5: Evolution of the temperatures of the system on the 21th of April, 1996.

Figure 5 shows the temperature evolution of the process on the simulation obtained for the meteorological conditions of the 21th April 1996. This evolution is presented starting from the sunrise (at t=0). During the first hours of insolation, both reactors 'a' and 'b' reach high temperature around 50°C (corresponding to T_h on figure 3). Then, the temperature stabilises and regeneration can occur through the endothermic decomposition of the salts in both reactors. Condensation occurs in the corresponding condensers at outside temperature (T_0 on figure 3). There are no thermal or mass connections between the two dipoles during this phase.

After the beginning of the night, around hour 12, both systems are cooled by convection with outside air and radiation to the nocturnal sky. Temperature of reactor 'b' decreases to approach the ambient temperature T_0. Then, solid absorption begins and evaporator 'b', where evaporation of ammonia happens, is brought to about 0°C ($T_{c/2}$ on figure 3) and absorbs heat from reactor 'a', which is thus brought to about 0°C at minimum. This allows the evaporation of ammonia at about -30°C in evaporator 'a'. This pole reaches a minimum of -40°C during that night. Thus, simulations proved the possibility to reach deep-freezing temperatures using low grade heat from simple flat plate solar collectors.

Figure 6 shows the power involved in the process during an average day of May, obtained from the dynamic simulation of the hour-by-hour evolution of the process. During the day phase, we can see the solar radiations received by the process. As the heat of reaction is twice as big as the evaporation/condensation heat, system 'b' needs to provide twice as much cold to system 'a' as the cold produced at -23°C by system 'a'. Thus the solar collector of system 'b' is twice as big as the solar collector of system 'a' and thus receives twice as much solar heat. The heat used by the system for the thermochemical reactions in both dipoles is lower than the heat received, as the collector efficiency, the thermal amplitude and the heat masses of the process are taken into account in the model. For an average day of May, we can also see that the heat necessary for the reaction is totally obtained by the system after only 8h, though solar heat is received during a longer time.

This is due to the dimensioning of the process for a good functioning over 6 months of the year, and the system is thus over-sized for an average day of May. The cold is produced during the night phase, in the evaporators.

The system practical COP is defined as the ratio:

- of the cold produced by evaporation in evaporator 'a'
- to the heat absorbed by the two solar collectors.

The numerical study of the performances of that process showed a practical system COP of 0.11 in average over the year.

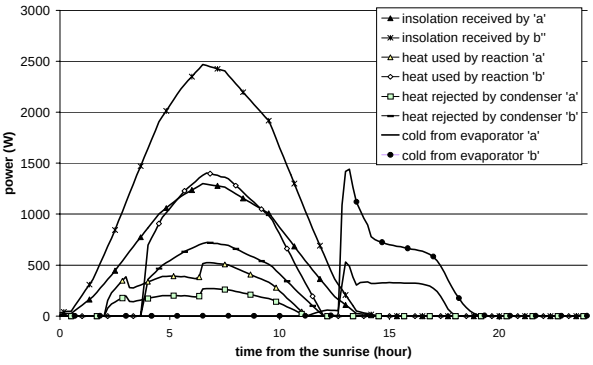

Figure 6: Evolution of the power inlets and outputs of the system during an average day of May.

The net solar COP of the solar system is defined as the ratio of :

- the cold produced by evaporation in evaporator 'a'
- to the solar radiations received by the solar collectors of both dipoles.

Considering an average solar collector efficiency of 0.55 over the year, the net solar COP of the process would be of 0.06, for the production of cold at the deep-freezing temperature of -30°C from low grade solar heat at about 70°C.

An exergetic analysis of the process leads to the determination of its exergetic yield. Figure 7 shows the evolution of the exergies inlets and outlets of the process for an average day of April. During the day phase, the system absorbs exergy through the reactor poles (2a) and (2b). During the night phase, exergy is rejected to the environment by reactor (2b), transferred from pole (2a) to pole (1b) through a thermal connection and useful exergy is produced by pole (1a) at deep-freezing temperature.

The exergetic yield of the process is defined as the ratio of:

- the exergy produced by pole (1a) during the night phase at low temperature
- to the exergies absorbed by poles (2a) and (2b) during the diurnal phase.

For this average day of April, the practical simulated exergetic yield is of 0.35. A simulation of the process during the whole year, using average data for each month of the year, showed that the average system yield would be of about 0.42.

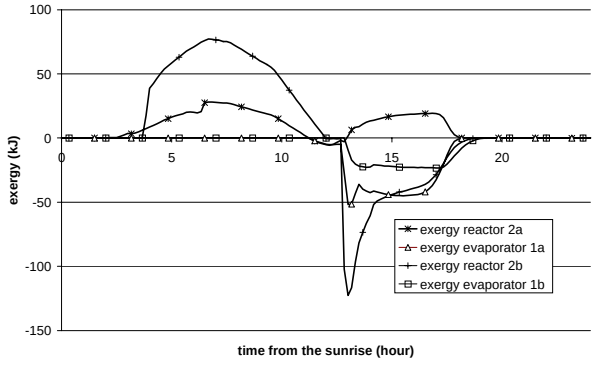

Figure 7: Evolution of the exergetic inlets and outlets of the system during an average day of April, starting from the sunrise at t=0.

CONCLUSIONS

The analysis of the exergies involved in a thermochemical process for cold production allows to distinguish between the quantity and quality of the inlet and outlet energies. A low quality of heat (near the ambient temperature) at the inlet must be balanced by a high quantity, if the quality of the heat desired at the outlet is also high at a given quantity. The study of the $\theta = f(Q)$ diagram allowed to design a new process to produce cold at deep-freezing temperature using low grade heat from simple flat solar collector. This process presents an ideal COP of 0.5 and for the chosen reacting components $BaCl_2$ and NH_3, a COP of 0.31. A numerical simulation of the designed process allowed to calculate the practical COP of the process, taking into account the dynamic of the functioning and the metal, reactive medium and fluids masses involved in the real process. This practical COP was found to be about 0.11 in average over the year.
A numerical exergetic analysis also showed that the designed deep-freezing process could have an exergetic yield of about 0.35, to be compared with the ideal exergetic yield of 1 fixed during the process design.
This process is now being build at PROMES laboratory to experiment this first type of process allowing deep-frozen food conservation using low grade solar heat.

ABSTRACT

This work evaluates the environmental impact of Wastewater Treatment Plants (WTP) based on data generated by the exergy analysis, calculating and applying environmental impact indexes for two WTP located in the Metropolitan Area of São Paulo. The environmental impact of the waste water treatment plants was done by means of evaluating two environmental impact exergy based indexes: the environmental exergy efficiency ($\eta_{env,exerg}$) and the total pollution rate ($R_{pol,t}$). The environmental exergy efficiency is defined as the ratio of the exergy of the useful effect of the WTP to the total exergy consumed by human and natural resources, including all the exergy inputs. That relation is an indication of the theoretical potential of future improvements of the process. Besides the environmental exergy efficiency, it is also used the total pollution rate, based on the definition done by Makarytchev [1], as the ratio of the destroyed exergy associated to the process wastes to the exergy of the useful effect of the process. The analysis of the results shows that this method can be used to quantify and also optimise the environmental performance of Wastewater Treatment Plants.

Keywords: exergy efficiency; environmental impact; wastewater treatment plants

NOMENCLATURE

$B_{Deact.}$ exergy of additional natural resources destroyed during waste deactivation [kW]
$B_{Disp.}$ exergy related to waste disposal of the process [kW]
$B_{Nat.Res}$ exergy of the natural resources consumed by the processes [kW]
BOD Biochemical Oxygen Demand [mol/L]
$B_{Prep.}$ exergy required for extraction and preparation of the natural resources [kW]
$B_{Product}$ exergy of the useful effect of a process [kW]
B_{Waste} exergy of waste, which includes the exergies of solid wastes, rejected heat, and emissions [kW]
COD Chemical Oxygen Demand [mol/L]
$\eta_{env,exerg}$ environmental exergy efficiency
$R_{pol,t}$ total pollution rate
WTP Wastewater Treatment Plants

INTRODUCTION

There is an increasing demand for more sustainable wastewater treatment systems. However, the criteria needed to characterize such a system are not fully developed. One important tool in the analysis of the sustainability of a wastewater treatment system is the exergy analysis. Hellström [2] showed how an exergy analysis could be used to estimate the consumption of physical resources at a wastewater treatment plant.

Some authors have suggested that the quantification of the environmental impact of energy conversion processes can be better driven by the use of the exergy concept (Rosen; Dincer [3]; Gong [4]; Wall; Gong [5]). Others went beyond and calculated that impact based on the exergy (Botero [6]; Creyts; Carey [7]; Gong; Wall [8]; Makarytchev [1]); Rosen; Dincer [9]; Valero; Arauzo [10]). According to Szargut [11], exergy is

defined as the amount of work obtainable when some matter is brought to a state of thermodynamic equilibrium with the common components of the natural surroundings by means of reversible processes, involving interaction only with those components of nature.

Exergy can be defined as a sustainable development registration that emphasizes the connection between generated services/products and used resources. This fact makes exergy a better measure of the damage and a good ecological index since a high exergy efficiency means less exergy wastes to the environment or less environmental damage (Gong [4]; Gong; Wall [8]).

Based on this premise, in this work the "exergy efficiency" is proposed as an environmental performance index which includes the aspects of energy efficiency and environmental impact of the energy conversion processes.

The evaluation of the environmental impact of energy conversion processes using the environmental exergy efficiency, $\eta_{env,exerg}$, is complemented with the calculation of the total pollution rate $R_{pol,t}$ (Makarytchev [1]).

WASTEWATER TREATMENT PLANTS

The analysis of environmental impact was applied to two Wastewater Treatment Plants (WTP), located in the Metropolitan Area of São Paulo, that belong to Tietê River Depollution Program.A detailed description of WTPs Barueri and Parque Novo Mundo is presented in Mora [12]. In Fig. 1, it is illustrated the flowchart of WTPs Barueri and Parque Novo Mundo.

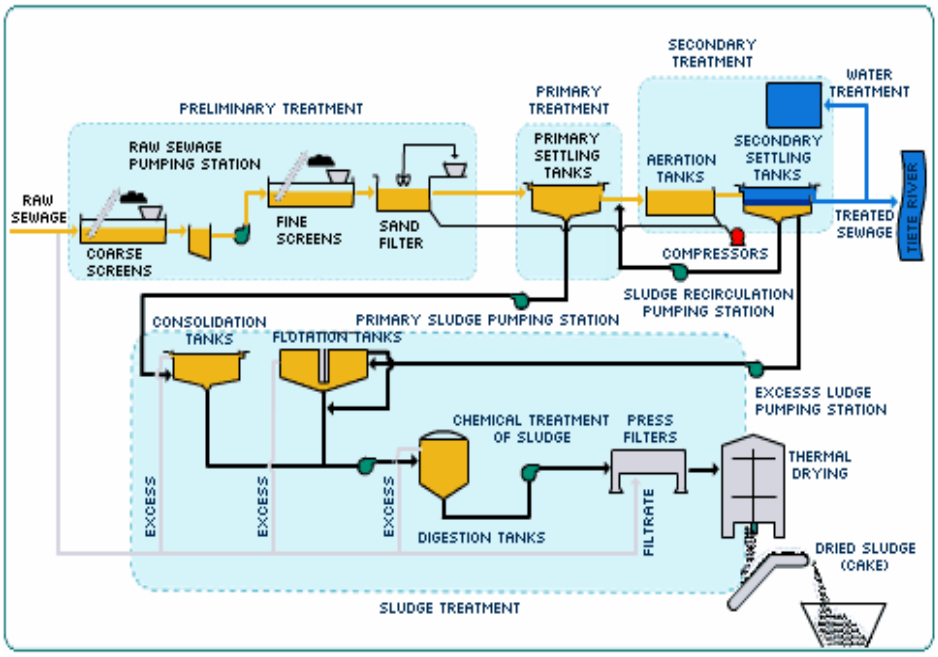

Fig. 1 Wastewater Treatment Plant (SABESP [13])

The plant type illustrated are conventional and secondary activated sludge treatment with organic material removal of 90% Biochemical Oxygen Demand (BOD). The treatment process that take place in the plants consist of the following stages: a) The Preliminary Treatment consist of two

phases: screening and sand removal. Screening removes large solids, which are retained by the screens. The main reasons for screening are to protect the pumps and tubes, later treatment units and the tanks. In sand removal, the sand is removed by sedimentation. The aims of sand removal are to protect equipment from wear and turbulence, eliminate or reduce the risk of blockages in pipes, tanks, siphons and passages, and simplify the liquid transportation, especially transfer of sludge (see Fig.1).

b) The Primary Treatment consist of primary settling tank which tanks are rectangular or round. Sewage flows slowly through the tanks, allowing suspended solids to gradually settle to the bottom of the tank. This solid mass, called primary sludge, can be consolidated at the bottom of the tank and sent directly for digestion, or can be sent to the consolidation tanks. A large part of these solids is made up of organic matter. Depending on the nature and size of the suspended solids, rotating sieves may be used instead of the screening system or the primary settling tanks (WTP PNM). The aim is to separate the larger suspended solids, by means of flowing them through the moving sieves, from the center to the outside. The retained solids are continuously removed in buckets.

c) The Secondary Treatment is made of three phases. In the aeration tank (phase one), organic matter is removed by biochemical reaction, using microorganisms (bacteria, protozoans, fungi) in the aeration tank. This process relies on contact between the microorganisms and the organic material in the sewage, which forms their food. They convert the organic material into carbon dioxide, water and their own cell structure. The secondary settling tanks perform an important function in the activated sludge process (phase two), being responsible for the separation of the suspended solids present in the aeration tank, allowing a clarified liquid to flow out, leaving sediments solids at the base of the tank, which can be returned in a higher concentration. The effluent from the aeration tanks is settled, so that the activated sludge is separated and returns to the aeration tanks. The return of this sludge is necessary to supply the aeration tanks with a sufficient quantity of microorganisms to keep the feeding process going in sufficient strength to decompose the organic material efficiently. The liquid effluent from the secondary settling tanks is either released directly or conveyed for treatment so that it can be reused internally or sold for uses such as washing streets and watering gardens. In the excess sludge pumping station hapes the third stage of the secondary treatment: the sludge formed from the suspended solids by means of the alimentation of microorganisms must be removed to maintain equilibrium in the system (solids in = solids out). The sludge is extracted and sent for treatment (see Fig.1).

d) The Sludge Treatment consists of five phases: i) Consolidation: this stage takes place in consolidation and flotation tanks. As the sludge still contains large quantities of water, its volume must be reduced. The consolidation process increases the solid content in the sludge, reducing its volume. This process can increase the proportion of solids from 1% to 5%. In this way, subsequent units, such as digester tanks and drying units have less work to do. The most common methods include gravity consolidation and flotation. Gravity consolidation is based on the principle of zone sedimentation, as in the conventional settling tanks. The consolidated sludge is removed from the base of the tank. Flotation involves the introduction of air in a compression chamber. When the solution is depressurized, the dissolved air forms micro bubbles that carry the clumps of sludge to the surface, where they are removed. ii) Anaerobic Digestion: digestion has the following aims: to destroy dangerous microorganisms, to stabilize unstable substances and organic material present in the crude sludge, reduce the volume of the sludge through liquefaction, gasification and consolidation, to enable the sludge to reduce its liquid level, and to allow the use of the sludge – after stabilization – as a fertilizer or soil conditioner. Without oxygen, only anaerobic bacteria survive, which are able to use combined oxygen. Acidogenic bacteria break down carbohydrates, proteins and lipids, turning them into volatile acids. Methanogenic bacteria convert a large part of these acids into gases, principally methane. The stabilization of these substances can also be performed by addition of chemicals, a

process known as chemical stabilization. iii) Chemical Conditioning: chemical conditioning results in the coagulation of solids and the freeing of absorbed water. Conditioning is used before the mechanical drying systems, such as filtration, centrifuging, etc. The chemicals used include iron chloride, line, aluminum sulfate and organic polymers. iv) Press Filters: drying in the press filters occurs under high pressure. The advantages of this system include: high concentration of solids in the sludge cake, low turbidity in the filtrate and high solid retention. The resulting proportion of solids is between 30% and 40% for a 2 to 5 hour filtration cycle – the time needed to fill the press, maintain it under pressure, open it, remove the cake and close the press. v) Thermal Drying: thermal drying of the sludge is the process of reduction through evaporation of water into the atmosphere by means of heat, resulting in a proportion of solids between 90% and 95%. This reduces the final volume of the sludge significantly SABESP [13].

ENVIRONMENTAL EXERGY ANALYSIS OF WASTEWATER TREATMENT PLANTS

Environmental impact exergy based indexes

The environmental impact of the waste water treatment plants was done by means of evaluating the values of two environmental impact exergy based indexes: the environmental exergy efficiency ($\eta_{env,exerg}$) and the total pollution rate ($R_{pol,t}$), as proposed by Makarytchev [1] and Mora and Oliveira Jr. [14]. The environmental exergy efficiency is defined as the ratio of the final product exergy (or useful effect of a process) to the total exergy of natural and human resources consumed, including all the exergy inputs. That ratio is also an indication of the theoretical potential of future improvements

for a process. The environmental exergy efficiency is calculated according to Eq. (1).

Exergy evaluation of the environmental impact of the WTP

The analysis of the environmental impact was realized for the Wastewater Treatment Plants Barueri and Parque Novo Mundo (PNM). Based on the data supplied by SABESP (São Paulo Wastewater Treatment Co.), an exergy analysis of the two WTP was realized considering operation in steady state conditions. The chemical exergies of the substances were determined according to data presented by Szargut et al. [11].

A detailed description of exergy calculations of WTPs Barueri and Parque Novo Mundo are showed in Mora [12].With the information generated by this exergy analysis, the environmental exergy efficiency and the total pollution rate were determined and compared.

In Fig. 2 and Fig. 3, are presented the exergy balances for the two Wastewater Treatment Plants

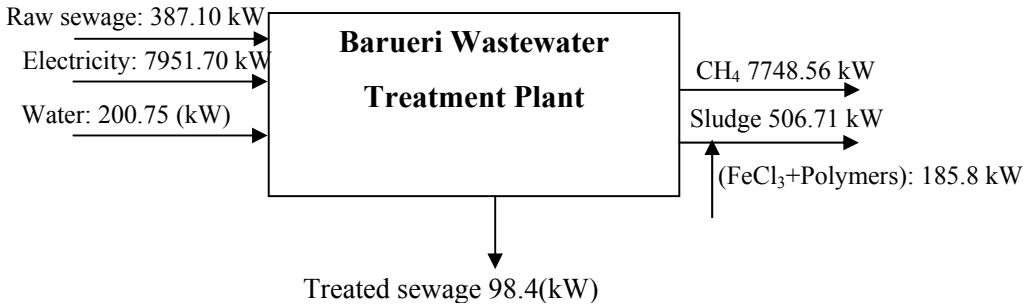

Fig 2. Exergy balance of the Parque Novo Mundo Wastewater Treatment Plant

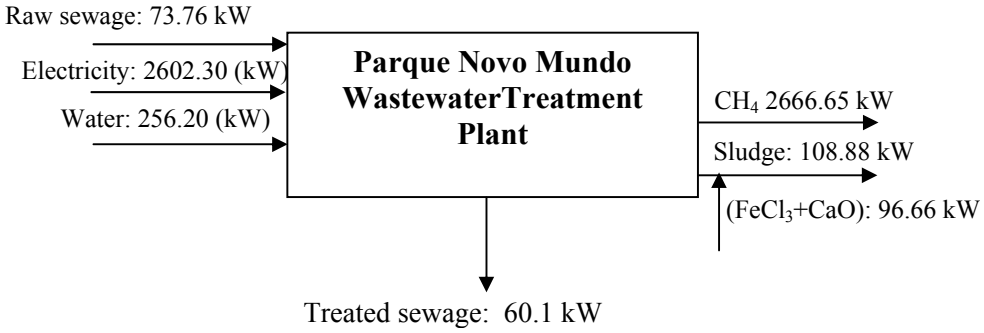

Fig. 3 Exergy balance of the Barueri Wastewater Treatment Plant

In Table 5 are presented the values of the input, output, destroyed and lost exergy flows for Parque Novo Mundo and Barueri. Wastewater Treatment Plants.

In Table 6 are presented the values of the calculated exergy indexes based on the results of the exergy balances. These indexes were used in the evaluation of the environmental impact of the two Wastewater Treatment Plants.

Another important term in the calculation of the exergy indexes is the exergy associated to the wastes of the processes (produced gas and dehydrated mud). If all this exergy was associated to an useful exergetic effect, the values of the $\eta_{env,exerg}$ for WTP Barueri and PNM would increase significantly. These values are presented in Table 7.

	Exergy

CONCLUSIONS AND RECOMMENDATIONS

The present work proposes a scientific methodology based on an exergy criterium to evaluate and quantify the environmental impact of energy conversion processes that take part in waste water treatment plants In this way, it is possible to compare and characterize the environmental exergy performance, and the destruction of the exergy of these processes in the environment.

An overall comparison of the results obtained through the calculation of the indexes of environmental impact ($\eta_{env,exerg}$, $R_{pol,t}$), (see Table 6 and 7), shows that the process that causes the smallest impact in the environment (not considering the cases where the methane and the mud of WTPs are useful effects) is the Parque Novo Mundo, Wastewater Treatment Plant since it presents the largest $\eta_{env,exerg}$ (0.02) and the smallest $R_{pol,t}$ (47.8). In this comparison it is also observed that in agreement with the $\eta_{env,exerg}$ values, (0.01), and $R_{pol,t}$ (85.8), the process that causes the largest impact in the environment is the Wastewater Treatment Plant Barueri, if the by-products (methane and mud) are not considered as useful effect.

The low values of the environmental exergy efficiency ($\eta_{env,exerg}$) for two WTP , are due mainly to the high consumption of electricity for the small generated product, besides the great amount of methane and mud wasted. The electric power consumption represents the largest percentage of the input exergy in the WTP.

Another important fact to be considered in the low values obtained in the environmental exergy efficiency of WTPs, is that the exergy contained in the by-products generated (methane and the mud) is not being used at the moment. If that exergy was considered as a part of the useful effect of the processes of WTP, the values of the $\eta_{env,exerg}$ for WTP Barueri and PNM would be 0.98 and 0.97, and the values of the pollution rate ($R_{pol,t}$) would be zero. From the analysis of these last results, it is observed the great potential improvement that these processes would have, by using the mud for agricultural purposes and the methane as a fuel.

Finally, it was concluded that the exergy analyses of the environmental impacts supply a coherent approach with the technological options that excel for the sustainability of environmental solutions, allowing an efficient environmental performance evaluation.

From the analysis of the obtained exergetic indexes, it can be observed that in spite of the limitations of the exergy concept with respect to the toxicity and the biological quality of any substance, it is an useful tool in the quantification of the environmental impact of the energy conversion processes, from the point of view of the processes environmental performance ($\eta_{env,exerg}$), as well as in the characterization of the required exergy to deactivate the process wastes ($R_{pol,t}$).With the obtained results of this evaluation and quantification, it can be made the optimization of the environmental performance of the process, what is reflected directly in its economical analysis.

To complement this work, it is proposed to include a thermoeconomic analysis in the methodology presented for the environmental evaluation of

energy conversion processes that take place in wastewater treatment plants.

ENERGY AND POLLUTION EMBODIED IN TRADE: THE CASE OF NORWAY

Glen P. Peters* **and Edgar Hertwich**
Industrial Ecology Programme
Norwegian University of Science and Technology
NO-7491 Trondheim
Norway

ABSTRACT

Access to resources and energy, but also policy and historical development, shape the industrial structure of countries. This implies that some countries specialize in energy-intensive and pollution-intensive products. National environmental regulation and international agreements are also expected to shape the global patterns of production, as the concern about "carbon-leakage" under the Kyoto Protocol indicates. Most empirical investigations of the energy and pollution embodied in trade have assumed that imports are produced with the same technology as exports. These investigations were able to reflect differences in the composition of imports and exports, but not differences in pollution control technology, efficiency, or energy mix. We calculate the energy and pollution embodied in trade for Norway, taking into account the energy and pollution intensity of important trading partners. Our investigations indicate that Norwegian exports are more energy intensive than imports. In contrast, due to Norways energy mix and technology, Norwegian exports are often less pollution intensive than imports. This leads us to the hypothesis that, for the case of Norway, there are environmental benefits from trade and a specialization in energy-intensive production is environmentally preferable.

INTRODUCTION

As time passes it is becoming increasingly accepted that global climate change is of major concern and not just a scientific hypothesis. Most governments and many companies are publicly acknowledging the importance of reducing global air pollutants. With the increase in global free trade, many are questioning the effects of trade on the environment. On an economic level, most economists would argue that free trade is beneficial to both the exporting and importing countries. However, do these benefits also

occur on the environmental level?

Many authors have estimated the pollution embodied in trade [16, 8]. For instance, approximately 70% of the reported CO_2 emissions in Norway occur in the production of Norwegian exports [4]. Similarly, a portion of each countries consumption is imported; hence a significant portion of a countries environmental impacts may occur in foreign regions. Further, it has been found as global trade has increased, so has the pollution embodied in trade [2].

For countries with relatively low emissions in energy production, it is likely that an imported good will have a higher environmental impact than if the good was produced domestically. In the case of Norway, where hydropower represents nearly 100% of the electricity mix, imports from China will have a significantly higher environmental impact than if the import was produced domestically. Whilst it may be economical to increase trade with China, the resulting environmental impacts may be detrimental.

Current global climate change policies, such as the Kyoto Protocol, have been criticized from many aspects. One notable criticism is that developing countries are not required to reduce emissions. Another notable, but less debated criticism is the role of trade and the concept of "carbon leakage" [16, 2]; it is possible for a country to reduce its overall reported emissions by increasing imports. One way around this issue is to make the consumer responsible for emissions instead of the producer [10]. From an environmental perspective it is desirable for consumers to choose goods that have the lowest impacts.

Norway is an ideal country to study issues of trade and the environment. Due to its unique energy mix, Norway should have a comparative advantage in energy intensive goods. This article determines the energy and emissions embodied in Norwegian trade. By comparing the results with Norway's major trading partners, it is argued that Noway should produce energy intensive goods.

This article is structured as follows: First, the theoretical methodology is presented. Second, the data sources and data manipulations are discussed. Then, calculations of energy and emissions embodied in trade are shown. The results are then discussed and interpreted.

METHODOLOGY

The theoretical framework has been presented in detail in [13] and so only the main equations are shown here. Several applications of this framework are presented in [12]. The model is based on input-output analysis (IOA) [9, 15]. In summary, the total output of the economy is given by intermediate consumption and final consumption,

$$x = Ax + y \tag{1}$$

where A is the interindustry requirements matrix and y represents various demands on the economy. Solving for the total output, x, gives

$$x = (I - A)^{-1} y \tag{2}$$

The interindustry requirements matrix A represents the technology of an economy. It can be broken down into two components representing the interindustry requirements of domestically produced goods and the interindustry requirements of imported goods, $A = A^d + A^i$.

In this article Norway (NO) is the domestic economy. Norway trades with other regions which have different technologies. It is assumed that there is interindustry trade between Norway and the other regions, but the other regions do not trade with each other [13, 8]. The individual outputs in Norway and the trading regions is given by,

$$x_{NO} = (I - A^d_{NO})^{-1} y^d_{NO} \tag{3}$$

$$x_i = (I - A_i)^{-1} M_i \tag{4}$$

where $M_i = s_i(A^i_{NO} x_{NO} + y^i_{NO})$ is the total imports into Norway from region i, $A^i_{NO} x_{NO}$ are the imports into industry, y^i_{NO} are the imports to final demand, and s_i is the share of imports from each region. The pollution embodied in trade is then calculated as,

$$E_i = F_i x_i \tag{5}$$

For some calculations, it is assumed that each region has the same technology as Norway, in which case,

$$A_i = A_{NO} \qquad F_i = F_{NO} \tag{6}$$

DATA

To reduce the required data, data was only collected for Norway's seven major importing partners:

Region	Code	Import	s_i
Sweden	SE	14%	19%
United Kingdom	UK	13%	14%
North America (US)	NA	10%	12%
Germany	DE	10%	25%
Denmark	DK	7%	14%
Japan	JP	4%	7%
Developing (CH)	DC	4%	10%
Total		61%	∼100%

Table 1: The aggregation of Norway's import trade.

Sweden (SE), United Kingdom (UK), United States (US), Germany (DE), Denmark (DK), Japan (JP), and China (CH). These countries represent 61% of the import value of Norway's commodity and services imports. The minor trading partners were then aggregated under one of the seven major importing partners according to energy use per capita, CO_2 emissions per capita, and gross domestic product per capita[1]; see Table 1. Using this method 100% of Norway's imports are captured. The aggregated importing regions are: Sweden (SE), United Kingdom (UK), North America (NA), Germany (DE), Denmark (DK), Japan (JP), and Developing Countries (DC). Most European countries were assumed to have German, Danish, or Swedish technology and most developing countries were assumed to have Chinese technology; this explains the large increase in import shares for those regions.

Trade data

To use the framework described above requires the share of imports directly into industry and final demand categories from each of Norway's main import partners. This data was unavailable, but Statistics Norway[2] publishes data on the total share of imports from all countries into Norway. Using this trade data, for both commodities and services, the share of imports from each region was estimated using

$$s_i = \frac{M_i}{M_{total}} \tag{7}$$

where M_i is the total imports from region i and M_{total} is the total imports into Norway; the calculated values are shown in Table 1. From this data the share of imports directly into industry, $A_{i,NO} = s_i A^i_{NO}$, and to final demand, $y_{i,NO} = s_i y^i_{NO}$, can then be estimated.

Table 2: A summary of the data used.

Input-output, energy and emissions data

The input-output (IO), energy and emissions data came from a variety of sources. As a result the data required several manipulations to make the complete data set consistent. First, the data was mapped into a common industry classification with 49 sectors[3]. Second, the Consumer Price Index (CPI) in each country was used to convert the monetary data from the base year into 2000 values [4]. Finally, the currencies were converted into Norwegian Crown (NOK) for the base year of 2000[5]. Unfortunately, not all the data was available in basic prices. The producer prices include taxes and subsidies and so are higher than the basic prices. Where possible, adjustments were made for Financial Intermediation Services Indirectly Measured (FISIM) [1]. For this project, it was not possible to obtain energy data for all regions. The data is summarized in Table 2. The main sources of data for each region are now discussed.

Norway

All the Norwegian data was supplied by Statistics Norway for the year 2000 in basic prices. Domestic production data was provided for interindustry flows Z^d, final demand categories, and gross fixed capital formation, K^d. Capital was internalized into the in-

[3] We used a modified NACE classification [12].

[4] CPI values taken from the OECD's sourceOECD database; `http://caliban.sourceoecd.org/`

[5] `http://www.oanda.com/convert/fxhistory`

terindustry coefficients using

$$A^d_{NO} = (Z^d + K^d)\hat{x}^{-1}_{NO} \tag{8}$$

where x_{NO} is the total output of the Norwegian economy and the hat $\hat{\cdot}$ represents diagonalization [7, 13]. In addition, Statistics Norway provided data for the flow of imports into industry, Z^i, and into final demand categories. Capital investments were not distributed by industry for imports and so the interindustry coefficient matrix for imports is given by

$$A^i_{NO} = Z^i\hat{x}^{-1}_{NO} \tag{9}$$

Foreign regions

The IO data for Denmark, Germany, Sweden, and United Kingdom came from the European Unions' Eurostat database[6]. The data was provided in basic prices for 2000; except for the United Kingdom which was 1995. The energy and emissions data was obtained from each countries central statistical offices.

The data for the United States of America was taken from two sources. The IO data came from the Bureau of Economic Analysis[7] (BEA) and the emissions data from Missing Inventory Estimation Tool (MIET) Version 2 [14]. The MIET uses 1996 data and is at the product level. Manipulations were made using the IO data to convert the MIET data into the industry level. Unfortunately, the US data is only available in producer prices and not basic prices. Energy data was not available for this study.

The Japanese data was obtained from the Embodied Energy and Emissions Intensity (3EID) project[8] [11]. The data was only available for 1995 and in producer prices.

The Chinese data was constructed at the International Institute for Applied Systems Analysis (IIASA) [5]. The IO data was taken from 1997 and was only available in producer prices. The emissions data was constructed from 1995 and 2000 data and then interpolated for 1997 to allow combination with the 1997 IO data.

Table 3: The emission intensities in each region.

CALCULATIONS

Emission intensities

An important quantity in this analysis is the emission intensity; the total, direct plus indirect, CO_2 produced per Norwegian Crown (NOK),

$$F_{i,total} = F_i(I - A_i)^{-1} \tag{10}$$

This is a row vector, with each element representing the emissions per unit of output of that sector. The emission intensity multiplier is defined as the sum of the vector elements,

$$F_{i,multiplier} = \sum_j \{F_{i,total}\}_j \tag{11}$$

and gives an indication of the overall emission intensity in a given region.

Table 3 shows the multiplier of the emissions intensity for each of the regions collected for the following analysis; also shown is the emissions intensity for the electricity and hot water production sector. Due to Norway's high use of hydropower to generate electricity, it has significantly lower emissions intensity in the electricity sector. Despite this, the emission intensity multiplier for all Norwegian industries is comparable to some other regions; this is due to the high emissions from some transport and export industries and the aggregating effect of the multiplier. This highlights that the emission intensity multiplier can be misleading and only gives a general comparison. For instance, compared to China, Norway releases over 300 times less CO_2 in the production of an equivalent value of electricity, and 17 times less CO_2 in the production of an equivalent value of total goods. These differences show

Country	Multiplier MJ/NOK	Electricity MJ/NOK
NO	39.9	12.2
DK	31.6	9.4

UK	42.1	6.8
JP	32.5	4.5

Table 4: The energy intensities in each region.

that it is crucial to incorporate the different technology of different regions when determining emissions embodied in trade.

Table 4 shows the multiplier for energy intensity and the energy intensity of the electricity sector for the countries with readily available data. The last column represents the output of electricity compared to the value; reflecting Norway has cheaper electricity and Japan dearer. Of more interest is the total multiplier for energy intensity; which is roughly the same in each region. This reflects the fact that most industrial processes compared across regions have similar energy intensities. In an energy analysis, it is not as important to include the individual technologies from each country.

Emissions embodied in trade

Table 5 shows the emissions embodied in Norwegian trade. The columns represent emissions from the production of domestic demand, the production of export demand, and the production of imports. In each column, the emissions from each region represents the emissions to produce the import requirements for each demand; for instance, Germany (DE) emits 2.0 million tonnes of CO_2 to produce imports directly into the Norwegian production of exports and emits 1.3 million tonnes of CO_2 to produce imports for Norwegian final demand. Recall that the share of imports for each region is increased through aggregation; refer to Table 1. These same calculations can be performed assuming that imports are produced with Norwegian technology; Table 6.

Several results can be drawn from these tables. First, of the Norwegian domestic emissions, 72% of the emissions result from exports; however, only 38% of Norway's domestic output is from exports. This signifies that production of Norwegian exports are more CO_2 intensive than production of domestic

demand. Second, about 50% of the impacts from Norwegian consumption activities occur in other regions. Over half of these impacts occur in developing countries which represent only 10% of Norwegian imports. Third, assuming other regions have Norwegian technology, greatly underestimates the impacts of Norwegian imports.

These results highlight an important issue resulting from climate change policies such as the Kyoto Protocol; namely, "carbon leakage" [16]. A country that is a part of the Kyoto Protocol may reduce its emissions by importing from a foreign region. If the foreign country has a worse emissions profile than the domestic economy, then total global emissions will increase due to trade. This problem can be lessened by including all countries in the Kyoto Protocol. An alternative approach is to make the consumer, and not the producer, responsible for emissions [10].

Currently, the producer is responsible for CO_2 emissions. Total emissions in a country are determined from all producing industries; whether for domestic production or export. If the consumer is respon-

Table 9: The balance of trade for energy embodied in Norwegian trade (PJ).

sible, then the total emissions for a given country are the emissions emitted producing goods for domestic consumption and the emissions emitted in the production of imports for domestic consumption. If CO_2 emissions are taken from a consumer perspective, then the consumer must seek the countries with the most CO_2 efficient production processes. The net difference between producer responsibility and consumer responsibility is the balance of trade for emissions. Table 7 shows that from a consumers' perspective Norway has a better emissions performance. This is due to the CO_2 intensive nature of Norway's export industry. Overall, this implies that Norway is a net exporter of CO_2.

Table 3 indicates that Norway has an overall superior emissions performance than other regions. This need not be the case for specific industries. Considering that Sweden, for instance, has a very similar overall emissions intensity multiplier to Norway indicates that it may be more CO_2 efficient in many sectors. Inspection of the raw data shows this to be the case; the emissions intensity in many industries is lower in Sweden than in Norway.

Energy embodied in trade

Unfortunately, for this study, data could not be collected for the energy use by industry sector in China, United States, or Sweden; see Table 2. The energy intensities for the remaining countries is shown in Table 4. Between separate countries, the energy intensity is very similar. Further, Norway does not have the lowest energy intensity. This perhaps reflects the fact that Norway does not have the highest energy efficiency; which may be driven by a low electricity cost. Given that most industrial processes of the same type require similar energy inputs, regardless of the producing country, it is not surprising that the energy intensities are roughly equal. Difference would arise due to problems with aggregation, different product mixes, slightly different technologies, and different energy efficiencies in industrial processes. Given this, it is reasonable to assume that, for energy use, separate regions have the same technology as Norway. For the calculations below, this assumption is followed unless otherwise specified.

Table 8 shows the energy embodied in Norwegian production and consumption with imports produced using Norwegian technology. The shares for the energy embodied in imports from the separate regions can easily be calculated assuming a linear scaling using the import shares; see Table 1. Comparison with Table 5 shows that a significantly smaller portion of energy is embodied in trade compared to carbon emissions. This again highlights the low CO_2 intensity of Norway's production compared to imports. Table 9 shows the corresponding balance of trade calculations for energy. It is clear that Norway is a net exporter of embodied energy.

Another interesting way to look at the embodied emissions and energy data is to consider the ratio of CO_2 emitted to energy used. Table 10 shows this for Norway; a ratio of Table 5 and Table 8. Several conclusions can be drawn from this table. First, Norwegian imports are more CO_2 intensive then domestic production. Second, Norwegian exports emit more CO_2 per energy input than Norwegian domestic production (due largely to Norway's offshore activities). These two points imply that, from an environmental perspective, Norway should supply more

of its own products; further, Norway should be encouraged to export more energy intensive goods.

DISCUSSION

From an environmental perspective, it is desirable to produce goods where they have the lowest environmental impacts. However, care needs to be taken when comparing energy and emissions intensities from a monetary perspective. If it is assumed that, in a given sector, one unit of monetary output gives the same physical output in each country, then the monetary perspective would be valid. However, this need not be the case[9]. One possible way around this issue is to use Purchasing Price Parity (PPP) instead of Market Exchange Rates (MER) for the currency conversions [6]. Although, it is likely that the PPP would vary from sector to sector. This area requires more research.

If it is assumed that the industry classification is so disaggregated that the same technologies are used in each country to produce the output from a given industry then an analysis of the CO_2 to energy input may be a valid measure of where to produce with the lowest environmental impacts. For the data currently available, this is unlikely to be a reliable measure.

For the current data available, it is best to assume that, for each industry, one unit of monetary output gives the same physical output in each country. This implies that production of a given good should occur in the country with the lowest emissions intensity. For many industries (not all), this would imply that Norway should be encouraged to produce and export more[10]. Further, due to Norway's extensive use of hydropower it can be generalized that Norway should have a comparative advantage in the production of energy intensive goods; Table 10. However, in the current political climate this may not automatically happen.

In the Kyoto Protocol, it is possible for a region to reduce its overall emissions by increasing imports, possibly from a country with worse environmental performance. One way to encourage greater exports from regions with low emissions intensities is to make the consumer responsible for emissions. This approach would encourage consumers to seek the countries with the lowest emission intensities. Although, from a computational point of view the calculations are far more complex with this approach; difficulties include: trade data, transportation, exchange rates, and inflation. Perhaps a better solution is to make the Kyoto Protocol apply across all regions. This would have a similar effect of encouraging all regions to reduce CO_2 emissions; automatically, this would include the export sectors in current non-Kyoto countries.

CONCLUSION

A theoretical framework was presented to calculate energy and emissions embodied in trade. This framework was applied to Norway. It was shown that a significant portion of Norway's induced emissions result from imports; a disproportionate share coming from developing countries. Further, it was found that Norway is a net exporter of carbon emissions. Similar calculations were performed for embodied energy; although, it was found that the energy intensities across countries is roughly constant compared to emission intensities.

The results were then discussed in terms of current climate change policies. It was argued that Norway should be encouraged to produce and export more due to its extensive use of hydropower. One way to achieve this is to make the consumer, and not the producer, responsible for environmental impacts. Alternatively, a possibly less data intensive approach, is to have all countries comply with global climate change policies, such as the Kyoto Protocol.

[9] For instance, the export price of unwrought aluminium in 2000 varied considerably across regions (in kg/US$); NO 1.73, SE 1.70, UK 1.61, US 1.44, DE 1.67, DK 1.42, JP 2.55, CH 1.45. Source: `http://www.unctad.org/`

[10] It is noted that hydropower is a finite resource; however, efficiency impovements would make more energy available for increased production.

ACKNOWLEDGEMENTS

ABSTRACT

Growing economies have the dual challenge of economical and industrial growing, but in a sustainable way and with protection of Ecosystems, all prior requirements are a must that either are satisfied or Human Kind will suffer the irreparable loss of Earth Biosphere. Prospective studies show that for the period 1990 – 2010 the petroleum will be heavier and richer in sulphur. Mexican petroleum company, PEMEX, has been making serious efforts in order to reduce environmental negative impact through a better use of energy in all his infrastructure and the use of bottom of barrel technologies in order to make a better use of heavier petroleum, but PEMEX must still deal with the burning of heavy fuel oil with a high sulphur content and the bottom of barrel sub products. In order to make a more sustainable use of Mexican heavy petroleum the actual "Life Cycle" of Mexican Bottom of Barrel crude oil can be modified though the proposal of producing an activated carbon (CAFOB) from Mexican petroleum vacuums residue and Mexican petroleum coke and apply it in the flue gases desulphuration. To achieve this goal, activated carbon was made from Mexican petroleum vacuums residue and petroleum coke. Desulphuration adsorption tests were made with experimental (CAFOB) and commercial activated carbons and a synthetic flue gas mixture (SO_2=2000 ppm) similar in composition to flue gases produced from the burning of Mexican heavy fuel oil. Commercial activated carbons were used as reference materials for adsorption tests. The CAFOB180M experimental activated carbon showed a good desulphuration capacity compared to commercial activated carbon showing in this way the potential use of CAFOB for Mexican heavy fuel oil flue gas desulphuration in the processing and use in a more sustainable way of Mexican heavy petroleum through the modification of actual "Life Cycle" of Mexican Bottom of Barrel crude oil.

INTRODUCTION

Growing economies have the dual challenge of economical and industrial growing, but in a sustainable way and with protection of Ecosystems, all prior requirements are a must that either are satisfied by all economies, or Human Kind will suffer the irreparable loss of Earth Biosphere [1]. Nowadays and in a near future the main source of energy is and will be the petroleum, fact that will produce direct and indirect environmental pressures, because prospective studies of petroleum worldwide markets show that for the period 1990 – 2010 the petroleum will be heavier, with a diminishing of about 0.4 ºAPI, and richer in sulphur with an increase of about 25% in weight content [2, 3].

During the First Global Ministerial Environment Forum in Malmö, Sweden from 29 to 31 May 2000, more than 100 Ministers of Environment signed the Malmö Declaration, recalling the Stockholm Declaration of the United Nations Conference on the Human Environment and the Rio Declaration of the United Nations Conference on Environment and Development, the Barbados Declaration on the Sustainable Development of Small Island Developing States as well as the Nairobi Declaration on the Role and Mandate of the United Nations Environment Programme. [4].

The Life Cycle Initiative is a response to the call from governments for a life cycle economy in the Malmö Declaration. It contributes to the 10 year framework of programmes to promote sustainable consumption and production patterns, as requested at the World Summit on Sustainable Development (WSSD) in Johannesburg in 2002. Its mission is to develop and disseminate practical tools (Life Cycle Thinking, Life Cycle Management and Life Cycle Assessment) for evaluating the opportunities, risks, and trade-offs, associated with products and services over their whole life cycle.
[5].

Life Cycle Assessment (LCA) is a "cradle-to-grave" approach for assessing industrial systems. "Cradle-to-grave" begins with the gathering of raw materials from the earth to create the product and ends at the point when all materials are returned to the earth. LCA evaluates all stages of a product's life from the perspective that they are interdependent, meaning that one operation leads to the next. LCA enables the estimation of the cumulative environmental impacts resulting from all stages in the product life cycle, often including impacts not considered in more traditional analyses (e.g., raw material extraction, material transportation, ultimate product disposal, etc.). By including the impacts throughout the product life cycle, LCA provides a comprehensive view of the environmental aspects of the product or process and a more accurate picture of the true environmental trade-offs in product selection [6].

MEXICAN BOTTOM OF BARREL LIFE CYCLE

Mexican petroleum company, PEMEX, has been making serious efforts in order to reduce environmental negative impact through a better use of energy in all his infrastructure and the use of bottom of barrel technologies in order to make a better use of heavier petroleum, but PEMEX must still deal with the burning of heavy fuel oil with a high sulphur content and the bottom of barrel sub products like coke.

The actual Life Cycle of Mexican Bottom of Barrel, as shown in Figure 1, begins with the petroleum extraction and stabilization, thereafter it is send to refineries. In refineries different qualities of petroleum are blended, desalted and send to atmospheric and vacuum distillation plants. The bottom of barrel is produced in these plants and contains all metals and heavy fractions of petroleum. Atmospheric and vacuum residues are processed in a coking process that produces light fractions and coke. The coke does have a good low heating values, therefore it has been used as base fuel for thermoelectrical plants, like the one called Tamuin, localized in San Luis Potosi Mexico, that will burn the coke in fluidised bed boilers at low temperature with the consequence of producing very low NOx quantities, and will neutralized the

acid flue gases with lime. Finally the residues will be used in a clinker process.

In order to make a more sustainable use of Mexican heavy petroleum the actual "Life Cycle" of Mexican Bottom of Barrel crude oil can be modified through the proposal of producing an activated carbon (CAFOB) from Mexican petroleum vacuum residues and Mexican petroleum coke and apply it in flue gases desulphurization of refineries.

METHOD

In order to sustain such an hypothesis, experimental work was done to achieve this goal. Activated carbon made from Mexican petroleum vacuum residues and petroleum coke, named as CAFOB and a synthetic flue gas was produced and desulphurized in a reactor by using the CAFOB as adsorbent. The synthetic flue gas composition is shown in Table 1.

CAFOB was produced from Mexican petroleum vaccuum residue and Mexican petroleum coke, carbonized at 823 K and steam activated at 1123 K.

In order to have an idea of the desulphurization potential of CAFOB, commercial activated carbons were used for the desulphurization of the same kind of flue gases and compared.

Commercial activated carbons, NORIT RB3 y RBHG3, were used as reference materials for the SO_2 adsorption capacity tests.

The NORIT RB3 is an extruded water steam activated carbon produced from vegetable matter and suggested for gas desulphurization applications; on the other hand the NORIT RBHG3 is extruded sulphur impregnated steam activated carbon.

Synthetic gas mixture desulphurization tests were carried out on experimental and commercial sorbents. The SO_2 exit concentration was measured, with constant inlet gas mixture temperature.

RESULTS ANALYSIS

The experimental CAFOB showed a better desulphurization capacity compared with the commercial activated carbon NORIT RBHG, and an almost similar capacity compared with the NORIT RB3, as shown in Figure 2, Figure 3 and Table 3. The experimental results were statistically analyzed and showed significant statistical differences. The RB3 and CAFOB 120 showed a similar efficiency and both showed a difference if compared to the other experimental CAFOB´s and the RBHG3, showing a removal capacity (circa 70%) that is higher than the one showed by the RBHG3 (circa 48%) and not so far away from the one showed by the RB3 (circa 80%), therefore the potential application of CAFOB for Mexican heavy fuel oil flue gas desulphurization is good prospective and the actual "Life Cycle" of Mexican Bottom of Barrel crude oil could be modified as shown in Figure 4, by introducing the CAFOB process instead of the coke product.

Some of the principal impacts in the Mexican bottom of barrel Life Cycle Environmental improvement proposal are shown in Table 4. One of the most important impact can be detected in the removal of SOx from flue gases. SOx can have negative impact either in ecosystems, human health, cultural heritage or infrastructure, and the cost of correction such negative impacts can be high.

Also there are other positive impact in the economical aspect, because more valuable light products can be recovered during the CAFOB production, and also commercial sulphur can be obtain by making use of refineries sulphur plants, were SOx and H_2S are converted to elemental sulphur.

If internal refinery costs of raw materials for CAFOB production are taking into consideration, the preliminary CAFOB production cost is appropriate to be considered as a possible candidate for flue gas treatment as shown in Table 5, if compared to the production costs of 300 USD/ton for a lower cost sorbent such as activated char made from Illinois coal, $326 USD/ton, or less than $300

USD/ton low surface area (270 m^2/g) activated carbon made from German brown coal produced by a STEAG for their U.S. market, STEAG has pioneered flue gas cleanup in Europe. Other technological options has the disadvantage that the required material for the gas treatment must be imported into the refinery, materials that are considered as wastes cannot be incorporated to the specific refinery bottom of barrel Life Cycle and some technologies and the produced wastes cannot so easily be incorporated into other processes and the by-product (waste) and waste water generated by other FGD requires environmentally friendly disposal system which further increases both capital and operational cost. [6,7]

When CAFOB cannot be recycled anymore , it can be used as a fuel and flue gases can be treated by lime injection, as in Tamuin plant, and the ashes can be introduced completely to the clinker process.

CONCLUSIONS

Nowadays Mexico and other countries must deal with the challenge of making a better use of heavier petroleum. One option is to make a modification to the bottom of barrel Life Cycle with the introduction of CAFOB production that could have positive environmental, energetic and economical impacts

Table 3 Principal impacts in the Mexican bottom of barrel Life Cycle Environmental improvement proposal

Life Cycle Step	Life Cycle Impact		
	Environmental	Energetic	Economical
Mexican petroleum processing	Sulphur in petroleum that is send to atmosphere when heavy fuel oil is burned can be reduced by introduction of CAFOB in the cycle.	The upgrade of residuals to commercial products in the Mexican petroleum Processing without importing energy into the Cycle, gives the possibility of making a better use of energy..	Acid emissions economical environmental impact can be reduced through the CAFOB flue gases desulphurization. Recoverd sulphur can be commercialized
CAFOB Generation	CAFOB production process will generate flue gases incide the cycle.	CAFOB production process will generate light hydrocarbons that can be used as fuels.	CAFOB production process will generate light hydrocarbons with commercial value
CAFOB Application	SOx emissions are reduced and recovered as comercial sulphur products.	More energy can be recovered from flue gases without corrosion problems.	CAFOB application could have a commercial value.
CAFOB Regeneration	CAFOB regeneration process requires less energy, therefore the flue gases emissions are reduced if compered with CAFOB production.	Energy is required during the regeneration process.	Sulphur comercial products are recovered during the process
CAFOB Disposition	CAFOB can be used as fuel in a fludized bed with lime inyection. NOx emissions are reduced and solid subproducts can be used as raw material in clinker production.	CAFOB can be burned as fuel	Either CAFOB or ashes produced from CAFOB burning can be considered as raw material in clinker process.

Table 4 CAFOB cost production

Raw material	Unitary Cost	Requirements	Cost (USD/ton CAFOB)
Coque	3 to 5 USD/ 1000 kg	1 098 $kg*h^{-1}$	5.49
Vacuum Residue	8 to 9 USD/barrel	470.6 $kg*h^{-1}$	24.80
Natural Gas	4 USD/MMBTU	347.9 kW	4.75
Steam	12 USD/1000 kg	494.1 kg	5.93
TOTAL			40.97

LIFE CYCLE ASSESSMENT OF HYDROGEN PRODUCTION

Christian Solli*, Anders H. Strømman and Edgar G. Hertwich
Industrial Ecology Programme
Norwegian University of Science and Technology
7491 Trondheim
Norway

ABSTRACT

A comparative hybrid life cycle assessment was conducted to assess two different methods for hydrogen production. Environmental impacts from nuclear assisted thermochemical water splitting are compared to hydrogen production from natural gas steam reforming with CO_2-sequestration. The results show that the two methods have significantly different impacts. The nuclear alternative has lower impacts on global warming potential, acidification and eutrophication, and much higher impacts from radiation and human toxicity. A weighting procedure is not applied, hence no overall "winner" can be proclaimed. The relative importance of different impacts remains a challenge for eventual decision makers. Further, the assessment has demonstrated the importance of including economic inputs in a comparative assessment; ordinary process-LCA may produce distorted results since a larger fraction life cycle impacts may occur in one study compared to another.

INTRODUCTION

Hydrogen is currently being promoted as a possible future energy carrier. It provides the opportunity for high efficiency conversion to electricity in a fuel cell without any emissions to air except from water vapor. In light of a growing fear of the environmental consequences from the release of greenhouse gases, it's use is favorable in applications such as the transport sector. Hydrogen is not an energy source. It does not occur naturally in great pro-

*Corresponding author: Phone: +4791567304
Email: christian.solli@ntnu.no

portions, and has to be produced from primary energy sources. For hydrogen to be environmentally preferable as an energy carrier, it therefore has to be *produced* in such a manner that the total environmental repercussions is lower than those of other energy carriers such as gasoline. Hydrogen can be produced from fossil fuels, biomass and splitting of water. Several publications provide comprehensive reviews of hydrogen production methods [13, 5, 19]. Two candidates for large-scale production of hydrogen in the near future are nuclear assisted thermochemical water splitting and natural gas steam reforming. They may both serve as hydrogen producing technologies in the transition to a hydrogen fueled future. It is therefore interesting to investigate their relative environmental performance to gain a better understanding of the possible roads to the hydrogen society.

HYBRID LIFE CYCLE ASSESSMENT

Life cycle assessment (LCA) is an analytic tool developed for assessing the environmental impacts of a product or service throughout its entire life cycle, from resource extraction to final disposal. LCA is formalized in the International Organization for Standardization standards 14040-43 and the theory will not be discussed in further detail here.

Another way to determine system-wide environmental impacts is to combine economic input-output analysis with environmental data on the different economic sectors of the economy. This approach was first introduced by Wassily Leontief in 1970 [18]. The idea is that a given demand of commodities from an economic sector will induce economic activity in other sectors. If it is possible to calculate the total induced economic activity from a given demand, one could combine these results with environmental data of the sectors in the economy to produce total environmental impacts for a given demand. The methodology has been further developed since 1970; see for example [28] and [15].

Recent efforts have combined the strengths of process LCA and environmental input-output analysis (see for example [12, 25]). While process LCA provides detailed data on the "close" parts of the system that is assessed, input-output analysis can offer to calculate the environmental burdens arising further out in the system. The construction of an industrial facility will not only require materials such as cement, steel, wood etc., usually accounted for in a process-LCA, but also a significant amount of services from carpenters, electricians, financial sectors and others. They all use equipment and energy doing their job, and the input-output approach offers the possibility to include these inputs through demanding services from an economic sector. The difference between the cost of some sort of equipment and the cost of the materials needed for its construction could be demanded from a sector such as, for example, *construction services*. This results in an induced demand in the whole economy and a set of environmental impacts that can be added to the impacts from process-LCA to yield total environmental impacts.

METHOD OF CALCULATION

The computations of LCA are best performed within a matrix framework, allowing for more flexible and sophisticated analysis.

Unit processes along the life cycle of a product or service can be identified. These are called *foreground processes*. They may all have inputs of products from each other or other processes not specified as a part of the foreground system. The foreground processes can be organized in a matrix $\mathbf{A}_{ff}$ describing the flows between the different processes in the system on a unit output basis. The environmental flows (emissions and raw material use) are assembled in a matrix $\mathbf{E}_f$; also on a unit output basis.

Various LCA-databases have been developed, containing standard LCI-data for different processes. These are contained in matrices called $\mathbf{A}_{pp}$. Their corresponding emissions are given in $\mathbf{E}_p$. These databases can be used to model background processes needed as inputs to the foreground system. The demands from the foreground system to the background system are assembled in matrix $\mathbf{A}_{pf}$.

In order to estimate the environmental impacts of activities not covered in the foreground system or the LCA databases, a combination of input-output analysis and ordinary process-LCA is applied. The difference between the price of a unit equipment and

the cost of its material inputs can be called the *value added* (*VA*),

$$VA = EC - \sum_i W_i \cdot MC_i \tag{1}$$

where EC is the total cost of a unit equipment, W_i is the weight of material i used in the equipment and MC_i is the unit cost of material i. We can now calculate VA for each of the unit processes. The VA must be assigned to an industrial sector or a commodity group, e.g. *Equipment manufacturing* if there is such a sector present in the input-output matrix.

A matrix $\mathbf{A}_{nn}$ describes the interindustry demands in the economy and its corresponding emission matrix, $\mathbf{E}_n$, the environmental flows arising from the one unit output of each process. The demand of the different foreground processes from the background economy can now be assembled of the VA values into a matrix $\mathbf{A}_{nf}$. Matrices $\mathbf{A}_{ff}$, $\mathbf{A}_{pp}$, $\mathbf{A}_{nn}$, $\mathbf{A}_{pf}$ and $\mathbf{A}_{nf}$ can be arranged into a matrix,

$$\mathbf{A} = \begin{pmatrix} \mathbf{A}_{ff} & 0 & 0 \\ \mathbf{A}_{pf} & \mathbf{A}_{pp} & 0 \\ \mathbf{A}_{nf} & 0 & \mathbf{A}_{nn} \end{pmatrix} \tag{2}$$

Corresponding **E**-matrices can be arranged into one large **E**-matrix. With a given demand of foreground processes **y**, the total induced demand of processes, **x**, can now be calculated as,

$$\begin{pmatrix} \mathbf{x}_f \\ \mathbf{x}_p \\ \mathbf{x}_n \end{pmatrix} = \left[I - \begin{pmatrix} \mathbf{A}_{ff} & 0 & 0 \\ \mathbf{A}_{pf} & \mathbf{A}_{pp} & 0 \\ \mathbf{A}_{nf} & 0 & \mathbf{A}_{nn} \end{pmatrix} \right]^{-1} \cdot \begin{pmatrix} \mathbf{y}_f \\ 0 \\ 0 \end{pmatrix} \tag{3}$$

The total environmental flows, **e**, arising as a result of the induced process activity are calculated by

$$\mathbf{e} = \mathbf{E} \cdot \begin{pmatrix} \mathbf{x}_f \\ \mathbf{x}_p \\ \mathbf{x}_n \end{pmatrix} \tag{4}$$

The impact assessment results, **c**, are now calculated by multiplying the **e**-vector with a characterization matrix **C**,

$$\mathbf{c} = \mathbf{C} \cdot \mathbf{e} \tag{5}$$

The matrix structure of the computations is ideal for further analysis. Exploration of process contributions to the different impacts and contributions from foreground, background and input-output parts of the system can be performed with simple straightforward matrix manipulations. This is not explained further in this paper.

SYSTEM DESCRIPTION

The assessment has been conducted with the aim of comparing hydrogen production from natural gas steam reforming and nuclear power. The natural gas based system includes inputs and outputs from natural gas extraction, processing to produce hydrogen, separation and CO_2 sequestration. Data from this case was obtained from a previous study [24].

Hydrogen can be produced from nuclear heat via thermochemical water cracking; a technology described by the industry itself as a promising and realistic option for large scale hydrogen production in the future [4, 20]. Numerous chemical cycles can, combined with heat, produce hydrogen from water. Through a large survey a process called the Iodine-Sulphur (I-S) cycle was found most attractive [4]. The process needs a coolant outlet temperature at least above 850 degrees celcius. This implies new reactor technology to supply the heat. General Atomics (GA) has performed a feasibility study and found a helium cooled high temperature reactor most suited for the task [4]. The concept is called the Hydrogen-Modular Helium Reactor (H_2-MHR) and will deliver the required high temperatures (950 degrees outlet temperature). The reactor will use uranium as fuel with an average enrichment of approx. 13 % U-235 [21]. In principle this system shares most of the current nuclear systems' processes. The main difference is that the electricity producing unit is replaced by hydrogen production. However, it also differs in the internal characteristics of the unit processes e.g. reactor technology and enrichment level. The system analyzed can be divided into seven main stages:

1. Mining and milling produce concentrated uranium in the form of U_3O_8.

2. The conversion stage converts U_3O_8 to the form UF_6 needed in the enrichment process.

3. Enrichment brings concentration of the fissile isotope U-235 to a desired level.

4. In fuel production the chemical composition is altered once again to UO_2 (light water cooled reactors) or UC, UC_2 or UCO (gas cooled reactors).

5. The fuel is then irradiated through use in a nuclear reactor, generating heat for the hydrogen production process.

6. Hydrogen is produced through thermochemical water splitting. Different chemical reactions supported by catalyst chemicals and heat produce hydrogen and oxygen from the input of pure water.

7. Spent fuel is treated in several stages before final storage in a deep geological repository.

The production of 1 TJ hydrogen (higher heating value, HHV) delivered at approx. 37 bars is the basis for the assessment.

Two LCA-databases and one input-output database are used to provide background processes and economic inputs to the foreground processes[1]. It is assumed zero loss of uranium throughout the fuel cycle.

It should further be noted that the hybrid approach is only applied to the nuclear heat facility and the hydrogen production unit. It proved difficult to obtain inventory data and prices for the inputs from the fuel cycle. Fuel cycle foreground processes are therefore modeled entirely with inputs from LCA-database processes. It is, however, assumed that the input data in the LCA-database are covering most subprocesses thus minimizing the *VA* discussed earlier. The construction and demolition of the fuel cycle facilities are included in the LCA-database data. Full system description and inventory data can be viewed in [22].

RESULTS

Not much has been done to evaluate the life cycle environmental burdens arising from nuclear hydrogen production, but some publications assess nuclear electricity production. This includes the ExternE studies [6], which focus mainly on the life cycle external costs arising from the release of radionuclides in the nuclear fuel cycle and the potential for accidents, excluding numerous other possible environmental issues. The Swedish electrical company Vattenfall has conducted LCAs for their different electricity producing technologies, including nuclear power [3]. Some work has also been done in Korea [17, 16]. Other studies apply a life cycle approach to assess nuclear power generation, but fails to include a comprehensive list of impacts, focusing on selected impact categories [29, 23, 10]. There is also nuclear LCA data as a part of the database ETH-ESU 96 [9] and Ecoinvent [7].

For the impact assessment two different methods were used; the CML 2000 baseline method[2] and the Eco-Indicator 99 method[3] Only results for selected impact categories are presented in this paper, for a more comprehensive presentation of the results consult [22]. To be able to assess impacts from radiation, the radiation impact category from Eco-Indicator 99 has been used. The indicators are shown in Table 1.

Impact category	**Indicator**
GWP	kg CO_2-equivalents
HTP	kg 1,4 DB-equivalents[a]
AP	kg SO_2-equivalents
EP	kg PO_4^{3-}-equivalents
R	Disability Adjusted Life Years (DALY)

[a] 1,4 Diclorobenzene- equivalents

system performs better for human toxicity and radiation whereas the nuclear alternative has a better score for global warming, acidification and eutrophication.

It is also interesting to investigate the difference in where the impacts occur for the two options. Figures 1 and 2 shows the contribution of foreground-, background- and input-output processes to the different environmental impacts. The GWP shows

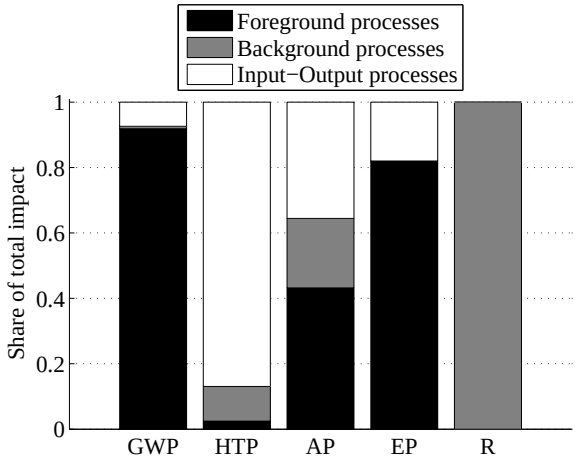

Figure 1: Impacts of hydrogen production from natural gas from foreground, background and economic inputs.

a large difference between the systems. Almost all greenhouse gas emissions in the natural gas case occur in the foreground processes whereas for the nuclear case, economic inputs and background processes dominate the impacts. This is not so strange considering the use of natural gas to fuel the boilers in the steam reforming process for natural gas. For the HTP we see that the foreground processes play

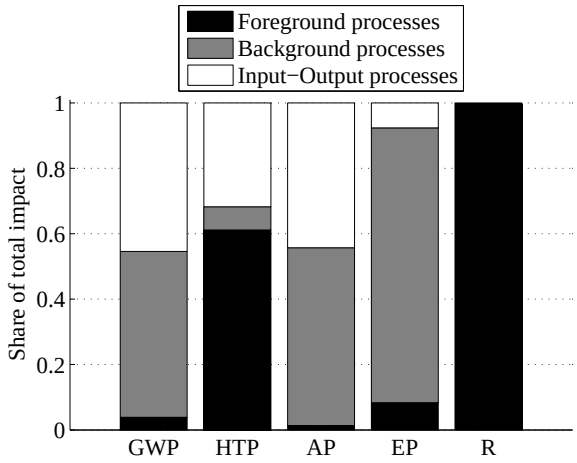

Figure 2: Impacts of nuclear hydrogen production from foreground, background and economic inputs.

a much more important role in the nuclear system. The major part of the impacts comes from fuel cycle activities. In impact categories AP and EP however, foreground processes contribute larger in the natural gas case. The radiation impacts from the nuclear system is dominated by foreground contributions, especially the mill tailings that continue to exhale radon for thousands of years. For the natural gas case, radiation impacts occur only in the background system. Generally we see that input-output contributions are significant for both systems.

Details of nuclear hydrogen production

To gain a better understanding of the environmental performance of the nuclear system, as well as identifying areas of improvement, it is interesting to identify the upstream impacts for each foreground process. These results are shown in Table 3.

Global warming potential (GWP)
For the global warming potential the most important contributions occur upstream the operation of the power plant, hydrogen plant, conversion and milling. Most of this is due to induced activity in background- and input-output matrix. The GWP impacts are quite evenly distributed, i.e. not many large contributors; the ten largest contributors account for

Foreground process	GWP	HTP	AP	EP	R
Constr. NPP	5	3	6	1	0
Constr. H2-plant	6	3	6	1	0
Mining	5	26	6	25	1
Milling	16	38	25	38	0
Mill tailings	0	0	0	0	99
Conversion	16	2	8	16	0
Enrichment	6	1	3	2	0
Fuel fabrication	0	0	1	0	0
Spent fuel mgmt.	9	2	10	11	0
Mgmt. of LLW	0	0	0	0	0
Operation NPP	18	15	20	3	0
Operation H2-plant	19	11	16	3	0

Table 3: Total upstream impacts for the different foreground processes (in % of total)

about 60 % of total.

Human toxicity potential (HTP)
Mining and milling are the most important contributions to this impact category, alone accounting for more than 60 % of impacts. This is mostly the direct impacts from the mining and milling processes. Further, there is a significant difference between open pit and underground mining, meaning that the HTP is somewhat sensitive to the type of mining technology. Open pit mining is significantly better than undergroundmining in this impact category. The impacts from the operation of reactor and hydrogen plant are mostly due to induced economic activity.

Acidification potential (AP)
Impacts caused by inputs to spent fuel management, milling and operation of reactor/hydrogen plant dominate this impact category (about 70-80 % of total). It is therefore sensitive to the assumption that fuel rods are not pushed out of the fuel assembly before managing the spent fuel. Impacts occur almost entirely in background and input-output processes. This is further emphasized in Figure 2.

Eutrophication potential (EP)
Mining and milling contribute most to the eutrophication potential, closely followed by the conversion process and spent fuel management. The dominating direct impacts mainly come from background processes in the LCA-database.

Radiation (R)
Milling of uranium is the most important contributor to human health impacts from radiation. This implies that efforts towards reducing the radiation impacts from from the nuclear cycle should be directed at improved management of mill tailings. UNSCEAR [27] points out that radon emissions from tailings are highly dependent on how they are treated. It also follows that radiation impacts are not sensitive to mining and enrichment technology.

DISCUSSION AND CONCLUSIONS

The assessment has shown that a hybrid approach to LCA is needed to assess the total environmental impacts from the life cycle. For some impact categories a significant amount of the impacts come from the acquisition of economic activities. One of the most important lessons from this is that ordinary process-LCA fails to calculate all impacts from the life cycle. This may not be a problem if the goal of the LCA is to learn more about a product and identify areas of improvement potential; but in a comparative assessment, a significantly larger fraction of impacts may be accounted for in one system or for one impact category than in another through process-LCA. Figures 1 and 2 illustrate that a comparative assessment based on process-LCA alone may give misleading results. It is obvious that only performing a process-LCA can lead to wrong conclusions.

Since the input-output processes are important contributors to some of the impact categories, the results are sensitive to the assignment of costs to economic sectors. This procedure has been done based on our subjective understanding of correlation between different costs and the names of the economic sectors.

It should be kept in mind that the results are quite sensitive to the quality of the databases used since much of the inventory has been constructed using these databases. The input-output database contains highly aggregated data and it is also assumed that the structure of the economy in which the plant is built is equal to that of OECD Europe. Results could therefore be seen more as indicative than exact quantification of impacts.

Natural gas derived hydrogen performs better for human HTP and R, the nuclear system is better on GWP, AP and EP. Results from the impact assessment does, however, not prioritize between the dif-

ferent impact categories; i.e. no weighting procedure is applied. It is therefore impossible to claim an overall best alternative for hydrogen production, comparison between the two alternatives can only be performed impact category by impact category. For an introduction to weighting in LCA, consult [8] or [26].

Improved management of mill tailings is clearly the most important strategy for reducing the human health impacts from ionizing radiation. This is due to the long term exhalation of radon gas from the tailings.

It is hard to discuss aspects of nuclear power without commenting on the politically hot issues of accidents, proliferation and spent fuel management. In an LCA context only impacts resulting from routine operation are accounted. It should be mentioned that the reactor concept assessed in this paper is described as meltdown proof and that it offers high proliferation resistance. The use of coated particles in the fuel is also said to maintain its integrity for at least a million years in a geologic repository [14]. It has not been our ambition to question this information and only routine impacts have been included.

THERMOECOLOGICAL COST OF ELECTRICITY GENERATION IN COAL FIRED STEAM POWER PLANTS

Wojciech STANEK*
Technical University of Silesia
Institute of Thermal Technology
ul. Konarskiego 22, 44-100 Gliwice
Poland

ABSTRACT

The depletion of the limited non-renewable resources is one of the most important factor for the future existence of mankind. Exergy can be applied as a measure of the quality of limited natural resources. The thermoecological cost can be defined as cumulative exergy consumption of non-renewable natural resources connected with the production of some particular product and the additional cumulative exergy consumption connected with prevention and compensation of environmental losses. The paper presents the analysis of the thermoecological cost of electricity production in coal-fired steam power plants. The methodology of evaluating the thermoecological cost taking into account life cycle of considered product is discussed. The paper includes also the description of the method of calculation of the thermoecological cost resulting from rejection of harmful substances to natural environment. In this case two methods are discussed: the first method is based on monetary indices of harmful impacts of the waste products rejected to natural environment and the second is based on the idea of abatement cost. Results of calculations of the thermoecological cost of electricity taking into account life cycle of installation have been presented. Calculations have been made for Polish conditions, where majority of electricity is produced in coal fired (energy hard coal and lignite) steam power plant.

Key words: natural resources, cumulative exergy consumption, thermoecological cost, life-cycle assessment.

NOMENCLATURE

a_{ij}	coefficient of the consumption and of *i*-th product per unit of *j*-th major product
f_{ij}	coefficient of by-production of *i*-th product per unit of *j*-th major product
a_{rj}	coefficient of the consumption of *r*-th imported semi-finished product per unit of *j*-th major product,
b_{sj}	exergy of *s*-th non-renewable natural resource immediately consumed in the process under consideration per unit of *j*-th product
B	annual exergy consumption of non-renewable natural resources
ec	energy hard coal
lig	lignite
GDP	annual gross domestic product,
P_k	annual production of *k*-th aggressive component of waste products rejected to the environment in the considered region

p_{jk} amount of *k*-th aggressive component rejected to natural environment per unit of *j*-th product

ρ_j specific thermoecological cost of the *j*-th product

ρ_r specific thermoecological cost of imported *r*-th good

ρ_{ex} thermoecological cost burdening exploitation of the plant (mainly fuel consumption)

ρ_{LCA} total thermoecological cost taking into account total life time of the plant

w_k monetary coefficient of ecological damages per unit of the *k*-th aggressive waste product

ζ_k cumulative exergy consumption of non-renewable resources due to the emission of unit of the *k*-th waste product

INTRODUCTION

The paper deals with the problem of depletion of natural resources resulting from production of electric energy. Methodology of evaluation of unfavourable ecological effects of human activity basing on thermoecological cost is discussed. Such a unfavourable effects result from two reasons: consumption of non-renewable natural resources and rejection of harmful waste material to the natural environment. Rejection of harmful substances to the natural environment causes losses in fields of human health, nature, buildings, agriculture etc. For this reason we should pay additional expenses for decrease or compensate these unfavourable effects as far as it is profitable from the environmental point of view. The measure of such a profitability is discussed by means of definitions of two kinds of environmental factor: thermoecological cost of rejection of waste products and thermoecological cost of decrease of harmful impacts.

Production of electricity influences the depletion of natural resources mainly due to consumption of non-renewable fossil fuels. In Polish conditions majority of electricity is generated in energy hard coal- and lignite-fired steam power plants. Installed power in Polish power plants at the end of the year 2003 amounted to 32268 MW [23]. Of which [23] 28803 MW (64%) was installed in energy hard coal-fired power plant and 9304 MW (45%) in lignite-fired power plant. Yearly average load reached 62% of installed power [23]. Average net energy efficiency of electricity generation in Polish conditions is equal 34.5%.

These are the main Polish power plants with installed power greater than 150 MW [22]: 1. Power Plant Bełchatów SA 4420 MW (lig.), 2. Power Plant Kozienice SA 2820 MW (ec), 3. Power Plant Turów SA 2166 MW (lig.), 4. Power Plant Połaniec SA 1800 MW (ec), 5. Power Plant Rybnik SA 1775 MW (ec), 6. Power Plant Dolna Odra SA 1742 MW (ec), 7. Power Plant Jaworzno SA 1635 MW (ec), 8. Power Plant Opole SA 1479 MW (ec), 9. Power Plant Pątnów SA 1200 MW (lig.), 10. Power Plant Łaziska SA 1155 MW (ec), 11. Power Plant Łagisza SA 840 MW (ec), 12. Power Plant Siersza SA 786 MW (ec), 13. Power Plant Adamów SA 600 MW (lig), 14. Power Plant Ostrołęka SA 600 MW (ec), 15. Power Plant Skawina SA 590 MW (ec), 16. Power Plant Konin SA 523 MW (lig), 17. Power Plant Stalowa Wola SA 341 MW (ec), 18. Power Plant Halemba SA 200 MW (ec), 19. Power Plant Blachownia SA 158 MW (ec).

Power Plant Opole is characterized by highest (in Polish conditions) value of net energy efficiency of about 36.5% [22]. The longest distance between coal mines located in Southern Poland and Power Plant Dolne Odra located in north of Poland is about 600 km.

Besides of consumption of fossil fuels the generation of electricity is burdened by additional consumption resulting from rejection of harmful substances to natural environment and external costs due to expenditures for construction of plant, transportation, redecorations during life cycle and recycling of materials after decommissioning of existing plant.

As different resources and products are consumed in each of mentioned steps of lifetime of power plant we have to take common measure that let us compare all of these unfavourable effects. For this purpose we can apply exergy [11],[12],[13],[14]. Not only the consumption of fossil fuels influences the total expenditures burdening the thermoecological cost so the author propose to connect the methodology of exergo-ecology analysis with the methodology of life cycle assessment to determine full impacts. The author propose the concept of Thermo Ecological

Life Cycle Assessment (*analysis from the cradle to the grave*) as a tool for for comprehensive evaluation of environmental contribution of human activity. Cumulative Exergy Life Cycle Assessment has been also taken into account in [2].

CONCEPT OF THERMOECOLOGICAL COST

According to J. Szargut [12],[14] the *thermo-ecological cost* is defined as the cumulative consumption of non-renewable exergy connected with the fabrication of a particular product including additionally the consumption resulting from the necessity of compensation of environmental losses caused by rejection of harmful substances to the environment (Fig 1.)

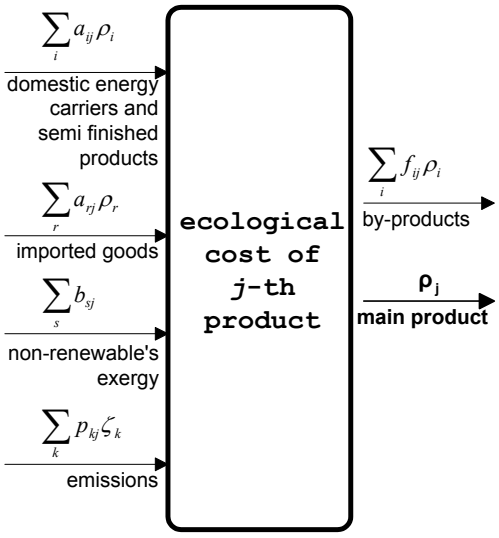

Fig. 1 Balance of thermoecological cost

The index of thermo-ecological cost can be determined by solving the set of thermoecological cost balance equations:

$$\rho_j + \sum_i \left(f_{ij} - a_{ij}\right)\rho_i - \sum_r a_{rj}\rho_r = \\ = \sum_s b_{sj} + \sum_k p_{kj}\zeta_k \qquad (1)$$

This set should comprise all the branches of domestic economy. However, it would be difficult to solve such a problem. For this reason in practical calculation only strongly connected production processes are taken into account. In analysis described in next sections 33 branches of domestic economy are taken into account. Method of determination of the factor ζ_k is discussed in details in next sections of the paper.

The thermodynamic evaluation of environmental losses and natural resources has been also considered in [1],[2],[3],[4],[5],[17],[18].

Some of thermoecological cost balance equations include the thermo-ecological cost of imported goods which represent additional unknowns in the equation set. These unknowns may be determined using an iterative method described in [8].

THERMOECOLOGICAL LIFE CYCLE ASSESSMENT

The Thermo Ecological Life Cycle Assessment (TELCA) based on methodology, described in previous section, comprises the following phases:

1. **Construction Phase** encompasses project, extraction of raw materials, semi-finished products fabrications, transport expenditures in the construction phase. All of these expenses influence the final thermoecological cost burdening the final useful consumptive product. This phase has a significant contribution in case of processes that are based on renewable sources of energy. For instance, in case of wind power plant the thermoecological cost results mainly from expenses in construction phase.
2. **Operation phase** is defined as a period of time between the end of construction phase and the beginning of decommissioning phase. In processes utilising non-renewable resources this phase is predominant in the cumulative consumption of natural resources, mainly energy carriers.
3. **Decomissioning phase** of plant concerns the period at the end of life of installation. Thermoecological cost in this phase results from expenditures for develop the remains of the system and e.g. some expenditures for reclamation of terrain.

The general form of the objective function in case of thermoecological cost minimisation taking into account the life – time of product has been formulated by J. Szargut and presented in [13].

Basing on the concept presented in [13] in order to taking into account total resources expenditure during whole life-time the thermoecological cost balance equation (1) used so far [8],[9],[10] should be extended by the following components:

1) cumulative consumption of exergy of non-renewable resources in the construction phase:

$$a_{1j} = \frac{\frac{1}{\tau}\sum_m G_m \rho_m}{P_j} \quad (2)$$

where: τ – total life time of j – th productive process, G_m – consumption of construction materials during the construction phase, ρ_m – index of thermoecological cost of m – th material consumed in construction phase, P_j – total annual productivity of j – th process,

2) cumulative exergy consumption of non-renewable natural resources resulting from necessity of redecoration during operational phase of j – th productive process:

$$a_{2rj} = \frac{\frac{1}{\tau}\sum_r G_r \rho_r}{P_j} \quad (3)$$

where: G_r, ρ_r – consumption and thermoecological cost of materials used for redecoration during total life time of considered plant,

3) cumulative consumption of exergy of non-renewable resources during decommissioning of considered plant:

$$a_{3j} = \frac{\frac{1}{\tau}\left(\sum_l G_l \rho_l - \sum_u G_u \rho_u u_{rec}\right)}{P_j} \quad (4)$$

where: $\sum_i G_i \rho_i$ – additional thermoecological cost resulting from decommissioning of installation of j – th productive process, $G_u u_{\mathrm{rec}}$ – amount of u – th recyclable material that will be recycled, ρ_u – thermoecological cost of u – th recyclable product.

Each productive process is inseparably connected with additional consumption resulting from the needs for transportation. These expenses resulting both from construction of means of transport as well as resource expenses during the period of its operation (fuel consumption, emissions of harmful substances, expenses for redecoration of transportation). For example the thermoecological cost resulting from needs for transportation of fuel to power plant by means of cars results from the following formulas:

a) cost dependent on fuel consumption:

$$\rho_{t1} = \frac{\bar{e}_f}{\eta_{Eek} W_{dek}} l\left(\gamma_f + \sum_k p_k \zeta_k\right) \quad (5)$$

where: $\bar{e}_f$ – average specific consumption of chemical energy of fuel by means of transportation e.g. MJ/(t·km), η_{Eek} – energy efficiency of considered power plant, $W_{d\mathrm{ek}}$ – lower heating value of fuel transported to considered power plant, l – average distance of transportation of fuel to power plant, γ_f – ratio of thermoecological cost per unit of chemical energy of fuel, p_k – specific emission of k – th harmful substance per unit of consumed chemical energy of fuel, ξ_k – thermoecoloical cost of k – th harmful substance;

b) cost independent on amount of consumed fuel:

$$\rho_{t2} = \frac{1}{\tau_{LT}} \frac{\sum_i G_i \rho_i (1 - u_i)}{\eta_{Eek} W_{dek}} \frac{l}{V \tau_d \mu G \tau_R} \quad (6)$$

where: τ_{LT} – life time of transportation means, $\sum_i G_i \rho_i$ – thermoecological cost burdening the construction of transportation means, u_i – index of recycling of materials after life time of transportation means, $V\tau_d$ – average daily mileage, μ – degree of utilising the transportation means, G – carrying capacity of transportation means, τ_R – annual operational time.

Formulas (5) and (6) expresses the thermoecological cost burdening the transportation of fuel required for production of 1 MJ of electric energy. Such a relations can be applied for determination of any transportation replacing in denominator the term of $\eta_{Eek} W_{dek}$ by means of adequate amount of other transported good. Quoted formulas let to investigate the influence of the transportation distance between mine and plant on the indices of thermoecological cost of electricity.

THERMOECOLOGICAL ASSESMENT OF REJECTION OF HARMFUL SUBSTANCES

Fig. 2 presents the connections between j – th productive process and rejections of harmful substance to the natural environment.

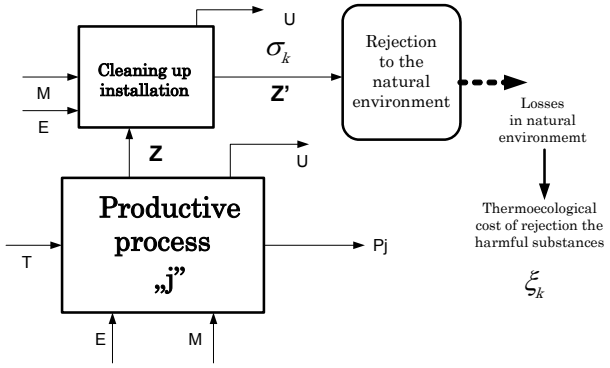

Fig. 2 Rejection of harmful substances to natural environment

Symbols in Fig. 2 concerns: *E* – energy, *M* – raw materials or semi-finished products, *U* – by-products, *T* – transport, P_j – main product of *j*-th productive process, ***Z*** – harmful waste products generated in *j*-th productive process transferred to cleaning up installation, ***Z'*** – harmful waste products rejected to natural environment.

From the thermoecological point of view this chain (Fig. 2) can be divided in two characteristic stages. The first stage encompasses the thermoecological cost resulting from the necessity of cleaning of harmful products of *j* – th productive process while the second stage is the rejection of harmful substance *k* to the natural environment. The environmental losses are caused by both of such phases. The first phase require some expenditure of exergy of natural resources [4],[5],[19] to cleaning up of the stream ***Z*** (abatement cost). The rejection of harmful substance causes environmental losess in the fields of human health, useful industrial and other manufactured products (machines, buildings, transportation equipment) and losses in agriculture and forestry. All of such losses required some additional resources expenditure to compensate them. Thermoecological cost resulting from rejection of harmful substances to natural environment can be evaluated by means of monetary indices of harmful impacts w_k [14],[15]:

$$\zeta_k = \frac{Bw_k}{GDP + \sum_k P_k w_k} \qquad (7)$$

The value of ζ_k has been calculated in [8],[10],[15]. For the main harmful substances (NO_X, SO_2, dust), the following values have been obtained: $\zeta_{SO2} = \zeta_{NOx} = 45$ MJ/kg, $\zeta_d = 9{,}3$ MJ/kg.

Table 1 presents the expenditures necessary for cleaning the main harmful substances SO_2, NO_x, dust and CO_2 (*abatement cost* = thermecological cost burdening the operation of cleaning installation), thermoecological cost and sustainability index. Sustainability index is defined as a ratio of thermoecological cost per abatement cost. The concepts of abatement has been proposed and discussed in [19]. The indices of thermoecological abatement cost were determined in [10]. For example, in case of CO_2 removal the thermoecological abatement cost can be determined by means following formula:

$$\sigma_{CO_2} = \beta_{\mathrm{el}}\rho_{el} = \frac{\sum N + N_t}{\frac{N_{\mathrm{el}0}}{\eta_{\mathrm{Eel}} W_d} m''_{CO_2}\eta_{\mathrm{CO}_2}}\rho_{el} \qquad (8)$$

where: $\sum N$ - total electric consumption resulting fm CO_2 removal, N_t - additional electric energy consumption resulting from CO_2 transportation, N_{el0} - electric power of plant before without CO_2 removal, η_{Eel} - net energy efficiency of power plant, W_d - net calorific value, m''_{CO_2} - amount of CO_2 generated per unit of fuel, η_{CO_2} - efficiency of CO_2 removal.

The value of σ_{CO_2} has been determined basing on data presented in [7].

Harmful substance	Abatement cost	Thermoeco--logical cost	Sustaina-bility
	MJ/kg	MJ/kg	%
CO_2	4.4	= =	= =
SO_2	17.5	45.0	38.0
NO_x	26.0	45.0	58.0
dust	0.5	9.5	5.0

Table 1: Comparison of abatement and thermoecological cost

Cleaning of waste product is profitable when the sustainability index is less than 1. Presented results show that cleaning of flue gases from dust using electrostatic precipitator is relatively high efficient from ecological point of view in comparison with other pollutants taken into account.

Because it is impossible to determine the thermoecological cost of CO by means of monetary indices of harmful impact (eq. 7) the method of abatement cost can be applied as a approximate method of evaluation of

thermoecological cost of rejection of CO_2 to the natural environment.

EXAMPLE CALCULATIONS OF THERMOECOLOGICAL COST OF ELECTRIC ENERGY PRODUCED IN COAL FIRED POWER PLANT

As it has been pointed out in previous sections of the paper in Polish conditions majority of electric energy is produced in conventional steam power plant fired by coal extracted in domestic coal mines. Power plants fired by lignite are located in neighbourhood of coal mines. The share of lignite-fired power plants in total production is about 40%. Majority of the rest of production is produced basing on energy hard coal extracted in Southern Poland. Table 2 presents selected properties of typical energy coal (lignite – lig. and four types of energy hard coal – ec extracted in Polish coal mines.

Fuel parameter	Unit	lig.	ec-1	ec-2	ec-3	ec-4
moisture fraction, w	kg/kg	52.1	20.0	7.0	5.0	7.0
ash fraction, p	kg/kg	8.6	20.0	20.0	20.0	20.0
coal fraction, c	kg/kg	25.9	45.9	58.8	61.5	58.0
LHV, W_d	MJ/kg	7.8	17.4	22.0	24.4	23.0
emission of CO_2	kg/kg	0.95	1.68	2.15	2.26	2.13
emission of CO_2	kg/MJ	0.12	0.10	0.10	0.09	0.09

Table 2: Parameters of typical Polish lignite and energy coal

For each type of coal presented in table 2 calculations of thermoecological cost have been done using methodology of life cycle assessment described in previous sections. It has been taken into account (table 3 and 5) that the average net energy efficiency of electricity production in Polish conditions is equal to 34.5%. In each variant of calculation presented in table 3 and 5 it has been assumed that the distance between coal mine and power plant is equal 50 km. In case of lignite power plant car transport of fuel has been taken into account while in case of hard energy coal both car and train transport has been taken into considerations. Data concerning the resources investment expenditures in the construction phase of the plant as well as energy consumption in this phase has been evaluated basing on [6], [20], [24].

Results of calculations of thermoecological cost presented in table 3 - 5 encompasses the value of thermoecological cost ρ_{LCA} taking into account life cycle of product and ratio $r_{el} = \rho_{LCA}/\rho_{ex}$ of total thermoecological cost ρ_{LCA} per thermoecological cost ρ_{ex} resulting from operational expenditures of the plant. Tables 3 - 5 also present the share of exploitation, construction phases, expenditures for transport and thermoecological cost of CO_2 in the total thermoecological cost ρ_{LCA} of electricity.

The results of calculations of the influence of kind of coal (included in table 2) upon the thermoecological cost are presented in table 3.

Parameter	lig.	ec-1	ec-2	ec-3	ec-4
ρ_{LCA}	4.71	4.11	4.11	4.08	4.09
ρ_{LCA} / ρ_{ex}	1.25	1.23	1.23	1.22	1.22
Structure of ρ_{LCA}, %					
Plant operation	80.0	81.4	81.4	82.0	82.0
CO_2	13.2	12.0	12.2	11.5	11.5
Construction	6.2	6.1	6.1	6.1	6.1
Transport	0.6	0.5	0.4	0.3	0.4

Table 3: Electricity thermoecological life cycle assessment for different types of coal

Thermoecological cost of electric energy produced in lignite-fired power plant is about 15% greater than in case of hard energy coal-fired power plant because of differences in thermoecological cost [8], [10] of lignite (γ_{lig}=1.2 MJ/MJ) and hard energy coal (γ_{ec}=1.12 MJ/MJ). The share of operation phase of power plant presents about 80% of total thermoecological cost ρ_{LCA}. This number confirmed that the resource expenses in other phases than operational one are not negligible. Significant influence on the results of calculation has the thermoecological cost of CO_2, especially in the case of lower quality fuel (lig., ec-1). In such a cases the amount of combusted fuel is higher than in high quality ones.

Table 4 presents results of calculations of thermoecological cost of electric energy for different values of net energy efficiency in the range of 30 to 40%. The value η_{Eel} = 36.5% corresponds to the highest value in domestic conditions while the average values for whole energy system is equal to 34.5%. The highest value of net energy efficiency is achieved in Power Plant Opole.

Shift of the production of electricity from the "average" power plant (η_{Eel} = 34.5%) to power plant characterized by efficiency equal to 36.5% leads to decrease of thermoecological cost of

electricity by 0.21 MJ/MJ (5.2% in relation to the index calculated for η_{Eel} = 34.5%).

Net energy efficiency, %	30.0	34.5	36.0	36.5	40.0
ρ_{LCA}	4.66	4.08	3.92	3.87	3.56
ρ_{LCA} / ρ_{ex}	1.21	1.22	1.22	1.22	1.23
Structure of ρ_{LCA}, %					
Plant operation	82.6	82.0	81.8	81.7	81.2
CO_2	11.6	11.5	11.5	11.5	11.4
Construction	5.4	6.1	6.4	6.4	7.0
Transport	0.4	0.3	0.3	0.3	0.3

Table 4: Electricity thermoecological life cycle assessment for various net energy efficiency

Annual consumption of exergy of natural resources was on average [10], [21] on the level of about 3500 PJ/year in last five years. The annual savings of exergy of natural resources due to increase the net energy efficiency from η_{Eel} = 34.5% up to 36.5% would be on the level of 14% of total present consumption of exergy of domestic natural resources.

Table 5 presents the results of calculations of thermoecological cost in dependence on distance of transportation between coal mine and power plant.

Distance, km	50	100	300	600
ρ_{LCA}	4.08	4.10	4.15	4.24
ρ_{LCA} / ρ_{ex}	1.22	1.22	1.24	1.27
Structure of ρ_{LCA}, %				
Plant operation	82.0	81.7	80.6	79.0
CO_2	11.5	11.5	11.3	11.1
Construction	6.1	6.1	6.0	5.9
Transport	0.3	0.7	2.0	4.0

Table 5: Electricity thermoecological life cycle assessment for various distance between coal mine and power plant

It has been assumed that the longest distance between coal mine located in Southern Poland and power plant No 6 (Fig. 1) located in the north of Poland is equal to 600 km.

In case of $L = 50$ km the share of resource expenditures connecting with transport of fuel in total thermoecological cost of electricity ρ_{LCA} is about 0.4% and has not significant influence on final result of ρ_{LCA}, while in the case of $L = 600$ km the share amounts to 4% and for this reason can not be neglected in considerations concerning evaluation of ρ_{LCA}.

In all of considered cases (table 3,4,5) the share of thermoecoogical cost of CO_2 is between 11÷13% of total thermoecological cost of electricity, while the share of resource expenditures connected with construction and decommissioning of the plant are between 6÷7%

All the presented numbers show that although dominating influence of energy carriers in productive processes (operation phase) based on utilization of non-renewable natural resources also external costs (eg. manufacturing of semi-finished products for construction of power plant, transport, etc.) can not be neglected. The real environmental load measured as depletion of non-renewable natural resources can be evaluated by means of combination of thermoecological cost analysis [10], [14] and Life Cycle Assessment Methodology (THELCA).

SUMMARY AND CONCLUSIONS

Methodology of evaluation of unfavourable ecological effects of human activity by means of concept of thermoecological cost analysis has been discussed. The detailed description of method of evaluation the thermoecological cost resulting from rejection of harmful substances to natural environment is also presented. The description of the method of determination of full environmental load caused by productive processes are proposed by combination of the concepts of thermoecological cost analysis and concept of Life Cycle Assessment (THELCA). The example calculation has been made in case of electric energy productions. Considerations comprises the direct and indirect resource expenditures connected with fabrication of considered product. In the set of balance equations of thermoecological cost 33 additional productive processes have been introduced. Obtained results confirmed that although the production of electricity in Polish conditions is mainly based on consumption of non-renewable energy resources the external costs can not be neglected ($r_{el} = \rho_{LCA} / \rho_{ex}$ = 1.21÷ 1.27) The full thermoecological cost of electricity is approximately divided between 80% - plant operation, about 12% - CO_2 thermoecological cost, 6% - construction and decommissioning of the plant, 0.5 – 4 % - transport of fuel to power plant. The results are dependent on the accuracy of data introduced into consideration. There are a significant difference between sources of data

especially in the case of data concerning the construction phase. For this reason it is planned to continue the investigation concerning THELCA analysis. It seem to be important to introduce the sensitivity analysis in order to determine the importance of particular input data on final results of THELCA analysis.

ABSTRACT

The present work is based on the application of Industrial Ecology with the vision of the solid waste management in a medium size lumber company. This organization this located in the municipal district of Ponta Grossa, State of Parana, south of Brazil. The sawmill's activity is the production of fences from reforested pine, that are destined to the North American and European markets. The daily amount of residues generated in the production process is of approximately $50m^3$, generating a monthly volume of $1200m^3$. The fact of not practicing a segregation process of the residues makes this reuse unfeasible for processes such as the production of OSB and MDF in local industries. A great amount of this material is dispersed in an open field at the sawmill's perimeter and set fire to without producing any benefits. This only brings safety risks to the low-income population that lives in the neighborhood and also a great amount of pollution, due to smoke that is dispersed over the area that is constituted by low-income residences. The objective of this work was in finding an economical solution that reduced the environmental pollution via the vision of Industrial Ecology. The results found result were the generation of electric power in a local thermo-electrical facility.

Key words: Industrial Ecology, Wood residue, Clusters

INTRODUCTION

With to growing reduction of the world's fossil fuels new alternatives of energy supply are appearing and being refined. These alternatives contribute to the carbon dioxide reduction in the atmosphere. Due to Brazil's geographical characteristics, a vast energy production capacity through hydroelectric generation is available. Not all Brazilian regions are provided with the capacity to generate hydropower so other alternatives have to be implemented. According to data from the National Agency of Electric Power (ANEEL) [1], the electric power consumer market presents a growth of 4.5% per year and it will surpass the need of 100 thousand MW in the year of 2008. The Brazilian government, through technical studies, verified that in a medium period there is going to be the need of investments of around two billion and half American dollars to accomplish the expansion of the electrical grid and to attend the growing demand of the consumer market. To accomplish this, alterations in the investment structure in electric power will happen with the installation of thermo electrical generation units. It

* Corresponding author: Phone +55 42 8801-2523
e-mail: tomagner@yahoo.com

is verified, that due to the need of supplying internal demand for electric power, cost reduction and a better management of residues a range of lumber processing industries are installing electric co-generation units in their productive units. In the area where the study was accomplished, two large organizations possess such co-generation systems.

JUSTIFICATION AND DELIMITATION

The intention of this study is to demonstrate that the application of Industrial Ecology (IE) principals can go beyond pollution control. Applying IE it is possible to develop new products or new possibilities of commercial partnerships among organizations; in addition, they develop great benefits, such as economical and environmental, due to better use of the resources.

This work is delimited to analyzing the interaction possibility among a medium size lumber industry with possible industries that can use the not segregated residues that are generated.

INDUSTRIAL ECOLOGY

The analogy with the natural ecosystems is the base for the conception of a new industrial model that breaks the unsustainable path promoted by societies since the beginning of the industrial revolution. Fosch and Gallopoulos popularized the concept of Industrial Ecology, which in synthesis explains that the traditional models of industrial activities; accomplish the extraction of raw materials, develop products to be sold, adding to the production process the disposition of the generated residues. For them this productive model should be transformed in a model that integrates all of the productive activities in a holistic way by this way generating an Industrial Ecosystem [2]. Erkman [3] uses a vision of immediate use for the concept of Industrial Ecology, explaining the exchange among organizations for the creation or reorganizations of industrial districts for the use of residues or by-products.

It is observed by this that Industrial Ecology provides a holistic vision of the industrial systems. By this way, Industrial Ecology is a principal that guides industrial systems towards a sustainable use of natural resources. For the development of a holistic industrial producing vision, there is the need for the development of new productive conglomerates that are integrated production wise.

The concepts of Industrial Ecology can guide business strategies and operational practices for a growing approach to sustainability. The application of this concept is largely associated to the development of industrial conglomerates (clusters) and the reorganization of the existing conglomerates. Promoting the dismemberment of the open lineal industrial systems model, to similar systems found in the natural environment, that is, cyclical systems. Where the productive cycle (extraction/processing/discard) interacts with other processing units in the same system or in other industries. Searching to reduce to the maximum, possible, the entropy and with this resembling the synergy found in natural ecosystems.

With the development of an intra-organizational synergy through the generated residues, there is the possibility of reduction of the energy demand, the reduction of environmental impacts, the development of new business opportunities and the possibility of development of new products. Assuming the form of an industrial symbiosis system.

Chertow [4] explains that industrial symbiosis is constituted by a group of organizations that work in a collaborative form through the exchange not only of residues. They seek the reduction of consumption of natural resources and the reduction in pollutant emissions. In the network formed by this symbiosis there is the union of industries that look for competitive advantage involving the exchange of materials, energy, water and by-products. With this intra-organizational symbiosis, there is the formation of an industrial ecosystem where the cycle is as closed as possible. Gertler [5] explains that a community or a network of companies and other organizations in a region that decide to interact through exchange making use of by-products and or energy, in way to reach benefits, are accomplishing an Industrial Ecology system.

Industrial Ecology can be visualized as being a holistic vision of the industrial process that considers the integration of the components that configure industrial economy in a way that imitates the existent relationships in the biosphere. Another observed factor is the consideration of the technological dynamics that promotes the evolution of technological clusters. Being these

clusters key elements for the transition from the traditional industrial system, to an industrial ecosystem that promotes sustainability.

SUSTAINABILITY

Management in a sustainable manner began to be a requirement so that the organizations prolong permanence in the national and international markets. According to the Brundtland Commission [6], sustainable development is the development that assists to the needs of the present generation without committing future generations. Kraemer [7] comments that society is in a transition period, because the current lifestyle paradigm that promotes individualism, consumption, that all things are disposable and of economic development at any price is shifting in a sustainable direction. The short-term development, of excluding capitalism, does not answer in a satisfactorily manner the concerns with the future. The need for a new direction with a new paradigm, is not yet defined.

By this, it is observed that there is the need for society to act in an integrated manner in all levels and not in the Cartesian method. Robèrt [8] comments that there should not be any conflicts among environmental and economical interests, since human affluence depends on the capacity of nature to recycle debris in the form of generating resources and to provide the indispensable resources for the maintenance of life.

The concern for the environment together with socioeconomic factors made the concept of sustainable development appear. Montibeller Filho[9] and Lerípio [10] explain that the main factor for organizations to alter the perception regarding residues is the search for sustainability.

In synthesis, the vision that the principals of Industrial Ecology promote are the development of a maintainable industrial system. This is due to the maximum sustainable use of all resources.

USING THE CURRENT DEVELOPING LUMBER CLUSTER

Clusters are concentrated groupings of interrelated companies and correlated institutions, in a certain sector, linked by common and complementing elements. The formation of a cluster varies from a single city or state to an entire country or even a net of neighboring countries [11].

Porter explains that the interconnections of a group of companies and institutions in a cluster, accentuates the coordination opportunities and mutual refinement. The interconnections create refinement in areas of common interest, without threatening, distorting competition or restricting the intensity of rivalry, providing an efficient system for dialogue among correlated companies and suppliers. These interconnections bring the opportunity of developing industrial symbioses for residue and energy harness.

A Local Productive Arrangement (LPA) defined by Melo & Casarotto Filho [12] as being a concentration of companies of the same sector, under the form of a structured system, with the presence of interrelations in this group of companies. Cassarotto Filho [13] complements this concept with the following vision: A LPA is a great associative network, through mechanisms of integration of all of the representative entities of the area that are seeking development. The local productive system can be defined as an area strongly structured, containing one or more clusters, with territorial planning, high public and privet interaction, and respecting local culture with the objective of assuring the inhabitants quality of life. In this way, the structured system in the LPA can combine all elements of residue in a manner that a holistic and sustainable vision is achieved.

Albagli and Brito [14] define LPA as being a significant grouping of organizations that act around a main productive activity, as well as correlate companies in the same geographical space (a municipal district, group of municipal districts or region). A LPA possesses a local cultural identity, articulation bonds, interaction, cooperation and learning amongst themselves and with other local organizations. These local organizations can be public and privet institutions, promotion and consultancy, technical schools and universities, research institutions, class entities and support institutions to organizations. The possibilities of the implementation of Industrial Ecology as a policy are possible due to the fact that public, private and educational organizations can promote and develop the needed support for the integration and development of a sustainable management system.

LPA or clusters possess the function of strengthening key organizations and the organizations and institutions that supply their needs, such as technological demands and of raw materials. According to Porter [15], the more the groupings grow more resources tend to flow to them and moves away from organizations that work in an isolated manner. This aspect detaches the importance of the geographical proximity among the industries, many times, in a single city or area of a country. The geographical concentration integrates and strengthens the process, this way maintaining the developed competitive advantages and facilitating the implementation of the processes needed in Industrial Ecology.

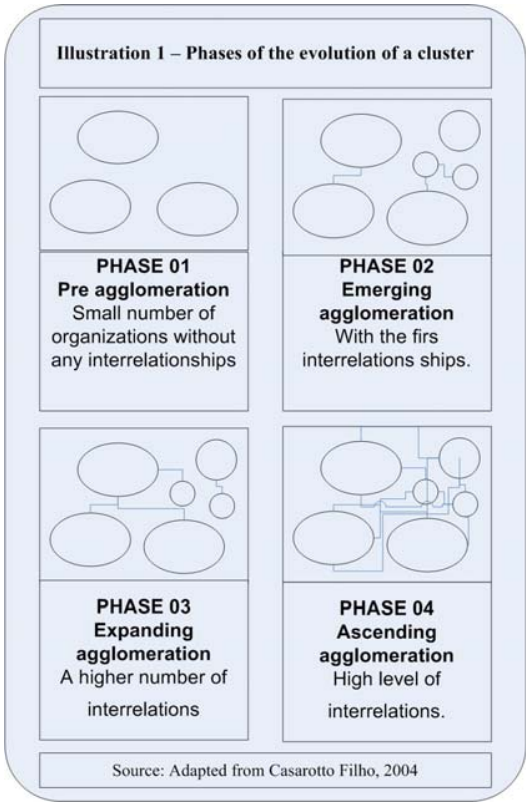
THE LUMBER LPA

In spite of the lumber cluster in the region is still growing according to the Institute of Forest Handling and Agricultural Certification (IMAFLORA), the state of Parana, is responsible for more than 60% of the national production of lumber blocks. The lumber used in the LPA is from plantation pine forests of *Taeda and Eliottis Pine.* These are the main species grown in the South and Southeast of the country. The States of Parana is one of the largest cultivators of forests with these species and it is in this area that the industry is concentrated. This wood is utilized due to the great acceptance in the international market, besides being the species that is planted abundantly in the region because its adaptation to climate condition.

This opens opportunities for the implementation of Industrial Ecology because the lumber cluster is still in development in the Ponta Grossa region, and adaptation is still possible.

LPA EVOLUTION

It is observed, through field research, that the lumber LPA of the Ponta Grossa area is in an intermediate state of evolution. It is between Phase 02 and the Phase 03 as it can be observed in illustration 01, where not all of the organizations are interlinked, but begin the process in a slow manner, mainly because the lack of a clustering development policy.



The interrelation process in the LPA is in a stage that only the raw material suppliers are interlinked. This initial stage opens the possibility to develop not only clustering policies but also policies that encourages lumber organizations to develop internal waste management systems. These management systems would treat waste as new raw materials for other organizations and not only as a problem to be solved.

This LPA is intensity more developed in the production sector. It is in this area that the largest interrelations are observed among organizations. The organizations that in the initial production phases accomplished the totality of the production process are now modifying their systems. A segregation of the production process is happening in the LPA. Countless companies are only accomplishing the unfolding of the logs and the drying of the boards and reselling this material. Other organizations are acquiring the boards and transforming them in goods.

This growing segregation of the production processes is opening opportunities for new organizations that can develop new products with

the generated waste. In this phase, only energy is being produced.

OBJECTIVE

The general objective of this study is to verifying the possibility in developing a symbiosis between the studied organization and a larger organization that can take advantage of the generated residues.

To accomplish such objective the following specific objectives were elaborated:

- Verify the current model of residue management of the organization;
- Analyze through the principals of Industrial Ecology the possible alternatives for the destination of the residues.

THE CASE STUDY

The analyzed organization will be a medium size organization, possessing 25 employees. It is located in the municipal district of Ponta Grossa State of Parana, a southern state of Brazil, in a periphery neighborhood with a low-income population.

The industrial activity is the production of wooden fences for the North American and European markets. The wood used is Taeda Pine and Eliotis Pine, from reforestations in the vicinity of the city.

The fences are the "Dog Ear" model. This fence possesses a simple, economical and easy production design. One of the extremities of the fence is cut in an angle that results in the aspect of a dog-ear. The following dimensions are processed; 1280 mm of length, 150 mm of width and 254 mm of thickness and the finish is accomplished through a planer.

For the fence production, it is necessary only the superior part of the log, this is because this section possesses the necessary dimensions and has a reduced market price due to the limited use for other products. After having dismembered the logs in to boards of varied dimensions, they are exposed outdoors for air-drying until reaching a medium coefficient of humidity of 18% in a period of 7 to 10 days, to achieve the final product with the intended quality.

CURRENT MODEL OF RESIDUE MANAGEMENT

During the productive process, daily there is a generation of approximately $50m^3$ of residues. The average total volume of residues generated monthly is of $1200m^3$, and these residues do not possess a specific destiny. Such fact is due to the non-accomplishment of a segregation of the material, that it is constituted of several types of sawdust. This sawdust is composed of small particles of dust to larger pieces with an average of 15 cm x 40 cm x 2,54cm. The non-segregation incapacitates the possibility to designate the residue for the traditional processes of reuse, which is the production of OSB and MDF in a local industry that needs this material with appropriate characteristics.

In the process of drying the wood a dry kiln is not used, what impedes in not using the sawdust for feeding of a boiler system. By this way a percentage of this material is dispersed in an open field on the perimeter of the sawmill, that later fire is set to, not producing any environmental or economical benefit. It is noticed that this action brings risks to the safety of the industry, to the employees and generates atmospheric pollution due to smoke that disperses in the whole area of the factory and to the neighboring houses. A percentage of the residue is given freely to local farmers that use the sawdust as animal beds for poultry and swine breading. A percentage is taken to a sanitary landfill, generating transport increment cost and occupying the landfill with useful material.

This management model is common among the small and medium lumber mills found in the area of the study. Such model is unsustainable due to the non-use of existing opportunities and of the generated pollution. The development of a local and regional policy that foments the principal of Industrial Ecology would generate the possibility to reformulate the current models of residue management.

WASTE MANAGEMENT WITH INDUSTRIAL ECOLOGY PRINCIPALS

Following the principals proposed by Industrial Ecology an initial management plan for the sawdust residues was developed, where low cost modifications were proposed to be implemented.

The first modification to be accomplished is the construction of an enclosed area where the residues are gathered. This allocation of the sawdust in a single enclosed area avoids the danger of possible fires and makes possible a calculation with larger precision of the generated volume.

The second modification in the process is to enter in contact with other larger mills, which possess a thermo electrical unit fed with wood residues. It is observed that the samples of the residue should be tested and approved for the used in the electric power generation, generating the first symbiosis among organizations.

The third modification is the contact with a factory that produces boxes for the accommodation of fruits. Usually this type of organization possesses conditions of using the 150 mm x 400 mm boards that are discarded in the production of the fences. This action generates the second symbiosis among organizations.

The next stage is the proposal for the development of a log debarker. The process of removing the tree bark will make it possible that the bark is sold to local breeders in the area and part of the sawdust can be sold to the local MDF/OSB production facility.

It is proposed that the project for the development of the debarker equipment is accomplished by the local CEFET PR (Federal Center of Technological Education) generating the possibility of a greater interaction between the industry and university.

CONCLUSION

This study allowed the visualization of the opportunities for the development of Industrial Ecology with simple actions in developing countries. The possibility to create a symbiosis between organizations and universities that develop a change in the current non-sustainable paradigm. This change modifies the vision of the generation of residues without destination to the generation of new raw materials, which will produce business opportunities will still reduce the negative impact over the environment.

It is observed that the rearrangement of the current industrial agglomerates in the molds of Industrial Ecology and of sustainable development should also be a focus for the development local and regional policies. Without this collaboration and stimulation, industries that need modification in the production cycle will not be reached.

Another observed factor is the non-existence of professionals, inside of organizations of this activity, responsible for the management and development of new destinies for the generated residue. In addition there is no simulation, on behalf of the municipality responsible for industrial development, in the readapting the industrial system for a sustainable reality.

ABSTRACT

In this study we investigate an inter-industrial and inter-regional recycling system for industrial waste by the cement industry in Japan. We develop a linear programming model that represents cement production processes and waste transportation of all cement factories in Japan. We assess inter-regional material flows of industrial waste, and environmental effects of recycling.

INTRODUCTION

In Japan, there is a growing concern that a shortage of landfill space will become a big issue in the near future, due to the great amount of waste generated and the difficulty of the expansion of landfill capacity. Recycling is considered as a key way to decrease the final disposal waste

Industrial ecology, a recent and interdisciplinary field, provides a concept to deal with such problems: The basic idea is to design an inter-industrial recycling system that utilizes waste from one industry as a resource for other industries, and that reduces the amount of waste emitted from the entire system, as well as the resources extracted from the environment. Seen from such a perspective, the cement industry can represent the central part of the system, because diverse wastes can be used as raw materials in the cement production processes.

The Japanese cement industry already utilizes substantial amounts of industrial waste, such as blast furnace slag from the steel industry, and fly ash from coal-fired power stations and other industries. Increased recycling of waste in the cement industry is expected to reduce energy consumption and CO_2 emissions, and to reduce the final disposal of waste from other industries.

When assessing the feasibility and environmental effects of recycling, it is important to consider the long-distance transport of waste that occurs as a consequence of the disparate location of cement factories in Japan. The increasing cost of waste transportation can be a bottleneck for encouraging the spread of recycling systems. In order to design an inter-industrial and inter-regional recycling system, it is essential to appraise the information about the location and the amount of sources of waste, and the capacity of recycling at the cement factories.

There are several studies that deal with environmental effects of the recycling of industrial wastes in the cement industry. Although Fujiwara et al [1] developed environmental input-output table and estimated the reduction of CO_2 emission by the recycling, the cement process model developed in this study is insufficient to describe the real process. Wada et al [2] developed a linear programming model including a sub-model of waste transportation to evaluate environmental effects caused by the increasing of waste-mixed cement production. The sub model of waste transportation can consider all possible transport between sources of blast furnace slag or coal fly ash and cement factories in Japan. This model, however, is inadequate because it considers only road transport.

In this study we investigate an inter-industrial and inter-regional recycling system for industrial waste recycled by the cement industry in Japan. We develop a linear programming model that represents cement production processes and waste transportation of all cement factories in Japan. We assess inter-regional material flows of industrial waste, and environmental effects of recycling.

MODEL

Overview

The model in this study consists of two parts; one part is a model of transport process between sources of blast furnace slag or coal fly ash and cement factories, and the other part is a model of cement production processes that utilize natural resources or wastes. The model is a linear programming model combining two problems: 1) the optimal transport of wastes and 2) the optimal production of cement factories. These two problems are solved simultaneously. We set two objective functions; minimizing the total system cost and minimizing the total CO_2 emission from the system.

Formulation

The formulation of the model is as follows.

Objective function I

minimize $totalCost$

$$totalCost = cementCost + roadCost + railCost + seaCost \quad (1)$$

$$cementCost = \sum_h \sum_k cCement(k) \cdot x(h,k) \quad (2)$$

$$roadCost = \sum_w \sum_p tRoad(w,p,p') \times [d(p,p') \times cRoad + cRoadInt] \quad (3)$$

$$railCost = \sum_w \sum_m tRail(w,m,m') \times [d(m,m') \times cRail + cRailInt] \quad (4)$$

$$seaCost = \sum_w \sum_n tSea(w,n,n') \times [d(n,n') \times cSea + cSeaInt] \quad (5)$$

Objective function II

minimize $totalCO2$

$$totalCO2 = cementCO2 + roadCO2 + railCO2 + seaCO2 \quad (6)$$

$$cementCO2 = \sum_h \sum_k co2Cement(k) \cdot x(h,k) \quad (7)$$

$$roadCO2 = \sum_w \sum_p tRoad(w,p,p') \times co2Road \quad (8)$$

$$railCO2 = \sum_{w} \sum_{m} tRail(w,m,m') \times co2Rail \quad (9)$$

$$seaCO2 = \sum_{w} \sum_{n} tSea(w,n,n') \times co2Sea \quad (10)$$

Constraints

1) a model of cement production processes

$$\sum_{k} a(w,k) \cdot x(h,k) = y(w,h) \quad (11)$$

$$\sum_{h} \sum_{k} a(prod,k) \cdot x(h,k) \geq Demand(prod) \quad (12)$$

2) a model of waste transportation process

$$y(w,h) = \sum_{i} tRoad(w,i,h) + \sum_{m} tRoad(w,m,h) + \sum_{n} tRoad(w,n,h) \quad (13)$$

$$s(w,i) \geq \sum_{h} tRoad(w,i,h) + \sum_{m} tRoad(w,i,m) + \sum_{n} tRoad(w,i,n) \quad (14)$$

$$f(w,j) = \sum_{h} tRoad(w,j,h) + \sum_{m} tRoad(w,j,m) + \sum_{n} tRoad(w,j,n) \quad (15)$$

$$\sum_{i} tRoad(w,q,m) + \sum_{n} tRoad(w,n,m) + \sum_{m'} tRail(w,m',m) = \sum_{i} tRoad(w,m,q) + \sum_{n} tRoad(w,m,n) + \sum_{m'} tRail(w,m,m') \quad (16)$$

$$\sum_{i} tRoad(w,q,n) + \sum_{m} tRoad(w,m,n) = \sum_{n'} tSea(w,n,n') \quad (17)$$

$$\sum_{n'} tSea(w,n',n) = \sum_{h} tRoad(w,n,h) + \sum_{m} tRoad(w,n,m) \quad (18)$$

Equation (11) expresses the material balance between processes of the cement production. Equation (12) is a constraint that the total amount of cement produced must be larger than the total demand of cement. Equation (13) expresses that the amount of waste utilized for a factory h equals to that of waste transported to a factory h. Equation (14) and (15) expresses that the total amount of waste transported from a source i or j is less than that of waste generated at i or j. Equations from (16) to (18) are constraints on waste transportation processes, which set the material balance at the nodes of the transport network.

Cement production processes

The flow diagram of the cement production is shown in Figure 1. The cement production processes consist of the clinker production process and the cement mixing process. At the clinker production process, clinker is produced by calcinating limestone, clay and other raw materials. At the cement production process, cement is produced by crushing and mixing clinker and gypsum. The cement mixed with wastes at the cement production process is called blast furnace cement or fly ash cement, because of its unique characteristics. These cement types are mainly utilized in public civil engineering and construction because of their strength and workability. In this model, we distinguish three types of cement, and set their demands respectively. Despite the difference of raw materials used in blending, we assume that there is only one type of clinker with average characteristics.

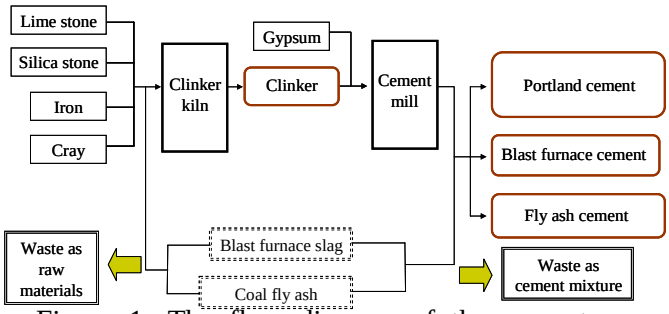

Figure 1: The flow diagram of the cement production

Input-output data of the cement production processes are shown in Table 1. In this table, a negative number means input to the process. For example, material inputs are gypsum (0.02), blast furnace slag (0.40) and clinker (0.58) for a unit amount of the product of the blast furnace cement. The process costs are represented by ¥(yen)/t (1,000yen 7.17euro). The data sources are the Japanese input-output table [3], blending calculation of cement [4], and statistics of cement

industry [5].

Table 1: The input output table of the cement production processes

		cement production processes					
		1	2	3	4	5	6

Waste transportation process

The overview of the waste transportation process model is shown in Figure 2.

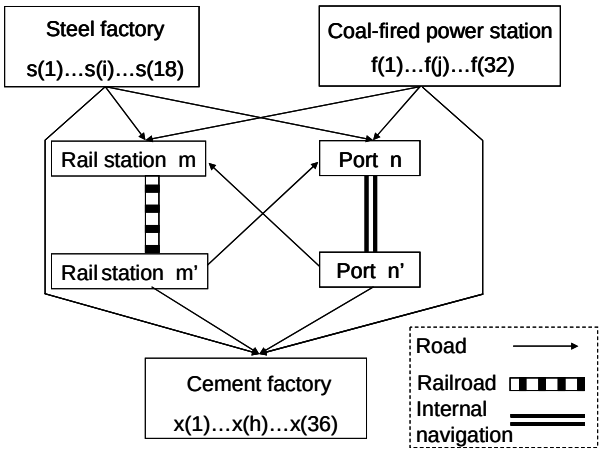

Figure 2: The overview of the waste transportation process

The model deals with three transportation modes; road, rail, and internal navigation (shipping). We use data for the fiscal year 2000 about the amount of waste generated in the steel factories and the coal-fired power stations. In Japan, there are 36 cement factories, 18 steel factories with blast furnaces, and 32 coal-fired power stations. The model includes 72 major railway stations and 64 ports as nodes of the transport network.

The transport costs and the CO_2 intensity of transport are shown in Table 2 [6].

Table 2: Transport cost and CO_2 intensity

Transport cost function	
Road (\/t)	1500 + 18.5×d(km)
Railroad (\/t)	951 + 4.34×d(km)
Internal navigation (\/t)	1300 + 4.26×d (mile)

CO_2 intensity of transport		
Road	(t-CO_2/t-km)	1.74×10^{-4}
Railroad	(t-CO_2/t-km)	2.10×10^{-5}
Internal navigation	(t-CO_2/t-mile	7.04×10^{-5}

SIMULATION AND RESULT

We apply the model to simulate an inter-industrial and inter-regional recycling system in Japan. The demand of cement products and the amount of waste recycled as cement materials are valid for the fiscal year 2000. Using GAMS (General Algebraic Modeling System) [7], an optimization software, we calculate the system that minimizes both cost and CO_2–emissions. The amounts of waste generated and utilized at each factory are aggregated into 10 regions as shown in Figure 3. The amount of waste transportation of each region and each mode will be shown as the result of the simulation.

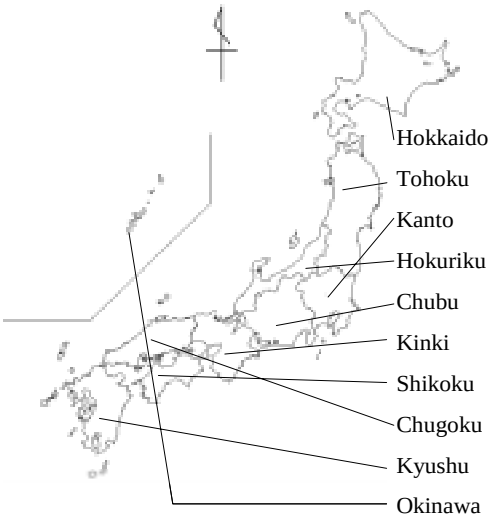

Figure 3: 10 regions in Japan

The capacity of cement production of all factories is shown in Figure 4.

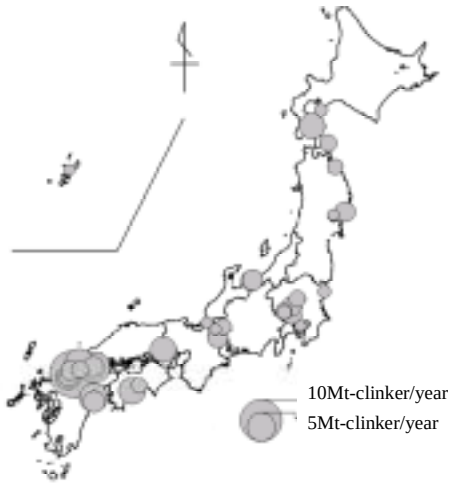

Figure 4: The capacity of the cement production of all factories

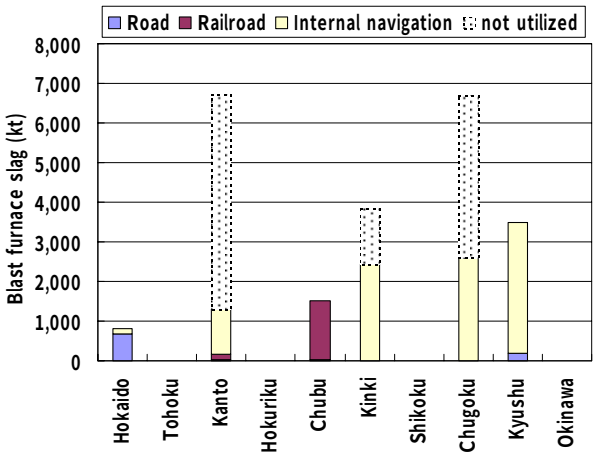
Cost-minimizing system

The amounts of waste generated and transported to cement factories in each region are shown in Figure 5. The amounts of waste utilized for cement production in each region are shown in Figure 6. There are wastes transported inter-regionally, so that the amount of waste in one region in Figure 5 and Figure 6 is not necessarily the same.

Blast furnace slag generated in Kanto and Chugoku , and coal fly ash generated in Tohoku are not utilized in the cement industry as much as other regions.



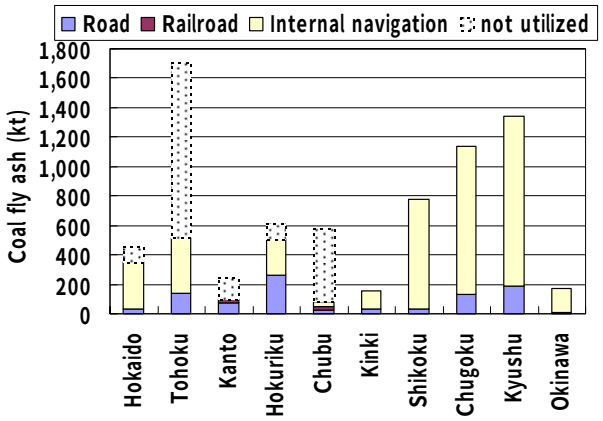


Figure 5: The amounts of wastes generated and transported to cement factories
(upper: blast furnace slag, lower: coal fly ash)

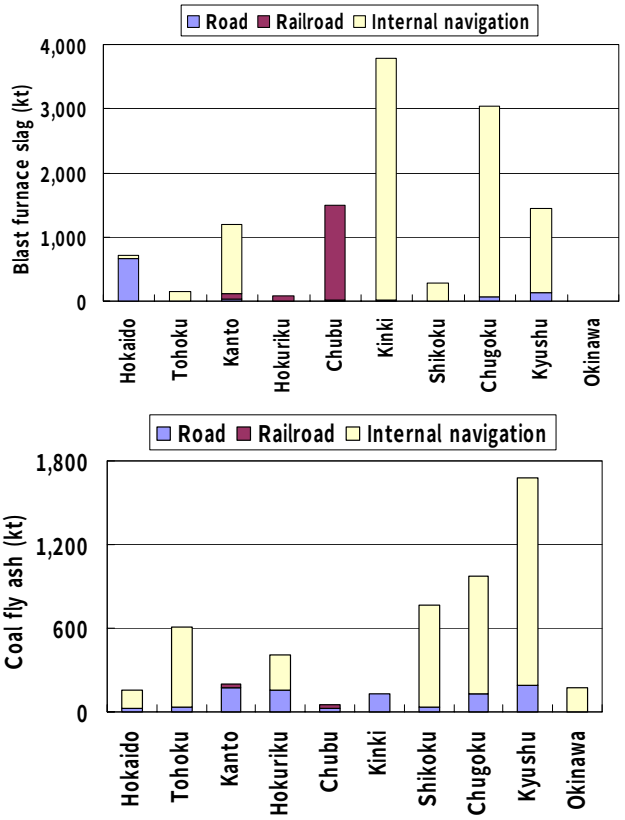

Figure 6: The amounts of wastes utilized for cement production
(upper: blast furnace slag, lower: coal fly ash)

The main transportation mode used is internal navigation, because road and rail are associated with high cost.

CO_2-minimizing system

The amounts of wastes generated and transported to cement factories in each region are shown in Figure 7. The amounts of waste utilized for cement production in each region are shown in Figure 8. There are wastes transported inter-regionally, so that the amount of waste in one region in Figure 7 and Figure 8 is not necessarily the same.

Blast furnace slag generated in Kanto and Chugoku , and coal fly ash generated in Tohoku are not utilized as much as other regions.

Contrary to the result of the cost-minimizing system, rail transport is used more because of its low CO_2 intensity.

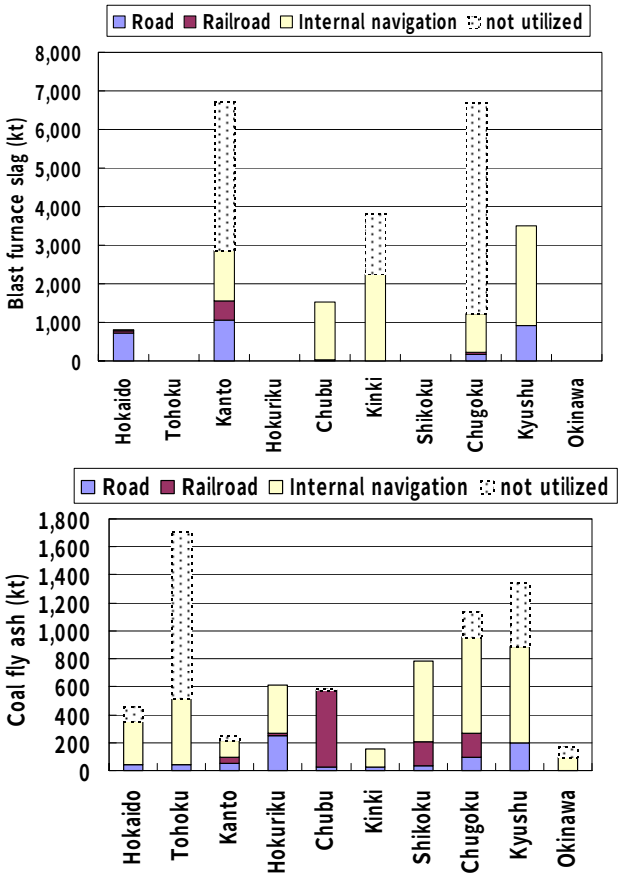

Figure 7: The amounts of wastes generated and transported to cement factories

(upper: blast furnace slag, lower: coal fly ash)

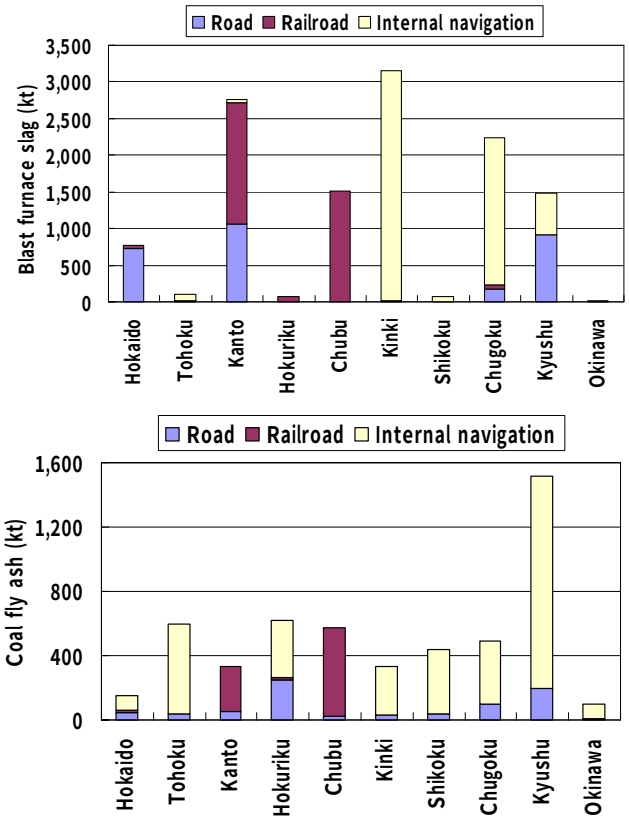

Figure 8: The amounts of wastes utilized for cement production

(upper: blast furnace slag, lower: coal fly ash)

DISCUSSION

We discuss differences between the result of the cost-minimizing and the CO_2-minimsing systems. The difference between the amounts of wastes utilized for cement production in each region is apparent, whereas the difference between the amounts of wastes generated and transported in each region is not significant. With regard to blast furnace slag, the amount utilized in Kanto is higher in the CO_2-minimizing system compared to the cost-minimizing system. Regarding coal fly ash, he amount utilized in Chubu and Kinki is higher in the CO_2-minimizing system. The difference is due to the difference of the transportation, that is whether rail is used or not. With respect to the

CO_2-minimizing system, waste transportation to the inland cement factories by railway is high.

The total cost and total CO_2 emissions of each system are shown in Table 3. The total cost of the CO_2-minimizing system is 2% higher than that of cost-minimizing system; on the other hand, the CO_2 emissions of each system are almost same. That is because the ratio of the transport cost to the total cost is much higher than that of the transport CO_2 to the total CO_2.

The CO_2 emissions from the transport process are negligibly small compared with those occurring during the cement production processes. Hence, when considering the reduction of CO_2 emission, it is more important to increase the usage of the mixed cement and the recycle of wastes for the cement production. The waste transportation is less important to CO_2 emission, but affects the total cost. In conclusion, the waste transportation is important in order to encourage recycling waste for a cement production, in respect of the cost, and the recycle leads to CO_2 reduction.

Table 3: Total cost and CO_2 emission

Cost (10^{10}yen)

	Cement production process	Waste transportation process	Total
Cost minimum sytem	58.8	2.7	61.5
CO_2 minimum sytem	58.8	4.0	62.8

CO_2 emission (10^6 t-CO_2)

	Cement production process	Waste transportation process	Total
Cost minimum sytem	60	0.066	60
CO_2 minimum sytem	60	0.051	60

CONCLUSION

We have developed inter-industrial and inter-regional waste recycling model. We simulate cost and CO_2-minimizing systems, and find viable solutions. In conclusion, the waste transportation is important in order to encourage recycling waste for cement production, with respect to the cost, as well as to CO_2 reductions. Thus, making waste transportation more efficient is an effective means for CO_2 reduction.

ENERGY LEVEL COMPOSITE CURVES – FROM THEORY TO PRACTICE

Rahul Anantharaman[1], Ola Sørås and Truls Gundersen
Norwegian University of Science and Technology
Department of Energy and Process Engineering
N-7491 Trondheim
Norway

ABSTRACT

Energy Level Composite Curves (ELCC) – a synergy of Exergy Analysis and the Composite Curves of Pinch Analysis – is a novel method for the integration of energy intensive processes that was recently developed by our group. This was the first methodological attempt to represent thermal, mechanical and chemical energy in a graphical form similar to Composite Curves.
In this paper, we present a simplified methodology that represents the thermal and mechanical energy of a process in a graphical form and a preliminary energy targeting strategy is developed for use with the ELCC. Results and our experiences of applying this new methodology for the energy integration of a methanol plant in Norway are also presented.

INTRODUCTION

Pinch Analysis is a thermodynamic approach to energy integration based on simple, yet powerful, graphical representations; but fails to account for changes in pressure and chemical composition in the process under consideration. Exergy Analysis identifies major causes of thermodynamic imperfections in thermal and chemical processes. Exergy based methodologies, however, lack the simple representations that have made Pinch Analysis well recognized and applied in the process industries. Further, there is no direct link between exergy and cost; in many cases exergy and cost are competing properties of a plant. Optimization methodologies enable the engineer to address the multiple trade-offs that are an integral part of energy integration which would not be possible to solve manually. The downside of this is that optimization is not simple and at present cannot solve large industrial problems due to combinatorial explosion (binary variables used to model discrete decisions) and local optima problems (non-linear and non-convex models).

ENERGY LEVEL COMPOSITE CURVES

The Energy Level Composite Curves (ELCC) [1] is a novel method for energy integration developed by our group that incorporates pressure and composition changes in the process in addition to temperature. ELCC, a graphical tool, draws on

[1] Corresponding author: Phone: +47 7359 6937 Fax: +47 7359 8390 E-mail: rahul.anantharaman@ntnu.no

earlier strategies of Combined Pinch and Exergy Analysis [2] and Composite Curves of Pinch Analysis [3], [4], [5].

Energy Level

Energy Level (Ω) is defined as [2]:

$$\Omega = \frac{Exergy}{Energy} \qquad (1)$$

This definition of energy level enables graphical representation of processes involving energy in terms of heat and work. Table 1 lists energy levels for some special cases.

Case	Energy Level
Work	1
Heat	$\eta_c = 1 - T_0 / T$
Steady state flow system	$\Delta Ex / \Delta H$

Table 1: Energy levels for special cases

The Energy level concept was introduced [2] to visualize energy quality loss in a process unit and screen for potential process modifications.
Rather than evaluate the energy level of a process unit, it was observed by Anantharaman et al. [1], that evaluating energy level at the supply and target conditions of a process stream gives a better understanding of the energy requirements and behavior of the stream. This is similar to Pinch Analysis where stream supply and target temperatures are considered to evaluate the heat content of the stream.
A stream with increasing energy levels is an energy sink and a stream with decreasing energy levels is an energy source. Further extending the analogy to Pinch Analysis, an energy source at higher energy levels can be integrated with an energy sink at lower energy levels.
Thus, energy level in ELCC is equivalent to temperature in Composite Curves of Pinch Analysis.

Evaluating Energy Level
Energy level at supply and target conditions is evaluated as:

$$\Omega = \frac{(H - H_0) - T_0 (S - S_0)}{H - H_0} \qquad (2)$$

In this paper, only pressure and temperature contributions to exergy are taken into account for evaluating energy level as the focus is mainly on identifying opportunities for pressure exchange (in the form of shaft work) in addition to heat exchange. This simplification is a necessary first step to develop a systematic method for temperature and pressure exchange before considering composition. The implication is that streams undergoing composition change cannot be analyzed by this method.
This simplification would be unacceptable in the exergy analysis of a chemical plant where exergy and energy accounting is carried out.
Evaluating energy level using Equation 1, incorporating chemical exergy, involves developing a new and common reference state calculation procedure for enthalpy and exergy that ensures positive values. This is a principle area of research in our group.

ELCC – construction and analysis

The Energy Level – Enthalpy diagram is constructed by plotting energy level intervals of process streams against cumulative values of enthalpy differences – similar to the construction of Composite Curves in Pinch Analysis. There are two curves – one for energy level increasing streams (energy sink curve) and the other for energy level decreasing streams (energy source curve).
A step-by-step procedure for constructing an ELCC is detailed in [1] with an example.
The analysis of an ELCC is similar to Composite Curves in Pinch Analysis. The ELCC provides physical insight to the engineer regarding energy integration between the streams on the energy source curve and the energy sink curve.
When considering heat transfer between streams, Table 1 shows that the principle of transferring energy from a higher energy level value to a lower value is valid as higher temperature streams will have higher energy level.
Similar to the idea of vertical heat transfer between Composite Curves to minimize heat transfer area, one would expect that streams on the

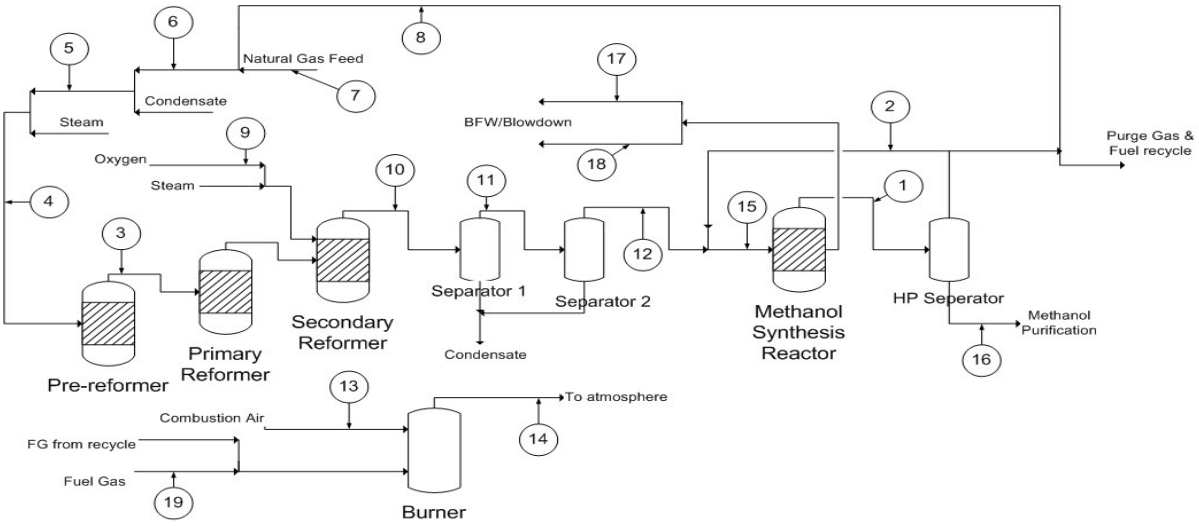

Figure 1: Methanol Plant case study process flow sheet with stream numbers

energy source curve should be integrated with streams placed adjacently below on the energy sink curve to maximize total energy integration. Further, one would also expect that, integration between energy sources and sinks should start where the vertical distance is the least.

An important aspect of the ELCC is that it functions as an idea generator rather than a design generator. This methodology cannot give any explicit recommendation for integration between process units. A high energy level of a stream can be caused by high pressure or high temperature or a combination of these. Obviously, we have to distinguish between pressure exchange and heat exchange.

To alleviate this drawback, and to identify scope for integration, a preliminary targeting methodology has been developed in this paper that can be used together with the ELCC.

The authors have developed an Excel Add-in, called HYSYSLink, to construct the ELCC from a HYSYS simulation.

METHANOL PLANT CASE STUDY

The methanol process is ideally suited for energy integration studies using this methodology as it is an energy intensive process with an enormous interplay of thermal, mechanical and chemical energy in the plant. In our earlier work, [1] and [6], we tested the methodology on a simple literature based simulation of a methanol plant.

In this work, a methanol plant in Norway is used to test the efficacy of the methodology for industrial cases. The utility system was not included in these energy integration studies to simplify the case under consideration.

Figure 1 shows the process flow diagram for the methanol plant under consideration. The 900,000 tonnes/year plant has a reforming section consisting of combined reforming with a pre-reformer and a Lurgi low pressure methanol synthesis section.

A HYSYS simulation model of the plant was used to perform energy integration studies. As the simulation model did not have detailed distillation column models in the purification section, the energy integration studies did not consider that section.

Energy Integration study using ELCC

The Excel Add-In, HYSYSLink, is used to construct the ELCC for the plant as shown in Figure 2. The stream data is given in Appendix A.

From the curves and stream data, it can be deduced that Streams 14, 10 and 11 are large energy sources and it is possible to transfer energy to the energy sinks. As discussed earlier, starting where the distance between the curves is minimum (Ω pinch*)* Stream 14 can potentially be integrated with Streams 3, 4, 7 etc in that order.

A study of all the potential matches shows that the plant is already well integrated with minimum scope for further integration. A targeting method

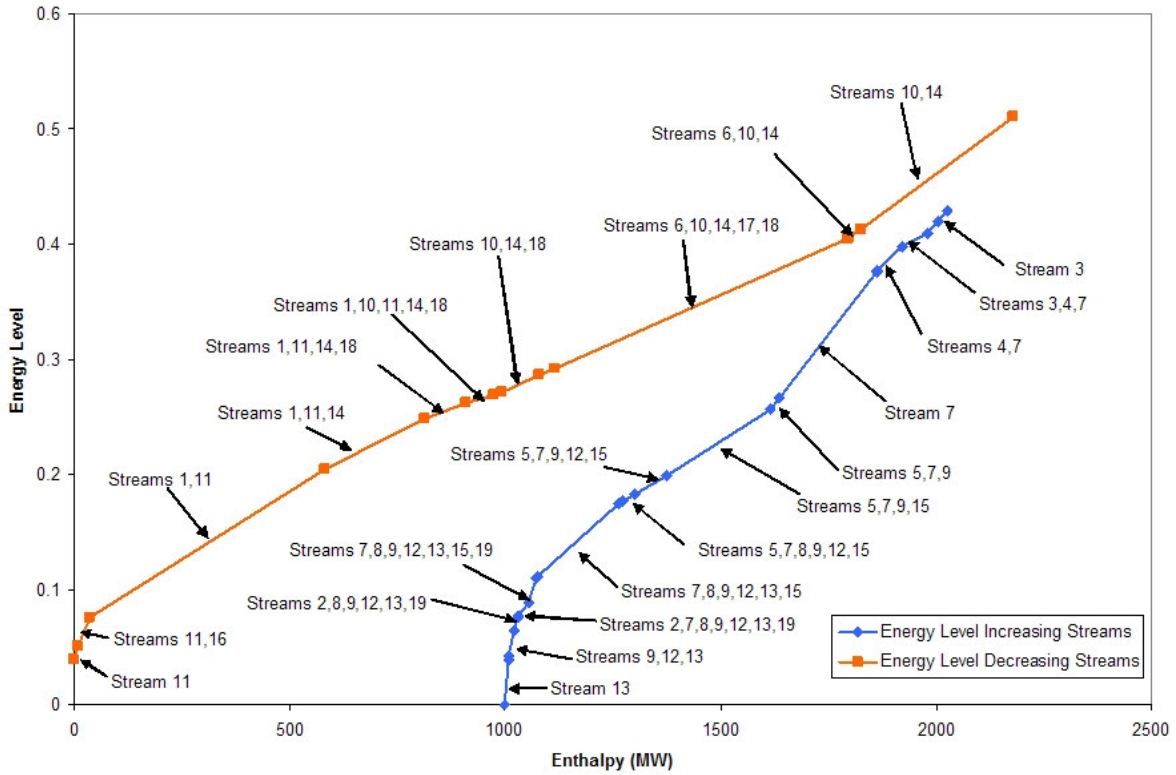

Figure 2: Energy Level Composite Curves for Methanol Plant Case Study

is required in such cases to verify if the plant is sufficiently integrated or if further scope for integration exists.

Streams 2, 12, 14 and 19 involve an increase in pressure. Electricity is imported from the utility section to supply their needs.

Many streams undergo a small change in pressure that can be attributed to pressure drops in heat exchangers.

Stream 16 represents an interesting possibility. It is the only stream in the process undergoing a substantial pressure drop (7751 kPa to 1100 kPa). The stream is a liquid and hence cannot be expanded to generate shaft work that could have been used to satisfy pressure increasing streams. This is indicated by the low energy level of Stream 16.

It could be possible to vaporize the liquid stream and superheat it (increase its energy level), expand the stream to generate electricity and then further cool it to the target temperature.

The effectiveness of this scheme depends on whether the excess energy required for vaporizing and cooling the stream is available in the process at the required level – without any additional heating or cooling utilities. This can also be verified with a targeting method.

MINIMUM ENERGY TARGETS

The minimum energy target consists of four components – hot utility, cold utility, work consumed and work obtained.

Linnhoff and Dhole [7] extended Pinch Analysis for the design of low-temperature processes to yield shaft work targets directly from basic process data. The Exergy Grand Composite Curves is used generate shaft work targets for retrofit schemes in refrigeration systems. This procedure cannot be extended to chemical process systems where a change in pressure translates into shaft work.

The following is a preliminary utility target procedure based on heuristics and Pinch Analysis.

Pressure – Temperature relationship

Before developing an algorithm to obtain minimum energy requirement, it would be worthwhile to refresh the pressure-temperature relationship in process plants.

1. Temperature change from supply to target temperature is possible with very small pressure drop – one dimensional in temperature.
   ⇒ Heat transfer
2. For incompressible fluids (liquids), pressure change does not cause any significant change in temperature – one dimensional in pressure.
   ⇒ Pumping liquids
3. For compressible fluids (gases), pressure change results in a considerable change in temperature – two dimensional (temperature and pressure).
   ⇒ Adiabatic expansion and compression of gases
4. Simultaneous pressure and temperature change is possible without any change in enthalpy
   ⇒ Isenthalpic expansion of fluids through a valve

Further, streams undergoing a pressure change almost always (except in the isenthalpic expansion case) exchange energy in the form of shaft work in addition to heat. Streams undergoing temperature change only exchange energy in the form of heat.

First Law and Target for available energy

The enthalpy change of a process stream is given by the first law of thermodynamics for flow processes as

$$\Delta H = Q - W \tag{3}$$

Q is defined to be positive when heat is added to the system and W is defined to be positive when work is done by the system.

The enthalpy change is a constant for a stream with a given set of process conditions (process path).

Earlier work [8] approaches the criteria of the optimal process path from an exergy perspective. Work W is total exergy while the exergy of heat Q is $\eta_c Q$. For a process with $\Delta H>0$, e.g. a compression process, the thermodynamic criterion for optimal path between supply and target conditions would be where the following functional would be minimum

$$\int_{\text{supply}}^{\text{target}} (\eta_c \delta Q - \delta W) \tag{4}$$

As work is done on the system in a compression process and Carnot efficiency is normally less than 0.7 for typical process conditions, paths involving more heat and less work are optimal. The opposite is true for processes where $\Delta H<0$.

This is valid from a simple economic perspective too. Electricity is usually the most expensive utility and hence its consumption must be minimized and, conversely, its production must be maximized.

If work is done by the system for a process with $\Delta H>0$, minimization of Eq. 4 is unconstrained and would require additional process constraints for solution. Similarly to the above discussion, the converse is true for processes with $\Delta H<0$.

This work presents a completely new stream data situation, compared to Pinch Analysis, as it deals with varying pressures and temperatures. There are many possible paths from supply to target conditions. It is elaborated in the next section.

Optimal path heuristics

As seen from the earlier section, optimal path heuristics imply minimizing or maximizing work for a given process stream from its supply to target conditions.

For a stream at supply conditions (T^s, P^s) and target conditions (T^t, P^t) there are four possible situations above atmospheric pressure [8]:

1. $T^s < T^t$, $P^s < P^t$ *(heating + compression)*
2. $T^s > T^t$, $P^s > P^t$ *(cooling +expansion)*
3. $T^s > T^t$, $P^s < P^t$ *(cooling+ compression)*
4. $T^s < T^t$, $P^s > P^t$ *(heating + expansion)*

Outlined below are heuristics for each of the above cases.

1. To increase pressure from P^s to P^t, shaft work is always necessary – either by pumps or compressors. For vapor streams,

compression at lower temperatures is optimal since this requires lesser work. Further, temperature is also increased in the process. To obtain minimum work, interstage cooling can be considered, particularly in cases where temperature at the outlet of a single stage compression is greater than T^t.

2. A supply pressure higher than the target pressure offers a potential to gain shaft work in an expander. In the case of a vapor stream, expansion must be done at the highest possible temperature to extract maximum work. Liquid streams can be expanded isenthalpically in a valve. Alternatively, the liquid stream can be vaporized and superheated, passed through an expander and cooled to the target temperature.
3. In case of vapor streams cool to temperature below T^t and then compress for minimum shaft work. For liquid streams, the sequence of pumping and cooling is not important.
4. As $P^s > P^t$ shaft work can be extracted. To get maximum work for a vapor stream, heat the stream to a temperature greater than T^t and then expand the stream. A liquid stream can be heated and then expanded isenthalpically or vaporized and superheated, expanded and then cooled. The choice of path depends on heating and cooling availability in the system under consideration.

In all the above instances, it is clear that by assuming optimal path heuristics based on shaft work, opportunities for process heat integration are ignored. For a rigorous calculation, optimization methods will have to be employed.

There are many possible paths for going from the supply state to the target state. Only a few paths, relevant to the case study on hand, are dealt with here. As the methodology is applied to other case studies, the path possibilities will be expanded.

Algorithm for Energy Targeting

1. For each stream
   a. If $P^s < P^t$ use the suitable optimal path heuristic 1 or 3 to evaluate the minimum shaft work. Based on information from the optimal path heuristics, split the stream into one or more work streams and one or more heat streams.
   b. If $P^s > P^t$ and $(P^s - P^t) > 5$ bar*, use the suitable optimal path heuristic 2 or 4 to evaluate the maximum shaft work. Based on information from the optimal path heuristics, split the stream into one or more work streams and one or more heat streams.
   c. If $P^s > P^t$ or $(P^s - P^t) < 5$ bar*, treat the entire stream as a heat stream.
2. At the end of Step 1, the minimum work consumed and maximum work obtained can be evaluated.
3. Use the Heat Cascade method of Pinch Analysis for all the heat streams to evaluate the minimum hot and cold utilities.

METHANOL PLANT ENERGY TARGET

The HYSYSLink Excel Add-in is modified to evaluate the energy targets for a HYSYS simulation.

Applying the optimal path heuristics detailed earlier to Streams 12, 13 and 14, it is seen that

- Stream 12 uses heuristic 2 and requires no subsequent heating. It is entirely a work stream.
- Stream 13 follows heuristic 2 and requires subsequent heating.
- Stream 14 follows heuristic 3.

Base case – existing plant

Table 2 shows the energy targets obtained for the plant (as in Figure 1) using the new algorithm (with a ΔT_{min} of 40ºC for heat cascade calculations) and actual consumption from the simulation model.

Detailed examination of the process flowsheet and the ELCC shows that the target is not achieved as

* The maximum pressure drop through a set of heat exchangers for a stream is taken to be 5 bar for this case study. This will change depending on the case on hand and can be evaluated as a function of $(T^t - T^s)$ and P^t / P^s. This function has not been developed in this work.

energy source, Stream 10, is not integrated with any energy sink. This stream is instead used to generate HP steam and supplies energy to reboilers in the methanol purification section. In addition, a few other streams are not integrated because of locational and process constraints.

	Target	Actual
Hot Utility (MW)	0.0	1.84
Cold Utility (MW)	240	284.22
Work Consumed (MW)	17.34	17.4
Work Obtained (MW)	-	-

Table 2: Base case actual and theoretical energy targets

The results show that the energy targeting model can be applied to generate good estimates for utility consumption that can be realized.

With proposed modification from the ELCC

The energy source Stream 16 is considered for integration as indicated in the case study section. The optimal path heuristic for Stream 16 is 2. The stream is split up into three parts – two heat streams and one work stream.
Table 3 shows the energy targets obtained after process modification with a ΔT_{min} of 40ºC for heat cascade calculations.

	Target after modifications	Base Case Target
Hot Utility (MW)	0.0	0.0
Cold Utility (MW)	234.47	240
Work Consumed (MW)	17.34	17.34
Work Obtained (MW)	5.5	-

Table 3: Energy targets for base case and after process modification

The results show that no additional hot or cold utility is consumed as compared to the base case and hence the proposed modification is theoretically possible.
The plant is tightly integrated with the utility system and unless a detailed heat exchanger network synthesis study is performed, it is not possible to evaluate the actual effect on the overall plant energy consumption. This is outside the scope of this paper.

CONCLUSION

The Energy Level Composite Curve methodology was modified and extended to incorporate energy targets to be used with the ELCC for energy integration. Energy integration study of a methanol plant in Norway was performed using this methodology. An integration scheme was proposed that would have been difficult to visualize by other techniques. The energy targets for the base case and proposed integration scheme was evaluated. The proposed modification reduced the theoretical cold utility target by 5.53 MW and 5.5 MW of work is obtained.
The ELCC and targeting methodology can be fine tuned and modified with insights gained from energy integration studies of the entire plant including the utility section.
The targeting methodology must be modified to take heat integration into consideration while developing the work targets. An optimization scheme would be best suited for this.
Finally, the methodology should be expanded to include composition change in addition to pressure and temperature change to ensure that the entire chemical plant can be analyzed for energy integration.
This energy integration strategy, still in its early phase of development, has shown considerable promise when applied to an industrial case study. Substantial work is required to develop a complete systematic framework that incorporates thermal, mechanical and chemical energies.

ABSTRACT

The expenditure of primary energy can be reduced and the economics of process plants in the food industry can be improved by intelligent application of Process Integration (PI). Since a greater part of the products in the food industry is processed in batches, the use of Thermal-Energy Storage (TES) may be required to achieve these improvements. Further improvements may be achieved if there is a need, in the plant, for heating water at low-or-medium-level temperatures for cleaning purposes and there are significant quantities of medium-to-low-temperature heat recoverable. Such conditions are often encountered in the food industry. However, the extent to which PI is utilized is much smaller than the number of potential applications. The present paper will address this topic, give some reasons for the underuse of PI, and indicate some principles, methods, and directions that, when applied, could increase the use and usefulness of PI by incorporating TES, thus fulfilling PI's promises of improved operation, reduced energy consumption, reduced environmental impact, and improved economics. The application of these procedures is illustrated through the description of two cases.
Keywords: Heat Recovery. Industrial Process Integration. Batch Processes, Hot Water

τ= Delay

INTRODUCTION

The Present Study

A number of reasons can be given for heat recovery (HR) not achieving wide-spread use in the food industry (or in industry in general for that matter) thus not realizing its potential benefits with respect to energy savings, emission reduction, resource depletion, and economic gain. The prime reason is that production in the food industry most often is based on batch processes that in turn lead to operational complexity or expensive hardware. Other reasons that may be given are unproven system design, high cost of engineering, design, and construction, insecure feelings caused by

[1] Parallelvej 2, hda@cowi.dk
[2] Building 402, Nils Koppel´s Allé, bq@mek.dtu.dk

unproven system configurations, and operational complexity. All these reasons may be true to some extent, but some simple considerations, described in the first section below, show that the delay caused by the time required for engineering, design and construction may be a decisive factor. The central theme of the present work is then to present and justify some measures by which this time can be reduced to a minimum. This will be done by developing standard off-the-shelf components and systems. Since these solutions are off-the-shelf, they will only achieve almost-optimal operation. However, it can easily be demonstrated that it is better to have high number of industrial plants achieve almost-optimal energy recovery, than to have a small number of plants achieve optimal energy recovery.

Background

During the last 10 years, the Process-Integration projects in the Department of Mechanical Engineering of the Technical University of Denmark have focused on heat recovery in Batch Processes. These projects were initially directed towards the development of computationally efficient algorithms for the synthesis of energy-efficient process networks. The resulting algorithms that utilized both direct[3] and indirect[4] heat recovery, have always included one or more TES´s.

In the Ph.D. study of Mikkelsen (1998), methods for the generation of Heat Exchanger Networks (HENs) for industrial batch processes incorporating TES were developed.

The Ph.D. study of Krummenacher (2001) of EPFL, Switzerland, refined and extended the studies and confirmed the results of the previous Danish studies.

The latest studies have been carried out as a part of a Ph.D.thesis that has been completed recently by Dalsgård (2002). In this work, 11 industrial process plants in Lithuania and Denmark were studied and recommendations for modifications of the existing energy systems, or the design of novel systems, were given. A number of these recommendations have been implemented. The observations and conclusions of the rather theoretically oriented work of Mikkelsen and Krummenacher and rather practical work of Dalsgård point in the same direction.

Efficient, expedient, and appropriate procedures are crucial for the profitability of heat recovery in industrial process networks. The results of these three studies represent an important base of knowledge for deciding the priorities of the different heat recovery schemes and the selection of the order in which the various excess heats should be recovered

Since the selection and design decisions of a heat-recovery scheme for one subsystem invariably limit the choices available for the remaining subsystems, it was concluded that the challenge was, and will be, also in the future, the development of a selection procedure for the order in which the various heat-recovery measures are to be introduced into the system design.

The paper will discuss these issues and will present qualitative considerations and the logical chains of arguments that have led to a number of simplified mathematical expressions to be used in the preliminary evaluation and conceptual design of heat recovery systems incorporating TES in industrial process networks resulting in the concrete recommendation of using heating of water for cleaning purposes to achieve economical heat recovery by introduction of TES in batch-process networks.

The basic ideas contained in the present paper have been presented at the energy-storage conference FUTURESTOCK 2003 by Dalsgård and Qvale (2003), but the treatment has been shifted from TES towards PI as a result of responses from colleagues and experiences gained during the past year, and also with the aim of making the basic thoughts accessible to the new and different audience of ECOS 2005.

THE IMPORTANCE OF TIME

Many aspects of the activities concerned with the preliminary studies, with the design, and with the implementation of energy recovery and energy management in industrial process plants are often considered only after the completion of the design of the plant or even after the completion of the

[3] Direct heat recovery implies that heat is exchanged directly between the hot process stream and the water stream to be heated. The TES in the water stream is used to adjust the water flow to the, usually time-varying, demand.

[4] Indirect heat recovery implies that the heat is first transferred to a TES system, normally with storage of water at two temperature levels. Thereafter, heat is transferred to the water stream in accordance with the time-variations of the demand.

construction of the plant. A process-integration study, followed by design and implementation can easily last many months, maybe as much as an entire year. The situation could then pretty much be as shown in Figure 1. The curve labeled NPV1 shows the development of the Net Present Value of the originally designed process (1). It starts, at time zero, with a rather substantial deficit in the form of the initial investment required for the installation of the process equipment. This deficit is reduced with time until the initial investment has been paid. In the present case this Pay-Back Period is 7.28 years

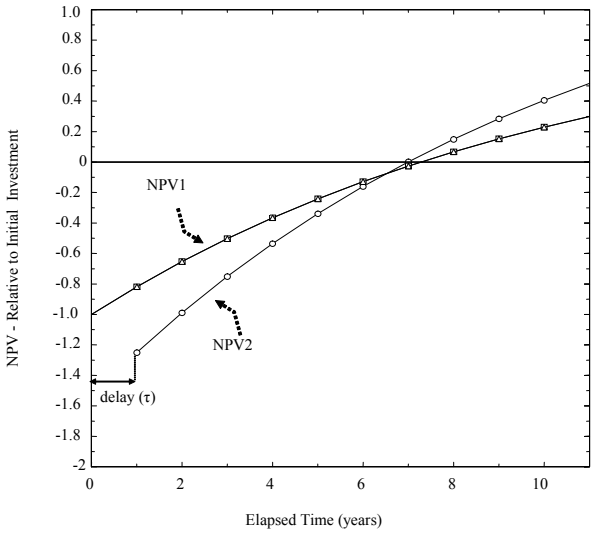

Figure1: The Development of the Net Present Value of the Two Projects
(The interest rate equals 10 percent/year).

In order to improve the performance of this industrial process plant, Process Integration studies are initiated. The engineering activities associated with these Process Integration studies lead to a delay. The activities are only interesting if they lead to improved energy utilization (and associated improved resource utilization and reduced environmental strain). The initial investment may or may not be reduced relative to the original. The consequence of the delay caused by engineering is that the Net Present Value of the improved project may lag behind the original project for a number of years. Figure 1 illustrates the case for the delay equal to one year, a considerable improvement of running surplus of 44 percent, and an increase of the initial investment of 25 percent. It is seen that even for this very successful application of Process Integration, it takes more than six years before the economic balance of the improved project (2) overtakes the original project(1).

In Figure 2, the time required to recover the cost of the improvement is presented as a function of the delay caused by engineering. Both a decrease and an increase of the initial investment are considered (plus/minus 25 percent) and two levels of interest rates (0.0 percent and 10.0 percent). It is seen that, in cases where the investment costs decrease or remain constant, the improved solution very quickly overtakes the original version. But in cases where the costs increase, the improved version will overtake the original version only after a period of time that may exceed the pay-back period for the original project. It is seen that when the interest rate is varied over a limited range, the effect is only of secondary importance.

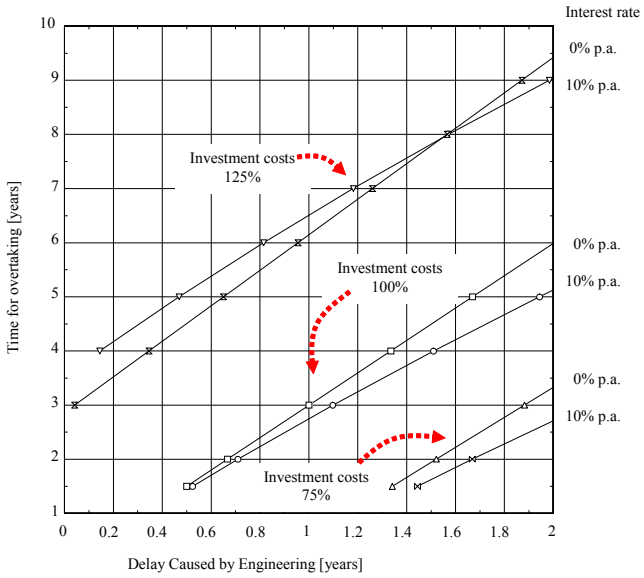

Figure 2: Time Required for the Net Present Value of an Improved Project (2) to Overtake that of the Original Project (1) for different real-interest rates.

This situation can also be regarded from a different viewpoint. It would be reasonable to postulate that for the delay caused by Process Integration to be acceptable, the investment should be paid back at the latest at the same point in time as the investment in the original plant. This situation is illustrated in Figure 3, which shows the acceptable delay for a given increase of cost and expected gain in performance. The payback period is chosen to be three years, the delay τ is one year, and the real interest rate is assumed to be zero, which is in

quite close agreement with the prevailing conditions in the industrial world at present.
As shown in Figure 3 it will be necessary to increase the relative savings (Savings/Investment) if the PI-project is delayed and if the invested money has to be paid back at a given time. This can e.g. be done by reducing the investment and at the same time keeping actual annual savings (illustrated by the straight lines). If the suggested solutions are more expensive than the original one it will be necessary to increase the annual savings even more (jump to line with a greater slope).

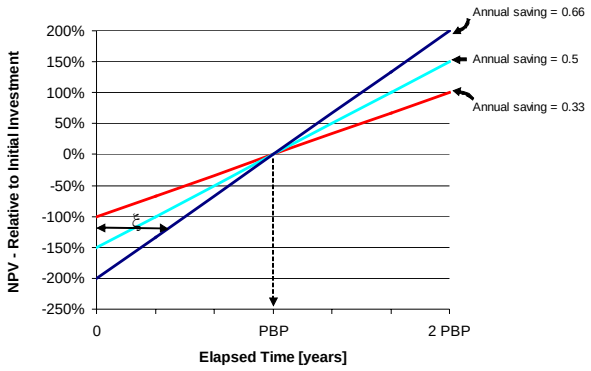

Figure 3: The return of investment (profit) related to the time for implementation (or delay) and the annual saving potential.

In this view, all relationships between variables are linear. As a consequence, the results may be condensed in the very simple non-dimensional curve shown in Figure 4.

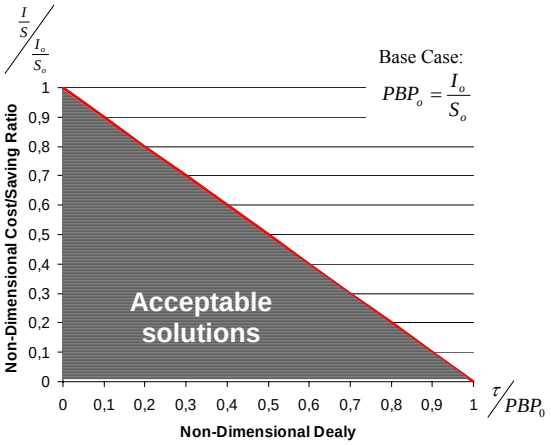

Figure 4: Non-dimensional decision diagram

Figure 4 shows the relationship between acceptable time delay (τ), investment (I), and saving potential (S). It is seen from the above that, it would be very difficult to convince managers (that want to show the company stockholders, represented by the Board of Directors, how clever and competent they are) that Heat Recovery and Process Integration are for the best of the company.
What can be done to change or ameliorate the situation?

1. Provide information and education so that the principles of Process Integration are known in the companies
2. Reduce the time required for Engineering by developing efficient methods and user-friendly computer programs.
3. Develop Standard Systems Solutions.
4. Apply Proven Technology (Known characteristics with respect to operability, controllability, and flexibility)
5. Initiate the PI activities simultaneously with the design of the plant, and avoid the introduction the energy-efficiency measures as an afterthought.

The ultimate goal would be to have Process Integration enter as a natural, generally accepted, and indispensable element in the initial stages of the planning of the new plant.
Using Standard System Solutions may lead to systems that are not absolutely optimal, but both for the plant in question and for society in general, such a procedure may result in the best overall performance. Albeit not rigorously, logically, and mathematically the optimal system, it may still be better than any realistic alternative.

THE RECOVERY OF HEAT IN BATCH PROCESSES FOR CLEANING WATER APPLICATION, USING INDIRECT HEAT RECOVERY

The general observation that has been documented in a number of articles is that, when applied intelligently, Process Integration may improve the economics of industrial process plants very significantly. Mikkelsen (1999) developed methods for PI in batch by incorporation of TES into Heat-Exchanger Networks (HEN). However, the methods although being very effective, required a deep and thorough understanding of thermodynamics AND Process Integration. Krummenacher (2001) substantiated these results. He, furthermore, observed that the application of

heat recovery by heating of water for cleaning purposes could represent an alternative, that in many situations would be extremely interesting both thermodynamically, technically, and economically. Simultaneously, Dalsgård (2002) carried out Process Integration studies of a number of plants in Lithuanian and Danish food industry. These studies showed, through extensive case studies, that heating water for cleaning purposes was an interesting alternative. In particular, this alternative was perceived as proven technology and, therefore, without risk. Furthermore, the solutions that were proposed and subsequently implemented were based on standard components and available on short notice. Thus, the solutions were psychologically digestible and would not entail delays and high costs caused by extensive engineering work.

Let us consider the conceptually simple situation taken from a process plant operating with batch processes, shown in figure 5. One hot process stream is going to be cooled and one cold stream has to be heated. The processes do not take place at the same time. The heating and cooling can be achieved by using available utilities. This will require the expenditure of primary energy. This is the solution with the lowest investment and the most flexible operation, but has the highest energy demand. This solution could serve as reference. We assume that Process-Integration studies of the system have resulted in the selection of these two streams for heat recovery. If the processes were taking place simultaneously, this heat recovery could take place directly. Thus it is called Direct Heat Recovery (DHR) and is illustrated in Figure 6. This is the best solution seen from an energy-demand point of view and could thus serve as a second reference point. However, if the processes do not take place simultaneously, heat will have to be removed during one period, stored in a system for storage of thermal energy storage, and given off to the cold stream during a later period. This is labeled Indirect Heat Recovery (IHR). This is shown in Figure 7. It is clear from this illustration that the temperature differences over which the heat is exchanged in the heat exchangers could be reduced to one half of what it was with DHR thus leading to the need for a heat exchanger that is twice as big. However, this will not be the case in real life. The heat exchanger will be optimized leading to approximately the same size as in the case of DHR. Therefore, the unit cost of the optimized heat exchanger used for recovery of heat is the same in the four situations depicted in Figures 6, 7, and 8 However the amount of heat transferred will be reduced.

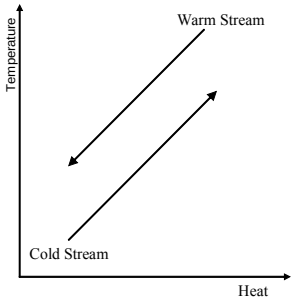

Figure 5: Process Streams. No Heat Recovery.

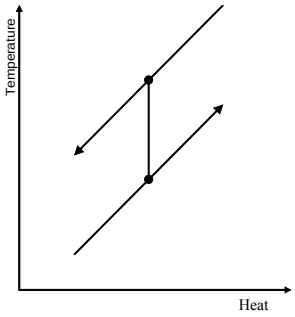

Figure 6: Direct Heat Recovery.

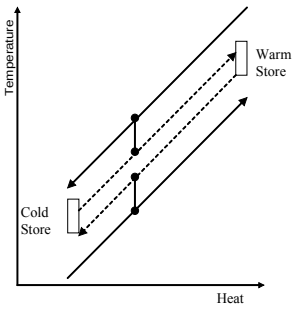

Figure 7: Indirect Heat Recovery, Using TES.

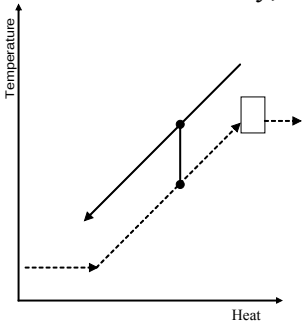

Figure 8: Direct Heat Recovery for Cleaning Water, Using TES.

If the two streams were perfectly matched initially, the heat recovered would be reduced for the optimized heat exchangers, thus requiring supplementary heating and cooling by utilities. But as noted before, the establishment of this supplement would be quite cheap.

These situations have been studied and evaluated. The parameter values are shown in the section DATA. The resulting simplified expressions have been developed assuming that the food processing plants include a number N_{HR} of similar processes that can be used for energy recovery, thus $N_{HR}>>1.0$ and that the cost of the cleaning-water heat exchanger C_{XC} is the same as that of the heat-recovery heat exchanger C_{XHR}. The resulting simplifying expressions are shown in the Table 1.

It is seen that the cheapest in terms of investment is the heating and cooling by utilities, but that the second cheapest solution and, therefore, the second most attractive short-term solution for industrial batch processes is the heat recovery by heating of water.
When the savings of energy is included through the cost of heating and cooling by utilities, the other alternatives become attractive and the investments can be written off. And these savings have to be allowed to be accumulated over an extended period of time periods such as, for example, four or eight years.

CASES

Superstructure

A superstructure was developed. This superstructure could have been the base for the design of the two examples in the present section, but the situation was actually the reverse. These two examples, together with a number of other cases formed the basis for the suggested superstructure. The superstructure can be put to use in similar situations in the future, Dalsgård (2002).

Example A

The company DANPO was to establish a new chicken processing plant in 1999. A Process Integration project was started up quite early in the planning phase. The resulting water heating system was quite simple as seen from Figure 9. The structure of the heat recovery network was not much different from the ordinary heating and hot water systems.

	Investment Cost (Simplified Expressions)	Saved Cost of Investment Relative to the next Higher Case (Simplified Expressions)	Minimum Required Load Duration (hours)
Indirect Heat Recovery (IDH)	$N_{HR}(2C_{XHR}+C_S)$		817
		$½N_{HR}(3C_{XHR}+2C_S)-C_S$	
Heat Recovery by Heating of Water for Cleaning (C)	$½N_{HR}(C_{XC}+C_{XU})+C_S$		375 (817 for Closed System)
		$½N_{HR}C_{XU}+C_S$	
Direct Heat Recovery (DH)	$½N_{HR}C_{XHR}$		347
		$½N_{HR}C_{XHR}$	
Heating and Cooling by Utilities (U)	$N_{HR}C_{XU}$	With the numbers used in this study the required load duration would be infinite, implying that the costs of fuel and equipment would never be recovered.	

Table 1: Simplified Expressions of Cost Functions and Reduction of Investment.

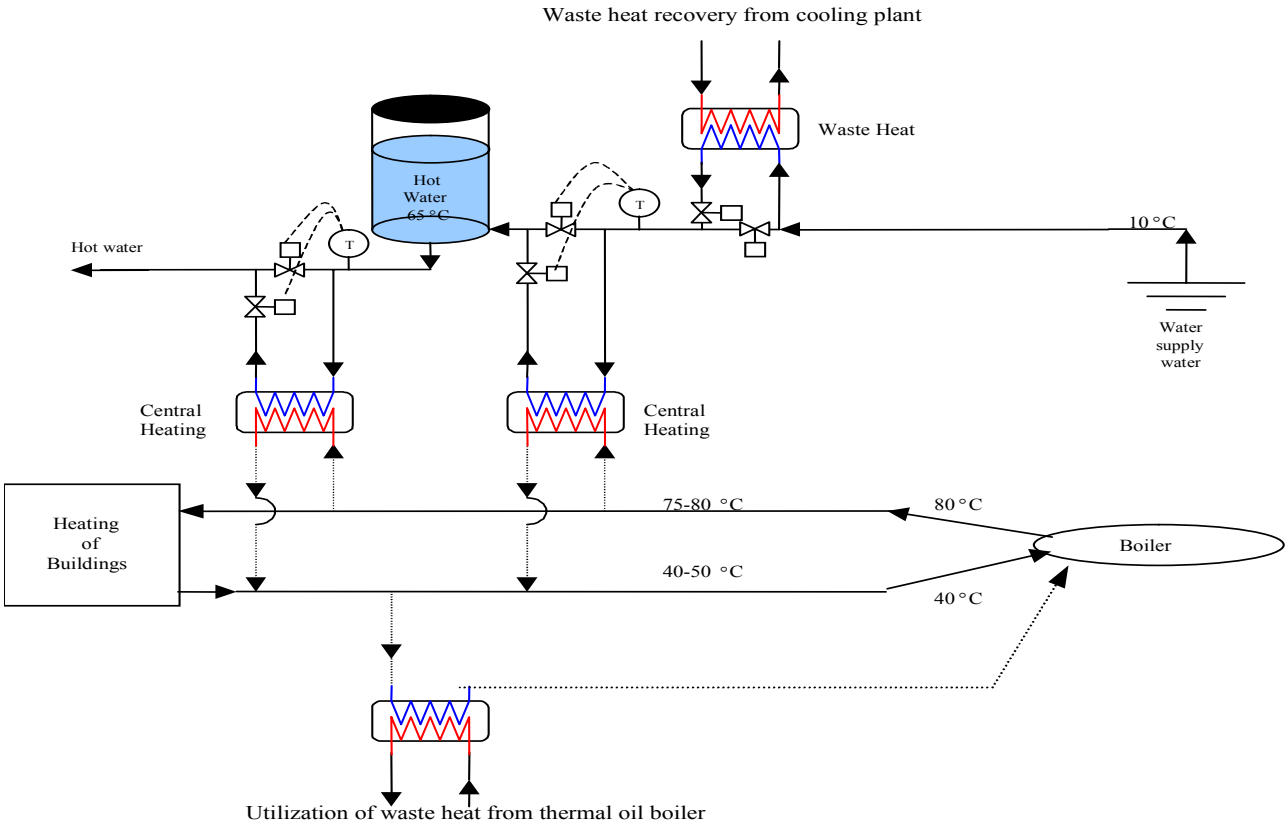

Figure 9: Heat Recovery Network at Poultry Factory (Danpo).

Integration between the cooling plant, which is present in most food factories, and the hot water production formed the basic structure for the heat recovery. The hot water system was successfully integrated with a boiler flue-gas heat recovery system. The heat from the flue gas was passed on to the hot water through the central heating system.

The amount of excess heat from the cooling plant increased dramatically as a result of the decision to install an ammonia-based cooling system instead of CO_2-freezers.

The excess heat from a cooling plant is generated at three points:

- from the cooling of lubrication oil in the NH_3 system's compressors,
- from cooling of superheated NH_3 gas
- from the compressors, from condensing of NH_3

The Danpo A/S Farre facilities need approx. 120 m^3 of hot water per 24 hours for cleaning purposes. This amount corresponds closely to the excess heat available from the NH_3 cooling system. Calculations showed that 2,500 MWh/year could be drawn from the excess heat, and a 120-m^3 storage tank was subsequently included in the facility layout. The water in the tank is kept at approx. 65°C by the excess heat (backed up by the natural gas boiler). Savings on natural gas expenses have been calculated to 2500 MWh or EURO 70,000 per year. Payback for the water tank system is 3.2 years. However, the pay-back period was, due to a grant from the Danish Energy Agency, reduced to 2.3 years.

The facilities are not able to use all their excess heat and some of the heat is led to the nearby Danpo A/S chicken slaughterhouse via a rediscovered, old pipeline. Natural gas savings there have been calculated to EURO 6,000 per year.

Example B

Danish Crown was going to build a new slaughterhouse in Denmark, this being one of the biggest in Europe. The resulting hot-water system is shown in the figure below.
Beside the illustrated heat recovery system for cleaning water, it is planned to use the central heating system to recover and distribute waste heat form the singeing ovens in the black slaughtering hall (Ovens for hair removal and decontamination of pigs).

The overall heat recovery systems supply the slaughterhouse with 20.000 MWh/year worth 500,000 EURO per year (excl. energy tax). The recovered heat corresponds to approximately 35% of the total heat demand. The pay back period is less than 3 years.

SUMMARY AND CONCLUSIONS

The present paper is striving to translate and generalize the results of past studies and particularly three Ph.D. theses (Mikkelsen (1998), Krummenacher (2001), and Dalsgård (2002)), into practical methods and procedures for developing efficient energy systems for batch processes in the food industry.
The goal is actually twofold: First, to develop energy-efficient and economically interesting energy systems through the application of Process Integration to improve the economics of TES system by increasing the return on investment.
Second, to raise the level of knowledge, acceptance, and interest for the use of Process Integration for retrofit of energy systems and the use of TES.

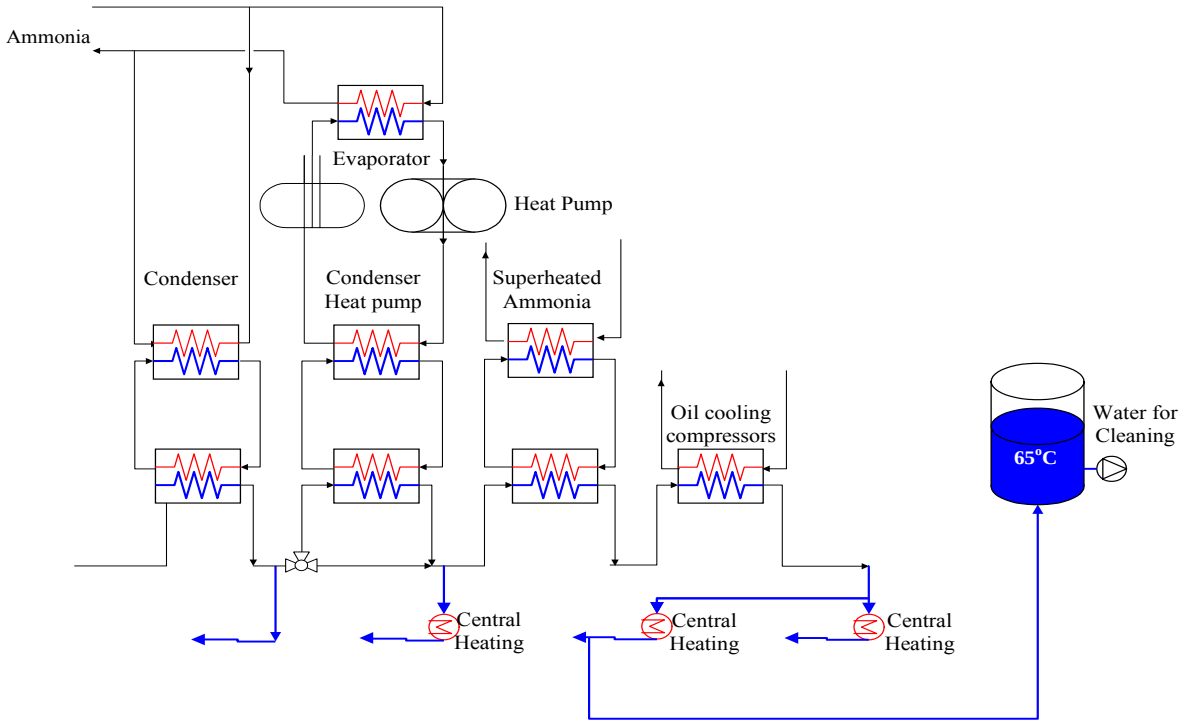

Figure 10. Heat Recovery from Danish-Crown Cooling Plant

In the present context, the first goal may be the most interesting. Over the years, the improvement of the economics of PI through the application of TES has been amply documented, for example in Mikkelsen (1999). It has been shown that a reduction of Pay-Back periods for the return on investment of the redesigned energy system including TES with a factor of two and three can be achieved.

The second task is aimed at raising the general awareness and use of PI and TES, thereby increasing the efficiency and economics of energy systems thus improving the economics of existing industrial process plants and decreasing their consumption of resources (primary energy).

The third task is aimed at improving the effectiveness of PI, first, by decreasing the time required for studies. The importance of this was demonstrated through some simple annuity consideration in the introduction of the present paper. The central theme here is the development of standard solutions based on "Proven Technology".

The standard system solution found to be the most interesting in the present context, was the use of heat recovery for heating of water for cleaning purposes. This was advocated theoretically by Krummenacher and, practically, by Dalsgård.
The simple considerations of the present study show that their recommendations have a general validity: If there is a need for warm cleaning water, the use of heat recovered from the cooling of warm process streams to heat the cleaning water will always be economically superior to heating a cool process stream.

APPENDIX. DATA AND ASSUMPTIONS SELECTED FOR THE STUDIES.

Data

Temperatures in the store 90C and 30C
Temperature difference over water-to-water heat exchanger 3 C
Temperature difference over gas-to-water heat exchanger 30 C
Temperature difference over gas-to-gas heat exchanger 30 C
Cost of heat exchangers:
- Water-to-water 200DKK/kJ/s
- Gas-to-water 1000DKK/kJ/s
- Gas-to-gas 2000DKK/kJ/s
- Water-to-cleaning water 200DKK/kJ/s
- Gas-to-cleaning water 1000DKK/kJ/s
- Utility 50 DKK/kJ/s

Cost of heat store 12x 10^{-3} DKK/kJ
Cost of hot utility $20*10^{-6}$ DKK/kJ
Cost of cold utility $20*10^{-6}$ DKK/kJ
Capitalization factor 4
Number of batches per year 1000

ABSTRACT

In this paper we set out the principles for using the grand composite curve (GCC) of mass exchange network synthesis (MENS) for selection of mass separating agents (MSAs). These principles enable us to systematically choose between alternative MSAs as well as the minimum flow rate for each MSA selected. This has not been possible using procedures developed so far. Of particular note is that the cheapest MSA is not necessarily the one with the lowest cost per unit mass of MSA, but rather the one with the lowest overall cost of removal of the mass load, which depends on both the MSA cost and its permissible concentration change. We illustrate the principles presented by application to two example problems.
Keywords: Mass Exchange Network Synthesis, Grand Composite Curve, Mass Separating Agents

INTRODUCTION

Up till now it has not been possible to systematically choose between available external Mass Separating Agents (MSAs) in Mass Exchange Network Synthesis (MENS).

In Heat Exchange Network Synthesis (HENS) the Grand Composite Curve (GCC) has long been established as a tool for choosing how much of each utility to use (Linnhoff, et al., 1982). The power of the HENS GCC is that it provides a visual means of identifying the flow of energy in a heat exchange network and allows for easy selection of HEN utilities. In spite of the many analogies between HENS and MENS, there has been limited application of the GCC to the selection of MSAs in Mass Exchange Network Synthesis (MENS) (Shenoy, 1995). Shenoy developed the GCC for MENS based on the minimum composition difference in the lean phase, ε, and applied it to one example problem and two other problems. He assumed that in placing the alternative MSAs the order of selection was cheapest cost in terms of MSA cost per unit mass.

We propose to show that a GCC for MENS has similar benefits to the GCC for HENS, especially with regard to selection between alternative external MSAs. As before, we expect that the HENS procedures will provide a foundation from which to work, but there will be features of MENS requiring different approaches (Hallale and Fraser, 1998, 2000a, 2000b, Fraser and Hallale, 2000).

In this paper we will first describe the use of the Grand Composite Curve in HENS. We will then discuss the features of the MENS Composite Curve on which the GCC will be based, pointing out differences between the HENS and MENS cases. Finally, we will present our proposal for use of the MENS Grand Composite Curve, and illustrate this with two examples.

The HENS Grand Composite Curve

The Grand Composite Curve, which is derived directly from the Problem Table, shows the cascade of energy in a heat exchanger network (Figure 1, Linnhoff et al., 1982). It clearly shows the process heat sink above the pinch and the

[1] Corresponding author: Phone: +27-21-650-2515, Fax: +27-21-650-5501, Email: dmf@chemeng.uct.ac.za

process heat source below the pinch, where the pinch is the point that the curve touches the vertical temperature axis. It also shows regions in which the process streams may satisfy their own needs (the two shaded portions of the curve). Most importantly, it allows you to choose the most appropriate combination of utilities from a variety of possibilities, e.g. steam at different temperature and pressure levels. Note that the Problem Table (and hence the GCC) uses modified stream temperatures to bring hot and cold stream temperatures to a common basis, with $\frac{1}{2}\Delta T_{min}$ being subtracted from hot stream temperatures and added to cold stream temperatures.

Figure 1 illustrates how a number of utilities are used to satisfy the heat surplus and demand below and above the pinch respectively. Note how the supply and target levels of each utility are represented. In most cases the shape of the curve dictates the most appropriate choice of utility level and load. Where the selection is not as apparent, a more rigorous set of guidelines is required. Linnhoff et al. (1982) proposed the following set of principles for this purpose:

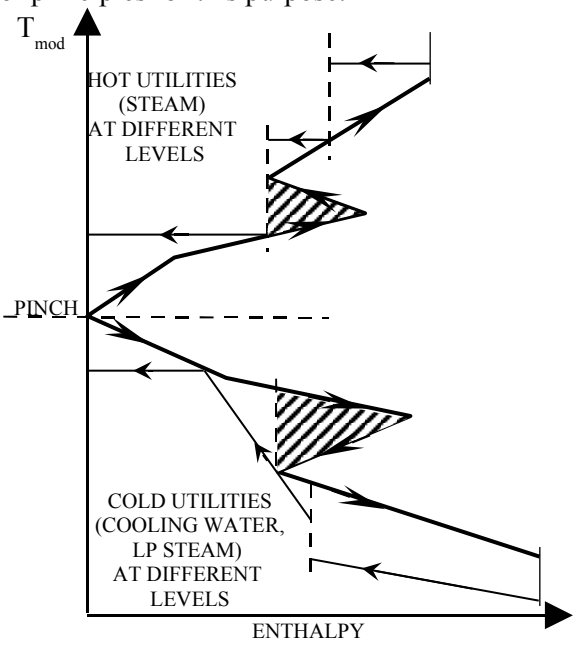

Figure 1. HENS Grand Composite Curve (from Linnhoff et al., 1982)

1. Maximise the use of the least expensive utilities. Note that in HENS it is generally true that the further away from ambient conditions you are, the more expensive the utility is (whether hot or cold), so it is obvious which are the least expensive utilities.
2. Minimise the flow of a particular utility by maximising the slope of the operating line, i.e. attempt to have an operating line with the most negative slope below the pinch and most positive slope above the pinch.
3. Where several choices and combinations are possible, evaluate whether the reduced operating cost achieved by the addition of more levels (i.e. use of more utilities) justifies the added capital costs required (because of the lower driving forces for heat transfer).
4. Each time a utility operating line touches the energy cascade curve a new pinch is created and the number of units – and the capital cost – required to satisfy the exchange increases. In these cases it might be beneficial to relax either the load or target level of the utility to avoid an additional pinch (which also leads to a more constrained system of matches).

This set of principles will form the foundation for the use of the MENS GCC presented in this paper.

The MENS Composite Curves

We will use the most general MENS Composite Curves (see Figure 2), namely the y-y* composite curve for overlapping MSAs (i.e. where different MSAs exist in the same composition interval), developed by Hallale and Fraser (2000a, 2000b). Here the MSA composition is expressed as the corresponding rich stream composition with which it is in equilibrium, allowing overlapping MSAs to be plotted on a common basis. Note that for MENS the excess capacity of the process MSAs is the equivalent of hot utility in HENS, and the load for external MSAs is the equivalent of cold utility.

As opposed to the minimum composition difference, ε, in the lean phase (introduced by El-Halwagi and Manousiouthakis, 1989), we use the minimum composition difference, Δy_{min}, in the rich phase. For a linear equilibrium function relating the composition in the rich phase to the composition in the lean phase (MSA):

$$y^* = m_j x + b_j \qquad (1)$$

(where the subscript j denotes the different MSAs), these minimum composition differences are related to each other as follows:

$$\Delta y_{min} = m_j \varepsilon \qquad (2)$$

This implies that for a fixed value of ε each MSA has a different value of Δy_{min}, but in this approach we use a global value for Δy_{min} instead (so each MSA effectively has a different value of ε).

Construction of the Grand Composite Curve (GCC) for MENS

As mentioned above, one of the main purposes for developing the GCC for MENS is that it will aid in external MSA selection. For this reason, only the data for rich streams and process MSA streams must be used in its construction. The construction involves using the Composition Interval Table (CIT), set up in much the same way as the HENS Problem Table. The mass cascade from this table is plotted against a modified y value, y_{mod}, similar to the modified HENS temperature. This value is calculated as shown in Equations 3 and 4 below:

$$y_{mod} = y - \tfrac{1}{2}\Delta y_{min} \quad \text{Rich streams} \quad (3)$$

$$y^*_{mod} = y^* + \tfrac{1}{2}\Delta y_{min} \quad \text{Lean streams} \quad (4)$$

Note that the value of Δy_{min} used in Equations 3 and 4 should preferably be the optimum value obtained from supertargeting of the problem being considered (Hallale and Fraser, 2000c, 2000d). The MENS GCC is plotted directly from the CIT, with y_{mod} being plotted against mass exchanged, as shown in Figure 2. The Pinch is where the curve touches the vertical composition axis. Also note that we are using Δy_{min} in determination of y_{mod}, and not ε as used by Shenoy (1995).

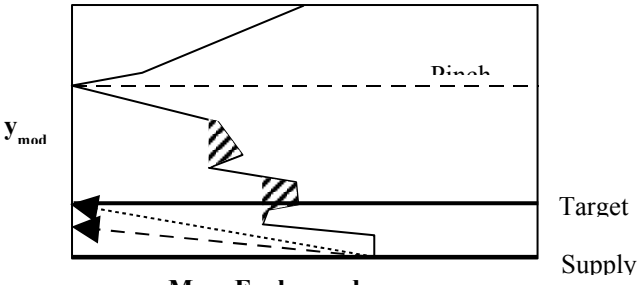

Figure 2. MENS Grand Composite

Procedure for using the MENS Grand Composite Curve to target MSAs

1. Construct the GCC and adjust the process MSA flow rates (if desired):

The first step in using the Grand Composite Curve (GCC) is to decide on any reduction in process MSA flow rates. This is decided as follows:

- For process MSAs that exist entirely above the pinch: The use of any one of them may be reduced to eliminate the excess capacity of the process MSAs. In this case you could choose to redraw the GCC to reflect the change above the pinch. If the excess capacity of the process MSAs has been eliminated, the GCC will start from the vertical composition axis at the top.
- For process MSAs that exist only below the pinch: Their use should not be reduced, as it will lead to an increase in the loading on the external MSAs.
- For process MSAs that cross the pinch: A reduction in flow rate will cause the load on the external MSAs to be increased. There appears to be no point in reducing the flow rate of such an MSA, even if it is the only MSA above the pinch. If it is decided to reduce the flow rate of such an MSA, the GCC will need to be recalculated before proceeding to the next step.

2. Eliminate self-sufficient areas below pinch on GCC:

Determine which areas of the Grand Composite Curve (GCC) are self-sufficient (i.e. no external MSA is required for these mass transfers). As for HENS, these are pockets (areas that overlap), shown by the shaded regions in Figure 2.

3. Identify and cost possible external MSA technologies:

The next step of the analysis is to identify all external MSA technologies that will perform the required mass transfer, check if their operating composition range is suitable for the problem in hand, and then rank those that remain in terms of cost of removal of the required mass. For each external MSA the following data is needed: supply and target compositions, equilibrium relationship for transferred component, cost.

Check the supply and target compositions of the available technologies and eliminate any MSA where the supply composition is above the pinch composition (since the region above the pinch is satisfied with process MSAs, supplying an external MSA in this region is redundant). If the target composition of an MSA is above the pinch it should be reduced to less than or equal to the pinch composition (no mass transfer across the pinch).

Calculate the minimum removal cost for each remaining MSA, C_{min}, as given by Equations 5 to

7. This cost is obtained by assuming that each MSA would remove the total mass required by external MSAs, $M_{removed}$, over its maximum concentration range, Δx_{max}. The total mass required is the last entry in the CIT, and the final point of the GCC. Note that L_{min} represents the minimum MSA flow rate (kg/s) and C_{MSA} the unit cost of the MSA ($/kg).

$$\Delta x_{max} = x_t - x_s \quad (5)$$

$$L_{min} = M_{removed}/\Delta x_{max} \quad (6)$$

$$C_{min} = C_{MSA} * L_{min} \quad (7)$$

Finally in this step, rank the MSAs in terms of increasing minimum removal costs, C_{min}. This order will not necessarily be the same as you would get if you simply ranked them according to their unit costs, C_{MSA} (Shenoy, 1995); rather the order is in terms of increasing ($C_{MSA}/\Delta x_{max}$).

4. Select how much of each external MSA is to be used:

Now select which of the MSAs is to be used to transfer the required mass and determine the minimum flow rate for each selected MSA. It is helpful to plot each of the MSAs on the GCC to assist in this process, over the full range of mass to be exchanged.

The slope of the operating line of MSA S_j is $-m_j/L_j$. Since m_j is given, once the slope is known, the flow rate of the MSA can be determined. A line with the steepest possible slope therefore corresponds to the minimum, and hence cheapest, MSA flow rate. Here $L_j = L_{min}$ (as defined in Equation 6). A line of lower slope also transfers the required mass, but would correspond to a greater MSA flow.

Start at the supply composition of each MSA and attempt to reach its target composition. If the target composition cannot be met, then calculate the highest final composition that the MSA can reach, by just touching the GCC at the closest approach so as to maximise the slope, as shown in Figure 4 (if the operating line crossed the GCC it would represent infeasible mass transfer). In this case $L_j > L_{min}$.

Two options are available in this situation, neither of which is ideal in that the target composition cannot be met for the complete mass transfer. The first of these options is to use the MSA in a mass exchange operation that pinches with the GCC, as shown in the dotted line in Figure 3. The second is to split the MSA and to use two exchange operations, the first also pinches with the GCC, while the second completes the necessary mass transfer (dashed lines in Figure 3).

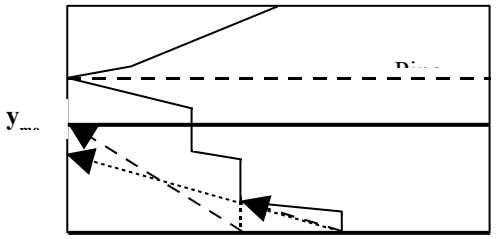

Figure 3. Alternatives when target composition cannot be reached directly

Choosing between the alternatives shown in Figure 3 is not a simple matter. The slopes of the lines touching the GCC are clearly equal. The second dashed line is essentially ideal for its part of the mass transfer. This does not necessarily mean that the configuration given by the dashed lines is the best alternative, however. For example, the capital cost of using two mass exchange operations may make the second alternative less cost effective than the first. The total MSA usage for the two dashed lines is also greater than the usage for the dotted line. Decisions in these circumstances therefore require more thorough economic evaluation.

Complete the problem using the cheapest possible MSAs, in order. In Figure 4 we see an example of this. The number of "$" symbols represents the relative cost of each MSA. For example, depending on the costs of the MSAs shown in Figure 4, it may be cheaper to transfer the entire amount using the more expensive MSA (represented by the dashed line) as only a single exchanger type may be necessary, rather than use two different MSAs (shown by the dotted line). These alternatives also have capital cost implications which need to be taken into account.

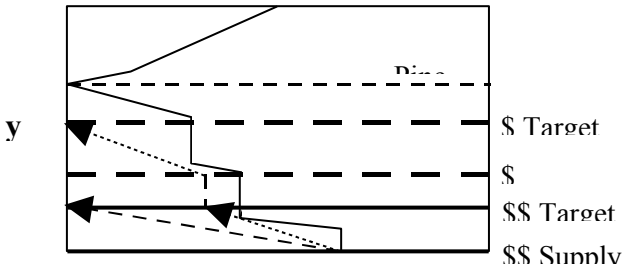

Figure 4. Single versus Multiple MSAs

Occasionally the most expensive MSA must be used, because of the concentration levels of the MSAs on the supply side.

5. Choose between possible options:

If more than one possible combination of MSAs has been identified, calculate the operating cost associated with each option. Perform a final comparison between all the possible options based on their individual operating costs as well as their capital cost implications.

Examples

In order to demonstrate the validity of the proposed procedure, two problems will be presented.

Example Problem 1 (Dephenolisation of rayon wastes, El Halwagi, 1997)

In El Halwagi's solution of this problem activated carbon is the only external MSA. Air, light oil, and ion exchange resin are all possible external MSAs that are technologically feasible candidates for the required separation (El-Halwagi, 1997; Hallale, 1998). We will demonstrate the use of the Grand Composite Curve to choose between these four alternatives.

Step 1: The GCC is constructed, taking only the two process MSAs (S_1 and S_2) and the two rich streams (R_1 and R_2) into account. The optimum Δy_{min} value of 0.000255 is used to determine the targets (Hallale, 1998). The supply composition of S_2 is at the pinch ($y_{mod} = 0.015428$), so its load may be reduced from 3.0 to 2.48 kg/s (the MSA flow rate that exactly removes the required amount of phenol). Figure 5 shows the GCC both before (solid line) and after (dotted line) adjustment of the process MSA flow rate. Note that there is now no surplus capacity of process MSAs and that the curve does not change below the pinch.

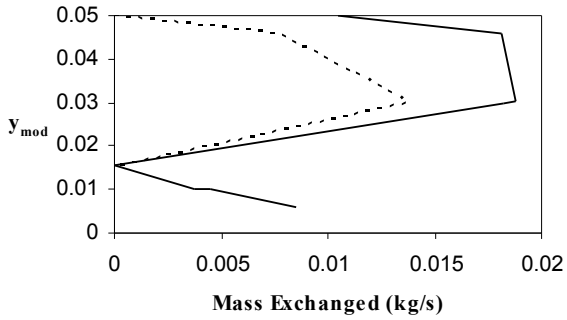

Figure 5. GCC for Example 1

Step 2: There are no regions below the pinch where there are any pockets.

Step 3: For the removal of phenol from aqueous streams, the MSAs listed in Table 1 are possible candidates. All the possible external MSAs listed in Table 1 fall within the region below the pinch. This is verified by converting their individual supply and target compositions to the equilibrium composition in the rich phase, y*, and then to y^*_{mod} values using Equation 4 (as given in Table 1).

Table 1. Available technologies for the removal of phenol from aqueous streams

Technology	MSA	x_s (mass ratio)	x_t (mass ratio)	m_j	b_j	$y^*_{s,mod}$	$y^*_{t,mod}$
Activated Carbon	S_3	0	0.110	0.02	0	0.0001275	0.002328
Air	S_4	0	0.029	0.04	0	0.0001275	0.001288
Light Oil	S_5	0.0013	0.015	0.71	0.001	0.0020505	0.011778
Ion Exchange Resin	S_6	0	0.170	0.09	0	0.0001275	0.015428

Table 2. Minimum operating cost for each MSA

Technology	MSA	Δx_{max}	L_{min} (kg/s)	C_{MSA} ($/kg)	$C_{MSA}/\Delta x_{max}$ ($/kg)	C_{min} ($/hr)
Activated Carbon	S_3	0.110	0.077	0.081	0.736	22.5
Air	S_4	0.029	0.292	0.060	2.067	63.1
Light Oil	S_5	0.0137	0.619	0.010	0.730	22.3
Ion Exchange Resin	S_6	0.170	0.050	0.212	1.247	38.1

Table 2 shows the minimum operating cost for each of the available MSAs, based on $M_{removed} = 0.008475$ kg/s. The order of increasing MSA costs is: S_5, S_3, S_6, S_4. Note that the second last column in Table 2 ($C_{MSA}/\Delta x_{max}$) can be used for this ranking, rather than the last column (C_{min}), which requires a knowledge of $M_{removed}$, and that while the minimum flow of S_5 is much greater than that of S_3, their relative costs mean that the overall costs for the two are very close. This closeness of costs

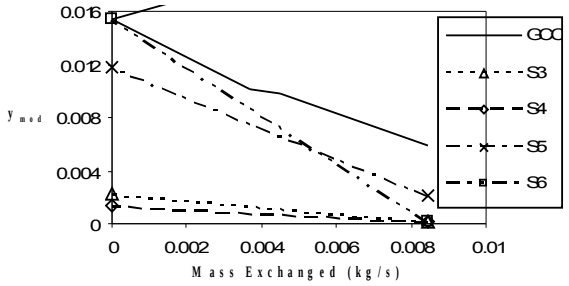

Figure 6. GCC for Example 1 below pinch showing all external MSAs

for S_5 and S_3 means that other considerations may be significant in choosing between them.

Step 4: Plot each of the available MSAs on the Grand Composite Curve. Since only the region below the pinch is of interest, it is most convenient to focus on this part of the curve as presented in Figure 6. Each MSA is plotted over the full range of mass to be exchanged and its full composition range. In this case any of the MSAs could remove the total load on its own, as is evident in Figure 6. On the basis of operating costs, either S_3 or S_5 would be the preferred choice.

Step 5: Looking at Figure 6, with the operating costs for S_3 and S_5 being so close, it seems that S_3 would have the larger driving forces and should have the edge over S_5 in terms of capital investment. This is as far as we need to go with this problem, and the procedure proposed has proved effective in determining the most cost effective MSA from a set of four possibilities.

Example Problem 2 (Howe and Hugo, 2000)

The data for this problem can be found in Table 3.

Table 3. Data for Example Problem 2 ($\Delta y_{min} = 0.001$)

Rich Streams	G_i (kg/s)	y_s (mass ratio)	y_t (mass ratio)	Lean Streams	L_j (kg/s)	x_s (mass ratio)	x_t (mass ratio)	m_j	b_j	C_{MSA} ($/kg)	$y^*_{s,mod}$	$y^*_{t,mod}$

R_8	0.01	0.021	0.0012	S_8	∞	0.000	0.00425	2.00	0.000	5.0	0.00050	0.00900

Step 1: The GCC is constructed from the CIT for a Δy_{min} of 0.001, and shown in Figure 7. Note that in this case all the process MSAs except S_1 and S_4 are entirely below the pinch, at $y_{mod} = 0.0695$, and S_1 and S_4 both cross the pinch. There is therefore no incentive to reduce the flow rate of any of the process MSAs, and the GCC does not change.

Step 2: Remove self-sufficient areas, as shown in Figure 8, which only shows the GCC below the pinch. The dotted lines indicate the regions that no longer need to be considered.

Step 3: The possible external MSAs are identified in Table 3, together with the required data. The supply and target compositions of the external MSAs (converted to y^*_{mod}) are also shown in Table 3. They are all below the pinch. Table 4 shows the relative costs for removal of all the mass by each of the external MSAs. For this problem $M_{removed}$ is 0.040313 kg/s. Note that in this case the relative costs per unit mass are amplified in the minimum removal costs, and that the costs increase by an order of magnitude for each successive MSA. The cheapest MSA is S_6, followed by S_7 and then S_8.

Table 4. Minimum operating cost for each external MSA in Example 2

MSA	Δx_{max}	L_{min} (kg/s)	C_{MSA} ($/kg)	$C_{MSA}/\Delta x_{max}$ ($/kg)	C_{min} ($/s)
S_6	0.150	0.269	1.4	9.33	0.376
S_7	0.025	1.612	2.1	84.0	3.39
S_8	0.00425	9.485	5.0	1176	47.4

Step 4: The maximum possible transfer of mass to all of the MSAs is shown in Figure 9, using the full composition range in each case. It will be noted that neither S_6 nor S_7 can carry the full load because their supply compositions are too high.

First use S_6 to transfer as much mass as possible, starting from where it touches the GCC. No

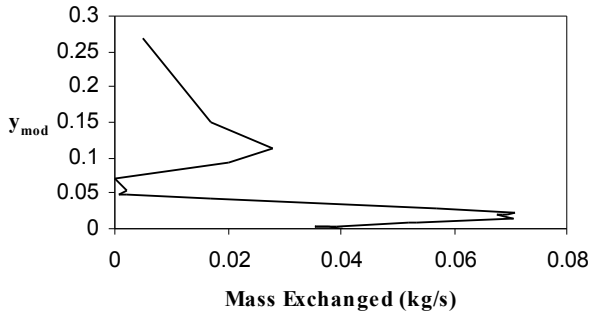

Figure 7. GCC for Example 2

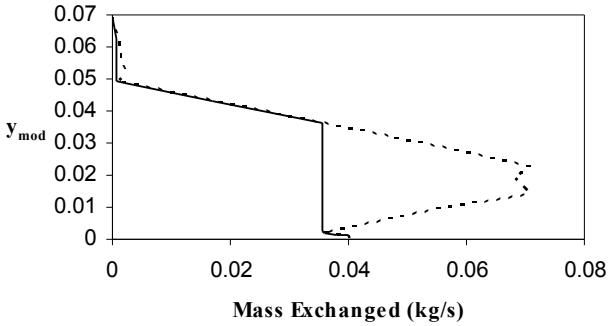

Figure 8. GCC for Example 2 below pinch showing elimination of self-sufficient areas

further mass can be transferred using S_7, as it also touches the GCC at the same mass exchanged. The remaining mass must therefore be transferred using S_8, even though it is the most expensive MSA. The complete mass transfer operation is represented in Figure 10. This is Option 1.

Figure 11 shows the region in which S_8 is used in greater detail. This illustrates that you must be careful not to let the MSA cross the GCC line.

Another possibility is shown in Figure 10, where S_8 is allowed to reach its target composition. This does not increase the flow of S_8, but it does mean that less S_6 will be used (note the higher slope for S_6 in Figure 10). This is Option 2.

Step 5: Finally we compare the total operating cost of each of the alternatives identified. The four alternatives investigated are the two options shown in Figures 12 and 14, and another two options using S_7 instead of S_6 (Options 3 & 4). The results are presented in Table 5.

It is clear from Table 5 that, as anticipated, Option 2 is in fact the cheapest from an operating cost point of view ($107 900/hr). This shows that it may not be best to always transfer the maximum amount of mass using the cheapest MSA. Seeing as Options 1 and 2 are quite close in terms of operating costs, consideration will need to be given to the capital costs of each of these alternatives before making a final decision between them.
Table 5 also shows the costs of using S_7 instead of S_6 (Options 3 and 4). Given the dominance of the S_8 costs in this problem, the total costs using S_7 do not increase by much and the larger driving forces for S_7 compared to S_6 might make Option 4 the most attractive.

Table 5. Actual operating cost of alternatives in Example 2

Option	MSAs	Δy^*_{mod}	Slope (s/kg)	L_j (kg/s)	C_{MSA} ($/kg)	Operating Cost ($/hr)	Total Operating Cost ($/hr)
1	S_6	0.0210	-0.593	0.236	1.4	1190	108 600
	S_8	0.001635	-0.335	5.966	5.0	107380	
2	S_6	0.0210	-1.404	0.100	1.4	500	107 900
	S_8	0.0085	-0.335	5.966	5.0	107380

4	S_7	0.02225	-1.487	0.598	2.1	4520	111 900
	S_8	0.0085	-0.335	5.966	5.0	107380	

CONCLUSION

We have proposed a set of procedures for using the MENS Grand Composite Curve for choosing between possible external MSAs, just as the HENS GCC is used for choosing between available hot utilities and available cold utilities. These procedures not only determine the best MSAs to use, but also the minimum flow rates for each of them. We have shown that care should be taken when determining the cheapest MSA. This may not be the MSA with the lowest cost per unit mass of MSA, but rather the one with the lowest cost for removal of the required mass load. This removal cost depends on both the cost of the MSA as well as the concentration range over which it can work.

We have demonstrated the validity of these procedures by application to two examples.

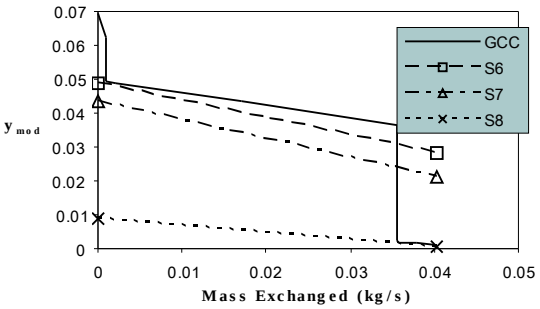

Figure 9. GCC for Example 2 showing all the external MSAs carrying the full load

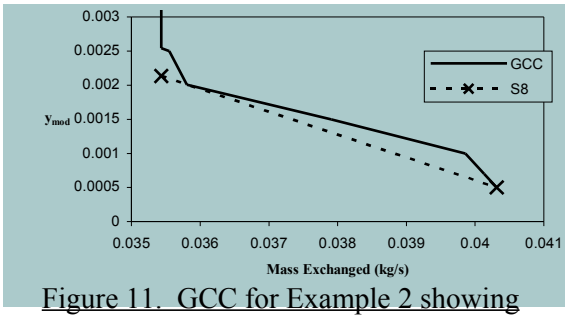

Figure 11. GCC for Example 2 showing expanded region for S_8

This paper has again shown that HENS procedures form a good basis for MENS procedures, but that they need to be extended to cover the significant differences between HENS and MENS.

ABSTRACT

The recycling concept presented here converts mixed plastic waste chemically to new plastic, the Plastic waste to Plastic concept (PtP). The PtP concept has been developed by Norsk Hydro. After a suitable pre-treatment, the waste is converted thermally to synthesis gas in a gasifier. The synthesis gas is used in methanol production, which is then converted to olefins by use of a patented MTO (Methanol to Olefins) process. Olefins are the raw material in production of new plastic. The UOP/Hydro MTO process makes the system innovative as it provides a closed-loop recycling process for plastic. All the technology steps exist, though not yet realized in a continuous process train. The recycling concept facilitates production of virgin plastic from old, mixed and contaminated plastic waste. The carbon in the plastic waste is captured thereby preventing releases of CO_2 to the atmosphere, additionally CO_2 releases from alternative production of plastic is avoided.

INTRODUCTION

Plastic waste is a valuable source of both energy and chemicals. The present situation, however, shows that more than 60% of the plastic waste in Western Europe is landfilled or burned without recovering the energy or material [1]. This paper presents a new concept for recovery of plastic waste, where co-production of chemicals and energy is utilizing the potential of plastic waste.

Most of the plastic waste recycled today is treated mechanically by a melting process. This treatment requires a high purity feedstock, since any impurities that remain in the feed will result in down-cycling of the material; this is true even if the impurities are other plastic material. The result is that only relatively pure and large plastic waste streams are economical to treat in a mechanical process, and the material produced is of lower quality than the virgin material. In addition, the capacity of mechanical recycling is limited. In this paper a recycling concept for large scale, mixed and contaminated waste is presented, where the quality of the recycled material is equal to plastic produced from virgin sources.

PLASTIC WASTE TO PLASTIC, PtP

The Plastic waste to plastic (PtP) concept is developed by Norsk Hydro and offers a closed-loop system for a large scale recycling of mixed plastic waste back to plastic. The concept envisages combining existing technologies for waste treatment and production of valuable chemicals. The produced chemicals provide new feedstock to the plastic industry. The concept is outlined in Figure 1. The black arrows and text show the core strategy, taking plastic waste back to plastic. The mixed plastic waste is collected and pre-treated making it usable in a gasification process. The plastic waste is broken down to the chemical components, CO and H_2, in the gasifier. In order to produce new plastic material, the CO and H_2 are converted to methanol which is further reacted over a catalyst to produce olefins by use of the patented UOP/Hydro Methanol to Olefins process (MTO). Olefins are the feedstock in the production of plastic; e.g. PVC, PE, PP and PET. The mixed plastic waste also contains metals and other inorganics, which will be separated from the synthesis gas in the gasifier and recovered. The metals can replace virgin metals and the other inorganics are recovered as a glasified slag, known as frit and usable e.g. in roadbeds or in cement production.

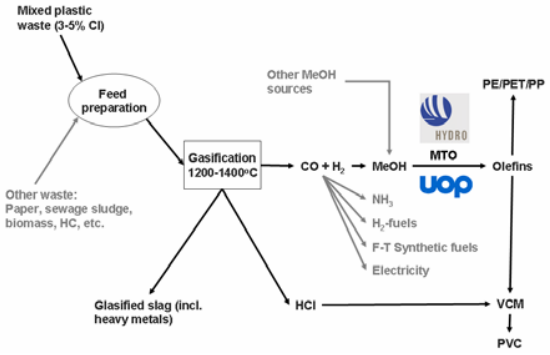

Figure 1: The Plastic waste to plastic (PtP) concept is shown schematically. The black path is the original PtP concept, whereas the grey paths are options included to increase the flexibility of the concept.

The grey arrows given in Figure 1 are the possible add-ons both as input and output. The extended PtP concept offers increased flexibility with its possibilities for alternative feedstock and product extractions at various stages in the process chain. All carbonaceous material is a potential feedstock in the concept. These other waste sources include paper, sewage sludge, wood, biomass and all other hydrocarbons, both renewable and non-renewable. The synthesis gas can be used to produce a number of products including methanol, ammonia, hydrogen, Fischer-Tropsch synthetic fuels and electricity. The possibility for extracting intermediates makes it possible from the single core technology, to add flexible downstream technologies that match market needs, technology developments, and existing legislation (which e.g. specifies targets for plastic-to-plastic, plastic-to-other material products, and plastic-to-energy recovery). Every intermediate can also be produced from alternative feedstocks, like introduction of methanol as shown in Figure 1. The possibility to use alternative feedstocks provides opportunities for varying the scale of different parts of the process train.

Substances (e.g. heavy metals) in the plastic waste not wanted in new polymers can be removed from the recycling chain in the gasifier. Reasons for wanting to remove substances can be based on environmental and/or product quality concerns.

An additional benefit of this concept when the waste material is recycled back to new plastic, instead of being burned, is the opportunity to capture the carbon and thereby preventing releases of CO_2 to the atmosphere. Since the carbon is captured, the

ethylene produced could be seen as green sourced. At the same time, CO_2 emissions from alternative production of ethylene are avoided.

Two operating processes worldwide produces chemicals from plastics waste, one in Germany and one in Japan. SVZ in Germany produces methanol from mixed waste [2] and Ebara in Japan produces ammonia from plastic waste [3], they are both gasifying the plastics waste.

UNITS AND REACTIONS

All carbonaceous material, including all sorts of polymers, can be treated in this concept. In order to be able to gasify the waste, a calorific value of at least 20MJ/kg is required. High calorific material such as PE, coal and oil can be added to increase the calorific value if low calorific material like PVC and polymers with high filler content (inorganics) is treated. Most gasifiers have a chlorine limit of 3% in order to avoid severe corrosion. Plastic material with brominated flame retardants are destructed in the process.

A minimum of feed pre-treatment is needed for gasification processes [4]. The level of pre-treatment is dependent of the gasification process chosen as the various reactors can treat various feeds. Large metal and other inorganic parts are removed, and the material crushed down to suitable particle sizes, ranging from 5mm to 10cm. Fixed bed gasifiers generally need less feed treatment than fluidised bed gasifiers, as the former can treat larger particles. The latter will, however, give syngas with higher and more uniform quality [5].

Gasification is a thermal upgrading process using oxygen, air, steam, or a combination thereof, in the reaction with the carbonaceous material. The product gas consists mainly of CO and H_2, normally called synthesis gas, and small amounts of CO_2, H_2O and CH_4 [6]. Pure O_2 is chosen as the oxygen source in this concept to assure a high calorific syngas; hence the following overall, strongly exothermic, reaction will take place in the gasifier. In the Equation the subscript p is used to indicate that this is a reaction with various polymers, which consists of different monomers (C_xH_y).

$$\left(C_xH_y\right)_p + \frac{x \cdot p}{2} O_2 \rightarrow (x \cdot p)CO + \left(\frac{y \cdot p}{2}\right) H_2 \quad (1)$$

By adding water to the synthesis gas produced, the H_2/CO ratio can be controlled. The slightly exothermic reaction is known as the Water-Gas-Shift (WGS) reaction, and is given below.

$$CO + H_2O \leftrightarrow CO_2 + H_2 \quad (2)$$

When plastic waste is used as the carbonaceous material in the gasification, other components than carbon and hydrogen will also be present. The chlorine present will form HCl in the gasifier. Due to the high temperatures in the reactor and direct quench [7] the level of dioxin reported is well below the legal limits [8]. The detailed reactions involved in the conversion are given in Aguado and Serrano [4]. More details on the gasification unit in the PtP concept are also given in Kaggerud et al. [9].

Dependent on the feedstock various gas treatment is necessary. Chlorine will always be present as HCl in the syngas, and has to be removed. It is normally removed by an aqueous solution of $Ca(OH)_2$ which forms $CaCl_2$ with HCl. This can either be done in a direct quench, or in a separate gas treatment unit. Thermodynamically the latter is advantageous [10]. Small amounts of sulphur can also be present in the feedstock. Sulfur forms H_2S and small amounts of COS in the gasifier, which has to be removed. Solid particles are removed in a filter.

The next step in the concept is the production of methanol from syngas, which is achieved by a conventional methanol process. The main reactions are given below, both are exothermic reactions. In order to obtain maximum catalyst activity, 5% of the feed should be CO_2 [11].

$$CO + 2H_2 \rightarrow CH_3OH \quad (3)$$

$$CO_2 + 3H_2 \rightarrow CH_3OH + H_2O \quad (4)$$

The UOP/Hydro Methanol to Olefins process, MTO, is designed to selectively convert methanol, either crude or refined, into olefins. The reaction takes place in a circulated fluidized bed, with a yield of 80% ethene and propene. The yield can be increased to above 90% by use of an olefin cracking process (OCP) for the C_{4+} reactor product [12]. The yield is higher than traditional thermal cracking of ethane and propane to olefins, which is of course beneficial for the energy usage in the separation sequence. The process is robust with regard to methanol quality, making it possible to operate with crude methanol.

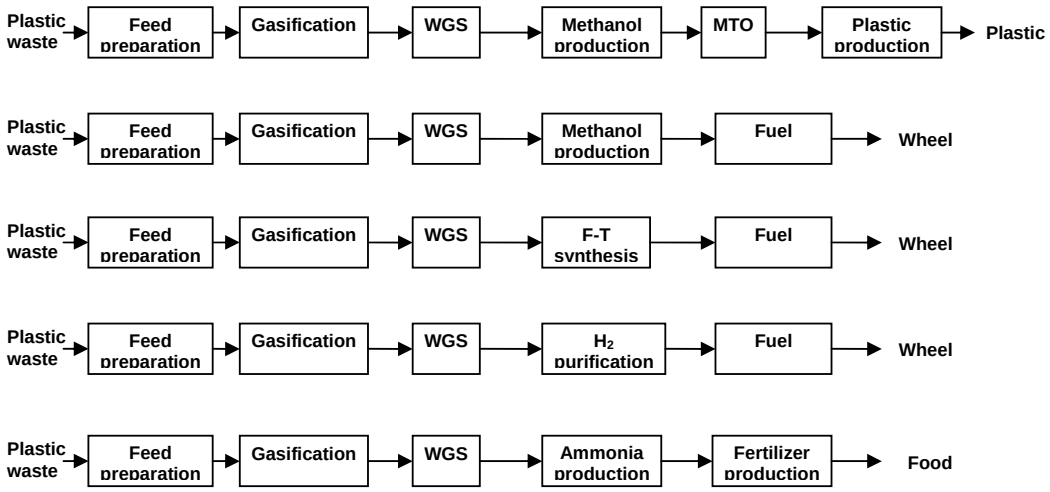

Figure 2: Possible process trains for processing of plastic waste

The olefins produced in the MTO-process will be used in production of new plastic, like PVC, PE, PET and PP. The catalyst used in the MTO process is based on a silicoaluminophosphate, SAPO-34. The principal reaction is given below [12].

$$5CH_3OH \rightarrow CH_2CH_2 + CH_2CHCH_3 + 5H_2O \quad (5)$$

Based on extensive tests in the demonstration plant, the MTO process is to be scaled up to a single train unit with capacity of up to one million tonnes of light olefins per year [12]. Basic engineering of the first planned commercial MTO plant based on stranded gas has been carried out. The plant will be part of a petrochemical complex in Nigeria, and is scheduled to come on stream in 2006. The plant will convert 2.5 million tonnes methanol into 400,000 tonnes of ethylene and 400,000 tonnes of propylene [13]. The MTO plant is flexible wit regard to the C_2/C_3-ratio, and typically the ratio can be modified within a range of 0.75-1.5 by adjusting the operating severity, with higher temperature leading to higher C_2/C_3-ratio [12].

SYSTEM EVALUATION

The core strategy in the PtP concept is shown in Figure 1 together with potential add-ons both in input and output. When the various process trains in Figure 1 are broken down to single process trains, the result is as shown in Figure 2, the core strategy is given as the first line. Of course, Figure 2 is not exhaustive and even further alternatives are possible. The core concept has been evaluated with respect to carbon efficiency in the various steps.

Definition of the carbon efficiency for step i:

$$\eta_C^i = \frac{(n_C)_{out}^i}{(n_C)_{in}^i} \quad (6)$$

The total carbon efficiency in the entire process train is then:

$$\eta_C = \prod_i \eta_C^i \quad (7)$$

The evaluation of the core PtP concept has been done by using the stoichiometric reactions given as Equations 1, 2, 3 and 5. For simplicity Equation 4 is omitted. The carbon efficiency is based on atom balances. In order to show the maximum potential for the core concept, all unit efficiencies are set to 1. In Figure 3 the stepwise decrease in carbon efficiency for various feed compositions is given. Compared with Figure 2, WGS is included in the methanol production unit as WGS is done to adjust the H/C-ratio for the methanol process. The maximum efficiency that can be achieved by this route is when the unit efficiency for all process steps equal 1, this is shown in Figure 3. Unit efficiency is the internal efficiency in the process, e.g. gasification. As can be seen from the figure, for all feed compositions lower than 80/20 the carbon

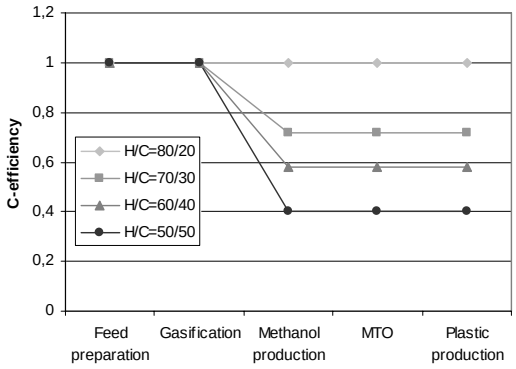

Figure 3: Stepwise decrease in carbon efficiency for various feed compositions, all unit operations have an efficiency set to 1. (The WGS is included in the methanol production unit)

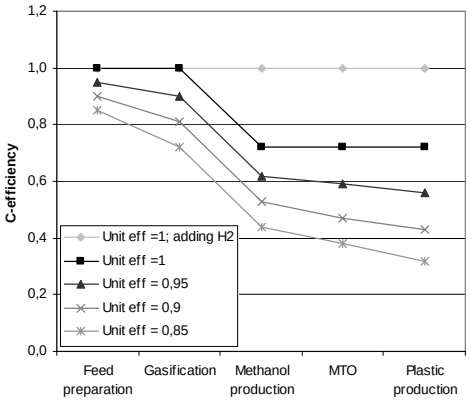

Figure 4: Carbon efficiency with decreasing unit efficiency in the PtP concept, H/C-ratio in the feed set to 70/30.

efficiency drops in the methanol production. The reason for this is the low hydrogen content in the waste compared to methanol; hence CO in the syngas has to be shifted to hydrogen by use of the WGS-reaction (Eq. 2), producing equal amounts of CO_2.

A high H-content in the feed gives a higher C-efficiency due to the high H/C-ratio needed in the methanol production. For an H/C-feed composition of 80/20 there is enough hydrogen available in the waste material to produce methanol without shifting the synthesis gas stream towards more hydrogen, hence no drop in efficiency will take place. Plastic waste will typically have a H/C-ratio of 65/35-70/30, hence a drop in efficiency will occur in methanol production. In order to avoid this drop in efficiency, a hydrogen-rich feed can be added to the plastic waste feedstock.

As the unit efficiency drops, the total carbon efficiency will of course drop as well. For calculations where the H/C-ratio is set to 70/30, the total carbon efficiency will drop from 0.72 at unit efficiency 1 to 0.43 at unit efficiency of 0.9; this is shown in Figure 4. Due to the long process train a small decrease in unit efficiency will result in a large drop in the total carbon efficiency. The main drop in efficiency is still the methanol production, for the same reasons as explained above. However; as the unit efficiency drops substantially, the other steps in the process will contribute more to the efficiency drop. For a unit efficiency of 0.85 the total carbon efficiency is as low as 0.32. For such low unit efficiencies the drop in carbon efficiency is spread more uniformly along the process train.

In Figure 4 it can be seen that the absolute difference in carbon efficiency is larger in the gasification step than in the methanol production, the relative difference is however larger in the methanol production step. The relative difference in efficiency shows the stepwise decrease in efficiency throughout the process train. To overcome the decrease in efficiency in the methanol production step, H_2 can be added to the syngas in order to adjust the H/C-ratio in favour of the methanol production unit. The effect of the additional H_2 is shown as the upper line in Figure 4. The efficiency drop in the methanol production can be solved by additional H_2, however, the challenge with a long process train remains. The production of hydrogen is not included in the efficiency calculations.

The evaluation above concentrate on the carbon efficiency. In the MTO-process, however, H_2O is being split off. This water has to be recycled in within the concept in order to maintain a high overall efficiency.

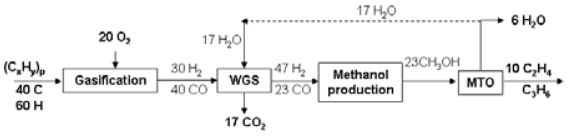

Figure 5: Simplified flow diagram for the core process train in the PtP concept. (Figures rounded up to the nearest whole number.)

In Figure 5, a simplified flow diagram shows the material flow in the concept. The input to the process train is plastic waste $(C_xH_y)_p$, oxygen and steam (steam might be recycled from the MTO

reactor). The output is the olefin product (C_2H_4 and C_3H_6), CO_2 and water. A rough stoichiometric molar balance is given in Figure 5. For simplicity the main product is ethene, however, as mentioned before different compositions of the olefin product is possible. The feed composition used is H/C=60/40, and all unit efficiencies are set to 1. The overall carbon efficiency is ~0,6 for the material balance in Figure 5, which is in agreement with the efficiency given in Figure 3. As indicated above, the reason for the low carbon efficiency is the high hydrogen content in the intermediate product methanol. In order to produce enough H_2 for the methanol production, water is reacted with CO (Eq. 2) and consequently equal amounts of CO_2 are produced.

In the MTO process, equal amounts of water are being split off as methanol is converted to olefins. The water can however be recycled to the WGS reactor, reducing the loss of water significantly. Recycling of water from the MTO to the WGS reactor will decrease the overall loss of atoms in the process train.

The main obstacle in the concept is the high hydrogen content in the intermediate product methanol, compared to both the waste plastic and the plastic product. To increase the carbon efficiency in the system various actions can be taken. Chemical integration with other process trains where the high carbon content can be utilized in other products is one option. Additional input of hydrogen or hydrogen-rich chemicals, or utilization of the intermediate products are other possibilities. These are shown as the grey arrows in Figure 1. The introduction of other feed and by-products can increase the efficiency of the concept; the extended PtP concept. As the high hydrogen content in the methanol is a main obstacle in the concept, another way to improve the efficiency of the concept is to avoid the formation of methanol by using alternative pathways from syngas to olefins. A catalytic process which converts synthesis gas into olefins by a direct route will of course be beneficial; however, this process does not exist for commercial operation.

DISCUSSION

Western Europe generates around 20 million tonnes of plastic waste annually. In 2002, 13% was recycled and 22% incinerated with energy recovery while the major part is still landfilled [14]. The EU post-consumer waste Directives will force more plastic waste to be recycled. These Directives include; The Packaging and Packaging Waste (1994), End-of-life Vehicles, ELV, (2000), Waste Electrical and Electronic Equipment, WEEE, (2003). The Packaging and Packaging waste Directive is at present being revised. The new recycling target for plastic will be 22.5%, up from today's 15% [15]. This target is only to be achieved by recycling plastic waste back to plastic. As a result of these post-consumer waste Directives, we have estimated that an additional recycling capacity in the order of 2 million tonnes is requested in 2008. It is envisaged that only a limited part of this could be achieved by mechanical recycling. This is due to lack of end-markets for the recycled material and the presence of large quantities of mixed plastic waste [1].

Household waste accounts for almost 70% of the total amount of plastic waste. This waste stream is often contaminated with food, detergents, metals, paper etc. Only 8% of the plastic waste from households is recycled at present [14]. This source is an excellent feedstock for the PtP concept. The most important driver for increased recycling might be the ban on landfilling of carbonaceous material. Several European countries are about to illegalise the deposit of plastic material, hence the plastic waste will have to be recovered [16].

In the future, there will be even more plastic waste generated than there is today. Furthermore, consumer choice increases the variety of polymers and additives. This can sometimes be for good reasons such as longer shelf-life of food in packaging or merely for aesthetic purposes. These changes create a major challenge for mechanical recycling, since everything that goes into such recycling is bound to come out in the recyclate. This also applies to additives that may have been phased out or become obsolete. Mechanical recycling hence often implies down-cycling. APME has recently raised a concern that the availability of end-markets for plastic waste recyclate may be a limiting factor for the long term sustainability of high rates of mechanical plastic waste recycling [1]. In the PtP concept, plastic waste is broken down to the chemical components CO and H_2, which can be purified and used to produce a variety of products. As the market requires high quality plastic material, the plastic waste can be used as a feedstock to meet this requirement.

The PtP can be used to produce high quality plastic as all the impurities are removed in the process train, whereas products from mechanical recycling will decrease in quality for each time is it recycled. The decrease in quality is with respect to both chemical and physical properties, like mixing of polymers,

fillers, banned chemicals, colour, strength, etc. To compensate for the decrease in strength, more recycled material than virgin material is needed to fulfil the same function. The consequence is that 1 kg of virgin material in a car cannot be replaced by only 1 kg of recycled material, but i.e. 1,1 kg of recycled plastic. This means that when different processes are to be compared, the real material consumption has to be taken into account, focusing on the functional unit the material shall fulfil. In order to account for this difference, a substitution factor has been proposed, defined as "*the quantity of virgin material (kg) that can be replaced by one kilo of recycled plastic in order to achieve equivalent performance*". [17]

Energy recovery

Why do we not just recover the energy of the waste material? There are several reasons for recovering the material in the plastic waste. First of all, according to the EU waste hierarchy material recycling is preferred to energy recovery. The waste hierarchy have the following preferred order:

1. *Waste prevention*

2. *Recovery*
   i) reuse
   ii) material recycling
   iii) energy recovery

3. *Disposal*

The waste hierarchy has been criticized lately as it would prevent development of more efficient waste management systems [18, 19]. The waste hierarchy gives general guidelines for treatment of waste. More careful investigation is of course needed for each specific case.

Second, the need for feedstock for production of materials also after the fossil fuel age argues that plastic waste should be recycled as material. The waste will always be present, even after the oil and gas are consumed. In addition, less CO_2 emissions than in production of plastic from virgin resources, are formed as the plastic waste is used as feedstock in production of plastic.

To become sustainable, energy and materials will have to be produced from renewable resources. In addition we will have to take care of the waste that we are generating. As the waste is at a high energy level, it should be kept at this high energy level by recycling it back to new materials. Polymers will be seen as highly efficient materials with respect to natural resources, cost, weight and greenhouse gas emissions. To safeguard that impression, cost-efficient recycling solutions that handle large volumes of diverse polymers will have to be developed, to demonstrate that plastic wastes do not have inherent recycling limits.

The plastic recycling system can be extended by use of alternative feedstock and product extractions at various stages in the process chain. This will offer an increased flexibility of the process. As the plastic waste or an alternative carbonaceous feedstock is converted to synthesis gas in the process, it opens up for a variety of products. Bulk chemicals like methanol and ammonia are produced from synthesis gas. In addition, H_2, various fuels, heat and electricity can be produced from synthesis gas. Plastic waste is an interesting substitute for natural gas feed, as the waste always will be present. A superstructure similar to the one given in this paper has been set up for natural gas [20]. More ideas for chemical and process integration through co-production of energy and materials are outlined in the paper referred to above.

CONCLUSION

In this paper, a new concept is presented for closed-loop large scale recycling of mixed plastic waste, with a gasifier and the MTO process as key process steps. The concept facilitates production of new modern plastic from old, mixed and contaminated plastic waste. Organic constituents in the plastic waste e.g. polybrominated flame retardants are destructed and inorganic constituents e.g. heavy metals are extracted and immobilized. In comparison to mechanical recycling, no sorting is needed and down-cycling is avoided. The concept will fill the gap between what is achievable by mechanical recycling and the targets for recycling given in EU post-consumer waste directives.

The main obstacle for a high carbon efficiency in the core PtP concept is the high H/C-ratio needed in the intermediate product methanol compared to the ratio in both the feedstock and end-product. The carbon efficiency drops rapidly with decreasing unit efficiency due to the long process train. To overcome this challenge, integration with other process trains, production of products with a high carbon content or supply of additional hydrogen-rich

feedstock to the process train are obvious possibilities.

In this paper, focus has been on chemical integration and utilisation of the atoms that enters the process train. Of particular interest is of course also the energy flow and possibilities for process integration in the PtP concept. This is published in [10], and will be examined in detail in further work.

COMBINED EXERGY AND PINCH ANALYSIS FOR OPTIMAL ENERGY CONVERSION TECHNOLOGIES INTEGRATION

François Marechal*, Daniel Favrat
Laboratory for Industrial Energy Systems, Ecole Polytechnique Fédérale de Lausanne
CH-1015 Lausanne

ABSTRACT

Exergy concept combined with pinch based approach are used for studying the optimal integration of energy conversion systems. The analysis first considers the representation of the hot and cold composite curves of the process and defines the energy and the exergy requirements. The basic assumption of the $\Delta T min$ required for the pinch analysis is represented as an exergy loss that increases the exergy requirement of the process. The exergy composite curves put the focus on the opportunities for heat pumping in the process. The optimal integration of the utility system is then realised by extracting the energy conversion system configuration from a superstructure using a Mixed Integer Linear Programming formulation in which the heat cascade definition and the combined heat and power production balances are introduced as constraints and where the exergy losses minimisation is used as an objective function. The balanced exergy composite curves are used to visualise the exergy losses in the heat exchanges and the analysis of the results is made using a definition of the exergy efficiency that accounts for the pinch point location, the process exergy and the exported energy services.

Keywords: process integration, energy conversion integration, exergy analysis, second law analysis

NOMENCLATURE

CHP	Combined heat and power
ΔT_{min}	Minimum heat recovery approach temperature
e_{fuel}	specific exergy of the fuel (kJ/kg)
f_{fuel}	fuel flowrate (kg/s)
E_{cool}	exergy available below the pinch point (kW)
E_{frg}	exergy required for the refrigeration(kW)
E_{heat}	exergy required above the pinch point (kW)
E_{res}	exergy resource consumed by the process(kW)
GT	Gas turbine
HP	Heat pump system
LHV	Lower Heating Value (kJ/kg)
MER	Minimum Energy Requirement
MILP	Mixed Integer Linear Programming
W	Electrical power (kW)

INTRODUCTION

When considering the energy efficiency of a process, pinch based approaches [1] target the identification of the possible energy recovery by heat exchange and define this way the minimum energy requirement (MER) of a process. The integration of the energy conversion technologies concerns the way the minimum energy requirement will be satisfied by converting energy resources into useful energy for the process, considering the combined heat and power production, the integration of steam networks, heat pumps and refrigeration systems. It represents a major step in a process integration study because it defines the cost of the energy requirement together with the complete list of streams to be considered in the heat exchanger network design. It is usually solved by applying optimisation techniques based on mixed integer linear programming techniques [2, 3] that aim at selecting the most appropriate technology and to determine the optimal flowrates in the energy conversion technologies.

By allowing the comparison of different forms of energy, exergy is a rigourous way of analysing energy conversion systems. In the context of process integration analysis, the exergy concept is combined with the pinch analysis for reducing the energy requirement of the process [4, 5], optimising the energy conversion system integration and realis-

ing combined heat and power production. The exergy composite curve concept has been introduced by Dhole [6] for this purpose. The exergy delivered (E) by a stream delivering heat (Q) from T_{in} to T_{out} is computed by : $E = Q(1 - \frac{T_a}{T_{lm}})$ where T_{lm} is the logarithmic mean of temperatures computed by $T_{lm} = \frac{T_{in} - T_{out}}{ln(\frac{T_{in}}{T_{out}})}$ and T_a is the ambient temperature, all temperatures being expressed in K. When considering the hot composite curve, the heat delivered is represented by the temperature-enthalpy diagram, the exergy delivered is computed by replacing the temperature axis by the Carnot efficiency $(1 - \frac{T_a}{T})$. It corresponds then to the area between the composite curve and the enthalpy axis (figure 1, right). The same procedure is followed for the cold streams to define the exergy required by the cold streams. Favrat and Staine [4] have added to this representation, the exergy losses related to the compression work (as a function of the pressure drop) and the grey exergy. The grey exergy is the exergy required to construct the heat exchangers. It includes the raw materials exergy content as well as the exergy consumed in the construction process. This concept is then used to determine the optimal value of the ΔT_{min}. The exergy analysis has been extended to account for the chemical reactions or the physical separations of the process operations [7, 5]. The graphical representation in [7] uses $\frac{\Delta H - T_a \Delta S}{\Delta H}$ as Y-axis that is an extension of the Carnot factor $(1 - \frac{T_a}{T})$. Marechal et al. in [8] use the concept of exergy to target the combined heat and power production by integrating rectangles in the Grand composite curve. The area of the rectangles is proportional to the mechanical power production, the height referring to the Carnot efficiency and the width being proportional to the heat load.

The goal of this paper is to discuss the application of exergy concepts for helping in the design of optimal energy conversion systems for a given process.

MINIMUM ENERGY REQUIREMENT

Based on the definition of a minimum approach temperature difference (ΔT_{min}), composite curves are used to compute the maximum energy recovery between the hot and the cold streams of a process. The temperature is a topological indicator in the sense that it allows to pinpoint the process operations concerned with the pinch points or the pseudo pinch points. Four zones are of importance in the hot and

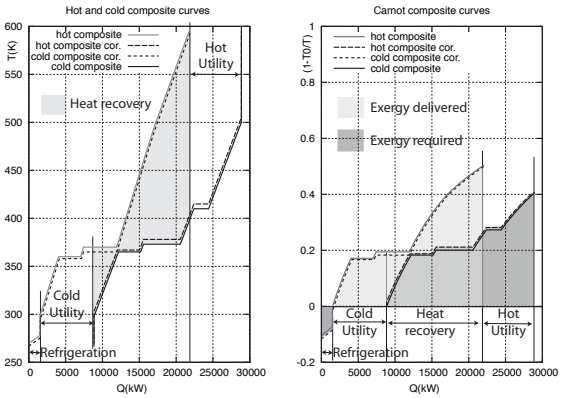

Figure 1: Exergy composite curves defining the process requirements

cold composite curves (figure 1, left). On the right, we visualise the hot utility requirement. The heat recovery zone represents the possible heat recovery by exchange between hot and cold streams of the process. The remaining heat of the hot stream has to be evacuated by cold utility. The left part of the graph defines therefore the cold utility requirement, the later being divided between cooling requirements above the ambient temperature and the refrigeration requirements below the ambient temperature. When using the Carnot efficiency ($(1 - \frac{T_a}{T})$) as the Y-axis, the area between the Xzero-axis and the cold composite curve (figure 1,right) represents the exergy required to heat up the process cold streams while the area below the hot composite and the zero axis represents the exergy delivered by the hot streams of the process. The difference between the two areas represent the net exergy balance available from the process streams through heat exchange. From this available exergy, a first exergy loss will be associated to the passage in the corrected temperatures domain that is obtained by shifting vertically the hot streams downwards and the cold streams upwards from a value of $\Delta T_{min}/2$. More rigourously, the exergy loss is computed considering the contribution $\Delta T_{min}/2_j$ of each stream j that is proportional to its heat film transfer coefficient.

The Grand composite curve (figure 2, left) describes as a function of the temperature, the way energy has to be supplied to or removed from the system. The process Grand composite curve is divided into three zones : above the process pinch point, the system is

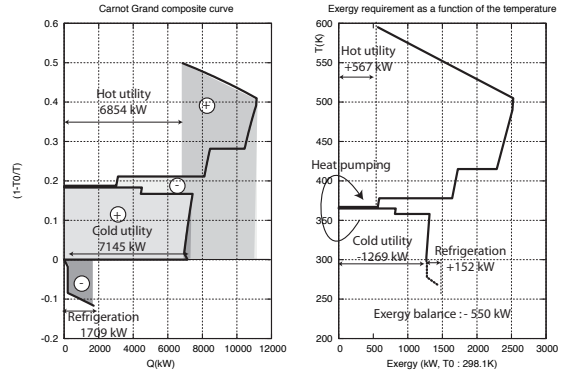

Figure 2: Exergy Grand composite curves of the process requirements

a heat sink to be supplied by a hot utility. Below the process pinch point and above the ambient temperature, the process is a heat source. Below the ambient temperature, the process requires refrigeration. The feasibility rule of the utility integration is that the Grand composite curve of the utility system should envelop the process Grand composite curve.

When considering the exergy Grand composite curve (figure 2,left), the process exergy requirement is defined by a difference of areas. In this diagram, it should be noted the special role of the self-sufficient pockets (right part of the graph), the area of which represents the possible mechanical power recovery by combined heat and power production. The composite curve on figure 2,right represents the cumulated exergy required by the process as a function of the temperature. The exergy balance shows an overall exergy availability. However, from the definition of the pinch point, it is necessary to divide the system into three sub-systems, considering the exergy balance for each of the systems. Comparing the energy requirement and the exergy requirement allows to set efficiency target for the energy conversion system. This exergy may be recovered partly by properly integrating combined heat and power devices (Rankine cycles), while exergy transfer between sub-systems will only be possible by heat pumping.

INTEGRATION OF ENERGY CONVERSION SYSTEMS

The integration of the energy conversion system aims at defining the complete list of streams to be considered including the hot and cold streams of the utility sub-system, prior any heat exchanger network design. The utility streams are defined so that they will minimise the cost of the energy requirement and/or make the best use of the process exergy. The calculation of the best system will start with the definition of a utility system superstructure that will include the possible conversion technologies that are envisaged. The analysis of the grand composite curve, applying the rules for optimal placement of Townsend et al. [9] and other rules for the optimal CHP integration, help in defining the list of energy conversion technologies able to supply the energy requirement of the process with a maximum of efficiency. In order to solve problems where several utilities are considered, MILP formulations have been proposed [2, 10]. The mathematical formulation (eq. 1) of the targeting problem exploits the concept of Effect Modelling and Optimisation (EMO) [3, 11]. It is used to select the equipments in the superstructure and determine their optimal operating flowrates in the integrated system. This approach assumes that the temperature and pressure levels of the energy conversion technologies are known. Two variables are associated with any utility technology w : the integer variables y_w represents the presence of the technology w in the optimal configuration and f_w its level of utilisation ($fmin_w \leq f_w \leq fmax_w$). The objective function is the total cost including the operating costs and the annualised investment cost, both expressed in $€/year$. Other objective functions like minimum operating cost or minimum of emissions may also be used. The annualising factor is computed knowing the interest rate i and the expected life time of the investment n_{years}.

$$\min_{R_r, y_w, f_w} \sum_{w=1}^{n_w} (C2_w f_w) + Cel_i Wel_i - Cel_s Wel_s) * t + \sum_{w=1}^{n_w} (C1_w y_w) + \frac{i(1+i)^{n_{years}}}{(1+i)^{n_{years}} - 1} \sum_{w=1}^{n_w} (ICF_w y_w + ICP_w f_w) \quad (1)$$

subject to

Heat balance of the temperature intervals

$$\sum_{w=1}^{n_w} f_w q_{w,r} + \sum_{i=1}^{n} Q_{i,r} + R_{r+1} - R_r = 0 \qquad \forall r = 1,...,n_r \quad (2)$$

Electricity consumption:

$$\sum_{w=1}^{n_w} f_w w_w + Wel_i - Wc \geq 0 \quad (3)$$

Electricity exportation

$$\sum_{w=1}^{n_w} f_w w_w + Wel_i - Wel_s - Wc = 0 \quad (4)$$

Existence of technology w

$$fmin_w y_w \leq f_w \leq fmax_w y_w \quad {}^{\forall w=1,...,n_w}_{y_w \in \{0,1\}} \quad (5)$$

Thermodynamic feasibility of the heat recovery and utility systems

$$Wel \geq 0, Wel_s \geq 0 \quad (6)$$

$$R_1 = 0, R_{n_{r+1}} = 0, R_r \geq 0 \qquad \forall r = 1,...,n_{r+1} \quad (7)$$

R_r $[kW]$ (r=1,n_r+1) is the heat cascaded from the temperature interval r to the lower temperature intervals, n is the number of process streams, Q_{ir} $[kW]$ is the heat load of the process stream i in the temperature interval r ($Q_{ir} > 0$ for hot streams), Wel_s and Wel_i are respectively the net production and net import of electricity $[kW]$; $C1_w$ and $C2_w$ are respectively the fixed and the proportional cost of using the technology w; ICF_w and ICP_w are respectively the fixed and the proportional cost related to the investment of using technology w. Although the formulation is linear, it allows this way to account for size effect in the investment; n_w is the number of technologies proposed in the utility system superstructure; q_{wr} is the heat load of the technology w in the temperature interval r for a given reference flowrate, ($q_{wr} > 0$ for a hot stream) ;w_w is the mechanical power produced by the reference flowrate of technology w; ($w_w > 0$ for a mechanical power producer); Cel_s and Cel_i are respectively the selling price and the import price of electricity $[€/kW]$; t is the total annual operation time $[s/year]$; Wc $[kW]$ is the overall mechanical power needs of the process; ($Wc < 0$ if the overall balance corresponds to a mechanical power production).

This method may be applied to any kind of energy conversion technologies. It is based on the assumption that the operating conditions have been defined for each of the equipment concerned and that only the flowrates are unknown. This is a limiting assumption but it allows to solve most of the problems of energy conversion integration mainly because non linearities may usually be solved by discretising the search space. The method has been further adapted to compute the optimal integration of steam networks [12], to incorporate restricted matches constraints [13], to integrate refrigeration cycles [14] and Organic Rankine Cycles[15] as well as heat pumps [16].

The grand composite curve resulting from the optimisation is the balanced composite curves. An example of such curves is given on figure 3, left. This representation is characterised by a number of pinch points, one being the process pinch point, the others corresponding to the maximum use of the cheapest utilities to satisfy the process requirement. In the Carnot representation (figure 3, right) the area between the curve and the Y-axis represents the exergy losses in the system heat transfer. Two curves are presented, the external one represents the overall exergy losses, while the internal one that feature pinch points represents the one computed with the corrected temperatures. The area between the two curves represents therefore the exergy losses relating to the assumptions of the $\Delta T_{min}/2_j$ contributions of the streams. Analysing the inner curve allows to identify further improvement for the energy conversion by modifying for example the operating conditions (pressures or temperatures) in the energy conversion technologies. Integrated composite curves [17] may be used to analyse the integration of subsystems in the process. The figure 4 shows for example the integration of the steam network in the system under study. The energy balance of the hot and cold streams of the steam network is the net mechanical power production. When appropriately placed, it corresponds to a supplement of energy to be supplied to the system. The fact that it appears on the left of the temperature axis proves that the steam network characteristics are appropriate for the optimal production of mechanical power. In the Carnot factor ordinate, the area between the two curves gives an indication of the quality of the exergy use in the corresponding sub-system.

One heuristic rule resulting from the exergy analysis is to try to reduce to a minimum the area between the hot and cold composite curves of the integrated

systems including the energy conversion system.

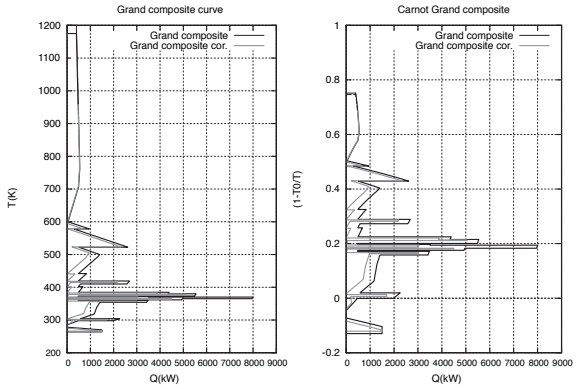

Figure 3: Balanced Grand composite curves of the integrated system

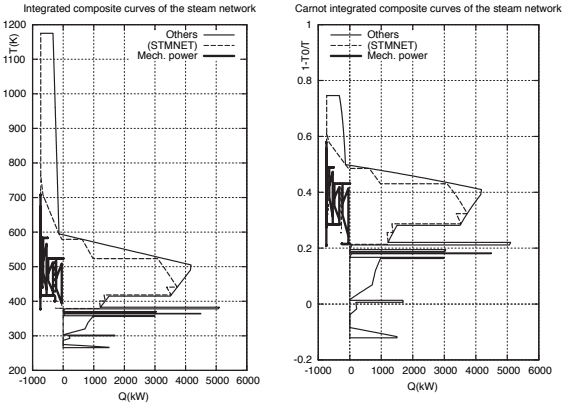

Figure 4: Integrated composite curves of the steam network

Using the exergy losses as an objective function

Due to the linear nature of the problem, the use of the energy cost as an objective function may reveals some difficulties [16]. When the cost of fuel and electricity is such that the electrical efficiency of a cogeneration unit is attractive without the use of heat (i.e. when the electrical efficiency of the unit $\eta_{el} = \frac{W_{el}}{LHV_{fuel}}$ is greater than $\frac{C_{LHV}(€/kJ)}{C_{el}(€/kJ_e}$)) there is an economical interest to produce electricity even without cogeneration). In this case, the linear programming procedure leads to a situation where the cogeneration unit is used at its maximum. This situation usually does not occur when the investment cost are properly considered or when the cost of the different forms of energy are coherent with respect to the electrical efficiency. Nevertheless, the relative price of the different forms of energy will influence the technology selection and their level of usage in the integrated solution. When the target is the maximisation of the system efficiency, alternative formulations that take into account the value of energy in the objective functions have to be considered. The minimisation of the exergy losses (eq. 8) is an alternative way of formulating the objective function.

$$\underset{R_k, y_w, f_w}{Min} \sum_{w=1}^{n_w} (f_w * (\Delta Ex_w - \sum_{k=1}^{n_k} \Delta ex_{wk} + w_w)) \qquad (8)$$

In this relation, ΔEx_w is the exergy consumed to produce the hot and cold streams and the electricity of the conversion unit w, Δex_{wk} is the heat-exergy supplied by the ns_w hot and cold streams of the conversion unit w in the temperature interval k. Δex_{wk} is given by (9).

$$\Delta ex_{wk} = \sum_{s=1}^{ns_w} q_{sk} * (1 - \frac{T_a * ln(\frac{T_{k+1}+\Delta T_{min}/2_s}{T_k+\Delta T_{min}/2_s})}{T_{k+1} - T_k}) \qquad (9)$$

Using this formulation, it is possible to define the set of energy conversion technologies that minimises the exergy losses of the system. It is even possible to introduce the aspects related to the investment by adding the grey exergy into the ΔEx_w term.

EXAMPLE

Let us consider the system requirements defined on table 1. These result from the hot and cold composite curves of figure 1 and the Grand composite curve of figure 2. For the calculations, we assumed that all the possible process improvements were already implemented before analysing the energy conversion technologies integration.

Table 1: Minimum energy and exergy requirements of the process

	Energy	Exergy
Heating (kW)	+6854	+567
Cooling (kW)	-6948	- 1269
Refrigeration (kW)	+1709	+ 157

Several optional energy conversion system configurations are studied, the results are summarized in table 5 where the energy consumption of the energy

conversion sub-systems are presented. The simplest solution (option 1) is to integrate a boiler using natural gas (with a LHV of 44495 kJ/kg) and to cool the process with cooling water. The refrigeration needs will be supplied with a refrigeration cycle using ammonia (R717). The operating conditions of the refrigeration cycle (table 2) have been obtained by simulation considering the temperature levels in the composite curve and the ΔT_{min} to be reached in the heat exchangers. The integrated composite curves presenting the results of the optimisation are presented on figure 5 (left). The refrigeration cycle consumption is of 314 kW corresponding to an exergy efficiency of 50 %. It should be noted that the energy consumption is higher than the MER due to the losses at the boiler stack (398 K). The solution accounts for the possibility of air preheating to valorise the energy excess available in the process. The heat load of air preheating is of 131 kW. In order to valorise the exergy potential, a steam network has been integrated (Option 2). The steam network headers are given on table 3, the isentropic efficiency of the turbines are assumed to be of 70 %.

Table 2: Refrigeration cycle characteristics

Refrigerant			R717	Ammonia	
Reference flowrate			0.1	kmol/s	
Mechanical power			394	kW	
	P	T_{in}	T_{out}	Q	$\Delta T min/2$
	(bar)	(°K)	(°K)	kW	(°K)
Hot str.	12	340	304	2274	2
Cold str.	3	264	264	1880	2

Applying the rules of the appropriate placement of heat pumping devices, 3 heat pumping cycles have been proposed and simulated (table 4).

The high values of the COP are explained by the very small temperature raise to be obtained from the heat pump when considering small $\Delta T_{min}/2$ values for the heat exchangers. Using the optimisation tool, the optimal flowrates in the three cycles have been computed together with the new value of the fuel in the boiler house (Option 4). In the example considered, this leads to a situation where the whole heat requirement may be provided by the heat pumps. When the steam network is considered together with the heat pumps (Option 5), the results are slightly

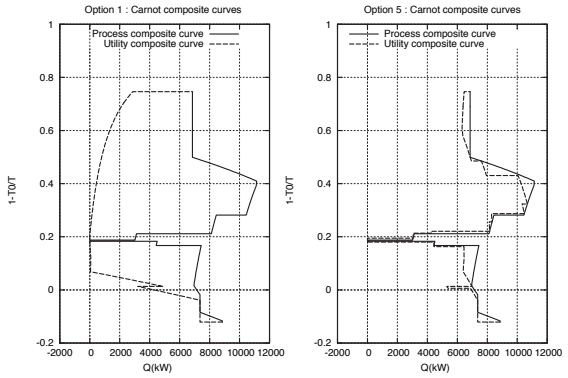

Figure 5: Carnot integrated composite curves of the energy conversion system for options 1 (left) and 5 (right)

different since in this case, an additional amount of energy is required by the system to balance the mechanical power produced by expansion in the steam network. The solution of heat pumping is then compared with a combined heat power production using a gas turbine (Option 3). In this situation, the two options are conflicting.

Energy and Exergy efficiency

The summary of the energy conversion system integration is given on table 6. It is shown that a MER of 6854 kW for the heating requirement and of 1709 kW for the refrigeration requirement is finally supplied with an equivalent 893 kW of fuel when considering the possibility of heat pumping and when converting the exergy content of the process streams. Compared to the boiler house solution, the new situ-

ation corresponds to a reduction by a factor 8 of the fuel consumption. These data have been computed by considering a fuel equivalence of 55% for the electricity production (column Total 1). The order of the solutions will be different if we consider the European mix (38.7%) for the fuel equivalence (Table 6, column Total 2). In order not to rely on the definition of a fuel equivalence, an exergy efficiency η_{ec} of the energy conversion system will be computed considering the exergy of the process. In this definition, we consider that the energy services delivered, i.e. the process exergy requirement ($E_{heat} + E_{frg}$) and the export of electricity (Wel_s), will be satisfied with an efficiency of η_{ec} leading to an exergy consumption of $\frac{E_{heat}+E_{frg}+Wel_s}{\eta_{ec}}$, while the exergy excess (E_{cool}) will be converted with an efficiency of η_{ec}. The balance (eq. 10) is equal to the energy resources ($E_{res} = f_{fuel} * e_{fuel} + Wel_i$) converted in the energy conversion system. Solving (10) gives the definition of the exergy efficiency of the system (eq. 11). In Table 6, it can be seen that the options that do not convert the exergy excess (E_{cool}) have smaller exergy efficiencies. The best solutions are the one that realise heat pumping that "pump" the excess of exergy from below to above the pinch point.

$$E_{res} = \frac{E_{heat} + E_{frg} + Wel_s}{\eta_{ec}} - E_{cool} * \eta_{ec} \qquad (10)$$

$$\eta_{ec} = \frac{E_{res} - \sqrt{(E_{res})^2 + 4E_{cool}(E_{frg} + E_{heat} + Wel_s)}}{-2E_{cool}} \qquad (11)$$

CONCLUSIONS

The application of the exergy concept combined with pinch based methods for analysing the optimal integration of energy conversion system of industrial processes has been studied. The exergy composite curves is used to compute the minimum exergy requirement of the process, considering the pinch point location. The exergy requirement is obtained by first considering an exergy loss resulting from the definition of the ΔT_{min}. The remaining exergy requirement is divided into three contributions: the exergy required above the pinch point, the exergy produced as energy excess between the pinch point and the ambient temperature and the exergy required for refrigeration. Starting with an energy conversion system superstructure, a linear programming formulation is used to extract the optimal energy conversion system configuration that supplies the process energy requirement and that integrates the combined heat and power production and the heat cascade. In this formulation, it is possible to use either the energy cost or the exergy losses as an objective function. The exergy balanced composite curves and the exergy integrated curves are used to visualise the exergy losses in the system. The exergy efficiency of the conversion system is defined by comparing the exergy resource consumption with the exergy export and the process exergy, making the distinction between the exergy available and the exergy required. This efficiency definition sets the focus on the ex-

ABSTRACT

Integrated Energy Systems (IES) combine a distributed power generation system (DG) such as a microturbine generator (MTG) or a fuel cell with thermally activated technologies (TAT) such as absorption cooling. This integration maximizes the efficiency of energy use by utilizing on-site most of the waste heat generated by DG, and reduces harmful emissions to the environment.

This study investigates the energy and exergy performance of an IES. This system is comprised of an MTG with internal recuperator and a novel absorption cooling cycle. The absorption cycle is a single effect-double effect exhaust fired cycle, which increases the heat exchanged from the MTG exhaust gases using two generators at two different levels of temperature.

The selection of the DG element, the TAT element and their internal configurations is based upon a real IES commercial unit that has been tested in the APEP-UCI DG testing facilities in Irvine, California. This unit has an electrical power capacity of 28 kW and a cooling capacity of 14 refrigeration tons (49.2 kW).

Inputs for the thermodynamic models developed for the MTG and for the absorption cycle are derived from experimental variables that will be controlled in the testing phase. The MTG model is using empirical correlations for key model parameters (pressure ratio, turbine inlet temperature, etc.) from previous studies in order to predict the observed change in performance with part load operation. The calculated mass flow rate and temperature of the exhaust gases are inputs for the absorption cycle model, together with cooling and chilled water inlet temperatures and flow rates. Heat and mass transfer efficiencies along with heat transfer coefficients for the suite of heat exchangers comprising the single-double effect absorption cycle are determined from proprietary testing data provided by the manufacturers.

INTRODUCTION

Integrated Energy Systems (IES) combine a distributed power generation system (DG) such as a microturbine generator (MTG) or a fuel cell with thermally activated technologies (TAT) such as absorption cooling, water heating, or desiccant dehumidification. Other acronyms often used in the literature to refer to the same IES concept are CHPB (cooling, heating, and power for buildings), BCHP (building cooling, heating, and power) and CCHP (combined cooling, heating, and power). This integration maximizes the efficiency of energy use by utilizing on-site most of the waste heat generated by DG, and subsequently reduces harmful emissions to the environment.

In the past decades the implementation of an IES in a particular facility involved the selection and purchase of the disparate components of an IES (i.e.: the prime mover, the heat exchanger, the chiller), followed by a customized, rather costly installation onsite. However, the current trend of Japanese and US DG manufacturers is to develop pre-engineered packaged units that will significantly reduce costs, boost system efficiency, and simplify the installation process to the point of a plug-and-play process. This integration will likely encourage many building and industry owners to adopt IES rapidly [1]. Some integrated products are in the development phase, and a few are already commercial.

The Advanced Power and Energy Program (APEP) at the University of California, Irvine (UCI) has developed a test rig facility in order to test and evaluate the operational and emissions performance of both DG power-only and IES units. After several years of experience with power-only and CHP tests of MTGs from several manufacturers [2], the first tests with a CCHP commercial unit will be accomplished in 2005. This IES unit is manufactured by Takuma Company, Ltd. for the Japanese market and consists of a 28 kW MTG with recuperator and a novel single effect-double effect exhaust fired absorption chiller with a cooling capacity of 14 refrigeration tons (49.2 kW) and a nominal coefficient of performance (COP) of 1.

As a first step prior to the test phase, thermodynamic models for the MTG and the chiller integrating characteristics of the commercial unit were developed. The purpose of this paper is to present these models and to investigate the energy and exergy performance of the integrated energy system at different operating conditions.

DESCRIPTION OF THE INTEGRATED ENERGY SYSTEM TO BE TESTED

The IES commercial unit to be tested consists of a MTG element, Takuma TCP30 model, and an exhaust fired absorption chiller/heater element, Takuma EGT-15 model.

The first element is a 30 kW capacity single-shaft turbine with recuperator manufactured by Capstone Turbine Corporation. This assembly uses air bearings, has a rotating speed of 96000 revolutions per min, and has a permanent magnet type high-speed generator [3].

The absorption chiller/heater is a single effect-double effect exhaust fired unit with 49.8 kW of heating capacity and 49.2 kW (14 refrigeration tons) of cooling capacity and uses the system

water-LiBr as working fluid mixture. The single-double effect cycle used in this chiller increases the heat exchanged from the MTG exhaust gases using two generators at two different temperature levels. The exhaust gases leaving the high temperature generator of the double effect cycle can then be further utilized to drive the single effect cycle and produce an extra cooling effect.
The exhaust gases from the MTG are directed to the absorption chiller through insulated ducting to minimize losses. Figure 1 shows a picture of the Takuma IES unit already located in APEP's test facilities. Figure 2 presents a schematic flowchart with energy fluxes of the MTG and the absorption chiller integrating the unit.

Figure 1: IES unit installed in APEP's test facilities (4th and 5th units starting from bottom to top of picture).

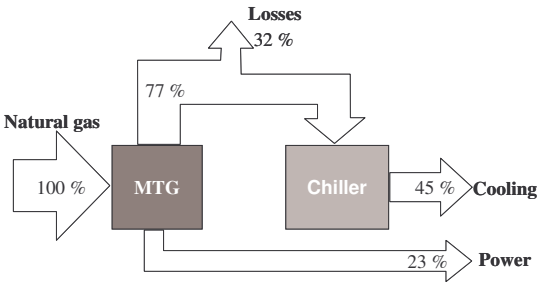

Figure 2: Schematic heat fluxes of the MTG and the absorption chiller cycle integrating the IES unit working in cooling mode.

MICROTURBINE

Thermodynamic cycle

Figure 3 shows the components of the microturbine generator that are included in the thermodynamic model. The air entering the MTG (state point 1) is compressed in the air compressor to state point 2. Then, air goes to the recuperator, where it is heated by the heat of the rejected exhaust gases (state point 3). Air enters with compressed natural gas into the adiabatic combustion chamber. The resulting high temperature combustion gases (state point 4) are then fed to the gas turbine, where they are expanded from state point 4 to state point 5. After the turbine, the rejected gases flow through the recuperator where heat is transferred to incoming air. The temperature of the exhaust gas downstream of the recuperator is still high enough to drive an absorption cycle, as explained in next section.

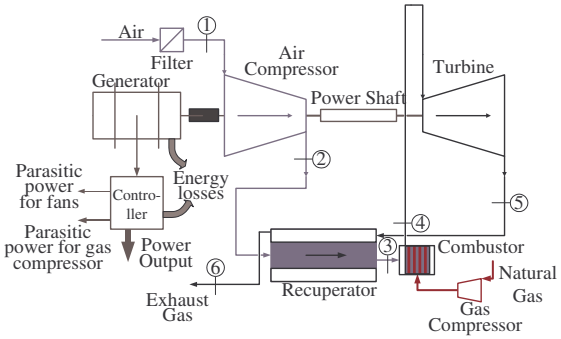

Figure 3: Schematic of the microturbine generator process.

MTG Simulation Methodology

A thermodynamic model was developed for the MTG using the program Equation Engineering Solver (EES). Most of the mathematical equations used to describe the cycle can be found elsewhere [4]. The combustion process is not treated as a black box, however. The chemical reaction between the fuel and the air in the chamber is modeled and excess air and exhaust gases compositions are obtained. Some input parameters of the cycle (air compressor and turbine isentropic efficiencies, recuperator efficiency, combustor efficiency, and fuel compressor isentropic efficiency) were determined on the basis of manufacturers' data at full load conditions, and were assumed constant for the operating range

studied. To account for changes in performance of the MTG unit with part-load operation some other parameters (i.e. turbine inlet temperature, pressure ratio, recuperator heat loss coefficient, generator heat losses, and controller heat losses) were correlated to net power output using literature experimental data for the same MTG unit [4].

Input data are presented below. The first three parameters will vary during the future experimental testing process and their effect on the performance parameters will be analyzed. The rest are assumed constant for the range of operating conditions investigated:

- Net power output
- Air inlet temperature
- Fuel inlet temperature
- Air compressor isentropic efficiency
- Turbine isentropic efficiency
- Recuperator efficiency
- Combustor efficiency
- Fuel compressor isentropic efficiency
- Inlet compressor pressure

Output data are:

- Pressures, temperatures, gas compositions, mass flows, enthalpies, entropies, exergies of the flows
- Mechanical or thermal power and irreversibility rate of the main components
- Electric efficiency of MTG based on natural gas higher heating value (HHV)

The principal assumptions of the MTG model are:

- No pressure losses
- No heat losses in turbine, compressors and combustion chamber
- Natural gas is treated as pure methane
- Air, methane and combustion gases are treated as ideal gases

ABSORPTION CHILLER

Thermodynamic Cycle

The novel configuration of the single-double effect absorption cycle shown in Figure 4 combines a series flow double effect cycle with a single effect cycle. Detailed description of the separated cycles can be found elsewhere [5].

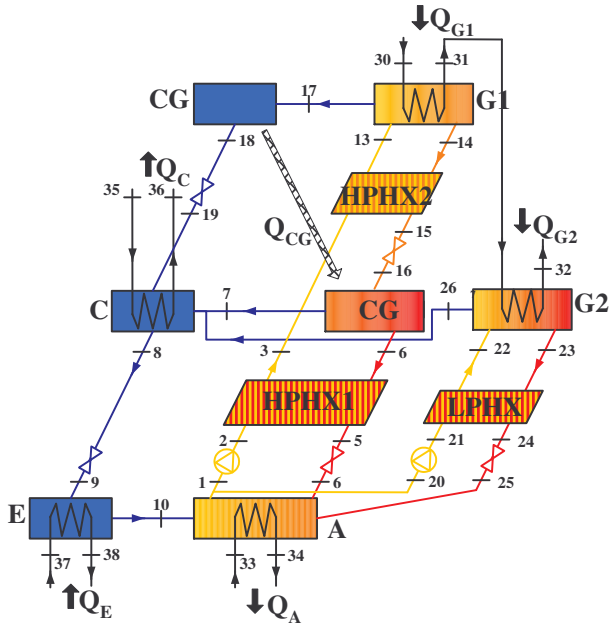

Figure 4: Components, state points and heat exchanges of a single-double effect absorption cycle.

Both cycles share common components, namely the absorber, the evaporator, and the condenser. The single-double effect cycle is comprised of 9 main components. The names of each of the components, the cycle they belong to, and the abbreviations used in Figure 4 are shown in Table 1.

Abbreviation	Complete Name	Belongs to
A	Absorber	Single & Double effect cycles
C	Condenser	Single & Double effect cycles
CG	Condenser-Generator	Double effect
E	Evaporator	Single & Double effect cycles
G1	High Pressure Generator	Double effect
G2	Low Pressure Generator	Single effect
HPHX1	High pressure solution heat exchanger 1	Double effect

HPHX2	High pressure solution heat exchanger 2	Double effect
LPHX	Low pressure solution heat exchanger	Single effect

Table 1: Abbreviations used in Figure 4.

The following heat transfers take place with external fluids. Heat is supplied at high temperature (270-280 °C) in generator G1 from the exhaust gases exiting the MTG. After G1, the relatively lower temperature gases (160-170 °C) supply extra heat in generator G2, which drives the single effect cycle and provides extra cooling (Figure 5).

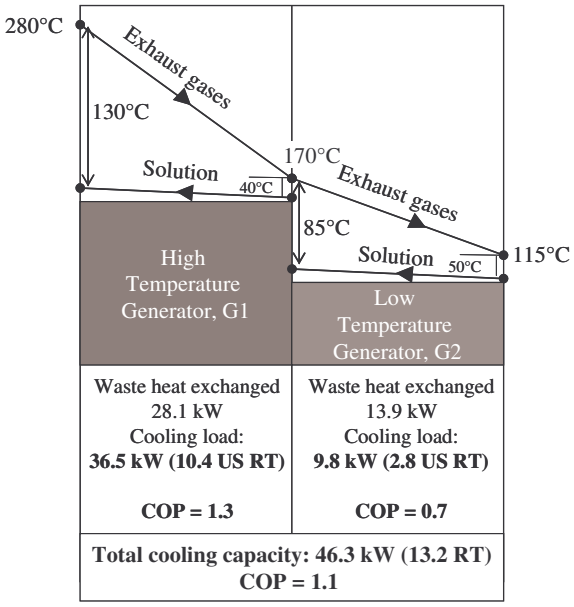

Figure 5: Temperature distribution and heat exchanged of exhaust gases in the two generators of the EGT15 chiller.

This novel cycle arrangement enables a better utilization of the MTG exhaust gases exergy. Heat is dissipated in absorber A and condenser C to cooling water in a series flow arrangement of cooling water. Chilled water is produced in the evaporator E.

Internal heat is transferred from condensing refrigerant vapor to the absorbent solution in the condenser-generator assembly CG. In the CG, part of the refrigerant is evaporated from the incoming solution on the cold side. On the hot side superheated refrigerant vapor is condensed. Between hot and cold solution streams heat is recovered in the solution heat exchangers HPHX1, HPHX2 and LPHX. The absorbent solution is in a series flow arrangement. The rich-in-water solution leaving the absorber A is preheated by the solution heat exchangers and then directly enters the generator G1. Now the rich-in-water solution will be gradually concentrated in salt in the different generators G1 and CG.

Chiller Simulation Methodology

A computer code for the simulation of the cycle has been established using the program EES. Properties for water-LiBr are integrated in EES, except the specific entropy, which has been calculated following Kaita [6]. The specific exergy calculation is given by Misra et al. [7].

Some input parameters in the model coincide with the experimental variables that will be controlled in the experimental testing phase. Others such as mass exchange efficiencies along with heat transfer coefficients for the suite of heat exchangers comprising the cycle are determined from proprietary manufacturer's testing data at nominal conditions and are assumed constant for the studied working range. The list of input variables of the model is presented below:

- Inlet temperatures and flow rates of external fluids.
- Temperature difference for subcooling in condensers and superheating in evaporator.
- Overall heat transfer coefficients in heat and mass exchangers.
- Mass exchange efficiencies, η_m, defined as:

$$\eta_m = \frac{X_{out} - X_{in}}{X_{eq,out}(T_{out}, P_{out}) - X_{in}} \quad (1)$$

- Percentage of heat loss in exhaust gas-driven generators, α.
- Ratio of outlet absorber solution flow rate to double effect cycle over flow rate to single effect cycle, f.

The same type of output data for each state point presented above for the MTG model is also obtained for the chiller model. The principal performance parameter for the absorption chiller is the COP. This parameter is defined as the ratio

of driving heat supplied by exhaust gases in generators G1 and G2 over cooling produced:

$$COP = \frac{Q_E}{Q_{G1} + Q_{G2}} \quad (2)$$

Principal assumptions of the chiller thermodynamic model are:

- The refrigerant vapor leaving the evaporator is pure water.
- Exhaust gas fired generators operate in cross-current flow.
- No liquid carryover from evaporator
- The solution and refrigerant valves are adiabatic
- No heat losses
- No pressures losses

Exergy Analysis

Assessment of overall IES efficiency based on exergy efficiency is recommended ([8], [9]), as this approach takes into account the disparate energy qualities of the driving natural gas chemical energy, the electric power generated in the MTG, and the cooling produced in the single-double effect absorption chiller. The exergy efficiency is defined as the useful exergy output divided by the exergy input, enabling us to compare cycles with different types of energy inputs. For the selected IES the exergy efficiency can be expressed as:

$$\Psi_{IES} = \frac{\dot{E}_{chw} + \dot{E}_{MTG}}{\dot{E}_{fuel}} = \frac{m_{chw}(e_{out} - e_{in})_{chw} + W_{MTG}}{m_{fuel} LHV \cdot 1.04} \quad (3)$$

The expression for exergy flow of natural gas ($\dot{E}_{fuel}$) is taken from Kotas [9].

RESULTS AND DISCUSSION

MTG model results show good agreement with manufacturer's nominal values at full load and with literature experimental values at part load performance [4]. Figure 6 shows predicted values for electric efficiency (based on the HHV of natural gas), and mass flow rate and temperature for the exhaust gases leaving the recuperator, all as a function of MTG net power output. These last two output variables, which characterize the heat content of the waste heat stream, are used as inputs in the chiller model and have a significant effect on the performance of the chiller. As some parasitic losses such as fan electric motors are practically independent of power output, electric efficiency decreases slightly with decreasing power outputs. Both air flow rate and natural gas flow rate (not shown) vary in a fairly linear fashion with MTG output power. The non-linear increase of exhaust gas temperature with output power responds to the empirical correlation of inlet turbine temperature as a function of power used as an input to the model.

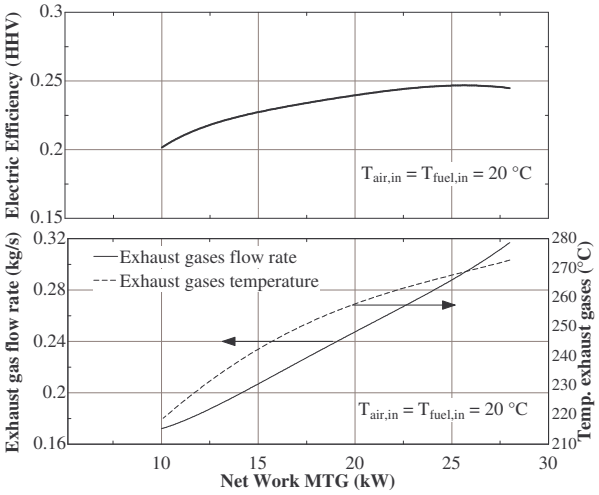

Figure 6: MTG electric efficiency based on HHV (above) and exhaust gases flow rate and temperature (below) versus net MTG power output.

The MTG model also predicts well the expected reduction in electric efficiency with an increase in ambient air temperature (not shown).

Figure 7 presents predicted results for chiller cooling load and coefficient of performance as a function of inlet chilled water temperature when the MTG is operating at full load and cooling water temperature is at nominal conditions. Similarly, Figure 8 shows how the same performance parameters are affected by inlet cooling water temperature. An increase of inlet chilled water temperature with constant intermediate level temperature or a decrease of inlet cooling water temperature with constant low temperature level both result in higher COPs and higher cooling loads. This is due to the decrease in the temperature lift between low and intermediate temperature levels, which is

thermodynamically more favorable. The study of the effect of cooling water temperature is limited to values above 26.5 °C as lower temperatures lead to crystallization of LiBr for the solution streams at the absorber inlet (state points 5 and 24 in Figure 4).

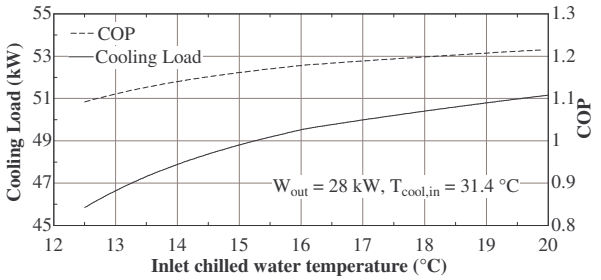

Figure 7: Effect of chilled water inlet temperature on chiller cooling load and on COP for full load MTG conditions.

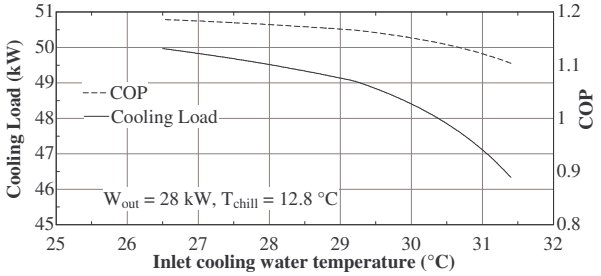

Figure 8: Effect of cooling water inlet temperature on chiller cooling load and on COP for full load MTG conditions.

Unlike the MTG model, which includes empirical correlations of some parameters to account for the control strategy of the real unit, these types of correlations are not available for the chiller model. This means that the model is predicting how the chiller would behave if no controls had been implemented. For that reason predicted results for chiller performance at part load MTG operating conditions (Figure 9) are restricted to a very narrow range (25.6-28 kW). With mass flow rates and temperatures of the exhaust gases corresponding to MTG loads below 25.6 kW the model predicts crystallization will occur at solution stream 24, which leaves the solution heat exchanger of the single effect cycle. The control devices implemented in the real unit prevent crystallization by changing flow rates and, according to manufaturer's data, should enable some cooling production at MTG part load performances as low as 15 kW. However, Figure 9 estimates correctly the expected trends of decreasing cooling capacity with decreasing MTG power output.

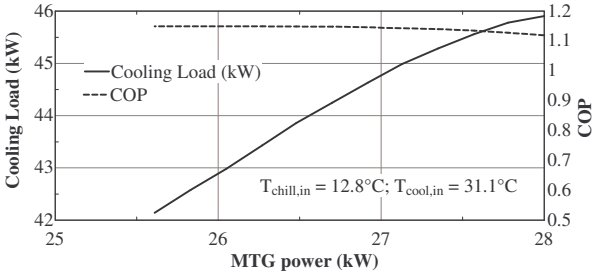

Figure 9: Effect of MTG power output on chiller cooling load and on COP.

Energy efficiencies have been assessed individually for the MTG cycle and the absorption cycle that integrate the IES presented in this study. The exergy efficiency is applied to compare overall efficiencies of three similar IESs that vary in the configuration of the chiller. The chiller absorption cycles chosen are the single-double effect studied in this work, the single effect cycle and the double effect cycle. The MTG power is the same for the three IESs. presents exergy results for the three IES configurations. As expected, the IES with the novel single-double effect absorption cycle is the one with the highest overall exergy efficiency, as it produces the largest cooling for the same amount of natural gas driving energy.

CONCLUSIONS

A theoretical analysis of a commercial integrated energy system consisting of a microturbine and an absorption chiller was presented as a first step for planning and executing performance tests of the real unit at the APEP DG-IES test facility. Steady-state models for the MTG and the chiller were developed and results analyzed. The principal findings of this study are:

- The MTG model predicts that the electrical efficiency, as well as the exhaust gas flow rate and temperature increase with power output, in good agreement with published experimental data.

	IES with Single-Double effect chiller	IES with Double effect chiller	IES with Single effect chiller
m_{fuel} (kg/s)	0.0027	0.0027	0.0027
$\dot{E}_{fuel}$ (kW)	106.6	106.6	106.6
$\dot{E}_{MTG}$ (kW)	28	28	28
Cooling (kW)*	46.2	37.6	29.4
$\dot{E}_{chw}$ (kW)	2.35	1.91	1.49
Ψ_{IES}	0.285	0.281	0.277

* Cooling refers to an energy flow and not to an exergy flow.

Table 2: Determination of overall IES exergy efficiencies with three different cycle configurations for the absorption chiller.

- The absorption chiller model predicts the increase of COP and cooling load with increasing chilled water temperatures and decreasing cooling water temperatures, with maximum COPs above 1.2.
- Part load performance of the chiller is not accurately represented by the current model. The absorption chiller model should be improved with empirical correlations obtained in the future test phase to take into account chiller crystallization and part load controls.
- The overall exergy efficiency of the studied IES with the novel chiller using a single-double effect absorption cycle is higher than the ones resulting from the same MTG and exhaust gas fired single or double effect chillers.

The second part of this project is the actual performance evaluation of the commercial IES. Preliminary results of this test phase will be presented in a second paper.

ABSTRACT

This paper describes the application of a set of advanced composite curves to evaluate the potential to release usable excess heat (hereafter referred to as Q_{xs}) from an existing process industry. Throughout this paper Q_{xs} is defined as heat at enough high temperature to be interesting for use e.g. for district heating. Studies using the advanced curves reveal information about the existing HEN that traditional graphical methods are not able of, and that for almost the same collected information from the process. This allows for estimations on the heat recovery potential and existing pinch violations before detailed calculations.

These curves have earlier been presented in connection with integration of CHP, HP and retrofitting HEN's. The curves have also been used to evaluate the Q_{xs} potential in one doctoral thesis, but the methodology was not explained in detail, but rather used as a tool among many.

In this paper we broaden the discussion on how to use the curves, which traps there might be and how to interpret and use the results.

Important questions that are answered are for example:

- How does the Q_{xs} potential change when the pinch temperature changes?
- At which temperature is it possible to release Q_{xs}?
- How could the Q_{xs} be made available?
- How can the Q_{xs} potential be revealed?

Keywords: Advanced composite curves, Pinch technology, Process integration

INTRODUCTION

Process energy savings have been high listed on plant managements' agenda since the oil crisis in the 1970's. In the years following, the first systematic methods for energy savings appeared [1-3], and during the 1980-1990's a number of methods developed, using pinch technology, mathematical programming or exergy analysis. Global warming due to anthropogenous release of greenhouse gases has later become an important issue. The reduction of fossil fuel use is becoming increasingly important in an economic perspective due to CO_2 emission trading systems [4]. For industries using biofuels, energy reductions could lead to incomes from sold released biomass. Revamp of plants is a highly complex task, including evaluation of many different measures that some time compete, some time have synergistic effect. In most cases not only one measure is considered, but rather a combination of different measures.

All this motivates for finding methods that are even better than existing in finding cost-effective energy recovery potentials, and could take many different measures into consideration.

This paper present results from work by the authors [5, 6] in HEN retrofit, and by Nordman and Bengtsson [7] in the area of assessing the

potential for releasing usable excess heat. The paragraphs about HEN retrofit and HP and CHP integration should be seen as an overview of the usefulness of the advanced curves.

EARLIER WORK

Pinch analysis have for the last decades provided new modes for analysing energy systems systematically. Most of the techniques developed origin from grass-root design and analysis, where no existing equipment constrain the potential for energy recovery projects. Methods that take existing equipment (heat exchangers) into consideration are the α-method [8], the path analysis method [9], the RTD method [10, 11] and the network pinch concepts [12]. The Matrix method [13] also takes piping cost, which can be a large part of a retrofit, into consideration. These methods are all specific for HEN retrofit. At Chalmers, a graphical method, consisting of advanced composite curves, for analysing energy systems in retrofit situations have been developed. These curves have proven useful not only for HEN retrofitting [5] but also for integration of Heat Pumps (HP) [14] and Combined Heat and Power (CHP) [15].
In this paper, the curves' ability to predict the potential to release usable excess heat, Q_{xs}, is presented. Integration of HP and CHP is also discussed briefly.

ADVANCED COMPOSITE CURVES

Construction of the Advanced Curves and Differences from "Traditional" Curves

The method uses four composite curves above and below the pinch respectively.
Only the construction of the curves above the pinch is explained, the curves below the pinch are constructed in the same way as described for the curves above pinch.
The four curves above the pinch are called Hot Utility Curve (HUC), Theoretical Heat Load Curve (THLC), Actual Heat Load Curve (AHLC) and Extreme Heat Load Curve (EHLC). The corresponding names below the pinch is Cold Utility Curve (CUC), Theoretical Cooling Load Curve (TCLC), Actual Cooling Load Curve (ACLC) and Extreme Cooling Load Curve (ECLC).

The Hot Utility Curve (HUC) is a composite curve of the *utility* streams in the existing heaters plotted at real temperatures. Correspondingly, the Actual Heat Load Curve (AHLC) is a composite of the parts of the *process* streams that run in the existing heaters.

The EHLC shows the temperatures where heat would be supplied if the heat exchange were carried out so that all external heat was supplied at the highest possible temperature (with the same Q_H as the AHLC). This corresponds to the overshooting part of the cold CC. Traditional grass-root theory refers to this as vertical heat exchange (provided all streams have the same heat transfer coefficient).

The THLC shows the lowest possible temperatures where heat would be supplied if all thermodynamic possible measures for energy conservation had been used (for the present Q_H) with a given EMAT (<HRAT). The THLC should be plotted with as low EMAT that would be acceptable when building a new heat exchanger, e.g. 5K according to Gundersen [16]. Theoretical minimum could of course be 0K, but that would yield unrealistic targets in practice. The THLC can therefore be seen as a GCC for the process, but plotted with ΔT_{min} = EMAT instead of ΔT_{min} = HRAT although Q_H is set the same as for ΔT_{min} = HRAT, with the pockets removed, and plotted at real temperatures. It is important to notice that the Q_H is the same as for the actual ΔT_{min} (= HRAT), but that the heat demand is now at lower temperatures. The difference in Q_H between systems of ΔT_{min} = EMAT and ΔT_{min} = HRAT corresponds to the amount of heat that could be saved in a correct built network when the ΔT_{min} decreases from the actual value (HRAT) to ΔT_{min} = EMAT. The construction of the THLC requires that the problem be not divided in the pinch. The reason is when HRAT is greater or much greater than EMAT, there is a possibility to successively shift heat from below the pinch to above, until ΔT_{min} = EMAT is reached. This amount of heat could ultimately be saved as utility; therefore it is plotted at the utility temperature level. When multiple utility levels are present it is not obvious which of the utility levels should be chosen. This is discussed further below.
The major difference between the advanced curves and traditional curves is that information

about the existing network structure is included in the advanced curves via the HUC/CUC and the AHLC/ACLC. Construction of these curves requires gathering of information on both utility and process streams in heaters and coolers. This is however the only additional information that is needed compared to traditional methods, but allows for more details in the analysis of measures, both stand-alone and combinations of measures.

The fact that the curves are all plotted at the real temperatures removes any hesitation that occur when measures is integrated versus the GCC, e.g. the correct integration temperature of HP and CHP is directly assessed.

Four possible measures are discussed in this paper, increased heat recovery by heat exchange, HP, CHP and introduction of new processes using excess heat from the existing process.

APPLICATIONS

Figure 1 shows an example of a network, Figure 2 shows all the corresponding advanced curves and Figure 3 shows the CC with the parts that constitutes the EHLC and ECLC indicated.

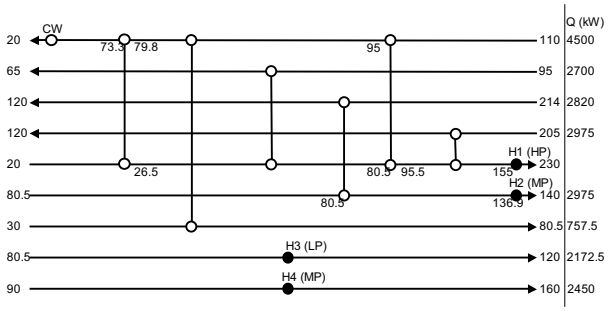

Figure 1: Grid diagram of the HEN in example 1.

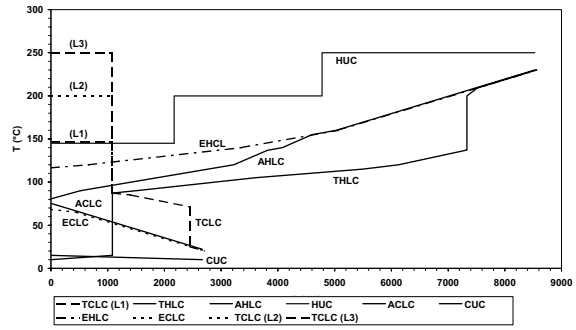

Figure 2: Advanced Curves for Example 1.

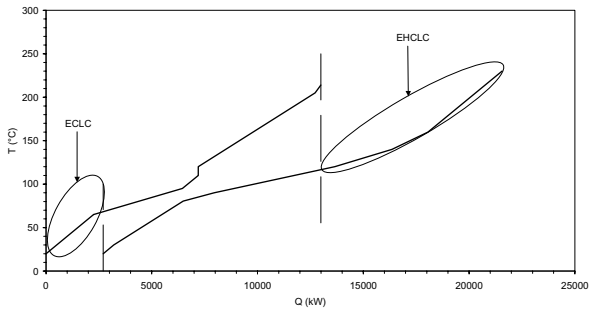

Figure 3: Composite Curves for Example 1, showing the EHLC and ECLC.

HEN Retrofit

The intersection between the THLC and the TCLC gives the practical heat saving potential by increased heat recovery. The amount of heat to the left of the intersection corresponds to the pinch violations that would be possible to remove when lowering the Q_H from present HRAT to HRAT = EMAT. It has been shown that it is not always economically feasible to remove all pinch violations [13], instead, one could evaluate the portion of the pinch violations that could be removed by HEN retrofit, given a certain PBP (Figure 4). By this approach, some pinch violations may be left unchanged, but this heat could be used for other measures as discussed below.

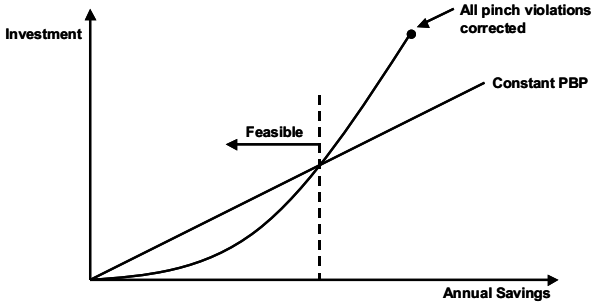

Figure 4: Investment cost vs Annual Savings Plot.

By plotting the EHLC, the AHLC and the THLC, the temperature-wise limits as well as the actual placement of heaters is shown. The AHLC cannot lie outside the EHLC, and generally not outside the THLC (unless a very small approach temperature is used in existing heat exchangers). It has been shown that it is relatively cheaper to save one unit of heat when the AHLC lies close to the THLC. When the AHLC closes in on the EHLC, the cost per saved unit heat increases, sometimes drastically. Heaters placed low in

temperature should therefore generally be considered for retrofit first [5, 6].

Multiple Utility Levels

When there are multiple hot utility levels present, as in the example, it is not evident which temperature level the part of the ACLC that corresponds to pinch violations should be plotted at. The utility level(s) that can be released by cutting the AHLC from the left is what should be chosen. One must therefore look at which utilities the streams composing the AHLC are connected to. The important thing to remember is that the cold streams composing the AHLC are governing, not the HUC streams. In the example, the part of the AHLC that could be saved by correcting pinch violation corresponds to about 1100kW. In the low temperature region this corresponds to saving heat in one ore more of the heaters H2, H3 or H4, Figure 1.

From the grid diagram, Figure 1 it can however be concluded that the only heater already connected to a cooler through a path is the one using HP steam. This heater may seem to be cheaper to unload, since it "only" requires area enhancement in existing heat exchangers. Unloading any of the three other heaters first requires insertion of a new heat exchanger to create a path between the cooler and the heater in question, then probably also area enhancement in existing heat exchangers. It has however been showed that heaters low in temperature are in general cheaper to release [6]. The reason is twofold, releasing heaters placed high requires many rearrangements of existing units, and poorer temperature driving forces result in large heat exchanger areas.

Heat Pump Integration

In general, heat pumps should be integrated so that the evaporation takes place where there is a surplus of heat, and the condensation where there is a deficit of heat. In most industrial cases this means around the pinch. There is also the possibility to integrate a HP around a "nose" in the GCC, but that is not discussed further here.

When using the advanced composite curves, integration can generally be carried out at three levels; integration against the HUC/CUC, against the AHLC/ACLC and against the THLC/TCLC. A combination of the curves could also be used, e.g. integration against the HUC/ACLC. Integration against the HUC/ CUC would require least changes in the HEN, but the COP would be lower due to the higher temperature lift required, and the HP size may not be as big as could be achieved by integration against the AHLC/ACLC (Figure 5). The most extreme case is to integrate the HP against the THLC/TCLC curves, but that would in most cases require a large retrofit of the HEN so the heat/cooling demand changes from the AHLC/ACLC situation to the THLC/TCLC ditto to *create* a foundation for successful HP integration.

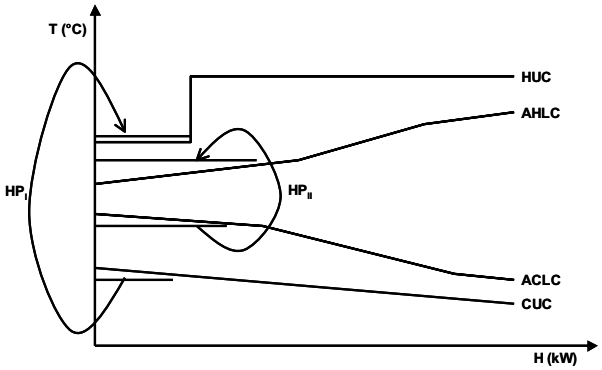

Figure 5: Heat Pump Integration Potential using Advanced Curves.

Which level of the abovementioned should be used is a trade-off between the COP and size of the HP, and the cost of the necessary rearrangements in the HEN to facilitate the HP. Which complexity levels that results in best project economy could be determined by the method developed by Wallin [14].

CHP Integration

As an example of CHP integration, a simple GT is used. When a GT is to be integrated, a number of key figures must be determined, e.g. GT size (MW), stack and exhaust temperature and the quantity of supplementary firing needed. Supplementary firing could be left out in a simple GT cycle if the GT size exactly match the heat demand, but this is almost never the case, since GTs are manufactured and delivered in fixed sizes. Another situation when supplementary firing could be left out is if there is already a heat generation system available, and the GT is integrated primary for electricity generation.

The size of the GT is determined from the T-H diagram, where the slope of the GT line equals 1/(F*Cp). A steep slope of the line indicates a

small GT and correspondingly a flat slope indicates a large GT.
The GT could be integrated against the HUC, AHLC or THLC respectively (Figure 6).

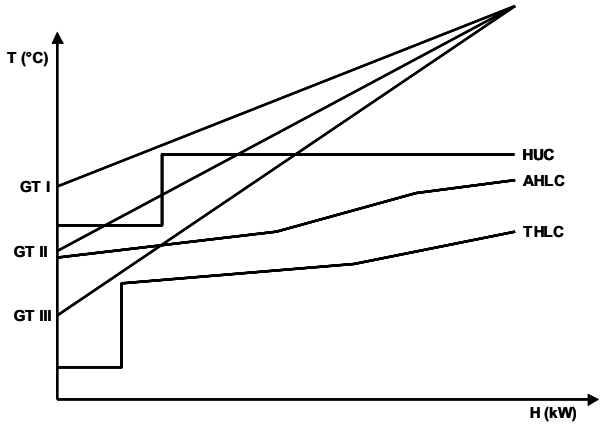

Figure 6: Gas Turbine Integration using Advanced Curves.

Which curve to integrate against is a matter of project economy, which is a function of not only the GT investment cost, but also the cost of retrofitting the HEN. Integration against the HUC requires little or no changes in the HEN but may give a less profitable GT than if the integration is done against the AHLC or THLC. To analyse the most profitable investment, many combinations should be looked upon, and the total project economy be evaluated for each of these combinations. A method to carry out this complex integration task has been presented by Strömberg and Berntsson [15].

Usable Excess Heat

When the potential for releasing usable excess heat is assessed, the THLC and TCLC are used.
Two ways of increasing the total efficiency in the plant exist; to decrease the heat demand for the current process, or to utilize the currently added heat more efficiently. Using the added heat more efficiently requires release of usable excess heat. Basic pinch theory establishes the pinch rule that says that heat surplus only appears below the pinch, whereas deficit appears above the pinch.
The surplus can then not be used for heating purposes. This rule is only valid for a given, fixed set of stream data. The heat surplus below the pinch *may* be used if:

1. New processes are added to the overall process (New cold streams are added to the stream set).
2. New design of existing processes lead to existing hot and cold streams' data changes.

Instead of correcting pinch violations, it might be economically justified to keep the current heat demand, and instead integrate new processes. This is done against the curves using background/foreground analysis. Non-conventional evaporation is a good example of such integration [7, 17]. A combination of removing some amount of pinch violations, and use the remaining heat for integration of new processes could of course also be considered. Which combination of measures should ultimately be chosen is determined by the economic evaluation of possible and viable combinations.
It is important to notice that all cooling demand depicted in the TCLC is excess heat. However, the amount of this excess heat that is useful for other applications depend on the temperature level at which it is released. In different industries, the operating conditions for particular process parts and unit operations are believed well known. However, when using other, new sources of heat, e.g. excess heat, for a certain process, one must also relax the design and operating conditions for that process. For example, in the pulp and paper industry, excess heat of 80 °C is not of much use when the existing process is analysed. Excess heat of 60-80°C could however be used for pre-evaporation of black liquor or effluents, district heating or heating of facilities in the plant if new or redesigned processes are integrated. The key question here is to relax the process under consideration from the background, and study it as a foreground process. Process integrated evaporation of black liquor is taken as an example here and explained using the GCC. From the existing GCC Figure 9, the evaporation is excluded and added as a stand-alone unit, Figure 7. When this is done, changing the design of and operating conditions for the evaporators, a process integrated design using now usable excess heat could be derived, Figure 8. Work by Algehed [17] and Bengtsson [18] has shown that substantial live steam savings, between 16 and 90 % of initial consumption, could be achieved by this approach.

In the same way new processes should be added and integrated as foreground processes to the existing process (background).

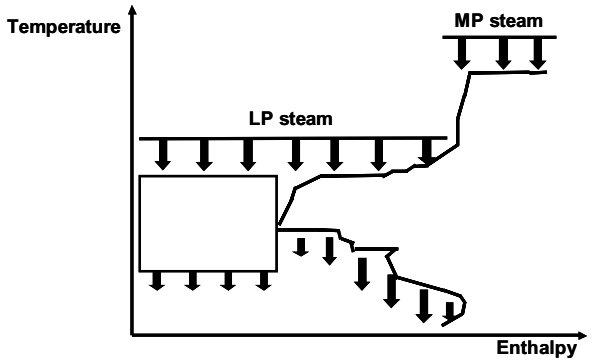

Figure 7: Conventional evaporation plant as foreground.

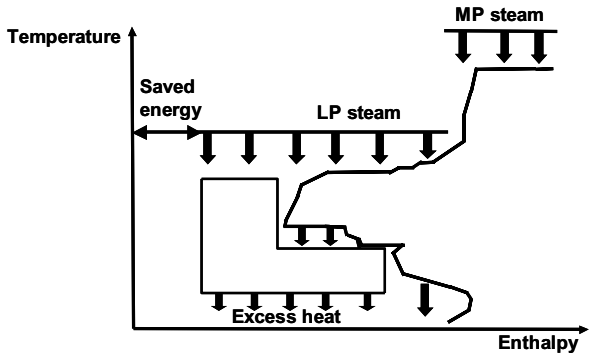

Figure 8: Process Integrated Evaporation.

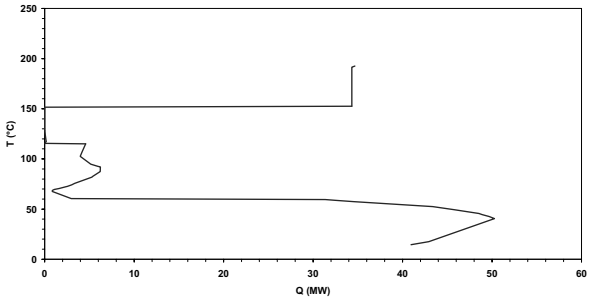

Figure 9: GCC for the Pulp Mill Example.

In many industrial projects Chalmers have participated, there has often been an attitude that there is no usable excess heat available in the plant. This is often based on studying the GCC, plotted for the HRAT that corresponds to the existing heat demand. If instead the same process is examined using the advanced curves, a quite different picture could be the result, especially if the difference between the HRAT and EMAT is large.

As an example of this, Figure 9 and Figure 10 present the GCC and the THLC/TCLC for a pulp and paper plant. The GCC is plotted for a HRAT of 15°C, so that the existing heat demand is met.
When the GCC is analysed, about 0.9 MW of excess heat is available above 67.5°C (this heat could be released up to 115°C) out of a total of about 41 MW. All temperatures are in this case adjusted. This amount of excess heat would probably not be very efficient to use for other processes, and the analysis might stop here.
If, on the other hand, the advanced curves were used, a completely different picture appears.
The THLC and TCLC in Figure 10 shows a potential to release 7.5 MW above 98°C, whereof 4.7 MW at or above 122°C. All temperatures are in this case real temperatures.

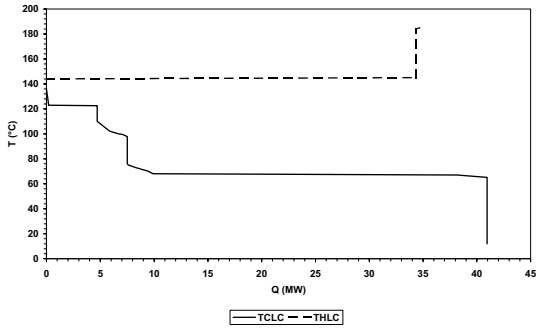

Figure 10: THLC and TCLC for the Pulp Mill Example.

Important to remember is that both the GCC and the advanced curves are constructed out of stream data only, so what is causing the difference in the results?
The answer to this is the advanced curves show the potential excess heat release if a given EMAT is used to retrofit the HEN. This means that in the existing HEN it might not be possible to release the excess heat at the temperatures indicated in the advanced curves, but there is the possibility to do this. A new process using excess heat at high temperatures could therefore be considered, but when the investment is evaluated, the cost of retrofitting the HEN to fit the new process must be added.

Shifting Pinch Point

One additional "phenomenon" that should be recognised is when the pinch point shifts from one stream to another. In the example above, the pinch point remains the same from 15K down to

5K, but the situation could have been quite different. Figure 11 shows the pinch point temperature versus the HRAT for the example. It can bee seen that between HRAT = 15K and HRAT = 17K, there is a shift in pinch temperature from 128.5 °C to 67.5 °C.

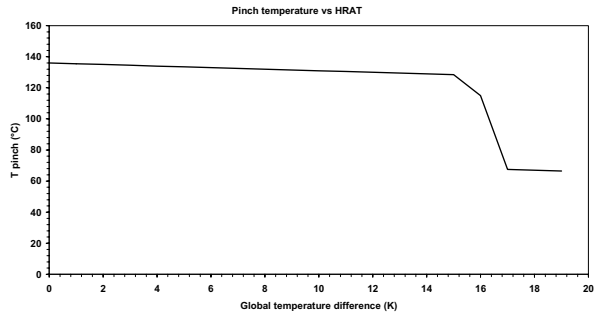

Figure 11. Pinch Temperature vs HRAT.

If the existing heat demand had been e.g. 35.9 MW, corresponding to a HRAT of 18K, the GCC would look as depicted in Figure 12. According to this GCC, practically no usable excess heat could be released. By plotting the GCC for a lower HRAT, e.g. 5K would help seeing the potential, but this curve would miss the true potential by the amount of heat that differs between the existing HRAT and the HRAT that the curve is plotted with.

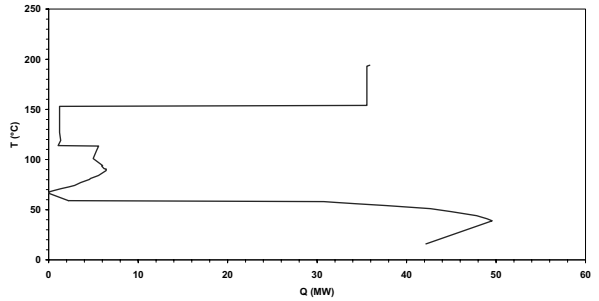

Figure 12: Pulp Mill GCC for HRAT = 18K.

CONCLUSIONS

In this paper, a set of advanced curves for energy integration has been presented. The usefulness of these curves, especially in the case of identifying useful excess heat and integration of new processes, but also for evaluating the HEN retrofit potential has been demonstrated. A brief discussion of Heat Pump and Gas Turbine integration was also presented to demonstrate the broad application range of these curves. The importance of taking all possible measures into consideration in a heat recovery project has been stressed.

PROCESS INTEGRATION-CASE STUDY SODIUMTRIPOLYPHOSPHATE MANUFACTURE

Predrag Rašković [1]
University of Nis
Faculty of Technological Engineering
16000 Leskovac
Serbia and Montenegro

ABSTRACT

The reference object for Process Integration, in this paper, is the sodium tripolyphosphate manufacture in "*IHP-Prahovo*", the biggest factory for producing base chemical products in Serbia and Montenegro. The sodiumtripolyphosphate-$Na_5P_3O_{10}$ manufacture is one of the most complex processes in the chemical industry. The overall process could be divided in two parts: the wet process part, where the raw material is primarily treated with chemical reactions, and the dry (final) process part based on thermal treating of the material.
The retrofit project, for dry process part, consist of five closely connected phases: modeling, simulation, optimization, Process Integration and energy efficiency analyses.
Process Integration of dry process is realized by Thermodynamic methods, Exergy analyze for the flue gas recirculation models, and Pinch design method for heat exchanger network models. The results indicate much better energy performance for project realized on heat exchanger network models.

Key words: Process Integration, sodium tripolyphosphate, IHP-Prahovo, software tool.

$Q_{C,min}$	minimum external cooling [W]
HRAT	heat recovery approach temperature [^{0}C]
W	heat capacity flow rate [kW/^{0}C]
$\Delta Tmin$	minimum approach temperature [^{0}C]

INTRODUCTION

The reference object for Process Integration, in this paper, is the sodium tripolyphosphate manufacture in "*IHP-Prahovo*", the biggest factory for producing base chemical products in Serbia and Montenegro.

Sodium tripolyphosphate (*STPP*)- $Na_5P_3O_{10}$, is a solid inorganic compound in regular and compact laundry detergents, automatic dishwashing detergents, also in human foodstuffs, animal feeds, industrial cleaning processes and ceramics manufacture.
The stable form of STPP is the hexahydrated salt. Sodium tripolyphosphate exists in two major crystalline forms, known as Phase I (or Form I) and Phase II (or Form II). Phase I material is formed if the process temperature is maintained above 450^{0}C, while Phase II material is formed at temperatures below 450^{0}C. The transition temperature between them is about 420^{0}C. The two crystalline forms have different properties and in many applications they are not interchangeable.
The annual production of *STTP* in "*IHP-Prahovo*" is about 45000 t/year. The most significant part in

[1] Corresponding author : Phone +381 64 2659230, E-mail: buki@bankerinter.net

plant production cost is the heavy oil consumption (approximately 7000 t per year). More than 90% of the consumption is executed in the final process part (dry part), based on thermal treating of material. Because of that fact, the research is focused on them. The energy system's retrofit project, consist of 5 closely connected phases, presented in flowchart on *Fig.1*.

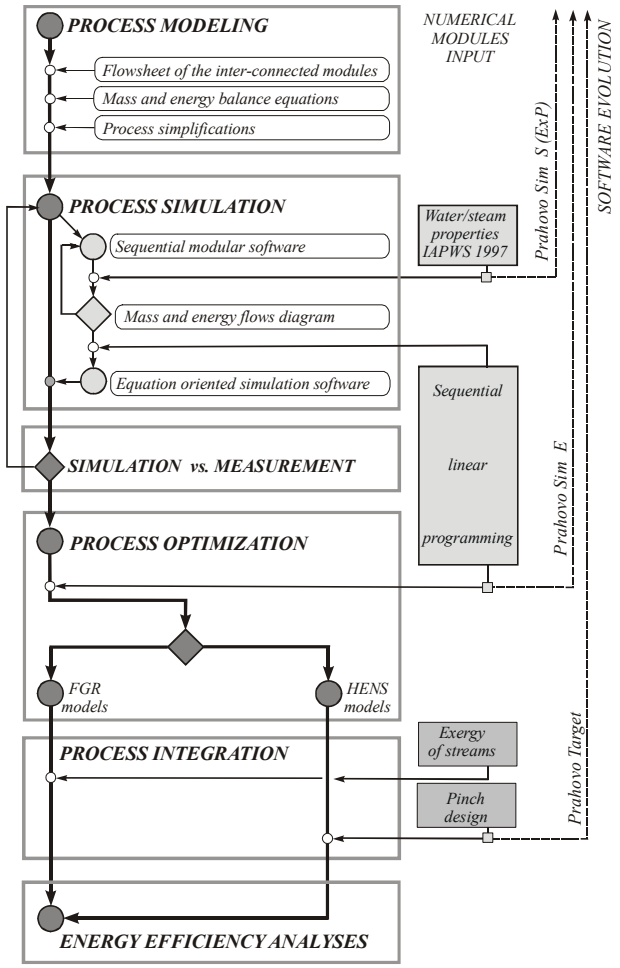

Figure 1. Flowchart of retrofit project

The main part in this paper will be dedicated to the phase of Process Integration, with briefly presentation of important facts from previous phases. As this is the first published work after the research is completed, author decided to present the main ideas without the detailed diagram analyses.

TECHNOLOGICAL SCHEME OF SODIUM TRIPOLYPHOSPHATE MANUFACTURE

Existing production plant for *STPP* [1] in "*IHP-Prahovo*" (*Fig. 2*) essentially consists of a two parts:

- *Wet proces part*, where the raw material is primarily treated with chemical reactions,
- *Dry (final) process part,* based on thermal treating of semifinished product from previous part.

In the *Wet process plant***,** phosphoric acid is first purified and then neutralized with alkaline compound such as sodium hydroxide or sodium carbonate. The result of this operation is an aqueous solution (orthophosphate solution also called "make up liquor"), such that the mole ratio of sodium to phosphorus is on the order of about 1.67:1. This solution contains the equivalent of monosodium orthophosphate and disodium orthophosphate in a mole ratio of 1:2.

In the *Dry process plant***,** the solution is sprayed into the spray dryer (atomizer) in a finally atomized state and dried into a predominately orthophosphate material[2]. Heated gas (flue gas), from atomizer oil firing unit[3], is employed in the spray dryer to accelerate the heating of sodium orthophosphate solution.

The moisturized product is then calcined in the rotary kiln (calciner) in order to convert orthophosphate into sodium tripolyphosphate[4]. Heating agent in calciner is the flue gas from another, calciner firing unit. The final temperature, within the range of from about 300 ^{0}C to about 600^{0}C, is selected in order to produce the desired Form I, and/or Form II, content in the final *STPP* product. The obtained product is generally in agglomerated form. The agglomerates are cooled and sized to yield a sodium tripolyphosphate product which is separated into granules (size about 1mm in diam.).

The gas stream emanating from either the spray dryer or the calciner is passing through a solid recovery zone (cyclone battery of centrifugal separators) to remove the bulk of any sodium tripolyphosphate powder that has been entrained in the gas stream. Such treated gas stream is then passing through a scrubber, containing a liquid scrubbing solution which contacts the gas. The scrubber also takes up remaining amounts of finally powdered sodium tripolyphosphate which were not caught in the centrifugal separator.

---

[2] mixture $2Na_2HPO_4 \div NaH_2PO_4$

[3] In the spray dryer the flue gas is coming as the mixture of recirculation and *fresh* flue gases from mixture chambers.

[4] $2Na_2HPO_{4(s)}+2NaH_2PO_{4(s)} \rightarrow 2Na_4P_2O_{7(s)}+2Na_2H_2P_2O_{7(s)}+3H_2O$

$2Na_4P_2O_7+ 2Na_2H_2P_2O_7 \rightarrow 2Na_5P_3O_{10}+H_2O$

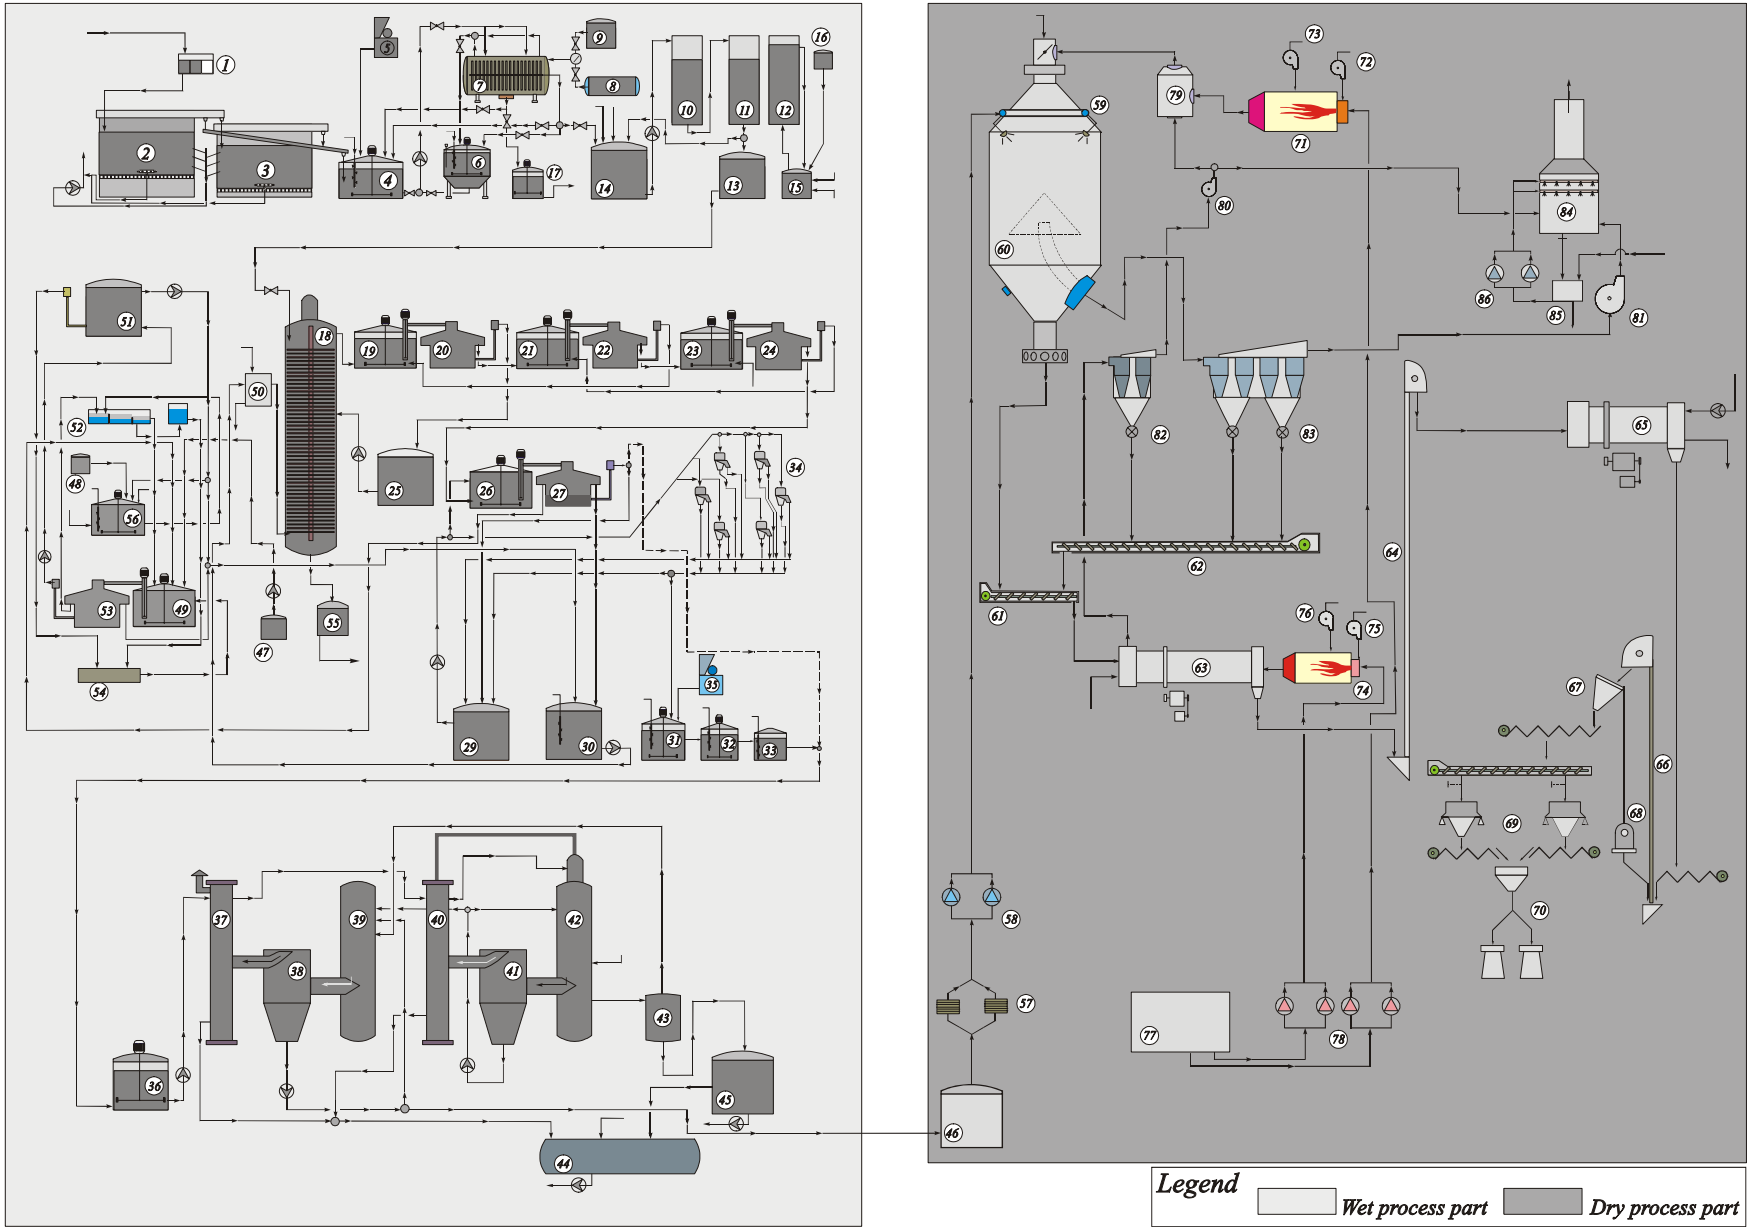

Figure 2: Technological scheme of sodium tripolyphosphate manufacture in *IHP Prahovo*

RETROFIT PROJECT OF DRY PROCESS PART

Retrofit project of dry process part (*Fig. 1*), start with modeling phase [5]. Physical model is created as the network of inter-connected modules (*Fig. 3a*). Mathematical model is based on mass and energy balance equations with, according to the technology limits, some simplifications. The most important are:

- Model is a continuous and steady state,
- Some of the streams are the ideal mixtures of air, dry flue gases, vapor in gases and sodium tripolyphosphate powder. For such stream, balance equations are created for each component,
- bulk mass flow and the vapor content in flue gases are the function of belonging stream mass flow and fuel specification respectively.

Process simulation is primary made by the use of spreadsheet software tool-*Prahovo sim S (ExP)*[5] [2] which includes the water/steam simulator.

The results of the software confirmed the proposed mathematical models of process units, and enabled the global connection of mass and energy flows (*Fig. 3b* and *3c*). Another important conclusion was that the influence of the pumps, fans and pipes heat loses are negligible in the overall heat balance.

Numerical integration of equation-oriented software (named *Prahovo sim E*) is developed on *Visual Studio C++* programming platform. It's solving procedure is based on *Sequential Linear Programming* (*SLP*) technique for non-linear simulation/optimization.

The results obtained by the use of *Prahovo Sim E* are compared with plant operating measurement, which are made in present and past time, for production of both crystal form of *STTP*. The author concluded, that the average mistake of about 5.84%, could be good starting point for the next retrofit project phases.

Energy system optimisation was done in two ways: one by adding the new possibilities for flue gas recirculation (*FGR* models) and another by adding the new heat exchangers in existing plant (*HENS* models).

The additional improvements for the next, Process Integration phase, are realized by the use of Thermodynamic methods. For the first, *FGR* models, numerical module for exergy calculation enabled the use of Exergy analyze. For the second, *HENS* models, pinch numerical module[3] enabled Process Integration by Pinch design method. On that way software *Prahovo sim E* evolved in a final form named *Prahovo Target.*

PROCESS INTEGRATION OF *HENS* MODELS

Process Integration of *HENS* models, by the ordinary use of pinch design method, was limited for only 3 streams of existing model. These streams passed through the complex chemical operation (combustion, spray drying, calcining, scrubbing), and their possible matching are in accordance with mass and energy balance of the plant. The results of their integration would be the slight increase of the plant energy efficiency.

On the other side, involving the new, let me call them *promising*, streams, in Pinch design task, is limited by two reasons:

- Their fixed input/output energy parameters, doesn't enabled matching with other streams,
- Changing of their parameters[6], will complete the pinch design task, but the final solution would break the overall mass and energy balance, due to existence of chemical operation.

To exceed these limitations, plant was first reconfigured by adding the modules of new heat exchangers (*Fig 5a* and *b*) in existing physical and mathematical model. These exchangers present just fictive elements, for possible heating/cooling of the streams. Their purpose is to ensure the overall plant balance equations. Energy parameters of *promising* streams becomes the preassigned parameters (included in software input menu) of new formed optimization task. The optimization result automatically generates the base Pinch design task, and enabled future improvements by other Pinch design phases [6].

Software flowchart for that operation is presented in *Fig 3* (stages are on light gray background, connected with dashed dark gray line).

[5] Developed on *Microsoft Excel* programming platform by sequential modular approach

[6] On example changing the temperature or mass flow rate of primary and secondary air in combustion chambers

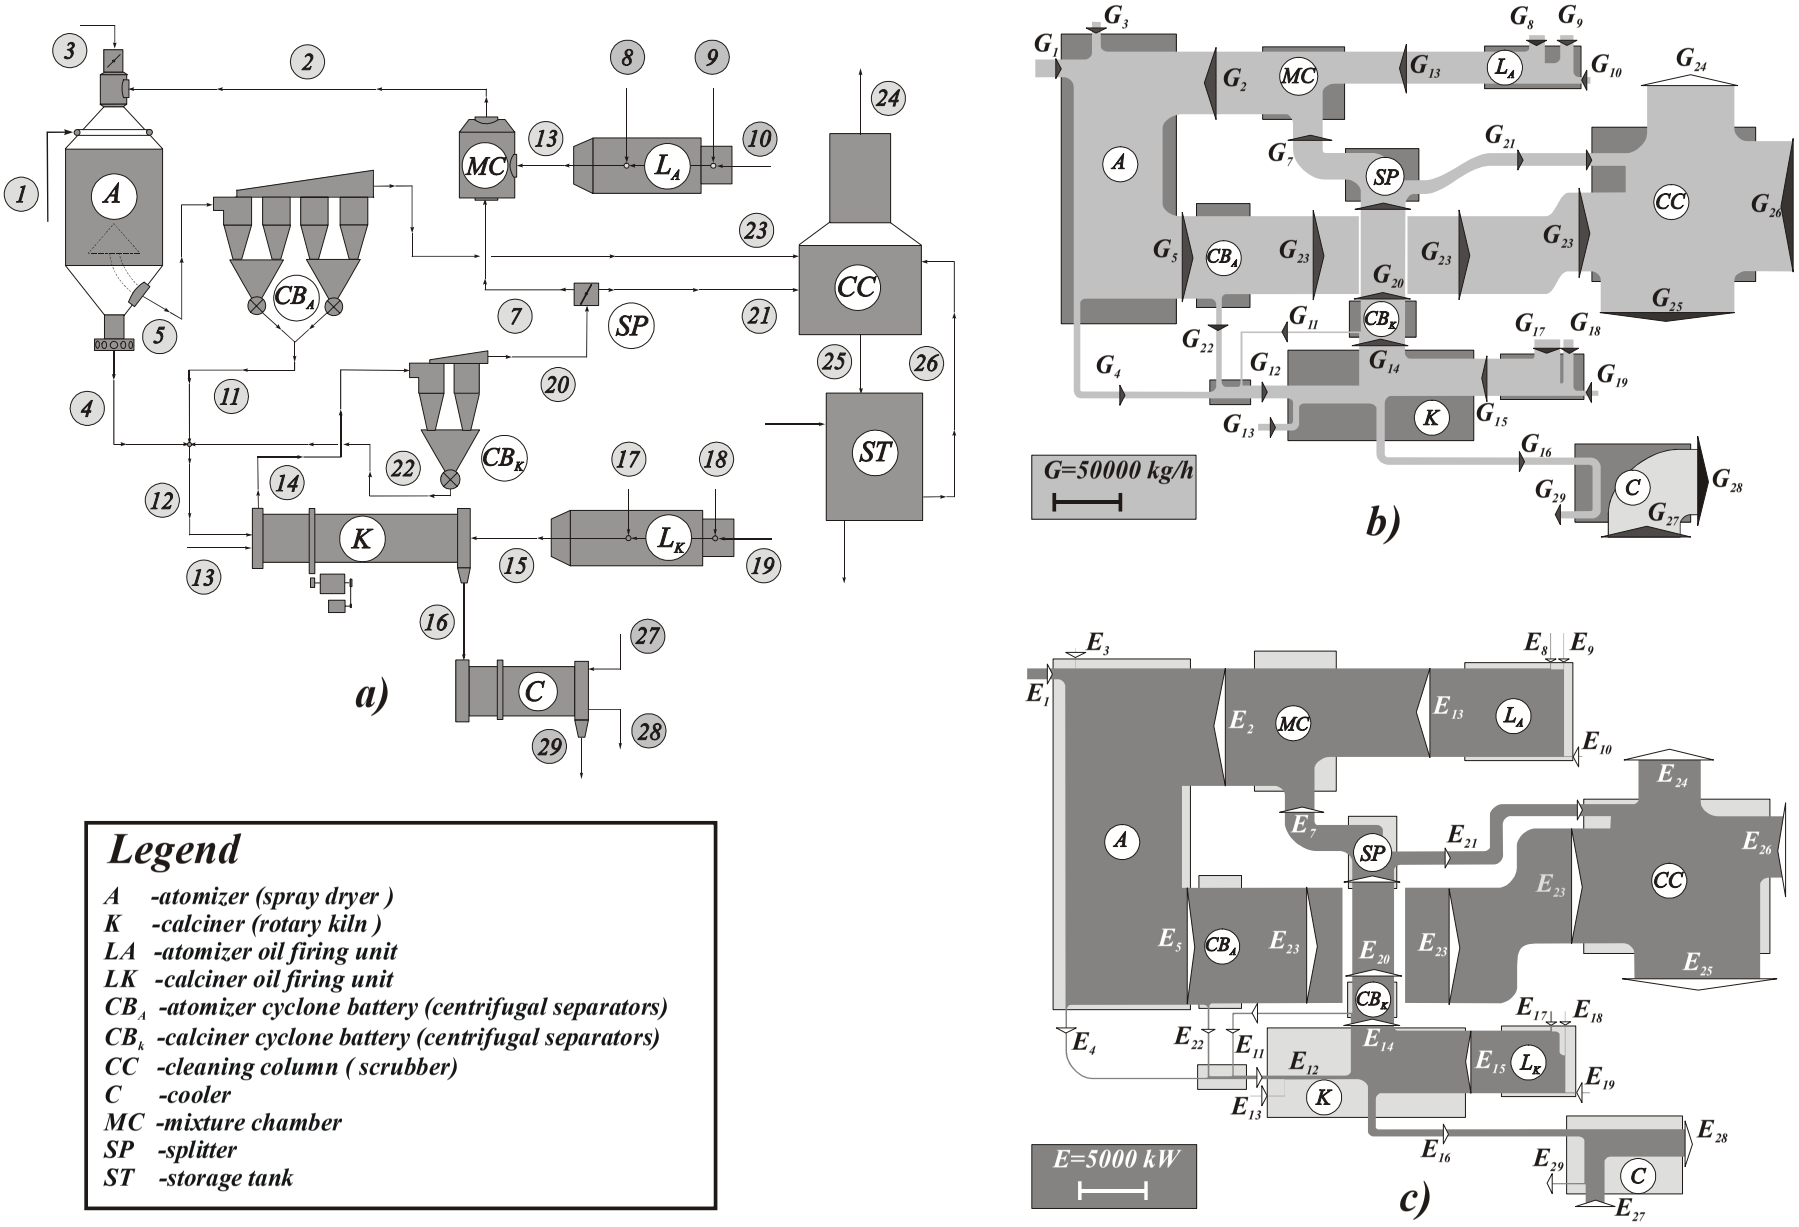

Figure 3: Physical model of dry process part (*a*) with mass flow (*b*) and energy flow (*c*) diagrams

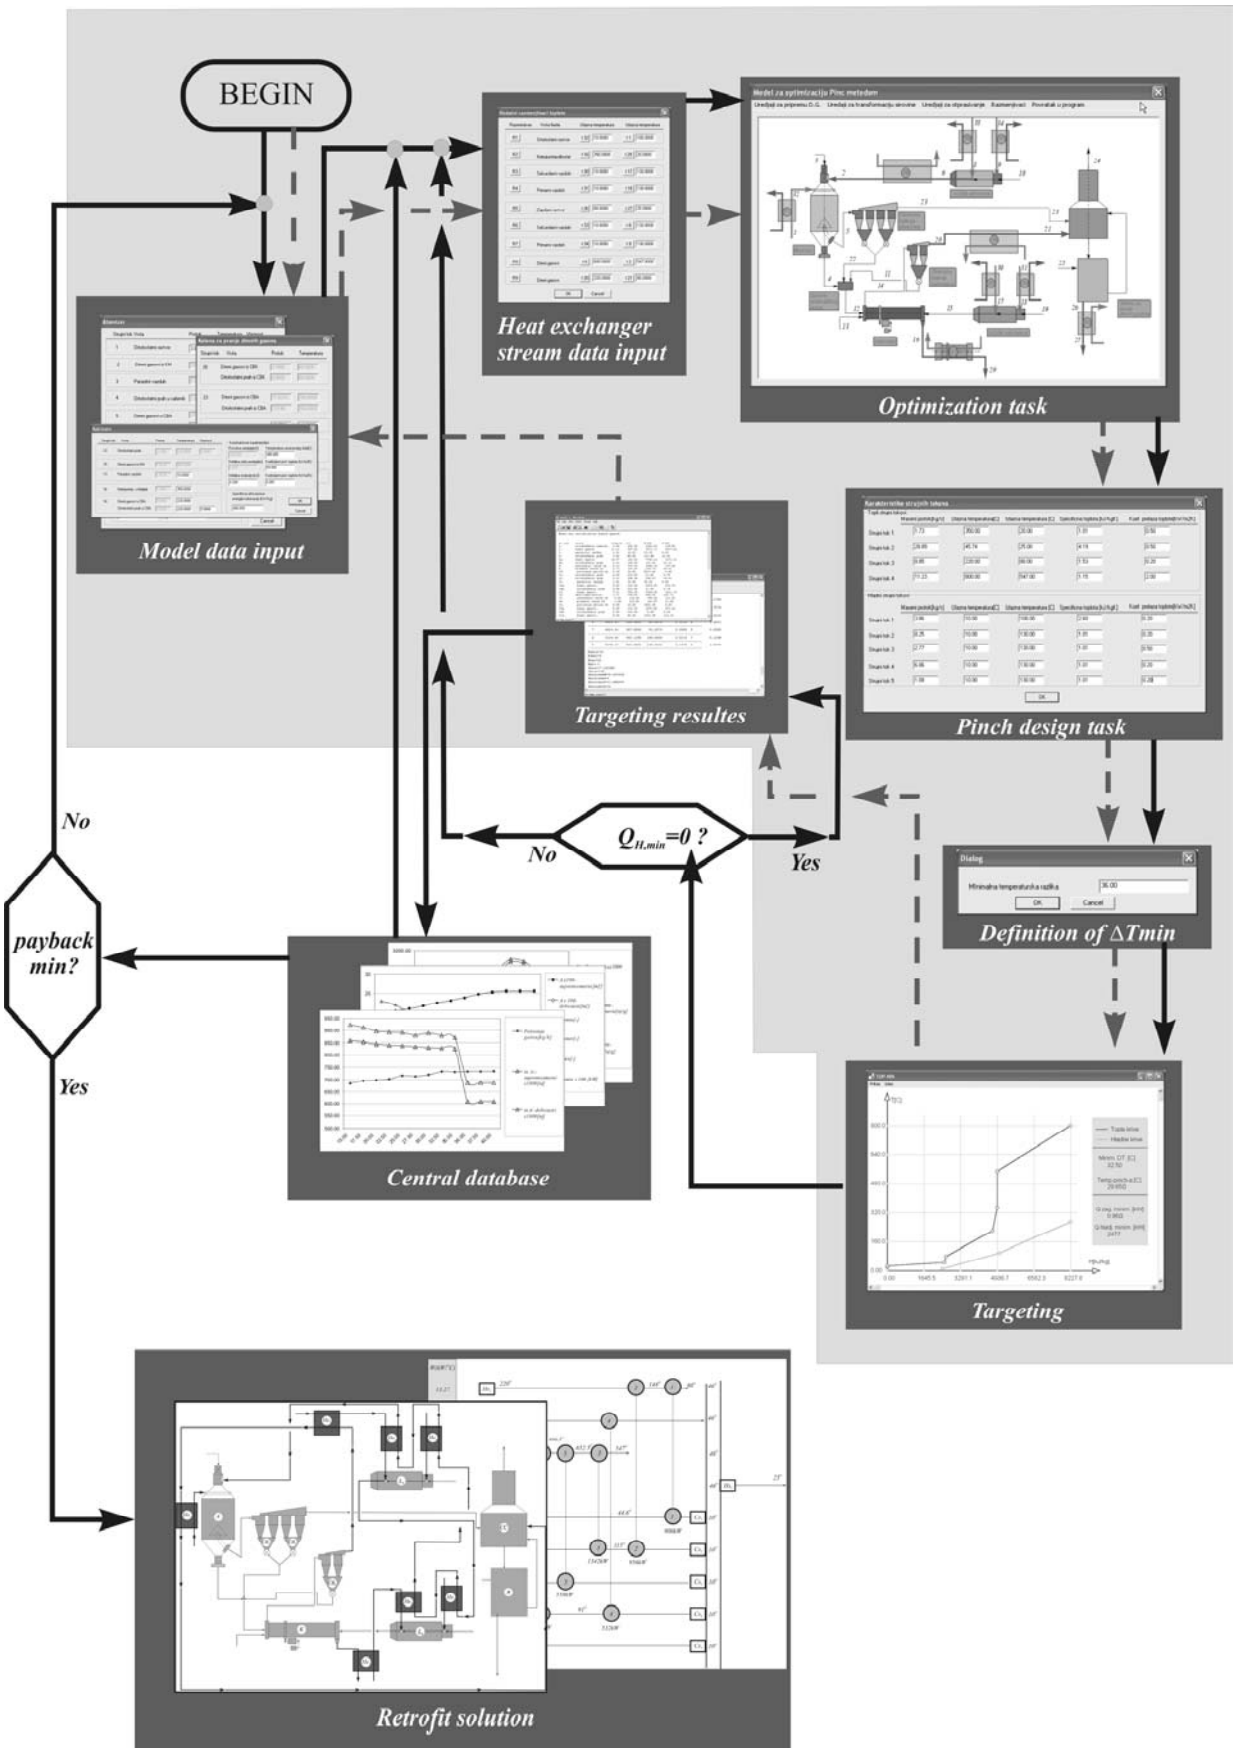

Figure 4: Software flowchart of Process Integration for HENS models

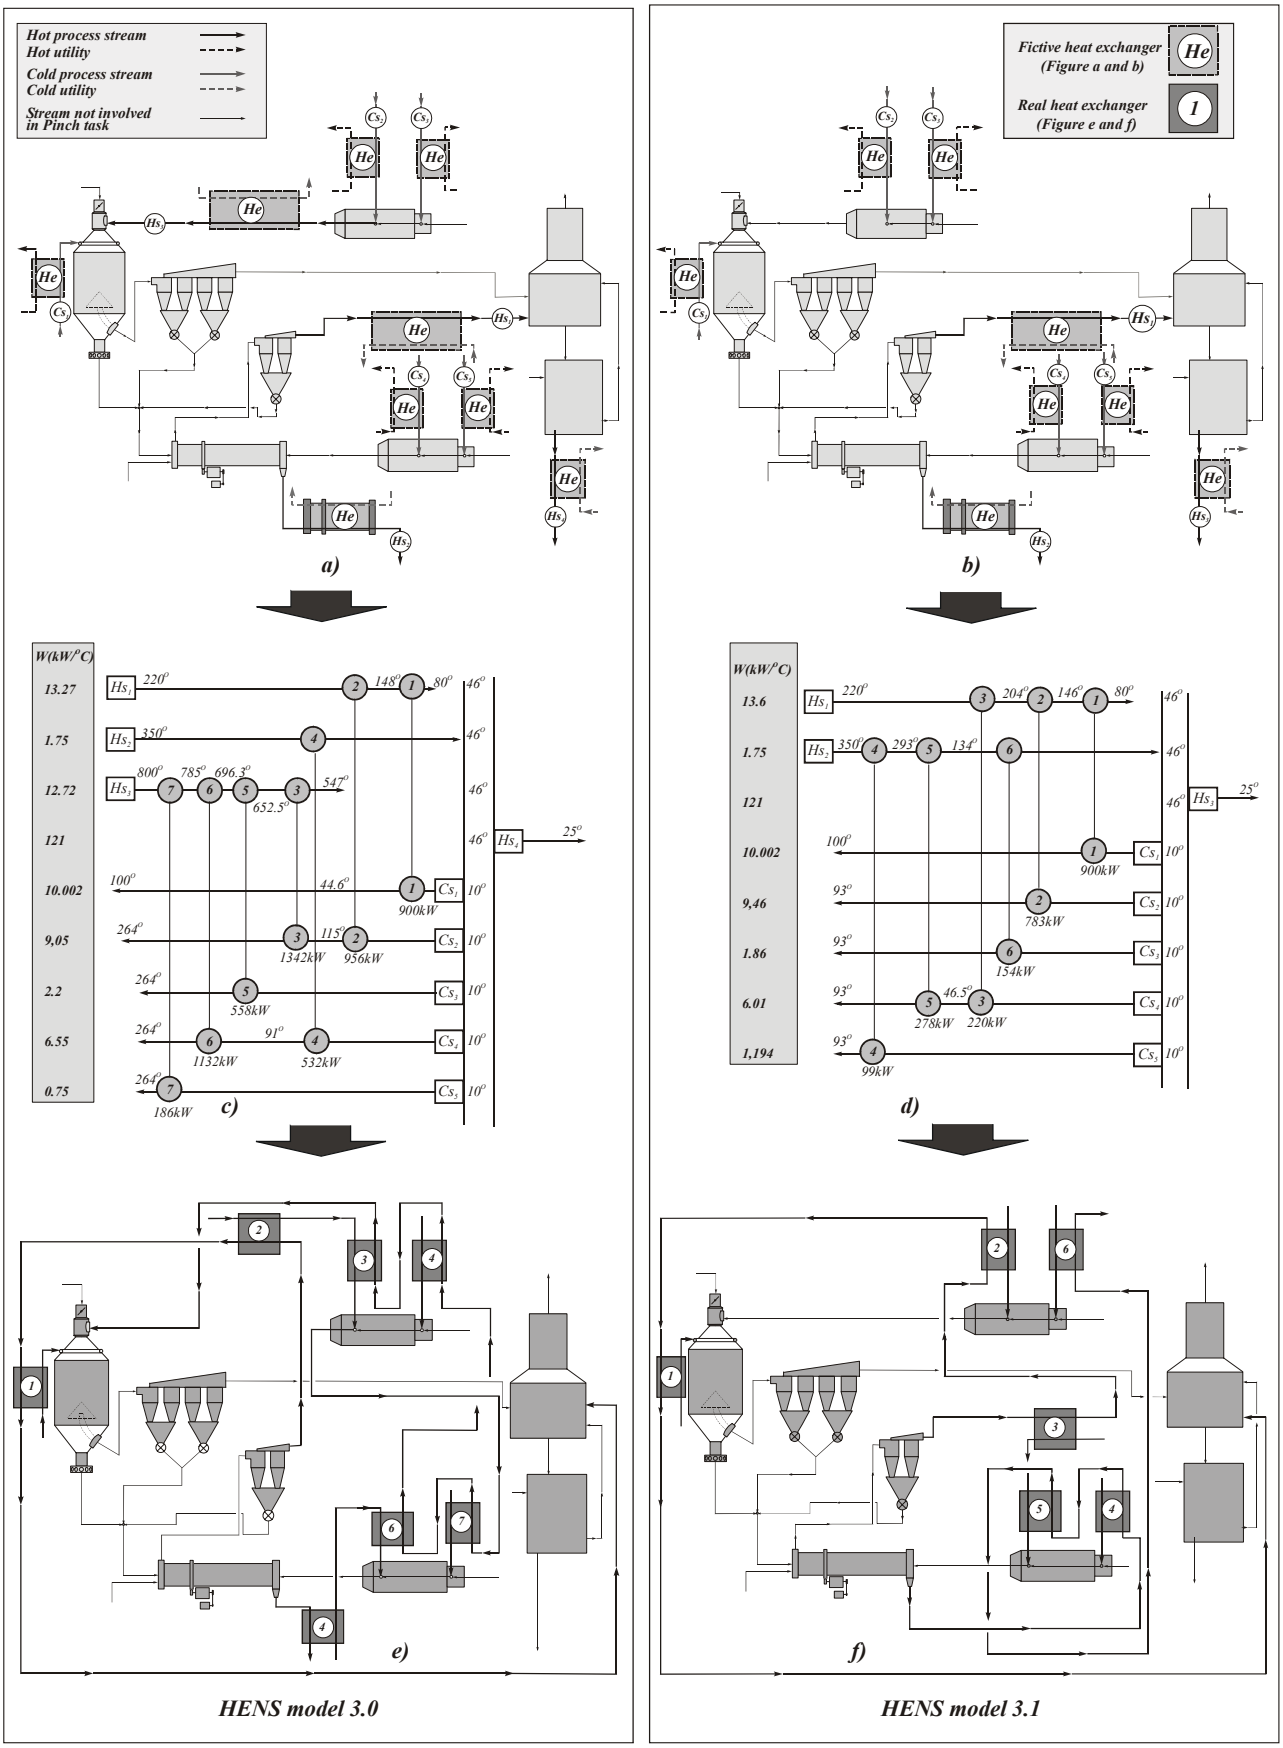

Figure 5: Retrofit project for HENS models

After the development of software *Prahovo Target,* next goal was the creation of retrofit solution without use of any new external heating/cooling. Elimination of the external heating conect the operating cost with oil consumption in the system.
By previously explained procedure, in first research circle, composite curves are put in threshold problem statement for specific *ΔTmin*. Operating and investment cost for that state, obtained from targeting phase, are loaded in intermediary (*Targeting results*) and central database for energy efficiency analyses. The research circle is then repeated for different value of *ΔTmin.* In the second research circle procedure is the same, but this time with different process parameters. Graphical explanation of this investigation is presented by software flowchart in *Fig. 4* (stages are connected with dark solid line).

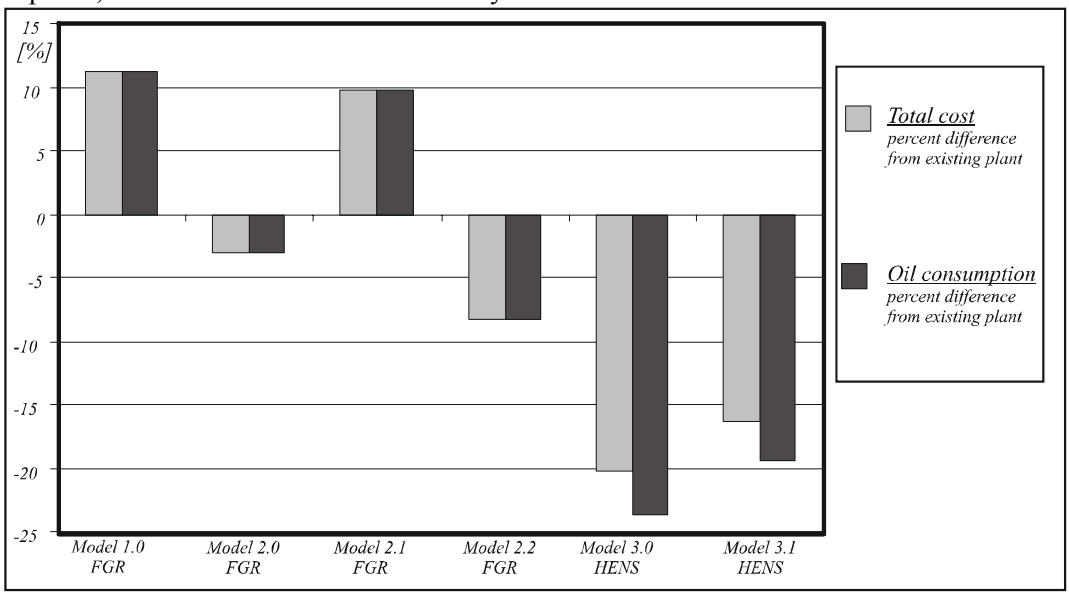

Fig 6: Economic analyses of retrofit solutions

RESULTS AND DISCUSSION

Process Integration was applied on two different *HENS* models, presented in *Fig 5* (*named Model 3.0* and *Model 3.1*). The economic analysis of targeting results, indicated $\Delta Tmin=36^0C$ as the optimal *HRAT* value for the both models. By that value, in grid diagrams (*Fig. 5c* and 5d) there is only one stream (stream from storage tank) which needs external cooling. As the technology process doesn't limit its target temperature, the purpose for cooling could be neglected. This fact has important effect on the investment cost of design. The final retrofit solutions are presented in *Fig. 5e and 5f.*
General comparing of *FRG* and *HENS* models solutions, was done on the basis of the same important energy inputs, and the same physicochemical property of raw and final materials. The results are presented in *Fig. 6*. They clearly indicated better energy performance for retrofit project realized by the use of *HENS* models.

ENERGY INTEGRATION AND SUSTAINABILITY IMPROVEMENT OF AN ECO-INDUSTRIAL NETWORK

Toshko Zhelev, Bernadette O'Regan, Richard Moles
Center for Environmental Studies
University of Limerick, Limerick, Ireland

Abstract:
The paper focuses on problems and challenges related to the integration, resources management and environmentally benign operation of urban based SMEs forming clusters of mutual trust and benefits known as Eco-industrial network. Presented analysis is based on the conceptual approach of design and redesign and utilises the experience in energy integration of remote areas of integrity, reuse/recovery/utilization of resources between partner factories, guided design changes for beneficial solutions and incorporates an optimality criteria (multiple resources management – water, energy, effluents) with environmental impact considerations. It proposes a procedure assisting decision making when centralized versus distributed waste treatment competes with balanced/mixed options. This procedure is tailored to assist partner companies to decide what part of waste to treat on their own production site and what part of it to send to a centralized service or neighboring company for treatment. An attempt is reported to bring together in one analysis the products, raw materials and services, accounting for their sustainable origin (history) and required treatment (future), considering possibilities for guided waste recovery and utilization in other areas of integrity and finally focusing on production/process management for maximum efficiency and sustainability through combined Emergy-Pinch analysis.

INTRODUCTION

The International Energy Agency (IEA) defined process integration as *Systematic and general methods for designing integrated production systems, ranging from individual processes to total sites, with special emphasis on the efficient use of energy and reducing environmental effects* (Gundersen, 1997). Currently, process integration can be seen as a holistic approach to process design, retrofitting and operation, which emphasizes the unity of the process. It can be seen as a common term for the application of methodologies developed for system-oriented process plant design. The three major features of process integration methods are: The use of heuristics (insight) about design and economy; the use of thermodynamics (e.g. pinch analysis, exergy analysis) and the use of optimisation techniques. Examples of the efficiency criteria used are capital investment, energy efficiency, emissions, operability, flexibility, controllability, safety and yields (Gundersen, 1997). Recently, a new wider concept specified as *comprehensive process integration* was introduced by Markka Hurme (2005) and defined as design, operation and management of industrial processes with system-oriented and integrated methods, models and tools. It covers not only energy and utility flows but also all material and information flows with the aim to balance their use for optimised process performance. Comprehensive process integration aims to integrate different elements of production (raw materials,

utilities) using various performance criteria and different scopes and areas of application (process, site, community) during the whole life cycle of the plant (industrial activity). Finally the process integration principles can be seen in accordance with the principles of sustainable development and industrial ecology; especially, when the definition "site" is extended to include the environment and society.

In the case of this research, the intention is to utilise the concept of integrating areas, sites and industrial activities of particular integrity with the view of better and more efficient performance accompanied with more environmentally friendly operation that is recognised by the local society. The core element of such integration remains at the systematic approach to energy and material flows, where the effluent's flows and waste management becomes a new dimension.

ECO-INDUSTRIAL NETWORK

The drive for integration leading to possible economic and environmental benefits has turned our focus onto local small and medium enterprises (SMEs) located in the Mid-West region of Ireland. The Mid-West region of Ireland comprises County Limerick, County Clare and County Tipperary and includes approximately 10% of the national land area and population of Ireland. The industrial base is dominated by light industry such as electronics, instruments, pharmaceutical and healthcare, metals and engineering. The attractiveness of the Mid-West as a location for industry is demonstrated by the large number of foreign-owned plants established in the region. It is estimated that there are approximately 400 SMEs in the Mid West region.

While SMEs contribute to growth, employment and rural development they also exert quite significant impacts on the environment. It is estimated that in total SMEs are responsible for 70% of all industrial pollution across the EU (EC Enterprise Directorate General. 2004).

The announcement of our research in the area of industrial integration has attracted significant interest in the region and already 22 SMEs from the Mid West region formally expressed commitment to this project. Many of these companies already work together in areas other than sustainability and this basis has established such crucial advantages as mutual trust.

There are many successful international examples of SMEs integration to form Eco-Industrial networks and these have been successful in terms of the reduction of environmental impacts. e.g. waste reduction, resource use reduction, improved transport management, etc. and improved competitiveness for the companies involved. Such are: Kalundborg - Denmark and Styna - Austria; the INES project in Rotterdam Harbour and the UK National Industrial Symbiosis Programme (Internet Reference 6). But there is still significant work to be done in terms of integration methodology development and methodology generalisation.

THE CONCEPT

Eco-Industrial development is characterised by closely co-operating manufacturing and service industries working together to improve their environmental and socio-economic performance by improving their energy resource use and waste disposal efficiency through identification of options for reuse recycling or regenerative reuse of resources across areas of integrity. This may be as simple as identifying one SME's waste which could be used as a raw material by another business, or as complex as rethinking the transport and supply

logistics for the entire cluster or maximising economic and environmental performance using grass-root multi-objective optimisation methodology.

The attraction in the concept of Eco-Industrial development lies in its application of the natural ecosystem metaphor to "industrial ecosystems". The ideal of the metaphor is that industrial ecosystems function according to the system development principles of natural ecosystems, i.e. closed loops and waste utilisation between industrial actors (Singhal and Kapur, 2002). A local or regional industrial system is encouraged to move towards an interactive system through cooperative waste material and waste energy utilisation (recycling of matter, cascading of energy) and sustainable use of local renewable natural resources of matter and energy between the industrial actors. By reducing the waste management costs, emission control costs, raw material and energy costs, transportation costs, costs resulting from the implementation of measures required in environmental legislation and by improving the environmental image as well as the "green market situation" of the network, economic gains are possible.

The goal of Eco-Industrial development is, at the minimum, to generate the least damage in industrial and ecological systems through the optimal circulation of materials and energy (Cohen-Rosenthal, 2004).

All companies participating in this project confidently expect that by improving their performance with respect to sustainability they will gain economically through shared marketing initiatives, accessing green markets and gaining recognition as responsible stakeholders within the local community.

SYSTEM ORIENTED METHODS

System oriented methods provide practical ways to find required minimums for energy, raw material and water use in process integration at a system level. Unfortunately, until now most of the methods developed consider each of the resources in question separately.
The information available for the process design changes during the process life cycle stages because of process development, design, operation and retrofit. In the case of an existing network of companies this increases the level of complexity. Therefore to guide the decision maker towards the total optimum, a more complex view of analysing process integration efficiency is required.

First the alternatives are generated, analysed by calculation and evaluation of indicators. In the beginning of the project the process design activities are first aligned with the strategic targets of the company. To facilitate this, the company management has to define strategic goals and priorities for the design/redesign/operation. At the same time, this information will identify many design constraints.

AREAS OF INTEGRITY

An energy integration concept developed by (Ahmad and Hui, 2001) may have an important impact on the task of beneficial integration within the Eco-Industrial Network. The concept utilises the natural division of process plants in logically identifiable regions (areas of integrity) and the potential for heat (energy) recovery between these areas. The optimisation task in this case is defined as the identification of schemes of energy recovery between areas of integrity which offer maximum heat flow between these areas (maximum integrity) that secures minimum energy import to the system with least number of

interconnections between the regions. Ahmad and Hui, 2001 propose procedures, which translate the heat-flow-schemes into actual heat exchanger network designs.

The proposed methodology generates solutions ensuring maximum energy recovery between areas of integrity with minimum capital investments. This concept can be adapted without changes for the purposes of energy conservation within an Eco-Industrial Network. The areas of integrity in this case are the SMEs themselves and the integration of energy will be done with minimum re-piping or other type of interconnections between them.

EMERGY ANALYSIS FOR INTEGRATION

To address the levels of integration and sustainability a logical question arises – is there a way to address and analyse the vast majority of resources and goods, as well as the services, treatment and operations involving these resources? It is known for quite some time that the concept of *emergy* provides resources for such a combination.

The available solar energy used up directly or indirectly to make a service or product available, defined as *emergy* by (Odum, 1996), was applied by a number of authors to compare inputs of different origin, such as human labour, trucks, energy, fuels, chemicals, utilities, plant cost, etc. *Solar emergy* is the solar energy directly or indirectly necessary to obtain a product or a flux of energy in a process; it is an extensive quantity and its unit is the *solar emergy joule* [sej]. To convert inputs and other kind of flows into the solar equivalent, it is necessary to know the solar transformity, which is the *emergy* necessary to obtain one unit of product. Unlike the *emergy*, transformity is an intensive quantity and usually measured in [sej/J]. Transformity calculation is a difficult task stimulating researchers to exchange data and build databases establishing a common ground for analysis.

An interesting feature of *emergy analysis* is that it gives historical information about the resource or activity in question. Any *emergy* in the particular moment of interest contains all emergies of stage changes occurring on the way to that stage. The *emergy* value associated with a product is the sum of the all energies that were used to produce it. Another useful feature of *emergy analysis* is the ability to identify critical processes/stages/units. This makes it suitable for the purposes of environmental pre- and post-impact consideration in the Eco-Industrial Network.

In 2004, Zhelev & Ridolfi (2004) promoted the concept of combining emergy analysis with Pinch analysis – a recognised tool for resource management in industry. These two methods give the missing link between the industrial resources management for economic benefits and the environmental impact assessment comparing alternative solutions. The restriction in this particular case is that the combined analysis addresses energy resource only.

EMERGY-PINCH ANALYSIS FOR ENERGY CONSERVATION

As suggested earlier by Zhelev & Ridolfi (2004) the amalgamation between *Emergy* and *Pinch* concepts can provide a range of benefits. Details about technicalities of the combined procedure are provided again here. To apply the Pinch concept one needs to construct the Composite curve. The streams, being either wastewater or energy, are defined in emergy units and in the way that can support emergy composite construction for the purpose of further targeting. Each stream is represented in a specific way. There is a portion of information (transformity) describing the past emergy investment, the "history" of the stream; a second portion, showing the "market" potential of the stream in terms of usability,

as it is the heat (temperature) potential for a thermal stream or the concentration limits, if it is a water stream; the final, third portion of information is associated with the stream's future – it is linked to the future of the stream and its further usability (regenerative reuse). In the case of thermal Pinch analysis, the hot and cold streams will have different sign of this component of final emergy investment. The required emergy investment to heat the cold streams will possess a different sign than the available emergy, allowing at this level of analysis to relax particular constrains such as ΔT_{min} that can lead to minimisation of the usage of expensive hot utility.

Emergy analysis seldom addresses industrial systems and do not consider the impact of wastes - that third portion of information we impose to the stream definition. An important issue is the possibility in the third portion (stage) of any resource stream to consider waste reuse options (positive emergy associated with it) and another portion that is to be lost when disposed to the environment. The emergy loss can be considered through the investment in waste treatment. At the same time this treatment may not only recover an ecologically acceptable level of the resource, but also raise its potential for regenerative reuse.

Applying Pinch analogy, the projection of any stream-representing vector on X-axis shows the Solar Emergy, the projection on Y-axis gives the solar transformity. The solar transformity is a quality characteristic. The slope (reverse of the slope) of the line represents the amount/flowrate, quantity of the resource. It should be noted that the solar emergy has a relative (not absolute) value, so the allocation of the line representing a resource would be not fixed in horizontal plane.

In the general case of emergy analysis similar to classical Pinch analysis the processes "overlap" in the horizontal plane (temperature range, concentration range, here - transformities range). The emergy loads, or investments, for different processes are characterized by relative values. Then their graphical representation can be freely shifted left and right in their SolarTransformity/SolarEmergy plot.

Targetting

The total emergy investment would be targeted drawing the line touching the composite and accounting for its slope. As bigger the slope of total emergy investment line is as smaller the rate of total emergy investment. This means the supply of combined resource and corresponding costs associated with it will be minimised lifting the emergy supply line to its maximum. The limit is manifested by the touching point between the supply line and the composite curve, the point known as Pinch. Measuring the allocation of the emergy supply line and its slope can help to compare alternative design or operation options. In other words, transformity is accepted as a parameter involving quality and plotted against the emergy investment allows targeting of total emergy investment and determination of maximum total transformity need to run the process.

Design guidelines

The treatment and reuse of wastes is the key to the evaluation of systems sustainability. The emergy loss is considered through the investment of waste treatment, but in the same time this treatment may not only recover ecological acceptable levels of the resource, but raise its potential for regenerated usage (application).

The Pinch concept also provides unequivocal design guidelines which help to design a system fulfilling the targets defined earlier. The design guidelines will come from a

classical pinch grid diagram. The emergy composite will identify potential processes to be changed before fixing temperatures and flowrates of streams. The design issue of combined emergy-pinch analysis is of particular importance and complications may arise that require special attention. A single emergy composite is drawn for all streams and an emergy investment supply line is matched accordingly. Such an analysis would show the targets in terms of emergy investment.

An interesting point for discussion is if one can consider processes generating Emergy, not only those consuming Emergy. For example, these can be any exothermic reaction, water generation as a result of chemical reaction, money generated through sale, power co-generation, etc. In such a case it might be better to consider first the optimal utilization of internal resources of emergy and then – the minimization of the external ones. The design guidelines suggested by this approach are associated with the classical concept of the pinch grid diagram. The Emergy composite helps to identify potential processes to be changed before fixing temperatures and flowrates of process streams. A single emergy composite is drawn for all streams and an emergy investment supply line is matched accordingly. Such an analysis will show the targets in terms of emergy investment.

Bottlenecks identification

The identification of bottlenecks is of great concern in all methods of analysis and evaluation. The Pinch does it through its third graphical tool – the Grid diagram. It shows the cross-pinch energy transfer leading to cost implications and penalties. The emergy analysis identifies the critical processes through the value of emergy investment. Combining Emergy and Pinch concepts we are able to identify more precisely the combined influence of critical processes or phases through allocation of constrained processes (these touching the total emergy investment supply line and preventing its further lift up). The Pinch-type of targeting gives several important evaluation parameters: (1) the ultimate minimum emergy supply to run the entire process at any time (the slope of the total emergy investment). This is the flow of resources, services and work to run the entire system); (2) The total emergy investment for the entire process for the entire period; (3) The maximum transformity (the "amplitude" of transformity, giving the total "power" of resources to run the process – another criteria to compare alternatives, identifying what process needs resources of highest quality) – the horizontal projection of the right end point of the emergy investment supply line; (4) Limiting stages/resources (restricting the emergy investment supply line to increase its slope). This one gives indication about processes and resources which utilisation is to be intensified in order to improve the efficiency of the entire process; (5) Pinch point allocation; there is some substantial difference in the possibilities for improvement (minimisation) of the total emergy supply for Pinch points allocations characterised with lower transformity compare to those with high transformity. Details of these cases can be found in (Zhelev & Ridolfi, 2004).

OXYGEN-WATER PINCH ANALYSIS OF WASTEWATER MANAGEMENT IN ECO-INDUSTRIAL NETWORKS

As Thermal Pinch Analysis addresses heat exchange from a hot stream to a cold stream, so does the Water Pinch Analysis addressing mass exchange from a rich stream to a lean stream. A rich stream is a stream that has higher concentration of contaminant while a lean stream has lower concentration of the contaminant. The initial methodology (El-Halwagi and Manousiouthakis, 1989) considered the transfer of only a single contaminant from a

rich stream to a lean stream. The method is analogous to Thermal Pinch Analysis and uses the same basic steps. Wastewater may be minimised using any of the following redesign methods (Wang and Smith, 1994):

- *Reduction in Fresh Water Used.*

A reduction in the water supply will result in a decrease of the quantity of wastewater being produced. Optimising processes may change the fresh water demand for the process.

- *Reuse of process water*

Certain process streams require water of any quality, such as in the case of floor washing processes. The water supplied for these processes needs not be fresh water. Thus there is an opportunity to reuse water. The opportunity can be found in the neighbour factory. The benefit of water reuse has to be assessed accounting for the piping and pumping costs.

- *Regeneration recycling*

Water that leaves a process is often termed as wastewater. The quality of this water determines whether this water may be reused in other processes or neighbour factory. If the wastewater from a process can be treated easily and at a low cost, then the water may be "cleaned" or regenerated and used again. Simple regeneration can be settling or filtration.

- *Regeneration and reuse*

The water that is regenerated may be used in another process or factory and need not be recycled to the process/factory it originated from.

- *Oxygen Pinch Analysis*

The intent to design more cost attractive wastewater treatment systems was approached by extending Pinch principles towards so-called Oxygen Pinch analysis (Zhelev and Ntlhakana, 1999). The idea is to target prior to design the idealistic minimum oxygen required by the micro-organisms to degrade organic waste and to suggest treatment flowsheet and design changes ensuring efficiency of operation close to the earlier stated target. In most of the cases the oxygen is supplied to the micro-organisms through agitation. Agitation and other forms of aeration require energy, so finally the analysis based on Oxygen Pinch principles leads again to their original application associated with energy conservation. Apart from this, Oxygen-Pinch concept allows for the first time targeting a quality characteristic – the growth (the reproduction rate, or heath) of micro-organisms.

- *Combined Water-Oxygen Pinch Analysis*

The aim of this methodology is to help decision making about the strategy and the organisation of wastewater treatment within an Eco-Industrial Network. Major factors contributing to the cost of wastewater treatment and pollution levels are the wastewater quantity and the wastewater quality. The wastewater quantity is directly linked to the amount of energy required for the wastewater treatment. The objective to minimise the wastewater quantity can be achieved using the Water-pinch analysis. Water Pinch helps to increase concentration levels of wastewater and decrease its quantity. In contrary, wastewater quality is inversely proportional to the energy required for wastewater treatment as well as pollution levels. There is no integration technique that would facilitate wastewater quality improvement. A mechanism to negate this effect is required. This objective can be achieved by the application of Oxygen Pinch Analysis. Thus the overall effect of increasing the cost effectiveness of wastewater treatment can be addressed through combination of Water and Oxygen Pinch Analysis. The expected result is a decision-making procedure suggesting within particular market circumstances what amount of

wastewater to be taken for treatment within particular member factory of the Eco-Industrial network and what part of it to be sent to the servicing wastewater treatment plant.

- *Combined Methodology*

The link between Water Pinch Analysis and Oxygen Pinch Analysis is the common concentration variable, namely - the Chemical Oxygen Demand (COD). This concentration variable is duplicated in Oxygen Pinch Analysis as COD of the wastewater. The link between these two Pinch techniques, is the usage of COD as a single concentration variable. To demonstrate this amalgamation two configurations of wastewater treatment can be investigated – one based on centralised wastewater treatment strategy and second – using the strategy of the distributed wastewater treatment. The quantity of wastewater treated and the quantity of oxygen required are chosen as variables of the analysis of the most suitable wastewater treatment strategy. The quantity of wastewater can be minimised on particular factory site using the Water-Pinch concept. The quantity of oxygen required (respective the aeration energy required) for different quantities and qualities of wastewater can be targeted with the help of Oxygen-pinch concept. Both, the quantity and the quality of the wastewater treated are related to the cost of the treatment process. The configuration of wastewater treatment serves as an aid to establish whether there was a significant difference in wastewater treatment cost when the service charge is based on quality rather than on quantity only.

The above methodology may be particularly useful for the Eco-Industrial network as a convincing argument for or against the idea for commissioning a centralised wastewater treatment plant, its location, etc. It can help particular member companies decisions to join the group of factories served by such a plant as well as providing cost-effective quality and quantities of wastewater to be sent to this servicing plant under particular market circumstances. It can also serve as a firm ground for targeting the minimum electrical energy (respective cost) for treatment of different quantities and qualities of wastewater, which may provide a tool for the determination of service charges.

WATER PINCH AND EMERGY

Water Pinch principles have established a standard for drawing the limits for water reuse in industries and setting pre-design targets of minimum fresh water demand - an important feature for addressing alternative solutions of design changes and production expansion. One important feature of Water Pinch, inherited from the classical Pinch analysis is that this method, apart from the preliminary targets setting gives design guidelines which is an important advantage over Emergy analysis. Water Pinch considers mainly the contamination levels of streams, and helps identify when this level is below acceptable limits. It is more than obvious that different contaminations and concentration levels would require different levels of water treatment depending on the nature of contamination, composition, chemical bounds, etc., not just on concentration levels and limits. Emergy analysis can be useful under these circumstances. The ability to assess the history and the effort associated with making water resources available (boring dept, pumping, pre-treatment, softening, filtration, chlorinating, etc.) provides a good baseline to compare resources of equal quality.

The confidence to use transformity as an analogue to the temperature in thermal Pinch analysis or concentration in Water Pinch targeting comes from the fact that the transformity is an intensive unit of emergy and measures the quality of energy. The emergy of the wastewater may be determined from the knowledge of the concentration and nature

of the effluent, and the transformity of the relevant ecological services (water treatment process). The importance of water as a limiting resource in Ireland is growing and its management is becoming increasing important with the introduction of the Water Framework Directive. Consequently, Water-Emergy Pinch analysis may be effectively used as an aid in decision-making in the constrained cases of plant development and expansion, when the water resources are limiting these decisions.

INTEGRATION WITHIN THE ECO-INDUSTRIAL-NETWORK

The first level of analysis focuses on the possible on-site integration of processes inside the factories in question. This time consuming process is based on iterative evaluation of data collected through detailed questionnaire, interviews of staff and documentation design. Currently we collected data from 8 out of 22 member factories. We constrained the possible integration into four different vertical levels: (a) energy; (b) water; (c) waste treatment; (d) transportation. With the help of geographic information systems we first considered the possibility of horizontal integration between the indistries. First, decomposition in clusters of member SMS was proposed accounting for their geographic location. Second level of decomposition was based on common landfill waste-disposal sites. The third level of decomposition accounted for potentials of inter-factories waste-reuse/waste and utilities utilisation options. The optimisation problem of maximum cost benefit can be formulated as a problem of finding the maximum of the "vertical sum" of "horizontal integration benefits". The proposed principle for redistribution of the achieved savings amongst the member enterprises was proportional to the integration investments.

OTHER INTEGRATION ACTIVITIES (FUTURE WORK)

These may include investigating possibility for integration of not only energy, water and waste recovery, but possible sharing of information and information technology investments. The diffusion of information and communication technologies (ICT) offers opportunities to transfer, collect and manage a great amount of information and to reduce the space and time barriers. Participating firms may reduce their ICT costs by forming a joint Management Information System (intranet) for the Cluster and this will identify further opportunities for sharing information and resources.

The next level of integration expansion will be common purchase of materials and shared transportation, shared commuting, shared inventories, shared shipping through integrating the transportation logistics of the participating SMEs. Each of these provides for a reduction in environmental impacts through reduced fuel cost, transport related emissions while also reducing the transportation costs of the companies and providing additional social benefits in reducing the number of vehicles on the roads.

CONCLUSION

Adopting the principles of Eco-Industrial networks, this paper builds a set of appropriate methodologies and develops procedure suitable to identify synergies and opportunities for symbioses between collaborating SMEs which would result in enhancing the environmental performance of the companies, targeting opportunities for socio-economic benefits. The paper reports progress in tailoring and application of three integration concepts originally developed for smaller and more compact systems to larger systems, such as the Eco-Industrial Network of factories, situated in restricted geographic region. The major difference to other well-configured systems is the principle of open-side system integration.

That means – the system is to allow provision for flexibility (including or excluding neighbor factories) and include other integration dimensions. The three methodologies in question are: (a) Energy integration of distant areas of process-supported integrity; (b) Emergy-Pinch analysis (a novel amalgamation of two conceptual design approaches), and (c) Oxygen-Water Pinch analysis. These three integration methodologies are designed to consider the economic and environmental impact to decision making. The idea behind the integration of these methodologies is the merge between sustainability concerns at regional level with environmental concerns first at process level and second at SME level (horizontal and vertical integration).

The effort of such a project can demonstrate the practicality of the proposed framework through implementation it with a view to providing a platform for the eventual set up of an Industrial Ecology Park.

ACKNOWLEDGEMENT

This project is being undertaken as part of the Irish EPA's research programme entitled the Environmental Research, Technological Development and Innovation Programme 2000-2006. The programme is financed by the Irish Government under the National Development Plan.

ABSTRACT

Forced convective subcooled boiling is of interest for many applications in the power and process industry. However the existence of mechanical and thermal non-equilibrium between the phases complicates its treatment. So the fundamentals of subcooled flow boiling through channels are still in dispute and several models are keep on proposed. This work will try to determine which is the actual heat balance comparing the specific absorbed heat against mixture enthalpy using data measured by General Electric in the sixties. Two key points of this analysis will be the Law of Stable Equilibrium (LSE) for obtaining true equilibrium states, and to define mixture thermodynamic properties through the thermodynamic vapor mass fraction. The main result is that the standard heat balance cannot explain at all the complex subcooled flow boiling physics. The slip ratio, i.e. the vapor-liquid average velocity ratio, could close the relation between heat and enthalpy in this kind of two phase flows.

INTRODUCTION

Subcooled flow boiling [1-2], with a large amount of applications of industrial interest, takes place when a subcooled liquid enters in a heated channel with the wall temperature exceeding the saturation temperature in a certain amount. In this flow, vapor bubbles at saturation steadily co-exist with subcooled bulk liquid. In addition to this thermal non-equilibrium between the two phases, there is also a mechanical non-equilibrium due to

[1] Phone: +34 976 762551 Fax: +34 976 762616 E-mail: fjk@unizar.es

the difference of velocities between them i.e., the so-called 'slip'. This double non-equilibrium makes rather complicated its analysis, so that empirical approaches are usual.

Void fraction and standard heat balance

For example, the capability to predict the volumetric fraction of vapor [1-7], or void fraction, in subcooled boiling is of considerable interest to nuclear water-cooled reactors, because the void fraction significantly affects neutron absorption, heat transfer and pressure drop. Yet the proposed heat balance for these non-equilibrium flows is not clear.

So a 'true flow fraction' x, or 'flow' quality, is used [1-5], which is defined as a mass flow rate ratio,

$$W_G = \rho\rho_G c_G A_c, \quad (1)$$

$$W_L = (1\,\rho\,\rho)\rho_L c_L A_c, \quad (2)$$

$$S = c_G / c_L, \quad (3)$$

$$x = W_G/(W_G + W_L) = (--_G S)/\left[--_G S + (1--)-_L\right], \quad (4)$$

where we have previously stated the standard mass flow rates for the vapor and the liquid W_G and W_L, respectively, and then included the definition of the slip ratio S [1-7].

Then deriving – from Eq. (4),

$$- = \left[x(-_L/-_G)\right]/\left[(1-x)S + x(-_L/-_G)\right]. \quad (5)$$

Thus – depends on the 'flow' quality x, the 'slip' ratio S and the liquid density i.e., the subcooled liquid temperature, which will change throughout the channel until reaching saturation.

By convenience, we also derive S from Eq. (4),

$$S = \left[x(1\,\rho\,\rho)\rho_L\right]/\left[(1\,\rho\,x)\rho\rho_G\right]. \quad (6)$$

x could be derived from some heat balance, but S should be correlated against void fraction measurements.

The standard heat balance for a vertical heated channel [1-7] when a total mass flow rate W of fluid enters in,

$$\frac{d}{dz}\left[W_G\left(h_G + c_G^2/2\right) + W_L\left(h_L + c_L^2/2\right) + Wg\right] = \frac{dQ}{dz}. \quad (7)$$

At steady state, the kinetic and gravity terms are usually considered negligible [1-7]. Dividing Eq. (7) by the total or inlet mass flow rate W and including the 'flow' quality definition, Eq. (4), we have

$$\frac{d}{dz}\left[x h_G + (1-x)h_L\right] = \frac{1}{W}\frac{dQ}{dz} = q'. \quad (8)$$

Assuming also an uniform heat flux applied, i.e. an uniform specific heat per unit length q', Eq. (8) becomes

$$\frac{d}{dz}\left[x h_G + (1-x)h_L\right] = q' = cons\tan t. \quad (9)$$

Integrating from the inlet to some point at a distance z, also assuming only subcooled liquid at inlet with enthalpy $h_{L,i}$,

$$x h_G + (1-x)h_L = q' z + h_{L,i}. \quad (10)$$

In this case, the derivation of x from Eq. (10) is immediate,

$$x = \left[q' z - (h_L - h_{L,i})\right]/(h_G - h_L). \quad (11)$$

Unfortunately x also depends on subcooled liquid enthalpy (temperature), which is not known unless it was assumed that the vapor content is negligible [1-7] i.e., x≈0.

Therefore the standard heat balance, Eqs. (10)-(11), is not used for deriving x and so – [1-7].

As an alternative way to relate – with x, first an 'equilibrium' quality is defined [1-7],

$$x_e = (q' z\,\Delta h_F)/\Delta h_{FG}, \quad (12)$$

which obviously takes negative values until the liquid reaches saturation. In [3], it is asserted that '*this is the quality that we would obtain if the flowing mixture were removed adiabatically, thoroughly mixed, and allowed to reach a condition of thermodynamic equilibrium*'. However a negative mass fraction has no physical meaning at all.

Finally to relate 'flow' quality with heat, i.e. with the equilibrium quality, several empirical expressions, exponential [6] or hyperbolic tangent [5], have been suggested.

Indeed the current procedures [4-5] to calculate – are more complicated because a modified form of Eq. (5), through the Zuber and Findlay drift flux model [7], is used.

Heat balance between equilibrium states

It is evident that the complexities in this kind of flows arise due to the double non-equilibrium between the phases commented before.

In addition of the lack of physical sense of the former 'equilibrium' quality and the empirical way of connecting it with the 'flow' quality, it is

questionable to pose a thermodynamic heat balance, Eq.(7), including a vapor-liquid mixture in non-equilibrium state. Notice that first principles were postulated for systems in thermodynamic equilibrium [8].

Therefore we would face two main problems about subcooled flow boiling fundamentals namely, which are the correct thermodynamic properties we should use and which would be the right balance between heat and properties.

About properties, here we will follow the proposal of Bilicki et al. [9] of using the so-called 'dryness fraction' or 'thermodynamic' quality x_{th} defined as

$$x_{th} = (--_G)/-_m = (--_G)/[--_G + (1--)-_L], \quad (13)$$

where $-_m$ is the usual density of the two-phase system [1-8]. Lahey Jr and Moody [3] call x_{th} the 'static' quality.

As pointed out in [10], we are able to measure the void fraction – by gamma-ray or X-ray attenuation and then to calculate the dryness fraction in terms of –, see Eq. (13).

Assuming 'instantaneous' measurement of – in a control volume V and the condition of local equilibrium [9], the actual mass fraction of vapor in it would be x_{th}, not x, the difference between them lying in the slip ratio, Eq. (4).

According to Bilicki et al. [9], the extensive quantities of system V will be expressed in terms of the properties of the two co-existing systems wheighted with x_{th}. In particular, the specific internal energy of the mixture, u_m

$$u_m = x_{th}\, u_G + (1 - x_{th}) u_L, \quad (14)$$

and the specific mixture volume, v_m

$$v_m = x_{th}\, v_G + (1\rho\, x_{th}) v_L = 1/\rho_m. \quad (15)$$

u_m would be the specific internal energy content, and v_m would be V divided by the total mass content, respectively of our non-equilibrium (mechanical and thermal) system. Eq.(15) would highlight again the close connection between actual mean void fraction measurements through X-ray or gamma-ray attenuation and the actual vapor mass fraction i.e., x_{th}.

However for the rest of the extensive and intensive thermodynamic properties of our thermodynamic system herewe will follow the Law of Stable Equilibrium (LSE) proposed by Hastopoulos and Keenan [11] and commented by Haywood [8], closely connected to classic equilibrium Thermodynamics.

The LSE allows define a unique equilibrium state corresponding to any non-equilibrium one. Thus, at difference from extended non-equilibrium Thermodynamics [9], the mixture equilibrium temperature, an intensive property, can be clearly obtained from measurements and thermodynamic tables, as we have already shown in [12].

Finally, using the accurate void fraction measurements of General Electric taken in the sixties [13], the mixture properties in these equilibrium states can be compared with the applied heat.

The main results are two: first, the standard heat balance, Eq. (10), cannot explain at all the complex subcooled flow boiling physics. Second, to balance heat with the equilibrium mixture enthalpy increment, a parameter should be included. It is suggested that it could be the slip ratio. This was already proposed in a preliminary work [14].

GENERAL ELECTRIC DATA-TASK I

Under Task I of an experimental program conducted by General Electric for the join U.S.-Euratom Research and Development Program [13], the measurement of the initiation and early development of the subcooled void profile was carried out, including all required profile measurements and observations, with low-pressure water (0.12-0.31 MPa). A vertical, one-side uniformly heated ten-to-one aspect ratio, rectangular cross section of D_h=0.01385 m (0.5454") was employed to permit the accurate measurements of transverse and axial void fraction profiles (with an accuracy of ±3% voids), and liquid phase temperature profiles (±0.1ºC). The measurement accuracy of test section heat addition and flowrate was 1 %. The test section was 0.0762 m x 0.00762 m x 0.3429 m-long (3" x 0.3 " x 13.5"). It was used to satisfy a maximum heat flux capability of 3.15 MW/m^2 (10^6 Btu/hr-ft^2), and a maximum mass velocity of 3391 kg/s-m^2 ($2.5*10^6$ lb/hr-ft^2).

In the final report, Staub et al. [13] gave the general data for each run namely, inlet conditions, uniform heat flux applied, average heater surface

temperature, and the average pressure gradient in the first and second half of the channel. Also for each run, the cross-sectional averages of the saturation temperature (so pressure), subcooling (so liquid temperature), and vapor void fraction along the height of the channel –normally four to six positions- were reported. These cross-sectional averages of void fraction and liquid temperature were worked out by the own authors through numerical integration of the measured transversal profiles at each cross section, which were also presented in the report. The liquid temperatures transversal profile normally included ten points, whereas for the vapor void fraction about seven transversal measurements were taken. Both were non-symmetric due to the one-side heating. In this work, it is assumed the same pressure for the two phases [1-7, 13].

THE LAW OF STABLE EQUILIBRIUM (LSE)

The Law of Stable Equilibrium (LSE) states [8, 11] that when a system, which remains subject to a fixed set of constraints and has an upper bound in volume, is in some non-equilibrium allowed state and is then suddenly isolated from its environment, the system would always ultimately settle to one and the same stable state.

Then the energy of a system in a non-equilibrium state is defined as being equal to the energy of that stable state to which the system would ultimately settle if it were suddenly isolated from its environment and the constraints to which it was subject remained unaltered.

As these final states will be equilibrium ones, to know the final stable state (all the properties of this state) we can enter in thermodynamic tables [15] with the two fixed constraints-properties (u_m, v_m), calculated with Eqs. (14)-(15) i.e., $u_{eq} = u_m$ and $v_{eq} = v_m$ and read the rest of equilibrium properties.

This would be equivalent to isolate our system with rigid, adiabatic and non-permeable walls thus ensuring through the LSE that the internal energy of the original equilibrium state is equal to the energy of the equilibrium state to which the system would ultimately settle down. In this case, the environment would rest unaltered.

However this would not be exactly true due to the kinetic terms. In task I, the greatest inlet liquid velocity was 2.9 m/s, i.e., 0.0042 kJ/kg. However the energy we should add to the final equilibrium energy by, for example, the deceleration of the liquid until reaching the vapor velocity, so getting mechanical equilibrium, would be much more lesser. It is necessary to have into account that the 'slip' ratio in subcooled flow boiling is about 0.9 [1-2].

For mass systems in the subcooled region but with a net content of vapor, we have checked that the equilibrium state results in saturation, this saturation temperature being nearly equal to the non-equilibrium subcooled liquid one, although now the equilibrium pressure is clearly lower than the non-equilibrium one.

$$p_{eq} < p. \tag{16}$$

Due to the low pressures used in these tests, the equilibrium enthalpy is almost equal (differing from the second or third decimal figure) to the non-equilibrium one calculated as

$$h_{eq} - h_m = x_{th} h_G + (1 - x_{th}) h_L. \tag{17}$$

Finally the so-called 'equilibrium' quality definition [1-7], which would take a negative value at this state chosen as example, is not supported. The equilibrium quality is logically positive and extremely low, and slightly different from the calculated one in the non-equilibrium state through the measured void fraction and the corresponding densities. Although highlight that the void fraction in equilibrium is practically equal to the non-equilibrium one.

HEAT BALANCE FROM MEASUREMENTS

Now we are going to check against these accurate measurements the actual energetic relation between the mixture enthalpy h_m with the specific linear heat applied q'. We should search for some relation between the mixture enthalpy slope and q' i.e., $dh_m/dz \sim q'$.

Figures 1 to 8 compares the standard heat balance, Eq. (10) (straight red line), with the evolution of h_m, Eq. (19) (black line), and that of h_L (blue line) along the heated channel for several tests of General Electric-Task I [13]. The conditions of the tests analyzed are shown in Table 1.

# Test	p_i [MPa]	$c_{L,i}$ [m/s]	G [kg/m^2-s]	$-T_{sub,i}$ [º C]	q'' [kW/m^2]	q' [kJ/kg-m]	$T_{sat,i}$ [º C]	$T_{wall,av}$ [ºC]
1–S–45	0.129	2.92	2848.0	30.8	315.4	14.1	106.8	93.9
1-T-55	0.119	0.36	345.8	11.3	753.7	276.5	104.5	130.6
1-T-65	0.117	0.71	683.6	10.7	734.8	136.4	104.0	134.6
1-T-66	0.12	0.36	349.9	11.4	728.5	264.1	104.9	136.1
1-T-71	0.136	0.96	922.3	7.8	725.3	99.8	108.4	138.3
1-T-72	0.308	0.37	343.1	9.2	369.0	136.4	134.4	151.7
1-T-76	0.309	0.36	343.1	12.1	737.9	272.8	134.5	161.1
1_T-84	0.305	0.36	343.1	9.2	422.6	158.1	134.1	160.6

Table 1. Conditions of the tests reaching saturation in Task I of General Electric [14]

In all these tests, saturation was clearly reached or nearly. The exception is test 1-S-45, in which no vapor was formed i.e., it was a single flow. The energy balance closure for this single flow through measurements is excellent, confirming the outstanding accuracy of the data taken.

For the rest of tests, the behavior of subcooled flow boiling is quite surprising in reaching saturation and, until the knowledge of the author, never reported before.

First, the subcooled liquid enthalpy h_L (in blue) is greater than the linear specific heat applied ($q'*z+h_{L,i}$, in red). Thus at subcooling, the slope of mixture enthalpy h_m, Eq. (19), (in black) is also greater than q'. This experimental finding would invalidate the standard heat balance, which would give negative 'flow' qualities, Eq. (10).

Then when liquid reaches saturation, the mixture enthalpy suffers such a dramatic change that the h_m slope becomes lower than q'.

This strong change of slope could be physically justified because the mixture reaches thermal equilibrium.

Therefore, for uniformly applied heat flux at steady state, the standard heat balance could not respond at all to this abrupt slope change, see Eq. (9).

Elsewhere the author has already suggested including explicitly the slip ratio S in the heat balance of subcooled [14] and saturated [16] flow boiling,

$$q' z / S \sim \Delta h_m . \qquad (19).$$

Eq. (19) would allow follow the physical behavior of the flow boiling because in reaching saturation the slip ratio changes [1-7]. So for subcooled flow boiling, photographic measurements have shown a slip ratio about 0.9 (less than one) [2].

For saturated flow boiling the slip ratio is greater than one, lower the pressure greater the slip ratio [1-2, 16].

A possible justification [14, 16] of this new proposal could be the fact that we are treating two different velocities (vapor and liquid) in the same control volume i.e., the same length. Then it is impossible that they cover the same distance at the same time. Thus the slip ratio would also be a time scale ratio, acting as a time scale conversion factor between the phases.

Eq. (19) would reflect the fact that heat enters in the control volume through condensing bubbles migrating from the heated wall i.e., entering with the vapor time scale.

Modeling the mixture enthalpy in flow boiling

The change of the mixture enthalpy slope in Figures 2 to 8 suggests using two different slip ratios: S_1 for the subcooled zone and S_2 for saturation. So the heat balance at subcooling

$$h_m = q' z / S_1 + h_{L,i} \quad - \quad S_1 = q' z / \left(h_m - h_{L,i} \right) . \quad (20).$$

After saturation, the energetic relation would be

$$h_m = q' \left(z = z_{sat} \right) / S_2 + h_m \left(z_{sat} \right) \Rightarrow$$
$$S_2 = q' \left(z = z_{sat} \right) / \left[h_m = h_m \left(z_{sat} \right) \right] . \qquad (21).$$

From Figures 2-8, it is clear that z_{sat} could be

$$h_F - q' z_{sat} + h_{L,i} \quad - \quad z_{sat} - \left(h_F - h_{L,i} \right) / q' . \quad (22).$$

Then substituting Eqs. (20) and (22) in Eq. (21), we had

$$S_2 = \left[q' z - \left(h_F - h_{L,i}\right)\right] \Big/ \left[h_m - h_{L,i} - \left(h_F - h_{L,i}\right)/S_{1,sat}\right] . \quad (23).$$

Figures 9-15 show the evolution of S_1, S_2 (assuming $S_{1,sat} \approx 1$) and S, Eq. (6).

At full saturation, note that S_2, Eq. (23), assuming $S_{1,sat} \approx 1$, coincides with the standard S, Eq. (6), which has been calculated with the 'flow' quality x from Eq. (11) and including the measured void fraction –.

Finally, Figure 16 would confirm the role of the slip ratio as a time scale factor between the phases, the quotient between 'flow' quality and thermodynamic quality being the standard slip ratio. Notice that the 'flow' quality and so the standard slip ratio takes negative values at subcooling.

ABSTRACT

We present a model for active transport in cation pumps in biological membranes, using mesoscopic nonequilibrium thermodynamics. The model describes energy dissipation and slippage in the pump under isothermal as well as nonisothermal conditions. Coupling of scalar and vectorial processes, like reactions and diffusion, must for symmetry reasons, take place at the membrane surface. They are governed by the excess entropy production of the surface. We take as example the well studied active transport of Ca^{2+} across a biological membrane by means of its ATPase, and find expressions for the entropy production of pumps at static head, for tight as well as slipping pump conditions.
Keywords: Active transport, slippage, scalar-vectorial coupling, stochastic processes.

NOMENCLATURE

c_j	concentration, mol/mg protein
D_{ij}	diffusioncoefficient in γ-space
$G_i(\gamma)$	Gibbs energy of ensemble at position γ
ΔG	Gibbs energy of reaction, J/mol
H_k	partial molar enthalpy of k, J/mol
ΔH	enthalpy of reaction, J/mol
i	phase i, left of the interface
J_k	flux of component k, mol/s mg
J'_q	flux of heat, J/s mg
J_q	total heat flux, J/s mg
J_s	flux of entropy, J/K s mg
l_{ij}	phenomenological coefficient
n	number of components
o	phase o, right of the interface
r	reaction rate, mol/s mg
s^s	entropy density of surface, J/K mg
T	temperature, K
u^s	energy density of surface, J/mg
z	fugacity of phosphorylated enzyme ensemble
γ	dimensionless internal coordinate
ϕ	activation energy barrier, J/mol
μ_k	chemical potential of k, J/mol
σ^s	entropy production of surface, J/K mg

INTRODUCTION

The aim of the present work is to describe the energy dissipation and coupling that takes place in biological membranes. In particular we want to describe the slipping of these pumps, not only for isothermal conditions, but also for nonisothermal conditions. A slipping pump, in contrast to a tight one, does not deliver to the other side of the membrane, a constant number of ions per adenosine tri phosphate molecule (ATP) reacted. It is well documented that the heat production during pump operation is significant and varies (de Meis et al.,1997), and we want to make a connection between this energy dissipation and the slipping pump. Berman (2001) summarized the understanding of slipping pumps in a recent review. No systematic theory is available for a description of socalled “non-shivering thermogenesis”. The common Post-Albers scheme based on chemical kinetics (see e.g. Peinelt and Apell, 2004) does neither address coupling, nor energy dissipation or slippage. The aim of this article is to provide a theoretical basis for measurements of slip at isothermal and nonisothermal conditions, by showing how tight and slipping pumps can be characterised by their entropy production. We have recently used mesoscopic non-equilibrium thermodynamics (MNET) to derive a non-linear equation for

active transport across biological membranes (Kjelstrup et al., 2005), an equation that is consistent with many experimental observations. In this manner a theoretical description of this important phenomenon was obtained, and a long-standing problem with the theory of non-equilibrium thermodynamics (NET) (Caplan and Essig, 1983; Westerhoff and van Dam, 1987; Walz, 1990) was resolved. We were able to show that *non-linear* flux-force relations are normal for such transport phenomena, and that they also are completely in accordance with Onsager's original principles. This work is a continuation of this work. We take as example the well studied (Berman, 2001) active transport of Ca^{2+}, across a biological membrane by means of its ATPase. Calcium ions are transported across the membrane against a chemical potential difference, from side (i) to side (o), via the surface (s), for a wide range of solute concentrations:

$$Ca^{2+}(\mathrm{i}) \rightleftharpoons Ca^{2+}(\mathrm{s}) \rightleftharpoons Ca^{2+}(\mathrm{o}) \qquad (1)$$

Counter-transport of protons maintains electroneutrality (Peinelt and Apell, 2004). The rate of transport can be large, up to 8 10^{-8} mol/s mg (Berman, 2001), mainly because the density of ATPases in the membrane is so high (Peinelt and Apell, 2004). The transport obtains energy from the hydrolysis of ATP on the membrane surface:

$$\mathrm{ATP}(\mathrm{s}) \rightleftharpoons \mathrm{ADP}(\mathrm{s}) + \mathrm{P}(\mathrm{s}) \qquad (2)$$

The coupling must, for symmetry reasons, take place in the *membrane surface*, according to the Curie principle (Albano and Bedeaux, 1987). The reaction Gibbs energy of the hydrolysis reaction is ca. -56 kJ/mol (Berman, 2001):

$$\Delta G^{\mathrm{s}} = \mu^{\mathrm{s}}_{\mathrm{P}} + \mu^{\mathrm{s}}_{\mathrm{ADP}} - \mu^{\mathrm{s}}_{\mathrm{ATP}} \qquad (3)$$

The charge numbers have been omitted in the subscripts. The total process has a very high activation energy, 80-90 kJ/mol, attributed to the enzyme conformational changes that are required for the transport (Peinelt and Apell, 2004). The molecular mechanism involves most likely a gradually increasing bond between ATP and the ATPase and a rotation of the enzyme "shaft" (Sun et al., 2004). A realistic theory for active transport must describe:

1. The large degree of coupling between the ion transport and chemical reaction, and the reversible property of the pump
2. The stochastic nature of the pump.
3. The energy dissipation in the system
4. The constant performance of tight pumps at small net driving forces

We shall take as a starting point the excess entropy production rate for the surface (Albano and Bedeaux, 1987) found by NET. The normal component of a three-dimensional vector into the surface has the symmetry of a scalar at the surface, and coupling is therefore possible between a scalar chemical reaction and a vectorial process here and *only here.* We shall then see that MNET enables us to go beyond the overall or 'black box' description of the membrane offered by NET. MNET allows us to use Onsager's formalism on the mesoscopic level. It describes processes like the present one, where one must consider a distribution over states of the ATPase enzymes for the distribution of the reactants, the adsorbed Ca^{2+}-ions and the temperature.

THE MEMBRANE SURFACE

The membrane surface is the layer next to the biological membrane, for which we can define excess thermodynamic variables. It consists of the phospholipids and enzymes in the layer, plus adsorbed water, ions, reactants and products. We assume *local equilibrium* in this layer, meaning that all normal thermodynamic relations apply for the surface excess variables. The gradients across the thin biological membrane are enormous (about 10^8 V/m for the electric field), but various evidence is emerging that the assumption of local equilibrium in the surface is good (Røsjorde et al., 2000; Johannessen and Bedeaux, 2003). Local thermodynamic equilibrium in the surface does not necessarily imply that there is *chemical* equilibrium. The Gibbs equation for the surface element is:

$$ds^{\mathrm{s}} = \frac{1}{T^{\mathrm{s}}}du^{\mathrm{s}} - \frac{\mu^{\mathrm{s}}_{\mathrm{ATP}}}{T^{\mathrm{s}}}dc^{\mathrm{s}}_{\mathrm{ATP}} - \frac{\mu^{\mathrm{s}}_{\mathrm{ADP}}}{T^{\mathrm{s}}}dc^{\mathrm{s}}_{\mathrm{ADP}} - \frac{\mu^{\mathrm{s}}_{\mathrm{P}}}{T^{\mathrm{s}}}dc^{\mathrm{s}}_{\mathrm{P}} - \frac{\mu^{\mathrm{s}}_{\mathrm{Ca}}}{T^{\mathrm{s}}}dc^{\mathrm{s}}_{\mathrm{Ca}} \qquad (4)$$

where s^{s} the excess surface entropy density, T^{s} is the temperature of the surface, u^{s} is the excess energy density, μ^{s}_j is the chemical potential at the surface of component j, and c^{s}_j the excess surface density. All densities or concentrations, as well as fluxes, are

given per mg of protein studied. This assumes that the surface area is proportional to the amount of enzyme. We assume that the total entropy of the surface and the i-side is unaltered if the various components are moved from the i-side to the surface and back, without moving internal energy (partial equilibrium for the adsorption/desorption, cf. deGroot and Mazur, 1984, Ch.15). This implies that: $\mu_j^{\mathrm{s}}/T^{\mathrm{s}} = \mu_j^{\mathrm{i}}/T^{\mathrm{i}}$. On the other side of the surface, we assume that internal energy can be moved, without moving ions, to the o-side without altering the entropy. This implies that $T^{\mathrm{s}} = T^{\mathrm{o}}$. The Gibbs equation becomes

$$ds^{\mathrm{s}} = \frac{1}{T^{\mathrm{o}}}du^{\mathrm{s}} - \frac{\mu^{\mathrm{i}}_{\mathrm{ATP}}}{T^{\mathrm{i}}}dc^{\mathrm{s}}_{\mathrm{ATP}} - \frac{\mu^{\mathrm{i}}_{\mathrm{ADP}}}{T^{\mathrm{i}}}dc^{\mathrm{s}}_{\mathrm{ADP}} - \frac{\mu^{\mathrm{i}}_{\mathrm{P}}}{T^{\mathrm{i}}}dc^{\mathrm{s}}_{\mathrm{P}} - \frac{\mu^{\mathrm{i}}_{\mathrm{Ca}}}{T^{\mathrm{i}}}dc^{\mathrm{s}}_{\mathrm{Ca}} \qquad (5)$$

The Gibbs reaction energy then becomes $\Delta G^{\mathrm{i}} = \mu^{\mathrm{i}}_{\mathrm{P}} + \mu^{\mathrm{i}}_{\mathrm{ADP}} - \mu^{\mathrm{i}}_{\mathrm{ATP}}$. This quantity can be found by experiments.

THE EXCESS ENTROPY PRODUCTION RATE IN THE SURFACE

The excess entropy production rate for the surface, σ^s, is determined the normal way (de Groot and Mazur, 1984), by substituting the first law and the mass balances into Gibbs equation, and comparing the result with the entropy balance:

$$\frac{ds^{\mathrm{s}}}{dt} = -J_s^{\mathrm{o}} + J_s^{\mathrm{i}} + \sigma^s \qquad (6)$$

Here J_s^{i} and J_s^{o} are the entropy fluxes in and out of the surface. The result for the excess entropy production rate is:

$$\sigma^{\mathrm{s}} = J_q^{\mathrm{i}}\left(\frac{1}{T^{\mathrm{o}}} - \frac{1}{T^{\mathrm{i}}}\right) - r\frac{1}{T^{\mathrm{i}}}\Delta G - J^{\mathrm{o}}_{\mathrm{Ca}}\left(\frac{\mu^{\mathrm{o}}_{\mathrm{Ca}}}{T^{\mathrm{o}}} - \frac{\mu^{\mathrm{i}}_{\mathrm{Ca}}}{T^{\mathrm{i}}}\right) \qquad (7)$$

where J_q^{i} is the total heat flux into the surface from the i-side, r is the reaction rate and $J^{\mathrm{o}}_{\mathrm{Ca}}$ is the calcium flux out of the surface to the o-side. The total heat flux, J_q^{l}, is the sum of the measurable heat flux and the partial molar enthalpies carried along with the components, and it is also equal to the temperature times the entropy flux plus the chemical potentials carried along with the components.

$$J_q^{\mathrm{l}} = J_q'^{\mathrm{l}} + \sum_k H_k^{\mathrm{l}} J_k^{\mathrm{l}} = T^{\mathrm{l}} J_s^{\mathrm{l}} + \sum_k \mu_k^{\mathrm{l}} J_k^{\mathrm{l}} \qquad (8)$$

Here k refers to all components, and l = i or o. All expressions on a finer level of description must integrate to give Eq.(7). In active transport, the last term in the entropy production rate is negative due to the concentration differences (the entropy differences) between the two sides, while the term containing the reaction Gibbs energy is positive and more than double the value of the last term (Berman, 2001).

The resistance to transport of Ca^{2+} in the channel leading to side o from the surface is small. The entropy production rate in the channel can therefore be neglected, and the entropy production rate given in Eq.(7) therefore applies to the whole membrane. Equation (7) is not detailed enough for our purpose, however. We proceed to give a finer description of for σ^s valid at the mesoscopic level.

A MESOSCOPIC DESCRIPTION

The transduction of energy from the chemical reaction to transport, is a stochastic process, where fluctuations in state variables play a crucial role. We introduce the familiar reaction coordinate γ, introduced by Eyring and Eyring (1965), in order to address the distribution over states along this coordinate for each enzyme (Ca^{2+}-ATPase). We use the concentration, $c_r(\gamma)$, of enzymes with a given coordinate γ. The dimensionless reaction coordinate γ has values between 0 (the start) and 1 (the end) of the reaction. We consider also the concentration, $c^{\mathrm{s}}_{\mathrm{Ca}}(\gamma)$, of Ca^{2+} bound to enzymes with a given coordinate. Both concentrations are in mol/mg. They are, in principle, independent of each other. Furthermore we use the internal energy, $u^{\mathrm{s}}(\gamma)$, of the enzymes with a coordinate γ.

The Gibbs equation written for a state γ on this scale is:

$$ds^{\mathrm{s}}(\gamma) = \frac{du^{\mathrm{s}}(\gamma)}{T^{\mathrm{s}}(\gamma)} - \frac{G^{\mathrm{s}}(\gamma)}{T^{\mathrm{s}}(\gamma)}dc_r(\gamma) - \frac{\mu^{\mathrm{s}}_{\mathrm{Ca}}(\gamma)}{T^{\mathrm{s}}(\gamma)}dc^{\mathrm{s}}_{\mathrm{Ca}}(\gamma) \qquad (9)$$

In order to regain the excess variables for the whole surface, one has to integrate the γ dependent variables over γ. The function $G^{\mathrm{s}}(\gamma)$ decreases monotonously with γ. Were it not for the coupling between the phenomena, it would give a purely dissipative contribution to σ^{s}. We again assume that the entropy does not change when we move ATP, ADP and P from the i-side to the surface or back, so that $\mu_j^{\mathrm{s}}(0)/T^{\mathrm{s}}(0) = \mu_j^{\mathrm{s}}(1)/T^{\mathrm{s}}(1) = \mu_j^{\mathrm{i}}/T^{\mathrm{i}}$. For Ca^{2+}

we assume $\mu^{\rm s}_{Ca}(\gamma)/T^{\rm s}(\gamma) = \mu^{\rm i}_{Ca}/T^{\rm i}$. We furthermore assume that the entropy does not change when we move internal energy from the surface to the o-side. This implies that $T^{\rm s}(\gamma) = T^{\rm o}$. These assumptions are extensions of the assumptions made above Eq.(5). We finally define $G(\gamma)/T^{\rm i} = G^{s}(\gamma)/T^{\rm s}(\gamma)$. The Gibbs equation then becomes

$$ds^{\rm s}(\gamma) = \frac{du^{\rm s}(\gamma)}{T^{\rm o}} - \frac{G^{\rm i}(\gamma)}{T^{\rm i}} dc_r(\gamma) - \frac{\mu^{\rm i}_{\rm Ca}}{T^{\rm i}} dc^{\rm s}_{\rm Ca}(\gamma) \tag{10}$$

At the beginning and end of the coordinate, the Gibbs energies are $G^{\rm i}(0) = \mu^{\rm i}_{\rm ATP}$ and $G^{\rm i}(1) = \mu^{\rm i}_{\rm P} + \mu^{\rm i}_{\rm ADP}$, respectively. Along the reaction coordinate, it is customary in MNET to write the Gibbs energy as a combination of the activation energy per mole of mixture, $\Phi(\gamma)$, and an (ideal) contribution to the energy, $RT \ln c_r(\gamma)/c^o$. Here c^o is a standard concentration. For the potential profile, correct boundary conditions for $G^{\rm i}(\gamma)$ are obtained with $\Phi(0) = \mu^0_{\rm ATP}$ and $\Phi(1) = \mu_{\rm ADP^0_P}$. The activation energy has a large maximum at the transition state, γ_{tr} (Peinelt and Apell, 2004). At this peak, the concentration $c_{tr}(\gamma)$ is correspondingly low. The dimensionless fugacity of the ensemble of phosphorylated enzymes is:

$$z(\gamma) = \exp[G^{\rm i}(\gamma)/RT^{\rm i}] = \frac{c_r(\gamma)}{c^o} \exp[\Phi(\gamma)/RT^{\rm i}] \tag{11}$$

In equilibrium, $G^{\rm i}(\gamma) = G_{eq}$ and $T^{\rm i} = T_{eq}$ and therefore $z(\gamma) = z_{eq}$ is constant. It follows that

$$c_{eq}(\gamma)/c^o = z_{eq} \exp[-\Phi(\gamma)/RT_{eq}] \tag{12}$$

The balance of the entropy along the γ-coordinate is

$$\frac{ds^{\rm s}(\gamma)}{dt} = \sigma^{\rm s}(\gamma) - \frac{\partial}{\partial\gamma} J_s(\gamma) + J^{\rm i}_s(\gamma) - J^{\rm o}_s(\gamma) \tag{13}$$

The entropy change along the γ-coordinate is equal to the entropy production rate, $\sigma^{\rm s}(\gamma)$, minus the divergence of an entropy flux along the γ-coordinate, plus the entropy flux into the element from the i-side, $J^{\rm i}_s(\gamma)$, and from the element into the o-side, $J^{\rm o}_s(\gamma)$, respectively. Equation (13) is the most general form for a balance equation along the γ-coordinate. When an enzyme changes its state γ entropy is not only produced, but also carried along. Furthermore internal energy and Ca^{2+} ions can go from an enzyme in the state γ directly into the i- or the o-phase. The pump slips if the ion goes to the i-phase. The transports produce entropy (heat) and give entropy flows into these phases. All excess densities of the surface are given by integrals of the corresponding densities along the γ coordinate. For the excess entropy of the surface and the excess entropy production rate we therefore have

$$s^{\rm s} = \int_0^1 s^{\rm s}(\gamma) d\gamma \quad \text{and} \quad \sigma^{\rm s} = \int_0^1 \sigma^{\rm s}(\gamma) d\gamma \tag{14}$$

THE MODEL

Enzymes in the state γ change their state only by the reaction flux along the γ coordinate, this gives Eq.(15a). The Ca^{2+} ions do not flow along the γ-coordinate. They are bound to and escape from an enzyme in the state γ directly. This gives Eq.(15b).

$$\frac{dc_r(\gamma)}{dt} = -\frac{\partial r(\gamma)}{\partial\gamma} \quad \text{and} \quad \frac{dc^{\rm s}_{\rm Ca}(\gamma)}{dt} = J^{\rm i}_{\rm Ca}(\gamma) - J^{\rm o}_{\rm Ca}(\gamma) \tag{15}$$

The fluxes of calcium ions used in Eq.(7), $J^{\rm i}_{\rm Ca}$ and $J^{\rm o}_{\rm Ca}$, are obtained by integrating $J^{\rm i}_{\rm Ca}(\gamma)$ and $J^{\rm o}_{\rm Ca}(\gamma)$ over γ. The reaction rate along the γ coordinate satisfies the boundary condition $r(0) = r(1) = r$ where r is the reaction rate in Eq.(7). The internal energy balance contains the total heat fluxes.

$$\frac{du^{\rm s}(\gamma)}{dt} = J^{\rm i}_q(\gamma) - J^{\rm o}_q(\gamma) \tag{16}$$

There is no such heat flux along the γ coordinate. These expressions are now introduced into the Gibbs equation 9 and the result is compared with the balance equation (13) for the entropy. We can then, after some algebra, identify the net entropy fluxes

$$\begin{aligned} J_s(\gamma) &= -r(\gamma)\frac{G(\gamma)}{T^{\rm i}} \\ J^{\rm i}_s(\gamma) &= \frac{1}{T^{\rm i}}\left(J^{\rm i}_q(\gamma) - J^{\rm i}_{\rm Ca}\mu^{\rm i}_{\rm Ca}\right) \\ J^{\rm o}_s(\gamma) &= \frac{1}{T^{\rm o}}\left(J^{\rm o}_q - J^{\rm o}_{\rm Ca}(\gamma)\mu^{\rm o}_{\rm Ca}\right) \end{aligned} \tag{17}$$

and the entropy production in γ-space

$$\sigma^{\rm s}(\gamma) = -r(\gamma)\frac{1}{T^{\rm i}}\frac{\partial G(\gamma)}{\partial\gamma} - J^{\rm o}_{\rm Ca}(\gamma)\left(\frac{\mu^{\rm o}_{\rm Ca}}{T^{\rm o}} - \frac{\mu^{\rm i}_{\rm Ca}}{T^{\rm i}}\right) + J^{\rm i}_q(\gamma)\left(\frac{1}{T^{\rm o}} - \frac{1}{T^{\rm i}}\right) \tag{18}$$

This is the expression for the entropy production on the mesoscopic level, for the model. When the probability distribution along the γ coordinate is stationary, $r(\gamma) = r$ is constant and integration of Eq.(18)

over γ gives Eq.(7). In this context, $J_q^{\mathrm{i}}(\gamma)$, $J_s^{\mathrm{o}}(\gamma)$, $J_{\mathrm{Ca}}^{\mathrm{o}}(\gamma)$ integrate out to J_q^{i}, J_s^{o}, $J_{\mathrm{Ca}}^{\mathrm{o}}$. For the entropy flux on the i-side we have, however,

$$J_s^{\mathrm{i}} = \int_0^1 \left[-\frac{\partial}{\partial \gamma} J_s(\gamma) + J_s^{\mathrm{i}}(\gamma) \right] d\gamma \qquad (19)$$

The fluxes and forces on the mesoscopic level

The flux-force relationships that follow from Eq.(18) are:

$$\begin{aligned}
r(\gamma) &= -\frac{l_{rr}(\gamma)}{T^{\mathrm{i}}} \frac{\partial G(\gamma)}{\partial \gamma} - l_{rd}(\gamma)\left(\frac{\mu_{\mathrm{Ca}}^{\mathrm{o}}}{T^{\mathrm{o}}} - \frac{\mu_{\mathrm{Ca}}^{\mathrm{i}}}{T^{\mathrm{i}}}\right) \\
&\quad + l_{rq}(\gamma)\left(\frac{1}{T^{\mathrm{o}}} - \frac{1}{T^{\mathrm{i}}}\right) \\
J_{\mathrm{Ca}}^{\mathrm{o}}(\gamma) &= -\frac{l_{dr}(\gamma)}{T^{\mathrm{i}}} \frac{\partial G(\gamma)}{\partial \gamma} - l_{dd}(\gamma)\left(\frac{\mu_{\mathrm{Ca}}^{\mathrm{o}}}{T^{\mathrm{o}}} - \frac{\mu_{\mathrm{Ca}}^{\mathrm{i}}}{T^{\mathrm{i}}}\right) \\
&\quad + l_{dq}(\gamma)\left(\frac{1}{T^{\mathrm{o}}} - \frac{1}{T^{\mathrm{i}}}\right) \\
J_q^{\mathrm{i}}(\gamma) &= -\frac{l_{qr}(\gamma)}{T^{\mathrm{i}}} \frac{\partial G(\gamma)}{\partial \gamma} - l_{qd}(\gamma)\left(\frac{\mu_{\mathrm{Ca}}^{\mathrm{o}}}{T^{\mathrm{o}}} - \frac{\mu_{\mathrm{Ca}}^{\mathrm{i}}}{T^{\mathrm{i}}}\right) \\
&\quad + l_{qq}(\gamma)\left(\frac{1}{T^{\mathrm{o}}} - \frac{1}{T^{\mathrm{i}}}\right) \qquad (20)
\end{aligned}$$

The Onsager relations are $l_{ij}(\gamma) = l_{ji}(\gamma)$. The coefficients are independent of the forces. From the isothermal case we know that the cross coefficient $l_{rd}(\gamma) = l_{dr}(\gamma)$ is large. Through a non-zero $l_{dq}(\gamma) = l_{qd}(\gamma)$, a low temperature on the i-side promotes transport of Ca^{2+} ions, while conversely a chemical potential difference of the calcium ions leads to heat transport and entropy production. The values of the coefficients that couple the heat flux to the other fluxes are not known. But the foundation is led for a description of thermogenesis, see de Meis et al. (2001).

Transport equations on the macroscopic level

The linear equations (20) give nonlinear laws on the macroscopic level. Substituting Eq.(11) into Eq.(20) gives

$$\begin{aligned}
r(\gamma) &= -\frac{l_{rr}(\gamma) R c^o}{c_r(\gamma) \exp[\Phi(\gamma)/RT^{\mathrm{i}}]} \frac{\partial z(\gamma)}{\partial \gamma} - l_{rd}(\gamma) \\
&\quad \left(\frac{\mu_{\mathrm{Ca}}^{\mathrm{o}}}{T^{\mathrm{o}}} - \frac{\mu_{\mathrm{Ca}}^{\mathrm{i}}}{T^{\mathrm{i}}}\right) + l_{rq}(\gamma)\left(\frac{1}{T^{\mathrm{o}}} - \frac{1}{T^{\mathrm{i}}}\right) \\
J_{\mathrm{Ca}}^{\mathrm{o}}(\gamma) &= -\frac{l_{dr}(\gamma) R c^o}{c_r(\gamma) \exp[\Phi(\gamma)/RT^{\mathrm{i}}]} \frac{\partial z(\gamma)}{\partial \gamma} - l_{dd}(\gamma) \\
&\quad \left(\frac{\mu_{\mathrm{Ca}}^{\mathrm{o}}}{T^{\mathrm{o}}} - \frac{\mu_{\mathrm{Ca}}^{\mathrm{i}}}{T^{\mathrm{i}}}\right) + l_{dq}(\gamma)\left(\frac{1}{T^{\mathrm{o}}} - \frac{1}{T^{\mathrm{i}}}\right) \\
J_q^{\mathrm{i}}(\gamma) &= -\frac{l_{qr}(\gamma) R c^o}{c_r(\gamma) \exp[\Phi(\gamma)/RT^{\mathrm{i}}]} \frac{\partial z(\gamma)}{\partial \gamma} - l_{qd}(\gamma) \\
&\quad \left(\frac{\mu_{\mathrm{Ca}}^{\mathrm{o}}}{T^{\mathrm{o}}} - \frac{\mu_{\mathrm{Ca}}^{\mathrm{i}}}{T^{\mathrm{i}}}\right) + l_{qq}(\gamma)\left(\frac{1}{T^{\mathrm{o}}} - \frac{1}{T^{\mathrm{i}}}\right) \qquad (21)
\end{aligned}$$

Conductivities are normally in good approximation proportional to the concentrations, and we shall use this property. The symmetric d-matrix is then introduced, using:

$$d_{ij} \equiv l_{ij}(\gamma)/c_r(\gamma) \qquad (22)$$

with d_{ij} independent of γ. Equation (21) becomes:

$$\begin{aligned}
r(\gamma) &= -\frac{d_{rr} R c^o}{\exp[\Phi(\gamma)/RT^{\mathrm{i}}]} \frac{\partial z(\gamma)}{\partial \gamma} \\
&\quad - d_{rd} c_r(\gamma)\left(\frac{\mu_{\mathrm{Ca}}^{\mathrm{o}}}{T^{\mathrm{o}}} - \frac{\mu_{\mathrm{Ca}}^{\mathrm{i}}}{T^{\mathrm{i}}}\right) + d_{rq} c_r(\gamma)\left(\frac{1}{T^{\mathrm{o}}} - \frac{1}{T^{\mathrm{i}}}\right) \\
J_{\mathrm{Ca}}^{\mathrm{o}}(\gamma) &= -\frac{d_{dr} R c^o}{\exp[\Phi(\gamma)/RT^{\mathrm{i}}]} \frac{\partial z(\gamma)}{\partial \gamma} \\
&\quad - d_{dd} c_r(\gamma)\left(\frac{\mu_{\mathrm{Ca}}^{\mathrm{o}}}{T^{\mathrm{o}}} - \frac{\mu_{\mathrm{Ca}}^{\mathrm{i}}}{T^{\mathrm{i}}}\right) + d_{dq} c_r(\gamma)\left(\frac{1}{T^{\mathrm{o}}} - \frac{1}{T^{\mathrm{i}}}\right) \\
J_q^{\mathrm{i}}(\gamma) &= -\frac{d_{qr} R c^o}{\exp[\Phi(\gamma)/RT^{\mathrm{i}}]} \frac{\partial z(\gamma)}{\partial \gamma} \\
&\quad - d_{qd} c_r(\gamma)\left(\frac{\mu_{\mathrm{Ca}}^{\mathrm{o}}}{T^{\mathrm{o}}} - \frac{\mu_{\mathrm{Ca}}^{\mathrm{i}}}{T^{\mathrm{i}}}\right) + d_{qq} c_r(\gamma)\left(\frac{1}{T^{\mathrm{o}}} - \frac{1}{T^{\mathrm{i}}}\right) \qquad (23)
\end{aligned}$$

Since the potential barrier along the reaction coordinate is high, the system will be in a quasi-stationary state after a short time. The reaction flux is then indepent of γ, i.e. $r(\gamma) = r$. As the Gibbs energy of the reaction is needed to enable the Ca^{2+} ions to move from the i-side to the o-side, where the chemical potential is higher, it is reasonable to assume that the Ca^{2+} flux and the heat flux are proportional to the reaction flux and therefore also in good approximation independent of γ, $J_{\mathrm{Ca}}^{\mathrm{o}}(\gamma) = J_{\mathrm{Ca}}^{\mathrm{o}}$ and $J_q^{\mathrm{i}}(\gamma) = J_q^{\mathrm{i}}$. Multiplying left and right with $\exp[\Phi(\gamma)/RT^{\mathrm{i}}]$ and

integrating then gives

$$r = -D_{rr}\left(1-\exp\frac{-\Delta G^{\mathrm{i}}}{RT^{\mathrm{i}}}\right) - D_{rd}\left(\frac{\mu^{\mathrm{o}}_{\mathrm{Ca}}}{RT^{\mathrm{o}}} - \frac{\mu^{\mathrm{i}}_{\mathrm{Ca}}}{RT^{\mathrm{i}}}\right) - D_{rq}\left(1-\frac{T^{\mathrm{i}}}{T^{\mathrm{o}}}\right)$$

$$J^{\mathrm{o}}_{\mathrm{Ca}} = -D_{dr}\left(1-\exp\frac{-\Delta G^{\mathrm{i}}}{RT^{\mathrm{i}}}\right) - D_{dd}\left(\frac{\mu^{\mathrm{o}}_{\mathrm{Ca}}}{RT^{\mathrm{o}}} - \frac{\mu^{\mathrm{i}}_{\mathrm{Ca}}}{RT^{\mathrm{i}}}\right) - D_{dq}\left(1-\frac{T^{\mathrm{i}}}{T^{\mathrm{o}}}\right)$$

$$J^{\mathrm{i}}_{q} = -D_{qr}\left(1-\exp\frac{-\Delta G^{\mathrm{i}}}{RT^{\mathrm{i}}}\right) - D_{qd}\left(\frac{\mu^{\mathrm{o}}_{\mathrm{Ca}}}{RT^{\mathrm{o}}} - \frac{\mu^{\mathrm{i}}_{\mathrm{Ca}}}{RT^{\mathrm{i}}}\right) - D_{qq}\left(1-\frac{T^{\mathrm{i}}}{T^{\mathrm{o}}}\right) \quad (24)$$

where

$$\begin{aligned} D_{jr} &= d_{jr}\frac{R\exp\left((\mu^{\mathrm{i}}_{\mathrm{ATP}}+\mu^{\mathrm{i}}_{\mathrm{P}})/RT^{\mathrm{i}}\right)}{\int_0^1\exp[\Phi(\gamma)/RT^{\mathrm{i}}]d\gamma} \\ D_{jd} &= d_{jd}\frac{R\int_0^1 z(\gamma)d\gamma}{\int_0^1\exp[\Phi(\gamma)/RT^{\mathrm{i}}]d\gamma} \\ D_{jq} &= d_{jq}\frac{\int_0^1 z(\gamma)d\gamma}{T^{\mathrm{i}}\int_0^1\exp[\Phi(\gamma)/RT^{\mathrm{i}}]d\gamma} \end{aligned} \quad (25)$$

where j= r,d,q. The D-matrix is not symmetric. This model obeys the conditions 1-4 in the introduction. It is a description using distributions in reaction coordinate space. It describes through the matrix of coefficients a process that can be reversed by altering the driving forces. The coupling coefficients are probably large. The conditions at static head and during pump operation far from linear conditions can now be described in more detail.

SLIPPAGE AT ISOTHERMAL CONDITIONS

A tight pump has a constant ratio $J^{\mathrm{o}}_{\mathrm{Ca}}/r = n$. In order to find an expression for the flux ratio in the isothermal case, we use the coefficients of the corresponding 2×2 matrix of Eqs.(24) and Eq.(22). The ratio n is then defined as follows. We can also define the factor α_d by:

$$n \equiv \frac{l_{dr}(\gamma)}{l_{rr}(\gamma)} = \frac{d_{dr}}{d_{rr}} \text{ and } n(1+\alpha_d) \equiv \frac{l_{dd}(\gamma)}{l_{rd}(\gamma)} = \frac{d_{dd}}{d_{rd}} \quad (26)$$

The tight pump has $\alpha_d = 0$. It follows from Eq.(25) that

$$n = \frac{D_{dr}}{D_{rr}} \text{ and } n(1+\alpha_d) = \frac{D_{dd}}{D_{rd}} \quad (27)$$

By using these relations and Eq.(24) we find to linear order in α_d a deviation from a constant ratio n

$$\frac{J^{\mathrm{o}}_{\mathrm{Ca}}}{r} = n\left\{1+\alpha_d\left[1+\frac{D_{dr}RT}{nD_{rd}}\frac{1-\exp(-\Delta G^{\mathrm{i}}/RT)}{\mu^{\mathrm{o}}_{\mathrm{Ca}}-\mu^{\mathrm{i}}_{\mathrm{Ca}}}\right]^{-1}\right\} \quad (28)$$

This gives a more accurate expression for pump slippage than is possible to obtain from NET. The value of $\alpha_d < 1$ measures the degree of slip, or the deviation from the "stochiometric" pump value n. Under normal operating conditions $\left(1-\exp\left(-\Delta G^{\mathrm{i}}/RT\right)\right)$ is large and negative, while $\left(\mu^{\mathrm{o}}_{\mathrm{Ca}}-\mu^{\mathrm{i}}_{\mathrm{Ca}}\right)$ is positive and smaller. This explains how the flux ratio deviates from the constant n when the temperature is constant.

The static head condition is defined by $J^{\mathrm{o}}_{\mathrm{Ca}} = 0$ (Caplan and Essig, 1983). Equation 28 gives the following ratio of thermodynamic forces at static head at constant temperature:

$$RT\left(1-\exp\frac{(-\Delta G^{\mathrm{i}})}{RT}\right)/(\mu^{\mathrm{o}}_{\mathrm{Ca}}-\mu^{\mathrm{i}}_{\mathrm{Ca}}) = -n(1+\alpha_d)\frac{D_{rd}}{D_{dr}} \quad (29)$$

to linear order in α_d. By substituting Eq.(29) into Eq.(24a) and using Eq.(26) one obtains for the reaction rate at static head

$$r = -\alpha_d D_{rr}\left(1-\exp\frac{(-\Delta G^{\mathrm{i}})}{RT}\right) \quad (30)$$

to linear order in α_d. The entropy production of the slipping pump at static head is obtained by integrating Eq.(18), which gives

$$\sigma^{\mathrm{s}} = \alpha_d D_{rr}\frac{\Delta G^{\mathrm{i}}}{T}\left(1-\exp\frac{(-\Delta G^{\mathrm{i}})}{RT}\right) \quad (31)$$

The tight pump has $\sigma^{\mathrm{s}} = 0$, at static head. For all other conditions there is a positive entropy production. Not all of the energy that is latent in the enthalpy of reaction is then converted to energy storage, in terms of raising the chemical potential of the ion. This mismatch makes a heat source at the surface. We proceed to study the slippage under such conditions.

NON-ISOTHERMAL SLIPPAGE

The non-isothermal case was investigated by De Meis and coworkers (1997). They found that the heat released per mol ATP hydrolyzed was constant, and depended on the state of the vesicles

with reconstituted ATPase. The heat production per mol was 118 kJ/mol, about three times higher in the leaky vesicles than in the intact ones where it was 42 kJ/mol. These observations are important; they show that the pumping activity is correlated to a significant heat production. It is thus likely that small temperature differences exists as a consequence. The authors demonstrated large heat effects not only under forward, but also under reverse pump operating conditions. The authors went on to show that the heat production did not depend on the Ca^{2+}-gradient. We may speculate that this corresponds to setting $D_{dq} = D_{qd} = 0$ and $D_{rq} = D_{qr}$ being finite. The temperature increase of the surface and the o-side induced by the reaction can then be written as

$$T^{\mathrm{o}} - T^{\mathrm{i}} = -\alpha_T r \Delta H \tag{32}$$

where the reaction enthalpy is negative and α_T is a factor defined by this equation. By combining this with Eq.(24), we obtain

$$\frac{J^{\mathrm{o}}_{\mathrm{Ca}}}{r} = n + n\left[\alpha_T \frac{D_{rq}}{T^{\mathrm{o}}}\Delta H\right] + n\alpha_d\left[1 + \frac{D_{dr}R}{nD_{rd}}\frac{(1-\exp(-\Delta G^{\mathrm{i}})/RT^{\mathrm{i}})}{\mu^{\mathrm{o}}_{\mathrm{Ca}}/T^{\mathrm{o}} - \mu^{\mathrm{i}}_{\mathrm{Ca}}/T^{\mathrm{i}}}\right]^{-1} \tag{33}$$

This expression shows that the presence of a temperature difference also leads to a reduction in the stoichiometric number *n*, or to an increased slip in the pump. The issue of slipping pumps has not been adressed by MNET before.

DISCUSSION

We have shown above that active transport in biological systems can be described with MNET on a stochastic level by introducing the reaction coordinate γ. We have considered the density of ATPase enzymes in the state γ along the reaction coordinate, $c(\gamma)$, the concentration, $c_{\mathrm{Ca}}(\gamma)$, of Ca^{2+} adsorbed to enzymes in the state γ and the temperature, $T^{\mathrm{s}}(\gamma)$, of these enzymes in states given by the variable γ. The description gave a nonlinear relation between the ion flux and the chemical driving force, and, if present, also a thermal driving force. The description can be seen as a generalization of the linear description given by Caplan and Essig (1983). MNET does not have transport coefficients that depend on the force. This can be used to argue against non-linear coefficients as a possible explanation of non-linear behaviour, cf. Walz (1990) and references therein. A nonlinear flux-force relation is not enough to infer slippage, however, as is evident from Eq.(28). This was also pointed out by Garlid et al. (1992) who studied leak pathways in mitochondria.

We have stated that the coupling takes place *in the surface*. The surface must be understood as the space covered by the ATP-binding site(s) plus the molecular links to the ion binding site(s), all positions where the fluctuations in γ-space takes place. The gradients at the surface are probably very large. Long-range correlations are then typical (Torner and Rubi, 1991). An interdependency of fluctuations at different points, that follow from long-range correlations, may capture the interplay between a gradually increasing bond strenght for ATP during conversion and the known motion at another part of the enzyme that pumps the ion across (Sun et al.2004). It is reasonable that a stochastic pump process has a certain probability for slippage. We have here calculated how slippage may depend on the value of the driving forces.

When the equality $l^2_{rd}(\gamma) = l^2_{dr}(\gamma) = l_{rr}(\gamma)l_{dd}(\gamma)$ holds, the pump is tight. The process is close to being reversible, and the entropy production rate is small, compatible with the observation of de Meis and coworkers (1997). In such a situation, when the stress on the system is not too large, there is probably enough time for a molecule, or an ion, to seek new favorable attachments, without necessarily loosing too much of the energy. Under extreme solution conditions, the fluctuation pattern may change, making reversible transitions less favorable, and the entropy production larger.

There is always dissipation of energy connected to the pump, and the present theory describes this as well as the heat fluxes. A large heat production was measured during active transport (de Meis et.al 1997). Also Antes et al. (2003) describe the need to thermostat the hot spots in the ATPase regions in molecular dynamics simulations of the hydrolysis. These measurements and calculations give support to the present description. The reversible property of the pump can be compared to a reversible electrochemical system. The electrode reaction gives electric energy in the electrochemical cell, here the chemical reactions gives an increased chemical potential for Ca^{2+}. In an electrochemical cell, there is a reversible heat effect, due to the entropy of reaction, a Peltier heat. Here, there is a reversible heat

effect connected to the energies of transfer. This will be elaborated on in the future.

Since there is often a significant heat production during operation, and because of the stochastic nature of the process, one might consider overheating as an additional cause of slippage, as demonstrated by Eq.(33). This is a new explanation for slippage. Most likely is $T^{\mathrm{o}} > T^{\mathrm{i}}$. The higher the temperature becomes, the smaller is the likelihood for the right detachment / attachment of chemical bonds, and a higher probability for slip arise.

Models discussed in the literature can be discussed on the background of the present theory. The alternating access model (see Berman, 2001) fits only with the picture of a tight pump, and is thus unrealistic. The binding-zipper model (see Sun et al. 2004), where the chemical energy is uniquely transferred to the shaft of the rotating pump, is also pictured as a tight pump, even if the authors do not address ion transport explicitly. Berman emphasized the stochastic nature of a slipping pump and proposed a continuum of states rather than a cycle of discrete states. The events described here in $\gamma-$space are of this nature. The present theory may cover most of the energy-barrier model of Lauger (see Berman, 2001).

CONCLUSION

The aim of this paper was to show that nonlinear expressions for the fluxes in terms of their driving forces can be derived for active transport in biological systems. We have shown this using MNET, a theory that capture nonlinearities that otherwise remain hidden in the macroscopic NET-theory. We have used MNET for the first time to analyze phenomena related to slippage and uncoupling of ion pumps. Active transport means coupling at the membrane surface and positive coupling coefficients. We propose a hypothesis for slipping pumps, where also the temperature of the surface may play a role for the slip. The hypothesis may be tested with the equations that are provided. We have somewhat arbitrarily taken active transport of Ca^{2+} as an example, but the scheme should be transferable to many kinds of transport processes that obtain their energy from chemical reactions, as molecular motors. We hope in this way to provide more options for analysis of experiments in this important domain.

ABSTRACT

Spray combustion of water-emulsified fuel induces an effective decrease in total combustion time, carbonaceous residues and NO_X compared to pure fuel, thanks to the micro-explosion phenomenon. Designing emulsion-burning appliances requires to calculate the micro-explosion delay included in total combustion time. This rather technical contribution addresses the problem of how to model the process of microexplosions in emulsions. The authors describe a numerical method to account for thermal conduction effects and analyze its effect upon the microexplosion delay. Some of the expressed physical quantities may be useful for other researchers in this field. The evolution of the emulsion droplet (radius and temperature through the time) is faced with experimental micro-explosion delay, for three cases of emulsion droplet (different initial diameters and temperatures). Finally, observations resulting from this comparison are discussed.

Keywords : waste oils, heavy fuels, emulsion, combustion, micro-explosion delay

∞ Away in the gaseous phase

INTRODUCTION

Residual oil and heavy fuels from engines, cooking, refineries and other sources represent pollutant combustibles. Burning of a water-in-oil emulsion enables environmental advantages, such as reduction in NOx formation [1,2].

The difference in volatility between oil and water causes the water to vaporise and fragment the around oil, namely to generate the physical phenomenon of micro-explosion. The water droplets are not supposed to vaporise at boiling point inside the emulsion [3], so they reach a metastable state that breaks up at a temperature between their boiling point and their well-known spinodal limit [4]. Micro explosion delay lies between these bounds, but nucleation can be induced by random solid impurities. So micro-explosion criteria still have to be defined and validated.

In all cases, the micro-explosion phenomenon creates numerous small child droplets from one initial emulsion droplet [5] : It also induces more fragile-shaped carbonaceous residues, expected to burn out faster [6].

Law [4] indicates whether, but not when micro explosion occurs. Using nucleation theory, Wei Biao Fu [3] gives a criterion for micro explosion based on the size of the emulsion droplet and its volume fraction of water. As far as we know, no thermal model of the emulsion droplet does provide any micro-explosion delay.

This paper exposes first a modelisation of heat transfer at the surface and inside of the emulsion droplet. Thus, the results of the model are faced with experimental micro-explosion delay from Gollahalli [7]. Finally, observations of these comparisons are discussed.

Authors would like to emphasize the fact that all thermo-physical properties of fuel and gaseous phase are implemented as pressure and temperature dependent.

THE SPHERE LAYERS MODEL

The dispersed phase is inserted as spheres of water subtracting volume and showing heat-exchanging surface within the spherical layers of fuel (figure 1). These volumes and surfaces are re-calculated without any geometrical approximation at every step of time, taking thermal expansions of fuel and water into account. In each sphere layer, the number of water droplets is assumed to maintain the same volume fraction of water in the whole emulsion droplet. The water droplets are assumed to be all the same initial radius R_W.

Governing equations and hypotheses

Heat balance is calculated for a sphere layer l, considering conductive heat transfer from

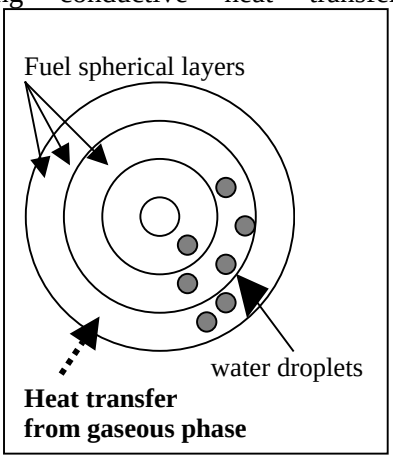

Figure 1 : The sphere layers model

neighbourhood l+1 and l-1, and heat transfer to dispersed phase Q_l (equation 1).

$$m_l c_{Pl} \frac{dT_l}{dt} = \frac{\lambda_{CH}}{dr}(S_{l-1}(T_{l-1} - T_l) + S_l(T_{l+1} - T_l)) - Q_l \qquad (1)$$

Conductive heat tansfer is modelled across the surface between sphere layers. Later in this paper, the error induced by spatial discretisation is evaluated by comparison with analytical conduction in a sphere.

The hypothesis consisting of no convection inside the emulsion droplet is adopted. It is made by numerous authors [8,9] considering fuel as viscous enough to prevent internal circulation. This is especially true for heavy fuel oil because of their higher viscosity compared to lighter ones [10]. Similarly, only conduction in taken into account at the surface of internal droplets of water (equation 2):

$$Q_l = N_{W,l} \frac{\lambda_{CH}}{r_W} S_{W,l} \left(T_l - T_{W,l}\right) \qquad (2)$$

This heat transfer to water droplets enables to determine their thermal expansion.

At the surface of the emulsion droplet, both convective and radiative heat transfer from gaseous phase are calculated (equation 3). The correlation of Ranz and Marshall [11] is used for convective coefficient α. This gradient boundary condition is implemented using T_{ext} and T_{ext-1}, respectively

temperature of surface and under-surface layers, provided by the sphere layers model.

$$\frac{T_{ext}-T_{ext-1}}{dr}=\frac{\sigma E_{CH}E_G}{\lambda_{CH}}\left(T_G^4-T_{ext}^4\right)+\frac{\alpha}{\lambda_{CH}}\left(T_G-T_{ext}\right) \qquad (3)$$

Vaporization and boiling

Heavy fuels consisting of long hydrocarbonated chains have a higher boiling point compared to lighter fuels, especially at pressures higher than 1 bar. Hence, diffusion-limited evaporation mass flux (equation 4) W_{vap} at the surface of the emulsion droplet is of crucial relevance to determine the quantity of fuel evaporated prior to micro-explosion.

$$W_{vap}=k_C S_P\left(\frac{P_{sat,CH}\left(T_{ext}\right)}{RT_{ext}}-C_\infty\right) \qquad (4)$$

The binary gas-phase diffusion coefficient k_C is obtained by correlation of Fuller et al. (equation 5) [12]. This correlation enables to take into account variations in diffusion coefficient k_C caused by temperature and pressure in gaseous phase.

$$k_C=\frac{1.10^{-3}\times\left(\frac{1}{M_{CH}}+\frac{1}{M_G}\right)^{\frac{1}{2}}}{\left[\left(\sum_G v\right)^{\frac{1}{3}}+\left(\sum_{CH} v\right)^{\frac{1}{3}}\right]^2}\times\frac{T_G^{1.75}}{P_G} \qquad (5)$$

The surface layer is applied the following heat balance (equation 6). Once boiling point T_b is reached by the surface layer, heat imput from gaseous phase is considered to compense latent heat, plus droplet heating. So, while boiling, the surface layer keeps the constant temperature T_b.

$$S_{ext}\sigma E_{CH}E_F(T_G^4-T_{bp}^4)+S_{ext}\alpha(T_G-T_{bp})$$
$$-\frac{\lambda_{CH}}{dr}S_{ext-1}(T_{bp}-T_{ext-1}) \qquad (6)$$
$$=-L_{CH}\frac{dm_{CH,ext}}{dt}-L_W\frac{dm_{W,ext}}{dt}+\frac{m_{W,ext}Cp_{W\left(T_{W,ext}-T_{bp,W}\right)}}{dt}$$

$dm_{W,ext}$ is the mass of water removed whith a mass $dm_{CH,ext}$ evaporated, so $dm_{W,ext} = f\,(dm_{CH,ext}+ dm_{W,ext})$ When removed from the surface, liquid water is embedded in fuel, being above the boiling point of water. So these removed water droplets are considered to break up their metastable state. The last term on the right in equation 6, which accounts for this breaking up, will be explained later in the part about metastable states.

The surface sphere layer thickness dr is to be noticed : Contrary to inside layers in equation 1, dr decreases in equation 6, because the surface layer is evaporating or boiling. So, dr decreases until tiny values putting computations at risk of divergence. A criterion of critical thickness for the surface layer is defined (inequation 7).

$$V_{l=ext}\le 1\%\,V_{l=ext,t=0} \qquad (7)$$

Once this criteria reached because of a tiny enough dr, the remaining liquid fuel is considered as instantly depleted, so the under-surface layer is becoming the surface layer.

Results and tests for time and space steps

Results are obtained through a finite-differences numerical method, forward in time and centered in space. Considering the results shown in Figure 3, the space step is set to 10 µm or less. Thermal expansion of fuel and water, evaporation and boiling result altogether in variation of droplet radius through the time (figure 2). In figure 2, a test for the time step is made, using a constant space step of 10 µm, which is a maximum as determined from Figure 3.

In figure 2, the radius is slightly increasing due to thermal expansion until 5 ms, when evaporation compensates, then counter-balances expansion, making the radius decrease. This decreasing of

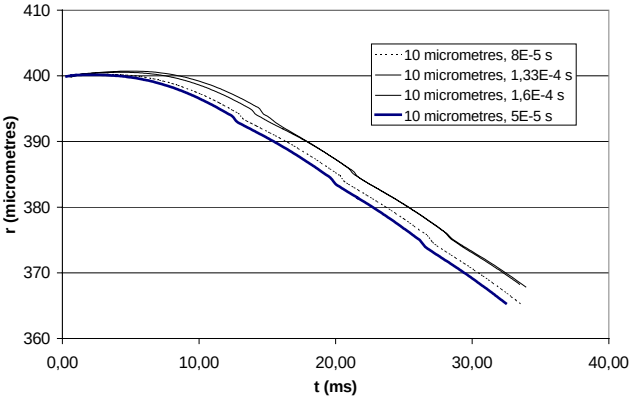

Figure 2 : Test for time step

radius is determined by the quantity of fuel evaporated.

Time and space steps are ensured to enable modelisation of conduction by Fourier's law. Fourier's law is not valid under some hundreds of nanometers in gases, and this critical distance still decreases for liquids and solids. In this paper, 2 µm is a minimum for the sphere layer thickness, which is the space step. The relaxation time of particles responsible for conduction of heat are : 10^{-11} s (phonons), 10^{-13} s (electrons). In this model, 10^{-6} s is a minimum.

So, equations 1-6 can be properly used to modelize heat transfer, and space and time steps are respectively chosen as : 10 µm and 1,33.10^{-4}s.

Validation with analytic conductive heat transfer

The phenomena influencing micro explosion delay (evaporation and boiling rate, heat transfer to dispersed phase, a.s.o…) are determined by temperature. So special care is taken to ensure a validated heat transfer across the emulsion droplet.
The well-known analytical conductive heat transfer within a sphere (equation 8) is used in [9] :

$$\rho C_p \frac{dT}{dt} = \lambda_{CH}\left(\frac{\partial^2 T}{\partial t^2} + \frac{2}{r}\frac{\partial T}{\partial t}\right) \qquad (8)$$

Figure 3 shows the temperature at the center of a pure oil droplet, both calculated by Jacques [9] using equation 8, and by the sphere layers model, using the same thermophysical properties and heat input at the surface. The influence of decreasing sphere layer thickness can be noticed as a convergence.

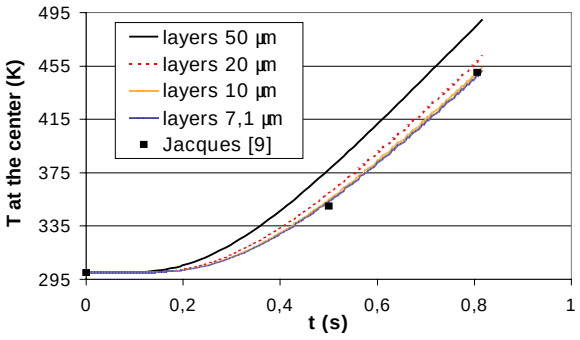

Figure 3 : Space step vs. analytical results

Criteria for micro-explosion

The metastable state of inside water is favourized by enclosure in around oil, fast heat transfer and micrometric scale [5]. It is broken up, (e.g. sudden phase change to steam) between boiling point and well-known spinodal limit [4]. Between these two bounds, the nucleation sites may consist of impurities, randomly dispersed across the emulsion droplet. Although a metastable droplet put in contact with the gaseous phase by means of evaporation, or by violent disruption in the neighborhoud [2] is clearly not supposed to remain in metastable state.
As it is done in this paper, micro explosion delay is not –unless from experimental data- indicated as precise delay, but between these bounds, also considering radius decreasing.

Production of steam out of metastable state

As considered by Wolfe [13] at breaking up of metastable state, enthalpy above boiling point compenses latent heat, so liquid water of mass m_W is partly, but suddenly vaporized (equation 9) into a mass of steam m_{steam} .

$$m_{steam} = \frac{m_W Cp_W (T_{W,l} - T_{bp,W})}{L_W} \qquad (9)$$

The remaining liquid water is supposed to lower its temperature until boiling point. The last term on the right in equation 6 represents the latent heat furnished by this breaking up of metastable state.
Considering pressure in the gaseous phase, the volume of potentially produced steam V_{steam} is then obtained from tables. In this model, V_{steam} would be the steam produced from all the liquid water above boiling point in the emulsion droplet.

VALIDATION OF MICRO-EXPLOSION DELAY

Experiments of Gollahalli [7] enable us to an experimental validation ensuring all the necessary variables (table 1). Moreover, these experiments were carried out using the drop tower technique, without suspending filament for the droplet, which is known as a nucleation site that shortens the micro explosion delay [14]. Furthermore, Gollahalli did not use any additional surfactant to prepare the emulsions. Although the gaseous phase is a flame of natural gas in [7], only convective heat transfer is taken into account in equation 3.
Three different cases of emulsion droplet (e.g. with different initial temperatures and diameters, cf. table 1) are computed and faced with experimental micro-explosion delays obtained by Gollahalli [7].
For each case, two curves are provided through the time since injection :

(a) The variation of droplet radius (r_p), plus the radius at which internal water droplets attain 373,15 K (r_{bp}), thus entering metastable state

(b) The variation of droplet volume (V_p), plus the variation of the volume of potentially produced steam V_{steam} (cf. equation 7)

In his experiments, Gollahalli observed evaporation of the emulsion droplets prior to micro-explosion, which accounts for the importance of evaporation in equations 4 and 5.

The micro-explosions he observed were unique, e.g. without any secondary or tertiary explosions, which indicates disruption of the whole droplet. Although Gollahalli does not indicate the range of reproducibility of his experimental results in [7], observed gaps between measurements lie up to 30 ms.

Parameter	**Value**
Initial diameter of emulsion droplet	1000 μm or 800 μm
Initial emulsion temperature	300 K or 330 K
Dispersed phase	10 μm – diametered water droplets mass fraction : 0,1
Gaseous phase temperature	1400 K
Relative velocity to gaseous phase	5 $m.s^{-1}$
Case of emulsion burning in [7]	**Initial temperature and diameter of emulsion droplet**
Case #1	300 K , 800 μm
Case #2	300 K , 1000 μm
Case #3	330 K , 1000 μm

Table 1 : Experiments of Gollahalli [7]

In Figures 5.a and 6.a (cases #1 and #2), experimental micro-explosion delay is observed when R_{bp} is the half of the initial radius of the emulsion droplet, according to the model. In case #3 (Figures 7.a), at the experimental micro-explosion, R_{bp} is more than half of the initial radius of the emulsion droplet.
In all cases #1, #2 and #3, experimental micro-explosion is observed after V_{steam} is more than V_p, so micro-explosion could theoretically happen (Figures 5.b, 6.b and 7.b). In 2 cases out of 3, micro-explosion happens when $r_{bp} = 50\% \; r_{p,t=0}$.
In the future, more situations with other varying parameters (temperature in gaseous phase, mass fraction of water, a.s.o.) should be examined and faced with the time of occurrence of micro-explosion.

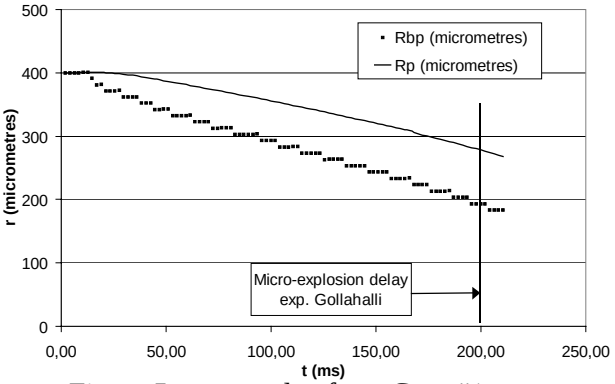

Figure 5.a : r_{bp} and r_p from Case #1

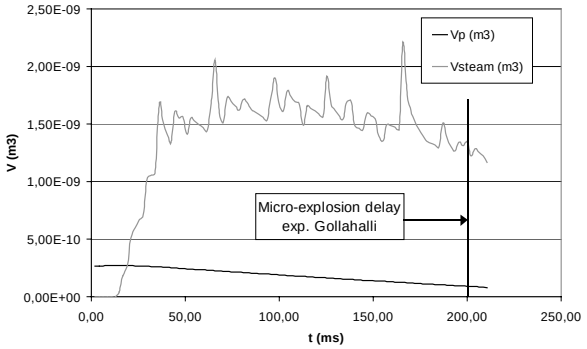

Figure 5.b : V_p and V_{steam} from Case #1

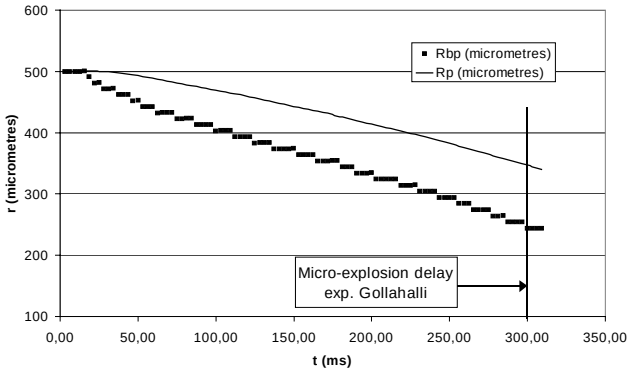

Figure 6.a : r_{bp} and r_p from Case #2

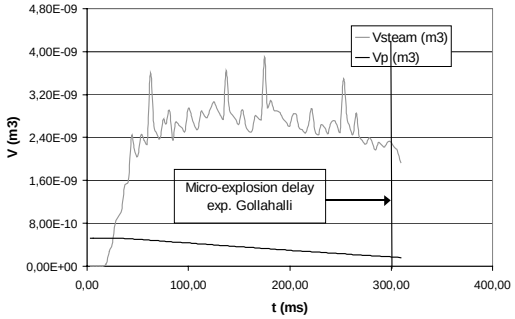

Figure 6.b : V_p and V_{steam} from Case #2

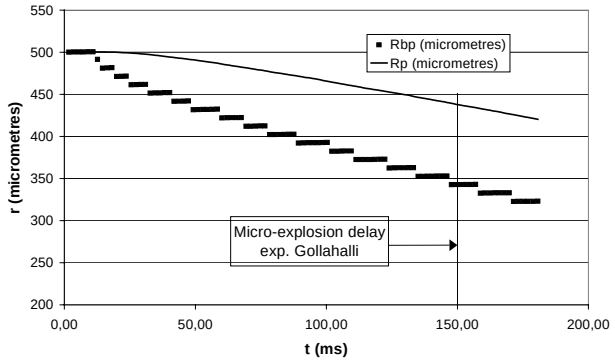

Figure 7.a : r_{bp} and r_p from Case #3

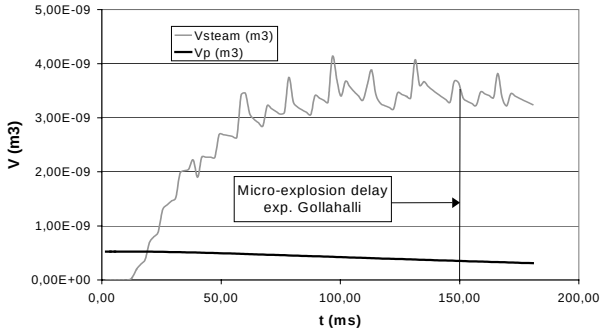

Figure 7.b : V_p and V_{steam} from Case #3

CONCLUSION

A thermal modelisation of the emulsion droplet is made, enabling to determine temperature distribution, radius distribution and potentially-produced steam through the time.

A comparison is made with experimental measurements of micro-explosion delay, without suspending filament or additional surfactant that could start nucleation.

Results from the model are in accordance with the experimental micro-explosion delay, although they indicate that micro-explosion is also possible before experimental observations.

Further work should consist of modelisation and validation of more situations, to closer inquire criteria for the onset of micro-explosion.

RATE LIMITING PROTON HYDRATION IN THE HYDROGEN ELECTRODE OF THE POLYMER ELECTROLYTE MEMBRANE FUEL CELL

A.K. Meland, D. Bedeaux, S. Kjelstrup*
Department of chemistry, Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT

We show how one can obtain information on the three-phase contact of the electrode in the polymer electrolyte fuel cell, using nonequilibrium thermodynamics in combination with impedance spectroscopy. The isothermal hydrogen adsorption and reaction at the E-TEK electrode of a polymer electrolyte fuel cell with a Nafion®117 membrane is investigated at 30°C and 1 bar. We have earlier reported that adsorption and diffusion of gas to the three-phase contact is rate-limiting. We proceed to show how charge transfer and hydration and transport into the membrane play a role. The adsorption/diffusion step takes place in a layer located before the platinum surface, while the charge transfer takes place at (predominantly) the metal particle surface, while the third step is on the membrane side of the metal surface.

INTRODUCTION

Electrochemical impedance spectroscopy (EIS) is an experimental technique that can separate phenomena with different relaxation times, and is thus useful for determination of rate-limiting steps at electrode surfaces [1]. It has been used widely, also in studies of rather complicated three-phase contacts, which are typical for fuel cell electrodes.

The fuel cell electrodes consist of a porous matrix of carbon black that allow gas diffusion up to the catalyst (Pt) particles. The gas reacts at the catalyst, which is in contact with the proton-conducting membrane. We have started a systematic study of this nanoporous material, by investigating the hydrogen electrode in a cell with two such electrodes [2]. Our aim is to study the CO tolerance of this electrode [3, 4].

We predict first the impedance spectrum for the two electrodes. Details of the mechanism shall be concluded by comparing experimental and theoretical results. We consider a common membrane electrode assembly, namely the E-TEK electrode with 0.5 mg Pt/cm^2 and a Nafion®117 membrane. It has been common to assume that the rate limiting pro-

cess in the electrode backing of the anode (as well as the cathode) is diffusion in the gas phase. In our previous analysis [2], we argued that the good fit to a Gerischer phase element, indicated that the reversible adsorption reaction of hydrogen to carbon black along the pore walls and the subsequent diffusion along the surface to the catalyst plays a more important role.

In the previous paper [2], we did not consider in detail the steps following the adsorption and diffusion. We shall now proceed to do so. We analyze in particular how water affects the behavior of the system. The paper is organized as follows. We derive in sections 2 and 3 the impedance of the hydrogen electrode using a two-layer model. The first layer is that of the porous carbon layer supporting the catalyst particles, the so-called adsorption-diffusion layer. The next layer is the surface layer of the catalyst, where the charge transfer reactions take place. The experiments and the results are described in section 4 and 5 and discussed in section 6.

THE STEPS IN THE ELECTRODE REACTION

According to earlier evidence, we assume first that hydrogen gas is absorbed as hydrogen along the pores in the carbon matrix:

$$\frac{1}{2}\mathrm{H_2(g)} \rightarrow \frac{1}{2}\mathrm{H_2(a)} \qquad \text{(ad)}$$

The adsorption reaction is labelled "ad". The hydrogen proceeds to diffuse along the pore surface to the platinum catalyst, located between the porous carbon matrix and the cation exchange membrane. During the diffusion process some of the hydrogen desorbs back to the gas phase. We assume that the process is a first order reaction in both directions:

$$r = k^{\mathrm{a}}_{\mathrm{H_2}} c^{\mathrm{g}}_{\mathrm{H_2}} - k^{\mathrm{d}}_{\mathrm{H_2}} c^{\mathrm{a}}_{\mathrm{H_2}}(x,t) \qquad (1)$$

Here $k^{\mathrm{a}}_{\mathrm{H_2}}$ and $k^{\mathrm{d}}_{\mathrm{H_2}}$ are rate coefficients (superscripts a and d refer to adsorb and desorb, respectively). We use a course-grained description in which both concentrations are given in mol/m^3. The course-grained concentration $c^{\mathrm{g}}_{\mathrm{H_2}}$ is the concentration in the pores times the porosity of the layer. The course-grained concentration $c^{\mathrm{a}}_{\mathrm{H_2}}$ is the surface excess concentration in mol/m^2 times the surface area of the pores per unit of volume in m^{-1}. The adsorption reaction was assumed to take place on the metal surface, see e.g. [5], while we located this reaction to the surface of the pores in the carbon. In the following we assume the Volmer mechanism, where the molecule dissociates into protons and electrons in active sites on the surface of the platinum:

$$\frac{1}{2}\mathrm{H_2(a)} \rightarrow \mathrm{H^+(s)} + \mathrm{e^-(a)} \qquad \text{(ct)}$$

This charge transfer reaction is labelled ct. An excellent discussion of the relevant sites on Pt, that are active in the reaction, was given by Chen and Kucernak [5]. The protons are next bound to a water molecule and move into the cation exchange membrane (m) as hydronium ions

$$\mathrm{H^+(s)} + \mathrm{H_2O(m)} \rightarrow \mathrm{H_3O^+(m)} \qquad \text{(cm)}$$

This proton hydration reaction is labelled cm. Protons may bind to more than one water molecule. Electrons are transported into the anode carbon matrix (also indicated by a).

The thickness of the carbon matrix in the experiment is in the order of 0.5 mm, while the thickness of the catalyst layer is in the order of 0.01 mm. In the theory given below we use a continuous model for the carbon matrix. It is sufficient to use a sharp interface for the catalyst layer. Such a description is obtained from the excess entropy production rate, and the resulting fluxes and forces, for the electrode surface.

The reaction Gibbs energy of the absorption reaction in front of the metal surface is:

$$\Delta_r G^{\mathrm{s}}_{\mathrm{ad}} = \frac{1}{2}\mu^{\mathrm{s}}_{\mathrm{H_2}} - \frac{1}{2}\mu^{\mathrm{g}}_{\mathrm{H_2}} \equiv \frac{1}{2}\mu^{\mathrm{a}}_{\mathrm{H_2}}(x=0) - \frac{1}{2}\mu^{\mathrm{g}}_{\mathrm{H_2}} \qquad (2)$$

where $x = 0$ indicates the position of the catalyst surface. The chemical potential of hydrogen just before the surface and at the surface are the same, $\mu^{\mathrm{s}}_{\mathrm{H_2}} = \mu^{\mathrm{a}}_{\mathrm{H_2}}(x=0)$. The hydrogen gas in the experiment has a constant (position and time independent) pressure, leading to a constant $\mu^{\mathrm{g}}_{\mathrm{H_2}}$ as well as constant $c^{\mathrm{g}}_{\mathrm{H_2}}$. The superscripts s indicates a property of the surface. The bulk anode is located at $x < 0$ and the membrane at $x > 0$. In our coarse grained description, transport takes place along a coordinate normal to the surface of the membrane. All variables are then independent of coordinates parallel to the surface.

In the description of the electrochemical processes at the surface, we need the change in Gibbs energy

at the surface from the reaction of neutral species. For the ct reaction we then have:

$$\Delta_n G^{\rm s}_{\rm ct} = -\frac{1}{2}\mu^{\rm s}_{\rm H_2} \equiv -\frac{1}{2}\mu^{\rm a}_{\rm H_2}(x=0) \qquad (3)$$

and for the cm reaction we have:

$$\Delta_n G^{\rm s}_{\rm cm} = -\mu^{\rm s}_{\rm H_2O} \equiv -\mu^{\rm m}_{\rm H_2O}(x=0) \qquad (4)$$

For the total electrode reaction, we have the sum of the above terms:

$$\Delta_n G^{\rm s} = -\frac{1}{2}\mu^{\rm g}_{\rm H_2} - \mu^{\rm m}_{\rm H_2O}(x=0) \qquad (5)$$

At the surface there is an adsorption of protons, $\Gamma_{\rm H^+}$, hydronium ions, $\Gamma_{\rm H_3O^+}$, and electrons, $\Gamma_{\rm e^-}$. We can take the catalyst surface to be electroneutral, by choosing its thickness such that the total adsorptions (in mol/m^2) of positive ions is equal to the adsorption of electrons:

$$\Gamma_{\rm H^+} + \Gamma_{\rm H_3O^+} = \Gamma_{\rm e^-} \qquad (6)$$

The polarization of the surface is an important property. There are here two contributions to this polarization, one is due to proton-electron pairs and the other one is due to hydronium ion-electron pairs. The number of moles of the proton-electron dipoles per unit of surface area is given by $\Gamma_{\rm H^+}$ and the number of moles of hydronium ion-electron dipoles by $\Gamma_{\rm H_3O^+}$. The charge densities of the proton and the hydronium layer are equal to the potential difference between these layers and the electron layer times the capacitances, $c^{\rm s}_{\rm H^+}$ and $c^{\rm s}_{\rm H_3O^+}$, of these two dipole layers

$$F\Gamma_{\rm H^+} = c^{\rm s}_{\rm H^+}\Delta_{\rm s,H^+}\phi \quad \text{and} \quad F\Gamma_{\rm H_3O^+} = c^{\rm s}_{\rm H_3O^+}\Delta_{\rm s}\phi \qquad (7)$$

where F is Faraday's constant. The ct reaction increases the number of adsorbed dipoles of the first kind while the cm reaction decreases it. We therefore have

$$\frac{d}{dt}\Gamma_{\rm H^+} = r^{\rm s}_{\rm ct} - r^{\rm s}_{\rm cm} \qquad (8)$$

where $r^{\rm s}_{\rm ct}$ and $r^{\rm s}_{\rm cm}$ refer to the reaction rates. Similarly the cm reaction increases the number of dipoles of the second kind while the electric current decreases it. This gives

$$\frac{d}{dt}\Gamma_{\rm H_3O^+} = r^{\rm s}_{\rm cm} - \frac{j}{F} \qquad (9)$$

It therefore follows from Eqs.(7)-(9) that

$$r^{\rm s}_{\rm ct} = r^{\rm s}_{\rm cm} + \frac{c^{\rm s}_{\rm H^+}}{F}\frac{d\Delta_{\rm s,H^+}\phi}{dt} \quad r^{\rm s}_{\rm cm}F = j + c^{\rm s}_{\rm H_3O^+}\frac{d\Delta_{\rm s}\phi}{dt} \qquad (10)$$

As the hydronium ions are on the surface with the membrane, the potential difference between this layer and the electron layer is the full potential difference $\Delta_{\rm s}\phi$ across the surface. The protons are closer to the electron layer, so the potential difference between this layer and the electron layer $\Delta_{\rm s,H^+}\phi$ is smaller.

THE ELECTRODE IMPEDANCE

The variables in the oscillating field

Impedances are measured as a function of the frequency ω of the alternating potential, in the presence of a constant applied potential. The cell under investigation is symmetric, so we consider the potential difference between the anode and the center of the membrane:

$$\Delta\phi = \Delta\phi_{\rm dc} + \Delta\phi_{\rm ac}\exp(i\omega t) \qquad (11)$$

The potential difference between the center of the membrane and the cathode is the same. We disregard here the *emf* of both surfaces, which are equal and opposite. The contributions due to the bulk anode (and cathode) are negligible. Both contributions are the sum of the potential difference across the anode surface and (half) the membrane

$$\Delta\phi_{\rm dc} = \Delta_{\rm s}\phi_{\rm dc} + \frac{1}{2}\Delta_{\rm m}\phi_{\rm dc} \quad \Delta\phi_{\rm ac} = \Delta_{\rm s}\phi_{\rm ac} + \frac{1}{2}\Delta_{\rm m}\phi_{\rm ac} \qquad (12)$$

The electric current, as well as all other variables, similarly have a dc and an ac contribution. In the membrane, which conducts only protons, one has

$$\Delta_{\rm m}\phi_{\rm dc} = r_{\rm m}\, j_{\rm dc} \ \text{ and } \ \Delta_{\rm m}\phi_{\rm ac} = r_{\rm m}\, j_{\rm ac} \qquad (13)$$

The corresponding relations for the potential differences across the surface shall be derived below. For the dc and the ac contributions to the reaction rates one has, using Eq.(10),

$$Fr^{\rm s}_{\rm ct,dc} = Fr^{\rm s}_{\rm cm,dc} = j_{\rm dc} \qquad (14)$$

and

$$\begin{aligned} Fr^{\rm s}_{\rm ct,ac} &= Fr^{\rm s}_{\rm cm,ac} + i\omega c^{\rm s}_{\rm H^+}\Delta_{\rm s,H^+}\phi \\ Fr^{\rm s}_{\rm cm,ac} &= j_{\rm ac} + i\omega c^{\rm s}_{\rm H_3O^+}\Delta_{\rm s}\phi \end{aligned} \qquad (15)$$

The adsorption-diffusion layer in front of the catalyst

The time dependence of the concentration of hydrogen at position x in the anode is given by

$$\frac{\partial c^{\rm a}_{\rm H_2}}{\partial t} = D\frac{\partial^2 c^{\rm a}_{\rm H_2}(x,t)}{\partial x^2} + \frac{1}{2}k^{\rm a}_{\rm H_2}c^{\rm g}_{\rm H_2} - \frac{1}{2}k^{\rm d}_{\rm H_2}c^{\rm a}_{\rm H_2} \quad (16)$$

where D is the diffusion constant. Equilibrium in the adsorption reaction gives, using Eq.(1), the equilibrium concentration of hydrogen

$$c^{\rm a}_{{\rm H_2},eq} = c^{\rm g}_{\rm H_2}\frac{k^{\rm a}_{\rm H_2}}{k^{\rm d}_{\rm H_2}} \quad (17)$$

A constant hydrogen pressure in the pores gives a constant gas concentration, $c^{\rm g}_{\rm H_2}$ and therefore also a constant value for $c^{\rm a}_{{\rm H_2},eq}$. We introduce the deviation from the equilibrium concentration

$$c^{\rm a}_{\rm H_2}(x,t) \equiv c^{\rm a}_{{\rm H_2},eq} + \delta c^{\rm a}_{\rm H_2}(x,t) \quad (18)$$

Equation (16) then becomes to linear order in $\delta c^{\rm a}_{\rm H_2}$

$$\frac{\partial \delta c^{\rm a}_{\rm H_2}(x,t)}{\partial t} = D\frac{\partial^2 \delta c^{\rm a}_{\rm H_2}(x)}{\partial x^2} - \frac{1}{2}k^{\rm d}_{\rm H_2}\delta c^{\rm a}_{\rm H_2}(x,t) \quad (19)$$

The first paper [2] gave the solutions of this equation for dc and ac currents. We repeat the expressions needed, and refer to the first paper for their derivation. For a dc electric current the total Gibbs energy change of the whole reaction diffusion layer was

$$\begin{aligned}\Delta_r G_{\rm ad,dc} = \delta\mu^{\rm s}_{{\rm H_2},{\rm dc}} &= \delta\mu^{\rm a}_{{\rm H_2},{\rm dc}}(x=0) \\ &= -\frac{j_{\rm dc}RT}{2Fc^{\rm a}_{{\rm H_2},eq}\sqrt{2Dk^{\rm d}_{\rm H_2}}} \end{aligned} \quad (20)$$

The ac contribution to the total Gibbs energy change of the reaction/ diffusion layer was:

$$\Delta_r G_{\rm ad,ac} = \delta\mu^{\rm s}_{{\rm H_2},{\rm ac}} = \delta\mu^{\rm a}_{{\rm H_2},{\rm ac}}(x=0) = -Z_{\rm ad}F^2 r^{\rm s}_{\rm ct,ac} \quad (21)$$

where the contribution to the impedance was

$$Z_{\rm ad} = \frac{RT}{2F^2 c^{\rm a}_{{\rm H_2},eq}\sqrt{2Dk^{\rm d}_{\rm H_2}(1+i\omega\tau_{\rm ad})}} \quad (22)$$

and where the relaxation time in the absorption process was

$$\tau_{\rm ad} = \frac{1}{k^{\rm d}_{\rm H_2}} = \frac{c^{\rm a}_{{\rm H_2},eq}}{c^{\rm g}_{\rm H_2}k^{\rm a}_{\rm H_2}} \quad (23)$$

$Z_{\rm ad}$ is the impedance of a Gerischer element. Experimental results for the hydrogen electrode of the fuel cell fitted well to this asymmetric element [2], while the symmetric constant phase element and the element one obtains for a self-similar fractal surface structures [6] can only be fitted with much larger inaccuracies. A Warburg element does not describe the measurements at all.

The charge transfer reactions at the catalyst surface

Consider next the catalyst surface, or the interface between the membrane and the adsorption-diffusion layer in the electrode. The excess entropy production rate of this surface, $\sigma^{\rm s}$, contains the information about the surface dynamics. For isothermal conditions, the contributions due to the alternating fields are [7]:

$$\begin{aligned} T\sigma^{\rm s}_{\rm ac} &= -r^{\rm s}_{\rm cm,ac}F\left(\Delta_{\rm s}\phi_{\rm ac} - \Delta_{\rm s,H^+}\phi_{\rm ac}\right) \\ &\quad -r^{\rm s}_{\rm ct,ac}\left(F\Delta_{\rm s,H^+}\phi_{\rm ac} - \Delta_r G^{\rm s}_{\rm ad,ac}\right) \end{aligned} \quad (24)$$

Using the fact the two reactions occur consecutively, the coupling of these reactions may be neglected and the theory of non-equilibrium thermodynamics then prescribes that the forces and the fluxes are related by

$$\begin{aligned} \Delta_{\rm s,H^+}\phi_{\rm ac} - \frac{1}{F}\Delta_r G^{\rm s}_{\rm ad,ac} &= -\rho^{\rm s}_{\rm ct}Fr^{\rm s}_{\rm ct,ac} \\ \Delta_{\rm s}\phi_{\rm ac} - \Delta_{\rm s,H^+}\phi_{\rm ac} &= -\rho^{\rm s}_{\rm cm}Fr^{\rm s}_{\rm cm,ac} \end{aligned} \quad (25)$$

where $\rho^{\rm s}_{\rm ct}$ and $\rho^{\rm s}_{\rm cm}$ are the resistivities of the ct and cm reactions. Electrochemical reaction rates are normally not related to their driving forces by linear relations. In this experiment, the alternating contribution to the forces are small (± 5 mV), however, so that we can use a linear theory. Adding the two relations in Eq.(25) one obtains

$$\Delta_{\rm s}\phi_{\rm ac} - \frac{1}{F}\Delta_r G^{\rm s}_{\rm ad,ac} = -\rho^{\rm s}_{\rm ct}Fr^{\rm s}_{\rm ct,ac} - \rho^{\rm s}_{\rm cm}Fr^{\rm s}_{\rm cm,ac} \quad (26)$$

The adsorption-diffusion layer has an impact on $\Delta_{\rm s}\phi_{\rm ac}$, because this layer determines the chemical potential of hydrogen atoms at position $x = 0$. The resistivity is independent of the driving force, but can depend on the temperature and the polarization induced by the dc-field. The dc contribution to the excess entropy production rate is found using $\omega = 0$

and $j_{dc} = Fr^{s}_{ct,dc} = Fr^{s}_{cm,dc}$. This gives

$$T\sigma^{s}_{dc} = -j_{dc}\left[\Delta_s\phi_{dc} + \frac{1}{F}\left(\Delta_n G^{s}_{cm,dc} + \Delta_n G^{s}_{ct,dc}\right)\right] \tag{27}$$

For small dc-currents the linear law is thus:

$$\Delta_s\phi_{dc} + \frac{1}{F}\left(\Delta_n G^{s}_{cm,dc} + \Delta_n G^{s}_{ct,dc}\right) = -\left(\rho^{s}_{ct} + \rho^{s}_{cm}\right) j_{dc} \tag{28}$$

The surface impedance and the surface properties

The impedance of the catalyst surface is defined as:

$$Z^{s} \equiv -\frac{\Delta_s\phi_{ac}}{j_{ac}} \tag{29}$$

We find the surface impedance by adding Eqs.(21) and (26). This gives:

$$\Delta_s\phi_{ac} = -\left(\rho^{s}_{ct} + Z^{s}_{ad}\right) Fr^{s}_{ct,ac} - \rho^{s}_{cm} Fr^{s}_{cm,ac} \tag{30}$$

It furthermore follows from Eqs.(10) and (7) that

$$\begin{aligned} Fr^{s}_{ct} &= Fr^{s}_{cm} + i\omega c^{s}_{H^+}\Delta_{s,H^+}\phi \\ Fr^{s}_{cm} &= j_{ac} + i\omega c^{s}_{H_3O^+}\Delta_s\phi \end{aligned} \tag{31}$$

By combining Eqs.(25) and (29)-(31), we obtain the impedance of the surface

$$Z^{s} = \frac{\rho^{s}_{cm} + Z_{ct}}{1 + i\omega c^{s}_{H_3O^+}\left(\rho^{s}_{cm} + Z_{ct}\right)} \tag{32}$$

where

$$Z_{ct} = \frac{\rho^{s}_{ct} + Z_{ad}}{1 + i\omega c^{s}_{H^+}\left(\rho^{s}_{ct} + Z_{ad}\right)} \tag{33}$$

In the present experiments, we measure the response of two identically made electrodes plus membrane electrolyte. When a dc-current is passing the cell, one electrode will be a sink for hydrogen, while the other will be a source for hydrogen. The impedances of the two electrodes are the same, however. Both electrodes therefore give the same contribution to the measurement, also when the electrodes are polarized. In terms of the measured impedance, Z^{cell}, and the membrane impedance, Z^{mem}, the impedance of one electrode is then;

$$Z^{s} = \frac{1}{2}(Z^{cell} - Z^{mem}) \tag{34}$$

The membrane impedance is found by taking the limit of Z^{cell} for $\omega \to \infty$. The results that are calculated for Z^{s} from Eq.(34), can now be fitted to formulas (32) and (33) using Eq.(22) for Z_{ad}.
A constant phase element (CPE) shall be used for the charge transfer step in Eq.(32), rather than the capacitance. Eq.(33) then becomes:

$$Z_{ct} = \frac{\rho^{s}_{ct} + Z_{ad}}{1 + T_{ct}(i\omega)^{\alpha}\left(\rho^{s}_{ct} + Z_{ad}\right)} \tag{35}$$

When α equals 1, one has $T_{ct} = c^{s}_{H^+}$. The more depressed the semi-circle is, the lower is the α-value. We found α to be typically 0.82. We define the relaxation time for the charge transfer reaction:

$$\tau_{ct} \equiv \left(T_{ct}\,\rho_{ct}\right)^{1/\alpha} \tag{36}$$

The fit of the experimental results to the theoretical expressions gave Y_0 and τ_{ad} in the following expression for Z_{ad}:

$$Z_{ad} = \frac{1}{Y_0\sqrt{\tau^{-1}_{ad} + i\omega}} \tag{37}$$

The expression for the relaxation time, $\tau^{-1}_{ad} = k^{d}_{H_2}$, was given in Eq.(23).
The other variable is

$$Y_0 = \frac{2F^2}{RT} c^{a}_{H_2,eq}\sqrt{2D} \tag{38}$$

We see that knowledge of the diffusion constant for hydrogen along the pores, enables us to calculate $c^{a}_{H_2,eq}$ from this equation.

EXPERIMENTAL

For details about the membrane-electrode assembly, the gas humidifying system and other aspects of the experimental setup we refer to our first paper [2]. The impedance of the cell was measured at 30°C for different dc voltages. The impedance diagrams were recorded using a PAR 263A/94 potentiostat and a Solartron 1260 FRA. Z-plot software from Scribner Ass. Inc. was used to run the experiments. Measurements were made in a two-electrode set-up. The impedance was obtained by sweeping over the frequencies from 10 kHz to 10 mHz, recording 12 steps/decade, for each applied voltage. An amplitude of 5 mV was used in the experiments. The dc voltage varied from 0 to 60 mV in increments of 10 mV. Spectra were also recorded for systems exposed to a series of 30 experiments.

RESULTS

The impedance diagrams of Figs. 1 and 2 [2] were fitted to the expressions above. The spectra are given as Nyquist plots of Z^{cell}. The fitted results are presented in Tables 1-3. Table 1 gives the resistance of

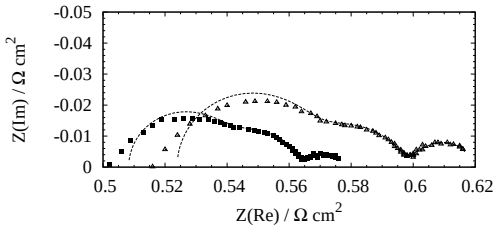

Figure 1: Impedance diagram for a freshly made PEMFC hydrogen electrode at 30^{o}C and 1 bar

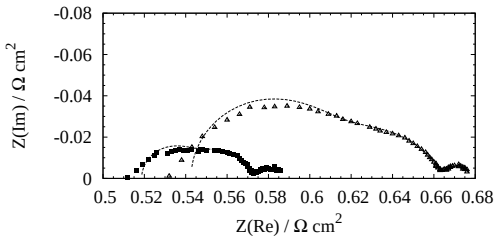

Figure 2: Impedance diagram for the PEMFC hydrogen electrode of Fig.1 used in 30 experiments, at 30^{o}C and 1 bar

the membrane R_Ω. It is, as expected, independent of the dc-voltage within the accuracy.

The first high frequency arc

The first arc in Figs.1 and 2 is, according to the model, related to the proton hydration. It was only possible to fit the first arc using a capacitance and a resistance, and not a constant phase element. When the applied dc potential increased, $c^{\text{s}}_{\text{H}_3\text{O}^+}$ decreased and ρ_{cm} increased.

The second arc: The constant phase element

The second arc in Figs.1 and 2, is according to the model, related to the charge transfer step. It is likely that the heterogeneity of the electrode causes a depression like the one we observe. This is also the motivation by us and others [3] to fit this second semi-circle to a constant phase element. The results show that T_{ct} is constant, while the resistance ρ_{ct} increases a little with the dc-potential. The variable

$\Delta\phi_{\text{dc}}$ (mV)	R_Ω (Ω cm^2)	$c^{\text{s}}_{\text{H}_3\text{O}^+}$ (F cm^2)	ρ_{cm} (Ω cm^2)
0	0.51	0.0071	0.035
10	0.53	0.0061	0.038
20	0.53	0.0057	0.041
30	0.53	0.0053	0.044
50	0.53	0.0049	0.047
60	0.54	0.0047	0.050

Table 1: Fitted results for the high frequency arc of the hydrogen electrode at 30 ^{o}C and 1 bar, for different applied dc potentials (5 % accuracy).

α_{ct} in the fit of the diagram to a CPE was constant (0.82).

$\Delta\phi_{\text{dc}}$ (mV)	T_{ct} (Ω^{-1} cm^{-2} s$^\alpha$)	α_{ct}	ρ_{ct} (Ω cm^2)
0	0.46$\pm$0.10	0.83	0.020$\pm$0.002
10	0.49$\pm$0.11	0.80	0.023$\pm$0.002
20	0.41$\pm$0.08	0.84	0.023$\pm$0.001
30	0.47$\pm$0.09	0.82	0.025$\pm$0.001
50	0.47$\pm$0.12	0.82	0.026$\pm$0.002
60	0.50$\pm$0.12	0.82	0.026$\pm$0.002

Table 2: Fitted results for the second arc of the hydrogen electrode at 30 ^{o}C and 1 bar, for different applied dc potentials

The third arc: The Gerischer element

The parameter Y_0 in the Gerischer element decreases when the dc-voltage increases, while the adsorption time τ_{ad} is constant within the accuracy. These results are essentially the same as those found in the first paper, where we simplified the description by assuming the water to be everywhere in equilibrium. They did also not vary by ageing. The relaxation times for the high an medium frequency phenomena were calculated, see Table 4. For τ_{cm} we used $\rho^{\text{s}}_{\text{cm}} c^{\text{s}}_{\text{H}_3\text{O}^+}$ while the relaxation time for the charge transport, τ_{ct}, was calculated using Eq.(36). The relaxation time for the slowest process was given in Table 3.

Ageing

As the electrode is being exposed to the oscillating field, even in the absence of an applied dc potential,

$\Delta\phi_{dc}$ (mV)	Y_0 (Ω^{-1} cm^{-2} s$^{1/2}$)	τ_{ad} (s)
0	190±20	6 ±2
10	180±16	8 ±1
20	160±10	8 ±1
30	150±10	8 ±1
50	130±10	8 ±1
60	120±10	8 ±1

Table 3: Fitted results for the Gerischer element of the hydrogen electrode at 30 ^{o}C and 1 bar, for different applied dc potentials

$\Delta\phi_{dc}$ (mV)	j (A cm^{-2})	τ_{cm} (10^{-4} s)	τ_{ct} (10^{-3} s)
0	0	2.49	3.5
10	0.016	2.32	3.7
20	0.030	2.34	3.9
30	0.043	2.33	4.4
50	0.070	2.30	4.6
60	0.083	2.35	5.0

Table 4: Calculated relaxation times for the cell at T=30^o C and 1 bar hydrogen gas, for different applied potentials

the first and the second arc obtains an increased resistivity. The Gerischer element remains unchanged.

DISCUSSION

The three arcs can be characterized as follows.

- The first arc has few signs of depression, and its relaxation time is independent of the applied potential. Its resistance depends on ageing, but the relaxation time does not.
- The second arc needs to be modelled with a constant phase element. Its resistance depends on ageing and the applied potential. Among the three relaxation times, only τ_{ct} increases with applied potential.
- The Gerischer element does neither depend on the applied potential, nor on the ageing of the electrode or the assumption of equilibrium for water for all conditions

These properties do all support the model given above, with the three suggested rate limiting steps, if the ageing effect can be explained by a reduction in particle surface, or by particle agglomeration [8]. It is likely that proton hydration relaxation does not depend on the applied potential, but that the resistance of this step depends on the surface area. Pictures of the catalyst particles may further confirm this hypothesis. A rate-limiting role for water was suggested by others [9–11]. It is furthermore natural that the charge transfer step depends on the applied potential, as well as on the current density, as observed. The Gerischer element was discussed earlier [2]. The diffusion coefficient of molecular hydrogen inside the carbon pores is 2×10^{-4} m^2/s [12, 13]

$\Delta\phi_{dc}$ (mV)	$c^a_{H_2,eq}$ (mol m^{-3})	$k^d_{H_2}$ (1/s)	$k^a_{H_2}$ (1/s)
0	300	0.17	0.30
10	290	0.13	0.24
20	240	0.13	0.20
30	240	0.12	0.20
50	210	0.12	0.17
60	190	0.12	0.15

Table 5: Concentrations and rate constants for a pressure of 1 bar at 30^{o}C and varying potential.

where the porosity is 0.4 and the pore diameter 50 nm [13, 14]. The surface of the pores area per cubic meter carbon is about 3×10^7 m^2. The volume fraction of a 0.33 nm thick surface is about 0.01. Scaled for the surface volume and a tortuosity of around 7 [14] the gas diffusion coefficient gave an estimate of the course grained diffusion coefficient of about $D = 3\times10^{-7}$ m^2/s. The equilibrium concentration of adsorbed hydrogen, $c^a_{H_2,eq}$, can now be calculated using Eq.(38). The concentration of molecular hydrogen in the pores is found using the ideal gas law which gives 40 mol m^{-3}. Multiplied with the porosity, we have $c^g_{H_2} = 16$ mol m^{-3}, independent of the dc-potential. The rate constants $k^a_{H_2}$ and $k^d_{H_2}$ then follow from Eq. (23). The calculated results are given in Table 5. The density of adsorbed hydrogen decreases from about 2 to one molecule per square nanometer, when the dc-voltage increases. Concurrently the rate coefficient decreases by a factor of two. The density of the hydrogen in the pores as well as the rate coefficient for desorption are both constant.

CONCLUSION

Electrochemical impedance spectroscopy was performed of the fuel cell electrode E-TEK, Elat/Std/DS/V2 0.5 mg Pt/cm^2, 20 Pt/C, impregnated with 0.6 mg Nafion®/cm^2 (5 wt % solution). The membrane contact was Nafion® 117. The electrode was studied at 30^{o}C and 1 bar.

A model was developed to describe three arcs in the Nyquist plot. We conclude that proton hydration may play a role in the process, in addition to the charge transfer process and the adsorption and diffusion of gas along the carbon surface. The experiments can be taken as a support for the theoretical description of the electrochemical transport processes in the nanoporous material.

ABSTRACT

Many biological processes involve the translocation of a biomolecule through a pore or a channel. A common example is the entry of the DNA of a bacteriophage into the cell [1]. Translocation may occur by simple diffusion. However, this mechanism is very slow, and in many cases there are some proteins in the cell that facilitate the entry of the biomolecule by binding reversibly to it. The role played by these proteins is assumed to be the rectification of the diffusion, thus acting as a Brownian ratchet [2].

To analyze in detail the process of translocation, we study the dynamics of the passage of a stiff chain through a pore into a cell containing particles that bind reversibly to it [3]. Using Brownian dynamics simulations we investigate the mean first-passage time as a function of the length of the chain inside for different concentrations of binding particles. We find that, as a consequence of the interactions with these particles, the chain experiences a net force along its length which drives it into the cell significantly faster than by pure or even ratcheted diffusion. These results suggest a role of binding particles in the translocation process that is in general quite different from that of a Brownian ratchet. Furthermore, nonequilibrium effects contribute significantly to the dynamics; e.g., the force that pulls the biomolecule strongly depends on how fast the translocation occurs compared to the binding of proteins. The results of the simulations and the dynamics of translocation can be successfully described using Mesoscopic Non-Equilibrium Thermodynamics (MNET) [4], in terms of a generalized diffusion equation which unveils the origin of the pulling force and provides a complete description of the kinetics of both chain entry and particle binding.

Keywords: Translocation, Brownian ratchet, Mesoscopic Non-Equilibrium Thermodynamics

NON-EQUILIBRIUM THERMODYNAMICS FOR NANOSYSTEMS

J.M. Rubi

Departament de Fisica Fonamental, Universitat de Barcelona, Diagonal 647, 08028, Barcelona, Spain

Nonequilibrium thermodynamics was proposed as a theoretical framework to analyze irreversible processes taking place in large scale systems. The theory has been successfully applied to systems of a very different nature, pertaining to different areas such as physics, physical-chemistry, biology and engineering. The scheme of non-equilibrium thermodynamics was extended to incorporate internal degrees of freedom to the set of thermodynamic variables. These degrees of freedom can, for exemple, represent the orientation of a macromolecules or a reaction coordinate and were assumed to undergo a diffusion process along an internal coordinate. We have shown that when endowed with probabilistic elements the method can also be used to analyze the irreversible behaviour of nanosystems for which the presence of fluctuations and the nature of the environment become elements of primary importance in the dynamics of the system. In this scheme the chemical potential and the probability density play the role of conjugate mesoscopic thermodyamic variables. The proposed theory: mesoscopic nonequilibrium thermodynamics (MNET) is offered as a general formalism able to characterize the irreversible behavior of small scale systems.
In the last years, we have shown the applicability of mesoscopic non-equilibrium thermodynamics to a broad variety of situations such as chemical kinetics electrochemistry, nucleation and growth, evaporation and condensation phenomena, active transport in biological systems and diffusion in the presence of entropic barriers. Our approach opens the way to the study of nanosystems through non-equilibrium thermodynamics methods.

ABSTRACT

The maximum power processes of multi-source endoreversible engines with stationary temperature reservoirs are investigated. We prove that the optimal solution is always time independent with a single hot and a cold engine contact temperature. The heat reservoirs fall into three groups: The hot reservoirs which are connected at all times for heat delivery, the cold reservoirs which are connected at all times for heat drain, and possibly a group of reservoirs at intermediate temperatures which are unused. This phenomenon is demonstrated for a three-source system. We find that for a commonly used class of heat transfer functions, including Newtonian, Fourier and radiative heat transport, the efficiencies at maximum power are the same as for two-reservoir engines with appropriately chosen properties.
*Keywords:*heat engine, endoreversible, optimization, reservoirs

INTRODUCTION

Heat engines with several heat sources are common for many real-world applications such as industrial heat-recovery systems and solar energy installations. In such installations several different heat sources are present, which provide heat at different rates, and, even more importantly, at different temperatures. For instance in solar energy installations these differences can come about because the angle towards the sun may differ or because some solar collectors might be at a larger distance from the central plant and thus the losses along the transport pipes cause a change in the effective temperature at the engine.

This paper investigates the performance limits for such engines. In particular we study maximum power processes for an endoreversible engine [1–3] operating between several heat reservoirs. The average power output is used as a criterion of thermodynamic merit. Methods of averaged nonlinear programming [4–6], which are already well established for the optimization of thermal systems with two heat reservoirs [7–9], are applied to determine the maximum possible average power output and the corresponding optimal contact functions between the heat reservoirs and the power converting subsystem.

In this model all irreversible processes are associated with the interactions between the heat engine and the heat reservoirs while the processes inside the reservoirs and power converting subsystem are reversible (i.e. the endoreversibility hypothesis [1]). This study thus complements earlier work on staged and combined systems, see for instance [10–19].

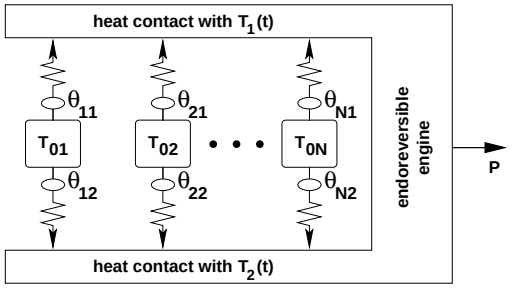

Figure 1: A multi-source endoreversible engine.

MODEL

A model of a multi-source endoreversible heat engine is depicted in figure 1. It consists of a power converting subsystem operating reversibly between two temperature contacts $T_1(t)$ and $T_2(t)$ and of N heat sources/sinks at constant temperatures T_{0i} where $i \in [1,N]$. The heat transfer laws between source i and engine contact $\alpha \in \{1,2\}$ have the form

$$\tilde{q}_{i\alpha}(T_{0i},T_\alpha,\theta_{i\alpha}) = \theta_{i\alpha} q_{i\alpha}(T_{0i},T_\alpha), \quad i \in [1,N]\,. \quad (1)$$

The contact functions $\theta_{i\alpha}$ describe the extent of the contact between reservoir and engine. They are equal to one if the i-th reservoir is fully connected to contact α and are equal to zero if there is no contact. Thus $0 \le \theta_{i\alpha}(t) \le 1$.

In the following we assume that the functions $q_{i\alpha}(T_{0i},T_\alpha)$ show the standard behavior of heat transfer as a function of T_{0i} and T_α, i.e. heat flows from high to low temperature: $q_{i\alpha}(T_{0i},T_\alpha) > 0$ if $T_{0\mathrm{i}} > T_\alpha$, $q_{i\alpha}(T_{0i},T_\alpha) < 0$ if $T_{0\mathrm{i}} < T_\alpha$, and $q_{i\alpha}(T_{0i},T_\alpha) = 0$ if $T_{0\mathrm{i}} = T_\alpha$.

POWER OPTIMIZATION

Our aim is to determine maximum power processes for this multi-source engine as well as the efficiency at maximum power. The system is operated under cyclic conditions with a fixed cycle time τ_{tot}, i.e. internal energy and entropy of the endoreversible engine is the same at the beginning and the end of the cycle. The system is optimized for maximum average power output $\bar{P}$. This is equivalent to the maximization of the time-averaged sum of the heat flows

$$q_\Sigma(T_0,T_1(t),T_2(t),\theta_1(t),\theta_2(t)) = \sum_{i=1}^{N} \tilde{q}_{i1}(T_{0i},T_1,\theta_{i1}) + \tilde{q}_{i2}(T_{0i},T_2,\theta_{i2})\,, \quad (2)$$

where the vectors θ_α of the contact functions and the vector T_0 of the reservoir temperatures are defined as

$$\theta_\alpha = (\theta_{1\alpha},\theta_{2\alpha},\ldots,\theta_{N\alpha}) \quad \text{and} \quad (3)$$
$$T_0 = (T_{01},T_{02},\ldots,T_{0N})\,. \quad (4)$$

The optimization problem can be stated formally as the maximization of the functional

$$I = \bar{P} = \overline{q_\Sigma}\,,[T_0,T_1(t),T_2(t),\theta_1,\theta_2] = \frac{1}{\tau_{\mathrm{tot}}}\int_0^{\tau_{\mathrm{tot}}} \sum_{i=1}^{N} (\tilde{q}_{i1}(T_{0i},T_1,\theta_{i1}) + \tilde{q}_{i2}(T_{0i},T_2,\theta_{i2}))\,\mathrm{d}t \to \max_{\{T_\alpha,\theta_\alpha\}} \quad (5)$$

by varying the engine contact temperatures T_1 and T_2 and all the contact functions θ_α subject to the restriction of entropy balance

$$\overline{s_\Sigma} = \overline{s_\Sigma}[T_0,T_1(t),T_2(t),\theta_1,\theta_2] = \frac{1}{\tau_{\mathrm{tot}}}\int_0^{\tau_{\mathrm{tot}}} \sum_{i=1}^{N} \left(\frac{\tilde{q}_{i1}(T_{0i},T_1,\theta_{i1})}{T_1} + \frac{\tilde{q}_{i2}(T_{0i},T_2,\theta_{i2})}{T_2}\right)\mathrm{d}t = 0\,. \quad (6)$$

This restriction is due to the cyclic operation of the system.

The temperatures $0 < T_1(t), T_2(t) < \infty$ of the endoreversible engine and the elements of the vector θ_α of contact functions are the $2N+2$ controls of the system. These elements satisfy the conditions

$$0 \le \theta_{i\alpha}(t) \le 1\,, \quad i \in [1,N] \quad \alpha \in \{1,2\}\,. \quad (7)$$

Equations (5–7) can either be optimized by using optimal control theory or by a special kind of nonlinear programming. As the objective as well as the constraint are both in the form of a time average over a given interval, we will here use averaged nonlinear programming. The Lagrangian for this problem has the form [4–6]

$$\mathscr{L} = \sum_{i=1}^{N} (\tilde{q}_{i1}(T_{0i},T_1,\theta_{i1})\left[1-\frac{\lambda}{T_1}\right] + \tilde{q}_{i2}(T_{0i},T_2,\theta_{i2})\left[1-\frac{\lambda}{T_2}\right]) \to \max_{\{T_\alpha,\theta_\alpha\}}\,, \quad (8)$$

where λ is a kind of Lagrange multiplier associated with the entropy balance, eq. (6).

The theory of averaged programming [4, 5] states that the solution for the optimal controls are piecewise constant functions taking values out of a set of

no more than $m+1$ *base points* where m is the number of averaged constraints of the problem (see [6], p. 78 ff).

The first point to note is thus that T_1 and T_2 are piecewise constant in time. The second point is that there is only one averaged constraint (6) here, and consequently there are no more than two base points for the controls and in particular for the temperatures $T_1(t)$ and $T_2(t)$. Let us call them T_h and T_c. As the optimization problem set up above is fully symmetric in the two contacts 1 and 2, the two base points are either of the form $(T_1,T_2)=(T_\mathrm{h},T_\mathrm{c})$ and $(T_1,T_2)=(T_\mathrm{c},T_\mathrm{h})$, or there is only one base point which then must have $T_1=T_2$. In the latter case the engine does not produce any power, so we exclude this case from our further considerations. In the first case we need to discuss only one of the base points and can thus assume $T_\mathrm{c}<T_\mathrm{h}$ without loss of generality.

From a physical point of view this means that, even though in principle the temperatures at the contacts of the endoreversible engine could change, it is optimal to run the engine in a stationary mode with fixed temperatures.

OPTIMAL CONTACT FUNCTIONS

We now turn to the variation of $\mathscr{L}$ with respect to the controls $\theta_{i\alpha}$. The Lagrangean $\mathscr{L}$ depends linearly on each $\theta_{i\alpha}$, so that $\mathscr{L}$ will attain its maximum only at the boundary values $\{0,1\}$ of the admissible range of $\theta_{i\alpha}$. This determines a rule for the contact functions:

$$\theta_{i\alpha}(T_{0i},T_{i\alpha})=\begin{cases}1 & \text{if} \quad \left[1-\frac{\lambda}{T_\alpha}\right]q_{i\alpha}(T_{0i},T_\alpha)>0\\ 0 & \text{if} \quad \left[1-\frac{\lambda}{T_\alpha}\right]q_{i\alpha}(T_{0i},T_\alpha)<0\end{cases}$$

$$\in[1,N] \quad \alpha\in\{1,2\}. \tag{9}$$

Let us take a closer look at this rule. $q_{i\alpha}(T_{0i},T_\alpha)<0$ means that the contact α connects with reservoirs which serve as heat sinks and thus fulfill the condition $T_{0i}<T_\alpha$. In the opposite case, i.e. $q_{i\alpha}(T_{0i},T_\alpha)>0$, this implies the condition $T_{0i}>T_\alpha$. The working fluid then connects to reservoirs which act as heat sources.

We now distinguish three cases:

$T_\mathrm{h}>T_\mathrm{c}>\lambda$:

$$\left[1-\frac{\lambda}{T_\mathrm{h}}\right]>0 \quad\Rightarrow\quad \begin{cases}\theta_{i\mathrm{h}}(T_{0i},T_\mathrm{h},\lambda)=1\\ \quad\text{if } q_{i\mathrm{h}}>0 \text{ i.e. } T_{0i}>T_\mathrm{h}\\ \theta_{i\mathrm{h}}(T_{0i},T_\mathrm{h},\lambda)=0\\ \quad\text{if } q_{i\mathrm{h}}\le 0 \text{ i.e. } T_{0i}\le T_\mathrm{h},\end{cases} \tag{10}$$

$$\left[1-\frac{\lambda}{T_\mathrm{c}}\right]>0 \quad\Rightarrow\quad \begin{cases}\theta_{i\mathrm{c}}(T_{0i},T_\mathrm{c},\lambda)=1\\ \quad\text{if } q_{i\mathrm{c}}>0 \text{ i.e. } T_{0i}>T_\mathrm{c}\\ \theta_{i\mathrm{c}}(T_{0i},T_\mathrm{c},\lambda)=0\\ \quad\text{if } q_{i\mathrm{c}}\le 0 \text{ i.e. } T_{0i}\le T_\mathrm{c}.\end{cases} \tag{11}$$

In this case all $\tilde{q}_{i\alpha}$ are either positive or vanishing which means that due to the entropy constraint all $\tilde{q}_{i\alpha}$ have to equal zero and thus no power is produced. We therefore exclude this case from our further consideration.

$\lambda>T_\mathrm{h}>T_\mathrm{c}$:

$$\left[1-\frac{\lambda}{T_\mathrm{h}}\right]<0 \quad\Rightarrow\quad \begin{cases}\theta_{i\mathrm{h}}(T_{0i},T_\mathrm{h},\lambda)=0\\ \quad\text{if } q_{i\mathrm{h}}>0 \text{ i.e. } T_{0i}>T_\mathrm{h}\\ \theta_{i\mathrm{h}}(T_{0i},T_\mathrm{h},\lambda)=1\\ \quad\text{if } q_{i\mathrm{h}}\le 0 \text{ i.e. } T_{0i}\le T_\mathrm{h},\end{cases} \tag{12}$$

$$\left[1-\frac{\lambda}{T_\mathrm{c}}\right]<0 \quad\Rightarrow\quad \begin{cases}\theta_{i\mathrm{c}}(T_{0i},T_\mathrm{c},\lambda)=0\\ \quad\text{if } q_{i\mathrm{c}}>0 \text{ i.e. } {}_{0i}>T_\mathrm{c},\\ \theta_{i\mathrm{c}}(T_{0i},T_\mathrm{c},\lambda)=1\\ \quad\text{if } q_{i\mathrm{c}}\le 0 \text{ i.e. } T_{0i}\le T_\mathrm{c}.\end{cases} \tag{13}$$

In this case all $\tilde{q}_{i\alpha}$ are either negative or vanishing which means that due to the entropy constraint all $\tilde{q}_{i\alpha}$ have to equal zero and thus no power is produced. Again we therefore exclude this case from our further consideration.

$T_\mathrm{h}>\lambda>T_\mathrm{c}$:

$$\left[1-\frac{\lambda}{T_\mathrm{h}}\right]>0 \quad\Rightarrow\quad \begin{cases}\theta_{i\mathrm{h}}(T_{0i},T_\mathrm{h},\lambda)=1\\ \quad\text{if } q_{i\mathrm{h}}>0 \text{ i.e. } T_{0i}>T_\mathrm{h}\\ \theta_{i\mathrm{h}}(T_{0i},T_\mathrm{h},\lambda)=0\\ \quad\text{if } q_{i\mathrm{h}}\le 0 \text{ i.e. } T_{0i}\le T_\mathrm{h},\end{cases} \tag{14}$$

$$\left[1-\frac{\lambda}{T_\mathrm{c}}\right]<0 \quad\Rightarrow\quad \begin{cases}\theta_{i\mathrm{c}}(T_{0i},T_\mathrm{c},\lambda)=0\\ \quad\text{if } q_{i\mathrm{c}}>0 \text{ i.e. } T_{0i}>T_\mathrm{c}\\ \theta_{i\mathrm{c}}(T_{0i},T_\mathrm{c},\lambda)=1\\ \quad\text{if } q_{i\mathrm{c}}\le 0 \text{ i.e. } T_{0i}\le T_\mathrm{c}.\end{cases} \tag{15}$$

In this case only reservoirs with positive $q_{i\mathrm{h}}(T_{0i},T_\mathrm{h})$ are connected to the engine contact at T_h, i.e. those with $T_{0i}>T_\mathrm{h}$. In the same way only negative $q_{i\mathrm{c}}(T_{0i},T_\mathrm{c})$ are connected to the engine contact at T_c, i.e those with $T_{0i}<T_\mathrm{c}$.

Note that due to the stationarity of T_h, T_c, and λ the contact functions are also independent of time.

HOT, COLD, AND UNUSED RESERVOIRS

We can now draw a number of interesting and surprising conclusions from the structure of the optimal contact functions. First of all it is clear that a reservoir will be at most connected to one heat contact. Those reservoirs with temperatures above the hot contact temperature will deliver heat, those with temperatures below the the cold temperature contact will receive heat. All reservoirs with temperatures in the range between T_c and T_h are therefore never connected during a cycle; these reservoirs are referred to as *unused reservoirs*.

As a consequence the set of N heat reservoirs is divided into three subsets R_h, R_c, and R_u of *hot*, *cold* and *unused* reservoirs, respectively. Note that the unused set may be empty depending on the temperatures of the reservoir. Also, it is clear that the hotest and coldest reservoirs are always active in a finite power producing solution.

CONSTRUCTION OF HEATING AND COOLING FUNCTIONS

To determine the heat flows resulting from the above rule, the heat transfer functions for each reservoir are separated into heat input and output functions,

$$q^+_{i\mathrm{h}}(T_{0i},T_\mathrm{h}) = \begin{cases} q_{i\mathrm{h}}(T_{0i},T_\mathrm{h}) & \text{if} T_{0i}\geq T_\mathrm{h} \\ 0 & \text{if} T_{0i}<T_\mathrm{h} \end{cases} \quad (16)$$

$$q^-_{i\mathrm{c}}(T_{0i},T_\mathrm{c}) = \begin{cases} 0 & \text{if} T_{0i}>T_\mathrm{c} \\ q_{i\mathrm{c}}(T_{0i},T_\mathrm{c}) & \text{if} T_{0i}\leq T_\mathrm{c} \end{cases} \quad (17)$$

for each $i\in[1,N]$. The total rate of heat input to and from the endoreversible engine are calculated as the sum of all contributions $q^+_{i\mathrm{h}}(T_{0i},T_\mathrm{h})$ and $q^-_{i\mathrm{c}}(T_{0i},T_\mathrm{c})$,

$$q^+(T_0,T_\mathrm{h}) = \sum_{i=1}^{N} q^+_{i\mathrm{h}}(T_{0i},T_\mathrm{h}) \quad (18)$$

$$q^-(T_0,T_\mathrm{c}) = \sum_{i=1}^{N} q^-_{i\mathrm{c}}(T_{0i},T_\mathrm{c})\,. \quad (19)$$

The heat exchange causes an entropy change of the working fluid. The rates of entropy flow to the working fluid are easily obtained by dividing the corresponding heat exchange rate by the current temperature of the working fluid. Specifically, the rates of entropy change are

$$s^+(T_0,T_\mathrm{h}) = \frac{q^+(T_0,T_\mathrm{h})}{T_\mathrm{h}} \quad (20)$$

$$s^-(T_0,T_\mathrm{c}) = \frac{q^-(T_0,T_\mathrm{c})}{T_\mathrm{c}}\,. \quad (21)$$

OPTIMAL TEMPERATURES FOR THE ENGINE CONTACTS

The Lagrange function (8) can now be expressed in terms of the above defined functions:

$$\mathscr{L} = q^+(T_0,T_\mathrm{h})\left[1-\frac{\lambda}{T_\mathrm{h}}\right] + q^-(T_0,T_\mathrm{c})\left[1-\frac{\lambda}{T_\mathrm{c}}\right]. \quad (22)$$

Already at this point it is apparent that the optimization of a multi source heat engine is equivalent to the optimization of a two-reservoir heat engine with the heat transfer functions defined above.

In order to determine the optimal temperatures we use the optimality condition $\partial\mathscr{L}/\partial T_\mathrm{h}=0$ and $\partial\mathscr{L}/\partial T_\mathrm{c}=0$ which can be rewritten as

$$\lambda = \frac{\partial q^+(T_0,T_\mathrm{h})}{\partial T_\mathrm{h}} T_\mathrm{h}\left(\frac{\partial q^+(T_0,T_\mathrm{h})}{\partial T_\mathrm{h}} - \frac{q^+(T_0,T_\mathrm{h})}{T_\mathrm{h}}\right)^{-1}, \quad (23)$$

and

$$\lambda = \frac{\partial q^-(T_0,T_\mathrm{c})}{\partial T_\mathrm{c}} T_\mathrm{c}\left(\frac{\partial q^-(T_0,T_\mathrm{c})}{\partial T_\mathrm{c}} - \frac{q^-(T_0,T_\mathrm{c})}{T_\mathrm{c}}\right)^{-1}. \quad (24)$$

Together with the constraint on the entropy as given by eq. (6) these equations determine the values of λ, T_h, T_c for given laws of heat conduction $q_i(T_{0i},T)$ and reservoir temperatures T_{0i}. These equations are used to analytically or numerically calculate optimal solutions.

A SPECIAL CLASS OF HEAT TRANSPORT EQUATIONS

We now restrict our analysis to an important subclass of heat transport equations. This class is characterized by a special structure in which the net heat flow is a sum or difference of two terms, where each system contributes to the heat flow based on just its own temperature:

$$q_{i\alpha}(T_{0i},T_\alpha) = q^{(\mathrm{r})}_{i\alpha}(T_{0i}) + q^{(\mathrm{s})}_{i\alpha}(T_\alpha). \quad (25)$$

This structure includes for instance Newtonian heat transfer, Fourier heat transfer, and heat transport by radiation. An example of a transport rule which does not comply with this structure is due to Anand:

$$q_{i\alpha}(T_{0i},T_\alpha) = (T_{0i}-T_\alpha)^\gamma. \quad (26)$$

For transport equations of the form (25) the summed up heat flows obey

$$q^+(T_0,T_\mathrm{h}) = \sum_{i\in R_\mathrm{h}} q^{(\mathrm{r})}_{i\mathrm{h}}(T_{0i}) + \sum_{i\in R_\mathrm{h}} q^{(\mathrm{s})}_{i\mathrm{h}}(T_\mathrm{h})$$

$$= q_{\rm h}^{(\rm r)}(T_0) + q_{\rm h}^{(\rm s)}(T_{\rm h}) \qquad (27)$$

$$q^-(T_0, T_{\rm c}) = \sum_{i\in R_{\rm c}} q_{i{\rm c}}^{(\rm r)}(T_{0i}) + \sum_{i\in R_{\rm c}} q_{i{\rm c}}^{(\rm s)}(T_{\rm c})$$

$$= q_{\rm c}^{(\rm r)}(T_0) + q_{\rm c}^{(\rm s)}(T_{\rm c})\,. \qquad (28)$$

Thus the system behaves as if connected to only two reservoirs.

If further the multiple sources are coupled to the engine by transport rules with the same T dependent function f, i.e.

$$q_{i\alpha}(T_{0i}, T_\alpha) = a_{i\alpha}(f(T_{0i}) - f(T_\alpha)). \qquad (29)$$

then the summed up heat transfer functions q^+ and q^- have the same structure

$$q^+(T_0, T_{\rm h}) = a_{\rm h}(f(T_{0{\rm h}}) - f(T_{\rm h})) \qquad (30)$$

$$q^-(T_0, T_{\rm c}) = a_{\rm c}(f(T_{0{\rm c}}) - f(T_{\rm c})) \qquad (31)$$

with $a_\alpha = \sum_{i\in R_\alpha} a_{i\alpha}$ and

$$T_{0\alpha} = f^{-1}\Big(\sum_{i\in R_\alpha} a_{i\alpha} f(T_{0i}) \Big/ \sum_{i\in R_\alpha} a_{i\alpha}\Big). \qquad (32)$$

Note that Newtonian, Fourier, and radiation heat transfer have this property.

As an example let us consider a system with three heat reservoirs. The temperatures of these reservoirs are T_{01}, T_{02}, and T_{03}. Whenever they are connected to either of the two contacts of the engine, the heat exchange is assumed to obey a linear transport law,

$$q_i(T_{0i}, T) = \alpha_i(T_{0i} - T). \qquad (33)$$

The temperatures of the three reservoirs are chosen to be $T_{01} = 1$, $T_{02} = 1.6$, and $T_{03} = 4$. We set the heat conductances $\alpha_1 = \alpha_3 = 1$ by an appropriate choice of units. We then vary the heat conductance α_2 of the intermediate reservoir T_{02} between 0 and 5 in steps of 0.1 and study how the behavior of the system changes.

The power output of these systems have been numerically determined. In this particularly simple example we used a less general method than the one introduced above in eqs. (23) and (24). Here we expressed the heat flows at the two contacts in terms of the respective entropy flows: $q^+(s^+)$ and $q^-(s^-)$. Whether such an approach is possible depends on the heat transport equations: one cannot always determine the heat flow as a single-valued function of the entropy flow. If one can then the advantage of this approach lies in the fact that the entropy constraint can explicitely be fulfilled by setting $s^+ = -s^-$. In our case the power output $q^+(s^+) + q^-(-s^+)$ was easily optimized by a line search varying s^+. However the reader should be aware that the power output might not be a unimodal function.

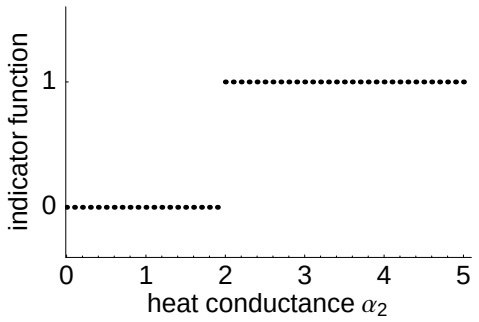

Figure 2: The indicator function $ind(\alpha_2)$ takes the value equal to the reservoir together with which reservoir 2 is used or zero in case it is not used at all.

In the following we analyze the dependence of the results on the value of the heat conductance α_2. The system shows a cross-over behavior at a critical heat conductance. This cross-over is intimately connected to the phenomenon of unused heat reservoirs.

In figure 2 the indicator function $ind(\alpha_2)$ shows how the intermediate heat reservoir is used: For small heat conductances the second reservoir is not used at all, here indicated by $ind = 0$, only reservoir 1 is connected to the cold contact and reservoir 3 is connected to the hot contact. With increasing heat conductance α_2 the reservoir becomes more and more important and – at the critical point – it is connected to the cold engine contact together with reservoir 1, here indicated by $ind = 1$.

Figure 3 shows the resulting maximal power output as a function of α_2. The dots represent the results of the numerical optimization. With increasing α_2 the power stays constant at 0.5 until reservoir 2 is switched on, then the power increases.

In figure 4 the corresponding efficiency at maximum power is shown. The behavior discussed above can be understood in terms of a Curzon-Ahlborn engine operating between two heat baths.

Initially the system uses only two of the three heat

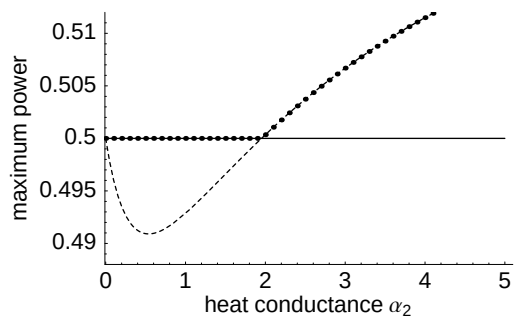

Figure 3: The maximal power output as a function of heat conductance α_2. Dots show the numerical solution for three reservoirs at $T_{01} = 1$, $T_{02} = 1.6$, and $T_{03} = 4$ and conductances $\alpha_1 = \alpha_3 = 1$. The solid line is the optimal solution of a Curzon-Ahlborn engine operating between reservoirs 3 and 1 only, while the dashed line is the optimal solution for operation between reservoirs 3 and the combined reservoirs 1 and 2.

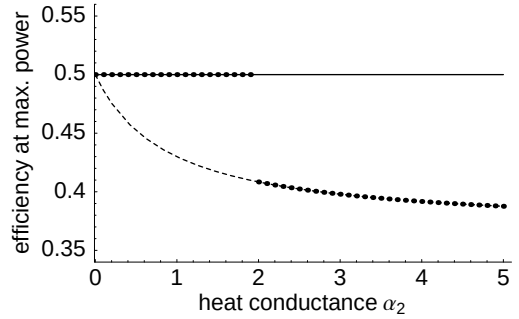

Figure 4: The efficiency at maximum power. Same nomenclature as in Fig. 3.

reservoirs: the hottest and the coldest. Then power and efficiency at maximum power are those of the Curzon-Ahlborn engine:

$$\begin{aligned} P_{\rm opt} &= \frac{\alpha_1\alpha_3}{\alpha_1+\alpha_3}(\sqrt{T_{01}}-\sqrt{T_{03}})^2, \\ \eta_{\rm CA} &= 1-\sqrt{\frac{T_{01}}{T_{03}}} = 1-\sqrt{\frac{1}{4}} = 0.5. \end{aligned} \quad (34)$$

These values are displayd as a solid line in figures (3) and (4). The dashed line corresponds to a Curzon-Ahlborn engine which operates between reservoir 3 as the high temperature reservoir and reservoirs 2 and 1 combined as the cold reservoir.
The results demonstrate very nicely that as soon as the dashed line crosses the solid line, reservoir 2 is put into use. This reservoir shows a cross-over from unused to used at which the power output is nondifferentiable but continuous, not unlike a second order phase transition. The efficiency on the other hand changes in a step-like fashion.

SUMMARY

In this paper a power-producing endoreversible engine which exchanges heat with several (two or more) constant temperature heat sources was considered. The heat transport is general and includes heat transfer processes obeying Newtonian, Fourier, and radiative heat transport. One of the interesting questions for such systems is how the different heat reservoirs are used in an optimal fashion. The system was optimized for maximum power output in case of cyclic operation using averaged nonliear programming methods. The optimal solution shows a number of interesting properties: First, it was shown that there are conditions where some reservoirs should not be connected at all in order to achieve an optimal performance of the system. These reservoirs are referred to as *unused reservoirs*. The hottest and the coldest reservoir will always be used.
The second important finding is that the optimal operation is a stationary one, where the *used* reservoirs and the power-producing subsystem contact temperatures are time-indepent.
We analysed a special class of heat transfer functions which includes the often used Newtonian, Fourier, and radiative heat transport. For this class of transport laws we showed that a multi-source endore-

versible engine is equivalent to a two-source engine with a particular choice of transport laws.
These results were finally exemplified by a simple three-heat source engine for which the heat conductance to the reservoir with the intermediate temperature was varied.

ENTROPY PRODUCTION MODELING IN CFD OF TURBULENT COMBUSTION FLOW

Ivar S. Ertesvåg*, Jostein Kolbu†
Department of Energy and Process Engineering
Norwegian University of Science and Technology
NO-7491 Trondheim, Norway

Abstract

A model for predicting the detailed field of entropy production by computational fluid dynamics (CFD) of turbulent flows with combustion is developed. The model is based on the widely used Eddy Dissipation Concept for turbulent combustion (EDC) by Magnussen and co-workers. It can be applied with an infinitely-fast-chemistry assumption or in conjunction with a detailed chemical mechanism (e.g. GRI Mech). The model is tested for a simple laboratory flame. The results are good when compared with results from a conventional box-model (overall) entropy-balance analysis.
Keywords: Turbulent combustion, EDC, CFD, entropy production, irreversibility

INTRODUCTION

For several decades, the methods of 2nd-law or exergy analysis of thermal and chemical systems have been developed and utilized. These methods are primarily flowsheeting approaches, where energy and exergy balances are put up for a number of interconnected subsystems or components (*e.g.* compressors, combustors, heat exchangers). Then the entropy production or the irreversibility (a.k.a. "lost work") of each component can be computed.

In parallel, methods for computing detailed flowfields without and with chemical reactions have been developed (known as computational fluid dynamics, CFD). In the context of turbulent combustion, Magnussen's EDC has become a standard model for technological applications. These methods provide detailed fields of velocity, temperature and concentrations of species throughout combustors or other devices.

For accurate optimization, a more detailed knowledge of the entropy production may be desired. The CFD approach can be extended to provide a detailed field of the entropy production as well. The basic formulation for this is known from several textbooks. For laminar flows, these equations can be solved numerically, see *e.g.* [9]. However, as most flows are turbulent, a model for entropy production is required, along with the models for turbulent transport, mixing, and combustion. One of the few attempts (the only?) is presented in [8], where combustion modeling was based on a prescribed-pdf method. In the present study, entropy modeling is based on the EDC [2–4, 6].

BASIC THEORY

Transport equations

The notation, terminology and basic assumptions are primarily those customarily used in fluid-mechanics and combustion literature (*e.g.* [2, 7, 10]). In some instances this differs from the irreversible-thermodynamics literature. The exposition follows an Eulerian and barycentric description, and continuity is assumed. The flow and scalar fields of reacting flows can be described by the following partial differential equations, often known as transport equations.

Momentum:

$$\underbrace{\frac{\partial}{\partial t}(\rho u_i)+\frac{\partial}{\partial x_j}(\rho u_i u_j)}_{\rho Du_i/Dt}=\frac{\partial}{\partial x_j}(-p\delta_{ij}+\tau_{ij})+\rho f_i. \quad (1)$$

Here, ρ is density, u_i Cartesian velocity components,

p pressure, τ_{ij} is the viscous stress tensor, f_i body-force acceleration, and δ_{ij} is the Kronecker tensor.
Mass of species:

$$\rho\frac{DY_k}{Dt} = \frac{\partial}{\partial x_j}(-j_{k,j}) + R_k. \tag{2}$$

Here, Y_k is the species mass fraction, $j_{k,j}$ the mass flux, and R_k the volumetric reaction rate. When this equation is summed for all species, the continuity equation is obtained:

$$\frac{\partial\rho}{\partial t} + \frac{\partial}{\partial x_j}(\rho u_j) = \frac{D\rho}{Dt} + \rho\frac{\partial u_j}{\partial x_j} = 0. \tag{3}$$

Energy:

$$\rho\frac{De}{Dt} = \frac{\partial}{\partial x_j}\left(-q_j - \sum_k h_k j_{k,j}\right) - p\frac{\partial u_j}{\partial x_j} + \tau_{ij}\frac{\partial u_i}{\partial x_j} + Q \tag{4}$$

Here, e is the specific internal energy of the mixture, q_j the heat flux, h_k the specific enthalpy, and Q the volumetric energy production, either by internal sources (heating) or by radiation. The second last term is the dissipation term, in the following denoted Φ. This equation can readily be rewritten into an equation for the enthalpy, $h = e + p/\rho$.

Flux relations

The preceeding equations includes terms for molecular fluxes. For most combustion cases, and indeed turbulent combustion cases, the following models are appropriate. For Newtonian fluids, the viscous stress tensor is expressed

$$\tau_{ij} = \mu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) - \tfrac{2}{3}\mu\frac{\partial u_l}{\partial x_l}\delta_{ij}. \tag{5}$$

Mass diffusion is modeled by Fick's law,

$$-j_{k,j} = \rho\mathscr{D}_k\frac{\partial Y_k}{\partial x_j}, \tag{6}$$

and heat transfer by Fourier's law,

$$-q_j = \lambda\frac{\partial T}{\partial x_j}. \tag{7}$$

Here, the dynamic viscosity μ, the thermal conductivity, λ, and the specific heat capacity, c_p, are for the mixture, whereas the diffusion coefficient, $\mathscr{D}_k$, is for the individual species.

Entropy

Later on, we will make use of the fact that the chemical potential (here used on a mass basis) for ideal gases is equal to the specific Gibbs function: $\mu_k = g_k = h_k - Ts_k$. With material derivatives, the classical Gibbs' equation can be expressed

$$T\rho\frac{Ds}{Dt} = \rho\frac{De}{Dt} - \frac{p}{\rho}\frac{D\rho}{Dt} - \rho\sum_k \mu_k\frac{DY_k}{Dt}. \tag{8}$$

From this and the energy and mass balances, an entropy equation can be developed on the form

$$\rho\frac{Ds}{Dt} = \frac{\partial}{\partial x_j}\left(-\frac{q_j}{T} - \sum_k s_k j_{k,j}\right) + \left(-\frac{q_j}{T^2}\right)\frac{\partial T}{\partial x_j} + \frac{1}{T}\sum_k\left(-j_{k,j}\right)\left(\frac{\partial\mu_k}{\partial x_j}\right)_T + \frac{Q}{T} + \frac{\Phi}{T} - \frac{1}{T}\sum_k \mu_k R_k. \tag{9}$$

TURBULENCE MODELING

Averaging

For turbulent reacting flows, it is convenient to include the density in the averaged quantities. This is known as mass-weighted Reynolds average or Favre average [2, 7]. The quantities such as velocity, specific enthalpy, species mass fraction, and temperature are decomposed into mean and fluctuating values as $\phi = \tilde{\phi} + \phi''$, where ϕ is a general variable. The mass-weighted mean value is defined

$$\tilde{\phi} = \frac{\overline{\rho\phi}}{\overline{\rho}}. \tag{10}$$

A consequence of this definition is that $\overline{\rho\phi''} = 0$, whereas in general, $\overline{\phi''} \neq 0$. The overbar shows average (statistical expectation). If the density does not fluctuate, or does not correlate with the other quantity, the Favre average is equivalent to the Reynolds average.

Continuity

The mass-weighted Reynolds-averaged (Favre-averaged) continuity equation is

$$\frac{\partial\bar{\rho}}{\partial t} + \frac{\partial}{\partial x_j}(\bar{\rho}\tilde{u}_j) = 0. \tag{11}$$

Momentum and turbulence transport

The mass-weighted Reynolds average (Favre average) momentum equation can be written

$$\frac{\partial}{\partial t}(\bar{\rho}\tilde{u}_i)+\frac{\partial}{\partial x_j}(\bar{\rho}\tilde{u}_i\tilde{u}_j)=-\frac{\partial \overline{p}}{\partial x_i} + \frac{\partial}{\partial x_j}\left(\overline{\tau}_{ij}-\overline{\rho u_i'' u_j''}\right)+\overline{\rho f}_i. \quad (12)$$

This is a derivation from Eq. (1). The new quantities appearing in this equation, $\overline{\rho u_i'' u_j''}$, represent convective transport of mean momentum by the action of turbulent motion. Their effect is similar to the (viscous) stresses, and they are known as Reynolds or turbulence stresses. From these, the turbulence energy is defined $\bar{\rho}\tilde{k}=\frac{1}{2}\overline{\rho u_i'' u_i''}$. A simple and frequently used model for the Reynolds stresses is the turbulence-viscosity model:

$$-\overline{\rho u_i'' u_j''}=\mu_t\left(\frac{\partial \tilde{u}_i}{\partial x_j}+\frac{\partial \tilde{u}_j}{\partial x_i}\right)-\frac{2}{3}\left(\bar{\rho}\tilde{k}+\mu_t\frac{\partial \tilde{u}_l}{\partial x_l}\right)\delta_{ij}. \quad (13)$$

This model is an analogy to Eq. (5). However, the turbulence viscosity, μ_t, is not a material property but a quantity characteristic of the flow. It can be regarded as a product of a turbulence length scale and a turbulent velocity scale. These scales can be expressed from lengths and velocities of the flow situation. However, a more general approach is to solve these scales from transport equations. The by far most popular model, which will be used here, is the k-ε model. Then the turbulence viscosity is modeled

$$\mu_t=\bar{\rho}C_\mu\frac{\tilde{k}^2}{\tilde{\varepsilon}} \quad (14)$$

Similar quantities, representing turbulence transport of scalars, will appear in mean-scalar transport equations in the following. When a general scalar is denoted ϕ, the Reynolds or turbulence fluxes are modeled

$$-\overline{\rho\phi'' u_j''}=\Gamma_{\phi,t}\frac{\partial\tilde{\phi}}{\partial x_j}=\frac{\mu_t}{\sigma_\phi}\frac{\partial\tilde{\phi}}{\partial x_j}. \quad (15)$$

This is known as the general gradient model. The turbulence Prandtl/Schmidt numbers, σ_ϕ, have to be specified in the model. The mean molecular diffusive flux may also be modeled by the same formalism or by more exact expressions of that term.
It should be noted that models solving transport equations for the Reynolds stresses are also an realistic option for turbulent combusting flows. However, these aspects of turbulence modeling are beyond the scope of this study.

Turbulence energy and dissipation rate

The modeled transport equation for turbulence energy can be written

$$\frac{\partial}{\partial t}\left(\bar{\rho}\tilde{k}\right)+\frac{\partial}{\partial x_j}\left(\bar{\rho}\tilde{k}\tilde{u}_j\right)=P^k+D^k+\Pi^k-\bar{\rho}\tilde{\varepsilon}. \quad (16)$$

In this equation, the production term,

$$P^k=-\overline{\rho u_i'' u_j''}\frac{\partial\tilde{u}_i}{\partial x_j}, \quad (17)$$

is closed as the Reynolds stresses already are modeled. The model expressions for the remaining terms vary according to the chosen model. The diffusion term is usually modeled by a molecular term and a turbulence term according to the general-gradient model,

$$D^k=\frac{\partial}{\partial x_j}\left(\left(\mu+\frac{\mu_t}{\sigma_k}\right)\frac{\partial\tilde{k}}{\partial x_j}\right). \quad (18)$$

The pressure term, Π^k, is very often neglected, as a generic and fully accepted model is still to be developed. Finally, the dissipation rate of turbulence energy,

$$\bar{\rho}\tilde{\varepsilon}=-\overline{\tau_{ij}\frac{\partial u_i''}{\partial x_j}}, \quad (19)$$

is solved from a separate transport equation. The terms as shown here follows the "standard" k-ε model for high-Reynolds number flows [5].
The dissipation-rate equation can be written

$$\frac{\partial}{\partial t}\left(\bar{\rho}\tilde{\varepsilon}\right)+\frac{\partial}{\partial x_j}\left(\bar{\rho}\tilde{\varepsilon}\tilde{u}_j\right)=D^\varepsilon+S^\varepsilon, \quad (20)$$

where the diffusion term is modeled analogously to Eq. (18) in the turbulence energy equation,

$$D^\varepsilon=\frac{\partial}{\partial x_j}\left(\left(\mu+\frac{\mu_t}{\sigma_\varepsilon}\right)\frac{\partial\tilde{\varepsilon}}{\partial x_j}\right), \quad (21)$$

and the source term is modeled as a balance between production and destruction:

$$S^\varepsilon=\frac{\tilde{\varepsilon}}{\tilde{k}}\left(C_1P^k-C_2\bar{\rho}\tilde{\varepsilon}\right). \quad (22)$$

Mass of species

The transport equation for mean mass fraction is

$$\frac{\partial}{\partial t}(\bar{\rho}\tilde{Y}_k)+\frac{\partial}{\partial x_j}(\bar{\rho}\tilde{Y}_k\tilde{u}_j)=\frac{\partial}{\partial x_j}\left(-\overline{j_{k,j}}-\overline{\rho Y_k''u_j''}\right)+\overline{R_k}. \tag{23}$$

The diffusive molecular and turbulence fluxes of species mass are often modeled according to the general gradient model, corresponding to Eq. (15) or Eq. (18) above. Moreover, the reaction term (species production term) has to be modeled, see below.

Energy

The energy equation, Eq. (4), can be rewritten to an enthalpy equation. The averaged version of this equation is

$$\frac{\partial}{\partial t}(\bar{\rho}\tilde{h})+\frac{\partial}{\partial x_j}(\bar{\rho}\tilde{h}\tilde{u}_j)=\frac{\partial \bar{p}}{\partial t}+\tilde{u}_j\frac{\partial \bar{p}}{\partial x_j}+\overline{u_j''\frac{\partial p}{\partial x_j}}$$
$$+\frac{\partial}{\partial x_j}\left(-\overline{q}_j-\sum_k\overline{h_k j_{k,j}}-\overline{\rho h''u_j''}\right)+\overline{\Phi}+\overline{Q} \tag{24}$$

In this equation, the third term at the right-hand side is equivalent to the pressure term Π^k in Eq. (16), and has to be modeled (often neglected).
The treatment of the diffusive fourth term depends both on the approximations for the heat and the molecular flux and on the numerical approach. However, the third part, the turbulence diffusion of enthalpy, is modeled according to the general gradient model, Eq. (15).

Combustion modeling

The Eddy Dissipation Concept for turbulent combustion (EDC) [2–4, 6] can be used to model the interaction between turbulence and combustion. A cascade model is used to link the fine turbulence structures (where reactions are assumed to occur) to the mean flow and large-scale turbulence (that is described by turbulence models). The fine structures are modeled as a reactor, Fig. 1. The reaction rate is obtained from a mass balance for each species.
When a fast-chemistry assumption (*i.e.* "mixed is burnt") is applied, the average reaction rate in Eq. (23) is modeled

$$\overline{R}_{\mathrm{fu}}=-\frac{\bar{\rho}\gamma^*\dot{m}^*\chi}{1-\gamma^*\chi}\tilde{Y}_{\mathrm{min}}, \tag{25}$$

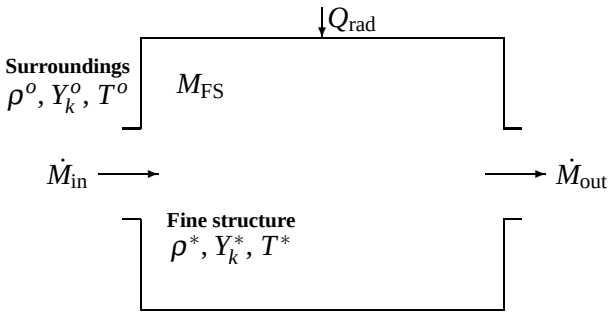

Figure 1: Schematic fine structure reactor of EDC

where

$$\tilde{Y}_{\mathrm{min}}=\min\left(\tilde{Y}_{\mathrm{fu}},\frac{1}{r}\tilde{Y}_{\mathrm{ox}}\right). \tag{26}$$

Here, r is the stoichiometric oxidizer (*i.e.* air or oxygen) requirement on a mass basis for the specific fuel, and subscripts "fu" and "ox" denote fuel and oxidizer, respectively. The quantities γ^* and $\dot{m}^*$ are the mass fraction of turbulence fine structures and its mass exchange with the surrounding fluid, respectively (cf. Fig. 1). These are related to the turbulence-cascade model of the EDC [2, 3] and are expressed as functions of the turbulence energy $\tilde{k}$ and its dissipation rate $\tilde{\varepsilon}$. The chemical reactions are assumed to occur in the fine structures, *i.e.*, the small turbulence scales. The mass exchange is the reciprocal of the fine-structure residence time, $\tau^*=1/\dot{m}^*$, which is proportional to the Kolmogorov time scale. The quantity χ is the fraction of fine structure that is reacting, and is a function of the concentrations of fuel, oxidizer, and product. The implementation of chemical kinetics is described by [4]. Then the reaction rate for a chemical species is expressed

$$\overline{R}_k=-\frac{\bar{\rho}\gamma^*\dot{m}^*}{(\gamma^*)^{1/3}}(Y_k^o-Y_k^*). \tag{27}$$

Here, Y_k^o and Y_k^* are the mass fraction of species k entering into and leaving the fine-structure reactor, respectively. The reacting turbulence fine structures are regarded as a perfectly stirred reactor, and the species mass balances of the reactor is solved with the use of data from a chemical-kinetics mechanism (*e.g.* GRI-Mech).
The model in Eq. (27) is obtained from a species mass balance for the reactor (Fig. 1), while Eq. (25) is the special case for fast chemistry. An energy balance for the reactor provide a model for the reactor

and mean temperatures. Similarly, we will use an entropy balance to model the entropy production.

Mean Entropy Equation

Above, the transport equation for entropy was expressed from the equations for species mass, continuity, and energy, by using Gibbs' relation. However, for the mean quantities, there exist no simple relation corresponding to the Gibbs relation or Eq. (8.)

The equation for the average of the entropy, can be written as the mean of Eq. (9),

$$\begin{aligned}\frac{\partial}{\partial t}(\bar{\rho}\tilde{s}) + \frac{\partial}{\partial x_j}(\bar{\rho}\tilde{s}\tilde{u}_j) \\ = \frac{\partial}{\partial x_j}\left(\overline{-\frac{q_j}{T} - \sum_k s_k j_{k,j}} - \overline{\rho s'' u_j''}\right) \\ + \overline{\left(-\frac{q_j}{T^2}\right)\frac{\partial T}{\partial x_j}} + \overline{\sum_k \left(-\frac{j_{k,j}}{T}\right)\left(\frac{\partial \mu_k}{\partial x_j}\right)_T} \\ + \overline{\left(\frac{Q}{T}\right)} + \overline{\left(\frac{\Phi}{T}\right)} - \overline{\left(\frac{1}{T}\sum_k \mu_k R_k\right)} \end{aligned} \quad (28)$$

The five last terms are the mean entropy production. It should be noted that the average of the products and ratios are not readily rewritten into terms containing products of mean values. This means that models for transport and production of mean entropy have to be developed.

As an example of the required modeling, the viscous-dissipation term can be inspected: The dissipation term of the entropy equation can be split in a mean-flow term and a turbulence term,

$$\overline{\left(\frac{\Phi}{T}\right)} = \overline{\left(\frac{\tau_{ij}}{T}\right)}\frac{\partial \tilde{u}_i}{\partial x_j} + \overline{\frac{\tau_{ij}}{T}\frac{\partial u_i''}{\partial x_j}}. = \overline{\left(\frac{\tau_{ij}}{T}\right)}\frac{\partial \tilde{u}_i}{\partial x_j} + \overline{\left(\frac{\rho\varepsilon}{T}\right)}. \quad (29)$$

Notice here that ε denotes the non-averaged dissipation rate of turbulence energy, cf. Eq. (19).

Provided that, but only then, the correlations between temperature and the other quantities are weak, the mean temperature can be left outside. For the viscous term, this is a reasonable assumption. However, for the other terms, the assumption would imply that the fluctuations of temperature and species mass fractions were small – which is certainly not the case in turbulent combustion.

ENTROPY MODELING WITH THE EDDY DISSIPATION CONCEPT

Overall approach

Turbulent motion may be regarded as eddies of sizes ranging from the external dimensions of the flow down to the smallest scales where the eddies are disrupted by viscous forces. This can be depicted as an energy cascade [3]. Combustion takes place at all scales, but mainly in the smallest scales. There, the gradients, and hence, the molecular fluxes, are the largest. Similarly, entropy is produced at all scales but mainly in the smallest eddies of turbulence.

When modeling the entropy production with the EDC, the approach will be to split the production into a large-scale (i.e. mean-flow and large-scale turbulence) contribution and a fine-structure contribution.

$$P^{\tilde{s}} = P^{\tilde{s}}_{\mathrm{LS}} + P^{\tilde{s}}_{\mathrm{FS}} \quad (30)$$

The large-scale contributions to entropy production are modeled by using the mean values in the production terms:

$$P^{\tilde{s}}_{\mathrm{LS}} = \frac{\overline{\tau}_{ij}}{\tilde{T}}\frac{\partial \tilde{u}_i}{\partial x_j} + \frac{\lambda}{\tilde{T}^2}\left(\frac{\partial \tilde{T}}{\partial x_j}\right)^2 + \sum_k \frac{\mathscr{R}_u}{M_k}\frac{\bar{\rho}\mathscr{D}_k}{\tilde{Y}_k}\left(\frac{\partial \tilde{Y}_k}{\partial x_j}\right)^2. \quad (31)$$

Here, $\mathscr{R}_u$ is the universal gas constant, and M_k is the molar mass. The radiation term is neglected in this study. In the EDC, the reactions are assumed to take place in the fine structures, and hence, there are no large-scale contributions from reactions.

Turbulence fine-structure entropy modeling

In the EDC, a mass-weighted (Favre) average (cf. Eq. 10) is expressed [2, 6] as

$$\tilde{\varphi} = \gamma^*\chi\varphi^* + (1-\gamma^*\chi)\varphi^o. \quad (32)$$

The general variable ϕ can represent the entropy production, σ. Thus, $\bar{\rho}\tilde{\sigma} = \overline{\rho\sigma}$ is the mean of the sum of entropy-production terms of Eq. (9), and σ^* and σ^o are the entropy production rates on a mass basis of the reactor and its surroundings, respectively. Here, in conjunction with Eq (30), the contribution of fine-structures to mean entropy production will be modeled by

$$P^{\tilde{s}}_{\mathrm{FS}} = \bar{\rho}\tilde{\sigma}_{\mathrm{FS}} = \bar{\rho}\left(\gamma^*\chi\sigma^* + (1-\gamma^*\chi)\sigma^o\right). \quad (33)$$

This formulation is based on the assumption in EDC that all reactions take place in the reactor. Furthermore, the major part of localized heat and mass exchange due to reactions also take place in the reactor or its vicinity. After exiting the reactor, the products are mixed with the surroundings.
Similar to the mass and energy balances [2], an entropy balance for the reactor can be put up to determine the reactor entropy production,

$$\sigma_1^* = \dot{m}^* \sum_k (Y_k^* s_k^* - Y_k^o s_k^o) - \frac{Q_{\text{rad}}}{\rho^* T^*} \qquad (34)$$

Here, the notation of the EDC is followed: The superscripts * and ^{o} refer to properties of the reactor and the surroundings of the reactor, respectively. $\dot{m}^*$ is the mass inflow rate to the reactor divided by the mass of the reactor. Its reciprocal is the residence time of the reactor. The last term is entropy transferred by radiation inflow, cf. Fig. 1. In this study, radiation term is neglected. However, when a radiation model is implemented with the combustion model (for energy exchange), it can readily be implemented in the entropy production model as well.
The expression above does not include the post-reaction mixing. This can be modeled

$$\sigma_2^* = \dot{m}^* \sum_k (Y_k^* (s_k^* - \tilde{s}_k)) \qquad (35)$$

for the mass exiting from the fine-structure reactor. Here, $\tilde{s}_k$ denotes the entropy of the species based on mean composition, pressure and temperature. The two contributions should be added; $\sigma^* = \sigma_1^* + \sigma_2^*$. At this stage, the last term of Eq. (33), σ^o, is left for future considerations.
The model in Eqs. (33)-(35) is decoupled from the specific formulation of the terms in Eq. (9). The idea of this model is that reactants enter the reactor with properties of the surroundings, whereas products leave the reactor with properties of the reactor.
The model can be used both with the "fast chemistry" assumption, and with a detailed mechanism for chemical kinetics. When EDC is implemented in a code, the quantities Y_k^*, Y_k^o, T^*, and T^o are already computed. Then, the mole fractions X_k^* and X_k^o and the partial pressures p_k^* and p_k^o can readily be calculated. Eventually, the only task remaining is to determine the specific entropies

$$s_k^* = s_k(T^*, p_k^*) \quad \text{and} \quad s_k^o = s_k(T^o, p_k^o). \qquad (36)$$

For readers familiar with the EDC, it can be mentioned that a simpler expression involving $\tilde{Y}_{\text{min}}$ (cf. Eq. 25) is not obtainable for the model in Eq. (34).

The investigations of [1] indicate that the reactions as such only give a minor contribution to entropy production, compared to the associated mass and energy exchange. Basically, the model in Eqs. (33)-(35) should be a model including all the localized (small-scale) entropy-producing processes in the turbulent combusting flow. That is, all processes (*e.g.* local mass transfer) that affects the field of temperature and partial pressures. Even though the individual processes are not specified, when their effects are seen in the temperature and composition fields, they are also included in the entropy-production model.

PREDICTIONS

For exemplary calculations, the model was applied to a jet flame. The fuel is a 1:1 mixture of H_2 and N_2, and the fuel jet diameter, bulk velocity, and Reynolds number are 8 mm, 34.8 m/s, and 10000, respectively. The jet is situated in a air coflow with diameter 400 mm, and velocity 0.2 m/s. Both flows have temperature 300 K. This is case "H3" in the database of the International Workshop on Measurement and Simulation of Turbulent Nonpremixed Flames. The predictions were made using the general-purpose CFD code Spider, which is based on finite volumes and non-orthogonal curvilinear computational mesh. In this case, a 2-dimensional rectangular mesh with axial symmetry was used. The turbulence model was the standard k-ε model, except for the round-jet modification of the constant $C_2 = 1.83$ (Eq. 22) and turbulence Prandtl and Schmidt numbers of 0.5. Buoyancy was included in the momentum equation. Combustion was modeled with the EDC and fast-chemistry assumption (Eqs. 25–26). Thermophysical data, including enthalpy and entropy, were obtained from the Chemkin Library.

The inlet boundary was specified as fixed values. For the jet flow, these were approximated to calculations of a fully developed pipe flow. The outlet was a parallel flow, and at the outer boundary zero radial transport was assumed.

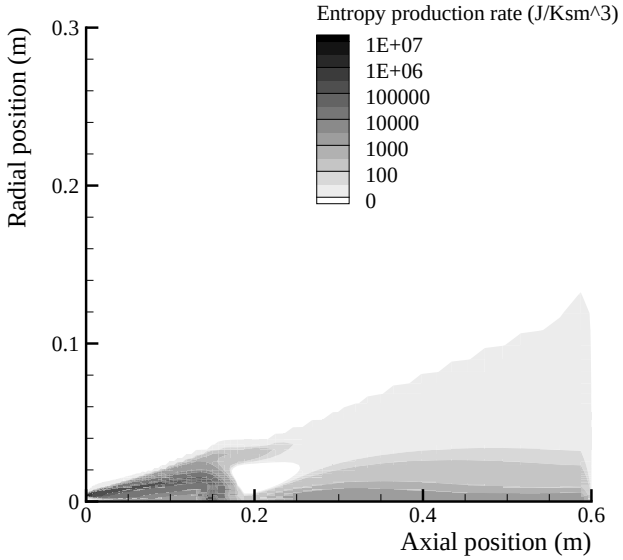

Figure 3: Mean entropy production rate

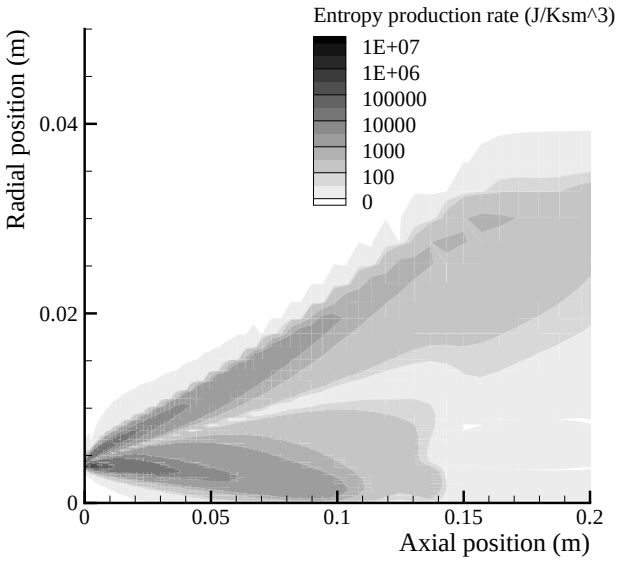

Figure 5: Entropy production due to mean temperature gradients, 2nd term of Eq. (31)

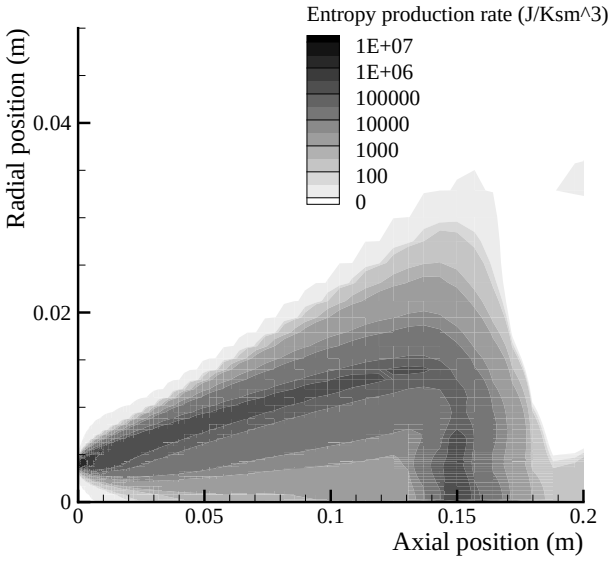

Figure 6: Fine-structure contribution to entropy production model in Eqs. (33)-(35)

RESULTS AND DISCUSSION

The geometry and the simulated mean temperature field of the jet are shown in Fig. 2. This and the species field (not shown) resembled experimental data quite well. The modeled mean entropy production is shown in Figs. 3–4. This is the sum of the contributions from the mean-field, Eq. (31), and from turbulence fine structures, Eqs. (33)-(35). In the former, the heat-flux contribution, that is, the 2nd term of Eq. (31), was by far the largest. This term gave some relatively large local values and is shown in Fig. 5. The major production, however, was found in the fine-structures, shown in Fig. 6. Here, the effects of chemical reactions and pre-reaction mixing are included through the model in Eq. (34). However, the main contributor was the post-reaction mixing term, Eq. (35). This finding corresponds well with the result obtained in [1].

No experimental data are available on entropy production. However, when the volumetric entropy production rate is integrated over the computed domain, it should be comparable to results of an overall entropy balance for the same case. Here, such a balance was evaluated based on the mean values. Then, the sum of entropy inflow to all inflow cells minus the entropy outflow from all outflow cells was 8.62 W/K. The inflow has no concentration fluctuations and only small temperature fluctuations. In the outlet, these fluctuations will be larger, and hence, the outflow entropy somewhat larger. Thus, the entropy production was somewhat overestimated when using the overall balance based on mean values. Nevertheless, it should be a good indication of the correct result.

The entropy production computed from the model presented above, was 6.14 W/K, or 71 % of that found from the simple balance. The fine-structure model gave 5.88 W/K, of this 2.36 W/K from Eq. (34) and 3.52 W/K from Eq. (35), while the mean-temperature term (Eq. 31) gave 0.25 W/K.

CONCLUDING REMARKS

The Eddy Dissipation Concept (EDC) for turbulent combustion has been extended to include modeling of entropy production. The results obtained are very good when compared with an overall entropy balance of the same case.

THE SECOND LAW OF THERMODYNAMICS AND EVOLUTION OF LIVING SYSTEMS

Georgi P. Gladyshev*
International Academy of Creative Endeavors
San Diego, USA – Moscow, Russia
N. N. Semenov Institute of Chemical Physics, Russian Academy of Sciences

ABSTRACT

The classical formulations of the second law of thermodynamics are presented. Some mistakes in the understanding the physical meaning of this general law of nature are noted. It is asserted that many misunderstandings of the second law of thermodynamics are related to terminological confusion and the underestimation (the disregard) of the theory developed by J.W. Gibbs and other founders of "true thermodynamics," which is impossible to disprove. To a certain approximation, R.Clausius and J.W. Gibbs' thermodynamics is applied to describing the evolution of living systems. This is possible due to the law of temporal hierarchies and the premise that the functions of state of living systems have real physical meaning at practically all hierarchical levels and at every moment of time. Making no pretensions to perfection, the author offers some advice to researchers dealing with thermodynamics. The author believes that, when considering thermodynamic problems, "ambiguous" terms and definitions should be clarified preliminarily in order to preclude possible misunderstandings. It is also advisable to refer to the classical works (including textbooks and encyclopedias) that the authors of publications have used. This will allow the correctness of the results reported to be estimated at least preliminarily.
Keywords: Second law, thermodynamics, chemical thermodynamics, entropy, Gibbs function, Gibbs energy, full differential, law of temporal hierarchies, evolution, living systems, quasi-closed systems.

"… the true and only goal of science is
to reveal unity rather than mechanisms"

Henri Poincaré

Classics of science enunciated the second law of thermodynamics, one of general laws of nature, in the first half of the 19th century. Well-known formulations of this law are associated with the names of N.L.S. Carnot (1824), R. Clausius (1850), and W. Thomson (Lord Kelvin) (1851). *

Although the formulations themselves are different, mainly because of the difference in phrasing, they may be considered equivalent. Many authors have attempted to change or improve the formulations as regards their physical meaning, yet none has succeeded. The meaning (essence) of these formulations has not been disproved to date [1–23]. However, new concepts have extended the possible applications of the second law of thermodynamics

* Georgi P. Gladyshev: E-mail: academy@endeav.org

to different sciences, especially chemistry and, as it turned out later, biology. This became possible mainly due to J.W. Gibbs' works performed in 1873–1878. To a certain approximation, the methodology of Gibbs thermodynamics [2] has been extended to date to all hierarchies of natural systems, which are generally open ones [17]. The discovery of the law of temporal hierarchies, which may be considered a new general law of nature, has determined the extension of Gibbs's theory to living systems [17, 22–28]. This law [17] makes it possible to apply thermodynamics (more precisely, the hierarchic thermodynamics of quasi-closed systems), to all hierarchies of the real world, particularly, living objects and biological systems, to quite a good approximation. I believe that the discovery of this law confirms the universality of classical thermodynamic methods, and the name of Josiah Willard Gibbs even more vividly symbolizes the future of science that confirms the validity of general laws of nature as applied to the evolution of all material systems at all organizational levels of our world. Advances in classical thermodynamics (as well as approximate thermodynamics, i.e., the quasi-equilibrium thermodynamics of quasi-closed systems) are described in a number of textbooks and monographs. They are certainly numerous; I would especially recommend the works [1–17], which will be very useful for all beginner researchers.

Clausius' formulation of the second law of thermodynamics, also known as the Clausius principle, states that a process that involves no changes except for the transfer of heat from a warmer body to a colder body is irreversible, i.e., heat cannot spontaneously pass from a colder body to a warmer one [7--10].

Clausius introduced the concept of entropy (S), a function of state of a system (a function that has a full differential). According to the Clausius inequality,

$$dS \geq \delta Q / T, \qquad (1)$$

where the equality sign pertains to reversible processes and the inequality (greater-than) sign, to irreversible ones.

Expression (1) is suitable for a simple isolated system, which can exchange neither substance nor energy with the environment and whose internal energy (U) and volume (V) are constant. In such systems only the work of expansion or no work at all is performed In this case, the second law of thermodynamics may be written as

$$dS_{U,V} \geq 0 .$$

Thus, the entropy of this system increases when irreversible processes occur, and it is maximum in the state of thermodynamic equilibrium.

The second law of thermodynamics according to Thomson (Thomson's principle) states that the process during which work is transformed into heat without any other changes in the system's state is irreversible. This means that all heat withdrawn from a body cannot be entirely transformed into work unless the system is changed in other respects. This formulation is equivalent to the statement that the perpetuum mobile of the second kind is impossible [7-10].

Carnot's theorem is also equivalent to the impossibility of the perpetuum mobile of the second kind. According to this theorem, no heat engine can have a higher efficiency than that of the Carnot cycle, $\eta = (T_1 - T_2)/T_1$, which is determined only by the temperatures of the heater and the cooler (T_1 and T_2, respectively). Carnot's theorem lays the basis for the absolute temperature scale.

Sometimes, the second law of thermodynamics is formulated as the well-known C. Caratheodory's principle (1909).

In the kinetic theory of gases, the second law of thermodynamics is substantiated by Boltzmann's H theorem. Here, H is the Boltzmann H function (to be precise, functional) determined from the mean logarithm of the particle distribution function. The Boltzmann H function is proportional to the entropy of a perfect gas.

The physical meaning of entropy is revealed in statistical physics. Boltzmann demonstrated that the entropy is related to the logarithm of thermodynamic probability (W):

$$S = k \ln W,$$

where k is the Boltzmann constant.

Note that the Boltzmann's substantiating the statistical basis of the second law of thermodynamics, as well as the statistical substantiation of phenomenological thermodynamics suggested by Gibbs, involves ideal models, e.g., a perfect gas. In the case of more complex systems [3-4, 8], where pronounced (especially, strong) interactions

between particles (molecules) are observed, it is difficult to perform the calculations. Therefore, it is obvious that these models are unlikely to be effective when studying most natural systems (e.g., biological), i.e., the systems that are far from corresponding to ideal or simple models.

The thermodynamics of nonequilibrium processes deals with the rate of increase in or (which is the same) production of entropy. Therefore, it is sometimes asserted that nonequilibrium thermodynamics provides "the quantitative characteristic of the second law of thermodynamics" [7]. In the given case, however, this statement is reasonable only when applied to transformations in simple isolated systems where all processes are close to equilibrium. Only in a system that is close to equilibrium can the differential of this function of state of the system (entropy) be considered to be a full one, to an acceptable approximation. However, all the aforesaid is usually underestimated; therefore, many works on nonequilibrium thermodynamics, especially the thermodynamics of systems that are far from equilibrium, remain a faint "future hope." Some of these works, I daresay, are mere "mathematically trimmed" fantasies useless for real life [22–24].

Historically, the formulations of the second law of thermodynamics were closely associated with the study of heat engines. This approach has been developed by physicists, mainly thermal physicists, and heat engineers. Another trend in the use of the second law of thermodynamics is related to the attempts of some mathematicians and physicists constructing ideal and simple models to explain many natural phenomena in statistical terms. However, since all interactions in real systems are impossible to take into account, there is but little hope that calculations in the framework of these models will successfully solve the problem. Hence, only the phenomenological thermodynamics of systems close to equilibrium (equilibrium or quasi-equilibrium thermodynamics) is likely to ensure the insight into many natural phenomena and make reliable quantitative predictions.

The above formulations of the second law of thermodynamics are, in a sense, somewhat outside the realm of the chemistry of molecular and supramolecular systems. These formulations may seem to be even farther from biology, sociology, and other sciences that are mainly based on chemistry (both molecular chemistry per se and the chemistry of supramolecular structures), which we perceive as "chemistry around us." Therefore, it is not unexpected that a purely physical (rather than physicochemical) approach to the origin of life, biological evolution, and aging of living organisms has lead to numerous misunderstandings—one might say, even to tragic errors—in life science. It should suffice to mention L. Boltzmann's, E. Schrödinger's, I. Progogine's [29–31], and other researchers' fallacies accounted for by neglecting (to some or another extent) Gibbs's works and underestimating the possibilities offered by thermodynamics. In some of my publications, I emphasized the substantial misunderstandings in this field [11, 20, 22, 23] that the founders of classical thermodynamics noted long ago [1, 2, 10–13].

To justify these statements, let me make a digression to cite the renowned scientists Boltzmann and Schrödinger [31] who asserted that living organisms struggle for negative entropy (also called negentropy). I will also cite some Prigogine's [29] quotations that appeared even on the cover of his books. The reader will find references to them in the Internet [31, 32].

I would like to note that the quotations presented below do not pertain to the second law of thermodynamics in its classical form [2, 9, 10]. Today, they may seem surprising, especially taking into account that all this was written several years after Gibbs published his works.

For example, Boltzmann (1886) wrote,

"The general struggle for existence of animate beings is therefore not a struggle for raw materials - these, for organisms, are air, water and soil, all abundantly available—nor for energy which exists in plenty in any body in the form of heat (albeit unfortunately not transformable), but a struggle for entropy, which becomes available through the transition of energy from the hot sun to the cold earth.".

Then, in 1944, Schrödinger wrote that *"the only way a living system stays alive, away from maximum entropy or death is to be continually drawing from its environment negative entropy. Thus the device by which an organism maintains itself stationary at a fairly high level of orderliness (= fairly low level of entropy) really consists in continually sucking orderliness from its environment. …Plants of course have their most powerful supply in negative entropy in sunlight…"*.

Later, Prigogine also supposed (on the basis of previous notions of Boltzmann, Schrödinger, and their followers in life science) that the phenomenon

of life is hardly consistent with the second law of thermodynamics. He noted, *"During the last decades, an opinion has widely spread that there is the apparent contradiction between biological order and laws of physics—particularly the second law of thermodynamics"* (1980). Prigogine also emphasized that *"this contradiction cannot be removed as long as one tries to understand living systems by the methods of equilibrium thermodynamics"*.

In order to solve these "contradiction", Prigogine [29] developed the theory of dissipative structures, i.e., the structures that appearing in systems that are **far from equilibrium.** Later, it turned out that the theory did not allow overcoming the aforementioned "contradictions." In fact, it made the imbroglio even more intricate. It later became obvious that Prigogine's views do not agree with the second law of thermodynamics [20, 22, 24]. This is so in many respects. Suffice it to say that, in the general case, the Prigogine entropy (S' or S_i) has no full differential. Therefore, his theory cannot be regarded as thermodynamic. This is a kinetic theory based on an "entropy" (Prigogine's entropy, S') which can be neither calculated nor measured.

Prigogine considered Gibbs's work to be mainly theoretical and stated that Gibbs's method is inapplicable to studying physicochemical transformations, such as chemical reactions, because the values used in this method are the functions of state pertaining to the whole system or its individual component. Prigogine actively publicized his views via scientific literature and textbooks [30]. As a result, many researchers refer to Prigogine's formulation of the second law of thermodynamics. Actually, this formulation applies to a particular speculative model and may be accepted only on certain premises that cannot be proved. Unfortunately, this concept (which, in a sense, contradicts the principles of science itself [5, 6]) was supported by many researchers. Owing to efficient publicity, these colleagues were convinced by hardly comprehensible (in physical terms) formulas and doubtful argumentation. In my opinion, the supporters of Prigogine's theory were, in a sense, deceived. Although Prigogine's theory proved an impasse, it still has its followers. Nevertheless, no numerical data obtained from either experiment or observations have confirmed the theory even at the qualitative level [20, 22]. Moreover, many physicochemical processes of the formation of spatially periodic structures (which Prigogine and his coauthors regarded as dissipative) were explained long ago in terms of the thermodynamic models of quasi-equilibrium systems (without involving the concept of dissipative structures). It is generally known that W.Ostwald (1897) used the notion of supersaturation to explain the existence of such systems in nature.

Thus, the aforementioned concepts by Boltzmann, Schrödinger, Prigogine, and their followers turned out to be at best tentative ones, or even a dead end. They hampered for many decades the search for the ways to explaining the evolution of living systems in physicochemical terms on the basis of the second law of thermodynamics. As noted above, only in recent decades were the principles of hierarchical thermodynamics (macrothermodynamics) formulated. I have managed to extend Gibbs's methodology so that it might be used for creating the physical (physicochemical) theories of the origin of life, biological evolution, and aging of living organisms [17, 22–28].

As noted above, the physical substantiation of the second law of thermodynamics deals with ideal processes and is based on the concept of statistical entropy. The nonequilibrium thermodynamics of systems that are far from equilibrium tries to study the changes in "kinetic entropy" (e.g., Prigogine's entropy S' or (S' or S_i), which, as mentioned above, has no full differential (even an approximate one) and cannot be calculated in principle! In addition, the approaches used in the nonequilibrium thermodynamics of systems far from equilibrium create difficulties related, e.g., to the notions on the thermodynamics of processes and the thermodynamics of systems.

One of the greatest merits of Gibbs and other renowned founders of classical thermodynamics is that they used the works by J.L. Lagrange, L. Euler, and other outstanding mathematicians (specifically, the variation principles developed by them) as a basis for the concepts on the functions of state of the system other than entropy (which, like entropy, have full differentials). The functions of state permit determining the directions of spontaneous processes and estimating the extent of their advancement in individual thermodynamic systems identified in the real world. In other words, the evolution of systems themselves can now be studied, to a certain approximation, if certain natural (independent) variables are constant. The

Gibbs function G (the Gibbs free energy or, more briefly, the Gibbs energy) can be used for studying equilibrium (quasi-equilibrium) processes and closed systems (the quasi-closed systems in which quasi-equilibrium transformations occur) at constant temperature and pressure. The Helmholtz function F (A) is applicable to studying these processes and systems at constant temperature and volume. Certainly, this is only true on the assumption that the functions of state (of the systems studied) have actual physical sense at any moment of time. This is true for systems close to equilibrium but not for those far from equilibrium. I would like to emphasize once more that the law of temporal hierarchies gives grounds for the use of the functions of state when the direction and the extent of advancement of the evolutionary processes that occur in quasi-closed systems are estimated at different hierarchical levels of living matter [17]. For clarity, let us make a digression on the law of temporal hierarchies.

The law of temporal hierarchies makes it possible to identify quasi-closed thermodynamic systems (subsystems) within open biological systems and to study the individual development (ontogenesis) and evolution (phylogenesis) of these subsystems via studying the changes in the specific (calculated per unit volume or mass) Gibbs function for the formation of a given higher monohierarchical structure out of lower monohierarchical structures. For example, it has been found that the specific Gibbs function for the formation of supramolecular structures of biological tissues ($\overline{\tilde{G}}_i^{im}$) tends towards its minimum in the course of ontogenesis (as well as phylogenesis and evolution as a whole):

$$\overline{\tilde{G}}_i^{im} = \frac{1}{V}\int_0^V \frac{\partial \tilde{G}^{im}}{\partial m}(x, y, z)dxdydz \to \min, \quad (2)$$

where V is the volume of the system, m is the mass of the microvolumes identified, x, y, and z are coordinates, the symbol "–" means that $\overline{\tilde{G}}_i^{im}$ is a specific value (i.e., calculated per unit macrovolume), and the symbol "~" emphasizes that the system is heterogeneous. Note that expression (2) implies that the intermolecular (supramolecular) interactions in all hierarchical structures of biological tissues (both intracellular and intercellular interactions) are taken into account. This is justified because the structural hierarchy does not necessarily coincide with the temporal one. For example, cells of some types do not divide; like organs, they age simultaneously with the body as a whole. However, for each supramolecular hierarchy (j–1), there exists a higher hierarchy (j+x) such that

$$t^{j-1} << t^{j+x},$$

where t^{j-1} and t^{j+x} are the mean lifetimes (or lifespan) of the elementary structures of the respective structural hierarchies in the living system; x = 0, 1, 2, etc.

Note that the internal medium and many fragments of nondividing cells are nevertheless renewed due to metabolism.

The use of expression (2) actually means that, in the given case, the law of temporal hierarchies assumes the following form:

$$\ldots << t^{m} << t^{im} << t^{organism} << t^{pop} << \ldots . \quad (3)$$

Here, t^{m} (t^{ch}) is the mean lifetime of molecules (chemical substance) involved in metabolism in the body, t^{im} (t^{supra}) is the mean lifetime of all intermolecular (supramolecular) structures of tissues renewed during individual growth and development, $t^{organism}$ is the mean lifetime of individual organisms in a population, and t^{pop} is the mean population lifetime. I have deliberately excluded the lifetimes of cells and some other complex supramolecular structures from the series of strong inequalities (3) for the reasons indicated above. However, this series certainly represents a general law of nature consistent with reality and reflecting the existence of temporal hierarchies in living systems.

The law of temporal hierarchies is related to the presence of metabolism or other forms of substance transformation at all hierarchical levels. Note that metabolism is an essential characteristic of living organisms.

This law (Gladyshev's law) allows strict demonstration of the possibility to identify (discern) quasi-closed monohierarchical systems (subsystems) within open polyhierarchical biological systems. This statement entirely agrees

with the experience accumulated in theoretical and experimental physics [3, 5]. I am convinced that this assertion cannot raise any objections.

It is impossible in this short article to list all important conditions for the use of some or another function of state of the system. Moreover, I do not think I have noted all of the main "delicate" points that beginners should take into account. Besides, I refer to just a few publications, those that are most important for me. It should also be noted that my paper, as well as most publications on thermodynamics, may contain some inaccuracies of wording resulting from the ambiguity of translation. For example, most professional scientists know about inexcusable confusions with the terms *isolated system* and *closed system* (originally English). Both terms are sometimes translated into Russian as *замкнутая система* (literally, *closed system*). So the terms are often regarded as equivalent or identical. Other errors result from semantic coincidence of some terms. For example, the Gibbs (or Helmholtz) free energy is often confused with energy in the ordinary sense. This is why many researchers have attempted to replace this term with the term *the Gibbs function* [19]. Another example is the term *complex system.* Here, the word *complex* has a double meaning. In thermodynamics, a complex system (as opposed to a simple one) usually means a system in which (or on which) a work other than the work of expansion is done [15, 16]. Sometimes, however, the word *complex* is used to emphasize a structural or some other heterogeneity of the system itself or the diversity of its elements. This also applies to the term *simple system,* and so on. Certainly, these and other such confusions may lead to blunders that escape a nonprofessional's notice. These and other similar errors creep into some textbooks, reference books, and then into the Internet. I presume the possible inaccuracy of my English in this paper is insignificant, and I hope that the above remarks will warn beginners about the erroneous views that may exist in thermodynamics. I think that all physicists, chemists, biologists, and other specialists that deal with thermodynamics should study the Gibbs phenomenological thermodynamics first of all. As noted above, this authentic (in a certain sense, true) thermodynamics is based on the notion of full differentials. Note that this approach to understanding the world surrounding us is intrinsically irrefutable. We may only discuss the accuracy of the Gibbs thermodynamics as applied to, e.g., quasi-closed systems the processes in which are close to equilibrium. In accord with the very essence of full differential (its mathematical meaning), as well as the first law of thermodynamics, the change in the function of state of the system accompanying the transition from one equilibrium state to another is independent of the way or mechanisms of this transition. Probably, the lack of our knowledge on actual complex systems may be partly attributed to the changes in entropy during this transition, because the entropy cannot be measured directly. The changes in phenomenological entropy accompanying transformations in both simple and complex systems may be calculated only if one has studied the corresponding thermal processes. In statistical terms, the entropy is calculated only for ideal systems (or systems close to ideal). It is impossible to perform any precise calculations of this function of state for systems with strong interactions between particles (molecules and supramolecular structures) on a statistical basis. I would like to emphasize that this applies to complex thermodynamic systems, i.e., the systems in which strong interactions occur.

Thermodynamics, owing to its impeccably reliable mathematical basis, may be regarded as a "machine" that always yields the right result if the premises are correct. Physical chemistry has repeatedly confirmed this [8–10, 14, 19]. Unfortunately, some physicists, biophysicists, biologists, and, especially, modern "philosophers" are still unaware of this experience of chemists and chemical technologists.

I would like to repeat that the aforementioned ambiguities, which are mainly related to the disregard of the correct use of many terms that are semantically similar but differ in physical meaning, result in confusion and misunderstandings. These misunderstandings discredit, at least in nonprofessionals' opinion, thermodynamics itself and science as a whole. Hence the numerous incorrect interpretations of the second law of thermodynamics, various dubious "views" on entropy [11, 13, 20, 22], and far-fetched "the functions of state of the system" in literature are appeared. Many authors, ignoring classical works in this field, apply different formulations of the second law of thermodynamics to systems where they are inherently inapplicable. Some of these authors suggest their own interpretations of this general law of nature. This debases science and education. Moreover, it can be said that several

"second laws of thermodynamics" have appeared, none of which having anything to do with reality. A good example is the aforementioned Prigogine's [29] interpretation of the second law of thermodynamics. This interpretation "extends" the well-known incorrect and indemonstrable statement by the great Boltzmann [31], who neglected the important concepts put forward by Clausius and Gibbs. The interpretation suggested by Prigogine has practically conquered the "scientific" world and still remains one of the trendiest interpretations of the second law of thermodynamics. I am well aware that it would be hopeless to argue with the visionaries that create or support these concepts: they have developed an excellent method for leading such debates. They unfailingly give lots of arguments, which are mostly quotations from published or oral statements made by other visionaries or by insufficiently informed scientists. It is often emphasized that those scientists are well known or even famous. However, the visionaries forget that scientists that are well known and famous in one field are not necessarily professionals in others. The only way to withstand this conjuncture is to refer the readers to classical works and serious textbooks written in a highly professional milieu of world-renowned scientific schools with centuries-long traditions.

Thus, making no pretensions to perfection, I would like nevertheless to offer advice to researchers dealing with thermodynamics, as well as other branches of science, and the editors of scientific periodicals. My advice is the following. **When discussing the problems of thermodynamics or using its mathematical tools for calculations, it is necessary to clarify "ambiguous" terms and definitions. It is also advisable to refer to the classical works (including textbooks, reference books, and encyclopedias) that the authors of publications used.** In this case, the correctness of the results reported in the publications can be at least preliminarily estimated.

I am grateful to Prof. M.M. Abdildin, Prof. G. Arrhenius, Prof. N.N. Bogolyubov, Jr., Prof. K.G. Denbigh, Prof. V.P. Kazakov, Prof. Yu.S. Lipatov, Prof. A.A. Logunov, Prof. V.V. Sychev, and Prof. V.M. Frolov for the support, systematic fruitful discussions, and valuable advice.

ABSTRACT

Considerations on entropy production are made to understand and model the reaction-rate enhancement observed in turbulent combustion affected by acoustic waves. The Eddy Dissipation Concept for turbulent combustion (EDC) is extended to account for the acoustic waves. It is argued that in combustors, acoustic waves often occur at length scales at the order of magnitude of the mean flow. Hence, the small-scale behaviour, including chemical reactions, is affected through the kinetic energy cascaded to turbulence fine structures. The energy input is enhanced by the large-scale entropy production due to acoustic waves, and increases the dissipation. Testing the modified model against available experimental data gave the correct response to acoustic waves.

1 INTRODUCTION

In the field of turbo-machinery, as in any other field, the efficiency of turbines, compressors and other components is inversely proportional to the distance of the real process from its ideal counterpart. This implies that the design goal is that of minimizing the exergy destruction in the device [2]. In order to achieve this, the detailed accounting for the local entropy production proposed by the authors [8-9,12,15] has been shown to provide additional insight into the dissipative mechanisms and consequently to be a proper designer's guideline to process improvement.

In this paper we suggest how entropy production can be used to model mixing mechanisms such as interaction with acoustic waves.

Our goal here is not to investigate efficiency, but to explore whether an entropic approach can provide a better understanding of combustion and

[1] Carmine.L.Iandoli@ntnu.no
[2] Ivar.S.Ertesvag@ntnu.no
[3] Enrico.Sciubba@uniroma1.it

lead to more accurate modeling of turbulent flames. As a first step we will show how the Eddy Dissipation Concept for turbulent combustion (EDC) by Magnussen and co-workers [5,11] can be related to the entropy generation and how considerations on entropy generation can improve such a model.

2 ENTROPY GENERATION AND ACOUSTIC WAVES

2.1 Turbulence cascade

Turbulent combustion is controlled by mass transfer from the large to the small scales of the flow. This is an intrinsically dissipative process which is governed by the turbulent characteristics of the flow. The large scales of the motion are loosing their energy by "cascading" it towards ever smaller scales, until the smallest viscous scales are reached where mechanical energy is fully converted into heat. In the absence of an energy input mechanism ("forcing") at some large scale, the turbulence is known to decay quite rapidly.

A possible modeling of the energy decay is the EDC [5,11]. This model provides a link between the local level of turbulent energy and dissipation rate and the time needed to achieve perfect mixing. The concept involves the explicit consideration of an energy cascade that transfers mechanical energy from the largest to the smallest scales. The model has been widely applied. However, the EDC in its present formulation does not seem to yield proper results when applied to the solution of problems involving highly unsteady processes such as pressure waves and their interaction with the heat release. In order to understand if, where, and how EDC can be improved, the general picture of the mixing process will here be observed from a different perspective.

By following a given control volume $\mathcal{V}$ in time, we see that it exchanges energy and momentum with the surroundings, changing its turbulence level in the process. What actually happens at the smallest scales is that the dynamics of the turbulence evolves not under the direct effect of the main flow, but just because of the evolution of the energy cascade. This evolution is a natural process that involves production of entropy and depends on the very structure of the flow. The turbulence cascade posses its own continuous set of time scales, and it is maintained as long as the main flow keeps "feeding" the turbulence energy. What happens is that part of the energy of the mean flow, the turbulence kinetic energy, is dissipated and converted into heat inside of each volume $\mathcal{V}$. In other words, turbulence is converting kinetic energy into heat while producing entropy. If the volume could reach a condition of equilibrium where no more turbulence energy is being added from the outside, all the turbulence energy would be converted very quickly into heat, until the flow within $\mathcal{V}$ first re-laminarises and then finally comes to a stillstand. In this sense, the turbulence kinetic energy may be considered as a measure of the potential entropy of the flow, or, in other words, as a measure of the distance from local thermodynamic equilibrium.

But we know that it is the turbulence energy dissipation rate that physically represents the local entropy production rate due to the transfer of momentum at the smallest scales: therefore, the ratio between dissipation rate and turbulent kinetic energy must functionally represent a measure of the distance between local and global equilibrium.

The above ideas may be applied when dealing with the calculation of the fine-structure volume fraction and the reactor residence time in the framework of the EDC (see expressions below).

In this sense, the energy cascade already represents the link between local entropy production (ε) and its distance from equilibrium (k).

The original formulation of the EDC given by Magnussen [10] can be revised on the basis of the concepts outlined above, but before doing that it is useful to show how the entropy production and the dissipation rates are related.

2.2 Entropy production

Entropy is generated due to reactions, mass fluxes, energy fluxes, and viscous dissipation. Here, it will be argued that the contributions from reactions and mass fluxes are mainly found in

smaller scales. Moreover, it is observed that pressure waves occur at the mean-flow scale level. Hence, the volumetric entropy production associated with pressure waves can be expressed

$$\sigma = \frac{\lambda}{T^2}\left(grad\left(T\right)\right)^2 + \frac{\Phi}{T} \qquad (1)$$

Here, the dissipation function is expressed

$$\Phi = \tau_{ij}\frac{\partial u_i}{\partial x_j}, \qquad (2)$$

and the velocity and temperature are used with their mean values. It can be noted that neglecting of the heat-transfer term implies that the compression is considered adiabatic.
Further considerations of entropy and CFD modeling of turbulent combustion with EDC are provided in [4].

2.3 Attenuation of pressure waves

The attenuation of pressure waves traveling through a fluid involves both thermodynamic and viscous effects. The pressure change resulting from the volume reduction ("compression") is not quite in phase with the change of density, and volume deformation energy is thereby converted into heat. Through interaction with the surrounding gas, the compressed portion loses thermal energy by diffusion, and a corresponding "relaxation" of the sound pressure results [8].
The effects of viscosity involve a similar diffusion from the moving part to the rest of the gas: They amount to irreversible transfers of kinetic energy from the organized motion of the sound wave to the disorganized translational motion of the molecules which constitutes their thermal energy.
The general picture of the pressure attenuation should also include the relaxation due to chemical reactions and the effects related to mixtures including non-monatomic gases, where there are other degrees of freedom of the molecules, other than the translational ones.
Neglecting for the moment chemical effects, we can say that an increase of the entropy generation rate is generated by a rate of variation of thermal energy per unit volume that must be equal to the loss of power (energy per unit time) per unit volume from the sound wave. In this case both temperature and momentum fluxes must be included into the entropy production term, Eq. (1)
For a simple-harmonic plane wave propagating through a perfect gas, the attenuation can be expressed as a fraction of its energy [6]:

$$2a = \frac{dQ}{I} = \frac{\sigma \cdot T}{I}, \qquad (3)$$

where the intensity is $I = \rho c u_0^2$. It is worth noticing that the attenuation is computed by comparing the local entropy production of the disturbance with its intensity, which is the same concept used in the EDC framework to evaluate the turbulence cascade.

Fluid motion is characterized by a continuous production of entropy: when the process involves a mixture, global equilibrium is achieved when the velocity, temperature and concentration gradients are identically zero. In this condition, each volume of fluid may potentially burn if the temperature is high enough. By following the evolution of a fluid volume, one may observe that the local entropic level increases in time, because of the local entropy production rate, which includes all of the dissipative effects. The conversion of the kinetic energy of the fluid into thermal energy can therefore be seen as a measure of the mixing achieved at the smallest scales. The way this mixing is achieved depends on the nature of the process itself: in the case of turbulence it is modeled by the energy cascade, while in the case of acoustic disturbances it still needs to be modeled. However, in the next paragraph we will show that acoustic waves do increase both the turbulent kinetic energy and the dissipation of the flow they travel through. It should be kept in mind that the attenuation of acoustic waves is a process which includes a transfer of energy to other frequencies, but in general is not governed by the turbulent energy cascade.
In fact, it must be remarked that viscosity and thermal conductivity are actually transmitting energy from the large scales of motion to the molecular scales. This can be easily proved without assuming any cascade model.
Equation (3) shows that the attenuation is governed by non-linear terms. This means that the larger the gradients, the larger the attenuation. In

this sense the higher frequencies, which are characterized by higher gradients, are attenuated faster. Similar considerations apply in the case of both pressure and velocity waves, but in this latter case it is easier to understand how the dissipation is achieved.

3 ACOUSTIC WAVES AND TURBULENCE DYNAMICS

The attenuation of sound waves is a process of energy transfer from large to small scales. This transfer is represented by the dissipation of the velocity fluctuations (turbulence energy) and is enacted by the dissipation function Φ which can be easily linked to the viscous entropy production, Eqs.(1)-(2).

Numerical tests [8] shown that the decay of acoustics waves follows a path similar to the decay of turbulent energy. In particular in a frequency range lower than the Taylor scales, which is related to the inertial sub range, acoustic energy is mostly transferred from a lower to a higher frequency with little dissipation, while in the dissipative range not all of the energy is transferred, but part of it is also dissipated and converted into heat.

However, the interaction between the kinetic energy produced in that case by the boundaries and the acoustic energy is yet to be modeled and in fact the turbulent kinetic energy k as well as the dissipation ε were not affected by the acoustic waves.

Direct interaction between shear stress due to acoustic waves and turbulence should be expected when the reciprocal of the mean strain rate (S^{-1}) and the turbulence time (k/ε) scale are in the same range [12].

In industrial combustion chambers these time scales are usually close enough to interact, but the intensity of such an interaction and its effect depend on the relative magnitude among the two energies involved. A first evaluation can be performed comparing the amplitude of velocity fluctuations due to turbulence and acoustics. In the operational range of a gas turbine burner, a high turbulence level is required to improve mixing, thus we can expect velocity fluctuations u' to be in the range of 1-2 m/s. As a very rough first approximation, the acoustically induced velocity fluctuations for plane waves such as those observed in combustors can be computed on the basis of [6]:

$$u_{acoustics} = p_{acoustics} / (\rho c) \qquad (4)$$

Acoustic pressure rarely exceeds *100 Pa*, while density is in the order of *0.2-0.3kg/m*^{3} and speed of sound is about *500 m/s*. Under these conditions the maximum $u'_{acoustics}$ we can expect is in the range 0.7—0.5 m/s, which is not far from the turbulence-induced velocity scale. Preliminary experiments have been performed to evaluate how acoustics affects turbulence. A turbulent stream was perturbed with acoustic drivers confirming that it is possible to modify the turbulent energy spectrum with acoustic waves [8]; an example of this interaction is reported in Fig. 1. In this case, the turbulent field is generated by a grid and an acoustic driver is perturbing the flow at different frequencies, in the figure we reported the effect of forcing at 263 Hz.

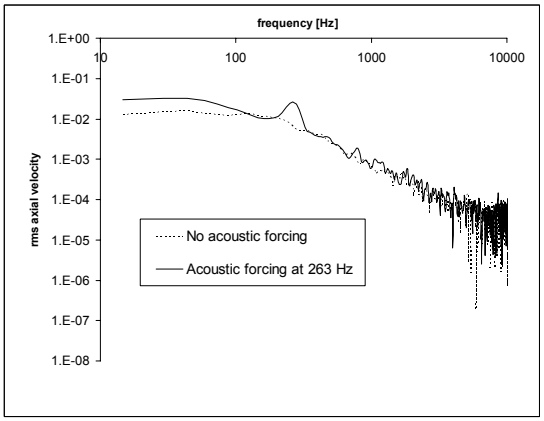

Figure 1: Axial velocity spectrum with and without acoustic forcing

The velocity spectrum shows that when perturbing the turbulent flow with an acoustic fluctuation, the effect of the perturbation is directly felt on the spectrum (the continuous line shows a peak in correspondence of the frequency of the perturbation). However this is the only appreciable effect on the stream.

The effect of the acoustic forcing on turbulence needs further investigations however theoretical analyses suggested that two kinds of effects can

be expected depending on the relative magnitude of acoustics and turbulence [12]. If the acoustic shear is strong enough, the flow should suffer a strong and highly dissipative distortion which has been treated by the rapid distortion theory. In this case a huge production of kinetic energy follows the distortion and then the turbulence field becomes anisotropic. However our experiments did not show any anisotropy in the flow field.
On the other hand, if the shear is not strong enough, the tiny anisotropy induced by acoustics will be redistributed among the Reynolds stresses, in this case the flow is experiencing a return to isotropy and the energy of acoustics does not appear in the turbulent kinetic energy budget [12]. Nevertheless the acoustic shear affects the energy flux among the stresses, and once isotropy is recovered, we should except that the decay of acoustic and turbulent energy should follow the same path.

4 ACCOUNTING FOR ACOUSTIC EFFECTS IN THE EDC

4.1 Kinetics of acoustic waves

In the framework of the EDC, the combustion rate is ruled by the amount of energy cascading to the fine structures, which are modeled as a reactor [5,11]. Any changes in the dissipation of turbulent energy should therefore affect the reactor parameters. Hence, the turbulence Reynolds number provides a measure of the distance of the reactor from global equilibrium and an acoustic wave does change such a distance. In particular, in the case of acoustic waves, the distance from equilibrium is increased as well as the entropy generation; therefore we should expect combustion to be enhanced.
Experimental tests have shown that acoustic waves indeed enhance combustion rate [1,7,14].
A possibility for modeling such an effect could be to include the increase in dissipation due to acoustics. Its modeling requires care because both dissipation and distance from equilibrium are increased by acoustic waves. We propose using the viscous term for the entropy generation as a measure of the dissipation and

$$k_{acoustic} = \tfrac{1}{2}\rho u^2_{acoustic} \qquad (5)$$

as a measure of the acoustic energy. Both terms however need to couple with turbulence, and thus in the following we will show a possible way to include them in the energy cascade.

4.2 The EDC cascade model

In the EDC, dissipation is pictured as a multi-step cascade, at each level of which a fraction of the turbulent energy is dissipated into heat (q_n) while the rest feeds mechanical energy (w_n) into the lower scale. For each level, the energy converted into heat is calculated by [5]

$$q_n = C_{D2}\nu\omega_n^2, \qquad (6)$$

while mechanical energy transfer is

$$w_n = \tfrac{3}{2} C_{D1}\omega_n u_n^2 . \qquad (7)$$

Here, C_{D1} and C_{D2} are model constants equal to 0.134 and 0.50, respectively. This mechanism proceeds until all the mechanical energy has been dissipated. Complete dissipation is achieved in the fine structures where, in the hypothesis that the Reynolds number is sufficiently high, the amount of turbulent energy converted into heat is

$$q^* = \tfrac{3}{4} w'' \approx \tfrac{3}{4}\varepsilon = 0.75 u'^3 / L' \qquad (8)$$

This equation links the dissipation at fine structures (q^*) and the turbulence velocity scale u'. The cascade also provides [5] a measure of the velocity fluctuations at the fine scales:

$$u^* = \left(C_{D2}/3C_{D1}^2\right)^{1/4} (\nu\varepsilon)^{1/4} \qquad (9)$$

In order to include the effect of acoustics, it should be considered that the velocity fluctuations associated with sound waves have a specific frequency which essentially depends on the geometry of the combustor. However, in practical applications sound is always produced at large scales, which allows us to assume that acoustics will affect the top of the cascade. This implies that the dissipation of acoustic energy will follow the same path as the turbulent energy, and in particular that fine structure velocity fluctuations can be expressed as:

$$u^* = \left(C_{D2}/3C_{D1}^2\right)^{1/4} \left(\nu\left(\varepsilon + T\sigma_{acoustic}/\rho\right)\right)^{1/4} \qquad (10)$$

The EDC model then uses u^* to evaluate the amount of mass that is molecularly mixed [5]:

$$\gamma_\lambda = u^*/u' = \left(3C_{D2}/4C_{D1}^2\right)^{1/4}\left(\nu\varepsilon/k^2\right)^{1/4}. \quad (11)$$

This quantity is interpreted as the ratio between mass of fine-structure regions and total mass. The ratio of the mass of the active reactor and total mass, and hence the reaction rate, is taken proportional to the square of γ_λ.

In order to account for the acoustic forcing, it is necessary to modify the turbulence velocity scale $u' = (2k/3)^{1/2}$. Here, we suggest modeling it as

$$u' = (2k/3)^{1/2} + p/\rho c, \quad (12)$$

where the additional term accounts for the velocity fluctuations due to a plain acoustic wave with intensity p. It is worth noticing that the amplitude of the fluctuations increases with decreasing density.

Although such a measure of the amplitude of an acoustic wave is not correct for sound propagation in open spaces, in combustors, sound is coupled to the acoustic modes of the burner, so that acoustic waves may be roughly approximated as plane. For more general cases, a strategy for a more accurate computation of velocity fluctuations should be considered.

The new mass fraction thus will be

$$\gamma_{\lambda,acoustic} = \left(\frac{3C_{D2}}{4C_{D1}^2}\right)^{1/4}\left(\frac{\nu\left(\varepsilon+\sigma T/\rho\right)}{k+\frac{1}{2}\left(p/\rho c\right)^2}\right)^{1/4} \quad (13)$$

Once the mass fraction is defined, the EDC model introduces a time scale, which is needed to define how long fuel and oxidizers are hosted in the reactor $\tau^* = (m^*)^{-1}$, where m^* is the mass flow to the fine structures modeled as

$$m^* = 2\frac{u^*}{L^*} = \left(\frac{3}{C_{D2}}\right)^{1/2}\left(\frac{\varepsilon}{\nu}\right)^{1/2}. \quad (14)$$

By substituting here the dissipation ε with the extended dissipation that includes the entropy generation ($\varepsilon+T\sigma_{acoustic}/\rho$), the new residence time becomes:

$$\tau^{*-1} = m^* = \left(\frac{3}{C_{D2}}\right)^{0.5}\left(\frac{\varepsilon+T\sigma_{acoustic}/\rho}{\nu}\right)^{0.5} \quad (15)$$

This expression shows that an increased energy forcing to the top of the cascade will indeed affect the fine structures and ultimately enhance combustion.

Notice that our main hypothesis is that acoustic is feeding the energy cascade from the level of the mean flow, and therefore our model cannot be used for high frequency acoustic waves, where the interactions of the wave trains with the cascade are different.

4.3 Entropy and acoustic waves

The calculation of the viscous dissipation in numerical simulation requires a careful evaluation of the amount of dissipation occurring at the large scales compared with the small ones. As a matter of fact, except for DNS, the latter are accounted by the turbulence model while only large scales variations are directly computed by means of the mean quantities of the motion.

A first remark is that acoustic waves observed in combustors are often related to the acoustic modes of the combustion chamber, which are in the range of 100 to 500 Hz. These frequencies correspond to rather long waves (in the order of 1 meter). In numerical computation of combustion chambers, such long scales of motion are easily calculated by the mean quantities and thus should not require any subgrid modeling.

Therefore it might be possible to evaluate the relevant entropy production only by means of the average quantities. In particular, the viscous dissipation term can be split into a contribution from the large and one from the small scales. The small-scale part is accounted for by the dissipation-rate of turbulence energy. The part associated with acoustic waves is the large-scale (mean) part

$$\frac{T\sigma_{acoustic}}{\rho} = \frac{\Phi_{acoustic}}{\rho} = \left(\frac{\Phi}{\rho}\right)_{LS} = \frac{\tau_{ij}}{\rho}\frac{\partial u_i}{\partial x_j} \quad (16)$$

where, again, the mean values of the quantities are used. The expression assumes density fluctuations are small compared with the mean.

5 TESTING THE EXTENDED EDC MODEL

Although the computation of $\gamma_{\lambda,acoustic}$ can be performed rather easily, the problem is to reproduce the behavior of the acoustic waves.

The investigation discussed in [8] shows that pressure waves and their decay can be computed with the available numerical tools, but that extreme care should be exercised to avoid the occurrence of erroneous results. In an acoustic field, sound is locally generated by density variations, but in the far field it propagates by velocity rather than density fluctuations. Acoustic signals are thus convected as velocity waves that travel through the field and are either reflected or absorbed by the boundaries. This implies that, regardless of the capability of the boundaries to reflect or adsorb pressure waves, in our case we need a numerical boundary treatment that allows both velocity and pressure to fluctuate freely.

The first step towards the evaluation and the validation of the suggested model is by testing statically the EDC reactor by assuming a given level of acoustic pressure and turbulence.

In order to test our model, we thus assume that the link between pressure and velocity waves is given by Eq. (4), which allows us also to estimate the magnitude of the velocity gradients.

The set up for our perfectly stirred reactor was taken accordingly with the experiments performed by [13]. In their work they acoustically forced a highly turbulent flame (Re 20000) by means of two loudspeakers at relatively low frequency (22-50 Hz). Their results indicate that the acoustics was enhancing combustion. On the basis of the combustor data reported in that paper, we assumed that reasonable values for the turbulent kinetic energy and dissipation were, respectively, 1.5 m^2/s^2 and 4 m^2/s^3. These values provide a measure of the turbulence level within the combustion chamber, and of course are not constant in space; however they should provide a reasonable input for the evaluation of τ^* and γ_λ (Eqs. (12) and (9)). In particular:

$$\begin{aligned} \gamma_\lambda &= 0.25 \\ \tau^* &= 17.32 \cdot 10^{-3} \text{s} \end{aligned} \tag{17}$$

Different frequencies are tested in [13], in particular we have investigated the effect of acoustic fluctuations at 22 Hz whit a measured pressure level of 35 Pa. Assuming the density and the speed of sound to be 0.5 kg/m^3 and 500 m/s, respectively, the amplitude of velocity fluctuations due to the acoustic wave can be computed as:

$$u'_{acoustic} = \frac{p}{\rho c} = \frac{35}{500 \cdot 0.5} \text{m/s} = 0.14 \text{m/s} \tag{18}$$

Velocity fluctuations will occur at the same frequency as pressure waves, thus the spatial behavior of the velocity wave will be:

$$\begin{aligned} u(x) &= u'_{acoustic} \sin(2\pi \cdot f \cdot x / c) = \\ &= 0.14 \sin(2\pi \cdot 22 \cdot x / 500) \end{aligned} \tag{19}$$

The analytical expression of the velocity wave allows us to evaluate the attenuation:

$$\frac{\sigma T}{\rho} = 5.8 \cdot 10^{-3} \tag{20}$$

From Eqs. (18) and (20), we can finally evaluate the new values for the mass fraction, Eq. (13) and the residence time, Eq. (15):

$$\begin{aligned} \gamma_{\lambda,acoustics} &= 0.268 \\ \tau^*_{acoustics} &= 1.730 \cdot 10^{-3} s \end{aligned} \tag{21}$$

The new values show that acoustics increases the volume fraction of about 7%, which may explain the enhancement of combustion observed in experiments [1]. The residence time is slightly reduced, but in this case such effect is too small to affect the reactor.

The effect of the changes in the parameters of the EDC was tested on an in-house finite-volume CFD code Spider.

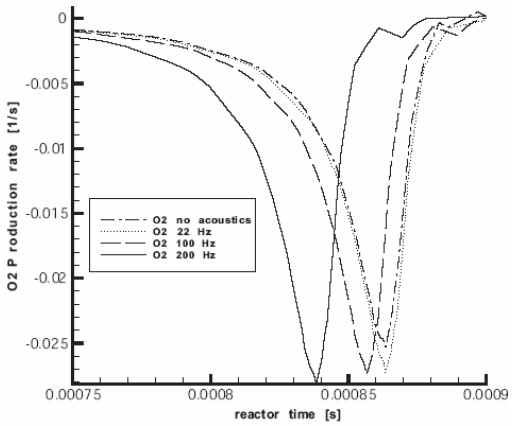

Figure 2: Consumption of O2 at different frequencies of acoustic forcing

Tests were performed with a stoichiometric mixture of CO_2, CH_4, and air, the production rates at different acoustic frequencies are reported in Fig.2.

Acoustics is affecting both the production of turbulent energy and its dissipation. In particular, while the residence time, Eq. (15), depends only on dissipation, the mass fraction, Eq. (13), is a function of both kinetic energy and dissipation. The evolution of each elemental reactor is ruled only by the residence time, while the volume fraction is a scale factor which does not affect the time behavior of the single reactor. For this reason, the differences in time observed for the different frequencies are due only to the residence time and thus to the dissipation. As a matter of fact the variations of the production rate across the frequency spectrum are quite small, and this can agrees with the fact that dissipation at the acoustic scale is almost negligible. Therefore, the trend of the O_2 consumption is related to the effect of the acoustic energy more than to its dissipation.

6 CONCLUSIONS

The EDC model for combustion can be re-interpreted as a measure of the distance between local and global equilibrium of a turbulent flow. Following this approach, we proposed a model that accounts for the mixing effects caused by acoustic waves. We used the viscous entropy production as a measure of the local distance from equilibrium, and the energy of the acoustic wave as a measure of the total equilibrium. The improved mixing was then evaluated using the turbulent energy cascade. The model seams to generate the correct response to acoustic forcing, and although further investigations must be performed, it may provide a feasible modeling for acoustic-flame interaction.

ABSTRACT

On the basis of minimum entropy generation principle, a new formulation of the boundary and initial-boundary value problems of heat conduction is proposed. Two independent approaches are presented-first is based on the first law of thermodynamics and second on Euler-Lagrange variational formalism. It is shown that minimization of entropy generation in steady and transient heat conduction processes is always possible by introducing additional heat sources. It means that irreversibility ratio according to the Gouy-Stodola theorem can be decreased. Numerical examples are presented.
Keywords: entropy generation minimization, heat conduction, boundary and initial-boundary value problems.

k – heat conduction coefficient [W/mK]
$\dot{q}$ - heat flux [W/m^2]
$\dot{q}_V$ - intensity of internal heat source [W/m^3]
s - specific entropy [kJ/kgK]
T – absolute temperature [K], also dimensionless
x_i – Cartesian coordinates (i=1,2,3)
Δ – change of the function
σ, σ_t – local and global intensity of entropy generation rate [W/m^3]
ρ - density of solid [kg/m^3]
τ – time [s]
∇ - operator nabla

INTRODUCTION

Differential equations describing heat conduction processes are usually derived from the first law of thermodynamics and in general take the forms

- transient processes

$$\mathrm{div}\left[k(T)\mathrm{grad}T(x_i,\tau)\right]+\dot{q}_V(T,x_i,\tau)=\rho c_p\frac{\partial T(x_i,\tau)}{\partial\tau} \quad (i=1,2,3) \tag{1}$$

- steady-state

$$\mathrm{div}\left[k(T)\mathrm{grad}T(x_i)\right]+\dot{q}_V(T,x_i)=0 \quad (i=1,2,3) \tag{2}$$

Eqs. (1) or (2) are usually derived by integral or differential ways but in both cases on the basis of enthalpy balances, [5,6].
Temperature scalar fields, transient or steady-state, result of the solution of Eqs. (1) or (2) with respect to the required initial and boundary conditions. Transient and steady state problems are known in literature as initial-boundary and boundary value problems, respectively. Different formulation to the classical boundary value problems can be obtained when differential heat conduction equation is derived from the minimum entropy generation principle [4]. According to the thermodynamics of irreversible processes [1],

entropy generation at steady state is at minimum. Introducing expression for local entropy generation

$$\sigma = \sigma(T, T_{x_i}) \equiv \frac{d_i s}{dt} = \frac{k(T)}{T^2}\left(\text{grad}T\right)^2 \qquad (3)$$

or

$$\sigma = \frac{k(T)}{T^2}\nabla T \circ \nabla T \qquad (4)$$

where T_{x_i} denotes gradient components $\partial T / \partial x_i$, the problem can be formulated in the following way: *find such a function* $T = T(x_i)$ *which satisfying required boundary conditions minimizes simultaneously integral*

$$\sigma_t = \int_{\Omega} \sigma(T, T_{x_i}) d\Omega \qquad i=1,2,3 \qquad (5)$$

over the whole domain Ω. Here σ_t represent global entropy production of the process.

MATHEMATICAL CONSIDERATIONS

Steady state processes

For 3D problem in Cartesian coordinates (*k=const*) the global entropy generation rate is

$$\sigma_t = \iiint_{\Omega} \sigma d\Omega = k \iiint_{\Omega} \frac{1}{T^2}\nabla T \circ \nabla T d\Omega \qquad (6)$$

$$T = T(x,y,z)$$

and its minimization leads to the Euler type heat conduction equation

$$\frac{\partial \sigma}{\partial T} - \frac{\partial}{\partial x}\left(\frac{\partial \sigma}{\partial T_x}\right) - \frac{\partial}{\partial y}\left(\frac{\partial \sigma}{\partial T_y}\right) - \frac{\partial}{\partial z}\left(\frac{\partial \sigma}{\partial T_z}\right) = 0$$

After calculation

$$\nabla^2 T - \tfrac{1}{T}\nabla T \circ \nabla T = 0 \qquad (7)$$

Second term describes intensity of the additional external heat source

$$\dot{\boldsymbol{q}}_V = -\tfrac{k}{T}\nabla T \circ \nabla T < 0 \qquad (8)$$

Eq.(7) can be written in the shorter form

$$\frac{\partial}{\partial x}\left(\frac{1}{T}\frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(\frac{1}{T}\frac{\partial T}{\partial y}\right) + \frac{\partial}{\partial z}\left(\frac{1}{T}\frac{\partial T}{\partial z}\right) = 0 \qquad (9)$$

or

$$\text{div}\left(\frac{\dot{\boldsymbol{q}}}{\boldsymbol{T}}\right) = 0 \qquad (10)$$

where $\dot{\boldsymbol{q}}$ is given by the Fourier's law ($\dot{\boldsymbol{q}} = -k\,\text{grad}\,T$), ($T = T(x,y,z)$).

Solutions to the 1D and 2D boundary problems with constant and temperature dependent thermal conductivity coefficient have been presented in details in the authors' paper [7] (also presented at ECOS'02). The problem of entropy generation at steady state heat conduction problem has been formulated in literature, for the first time, by Bejan [1,2].

In the following text, the initial-boundary and boundary value problems will be considered. An analysis of transient problem is a new extension of the method of entropy generation minimization principle.

Physical interpretation of Eq.(8) results from the Principle of Entropy Compensation [9] that:

"*The entropy of a system can be reduced only if it is made to interact with one or more auxiliary systems in a process which imparts at least a compensating amount of entropy*."

Graphical interpretations of classical heat conduction equation (Eq.(1) where *k=const*, $\dot{\boldsymbol{q}}_V = 0$ and $\partial T / \partial \tau = 0$) and Eq.(7) are presented in Fig.1.

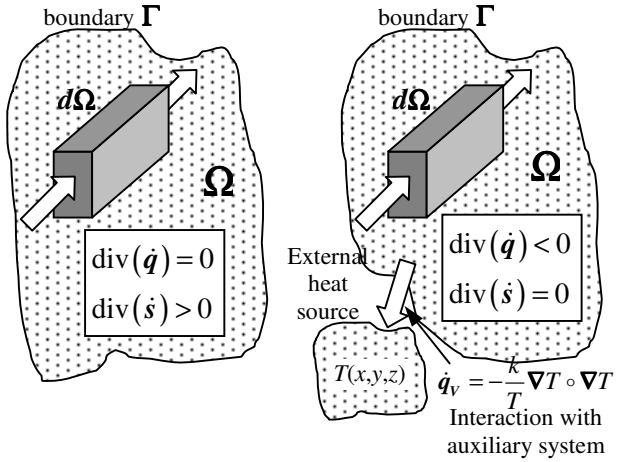

Figure 1: Graphical interpretation

Transient heat conduction - variational calculus approach

Global entropy generation rate is given by the integral

$$\sigma_t = \int_{\Omega}\int_{\tau} \frac{1}{T^2}\nabla T \circ \nabla T d\tau d\Omega \qquad (11)$$

$$T = T(x,y,z,\tau)$$

with the integral constraint

$$\Delta s = \int_{\Omega}\int_{\tau} \frac{\rho c_p}{T}\frac{\partial T}{\partial \tau} d\Omega\, d\tau = C \qquad (12)$$

where C is constant and its value is the same both for reversible and irreversible path (σ_t=0 or σ_t>0).
Variational calculus requires the function

$$K = \frac{k}{T^2}\nabla T \circ \nabla T + \lambda \frac{\rho c_p}{T}\frac{\partial T}{\partial \tau} \qquad (13)$$

to satisfy Euler-Lagrange equation

$$\frac{\partial K}{\partial T} - \frac{\partial}{\partial x}\left(\frac{\partial K}{\partial T_x}\right) - \frac{\partial}{\partial y}\left(\frac{\partial K}{\partial T_y}\right) - \frac{\partial}{\partial z}\left(\frac{\partial K}{\partial T_z}\right) = 0 \qquad (14)$$

where λ is a Lagrange multiplier [2]. After calculation we have

$$k\nabla^2 T - \tfrac{k}{T}\nabla T \circ \nabla T + \frac{\lambda}{2}\rho c_p \frac{\partial T}{\partial \tau} = 0 \qquad (15)$$

and from the fact, that Δs (see Eq.(12)) does not depend on the path of the process, λ must be equal to –2.
Thus, Eq.(15) becomes in the final form

$$a\nabla^2 T - \tfrac{a}{T}\nabla T \circ \nabla T = \tfrac{\partial T}{\partial \tau} \qquad (16)$$

$$T = T(x,y,z,\tau)$$

where additional external heat source is

$$\dot{q}_V = -\tfrac{a}{T}\nabla T \circ \nabla T \qquad (17)$$

Again, graphical interpretations are presented in Fig.2.

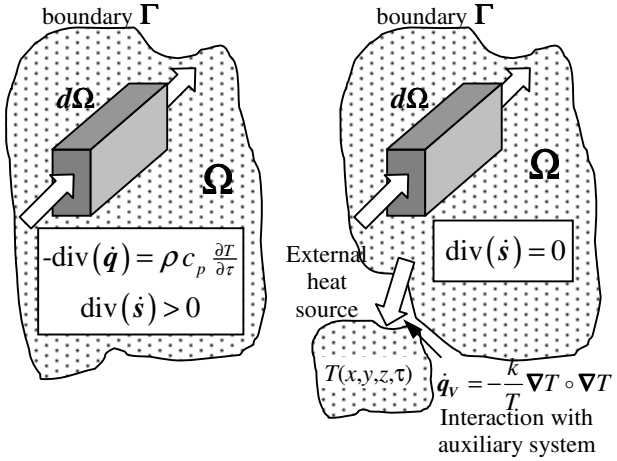

Figure 2: Graphical interpretation

NUMERICAL EXAMPLES

To illustrate differences between the solutions of classical and entropy generation minimization initial-boundary and boundary value problems two numerical examples will be considered.

Steady state problem.
Solve the boundary value problem

$$T = T(x,y) \quad (x,y) \in \Omega$$

$$\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} = 0 \qquad x \in (0,1) \quad y \in (0,1) \qquad (18)$$

$$T \in (1,e)$$

in the square (Fig.3)

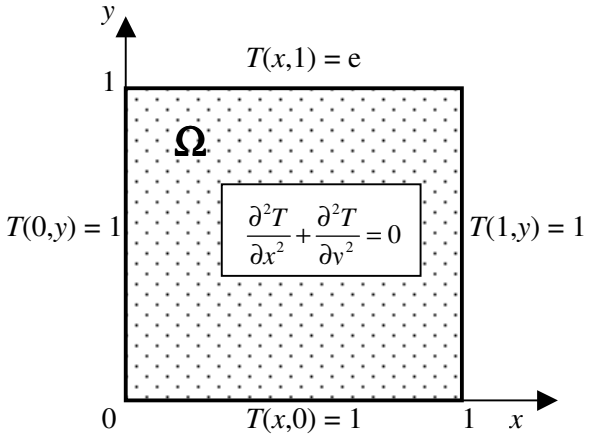

Figure 3: Classical boundary value problem.

with boundary conditions

$$T(0,y) = 1 \quad T(1,y) = 1$$
$$T(x,0) = 1 \quad T(x,1) = e \qquad (19)$$

Introducing from definition a new dependent variable

$$T^*(x,y) = T(x,y) - 1$$

the boundary value problem becomes (Fig.4)

$$\frac{\partial^2 T^*}{\partial x^2} + \frac{\partial^2 T^*}{\partial y^2} = 0 \qquad (20)$$

$$T^*(0,y) = 0 \quad T^*(1,y) = 0$$
$$T^*(x,0) = 0 \quad T^*(x,1) = e - 1 \qquad (21)$$

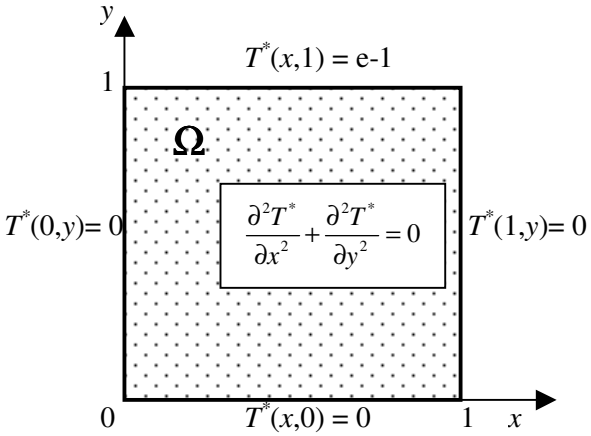

Figure 4: Simplified boundary value problem.

Similar problem formulated on the principle of entropy generation minimization is (Fig. 5)

$$\frac{\partial^2 T_1}{\partial x^2}+\frac{\partial^2 T_1}{\partial y^2}-\frac{1}{T_1}\left[\left(\frac{\partial T_1}{\partial x}\right)^2+\left(\frac{\partial T_1}{\partial y}\right)^2\right]=0 \qquad (22)$$

$$T_1 = T_1(x, y)$$

with the same boundary conditions (see Fig.5).

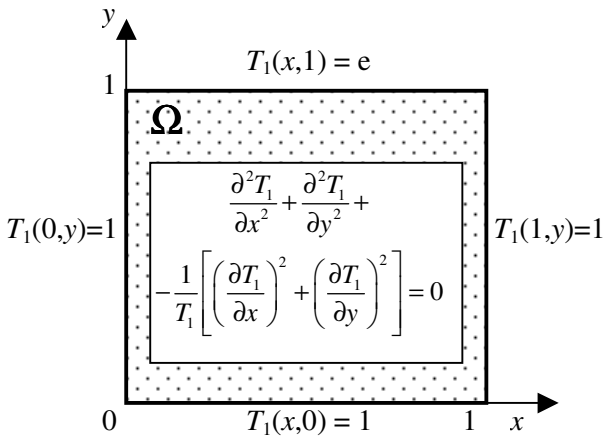

Figure 5: Modified boundary value problem.

Introducing from definition a new variable

$$Y = \ln T_1 \qquad Y = Y(x, y)$$

boundary value problem (22) and (19) becomes in the form (Fig.6)

$$\frac{\partial^2 Y}{\partial x^2}+\frac{\partial^2 Y}{\partial y^2}=0 \qquad (23)$$

$$Y(0, y)=0 \quad Y(1, y)=0$$
$$Y(x,0)=0 \quad Y(x,1)=e-1 \qquad (24)$$

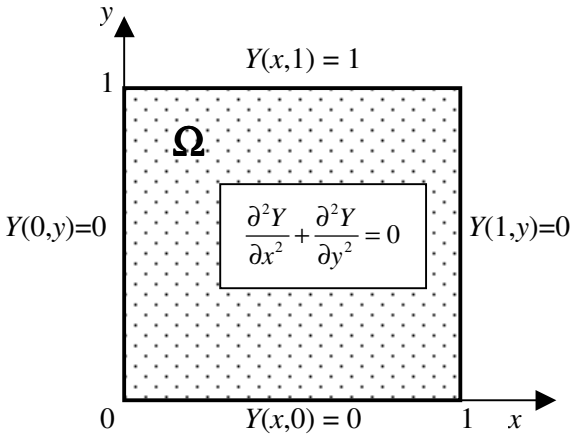

Figure 6: Modified boundary value problem.

Analytical solutions to the above two boundary value problems are known and have the form [5]

$$T^*(x, y)=\frac{4(e-1)}{\pi}\sum_{i=1,3,5...}^{\infty}\frac{1}{n}\frac{\sinh(n\pi y)}{\sinh(n\pi)}\sin(n\pi x) \qquad (25)$$

and

$$Y(x, y)=\frac{4}{\pi}\sum_{i=1,3,5...}^{\infty}\frac{1}{n}\frac{\sinh(n\pi y)}{\sinh(n\pi)}\sin(n\pi x) \qquad (26)$$

For the points of the same x,y coordinates

$$\frac{T(x, y)-1}{Y(x, y)}=e-1$$

and

$$\frac{T(x, y)-1}{\ln T_1(x, y)}=e-1$$

Thus

$$\delta T(x, y)=T_1(x, y)-T(x, y)=$$
$$=\exp\left(\frac{T(x, y)-1}{e-1}\right)-T(x, y)<0 \qquad (27)$$

Physical explanation that δT is always negative is simple as in the system an additional internal heat source exists $\dot{q}_V=-a/T\left(\partial T/\partial x\right)^2$, (see Eq.(17)).

Differences between solutions for $T \in (0,e)$ are shown in the Table 1.

T(x,y)	δT	%
1.0	0	0
1.2	-0.077	6.45
1.4	-0.140	10.00
1.6	-0.185	11.60
1.8	-0.212	11.80
2.0	-0.218	10.90
2.2	-0.200	9.05
2.4	-0.154	6.41
e	0	0

Table 1: Solution differences.

Transient problem

Solve the initial – boundary value problem of linear flow of heat in the solid bounded by two parallel planes.
Classical formulation:

$$a\frac{\partial^2 T}{\partial x^2}=\frac{\partial T}{\partial \tau} \quad T=T(x,\tau) \qquad (28)$$
$$x\in(0,1) \quad T\in(1,e)$$

$$T(0,\tau)=1$$
$$T(1,\tau)=1 \qquad (29)$$
$$T(x,0)=\mathrm{e}$$

Introducing

$$T^*(x,\tau)=T(x,\tau)-1$$

the problem is

$$a\frac{\partial^2 T^*}{\partial x^2}=\frac{\partial T^*}{\partial \tau} \qquad (30)$$

and

$$T^*(0,\tau)=0$$
$$T^*(1,\tau)=0 \qquad (31)$$
$$T^*(x,0)=\mathrm{e}-1$$

Entropy generation minimization formulation

$$a\frac{\partial^2 T}{\partial x^2}-\frac{a}{T}\left(\frac{\partial T}{\partial x}\right)^2=\frac{\partial T}{\partial \tau} \qquad (32)$$

$T=T(x,\tau) \qquad x\in(0,1) \qquad T\in(1,\mathrm{e})$

and using new variable

$$Y(x,\tau)=\ln T(x,\tau)$$

Eq. (32) takes the form

$$a\frac{\partial^2 Y}{\partial x^2}=\frac{\partial Y}{\partial \tau} \qquad (33)$$

with boundary conditions

$$Y(0,\tau)=0$$
$$Y(1,\tau)=0 \qquad (34)$$
$$Y(x,0)=1$$

The solution of (30) and (31) is [6]

$$T^*(x,\tau)=\frac{4}{\pi}(e-1)\cdot \cdot\sum_{n=0}^{\infty}\frac{1}{2n+1}\exp\left[-a(2n+1)^2\pi^2\tau\right]\sin(2n+1)\pi x \qquad (35)$$

and of (33) and (34)

$$Y(x,\tau)=\frac{4}{\pi}\cdot \cdot\sum_{n=1}^{\infty}\frac{1}{2n+1}\exp\left[-a(2n+1)^2\pi^2\tau\right]\sin(2n+1)\pi x$$

The difference of the above two solutions is also given by Eq. (27)

$$\delta T(x,\tau)=\exp\left(\frac{T(x,\tau)-1}{e-1}\right)-T(x,\tau)<0$$

and numerical values are listed in Table 1. As in the case of steady state conduction, the values of $\delta T(x,\tau)$ are negative resulting from the additional external heat source

$$\dot{q}_V^*=-\frac{a}{T}\nabla T\circ\nabla T \quad \text{(see Eq.(17))}$$

CONCLUSIONS

Minimization of entropy generation both in study state and transient heat conduction processes by introducing additional external heat sources. The most important conclusion is that the entropy generation principle can also be used in the case of transient problems. Many practical applications decreasing irreversibility ratio are possible, as for example: thermal insulation systems, storage systems, power generation (maximizing the power output), optimal combustion chamber temperature, solar-thermal power generation and refrigeration systems.

ABSTRACT

The 'negentropy' proposed first by Schroedinger is re-examined, and its conceptual and mathematical definition are proposed; which is shown to integrate Schroedinger's intention of its introduction, and the subsequent diverse notions in literature. This definition of negentropy is corroborated by its unique ability to state direct thermodynamic principles for order existence: '*Negentropy Principle*', and order evolution: '*Principle of Maximum Negentropy Production*'. These principles are the respective counterparts of the '*Entropy Principle*', and the '*Law of Maximum Entropy Production*'. The *Principle of Maximum Negentropy Production* combines the basic philosophies of the evolution theories postulated by *Darwin* and *de Vries*. The prime advantage of these two additional thermodynamic principles, is the resulting unified explanation of order creation, existence, evolution, and destruction; using thermodynamic principles only.

INTRODUCTION

The laws that govern an organization are derived from the two Laws of Thermodynamics. The First Law states that the total *quantity* of energy in an isolated system remains constant. The 2nd *Law of Thermodynamics* is also called the *Entropy Principle* (EP), and it came in to existence after the First Law was established. The 'entropy' refers to the diminished gradients of field variables, Grad(*F*), in a dissipation process, and is

[†]Corresponding author: Tel. ++91 (0)22 2576 7122, Fax. ++91 (0)22 2572 2602
E-mail: spm@aero.iitb.ac.in

the classical signpost of natural change [1]. The EP is a re-statement of a unifying law of nature; which implies that on a global basis, gradients of field variables are always diminished. Diminishing Grad(F) leads to dispersion, i.e. entropy increase. Thus, reducing Grad(F) and entropy increase are concurrent and synonymous.

The '*negentropy*' first came from Schroedinger [2], who stated: 'what an ordered sub-system feeds upon is negentropy; thereby succeeding in freezing itself from the entropy it cannot help producing'. However, in a footnote later, Schroedinger explains that neg*entropy* is free *energy*. Subsequently, others took *neg*entropy as entropy with a *negative sign* [3,4]; as they felt it erroneous to refer to neg*entropy* as free *energy*. However, *entropy with a negative sign* does not capture the intention of Schroedinger [2], who introduced it to identify the ability of the living system to increase organization. Later, Ho [5] explains that neg*entropy* is mobilisable stored *energy* in an organized system. However, views based on neg*entropy* as a form of *energy* are inappropriate to its nomenclature; since, stored *energy* should then be referred as 'neg' / 'pos' *energy*. Further, free / stored energy need not necessarily be utilised for increasing organisation; and hence, cannot always be associated with negentropy.

Earlier [6], order was explained indirectly (using the concept of '*entropy*' only), by identifying the effect of order creation and its' existence, on disorder increase. This explanation was demonstrated by a mathematical model.

Objectives, scope, and formulation

There is a lack of consensus on what should be the conceptual and mathematical definition of *negentropy*. The objective here is to propose its definition that unifies the existing assorted notions, and the concepts of order creation / origin, existence, evolution, and destruction; exclusively by thermodynamic principles. Since, thermodynamic principles are universally valid, the principles for order creation, existence, evolution, and destruction, are valid for all scales; ranging from biology to cosmology.

The two legitimate assumptions made, regarding the isolated system (ref. Fig. 1) that may comprise of ordered sub-systems, are elaborated below; thereby defining the scope of this investigation. These assumptions are the pre-requisites for ordered sub-systems to be created,

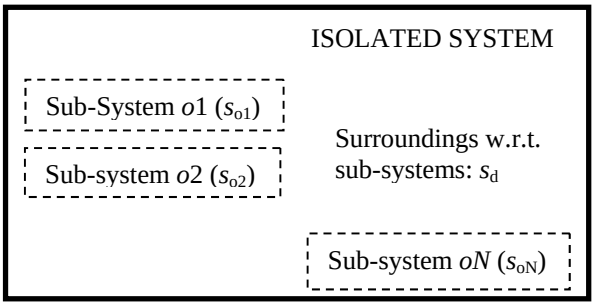

Figure 1: Schematic illustration of sustainable order in disorder, in an isolated system

and to co-exist with disorder [7].

Assumption *i*): $\ddot{S}_{IS} > 0$, (1)

as illustrated in Fig. 2. This assumption implies that the isolated system is sufficiently far from equilibrium. It is demonstrated that $\delta^2 S_{IS}$ is the Lyapounov function, especially when large deviations from equilibrium are considered [7]. As the isolated system approaches equilibrium, the sign of $\ddot{S}_{IS}$ changes at a particular Inflection Point (IP in Fig. 2); and thereafter,

$$\ddot{S}_{IS} < 0. \quad (2)$$

To the left (and bottom quadrant) of IP, the non-equilibrium system follows the *Law of Maximum Entropy Production* (LMEP), which states [8]: "the system will select the path or assemblage of paths out of available paths that minimises the potential or maximizes the entropy at the fastest rate for given constraints". This statement is a reflection of nature's law of preference for path of least resistance, for minimizing Grad(F). For given Grad(F), minimising resistance leads to maximising J; i.e. $\dot{S}_{IS} = J \cdot \text{Grad}(F)$ is maximised.

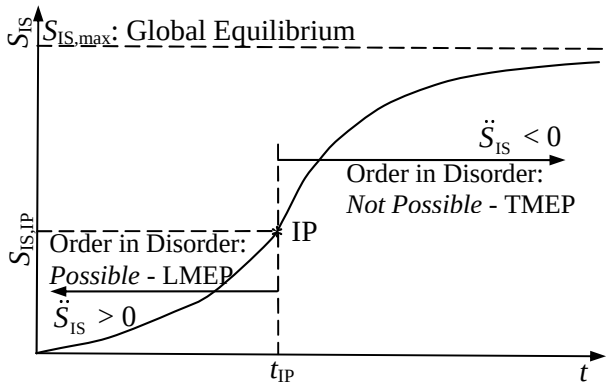

Figure 2: Schematic illustration of two distinct regimes, on S_{IS} vs. t plot

To the right (and top quadrant) of IP, S_{IS} increase gradually approaches the asymptote (global equilibrium). In this regime, the system characteristics are determined by its inertia; which prevents the system from reaching global equilibrium ($\dot{S}_{IS} = 0$). Hence, the system settles down to the tendency based on the Theorem of Minimum Entropy Production (TMEP), which states that [9] 'the variation of $\dot{S}_{IS}$ is negative or zero in non-equilibrium stationary states, in the vicinity of equilibrium (after crossing IP)'. Since, entropy production is minimised in this regime, dynamic order cannot be created; since, the objective of creation and existence of dynamic order is entropy production at a rate faster than had they not existed (ref. Statement 9 in [6]). Thus, creation and existence of dynamic order (in disorder) satisfy the inequality given by Eq. (1). The only possible ordered structures in the regime determined by the inequality in Eq. (2), are 'equilibrium-static-ordered-structures', e.g. crystals; which are characterised by the minimum of the Helmholtz free energy. Thus, dynamic ordered structures are feasible only to the left of IP, as indicated in Fig. 2. A practical illustration is the creation and existence of dynamic order only during the acceleration-phase of universe expansion [10].

Assumption *ii*): *The isolated system is dynamically unstable and chaotic*. This pre-requisite is a subset of *i*); the additional condition imposed by this assumption, is the requirement for large number of interactions within the isolated system. Stable existence of order in disorder necessitates stable exchange of mass and energy between ordered sub-systems and their surroundings (disorder), which is stabilised as per the Law of Large Numbers [7].

Introduction to 'negentropy'

The '*negentropy*' once appropriately defined, must encompass the following perspectives, with which it is associated:

i) It should have *negative* sign, but its implication/s should extend beyond *entropy with a negative sign*.
ii) It should have units of *entropy* or specific *entropy*.
iii) It should account for the existence of ordered sub-systems like living organisms and the solar system, by encapsulating Schroedinger's intentions [2].
iv) Since, S can never be negative, as per the 3rd *Law of Thermodynamics* {ref. e.g. [11]}, negentropy is a *relative* measure of deviation from equilibrium of ordered sub-system/s with respect to their surroundings.

In [6], the term, $s_d - s_o$, was identified as the criterion for sustainability of order in disorder. It is now proposed: $\boldsymbol{s_n = s_o - s_d}$. (3)

The negentropy is defined as "*the specific entropy deficit of ordered sub-system with respect to its surroundings*". This deficit is created due to creation of order, and exists for ordered sub-systems, *o*1-*oN* (ref. Fig. 1) so long as these ordered sub-systems exist; and reduces to zero when they completely merge with disorder. Since, s_n is a difference of two state functions, s_n is also a state function. Since, $s_o << s_d$, (3.1) s_n is always negative. This proposal for negentropy has the following direct implications:

a. Negentropy is based on *specific entropy*.
b. Negentropy is a *relative* concept: the term, $-s_n = s_d - s_o$, is specific entropy of surrounding disorder relative to ordered sub-system/s, and is the absolute value of negentropy. *Negentropy*, s_n, is a *relative* measure (contrast) of localised ordering / organization, with respect to surroundings (disorder).
c. For ordered sub-systems, *neg*entropy is *negative*: negentropy is zero when order is in equilibrium with disorder (order is destroyed).

The entropy of the isolated system comprising of order existing within disorder (ref. Fig. 1) is given as, $S_{IS} = m_o \cdot s_o + m_d \cdot s_d$. (4)

From Eq. (3), $S_{IS} = m_d \cdot (-s_n) + m_{IS} \cdot s_o$; where, $m_{IS} = m_o + m_d$. Hence, $s_{IS} = (m_d/m_{IS}) \cdot (-s_n) + s_o$. (4.1)

NEGENTROPY BASED PRINCIPLES

The s_n [Eq. (3)] has immediate implication in its ability to state thermodynamic principles for order existence and evolution, complementary to the existing, EP and LMEP; by referring to its negentropy. The increase / decrease of negentropy discussed hereafter are its modulus.

Negentropy Principle (NEP)

"*For order to exist* (*or when order exists*), *negentropy must increase* ($\dot{s}_n > 0$)."

Conversely, "when order ceases to exist, its negentropy begins to decrease ($\dot{s}_n < 0$), until $s_n = 0$". The s_{IS} [Eq. (4.1)] always increases, since S_{IS} always increases (EP) and m_{IS} is fixed

(*Conservation of Mass*). Further, $(m_d/m_{IS}) \approx 1$; since, $m_o << m_d$; {ref. [6]}, and Eq. (3.1). From Eq. (4.1), increasing s_{IS} implies the following two exclusive possibilities:

a. The $-s_n$ must increase (NEP), and order exists; since, s_o reduces, or remains the same, or may increase at a rate that is small enough for order to continue existing in disorder.
b. If $-s_n$ reduces or remains the same, the increase of s_o is faster than or the same rate as s_{IS} [from Eq. (4.1)], and order is converted in to disorder. Thus, compliance with NEP is a special case of EP.

For order to exist, $s_o \leq s_{o,thr}$ [6], where $s_{o,thr}$ is the threshold value of specific entropy above which, order begins to merge with disorder. This is the same as, $\text{Grad}(F)|_o \leq \text{Grad}(F)|_{o,thr}$; (5)
i.e. gradients of field variables across ordered sub-systems are lower than a threshold, but exist. Consequently, to satisfy the 2nd Law, the gradients of these field variables in the surrounding disorder are lower than the gradients of field variables in total (only) disorder (when localised order does not exist, represented by superscript '*'); i.e.

$$\text{Grad}(F)|_d < [\text{Grad}(F)|_d]^*. \quad (5.1)$$

Equation (5.1) results from the need to compensate for existing and maintained gradients of field variables across ordered sub-systems, given by Eq. (5); which reduce entropy production by reducing '*J*'. This deduction is an outcome of the inequality,

$$S_{IS} > S^*_{IS}; \quad (5.2)$$

which is Statement 2 in ref. [6]; where, $S^*_{IS} = m_{IS} \cdot s^*_{IS}$. Only if the inequality given by Eq. (5.2) is satisfied, the system may select the bifurcation branch that results in 'order in disorder'. From Eqs. (4) and (5.2),

$$(m_d/m_{IS}) \cdot (-s_n) + s_o > s^*_{IS}. \quad (5.3)$$

Since, $m_d < m_{IS}$, Eq. (5.3) also leads to, $(-s_n) + s_o > s^*_{IS}$. The s_n increase, increases the ensemble average of gradient of field variables, $\text{Grad}(F)|_o$, across the boundary between ordered structures and their surroundings [6].

Principle of Maximum Negentropy Production (PMNEP)

"*The isolated system comprising of order co-existing in disorder* '*will select the path or assemblage of paths out of available paths*' *that maximizes the negentropy at the fastest rate for given constraints*".

This statement is the counterpart of LMEP. Since, S_{IS} increases at the fastest rate for given constraints, s_{IS} also increases at the fastest rate for the same given constraints. From Eq. (4.1), there are again two possible ways of realising LMEP:

a. The $(-s_n)$ must increase at the fastest rate for given constraints (PMNEP); then s_o can remain the same, or reduce, or increase at a relatively slow rate. Thus, when order exists, LMEP reduces to PMNEP.
b. If $(-s_n)$ reduces or remains the same, s_o increases at the fastest rate given constraints [from Eq. (4.1)], and order is destroyed into disorder. Thus, compliance with PMNEP is a special case of the LMEP. From Eq. (4),

$$\dot{S}_{IS} = m_o \cdot \dot{s}_o + m_d \cdot \dot{s}_d; \quad (6)$$

assuming that m_o and m_d are constant. This assumption is discussed in [6]; as a case when the number / mass of ordered sub-systems destroyed, is the same as the number / mass of ordered sub-systems created. Further,

$$\dot{S}^*_{IS} = m_{IS} \cdot \dot{s}^*_{IS}. \quad (7)$$

Since, $\dot{S}_{IS} > \dot{S}^*_{IS}$ (from LMEP), from Eqs. (6) and (7), $(m_o/m_d) \cdot \dot{s}_o + \dot{s}_d > (m_{IS}/m_d) \cdot \dot{s}^*_{IS}$. (7.1)

Since, $m_o << m_d$, and consequently, $m_{IS} \approx m_d$ [6],

$$\dot{s}_d > \dot{s}^*_{IS}; \quad (8)$$

which states that specific entropy of surrounding disorder that has localised ordered sub-systems, increases at a faster rate than the alternative bifurcation branch that comprises of only disorder. Differentiating Eq. (3), and from Eq. (8), $-\dot{s}_n > \dot{s}^*_{IS} - \dot{s}_o$; i.e. rate of negentropy increase, exceeds the difference in rates of specific entropy increase of isolated system in state of total disorder, and specific entropy increase of order.

EVOLUTION AND THERMODYNAMICS

Several features of ordered organisms show an evolutionary trend, and many *rationales* are proposed. Schneider & Kay [12] state that ecosystems develop in ways, which increase their ability to degrade the incoming solar energy. They also state that '*Thermodynamics*' *can* make it possible for the study of ecosystems to be developed from a descriptive to predictive

science, founded on basic principle/s of physics. Toussaint & Schneider [13] state that as bio-systems develop, they follow certain trends: e.g. increase their total dissipation, develop more complex structures with more energy flow, increase their cycling activity, develop greater diversity, and generate more hierarchical levels. McShea [14] reviewed 8 candidate features that constitute these trends: entropy, energy intensiveness, evolutionary versatility, developmental depth, structural depth, adaptedness, size, and complexity. Later, McShea [15] states that "evolution shows a trend in hierarchical organization, revealed by the successive emergence of organisms with greater levels of *nestedness*, and greater development or *individuation* of the highest level."

There has been no basic guiding principle of physics dedicated to the explanation of existence of order, and in particular for evolution of ordered structures in to superior forms. By evolution of ordered structures to superior forms, the following two features, based on Schroedinger's intention of introduction of negentropy, are combined [2]: (*1*) superior ability to avoid spontaneously created gradients of field variables, that exceed the threshold value up to which order can withstand, $\text{Grad}(F)|_{o} \leq \text{Grad}(F)|_{o,thr}$ {discussed in [6]}, thereby prolonging the existence of ordered structures; and (*2*) ability to generate negentropy at increasing rates. So far, attempts to explain order evolution have been limited only to postulates / hypotheses / conjectures. One such popular theory is by Darwin [16], which begins with a postulate that life on Earth arose from non-living matter by an *unknown* process, and then proceeded to evolve into more complex life forms; by random mutation and natural selection process. This postulate is widely known as *the survival of the fittest*. Demetrius [17,18] showed that the use of evolutionary entropy (uncertainty in the age of the mother of a randomly chosen newborn), rather than the Malthusian parameter (parameter in the exponential equation of population growth), represents a non-equilibrium analogue of EP; and constitutes the operationally valid measure of Darwinian fitness (which is the relative probability of survival and reproduction for a genotype). The other exclusive theory is by *de Vries*: the *Mutation Theory*, which believes that mutations alone can bring about the abrupt changes in ordered structures; thereby divorcing evolution from *natural selection*. The role of *mutations* was later explained by experiments with mutability [19]. It is stated by a strong defender of Darwinism [20]: 'A biological explanation should invoke no factor other than the *laws of physical science*, natural selection, and the contingencies of history.'

Role of PMNEP in order evolution

The review on order evolution indicates divergence of view-points, primarily because they are not based on firm foundations (*Law/s of Physics*). *It is proposed here that PMNEP is the thermodynamic principle governing evolution of ordered structures in to superior forms*, which will now be elaborately justified. In PMNEP, '*The selection of path or assemblage of paths out of available paths, under given constraints*' (these constraints are determined jointly by ordered structures and their surrounding disorder), is the evolution of ordered structures, in to superior forms. Alternatively, ordered structures continue to evolve in to superior forms, as they select different path/s or assemblages of paths (under given constraints); with the objective of maximising *negentropy*. The evolution refers to the increasing ability of increasingly superior ordered structures, to simultaneously manage high negentropy production and yet avoid the resulting high values of spontaneously created '$\text{Grad}(F)|_{o}$' that can lead to their destruction.

Noticeable evolutionary trends are observed [21] over large geological time, as certain constraints are removed and / or minimal thresholds of parameters are reached [22]; which enable ordered structures to take *significantly*, and hence, noticeably different paths or their assemblages that enables negentropy increase at the fastest rate (under varying constraints). The PMNEP also integrates the basic notions in the theories by *Darwin* [16], and *de Vries* [19]. For instance, the notion of *survival of fittest* in *Darwin's Theory of Evolution* is explained by PMNEP; since, fitter ordered structures generate higher negentropy and still survive (for longer duration). The notion of mutation in the theory by *de Vries* refers to 'some constraints being removed / revised' in PMNEP, which enables selection of entirely different path or assemblages of paths that dramatically increase the rate of negentropy production; thereby leading to noticeable evolution.

ORDER AND NEGENTROPY PRINCIPLES

The governing principles for order creation, existence, and total destruction {formulated in [6]}, are now re-discussed; but using NEP and PMNEP, to the extent possible.

Statements of Directives

Statement 1 (*Creation of order*)

"*As the localised disequilibrium in an isolated system increases and exceeds a particular threshold, sustainable order is created within disorder, whenever there is a chance*."

The role of localised disequilibrium in this statement is explained by LMEP. Since, ordered flow produces higher entropy (and faster rate of approach to equilibrium) than only disorder, ordered structures are created when localised disequilibrium exceeds a certain threshold. For low disequilibrium, the inequality given by Eq. (1) is not satisfied, and disorder alone diminishes the low gradient/s of field variable/s. In particular, the system inertia prohibits formation of ordered structures. Hence, net excess entropy due to localised order (relative to state of total disorder) cannot be generated. Schneider & Kay [12] state the reformulated EP to extend it to non-equilibrium regions: 'As systems are moved away from equilibrium, they take advantage of all available means {*including localised ordering* [8]}, to resist externally applied gradients. Later, Toussaint & Schneider [13] re-state that in systems moved away from equilibrium, the system organizes in a way that reduces the effect of the applied 'Grad(F)'. When ordered structures are created and sustained, negentropy is initialised and begins to increase. The event of creation of order is the bifurcation point when *negentropy* is introduced, EP reduces to NEP, and LMEP reduces to PMNEP.

Statement 2 (*Creation of order*)

"*In an isolated system, created order within disorder is a state of higher net disorder than the preceding state of total disorder*."

The higher net disorder is an outcome of negentropy increase, due to creation (and sustained existence) of ordered sub-systems [6]. Alternatively, from Eq. (5.1), gradients of field variables are more diminished than in the state of total disorder. It was suggested by Schroedinger [2] that sustainable orders like flames are permitted to exist away from equilibrium, because they feed on negentropy in their environments; which was later popularised by Prigogine [7] by the term 'dissipative structures'. Schroedinger's [2] important point was that as long as sustainable orders produce entropy at a sufficient rate to compensate for their own internal ordering, i.e. negentropy increase, then the balance equation based on EP is not violated.

Statement 3 (*Existence of order*)

"*In an isolated system, order must coexist with disorder, but disorder can exist alone as total disorder*; *or total order does not exist*."

When order co-exists with disorder, negentropy exists; which is a relative concept: between order and disorder. However, EP holds regardless of whether negentropy exists or not.

Statement 4 (*Existence of order*)

"*In an isolated system, order and / or disorder must create more order and disorder for sustenance of created order*; *else, created order is converted in to disorder*."

When order exists, negentropy increases (EP); i.e. localised ordering / organization relative to surroundings (disorder) increases. Hence, more order is necessarily created. The s_o level is maintained locally by continuously draining out entropy to the surroundings (disorder), which is the sustenance of the fleeting disequilibrium [23]. Swenson [24] presented an ecological physical view which showed that - 'purposive, creative behaviour is a consequence of *a natural law* as per which, order is produced such that order acts back upon order to produce more order; i.e. for increasing negentropy.

Statement 5 (*Existence of order*)

"*In an isolated system, order can create more order only through disorder*."

Creation of more order results in negentropy increase by increasing s_d; since, order and its surroundings interact. Negentropy increase is due to intake of mass and energy from surroundings (processed to increase organisation), and by draining out 'excess entropy' to the surroundings. Thus, order is an open system, which interacts with its surroundings (disorder), for its existence.

Statement 6 (*Total destruction of order*)

"*As the disorder of an isolated system containing order increases and exceeds another higher threshold, all order is destroyed in to total disorder again, if there is a chance*."

The s_d increase due to creation and existence of order, is elaborated in [6]. The s_d also increases due to several other irreversible processes (not related to the operations of order in

disorder). The selection of path or assemblages of available paths to withstand increasing Grad(F)$|_o$ [$\leq$ Grad(F)$|_{o,thr}$] due to s_n increase, enables simultaneous existence of order, and compliance with NEP and PMNEP; which is order existence and evolution. Evolution enables superior forms of ordered structures to avoid with increasing probability, the spontaneously created high values of Grad(F)$|_o$ by surroundings, effectively by increasing Grad(F)$|_{o,thr}$. Over increasing geological times, the possibility of a mismatch between evolution and Grad(F)$|_o$ increases; in which case, the probabilistically created high Grad(F)$|_o$ [>> Grad(F)$|_{o,thr}$], destroy all order in to total disorder. Especially due to increasing s_n, i.e. due to increasing s_d, the probability that such an event occurs increases; since, the ensemble averaged Grad(F)$|_o$ increases with s_n. The event of total destruction of order is the bifurcation point, when *negentropy* vanishes together with NEP and PMNEP; leaving only EP and LMEP.

Statement 7 (*Creation, existence, and total destruction of order*)

"*In an isolated system, creation, existence and total destruction of order within disorder is a sequential train with increasing entropy thresholds for order creation and total destruction.*"

The sequential train with repeating compartments is illustrated in Fig. 3. The '$S = 0^+$' is the beginning, and the destination of this train is *equilibrium*. This train begins and ends with *Total Disorder*, and the ending is before the point IP in Fig. 2. The sequence of repetition of NEP and PMNEP, when order co-exists with disorder, is shown.

Statement 8 (*Existence of order*)

"*In an isolated system, disorder exists forever*; *but existence of order is fleeting*."

This statement spells the integral broken symmetry, between the principles based on entropy and *neg*entropy; since, negentropy exists only when order co-exists with disorder. In the sequential train in Fig. 3, principles based on

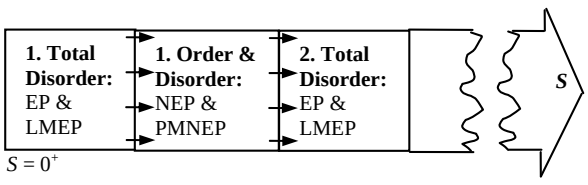

Figure 3: Sequential train illustrating repetitive sequence of validity of thermodynamic principles

entropy are valid in all compartments; but principles based on negentropy hold only in alternate compartments.

Statement 9 (*Creation, existence, & total destruction of order*)

"*In an isolated system, the role of creation and fleeting existence of order, is to increase the system entropy at a faster rate than had order not existed*."

This statement consolidates investigations on the role of order in disorder. During creation & fleeting existence of order, negentropy increases; which increases the system entropy faster (than the case without negentropy). Alternatively, the approach of the destination (vicinity of equilibrium) of the sequential train illustrated in Fig. 3, is hastened by order.

CONCLUSIONS

Schroedinger's negentropy is defined, to unify the intentions behind its introduction; and the diverse interpretations of researchers. The proposed definition enables formulation of two additional thermodynamic principles: *Negentropy Principle*, and *Principle of Maximum Negentropy Production*. The later is the basis for evolution of ordered structures in to superior forms, and combines the ideas behind the evolution theories postulated by *Darwin* and *de Vries*. The resulting unification of order creation, existence, evolution, and total destruction, by thermodynamic principles, is summarised by the block diagram in Fig. 4. The hierarchy of the 4 principles is based

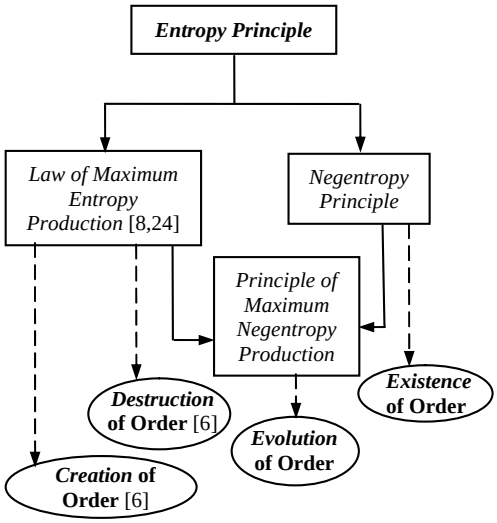

Figure 4: Unification of order creation, existence, evolution, and destruction; by thermodynamic principles

on their validity. The *Entropy Principle* continues as the ruling paradigm [25], since it is valid in all other principles below it. The *Law of Maximum Entropy Production* and *Negentropy Principle*, hold in *Principle of Maximum Negentropy Production*.

ABSTRACT

A local stability analysis of an endoreversible Curzon-Ahlborn-Novikov (CAN) engine, with Dulong-Petit heat transfer law, is presented. In this study, we consider two different optimum performance regimes. A CAN engine consists of a Carnot engine exchanging heat with external heat reservoirs T_1 and T_2 ($T_1 > T_2$), through a couple of thermal conductors both having the same conductance (α). In addition, the working fluid has the same heat capacity (C) in the two isothermal branches of the cycle. From the local stability analysis we conclude that the CAN engine is stable for every value of α, C, and $\tau \in [0.3,0.6]$ ($\tau = T_2 / T_1$). Moreover, our results also emphasize the importance of the heat transfer law on the engine stabilty. The results obtained with the Dulong-Petit heat transfer law are quite different from those obtained with Newton's law when $\tau \to 0$ and $\tau \to 1$.

NOMENCLATURE

E	Ecological function (W)
P	Power output(W)
T_1	Hot reservoir temperature(K)
T_2	Cold reservoir temperature(K)
η	Thermal efficiency
C	Heat Capacity (JK^{-1})
τ	Ratio of reservoir's temperatures
J_1	Heat flux from hot reservoir(W)
J_2	Heat flux towards cold reservoir(W)
α	Thermal conductance ($W/m^2K^{5/4}$)
T_0	Temperature(K)
t	Time(s)
λ_1, λ_2	Relaxation times(s)

INTRODUCTION

It is known that the limits imposed by Clasical Equilibrium Thermodynamics (CET) correspond to reversible processes. This represents a limitation for CET and leads to process-variable values too remote from the values reported in the literature. This limitation has been overcome, in great part, by the so called Finite Time Thermodynamics (FTT). Most of the studies in FTT have been focused on the steady-state energetic properties [1-7], which are important from a good-design viewpoint. Conversely, only a few of these studies had taken into consideration the system's dynamic properties: like the system respons to noisy perturbations or the steady-state stability. Most of the papers in this field consider that the heat flow between the working substance

[1] All correspondance should be addressed to R. T. Páez Hernández
email: phrt@correo.azc.uam.mx

and its surroundings is governed by Newton's cooling law [4-10]. However, Dulon-Petit heat transfer law is more realistic because it takes into account both conduction and radiation [11]. This cooling law is given by:

$$\frac{dQ}{dt} = \alpha\left(T_0 - T\right)^k, \qquad (1)$$

where dQ/dt is the heat exchange rate, α is the conductors' thermal conductance, T_0 is the environmental temperature, T is the body temperature, and k is an exponent in the range from 1.1 to 1.6 [11]. In 1993, Angulo-Brown and Páez-Hernández showed that a Dulong-Petit CAN engine renders more realistic efficiency values than those of a Newtonian model. They considered both the maximum-power and the ecological [12] regimes, and compared with values reported for different steam plants. The present work is structured as follows. In section II we analize the steady-state thermodynamic properties of a CAN endoreversible engine performing in a maximum power like regime. In section III we derive the differential equations governing the engine dynamics. In section IV, the local stability analysis is carried out. Finally, in section V we present the results corresponding to the ecological regime.
A schematic representation of a CAN engine is shown in Figure 1.

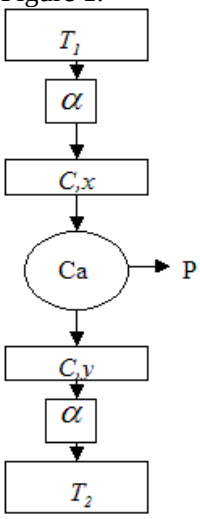

Figure 1. Schematic representation of a CAN engine. This machine consists in a Carnot cycle (Ca) which in every cycle exchanges the heat flows J_1 and J_2 with the reservoirs T_1 and T_2 respectively $\left(T_1 > T_2\right)$. This exchange of heat takes place through the thermal conductors, both with conductance (α). x and y represent the temperatures of working fluid along the isothermal branches of the Ca-cycle, and we take C as the heat capacity of the working fluid.

II STEADY-STATE ENDOREVERSIBLE CAN ENGINE

Consider the endoreversible engine depicted in the figure 1. The engine operates between temperatures T_1 and T_2, with $T_1 > T_2$. Heat flows irreversibly from T_1 to $\bar{x}$ and from $\bar{y}$ to T_2 ($T_1 > \bar{x} > \bar{y} > T_2$). Here and thereafter we use overbars to indicate steady-state values. The endoreversibility hypothesis states that the system is internally reversible. That is, a Carnot cycle operates between temperatures $\bar{x}$ and $\bar{y}$. This hypothesis further implies that the heat flows can be expressed as [13]

$$\bar{J}_1 = \frac{\bar{x}}{\bar{x} - \bar{y}}\bar{P} \qquad (2)$$

and

$$\bar{J}_2 = \frac{\bar{y}}{\bar{x} - \bar{y}}\bar{P}, \qquad (3)$$

where $\bar{J}_1$ and $\bar{J}_2$ are the heat flows from $\bar{x}$ to the engine and from the engine to $\bar{y}$, and $\bar{P}$ is the power output. In this study we consider heat transfer law that in steady-state heat flows are given by:

$$\bar{J}_1 = \alpha(T_1 - \bar{x})^k \qquad (4)$$

and

$$\bar{J}_2 = \alpha(\bar{y} - T_2)^k, \qquad (5)$$

with α the thermal conductance.
From equations (2)-(5) and the definition of efficiency given in [14],

$$\bar{\eta}_{MP} = 1 + (k-1) - \frac{\tau}{2} - \sqrt{\left(1 + (k-1)\frac{\tau}{2}\right)^2 + (\tau - 1)}, \quad (6)$$

it is possible to express temperatures $\bar{x}$ and $\bar{y}$ as

$$\bar{x} = \frac{T_1\left((1-\eta)^{1/k} + \tau\right)}{(1-\eta)^{1/k} + (1-\eta)} \quad (7)$$

and

$$\bar{y} = \frac{T_1(1-\eta)\left((1-\eta)^{1/k} + \tau\right)}{(1-\eta)^{1/k} + (1-\eta)}, \quad (8)$$

with $\tau = T_2/T_1$.

Moreover, we have that the power output is

$$\bar{P} = \bar{\eta}\,\bar{J}_1. \quad (9)$$

After a little algebra we obtain a expression for the power in terms of $\bar{x}$ and $\bar{y}$:

$$\bar{P}(\bar{x}, \bar{y}) = \alpha\left[\frac{\bar{y} - \bar{x}\tau}{\bar{y}^{1/k} + \bar{x}^{1/k}\tau}\right]^k. \quad (10)$$

III DYNAMICS OF THE CAN ENGINE WORKING IN THE REGIME OF MAXIMUM POWER.

Consider again figure 1. Now, the resrvoirs *x* and *y* are not real heat reservoirs but macroscopic objects with a heat capacity *C*. Therefore, their temperature changes according the following equations

$$\frac{dx}{dt} = \frac{1}{C}\left[\alpha(T_1 - x)^k - J_1\right] \quad (11)$$

and

$$\frac{dy}{dt} = \frac{1}{C}\left[J_2 - \alpha(y - T_2)^k\right]. \quad (12)$$

Both of these derivatives cancel when *x* and *y* take their steady-state values. We use the criterion that the flow from *x* to the work substance (J_1) and from the Carnot engine to *y* (J_2) are given in terms of the output power *P* by (see equations (2) and (3))

$$J_1 = \frac{x}{x - y}P \quad (13)$$

and

$$J_2 = \frac{y}{x - y}P. \quad (14)$$

Following of Santillán et al [13] we assumed that out of the steady state but no too far away, the power of a CAN engine depends on *x* and *y* in the same way that it depends on $\bar{x}$ and $\bar{y}$ in the steady state ($\bar{P}(\bar{x}, \bar{y}) \to P(x, y)$), applicable only in the neighborhood of the steady state:

$$P = \alpha\left[\frac{y - x\tau}{y^{1/k} + x^{1/k}\tau}\right]^k. \quad (15)$$

Substituting equations (13), (14), and (15) into (11) and (12) we obtain the next pair of differential equations for *x* and *y* in the maximum power regime:

$$\frac{dx}{dt} = \frac{\alpha}{C}\left[(T_1 - x)^k - x\left[\frac{y - x\tau}{y^{1/k} + x^{1/k}\tau}\right]^k\right] \quad (16)$$

and

$$\frac{dy}{dt} = \frac{\alpha}{C}\left[y\left[\frac{y - x\tau}{y^{1/k} + x^{1/k}\tau}\right]^k - (y - T_2)^k\right]. \quad (17)$$

IV LOCAL STABILITY ANALISIS

Let $f(x, y)$ and $g(x, y)$ be defined as

$$f(x, y) = \frac{\alpha}{C}\left[(T_1 - x)^k - x\left[\frac{y - x\tau}{y^{1/k} + x^{1/k}\tau}\right]^k\right] \quad (18)$$

and

$$g(x, y) = \frac{\alpha}{C}\left[y\left[\frac{y - x\tau}{y^{1/k} + x^{1/k}\tau}\right]^k - (y - T_2)^k\right]. \quad (19)$$

By construction, the values of the steady-state x and y are given by equations (7) and (8). If x and y are very close to the steady-state value, we can write $x(t) = \bar{x} + \delta x(t)$ and $y(t) = \bar{y} + \delta y(t)$, where $\delta x(t)$ and $\delta y(t)$ are small perturbations. By substituting into equations (18) and (19), and using the smallness of $\delta x(t)$ and $\delta y(t)$ we can make a first order approximation a Taylor series expansion obtaining following differential equations for $\delta x(t)$ and $\delta y(t)$:

$$\frac{d\delta x}{dt} = f_X \delta x(t) + f_Y \delta y(t) \qquad (20)$$

and

$$\frac{d\delta y}{dt} = g_X \delta x(t) + g_Y \delta y(t) \qquad (21)$$

where $f_X = \left.\frac{\partial f}{\partial x}\right|_{\bar{x},\bar{y}}$, $f_y = \left.\frac{\partial f}{\partial y}\right|_{\bar{x},\bar{y}}$, $g_X = \left.\frac{\partial g}{\partial x}\right|_{\bar{x},\bar{y}}$, and $g_y = \left.\frac{\partial g}{\partial y}\right|_{\bar{x},\bar{y}}$ are given by:[*2]

Assume that $\delta x(t)$ and $\delta y(t)$ are of the form [15],

$$\delta x(t) = a e^{zt} \qquad (26)$$

and

$$\delta y(t) = b e^{zt} \qquad (27)$$

with z a complex number that will be determined.

Substitution of equations (26) and (27) into equations (20) and (21) leads to the following set of homogeneous linear algebraic equations for a and b:

$$(f_X - z)a + f_Y b = 0 \qquad (28)$$

and

$$g_X a + (g_X - z)b = 0\,. \qquad (29)$$

This system of equations has non-trivial solutions only if the determinant of the matrix of coefficients is equals zero [16], i.e.

$$(f_X - z)(g_Y - z) - g_X f_Y = 0\,. \qquad (30)$$

This equation is called the characteristic equation. In conclusion, the only possible solutions to equations (20) and (21) are those with a z which is the solution of the characteristic equation (30). Denote the solutions of equation (30) as z_1 and z_2. They are numerically calculated, and both are real and negative. It follows then from equation (26) and (27) that any perturbation decays exponentially with time. The relaxation time depends on the absolute value of z_1 and z_2. Indeed, we can define two relaxation times λ_1 and λ_2 as

$$\lambda_1 = -\frac{1}{z_1} \quad \text{and} \quad \lambda_2 = -\frac{1}{z_2}\,. \qquad (33)$$

The smaller λ_1 and λ_2, the more quickly the system returns to the steady state after a perturbation.

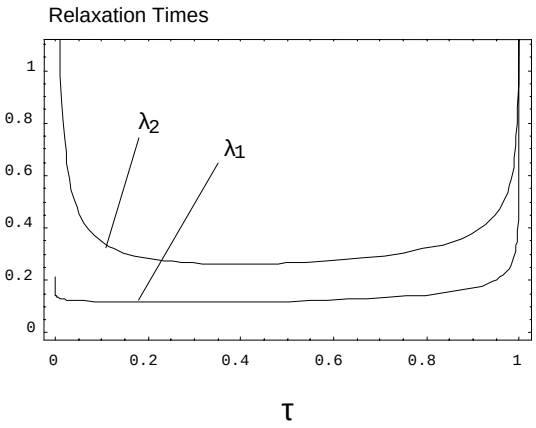

Figure 2.- This figure shows the dependency of the relaxation times λ_1 and λ_2 with the temperatures of both reservoirs for the maximum power regime for a Dulong-Peti's heat transfer law..

The plots of λ_1 and λ_2 are shown in figure 2. λ_1 and λ_2 are concave with a minimum value, depending of τ, with $\tau \in [0.3, 0.6]$ ($\tau = T_2 / T_1$). In conclusion, the engine's stability properties can be guaranteed.

V ECOLOGICAL CRITERION

Consider now the ecological regime, proposed by Angulo Brown [12], which consists in optimizing the function $E = P - \varepsilon T_2 \sigma$, that represents an

[*2] Due the size of equations (22), (23), (24) and (25) these are included in the appendix A at the end of the paper.

austere compromise between power output and energy of the engine, E is the so-called ecological function, P is the power output, T_2 is the cold reservoir temperature, ε is a parameter, and σ the entropy production. Following step by step the procedure shown in the last sections, with the exception that the expression for the maximum ecological efficiency $\eta_E = \eta_E(\tau, k)$, is used [19]. We obtain that z_1 and z_2 also are real and negative. Figure 3 shows the plots of the relaxation times λ_1 and λ_2 vs. τ. We can see that are concave with a minimum value, depending of τ, with $\tau \in [0.3,0.6]$ ($\tau = T_2 / T_1$).

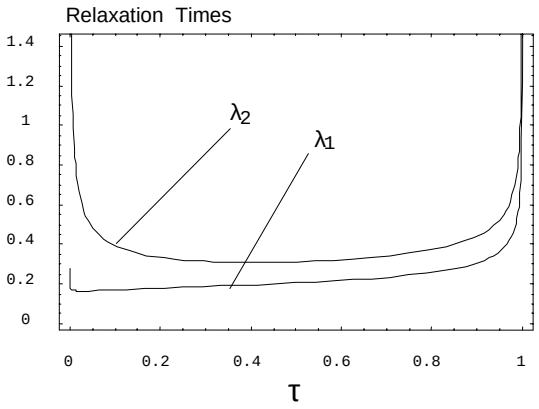

Figure 3.- Plot of the relaxation times λ_1 and λ_2 vs. τ, for the ecological regime governed by a Dulong-Petit's heat transfer law between the reservoirs and the work substance.

Then the engine's stability is guaranteed. In figure 4 (see appendix B) we present a qualitative phase portraits for different regimes and different heat transfer laws.

CONCLUSIONS

We have presented a local stability analysis for an endoreversible CAN engine, governed by a Dulong-Petit heat transfer law. The results were compared with those corresponding to the Newton's heat transfer law. We conclude that both regimes are quite susceptible to the governing heat transfer law. The curves that represent the relaxation times λ_1 and λ_2 are concave with a minimum value, so the CAN engine is stable for quite value of α, C, and $\tau \in [0.3,0.6]$ ($\tau = T_2 / T_1$), which agree with the data reported in references [17,18]. As shown in figure 3, when $\tau \approx 1$ the relaxation times λ_1 y $\lambda_2 \to \infty$. This means that, in this limit ($T_1 \approx T_2$), the hypothesis of little perturbations is not satisfied. because any perturbation would be as big as the system, which the local stability is nullified. Future work would involve studying, a no-endoreversible CAN engine will be considered for the same analysis.

GENERALIZED GIBBS ENTROPY, IRREVERSIBILITY AND STATIONARY STATES

ABSTRACT

A generalization of the Gibbs entropy postulate is proposed based on the BBGKY hierarchy as the nonequilibrium entropy for a system of N interacting particles. This entropy satisfies the basic principles of thermodynamics in the sense that it reaches its maximum at equilibrium and is coherent with the second law. By using this entropy and the methods of nonequilibrium thermodynamics in the phase space, a generalization of the Liouville equation describing the evolution of the distribution vector in the form of a master equation is obtained. After neglecting correlations in this master equation the Boltzmann equation was obtained. Moreover, this entropy remains constant in nonequilibrium stationary states and leads to macroscopic hydrodynamics. Nonequilibrium Green-Kubo type relations and the probability for the nonequilibrium fluctuations are also derived.

INTRODUCTION

According to the mechanicistic interpretation of the physical world, the basic laws of nature are deterministic and time reversible. However, at the macroscopic level we observe irreversible processes related to energy degradation which generate entropy. How do we reconcile the 'spontaneous production of entropy' with the time reversibility of the microscopic equations of motion?. At the end of the nineteenth century, Boltzmann tried to answer this question from a probabilistic point of view. According to him, entropy is a measure of the lack of knowledge of the precise state of matter and can be defined as a function of the probability of a given state of matter. This function associates a number $S_B(X) = \log|\Gamma_{M(X)}|$ to each microstate X of a macroscopic system, with $|\Gamma_M|$ being the volume of the region of the phase space Γ_M corresponding to the macrostate $M = M(X)$. The macrostate M is all of a group of states Y such that $M(Y) = M(X) = M$. In this sense, the Boltzmann entropy is a function of the microstate which at equilibrium coincides with the thermodynamic entropy. All systems in their irreversible evolution tend to a state of maximum probability or maximum entropy -the state of equilibrium- .

In contrast to the Boltzmann entropy, the Gibbs entropy is not a function of the individual microstate but rather a function of the probability distribution in a statistical ensemble of systems with both entropies coinciding at equilibrium. As a consequence of the incompressible character of the flow of points representing the natural evolution of the statistical ensemble in phase space , the Gibbs entropy is a constant of motion. Thus, it has been argued that the relevant entropy for understanding thermodynamic irreversibility is the Boltzmann entropy and not the Gibbs entropy [1], [2], [3].

In addition, the problem of the diverging character of the Gibbs entropy related to the negative sign of the entropy production in nonequilibrium stationary states apparently excludes the use of the Gibbs entropy in the statistical description of nonequilibrium systems [4], [5]. This raises the question as to how to define the nonequilibrium entropy and if possible, to give a thermodynamic description of nonequilibrium fluctuations. In other words: can Thermodynamics describe systems far from equilibrium? [6], [7].

Thus, from the moment when Gibbs first postulated his entropy formula, the definition of the nonequilibrium entropy and its relation to irreversibility has been an outstanding problem, now compounded by the fact that the entropy production is negative in nonequilibrium stationary states in apparent viola-

tion of the second law of Thermodynamics [8], [9]. This constitutes an open problem which must be solved.

A huge amount of work has been done on this subject trying to address the problem. On one hand, there have been attempts to extend the equilibrium entropy [10], [11], [12], [13] to nonequilibrium situations in order to avoid the divergence of the Gibbs entropy. On the other hand, work has been done to establish fluctuation theorems for the probability of the entropy production fluctuations [14]. In a previous work [16] we showed a way to circumvent the difficulty of reconciling the second law of thermodynamics with the reversible microscopic equations of motion in the framework of the BBGKY hierarchy. We proposed a functional of the set of s-particle reduced distribution functions as the entropy for a system of N interacting particles. This entropy does not enter into contradiction with thermodynamics, and as we show here, in addition to being time-dependent it enables one to perform a thermodynamic analysis of the stationary nonequilibrium states. In this sense, our theory constitutes an extension of the scope of thermodynamics to systems away from equilibrium.

I begin this contribution introducing the representation of the state of the isolated system in terms of the hierarchy of reduced distribution functions. Afterwards I develop the thermodynamic analysis and derive the entropy production which enables us to draw kinetic equations, in particular the Boltzmann equation. After that comes the analysis of the nonequilibrium stationary states of the system. Finally I stress the main conclusions.

HAMILTONIAN DYNAMICS

Let's consider a dynamical system of N identical particles whose Hamiltonian $H_N(\{\underline{q}^N,\underline{p}^N\})$ is given by

$$H_N=\sum_{j=1}^{N}\frac{\underline{p}_j^2}{2m}+\frac{1}{2}\sum_{j\neq k=1}^{N}\phi\left(\left|\underline{q}_j-\underline{q}_k\right|\right)\ , \qquad (1)$$

where m is the mass and $\phi\left(\left|\underline{q}_j-\underline{q}_k\right|\right)\equiv\phi_{jk}$ is the interaction potential. The state of the system is completely specified at a given time by the N-particle distribution function $F\left(\{\underline{q}^N,\underline{p}^N\};t\right)$ which evolves in time according to the Liouville equation. Nonetheless, an alternative description of the state of the system can be given in terms of the distribution vector [15]

$$\underline{f}\equiv\{f_0,f_1(\Gamma_1),f_2(\Gamma_2),.....,f_N(\Gamma_N)\}\ , \qquad (2)$$

with $\Gamma_s=(x_1,x_2,.....,x_s)$ and $x_j\equiv(\underline{q}_j,\underline{p}_j)$. Additionally, the set of quantities Γ_s can be grouped as the vector $\underline{\Gamma}\equiv\{\Gamma_1,\Gamma_2,.....,\Gamma_N\}$, and correspondingly $\underline{H}\equiv\{H_1,H_2,.....,H_N\}$ can be defined with H_s being the s-particle Hamiltonian. The distribution vector represents the set of all the s-particle reduced distribution functions $f_s(\Gamma_s)$ $(s=0,....,N)$, defined through

$$f_s=\frac{N!}{(N-s)!}\int F(x_1,..,x_s,x_{s+1},..,x_N)\,dx_{s+1}...dx_N\ . \qquad (3)$$

The evolution equations of these functions can be obtained by integrating the Liouville equation thereby constituting a set of coupled equations: the BBGKY hierarchy which can be written in a compact way as a generalized Liouville equation [16]

$$\left(\frac{\partial}{\partial t}-\mathscr{P}\mathscr{L}\right)\underline{f}(t)=\mathscr{Q}\mathscr{L}\underline{f}(t)\ , \qquad (4)$$

with

$$\begin{aligned}\langle s\,|\,\mathscr{P}\mathscr{L}\,|\,s'\rangle&=\delta_{s,s'}\left\{\sum_{j=1}^{s}L_j^o+\sum_{j<n=1}^{s}L'_{j,n}\right\} \qquad (5)\\ &=\delta_{s,s'}\,[H_s,...]_P\,,\end{aligned}$$

and

$$\langle s\,|\,\mathscr{Q}\mathscr{L}\,|\,s'\rangle=\delta_{s',s+1}\int\left\{\sum_{j=1}^{s}L'_{j,s+1}\right\}dx_{s+1}\ . \qquad (6)$$

where $|\ s\rangle$ represents the s-particle state defined through $\langle\Gamma_s|s\rangle=f_s(\Gamma_s)$ and where the projection operators $\mathscr{P}$ and $\mathscr{Q}$, its complement with respect to the identity, give the diagonal and nondiagonal part of the generalized Liouvillian $\mathscr{L}$, respectively. Here, $L_j^o=\left[H_j^o,...\right]_P$,where $[...,...]_P$ is the Poisson bracket, $H_j^o=\frac{\underline{p}_j^2}{2m}$, and $L'_{j,n}=\left[H'_{j,n},...\right]_P$, with $H'_{j,n}=\frac{1}{2}\phi_{j,n}$. Unlike the Liouville equation which remains invariant under time reversal

$$\begin{aligned}t\ &\longrightarrow\ -t\equiv t^*\ , \qquad (7)\\ \underline{p}_j\ &\longrightarrow\ -\underline{p}_j\ ,\ j=1,...,N\ \ ,\end{aligned}$$

this symmetry is broken in Eq. (4) due to the term on their right hand side

$$\left(\frac{\partial}{\partial t^*} - \mathscr{P}\mathscr{L}\right)\underline{f}(t^*) = -\mathscr{Q}\mathscr{L}\underline{f}(t^*) \,.$$

This means that under the operation of time reversal the densities f_s do not reverse their evolution. Thus, the diagonal part of the generalized Liouvillian accounts for the reversible evolution of the distribution vector while the nondiagonal part introduces irreversibility in the dynamics of $\underline{f}$ leading to dissipation. Hence, in the sense that the time-reversal symmetry is broken, the generalized Liouville equation given through Eq. (4) is irreversible. Irreversibility is manifested in the dynamics of the system when the adequate description, *i.e.* in terms of the distribution vector is used. Some degree of coarse graining is inherent to this description.

NONEQUILIBRIUM THERMODYNAMICS

As the expression for the nonequilibrium entropy I propose

$$\begin{aligned} S &= -k_B \mathrm{tr}\left\{\underline{f}\log\left(\underline{f}_o^{-1}\underline{f}\right)\right\} + S_o \\ &= -k_B \sum_{n=1}^{N} \frac{1}{n!}\int f_n \log\frac{f_n}{f_{o,n}}\, dx_1.....dx_n \; + S_o \,, \end{aligned} \quad (8)$$

a functional of $\underline{f}$, analogous with the Gibbs entropy postulate [17], [18], based on the fact that the distribution vector determines the state of the system. Here, k_B is the Boltzmann constant, $\underline{f}_o = \{f_{o,0}, f_{o,1}, f_{o,2}, ...\}$ is assumed to be the equilibrium distribution vector which corresponds with the equilibrium entropy S_o, satisfying $\mathscr{L}\underline{f}_o = 0$ whereas $\underline{f}_o^{-1}$ denotes the vector whose components are the inverse of the reduced distribution functions $f_{o,n}^{-1}$. Moreover, S is maximum at equilibrium when $\underline{f}$=$\underline{f}_o$ giving $S = S_o$, which can be proven by taking the first and second variation of S with respect to $\underline{f}$ while S_o and $\underline{f}_o$ remain fixed. This entropy is also coherent with the second law according to which S increases in irreversible processes such as the relaxation to equilibrium from an initially nonequilibrium state. This expression based on the BBGKY hierarchy is different from other developments in the literature such as the paper by Green and Nettleton [19]. Therefore, the rate of change of S which can be obtained by differentiating Eq. (8) with the help of Eq. (4) is

$$\begin{aligned} \sigma &= -k_B \mathrm{tr}\left\{\frac{\partial \underline{f}}{\partial t}\log\left(\underline{f}_o^{-1}\underline{f}\right)\right\} \\ &= -k_B \mathrm{tr}\left\{\mathscr{Q}\mathscr{L}\underline{f}\log\left(\underline{f}_o^{-1}\underline{f}\right)\right\} \,. \end{aligned} \quad (9)$$

This constitutes the entropy production corresponding to the relaxation passing from a nonequilibrium state to equilibrium. Here, the only contribution to the entropy production comes from the irreversible change of the distribution vector. The reversible change of the distribution vector is given by the mainstream current induced by the s-Hamiltonian flow in each one of the s-particle subspaces of the total phase space, in light of the fact that the Hamiltonian flow does not create entropy.
At equilibrium $\mathscr{P}\mathscr{L}\underline{f}_o = -\mathscr{Q}\mathscr{L}\underline{f}_o$ according to Eq. (4), neither $\mathscr{P}\mathscr{L}\underline{f}_o$ nor $\mathscr{Q}\mathscr{L}\underline{f}_o$ vanish, but rather both terms balance together. Hence, the thermodynamic current $\mathscr{Q}\mathscr{L}\underline{f}$ appearing in Eq. (9) contains an equilibrium contribution. Therefore, in order to get a completely nonequilibrium current maintaining the invariance of the entropy production, I define the new current $\underline{J}'$ through $\mathscr{Q}\mathscr{L}\underline{f} - \underline{J}' = -\mathscr{P}\mathscr{L}\underline{f}$, entering a continuity equation for $\underline{f}$

$$\frac{\partial}{\partial t}\underline{f} = \underline{J}' \,. \quad (10)$$

Thus for small deviations from equilibrium, Eq. (9) with the aid of Eq. (10) becomes

$$\sigma = k_B \mathrm{tr}\left\{-\underline{J}'\underline{X}\right\} \,, \quad (11)$$

where $\underline{X} = \underline{f}_o^{-1}\left(\underline{f}_o - \underline{f}\right)$ is the thermodynamic force conjugated with the current $\underline{J}'$. Following the methods of nonequilibrium thermodynamics [17], [20] in the phase space, from Eq. (9) the linear relation

$$\underline{J}' = -\underline{M}\,\underline{X} \quad (12)$$

is inferred, where the master or mobility matrix $\underline{M}$ acts on an arbitrary vector $\underline{Y}$ according to

$$\langle s\,|\underline{M}|\,s'\rangle\langle s'\,|\,\underline{Y} = \int M(s|s')Y_{s'}(x'_1,....,x'_{s'})dx'_1.....dx'_{s'} \,. \quad (13)$$

Note that in view of the definition of the current $\underline{J}'$ and the orthogonal character of the operators $\mathscr{P}$ and $\mathscr{Q}$, Eq. (12) leads to $\mathscr{Q}\underline{M}\,\underline{X} = \mathscr{Q}\mathscr{L}\underline{f}$ and $\mathscr{P}\underline{M}\,\underline{X} = -\mathscr{P}\mathscr{L}\underline{f}$.

Substituting the linear relation Eq. (12) into Eq. (11) and using the cyclic invariance of the trace, the entropy production is

$$\mathrm{tr}\,(\underline{X}\,\underline{M}\,\underline{X}) = \mathrm{tr}\,(\underline{X}\underline{\mathscr{Q}}\underline{M}\,\underline{X}) \geq 0\,, \qquad (14)$$

according to the second law of Thermodynamics. Therefore, M is a positive semidefinite matrix. In addition, the master matrix should be Hermitian

$$M(s|s') = M^{\dagger}(s|s') = M^{*}(s'|s)\,, \qquad (15)$$

as predicted by the Onsager symmetry relations. Here † refers to the Hermitian conjugate and * stands for the complex conjugated. Furthermore, due to the fact that $\underline{f}$ should be normalized, $\mathrm{tr}(\underline{f})$ is a constant quantity which is a function of N. It can be inferred from Eqs. (10) and (12) that $\mathrm{tr}(\underline{M}\,\underline{X}) = 0$ which, when the Hermitian character of the master matrix is taken into account, leads to the following constraints

$$\int M(s\mid s')dx_1.....dx_s = \int M^{\dagger}(s\mid s')dx'_1.....dx'_{s'} = 0\,. \qquad (16)$$

Hence, by using Eq. (12) the generalized Liouville equation (4) can be written

$$\left(\frac{\partial}{\partial t} - \underline{\mathscr{P}}\underline{\mathscr{L}}\right)\underline{f} = \underline{\mathscr{Q}}\underline{M}\underline{X}\,, \qquad (17)$$

with

$$\langle s\,|\underline{\mathscr{Q}}\underline{M}|\,s'\rangle\langle s'\mid \underline{X} = \delta_{s',s+1}\int M(s+1|s')X_{s'}dx'_1.....dx'_{s'}dx_{s+1}\,, \qquad (18)$$

written in analogy with Eq. (6). It should be mentioned that the presence of the master matrix in Eq. (17) notably simplifies the BBGKY hierarchy. In fact, the master matrix introduces a relaxation time scale. Hence, our theory is equivalent to a relaxation time approach to the study of the BBGKY hierarchy valid when there is a broad separation between the hydrodynamic and microscopic scales.

Here, Eq. (17) can be put into a more common form by introducing a new function $\underline{W}$ defined through [21]

$$f_{o,s'}W\left(s'\mid s\right) = -M\left(s\mid s'\right) + \delta\left(x'_1 - x_1\right).....\delta\left(x'_{s'} - x_s\right)\psi_s\left(x_1,....,x_s\right)\,, \qquad (19)$$

where the auxiliary function ψ_s is not arbitrarily selectable because of the constraints given by Eq. (16). Instead

$$\psi_s\left(x_1,...,x_s\right) = f_{o,s}(x_1,...,x_s)\int W(s|s')dx'_1...dx'_{s'} \qquad (20)$$

can be applied. Thus, Eq. (17) may be written in terms of the transition matrix as follows

$$\left(\frac{\partial}{\partial t} - \underline{\mathscr{P}}\underline{\mathscr{L}}\right)\underline{f}(t) = \underline{\mathscr{Q}}\underline{W}\underline{f}(t)\,, \qquad (21)$$

where

$$\langle s\,|\underline{\mathscr{Q}}\underline{W}|\,s'\rangle\langle s'\mid \underline{f} = \delta_{s',s+1}\int\{f_{s'}(x'_1,...,x'_{s'})W(s'|s+1) - f_{s+1}(x_1,...,x_{s+1})W(s+1\mid s')\}dx'_1...dx'_{s'}dx_{s+1}\,. \qquad (22)$$

The introduction of the transition matrix enables us to write Eq. (17) as a master equation.

A particularly interesting case corresponds to $s = 1$ where Eqs. (21) and (22) reduce to

$$\left(\frac{\partial}{\partial t} - L_1^o\right)f_1(x_1)) = \int\{f_2(x'_1,x'_2)W(x'_1,x'_2|x_1,x_2) - f_2(x_1,x_2)W(x_1,x_2\mid x'_1,x'_2)\}dx'_1dx'_2dx_2\,. \qquad (23)$$

This is not yet a kinetic equation; however, its uncorrelated part can be written as

$$\left(\frac{\partial}{\partial t} - L_1^o\right)f_1(x_1) = \int\{f_1(x'_1)f_1(x'_2)W(x'_1,x'_2|x_1,x_2) - f_1(x_1)f_1(x_2)W(x_1,x_2\mid x'_1,x'_2)\}dx'_1dx'_2dx_2\,, \qquad (24)$$

which is the famous Boltzmann equation. Analogous procedure can be followed to obtain the kinetic equations for the correlations coming from the components of $\underline{f}$ of an order higher than one.

NONEQUILIBRIUM STATIONARY STATE

Let us assume that a nonconservative field $h(t)$ acts on the system, modifying the Hamilton equations of motion

$$\dot{\underline{q}}_i = \frac{\partial H_N}{\partial \underline{p}_i} + \underline{C}_i(x_1,...x_N)h(t)\,,$$
$$\dot{\underline{p}}_i = -\frac{\partial H_N}{\partial \underline{q}_i} + \underline{D}_i(x_1,...x_N)h(t)\,, \qquad (25)$$

where $\underline{C}_i(x_j)$ and $\underline{D}_i(x_j)$ are coupling functions. This drive introduces a compressible contribution to the flow in the phase space which is reflected in the Liouville equation characterizing the phase space flow

$$\frac{\partial}{\partial t}F - [H_N, F]_P = -\frac{\partial}{\partial \Gamma_N}\cdot \dot{\Gamma}_N^{nc} F \ , \qquad (26)$$

where $\dot{\Gamma}_N^{nc} = (\dot{x}_1^{nc}, ..., \dot{x}_N^{nc})$, $\dot{x}_i^{nc} = (\underline{C}_i(x_j), \underline{D}_i(x_j))\, h(t)$. To Eq. (26) corresponds

$$\left(\frac{\partial}{\partial t} - \mathscr{P}\,(\mathscr{L} - \underline{G})\right)\underline{f} = \mathscr{Q}\mathscr{L}\underline{f} \qquad (27)$$

for the distribution vector, where $\underline{G}\underline{f} = \frac{\partial}{\partial \underline{\Gamma}}\dot{\underline{\Gamma}}^{nc}\underline{f}$ and $\langle s'|\mathscr{P}\underline{G}\underline{f}|s\rangle = \delta_{s,s'}\frac{\partial}{\partial \Gamma_s}\cdot \dot{\Gamma}_s^{nc}\ f_s$. Eq. (26) admits a stationary solution satisfying

$$[H_N, F_{st}]_P = \frac{\partial}{\partial \Gamma_N}\cdot \dot{\Gamma}_N^{nc} F_{st} \ , \qquad (28)$$

or equivalently

$$\dot{\Gamma}_N \cdot \frac{\partial}{\partial \Gamma_N}\ln F_{st} - \frac{\partial}{\partial \Gamma_N}\cdot \dot{\Gamma}_N^{nc} = 0 \ . \qquad (29)$$

Up to order one with respect to the external force, Eq. (28) becomes $[H_N, \ln F_{st}]_P = \frac{\partial}{\partial \Gamma_N}\cdot \dot{\Gamma}_N^{nc}$. To this stationary distribution function F_{st}, there is a corresponding stationary distribution vector $\underline{f}_{st}$ which can be obtained as a solution of the stationary version of Eq. (27) or computed directly from F_{st} by using Eq. (3), $\underline{f}_{st} \neq \underline{f}_o$.

In this stationary state the rate of change of the internal energy $U = \int H_N(x_1, ...x_N)F(x_1, ...x_N)dx_1....dx_N$, is given by

$$\frac{dU_{st}}{dt} = \int H_N(x_1, .., x_N) \qquad (30)$$
$$\times \frac{\partial}{\partial t}F_{st}(x_1, .., x_N)dx_1...dx_N = 0 \ ,$$

i.e. the energy is constant. Moreover, the total rate of change of the entropy is given by

$$\frac{dS_{st}}{dt} = -k_B \mathrm{tr}\left\{\frac{\partial \underline{f}_{st}}{\partial t}\log\left(\underline{f}_o^{-1}\underline{f}_{st}\right)\right\}$$
$$= k_B \mathrm{tr}\left\{\underline{G}\underline{f}_{st}\log\left(\underline{f}_o^{-1}\underline{f}_{st}\right)\right\} + \sigma_{st} = 0 \ , \quad (31)$$

which is also constant showing that entropy does not diverge. Hence, the stationary state coincides with the state of constant internal energy and entropy . In fact, In general the stationary average of any phase function remains constant. According to Eq. (31) the entropy production (9) reduces to

$$\sigma_{st} = -k_B \mathrm{tr}\left\{\underline{G}\underline{f}_{st}\log\left(\underline{f}_o^{-1}\underline{f}_{st}\right)\right\}$$
$$= k_B \mathrm{tr}\left\{\underline{f}_{st}\dot{\underline{\Gamma}}^{nc}\frac{\partial}{\partial \underline{\Gamma}}\log\left(\underline{f}_o^{-1}\underline{f}_{st}\right)\right\} \ , \qquad (32)$$

where $\underline{f}_{st}\dot{\underline{\Gamma}}^{nc}$ plays the role of a thermodynamic current $\underline{J}$ and $\frac{\partial}{\partial \underline{\Gamma}}\log\left(\underline{f}_o^{-1}\underline{f}_{st}\right)$ is the corresponding conjugated force $\underline{X}$. A mobility $\underline{M}$ matching both quantities and a diffusion coefficient $\underline{D}$ related to this mobility through an effective temperature T_{st} as $T_{st}\underline{f}_{st} = \underline{M}\cdot\underline{D}$ can be defined. Thus, one gets the phenomenological law

$$\dot{\underline{\Gamma}}^{nc} = T_{st}\underline{D}^{-1}\cdot\frac{\partial}{\partial \underline{\Gamma}}\log\left(\underline{f}_o^{-1}\underline{f}_{st}\right) \qquad (33)$$

allowing us to rewrite Eq. (32)

$$\sigma_{st} = \frac{k_B}{T_{st}}\mathrm{tr}\left\{\underline{f}_{st}\dot{\underline{\Gamma}}^{nc}\underline{D}\dot{\underline{\Gamma}}^{nc}\right\} \sim \frac{h(t)^2}{T_{st}} \ . \qquad (34)$$

By approximating $\underline{D}$ by its average value $D = \mathrm{tr}\left\{\underline{f}_{st}\underline{D}\right\}$ and by using Eq.(9), I find

$$D^{-1} = \frac{1}{T_{st}}\left(\frac{\mathrm{tr}\left\{\underline{f}_{st}\dot{\underline{\Gamma}}^{nc}\dot{\underline{\Gamma}}^{nc}\right\}}{-\mathrm{tr}\left\{\mathscr{Q}\mathscr{L}\underline{f}_{st}\log\left(\underline{f}_o^{-1}\underline{f}_{st}\right)\right\}}\right) \ , \qquad (35)$$

which constitutes a kind of Green-Kubo relation. Thus, I can assume that for small deviations from the stationary state

$$\widehat{\sigma} \equiv \frac{dS}{dt} - \sigma = -\frac{Dk_B}{T_{st}}\mathrm{tr}\left\{\underline{f}\,\dot{\underline{\Gamma}}^{nc}\dot{\underline{\Gamma}}^{nc}\right\} \ . \qquad (36)$$

This is a powerful relation because following Boltzmann, the probability of the nonequilibrium fluctuations can be defined

$$P_\tau(\dot{\underline{\Gamma}}^{nc}, t) \sim \exp\left(\frac{\widehat{\sigma}\tau}{k_B}\right) \qquad (37)$$
$$= \exp\left(-\frac{D\tau}{T_{st}}\mathrm{tr}\left\{\underline{f}\,\dot{\underline{\Gamma}}^{nc}\dot{\underline{\Gamma}}^{nc}\right\}\right) \ ,$$

where τ is a time scale shorter than the time scale in which $h(t)$ varies considerably. This probability enables us to compute the average value of any phase

function $\psi(\dot{\underline{\Gamma}}^{nc})$, as for example the compressibility factor $\underline{G}$, .
Since macroscopic hydrodynamics occurs in the N-particle subspace, it can be concluded that one can also recover macroscopic hydrodynamics from this description.

CONCLUSIONS

Here, I have presented a representation of the statistical description of a many-body system in terms of the distribution vector which reveals the irreversible component of the motion of this system. This component is hidden when one works with the standard Liouville equation but at the level of the generalized Liouville equation which entails a certain degree of coarse graining, this irreversible component becomes obvious. The Liouville equation is a closed equation for the phase space distribution function while the generalized Liouville equation encloses a set of coupled equations, each one in itself represents a contraction of the statistical description. But, as I have mentioned previously, the full statistical description in terms of the phase space distribution function is equivalent to the description in terms of the set of all the reduced s-particle distribution functions. In this scenario, I show that the Gibbs entropy given by the Gibbs entropy postulate is a non-conserved quantity throughout the motion in phase space. This entropy should increase up to its maximum value at equilibrium according to the second law. The consequences I have drawn from the Gibbs entropy are compatible with the explanation of irreversibility which follows from Boltzmann's entropy postulate.
By applying the methods of nonequilibrium thermodynamics in phase space, *i.e.* in the framework of the mesoscopic nonequilibrium thermodynamics MNET [22], [23], I obtain a linear relation between the irreversible rate of change of the distribution vector and the conjugated thermodynamic force which introduces a master matrix which should satisfy the properties required by the Onsager theory. This result simplifies the BBGKY hierarchy and enables us to break the hierarchy by neglecting higher order correlations thus obtaining the Boltzmann equation for the one-particle distribution function. This last result constitutes a test of our theory. Hence, based on the MNET I have founded a way for deriving kinetic equations.
I also point out that in our mesoscopic approach, the master matrix introduces a relaxation time scale which shows that our theory is valid when there is a broad separation between the hydrodynamic and microscopic scales. The existence of such a separation of time scales allows the rate of change of the distribution vector due to the main stream flow velocity in phase space to balance the irreversible change in order to achieve a stationary distribution at long time. This is precisely what is assumed to happen in the context of the phenomena described by the kinetic equations.
I have also shown that the entropy defined in terms of the distribution vector remains constant in a non-equilibrium stationary state, hence, divergences are avoided and the second law is satisfied. Also a kind of Green-Kubo relation was derived for a transport coefficient that can be defined in the system relating the power supplied to the system with the entropy production with the aid of a stationary temperature. Finally, following the Boltzmann principle I derive the expression of the probability for the nonequilibrium fluctuations. Therefore, the answer to the question raised at the beginning, can Thermodynamics describe systems far from equilibrium?, is obviously yes if one works at the adequate level of description, which corresponds to the distribution vector.

DEFINITIONS AND NOMENCLATURE IN EXERGY ANALYSIS AND EXERGOECONOMICS

George Tsatsaronis, Project Coordinator
Technische Universität Berlin
Institute for Energy Engineering
Marchstr. 18, 10587 Berlin
Germany

SUMMARY

This paper presents the definitions of some terms used in exergy analysis and exergy costing, discusses options for the symbols to be used for exergy and presents the nomenclature for the remaining terms.

1 INTRODUCTION

The number of publications dealing with exergy analysis and exergoeconomics has been increasing continuously in the last years. The symbols used in these publications and in textbooks (see Table 1) cover a rather large spectrum of the Latin and Greek alphabets. There is an urgent need for some consensus on the symbols to be used in the future. This will facilitate (a) the communication among practitioners, and (b) the further development of the disciplines of exergy analysis and exergoeconomics. The symbols used in section 2 and 3 are suggested for publications in journals and conference proceedings. In section 4 some alternatives are presented for use in textbooks.

2 EXERGY

Exergy of a thermodynamic system is the maximum theoretical useful work (shaft work or electrical work) obtainable as the system is brought into complete thermodynamic equilibrium with the thermodynamic environment while the system interacts with this environment only. The total exergy of a system consists of

- physical exergy (due to the departure of the temperature and pressure of the system from those of the environment),
- chemical exergy (due to the departure of the chemical composition of the system from that of the environment)
- kinetic exergy (due to the system velocity measured relative to the environment), and
- potential exergy (due to the system height measured relative to the environment).

The physical exergy consists of

- mechanical exergy (associated with the system pressure) and
- thermal exergy (associated with the system temperature).

For a given thermodynamic state at a temperature T and pressure p, the thermal exergy is usually calculated along the isobaric line at p (from state [T, p] to state [T_0, p]), whereas the mechanical exergy is calculated along the isothermal line at T_0 (from state [T_0, p] to state [T_0, p_0]).

Distinction between thermal and mechanical exergy might not always be unambiguous.

The chemical exergy of a system can be split into

- reactive exergy (associated in its calculation with chemical reactions), and
- nonreactive exergy (associated in its calculation with nonreactive processes such as expansion, compression, mixing and separation).

An option for splitting the chemical exergy into reactive and nonreactive exergy is presented in Reference [1]. The splitting of physical and chemical exergy might be useful for defining more accurate exergetic efficiencies and for improving the costing approach.

The symbol for exergy has been the subject of a lot of controversy in the past. The exergy symbol should be easy to use and recognize. We should not use two letters for this symbol (e.g., Ex) because (a) this is not common for important variables in thermodynamics, and (b) there is a potential for missinterpretations when it is used with superscripts and subscripts.

With exergy we mean the potential to generate work regardless of the cases, systems, or exergy components being actually considered. Therefore, it is logical to use only one and the same symbol for all cases, systems and exergy components, as well as for exergy destruction and exergy loss. The fact that in energy analysis we use traditionally different symbols for total energy, internal energy and enthalpy should not lead us to use different symbols for the physical exergy of a system and the physical exergy of a material stream simply because the equations used to calculate each of these physical exergies are different. If we would follow this way, we should use different symbols also for the exergy associated with both heat transfer and work, and we would soon come to a completely unacceptable situation regarding symbols for exergy.

If we now agree that a one-letter symbol should be used in all cases in conjunction with exergy, the question arises what letter should this be. The easiest and more natural approach for publications in journals and conference proceedings would be to use the letter E for exergy, as it has been used in Germany and some other countries from the very moment the exergy concept was introduced.

It should be considered that the vast majority of these publications involving exergy refer usually to control volumes at steady state. In these applications the relevant energy terms are only enthalpy, heat and work. Therefore, there is no danger of confusing total e**n**ergy, which is also denoted by E, with any form of e**x**ergy. In cases where both exergy and total energy appear in the same publication, a slightly different font can be employed for total energy, unless energy is mainly used and exergy is mentioned only in passing. In the last case, a slightly different symbol (for example, the roman font) can be used for exergy. This should not result in confusion because it is always clear from the context whether exergy or total energy is meant.

Thus, for publications in journals and conference proceedings, where a simple approach is very important, the following equations should be employed in exergy analysis. Alternatives are presented in section 4.

Total exergy of a system:

$$E_{sys} = E_{sys}^{PH} + E^{KN} + E^{PT} + E^{CH} \quad (1)$$

$$e_{sys} = e_{sys}^{PH} + e^{KN} + e^{PT} + e^{CH} \quad (1a)$$

To distinguish the physical exergy and total exergy of a system from the same exergies associated with a stream of matter, a subscript "*sys*" is used here for the exergies of the system.

Physical exergy of a system:

$$E_{sys}^{PH} = (U - U_0) + p_0(V - V_0) - T_0(S - S_0) \quad (2)$$

$$e_{sys}^{PH} = (u - u_0) + p_0(v - v_0) - T_0(s - s_0) \quad (2a)$$

Mechanical and thermal exergy of a system:

$$E_{sys}^{PH} = E_{sys}^{T} + E_{sys}^{M} \quad (3)$$

$$e_{sys}^{PH} = e_{sys}^{T} + e_{sys}^{M} \quad (3a)$$

Reactive and nonreactive exergy:

$$E^{CH} = E^{R} + E^{N} \quad (4)$$

$$e^{CH} = e^{R} + e^{N} \quad (4a)$$

In applications of the exergy concept, the subscript "*sys*" will be replaced by the abbreviation used for the component being considered (e.g., *ac* for air compressor, *hrsg* for heat-recovery steam generator, and *sr* for storage vessel).

Total exergy of a material stream:

$$E = E^{PH} + E^{KN} + E^{PT} + E^{CH} \quad (5)$$

$$e = e^{PH} + e^{KN} + e^{PT} + e^{CH} \quad (5a)$$

Physical exergy of a material stream:

$$E^{PH} = (H - H_0) - T_0(S - S_0) \quad (6)$$

$$e^{PH} = (h - h_0) - T_0(s - s_0) \quad (6a)$$

Mechanical and thermal exergy of a material stream:

$$E^{PH} = E^{T} + E^{M} \quad (7)$$

$$e^{PH} = e^{T} + e^{M} \quad (7a)$$

Please note that the terms E^{KN} and E^{PT} (e^{KN} and e^{PT}) in Equations (1) and (5) are calculated by

$$E^{KN} = \frac{1}{2} m \vec{v}^{\,2} \quad (8)$$

$$e^{KN} = \frac{1}{2} \vec{v}^{\,2} \quad (8a)$$

and

$$E^{PT} = mgz \quad (9)$$

$$e^{PT} = gz \quad (9a)$$

Here $\vec{v}$ is the system velocity measured relative to the environment and z represents the system height also measured relative to the environment.

3 OTHER EXERGETIC VARIABLES

3.1 The *product exergy* represents the desired result (expressed in terms of exergy) generated by the exergy system. The product exergy is denoted by E_P.

3.2 The *fuel exergy* represents the resources (expressed in terms of exergy) expended to provide the product exergy. The fuel exergy is denoted by E_F. The term "fuel exergy" here is not limited to fossil fuels but represents in general the exergetic resources used to drive (to "fuel") the process being considered.

3.3 The exergetic efficiency is the ratio between product exergy and fuel exergy and is denoted by ε (Greek epsilon). The inverse of the exergetic efficiency is denoted by the symbol κ (Greek kappa). The terms second-law efficiency and rational efficiency are not precise and should be avoided when an exergetic efficiency is implied by them.

3.4 The energetic efficiency, defined in a similar way as the exergetic efficiency but using only energy terms, is denoted by η (Greek eta).

3.5 The thermodynamic inefficiencies of a system consist of exergy destruction (E_D) associated with the irreversibilities (entropy generation) within the system and of exergy losses (E_L) associated with the transfer of exergy (through material and energy streams) to the surroundings. The use of the term irreversibility (instead of exergy destruction) and the symbol I should be avoided. The term irreversibility does not imply that the exergy concept is used because the exergy destruction can be calculated from entropy values alone.

4 ALTERNATIVES IN THE NOMENCLATURE

The suggestions made above refer to publications in journals and conference proceedings when exergy is mainly used and total energy is mentioned, if at all, in passing. For such applications addressed mainly to exergy

practioners, the letter E can used for exergy without creating confusion.

The situation might be different if we deal with students who might be easily confused by differences in notations. For textbooks an E should be used for total energy. This is in accord with current use in most textbooks.

Then we have the following options for the exergy symbol. The options presented in order of decreasing simplicity and degree of preference.

Option 1: Use the letter E in a different font, for example the roman font E (instead of an italic E). Experience with textbooks using this option (e.g., [2]) shows that this seldom results in confusion. Texts and instructors simply need to point out the different fonts being used.

Option 2: Use a Greek epsilon ($\mathcal{E}, \varepsilon$). This option requires that a letter different than ε (for example, Greek zeta ζ) is used for the exergetic efficiency since now ε represents the specific exergy.

Option 3: Use the letter X (x) which is the second one in the word exergy. This letter is used, however, to denote an unknown variable in mathematics.

Option 4: Use a Greek epsilon ($\mathcal{E}, \varepsilon$) for the exergy associated with material and energy streams and a Greek psi (Ψ, ψ) for the exergy associated with a system, to avoid the use of subscript "sys".

Option 5: Use the two letters Ex (ex).

It is apparent that several more options exist for exergy and also for the other variables associated with exergy costing. Authors should consider that simplicity and ease of use are very important factors in selecting the exergy symbol.

5 EXERGOECONOMICS: EXERGY COSTING

Exergoeconomics is the branch of engineering that appropriately combines thermodynamic evaluations based on an exergy analysis with economic principles to provide the designer or operator of an energy system with information (a) useful to the design and operation of a cost-effective system, and (b) not obtainable by regular energy analysis and economic analysis. Exergoeconomics rests on the notion that exergy is the only rational basis for assigning monetary costs to the interactions that a system experiences with its surroundings and to the sources of thermodynamic inefficiencies within it. We call this approach *exergy costing*. When exergy costing is **not** applied, authors should use a different term (e.g., thermoeconomics). Thermoeconomics, being a more general term and characterizing any combination of a thermodynamic analysis with an economic one, might also be used instead of the term exergoeconomics (but not vice-versa). The following definitions and symbols are recommended in publications dealing with exergoeconomics:

5.1 The exergetic cost of a stream represents the fuel exergy that needs to be supplied to the overall system to generate the exergy associated with that stream. The exergetic cost is denoted by E^c. The product and fuel exergetic costs are denoted by E_P^c and E_F^c, respectively. The unit of exergetic cost is the ratio between exergetic cost and corresponding exergy and is denoted by the symbol k^c.

5.2 The cost associated with an equipment item is denoted by Z.

5.3 The cost associated with a material or energy stream in exergoeconomics is denoted by the symbol C. The average unit cost (usually a cost per unit of exergy) is denoted by c.

5.4 When marginal costs are used, these must be explicitly defined. A λ (Greek lambda) may be used for this purpose.

The following section summarizes the symbols suggested here for publications in journal and conference proceedings.

6 NOMENCLATURE

c	average cost per exergy unit
C	cost associated with a stream
e	specific exergy
E	exergy
E_{sys}	total exergy of a system
E_{sys}^{PH}	physical exergy of a system
E^c	exergetic cost
h	specific enthalpy
H	enthalpy
k^c	unit of exergetic cost
p	pressure
s	specific entropy
S	entropy
T	temperature
u	specific internal energy
U	internal energy
v	specific volume
V	volume
$\vec{v}$	velocity relative to the environment
z	height relative to the environment
Z	cost associated with equipment

Greek letters

ε	exergetic efficiency
η	energetic efficiency
κ	inverse of the exergetic efficiency
λ	marginal cost (optional)

Subscripts

D	exergy destruction
F	fuel exergy
L	exergy loss
P	product exergy
sys	system
0	conditions of the thermodynamic environment

Superscripts

c	exergetic cost
CH	chemical exergy
KN	kinetic exergy or energy
M	mechanical exergy
N	nonreactive exergy
PH	physical exergy or energy
PT	potential exergy
R	reactive exergy
T	thermal exergy

ACKNOWLEDGEMENT

This project was initiated by Noam Lior. In addition to him, input was provided by many exergy practioners including the following:

Cai Ruixian
Michel Feidt
Christos Frangopoulos
Richard Gaggioli
Signe Kjelstrup
Andrea Lazzaretto
Giampaolo Manfrida
Alberto Mirandola
Michael Moran
Silvia Azucena Nebra
Gordon Reistadt
Ricardo Rivero
Enrico Sciubba
Antonio Valero
Michael von Spakovsky

Some of the above listed practioners disagree with some of the suggestions made here.

EXERGY ANALYSIS OF ZERO CO_2 EMISSION POWER PLANTS

V. Amati, P. Fiorini(*), E. Sciubba
University of Roma 1 "La Sapienza"
Mechanical and Aeronautical Engineering Department
Italy

ABSTRACT

A modular simulator code, CAMEL®, developed by the University of Roma 1, has been applied to a simulation of a series of "zero emissions" and high efficiency cycles. The code libraries have been augmented by adding property data for all working media involved (H_2, high temperature steam) and by developing some additional component models.
Due to the social, political and economic changing attitude towards greenhouse emissions, more and more processes are being considered that include CO_2 removal in some form. Of the different solutions for CO_2 separation recently presented in the literature, we chose here to analyze the one based on chemical or physical absorption upstream of the combustion process: pure hydrogen is burnt in presence of pure oxygen to produce superheated steam. Three different solutions are considered, all based on non-conventional plant configurations: two of them are H_2/O_2 cycles and the third one is the so called ZECOTECH® cycle. The main features of all three configurations are presented and their thermodynamic cycles are simulated in order to perform an exergetic analysis and to carry out a better insight of the losses and of their relative importance on the process performance indicators.
Keywords: simulation, innovative and "Zero Emission" cycles, exergetic analysis.

NOMENCLATURE

C	Compressor
cc	Combustion chamber
CSB	Coefficient of structural bond
E_d	Exergy destroyed in a component [kW]
E_F	Exergy resource [kW]
E_U	Useful exergy production [kW]
ex	Specific exergy [kJ/kg]
h	Specific enthalpy [kJ/kg]
HPT	High pressure turbine
HRSG	Heat recovery steam generator
K	Condenser
k	Specific heat ratio
LHV	Lower heating value [kJ/kg]
LMTD	Logarithmic mean temperature difference [°C]
LPT	Low pressure turbine
m	Mass flow rate [kg/s]
MPT	Medium pressure turbine
N	Number of stages
P	Net power output [kW]
$p_{out,MPT}$	Medium pressure turbine outlet pressure [bar]
q	Heat transfer for unit of mass [kJ/kg]
ST	Steam turbine
T	Temperature [K]
Tmax	Top cycle temperature [°C]
TTD	Terminal temperature difference [°C]
β	Total pressure ratio
ε	Exergetic efficiency
η	Energetic efficiency
η_s	Stage adiabatic efficiency

$\pi_{k,i}$ Coefficient of structural bond for component k, with the variation of the parameter x_i

INTRODUCTION

The need to cover an ever-increasing final energy demand and the consciousness of the necessity of setting a limit to the related emissions is prompting design engineers to concentrate their attention not only on the repowering of technically obsolete power plants but also on the development of "innovative" solutions. A long time perspective directs these studies towards the possibility of using renewable and "clean" energy sources. If one considers the present world energetic situation (energy resource availability, current state of art of the energy conversion technologies) and the foreseen developments in the short and medium term, it is immediately clear that the energy resources that can be realistically exploited for large scale production are still those of fossil origin, in particular coal. One of the problems related to the use of fossil fuels is of course the technology employed for the fuel treatment and combustion: any process involving a carbon-rich fuel implies CO_2 emission in the atmosphere. Several removal and sequestration techniques have been proposed, some based on chemical or physical fuel treatment upstream the power cycle, that is fed by a carbon-free syngas (for example coal gasification with production of H_2 and CO_2 removal through MEA or $CaCO_3$-methods [3], natural gas decarbonisation [8]). Others techniques are based on CO_2-capture in an intermediate phase of the power cycle [1].

In the present paper, the energetic and exergetic performance of some of the so-called "Zero Emission" innovative cycles of the first category are analyzed. All process calculation are performed by means of a modular code for the simulation of energy conversion processes; the code, CAMEL®, has been developed by the Authors' group at the Mechanical and Aeronautical Engineering Department of the University of Roma 1, "La Sapienza"[4,5]. The work is the result of three consecutive stages:

1) Up-dating of the code: it has been necessary in order to perform, with the same simulator, the analysis (and consequently the comparison) of innovative cycles that, until now, have been studied by using different codes. In this step the selected cycles have been used as a "test bench" to verify the performances of CAMEL®; for this reason they were chosen between those cycles for which a simulation was already performed; see that their plant configurations are the results of accurate and published analysis [3,6] only a brief description of them will be here reported. For all the details concerning the optimization and the methodology used in the plant design we recommend [3,6].

2) Simulation of the cycles and testing of the code: the results of the simulations have been compared with the available data. This stage has been positively completed: the code allows the simulation of different typology of power plants while the integration of other modular elements is actually in execution; they will make possible the simulation of the whole power generation process including all the sub-processes (coal gasification, CO_2 sequestration, O_2 production) that here cannot been considered.

3) After these works of implementation, calculation and testing, the new possibilities offered by the code have been exploited to develop the plant analysis by adding an exergetic evaluation of the cycles that will be here discussed more in detail.

THE PROCESSES SELECTED FOR THE ANALYSIS

The proposed plant configurations enact an internal combustion steam cycle fed by hydrogen: the oxidizer being pure oxygen, superheated steam is the product of the combustion, while cogenerated steam is injected in the combustion chamber as an "inert" to control the gas temperature and to limit oxygen consumption. The selected cycles are:

1-2) H_2/O_2 Cycle-case a (T_{max} = 1350°C, Figure 1) and case b (T_{max} = 1700°C). Both were proposed by the research group of the Science and Energy Technologies Department of the University of Roma 2, "Tor Vergata"[6].

3) ZECOTECH® Cycle, jointly developed by the Energy Department of ENEA (Italian National Agency for New Technologies, Energy and Environment), the Ansaldo Group and the Department of Mechanical and Aeronautical Engineering of the University of Roma 1, "La Sapienza"[3].

DESCRIPTION OF THE PLANT LAYOUTS

The proposed plant layouts are described in this section: Tables 1-3 contain the values of the most relevant thermodynamic parameters evaluated during the simulations.

Cycle n°1 and 2 (H_2/O_2 cycles)

The two examined cycles, (cycle n°1 in Figure 1), result in similar plant layout; but while Cycle (1) is designed by respecting the present or the short-term state of the art (T_{max}=1350°C and β=30), Cycle (2) is developed by considering the possible development for the gas turbine technology in the medium and long term (T_{max}=1700°C e β=70) [9]. It differentiates from Cycle (1) for the addition of a low pressure section (steam turbine and condenser) downstream the HRSG.

Cycle n°3 (ZECOTECH®)

A first study [3] was conducted on the potentialities of the cycle, considering both the power section than its necessary coupling with the chemical section in which the hydrogen synthesis and the sequestration processes take place. The resulted optimal plant configuration is shown in Figure 2.

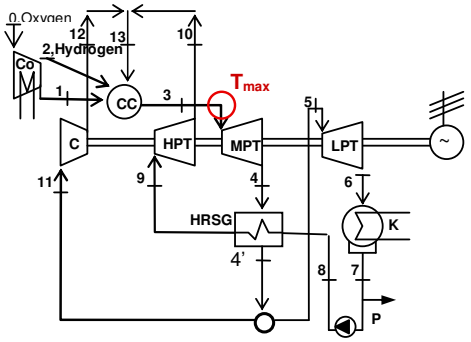

Figure 2: Plant layout of ZECOTECH® Cycle

The pressure level required by the sub-processes upstream the power unit (gasifier and decarbonator) limit the pressure in the combustion chamber to 30 bar. The MPT outlet pressure ($p_{out,MPT}$) was found to be one of the most influential parameters on cycle efficiency; for this reason, as a first step in this work, a sensitivity analysis was carried out to quantify the dependence of the cycle efficiency on the variation of $p_{out,MPT}$ for different T_{max}. Throughout the tests, the following assumptions were made:

a) Turbine and compressor adiabatic efficiencies are function of the total pressure ratio and of the consequent number of stages as reported in formulas (1) and (2), [10]. For the expansion and compression ratio of individual stages, the value of 2 for the turbine and of 1.25 for the compressor have been assumed. For a turbine we have:

$$\eta_{ad,TOT} = \frac{1-[1-\eta_s(1-\beta^{(1-k)/Nk})]^N}{1-\beta^{(1-k)/k}} \qquad (1)$$

Whereas for a compressor we have:

$$\eta_{ad,TOT} = \frac{\beta^{(k-1)/k}-1}{[1+(\beta^{(k-1)/Nk}-1)/\eta_s]^N-1} \qquad (2)$$

The stage adiabatic efficiency was assumed equal to 0.90 for the turbines and to 0.89 for the compressors.

b) Pressure losses along the circuit have been neglected; in the exchangers and in the combustion chamber they are equal to 2%:

c) Combustion energy efficiency is equal to 0.98;
d) The hydraulic efficiency of the pump is equal to 0.85;
e) The energy efficiency of the generator is equal to 0.98;
f) The coolant used in the intercooler and in the condenser is water at ambient conditions (298.15 K and 1.01 bar).
Figure 3 shows the results of the analysis: the optimal MPT discharge pressure decreases with increasing T_{max} : for T_{max}=1350°C the optimal pressure is equal to 1.5 bar, while for T_{max}=1700°C it is equal to 1 bar.

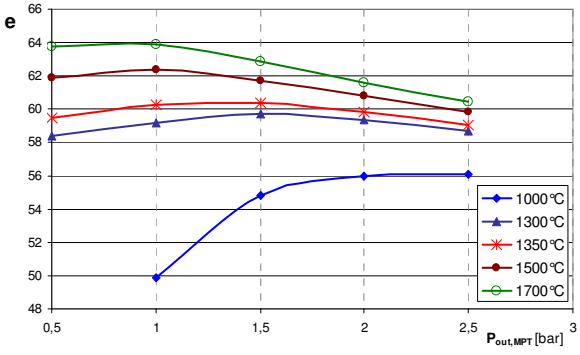

Figure 3: Exergetic efficiency as function of $p_{out,MPT}$

The following simulations of cycle (3), whose results are reported in Tables 2 and 4, have been performed with T_{max} respectively equal to those reached in cycles (1) and (2) (and with the optimal values of $p_{out,MPT}$), to compare the overall performances .

ENERGETIC ANALYSIS

On the basis of the results of the simulations the energetic performances have been examined and summarized in Table 3. For better comparison, the results obtained for the three plants are all referred to the unit of oxygen consumed. For LHV, the value of 114703 kJ/kg was assumed, in accordance to [6] and in order to compare their results with the ones of CAMEL®, even if we recognize that the usual value should be 120 MJ/kg.

	Cycle 1	Cycle 2	ZECOTECH®

EXERGETIC ANALYSIS

Purpose of this work is to perform an explicit exergy analysis of the plant, to identify the components that in each of the proposed solutions are affected by the highest irreversible losses and that consequently ought to be given more attention during the design phase. The results of such an analysis provide the designer with a better insight as of where a design modification is necessary, both at the single component and at a process level, to the purpose of better exploiting the available resources. For each cycle the following evaluations were made [2]:

a. Exergetic efficiency of each component, ε:
   $\varepsilon = E_U / E_F$
   with E_U and E_F respectively the useful product and the resource of the component, always evaluated in exergetic terms.

b. Exergy destroyed in each component, E_d (kW), and in the whole plant, $E_{d,tot}$ (kW).
c. Dimensionless loss parameters:
   - $E_d\% = E_{d(component)} / E_{d,tot} \times 100$
     Ed% is thus the percentage of exergy destroyed in the component with respect to the total exergy destroyed in the plant.
   - $E'_d\% = E_{d(component)} / E_F \times 100$
     This is the percentage of exergy destroyed with respect to the total exergy resource influx into the process.
d. Evaluation, for cycle (1) and (3), with T_{max}=1350°C, of the coefficient of structural bond or CSB, defined as [7,11]:

$$\pi_{k,i} = \frac{\left(\frac{\partial E_{d,tot}}{\partial x_i}\right)}{\left(\frac{\partial E_k}{\partial x_i}\right)} = \left(\frac{\partial E_{d,tot}}{\partial E_k}\right)_{x_i=var} \approx \left(\frac{\Delta E_{d,tot}}{\Delta E_k}\right)_{x_i=var} \quad (3)$$

π represents the ratio between the variation of the exergy destroyed in the plant ($E_{d,tot}$) to that destroyed in the k^{th} single component (E_k) when only the changing of parameter x_i is imposed. The CSB allows an examination of the positive or negative influence of each single component on the overall plant performance when some of the working parameters are changing. It is useful to recall the values π can assume and their meaning:

- $\pi_{k,i} > 0$: when the parameter x_i is changing, to a decrease in the exergy destruction in the k^{th}-component corresponds a decrease in the total exergy destruction of the plant. A value much higher than one can be explained as follows:
  1. Considering the third member in Formula 3, a small variation of E_k corresponds to a large variation of $E_{d,tot}$;
  2. Considering the second member of Formula 3, a high value of $\pi_{k,i}$ means that the derivative $\partial E_k/\partial x_i$ is much lower than $\partial E_{d,tot}/\partial x_i$: the parameter x_i has a much lesser influence on the exergy losses of the k^{th}-component than the one it has on the whole plant.

  When $0 < \pi_{k,i} < 1$, to a decrease of E_k corresponds a lower decrease of $E_{d,tot}$: this is due to the fact that other components at the same time are causing a $\Delta E_{d,tot}$ of opposite sign respect the one caused by the k^{th}-component.
- $\pi_{k,i} = 0$: the k^{th}-component does not influence the variation of $E_{d,tot}$.
- $\pi_{k,i} < 0$: when the parameter x_i is changing, to a decrease in the exergy destruction in the component k corresponds an increase in the total exergy destruction of the plant, that is higher for high values, in absolute terms, of $\pi_{k,i}$.

Cycle n°1 and 2° (H_2/O_2)

$E_{d,tot}$		**5728.59**	**100.00**	**41.74**

Table 5: Syntesis of the exergetic analysis of Cycle n° 1

For the intercooled compressor the analysis has been performed first on each single stage and the connected intercooler, and then for the multistage machine as a whole, in order to evaluate the effect of intercooling on the exergetic efficiency: it is well known that intercooling reduces the overall power absorption, but the exergetic cost of the use of an external coolant is such that it decreases the total efficiency: all single stages have an ε higher than 90% and intercooling decreases this value to 82.7%. The thermodynamic reason is clear: heat is transferred to a cooler medium (the cooling water) and dispersed in the environment with no further recovery. However, it must be considered that the ratio between the power-gain obtained with the intercooling (ΔP) and the exergetic cost associated to it ($\Delta ex_{coolant}$) is much higher than one:

$\Delta P = P_{non\ interc} - P_{interc} = 496 - 442 = 54$ kW

$\Delta ex_{coolant} = 3.5$ kW

And therefore there is a global advantage, at process level, in adopting an intercooled configuration.

The major percentage of loss is found, as expected, in the two combustion chambers and in the heat-recovery exchanger (HRSG); the former enacts an irreversible process (the transformation of

chemical into thermal exergy); the lower the temperature of the reactants, the higher the exergy losses: the temperature of the mixture steam-O_2 at the inlet of the cc2 is 1050°C versus 500°C at the inlet of cc1: the value of E_d for this last component is in fact much higher than for cc2.
In the HRSG the losses are, percentage wise, even higher than in cc2: such a high value is caused by the high temperature difference between the two streams inside of the heat exchanger: both the terminal temperature differences and the LMTDs for the two media (gasification with superheating and re-superheating) are very high:
$LMTD_1$ (gas, sh)=236 °C; TTD_1 (gas,sh)= 615°C;
$LMTD_2$ (rh) = 200 °C; TTD_2 (rh) = 700°C.
Such an analysis is useful because it directly suggests a process modification: that of substituting the hypercritical boiler with a subcritical one, with more than one pressure level. With this latter solution the thermal profiles of the two streams are shifted towards lower LMTDs.
All turbines present a very high efficiency that, as expected, increases with the respective outlet temperatures: exergy evaluates not only the enthalpic term (real enthalpy drop with respect to the ideal one): in the term in the denominator of ε, that represents the exergy input in the machine, an entropic term is also present that accounts for the real conditions of the stream at the outlet and for the possibility that it can be still used for another thermodynamic process. For this reason, the higher the outlet temperature, the higher the exergetic efficiency (for equal inlet conditions).
For cycle (2) the typology and the distribution of the losses are similar to those of cycle (1) but result in a lower amount (E'd= 40.9%).

Cycle n°1: evaluation of CSB

In this section we shall examine the modification of the plant working conditions with a variation of the top cycle temperature: we shall do this by evaluating the values of the CSBs for each component. All the other working parameters imposed as input in the simulation have been maintained constant while T_{max} is changed about its nominal value of 1350°C (± 10%). All the analysis has been performed considering equal exergetic input for each test (equal fuel consumption); for each run all the variations of the working parameters not fixed as input (as the steam mass flow rate) have been registered in order to evaluate π.

It is well known that increasing the top cycle temperature leads to an increase of the overall plant efficiency; also from an exergetic point of view, it results that the total losses decrease. The analysis of the signs and of the magnitude of CSB are useful to examine which components provide a higher contribution to this improvement and which ones, on the contrary, present a trend of their losses E_k discordant with the $E_{d,tot}$: for the latter, a negative value of CSB means that the optimization of their configuration and characteristic working parameters cannot be conducted by varying the chosen parameter x_i (in this case T_{max}), because this causes negative effects on the overall plant performance. Figure 4 presents the trends of CSB for the components more influenced by the variation of T_{max}: the intercooled compressor is not interested at all by this parameter while HPT, MPT, LPT present CSB >>1, which reflect their secondary influence on the value of $E_{d,tot.}$. On the contrary it is interesting to investigate about the CSB of the other components; we can observe the following:
a) Combustion chambers: they presents opposite signs of CSB: to an increase of T_{max} corresponds a decrease of the exergy destruction (CSB>0) for the first cc and an increase for the second one (CSB<0). This can be justified as follows: considering equal total fuel consumption, the necessity of reaching higher temperature for the combustion products has opposite consequences on the streams that flow through the two chambers; in the first cc there is a decrease of the fuel consumption and a higher T_{max} is guaranteed by injecting a lower rate of steam as inert: limiting the fuel mass flow rate leads here to a decrease of the combustion irreversibility rate. In the second cc, even if the reactants enter with a higher value of enthalpy, it is however necessary, to increase the temperature of the products, to increase fuel consumption and consequently the irreversible conversion of chemical to thermal exergy.

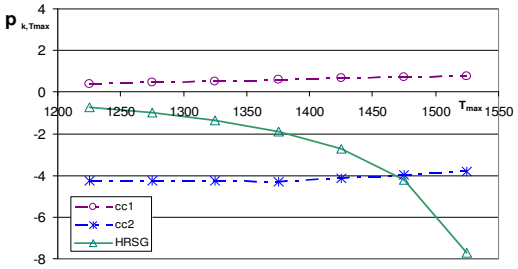

Figure 4: CSB for the components of Cycle 1.

b) HRSG: CSB<0, and its losses are always increasing with $T_{max.}$ This trend is due to the departure of the thermal profiles of the two streams, due to the fact that the hot gas outlet temperature (section n° 8 in Figure 1) is maintained equal for each test (to ensure equal inlet conditions into the pump) while the inlet temperature continues to increase. Consequently, the total heat transfer for unit of mass, q, is increasing in the exchanger. The outlet temperatures of the SH and RH steams (points 10 and 12) are maintained fixed because they represent respectively the value of the TIT for the ST and the temperature of the steam injected in the cc; this means that the higher value of q is exchanged with the external coolant in the phase of condensation and undercooling of the hot steam.
It is clear that, in a global perspective, a higher value of the top cycle temperature has positive effects on the plant performance; the negative value of the CSB characteristic of the HRSG is in fact more than counterbalanced by the value of the coefficients for the other components.
Such an analysis can guide designers' attention on the HRSG design: it is the only element that suffers from higher values of $T_{max,}$ and finding new solutions for its design could permit to better exploit the technological efforts connected with the reaching of higher TIT.

Cycle n°3 (ZECOTECH®)
The highest contribution to the total exergy destruction is again provided by the cc, the only one, in this case, of the plant. The losses in the HRSG on the contrary are much lower with respect to Cycles n°1 and 2, even if a direct comparison makes little sense due to the different connectivity.
The thermal profiles of the two streams are closer for the case 1350°C (LMTD=180°C) than for the case 1700°C (LMTD=260°C), and in this latter case the losses of the component are consequently higher (E_d=15%).

	ε	E_d	E_d%	E'_d%
C	0.9453	1125.7	3.22	1.48
HPT	0.9261	339.0	0.97	0.45
MPT	0.9530	2461.7	7.03	3.24
LPT	0.8967	875.0	2.50	1.15
PUMP	0.4746	182.4	0.52	0.24
HRSG	0.7718	4327.4	12.36	5.70
K	0.0517	642.7	1.84	0.85
cc	0.7855	25057.7	71.57	33.01
$E_{d,tot}$	-	***35011.6***	100.00	46.13

Table 6: Synthesis of the exergetic analysis of Cycle 3-T_{max} =1350°C

In percentage, the losses for the MPT are quite high; this is the turbine with the highest outlet temperature and also the highest efficiency (that is higher in the case of T_{max}=1700°C, ε=0.96); such high losses can be explained considering that while the MPT processes the entire mass flow rate of steam, only a fraction of the total mass flow rate flows in the other two turbines and in the compressor: 36% of the total is directed to the LPT and evolves in the HPT too, while the remaining 64% constitutes the flow rate of the compressor.

Cycle n° 3: evaluation of CSB
Even for this plant we shall evaluate the CSB considering the variation of $T_{max.}$ Figure 5 reports the results obtained by changing T_{max} around its nominal value and maintaining $p_{out,MPT}$ at the optimal value (1.5 bar).

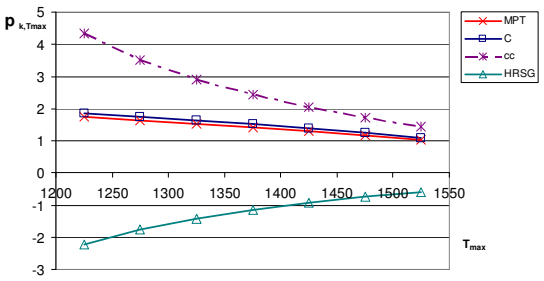

Figure 5: CSB for the components of Zecotech® Cycle, with a variation of T_{max}.

As expected, increasing the top cycle temperature leads to an improvement of the overall efficiency and it is accompanied by a decrease in the total exergy losses.
The components not displayed are those that are less influenced by a variation of T_{max} (LPT, HPT, K): the conditions of the streams at their inlet and outlet in fact remain constant during the tests (the TIT and expansion ratio of these two turbines are fixed as well as the outlet temperature of the water condensed), so that their decreasing losses are due only to the decrease of the steam mass flow rate in the plant.
The components which present CSBs closer to one have their performances more influenced by the variation of T_{max}, and this is the case for cc, MPT, HRSG and C (Figure 5). The cc and the MPT are directly influenced by this parameter, because it represents the gas outlet temperature of the burner and the inlet temperature of the downstream

turbine; the compressor is influenced only by the decrease of the steam mass flow rate (that is necessary to guarantee, with equal fuel consumption, a higher top cycle temperature), but more than the other components already analyzed: the decreasing steam rate is higher for the stream directed to the compressor than for the one fed into the LPT. Also in this plant, the HRSG has a negative CSB. It is possible to observe that the total heat transfer decreases with increasing T_{max}: the inlet condition of the water pumped (section 8, Figure 2) and the outlet temperature of the SH-steam (section 9) remain constant while the water mass flow rate decreases; the hot gas outlet temperature (section 4') is fixed too (because it coincides with the fixed LPT inlet temperature), while the inlet gas temperature (section 4) is increasing with T_{max}: the heat transfer is lower with respect to the base case because of the contemporary decreasing of the hot gas mass flow rate. Consequently, the growing irreversibility rate is due to the departure of the thermal profiles of the two streams.

CONCLUSION

The importance of the analysis of "innovative power cycles" has been discussed: the energy resources ought to be exploited with the maximum reachable efficiency compatible with the concepts of sustainability and eco-compatibility. The H_2-fed cycles examined belong to this new category of plant, but to define them as "high efficiency cycle" is not proper at all. The isolated power plants have demonstrated to have really high efficiency, but the analysis ought to be carried out considering all the sub-processes connected with the power generation unit: fuel treatment, gasification of coal, oxygen separation, CO_2 sequestration and removal. The principle of the exergetic analysis can highlight possible ways to follow to improve the plant design. The use of a complex simulation code proved to be a very useful instrument to execute all the necessary analysis, allowing for a fast and accurate evaluation of all the fundamental working parameters; moreover, the possibility of use a "home-made" code, CAMEL®, guaranteed a large flexibility of analysis: it has been used not only as a simple simulator of processes but even as a post-processing instrument for carrying out the desired energetic and exergetic analysis. It's necessary to complete the extension of the code to simulate the other sub-processes mentioned.

ABSTRACT

Absorption cycles are an alternative to compression cycles in cooling and refrigeration applications. The thermoeconomic analysis could contribute in improving their cost effectiveness. Our approach is based on the exergy and the structural analysis. Once the exergy analysis has been achieved by a structural analysis, the coefficients of structural bonds (CSB's) of the main heat and mass exchangers can be determined. The CSB's show how the modification of the irreversibility of one component, by means of a variation of its efficiency, affects the whole cycle. It will be wise to put much of the design effort in improving the efficiency of a component, knowing that a slight decrease of the irreversibility of that component, thanks to a higher efficiency, results in an important improvement in the total irreversibility of the cycle. This methodology is applied to a single effect ammonia-water absorption cooling cycle. We also study how the selection of efficiency parameters affects the results comparing CSB's of heat exchangers obtained from the minimum temperature differences or the UA-values.
Results show that the UA is a more suitable parameter than the minimum temperature difference. Concerning the CSB values, we obtain very high values for the condensate subcooler. Values above one are also observed for the absorber, condenser and generator. Lower values are found for the generator and the solution heat exchanger. A more detailed analysis should investigate the dependence of the CSB values on the range of efficiencies. As a further step, these results could be used in the thermoeconomic analysis and optimization.

NOMENCLATURE

CSB	Coefficients of structural bonds
CP	Product of mass flow and specific heat (kW K^{-1})
e	Specific exergy (kJ kg^{-1}, kJ $kmol^{-1}$)
$\dot{E}$	Exergy flow (kW)
h	Specific enthalpy (kJ kg^{-1})
$\dot{I}$	Irreversibility (kW)
$\dot{m}$	Mass flow
p	Pressure (bar)
$\dot{Q}$	Heat flow (kW)
R	Gas constant (kJ/kmol K)
s	Specific entropy (kJ kg^{-1} K^{-1})
T	Temperature (ºC or K)
UA	Product of heat transfer coefficient and heat transfer area (kW/K)
$\dot{W}$	Mechanical power (kW)
x_i	Parameter in the efficiency variation of the CSB, molar concentration
z	Concentration (mass fraction ammonia) (kg/kg)

Greek letters

γ	activity coefficient (-)

Indices

0	environmental state (25ºC, 1 bar)
ch	chemical
e	exit
i	inlet, component of the mixture
k	component k
ph	physical
t	total

Italic Numbers

9	Refrigerant expansion valve
10	Solution expansion valves
11	Adiabatic rectification plates

INTRODUCTION

Cycles used for cooling and refrigeration are mostly based on mechanically driven compression cycles. As the cooling demand in summer in southern countries leads to a peak in electricity consumption, alternative technologies use should be favoured.

One possibility consists in absorption cycles ([1, 2]). Their principal advantages compared to mechanically driven compression cycles are that they use natural refrigerants and, consequently, they do not contribute to the destruction of the ozone layer, and that they are thermally driven and consume only a little electrical energy. Besides some circulating pumps do not have moving parts.

Absorption cycles use a working pair consisting on a refrigerant and an absorbent. Generally these are water-Lithiumbromide (LiBr) and ammonia-water. They are not contributing to the destruction of the ozone layer and to the global warming effect. The basic absorption cycle structure is the single effect, with four basic components: absorber, generator, evaporator and condenser.

One important drawback in the actuality is the comparatively higher initial cost of absorption cycles compared to compression cycles. In order to reduce the cost of the absorption cycles we try to apply the thermoeconomic analysis and optimisation in order to get more cost-effective designs ([3, 4]). This has been done to some extent for compression systems ([5-10]), but less for absorption systems ([11-14]).

In this work we will present how we use the structural method of thermoeconomic optimisation

The exergy analysis can simplify this optimization by structural coefficients ([15, 16]). They show how local irreversibilities in components affect the overall irreversibility rate of the cycle.

In our case we will use the coefficients of structural bonds (CSB). The CSB of a component k, which is obtained by a parameter x_i, is defined by

$$CSB_{k;i} = \left(\frac{\partial \dot{I}_t}{\partial \dot{I}_k} \right)_{xi=\text{var}} \quad (1)$$

I_k is the irreversibility rate of the component k, I_t is the Irreversibility rate or also called the exergy loss of the whole cycle. In order to obtain the CSB we study the effect of a variation of a parameter x_i, which can be an efficiency-related parameter, on the irreversibility rate in the component under consideration and on the whole cycle.

Structural coefficients consider how the irreversibility of the whole cycle changes when we modify the irreversibility of one component by means of a variation of its efficiency. If a slight decrease of the irreversibility of one component due to a higher efficiency causes an important improvement in the total irreversibility of the cycle, it will be wise to put much of the design effort in improving the efficiency of this component. In the case of a high coefficient of structural bonds the benefit of a more efficient and thus more expensive component on the performance of the whole cycle will be considerable. Otherwise, if the coefficient of structural bonds is low, near unity, an improvement of the efficiency of the considered component is not economically worthwhile.

Modelling starts with first law analysis ([17-20]). Once obtained the corresponding results we can achieve the exergy analysis in order to obtain the irreversibilities ([21-24]). Now we can achieve the structural analysis using the coefficients of structural bonds.

In our study this methodology will be applied to an ammonia-water single effect cycle.

DESCRIPTION OF THE ABSORPTION CYCLE

Figure 1 shows a single-effect ammonia-water absorption cycle. The components are numbered in italics. Basic components are the absorber (*1*), the condenser (*2*), the generator (*3*), and the evaporator (*4*). The cycle is completed by the condensate subcooler (*6*), the solution heat exchanger (*7*), the condenser of the rectification column (5) and the adiabatic rectification plates. There are three adiabatic plates, which is the optimum number for this configuration ([20]).

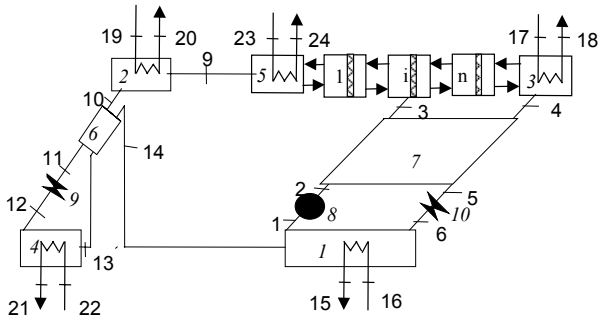

Figure 1: Single effect absorption cycle

The figure presents the cycle in a pressure-temperature plot. The pressure increase upwards and temperatures increase to the left. In the following description cursive letters refer to the components, normal ones to the state points.

The solution circulates between the absorber (*1*), where the refrigerant is absorbed at low pressure, and the generator (*3*), where the refrigerant is desorbed at high pressure (state points 1 to 6). The strong solution leaves the absorber (*1*), is preheated in the solution heat exchanger (*7*), and enters the rectification column in central plate two. Temperature and water concentration increases from plate one to plate three. The generator acts as the reboiler of the rectification column. The weak solution (4) leaves towards the absorber. In the condenser of the rectification column, we obtain the necessary liquid reflux, while the rest of the vapour (9) condenses completely in the condenser (10) and is cooled in the condensate subcooler (*6*). The condensate expands in the refrigerant throttle valve and enters the evaporator(*4*). Due to the water content of the mixture, the evaporation takes place with a temperature glide. The temperature increases during the vaporisation process as the liquid contains less and less ammonia, which is the more volatile component. Vaporisation in the evaporator is only partial. For total evaporation, the temperature glide would be too high. The cycle is closed when the vapour with a small liquid fraction (13) passes through the condensate subcooler (*6*) and enters the absorber (*1*). Streams 15 to 22 are the external heat transfer fluids (in all cases we assume this is water), which deliver or extract the heat.

The useful production of cooling takes place in the evaporator (*4*), heat is supplied in form of hot water to the generator (*7*), and heat is dissipated at an intermediate temperature in condenser (*2*) and absorber (*1*).
To obtain the necessary pressure changes, the cycles include the solution pump (*8*), the refrigerant expansion valve (*9*) and solution expansion valve (*10*).

Methodology of simulation for absorption cycle
A thermodynamic model was developed for the absorption cycle using the program Engineering Equation Solver (EES). Properties for ammonia water are given by Tillner-Roth and Friend [25].
We evaluated properties for all state point including specific exergies. After conducting the exergy analysis, we computed the irreversibilities.

The input data, output data, main assumptions and operating conditions are presented below.

The input data are:
- The cooling power of the evaporator, which is fixed in all calculations
- The inlet and outlet temperatures of the external fluids
- The minimum temperature difference in the heat and mass exchangers

The output data are:
- The pressures, temperatures, concentrations, mass flows, enthalpies, entropies and exergies of each current
- The thermal or, in the case of the solution pump, mechanical power and irreversibility rate of the main components.
- The COP and exergetic efficiency

The main assumptions are:
- Steady state
- There are no heat losses
- There are no pressure losses
- The refrigerant leaving the condensers is saturated liquid
- The solution leaving the generators is boiling
- The solution leaving the absorber is saturated
- On adiabatic rectification, plates leaving liquid and vapour are in equilibrium
- The solution and refrigerant valves are adiabatic

The operating conditions are:
- Evaporator cooling capacity 1000 kW

Temperatures:
- Chilled water inlet/outlet 6/12ºC
- Cooling water (parallel flow through absorber and condenser inlet/outlet) 27/35ºC
- Hot water inlet 90ºC
- Minimum temperature difference in the heat exchangers 5 K

The hot water outlet temperature is adjusted to minimise the CP-mismatch in the generator.

Steady state mass and energy balances for the components of the cycles are established as follows:
Global mass balance:

$$\Sigma \dot{m}_i = \Sigma \dot{m}_e \qquad (2)$$

Mass balance for ammonia:

$$\Sigma \dot{m}_i z_i = \Sigma \dot{m}_e z_e \qquad (3)$$

Energy balance:

$$0 = \dot{Q} - \dot{W} + \sum_i \dot{m}_i h_i - \sum_e \dot{m}_e h_e \qquad (4)$$

Exergy balance:

$$0 = \sum_i (1 - \frac{T_0}{T_i})\dot{Q}_i - \dot{W} + \sum_i \dot{m}_i e_i - \sum_e \dot{m}_e e_e - \dot{I} \qquad (5)$$

Specific exergy (eq.6) is made up of a physical (eq.7) and a chemical component (eq.8).

$$e = e_{ph} + e_{ch} \qquad (6)$$

$$e_{ph} = h - h_0 - T_0(s - s_0) \qquad (7)$$

$$e_{ch} = \sum_i x_i e_{ch,i} + RT_0 \sum_i x_i \ln(\gamma_i x_i) \qquad (8)$$

The properties indicated with the subscript 0 refer to the environmental state, which is defined as 25ºC and 1bar.

RESULTS AND DISCUSSION

Energetic analysis
Results of the energetic analysis for the different state points are presented in Table 1. These results

as well as the results for exergy analysis are obtained by fixing a minimum temperature difference in the heat exchangers of 5K, with the exception of the rectifier condenser, which has a minimum temperature difference of 20K.

State point	T [C]	p [bar]	z [kg/kg]	m [kg/s]	h [kJ/kg]	e [kJ/kg]
1	32	4,45	0,519	5,048	72,01	27,32

Table 1: Results of energetic analysis

Exergy analysis

The next step was the exergy analysis. After determining the exergies of the state points, we conducted the exergy analysis. Irreversibilites for the main components are shown in Table 2.

The highest irreversibilities are found in the absorber (*1*), followed by the evaporator (*4*), the solution heat exchanger (*7*) and the generator (*3*). This already includes nearly all the main heat exchangers. The irreversibility of condenser (*2*) and the condenser of the rectification column (*5*) were lower. Smaller contributions were made by the condensate subcooler, the solution pump (*8*) and the expansion valves (*9* and *10*). Irreversibilities in the adiabatic rectification plates (*11*) were also low. Table 3 present exergy in- and output to main components, including as reference also their thermal power and the design UA value.

Component	$\dot{I}$ [kW]
1	38,5
2	9,82
3	18,1
4	30,0
5	6,23
6	1,61
7	24,2
8	3,29
9	3,68
10	3,80
11	1,97

component	$\dot{Q}$ [kW]	UA [kW K^{-1}]	Exergy Input [kW]	Exergy Output [kW]	$\dot{I}$ [kW]
1	1327	259,8	58,2	19,7	38,5
2	1003	110,2	24,7	14,9	9,8
3	1402	280,4	225,6	207,4	18,2
4	1000	200	86,8	56,8	30

Table 3. Energy and exergy flow of main components (in kW) .

The irreversibilities are interesting information as they indicate us where exergy is destroyed. But their usefulness is limited in the sense that they do not show the best way to improve the cycle. For example it is not necessarily the best choice to increase the efficiency of the component with the highest irreversibility, in our case the absorber, as we do not know the interactions with the rest of the system.

Structural analysis

Once the irreversibilities are obtained, we can check how a change of the irreversibility of one component affects the rest of the cycle. This is done using the coefficients of structural bonds, as proposed by [15, 16]. In our case this means that we will vary the efficiency of the different heat

exchangers maintaining the efficiencies of the others constant. We will compare two different approaches. In the first one we use as parameter the minimum temperature difference ΔT_{min}, which will be varied in one component and fixed in the others. In the second case we will use the value of UA for the same purpose.

Figure 2 represents a plot of the irreversibility in the absorber versus the total irreversibility for different minimum temperature differences. We also include on the right scale the corresponding values of ΔT_{min}. As pressure loss is neglected with lower ΔT_{min} the irreversibility of the absorber is reduced. But more interesting is in which way the total irreversibility is affected. This information can be obtained quantitatively by the CSB:

$$CSB_{A;\Delta T_{\min,A}} = \left(\frac{\partial \dot{I}_t}{\partial \dot{I}_A} \right)_{\Delta T_{\min,A}=\text{var}} \qquad (9)$$

We achieved in Figure 2 a lineal interpolation of the values of I[1] versus I_t. The value of 1,51 represents the slope and gives us the mean values of the CSB of the absorber. This means if the irreversibility of the absorber can be reduced by 1kW due to an efficiency increase, the total irreversibility will decrease by 1,51kW. So the benefit for the total cycle is even greater than for the component due to their interactions.

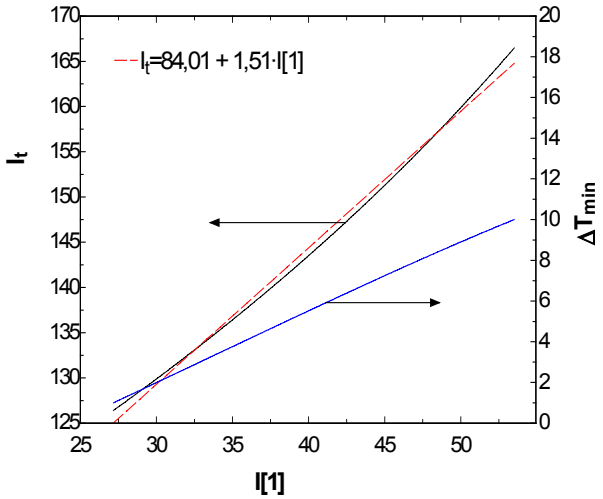

Figure 2 Irreversibility of the Absorber versus total Irreversibility varying ΔT_{min}

Figure 3 represents a similar plot with the difference that the parameter which is varied is UA of the absorber, and the UA-values of the other components are fixed. In order to be able to compare both figures we plotted in the right scale also the corresponding ΔT_{min} values.

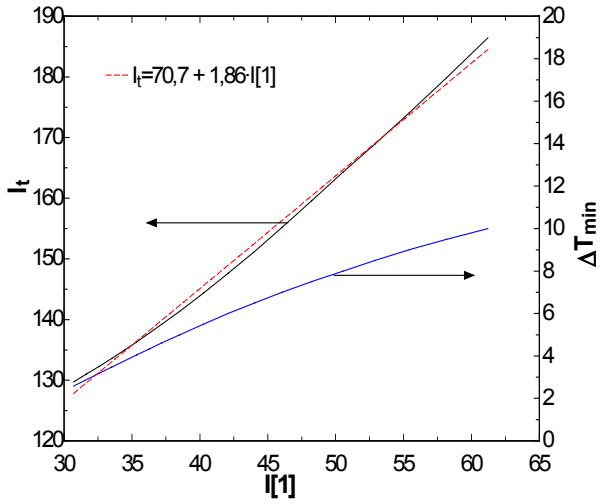

Figure 3 Irreversibility of the Absorber versus total Irreversibility varying UA

The CSB is now defined by

$$CSB_{A;UA_A} = \left(\frac{\partial \dot{I}_t}{\partial \dot{I}_A} \right)_{UA_A=\text{var}} \qquad (10)$$

The value obtained by a lineal interpolation is 1,86, which differs considerably from the formerly obtained value. The difference lies in the behavior of the other components. In the case of fixing ΔT_{min} their efficiencies will remain similar, but their exchange area can be different. In the case of fixing UA their size will be similar, but not their efficiencies. Table 4 presents the results for both parameters, which in some cases differs significantly.

Component number	ΔT_{min} [K]	UA [kW/K]
1	1,51	1,86
2	1,30	1,62
3	0,66	0,875
4	1,43	1,76
6	8,34	9,99
7	2,83	0,80

Table 4 Coefficients of structural bonds CSB for main components of the cycle

But which is the better parameter choice? Our purpose is the use of the CSB in the thermoeconomic optimization of the components. Thus we would like to know how the change of the design parameters of one component affects the whole cycle, while the rest of the cycle is unchanged. The term unchanged fits better to the parameter UA, as this means constant capital cost of the other components. So for us results obtained by variation of UA are more useful.
It is also worthwhile to observe the values. For example, it seems especially interesting to improve the condensate subcooler having a CSB of nearly 10. We can explain this the following way: As a design parameter we fix the cooling output. As a better condensate subcooler achieves lower enthalpies in the inlet of the evaporator, we need less refrigerant to obtain the needed cooling power. Proportionally to the refigerant flow also the solution flow rates will be reduced, and maintaining the UA of the heat exchangers their efficiency will increase.
In similar ways the CSB's of the other components can be explained. These results will be discussed in more detail in a later publication.

CONCLUSIONS

In our work we achieved the energy, exergy and structural analysis of an ammonia-water single effect cooling cycle. The exergy analysis helps us to determine the irreversibilities of the components of the cycle and the total cycle. As a further step we achieve the structural analysis using the coefficients of structural bonds. They indicate us how the irreversibility change in one component affects the rest of the system. The effect of two different parameters have been tested and compared: the minimum temperature difference in the heat exchangers and their UA value. We concluded that for the purpose of a thermoeconomic optimization of the cycle the UA values are more appropriate, as fixing the UA value of a component its capital cost is approximately constant.
Other interesting results of our work are the values of the CSB, which in the case of some components show relatively high values. In the case of a high coefficient of structural bonds the benefit of a more efficient and thus more expensive component on the performance of the whole cycle will be considerable.
This work will be continued for other cycle configurations. Once a set of CSB's is obtained they can be used in the optimization of the components.

ABSTRACT

The paper deals with the problem of the optimized design and conduct of a Claude refrigeration system. The performance of the system is related to the technical characteristics of the key pieces of the refrigeration equipment and is based on the laws of variation of the shares of the exergy destructions in the mechanical work input.
The studied working conditions have resulted from the optimization of the throttling stage after eliminating the technical incompatible variants from the point of view of the heat transfer in the recuperative stage.
This detailed analysis, based on the exergetic balance equation, succeeds in rendering evident the optimum design and operating condition of the whole cryogenic system.
Keywords: cryogenics, optimization, exergy, recuperative heat exchanger

ΔP pressure drop

ΔT temperature difference

INTRODUCTION

The comparative study based on the irreversibility of the working process shows that a way to improve the performance of the Linde refrigeration system is precooling of the forward cryogenic stream with an independent system or by its adiabatic expansion in an expander.

REFRIGERATION CYCLE FLOW DIAGRAM

Figure 1 presents the flow diagram and the T-s diagram for a refrigeration system by adiabatic expansion and throttling with the expander connected in parallel.

The exergetic analysis of the recuperative stage that operates below the environmental temperature reveals that the exergy destruction, that is equal to the anergy generation, increases with the decrease in temperature (eq. 1)

$$I = An_{gen} = T_0 \frac{Q}{T} \qquad (1)$$

Because the major cause of irreversibility is the temperature difference in the recuperative heat exchanger, this should decrease with temperature [1,2].

The expander of the Claude cryogenic system achieves this desideratum by precooling the return current and by the reduction of the incoming mass flow rate in the heat exchanger of the recuperative stage.

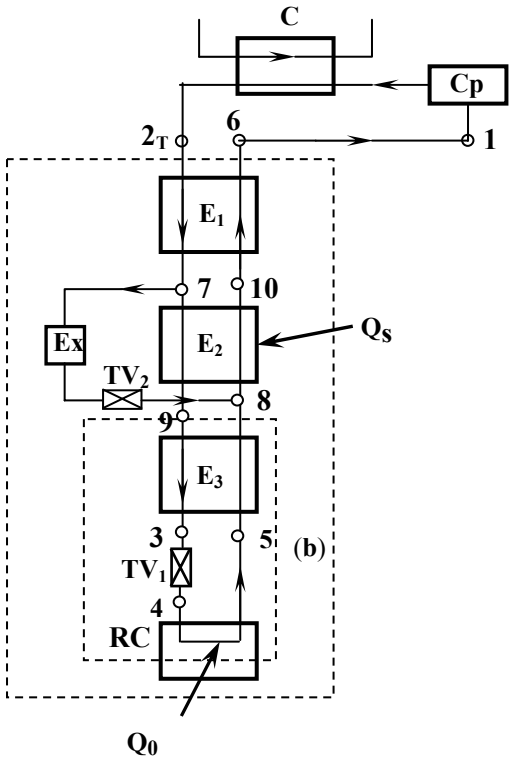

Figure 1,a

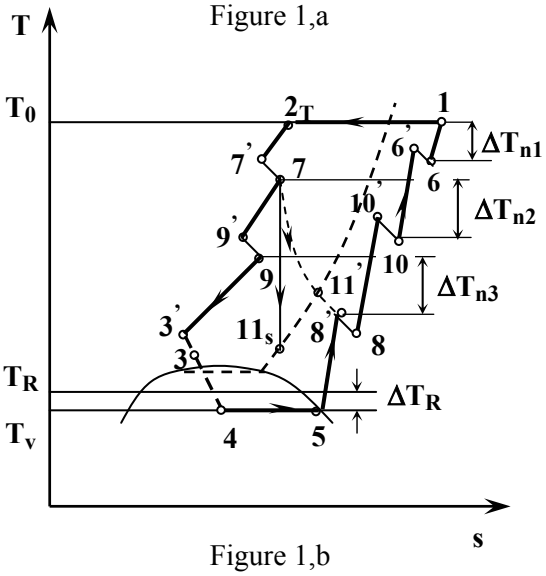

Figure 1,b

For 1kg/s of compressed gas the study was performed under the following assumptions:

- the gas is compressed in the compressor *Cp* and then cooled in the cooler *C* to the temperature of the surroundings $T_0 = T_{2T}$;
- the temperature difference ΔT_n at the warm end of the heat exchangers is due to the finite size of the apparatuses;

- for the engine expansion cycle (*Figure* 1,a) for every 1kg/s of compressed gas a fraction *F* is led to the expander *Ex* where is adiabatically expanded, producing mechanical work and cooled down; the rest is cooled in the recuperative heat exchangers *E*2 and *E*3 and then throttled in *VL*1.
- the pressure drops in the recuperative heat exchangers are schematized by throttlings.

EXERGETIC BALANCE

The exergetic balance equation [3] for 1kg/s of compressed gas gives:

$$\sum \hat{\mathrm{E}}\mathrm{x}_{\mathrm{Q}} = \hat{\mathrm{W}} + \sum \hat{\mathrm{I}} \qquad (2)$$

where

$$\sum \hat{\mathrm{E}}\mathrm{x}_{\mathrm{Q}} = \hat{\mathrm{E}}\mathrm{x}_{\mathrm{Q_0}} + \mathrm{ex}_{\mathrm{Qs1}} + \mathrm{ex}_{\mathrm{Qs2}} + \hat{\mathrm{E}}\mathrm{x}_{\mathrm{Qs3}} + \\ + \mathrm{ex}_{\mathrm{Qn1}} + \mathrm{ex}_{\mathrm{Qcp}} \qquad (3)$$

represents the sum of the heat exergies exchanged with the surroundings by 1kg/s of compressed gas while undergoing the refrigeration cycle (indices *1,2,3* refer to the engine expansion stage (*1,2*) and throttling expansion stage (*3*) respectively);

$$\sum \hat{\mathrm{W}} = \mathrm{w}_{\mathrm{cp}} + \hat{\mathrm{W}}_{\mathrm{Ex}} = -\left|\mathrm{w}_{\mathrm{cp}}\right| + \hat{\mathrm{W}}_{\mathrm{Ex}} \qquad (4)$$

is the whole technical mechanical work composed of the expended work w_{cp} in the compressor and the produced mechanical work in the expander $\hat{W}_{Ex}$;

$$\sum \hat{\mathrm{I}} = \mathrm{i}_{\Delta \mathrm{Pf1}} + \hat{\mathrm{I}}_{\Delta \mathrm{Pf2}} + \hat{\mathrm{I}}_{\Delta \mathrm{Pf3}} + \mathrm{i}_{\Delta \mathrm{Pr1}} + \\ + \mathrm{i}_{\Delta \mathrm{Pr2}} + \hat{\mathrm{I}}_{\Delta \mathrm{Pr3}} + \mathrm{i}_{\Delta \mathrm{T1}} + \hat{\mathrm{I}}_{\Delta \mathrm{T2}} + \hat{\mathrm{I}}_{\Delta \mathrm{T3}} + \\ + \hat{\mathrm{I}}_{\mathrm{t}} + \hat{\mathrm{I}}_{\mathrm{Ex}} + \hat{\mathrm{I}}_{\mathrm{ti}} + \mathrm{i}_{\mathrm{cp}} \qquad (5)$$

where the terms from the right hand member represent in order the exergy destructions due to: pressure drops in the forward $\left(\hat{I}_{\Delta P_f}\right)$ and return $\left(\hat{I}_{\Delta P_r}\right)$ gas streams of the recuperative heat exchangers, heat transfer at a finite temperature difference between the two currents of gas $\left(\hat{I}_{\Delta T}\right)$, throttle expansion in the throttling valve $\left(\hat{I}_t\right)$, compression process $\left(\hat{I}_{cp}\right)$ and expansion in the expander $\left(\hat{I}_{Ex}\right)$.

Inserting Equations. 3-5 into Equation. 2, gives:

$$\left|\mathrm{w}_{\mathrm{cp}}\right| = -\hat{\mathrm{E}}\mathrm{x}_{\mathrm{Q_0}} - \mathrm{ex}_{\mathrm{Qs1}} - \mathrm{ex}_{\mathrm{Qs2}} - \hat{\mathrm{E}}\mathrm{x}_{\mathrm{Qs3}} - \\ - \mathrm{ex}_{\mathrm{Qn1}} - \mathrm{ex}_{\mathrm{Qcp}} + \hat{\mathrm{W}}_{\mathrm{Ex}} + \mathrm{i}_{\Delta \mathrm{Pf1}} + \hat{\mathrm{I}}_{\Delta \mathrm{Pf2}} + \\ + \hat{\mathrm{I}}_{\Delta \mathrm{Pf3}} + \mathrm{i}_{\Delta \mathrm{Pr1}} + \mathrm{i}_{\Delta \mathrm{Pr2}} + \hat{\mathrm{I}}_{\Delta \mathrm{Pr3}} + \mathrm{i}_{\Delta \mathrm{T1}} + \\ + \hat{\mathrm{I}}_{\Delta \mathrm{T2}} + \hat{\mathrm{I}}_{\Delta \mathrm{T3}} + \hat{\mathrm{I}}_{\mathrm{t}} + \hat{\mathrm{I}}_{\mathrm{Ex}} + \hat{\mathrm{I}}_{\mathrm{ti}} + \mathrm{i}_{\mathrm{cp}} \qquad (6)$$

In *Equation* 6 the heat exergies have the following significance:

- $-\hat{\mathrm{E}}\mathrm{x}_{\mathrm{Q_o}} = \left|\hat{\mathrm{E}}\mathrm{x}_{\mathrm{Q_o}}\right|$, represents the exergy of the cooling capacity at the temperature level T_v, with the significance of the minimum work consumption necessary to undergo an inverse Carnot cycle limited by the evaporation temperature T_v and the surroundings temperature T_0;
- $-\hat{\mathrm{E}}\mathrm{x}_{\mathrm{Q_s}} = \left|\hat{\mathrm{E}}\mathrm{x}_{\mathrm{Qs}}\right| = \hat{\mathrm{L}}_{\mathrm{Q_s}}$, represents the lost exergy from imperfect thermal insulation;
- $-\mathrm{ex}_{\mathrm{Qn1}} = \left|\mathrm{ex}_{\mathrm{Qn1}}\right| = \mathrm{l}_{\mathrm{Qn1}}$, denotes the lost exergy with the heat coming from outside in process (6-1) and so unrecovered from the forward stream;
- $-\mathrm{ex}_{\mathrm{Qcp}} = \left|\mathrm{ex}_{\mathrm{Qcp}}\right| = \mathrm{l}_{\mathrm{cp}}$, represents for the compressor, the exergy of the heat transferred to the refrigeration system (a loss).

Taking into account the exergy destruction from heat transfer across a finite temperature difference $\Delta T_R = T_R - T_v$ in the refrigerating chamber $\hat{I}_{\Delta T_R} = \left|\hat{E}x_{Q_0}^{T_v}\right| - \left|\hat{E}x_{Q_R}^{T_R}\right|$, where $\hat{E}x_{Q_R}^{T_R}$ represents the exergy of the specific refrigerating power $\hat{Q}_0 = \hat{Q}_R$, at the temperature level T_R, and denoting that $(i,l)_{cp} = i_{cp} + l_{cp}$, *Equation* 6 becomes:

$$\left|\hat{\mathrm{W}}\right| = \left|\hat{\mathrm{E}}\mathrm{x}_{\mathrm{Q_R}}^{\mathrm{T_R}}\right| + \hat{\mathrm{I}}_{\Delta \mathrm{TR}} + \mathrm{l}_{\mathrm{Qs1}} + \mathrm{l}_{\mathrm{Qs2}} + \hat{\mathrm{L}}_{\mathrm{Qs3}} + \mathrm{l}_{\mathrm{Qn1}} + \\ + \mathrm{i}_{\Delta \mathrm{Pf1}} + \hat{\mathrm{I}}_{\Delta \mathrm{Pf2}} + \hat{\mathrm{I}}_{\Delta \mathrm{Pf3}} + \mathrm{i}_{\Delta \mathrm{Pr1}} + \mathrm{i}_{\Delta \mathrm{Pr2}} + \hat{\mathrm{I}}_{\Delta \mathrm{Pr3}} + \\ + \mathrm{i}_{\Delta \mathrm{T1}} + \hat{\mathrm{I}}_{\Delta \mathrm{T2}} + + \hat{\mathrm{I}}_{\Delta \mathrm{T3}} + \hat{\mathrm{I}}_{\mathrm{t}} + \hat{\mathrm{I}}_{\mathrm{Ex}} + \hat{\mathrm{I}}_{\mathrm{it}} + \mathrm{i}_{\mathrm{cp}} = \\ = \left|\hat{\mathrm{E}}\mathrm{x}_{\mathrm{Q_R}}^{\mathrm{T_R}}\right| + \sum_{1}^{14} \hat{\mathrm{I}}_{\mathrm{j}} + \sum_{1}^{4} \hat{\mathrm{L}}_{\mathrm{k}} \qquad (7)$$

where $\left|\hat{W}\right| = \left|w_{cp}\right| - \eta_m \cdot \hat{W}_{Ex}$ represents the mechanical work expended in the refrigeration cycle and $\hat{I}_{Ex} = (1 - \eta_m)\hat{W}_{Ex}$, the lost part of the mechanical work produced by the expander.

COEFFICIENTS OF PERFORMANCE FOR THE CLAUDE REFRIGERATION CYCLE

Exergetic efficiency

$$\eta_{\mathrm{Ex}} = \frac{\left|\hat{\mathrm{W}}_{\min \mathrm{C}}\right|}{\left|\hat{\mathrm{W}}\right|} = \frac{\left|\hat{\mathrm{E}}\mathrm{x}_{\mathrm{Q_R}}^{\mathrm{T_R}}\right|}{\left|\hat{\mathrm{W}}\right|} = 1 - \sum(\hat{\mathrm{I}}, \hat{\mathrm{L}}) \qquad (8)$$

Specific mechanical work input

$$K = \frac{\left|\hat{W}\right|}{\hat{Q}_R} = \frac{T_0 / T_R - 1}{1 - \sum\left(\hat{I}, \hat{L}\right)} \qquad (9)$$

OPTIMIZATION OF THE CRYOGENIC SYSTEM OPERATING

The considered refrigeration system (*Figure* 1) is equipped with coil type recuperative heat exchangers [4] (*Figure* 2). The forward (high pressure) gas stream flows inside the tubes.

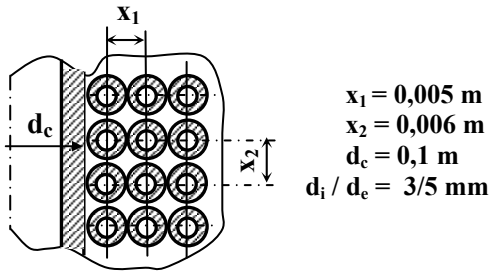

Figure 2

For this type of heat exchanger the heat transfer characteristics and gas-dynamic resistance are given by the following equations:

- for the forward gas stream

$$\Delta p_f = f_f \frac{L_m \cdot w_f^2}{2 d_i \cdot \rho_f}, \quad \text{where}$$

$$f_f = 0{,}34804\, Re_f^{-0{,}25} \qquad (10)$$

$Nu_f = 0{,}023\, Re_f^{0,8}\, Pr_f^{0,4}\, \xi_c$ - for the turbulent regime, and

$Nu_f = \frac{Re_p}{300} Pr_f^{0,37}\, \xi_c$ - for the transitory regime

- for the return gas stream (of low pressure)

$$\Delta p_r = 19{,}4 \cdot n \cdot Re_r^{-0{,}1} \frac{w_r^2}{\rho_r} \quad \text{and}$$

$$Nu_r = 0{,}009\, Re_r^{-1{,}1} \qquad (11)$$

The refrigerating agent is nitrogen [5,6]

Observing that the throttling stage has a major influence upon the overall efficiency of the system, the analysis starts with the optimization of the throttling stage.

The exergetic balance equation for the throttling stage gives:

$$\hat{Ex}_9 + \hat{Ex}_{Q0} + \hat{Ex}_{Qs3} = \hat{Ex}_8 + \sum \hat{I} \qquad (12)$$

where the exergy destruction is

$$\sum \hat{I} = \hat{I}_{\Delta Pf3} + \hat{I}_{\Delta Pr3} + \hat{I}_{\Delta T3} + \hat{I}_t \qquad (13)$$

Observing that

$$-\hat{Ex}_{Q_R}^{TV} = \left|\hat{Ex}_{Q_R}^{TV}\right|, \text{ and}$$

$$-\hat{Ex}_{Qs3} = \left|\hat{Ex}_{Qs3}\right| = \hat{L}_{Qs3}$$

equation 12 becomes:

$$\hat{Ex}_9 - \hat{Ex}_8 = \left|\hat{Ex}_{Q_R}^{T_R}\right| + \hat{I}_{\Delta T_R} + L_{Qs3} +$$

$$+ \sum \hat{I} = \left|\hat{Ex}_{Q_R}^{T_R}\right| + \hat{L}_{Qs3} + \sum \hat{I}_{t_{st}} \qquad (14)$$

The exergetic efficiency for the throttling stage becomes:

$$\eta_{Ex,t} = \frac{\left|\hat{Ex}_{Q_R}^{T_R}\right|}{\hat{Ex}_9 - \hat{Ex}_8} \qquad (15)$$

The optimal parameters of the throttling stage correspond to the maximum exergetic efficiency $\eta_{Ex,t}$

OPTIMIZATION OF THE OPERATING PARAMETERS

The analysis, achieved for T_R = 82 K, T_0=300K and q_s=2 kJ/kg, was looking for the operating parameters at the inlet of the forward gas stream in the recuperative heat exchanger of the throttling stage (p_9, T_9), for the temperature differences ΔT_{n3} and ΔT_R, and for the mass velocity w_{r3} in the return gas stream, for which the exergetic efficiency $\eta_{Ex,t}$ of the throttling stage is maximum.

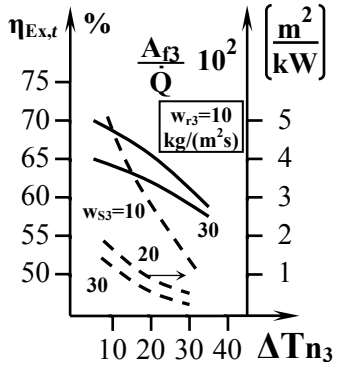
The optimization attempt has been achieved in the following stages:

a) `For every variant of study, the optimum value for w_{r3} has been determined for the minimum exergy destruction in the recuperative heat exchanger of the throttling stage $\left(\hat{I}_{E3} = \hat{I}_{\Delta Pf3} + \hat{I}_{\Delta Pf3} + \hat{I}_{\Delta T3}\right)_{min}$

b) The exergetic efficiency $\eta_{Ex,t}$ for the throttling stage is calculated at the variation of the decisional parameters $p_9, T_9, \Delta T_{n3}$ and w_{r3}. For pressure p_9 =12MPa the procedure is presented in *Figure* 3. Figure 3 reveals that for p_9=12MPa, for every temperature differences ΔT_R, the maximum value for $\eta_{Ex,t}$, called local maximum, is reached for the lowest values for ΔT_{n3} and w_{r3}.

c) In *Fgure* 4,a,b for different pressures p_9 for the forward gas stream, the variation of the local maximum for $\eta_{Ex,t}$ is presented for different values for ΔT_R and T_9. One observes that for every pressure p_9 the maximum value for $\eta_{Ex,t}$ is reached for the lowest temperature T_9 at the lowest ΔT_R (*Figure* 4,a,b).

d) The comparison of the maximum value for $\eta_{Ex,t}$ for different pressures p_9 points out that the maximum exergetic efficiency $\eta_{Ex,t}$ in the throttling stage corresponds to pressure p_9=12bar (*Figure* 5) and for minimum values for w_{f3}, ΔT_{n3}, ΔT_R, T_9. For economic reasons, the variation of the heat exchange surface in the throttling stage, for a refrigerating load of 1 kW $(A_{f3} / \dot{Q})$, is represented too.



p_9=12MPa T_9=135 K

ΔT_R=3 K

Figure 3

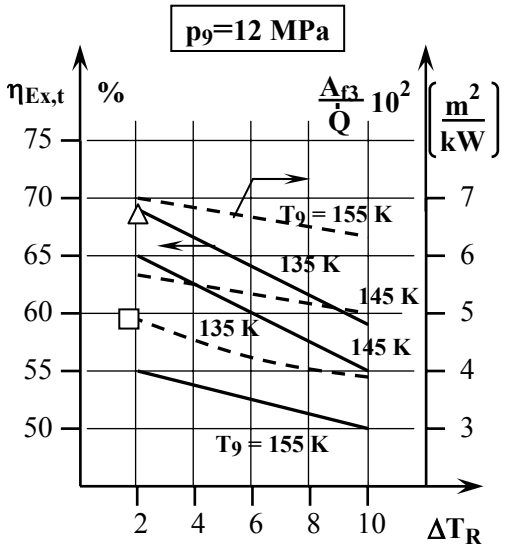


Figure 4,a

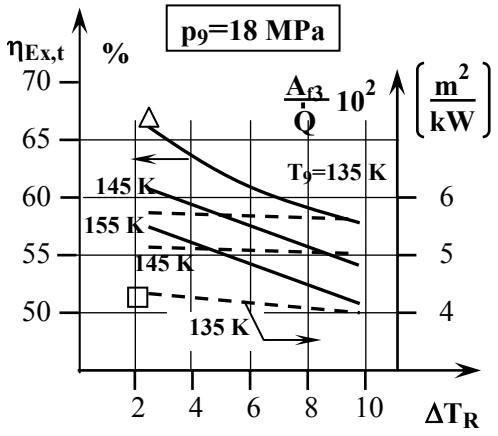

Figure 4,b

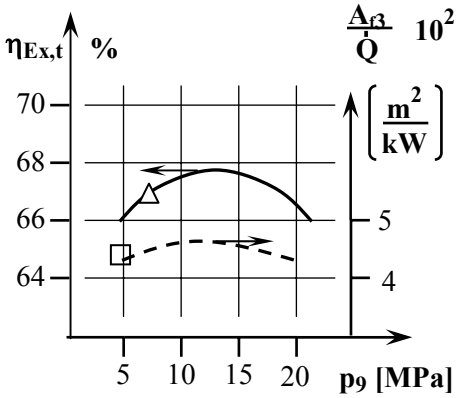

Figure 5

THE CONDUCT OF THE REFRIGERATION SYSTEM FOR OPTIMUM OPERATING OF THE THROTTLING STAGE

After optimization of the throttling stage, corresponding to the main throttling valve TV1, the whole system is optimized.

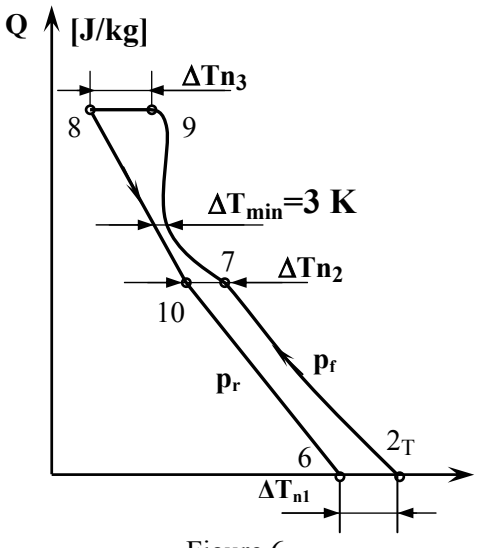

Figure 6

The analysis of the heat transfer in the recuperative heat exchangers points out that due to the variation of the thermophysical properties and to the inequality between the mass flow rates in the forward and return gas streams, the temperature difference in the recuperative stage with the expander located in parallel, can decrease below a minimum admissible (*Figure* 6).

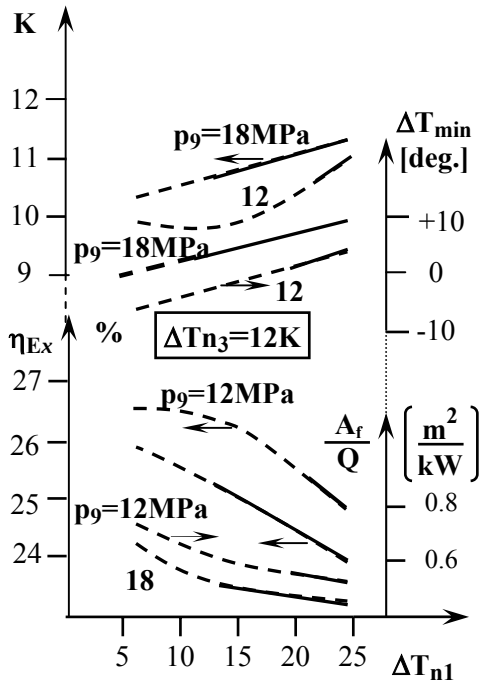

Figure 7,a

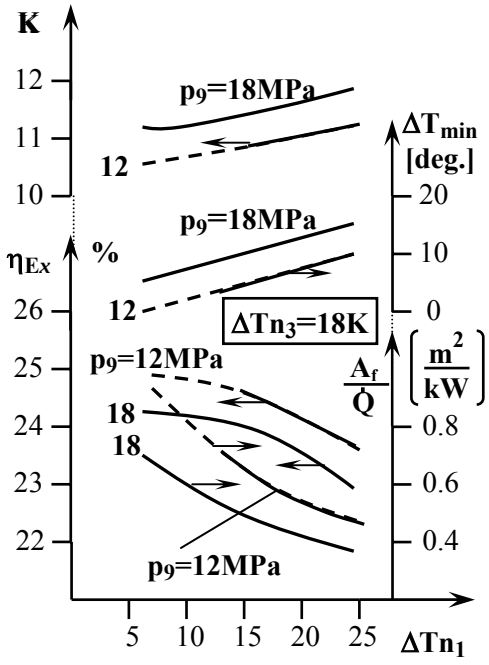

Figure 7,b

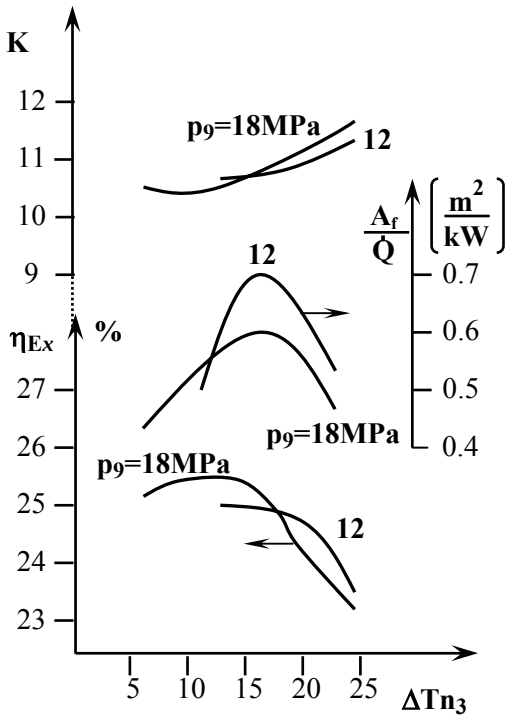

Figure 8

This technical incompatibility leads to the elimination of some of the variants, otherwise characterized by reduced exergy destruction. The eliminated variants are represented with dotted line (Figure 7,a,b).

The comparison of the maximum values for the exergetic efficiency $\eta_{Ex,t}$ for different pressures p_9 and temperature differences ΔT_{n1} reveals that the highest maximum is reached for p_9 = 18MPa, $\Delta T_{n3} \cong 12K$ and $\Delta T_{n1} \cong 12K$. For higher temperature differences ΔT_{n3}, the use of pressure p_9 = 12 MPa becomes economical (*Figure* 8).

INFLUENCE OF THE OPERATING CONDITIONS UPON THE CRYOGENIC REFRIGERATION SYSTEM

The analysis is performed in the following conditions: heat inleaks due to incomplete insulation $q_{s1} = q_{s2} = 2kJ/kg$, η_T =0.6, η_{Ex}=0.8, η_m =0.8, heat transfer surfaces are of the same type in all stages (*Figure* 2), p_9 =18 MPa, T_9 =135K, T_R = 82 K and ΔT_R = 3 K.

Influence of the temperature difference ΔT_{n3} at the warm bottom of the recuperative heat exchanger of the throttling stage

This influence ($\Delta T_{n3} = 12...24K$) analyzed for T_0=300K, ΔT_{n1}=6K, w_{r1}=7,5kg/(m^{2}s), w_{r2} = 5 kg/(m^{2}s), w_{r3} = 15 kg/(m^{2}s), p_{11} = 0,75 MPa, is presented in *Figure* 9.

One observes:

- the constancy of the efficiency η_{Ex} and of the forward gas stream state at the inlet in the throttling stage (p_9, T_9), and the increase in ΔT_{n3}, lead to a decrease in the specific thermal load of the second recuperative heat exchanger on the forward gas side, leading to a decrease in the fraction *F* of gas expanded (*Figure* 9,b); the decrease of fraction *F* explains the decrease in $\hat{W}_{Ex}$ and $\hat{I}_{Ex}$ (*Figure* 9,a);
- the increase in ΔT_{n3} has as consequence the augmentation of the enthalpy at the inlet of the throttling valve *TV*1 conducing to a reduction in the refrigeration power $\hat{Q}_R$ (*Figure* 9,a);
- as expected, the increase in ΔT_{n3} leads to an augmentation of the exergy destructions $\hat{I}_{\Delta T1}, \hat{I}_{\Delta T2}, \hat{I}_{\Delta T3}$, due to heat transfer across a finite temperature difference in the recuperative heat exchangers (*Figure* 9,a);
- for all recuperative heat exchangers, the optimum velocity ratios $\Omega = w_f / w_r$ for which the exergy destruction due to heat transfer across a finite temperature difference and gas-dynamic resistance are minimum, decrease at the augmentation of ΔT_{n3}; the maximum value for Ω is registered for the first heat exchanger (*Figure* 9,b);
- at the augmentation of ΔT_{n3}, for both the forward and return gas streams, the pressure drops in the recuperative heat exchangers *E*2 and *E*3 decrease while for *E*1 increases (*Figure* 9,b);
- at the augmentation of ΔT_{n3}, the heat transfer surface on the return gas side A_{r1} increases, while A_{r2} and A_{r3} decrease, a fact due primarily to the variation in the same sense of the refrigerating loads of the three heat exchangers (*Figure* 9,b).

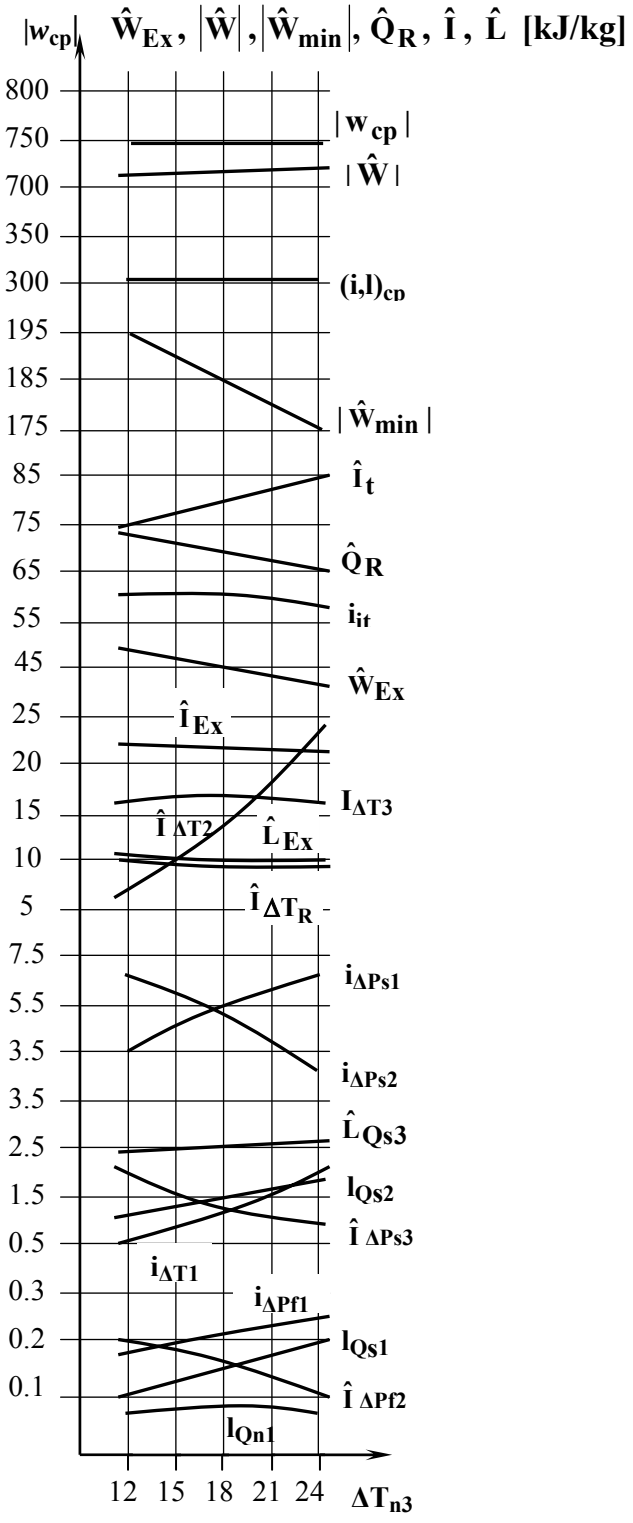

Figure 9,a

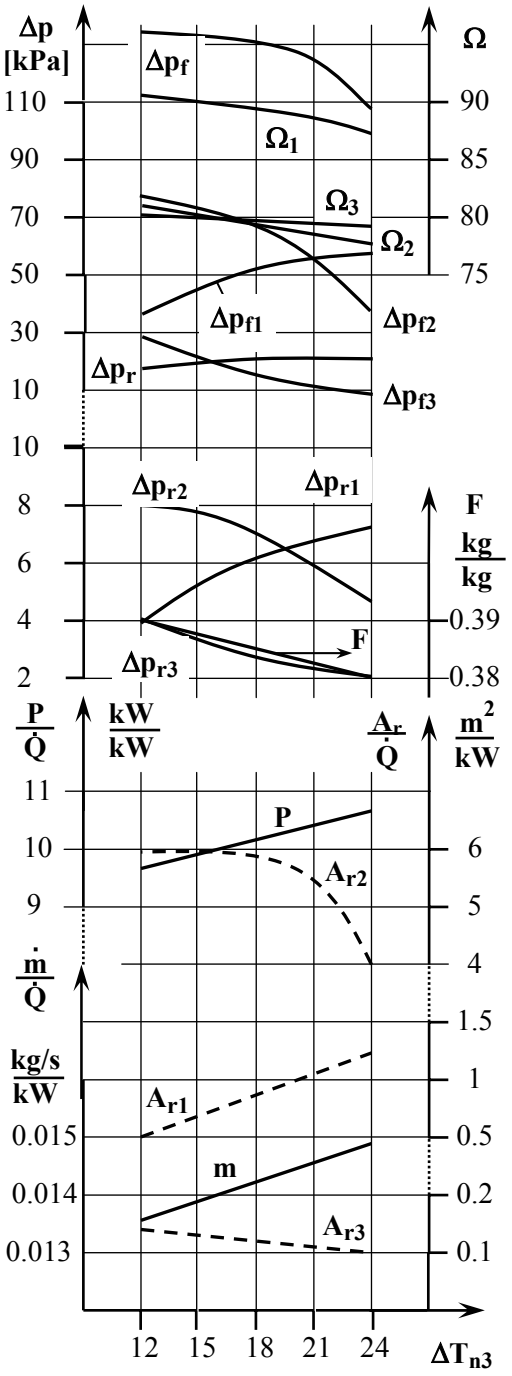

Figure 9,b

CONCLUSIONS

The throttling stage of the Claude cryogenic refrigeration system plays a decisive influence on the entire system performance.

In the aim of optimizing the whole refrigeration system, the operating parameters of the throttling stage have been determined on the basis of the maximization of the exergetic efficiency.

The optimum operating conditions can lead in the upper stages to technical incompatibilities such that the annulment of the heat transfer in the expander stage.

The specific geometry chosen for the recuperative heat exchangers, made possible the calculation of the pressure drops and associated exergy destructions and the size of the heat transfer surfaces. These data are capital for further thermoeconomic analysis where the investment and operating costs have to be balanced.

EXERGETIC COMPARISON OF ENERGY-BASED EFFICIENCY INDICATORS FOR COMBINED HEAT AND POWER (CHP)

Ivar S. Ertesvåg*

ABSTRACT

In many countries, legislative regulations in favor of combined heat and power production (CHP) have been implemented. Although these regulations put different emphasis on power production vs. process heat production, they are based on energy quantities and not on exergy. In order to analyze and compare the exergetic consequences of the various legislations, a relative avoided irreversibility (RAI) is defined. This can be regarded as the irreversibility that is avoided when a reference plant with separate production is replaced by an actual CHP plant. A series of natural-gas fired industrial and district heating CHP plants, under varying operational conditions, are used as test cases, and the consequences of the various legislations are shown. It is seen that some, but not all, CHP cases are exergetically beneficial to separate generation. The exergetic improvements were only to a limited degree captured by the various energy-based efficiency indicators. Some legislatively defined indicators appeared to discourage thermodynamic improvements.
Keywords: Exergy, CHP, cogeneration, efficiencies, legislation, comparison, evaluation

1 INTRODUCTION

Cogeneration or CHP is sometimes regarded as the materialization of the 2nd law of thermodynamics. First, electricity is produced from the high-exergy heat, and next, thermal energy is produced from heat at lower temperatures. On a 1st-law basis, CHPs provide a substantially higher output than plants for separate electricity generation.

Several countries have implemented legislations promoting CHP. The new EU CHP directive [1] contributes to this and describes the process for developing a future standard for CHP efficiencies. However, to define the "useful output" and "input", raises a number of methodological considerations that can be measured and expressed in a number of different ways, with also the potential for misleading or faulty comparisons. An increasing number of national definitions shows considerable differences in how to evaluate CHP efficiency. A common feature, though, is that they are not based on the 2nd law. A 2nd-law efficiency can be used to measure the performance of a plant and to compare with other plants. This can give a qualitative comparison and assessment of the various concepts of CHP evaluation mentioned above. The present study is an attempt to do a quantitative investigation of these concepts of evaluation. Then, the exergetic concequences of the various legislations can be discussed.

2 COMPARISON OF SYSTEMS FOR ENERGY CONVERSION

2.1 Relative Avoided Irreversibility

The exergy loss (irreversibility) of a certain case can be expressed $(1-\psi)E_{\text{in}}$, where ψ is the exergy efficiency, that is, the ratio of usable exergy output to exergy input, and E_{in} is the exergy input (usually the fuel exergy).

A case or process can be compared to a specified reference case. The irreversibility that is avoided by replacing the reference case by the new case will be

$$(1-\psi_{\text{ref}})E_{\text{in,ref}} - (1-\psi)E_{\text{in}} \quad (1)$$

where the subscript "ref" denotes a reference case. The term avoided irreversibility presumes that the case is an improvement from the reference case. However, the quantity will be negative if the utilization is worsened.
The term can be made dimensionless by the input to the reference case, and the Relative Avoided Irreversibility is expressed

$$\text{RAI} = (1-\psi_{\text{ref}}) - (1-\psi)E_{\text{in}} / E_{\text{in,ref}} \quad (2)$$

In a general notion, this quantity can be regarded as the irreversibility of the specific case or system, subtracted from the irreversibility that would have been there if the case or system was not applied.

2.2 Comparison with energy-based efficiencies or improvement indicators.

Quite a few efficiencies and efficiency-improvement indicators are defined on a technical or legislative basis. In most instances, these are based on energy considerations. Thus, all forms of usable energy, *e.g.* fuel, electricity, and heat, are accounted for by their energy value (*i.e.* heating value).

Similar to the outline above, a Relative Avoided Loss can be expressed

$$\text{RAL} = (1-\eta_{\text{ref}}) - (1-\eta)H_{\text{in}} / H_{\text{in,ref}} \,. \quad (3)$$

Here, η is some defined efficiency, H_{in} is the energy input (usually the fuel LHV), and subscript "ref" again denotes a reference case. This formulation can be used for the variety of efficiencies shown below. RAL is the loss of energy, according to the chosen definition of efficiency, that is avoided when the reference case is replaced by the actual case.

If the efficiency η in Eq. (3) is the total energy efficiency (e.g. electric energy plus heat divided by the fuel LHV), the RAL is the loss of energy that is avoided because the actual case has replaced the reference case. This is known as the Relative Primary Energy Savings (RPES). In most cases, the energy efficiency is different from the exergy efficiency. Other definitions of efficiency, based on technology or policy reasoning, give different evaluations of energy, and accordingly, of the utilized and lost energy.

For a thermodynamic comparison of the different indicators, the ratio of RAI to RAL can be used as metric. Thus, if

- RAI>RAL, the improvement is underestimated by the indicator,
- RAI=RAL, the improvement is evaluated in accordance with thermodynamics,
- RAI<RAL, the improvement is overestimated by the indicator,
- RAI/RAL<0, the emphasis of the indicator is in the wrong direction.

2.3 Efficiency indicators for combined heat and power (CHP)

The ratio of delivered useable energy to the energy input can be termed the total energy efficiency or CHP efficiency. For a system producing heat and power this can be expressed

$$\eta_{\text{CHP}} = (W+Q)/H \,, \quad (4)$$

where W is the mechanical power or electricity produced, Q is the thermal energy in delivered steam, and H is the input energy, usually the LHV of the fuel. In the context of CHP, the fractions of input energy that are converted to electric energy and heat can, respectively, be called electric efficiency and heat efficiency and expressed

$$\eta_{\text{el}} = W/H \quad (5)$$

$$\eta_{Q} = Q/H \quad (6)$$

These expressions are useful when evaluating the different methods of qualifying CHP.
To describe the quality difference between electricity and heat, the exergy efficiency can be defined. This is the ratio of exergy in the products

electricity and thermal energy to the exergy of the input

$$\psi = (W + E_Q) / E_F \quad (7)$$

Here, E_Q and E_F are, respectively, the exergy of the delivered thermal energy and the input exergy, while the exergy of electricity or mechanical energy is equal to its energy W.

Both thermodynamically, technically, and economically, electric energy differs from thermal energy. Several other parameters have been defined to account for this difference without making use of the exergy concept.

While electricity generation can be conducted nearly anywhere, the heat has to be generated near the user, and it has to be scaled according to the consumption. Thus, it may be useful to regard a CHP as a heat generator with surplus electricity generation. This is expressed by defining an Equivalent electrical efficiency (EEE) [3],

$$\eta_{\text{eel}} = W / (H - Q / \eta_{\text{Qref}}) \quad (8)$$

Here, the fuel energy to the CHP plant is supposed to be reduced by the fuel needed to produce the heat in a separate boiler with efficiency η_{Qref}. In the legislations of Spain and (with a slight modification) Portugal, this concept is used (cf. [4][5]). While in Eq. (8), a portion of the fuel (fuel for heating) is subtracted in the denominator, a fraction of the energy in the steam is added in the numerator in the efficiency defined by the US legislation PURPA,

$$\eta_{\text{PURPA}} = (W + 0.5 \cdot Q) / H \quad (9)$$

Also in Brazil, an efficiency close to this is used. Such efficiencies can be seen as a simplified exergy efficiency, without really taking into account the actual exergy content of the heat.

Feng et al.[6] suggested an adjusted exergy efficiency with the definition

$$\eta_{\text{adex}} = (W + E_Q + \xi \cdot (Q - E_Q)) / H \quad (10)$$

where ξ=0.12 is an adjusted exergy factor.

For all these efficiencies, an RAL can be defined according to Eq. (3). Other indicators may focus on the savings of energy or emissions. The relative primary energy savings (RPES) [3][4]can be written

$$\text{RPES} = 1 - H / H_{\text{ref}} \quad (11)$$

This is the fuel energy that is saved by the CHP when comparing to separate generation. The RPES is used as an indicator for the goodness of CHP systems in the Flemish legislation (Belgium). Other such indicators are (see [4][5]) the Relative CO_2 Emissions Savings (RCES; Walloon and Brussels-region legislations), the fuel-free electricity (Dutch legislation), and the Quality Index (QI; British legislation).

For natural-gas fired CHP, the Brussels RCES can be expressed equal to the RPES, while the Walloon RCES can be expressed equal to $\text{RPES} \cdot (H_{\text{ref}} / H_{\text{elref}})$. The RPES and the RCESs can be regarded as RALs, and the fuel-free electricity W_{free} can be related through

$$W_{\text{free}} / H_{\text{ref}} = \eta_{\text{elref}} \cdot \text{RPES} \quad (12)$$

where η_{elref} is defined below.

The Quality Index (QI) can be expressed as a relative Quality-Index improvement by

$$\text{RAL} = \text{QI} / \text{QI}_{\text{ref}} - 1 \quad (13)$$

All these RALs are based on energy considerations. At first sight, e.g. the RPES seems to represent mass of fuel and thus energy and exergy of the fuel as well. However, when the "saved" energy is evaluated, all forms of usable energy are accounted equally. That is, electric energy, fuel energy, and thermal energy in MP and LP steam are considered equal. From a thermodynamic consideration (1st and 2nd law), a system delivering an amount of heat in LP steam has higher losses than a system delivering heat in MP steam at a higher temperature. And actually, the system has a lower (1st-law) capacity when producing MP steam (see below).

2.4 Reference plants for separate generation of heat and power

For energy analyses, it is convenient to define reference plants for separate heat and power generation, with the electric and heat efficiencies η_{elref} and η_{Qref}, respectively. The reference amounts of fuel energy can be defined, $H_{\text{elref}} = W / \eta_{\text{elref}}$ and $H_{\text{Qref}} = Q / \eta_{\text{Qref}}$, and the sum $H_{\text{ref}} = H_{\text{elref}} + H_{\text{Qref}}$. These are the amounts required to produce the

same electricity and heat separately in the reference plants. The ratio of the actual to the reference fuel energy is

$$H / H_{\text{ref}} = (\eta_{\text{el}} / \eta_{\text{elref}} + \eta_Q / \eta_{\text{Qref}})^{-1} \quad (14)$$

Similarly, the reference fuel exergy for separate electricity generation can be expressed

$$E_{\text{F,elref}} = \alpha_{\text{F}} H_{\text{elref}} = \alpha_{\text{F}} W / \eta_{\text{elref}} \quad (15)$$

where α_F is a constant, usually close to unity (e.g. 1.04 for natural gas at standard state). The fuel exergy for separate heat generation will be discussed below.

The values of the reference efficiencies can be determined based on the notion of Best Available Technology (BAT) or based on an average of existing installations. In legislative regulations, the choice of reference values may be based on a compromise between existing technology and BAT. As the choice will affect the regarded goodness of any CHP plant, it is quite often an outcome of intense lobbying by the involved parties.

This procedure does not recognize the exergetic value or "quality" of thermal energy. The reference amount of fuel for separate heat generation is taken as the same value regardless of the temperature of the steam (or other heating media: water, oil, air, etc.). It can be argued that a conventional boiler has about the same efficiency for HP steam and LP steam, and even for hot water. Actually, this efficiency is determined more by the state of the outflow flue gas than by the state of the heating medium. However, it can be observed that for a CHP producing LP steam, the electricity generation is relatively lower than for a similar CHP producing MP or HP steam.

Moreover, low-temperature thermal energy can be generated by heat pumps. A system of separate electricity generation and heat pumps can supply an amount of heat that is larger than the fuel LHV used. Thus, for a proper exergetic comparison, the reference heat efficiency has to depend on the exergy of the heat. This corresponds to defining a reference heat-pump exergetic efficiency.

The exergy of heat can be written $E_Q = \alpha_Q Q$, which defines the exergy-to-heat ratio, α_Q. When provided by a heat pump, this heat requires the amount of work W_{QP}. These quantities can be related by the exergetic efficiency of the heat pump,

$$\psi_{QP} = E_Q / W_{QP} = \alpha_Q Q / W_{QP} \quad (16)$$

Furthermore, the heat-pump work can be assumed generated in a reference power plant as described above. Hence, the amount of fuel for separate generation of heat varies with the exergy of the steam (or other heating medium). It also depends on the exergetic efficiency of the heat pump. This efficiency may vary with the temperature levels involved but will, for convenience, be assumed constant in the following.

Two approaches can be followed to determine the reference fuel exergy for heat generation: 1) specify a reference exergy-to heat ratio, $\alpha_{Q\text{ref}}$ for heat generation, or 2) specify a reference exergetic efficiency $\psi_{QP\text{ref}}$ for a heat pump providing the heat.

In the first approach, the reference exergy efficiency for separate heat generation in a boiler can be expressed

$$\psi_{Q\text{ref,B}} = \frac{\alpha_{Q\text{ref}} Q}{\alpha_F Q / \eta_{Q\text{ref}}} = \frac{\alpha_{Q\text{ref}} \eta_{Q\text{ref}}}{\alpha_F} \quad (17)$$

Here, the reference is separate generation of the same amount of heat at the specified exergy-to heat ratio and a specified energy efficiency. This will give a reference amount of fuel exergy for the boiler (subscript "B") approach

$$E_{F,Q\text{ref,B}} = \frac{\alpha_Q Q}{\psi_{Q\text{refB}}} = \frac{\alpha_F \alpha_Q Q}{\alpha_{Q\text{ref}} \eta_{Q\text{ref}}} \quad (18)$$

When the actual heat generation is conducted by a heat pump using electricity (work) from a reference plant for separate power generation, the heat-generation exergy efficiency is

$$\psi_{Q\text{ref,QP}} = \frac{\alpha_Q Q}{\alpha_F (W_{\text{QPref}} / \eta_{\text{elref}})} = \frac{\eta_{\text{elref}} \psi_{QP\text{ref}}}{\alpha_F}. \quad (19)$$

The reference fuel exergy for separate heat generation in the heat-pump (subscript "QP") approach can then be expressed

$$E_{F,Q\text{ref,QP}} = \frac{\alpha_F W_{\text{QPref}}}{\eta_{\text{elref}}} = \frac{\alpha_F \alpha_Q Q}{\eta_{\text{elref}} \psi_{\text{QPref}}}. \quad (20)$$

The two approaches can be joined by setting $\alpha_{Q\text{ref}}\eta_{Q\text{ref}} = \eta_{\text{elref}}\psi_{\text{QPref}}$. This also leads to an expression for the coefficient of performance of the reference heat pump,

$$\text{COP}_{\text{ref}} = Q / W_{\text{QPref}} = \psi_{\text{QPref}} / \alpha_{Q\text{ref}} = \eta_{Q\text{ref}} / \eta_{\text{elref}} \quad (21)$$

Although this ratio is fixed to the reference efficiencies for heat and electricity, the requirement will be more demanding as the exergy ($\alpha_{Q\text{ref}}$) increases.

Now, reference amounts of fuel exergy for separate heat and power generation are defined, and the reference efficiency can be expressed

$$\psi_{\text{ref}} = \frac{\eta_{el} + \alpha_Q \eta_Q}{\alpha_{\text{F}}(\eta_{el} / \eta_{\text{elref}} + \alpha_Q \eta_Q / (\alpha_{\text{Qref}} \eta_{\text{Qref}}))} \quad (22)$$

This procedure allows a comparison of different systems and recognizes the quality of the thermal energy. The ratio of actual fuel-exergy input to the reference input is

$$E_{\text{F}} / E_{\text{F,ref}} = (\eta_{el} / \eta_{\text{elref}} + \alpha_Q \eta_Q / (\alpha_{\text{Qref}} \eta_{\text{Qref}}))^{-1} \quad (23)$$

It is readily seen that for a heating medium with $\alpha_Q = \alpha_{Q\text{ref}}$, the fuel-exergy ratio of Eq.(23) is equal to the fuel-energy ratio of Eq.(14).

Still, the reference exergy-to heat ratio, $\alpha_{Q\text{ref}}$, (or alternatively, the reference heat-pump exergetic efficiency ψ_{QPref}) has to be specified. In this study, a value of $\alpha_Q = 0.28$ was adopted. This is the ratio of exergy to enthalpy differences for instance of steam at 2.5 bar 140 °C (LP steam), when the environmental pressure and temperature are 1 bar and 15 °C. In combination with a reference electric and heat efficiencies of 0.55 and 0.90, respectively, this corresponds to a heat-pump exergy efficiency ψ_{QPref} of 0.46 and a reference COP of 1.64. These figures are technically achievable and are chosen here to enable a quantified analysis.

This choice of "quality" for the reference is modest. An alternative choice of $\alpha_Q = 0.40$ (MP steam, 21 bar, 330 °C) corresponds to a ψ_{QPref} of 0.65. Even at this level, a reference COP of 1.64 is technically feasible. On the other side, a low-exergy reference, e.g. hot water with $\alpha_Q = 0.15$ was an alternative. The choice of reference for exergy is largely arbitrary and a matter of taste, at least within the technically possible range. The issue is whether a medium-exergy thermal system should be accounted "neutral", "positive" or "negative". From a pedagogical viewpoint, it is preferred to have both "negative" and "positive" categories, as the choice made here implies.

3 TEST CASES OF CHP

3.1 Cases of industrial CHP

Two different configurations for a CHP plant have been considered in this study: A boiler with back-pressure steam turbine (ST) and condensing ST (BST plant), and a plant with gas-turbine with a flue-gas heat-recovery steam generator (HRSG) and condensing steam turbine (GT-plant) [4][5].

Table 1 Cases of industrial CHP, Boiler/steam-turbine (B3-) and gas-turbine with HRSG (GT2-) series with low-pressure (LP) and medium-pressure (MP) steam delivery. From [4][5].

	Steam delivery load (tonnes/h)				
	40	55	70	85	100
B3-LP (α_Q=0.28)					
W/H	0.240	0.224	0.207	0.191	0.174
Q/H	0.281	0.386	0.491	0.597	0.702
E_Q/H	0.079	0.108	0.138	0.167	0.197
B3-MP (α_Q=0.39)					
W/H	0.144	0.128	0.111	0.095	0.079
Q/H	0.319	0.439	0.559	0.678	0.798
E_Q/H	0.125	0.172	0.218	0.265	0.312
GT2-LP (α_Q=0.28)					
W/H	0.462	0.449	0.438	0.423	0.409
Q/H	0.241	0.332	0.418	0.452	0.483
E_Q/H	0.068	0.093	0.117	0.127	0.135
GT2-MP (α_Q=0.39)					
W/H	0.410	0.396	0.373	0.351	0.332
Q/H	0.274	0.377	0.464	0.512	0.545
E_Q/H	0.107	0.147	0.182	0.200	0.213

The fuel for all cases was natural gas. The cases selected are the operational mode III of the BST plant (maintained firing, reduced condensing ST load to increase steam delivery load), and the operational mode II for the GT/HRSG/ST plant, both with LP and MP steam delivery. The fuel-energy (LHV) consumption rate was 101 MW for the BST and from 117 to 147 MW for the GT

plant. Within each of the four series of cases, the steam delivery load increased from 40 to 100 ton/h. As the issue here is to investigate the efficiency indicators, most details of the plants will be left out. The key data are shown in Table 1. The RAIs for all 20 cases are seen in Fig. 1 (abscissa). Increased steam delivery load increases utilization compared to separate production. In the cases presented (except higher GT cases), reduced steam delivery was obtained by increasing load on the condensing steam turbine. It is seen that this reduces the RAI, which for the BST, becomes negative. Furthermore, it is seen that MP steam delivery gave higher RAI than LP steam, and that the GT systems gave higher RAI than the BST systems.

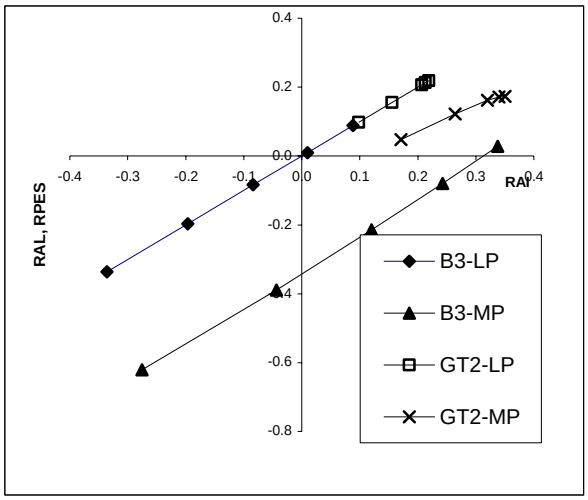

Figure 1 RAL based on the total energy (or CHP) efficiency vs. RAI for the industrial CHP cases. This RAL equals the RPES (Flandern, Brussels).

Figures 1 to 5 show the comparison between the exergy-based and energy based indicators. Here it should be noted that all indicators are defined or chosen with the purpose of promoting CHP. Each of the four series of cases has an RAI that is increasing with increasing steam delivery load. The closer a line between two cases is the diagonal line RAL=RAI, the closer the indicator resembles to the exergetic evaluation.

The Dutch fuel-free electricity (normalized with the reference amount of fuel energy) is proportional to the RPES and exhibit the corresponding behaviour.
The first graph, Fig. 1, shows the RAL based on the total energy efficiency or CHP efficiency. This RAL is equivalent to the RPES (used in Flandern legislation) and to the Brussels-region RCES. As the reference exergy-to-enthalpy ratio is chosen

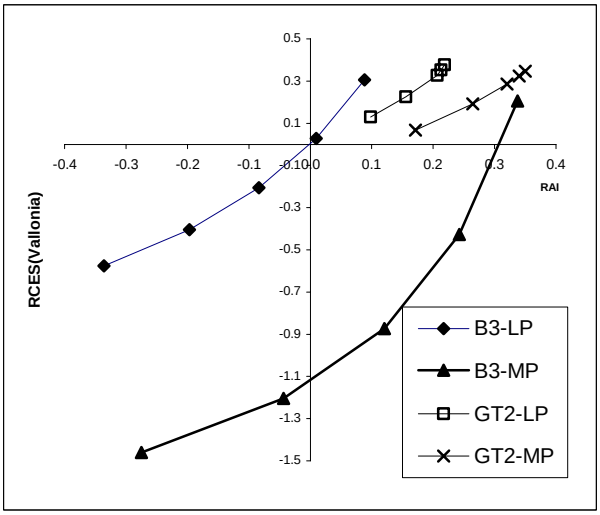

Figure 2 Walloon-legislation RCES vs. RAI.

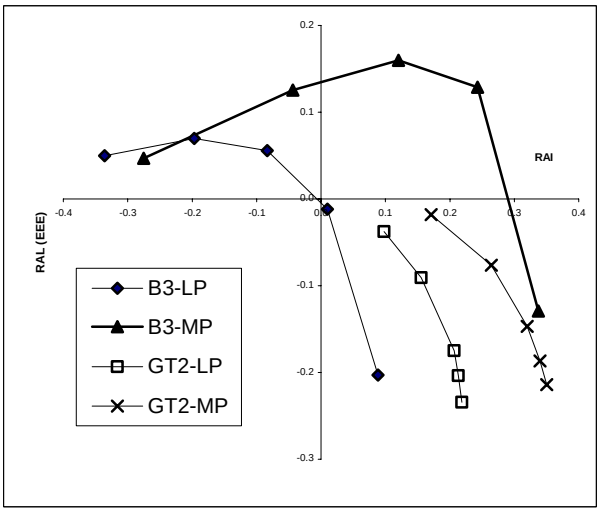

Figure 3 RAL based on EEE (Spain, Portugal) vs. RAI

equal to that of the LP steam, the LP cases lie on the line RAL=RAI. Hence, increased steam delivery for a specific plant is evaluated in accordance with exergy analysis. Improving a plant by replacing the boiler with a GT/HRSG is also encouraged by this indicator. However, it is seen that steam delivery at a higher temperature and exergy (MP steam) is punished by the energy indicator, giving a lower RAL in spite of increased RAI. The higher B3-MP cases are even found in the 4th quadrant, as the RAL takes negative values for positive RAI.

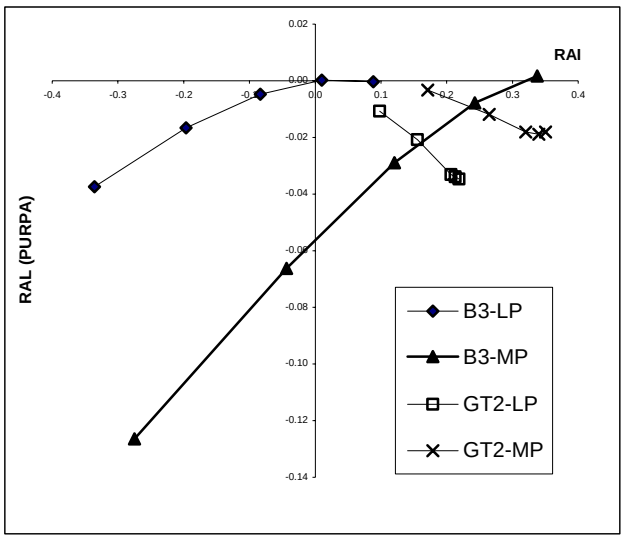

Figure 4 RAL based on US PURPA efficiency vs. RAI

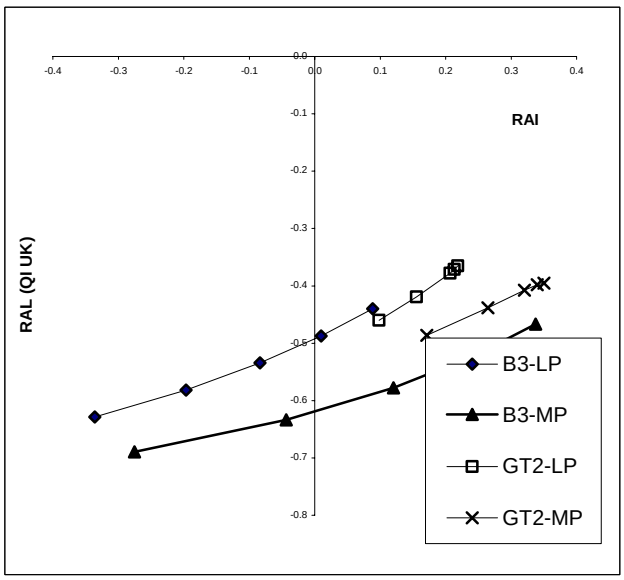

Figure 5 RAL based on British QI vs. RAI

Next, Fig. 2 shows the RCES of the Walloon legislation. This is similar to the RPES above, except that the points are moved clock-wise such that the impact of improvements are enhanced and several cases are raised above the RAL=RAI line in the first quadrant and below on the negative side.

For the present cases, with no in-house derived fuel, the efficiency of the Portuguese legislation becomes equal to the Equivalent electric efficiency (EEE), which is also used in Spain. The RAL based on this efficiency is shown in Fig. 3. This remarkable figure shows that most cases are found in the 2nd and 4th quadrant. Moreover, almost any improvement in terms of exergy utilization is answered with a poorer RAL. One exception in this picture is that the RALs for the higher boiler-MP cases are higher than those of the corresponding LP cases.

The efficiency of the US PURPA is somewhat related to the EEE above, and some of the same tendencies are seen in Fig. 4. In particular, the use of GT/HRSG is discouraged by this indicator, although not to the extent seen with the RAL based on EEE. For the BST configuration, we see some of the same picture as for the total efficiency and RPES above (Fig. 1). The efficiency proposed by Feng, Eq. (10), showed much the same picture as the PURPA efficiency, and is not included here.

The RAL based on the British Quality Index is shown in Fig. 5. It can be noted that higher steam load and higher RAI provide a less negative RAL. However, any other improvement is disregarded by this indicator.

It should be noted that the RAI values are affected by the choice of reference exergy-to-heat ratio, $\alpha_{Q\mathrm{ref}}$. A higher value will reduce the RAI, whereas the various RALs are not affected. Consequently, in all graphs, each point will be moved to the left. The change has less impact with a higher power-to-heat ratio. Nevertheless, the main picture described above will remain the same with a higher or lower value chosen for reference exergy-to-heat ratio.

3.2 Cases of CHP with district heating

In some countries, particularly Denmark, the legislation has been designed to promote small-scale CHP for district heating. This has brought forth a substantial number of natural-gas fired power-plants in the range 3-30 MW electric power, supplying their neighbourhood with space heating. Often, such plants are only operating during the heating season. A number of such cases are specified in Table 2. These data were taken from [7] and are long-term averages for plants in operation. Most of the cases are based on the K type (one B type) of natural-gas fired motor from Rolls Royce Marine Diesel of Bergen, Norway. We will regard these as representative for a number of existing plants. For such plants, the water supply and return temperatures, respectively, are typically 95°C and 50 °C. Here we have

assumed $\alpha_Q = 0.19$, although the value may be lower during parts of the heating season.

Table 2 Cases of district heating (α_Q=0.19).

Case	RR1	RR2	RR3	RR4	RR5	RR6
W/H	0.419	0.416	0.397	0.407	0.413	0.450
Q/H	0.341	0.445	0.531	0.521	0.515	0.450
E_Q/H	0.065	0.085	0.101	0.099	0.098	0.086

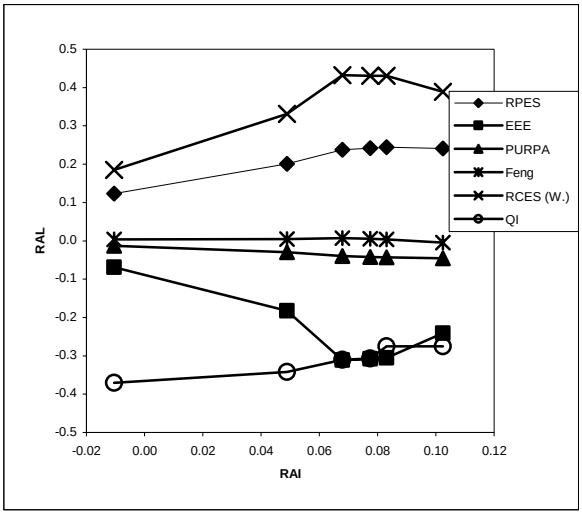

Figure 6 RAL based on various indicators vs. RAI for six cases of disctrict heating.

In Fig.6, these cases are presented from lowest (Case RR1) to highest (RR6) RAI. The corresponding RALs based on six different indicators are shown. It is seen that the total efficiency RAL (equivalent to RPES), encourage but overestimates the improvement, and the Walloon RCES even more. The RALs based on PURPA, EEE, and QI discourage improvements as five of the cases are found in the fourth quadrant of the graph. The RAL based on Feng's efficiency is close to zero for all cases.

It can be argued that for space heating, separate production will give more than 90% of the LHV. In fact, more than 105% can be achieved by using furnaces that condense some of the flue-gas water vapour. Even with his reference, the plant will turn out with positive RAL and RAI. However, the most efficient means for space heating is heat pumps. A relatively modest COP of 3.7 or less, combined with separate electricity production, will give the same RAL or fuel savings as in the cases specified. This shows that from a thermodynamic viewpoint, small-scale power plants with low-temperature heat production are advantageous to on-site heating by combustion, while the best way to provide space heating is heat pumps.

4 CONCLUDING REMARKS

The purpose of this study was to assess various 1st-law-based metrics for evaluating CHP systems. An expression for relative avoided irreversibility (RAI) was developed to enable exergetic comparison of alternative energy conversion systems. Similarly, the relative performance according to various technically or legislatively defined efficiency indicators can be expressed and compared to the RAI.

From a series of industrial and district-heating CHP test cases, it was seen that exergetic improvement (or disprovements) only to a limitied degree was captured by the various energy-based efficiency indicators. Some legislatively defined indicators appear to discourage thermodynamically based improvements.

EFFECT OF ENVIRONMENTAL CONDITIONS ON THE CALCULATION OF CHEMICAL EXERGY

Marisol Garfias* and Ricardo Rivero
Instituto Mexicano del Petróleo
Eje Central Lázaro Cárdenas 152
México, D.F.

ABSTRACT

Chemical exergy of any substance, in its standard state, is normally estimated from tabulated values obtained for normal conditions (298.15 K and 1 atm) and taking into account a model of reference species that considers the concentration of the most common components of real environment. In the present work, the effect on the chemical exergy of elements and compounds of ambient temperature, atmospheric pressure, air humidity, CO_2 concentration in the air and oceans salinity, is studied considering the Szargut model for determining the chemical exergy of a substance. Ambient temperature is the condition that has the greatest effect on the chemical exergy of a substance. This is due to the fact that Gibbs free energy for the formation reaction of the reference species and its environmental concentration depend on this condition. Furthermore, the chemical exergy value changes little when atmospheric pressure, air humidity, CO_2 concentration in the air and seawater salinity vary. Finally, at atmospheric pressure and constant relative humidity, the chemical exergy of any hydrocarbon increases when ambient temperature decreases.

Keywords: Standard chemical exergy, elements, environmental conditions.

NOMENCLATURE

b_y	Number of molecules of the additional element *y* present in a molecule of the reference species in seawater
Ex	Exergy [kJ/gmol]
ΔG	Gibbs free energy [kJ/gmol]
ΔH	Enthalpy [kJ/gmol]
h	Altitude [m]
j	Number of reference ions derived from one molecule of the element under consideration
K	Thermodynamic equilibrium constant of a reaction
m	Molal concentration or molality [mol/kg_{H2O}]
n	Number of moles
P	Atmospheric pressure [kPa]
$P°_{H2O}$	Water vapor pressure [kPa]
pH	Negative logarithm of hydrogen ion concentration
R	Ideal gas constant [kJ/gmol K]
S	Conventional seawater salinity [‰: parts per thousand]
T	Absolute ambient temperature [K]
x	Mole fraction
z	Charge, in electric units, of reference ion present in seawater

Greek symbols

ϕ	Atmospheric air relative humidity
γ	Activity coefficient (molal scale)

Superscripts

o	Standard state

Subscripts

c	Concentrational
el	Element
f	Reaction of formation
i	Species or component of a mixture

n Normal conditions of temperature (298.15 K), pressure (101.325 kPa) and concentration of the species
q Chemical
r Reactional
y Additional reacting species in the reference reaction

INTRODUCTION

Chemical exergy (Ex_q) of any substance is the maximum work that can be obtained by taking the system to chemical equilibrium with the environment at constant temperature and pressure. This has two contributions: reactional exergy (Ex_r), resulting from the chemical reactions necessary to produce species existing as stable components in the environment, from the initial composition of the substance; and concentrational exergy (Ex_c), which is a result of the processes requiered to match the chemical concentration of the produced species to their chemical concentration in the environment [1].
The calculation of Ex_q of a substance in its standard state ($Ex_q°$), is carried out considering the environmental conditions and species concentration in the reference environment, which are usually the normal temperature and pressure conditions, this is, 298.15 K and 101.325 kPa, and the mean concentration of the species in the environment at these conditions. It is important to point out that the standard state of a substance is its particular state at temperature *T* defined by general use at reference conditions of pressure, composition and physical state [2]. In this work, the standard state for gases is taken as the pure gas in the ideal-gas state at 101.325 kPa; while for liquids and solids, the standard state is taken as the pure liquid or solid in the real state at 101.325 kPa. The Ex_q of a substance is estimated at normal conditions (T_n and P_n) due to the fact that most of the information about thermodynamic properties and species concentration in the environment is available at these conditions; besides, these are considered the average in the environment. However, depending on the geographical place and season of the year, the environmental conditions may be different from the average. For example, in north hemisphere regions, the ambient temperature has a mean value of –20°C or less during winter, while, places that are close to the Equator, the environmental temperature can be higher than 40°C in the summer [3,4]. Besides, superficial seawater temperature varies between 30°C or more in tropical regions and –2°C under the Artic Ice [3,5].
The effect on $Ex_q°$ of elements and compounds of ambient temperature, atmospheric pressure and reference species concentration –air humidity, carbon dioxide concentration in the air and seawater salinity–, is studied considering the model proposed by Szargut for the calculation of chemical exergy of a substance.

CHEMICAL EXERGY OF COMPOUNDS AND ELEMENTS

According to Szargut [6, 7], to calculate Ex_q of any substance, reference species should be chosen as the most probable products of the interactions between the considered substance and the components of the natural environment. Reference species can be either gaseous components from the atmosphere, or species dissolved in seawater, or solid compounds present on the earth's surface.
Knowing the $Ex_q°$ values of elements, the $Ex_q°$ of any chemical compound can be determined by means of an exergy balance of its formation reaction, this is,

$$Ex_q^o = \Delta G_f^o + \sum_{el} n_{el}\ Ex_{q\,el}^o \qquad (1)$$

Now, the $Ex_q°$ of any element can be determined from $Ex_q°$ values of its reference species and from other elements present in the reference species, as well as from the $\Delta G_f°$ value of the reference species. Considering that species in atmospheric air follow the ideal gas behaviour, their $Ex_q°$ can be evaluated by:

$$Ex_{q\,i}^o = R\,T_n\,\ln\frac{P_n}{P_{i\,n}} = R\,T_n\,\ln\frac{1}{x_{i\,n}} \qquad (2)$$

The partial pressure of water in air, P_{H2O}, is obtained from the relative humidity definition (see Equation 3). The effect of temperature on the vapor pressure of water follows Antoine's expression [8].

$$\phi = \frac{P_{H_2O}}{P_{H_2O}^o} \qquad (3)$$

Standard chemical exergy of elements, whose reference species are dissolved in seawater, are obtained by means of Equation 4, which is derived from the model proposed by Morris, Steward and Szargut [7].

$$Ex^{o}_{q\,el} = -j\Delta G^{o}_{f\,i} + \tfrac{1}{2}\, jz_i Ex^{o}_{q\,H_2} - j\sum_y b_y Ex^{o}_{q\,y} - 2.303RT_n jz_i (pH) - jRT_n \ln(m_{i\,n}\gamma_i) \quad (4)$$

One example of the reaction used in Equation 4 is the formation of sulphate ion, species dissolved in seawater that contains the element sulphur and whose global formation reaction in an electrochemical cell is:

$$S + 2O_2 + H_2 \rightarrow SO_4^{2-} + 2H^+ \quad (5)$$

Activity coefficients of the species dissolved in seawater depend mainly on the ionic strength of the solution. The seawater *pH* (in the range of 7.8-8.2 [9, 10]) is controlled mainly by the carbon dioxide system with minor contributions from boric acid. Presently, molality, *pH* and γ_i values are calculated as function of salinity and temperature, in the same way as Rivero and Garfias determinated these values for the $Ex_q°$ estimation of elements [11], using the total hydrogen ion concentration scale for *pH* and the Pitzer's model for electrolyte mixtures in the case of activity coefficient. Moreover, in this study, the proportion among the species dissolved in seawater is considered constant for any salinity. Also, due to the fact that the concentration of the species dissolved in seawater changes slightly between 273.15 and 323.15 K at constant salinity [12], the proportion among the species present in the hydrosphere is assumed to be constant when seawater temperature varies.

Finally, Szargut [6, 7] establishes that $Ex_q°$ of the solid species in the environment (as an ideal solution) can be determined by means of the following expression:

$$Ex^{o}_{q\,i} = -R\,T_n \ln x_{in} \quad (6)$$

EFFECT OF AIR HUMIDITY ON $Ex_q°$

The water content in the atmospheric air depends on the geographical location and on the season of the year. Normally, the value of 0.7 is used for calculating the $Ex_q°$. Figure 1 shows the $Ex_q°$ as a function of the relative humidity for the most common elements found in the atmosphere and for those species which are directly affected for changes in humidity. In order to see the effect of relative humidity on $Ex_q°$ of a hydrocarbon, methane is included in the analysis ($\Delta G^{o}_{f\,CH4}$ = -50.79 kJ/gmol [13]).

Figure 1 shows that the lower the water content in the atmospheric air, the lower $Ex_q°$ of the elements (except for hydrogen), since the content of the rest of the species of the air increases, and therefore the reference species Ex_c decreases. Moreover, in the case of hydrogen, water itself and methane, the lower air humidity the higher the $Ex_q°$ because these substances are directly related either with the water concentration or with the $Ex_q°$ of hydrogen; e.g. methane, which is formed from two hydrogen molecules and one carbon molecule.

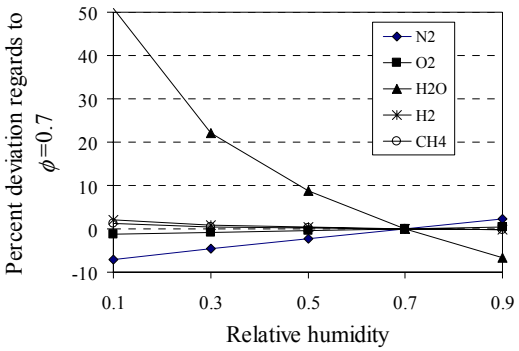

Figure 1: Atmospheric effect of water content on $Ex_q°$

It is important to note that $Ex_q°$ of carbon is not affected by the change of air relative humidity, because the difference between $Ex_q°$ of carbon dioxide and oxygen, from which $Ex_q°$ of carbon is obtained, remains constant whenever humidity varies.

EFFECT OF CO_2 CONCENTRATION ON $Ex_q°$ OF ELEMENTS

Due to the increase of the emissions from the fossil fuels combustion, the CO_2 concentration in the atmosphere has been increasing since the beginning of the industrialization process. Figure 2 shows how the $Ex_q°$ of CO_2 decreased only 2.2 % during the last century even though its

concentration in the air increased 19.4% during the same period [14].

Figure 2 shows that the value of $Ex_q°$ of other substances does not change significantly if the CO_2 concentration is different from 345 ppmv (Szargut's value) [6, 7]. Moreover, in the case of carbon and methane, whose $Ex_q°$ values strongly depend on $Ex_q°$ of carbon dioxide, the effect of CO_2 concentration on the $Ex_q°$ is less than 0.1%.

$Ex_q°$ of water is not affected by changing CO_2 concentration because humidity is kept constant, so it does not depend on the rest of the species of dry air, but on temperature and the total pressure of the medium.

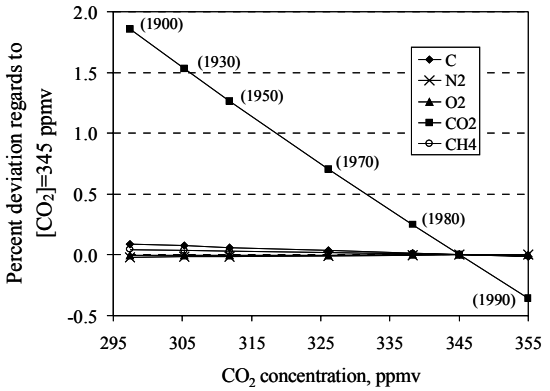

Figure 2: Effect of CO_2 concentration during the last century on $Ex_q°$

EFFECT OF SEEWATER SALINITY ON $Ex_q°$ OF ELEMENTS

Water salinity in the oceans is associated with latitude. Low salinity values are found in zones where rain precipitation is continuous or in the polar areas where salts are diluted by the fusion of ice, although during the winter salinity increases due to the opposite process. An example of this is the Baltic Sea of which salts content varies between 5 and 15‰. In contrast, in the subtropical regions where rain is scarce and water evaporation is high, the salinity can reach a value of 40‰, as it is the case of the Red Sea where, besides of being surrounded by earth, there are not fresh water supplies. The mean value of seawater salinity on Earth is 35‰.

In the present work, the effect of environmental conditions on $Ex_q°$ is analysed only for those elements, whose reference species dissolved in seawater were recommended by Rivero and Garfias in 2002 [11, 12]. The work obtained to change species concentration from pure substance to its concentration in the environment (Ex_c) decreases when the species concentration is increased in the environment, whenever the considered formation reaction of the reference species is the same. The effect of changing seawater salinity on $Ex_q°$ of the elements found in the ocean is very low (Figure 3), regardless of its value at T_n (298.15 K). The maximum deviation (1.1%) of the $Ex_q°$ value by increasing the salinity from 35 to 40‰ occurs for the bromide element.

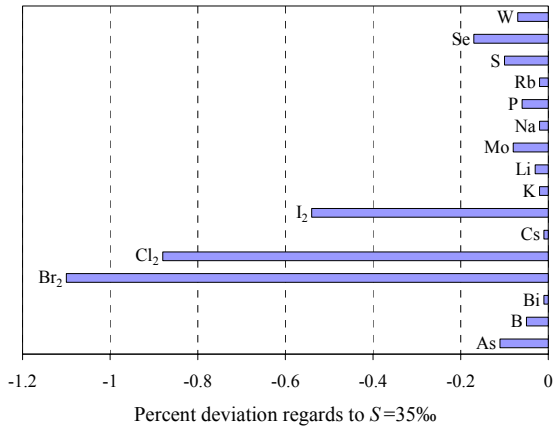

Figure 3: Effect on $Ex_q°$ of elements contained in the hydrosphere by increasing S to 40‰

EFFECT OF ENVIROMENTAL TEMPERATURE ON $Ex_q°$

The $Ex_q°$ of any substance strongly depends on the environmental temperature because its value fixes the change in the $\Delta G°$ of the reference reaction at equilibrium and to some extent also the concentration of the references species in the medium. In this work, the extreme conditions considered for terrestrial systems are 233.15 K (-40°C) as minimum temperature and 323.15 K (50°C) as maximum temperature.

The effect of temperature on the equilibrium constant of the reference reaction is given by [2]:

$$\frac{d(\ln K)}{dT} = \frac{\Delta H^o}{RT^2} \qquad (7)$$

If it is assumed that the $\Delta H°$ of the reaction is constant in the temperature range considered and its value is equal to the heat of reaction at normal

temperature T_n, the integral of Eq. (7) from the normal temperature T_n to the ambient temperature T becomes,

$$\ln \frac{K}{K_{T_n}} = \frac{\Delta H^o_{T_n}}{R}\left(\frac{1}{T_n} - \frac{1}{T}\right) \qquad (8)$$

Finally, using the relationship (Eq. (9)) between $\Delta G°$ and K of the reaction, the value change of $\Delta G°$ at a different temperature in reference to the normal is obtained by Eq. (10).

$$\ln K = -\frac{\Delta G^o}{RT} \qquad (9)$$

$$\Delta G^o = \Delta G^o_{T_n}\frac{T}{T_n} + \Delta H^o_{T_n}\left(1 - \frac{T}{T_n}\right) \qquad (10)$$

In general, the values of standard enthalpy and standard Gibbs energy for the formation reaction were taken from the same reference [8, 13, 15-18]; however, for some species $\Delta H_f°$ was obtained from $\Delta G°$ and entropy change of the reaction at 298.15 K.

Effect of temperature on $Ex_q°$ of elements and substances in the atmosphere

Figure 4 shows the percent deviation of the $Ex_q°$ of elements and reference species present in the atmosphere, as a function of environmental temperature. In the same figure, the $Ex_q°$ of methane is included.

When the environmental temperature varies, at atmospheric pressure and constant relative humidity (not constant absolute humidity), $Ex_q°$ value of the elements in the air changes significantly due to an important change of the water content in the atmosphere. For instance, at 323.15 K (50°C), the P_{H2O} increases almost 300% with respect to its value at 298.15 K (25°C), then the partial pressure in the air of the rest of the species decreases about 7% and consequently their $Ex_q°$ is increased. In the case of nitrogen, oxygen, and argon, the increase in $Ex_q°$ at 323.15 K is 35, 13 and 10%, respectively, whereas water $Ex_q°$ value decreases 30%, with respect to the normal temperature. Although, the $Ex_q°$ of carbon dioxide increases 9.3% at the same temperature, the $Ex_q°$ of the element carbon only increases 0.3%.

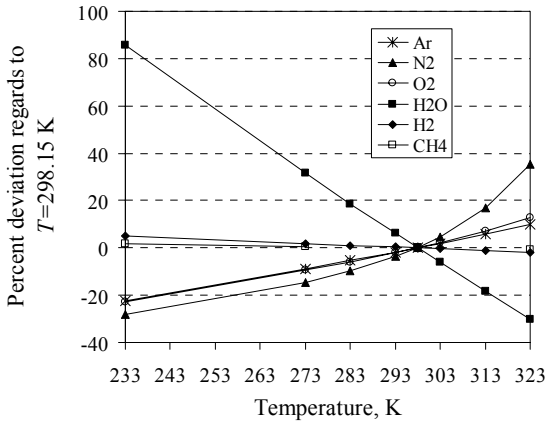

Figure 4: Effect of environmental temperature on $Ex_q°$ of elements and substances in the atmosphere

In the case of methane, the temperature effect is also small with a maximum variation at –40°C (1.7%), which is higher than its value at 25°C. When the environmental temperature and the water concentration, at constant atmospheric pressure and relative humidity, decrease and then the $Ex_q°$ of hydrogen increases, the value of the $Ex_q°$ of methane (Figure 4), as well as its $\Delta G_f°$ becomes higher. Since the $Ex_q°$ of carbon changes slightly with temperature and methane is formed by the double of molecules of hydrogen than carbon molecules, the change in the $Ex_q°$ value of the methane depends mainly on the change of the $Ex_q°$ of hydrogen. It is important to mention that if the P_{H2O} in the air is kept constant, and consequently its absolute humidity is kept constant during temperature change, the $Ex_q°$ of methane will show the opposite behaviour of the one shown in Figure 4, i.e., the higher temperature, the higher is $Ex_q°$ of methane [19]. However, maintaining a constant absolute humidity of air would imply a change in its relative humidity because of the variation of the $P°_{H2O}$.

Effect of temperature on $Ex_q°$ of elements present in the hydrosphere and lithosphere

When the environmental temperature is below zero degrees Celsius, a problem arises in the calculation of $Ex_q°$ of the elements of the hydrosphere and lithosphere, since seawater freezes at –2°C and so the reference species dissolved in seawater no

longer exits as such. This has no effect in the case of the elements in the atmosphere, since their $Ex_q°$ values do not depend on the $Ex_q°$ of the elements of the hydrosphere; however, the $Ex_q°$ of some elements of the Earth's crust (Ag, Ba, Cr, F_2, Hg, and Ra) depends on the exergy value of chlorine, potassium, phosphorus and sulphur which exits in seawater.

Information about frozen seawater composition is almost non-existent. Millero [20] indicates that frozen seawater has a higher relation of SO_4^{2-} to Cl^- ions with respect to liquid seawater because the sulphate ions are incorporated into the ice. Also, the relation Ca^+ to Cl^- changes due to the precipitation of calcium carbonate in the frozen sea. Assuming a frozen seawater composition would be extremely complex.

As the $Ex_q°$ of an element at 0°C is lower than its value at 25°C, it could be expected that if the temperature decreases further, this tendency would remain the same and vice versa. The only possibility that fulfills this assumption for all the elements is when the $Ex_q°$ of the elements of seawater and Earth's crust is determined at the same temperature at which the atmospheric air is, assuming that the species dissolved in seawater remain as such even when the temperature is below the seawater fusion point.

Figure 5 shows the percent deviation with respect to the value of $Ex_q°$ of elements on the hydrosphere and lithosphere at 25°C, when the temperature of the environment is –40°C, 0°C and 50°C. Figure 5 illustrates only the elements with the highest variation in the $Ex_q°$ value when changing temperature.

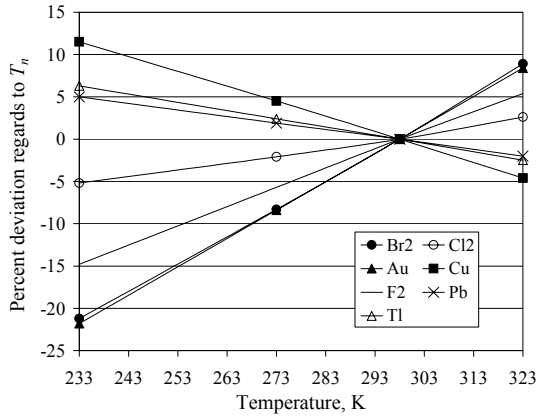

Figure 5: Effect of temperature on $Ex_q°$ of elements in seawater and Earth's crust.

There are two overall effects with temperature: the change of $\Delta G_f°$ and, the change of $Ex_q°$ of the reference species as well as of the others elements contained in the species.

In general, the higher the temperature, the lower the $Ex_q°$ value. This is reasonable since increasing the temperature of the reaction in which the element is transformed to its reference species and decreasing spontaneously (lower $\Delta G_f°$) more work from the surroundings is required for the reaction to take place and then the Ex_r decreases, i.e. the maximum useful work that can be obtained from that reaction.

In the case of elements Br_2, Cl_2, Cs, Rb, Ag, Au, F_2, Ir, Ni, Pd, Pt, Pu, Ra, Ru, and Te, the higher temperature the higher their $Ex_q°$. For the case of cesium and rubidium, when temperature increases, the $\Delta G_f°$ also increases. However, the behaviour of the $Ex_q°$ when temperature changes cannot be explained only by the tendency and magnitude of the $\Delta G_f°$ value, since in the case of Br_2, Cl_2, K, Li, Na, Ag, F_2, Ir, Ni, Pd, Pt, Pu, Ra, Ru, and Te, when temperature varies, the change in $Ex_q°$ and $\Delta G_f°$ do not follow the same tendency. Then, the change of $Ex_q°$ with temperature depends also on $Ex_q°$ of the reference species and of the other elements that are contained in the species.

In the case of gold, whose reference species is solid gold, the percent variation in its $Ex_q°$ is the only result of the temperature difference since its concentration remains constant. For the rest of the elements of the periodic table, the variation of $Ex_q°$ with environmental temperature is low, lower than 5%.

EFFECT OF ATMOSPHERIC PRESSURE ON $Ex_q°$

Although there are regions on the Earth with a height over sea level higher than 4,000 meters, in this work only altitudes where population live and chemical processes can be carried out, are considered. So, the values of 3,625 m (La Paz, Bolivia) and –244 m (Jericho, Israel) are assumed as maximum and minimum altitudes, respectively, with an atmospheric pressure of 0.65 and 1.03 atm. The pressure is related to altitude by [21]:

$$P_2 = P_1 \, e^{-Bh} \qquad (11)$$

P_2 is the atmospheric pressure at h, P_1 atmospheric pressure at sea level (1 atm), B a constant that

includes the air molecular weight, gravitational acceleration, R and T. At 25°C, B is equal to 1.168×10^{-4} m^{-1}. In general, the effect of atmospheric pressure on $Ex_q°$ of elements is very low or zero. In the case of elements whose reference species are in the air, the lower the pressure, the higher $Ex_q°$ of the rest of elements being in the atmosphere. The higher deviation (4.5%) on $Ex_q°$ is for nitrogen at 0.65 atm with respect to its value at 1 atm (see Figure 6).

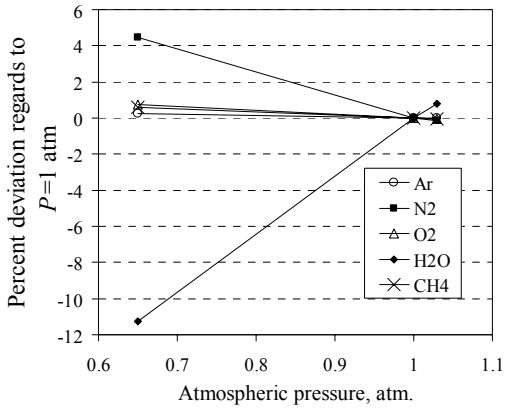

Figure 6: Effect of atmospheric pressure on $Ex_q°$ of elements and substances in the air

Changing atmospheric pressure, the $P°_{H2O}$ in the air keeps constant since its value depends only on temperature and relative humidity; however, the partial pressure and then the mole fraction value of the rest of species present in the atmosphere is modified, even though the proportion among them remains constant. Decreasing atmospheric pressure from 1 to 0.65 atm, the partial pressure of species different to water decreases by 35%. The molar fraction value of these species decreases, only by 1.2 % in this case, whereas the increment on x_{H2O} is almost 54%. The result is that $Ex_q°$ of water decreases 11% (see Figure 6) due to the increment of the water concentration in the medium, thus reducing its Ex_c. The lower molar fraction of the rest of species, the higher is their $Ex_q°$.

The variation on $Ex_q°$ value of elements present in the hydrosphere and lithosphere, by changing pressure, depends only on the variation of $Ex_q°$ of elements whose references species are in the atmosphere and which constitute reference species present in seawater and Earth's crust. If atmospheric pressure decreases to 0.65 atm, elements with the higher deviation in their $Ex_q°$ values are fluorine (1.8%), bromide (1.1%) and mercury (1%). In this case, the $Ex_q°$ of methane changes only 0.3% regards to its value at 1 atm, because this value is affected only by $Ex_q°$ of hydrogen, not by $Ex_q°$ of carbon or by $\Delta G_f°$, both of which do not change.

CONCLUSIONS

Ambient temperature is the condition that has the most important effect on the $Ex_q°$ of a substance, this is due to the fact that $\Delta G_f°$ of the reference species and its environmental concentration depend on this condition. If the substance is a component of the environment, such as nitrogen, oxygen and water, the effect of considering a temperature value different from 298K is higher than when the substance is not present. Moreover, when atmospheric pressure, air relative humidity, CO_2 concentration in the air and seawater salinity vary, the effect on $Ex_q°$ is very small.

Standard chemical exergy of water is the most sensitive value to changes in environmental conditions because its concentration in the environment is the one that changes more when any environmental property varies. In the case of steam water, the variation of its $Ex_q°$ value can be as high as 50%. Finally, at atmospheric pressure and constant relative humidity (not constant absolute humidity), $Ex_q°$ of any hydrocarbon increases when ambient temperature decreases. However, reducing temperature at constant air absolute humidity and atmospheric pressure, the $Ex_q°$ of a hydrocarbon decreases too; this is because of a change in relative humidity by the variation of water partial pressure.

ABSTRUCT: In this paper three advanced power systems, including the chemically recuperated gas turbine cycle (CRGT), the steam injected gas turbine cycle (STIG) and the combined cycle, were investigated through the exergy analysis. By comparing the results, the exergy destruction of combustion in CRGT cycle was lower 6.1% than that of the STIG cycle, which made the exergy efficiency of the CRGT cycle 2.6 percentage points higher. Through the exergy analysis based on the concept of energy level, the cascade utilization of chemical energy of natural gas in CRGT cycle was clarified. The exergy destruction during the mix process before combustion and the exergy loss of the exhausted gas in the CRGT cycle was increased rapidly compared to the combined cycle, which made the exergy efficiency of the CRGT cycle was about 5 percentage points lower than that of the combined cycle. At last the approach to improve the performance of CRGT was pointed out. The results obtained here give a deeper understanding of CRGT cycle and provide a new approach for the synthesis of innovative energy systems.

1 INTRUCTION

Thermal cycle is one of the active domains of energy and environment science. In the past several decades some advanced thermal cycles with gas turbine as core were proposed to improve the thermal efficiency of thermal cycle. These thermal cycles included the combined cycle (CC), steam injected gas turbine (STIG) [1, 2], humid air gas turbine (HAT) [3] and Kalina cycle [4]. The exhaust thermal energy from the gas turbine is used more and more efficiently, and it becomes more and more difficult to improve the performance of the thermal cycle. The current research was mainly focused on how to utilize the thermal energy of exhaust gas of gas turbine more efficiently.

The chemically recuperated gas turbine (CRGT), which was proposed in 1970's, was the first time to combine the thermal cycle with the chemical process of the steam reforming. In this paper we call it as the indirect energy release of the natural gas. Steam reforming was considered by several authors as a possibility to improve the efficiency of gas turbine cycles [5-7]. The basic chemically recuperated cycle was simulated in Ref. [8], and the thermal efficiency was 48.8%, which was higher than that of the steam injected gas turbine (STIG) and lower than of the combined cycle (CC). Then the CRGT was improved [12] by using reheated Brayton cycle as the topping cycle, and the thermal efficiency rose, however lower than that of the CC. Many researchers have noted that the calorific value of the fuel will be increased by the utilization of heat available at the turbine discharge, but the thermal efficiency of the cycle does not rise conspicuously. In order to understand the reason, the system was studied by the traditional exergy analysis [15], but no satisfied result was obtained.

The aims of this paper are (1) to clarify the role of the indirect energy release in the CRGT based on the concept of energy level, (2) to investigate the key factors that affect the performance of the indirect energy release. (3) to point out the method to improve the efficiency of the power cycle with steam reforming.

2 SIMULATIONS OF CYCLES

Three thermal cycles were simulated using ASPEN+ process simulation code, which were the CRGT, the STIG and the CC. The gas turbines in these cycles were without intercooling or reheat. Figures 1a 1b and 1c respectively show the schematic diagrams of the CRGT cycle STIG

cycle and the CC. In the three cycles the compression ratio is 15.0 and the inlet temperature of gas turbine is 1581K. The combustor pressure ratio is 0.97. The compressor isentropic efficiency is 0.89 and the turbine isentropic efficiency is 0.88.

HRSG: Heat Recovery Steam Generator
G: generator P: pump

Fig. 1a. CRGT cycle

In the reformer of the CRGT the approach temperature difference is 20K. According to Ref. [8], the chemical nonequilibrium can be described by the chemical equilibrium approach temperature difference ($\triangle T_{eq}$). $\triangle T_{eq}$ can either be specified or calculated from the following equation for a typical reformer using a nickel-based catalyst:

$$\Delta T_{eq} = 0 \qquad \text{if } T_{\text{out},2} \geq 923\text{K}$$

$$\Delta T_{eq} = 43.33(1.0 - \frac{T_{out,2} - 273}{650}) \quad \text{if } T_{\text{out},2} < 923\text{K}$$

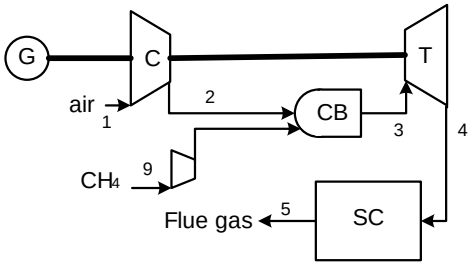
HRSG: Heat Recovery Steam Generator
G: generator P: pump

Fig. 1b. Simple STIG cycle

The hot-side reformer pressure ratio is 0.97 and the cold-side reformer pressure ratio is 0.9.

In the STIG cycle the hot-side HRSG pressure ratio is 0.99 and the cold-side HRSG pressure ratio is 0.95. The approach temperature difference of the HRSG is 20K.



C: compressor T: turbine CB: combustor
SC: Steam cycle G: generator

Fig. 1c.Combined cycle

In the combined cycle the steam cycle (SC) is with dual pressures and reheating. The high pressure is 12MPa and the temperature of the live steam is 535°C. The reheating pressure is 3.9MPa and the reheating temperature is 535°C. The low pressure is 0.5MPa and the temperature of steam is 260°C.

Table 1 presents the main results for the three cycles.

Table 1 Main result for CRGT, STIG and CC cycle

3 ANALYSES OF THE THREE CYCLES BASED ON EXERGY AND THE CONCEPT OF ENERGY LEVEL

3.1 Exergy analysis

Based on the simulation results of the three cycles, the exergy analyses were carried out. In this paper the combustion was divided into two steps. Firstly, the fuel, air and other stream such as the steam in the STIG cycle were mixed before combustion. Secondly, the mixture took reaction and the fuel was oxidated completely.

Table 2 Exergetic comparison of CRGT and STIG

	Exergy / kW		
	CRGT	STIG	CC
Exergy losses			
Mix before Com.	5.69	6.58	1.49
Combustor	24.54	26.14	28.11
Heat recovery	6.83	6.83	3.42
Power subsystem	9.54	8.85	11.06
Stack gas	6.39	7.19	4.09
Total losses	53.00	55.58	48.16
Work output	47.00	44.24	51.84
Exergy of fuel	100.00	100.00	100.00
Exergy efficiency	47.00%	44.42%	51.84%

The exergic analyses of the three cycles were presented in Table 2. The exergy efficiency of the CRGT cycle is 2.58 percentage points higher than that of the STIG cycle. In the CRGT cycle the ratio of steam to methane was 6.1 and in the STIG cycle the ratio was 6.9. As there was more steam mixed with air in STIG cycle, the exergy destruction of mix before combustion is 0.89 kW more than that in the CRGT cycle. For the same reason the exergy loss of stack gas in CRGT cycle was smaller than that of the STIG cycle. The energy destruction in combustor of the CRGT cycle is decreased 6.1% than that of the STIG cycle. Hence, the decrease of the exergy destruction of combustion looks like the primary reason that leads the exergy efficiency of the CRGT cycle higher than the STIG cycle.

With the same inlet temperature of gas turbine, the optimal pressure of the CRGT cycle and the STIG cycle is difference. The optimal pressure of the STIG is higher than that of the CRGT. When the pressure is lower, the efficiency of the CRGT cycle is higher than that of the STIG. As the pressure is increased, the outlet temperature of gas turbine will be decreased. So there will be less methane reformed, and the advantage of the CRGT cycle is weakened. As the pressure is high enough, the reforming reaction does not take place and the CRGT cycle does not work.

Comparing the CRGT cycle and the CC, the exergy destruction of combustion of CRGT is decreased by 3.571kW. As there is no steam in the mix before combustion, the exergy destructions in the process and the exergy loss of stack gas in CC are respectively decreased by 4.2kW and 2.3 kW compared with CRGT. The decrement of the exergy destruction in combustion is counteracted by the increment of the exergy destruction in mix. In the CRGT and STIG cycles the HRSG is single pressure, but in CC the HRSG is dual pressure. The exergy destruction in HRSG of the CC is decreased by 3.41 kW than the CRGT cycle.

3.2 The role of the steam reforming in CRGT cycle

In order to disclose the cascade utilization of natural gas in CRGT cycle, we analysis the steam reforming based on the concept of energy level. In Ref. [16] Masaru Ishida introduced the concept of energy level and also introduced many applications on difference thermal processes. The exergy analysis based on this concept can get more detail of the thermal process than the traditional exergy analysis. The defining equation of A is

$$A = \Delta E / \Delta H \tag{1}$$

where ΔH represents the quantity of transformed energy and ΔE represents the quality of transformed energy. When $A=0$, it represents the environmental status.

The steam reforming was presented in the Fig.2.

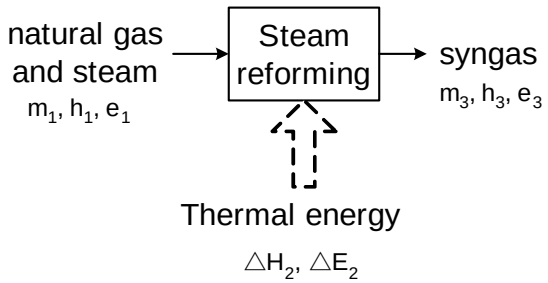

Fig. 2 Sketch map of the steam reforming

We assumed that the temperature of the reforming reaction is constant. The parameters of m, h and e, respectively, represent mass, enthalpy and exergy, and the subscript 1, 2 and 3 respectively represent reactant (mixture of natural gas and steam), thermal energy for reaction and the product of reforming reaction-syngas. Since the temperature has little effect on the enthalpy and exergy of fuel, here the enthalpy and exergy of the fuel are assumed as constants.

The energy balance of the reaction is based on the first law of thermodynamics

$$m_3 * h_3 = m_1 * h_1 + \Delta H_2 . \quad (2)$$

Similarly, the exergy balance of the reaction is based on the second law of the thermodynamics

$$(\Delta E_2 - \Delta E_w) = m_3 e_3 - m_1 e_1 \quad (3)$$

where ΔE_w is the exergy loss in the reaction. Eq. (3) can be rearranged as

$$m_3 e_3 = m_1 e_1 + (\Delta E_2 - \Delta E_w) . \quad (4)$$

Based on the Eq. (1), the energy level of the fuel and the synthetic fuel can be expressed as

$$A_1 = \frac{m_1 * e_1}{m_1 * h_1} = \frac{e_1}{h_1} \quad (5)$$

$$A_3 = \frac{m_3 * e_3}{m_3 * h_3} = \frac{e_3}{h_3} . \quad (6)$$

Substitute Eqs. (2) and (4) into Eq. (6), and yields

$$A_3 = \frac{m_1 * e_1 + \Delta E_2 - \Delta E_l}{m_1 * h_1 + \Delta H_2} . \quad (7)$$

The energy level of the thermal energy for reaction is

$$A_2 = \frac{\Delta E_2}{\Delta H_2} = 1 - \frac{T_0}{T_2} \quad (8)$$

where T_2 is the temperature at which the reaction takes place. The energy level of the thermal energy for reaction is equal to the efficiency of the Carnot cycle which woks between the temperature of reaction and environment.

Here, we define the parameter β which is the ratio of the thermal energy for reaction to the enthalpy of the reactant (fuel). The expression of β is

$$\beta = \frac{\Delta H_2}{m_1 * h_1} . \quad (9)$$

Substitute the Eqs. (5), (8) and (9) into Eq. (7) and predigest it. The following equation is obtained

$$A_3 = \frac{A_1}{1+\beta} + \frac{\beta}{1+\beta}(A_2 - \frac{\Delta E_w}{\Delta H_2}) \quad (10)$$

where $\Delta E_w/\Delta H_2$ is the energy level degradation of the thermal energy for reaction caused by the exergy loss in the chemical reaction. (A_2-$\Delta E_w/\Delta H_2$) can be understood as the energy level of reforming reaction, when the reaction is reversible. As $\Delta E_w/\Delta H_2$ is denoted by ΔA_w, the Eq. (10) becomes

$$A_3 = \frac{A_1}{1+\beta} + \frac{\beta}{1+\beta}(A_2 - \Delta A_w) \quad (11)$$

Eq. (11) can be rearranged as

$$A_3 = A_1(\frac{1}{1+\beta} + \frac{\beta}{1+\beta}\frac{A_2 - \Delta A_w}{A_1}) \quad (12a)$$

Eq. (12a) can be written as

$$A_3 = \alpha * A_1 \quad (12b)$$

where

$$\alpha = (1 + \beta\frac{A_2 - \Delta A_w}{A_1})/(1+\beta) \quad (13).$$

As $(A_2 - \Delta A_w) < A_1$, we can get $\alpha < 1$. From the Eq.(12b) the energy level of natural gas is decreased through the steam reforming.

Eq. (11) can be rearranged as

$$(1+\beta)A_3 = A_1 + \beta(A_2 - \Delta A_w) \quad (14)$$

The left side of the Eq. (14) is the exergy of syngas, and $(1+\beta)$ is the quantity of chemical energy of syngas. The first item on the right side of Eq. (14) is the exergy of methane, and the quantity of chemical energy of methane is equal to 1. The second item on the right side is the exergy of thermal energy absorbed by the reaction theoretically. From Eq. (14) we can see that the exergy of thermal energy and methane are changed into the exergy of syngas. As we know that the energy level of thermal energy is lower than that of syngas, it is upgraded. Here we can conclude that the decrement of the energy level of methane is not destructed, but it is utilized to upgrade the energy level of thermal energy.

When the syngas is combusted, the exergy destruction can be expressed as

$$(1+\beta)(A_3 - A_T) = (1+\beta)A_3 - (1+\beta)A_T \quad (15).$$

Substitute the Eq.(14) into Eq.(15) and predigest it

$$(1+\beta)(A_3 - A_T) = (A_1 - A_T) - \beta(A_T - A_2 + \Delta A_w) \quad (16)$$

The first item of right side of Eq. (16) is the exergy destruction of combustion of methane, as the methane is combusted directly. The combustion temperature is higher than that of the reforming reaction, the second item of right side of Eq. (16) is positive. Then we can say that in the combustion the exergy destruction of syngas is smaller than that of methane. Through the steam reforming the CRGT cycle utilizes the chemical energy of methane before combustion and causes the exergy destruction in combustion to be decreased. It is efficient utilization of the chemical energy of methane that made exergy efficiency of the CRGT cycle higher than that of the STIG cycle.

4 PERFORMANCE OF INDIRECT ENERGY RELEASE

The steam reforming is the key process in the CRGT cycle and it will affect the thermal efficiency of the power cycle. There are some parameters that will affect the utilization of natural gas in the CRGT. The first one is the ratio of steam to methane (s/c) in the reformer, the second one is the temperature of the reforming (tr) and the third one is the pressure of the reaction of reforming. As the pressure of reforming is decided by the pressure ratio of compressor, we assume that the pressure of reforming is 19 atm. Fig. 3 shows the effect of the parameters of s/c and tr to the mix and the combustion. As the temperature of steam reforming is increased from 600K to 1400K, the exergy destruction of combustion is decreased in Fig. 3. The methane/steam reforming is a highly endothermic reaction and the reaction is

$$CH_4 + H_2O = CO + 3H_2$$

$$(\Delta H^0_{298} = 206 \text{ kJ/mol}).$$

The high temperature will get the high conversion rate of natural gas into CO or H_2. When more methane is converted into CO and H_2, the reaction of reforming will absorb more thermal energy and the parameter of β rise. From Eq.(13) the parameter of α will reduce with the increment of the parameter β. From Eq. (14), the exergy destruction of combustion is decreased with the increment of the reforming temperature. On the other hand, when the temperature of reforming is increased, the temperature and the molecule number of syngas are increased. So the exergy destruction of mix is increased rapidly in Fig.4. Fig.5 expresses the effect of temperature of reforming on the sum of mix and combustion. There exists a proper reforming temperature, at which the sum of exergy destruction has minimum.

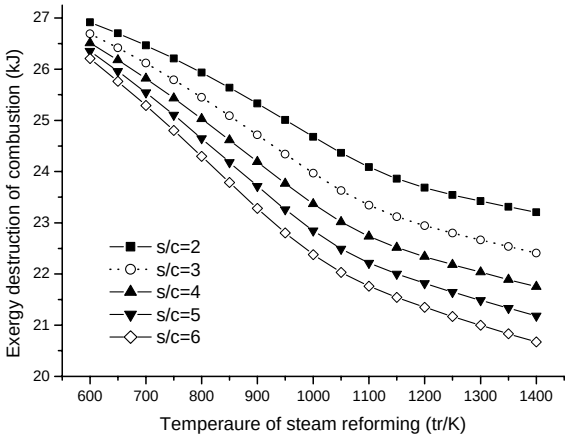

Fig. 3 Exergy destruction of combustion

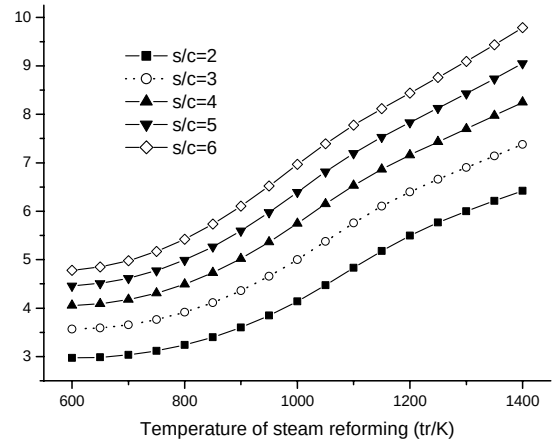

Fig. 4 Exergy destruction of mix

The ratio of steam to methane also affects the steam reforming. The increment of ratio (s/c) drives more methane reacted. The parameter of β is increased and α is decreased. The exergy destruction of combustion is decreased with the increment of s/c shown in Fig. 3. By contraries, the exergy destruction of mix is increased with the

increment of s/c, as the molecule number of syngas is decreased in Fig. 4. In order to reduce the exergy destruction of the sum, the parameter s/c should be smaller as shown in Fig. 5. As the parameter of s/c and tr are respectively 2 and 1000K, the sum of exergy destruction is 28.82kJ which is 0.78kJ less than that of the CC. The exergy exhaust gas is 4.66kJ and is 0.57kJ more than the CC. In a word the proper reforming temperature (950K—1050K) and the lower ratio of steam to methane will improve the performance of the indirect energy release.

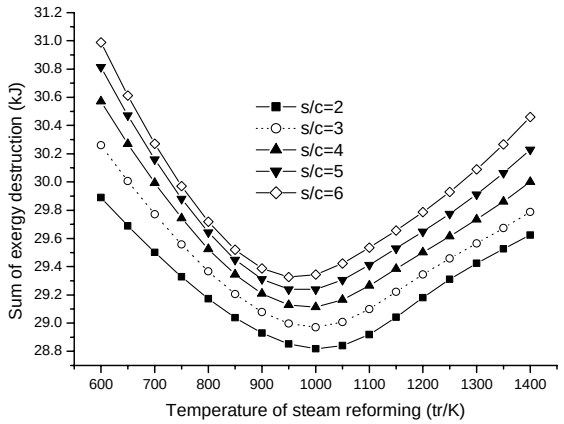

Fig. 5 Sum of exergy destruction

5 APPROACH TO IMPROVE CRGT

In order to improve the performance of the CRGT cycle, we can adopt several methods. (1) Keep the temperature of reforming between 900K and 1050K. In this range the indirect energy release has high performance in Fig. 5. (2) The ratio of steam to methane should be as low as it can be. In the practice it should be higher than 2. If the ratio is lower than 2, the carbon will be generated and the catalyzer will be poisoned. As the steam is decreased, the performance of the indirect energy release is improved. At the same time the exergy destruction of mix and exhaust will also be reduced. (3) The thermal energy of the exhaust gas of gas turbine should be utilized more efficiently in CRGT cycle. The thermal energy with higher temperature can be absorbed by the reaction of steam/methane reforming. A part of the thermal energy with lower temperature can generate steam for the reforming reaction and the other can be used to humidify the air of the combustion.

6 CONCLUSIONS

In this paper the indirect energy release in the CRGT cycle is studied, and it is the key process that makes the thermal efficiency of CRGT cycle higher than the STIG cycle. In the indirect energy release the chemical energy of natural gas is utilized before combustion and the energy level of fuel is decreased. The decrement of energy level of fuel makes the exergy destruction of combustion reduce. The exergy destruction during mix before combustion and heat exchange was increased as while as the exergy loss of exhaust gas. All of these make the thermal efficiency of the CRGT cycle lower than that of the CC. Based on the parameters analysis, the indirect energy release can utilize the natural gas more efficiently, when the temperature of steam reforming is about 1000K and the ratio of steam to methane is equal to 2. This paper gives a deeper understanding of CRGT cycle and provides a new approach for the synthesis of innovative energy systems.

ABSTRACT

Splitting the physical exergy of a working fluid into its thermal and mechanical components improves the accuracy of and facilitates an exergoeconomic optimization. In this paper graphical models are used to demonstrate the splitting of physical exergy. These models assist in understanding and using theoretical models.
Keywords: physical exergy, thermal exergy, mechanical exergy, isothermal expansion, isobaric heat transfer

INTRODUCTION

The accuracy of an exergoeconomic analysis and the quality of optimization may be improved when (a) the physical exergy of a working fluid is split into its thermal and mechanical exergy components, and (b) each exergy component is cost separately. The principles of costing exergy streams are discussed in References [1-8].

The splitting of physical exergy is discussed in References [1-3, 5, 9-14 and 19]. For this purpose either adiabatic and isothermal processes or isobaric and isothermal processes are considered.
The present paper complements the development presented by Paulus and the authors [14] and demonstrates graphically the interpretation of physical exergy splitting. The physical exergy may be graphically shown on various diagrams including the following:

On an *e*-*h*-diagram

The graphical model for splitting physical exergy into its components is used to estimate the effect of changing pressure and temperature of a material stream on the exergy value. The graphical demonstration of physical exergy as the sum of the thermal and mechanical exergy components using an *e*-*h*-diagram is given in References [10] and [11], Fig. 1.
It is necessary to recognize that analysis on an *e*-*h*-diagram is not as objective as the analysis on other thermodynamic diagrams of a working fluid, for example, on an *h*-*s*-diagram, or *T*-*s*-diagram. The

e-h-diagram is created by fixing the temperature and pressure of point «O» (p_O, T_O). In References [10] and [11] the temperature of environment is T_O=290 K (17°C) a values considered as standard for exergy analysis in the 1960's. Note, that for exergy analysis the following values of T_O: are accepted T_O=15°C (288K) as ISO standard; T_O=27°C (300K) in [17] for simplification of calculation data and T_O=25°C (77°F, 298K) as standard for modern applied thermodynamics [5].

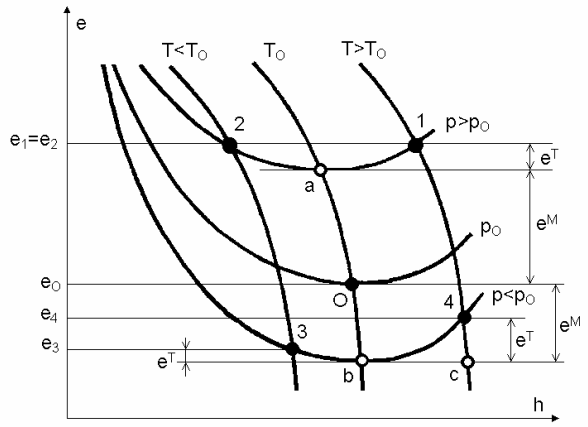

Figure 1: Thermal and mechanical components of physical exergy. Graphical interpretation on *e-h*-diagram by [10-11]:

Point 1 - $T_1>T_O$; $p_1>p_O$; $e^T=e^1-e^a$; $e^M=e^a-e_O$; $e^T+e^M=e^1-e_O$

Point 2 - $T_2<T_O$; $p_2>p_O$; $e^T=e^2-e^a$; $e^M=e^a-e_O$;

Point 3 - $T_3<T_O$; $p_3<p_O$; $e^T=e^3-e^b$; $e^M=e^b-e_O$; $e^T+e^M=e^3$; $e^M<0$; $e^T>0$

Point 4 - $T_4>T_O$; $p_4<p_O$; $e^T=e^4-e^c$; $e^M=e^c-e_O$

On a *p-V*-diagram

If exergy is potential work, then there must be an expansion machine where this work can be produced. This was proposed by Bošnjaković [9] and presented graphically as shown in Fig. 2a. Physical exergy is the area of *p-V*-diagram of an expansion machine. There are two parts:

- work produced by an isentropic expansion ($e^1 \equiv w_{s=const}$);
- work produced by an isothermal expansion ($e^2 \equiv w_{T=const}$).

Thus, the physical exergy is

$$e = -\int_1^3 v dp = -\int_1^2 v dp - \int_2^3 v dp \,, \qquad (1)$$

$$q = h_3 - h_1 - \int_1^3 v dp = h_3 - h_1 + e \,. \qquad (2)$$

If the process 2→3 is an isothermal expansion (*T=const*), then the amounts of heat and work are absolutely taken equal in this process $w_{2\to3}=q_{2\to3} = T(s_3 - s_2)$. Thus, if $T_3=T_O$, we have an equation for calculating physical exergy

$$e = h - h_O - T_O(s - s_O). \qquad (3)$$

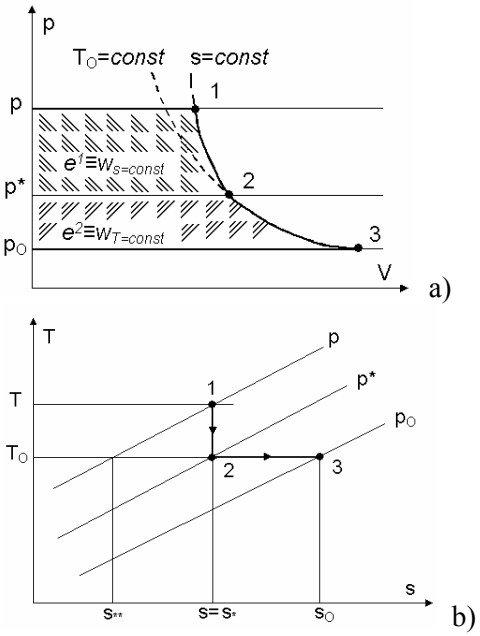

Figure 2: Graphical model of exergy by Bošnjaković [9]

BACKGROUND FOR PHYSICAL EXERGY SPLITTING

There are only three thermodynamic processes that can be used to develop the components of physical exergy: isothermal expansion (or compression), adiabatic expansion (or compression), and isobaric heat transfer.

Isothermal expansion. An isothermal expansion from p to p_O is an ideal process that cannot be realized in practice. The amount of heat required is absolutely taken equal to work generated.

This process can be carried out if there is a heat source of limited size with unlimited heat capacity or a heat source with limited heat capacity but unlimited size. From the theoretical point of view, the isothermal expansion can be carried out at any temperature level. Isothermal expansion at $T<T_O$ or $T>T_O$ demands additional energetic expenses (*T=const* only) that should be taken into account in the analysis. An isothermal expansion at $T<T_O$ or $T>T_O$ is according to Reference [15] a non-

equilibrium process that should not be considered in a theoretical analysis.

Isobaric heat transfer. An isobaric heat transfer process from T to T_O can be carried out at $p<p_O$, $p=p_O$ and $p>p_O$. For heat transfer realization at $p<p_O$ or $p>p_O$ additional energetic expenses are necessary.
Adiabatic expansion. An adiabatic expansion can be considered as the combination of isobaric heat transfer and isothermal expansion; therefore, this process can also be used in the analysis. Reference [18] contains a detailed analysis of an adiabatic compression process as sum of isothermal compression and isobaric heat transfer.

GRAPHICAL MODEL OF EXERGY

A graphical model is the illustration of a theoretical model. In the following, the graphical models of exergy for five different locations of point «☺» (p, T) with respect to the environmental point «O» are given on p-V-diagrams, T-s-diagrams and h-s-diagrams. Let us work "from simple to complex" and systematize the results.

On *p-V*- and *T-s*-diagrams

Model «A» (Fig.3). The coordinates of point «☺» are (p, $T=T_O$, $s<s_O$, h). An isothermal expansion leads from point «☺» to point «O» at T_O. The physical exergy of point «☺» has only a mechanical component. Thus the area on a p-V-diagram is equivalent to the mechanical component of physical exergy only.

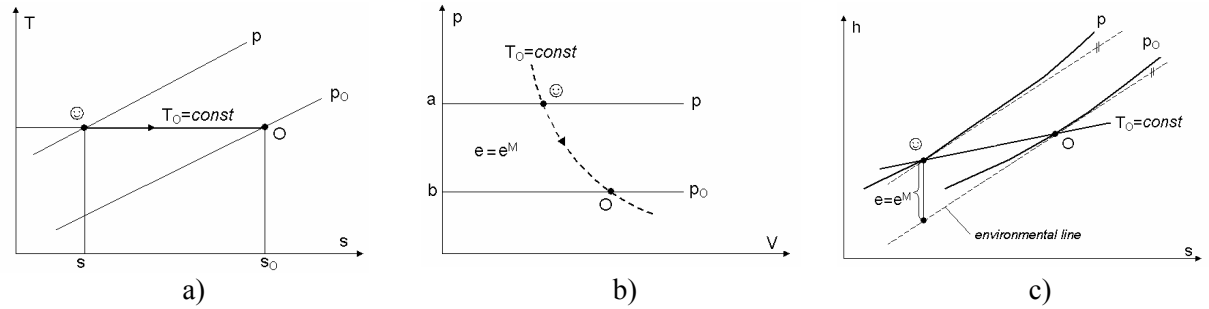
The graphical model of exergy is

$$e^{PH} = e^{M} \equiv \text{area (a-☺-O-b)}. \qquad (4a)$$

The theoretical model of exergy is

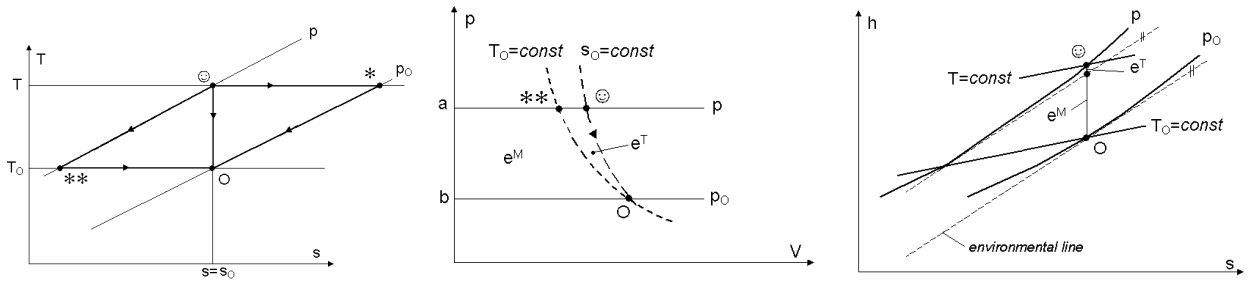
$$e^{PH} = e^{M} = T_O\left(s_O - s\right) - \left(h_O - h\right)_{T_O=const}. \qquad (4b)$$

Model «B» (Fig.4). The coordinates of point «☺» are (p, T, $s=s_O$, h). An isentropic expansion leads from point «☺» to point «O».
An adiabatic expansion from point «☺» to point «O» must be replaced by a combination of isobaric heat transfer and isothermal expansion for defining the thermal and mechanical components of physical exergy.



a) b) c)

Figure 3: Graphical model of exergy (*Model «A»*):
a) on T-s diagram; b) on p-V-diagram; c) on h-s-diagram



a) b) c)

Figure 4: Graphical model of exergy (*Model «B»*):
a) on T-s diagram; b) on p-V-diagram; c) on h-s-diagram

We may use one of the following two ways:

Way 1:
isothermal expansion $p \rightarrow p_O$ at $T=const$
+ isobaric cooling $T \rightarrow T_O$ at $p_O=const$
= way «☺» → «*» → «O»

This way should be excluded from the analysis because there is an isothermal compression process at $T>T_O$ (see [15]).

Way 2:
isobaric cooling $T \rightarrow T_O$ at $p=const$
+ isothermal expansion $p \rightarrow p_O$ at $T_O=const$
= way «☺» → «**» → «O»

The physical exergy of point «☺» represents the sum of the thermal and mechanical exergy components, hence the area of p-V-diagram consists of two parts.

Graphical model of exergy

$$e^{PH} = e^{T} + e^{M} \equiv$$
$$\equiv \text{area}\,(☺\text{-}**\text{-}O) + \text{area}\,(a\text{-}**\text{-}O\text{-}b). \quad (5a)$$

Theoretical model of exergy

$$e^{PH} = \underbrace{c_p\left(T - T_O\right)}_{e^T} + \underbrace{T_O\left(s_O - s^{**}\right) - \left(h_O - h^{**}\right)_{T_O=const}}_{e^M} \quad (5b)$$

Model «C» (Fig.5). This model was proposed in [9]. The coordinates of point «☺» are (p, T, $s<s_O$, h). An irreversible expansion leads from point «☺» to point «O» at $\Delta s>0$.
We may use the following ways for this model:

Way 1:
adiabatic expansion $p \rightarrow p^*$ at $s=const$
+ isothermal expansion $p^* \rightarrow p_O$ at $T_O=const$
= way «☺» → «*2» → «O»

Way 2a:
isothermal expansion $p \rightarrow p^*$ at $T=const$
+ adiabatic expansion $p^* \rightarrow p$ at $s_O=const$
= way «☺» → «*1» → «O»

Way 2b:
isothermal expansion $p \rightarrow p_O$ at $T=const$
+ isobaric cooling $T \rightarrow T_O$ at $p_O=const$
= way «☺» → «*» → «O»

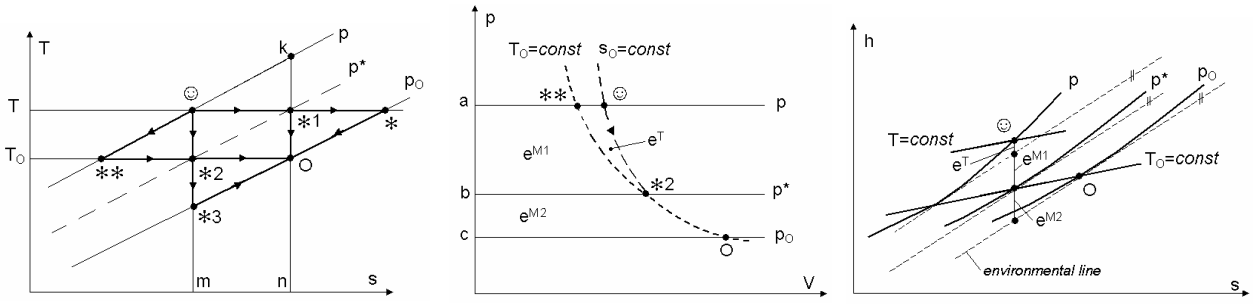
Way 2 (ways 2a and 2b) should be excluded from the analysis, as an isothermal compression occurs at $T>T_O$.

Way 3:
isobaric cooling $T \rightarrow T_O$ at $p=const$
+ isothermal expansion $p \rightarrow p_O$ at $T_O=const$
= way «☺» → «**» → «O»

Way 1 and way 3 are alternatives. An adiabatic expansion «☺» → «*2» (by way 1) is the sum of isobaric cooling and isothermal expansion «☺» → «**» + «**» → «O». It is clear that the physical exergy of point «☺» is the sum of thermal and mechanical exergy components. The area of indicator diagram consists of three parts: two parts are mechanical exergy components and one part represents the thermal component of physical exergy.

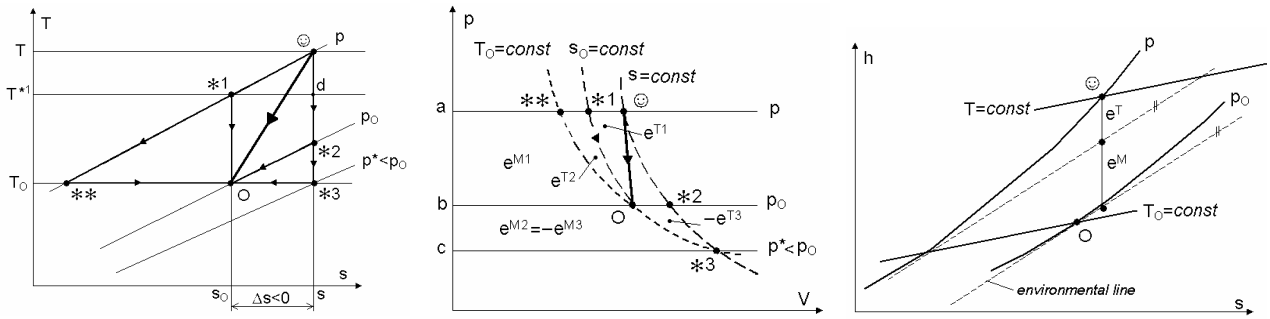
Graphical model of exergy

$$e^{PH} = e^{T} + e^{M1} + e^{M2}$$



a) b) c)

Figure 5: Graphical model of exergy (*Model «C»*):
a) on T-s diagram; b) on p-V-diagram; c) on h-s-diagram



a) b) c)

Figure 6: Graphical model of exergy (Model «D»):
a) on *T-s* diagram; b) on *p-V*-diagram; c) on *h-s*-diagram

$$e^{PH} \equiv \text{area}\,(☺\text{-}**\text{-}*2) + \text{area}\,(a\text{-}**\text{-}*2\text{-}b) + \text{area}\,(b\text{-}*2\text{-}O\text{-}c)$$

or

$$e^{PH} = e^{T} + e^{M}$$

$$e^{PH} \equiv \text{area}\,(☺\text{-}**\text{-}*2) + \text{area}\,(a\text{-}**\text{-}*2\text{-}O\text{-}c). \quad (6a)$$

Theoretical model of exergy

$$e^{PH} = \underbrace{c_p\left(T - T_O\right)}_{e^T} + \underbrace{T_O\left(s_O - s**\right) - \left(h_O - h**\right)_{T_O=const}}_{e^M} \quad (6b)$$

Model «D» (Fig.6). This model was proposed in [15]. The coordinates of point «☺» are (*p, T, s>sO, h*). An irreversible expansion leads from point «☺» to point «O» at $\Delta s<0$. This process does not comply with the second law of Thermodynamics; therefore it is necessary to use a "compensating process" for maintaining $\Delta s=0$.
It is possible to use the following ways in this model:

Way 1:
isothermal expansion $p \rightarrow p_O$ at $T=const$
\+ isobaric cooling $T \rightarrow T_O$ at $p_O=const$
= way «☺» → «*» → «O»

Way 1 (not shown in Fig.6a) is the same way as way 2b in *Model «C»*. Way 1 should be excluded from the analysis, as the isothermal compression occurs at $T>T_O$.

Way 2a:
adiabatic expansion $p \rightarrow p_O$ at $s=const$
\+ isobaric cooling $T^{*2} \rightarrow T_O$ at $p_O=const$
= way «☺» → «*2» → «O»

Way 2b:
isobaric cooling $T \rightarrow T^{*1}$ at $p=const$
\+ adiabatic expansion $p \rightarrow p_O$ at $s_O=const$
= way «☺» → «*1» → «O»

Way 2c:
adiabatic expansion $p \rightarrow p_O$ at $s=const$
\+ isothermal compression $T^{*3} \rightarrow T_O$ at $T_O=const$
= way «☺» → «*3» → «O»

Way 3:
isobaric cooling $T \rightarrow T_O$ at $p=const$
\+ isothermal expansion $p \rightarrow p_O$ at $T_O=const$
= way «☺» → «**» → «O»

The final exergy model is obtained by the following way:

Way 4:
isobaric cooling $T \rightarrow T^{*1}$ at $p=const$
(up to $s^{*1}=s_O$)
\+ isobaric cooling $T^{*1} \rightarrow T^{**}$ at $p=const$
\+ isothermal expansion $p \rightarrow p_O$ at $T_O=const$
\+ isothermal expansion $p_O \rightarrow p^*$ at $T_O=const$
− isothermal compression $p^* \rightarrow p_O$ at $T_O=const$
= way «☺» → «*1» → «**»→ «O» ← «*3»

Graphic model of exergy

$$e^{PH} = e^{T1} + e^{T2} + e^{M1} + e^{M2} - e^{M3}$$

$$e^{T2} + e^{M1} + e^{M2} \equiv \text{area}\,(**\text{-}*1\text{-}O) + \text{area}\,(a\text{-}**\text{-}O\text{-}b) + \text{area}\,(b\text{-}O\text{-}*3\text{-}c)$$

$$e^{T1} \equiv \text{area}\,(☺\text{-}*1\text{-}O),$$

The triangles ☺-*1-d and *2-O-*3 (Fig. 6a) are similar for ideal gases. Thus, if the adiabatic

expansion *2-*3 is the equivalent of isobaric cooling *2-O and isothermal compression *3-O, then the mechanical component of the physical exergy of process *3-O is e^{M3} ≡ area (b-O-*3-c), and the thermal component of the physical exergy of process is *2-O ≡ area (O-*2-*3). The value of the latter is equal to the thermal component of physical exergy of process ☺-*1, i.e. $e^{T1} = e^{T3}$. It is necessary to remember that now we argue not with definition of absolute values of physical exergy and its components but with the areas on the *p-V*-diagram that graphically describe the value of physical exergy.

Finally

$$e^{PH} = e^{T1=T3} + e^{T2} + e^{M1}$$
$$e^{PH} \equiv \text{area (O-*2-*3)} + \text{area (**-*1-O)} + \text{area (a-**-O-b)} \quad (7a)$$

The theoretical model of exergy becomes

$$e^{PH} = \underbrace{c_p(T - T_O) - T_O(s - s_O)}_{e^T} + \underbrace{T_O(s_O - s^{**}) - (h_O - h^{**})_{T_O=const}}_{e^M}. \quad (7b)$$

Model «E» (Fig.7). The coordinates of point «☺» are ($p>p_O$, $T<T_O$, $s<s_O$, h). Irreversible expansion from point «☺» to point «O» occurs at $\Delta s>0$.
It is possible to use following ways for this model:

Way 1:
isothermal expansion $p \rightarrow p_O$ at $T=const$
\+ isobaric heating $T \rightarrow T_O$ at $p_O=const$
= way «☺» → «*4» → «O»

Way 1 should be excluded from the analysis, as the isothermal compression occurs at $T<T_O$.

Way 2:
isobaric heating $T \rightarrow T_O$ at $p=const$
\+ isothermal expansion $p \rightarrow p_O$ at $T_O=const$
= way «☺» → «**» → «O»

Way 3:
adiabatic expansion → p_O at $s=const$
\+ isobaric heating $T^* \rightarrow T_O$ at $p=const$
= way «☺» → «*» → «O»

Way 4a:
adiabatic compression $p \rightarrow p^*$ at $s=const$
\+ isothermal expansion $p^* \rightarrow p$ at $T_O=const$
= way «☺» → «*3» → «O»

Way 4b:
isothermal compression $p \rightarrow p^*$ at $T=const$
\+ isobaric heating $T \rightarrow T_O$ at $p^*=const$
\+ isothermal expansion $p^* \rightarrow p$ at $T_O=const$
\+ isothermal expansion $p \rightarrow p_O$ at $T_O=const$
= way «☺» → «*2» → «*3» → «**» → «O»

However, way 4b requires heat transfer at $T<T_O$ and should be excluded.

Graphic model of exergy is

$$e^{PH} = -e^{M1} - e^{T1} + e^{M2} + e^{M3}$$

The adiabatic compression «☺» → «*3» (area a-*3-☺-b) is the sum

$$e^{M1} + e^{T1} \equiv \text{area (a-*2-☺-b)} + \text{area (*2-*3-☺)}$$

One mechanical component is

$$e^{M2} \equiv \text{area (a-*3-**-☺-b)}.$$

It is visible (by graphical interpretation only)

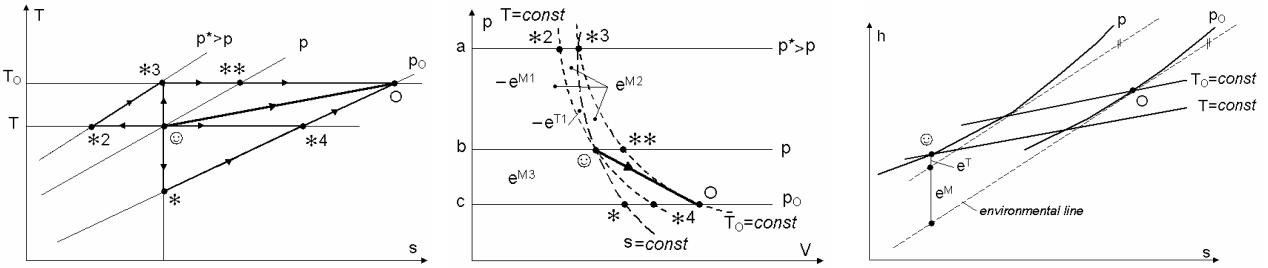
$$e^{T1} = e^{M2} - e^{M1}$$

Finally

$$e^{PH} = -e^{T1} + e^{M3}$$
$$e^{PH} \equiv -\text{area (*2-*3-☺)} + \text{area (b-☺-**-O-*4-*-c)} \quad (8a)$$

Theoretical model of exergy

$$e^{PH} = \underbrace{-c_p(T_O - T)}_{e^T} + \underbrace{T_O(s_O - s^{**}) - (h_O - h^{**})_{T_O=const}}_{e^M} \quad (8b)$$



a) b) c)

Figure 7: Graphical model of exergy (*Model «E»*):
a) on *T-s* diagram; b) on *p-V*-diagram; c) on *h-s*-diagram

On the basis of theoretical models of exergy analysis (by eqs. (4b), (5b), (6b), (7b) and (8b)) we conclude that for calculating the thermal and mechanical components of physical exergy it is necessary to have the following data:

- thermodynamic parameters in the point «☺» (p, T, h, s);
- thermodynamic parameters in the point «O» (p_O, T_O, h_O, s_O);
- values of enthalpy (h**) and entropy (s**) in point «**» where p**=p and T**=T_O.

Eqs. (4b), (5b), (6b), (7b) and (8b) can be written for engineering calculations of e^T and e^M (for all models of exergy) for any position of point «☺» (p, T, h, s)

$$e^{PH} = \underbrace{(h-h^{**})-T_O(s-s^{**})+}_{e^T} \qquad (9)$$

$$\underbrace{+T_O(s_O-s^{**})-(h_O-h^{**})_{T_O=const}}_{e^M}$$

Similar results were presented in a Tridimensional exergy diagram by Rivero [20].

On a *h-s*-diagram

Traditional graphical illustration of physical exergy is given on a *h-s*-diagram. The graphical representation of splitting the physical exergy into its components in the *h-s*-diagram is demonstrated in Figures 3c through 7c.

Let us consider an auxiliary line in a *h-s*-diagram as proposed in [9,17]. It is known that this so-called "environmental line" is the tangent on the isobaric line p_O=*const* at the point T_O

$$tg\,\alpha = \left(\frac{\partial h}{\partial s}\right)_{p_O=const} \qquad (10)$$

and

$$arctg\alpha = T_O\,.$$

By moving the environmental line in parallel from point «O» (p_O, T_O) to point "**" (T_O and p) it is possible to separate the thermal and mechanical exergy components as shown in Figures 3c through 7c.

CONCLUSIONS

The paper discusses different approaches to the graphical representation of the thermal and mechanical exergy components associated with the physical exergy of a stream of matter. A general procedure is proposed and its application on different thermodynamic diagrams is demonstrated.

The authors' proposition for calculating the thermal and mechanical components of physical exergy can be used in engineering calculations for analysis and optimization purposes.

ABSTRACT

The present paper discusses a calculation method for the sucrose – water solution exergy. To perform this calculation, correlations are presented to obtain some properties: density, solubility, specific heat, boiling point elevation, enthalpy and entropy. These properties permit to calculate the solution physical exergy. Moreover, a correlation for the water activity coefficient in the solution was obtained from the literature and an equation to calculate the sucrose activity coefficient is proposed. Both coefficients are used to determine the mixture exergy. Finally, a discussion of the reference system is performed, to complete the calculation of the chemical exergy.

Keywords: exergy, Sugar cane, sugar cane juice, solubility, specific heat, enthalpy, entropy

NOMENCLATURE

a	Activity
b	Specific exergy [kJ/kg]
c_p	Specific heat [kJ/kg K]
h	Specific enthalpy [kJ/kg]
p	pressure [kPa]
Pz	Purity coefficient [%]
s	Specific entropy [kJ/(kg K)]
t	temperature [°C]
T	temperature [K]
v	Volume [m^3]
x	mass fraction of solids [%]
y	molar fraction of solids
z	solution proportion in the mixture above solubility
$\tilde{\varepsilon}$	molar chemical exergy
γ	Activity coefficient
ρ	density [kg/l]

Subscripts

ch	Chemical
mix	Mixture
w	Water
0	reference state
sol	Solubility
Suc	Sucrose

INTRODUCTION

In the last years, the sugar and alcohol industry has increased in Brazil. Along the 2004/05 sugar crop 327 million tons of sugar cane will be produced, from which 51% will be used to produce ethylic alcohol and 49%, sugar. The sugar produced will be 22.05 million tons and 13.54 billion litres of ethylic alcohol.[1], summing up both types, hydrated and non-hydrated.

At the same time the production is increased, an effort is being made to improve the use of energy in the industry. In order to increase the electric energy cogeneration, a reduction of the process steam consumed is necessary, consequently, studies are being made in this direction [2], introducing also the concept of exergy [3].

To perform a thermodynamic analysis of the process, the calculation of the exergy of sugar – water solutions at different concentrations is essential, so, this paper is devoted to the discussion of a methodology to do that.

Some authors presented calculation methods of sugar-water solutions exergy, as Baloh [4,5]; Baloh and Wittwer [6], and Guallar – Paracuellos [7]. From this time to nowadays, some new correlations to calculate sugar-water solutions properties have appeared in the literature and also, from our point of view, a revision of the reference system adopted by these preview authors is necessary, so, a new calculation proposal is made in the present paper.

DENSITY AND SOLUBILITY

Some authors present the variation of the solution density with the concentration in the form of a table [8, 9], some others in a correlation form [10]. A simpler correlation, due to de Grut, is proposed by Peacock [11].

$$\rho = 1000\left[1+\frac{x(x+200)}{54000}\right]\left[1-\frac{0.036(t-20)}{(160-t)}\right] \quad (1)$$

Equation [1] is valid for temperature less than 100°C, a plot is showed in Figure 1,where the symbols do not indicate experimental values.

Data on solubility are reported for various authors [8,10,11,12]. Hugot [12] proposed a simple correlation:

$$x_{sol} = \frac{10000}{\left[100+0.355(158-t)\right]} \quad (2)$$

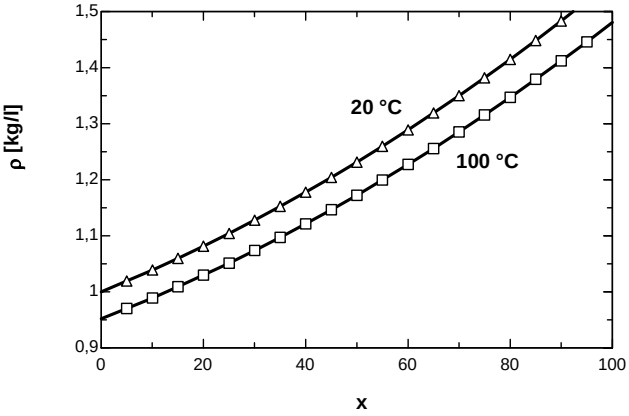

Figure 1: sugar-sucrose solutions density in function of solid mass fraction.

And Peacock [11], based on de Grut's data, developed another one, also simple:

$$x_{sol} = 63.753 + 0.13542 * t + 0.0008869 * t^2 - 2.222 * 10^{-6} * t^3 \quad (3)$$

The different correlations are compared in Figure 2, where the symbols only differentiate one from the other.

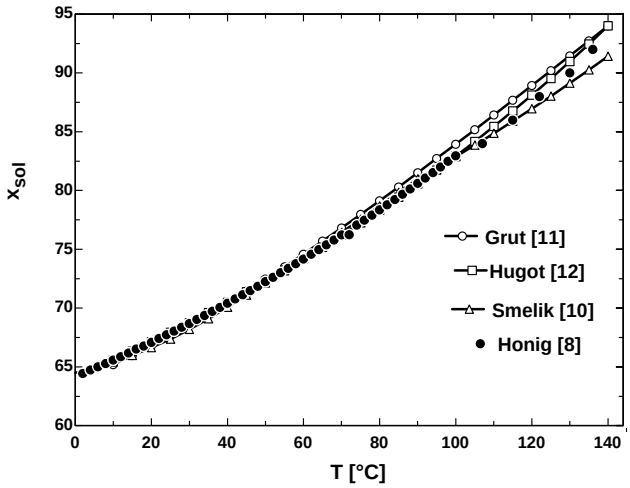

Figure 2: Sucrose in water solubility in function of temperature.

When the solution is above the solubility point, a new phase will appear, constituted by sugar crystals. Anyway, a mean value of the properties of both phases can be calculated.

In a mixture of both phases, the quantity of sucrose-water solution will be given by Eq. 4.

$$z = \frac{100-x}{100-x_{sol}} \quad (4)$$

The mean value of the mixture density can be calculated as following:

$$\rho_{mix} = z\rho_{sol} + (1-z)\rho_{suc} \quad (5)$$

In Equation (5) a value of 1.59 [kg/l] is adopted for the pure sucrose [6].

SPECIFIC HEAT

Various authors have presented values [6, 8, 9] and correlations [7, 10, 11, 12] to get the specific heat of sugar – water solutions. The correlation presented by Hugot [12] has the disadvantage of no taking into account the temperature effect. The correlation due to Janovskij and ArchangelskiJ, reported by Kadlec et al. [10], has the advantage that it takes into account the temperature effect and also it can be applied through a variation of 55 to 100 % in the *purity coefficient*- sugar content in the total solids. This concept is useful to calculate industrial solutions. This correlation is showed in Equation (6).

$$c_p = 4.868 - 0.0297 * x + 4.6 * 10^{-5} x * Pz + 7.5 * 10^{-5} x * t \quad (6)$$

In Figure 3, some of the correlations, above mentioned, are presented, a value of 100 % was considered for the purity coefficient. The symbols do not mean experimental values.

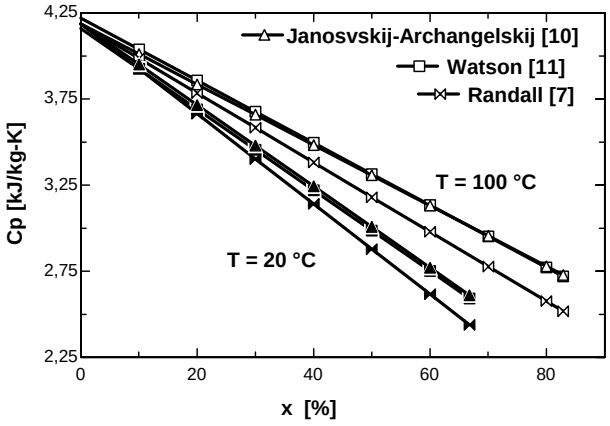

Figure 3: Specific heat in function of the solid mass fraction.

In order to calculate the specific heat of mixtures above the solubility point, a mean value can be obtained, as it was made in Equation (5):

$$c_{p\,mix} = z\,c_{p\,sol} + (1-z)\,c_{p\,suc} \quad (7)$$

Where a value for the pure sugar specific heat is needed. Hugot [12] propose the Equation (8), and Anderson el al. [13], the equation (9).

$$c_{p\,suc} = 1.161837 + 0.0035587 * t \quad (8)$$

$$c_{p\,suc} = 1.244 + 4.819x10^{-3}(t-25) + 6.238x10^{-6}(t-25)^2 \quad (9)$$

As can be seen in Figure 4, the correlation proposed by Anderson et al. [13] agrees well with the experimental data presented by Honig [8].

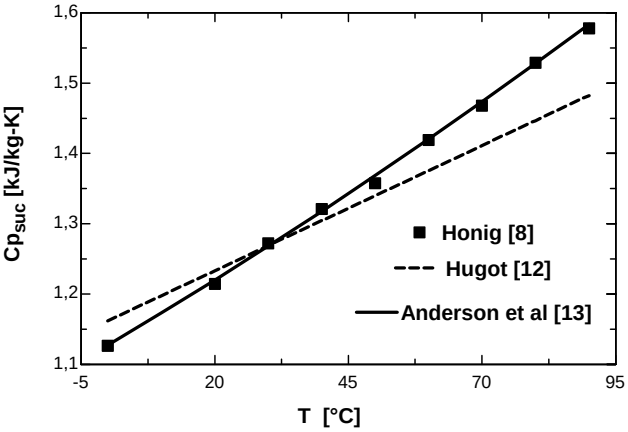

Figure 4: Specific heat of pure sucrose.

ENTHALPY

The enthalpy, at a given pressure, can be obtained from correlations of specific heat and volume varying with the temperature, as indicated in Equation (10) [14].

$$h(T,p) = h(T_0,p_0) + \int_{T_0}^{T} c_p(T',p)dT' + \int_{p_0}^{p}\left[v(T_0,p') - T_0\left(\frac{\partial v(T,p')}{\partial T}\right)_{p'}\Big|_{T=T_0}\right]dp' \quad (10)$$

In Eq. (10), all the authors neglect the second term [4, 5, 7, 10], so, we will do the same, integrating Equation (6), as Kadlec et al. did [10]. The result is showed in Equation (11).

$$h = (4.1868 - 0.0297 * x + 4.6 * 10^{-5} x * Pz)t + 3.75 * 10^{-5} x * t^2 \quad (11)$$

The Equation (12) is another one, proposed by Peacock [11].

$$h = 2.326\left\{\begin{array}{l}\left(\frac{x}{10}\right)\frac{(100+x)}{(900-8x)} \\ +1.8t\left[1-\left(\frac{x}{100}\right)(0.6-0.0009t)\right]\end{array}\right\} \quad (12)$$

For mixtures above the solubility point, a mean value can be obtained, as suggested by Baloh and Wittwer [6]. In the some way that was made in Equation (7), we get Equation (13), [10], where the enthalpy of the sucrose is calculated based in his specific heat, Equation (9).

$$h_{mix} = zh_{sol} + (1-z)h_{suc} \quad (13)$$

In figure 5, a graphic of the enthalpy in function of the solid mass fraction is showed; the Equation (11) is compared with Equation (12). The reference adopted was null enthalpy at 0 °C. The equation proposed by Peacock presents higher values around the maximum solubility point.

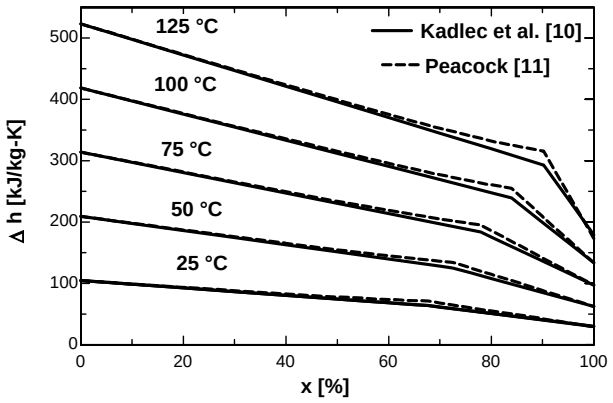

Figure 5: Enthalpy of sucrose – water mixtures in function of the solid mass fraction.

ENTROPY

Few authors treat this property; Baloh gives a Table of water – sucrose mixture entropy [4], whose reference was changed in order to compare with the results of this paper. Tekin and Bayramoğlu [15] reported equations for enthalpy and entropy, but the values obtained with them were without sense.

Anyway, as in the case of enthalpy, the entropy can be obtained through the integration of the Equation (14) [14], where, another time, the second term is neglected [4,5,7]. The result obtained is Equation (15). The Equation (16) calculates the pure sucrose entropy. In both cases, to change temperature scale, before to integrate, is necessary.

$$\Delta s = \int_{T_0}^{T}\frac{c_p(T',p)}{T'}dT' - \int_{p_0}^{p}\left(\frac{\partial v(T,p')}{\partial T}\right)_{p'}\Bigg|_{T=T_0} dp' \quad (14)$$

$$\Delta s = (4.1868 - 0.05018625x + 4.6*10^{-5}xPz)\ln\left(\frac{T}{T_0}\right) + \left(7.5*10^{-5}x\right)(T-T_0) \quad (15)$$

$$\Delta s_{suc} = -0.260000693\ln\left(\frac{T}{T_0}\right) + 0.005046934(T-T_0) \quad (16)$$

A graphic is shown in Figure 6, where the same procedure than before was used for mixtures above the solubility point. The reference adopted was of entropy null for T= 0°C. The results are compared with those of Baloh [4], a good agreement was obtained; some differences appear only around the maximum saturation point, for temperatures greater than 100 °C.

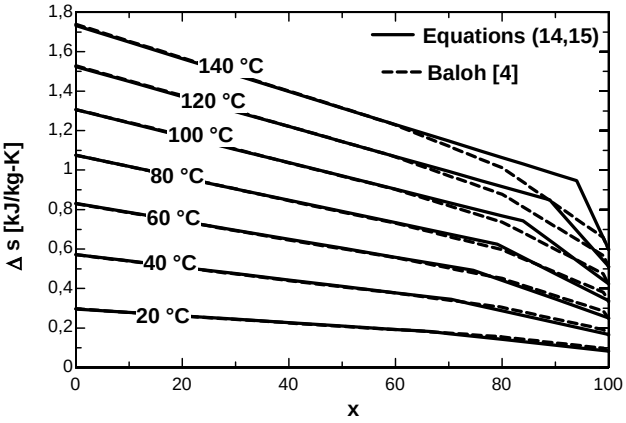

Figure 6: Entropy of sucrose-water mixtures in function of the solid mass fraction.

ACTIVITY

Considering a solution of sucrose-water in equilibrium with his vapour, we can write Equation (16), [7, 16]

$$p_{total}(t_0) = \gamma_w(y_{suc}, t)y_w p_w^0(t) \quad (17)$$

Where $\Delta t_{BPE} = t - t_0$ is the boiling point elevation and $p_w^0(t)$ is the water vapour pressure at temperature t (the vapour phase is constituted only by pure water).

Measurements of boiling point elevation permit to obtain activity coefficient values [7, 16].

Starzack and Peacock [16,17] provide a correlation to calculate the water activity coefficient:

$$\ln \gamma_w = \frac{Q}{RT} y_{suc}^2 \left(1 + A y_{suc} + B y_{suc}^2\right) \quad (18)$$

Where the activity is calculated as: $\gamma\, y = a$.

And the coefficients have the values:

$$\frac{Q}{RT} = \frac{-17638[J/mol]}{8.3143[J/(molK)]T[K]} = \frac{-2121.4052[K]}{T[K]} \quad (19)$$

$$A = -1.0038$$

$$B = -0.24653$$

In Equation (18), the reference values are:

$\gamma_w = 1 \quad for \;\; y_{suc} = 0, \quad so \quad a_w = 1.$

From (18), using the Gibbs – Duhem integrated equation; Equation (20), the value of the sucrose activity coefficient can be obtained, following the method described in [18].

$$\int_{y_{suc}}^{y_{suc}=y_{suc,sat}} d(\ln a_{suc}) = \int_{y_{suc}}^{y_{suc}=y_{suc,sat}} \frac{y_w}{y_{suc}} d(\ln a_w) \quad (20)$$

Where the integration limits were defined between a generic state and the saturated state corresponding to the maximum solubility. The superior limit was adopted in function of the calculation of exergy that will be performed afterwards; in fact, it corresponds to a state where the solution is in equilibrium with the solid pure sucrose; so, the reference value for the sucrose activity corresponds to pure sucrose, as suggested by Hougen et al. [19]. In this way, the condition (21) must be used [19]:

$$\gamma_{suc,sat} = \frac{1}{y_{suc,sat}} \quad (21)$$

Substituting in Equation (20) according to (18), operating and solving the integrals, we get Equation (22).

$$\ln\left(\frac{\gamma_{suc}}{\gamma_{suc,sat}}\right) = -\frac{Q}{RT}\left[2y_{suc} + \frac{(3a-2)}{2} y_{suc}^2 + \frac{(4b-3a)}{3} y_{suc}^3 - b y_{suc}^4\right]_{y_{sac}=y_{sac,sat}}^{y_{suc}} \quad (22)$$

Starzack and Peacock [17] reported another correlation for the water activity coefficient, due to Kadlec et al., which gave similar results to Equation (18), but as the work of the first authors was based in an extended bibliographic research, we decided to adopt their correlation.

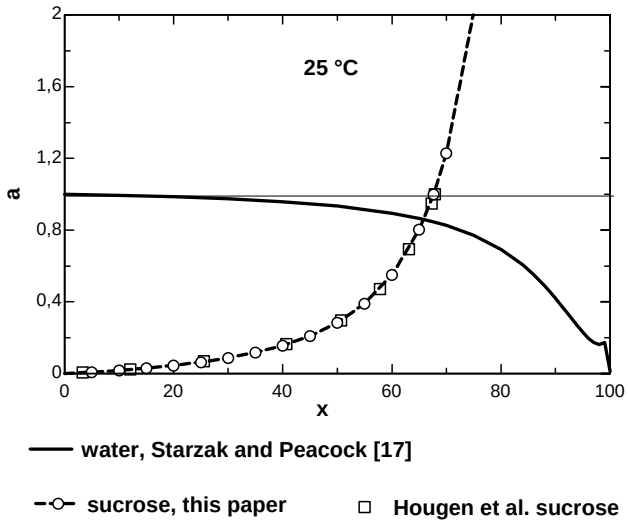

Figure 7: water and sucrose activity in function of the solid mass fraction.

In Figure 7, a graph of the water and sucrose activities correlations, at 25 °C, is presented, the results obtained with Equation (22) are compared with data given by Houghen et al.[19]. The agreement is very good.

EXERGY

Following Szargut et al. [20] and also Kotas [21], the exergy of a sucrose – water solution can be calculated as the sum of three terms:
(i) the physical exergy, which is the changing in exergy value when the system go from (T,p) to (T_0, p_0), (ii) the mixture exergy, which corresponds to the exergy needed to separate the two components, and (iii) the chemical exergy, which correspond to the change in exergy value from the pure components, set apart, to the final equilibrium of them with the pre-defined environmental system (See Figure 8).

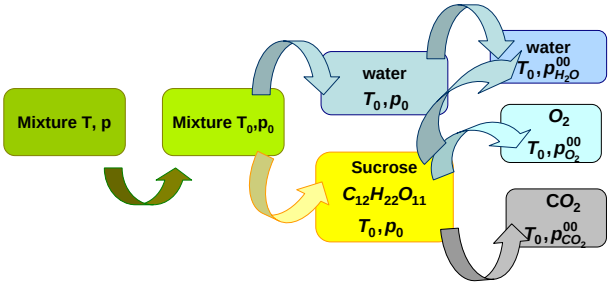

Figure 8: representation of the exergy calculation.

Each one of the above mentioned exergy terms are calculated as follows:

$$ex_{ph} = \int_{T_0}^{T} Cp\left(1 - \frac{T_0}{T}\right)dT = \Delta h - T_0 \Delta s \quad (23)$$

$$ex_{mix} = \frac{RT_0}{M_{mix}}\left[y_{suc} \ln a_{suc} + y_w \ln a_w\right] \quad (24)$$

$$ex_{chem} = \left[y_{suc} ex^{00}_{chem,suc} + y_w ex^{00}_{chem,w}\right] \quad (25)$$

Where the following values were adopted [20]:

$$ex^{00}_{chem,suc} = 6007800\,[\text{kJ/kmol}]$$
$$ex^{00}_{chem,w} = 900\,[\text{kJ/kmol}] \quad (26)$$

A graph of Equation (23) is showed in Figure 9, to get that, the equations (9), (13), (15) and (16) were used. A reference of t= 25 °C and 101,3 kPa was adopted.

The Equation (24) is represented in Figure 10. The equations (18), (21) and (22) were used, joined with the numerical values of (19). Null mixture exergy values are adopted for the pure substances.

In Figure 11, the total exergy is showed. As it can be seen, a unique line represents all the temperature values, this is due to the fact that the values of the chemical reference exergies of the pure products (Equation (26)) are very big.

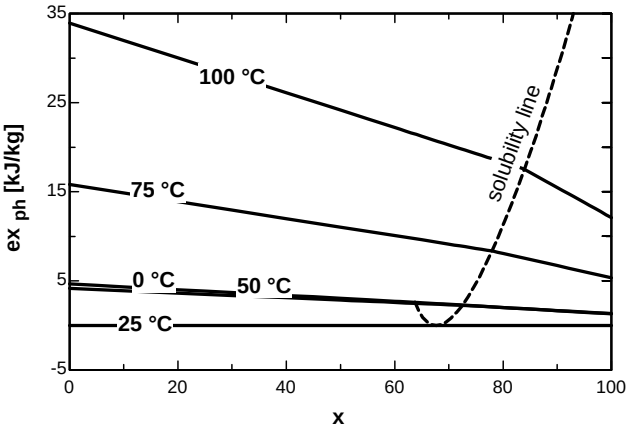

Figure 9: physical exergy of sucrose-water mixtures.

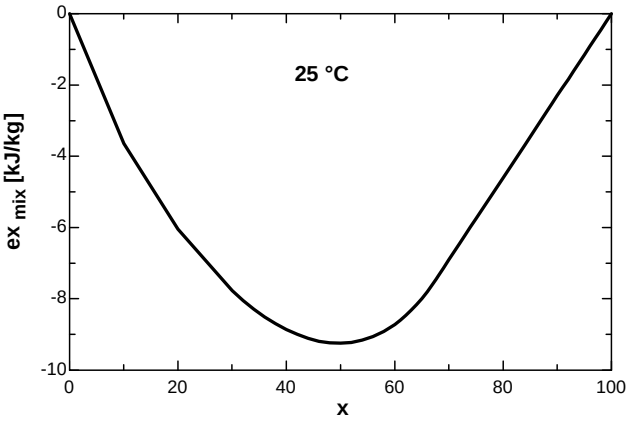

Figure 10: mixture exergy of sucrose – water system.

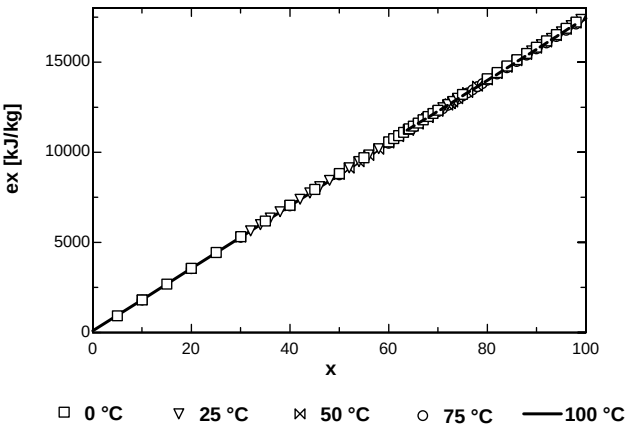

Figure 11: total exergy of the sucrose – water system.

The values of the reference exergies in Equation (25), Equation (26), for sucrose and water, were taken from Szargut et al. [20], so, the reference environment proposed by these authors was

adopted. Considering the elemental substances present in the system, which are carbon, oxygen and hydrogen, the reference substances adopted are: carbon dioxide, oxygen and water (in vapour state), all them diluted in the standard atmosphere detailed in [20]. What this means is that the sucrose was treated as a *fuel*, and, if we think that it is used for human feeding, it acts really as a fuel, because the man produces carbon dioxide when breathes. Anyway, it can also be burnt.

The reference state adopted in this work is different of that of Baloh [5] and Guallar [7], whom adopted the minimum value of mixture exergy at 25 °C (or 20 °C) as zero level, so, the value corresponding to minimum free energy and maximum solubility. Baloh [5] adopted also a null value of exergy for the sucrose at reference temperature. Guallar [7] adopted two different reference systems, when he analysis the sugar production process.

Since our final objective is to perform a complete exergetic analysis of the sugar and alcohol production process from sugar cane, where the elemental substances, carbon, oxygen and hydrogen are present also in the bagasse, used as fuel, we think that a unique reference system must be adopted to perform the exergy calculations.

CONCLUSIONS

A research on the properties of water – sucrose solutions was made; being as final objective to present an exergy calculation methodology. In order to reach this objective, values of density, solubility, specific heat, enthalpy and entropy are presented. Correlation and values from different authors were carefully compared.

An expression for the sucrose activity was developed from a correlation for the water activity in the solution, using the Gibbs – Duhem equation. In order to calculate the exergy, we need to adopt as reference states pure water and pure sucrose, this was also performed in the calculation of the activity coefficient. As this type of solutions have a solubility limit, careful calculations and considerations needed to be done. The reported correlations permit the complete exergy calculation of sucrose-water mixtures at any concentration. Other authors reported only a graphic as Baloh [5] or a description of the method as Guallar [7]. The calculation was performed using the EES® software as base; the authors offer the code developed to people interested on them.

Along the work some doubts appear, new research need to be done on some subjects.

A careful research can be made about the influence of the second integral term in Equations (10) and (14), the Equation (1) would be useful to do that.

The mixture properties, as enthalpy, entropy, free energy can be calculated from calorimetric data or from activity data. See, for example Gyftopoulos and Beretta [14]. The authors of this paper realized part of this work and compare the results, which presented differences. A complete discussion of these results could be done in a next paper.

Finally, in the last times, we have found some important mistakes at the literature in the calculation of the exergy of different types of solutions; we hope this work will contribute to lead the people think about that.

ACKNOWLEDGMENTS

The authors want to express their gratitude to Research Foundation of Sao Paulo State – FAPESP, to Coordination for the Improving of Superior Education - CAPES and to Research Council of Scientific and Technological Development – CNPq, for the financial resources to do this work.

Department of Mechanical Engineering
Brazil

ABSTRACT

The gasification technology has been process of study of many researchers, especially those involved in promoting large-scale electricity generation in sugarcane mills. This paper presents a simplified model for the gasification process based on chemical equilibrium considerations. The model consists in the minimization of the Gibbs free energy of the produced gas, constrained by mass and energy balances for the system. Despite the simplicity of the model, its results are reliable in identifying the tendencies of the working parameters of the system. A parametric study has been carried in order to verify the influence of many variables inherent to the model, such as: gasification temperature, moisture content, and air temperature, among others. The results were compared with those found in literature and real systems. Following this parametric study, an exergy analysis has been performed in order to evaluate irreversibilities associated to the process, and the influence of temperature, moisture, charcoal production, and thermal losses on them. Finally, a first attempt to integrate a gasifier into a sugarcane mill was performed, which showed the potential benefits regarding the use of such technology.
Keywords: biomass gasification, exergy analysis, sugarcane bagasse

NOMENCLATURE

a number of atoms of specie k in molecule j
A total number of atoms of specie k
b specific exergy (kJ/kg or kJ/mol)
B total exergy flow rate (kW)
c_p specific heat (kJ/kmol-K)
f coefficient of thermal losses (from 0 to1)
G Gibbs free energy (kJ/kg)
H total enthalpy flow rate (kW)
I irreversibility or exergy destroyed (kW)
j index for components
k index for atoms
LHV lower heating value (kJ/kg)
m mass flow (kg/s)
n total number of molecules j
p pressure (atm)
Q heat transfer (kW)
R gases constant (kJ/kmol-K)
tc ton of cane
T temperature (°C or K)
y molar fraction
Φ equivalence ratio
β coefficient for calculating chemical exergy
λ Lagrange multiplier
η efficiency

INTRODUCTION

Gasification is a thermo-chemical process in which a solid/liquid fuel is converted, due to the addition of heat in a sub-oxidizing atmosphere, into a mixture of gases (produced gas) with low calorific value. The gasification technology has been object of study of many researchers, especially those involved in promoting large-scale electricity generation in sugarcane mills. However, few of these studies focused on the process itself [1], being more concerned about the application of the produced gas in combined cycles and/or co-firing systems [2] [3].

Most recently, many works have been published in the field of gasification modeling by chemical equilibrium and its analysis. A non-stoichiometric model, which uses empirical relations in order to come closer to real operation of gasification of biomass, based on the operation of a circulating fluidized bed, was proposed in [4]. Gasification and combustion processes for CHO systems are analyzed based on first and second law analysis,

following a stoichiometric approach [5], [6]. These studies provided a fairly comparison between gasification and combustion, showing the principal irreversibilities associated with each process, and the advantages of one and another. The gasification of different biomass materials in an equilibrium model based on equilibrium constants for methane formation and shift reaction is, also, available in [7].

The aim of this paper is to develop a gasification model that might indicate energetic and exergetic behavior of the process. Also, allowing a parametric study in order to provide information regarding parameters that most influence the process. Finally, a first attempt to integrate a gasifier into a sugarcane mill is performed.

ENERGY AND EXERGY MODELING

It has been adopted the non-stoichiometric approach to find the chemical equilibrium, in which:

- ✓ Only gaseous species (CO, H_2, H_2O, CO_2 and N_2) have been considered in equilibrium;
- ✓ The volume of CH_4 and unconverted carbon have been calculated based on experimental data and empirical relations [4];
- ✓ The produced gas was modeled as a mixture of ideal gases;
- ✓ No nitrogen pollutants were presented (NO_x, N_2O).

The approach for the equilibrium calculations consists in solving a system of non-linear equations given by [8]:

– N equations related to equilibrium conditions:

$$\mu_j + \sum_{k=1}^{w} \lambda_k a_{jk} = 0 \text{ , for } j = 1,2,...,N \qquad (1)$$

– w equations related to material balances:

$$\sum_{j=1}^{N} \left(n_j \cdot a_{jk}\right) = A_k \text{ , for } k = 1,2,...,w \qquad (2)$$

As it was considered a mixture of ideal gases, Eq. (1) can be re-arranged [9]:

$$\Delta G_j^0 + RT \ln\left(y_j\right) + \sum_{k=1}^{w} \lambda_k a_{jk} = 0 \text{ , for } j = 1,2,...,n \qquad (3)$$

Same as in [4], the volumes of CH_4 formed and unconverted carbon were found using empirical correlations, according to experimental data from [4]:

$$\beta_{CH_4} = 0.11 \cdot (1 - \phi) \qquad (4)$$

$$n_{CH_4} = \beta_{CH_4} \cdot n_{C,\,initial} \qquad (5)$$

$$\beta_C = 1 - \left(-\phi / 0.1367\right) \qquad (6)$$

$$n_C = \beta_C \cdot n_{C,\,initial} \qquad (7)$$

These relations are taken into account, so non-equilibrium effects are considered [4].

In order to moderate the system, an energy balance was imposed to the problem:

$$\left(\sum \dot{H}_i\right)_{in} = \left(\sum \dot{H}_j\right)_{out} + \dot{Q}_{losses} \qquad (8)$$

$$\left(\sum \dot{H}_i\right)_{in} = \dot{H}_{air} + \dot{H}_{\substack{dry \\ biomass}} + \dot{H}_{\substack{biomass \\ moisture}} + \dot{H}_{steam} \qquad (9)$$

$$\left(\sum \dot{H}_j\right)_{out} = \dot{H}_{\substack{produced \\ gas,\,dry}} + \dot{H}_{\substack{unconverted \\ carbon}} + \dot{H}_{steam} \qquad (10)$$

$$\dot{Q}_{losses} = f \cdot \left(\sum \dot{H}_i\right)_{in} \qquad (11)$$

This balance is responsible for the determination of the temperature of the system for a given air-to-fuel ratio, or the other way round. All relations related to the calculation of thermodynamic properties are shown in the appendix. It must be pointed out here that this procedure is different from the one exposed in [4], in which both temperature and air ratio are considered independent variables.

The exergy analysis was carried out, according to the following equations:

$$\left(\sum \dot{B}_i\right)_{in} = \left(\sum \dot{B}_j\right)_{out} + \dot{I} \qquad (12)$$

$$\left(\sum \dot{B}_i\right)_{in} = \dot{B}_{air} + \dot{B}_{\substack{dry \\ biomass}} + \dot{B}_{\substack{biomass \\ moisture}} + \dot{B}_{steam} \qquad (13)$$

$$\left(\sum \dot{B}_j\right)_{out} = \dot{B}_{\substack{produced \\ gas,\,dry}} + \dot{B}_{\substack{unconverted \\ carbon}} + \dot{B}_{steam} \qquad (14)$$

The reference state was taken as $T_0 = 25°C$ and $p_0 = 1$ bar.

With the aim of evaluating the performance of the process, some parameters were considered [4], [5]:

$$\eta_{\substack{cold \\ gas}} = \frac{\dot{m}_{\substack{produced \\ gas}} \cdot LHV_{\substack{produced \\ gas}}}{\dot{m}_{\substack{dry \\ biomass}} \cdot LHV_{\substack{dry \\ biomass}}} \qquad (15)$$

$$\eta_{energetic} = \frac{\left(\sum \dot{H}_j\right)_{out}}{\left(\sum \dot{H}_i\right)_{in}} \qquad (16)$$

$$\eta_I = \frac{\dot{B}_C + \dot{B}_{\underset{mixture}{gases}} + \dot{B}_{\underset{gas}{steam}}}{\dot{B}_{\underset{biomass}{dry}} + \dot{B}_{air} + \dot{B}_{steam} + \dot{B}_{moisture}} \quad (17)$$

$$\eta_{II} = \frac{\dot{B}_{\underset{mixture}{gases}}}{\left(\dot{B}_{\underset{biomass}{dry}} - \dot{B}_C\right) + \dot{B}_{air} + \dot{B}_{steam} + \dot{B}_{moisture}} \quad (18)$$

$$\eta_{III} = \frac{\dot{B}_C + \left(\dot{B}_{\underset{mixture}{gas}} - \dot{B}_{air} - \dot{B}_{steam} - \dot{B}_{moisture}\right)}{\dot{B}_{biomassa}} \quad (19)$$

$$\eta_{IV} = \frac{\dot{B}_{\underset{mixture}{gases}} - \dot{B}_{air} - \dot{B}_{steam} - \dot{B}_{moisture}}{\dot{B}_{\underset{biomass}{dry}} - \dot{B}_C} \quad (20)$$

Eq. (15) states a relation between LHV of the produced gas and LHV of the biomass (cold gas efficiency). It does not represent a process index [4]. Eq. (16) represents the magnitude of energy losses of the system (if $\dot{Q}_{losses} = 0$, then its value equals 1). Eqs. (17) to (20) represent exergy efficiencies for the process, according to [6]:

- Eq. (17): relation between outlet exergy flow rate and inlet exergy flow rate, i.e., from what is made available, how much is used. It indicates the total destruction of exergy;
- Eq. (18): process efficiency, i.e., useful effect. This equation relates the exergy of the product (produced gas) and the exergy available for the process;
- Eq. (19): represents the degree of conversion of biomass exergy into products (produced gas and unconverted carbon);
- Eq. (20): expresses the difference in the produced gas exergy and exergy of air, steam and moisture divided by the difference between the dry biomass exergy and the unconverted carbon exergy, as defined in [6].

According to [6], the last equation represents the most stringent criterion, as it relates better to the function of the gasifier (conversion of solid/liquid fuels into a gas fuel).

SIMULATION

For the analysis of the gasification process, it was considered that the reduced molecular formula of sugarcane bagasse was: $CH_{1,61}O_{0,7}$ [10]. All equations shown above were solved using EES software [11] and a parametric study performed. The following variables were evaluated:

- Moisture in biomass;
- Temperature of air;
- Temperature of biomass;
- Volume of steam added;
- Thermal losses.

All relevant results are presented in graphics in order to ease visualization.

RESULTS

Base Case

Aiming to validate the model, it was considered a reference case, so that no moisture is presented in the biomass nor steam is added. Fig. (1) shows the molar fractions for different equivalence ratios.

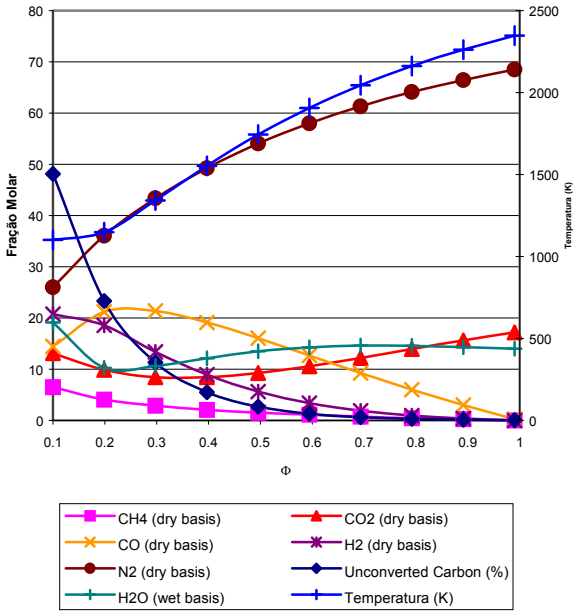

Figure 1 – Molar fractions for base case

As stated in [12], equilibrium models, which assume perfect gas behavior, cannot describe pyrolisis processes, due to the presence of liquid hydrocarbons as pyrolisis products. So, it has not been analyzed very low air-ratio values (below 0.10).

The curves found show the same tendency presented in [4], although some values are different.

Values for CO concentrations are higher than those in [4], while for H_2 they are lower. The different composition of fuel and modeling approach used in each work can explain these differences. Furthermore, both results present CO concentrations lower and H_2 concentrations higher than that found in real systems. However, this behavior does not affect the value of LHV, as

LHV for H_2 and CO are very close to each other [4].

Performance indexes can be evaluated in Fig. (2). For illustration of the destruction of the exergy, it has been used a specific value, which is related to the flow rate of dry bagasse fed to the gasifier. It could have been used the produced gas flow rate, but, as it varies with the air ratio, the results might be misleading. Also, it could have been considered the flow rate of wet bagasse, nevertheless, one proposition of this paper is to present the influence of moisture in the gasification process.

The model does not consider any advantages or disadvantages related to small or large-scale operation. The model is quite general, aiming the visualization of parameters that would enhance performance.

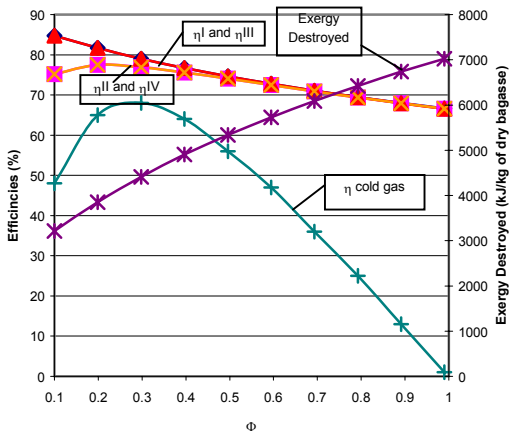

Figure 2 – Performance Indexes for base case

It can be observed from Fig. (2) that the best operating points for the process range between Φ equal to 0.15 to 0.30. In [5], it was found that the carbon boundary[1] lied in Φ equals to 0.255. This point represents the maximum value for process efficiency. This range, also, fits the maximum values for H_2 (Φ≈0.15) and CO (Φ≈0.25) concentrations in Fig. (1). The maximum value for η_{II} and η_{IV} lie in between those two maximum concentrations, what represents a trade-off between the availability of these gases. The existence of such a maximum may be related to the temperature of the process and the conversion of carbon. For air ratio values increasing from 0,15 to 0.30, the conversion of carbon into gas is accelerated (what increases efficiency); for values greater than 0.30, this conversion slows down. As discussed in [6], and also shown by the results of the model, as more air is supplied the process goes from gasification (Φ>0.15) to combustion (Φ >0.5), so temperature increases. This causes an increase in the exergy destruction, due to production of gases with lower chemical exergy and greater temperature differences between products and reactants. So, the presence of those maximum values for the efficiencies shows the trade-off between the conversion of biomass and temperature raise.

In [6], it was suggested operation temperature in the ranges of 1100K – 1200K, for atmospheric gasification, in order to achieve the highest efficiencies. In the model, this range fits exactly the points where Φ range from 0,15 to 0,25. In fact, they suggest operation temperature just above this range (1300K – 1400K) – Φ ranging from 0,25 to 0,35 in the model; so that 75% of the exergy contained in the biomass can be converted into chemical exergy of the produced gas. This statement agrees with the so-called cold gas efficiency in the model.

Parametric Study

Moisture content

One major concern in gasification process is the moisture content in biomass. If it is too high, then there will not be enough energy (low temperatures) to start up the process. To take place, gasification needs temperature above 800 K [13]. Fig. (3) shows the influence of moisture in the process temperature – Φ equal to 0,25:

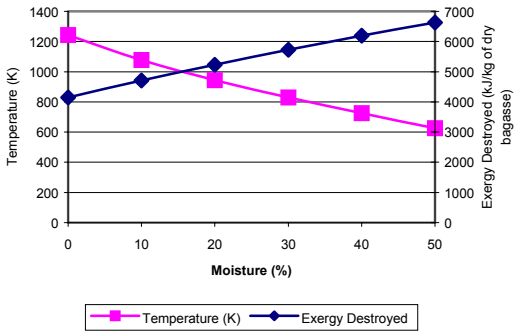

Figure 3 – Influence of moisture on the gasification temperature and exergy destruction

In sugar and alcohol mills, sugarcane bagasse leaves the milling process with 50% moisture, a too high value to start up the process. So, it is

[1] For air-to-fuel ratios greater than the carbon boundary, all carbon is converted into gas.

needed a dryer to operate a gasifier with sugarcane bagasse inside a mill, so biomass could be dried to less than 30% moisture.

Regarding the exergy destruction, an increase in moisture content, increases the destruction of exergy inside the gasifier (Fig. 3). This fact may be explained by:

- Although more H_2 is formed (more atoms of hydrogen are available with an increase in moisture), in order to maintain the process, more energy must be supplied, so exothermic reactions are favored, what promotes CO_2 formation – not a fuel gas.
- More moisture indicates that more energy is to be used in the vaporization of it, and less is available for endothermic reactions, responsible for the production of H_2 and CO.

These conclusions may be visualized in Fig. 4:

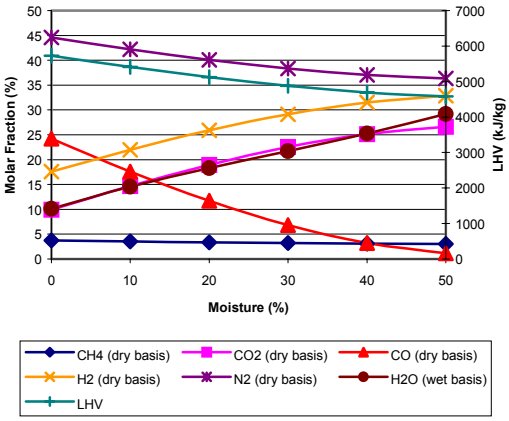

Figure 4 – Influence of moisture on the produced gas

Fig. (5) indicates a displacement of the optimum operation point to the right (and also to a lower efficiency value), as moisture content in biomass increases:

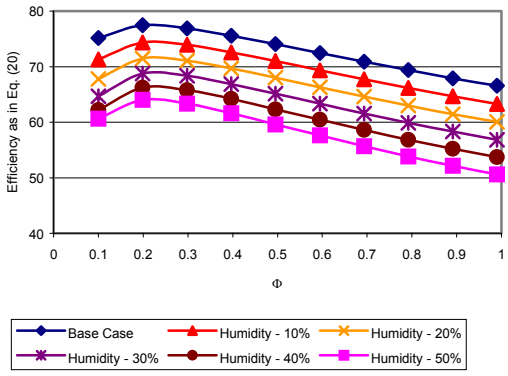

Figure 5 – Influence of moisture on the optimum operating point

From the previous analysis, this displacement is a result of the necessity of more energy to evaporate moisture, increasing the air-to-fuel ratio in order to favor exothermic reactions forming CO_2 and H_2O. The chemical exergies of these gases are lower than chemical exergies of CO and H_2, thus the total exergy of the produced gas is lowered, decreasing the exergy efficiency of conversion (Eq. (20)).

It must be pointed out that Souza-Santos [1] discusses, based in a kinetic gasification model, that if the bagasse drying system could not lead to moisture values below 30%, it might be preferable to feed the gasifier with wet bagasse (50% moisture), as it increases hydrogen availability.

Thermal losses

Despite the increase in H_2 formation, the influence of thermal losses is similar to that of moisture. It reduces the available energy in the process, jeopardizing reduction reactions, and increasing exergy destruction (heat transfer to environment).

Pre-heating of air and/or biomass at the entrance

In [6], the authors state that the main source of exergy destruction, in gasification and oxidation processes, is the presence of chemical reactions. Following them, heat transfer between products and reactants is a second major source of exergy destruction. In this sense, pre-heating air and/or biomass might reduce such destruction, due to lower temperature differences between products and reactants.

However, this reduction is quite small if compared with the increase of exergy destruction due to moisture or thermal losses.

Steam added

In biomass gasification processes, steam is added to the system in order to moderate temperature over the grate, so that no ash fusion occurs [12]. The influence of it in operation is the same that of moisture, but in a much lower scale.

Integration to a Sugarcane Mill

As in [6], the model presented optimum operation points for Φ ranging from 0,15 – 0,25, what represents that almost 75% of the exergy in the biomass is in the produced gas. Coupling this gasification process to a combined cycle, the exergy efficiency of the BIGCC (Biomass Integrated Gasification Combined Cycle), Fig. (6), would be, approximately, 30%; value greater

than the ones found in business practice – Brazilian sugarcane mills based in Rankine Cycles [3]. Fig. (7) is a first attempt to integrate this cycle to a sugarcane mill. For this integration, it has been considered the case of Usina Iracema, located in the state of São Paulo, Brazil. The mill crushes 20,000 t of raw cane per day, producing, approximately, 5,000 t of bagasse (with 50% moisture) per day.

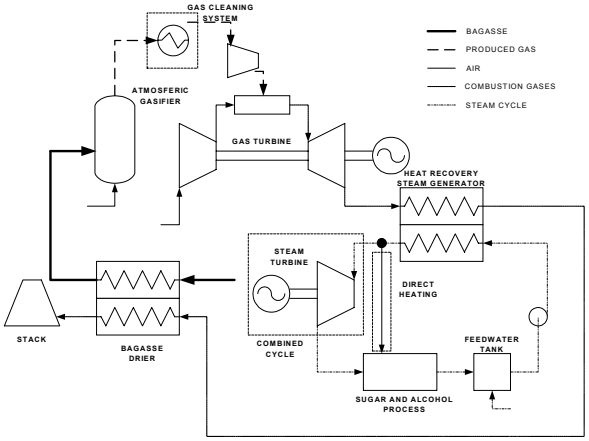

Figure 6 – BIGCC scheme considered in the analysis

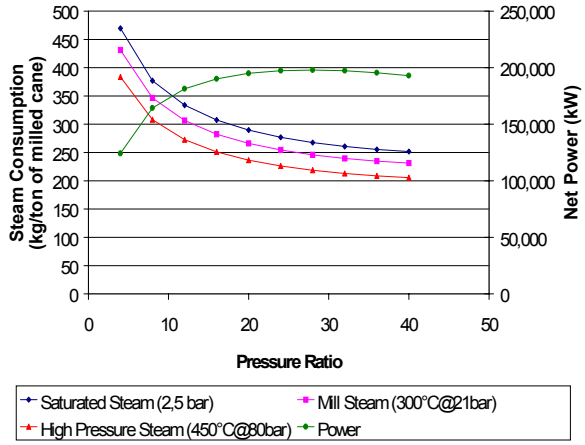

Figure 7 – BIGCC operation for different pressure ratios and steam qualities

It has not been considered any specific commercial gas turbine or HRSG (Heat Recovery Steam Generator) for this analysis. A simple energy balance (considering, inlet turbine temperature equal to 1400 K) was done, so that it could be found the air flow rate required in the gas turbine, the net power produced, and the quantity of steam available, considering different states. As expected, the maximum net power is produced when pressure ratio is, approximately, 30 (value greater than those found for natural gas). The reason for such behavior is the greater amount of produced gas required to achieve the turbine temperature.

It has not been seek, in this work, to analyze the operation/performance of combined cycles operating under low calorific values, even though it has been considered the power input necessary to compress the produced gas into the combustion chamber. More information regarding this subject may be found in [2], [3].

The specific power produced is 216 kWh/tc. This value represents seven times the usual power produced in sugar cane mill considered (30 kWh/tc). However, the steam required in the process (500 kg/tc) cannot be supplied by this system alone.

CONCLUSIONS

Despite the simplicity of the model, its results showed good agreement with results found in literature. This fact allows the following conclusions:

- Moisture is the main problem related to bagasse gasification: it is responsible for an increase in the destruction of exergy inside the reactor, as a result of an increase of the energy required to evaporate the moisture.
- Sugarcane bagasse must be dried to, at least, 30% moisture in order to start-up gasification, according to equilibrium considerations;
- Pre-heating air and/or bagasse may reduce irreversibilities, although it is not sufficient to compensate losses due to high moisture content and/or thermal losses.

It has not been evaluated the influence of moisture on CH_4 formation and the conversion of carbon. For such analysis a stoichiometric approach may be of more use than the one presented here, as it considers the reactions per se. However, the use of empirical relations may be jeopardized.

In Brazil, the steam consumption in sugarcane mills ranges from 400 to 550 kg of steam/tc. From Fig. (5), these values are unrealistic for systems operating with gasification. So, it can be concluded that, before designing a BIGCC System, it is necessary to carry out measures for steam saving, as described in [14], [15], in order to reduce consumption to 200-300 kg of steam/tc.

It is also required to study the influence of low calorific gas operation on commercial gas turbine, in order to evaluate performance and integration of a BIGCC system with processes plant, such as sugarcane mill.

ACKNOWLEDGMENT

The authors wish to acknowledge Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) for the financial support received (grant 03/12094-8), and Usina Iracema for their technical support and data.

APPENDIX

In what follows, the main relations for determining the thermodynamic properties of the streams are shown.

Gibbs free energies were evaluated by:

- Carbon Dioxide (CO_2):

$$\Delta G^0_{CO_2} = -1.3503 \cdot T - 394{,}353 \qquad (21)$$

- Carbon monoxide (CO):

$$\Delta G^0_{CO} = -88.381 \cdot T - 111{,}713 \qquad (22)$$

- Steam ($H_2O_{(v)}$):

$$\Delta G^0_{H_2O} = 55.186 \cdot T - 247{,}676 \qquad (23)$$

These relations were obtained through an analysis of the forming reactions of each component. Gibbs free energies for H_2 and N_2 are zero, because they are considered in their standard state [8].

The following values were used for chemical exergies [16]:

Component	Chemical Exergy (kJ/mol)
O_2	3.97
N_2	0.72
CH_4	831.65
CO_2	198.70
CO	275.10
H_2O	9.50
H_2	236.10
$C_{(graphite)}$	410.26

Table 1 – Chemical exergies for different components

Enthalpies for biomass and unconverted carbon were determined by the following relations:

- Biomass (CH_yO_z) [17]:

$$\bar{h}_{f_{biomass}} = h_{CO_2}(25°C,1bar) + \frac{y}{2}\cdot\bar{h}_{H_2O_{(v)}}(25°C,1bar) + PCI_{biomass} \quad (24)$$

$$\Delta h = \frac{0.003867\cdot\left(T_{biomass}^2 - T_0^2\right)}{2} + 0.1031\cdot\left(T_{biomass} - T_0\right) \quad (25)$$

$$\Delta\bar{h} = \bar{c}_{p_{biomass}}\cdot\Delta T \quad (26)$$

- Unconverted carbon ($C_{(s)}$) [18]:

$$\bar{h}_{f_{carbon}} = 0 \quad (27)$$

$$\Delta\bar{h} = \left[4.03\cdot\left(T_C - T_0\right) + \frac{1.14x10^{-3}\cdot\left(T_C^2 - T_0^2\right)}{2} + 2.04x10^5\cdot\left(\frac{1}{T_C} - \frac{1}{T_0}\right)\right]\cdot 4.18 \quad (28)$$

For the exergy of biomass, it was used a coefficient that relates the LHV of biomass to its chemical exergy (the physical exergy has been disregarded from the analysis) [16]:

$$b_{biomass} = \beta\cdot LHV_{biomass} \quad (29)$$

$$\beta = \frac{1.0414 + 0.0177\cdot\frac{H}{C} - 0.3328\cdot\frac{O}{C}\cdot\left[1 + 0.0537\cdot\frac{H}{C}\right]}{1 - 0.4021\cdot\frac{O}{C}} \quad (30)$$

And for carbon, the chemical exergy is 410.26 kJ/mol, and the physical part was obtained by:

$$\bar{b}_{ph} = \int_{T_0}^{T} c_p\cdot dT - T_0\int_{T_0}^{T} c_p\cdot\frac{dT}{T} \quad (31)$$

Using the following relation for c_p [18]:

$$c_p = \left[4.03 + 1.14x10^{-3}\cdot T - \frac{2.04x10^5}{T^2}\right]\cdot 4.18 \quad (32)$$

Enthalpies and entropies for all other components presented in the model were evaluated using the software EES [11].

The evaluation of the exergy of the produced gas was carried out using [19]:

$$\bar{b}_{ph} = \left(\bar{h} - \bar{h}_0\right) - T_0\cdot\left(\bar{s} - \bar{s}_0\right) \quad (33)$$

$$\bar{b}_{ch} = \sum y_j\cdot\bar{b}_j^0 + R\cdot T_0\cdot\sum y_j\cdot\ln\left(y_j\right) \quad (34)$$

$$\bar{b}_{\substack{produced\\gas}} = \bar{b}_{ph} + \bar{b}_{ch} \quad (35)$$

ABSTRACT

The aim of this work is to provide a tool to approach the energy actual market value. As exergy represents the quality of energy, the normal procedure to carry out the thermoeconomic optimization of a given thermal system involves the use of the exergy of each stream as the basic quantity. The usual method evaluates the cost rates appearing in the cost rate balance in terms of the associated rates of exergy transfer and the corresponding unit costs. In this work, the thermomechanical exergy of each stream is divided into two components with very different qualities and, as a consequence, with different unit costs. The component with higher quality can be assigned the same unit cost than work whereas the component with lower quality will usually be assigned a lower unit cost. Therefore, the cost rates of the entering or leaving streams of a system will result closer to actual economic values, especially in processes with important pressure variations. An example related to combined cycles is studied.
Keywords: thermoeconomic optimization, exergy, cost balance, combined cycle

NOMENCLATURE

c	Levelized cost per unit of thermobaric component, per unit of work or per unit of equivalent economic exergy [$/GJ or €/GJ]
c^{ta}	Levelized cost per unit of thermoambient component of thermomechanical exergy [$/GJ or €/GJ]
c_p	Specific heat capacity at constant pressure [kJ/(kg K)] of a gas
c_l	Specific heat capacity of a liquid [kJ/(kg K)]
$\dot{C}_{ik}$	Cost rate of the "fuel" i entering the component k [$/s or €/s]
$\dot{C}_{kj}$	Cost rate of the "product" j leaving the component k[$/s or €/s]

INTRODUCTION

The first step to approach the *optimal* design of a complex thermal system is, in many cases, to obtain the minimum irreversibility compatible with "the state of the art" of the system components manufacture. That is, the *thermodynamic* optimization is usually the first step to optimize thermal systems. But usually, a lower irreversibility demands a higher cost, and therefore, the most competitive solution of the new design requires a thorough analysis for a *thermoeconomic* optimization. This thermoeconomic analysis includes the economic evaluation of energy, especially in those systems transforming important quantities of it (thermal engines, chemical industries, etc.). In a number of cases, streams interchanging mass, heat and work are present in many ways in the diverse components of these systems.

A material or a product containing energy has a variable economic value depending on its *quality*. The *thermodynamic quality* of the energetic product is established attending to the product capacity to provide the maximum work interaction, respect to the unit of the product energy. Then, the thermodynamic quality of the energy of a stream is determined by its exergy.

Nevertheless, in the energy market, the *actual quality* of the product is based both on its thermodynamic quality and on the simplicity of the energy transformer required to obtain the above mentioned work interaction.

In this work the actual quality of the exergy of a stream is analyzed. To do so, the thermomechanical flow exergy is written as a sum of two components with different actual qualities. Then, a different unit cost consistent with the actual market value of the energy is proposed for each of these two components of the thermomechanical exergy.

THERMOBARIC AND THERMOAMBIENT COMPONENTS OF THE THERMOMECHANICAL EXERGY OF A STREAM

It is widely known the following distribution of the flow exergy rate by unit of mass flow rate ϕ into its two main components [1-3]

$$\phi = \left[\Delta\phi^{PT} + \Delta\phi^{KN} + \Delta\phi^{PH}\right] + \Delta\phi^{CH} = \Delta\phi^{TM} + \Delta\phi^{CH} \quad (1)$$

where the ensemble of the three first terms is called *thermomechanical exergy* $\Delta\phi^{TM}$, being $\Delta\phi^{PT} = gz$ the potential energy, $\Delta\phi^{KN} = 1/2\,v^2$ the kinetic energy and the physical exergy is $\Delta\phi^{PH} = h(p,T) - h(p_a,T_a) - T_a\left(s(p,T) - s(p_a,T_a)\right)$.

The term $\Delta\phi^{CH}(p_a,T_a)$ represents the chemical exergy in the ambient state $(p_a,T_a,v=0,z=0)$.

The state of reference or dead state is defined by $O(p_a,T_a,v=0,z=0)$ and a chemical composition in chemical equilibrium with the ambient.

Using the concept of total enthalpy h_t, Eq.(1) is written as follows

$$\phi = \left[h_t(p,T,v,z) - h(p_a,T_a) - T_a\left(s(p,T) - s(p_a,T_a)\right)\right] + \Delta\phi^{CH} = \Delta\phi^{TM} + \Delta\phi^{CH} \quad (1b)$$

rion of *actual quality* here introduced, an intermediate state $A(p_a, T_{as}, v=0, z=0)$ is established and then the following division is proposed

$$\Delta\phi^{TM} = \left[\phi(p,T,v,z) - \phi(p_a,T_{as})\right] + \left[\phi(p_a,T_{as}) - \phi(p_a,T_a)\right] \quad (2)$$

being T_{as} the temperature that, without changes in the chemical composition, meets the condition $s(p,T) = s(p_a,T_{as})$. That is, the thermodynamic state $A(p_a, T_{as}, v=0, z=0)$ is the one obtained after an isentropic expansion (or compression) from a state of pressure *p*, temperature *T*, velocity *v* and elevation *z*, to the ambient pressure p_a and kinetic and potential energy levels equal to zero, without changing the chemical composition The Eq.(2) can be written as

$$\Delta\phi^{TM} = \Delta\phi^{tb} + \Delta\phi^{ta} \quad (3)$$

where the first term of the right hand side

$$\Delta\phi^{tb} = h_t(p,T,v,z) - h(p_a,T_{as},v=0,z=0) \quad (4)$$

represents the work obtained (or required) in the adiabatic and isentropic expansion (or compression) process to ambient pressure, zero velocity and zero potential energy level. This component of the thermomechanical exergy has been called *thermobaric* component. The energetic quality of this thermobaric component can be comparable to that of work.

The second term of the right hand side of Eq. (3)

$$\Delta\phi^{ta} = \left[h(p_a,T_{as}) - h(p_a,T_a)\right] - T_a\left[s(p_a,T_{sa}) - s(p_a,T_a)\right] \quad (5)$$

represents an exergetic component of exclusively thermal-type at the ambient pressure p_a. The reversible conversion of it into work interaction becomes a very complex task. This component of the thermomechanical exergy can be designed by *thermoambient* component.

It is evident that the economic value of these two components is different, being higher the thermobaric than the thermoambient one in the thermal engines case.

The thermomechanical exergy $\Delta\phi^{TM}$ can be split in diverse forms, but taking into account the crite

Assuming, as an example, a gas perfect stream (c_p, R), for a (p_t, T_t) state it follows

$$\frac{T_{as}}{T_t} = \left(\frac{p_a}{p_t}\right)^{R/c_p}$$

$$\Delta\phi^{tb} = c_p(T_t - T_{as}) = c_p T_t\left[1 - \left(\frac{p_a}{p_t}\right)^{R/c_p}\right] \quad (6)$$

$$\Delta\phi^{ta} = \Delta h^{ta} - T_a\left[s(p_a,T_{as}) - s(p_a,T_a)\right] = c_p T_a\left(\frac{T_{as}}{T_a} - 1\right) - c_p T_a \ln\frac{T_{as}}{T_a} \quad (7)$$

Numerical values of $\Delta\phi^{ta}$, $\Delta\phi^{tb}$ and ϕ can be either positive or negative depending on the (p_t,T_t) and (p_a,T_a) states. Both thermobaric and thermoambient exergy components can have a wide variety of values in the different systems under study.

In the case of a hot gases stream in a state with $T_t = 1500\,\mathrm{K}$, p_t = 2MPa, $c_p = 1.16\,\mathrm{kJkg^{-1}K^{-1}}$ and $R = 0.287\,\mathrm{kJkg^{-1}K^{-1}}$, and an ambient state ($T_a = 300\ \mathrm{K}$; $p_a = 0.1\ \mathrm{MPa}$), the following results are obtained: $T_{as} = 715.7\,\mathrm{K}$, $\Delta\phi^{tb} = 909.8\ \mathrm{kJkg^{-1}}$ and $\Delta\phi^{ta} = 179.56\ \mathrm{kJkg^{-1}}$.

If a stream of an incompressible liquid at the state (p_t, T) of thermal specific capacity c_l is assumed, the following results are obtained

$$T_{as} = T \qquad \Delta\phi^{tb} = \frac{p_t - p_a}{\rho_l} \quad (8)$$

$$\Delta\phi^{ta} = \Delta h^{ta} - T_a\left[s(p_a,T_{as}) - s(p_a,T_a)\right] = c_l T_a\left(\frac{T}{T_a} - 1\right) - c_l T_a \ln\frac{T}{T_a} \quad (9)$$

In a wide range of technical devices, the processes underwent by the streams can be assumed as adiabatic ones. Even, when a heat exchanger is involved, the ensemble as a whole can also be considered as an adiabatic system. Therefore, the study developed here is applied to *adiabatic processes*.

RELATIVE ECONOMIC EVALUATION OF THERMOMECHANICAL EXERGY COMPONENTS. ADIABATIC PROCESSES

The economic value of energy in a given stream depends on its thermodynamic quality and then, in an early economic evaluation of the stream, exergy is used as a property with economic value.

Economic evaluation of exergy begins by assigning costs to the main components shown in Eq. (1), that is, by giving economic values to thermomechanical exergy $\Delta\phi^{TM}$ and thermochemical exergy $\Delta\phi^{CH}$.

For many energetic products or energetic supplies ("fuel"), the market value or actual economic evaluation of the chemical exergy $\Delta\phi^{CH}$ is based both on their amount of exergy and on other non-thermodynamic characteristics.

Consequently, when an energetic conversion is analyzed from a thermoeconomic point of view, to approach the actual energetic market situation, the chemical exergy component $\Delta\phi^{CH}$ is considered separately from the thermomechanical exergy one, $\Delta\phi^{TM}$.

Many thermodynamic processes take place without changes of chemical composition of the streams involved in. Therefore $\Delta\phi^{CH}$ does not change and does not participate in the thermoeconomic study performed.

Respect to the thermomechanical exergy $\Delta\phi^{TM}$, it must be pointed out that it is usually treated as a whole in the thermoeconomic analyses. But, as has been shown when the thermomechanical exergy has been split in the proposed manner, Eqs. (4) and (5), the thermobaric component $\Delta\phi^{tb}$ includes, in addition to the kinetic and potential energies, the amount of work extracted (or required) in a simple expansion (or compression) process. Therefore, conversion of thermobaric exergy $\Delta\phi^{tb}$ into work implies a direct process without complex processes. On the contrary, the thermoambient exergy $\Delta\phi^{ta}$ is exclusively constituted by thermal exergy at the ambient pressure and converting it into work is a rather complex task. Theoretically at least, it could be completely converted into work by means of a reversible process.

In order to approach the actual market values, different costs to both exergy components should be assigned when a thermoeconomic analysis is performed.

As can be deduced from Eq. (3), a given value of $\Delta\phi^{TM}$ can be the result of the sum of very different $\Delta\phi^{tb}$ and $\Delta\phi^{ta}$ quantities. As the economic value of both components is different, the corresponding economic value of the same quantity $\Delta\phi^{TM}$ can be very different depending on the system under study.

In this work, the economic evaluation of both thermomechanical exergy components is proposed as

$$c\Delta\phi^{tb} + c^{ta}\Delta\phi^{ta} = c(\Delta\phi^{tb} + \xi\Delta\phi^{ta}) \qquad (10)$$

where

$$\xi = \frac{c^{ta}}{c} \qquad (11)$$

is a parameter used to establish the relative economic value of the thermoambient and thermobaric exergy components. The quantities c and c^{ta} in Eq. (11) are the levelized unit costs of these two exergies with different qualities.

It is correct to think that the estimation of the ξ parameter will depend on each specific system and the place where the installation is working. In any case, the same value for all the streams and components in the specific system can be assumed. This hypothesis can be established if the relative cost of mechanical and thermal energy is assumed constant in a given situation (a cogeneration plant in a given country, for example). It must be pointed out that ξ is an economic parameter and not a thermodynamic one.

In power systems, this parameter can be estimated, for example, in the following way

$$\xi = \frac{\text{levelized unit cost of the natural gas energy GJ}}{\text{levelized unit cost of the electric energy GJ}}$$

Values between 0.3 and 0.4 are obtained in typical situations. Sensitive analyses can be performed with this parameter after the thermoeconomic study is made.

The quantity ($\Delta\phi^{tb} + \xi\Delta\phi^{ta}$) is called here *equivalent economic thermomechanical flow exergy*.

The cost rate of a stream, $\dot{C}_{st}$ ($/s o €/s), is generally expressed as the product of a levelized unit cost by the flow exergy of the stream, that is, $\dot{C}_{st} = c(\dot{m}\phi)$. Making use of the formulation proposed here, such cost rate can be written as

$$\dot{C}_{st} = c\left[\dot{m}(\Delta\phi^{tb} + \xi\Delta\phi^{ta})\right] \qquad (12)$$

now being c the levelized unit cost of the equivalent economic exergy. Thus, the levelized unit cost c is referred to the equivalent economic value of the product, which is closer to its actual market value.

Thermodynamic quality of $\Delta\phi^{tb}$ is assumed to be analogous to that of specific work. Thus, when they are obtained as energetic products at the same time, it is also assumed that both have equal economic values.

When a thermoeconomic study is applied to a complex system, the cost balance applied to each component k (energy converter), is based on the well known economic equation [1-3]

$$\sum_i \dot{C}_{ik} + \dot{Z}_k = \sum_j \dot{C}_{kj} \qquad (13)$$

written for a given period of time. When this equation is particularized to *adiabatic systems*, $\dot{C}_{ik}$ represent the cost rates of the streams $\dot{m}_i$ and work interactions $\dot{W}_i$ that, coming from the component i, enter the component k. All of them are known. $\dot{Z}_k$ stands for the investment, operation and maintenance cost rate of such component k. $\dot{C}_{kj}$ are the cost rates of the energetic products obtained (streams and work interactions) in k and entering other components j. $\dot{C}_{kj}$ are the unknowns precisely.

As only one economic equation by component is available, when more than one energetic product are obtained at the exit of the k component, some additional hypotheses are needed. Such hypotheses must relate the various products from the economic point of view in order to determine their unit costs [1-3].

That is, it is a common practice to apply diverse additional hypotheses based on the exergy of each stream to determine unit costs.

If Eq. (12) is introduced into Eq. (13), for a process without change of composition in the k component, the new formulation leads to

$$\sum_i \left[c_{ik}\dot{W}_{ik} + c_{ik}\dot{m}_{ik}(\Delta\phi_{ik}^{tb} + \xi\Delta\phi_{ik}^{ta})\right] + \dot{Z}_k = c_k\left\{\sum_j \left[\dot{W}_{kj} + \dot{m}_{kj}(\Delta\phi_{kj}^{tb} + \xi\Delta\phi_{kj}^{ta})\right]\right\} \qquad (14)$$

where c_{ik} represents the levelized unit cost of the "fuel" entering the k component, which coming from the outside or from other component i, has been calculated or estimated previously. In Eq. (14) c_k is the levelized unit cost of the *equivalent economic thermomechanical flow exergy* of the streams leaving the component k and entering any other component j. It also represents the levelized unit cost of the specific work obtained in this component. In other words, c_k represents the levelized unit cost of the energetic products.

It must be pointed out that Eq. (14) has been written stating a unique hypothesis common to all the products of every component in the whole specific thermal system. Such hypothesis is that a unique value of the ξ parameter is assumed.

Equation (14) makes evident the influence of the division of thermomechanical exergy into two components of different quality (thermobaric and thermoambient exergy), in the unit cost of a stream. As has been said, this feature allows to obtain costs of the products close to actual market values.

In addition to the previous equation, the exergy balance particularized to each component k is available. Using Eq. (3) the following is obtained

$$\sum_i \left(\dot{W}_{ik} + \dot{m}_{ik}\left(\Delta\phi_{ik}^{tb} + \Delta\phi_{ik}^{ta}\right)\right) = \sum_j \left(\dot{W}_{kj} + \dot{m}_{kj}\left(\Delta\phi_{kj}^{tb} + \Delta\phi_{kj}^{ta}\right)\right) + \dot{m}_{ka}\phi_{ka} + \dot{I}_k \qquad (15)$$

where the total exergy thrown to the ambient (lost exergy) and the irreversibility of the process are, respectively $\dot{m}_{ka}\phi_{ka}$ and $\dot{I}_k$.

To use the cost balance expressed as in Eq. (14), knowledge of the magnitudes of the thermobaric and thermoambient exergy components, $\Delta\phi^{tb}$ and $\Delta\phi^{ta}$, in every control section of the system is needed.

Provided the corresponding device efficiencies are available, Thermodynamics makes possible to determine the streams thermodynamic properties in the different control sections of the thermal system. The method of calculation for some simple cases is explained, as examples, in the following section.

As the unit cost of "fuels" is known and the magnitude and kind of the energetic products are also known, the only unknown value of Eq. (14) is c_k.

Thus, writing one equation, Eq. (14), for each system component, a lineal equation system is ob-

tained and then, the unknowns c_k can be determined.

THERMODYNAMIC EVALUATION OF THE THERMOBARIC AND THERMOAMBIENT COMPONENTS. ADIABATIC PROCESSES

A monophase stream without composition change

The following expressions can be written when a stream experiences an adiabatic process 1→2 in a component of the thermal system

$$\begin{aligned} &\dot{m}_1 h_{t1} + \dot{W}_1 = \dot{m}_1 h_{t2} + \dot{W}_2 \\ &\dot{m}_1 \phi_1 + \dot{W}_1 = \dot{m}_1 \phi_2 + \dot{W}_2 + \dot{I}_{12} \end{aligned} \qquad (16)$$

The subscripts 1 and 2 indicate the inlet and the outlet of the system component *k*, respectively. Here $\dot{I}_{12}$ represents the irreversibility rate in the process.

Assuming that thermodynamic properties at the inlet, section 1, are known and particularizing Eqs. (1) and (3) for the control sections 1 and 2, it follows that

$$\begin{aligned} &\Delta\phi_2^{CH} - \Delta\phi_1^{CH} = 0 \\ &\Delta\phi_2^{tb} - \Delta\phi_1^{tb} = \frac{\dot{W}_1 - \dot{W}_2}{\dot{m}} - (\Delta h_2^{ta} - \Delta h_1^{ta}) \\ &\Delta\phi_2^{ta} - \Delta\phi_1^{ta} = (\Delta h_2^{ta} - \Delta h_1^{ta}) - T_a \Delta s_{12}^{ta} \end{aligned} \qquad (17)$$

With any model of substance, at the constant pressure $p = p_a$, the following expressions are derived

$$\begin{aligned} &\Delta h_2^{ta} - \Delta h_1^{ta} = \int_{T_{as1}}^{T_{as2}} c_p(p_a, T)\, dT \\ &\Delta s_{12}^{ta} = \int_{T_{as1}}^{T_{as2}} \frac{c_p(p_a, T)}{T}\, dT \end{aligned} \qquad (18)$$

The value of T_{as2} is obtained calculating previously the state 2t. To do that, the device efficiency to determine the irreversibility process is required.

A two phase stream without chemical composition change

In technical applications, processes where both liquid and vapour phases either together or separated are quite frequently found. This is usual when the ambient state $O(p_a, T_a)$ is near to the biphasic states (vapour, liquid) of the substances.

This circumstance takes place in two cases of technical relevance: steam power plants and refrigerating plants. In the case of steam power plants the ambient state usually corresponds to liquid water, $O(p_a, T_a, \text{liquid})$.

To study a vapour stream with thermomechanical exergy $\Delta\phi_v^{TM}(p,T,v,z)$ is adequate to select the state of separation of the thermobaric and thermoambient components as $B\left[p_v(T_a), T_{as}\right]$. Here $p_v(T_a)$ represents the vapour pressure corresponding to the ambient temperature T_a. The value of T_{as} is given by the condition $s\left(p_v(T_a), T_{as}\right) = s(p,T)$. Therefore, the thermobaric component of a vapour stream is written as

$$\begin{aligned} \Delta\phi_v^{tb} &= \phi_v(p,T,v,z) - \phi_v(p_v(T_a), T_{as}) \\ &= h_v(p,T,v,z) - h_v\left(p_v(T_a), T_{as}\right) \end{aligned} \qquad (19)$$

which represents the specific work that can be obtained directly after an isentropic expansion. For calculation purposes it is evident that $h_v\left(p_v(T_a), T_{as}\right) = h_v\left(p_v(T_a), s(p,T)\right)$.

The thermoambient component is in this case

$$\begin{aligned} \Delta\phi_v^{ta} &= h_v\left(p_v(T_a), T_{as}\right) - h_l(p_a, T_a) \\ &\quad - T_a\left[s_v\left(p_v(T_a), T_{as}\right) - s_l(p_a, T_a)\right] \\ &= h_v\left(p_v(T_a), T_{as}\right) - h_{vs}(T_a) + h_{ls}(T_a) - h_l(p_a, T_a) \\ &\quad - T_a\left[s_v\left(p_v(T_a), T_{as}\right) - s_{vs}(T_a) + s_{ls}(T_a) - s_l(p_a, T_a)\right] \end{aligned} \qquad (20)$$

Here the subscripts "*ls*" and "*vs*" stand for saturated liquid and vapour, respectively, at the temperature T_a.

From Eq. (19) it follows that when $p_v(T_a) \ll p_a$ the value of $\Delta\phi_v^{tb}$ is high, and from Eq. (20) can be deduced that the value of $\Delta\phi_v^{ta}$ is low. That is, the thermomechanical exergy of a high pressure vapour stream that, for example, is to be expanded in a turbine, is mainly thermobaric component, high quality exergy as has been said. In this case the thermoambient component has a very low value, as can be appreciated next. At pressure $p_v(T_a) \ll p_a$ the steam can be taken as perfect gas, then

$$\Delta\phi_v^{ta} = c_{pv}(T_{as} - T_a) - c_{pv}T_a \ln\frac{T_{as}}{T_a} + \frac{p_v(T_a) - p_a}{\rho_l}$$
$$= c_{pv}T_a\left(\frac{T_{as}}{T_a} - 1 - \ln\frac{T_{as}}{T_a}\right) + \frac{p_v(T_a) - p_a}{\rho_l} \quad (21)$$

When $T_{as} = T_a$ (two-phase region) $\Delta\phi_v^{ta}$ is equal to the second member of the right hand side of Eq. (21), with very low value.

Heat exchanger with phase change

The case of a hot gases stream $\dot{m}$ that, at ambient pressure p_a, transfers its exergy (thermoambient component in this case) to a pressurized liquid stream $\dot{m}_l$ in various pressure steps, is studied. In the heat exchanger, this liquid stream at high pressure is transformed into various vapour streams with different pressure levels. This could be the case of the heat recovery steam generator (HRSG) in a combined cycle power plant. Making use of the exergy balance, Eq. (15), and rearranging

$$\dot{m}(\Delta\phi_1^{ta} - \Delta\phi_2^{ta}) = \sum_j \dot{m}_{vj2}\Delta\phi_{vj2}^{tb} + (\sum_j \dot{m}_{vj2}\Delta\phi_{vj2}^{ta} - \dot{m}_l\Delta\phi_{l1}^{tb}) + \dot{I}_{12} \quad (22)$$

Equations (18), (19) and (21) suggest that the exergy of a gas stream $\dot{m}$ at pressure near to ambient (exhaust gas stream of a gas turbine, for example), whose thermoambient component is much higher than its thermobaric component $\dot{m}\Delta\phi^{ta} \gg \dot{m}\Delta\phi^{tb}$, can be transferred directly (without external work) to a pressurized liquid stream until a vapour state is reached for which its thermobaric component is much higher than its thermoambient one, $\dot{m}_v\Delta\phi_v^{tb} \gg \dot{m}_v\Delta\phi_v^{ta}$. Thus, the higher possible value of the thermobaric component is obtained $\sum_j \dot{m}_{vj2}\Delta\phi_{vj2}^{tb} \gg (\sum_j \dot{m}_{vj2}\Delta\phi_{vj2}^{ta} - \dot{m}_l\Delta\phi_{l1}^{tb})$ in this process and a subsequent direct conversion into work can be performed in a turbine. It can be said that this process *regenerates the quality* of the exergy of the hot gases stream.

This possibility, suggested by thermodynamic considerations, gives rise to the denominated *combined cycle*, by means of a relatively simple process.

STUDY OF AN EXAMPLE RELATED TO COMBINED CYCLE POWER PLANTS

To make evident the influence of the thermomechanical exergy division into two components of different qualities, thermobaric and thermoambient ones, a simple case of interest in combined cycle power plants is presented.

A hot perfect gases stream $(\dot{m}, c_p, T_{c1}, p_{c1} \approx p_a)$ enters a unique pressure level steam generator to give a vapour stream $(\dot{m}_v, p_2, T_{v2} = T_{c1} - \delta_0, \delta_0 > 0)$ from a liquid water stream $(\dot{m}_l = \dot{m}_v, p_2, T_a)$. Inlet and outlet thermobaric and thermoambient component values are determined and compared. To reduce irreversibility, a counterflow arrangement is used. The process is constituted by two steps: *a*) heating of the pressurized liquid until the saturation temperature corresponding to the pressure p_2, $T_s(p_2)$ is reached. The corresponding gases temperature is $T_s(p_2) + \delta_1$, (pinch point δ_1); *b*) evaporation and overheating to achieve the final steam temperature.

The total energy balance leads to

$$\frac{\dot{m}_v}{\dot{m}} = \frac{c_p(T_{c1} - T_s(p_2) - \delta_1)}{h_v(p_2, T_{c1} - \delta_0) - h_{ls}(p_2)}$$
$$\Delta T_c = T_{c1} - T_{c2} = \left(T_{c1} - T_s(p_2) - \delta_1\right)\frac{h_v(p_2, T_{c1} - \delta_o) - h_l(p_2, T_a)}{h_v(p_2, T_{c1} - \delta_0) - h_{ls}(p_2)}$$

In addition to this, using Eq. (7)

$$\Delta\phi_1^{ta} - \Delta\phi_2^{ta} = c_p T_a\left[\frac{\Delta T_c}{T_a} + \ln\left(1 - \frac{\Delta T_c}{T_{c1}}\right)\right]$$

Using Eq. (19)

$$\Delta\phi_{v2}^{tb} = h_v(p_2, T_{c1} - \delta_0) - \left[T_a\left(s_v(p_2, T_{c1} - \delta_0) - s_{ls}(T_a)\right)\right] - h_{ls}(T_a)$$

The exergy of a liquid stream can be written in this case as follows

$$\phi_{l1}(p_2, T_a) = h_{l1}(p_2, T_a) - h_l(p_a, T_a) - T_a\left(s_{l1}(p_2, T_a) - s_l(p_a, T_a)\right)$$

For example, if $T_a = 30\,^{o}\mathrm{C}$, $p_a = 0.1\mathrm{MPa}$, $T_{c1} = 515\,^{o}\mathrm{C}$, $p_{c1} = p_a$, $\delta_0 = \delta_1 = 15\,^{o}\mathrm{C}$ and $c_p = 1.16\,\mathrm{kJkg^{-1}K^{-1}}$ it results that $\Delta\phi_1^{tb} = 0\,\mathrm{kJkg^{-1}}$, $\Delta\phi_1^{ta} = 226.6\,\mathrm{kJkg^{-1}}$ and $\Delta\phi_{v2}^{ta} = -0.09618\,\mathrm{kJkg^{-1}}$. To calculate the process irreversibility Eq. (22) is used.

To make evident the different economic value of the streams involved in Eq. (14), the quotient of the equivalent economic exergies leaving and entering the device, *k*, is calculated as

$$k = \frac{\dot{m}_v(\Delta\phi_{v2}^{tb} + \xi\Delta\phi_{v2}^{ta}) + \dot{m}\xi\Delta\phi_2^{ta}}{\dot{m}\xi\Delta\phi_1^{ta} + \dot{m}_v\Delta\phi_{l1}^{tb}}$$

The results obtained from the study of a steam generator with a unique pressure level are presented in Table 1 for different values of liquid water pressure, p_2. This pressure is also the pressure of the resulting steam entering the turbine. It can be observed that when p_2 rises, the steam quality *x* diminishes and more than one pressure level is required.

p_2 **MPa**	$\dot{m}_v/\dot{m}$	ΔT_c **°C**	$\Delta\phi_{v2}^{tb}$ **kJkg^{-1}**	$\frac{\dot{m}_v\Delta\phi_{v2}^{tb}}{\dot{m}\Delta\phi_1^{ta}}$
0.3	0.145	421.05	968.97	0.622
1.0	0.137	395.1	1132.14	0.683
2.0	0.130	375.4	1221.47	0.703
3.0	0.126	361.7	1270.30	0.707
4.0	0.123	351.03	1302.66	0.706

4.0	0.178	0.83	2.46	0.81
5.0	0.164	0.82	2.47	0.83

Table 1: Steam generator with a unique pressure level

In order to make evident the influence of the ξ parameter, the values of *k* for $\xi = 0.3$ and $\xi = 1$ are presented in the last two columns of Table 1. It can be observed that for a standard value of $\xi = 0.3$, *k* is greater than 2. On the contrary, if thermomechanical exergy is not divided into the two components of different quality, $\Delta\phi^{TM} = \Delta\phi^{tb} + \Delta\phi^{ta}$, case for which $\xi = 1$, values lower than unity are obtained for this quotient.

CONCLUSIONS

Thermobaric and thermoambient components of thermomechanical exergy defined here can have very different values giving rise to the same final thermomechanical numeric result. As a consequence, the actual quality of this thermomechanical exergy, quantified by the economic equivalent exergy, may have very different values depending on the relative contribution of these two components.

Division of thermomechanical exergy into two components with different qualities allows to obtain product unit costs closer to market values.

With this formalism a unique hypothesis is assumed: the quotient of the two thermomechanical exergy component unit costs is kept constant all over the specific thermal system. This feature makes unnecessary the particular hypotheses usually assumed for each economic equation in each system component.

ABSTRACT

The determination of the natural capital exergy is linked to the definition and thermodynamic properties of the Reference Environment (R.E.) used. Hence the importance of an appropriate selection of the R.E. The aim of this paper is to obtain and propose in ECOS 2005, an agreement on the legal international reference environment for evaluating the natural resources on Earth. For this purpose, all the R.E. models published so far are systematically analyzed, the best suitable methodology for calculating the standard chemical exergy of the chemical elements is chosen and shown and the variables used in the chosen methodology are updated using new geochemistry information and revisions done by other authors.

Keywords: Reference Environment, Reference Substance, Standard Chemical Exergy, Natural capital

INTRODUCTION

The natural capital can be evaluated from different points of view. One of them, and perhaps the most commonly known is the economic point of view. Nevertheless, as Naredo [1] analyzes, standard economy is only concerned with what which being directly useful to man, is also acquirable, valuable and produce-able. For this reason, most of the natural resources, remain outside the object of analysis of the economic system. The price-fixing mechanisms, rarely take into account the concrete physical characteristics which make them valuable. But natural capital has at least two physical features which make minerals or fresh water for example unusual: a particular composition which differentiates them from the surrounding environment, and a distribution which places them in a specific concentration. These intrinsic properties, can be in fact evaluated from a thermodynamic point of view in terms of exergy [2].

The thermodynamic value of a natural resource could be defined as the minimum work necessary to produce it with a specific structure and concentration from common materials in the environment. This minimum amount of work is theoretical by definition and is equal to the material's exergy (Riekert [3]). The exergy of a system gives an idea of its evolution potential for not being in thermodynamic equilibrium with the environment, or what is the same, for not being in a dead state related to the Reference Environment (R.E.). Therefore, for calculating the exergy of any natural resource, a R.E. should be defined. This R.E. must be determined by the natural environment and can be assimilated to a thermodynamically dead planet where all materials have reacted, dispersed and mixed.

Each of the R.E. definitions are fixed by their chemical composition. They have therefore different values of reference exergy and generate different exergies. This implies that the determination of the natural capital exergy is necessarily linked to the definition and thermodynamic properties of the R.E.

Hence the importance of an appropriate selection of a R.E. for evaluating natural resources.

SEARCHING THE BEST SUITABLE R.E. CATEGORY

So far, there have been many contributions to the determination of a R.E. They could be divided into two main groups: *Partial* and *Comprehensive Reference Environments*.

It is well known, that some authors such as Bosnjakovich [4], Gaggioli and Petit [5] and Sussman [6] established that the R.E. should be defined according to the specific characteristics of the analyzed process. This criterion is based on that being the exergy a parameter that quantifies the theoretical evolution of a system with respect to the R.E., some of the possible evolutions of the system, cannot be attained because of process limitations. Hence, only possibilities of evolution that the system can practically attain are analyzed. The R.E. is not a "dead state" anymore. For computing exergy changes of variable composition or chemically reactive steady flow processes, a *Comprehensive Reference Environment* is generally unnecessary. However, this is not the case when the point is to evaluate the natural capital on Earth. In this case, there are no process limitations and the resources can follow an evolution process towards the dead state, thus a comprehensive R.E. is required.

Within the known *Comprehensive Reference Environments*, all authors agree in dividing the Reference Substances (R.S.) that compose the R.E. into gaseous components of the atmospheric air, solid components of the external layer of the Earth's crust, and molecular components of seawater. Nevertheless, there are also criterion differences between the different authors. They could be classified into environments based on 1) *Szargut's criterion*, 2) *Chemical equilibrium* and 3) *Abundance*.

Abundance and *Szargut's criterion* are not opposite criteria. According to *Szargut's criterion*, among a group of reasonable abundant substances, the most stable will be chosen if they also complain with the "Earth similarity criterion". That is, if the stability of the possible different reference substances for a specific element (measured in terms of the formation Gibbs energy) is within a certain threshold, then the most abundant R.S. will be chosen. If the differences exceed this threshold, the most stable substance will be taken as R.S. as long as it does not contradict the "Earth similarity criterion". The stability threshold has not a fix value and depends on each element considered, since it is subjected to geological uncertainties. Thus for example in the case of Sb, the substance Sb_2S_3 is more abundant than Sb_2O_5, nevertheless, according to *Szargut's criterion*, Sb_2O_5, which is much more stable, will be taken as reference substance. This happens also with the substances listed in table 1. Nevertheless nitrates such as $Ca(NO_3)_2$, $NaNO_3$, KNO_3 are discarded, because being most stable but not abundant in the natural environment, would break the similarity criterion if they are taken as R.S. Therefore, Szargut's [7] dead environment is similar to the real physical environment and should represent the products of an interaction between the components of the natural environment and the waste products of the processes. The most probable products of this interaction should be chosen as reference species. Next section explains purposively the well known Szargut's methodology for obtaining the chemical exergy of the elements from the R.E.

Some authors define the chemical exergy by means of the *chemical equilibrium* with the real environment. Szargut stresses that it is not possible to attain an equilibrium with the system being not in the state of internal equilibrium (and the natural environment is far away from such equilibrium). Ahrendts [8] and Diederichsen [9] for example, stated that if the amount of different elements in the reference system is known and the temperature of the system is fixed, the quantity of each chemical compound and the value of each chemical potential is uniquely determined by the condition of *chemical equilibrium*. Even though Ahrendt's R. E. only included 15 elements, they represented more than 99% of the Earth's crust and thus his R.E. can be considered as a *Comprehensive Reference Environment*. Ahrendts calculated the composition of this environment in chemical equilibrium, having as a variable parameter the thickness of the crust layer.

Valero, Ranz and Botero [2], explained already why Ahrendt's R.E. was not suitable to evaluate the natural capital on Earth. Most of the metals cannot be evaluated because they form part of the 1% of the Earth's crust neglected by Ahrendts. His obtained R.E. is very different from the real environment and it is very unlikely an eventual evolution

towards it, since some processes are kinetically, biologically and/or geologically blocked.

Diederichsen updated and extended Ahrendt's model with new geochemical data and obtained among others, a R. E. including 75 elements. Furthermore, he allowed the composition of this environment to change with two variable parameters: thickness of the Earth's crust and ocean's depth. The final chosen environment should comply with the "Earth similarity criterion". The similarity with the Earth was measured with the equilibrium pressure, the oxygen and nitrogen content in the gas-phase and the equilibrium salt content in the oceans.

Even though Diederichsen [9] added more elements than Ahrendts [8] and included a new variable parameter, the composition of his new Reference Environment is still too different from the real Earth. According to the "Earth similarity criterion", the R.E. that best fits with the Earth's environment takes a crust thickness of only 0,1 m and an ocean's depth of 100 m. Greater values would move further away the R.E. from the real Earth, and would have among other features, reduced pressures and oxygen contents. As it happened with Ahrendt's model before, Diederichsen obtained high exergy values for oxygen. This happens because nearly all the oxygen of the air is consumed basically by the formation of nitrates and only in the limit, for a crust thickness of 0 m, the mean Earth pressure matches with that of the model. It seems therefore that achieving a R.E. in *chemical equilibrium* is in disagreement with the "Earth similarity criterion" and is not appropriate for the evaluation of natural capital on Earth. This idea fully fits with Lovelock's Gaia hypothesis [10]: the Earth is a life being and fights against thermodynamic stable equilibrium.

Kameyama et al. [11] proposed a reference environment with the criterion of chemical stability. The references are the most stable compounds among those with thermo-chemical data and can be integrated in the solid, liquid and gaseous environments. As Szargut stated in [12], some of the most stable compounds selected by Kameyama et al. like nitrates, compounds between rare elements (e.g. $PtBr_2$) or compounds with Fr as the reference species for the elements F, Cl, Br, I should not be recommended, because the probability of their formation in the environment is very small. Therefore, Kameyama et al. R.E. is not very suitable either to evaluate the scarcity of the natural capital.

According to Ranz [13], lots of minerals are compounds with the most common components of the upper continental crust, but are not very stable and do not represent the products of an interaction between the components of the natural environment and the waste products of industrial processes. Hence, Ranz [13] proposes a new R.E. very close to the real environment based on *abundance* and following *Szargut's criterion*. The solid phase of this new R.E. reproduces accurately the Earth's upper continental crust, since the solid reference species that make up this environment are the same as the most abundant types found in the Earth's upper continental crust. A problem with the Ranz proposed R.E. is that if we assign zero exergy to the most abundant substances, we are decreasing arbitrarily the natural capital, because many abundant minerals like sulfides naturally evolute to the most stable oxides. Therefore, as proposed by Valero, Ranz and Botero [2], we must return to Szargut's criterion of using the most stable substance, within the limits fixed by the "Earth similarity criterion".

Hence, our goal is to obtain an agreed legal international reference state for evaluating the natural resources on Earth, based on *Szargut's criterion* and methodology and using the more precise data used by Ranz and other authors such as Rivero [14], as well as new geochemical updates.

In the next section, Szargut's R.E. methodology is explained and the variables used are discussed.

CALCULATION METHODOLOGY: STANDARD CHEMICAL EXERGY OF THE CHEMICAL ELEMENTS

Chemical exergy expresses the exergy of a substance at ambient temperature and pressure. It is defined as a maximum work which can be obtained when the considered substance is brought in a reversible way to the state of reference substances present in the environment, using the environment as a source of heat and of reference substances necessary for the realization of the described process. The R.S. most common in the environment are accepted separately for every chemical element, and are mutually independent. Hence, the problem of equilibrium between the reference substances does not exist. It is impossible to formulate a chemical reaction in which only the reference substances take part.

Standard chemical exergy of chemical compounds

Methodology

Standard chemical exergy results from a conventional assumption of a standard ambient temperature and pressure and standard concentration of reference substances in the natural environment.
The standard chemical exergy of any chemical compound can be calculated by means of the exergy balance of a reversible formation reaction;

$$b_{chn} = \Delta G_f + \sum_e n_e b_{chne} \qquad (1)$$

where:
- ΔG_f formation Gibbs energy
- n_e amount of kmol of the element e
- b_{chne} standard chemical exergy of the element.

If the chemical element does not belong to the reference substances, its standard chemical exergy can also be calculated from Eq. 1, however, a reference reaction of this element should be formulated. This reaction contains only reference substances, additional as reactants and final as products. For example, following reference reaction holds for the element C: $C+O_2 = CO_2$, where O_2 is the additional and CO_2 the final reference substance. The standard chemical exergy of the reference substances are calculated prior to the standard chemical exergy of the element.

Discussion of the variables used

The formation Gibbs energy used by Szargut [12] was revised by Rivero [14] using [15], [16], [17], [18] and [19]. No substantial differences were found, except for sillimanite (Al_2SiO_5), whose new value is $\Delta G_f = 2440,9$ kJ/mol. The information source of Ranz [13] for obtaining ΔG_f, was Faure [20], which is a compilation of the literature from several authors. This source corroborates Rivero's revision and thus, it will be considered for the calculation of our particular R.E.

Gaseous reference substances

Methodology

Free chemical elements present in the atmospheric air (O_2, N_2, Ar, He, Ne, Kr, Xe) and the compounds H_2O, CO_2 are assumed as reference substances. Their standard chemical exergy results from the conventional standard concentration in the atmosphere;

$$b_{chn} = -RT_0 \ln \frac{P_{0n}}{P_n} = -RT_0 \ln z_0 \qquad (2)$$

where:
- R gas constant,
- T_0 standard ambient temperature (298,15 K),
- P_{0n} conventional mean ideal gas partial pressure in the atmosphere (kPa),
- P_n standard pressure (101,325 kPa),
- z_0 conventional standard molar fraction in the environment.

The values of standard chemical exergy of gaseous reference substances O_2, H_2O, CO_2, N_2 are calculated before other values because they are necessary in the calculation of standard chemical exergy of non-gaseous reference substances.

Discussion of the variables used

The universal gas constant is used (8,3143 kJ/(kmol K)) and the calculated standard chemical exergy relates to 1 kmol. Rivero and Garfias [14] accepted the reference pressure according to the conventional unit "physical atmosphere", thus 101,325 kPa. We are assuming the mean partial pressure calculated by Szargut and used by Ranz [13], which is the really appearing mean value and is equal to 99,31 kPa.
Table 2 shows the results obtained in this study for the chemical exergy of the gaseous substances. The obtained values are the same of those obtained by Szargut [12] and Valero, Ranz and Botero [2], since the methodology and the values used for this R.E. has been the same. The differences with Rivero and Garfias [14] are due to the different partial pressures in the atmosphere taken.

Solid reference substances

Methodology

For a prevailing part of chemical elements, solid R.S. commonly appearing in the external layer of the continental part of Earth's crust, have been assumed. However, the Earth's crust is a very complicated mixture of solid solutions and an exact calculation of the chemical exergy of its components is impossible. We can only approximately evaluate

that exergy, assuming that the reference species behave as components of an ideal solution. Hence, Eq. 2 can be applied also in this case.

The evaluation of the standard molar concentration of solid R.S. in the external layer of the Earth's crust is difficult. In past geochemical publications we can only find a mean mass concentration of particular chemical elements and some information about the chemical compounds containing the considered elements. Hence, the best considered way so far to obtain the standard molar concentration of R.S. in the solid environment, has been with following equation suggested by Szargut in [12]:

$$z_{0i} = \frac{1}{l_i} n_{0i} c_i M_0 \qquad (3)$$

where:

- n_{0i} mean molar concentration (in mol/kg) of the i-th element in the continental part of the Earth's crust,
- l_i number of the atoms of i-th element in the molecule of the reference species,
- c_i fraction of the i-th element appearing in the form of reference species,
- M_0 mean molecular mass of the upper layer of the continental part of Earth's crust.

The reference reactions of the elements having solid R.S. contain usually the gaseous R.S. Sometimes appear also solid reference species. For example, the solid R.S. of Mg is $Mg_3Si_4O_{10}(OH)_2$ the reference reaction for the element Mg has a form:

$$3\,Mg + 4\,SiO_2 + 1{,}5\,O_2 + H_2O = Mg_3Si_4O_{10}(OH)_2$$

In such case the standard chemical exergy of the appearing solid reference substance should be calculated prior to the calculation of the chemical exergy of the considered element.

Discussion of the variables used

The mean molar concentration of the elements in the upper continental crust n_{0i}, used in Szargut [12], was the recommended by Polanski and Smulikowski [21]. Ranz [13] used updated values mainly from Taylor and McLennan [22], [23]. For the elements: Br, C, Cl, F, S, Pt, Pu, Ra, Rh, Ru, Te, I, Hg and N, Taylor and Mclennan did not provide any information, therefore, Ranz used the values given by Wedepohl [24] for S, Br, C, F, I, Hg, N and for the remainig elements, the values used by Szargut [12]. Some authors like Plank and Langmuir [25] basing on their studies on marine sediments, suggested already in 1998 some revisions of the estimated values by Taylor and McLennan [22], [23] for Nb, Cs,Ti, Ta. As a consequence, McLennan [26] published in year 2001 new mean molar concentrations of the upper continental crust for the elements: Sc, Ti, V, Co, Ni, Nb, Cs, Pb, Ta. Grigor'ev published in year 2000 [27] the average mineral content of the upper continental crust obtained through a great number of quantitative mineralogical analysis of important rocks published mainly in the USSR and USA. Recently, Grigor'ev updated this information; this new analysis comprises 255 minerals corresponding to 99,13% of the total mineral content of the upper continental crust. Although Grigor'ev has not published this information yet, he gave permission to the authors of this paper, to use it. This valuable information will allow to obtain directly the standard molar concentration of the following 12 reference substances in the solid environment without using Eq. 3: $BaSO_4$, $CaCO_3$, Au, Fe_2O_3, $Mg_3Si_4O_{10}(OH)_2$, MnO_2, SiO_2, $SrCO_3$, ThO_2, SnO_2, TiO_2, $ZrSiO_4$. For the rest substances, Eq. 3 must be used, taking n_{0i} from the latest geochemical publications. First the values from McLennan [26] completed with those from Wedepohl [24] will be used. For the remaining elements not appearing in the latter publications, n_{0i} used by Szargut [12] will be applied.

The mean molecular mass of the upper layer of the continental part of the Earth's crust, was first estimated by Szargut [28]. The obtained value was M_0= 135,5 kg/kmol, applying the following estimation method: according to the geochemical data, the mean concentration values (in mol/kg) of particular chemical groups or elements in the external layer of the continental Earth's crust and the chemical compound formed from these groups were assumed. The first considered group was CO_2, which appears in the Earth's crust mainly in carbonates of Ca, Mg and Fe. Per 1 mol of $(CaO + MgO + FeO)$ 0,035 mol of CO_2 are present. The group CO_2 was partitioned between the mentioned groups and elements Zn, Cu, Pb and Cd, appearing also in the form of carbonates. The group SO_3 was partitioned between CaO and MgO forming sulphates. It was assumed that a prevailing part of metals (Sn, Co, Mn, Fe, Ni) appears in form of different oxides (Co_2O_3, Co_3O_4, Fe_2O_3, Fe_3O_4). It was also assumed that 8% of

Fe appears in form of free oxide Fe_2O_3. The remaining part appears in form of $FeTiO_3$, $FeCr_2O_3$ and silicates. For example, following silicates were assumed: $NaAlSi_3O_8$, $KAlSi_3O_8$, $NaFeSi_2O_6$, $MgSiO_3$, $CaO.Al_2Si_2O_7$. Because of the large content of SiO_2, a considerable part of it was assumed in free form. After estimating the composition of a mean sample of the lithosphere, its molecular mass was calculated.

Ranz [13] updated the molecular mass of the upper continental crust using more recent geochemical information and adopting not only a geochemical approach, but also a geological one. The methodology used was as follows: The international accepted norm CIPW [29] was applied to the mass fractions of the principal oxide groups obtained by Carmichael [30] for the cratonic and sedimentary layers, in order to redistribute the chemical components from the oxides to the mineral molecules that are representative in real minerals appearing in a rock. Next, the minerals of the norm and their respective relative masses were modified to adjust them to the real volumes of the principal groups of each rock. Finally, their molar fractions were calculated and the mean molecular mass of the whole was obtained. The resulting M_0 was equal to 145,5 kg/kmol. Even though this methodology used better geochemical values than the ones in Szargut [28], and included the geological approach, we cannot forget that the CIPW norm is an artificial way to obtain the possible minerals that can appear in a rock. It is therefore only an approximation as well.

In the light of Grigor'ev's analysis, a more accurate molecular weight of the upper continental crust, based on experimental results rather than assumptions, can be easily obtained. The new calculated value is M_0= 143,4 kg/kmol, which is very close to the estimation done by Ranz. The difference in the chemical exergy of the elements obtained with the new molecular weight is almost negligible: in average, taking a molecular weight equal to 143,4 instead of 145,5, makes a difference in the exergy of the solid reference substances of only 0,007%.

For the fraction of the i-th element appearing in the form of reference species (coefficient c_i), Szargut [31] associates values comprised between 0,5 for more abundant substances and 0,001 for less frequent substances from geochemical data given by Polanski and Smulikowski [21]. Ranz [13] obtained more accurate c_i coefficients for solid R.S. containing the most abundant elements in the upper continental crust. For this purpose, she used the mineralogical composition of the Earth's upper layer obtained with the CIPW norm before and updated geochemical information, mainly from Taylor and McLennan [23]. For minority elements, due to the lack of information, Szargut's [31] values were used. As long as a better mineralogical composition of the Earth's crust is done and the c_i coefficients are recalculated with this information, we will assume the c_i values obtained by Ranz [13]. Nevertheless, it must be stressed that choosing a certain c_i or another a 100 times greater, throws less differences in the chemical exergy of the elements than choosing another R.S.

Table 4 shows the results obtained in this study for the chemical exergy of the solid substances. The solid R.S. assumed were those taken by Szargut [12], basing on the *Szargut's criterion* mentioned before. The new chemical exergies obtained differ in 1,1% in average with respect to the values obtained by Szargut in [12]. Taking the empirical standard molar concentration of solid R.S. found in Grigor'ev [27] instead of calculating it with Eq. 3, implies a difference in the element chemical exergy of less than 4% except for Au (14%) and F (18%). For the latter elements, the greater difference is due to the greater sensitivity of Au to z_0, since its ΔG is equal to zero and the great proportion of atoms of Ca in the reference substance of F, respectively.

Reference substances dissolved in seawater

Methodology

Assumption of ionic or molecular R.S. dissolved in seawater ensures in many cases more exact determination of standard chemical exergy of chemical elements when compared with solid R.S. The calculation methods of thermodynamic functions of monocharged and bicharged ions are relatively exact. This is the case also when the reference substance is dissolved in molecular form with a very small degree of ionization.

The method of calculation of standard chemical exergy of elements with R.S. dissolved in seawater has been developed by Morris [32]:

$$b_{chn} = j\Bigg(-\Delta G_f + 0.5\,z\,b_{chH_2} - \sum_k \nu_k\, b_{chk} - \\ - R\,T_n\,[2.303\,z\,(pH) + \ln m_n\,\gamma]\Bigg) \quad (4)$$

where:

j	number of reference ions or molecules derived from one molecule of the element under consideration,
ΔG_f	formation Gibbs energy of the R.S.,
z	number of elementary positive charges of the reference ion,
ν_k	number of molecules of additional elements present in the molecule of reference substance,
b_{chH_2}, b_{chk}	standard chemical exergy of hydrogen gas and of the k-th additional element.
m_n	conventional standard molarity of the reference substance in seawater,
γ	activity coefficient (molarity scale) of the reference substance in seawater,
pH	exponent of the concentration of hydrogen ion in seawater (=8,1)

The activity coefficient of single ion can be calculated by means of the Debye-Huckel equation:

$$-\log\gamma_i = \frac{A\,z_i^2\sqrt{I}}{1 + a_i B\sqrt{I}} \quad (5)$$

where:

A	= 0,51 kg$^{1/2}$ mol$^{-1/2}$ for water at 25^{o}C,
B	= 3,287 * 10^9 kg$^{1/2}$ m^{-1} mol$^{-1/2}$ for water at 25^{o}C,
a_i	effective diameter of the ion,
I	ionic strength of the electrolyte.

The ionic strength of the electrolyte results from the following equation:

$$I = \frac{1}{2}\sum_i m_i {z_i}^2 \quad (6)$$

where:

m_i	molarity of the ion, mol/kg H_2O,
z_i	number of elementary electric charges of the ion.

The ion Cl^- prevails among the negative ions in seawater. Therefore, the data of chlorides can be assumed for activity coefficients of the positive ions Na^+, K^+. The activity coefficients of the negative ions Cl^- and SO_4^{-2} can be estimated in reference to the predominant positive ion Na^+.

Discussion of the variables used

The positive ionic R.S. have been assumed for the elements from the first column of the periodic system and for the monocharged and bicharged negative ions formed from acids. The elements from the second column of the periodic system appear in the seawater in form of positive bicharged ions, however, they are not recommended as R.S., because the so calculated standard chemical exergy of the elements leads to negative values of chemical exergy of some solid compounds common in the Earth's crust. Rivero and Garfias [14] have found the influence of salinity of seawater on the calculated values of standard chemical exergy of elements calculated by means of reference substances dissolved in seawater. However, an increased salinity (greater than 35‰ appears seldom (Red Sea), and the deviations are not large (usually less than 1,6%). Every introduction of solid reference substances can decrease the accuracy of calculations. Therefore we are assuming the solid reference substances only for the elements from the second column of the periodic system. Following ionic and molecular reference substances dissolved in seawater have been accepted in the recent publication of Szargut [33] and will be used for this proposal:

Cl^-, $AgCl_2^-$, $B(OH)_3$ aq, BiO^+, Br^-, $CdCl_2$ aq, Cs^+, Cu^{+2}, HPO_4^{-2}, $HAsO_4^{-2}$, $HgCl_4^{-2}$, IO_3^-, K^+, Li^+, MoO_4^{-2}, Na^+, Ni^{+2}, $PbCl_2$ aq, Rb^+, SO_4^{-2}, SeO_4^{-2}, WO_4^{-2}, Zn^{+2}.

Major ions in seawater are ions with fractions greater than 1 ppm. The Seawater Reference Environment taken into account in this proposal comprises the following major ions: Na^+, K^+, $HAsO_4^{-2}$, BiO^+, Cl^-, SO_4^{-2}, Br^-, $B(OH)_3$. Values of the activity coefficients and molarity of these species basing on information presented in Millero [34], Pilson [35] and Mottl [36] were reviewed and compared with those which Ranz and Rivero took into account. With the exception of SO_4^{-2} the differences are negligible from the point of view of the influence on the final exergy of the considered element. In case of SO_4^- Szargut and Ranz assumed a value of m = 1,17e-2, and Rivero m = 1,24e-2. The molarity

calculated basing on the three independent sources [34], [35] and [36] is estimated as m = 2,93e-2 and is almost 2,5 times greater. This difference decreases the chemical exergy of sulfur only about 2 kJ/mol. The rest of the obtained results are very similar to previous investigations and the differences are negligible.

Table 3 shows the results obtained in this study for the chemical exergy of the substances dissolved in seawater.

CONCLUSIONS

A revision of the different R.E. proposed so far has been done. The authors have agreed to choose as best suitable R.E. category for the evaluation of natural capital, a *Comprehensive Reference Environment* based on *Szargut's criterion*. The parameters used in the equations for calculating the chemical exergy of the elements, mainly ΔG, n_0, M_0, c_i, z_{0i} and m, have been revised and updated according to new geochemical information and revisions done by other authors. It has been stated, that the differences on the chemical exergy of the elements between the different authors is not very significant. Therefore, the current authors would like to propose in ECOS 2005 conference, to take the agreement of accepting internationally the R.E. presented in this paper for the evaluation of the exergy resources on Earth. Nevertheless, it has been seen, that this information can be furthered improved if more empirical updates appear. Presently, the authors of this paper are working on improving the data, but other interested authors are invited to join this research.

ABSTRACT

This work develops a thermodynamic model to assess the industrial acetaldehyde production by ethanol partial oxidation, and proposes an improved plant configuration in order to use the thermal exergy more efficiently. Exergy analysis was used as the evaluation tool. The model was able to predict all relevant thermodynamic properties of the process streams. The vapor phase was considered ideal, while the non-idealities on liquid phase were corrected by Wilson equation. The irreversibility sums 1076 kW – 5165 kJ/kg acetaldehyde. The irreversibilities are mainly produced in the oxidation reactor (458 kW), the waste heat boiler (118 kW), the acetaldehyde absorption tower (105 kW) and distillation tower (247 kW). The new approach reduces the irreversibilities to 925 kW, which represents a reduction of 14.7%. The modifications were made in the absorption and distillation towers and a new heat exchanger network was added, causing a 28 kW reduction.

INTRODUCTION

This work has two goals; the first one is to develop a thermodynamic model, which allows estimating

the components and energy balances of a chemical plant for acetaldehyde production, as well as its irreversibilities. The second goal is to propose a new plant configuration with lower exergy destruction [1].

An acetaldehyde production by ethanol partial oxidation plant [2], located in southeastern Brazil, was chosen as the case study. The plant operational data were used to compare and to validate the results of the thermodynamic model.

ACETALDEHYDE PRODUCTION

In the chosen production route, shown in the Figure 1, a mixture of ethanol and air converts into acetaldehyde by going through a catalytic layer; the reactions occur at a temperature range between 800 and 900 K. The reactions are:

$$CH_3CH_2OH_{(g)} \rightarrow CH_3CHO_{(g)} + H_{2(g)} \quad (1)$$

$$H_{2(g)} + \tfrac{1}{2}O_{2(g)} \rightarrow H_2O_{(g)} \quad (2)$$

$$CH_3CH_2OH_{(g)} + 3O_{2(g)} \rightarrow 2CO_{2(g)} + 3H_2O_{(g)} \quad (3)$$

A hot stream of acetaldehyde, water, non-converted ethanol and a mixture of gases - oxygen, nitrogen, hydrogen and carbon dioxide – leaves reactor RX1 to the waste heat boiler HE2, where it is cooled to 443 K and produces low pressure steam (550 kPa).

After that the stream follows to the acetaldehyde absorption tower T2 to be quenched with an alcoholic solution, which comes from the bottom of the distillation tower T3; acetaldehyde, water and ethanol are condensed while gases rise up through the tower. The heat released during condensation is removed by the cooler HE3 and coils installed inside the column. The gases, saturated with water and ethanol, leave the top of tower T2 and go to the next tower T4, to be quenched with chilled water. After that, the gases free from ethanol are released to the atmosphere at 288 K.

The liquid, a mixture of ethanol, water and acetaldehyde, leaves the column, is heated up by the pre-heater HE4, and follows to the distillation tower T3, which operates at 345 kPa. The pure acetaldehyde is removed at the top at 327 K, while the ethanol and water stream at bottom splits into two parts: one part goes to tower T2, and the other one is fed into tower T1.

The function of tower T1 is to strip the ethanol from water and recycle it to the process at azeotropic concentration; the water leaves the tower by the bottom as a waste. New raw ethanol is fed to top of the tower to cool it; the vapor of this tower is a mixture of water and ethanol, which feeds the evaporator EV1. In the evaporator EV1, operating at 340 K, the ethanol is mixed with air, compressed previously by the compressor C1.

Before feeding the reactor RX1, the ethanol-air mixture leaves the evaporator EV1 and goes to the pre-heater HE1 to be heated above dew point (393 K).

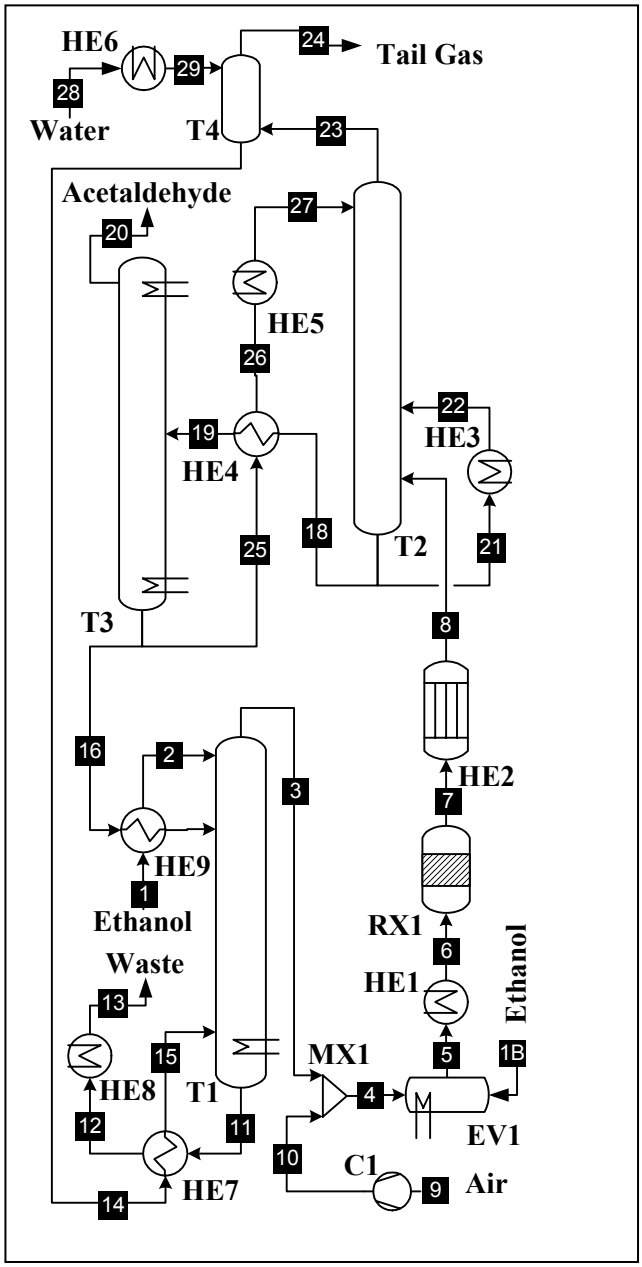

Figure 1: Acetaldehyde production plant

THERMODYNAMIC MODEL

The model [3,4] takes into account the seven main compounds: ethanol, water, acetaldehyde, oxygen, nitrogen, hydrogen and carbon dioxide; other chemical components are presented in a much lower concentration.

The thermodynamic model hypotheses [5] are:

- *Steady state conditions for all processes;*
- *Ideal vapor phase;*
- *Raoult's law corrected by Wilson's equation;*
- *Gas solubility depends only on temperature;*
- *Control volumes are perfectly insulated;*
- *No temperature or concentration gradient inside control volumes (for equilibrium stages);*
- *No short-circuit or carry-over in the equilibrium stages.*

The highest pressure occurs in tower T1 and it is equal to 345 kPa. As this pressure may be considered moderate, it is possible to assume ideal gas behavior for the vapor phase. However, this fact is not true for the liquid phase, in which the non-ideality must be corrected. The Wilson equation was chosen to evaluate the liquid phase activity coefficients.

Henry's law estimated the dissolved gases behavior. The reactor RX1 was considered as a black box in which reactions, done by Eq. 1 to 3, occur with given conversion rates for ethanol and oxigen, and acetaldehyde efficiency [4]. The air compression power was evaluated considering a polytropic compression of an ideal gas [4].

The calculation of the thermodynamic properties was performed as described below.

Vapor phase

The vapor phase enthalpy is evaluated by:

$$h_g = \sum_i y_i . h_{i,g} \tag{4}$$

$$h_{i,g} = h_{i,g}^0 + \int_{T_0}^{T} c_{p_{i,g}} dT \tag{5}$$

$$c_{p\,i,g} = a_i + b_i T + c_i T^2 + d_i T^3 \tag{6}$$

The entropy is calculated as follow:

$$s_g = \sum_i y_i . s_{i,g} - R . \sum y_i . \ln(y_i) \tag{7}$$

$$s_{i,g} = s_{i,g}^0 + \int_{T_0}^{T} \frac{c_{p_{i,g}}}{T} dT - R \int_{P_0}^{P} \frac{dP}{P} \tag{8}$$

Finally, the vapor phase exergy may be calculated by:

$$ex_g = \sum_i y_i . ex_{i,g}^0 + RT_0 . \sum_i y_i . \ln(y_i) + \ldots + \left(h_g - h_g^0\right) - T_0 . \left(s_g - s_g^0\right) \tag{9}$$

Liquid phase

For the liquid phase the properties are calculated as follow:

$$h_l = \sum_i x_i . h_{i,l} + h^e \tag{10}$$

$$h_{i,l} = h_{i,l}^0 + \int_{T_0}^{T} c_{p_{i,l}} dT \tag{11}$$

$$c_{p\,i,l} = a_i + b_i T + c_i T^2 + d_i T^3 + e_i T^4 \tag{12}$$

$$h^e = -R . T^2 . \left(\frac{\partial g^e / RT}{\partial T} \right)_{x,P} \tag{13}$$

$$g^e = RT . \sum_i x_i . \ln(\gamma_i) \tag{14}$$

$$s_l = \sum_i x_i . s_{i,l} - R . \sum_i x_i . \ln(x_i . \gamma_i) + s^e \tag{15}$$

$$s_{i,l} = s_{i,l}^0 + \int_{T_0}^{T} \frac{c_{p_{i,l}}}{T} dT \tag{16}$$

$$s^e = \frac{h^e - g^e}{T} \tag{17}$$

$$ex_l = \sum_i x_i . ex_{i,l}^0 + RT_0 . \sum_i x_i . \ln(x_i . \gamma_i) + \ldots + \left(h_l - h_l^0\right) - T_0 . \left(s_l - s_l^0\right) \tag{18}$$

Vapor-Liquid equilibrium

$$K_i = \frac{y_i}{x_i} = \frac{\gamma_i . P_i}{P} \tag{19}$$

$$P_i = e^{a_i - b_i/(T + c_i)} \tag{20}$$

$$\ln(\gamma_i) = 1 - \ln\left(\sum_{k=1,n} x_k . A_{i,k} \right) - \sum_{l=1,n} \frac{x_l . A_{l,i}}{\sum_{j=1,n} x_j . A_{l,j}} \tag{21}$$

$$A_{l,j} = \beta_{i,j} . e^{-\alpha_{i,j}/RT} \tag{22}$$

Equilibrium stage model

The separation steps are considered as equilibrium stages; the following sketch in the Figure 2 represents one equilibrium stage:

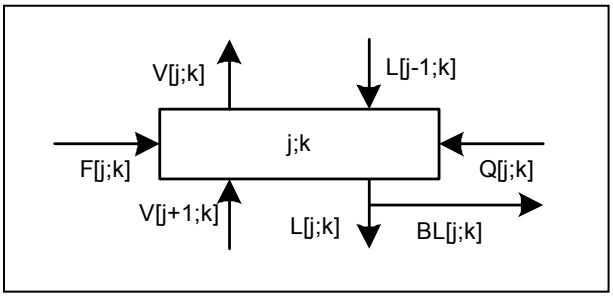

Figure 2: Equilibrium stage

The streams which leave the equilibrium stage $V_{i;j}$ e $L_{i;j}$ are the molar rate of the *i* component in the vapor and liquid phase respectively and they are in thermodynamic equilibrium, and obey the following equations:

$$y_{i,j,k} - x_{i,j,k}.K_{i,j,k} = 0 \qquad (23)$$

$$\sum_i x_{i,j,k} - 1 = 0 \qquad (24)$$

$$\sum_i y_{i,j,k} - 1 = 0 \qquad (25)$$

$$\begin{aligned} &x_{i,j-1,k}.L_{j-1,k} + y_{i,j+1,k}.V_{j+1,k} + z_{i,j,k}.F_{j,k} \\ &...- x_{i,j,k}.(L_{j,k} + BL_{j,k}) - y_{i,j,k}.V_{j,k} = 0 \end{aligned} \qquad (26)$$

$$\begin{aligned} &h_{l\,j-1,k}.L_{j-1,k} + h_{g\,j+1,k}.V_{j+1,k} + h_{l\,j,k}.F_{j,k} \\ &...- h_{l\,j,k}.(L_{j,k} + BL_{j,k}) - h_{g\,j,k}.V_{j,k} + Q_{j,k} = 0 \end{aligned} \qquad (27)$$

Where *i* identifies the chemical components (1 to 7), *j* is the equilibrium stage number and *k* names the unit the stage belongs to. The first equation (23) models the equilibrium liquid-vapor, while the equations (26) and (27) are the material and energy balances respectively. To solve the previous set of equations it is necessary to define all inlet streams $L_{j-1;k}$, $V_{j+1;k}$ and $F_{j;k}$, their concentrations $x_{i;j-1;k}$, $y_{i;j+1;k}$ and $z_{i;j;k}$, the stage pressure $p_{j;k}$, the heat duty $Q_{j;k}$ and the ratio $BL_{j;k}/L_{j;k}$. The solution will be the liquid $x_{i;j;k}$ and vapor $y_{i;j;k}$ concentration profile through the column, the liquid $L_{j;k}$, and the vapor $V_{j;k}$ molar rates, as well as the stage temperature $T_{j;k}$.

The irreversibility rate $I_{j,k}$ is evaluated by the exergy balance:

$$\begin{aligned} &ex_{l\,j-1,k}.L_{j-1,k} + ex_{g\,j+1,k}.V_{j+1,k} + ex_{l\,j,k}.F_{j,k}...- \\ &ex_{l\,j,k}.(L_{j,k} + BL_{j,k}) - ex_{g\,j,k}.V_{j,k} + Q_{j,k}.\theta_{j,k} = I_{j,k} \end{aligned} \qquad (28)$$

where $\theta_{j,k}$ is the Carnot factor, which is defined as follow:

$$\theta_{j;k} = 1 - \frac{T_0}{T^b_{j,k}} \qquad (29)$$

and $T^b_{j,k}$ is the boundary temperature.

Equilibrium multi-stage model

The columns T1, T2 and T3 are considered as an array of equilibrium stage. The set of equations are similar, the only difference is the number of equations. The index *j* represents the stage number inside a unit *k*.

Heat exchangers

The heat exchangers without phase change may be calculated as follow:

$$h_{l1,k}.L_{1,k} - h_{l2,k}.L_{2,k} + Q_{j,k} = 0 \qquad (30)$$

$$h_{l3,k}.L_{3,k} - h_{l4,k}.L_{4,k} - Q_{j,k} = 0 \qquad (31)$$

$$Q_{j,k} - (UA)_{j,k}.\tfrac{1}{2}.\left[(T_3 - T_1) + (T_4 - T_2)\right] = 0 \qquad (32)$$

Where $(UA)_{j,k}$ is heat transfer skill of the heat exchanger. The irreversibility is calculated by:

$$\begin{aligned} &ex_{l1,k}.L_{1,k} + ex_{l3,k}.L_{3,k} \\ &...- ex_{l2,k}.L_{2,k} - ex_{l4,k}.L_{4,k} = I_{j,k} \end{aligned} \qquad (33)$$

For the evaporator and reboilers the equations are simpler, since the heating medium is always low-pressure steam at T_S:

$$h_{l1,k}.L_{1,k} - h_{l2,k}.L_{2,k} + Q_{j,k} = 0 \qquad (34)$$

$$Q_{j,k} - (UA)_{j,k}.\tfrac{1}{2}.\left[(T_S - T_1) + (T_S - T_2)\right] = 0 \qquad (35)$$

$$ex_{l1,k}.L_{1,k} - ex_{l2,k}.L_{2,k} + Q_{j,k}.\theta_{j,k} = I_{j,k} \qquad (36)$$

$$\theta_{j;k} = 1 - \frac{T_0}{T_S} \qquad (37)$$

In case the heat exchanger is a cooler, the heat transfer temperature is not constant but varies between T_1 and T_2, so the Carnot factor should be an average value, estimated by:

$$\theta_{j;k} = \frac{\int_{T_1}^{T_2} Q_{j;k}.\theta_{j;k}.dT}{(T_2 - T_1).Q_{j;k}} = \frac{\int_{T_1}^{T_2} (T - T_1).\left(1 - \frac{T_0}{T}\right).dT}{(T_2 - T_1).(T_2 - T_1)} = \frac{\left[\frac{T_2^2 - T_1^2}{2} - (T_2 - T_1)(T_1 + T_0) + T_1.T_0.\ln\left(\frac{T_2}{T_1}\right)\right]}{(T_2 - T_1)^2}$$

RESULTS

All equations shown above were solved using EES software [6]. Two different plant configurations were simulated: the first one refers to the original plant and it was used for testing and validation of the model; the second one is the proposed configuration, in which exergy destruction is expected to be lower. Table 1 and 2 show the simulation results for the original configuration: mass flow rates (F), enthalpy flow rates (F.h); heat transfer rates (Q), exergy flow rates (F.ex); exergy rates (Q.θ); irreversibility rates (I) and percentage of the irreversibility rate (δ).

Table 2: Original configuration exergy balance

The above tables show that the main irreversibility rate, 428 kW and 42.6% of the total irreversibility rate of the process, occurs in the ethanol oxidation reactor (RX1); this results were already expected since oxidation reactions on gaseous phase at high temperature are far away from the equilibrium. The reactor, together with the acetaldehyde distillation tower T3, responsible for 347 kW of exergy destruction, the waste heat boiler HE2, responsible for more 118 kW, and the absorption tower T2, for 105 kW of exergy destruction, accounts for more than 86% of the total irreversibility rate of the process.

The simulation results were compared to the plant processes data. The data were collected during 7 days of stable run and their average values are shown in Table 3, as well the standard deviation. The stream number refers to the tags shown in black in Figure 1; the stream STEAM T1 is the steam rate for the T1 reboiler, STEAM T3 refers to the steam rate for the T3 reboiler, while RFLX is the T3 internal reflux. The calculated mass flow rate results show a maximum deviation from the measured data of -14%. The calculated temperature results show a maximum deviation from the measured data of 4.4%.

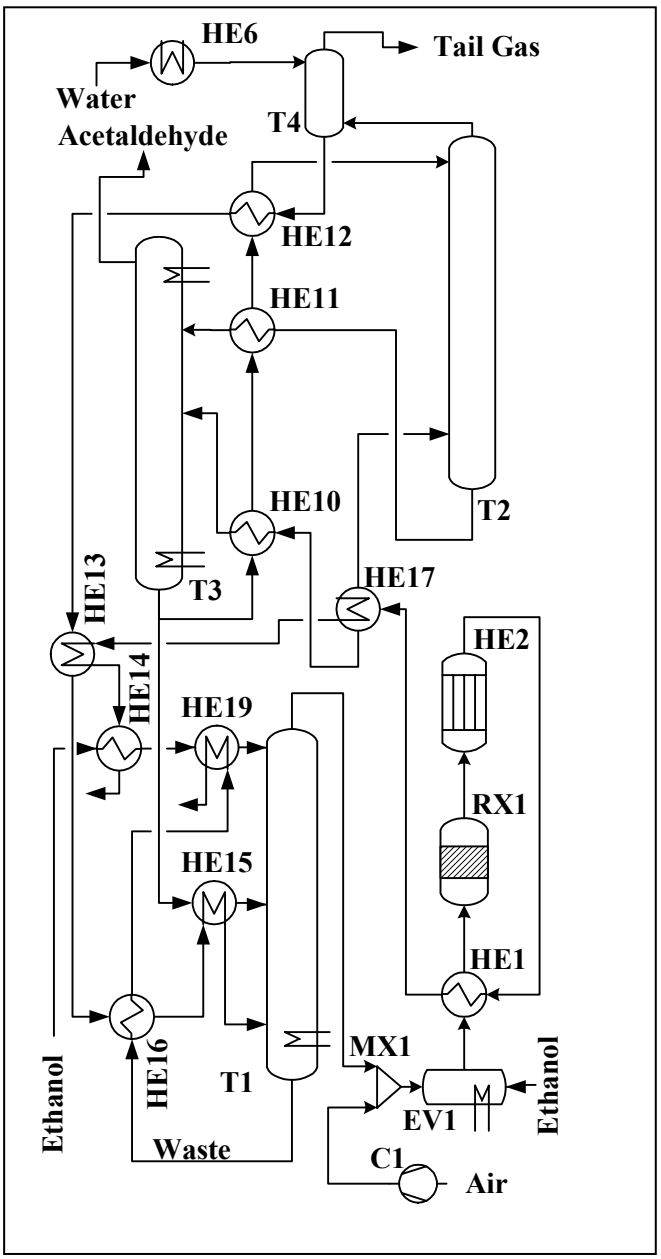

Figure 3: Proposed process configuration

An alternative process configuration was proposed, as shown in the figure 3, based on the following recommendations [1,5]:

- *Optimize the heat exchanger network;*
- *Feed the distillation tower T3 in two different points;*
- *Decrease the recycle between the distillation tower T3 and the absorption tower T2;.*
- *Choose the best feed tray for the tower T3;*
- *Install a condenser between the waste heat boiler and the absorption tower T2;*
- *Pre-heat the reactor by using the hot gases from the waste heat boiler;*
- *Decrease the amount of quench water of tower T4;*
- *Decrease the reflux ratio of the distillation tower T3.*

Table 5: Alternative configuration exergy balance

CONCLUSIONS

There are several causes of irreversibility on the acetaldehyde production process, and the most important are the oxidation reaction (458 kW), the heat exchange in the waste heat boiler (118 kW), the recirculation for cooling purposes in the absorption tower (105 kW) and the high reflux ratio in the distillation tower T3 (247 kW).

The exergy analysis of the acetaldehyde production plant, as stated here, allows indicating, quantifying and creating a hierarchy of the irreversibilities.

The proposed configuration, operating at the same feeding conditions of the original plant, destroys 925 kW of exergy, what correspond to a reduction of 14.1%.

The specific energy consumption of the plant was reduced in 28% comparing to the original one, from 5622 kJ/kg of acetaldehyde to 4032 kJ/kg. The exergy destruction was reduced from 5165 kJ/kg to 4440 kJ/kg, what corresponds to 14% of reduction.

ABSTRACT

Thermochemical recuperation (TCR) as the use of waste heat for the fuel reforming with H2O or CO2, leading to efficiency increase, is well known for gas turbine units. Less known, that the similar TCR is useful for piston engines(PE) as well. The difference is in low pressure of a mixture of fuel and H2O or CO2.
The paper is aimed at calculating of endothermal reactions of methane as fuel with H2O and CO2 by conditions, suitable for PE. It is shown that exergy of heat of exhaust gases is converted into exergy of reformed fuel (CO + Hydrogen).The results are presented as graphs of exergy efficiency versus temperature of the end of reaction. Within the limits of 800 – 1000 K the exergy efficiency of TCR is increased from 0.23 to 0.77 for CH4+CO2 and from 0.30 to 0.80 for CH4+H2O. Fuel economy in a diesel engine might reach 19%.

Introduction

The initiative to apply to piston engines the principle of thermochemical recuperation, well known from gas turbine systems, belongs to Gas Technology Institute, USA. To save place the literal citation [1] is used: *TCR is a promising concept for application to reciprocating engines. Rejected sensible energy from the engine combustion is recovered to support catalytic reformation of the fuel (natural gas) to a higher energy content fuel.*
Preliminary analysis by GTI indicates, that a TCR system could offer the following advantages over conventional power generating systems:

- *Reduced fuel consumption by virtue of increased cycle efficiency, which results from use of rejected heat from the engine.*
- *Reduced CO2 emissions by virtue of increased efficiency.*
- *Increased power output capacity.*
- *Ultra-low emissions of criteria pollutants (Nox,CO, etc.) and hazardous pollutants (HCs, formaldehyde, etc.) by virtue of improved combustion conditions.*

Theoretically, the TCR can reform all kinds of liquid and gaseous hydrocarbon fuels…
The H2-enriched fuel would increase the ignitability of the mixture due to its broad flammability limits and low ignition energy requirements, and increase flame speed relative to natural gas.

From energy balance point the TCR is a clear measure to decline the temperature of outgoing gases (e.g. losses) by virtue of absorption of their energy by incoming gases. In addition to GTI statements we wish to underline that TCR is promising for the efficiency increase in zero-emission (including automotive) piston engine systems[2], where fuel should be reformed not with steam, but with carbon dioxide.

In application to gas-turbine systems with CO2 capture and TCR the detailed analysis, demonstrating the exergy losses in gas turbine, fuel reactor e t.c. has been made by Bolland and Ertesvag[3]

Present paper is aimed at calculating the exergy balances of TCR for a piston engine to visualise the losses of reformer and select the needed reaction temperature by reforming with water and carbon dioxide as well. For simplicity the only gaseous fuel methane is considered.

Processes in TCR

The two endothermic reactions of fuel methane reforming are known:

$CH_4 + H_2O \Leftrightarrow CO + 3\ H_2$ (1)
$CH_4 + CO_2 \Leftrightarrow 2\ CO + 2\ H_2$ (2)

Schematics of a TCR is presented in Fig.1, where 1 and 2, 3 and 4 are the flows of incoming reactants, 5 is the flow of reaction products, 6,7,8,9 and 10 are flows of exhaust gases of piston engine, giving its sensible heat to support endothermic reactions.The main our assumption is the equilibrium, it means the validity of Hess law. Kinetics of reactions, affected by catalysts is not considered.

The equilibrium constant K by atmospheric pressure depends upon the temperature only [4]:

$$K = e^{-\frac{\Delta G_T^0}{RT_i}} \quad (3)$$

For the reaction (1):

$$\Delta G_T^0 = 188748 + 228{,}75 \cdot T_i - 69{,}61 \cdot T_i \cdot \ln T_i + \frac{80{,}711 \cdot 10^{-3}}{2} \cdot T_i^2 - \frac{22{,}874 \cdot 10^{-6}}{6} \cdot T_i^3 \quad (4)$$

and for the reaction (2):

$$\Delta G_T^0 = 230323 + 193{,}78 \cdot T_i - 71{,}75 \cdot T_i \cdot \ln T_i + \frac{106{,}81 \cdot 10^{-3}}{2} \cdot T_i^2 - \frac{36{,}06 \cdot 10^{-6}}{6} \cdot T_i^3 \quad (5)$$

The fraction of reformed methane till equilibrium for the two reactions is

$$m = \sqrt{\frac{\frac{\sqrt{k}}{2{,}6}}{1 + \frac{\sqrt{k}}{2{,}6}}} \text{ and } m = \sqrt{\frac{\frac{\sqrt{k}}{2}}{1 + \frac{\sqrt{k}}{2}}} \quad (6)$$

The fractions of reaction products for (1) and (2) are:

$$\mu_{CH_4} = \mu_{H_2O} = \frac{1-m}{2 \cdot (1+m)};\ \mu_{CO} = \frac{m}{2 \cdot (1+m)};\ \mu_{H_2} = \frac{3 \cdot m}{2 \cdot (1+m)} \quad (7)$$

$$\mu_{CH_4} = \mu_{CO_2} = \frac{1-m}{2 \cdot (1+m)};\ \mu_{CO} = \mu_{H_2} = \frac{m}{(1+m)} \quad (8)$$

The ratio of the amount of final reaction products to the incoming reactants (chemical coefficient of molecular change) is

$\beta = 1 + m$ (9)

The incoming reactants are at ambient temperature $T_1 = T_2 = To$. Due to heating their temperature increases. It is assumed, that reaction is getting started by $T_3 = T_4 = T_{AR}$, when m = 0.001. In reaction (1) T_{AR} =415 K, whereas in (2) T_{AR} = 515 K.
This heating energy is:

$Q_{H1} = H_2 - H_1 = H_7 - H_9$,
$Q_{H2} = H_4 - H_2 = H_8 - H_{10}$

Reactions in the point R take the energy:

$Qin = H_6 - H_7 - H_8 =$
$Q_R + (H_5 - H_3 - H_4)$

Exergy balance

Exergy flow from cooled flue gases is:
$\Delta E_{CQ} = E_{Qein} + E_{3P} + E_{4P} - E_{5P}$ (10)
Or per one mole

$$\Delta e_{cq} = e_{q_{ein}} + e_{3p} + e_{4p} - e_{rp}\ , \quad (11)$$

$$e_{q_{ein}} = q_{ein} \cdot \eta_c = q_{ein} \cdot (1 - \frac{T_0}{T_i})\ ;$$

$$q_{ein} = q_R + (h_{r5} - h_3 - h_4)\ ;$$

$$h_{r5} = 2 \cdot \beta \cdot h_5 = 2 \cdot \beta \cdot (a_M + \frac{b_M}{2} \cdot T_i + \frac{C_M}{3} \cdot T_i^2) \cdot T_i\ ;$$

$$a_M = \sum \mu_i \cdot a_i;\ b_M = \sum \mu_i \cdot b_i;\ C_M = \sum \mu_i \cdot C_i;$$

$$e_{rp} = 2 \cdot \beta \cdot e_{5p} = 2 \cdot \beta \cdot [(h_5 - h_0) - T_0 \cdot (s_5 - s_0)]\ ;$$

Molar exergy of the flow of a substance consists of the two parts (see Fig.1, c):

$$e_i = e_{ip} + e_{ic} \ , \quad (12)$$

where $e_{ip} = (h_i - h_o) - T_o(s_5 - s_o)$ is the physical exergy, depending upon the pressure and temperature of flow and e_{ic} = chemical exergy, depending on contents. In the Table 1 the standard chemical exergy, recommended by Szargut and Morris [5] is given.

In an endothermic reaction the thermal exergy is converted into exergy of substances and reaction losses:

$$\Delta e_{cq} = \Delta e_c + d_{RC} \ , \quad (13)$$

where

$$\Delta e_c = e_{rc} - e_{3c} - e_{4c} \ , \quad (14)$$

$$e_{rc} = 2 \cdot \beta \cdot e_{5c} = 2 \cdot \beta \cdot \Sigma \mu_i e_i \ .$$

$$e_{q_{ein}} = \Delta e + d_{RC} \ , \quad (15)$$

$$\Delta e = e_5 - e_3 - e_4, \ e_5 = e_{rp} + e_{rc} \ ;$$

$$e_3 = e_{3p} + e_{3c} \ ; \ e_4 = e_{4p} + e_{4c} \ .$$

Exergy efficiency of the TCR is defined as follows:

$$\eta_{ex.1} = \Delta e_c / \Delta e_{cq} = 1 - d_{RC} / \Delta e_{cq} \quad (16)$$

If to relate the gained chemical exergy in reformed fuel to the physical one from flue gases we get

$$\eta_{ex.2} = \Delta e / (\Delta e + d_{RC}) \quad (17)$$

Results of calculations

The results of computwer calculations of endothermic reactions and exergy conversion efficiency versus the temperature of reaction are given in the Table 3 and Fig.2.. It is seen that in the reforming with CO2 in reaction (2) the exergy taken from exhaust gases is greater than that by reforming with H2O. But exergy converted into the new fuel exergy in reaction (2) is less, than in (1), that is why the efficiency η_{ex1} for reaction (1) is higher. This difference vanishes when temperature exceeds 900 K.

If needed,the end of reaction might be by temperature less 1000 K. There are no rapid changes in the curves “contents versus temperature.”.

On the graphs Fig.2 the conversion of methane in reformed fuel in the temperature interval 800-1000 K is presented . By T= 1000 K the exergy efficiency might reach 80% .

In order to evaluate the possible increase of exergy of reformed fuel let us look at the figures, calculated for a gas-fuelled diesel of about 5000 kW capacity. The main exergy flows are in the Table 4.

The chemical exergy flow, which enters the cylinder is about 19%higher, than that of methane fuel (on account of the use of exergy of flue gases). As exergy efficiency of the diesel itself only slightly depends upon used fuel it shows the possible fuel economy by TCR of about 19%.

The percentage distribution of exergy, taken from flue gases E_{Qein} = 2070.23 kW is as follows: 20.75% is used for heating reformed fuel from 515 up to 1000 K, 76.05% is converted into chemical exergy of reformed fuel and 3.2 % is exergy destruction (internal losses due to entropy rise in chemical reaction).

Conclusion

Calculations, based on assumption on equilibrium, show a possibility to reach rather high exergy efficiency (about 80%) of TCR incorporated in a piston engine systems when reaction temperature is 900-1000 K. Fuel methane reforming by CO2 is only slightly less efficient than that by water. Fuel economy by TCR in a gas-fuelled diesel is about 19% due to such increase of exergy of the reformed fuel.

ABSTRACT

Performance criteria, such as efficiencies and coefficients of performance, for energy systems, are commonly used but often without sufficient understanding and consistence. The situation becomes particularly incoherent when simultaneous energy interactions of different types, such as work, heating and cooling, take place with a system. Also, the distinction between exergy and Second-Law efficiencies is not clearly recognized by many. It is attempted here to clarify the definitions and use of energy and exergy based performance criteria, and of the Second Law efficiency, with an aim at the advancement of international standardization of these important concepts.

INTRODUCTION

There are many ways to assess energy system performance, and they must be adapted to the particular use they are put to. While the underlying concepts of such assessments are often well known and documented for a number of systems and cases, there are no clear agreements or rules about efficiency definitions, and authors often use different, and sometimes unsuitable, efficiency definitions for the same systems. The situation becomes particularly incoherent when simultaneous energy interactions of different types, such as work, heating and cooling, take place with a system (cf. [1], [2]). This prevents logical comparison of results at best, and wrong results at worst. This paper, though highly abbreviated due to conference page limitations, is intended to provide some clarifications and uniformity in that area, make a few proposals, and start a discussion that would hopefully lead to accelerated international standardization of these important concepts.

The most common energy system performance assessment criteria are *energy based* ("First Law") and they are useful for assessing the efficiency of energy use, and can be easily converted to energy cost efficiencies if the prices of the energy forms of the useful outputs and paid inputs are known. Here we define as "useful" all energy interactions that have use by the system "owner", usually in terms of monetary value, and "paid" all energy interactions that have a direct cost, usually monetary, to the system owner (cf. [1]). Thus, for example, the heat inputs that come from the environment for which the owner doesn't need to pay aren't included. We hasten to add that analyses that address environmental impact will include exchanges with the environment too.

Since such energy-based criteria do not account for the quality of energy, expressed as exergy, *exergy-based* criteria are also appropriate as they account better for use of energy resources and give much better guidance for system improvement. They also can be converted to exergy cost efficiencies if the exergy values of the useful outputs and paid inputs can be rationally priced (cf. [3]).

Another set of criteria assess the difference between the performance of a system relative to an ideal one (reversible) which operates between the same thermodynamic limits. We shall call these *Second-Law-based* criteria, although many authors use this term for exergy-based criteria.

Ultimately, decisions on best designs are most often based on economical considerations, in which energy (or exergy) are only one part, and sometimes not the most significant one, where the other parts include capital investment, labor, insurance, taxes, etc.

It is also worth noting that while performance criteria are most often applied to the entire system, such as plant or energy conversion device, they can be applied at any level, such as to different components, inside spatial and temporal processes (cf. [4]-[7]), and down to the smallest particle interactions, when there is an interest in that kind of exploration.

2. ENERGY-BASED CRITERIA

2.1 Introduction

Figure 1 describes a generalized system exchanging heat (heating and cooling) and work with other systems and with the environment, and will be used in this paper. The many definitions of energy efficiency, are reasonably well known, and would not be reviewed here due to paper length limitations.

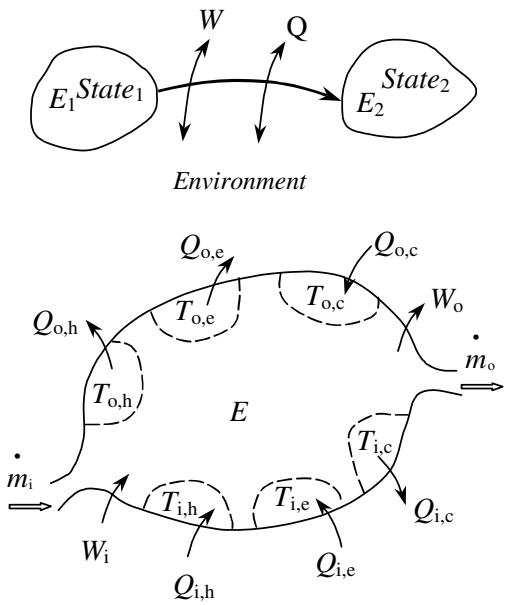

Fig. 1 Energy interactions

They include the

- *Total energy efficiency*, the ratio of all energy outputs to inputs, which is always equal to 1 and is thus useless for system performance assessment, although it should always be used in computations as a part of results validation.
- *Common (utilitarian, or "task") energy (First Law) efficiency* η_{lu} based on the practical energy needs (work, heat, refrigeration) of the system vendor or owner that are satisfied by the system, and that can be given a monetary value, and on the material and energy inputs to the system that must be paid for.
- *Coefficient of performance, COP,* used mostly in evaluating the performance of systems that produce primarily cooling .
- *Embodied energy efficiency*, it is often of interest (or should be…) to include in the energy efficiency assessment also the energy embodied in the production of the plant, in the materials produced by it, and in the materials and labor needed for its operation and for the distribution of its material products to the customer. A more consistent definition would also include the total energy investment, embodied in the fuel, materials and labor needed for the plant operation over its lifetime (L years), as well as the energy embodied in non-energy k products of the plant. A simple energy payback time, or preferably based on life-cycle-cost-analysis (LCA) is usually used as the evaluation criterion (cf. [8], [9]). To create a more equitable comparison between systems that produce different impacts on the environment, these embodied energies should also include the energy needed for restoration of the environment to its original state.
- *Energy criteria considering environmental effects,* since in some circumstances the objective of the analysis may include the energy impact of the system on the environment, including heat rejection to the environment or heat absorption from it, even though no direct (or immediate) monetary cost or benefit may be associated with it. This also would be of interest for finding the effects on ambient cooling or heating water consumption, etc. In that case we can define a thermal environmental impact ratio, all of the heat interactions with the environment (heat rejection and absorption) to the sum of the useful net power, heating and cooling produced.
- *Evaluation criteria based on economics,* include payback period, return on investment (ROI), and life cycle cost analysis (cf. ([3]), and those can be either restricted to the direct energy streams, or to the energy streams included embodied energy.

3. EXERGY EFFICIENCY, ε

3.1 Introduction

Just as there are various definitions of energy efficiencies as discussed above, there are also various definitions of exergy efficiency. We discuss here overall efficiency, the utilitarian (or "task") efficiency, and some ways to define the exergy.

Of help in these definitions is the exergy accounting for the system. For a thermodynamic system going through interactions between an initial state 1 and a later state 2, where the system exergy values are $A_{s,1}$ and $A_{s,2}$, respectively, the equation representing this accounting is

$$A_{s,2} - A_{s,1} = \sum_i A_i - \sum_o A_o - I \qquad (1)$$

where A_i and A_o are the exergy inputs and outputs to and from the system, respectively, and I is the total exergy loss (or destruction). Due to the Second Law, $I \geq 0$.

In steady state $A_{s,1} = A_{s,2}$, and Eq. (1) gives

$$\sum_o A_o = \sum_i A_i - I \qquad (2)$$

The irreversibility I is linked to the entropy generation S_{gen} by the equation

$$I = T_0 S_{gen} \qquad (3)$$

where T_0 is the dead state temperature (in absolute units).

3.2 The "total" (or "overall") exergy efficiency, $\hat{\varepsilon}_t$

$$\hat{\varepsilon}_t \equiv \frac{\left[\begin{array}{l}(\text{the system exergy at state 2}) + \\ \left(\sum_{\text{o}} \text{all exergy outputs}\right)\end{array}\right]}{\left[\begin{array}{l}(\text{the system exergy at state 1}) + \\ \left(\sum_{\text{i}} \text{all exergy inputs}\right)\end{array}\right]} = \frac{A_{s,2} + \sum_o A_o}{A_{s,1} + \sum_i A_i} \quad (4)$$

and the ingoing and outgoing exergy quantities may include work, heat and cooling, with or without mass flows. Incorporating Eq. (1) into (4) gives

$$\hat{\varepsilon}_t = \frac{A_{s,1} + \sum_i A_i - I}{A_{s,1} + \sum_i A_i} = 1 - \frac{I}{A_{s,1} + \sum_i A_i} \quad (5)$$

$\hat{\varepsilon}_t$ is used when the overall exergy efficiency of a system needs to be calculated, without interest in some of the individual outputs of the system. It is especially applicable when the system input and output streams do not maintain their integrity and the major part of the output is useful. It also has a more thermodynamic flavor than other efficiency definitions, in that it evaluates the efficiency of a process giving equal consideration to all outputs and inputs regardless of whether they are being used or paid for. For example, it offers a good starting point for ecological analysis of processes since it takes into equal consideration exergy components as diverse as useful work, heat and product materials on the one hand, and material and heat emissions to the environment on the other, on the output side, and paid fuel, work, and materials on the one hand, and "free" environmental heat on the other, on the input side.

In steady state $A_{s,1} = A_{s,2} = A_s$ and Eqs. (4) and (5) become

$$\tilde{\varepsilon}_t \equiv \frac{1 + \frac{\sum_o A_o}{A_s}}{1 + \frac{\sum_i A_i}{A_s}} \quad (6)$$

and

$$\tilde{\varepsilon}_t = 1 - \frac{I}{A_s + \sum_i A_i} \quad (7)$$

respectively.

Most often, the steady state total exergy efficiency is defined without consideration of the exergy value of the system, A_s, to more clearly focus on the exergy inputs and outputs only, and thus the best known form of the steady state total exergy takes the form

$$\varepsilon_t \equiv \frac{\sum_o A_o}{\sum_i A_i} = 1 - \frac{I}{\sum_i A_i} \quad (8)$$

3.3 The task (or "utilitarian") exergy efficiency, ε_u

Using the same logic as in definition of η_I, ε_u can be defined as the ratio between the exergy outputs useful to the owner, and the exergy inputs paid by the owner. The most common is the steady state definition:

$$\varepsilon_u = \frac{\sum_i |W_{u,i}| - \sum_i |W_{p,i}| + \sum_i |A_{hu,i}| + \sum_i |A_{cu,i}|}{\sum_i |A_{hp,i}| + \sum_i |A_{cp,i}|} \quad (9)$$

3.4 Exergy definitions

Work (including electrical energy) interactions are pure exergy and thus the exergy values of such interactions are equal to their energy values. Non-work energy interactions (heat for example) have values of exergy that depend on both the type of the energy interaction and the definition of the control system under consideration. The latter depends on the objective of the performance analysis. We can classify the types of non-work energy interactions and of typical objectives as follows [4].

Straight heat input or output

In general, the exergy of the system heat interactions of a system at constant temperature T with an environment at the dead state temperature T_0 for a process starting at time t_1 and ending at time t_2 is

$$\hat{A}_{h,i} = \int_{t_1}^{t_2} Q_{h,i}\left(1 - \frac{T_0}{T}\right) dt \quad (10)$$

when $T > T_0$ and $Q_{h,i}$ is the heat output from the system to the environment (or to a heat load at T_0), and

$$\hat{A}_{c,i} = \int_{t_1}^{t_2} Q_{c,i}\left(\frac{T_0}{T} - 1\right) dt \quad (11)$$

when $T < T_0$ and $Q_{c,i}$ is the heat input from the environment (or the cooling load at T_0) to the system, where all the parameters in the integral may vary with time. The efficiency becomes in the first case

$$\hat{\varepsilon}_u = \int_{t_1}^{t_2} \frac{W_u}{Q_{hi}(1-\frac{T_0}{T})} dt \qquad (12)$$

Stream-carried exergy

Exergy can be carried in and out of systems with a mass flow stream at the rate $\dot{m}a$, where $\dot{m}$ is the mass flow rate (in kg/s) and a is the specific exergy. a should include all the relevant exergy components including kinetic, potential, thermal, strain, and chemical as explained in detail in [4]. The sketch in Table 1 shows two common flow configurations: Fig. a. depicts a case in which the stream doesn't mix with the system and maintains its integrity, and Fig. b. depicts a case where a stream enters the systems, loses its integrity in it, and another stream exits the system.

The exergy exchange config-uration	 a.	 b.
The exergy change, A	$\dot{m}(a_1 - a_2)$ (13)	$\dot{m}_1 a_1 - \dot{m}_2 a_2$ (14)

Table 1 External stream-carried exergy configurations and magnitudes

The configurations described in Table 1 ignore exergy losses during the exchange between the stream and the system, in other words it is implicitly assumed that these losses are either negligible (infinite exchange coefficients) or that the analysis is not aimed at this purpose. A more rigorous model, which includes the exchange exergy losses, is described in Table 2. Figure a. describes a system where the external stream 1e→2e and a system stream 1s→2s interacting while maintaining their integrities. A sample case is when stream 1s→2s is the evaporator in a refrigeration system, and stream 1e→2e is the fluid that is being cooled by the evaporator (refrigerator).

The exergy exchange config-uration	 a.	 b.
The exergy change, A	$\dot{m}_e(a_{1e} - a_{2e}) =$ $\dot{m}_s(a_{2s} - a_{1s}) + I_{e\leftrightarrow s}$ (15)	$\dot{m}_1 a_{1e} - \dot{m}_2 a_{2e} =$ $A_{s2} - A_{s1} + I_{e\leftrightarrow s}$ (16)

Table 2 External stream-carried exergy configurations and magnitudes

Equation (15) represents the exergy balance in this case, where $I_{e\leftrightarrow s}$ is the irreversibility due to the interaction between the streams, and allows the inclusion of this irreversibility in the system efficiency calculation by ascribing the exergy (input or output) value to the external, rather than the system, stream, as was done in the model of Table 1 Fig. a.

Similar to the model of Fig. b in Table 1, that of the model in Fig. b of Table 2 represents input and output streams that aren't directly connected, but the one of Table 2 Fig. b includes the interactions between these streams and the system, with the associated irreversibility in Eq. (16). A sample case is a combustor with inputs of fuel and oxidant and an output of reaction products, when the exergy losses due to the combustion process (including mixing, chemical reaction, heat transfer) are wished to be taken into account (cf. [5]). Use of such a model is the basis for "intrinsic" exergy analysis that allows detailed (even spatial and temporal) determination of exergy changes in all interaction processes (cf. [4]-[7]).

4. SECOND-LAW EFFICIENCY

4.1 Introduction

Given the objectives of the system under consideration, such as power production, cooling, heating, materials processing, etc., and the thermodynamic limits, such as the top and bottom temperatures, pressures, and other thermodynamic potentials, it is useful to compare the performance of the system with one that would deliver the best thermodynamic performance between the same limits,

i.e. one in which all the processes are reversible. This indicates clearly a potential for improvement.

The Second-Law efficiency is defined here ([2] and many others) as the ratio of the First-Law efficiency of the system to the efficiency of a reversible system operating between the same thermodynamic states,

$$\eta_{II} = \frac{\eta_I}{\eta_{rev}} \tag{17}$$

To compute η_{II}, the cycle for which η_{rev} needs to be calculated must have a close relationship to the cycle under consideration, for which η_I is known, as stated at the outset. Starting with the work by Martinovsky,([10],[11]), Niebergall [12], and Stierlin [13], the definition for that purpose of a "model reversible cycle" was advanced by Morosuk and co-workers ([14],[15]) We now examine several cases for the definition of this reversible cycle.

4.5 Systems that simultaneously produce useful work, cooling and heating

In that case, and abbreviating the notations,

$$\eta_I = \frac{W_u + Q_{hu} + Q_{cu}}{Q_{hp}} = \eta_w + \eta_Q + COP_c \tag{18}$$

where W_u, Q_{hu}, and Q_{cu} are the useful outputs of work, heat and cooling, Q_{hp} is the paid heat input to the cycle, and the efficiency terms on the right hand side of the equation are defined as, the useful work production efficiency,

$$\eta_w \equiv \frac{W_u}{Q_{hp}} \tag{19}$$

the useful heat production efficiency,

$$\eta_Q \equiv \frac{Q_{hu}}{Q_{hp}} \tag{20}$$

and the useful cooling output *COP*,

$$COP_c \equiv \frac{Q_{cu}}{Q_{hp}} \tag{21}$$

It is often of practical utility to define the ratios of the cooling and heating energy outputs to the work output

$$r_c \equiv \frac{Q_{cu}}{W_u} \tag{22}$$

$$r_h \equiv \frac{Q_{hu}}{W_u} \tag{23}$$

and then eq. (18) takes the form

$$\eta_I = (1 + r_c + r_h)\eta_w \tag{24}$$

Equation (24) is useful when comparing efficiencies of systems that have the same values of the output heat-work ratios *r*.

The reversible system efficiency can be expressed similarly as

$$\eta_{rev} = \left(\frac{W_u + Q_{hu} + Q_{cu}}{Q_{hp}} \right)_{rev} = \tag{25}$$
$$= \eta_{w,rev} + \eta_{Q,rev} + COP_{c,rev}$$

where the efficiency terms on the right hand side of the equation, all for the reversible case, are defined as follows:
the useful work production efficiency,

$$\eta_{w,rev} \equiv \frac{W_{u,rev}}{Q_{hp,rev}} \tag{26}$$

the useful heat production efficiency,

$$\eta_{Q,rev} \equiv \frac{Q_{hu,rev}}{Q_{hp,rev}} \tag{27}$$

and the useful cooling output $COP_{c,rev}$,

$$COP_{c,rev} \equiv \frac{Q_{cu,rev}}{Q_{hp,rev}} \tag{28}$$

Similar to the energy balance shown in Fig. 1 but somewhat simplified for clarity, let us assume that a system produces useful work amount W_u, useful cooling Q_{cu} at temperature T_c, and useful heat Q_{hu} at temperature T_{hu}, has a paid heat input Q_{hp} at temperature T_{hp}, and has "free" heat output to- and input from- the environment, $Q_{i,e}$ and $Q_{o,e}$ at temperatures $T_{i,e}$ and $T_{o,e}$, respectively. The entropy balance for this reversible cycle is

$$\left(\frac{Q_{hp}}{T_{hp}} + \frac{Q_{cu}}{T_c} + \frac{Q_{i,e}}{T_{i,e}} - \frac{Q_{hu}}{T_{hu}} - \frac{Q_{o,e}}{T_{o,e}} \right)_{rev} = 0 \tag{29}$$

and energy conservation

$$Q_{hp} + Q_{cu} + Q_{i,e} - Q_{o,e} - Q_{hu} - W_u = 0 \tag{30}$$

In many power cycles the heat input and rejection is not even approximately isothermal. The reversible power cycle named after Lorenz [16] can serve as the "model ideal cycle" in such cases, and also serves well to introduce the "entropic temperature" concept useful in such analyses. This cycle consists of an isentropic compression stroke 1→2, followed by a stroke 2→3 in which heat is transferred to the working fluid at gradually increasing temperature till the top temperature T_3 of the cycle is reached, followed by an isentropic expansion stroke 3→4 to a lower pressure, and closed with a heat rejection stroke 4→1 at variable temperature. One case of the Lorenz cycle is the Brayton cycle (called by some the Joule cycle) in which the heat input and rejection strokes take place isobarically.

A common simplification is to express the efficiency of the Lorenz cycle in terms of an equivalent Carnot cycle operating between the

temperatures $\widehat{T}_h$ and $\widehat{T}_c$, also known as the *entropic temperatures*, defined by

$$\widehat{T}_h \equiv \frac{\int_2^3 TdS}{S_3 - S_2} \qquad \widehat{T}_c \equiv \frac{\int_1^4 TdS}{S_4 - S_1} \tag{31}$$

It is easy to show that the Carnot cycle operating between the temperatures $\widehat{T}_h$ and $\widehat{T}_c$ has the same efficiency as the Lorenz cycle, and the Lorenz cycle efficiency is thus

$$\eta_{rev,Lorenz} = 1 - \frac{\widehat{T}_c}{\widehat{T}_h} \tag{32}$$

Combining eqs. (29) and (30) to eliminate $Q_{o,e}$ yields

$$-Q_{hp}\left(1 - \frac{T_{o,e}}{T_{hp}}\right) + Q_{cu}\left(\frac{T_{o,e} - T_c}{T_c}\right) + Q_{hu}\left(1 - \frac{T_{o,e}}{T_{hu}}\right) + Q_{i,e}\left(\frac{T_{o,e} - T_{i,e}}{T_{i,e}}\right) + W_u = 0 \tag{33}$$

The terms in the parentheses are now named the reversible cycle efficiencies as follows:

$$\tilde{\eta}_{hp} \equiv 1 - \frac{T_{o,e}}{T_{hp}} \tag{34}$$

$$C\tilde{O}P_c \equiv \frac{T_c}{T_{o,e} - T_c} \tag{35}$$

$$\tilde{\eta}_{hu} \equiv 1 - \frac{T_{o,e}}{T_{hu}} \tag{36}$$

$$C\tilde{O}P_e \equiv \frac{T_{i,e}}{T_{o,e} - T_{i,e}} \tag{37}$$

Using Eqs. (33) - (37) we can express the paid heat input required to produce the useful work, cooling and heating outputs of the reversible cycle as

$$Q_{hp} = \left(W_u + \frac{Q_c}{C\tilde{O}P_c} + \tilde{\eta}_{hu}Q_{hu} + \frac{Q_{i,e}}{C\tilde{O}P_e}\right)\frac{1}{\tilde{\eta}_{hp}} \tag{38}$$

Replacing the denominator in Eq. (25) with the last expression gives

$$\eta_{rev} = \frac{\left(W_u + Q_{hu} + Q_{cu}\right)_{rev}}{\left(W_u + \frac{Q_{cu}}{C\tilde{O}P_c} + \tilde{\eta}_{hu}Q_{hu} + \frac{Q_{i,e}}{C\tilde{O}P_e}\right)\frac{1}{\tilde{\eta}_{hp}}} \tag{39}$$

Similar to the derivation of Eq. (24), we define for the reversible cycle the heat-work output ratios as

$$\tilde{r}_c \equiv \left(\frac{Q_{cu}}{W_u}\right)_{rev} \tag{40}$$

$$\tilde{r}_h \equiv \left(\frac{Q_{hu}}{W_u}\right)_{rev} \tag{41}$$

$$\tilde{r}_e \equiv \left(\frac{Q_{i,e}}{W_u}\right)_{rev} \tag{42}$$

and with the substitution of Eqs. (40) - (42), Eq. (39) takes the form

$$\eta_{rev} = \frac{\tilde{\eta}_{hp}\left(1 + \tilde{r}_c + \tilde{r}_h\right)_{rev}}{1 + \frac{\tilde{r}_c}{C\tilde{O}P_c} + \tilde{\eta}_{hu}\tilde{r}_h + \frac{\tilde{r}_e}{C\tilde{O}P_e}} \tag{43}$$

The Second Law efficiency is thus, using Eqs. (17), (18) and (25)

$$\eta_{II} = \frac{\eta_w + \eta_Q + COP_c}{\eta_{w,rev} + \eta_{Q,rev} + COP_{c,rev}} \tag{44}$$

or from Eqs. (24) and (43) gives another equation for η_{II} which is often easier to use:

$$\eta_{II} = \frac{\eta_w\left(1 + r_c + r_h\right)}{\tilde{\eta}_{hp}\left(1 + \tilde{r}_c + \tilde{r}_h\right)}\left(1 + \frac{\tilde{r}_c}{C\tilde{O}P_c} + \tilde{\eta}_{hu}\tilde{r}_h + \frac{\tilde{r}_e}{C\tilde{O}P_e}\right) \tag{45}$$

All of the terms in Eq. (45) except $\tilde{r}_e$ are known from choice or calculation, so if $\tilde{r}_e$ can be determined by some other means, η_{II} can be calculated.

Further simplification of efficiency comparisons is obtained if it is chosen that the heat-power outputs in the actual and reversible cycle are the same, $r_c + r_h = \tilde{r}_c + \tilde{r}_h$, and then Eq. (45) becomes

$$\eta_{II} = \frac{\eta_w}{\tilde{\eta}_{hp}}\left(1 + \frac{\tilde{r}_c}{C\tilde{O}P_c} + \tilde{\eta}_{hu}\tilde{r}_h + \frac{\tilde{r}_e}{C\tilde{O}P_e}\right) \tag{46}$$

If it can be assumed that the heat exchange with the environment occurs at the temperature of the environment, T_e, so $T_{i,e} = T_{o,e}$, Eq. (46) becomes

$$\eta_{II} = \frac{\eta_w}{\tilde{\eta}_{hp}}\left(1 + \frac{\tilde{r}_c}{C\tilde{O}P_c} + \tilde{\eta}_{hu}\tilde{r}_h\right) \tag{47}$$

and now η_{II} can be calculated without knowing $\tilde{r}_e$.

It is of interest to compare these Second Law efficiency equations with those defining the exergy efficiency presented in Section 3.

An example:

This example demonstrates one possible error that can be made when the exergy and Second Law efficiencies are used interchangeably, without realizing their distinct definitions, using the case of a compound cycle for cogeneration of power, heating and cooling proposed by the authors [17]. The plant operates in a parallel combined cycle mode with an ammonia-water Rankine cycle and an ammonia refrigeration cycle, interconnected by the absorption,

separation and heat transfer processes. It is driven by one external heat source fluid. In this paper, the heat source fluid is chosen to be air, entering the system at 450°C/1.043bar, and the net power output is 719 kW. Both refrigeration and heating output are at variable temperatures. The refrigeration output is 266.2kW, the working fluid (rich ammonia stream) provide refrigeration in a evaporator at the temperature range of -22.7°C to -15°C and pressure of 1.6 bar, with the corresponding *entropic temperature* (eq. (31)) T_c=250.5K. The heating fluid provide low level heat at the temperature range of 90° to 50°C and pressure of 1.013bar, the heat output is 308.9 kW, at the corresponding *entropic temperature* T_{hu}=342.8K. The heating fluid finally exhausts to the environment (T_e=298.15K), and the heat addition process is also a temperature variable process, at the *entropic temperature* T_{hp}=492.5K. the total heat input is 3496 kW.

The First Law efficiency:

$$\eta_I = \frac{W_u + Q_u + Q_c}{Q_{ip}} = 37.0\% \quad (48)$$

The refrigeration exergy output is (eq. (11))

$$A_c = Q_c\left(\frac{T_e - T_c}{T_c}\right) = 50.6 \text{ kW} \quad (49)$$

The heating exergy output is (eq. (10)):

$$A_{hu} = Q_{hu}(1 - T_e / T_{hu}) = 40.2 \text{ Kw} \quad (50)$$

The exergy input is

$$A_{hp} = Q_{hp}(1 - T_e / T_{hp}) = 1379.6 \text{ kW}$$

so, the exergy efficiency is (eq. (9).

$$\varepsilon = \frac{W_u + A_{hu} + A_c}{A_{hp}} = 58.7\% \quad (51)$$

To calculate the second law efficiency, we should first find the first law efficiency of a reversible cycle, which operates in the same thermophysical conditions and have the same power, heating and cooling outputs. Using eqs. (29), (30):

$$\begin{cases} \dfrac{Q_{hP,rev}}{T_{hp}} + \dfrac{Q_c}{T_c} - \dfrac{Q_{hu}}{T_{hu}} - \dfrac{Q_{0,rev}}{T_0} = 0 \\ Q_{hp,rev} + Q_c = Q_{hu} + W + Q_{0,rev} \end{cases} \quad (52)$$

where Q_0 is the heat amount exhausted to the heat sink.

(1) If the heat sink is chosen to be the environment with the temperature T_0=T_e=298.15K, then we can calculate the $Q_{hp,\,rev}$ from the above two equations to be $Q_{hp,\,rev}$=2052.1 kW, and the first law efficiency of the reversible system is:

$$\eta_{I,rev} = \frac{W_u + Q_u + Q_c}{Q_{hp,rev}} = 63.06\%$$

therefore, the Second Law efficiency of the system is (eq. (17)):

$$\eta_{II} = \eta_I / \eta_{I,rev} = 58.7\%$$

In this case, the Second Law efficiency is the same as the exergy efficiency.

(2) If the heat sink temperature is chosen to be at a value different than the environment temperature T_e, for example, if the heat sink is sensibly assumed to be the cooling water at T_0=303.15K, then $Q_{hp,\,rev}$=2108.4 kW, and the first law efficiency of the reversible system is thus:

$$\eta_{I,rev} = \frac{W_u + Q_u + Q_c}{Q_{hp,rev}} = 61.4\%,$$

and then the Second Law efficiency of the system is $\eta_{II} = \eta_I / \eta_{I,rev}$ = 60.3%, 2.7% higher than the exergy efficiency despite the smallness of the difference between the temperatures of the reference states (5 K, 1.6%).

ABSTRACT

Identifying and quantification of the losses allows us to improve the design of the systems. Energy losses are not necessarily indicative of the diversion from ideality .For instance; some processes have no energy losses, such as combustion of a fuel in an isolated vessel, yet the process is highly irreversible and therefore non-ideal. Thus energy analysis is not adequate for evaluation of the thermal system. Exergy analysis is a more powerful tool for evaluating of the systems and finding the type, location, and magnitude of the thermal losses in them.
The combustion process is one of the most important parts of the thermal systems; in this research the destruction of availability (exergy) during a combustion process is examined for adiabatic, constant pressure gaseous (methane) combustion. Exergetic efficiency of this irreversible process is obtained as a function of inlet air temperature, combustion pressure, air fuel ratio and the inlet air relative humidity. Since higher combustion pressure results higher exergetic efficiency but higher costs, the optimum combustion pressure is obtained from the exergoeconomic point of view.

INTRODUCTION

The design of efficient thermal systems that use nonrenewable energy sources is clearly important.∗ As pointed out earlier, Energy losses are not necessarily indicative of the derivation from ideality .For instance; some processes have no energy losses, such as combustion of a fuel in an isolated vessel, yet the process is highly irreversible and therefore non-ideal. Thus energy analysis is not adequate for evaluation of the thermal system.
Exergy analysis is a more powerful tool for evaluating of the systems and finding the type, location, and magnitude of the thermal losses in them. Identifying and quantification of the losses allows us to improve the design of the systems.

Since the thermodynamic optimizations of a thermal system usually appear to correlate in an inverse manner with capital costs, these methods should be integrated with engineering economics principles to determine the potential for cost effective improvement systems.
While it does not make sense to compare the energy cost of 1 kJ of electricity with that of 1 kJ of cooling water, it does make sense to compare them from the exergy point of view. So in the thermoeconomic analysis of the thermal systems the concept of exergy should be used instead of energy.
Work linking exergy and economics stems from researches carried out several decades ago that tied entropy to economics. One of the pioneers in this area was Nicolus G. Rogen whose 1971 book "The Entropy Law and The Economic Process" is cited continually and has motivated many research projects. [1]
Although an extensive literature exists concerning the destruction of availability, only a limited amount of work has been reported on the specific details for combustion processes (e.g. [2]) and no work has been reported on the thermoeconomic optimization of these processes.

EXERGY ANALYSIS

The concept of maximum work and availability can be extended to chemically reacting systems such as combustion process.
Since exergy destruction is a measure of irreversibility, it is important to consider the effect of the variation of the operating parameters on it.
In this study an isobar and adiabatic combustion of methane is evaluated by exergy and exergo-economic analysis.
For an adiabatic control volume, the exergy balance can be written as:

$$\dot{I} = \dot{E}_{in} - \dot{E}_{out} \qquad (1)$$

In a combustion process, inlet exergy is due to the chemical availability of fuel. Chemical availability is a measure of the maximum work when a gas or gas mixture comes to equilibrium with the environmental composition.
Chemical availability of a substance such as a fuel is examined as a chemical reaction occurs and the products of the reaction reach to equilibrium with the environmental composition.
Exergy loss can be simply obtained From Eq. 1. Calculation of products exergy entails calculation of the chemical composition of the products. Chemical composition of the products is obtained from the usual algorithms suggested in textbooks [3] by means of a computer code developed in C^{++}.
In this research the exergetic efficiency - defined as the ratio of the output exergy to inlet exergy - is plotted as a function of the operating parameters. Results are explained below:

Air fuel ratio

Fig. 1 depicts the effect of the air fuel ratio on the exergetic efficiency of the process.
As shown in the figure, increasing of the air fuel ratio leads to efficiency reduction.
This inverse relation is due to the products mass (moles) increase. Since higher products mass results lower flame temperature, a higher air fuel ratio results lower products exergy and so lower exergetic efficiency.

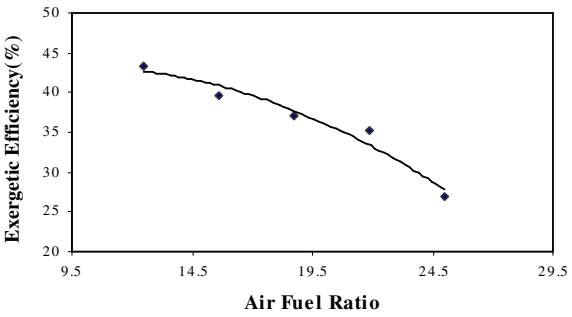

Figure 1: Exergetic efficiency as a function of air fuel ratio

Inlet Air Temperature

The effect of the inlet air temperature on exergetic efficiency is depicted in fig. 2. As shown in this figure, the inlet air temperature increase results in exergetic efficiency increase. Simply it can be understood that this increase is the result of the products temperature increase.

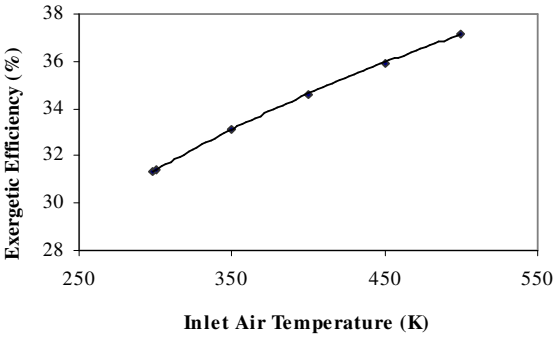

Figure 2: Exergetic efficiency as a function of inlet air temperature

Inlet air relative humidity

Fig. 3 shows the exergetic efficiency variation as a function of inlet air relative humidity.

As it is known, an increase in inlet air relative humidity leads to flame temperature reduction and this will reduce the products exergy. So as shown in the figure higher inlet air relative humidity will result lower exergetic efficiency.

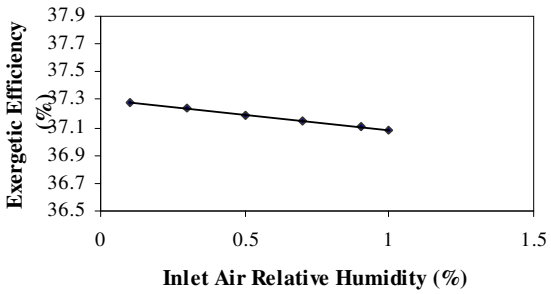

Figure 3:Exergetic efficiency as a function of inlet air relative humidity

Combustion pressure

As shown in fig. 4, higher combustion pressure results higher exergetic efficiency. This is due to flame temperature increase as a result of pressure increase.

According to the results explained above, inlet air temperature increase, inlet air relative humidity decrease and combustion pressure increase will lead to exergetic efficiency decrease. But clearly it is necessary to spend some exergy and even cost to do these improvements. So the combustion process should be analyzed by a more powerful method called exergoeconomy.

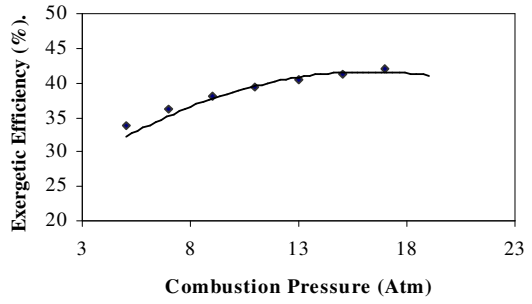

Figure 4: Exergetic efficiency as a function of combustion pressure

COMBINATION OF EXERGY AND ECONOMY

As mentioned before, the exergetic efficiency increase entails higher cost. For example, a higher combustion pressure leads to higher exergetic efficiency but a compressor unit should do this pressure increase.

Since using a compressor results some costs (capital and operating) there is an optimum combustion pressure that will minimize the total cost.

In this section a combustion process is optimized by exergoeconomy method in order to obtain the optimum combustion pressure.

Supposing an adiabatic combustion chamber and a compressor unit, the exergy balance can be written as follows [4]:

$$\dot{I}(x_i) = \dot{E}_{in}(x_i) - \dot{E}_{out}(x_i) + \dot{E}_{e.p}(x_i) \quad \textbf{(2)}$$

Since always there is some exergy loss in the actual processes, it is necessary to consume more input exergy to produce a certain amount of output exergy.

From the economic point of view, an objective function can be defined as follows:

$$C_T(x_i) = t_{op.} C_{in} \left(\dot{E}_{in}(x_i) + \dot{E}_{e.p}(x_i) \right) + aC_C(x_i) + b \quad \textbf{(3)}$$

This objective function represents the total cost required to produce a certain amount of exergy.

In this equation x_i is a parameter affecting the performance of the system. In this study x_i can be supposed to be the combustion pressure.

According to the usual mathematical method, this objective function should be differentiated to find the optimum combustion pressure. Thus:

$$\frac{\partial C_T}{\partial x_i} = t_{op} C_{in} \frac{\partial}{\partial x_i} \left(\dot{E}_{in}(x_i) + \dot{E}_{e.p}(x_i) \right) + a \frac{\partial C_c}{\partial x_i} \quad \textbf{(4)}$$

Differentiation of Eq. 2 also gives:

$$\frac{\partial \dot{I}}{\partial x_i} = \frac{\partial \dot{E}_{in}(x_i)}{\partial x_i} - \frac{\partial \dot{E}_{out}(x_i)}{\partial x_i} + \frac{\partial \dot{E}_{e.p}(x_i)}{\partial x_i} \quad \textbf{(5)}$$

As mentioned before, the optimum operating condition to produce a constant amount of exergy is required, so:

$$\frac{\partial \dot{E}_{out}(x_i)}{\partial x_i} = 0 \quad \textbf{(6)}$$

Thus:

$$\frac{\partial \dot{I}}{\partial x_i} = \frac{\partial}{\partial x_i}\left(\dot{E}_{in}(x_i) + \dot{E}_{e.p}(x_i) \right)$$

(7)

Substituting Eq. 7 in Eq. 4 results:

$$\frac{\partial C_T}{\partial x_i} = t_{op.} C_{in} \frac{\partial \dot{I}}{\partial x_i} + a \frac{\partial C_c}{\partial x_i} \qquad \textbf{(8)}$$

To optimize the objective function, make Eq. 8 zero. hence:

$$\frac{\partial Cc}{\partial \dot{I}} = -\frac{t_{op.} \cdot C_{in}}{a} \qquad \textbf{(9)}$$

Equation (9) shows that in the optimum x_i the slope of the tangential line to the capital cost – exergy loss graph equals $-\frac{t_{op.} \cdot C_{in}}{a}$.

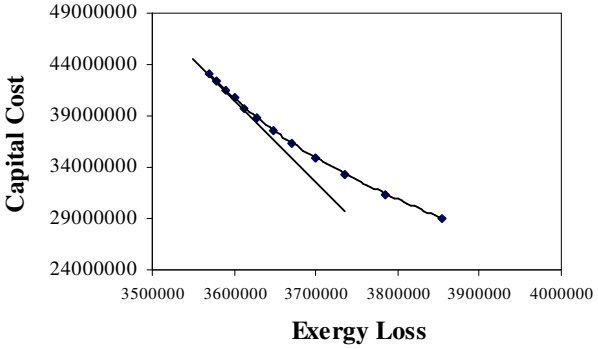

Figure 5: Capital cost as a function of Exergy Loss

The capital cost can be obtained from the experimental capital cost estimation diagrams given in textbooks [5].

Figure 5 depicts the variation of the capital cost as a function of exergy loss for different combustion pressure. The optimum condition is the point in which the slope of the tangential line equals $-\frac{t_{op.} \cdot C_{in}}{a}$ so, from this graph the exergy loss amount in the optimum condition can be graphically obtained.

As it is clear in fig. 5 in the optimum condition the exergy loss amount is approximately 3600000 (kW) that the corresponding combustion pressure will be 12.5 bar. It should be noted that this result obtained for a certain set of operating parameters such as inlet air temperature, air fuel ratio and inlet air relative humidity.

4. CONCLUSION

Adiabatic and isobaric combustion of methane has been considered by exergy analysis. Results showed that an increase in combustion pressure results an increase in exergetic efficiency so consequently lower fuel cost is required to produce a constant amount of exergy. On the other hand increasing the combustion pressure entails more costs due to the compressor set capital cost and its power consumption cost. So it is possible to find an optimum combustion pressure by means of the exergoeconomy method.

It should be noted that different situations such as economical factors (a, C_{in} and . . .) and physical parameters (air fuel ratio, inlet air temperature, inlet air relative humidity and . . .) would definitely conduct to different solutions.

ABSTRACT

Hot air engines (Stirling and Ericsson engines) are well suited for micro-cogeneration applications because they are noiseless, and they require very low maintenance. We study the coupling of an Ericsson engine *(i.e.* a Joule cycle reciprocating engine with external heat supply) with a system of natural gas combustion. In order to design this installation, we carry out energy, exergy and exergo-economic analyses that allow us to plot the exergy GRASSMANN diagram and evaluate the cost of the thermal and electric energy production. These simple analyses confirm the interest of such systems. The main result of this study is thus to draw the attention on Ericsson engines, unfortunately unfairly fallen into oblivion.

INTRODUCTION

In the low electrical power range (500 We … 50 kWe), combined heat and power (CHP), also called co-generation, does not have the same development as for higher power. This lack of success, although the market for residential cogeneration could be strong, is mainly due to the absence of suitable systems for this power range: internal combustion engines generate noise and vibrations. The market seems more promising for systems based on external combustion. Especially a lot of developments are devoted to CHP systems with kinematic or free piston Stirling engines and some of these systems are already commercially available.

We study a micro-cogeneration system based on an Ericsson engine coupled with a system of natural gas combustion. The objective of this system is to produce sanitary and heating hot water and 11 kW of electric output. In order to design this system, we carry out energetic, exergetic and exergo-economic studies.

CONFIGURATION OF THE STUDIED SYSTEM

Figure 1 shows the studied system. On the top of the figure, we can see a sketch of the combustion system with a combustion chamber and a heat exchanger, the air pre-heater. The burned gases transfer thermal energy to the Ericsson reciprocating engine through a heat exchanger called "heater". This Joule cycle [1] engine is located on the low part of the figure.

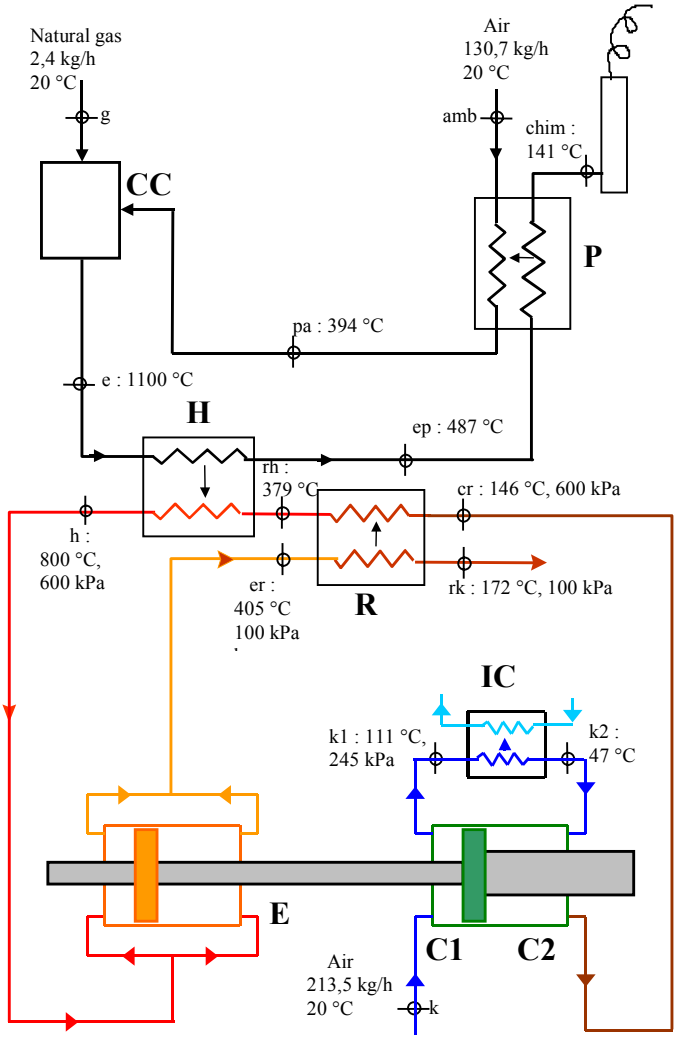

Figure 1: Energy system main features

There are several possibilities for the choice of the working fluid and for the layout of the engine. For instance, hydrogen or helium can be used as working fluid.
This naturally leads to high pressure, compact, engines, requiring a quite high level of technology. This is the usual choice for most Stirling micro-cogeneration systems developed up to now. However, for micro-cogeneration systems, it is not sure that the low size of the system is a determining factor, especially if reduced size is obtained from a high additional cost. We prefer a low-pressure system with air as the working fluid. In this case, we can use an open cycle. The engine is composed of 5 working spaces that we can easily locate on Figure 1: the heater, the recuperator, the inter-cooler, which are heat exchangers, and the expander space *E* and the compression spaces *C1* and *C2*. The engine operating principle is rather simple. Air is allowed at atmospheric temperature and atmospheric pressure and then, it is compressed. The compression is realized into 2 stages with water inter-cooling. Then, air goes through the recuperator where it recovers energy before going through the heater. There, it recovers the energy of the combustion gases before being expanded in the expansion cylinder. On the other hand, the expansion is realized in one stage in 2 parallel expanders without reheating. In the compression and expansion spaces, we have double-acting pistons.

ENERGY ANALYSIS

Modeling

A model is developed in order to obtain a suitable design for the cylinders and the heat exchangers. At this point of the study, the model used is not a dynamic model, but a 0-D global model whose variables are time-independent [1]. In order to study the energetic system under consideration, several quantities are assumed as inlet data. These are:

- The fuel mass flow rate; we consider natural gas with $\dot{m}_g = 0.67\ 10^{-3}$ kg/s.
- The combustion gas temperature at the outlet of the combustion chamber, and the inlet of the heater; we assume T_e = 1100 °C, in accordance with steel whose cost and machining is affordable.
- The compressed air temperature T_h in the engine is also limited for technological reasons of material thermal and mechanical resistance; we assume T_h = 800 °C; the energetic performance of the system obviously deeply depends on this temperature so that a detailed technical-economic study would be necessary to assess this value.
- The minimum working fluid pressure is the atmospheric pressure since the cycle is open; the maximum air pressure is set to $p_{cr} = 6.10^5$ Pa; it is well known that the cycle efficiency slowly decreases as the pressure ratio increases if the recuperator effectiveness is equal to 1 [2, p.538]; if the recuperator effectiveness is lower than 1, there is an optimum pressure that maximizes the power plant thermal efficiency [3, p.636]; for higher pressure values the efficiency decrease is quite slow; however we aim to maximize the global efficiency, not the thermal efficiency. The global efficiency depends also on the mechanical efficiency, which in turn depends on the pressure levels in the engine. Considering all this, our simulation results show that, from a pressure $p_{cr} = 6.10^5$ Pa, the power plant performance does nearly not vary when the pressure ratio increases.
- We set the heat exchanger effectiveness to the following values: E_P = 0.8, E_H =0.85, E_R = 0.9 and E_{IC} = 0.7 respectively for the combustion air pre-heater, the heater, the recuperator and the compressor inter-cooler; these are quite high values for gas/gas heat exchangers, but this high effectiveness of the exchangers is needed in order to obtain a high efficiency of the micro-cogeneration plant. It has been checked out that the chosen effectiveness values for the heat exchangers correspond to the best suitable heat exchangers transfer areas in the system [4].

In order to study the energetic system, the following assumptions are made:

- The combustion gases, the combustion air and the working fluid air are assumed to obey the ideal gas law; the specific heat of these gases is a polynomial function of temperature [5]; the combustion gases composition is computed from the composition of natural gas

and the computed excess air factor assuming a complete combustion;

- The pressure variations are realized in reciprocating piston/cylinder machines [6]; so the compression and the expansion are assumed to be isentropic in the cylinders; however the actual pressure ratio in the cylinders is different from the p_{cr} / p_k due to pressure losses trough the valves;
- Pressure losses trough the inlet and exhaust valves of the cylinders are modeled by

$$\Delta p = \xi \, \rho \frac{c^2}{2} \qquad (1)$$

The working air is assumed to obey the ideal gas law. This yields:

$$\frac{\Delta p}{p} \frac{T}{T_k} = \frac{\xi}{r} \frac{v^2}{T_k} \frac{v^2}{2} = \psi \qquad (2)$$

We consider that the valves around the cylinders can be designed so that the pressure loss factor ψ is the same for each valve and we assume ψ = 0.03; it should be noted that the performance of the system deeply depends on this value.

- A counter-flow shell and tube design is considered for all heat exchangers, the combustion gases (heater, pre-heater) and the low pressure air (recuperator) flowing out of the tubes; thermophysical properties of the fluids are computed at the mean temperature between the inlet and the outlet of the heat exchanger. The dynamic viscosity and thermal conductivity of the combustion gases are assumed to be the same of the ones of air. They are computed as a function of the mean temperature from a Sutherland relationship [7]. Heat transfer coefficients inside and outside the tubes are computed by the Gnielinski correlation [8] for clean pipes. In order to design the heat exchangers, we fix the maximal velocity of the fluid in the tubes and in the shell and we fix the tubes diameter for each heat exchanger.
- Mechanical losses are quite difficult to evaluate as the models developed for internal combustion engines are not appropriate. We consider a separate mechanical efficiency for the expansion and the compression cylinders. The net shaft power is then obtain from:

$$\left|\dot{W}_{net}\right| = \eta_{mec,E} \left|\dot{W}_E\right| - \frac{\dot{W}_C}{\eta_{mec,C}} \qquad (3)$$

In this relation we assume that both compression and expansion mechanical efficiencies are equal to 0.9. It is worth noting that the performance of the power plant deeply depends on this value.

- The cylinder volumes are computed from the working fluid mass flow rate and from the engine rotational speed. For technological reasons, and for mechanical efficiency, we choose a low speed, *i.e.* 1000 rpm. This leads to high cylinder capacities. The number of cylinders is determined by limiting the mean linear piston velocity to 8 m/s.
- The net power delivered by the engine is the shaft power. The electromechanical efficiency of the electric generator and the power consumption of the auxiliary pumps, ventilators, … are not taken into account. They are masked by the uncertainty on the mechanical efficiency.

Configuration chosen

The thermodynamic characteristics of the cycle are given in Figure 1. The energetic performances are reported in Tables 1 to 3. The net efficiency takes into account only the net shaft power, whereas the global efficiency (first principle) also takes into account the heat of the working air at the exhaust of the engine (state *rk*, Figure 1). Indeed the clean, dry, hot air at the exit of the engine can be directly used for heating purposes. The heat evacuated from the inter-cooler by the cooling water is also included in the net efficiency. The whole heat at the chimney (state *chim.*) is assumed to be lost.

EXERGY ANALYSIS

Exergy definition

The exergy concept was developed in order to propose a method of analysis taking the first two principles of thermodynamics into account. Exergy is defined as the maximal quantity of work that one can extract from a system, when it goes from its initial state to a state of equilibrium, if this process is made by interactions with the ambient environment. This maximal theoretical work is obtained during a completely reversible evolution towards the state of equilibrium with the environment reference state [2-3, 9-12]. In the absence of nuclear interactions, electromagnetic interactions, or surface tension interactions, the total exergy results from the sum of the physical exergy, the chemical exergy and the mechanical exergy (kinetic and potential exergy). In our study, the kinetic and potential exergies of the various flows can be neglected. The physical exergy is defined as follows:

$$ex^{ph} = (h - h_0) - T_0(s - s_0) \qquad (4)$$

The chemical exergy is defined by:

$$\overline{ex}^{ch} = \sum x_k \, \overline{ex}^{ch}_{0,k} + \overline{R}\, T_0 \sum x_k \ln x_k \qquad (5)$$

Calculation of exergy transfer rates and exergy efficiencies

The values of exergy transfer rates are calculated from Eqs (4) and (5), and from the results of the energy analysis. Table 6 shows these results. The designation of the streams is defined by reference to the states in Figure 1.

Stream	T	p	$\dot{m}$	$\dot{E}x$
	[K]	[10^5 Pa]	[kg/h]	[W]

er	678	1	213.5	8391
rk	445	1	213.5	1665

Table 6: Exergy transfer rates

For each component of the system, we can determine the exergetic efficiency and the exergy destruction in this component. The definition of the component exergetic efficiency depends on the function of the component. For example, if we consider the heater, its function is to heat air in the engine. Therefore, its exergetic efficiency can be defined as the ratio of the difference of exergy transfer rates

between the cold stream outlet and inlet of the heater, on the difference of exergy transfer rates between the hot stream inlet and outlet of the heater:

$$\eta_H = \frac{\dot{E}x_h - \dot{E}x_{rh}}{\dot{E}x_e - \dot{E}x_{ep}} \quad (6)$$

The heat rejected by the inter-cooler IC and by the exhaust air stream *rk* is assumed to be useful. If the exergy destructions related to the transfer of these thermal energies re not taken into account, the exergetic efficiency of the global system can be defined by the relation:

$$\eta = \frac{\dot{W} + \dot{E}x_{rk} + \dot{E}x_{k1} - \dot{E}x_{k2}}{\dot{E}x_g + \dot{E}x_{amb} + \dot{E}x_k} \quad (7)$$

Assuming no exergy losses in the components of the system under consideration, the rate of exergy destruction is obtained by the difference of the exergy transfer rates of the streams flowing in the component considered and the sum of exergy transfer rates of the streams flowing out of the component considered plus the time rate of energy transfer by mechanical work. For the heater, we obtain:

$$\dot{E}x_H^D = \dot{E}x_e + \dot{E}x_{rh} - \dot{E}x_h - \dot{E}x_{ep} \quad (8)$$

Table 7 shows the results.

Component	Exergetic efficiency	Rate of exergy destruction
	[%]	[W]

heater H	90.9	1801
recuperator R	93.8	420
compr. C1/C2	95.2 / 90.1	544
compression mech. system	90.0	1270
expander	99.6	107
expansion mech. system	90.0	2613
global system	38.5	19469

Table 7: Exergy efficiencies and exergy destructions

In order to visualize the rates of exergy transfer and exergy destruction, we draw the exergy GRASSMANN diagram (Figure 2).

We notice on this figure that the combustion chamber is the main source of exergy destruction. Indeed, the rate of exergy destruction in the combustion chamber amounts to 10.8 kW, that is the same value as the useful mechanical power produced by the engine. The heater and the mechanical systems of compression and expansion, each of them with an exergetic component efficiency of about 90 %, are also responsible for high rates of exergy destruction. But mostly, we can also see that the air pre-heater causes an important rate of exergy destruction in comparison with the exergy rates flowing trough this component. That explains its low exergetic efficiency.

EXERGO-ECONOMIC ANALYSIS OF THE SYSTEM

The exergo-economic analysis allows us to establish a cost balance for each element of the system, in order to determine the monetary value of the kilowatt of produced power and the exergy costs of the various streams *i*.
Assuming as previously that all components are adiabatic (no heat transfer to the environment or to other components, that is no exergy losses), this equation will be as follows [10]:

$$\dot{Z}_k + \left(\sum_i c_i \, \dot{E}x_i \right)_{in,k} = \left(\sum_i c_i \, \dot{E}x_i \right)_{out,k} + c_W \, \dot{W} \quad (9)$$

In Eq. (9), $\dot{Z}_k$ denotes the non-exergy-related cost rate associated with component *k*. It results from the cost rates associated to capital investment and operating and maintenance. For each component, $\dot{Z}_k$ would be known from a previous economic evaluation. The plant under consideration is made up of ten components *k*, namely the air pre-heater P, the combustion chamber CC, the compression spaces C1 and C2, the inter-cooler IC, the recuperator R, the heater H, and the mechanical compression and expansion devices. A linear system of 10 equations with 10 unknown factors, c_i and c_W, the costs per unit exergy of stream *i* or work, has thus to be solved.
To determine these costs, the cost of each component should have been assessed first. For the heat exchangers, we know the raw material cost (shell, tubes, ...), from pipe suppliers list prices, and we multiply this cost by an arbitrary

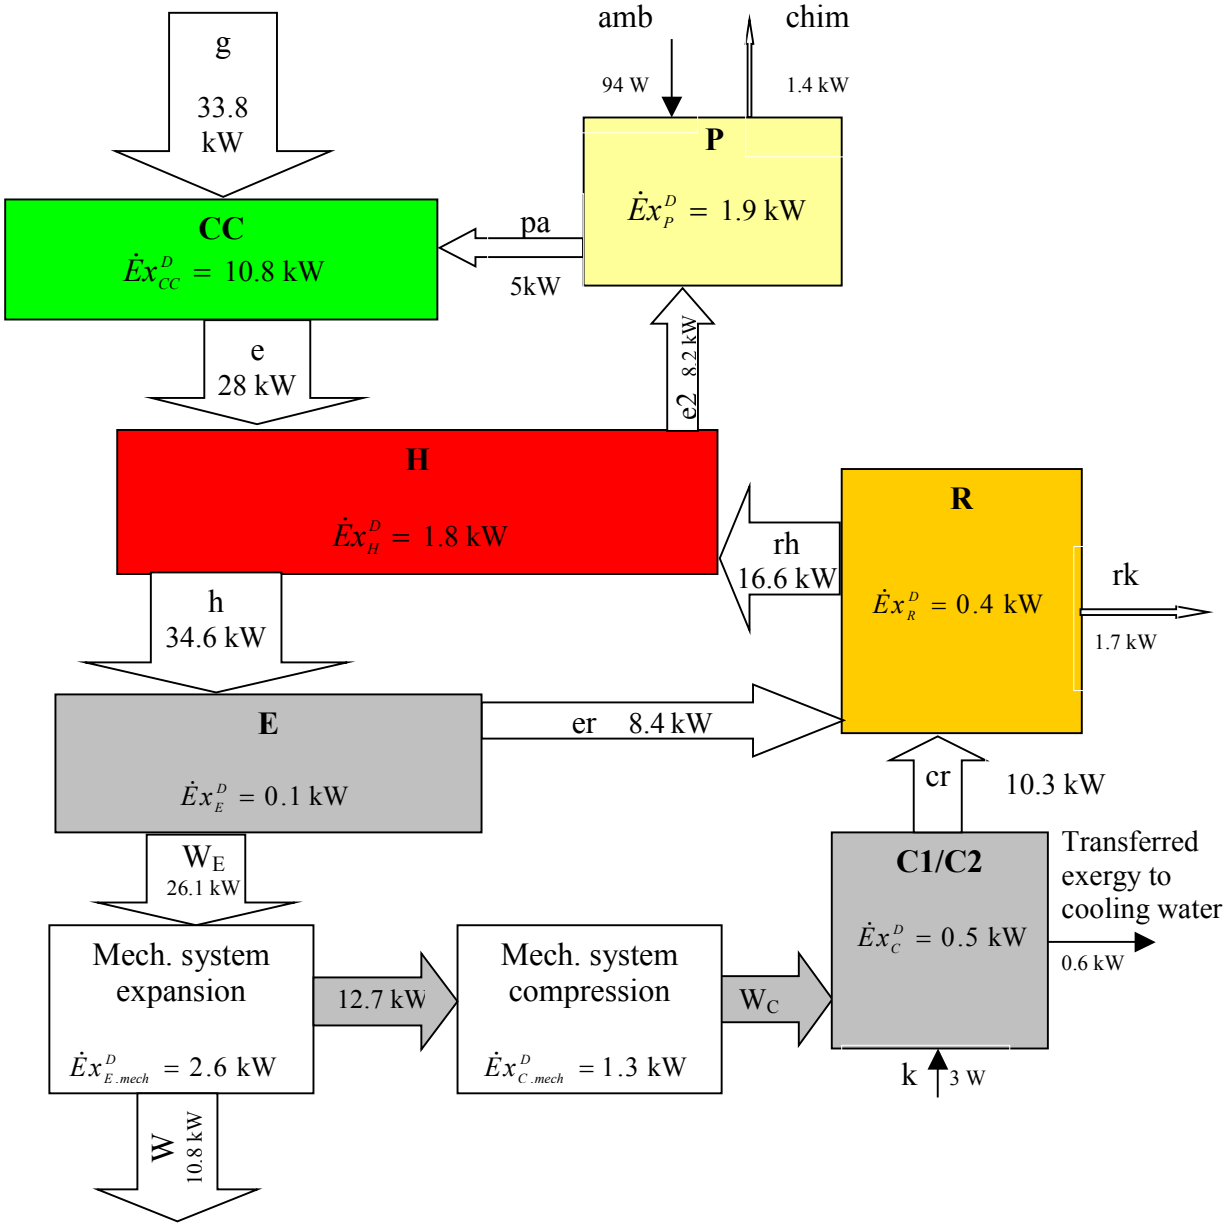

Figure 2: Rates of exergy transfer and exergy destruction

factor to take all costs into account, including heat exchanger manufacturing cost,... In our case, we multiply the raw material cost by 3. On the other hand, for the other components, we use an empirical relation such as:

$$P(X) = P(X)_{known} \left(\frac{X}{X_{known}} \right)^{\alpha} \qquad (10)$$

where $P(X)$ is the searched price of the device of characteristic value X; the couple (X_{known}, $P(X)_{known}$) and the value of the exponent α are evaluated from data taken from [10].

As soon as the price is determined, it is converted into price per unit time, knowing that we take into account a 10 years useful life for each component with 8000 operating hours by year. Table 8 shows the costs of the different exergy streams. The first line indicates the cost of the gaseous fuel, used as input data. The last line gives the cost of one kilowatt-hour of electric energy production. Each kilowatt-hour of electric energy production is accompanied by a (free) production of 1.2 kWh of recoverable thermal energy for heating or sanitary hot water

purposes. If we compare the value of 0.13 € with the domestic prices given by the French electric operator EDF (≈ 0.10 €/kWh of electric energy) and by the French natural gas supplier GDF (≈ 0.03 €/kWh of thermal energy), we notice that these values are close and therefore, the studied system could be profitable. However, the cost of the different component of this micro-cogeneration system should be known more exactly to refine these results.

Exergy stream	Cost [€ / kWh]
c_g	0.03
c_{pa}	0.09
c_e	0.05
c_{k1}	0.16
c_{k2}	0.20
c_{cr}	0.17
c_{rh}	0.17
c_h	0.11
c_{Wc}	0.15
c_{We}	0.12
c_W	0.13

Table 8: Cost of the different exergy streams

CONCLUSION

This communication presents the results of the energy study, the exergy study and the exergo-economic study of a micro-cogeneration system based on an ERICSSON engine. The exergy study allows to draw the GRASSMANN diagram and to observe the exergy streams and the exergy destructions in the system. Finally, the exergo-economic study allows to calculate the cost of the heat and of the electricity produced and to conclude to the possible profitability of the system by comparison with the prices given by the French energy suppliers.

It should be emphasized that the assumptions used in this work are quite severe and conservative. For instance, the assumed mechanical efficiency is low, the valve pressure losses are quite high, the amount of heat rejected at the chimney is important. Nevertheless, the modeled system proves to be interesting. The main issue of this work is to put a new light on an old, but cheap, simple, and efficient technology and to draw the attention on Ericsson engines, unfairly not yet brought out of oblivion.

ABSTRACT

In the paper, the design optimisation of a heat exchanger is discussed. The investigation is referred to the tube-in-tube condenser of an electric vapour-compression heat pump, with a two-phase refrigerant flowing in the inner tube and the water to be heated flowing in the annulus.
In order to include in the analysis economic aspects, a cost function to be minimised is introduced, defined as the sum of two contributions: i) the amortisation cost of the condenser, related to the heat exchange area; ii) the operating cost of the electric-driven heat pump in which the heat exchanger will work, depending on the overall exergy destruction rate in the system. In the paper, this latter contribution is related to the local irreversibility rate in the condenser, using the so-called structural approach.
The optimal trade-off between amortisation and operating cost is therefore investigated, by minimising the above-mentioned cost function.
A numerical example is discussed, in which, for a commercial heat exchanger, the design improvements needed to obtain a cost-optimal configuration are investigated. The analysis is carried out for two different refrigerants: R134a and-R410A.

1. INTRODUCTION

The optimisation of heat exchangers, also including evaporators and condensers of refrigeration and heat pump systems, has been widely studied in recent years. Different approaches were proposed, such as Entropy Generation Minimisation, Lyfe Cycle Analysis and Exergoeconomic or Thermoeconomic Analysis [1 - 7].
In this paper, the problem of determining the optimal trade-off between amortisation and operating costs for the condenser of a vapour-compression heat pump is discussed. Heat exchanger geometry, working fluids and heating capacity were fixed. Namely, the component under study was a tube-in-tube heat exchanger, made-up by two coaxial tubes. The fluid to be heated was water, flowing in the annulus between inner and outer tubes. As for the refrigerant, flowing in the inner tube, the analysis was carried out for two different fluids: R134a and R410A. A heating capacity of 10 kW was assumed.
A cost function to be minimised was introduced, defined as the sum of two contributions: the amortisation cost of the condenser and the operating cost of the electric-driven heat pump in which the component had to work.
For fixed heating capacity and flow arrangement, the amortisation cost related to the condenser was assumed to depend on the heat exchange area.
As for the operating cost, it was necessary to evaluate the influence of condenser design on the electric energy consumption of the heat pump in which it had to operate. For this scope, two different approaches are possible, depending on the hypothesis of the study. When the condenser is designed for a specific heat pump, a detailed simulation is possible for the system, allowing the designer to take into account the mutual interactions among all plant components.
However, this is not possible when the specific model of compressor, evaporator and expansion device to be matched with the condenser are not known at the moment in which it is designed. This is the hypothesis assumed in the paper.
In this case, the optimisation must be performed by isolating the device from the rest of the system. However, the influence of the condenser performance on that of the remaining components must be taken into account: this is possible using the so-called structural approach, in which an approximate correlation is assumed between the local exergy destruction rate in a given component and that of the system as a whole [8].
Two design variables were considered in the optimisation: the saturation temperature of the refrigerant, T_{sat}, and the internal diameter of the inner tube, D_{in}. These variables directly affect the heat exchange area, A, and the exergy destruction rate in the condenser, I. On their turn, A and I directly affect the cost function to be minimised, as previously mentioned. The annulus outer diameter, D_{out}, was kept constant, so that the external size of the heat exchanger, in radial direction, was fixed. Obviously, in general, this parameter could be a further decision variable, affecting the design analysis and optimization of the condenser.
In the following sections, the fundamentals of the structural method for thermoeconomic optimisation are shortly reminded. Then, a numerical example is developed, in which, for a fixed heating capacity of the condenser, optimum design conditions are investigated for two different refrigerants.

2. THE STRUCTURAL METHOD FOR THERMOECONOMIC OPTIMISATION

In this section, the method for structural thermoeconomic optimisation is shortly resumed [8].

For a given thermal system, the overall exergy destruction rate, I_{tot}, can be calculated as:

$$I_{tot}(\bar{\bar{y}}) = F_{tot}(\bar{\bar{y}}) - P_{tot} \quad (1)$$

where P_{tot} is the exergy flow rate representing the product of the process, F_{tot} is the external resource, or Fuel, consumed by the system, and $\bar{\bar{y}}$ is the matrix of all design variables affecting the performance of the system, whose component $y_{i,k}$ represents the k-th variable directly affecting the performance of device i. In the case under study, for example, the product

P_{tot} was represented by the increase of the physical exergy of the fluid to be heated in the condenser, and F_{tot} by the electric power required to driving the compressor.
If maintenance and other accessory costs are neglected, the economic cost of owning and operating the plant can be expressed as follows:

$$\Pi_{tot}(\bar{\bar{y}}) = c_F F_{tot}(\bar{\bar{y}})\tau + \zeta \sum_k Z_k(\bar{y}_k) \quad (2)$$

In eqn. (2), c_F is the cost per unit exergy of the Fuel, that is, in our case, the unit cost of the electric energy used by the heat pump, τ is the equivalent time of full-load operation planned for the system, on a yearly base, ζ is the amortisation factor and Z_k represents the cost of the generic k-th component.
In order to determine the optimal condition with respect to a fixed design variable, say $y_{i,k}$, when holding fixed all the others, the following condition can be obtained by differentiating eqn. (2):

$$\partial \prod_{tot} / \partial y_{i,k} = c_F \left(\partial F_{tot} / \partial y_{i,k}\right)\tau + \zeta \sum_i \left(\partial Z_i / \partial y_{i,k}\right) = 0 \quad (3)$$

This condition identifies a minimum or a maximum value, depending on the sign of the second order derivative.

Assuming a constant overall product, we have:

$$\Delta I_{tot} = \Delta F_{tot} \quad (4)$$

and differentiating with respect to the design variable to be optimised:

$$\partial I_{tot} / \partial y_{i,k} = \partial F_{tot} / \partial y_{i,k} \quad (5)$$

Combining equations (3) and (5) the optimum condition can be expressed as:

$$\partial \prod_{tot} / \partial y_{i,k} = CSB_{i,k}\ c_F \left(\partial I_k / \partial y_{i,k}\right)\ \tau + \zeta \sum_i \left(\partial Z_i / \partial y_{i,k}\right) = 0 \quad (6)$$

in which the coefficient of structural bond, $CSB_{i,k}$, has been introduced, defined as [8]:

$$CSB_{i,k} = \left(\partial I_{tot} / \partial y_{i,k}\right) / \left(\partial I_k / \partial y_{i,k}\right) \quad (7)$$

where I_k is the exergy destruction rate in the k-th component of the plant.
This coefficient allows one to establish a correlation between the local irreversibility rate in the k-th component to the overall exergy destruction. In other terms, it provides a measure of the impact of a change in the local performance on that of the system as a whole.
Eqn. (6) can be also expressed as:

$$\partial \prod_{tot} / \partial y_{i,k} = CSB_{i,k} c_F \left(\partial I_k / \partial y_{i,k}\right)\ \tau + \zeta \left(\partial Z_k / \partial y_{i,k}\right)\ +\ \xi_{i,k}\ (\partial I_k / \partial y_{i,k}) = 0 \quad (8)$$

In eqn. (8) the contribution due to the k-th component directly influenced by variable $y_{i,k}$ has been separated by those referred to the other components and the coefficient of external costs has been introduced:

$$\xi_{i,k} = \sum_{i \neq k} \partial Z_i / \partial I_k \quad (9)$$

The value of coefficient $\xi_{i,k}$ is negligible when the variation of $y_{i,k}$ does not influence significantly the cost of components different from the k-th. This may also happen, for example, when these latter components are available in standard sizes and the variation of the design variable $y_{i,k}$ is not sufficient to induce size variations in other components. If the coefficient $\xi_{i,k}$ can be settled to zero, the following final expressions for optimum conditions can be written:

$$\partial \Pi_{tot} / \partial y_{i,k} \ = \ CSB_{i,k} c_F \left(\partial I_k / \partial y_{i,k}\right)\tau + \zeta \left(\partial Z_k / \partial y_{i,k}\right)\ = 0 \quad (10a)$$

$$\partial^2 \Pi_{tot} / \partial y_{i,k}{}^2 > 0 \quad (10b)$$

By solving eqn. (10a), and controlling that eqn. (10b) is satisfied, the value of the design variable $y_{i,k}$ that minimise the overall cost Π_{tot} can be found.

3. CASE STUDY: PROBLEM DEFINITION

The methodology described in the previous section was applied to a commercial tube-in-tube heat exchanger to be used as the condenser in a conventional electric-driven vapour-compression heat pump. A schematic view of the condenser is provided in Figure 1. The main features of the heat exchanger are resumed in Table 1.
The following assumptions were used: i) Newtonian non-reacting pure fluids; ii) operation in steady-state conditions; iii) mono-dimensional flow conditions; iv) negligible exergy losses toward the environment.

The heating capacity of the condenser, $\dot{Q}$, was fixed, as well as the inlet and outlet temperatures of water. So, the water mass flow-rate and the

exergy flow rate corresponding to $\dot{Q}$ were practically fixed, too, since the contribution of pressure losses to the enthalpy and entropy variation of liquid water was negligible. This exergy flow rate represented the product of the heat pump under study, P_{tot}.

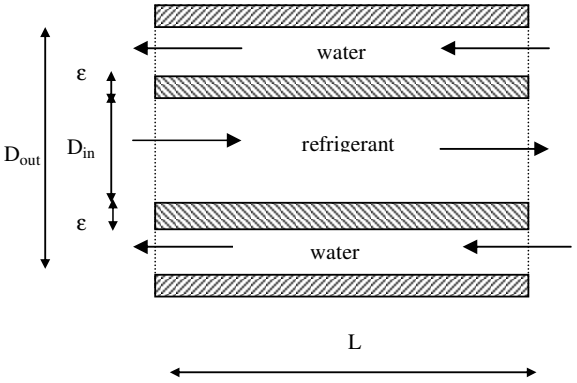

Figure 1. Schematic representation of the condenser analysed

Water outlet temperature:	50 °C
Refrigerant inlet	variable from 55 to 65
Refrigerant inlet quality:	1.0
Refrigerant outlet quality:	0

Table 1. Main features of the condenser under analysis.

In order to focus on the condensation process, de-superheating and sub-cooling were neglected, and therefore the refrigerant was always assumed in two-phase conditions. In other terms, for simplicity, the optimisation procedure was carried out leaving apart the de-superheating and the sub-cooling sections of the heat exchanger.

Referring to eqn. (10a):
- the unit cost of the electric energy required to move the compressor, c_F, was considered as an external parameter, and assumed equal to 0.10 € kWh^{-1} ; however, since this cost may vary sinificantly, depending on the mean electricity rate applied to the end user, the optimisation was also performed for different values of c_F (0.08 and 0.12 € kWh^{-1});
- a reference value of 2.0 was assumed for the *CSB* of the condenser, with respect to both design variables considered (T_{sat} and D_{in}, as discussed below); this reference value was based on the results provided by a simulation programme for conventional heat pump systems (basic configuration, with scroll compressor, tube-in-tube condenser and evaporator and thermostatic expansion valve), in typical operating conditions (evaporation temperature in the range 0 to 5 °C, condensation temperature in the range 55 to 65 °C) [9];
- the coefficient of external cost, $\xi_{i,k}$, was assumed equal to zero;
- the cost of the condenser was expressed as a function of the heat exchange area, measured from the refrigerant side, according to the following equation [10]:

$$Z = Z_o \left(\frac{A}{A_o} \right)^n \qquad (11)$$

where Z_0 = 1500 € and A_0 = 1.0 m^2 are the reference cost and area, respectively, and the exponent n was assumed equal to 0.75 [10];
- an operation time, τ, of 1500 hours per year was assumed;
- finally, a discount rate of 5% and a time horizon of 10 years was assumed, leading to a value of the amortisation factor $\zeta = 0.1295$ $years^{-1}$.

Two independent design variables were considered in the optimisation: i) the saturation temperature of the refrigerant, T_{sat}, at the beginning of the condensation process, directly affecting the heat exchange area; ii) the inner diameter of the inner tube, D_{in}, that also affects the heat exchange area, since both refrigerant and water heat-transfer coefficients depend on it. T_{sat} was assumed to vary in the range from 52 to 65 °C, with a step of 1 °C; D_{in} was assumed to vary in the range from 10 to 20 mm, with a step of 1 mm.

4. CASE STUDY: DESIGN ANALYSIS AND OPTIMISATION

The following procedure was used in the design analysis and optimisation of the condenser.

1) The water mass flow-rate was calculated as the ratio between $\dot{Q}$ and the enthalpy variation; pressure losses, slightly depending on the variables to be optimised, were here neglected.

2) For any value of the initial temperature of the refrigerant, T_{sat}, in the range of interest, the refrigerant mass flow rate was calculated, at first, as the ratio of the condenser heat duty, $\dot{Q}$, to the enthalpy of condensation - at constant pressure - corresponding to that temperature:

$$\dot{m}_r = \dot{Q} / \left(h_{r,in} - h_{r,out}\right) \qquad (12)$$

Since pressure drops induce a slight variation in the difference between inlet and outlet enthalpies, with respect to an ideal condensation at constant pressure, the result provided by eqn. (12) is approximate: so, after calculation of the heat-exchanger length and the corresponding pressure losses for the refrigerant, this mass flow rate was re-calculated, as described in the next point.

3) For any possible set of values of T_{sat} and D_{in}, the heat-exchange area, A, was calculated as follows. First, the overall thermal conductance, UA, was approximately estimated - neglecting all pressure losses - as the ratio of the condenser heating capacity, $\dot{Q}$, to the mean logarithmic temperature difference in the heat exchanger corresponding to the current values of T_{sat} and D_{in}:

$$UA = \dot{Q} / \Delta T_{lm} \qquad (13)$$

Then, the overall length of the condenser, L, was calculated as:

$$L = (\mathrm{UA}) \left[\frac{1}{\alpha_r \pi D_{in}} + \frac{\ln\left(\frac{D_{in} + 2\varepsilon}{D_{in}}\right)}{2\pi\lambda} + \frac{1}{\alpha_w \pi (D_{in} + 2\varepsilon)} \right] \qquad (14)$$

where α_w and α_r are the mean heat-transfer coefficients for water and refrigerant, for the current values of T_{sat}, D_{in} and mass flow rates.

The estimation of mean heat-transfer coefficients was based on the correlations available in the literature. In particular, the model recently proposed by Cavallini et al. [11] for horizontal smooth tubes was used for the two-phase flow: for any value of vapour quality in the range 0 to 1, the local heat-transfer coefficient is calculated with different correlations, depending on the local flow regime (annular, transition, stratified and slug flows). Finally, the arithmetic mean value of the local coefficients is calculated. Classical correlations were used for the single-phase flow in the annular section of the condenser [12].

As for pressure losses, they were obtained multiplying the L value by the mean pressure gradient. For the refrigerant, this latter was evaluated using the correlation proposed by Koyama et al. [13], especially suited for the refrigerants under analysis. For the cold fluid, classical correlations for single-phase flow in annular section were used [12].

An automatic control was introduced in the procedure in order to reject possible geometries characterized by unacceptable pressure losses: a maximum value of 60 kPa was fixed for both cold and hot sides of the condenser, in optimum conditions.

The physical properties needed for the analysis were obtained through tables available in the literature, for the water [14], and the REFPROP software, for the refrigerants [15].

4) At this point, the refrigerant mass flow-rate was re-calculated through eqn. (12), using the actual enthalpy variation between inlet and outlet of the condenser, and all calculations were iterated until satisfactory convergence was attained (difference between new and previous value of $\dot{m}_r$ less than 0.1%).

5) Finally, the heat-exchange area - refrigerant side - corresponding to the given set of T_{sat} and D_{in} values was obtained as:

$$A = \pi D_{in} L \qquad (15)$$

6) The entropy generation rate in the condenser, corresponding to the given values of T_{sat} and D_{in}, was calculated from the entropy balance, as:

$$\dot{S}_{gen} = \dot{m}_w \times \left(s_{w,out} - s_{w,in}\right) - \dot{m}_r \times \left(s_{r,in} - s_{r,out}\right) \qquad (16)$$

7) The exergy destruction rate in the condenser was evaluated as [8]:

$$I = T_0 \dot{S}_{gen} \qquad (17)$$

The ambient temperature, T_0, was settled to 280 K.

8) Once the heat-exchange area, A, and the exergy destruction rate in the condenser, I, were evaluated for any possible couple of T_{sat} and D_{in} values, each term of eqn. (10a) was expressed as a continuous and derivable function of each of these two variables, by regression of the data previously obtained. To this scope, for both dependent variables A and I, a regression with a polynomial of the third order, performed with respect to T_{sat} for fixed D_{in} and vice-versa, was always sufficient to reach a value of the coefficient of determination, R^2, greater than 0,999.

The functions $A = A(T_{sat}, D_{in})$ and $I = I(T_{sat}, D_{in})$ are graphically represented in Figures from 2 to 5. In particular, Figures 2 and 3 respectively show the values of the heat-exchange area and the corresponding exergy destruction rate, as a function of the saturation temperature T_{sat} and the inner diameter D_{in}, for the refrigerant R134a. In Figures 4 and 5, the same quantities are shown for R410A. Obviously, in any case, when the initial saturation temperature rises, the heat exchange area always decreases (Figures 2 and 4). On the contrary, the corresponding exergy destruction rate, mainly due to heat transfer irreversibility, always increases with T_{sat} (Figures 3 and 5). For any given couple of T_{sat} and D_{in} values, the heat exchange area was minimum for R134a.

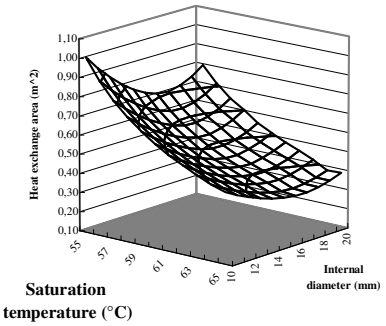

Figure 2. Heat exchange area vs. saturation temperature and internal diameter of the inner tube. Working fluid: R134a.

It is interesting to observe that, for both refrigerants, and for any fixed value of T_{sat}, both heat exchange area, A, and exergy destruction rate, I, have a minimum for a D_{in} value always ranging between 15 and 16 mm.

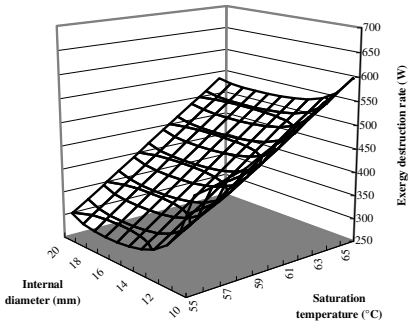

Figure 3. Eergy destruction rate vs. saturation temperature and internal diameter of the inner tube. Working fluid: R134a**.**

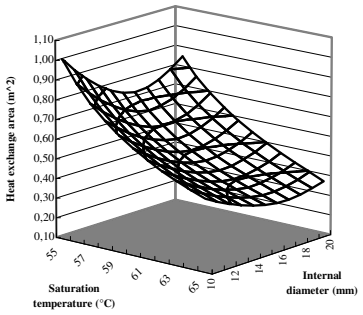

Figure 4. Heat exchange area as a function of saturation temperature and internal diameter of the inner tube. Working fluid: R410A.

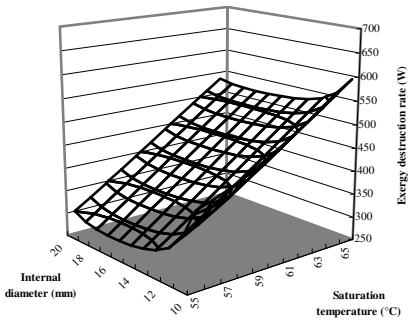

Figure 5. Exergy destruction rate vs. saturation temperature and internal diameter of the inner tube. Working fluid: R410A.

Obviously, these values are not casual. In the case of A, they correspond to the maximum of the overall thermal conductance per unit area, U, compatible with the values fixed for the external diameter of the condenser, D_{out}, and for the mass flow rates of the fluids.
With regard to I, the following comment can be made. For a given saturation temperature, the overall exergy destruction due to heat transfer is practically fixed, too: in fact, also the heat flow rate and the temperature of water are fixed. However, the contribution due to pressure losses still depends on D_{in}, and the minimum of I corresponds to the optimal distribution of the frictional irreversibility between cold and hot fluids. The dependence of I on D_{in} at constant T_{sat} is strong in the range from 10 to 13 mm, when the pressure losses for the two-phase flow are significant; the slope of the curves becomes very small in the range from 14 to 20 mm, when the contribution of the frictional losses to the overall irreversibility becomes very modest (from 2 to 6%).
In the case under study, the correlation between pressure losses and heat transfer coefficients are such that the minimum values of A and I are reached for values of D_{in} falling in a very small range.
Once the functional relationships $A= A(T_{sat}, D_{in})$ and $I= I(T_{sat}, D_{in})$ were obtained, optimum design conditions with respect to T_{sat} for fixed D_{in} - or inversely - could be found by solving eqns. (10). To determine the overall optimum conditions, with respect to both design variables, for a fixed set of all remaining parameters, a simple iterative procedure was followed:
- an initial value of T_{sat} in the range of interest was assigned;
- the corresponding optimum value of the internal diameter was calculated, by solving eqn. (10a) with respect to D_{in} and then verifying that eqn. (10b) was satisfied, too;
- the optimum value of the saturation temperature corresponding to this latter value of D_{in} was calculated by solving eqn. (10a) with respect to T_{sat} and then verifying that eqn. (10b) was satisfied, too;
- the optimum value obtained for T_{sat} was compared with the corresponding initial value and the procedure was iterated until convergence was attained, that is, until initial and calculated values were equal.
In all cases taken into consideration, the convergence of this procedure was practically immediate (less than one second, using a PC equipped with a Pentium III Processor and 256 MB RAM).
The most significant results of the optimisation are discussed in the following.
For any c_F in the range from 0.08 to 0.12 €/kWh, the optimum values of the internal diameter of the inner tube were practically equal to those that minimised A and I, namely optimum D_{in} = 16 mm for both refrigerant fluids.
Not only c_F, but also the remaining parameters CSB, τ, Z_0 and n did not influence the optimum D_{in}, even when varying of ± 20% with respect to the base-case.
As for the optimum values of T_{sat}, and the corresponding values of A and I, the results obtained for different values of the electric energy cost are summarised in Figg. from 6 to 8.
The optimal saturation temperatures (Fig. 6) always decrease with c_F, as expected. The optimum values range from 60 °C to 57 °C for R410A, from 59 °C to 56 °C for R134a.

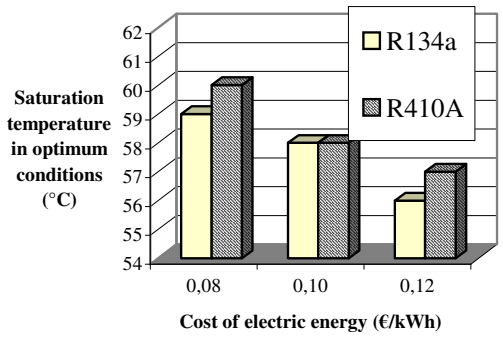

Figure 6. Saturation temperature in optimum conditions, for different values of the electric energy cost.

As a consequence, the heat exchange area required to optimise the thermoeconomic performance of the system increases with c_F (Fig. 7), whereas the corresponding exergy destruction rate decreases (Fig. 8). This irreversibility is mainly due to heat transfer, since, in optimum conditions, the contribution due to friction always ranged between 2 and 3% of the overall value.
So, it may be commented that the higher is the cost of electric energy that the final user has to afford, the greater is the profitability for him of investing money in selecting a condenser with an extended heat-exchange area, therefore

lowering the saturation temperature of the refrigerant: this induces a reduction of the irreversibility in the condenser and in the heat pump, leading to energy and money savings during system operation.

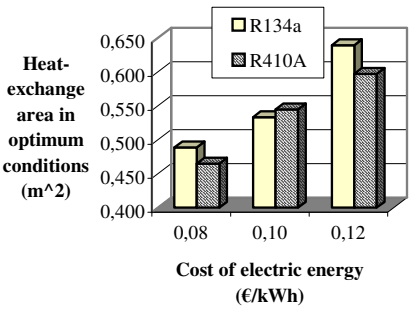

Figure 7. Heat exchange area in optimum conditions, for different values of the electric energy cost.

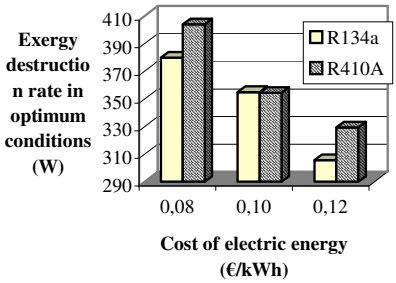

Figure 8. Exergy destruction rate in optimum conditions, for different values of the electric energy cost.

The influence of the working fluid on the optimum design was often remarkable, too, suggesting the importance of strictly relating the design of new condensers to the refrigerant to be used. However, it is useful to emphasize that the analysis presented here cannot be used directly to evaluate or compare the overall thermodynamic or thermoeconomic performance of the fluids: this problem can only be analysed by studying the performance of the overall heat pump system.

It may be also interesting to compare the results of the optimisation with those that would have been obtained by neglecting the structural effect induced by the condenser on the system as a whole (i.e.: assuming for the condenser CSB = 1). It was calculated that, in this case, the "optimum" values of the heat-exchange area would be from 30% to 39% smaller than the actual ones. This result highlights the importance of taking into account the structural effects when optimising single components of thermal systems.

A sensitivity analysis was also performed with respect to some of the independent parameters involved in calculations: Z_0, $CSB_{i,k}$, τ, α_r and c_F, again. As an example, the results obtained for R134a are shown in Fig. 9, referring to the dependent variable A. Diagrams related to the R410a was very similar.

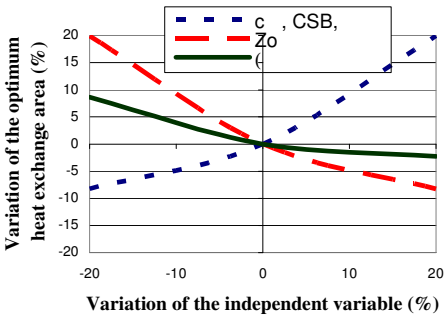

Figure 9. Sensitivity of the optimum heat exchange area to the independent parameters c_F, CSB, τ, Z_0 *and* α_r. Working fluid: R134a.

A unique curve is shown for three parameters: $CSB_{i,k}$, τ, and c_F: in fact, they have the same influence on the optimal values of A, due to the form of eqn. (10a). For example, if the actual CSB were 20% less than the value assumed in the reference case (i.e.: 1.8 instead of 2.0), the optimum heat exchange area would be about 8% smaller than that previously obtained (0.49 m^2 instead of 0.53 m^2).

Obviously, the dependence of the optimum conditions on Z_0 has an opposite sign, with respect to CSB, τ, and c_F: if the reference cost of the heat exchanger rises, the optimal area decreases.

With regard to the heat-transfer coefficient α_r, it can be noted, for example, that the heat exchange area increases if the actual value of α_r is lower than that assumed in the reference case: for instance, a 10% reduction of the heat transfer coefficient for R134a, with respect to the value predicted by correlations, would lead to a difference of about 4% between the optimum value of A calculated in the reference case (0.53 m^2) and the actual one (0.55 m^2).

This latter analysis is of special interest, since actual values of the heat-transfer coefficients can be significantly affected, for example, by the presence of compressor oil. Furthermore, the

correlations available to predict heat-transfer coefficients for two-phase flows are characterised by remarkable uncertainty.

4. CONCLUSIONS

In the paper, the search for the optimum design of a condenser to be used in a conventional vapour-compression heat pump was discussed. In particular, varying the inner tube diameter and the refrigerant saturation temperature, the optimal heat-exchanger area, *A*, was calculated, for a fixed heating capacity of the condenser.
The optimum values obtained for *A* appear greater than those usually adopted in commercial devices, especially for high values of the electric energy cost. In fact, when this latter cost increases, the weight of the irreversibility in the operation cost increases too, whereas the amortisation costs become less important: thus, greater investments, aimed at improving plant efficiency, become more and more advantageous. Although this conclusion could appear obvious, similar considerations are usually neglected, especially when plant designer will not be involved in meeting the expenses of operating the system.
The example presented in the paper should be also intended as a contribution to a wider diffusion of methods for thermoeconomic analysis and optimisation in the field of refrigeration and heat pumps. In this sector, characterised by emerging technologies and by the gradual introduction of new working fluids**,** these methods can be helpful in addressing the design and selection of new equipment, not less than in the field of power plant.
A further development of this study is currently in progress, aiming at including in the analysis environmental aspects, with special attention to those regarding the emissions of greenhouse gases (Total Equivalent Warming Impact).

EXERGOECONOMIC ANALYSIS OF ABSORPTION SYSTEMS FOR TURBINE AIR INLET COOLING IN TRIGENERATION PLANTS

G. Chiummo, A. Di Nardo, G. Langella*, C. Noviello
Department of Mechanical Engineering and Energetic
University of Naples "Federico II" - ITALY

ABSTRACT

The aim of the work is the analysis of energetic and economic advantage of installing an air cooling system at the inlet of a gas turbine set (compressor – combustor – turbine), in a 5 MW CHP plant. Two different solutions have been compared: the first one is an absorbption chiller fed by heat recovery from the gas turbine, through an heat exchanger; the second one is a traditional cooling system by CFC compression cycle, electrically fed by electrical generator coupled with gas turbine.

Keywords: Cogeneration, trigeneration, air cooling.

INTRODUCTION

It's well known that electrical output from a gas turbine combined heat and power plant, decreases with environmental temperature increasing, due to the bigger power requested from compressor unit (see Fig.1 below).

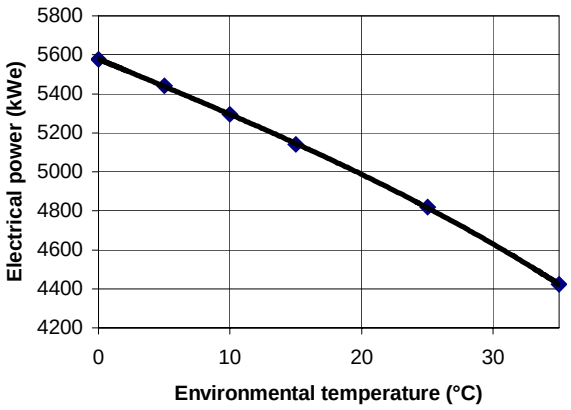

Figure 1: Gas Turbine Electrical power output VS environmental temperature

The relationships regarding the characteristic operating parameters of a gas turbine plant are here analysed. This is to remark the link between these parameters and the environmental temperature, in order to evaluate the benefit of installing an absorbption chiller or a CFC compression one, for inlet air cooling. The first is supposed to be fed by hot water or steam produced by heat recovery which can be performed through an heat exchanger or an heat recovery boiler, taking thermal power from gas turbine flue gas stream. The second option is a traditional chiller working with CFC compression cycle and fed electrically by gas turbine generator itself. Both of them have the task to cool inlet air to the compressor, avoiding electrical power decreasing during worm climate period, especially in summer.

Power output from the plant can be expressed :

$$\boldsymbol{Pe = \eta_e \eta_m \left(Pt - Pc \right)} \tag{1}$$

Mechanical power from the turbine unit and to the compressor unit are respectively:

$$Pt = \dot{m}_f c_p \left(T_3 - T_{4'} \right) = \dot{m}_f c_p T_3 \left(1 - \frac{T_{4'}}{T_3} \right) = \tag{2}$$

$$\dot{m}_f c_p T_3 \left(1 - \frac{1}{\beta^{\lambda \eta_{pt}}} \right)$$

$$Pc = \dot{m}_a c_p \left(T_{2'} - T_1 \right) = \dot{m}_a c_p T_1 \left(\frac{T_{2'}}{T_1} - 1 \right) = \tag{3}$$

$$\dot{m}_a c_p T_1 \left(\beta^{\lambda / \eta pc} - 1 \right)$$

Combining the formula above reported it can be written:

$$Pe = \eta_e \eta_c \begin{pmatrix} \dot{m}_f c_p T_3 \left(1 - \frac{1}{\beta^{\lambda \eta_{pt}}} \right) \\ - \dot{m}_a c_p T_1 \left(\beta^{\lambda / \eta pc} - 1 \right) \end{pmatrix} \tag{4}$$

$$Pe = \eta_e \eta_c \dot{m}_c \begin{pmatrix} (1+\alpha) c_p T_3 \left(1 - \frac{1}{\beta^{\lambda \eta_{pt}}} \right) - \\ \alpha c_p T_1 \left(\beta^{\lambda / \eta pc} - 1 \right) \end{pmatrix} \tag{5}$$

Last formula highlights the relationship among electrical power output, environmental temperature, turbine inlet and outlet temperature, air and fuel rates.
The maximum available heat recovery from flue gas is:

$$\boldsymbol{\dot{Q} = \dot{m}_{gas} c_p \left(T_{4'} - T_{ucr} \right)} \tag{6}$$

where specific heat values are averaged in temperature ranges considered.
From technical data of an existing 5 MW gas turbine CHP gas plant it has been possible to plot by interpolation the diagrams above reported, which represent the electrical power output, the flue gas rate and the T4' temperature vs environmental temperature (see figg. 1,2,3).

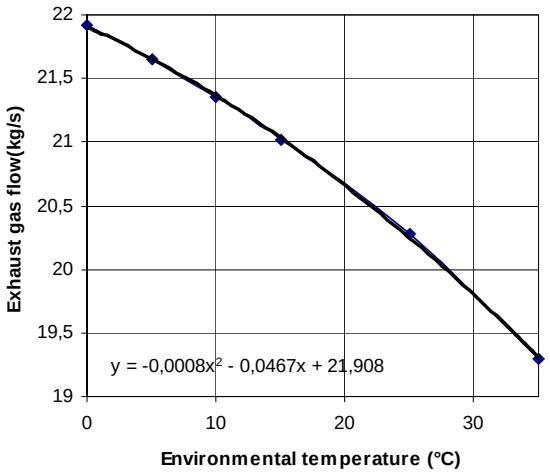

Figure 2: Turbine data.

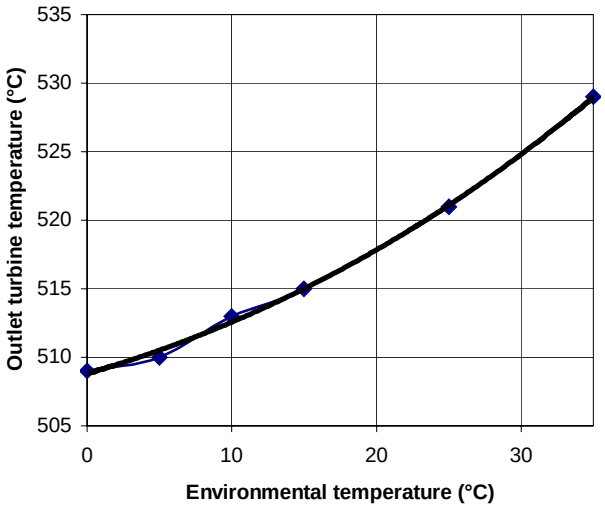

Figure 3: Turbine data.

OPTIONS ANALYSIS

The analysis regards the evaluation of technical and economical advantage coming from the installation of an absorbption cooling system or a CFC one, in order to cool inlet air to the compressor unit in a 5 MWe cogeneration plant. In both cases air temperature after cooling is set on 10 °C or more, so not very hard cooling are considered: that's to avoid turbine surcharge, but also because the temperature of available cool water is in the range 7-12 °C.
Different maximum cooling powers have been considered, together with the chance to reduce the load to 50%, with a minimum air cooled temperature value of 10°C. The two different cooling systems have been compared basing the analysis on electrical and thermal output without inlet air cooling (see Tab.1):

T(environment)	0°C	15°C	35°C
Electrical output	5577 kW	5142 kW	4423 kW
Thermal output	8776 kW	8560 kW	8134 kW

Table1: Nominal power output of the plant without air cooling

1. Absorbption chiller dedicated to air cooling and fed by Heat Recovery Steam Generator (HRSG) integrated by traditional boiler, in order to keep constant the reference thermal energy (see Fig.4).

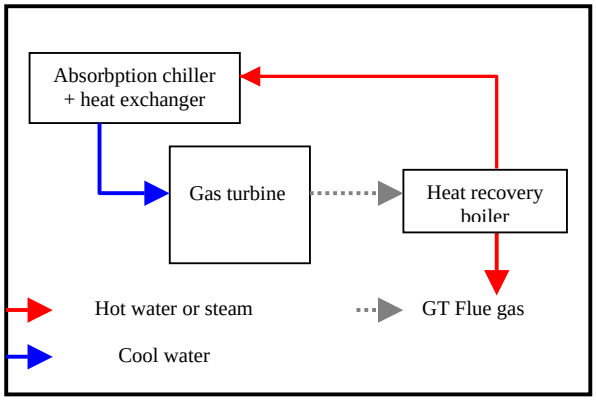

Figure 4: First option scheme.

.

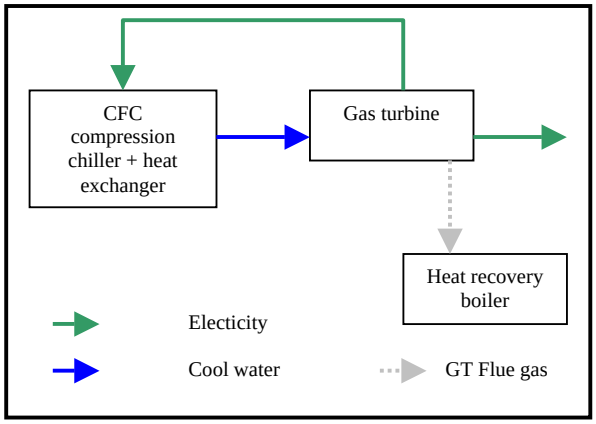

Figure 5: Second option scheme.

Naples meteorological characteristic has been the reference for daily temperature all year long. Temperature graph along the day has been assumed to be variable between a lower and a upper value, as shown in fig.6.

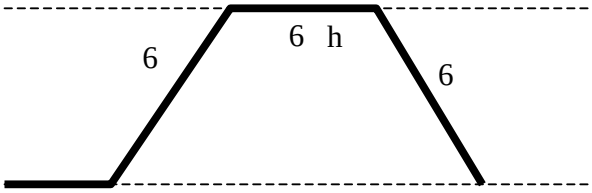

Figure 6: Daily Environmental temperature graph.

For both technical solution and for each cooling power, the number of operating hours of the cooling system has been calculated, in a typical day: for each cooling power (60, 120, 260, 360 KW), air temperature downstream the heat exchanger can decrease lower than 10°C, (which is temperature of the cold water stream) depending on environment initial temperature, limiting the operation time of the system and so this economical advantage; for this reason the cooling system has been considered to be variable in its load thru 50% min.

The positive variation of electrical production gained due to air cooling, with respect to traditional configuration, has been calculated all year long and translated in money considering a 0.12 €/kWh value.

Starting from cooling power required and considering a COP varying from 0.65 to 1.21 for absorption system, the global thermal energy to the cooling system has been calculated and translated in money, considering a 0.35€/kg cost for fuel and a boiler thermal efficiency equal to 0.90. In a similar way the case of electrically fed cooling system, a COP varying from 2.5 to 3.5 has been considered, in order to evaluate the electrical energy required to air cooling, which must be subtracted from total electrical output of the gas turbine coupled generator.

It has been considered also the thermal energy variation obtained from HRSG, due to a lower inlet temperature at the boiler, with respect to traditional configuration; finally the increase of fuel required from gas turbine, due to cooler inlet air, has been evaluated in both cases.

It has to be remarked also the influence of air humidity, which increases cooling power, especially in summer.

COP	0,65	1,1	1,2
P=60kW	16550	26769	28110
P=160kW	12182	33087	35832
P=260kW	361	29311	33113
P=360kW	-8046	25566	29979

Table 2: Annual economical benefit from absorption system (euro).

COP	2,5	3	3,5
P=60kW	23698	26669	28792
P=160kW	26804	32884	37227
P=260kW	20611	29030	35044
P=360kW	15464	25239	32222

Table 3: Annual economical benefit from electrical cooling system (euro).

NUMERICAL RESULTS

Through reported diagrams, electric energy, thermal one and efficiencies of two plant configurations are compared. Data are referred to one year period, with cooling system operating in hours which respect the restrictions before shown.

In the absorbption chiller configuration electrical output is clearly higher than configuration with cooling system (1.3 – 2.3 % more and 1 – 1.4 % more respectively, with respect to reference solution); in fact electrical cooling system is fed by part of electrical output of machine itself which, for not so high cooling power and not so low COP, presents electrical efficiency quite similar to reference configuration and higher thermal output (0.2-0.4%) with thermal efficiency lower than reference values (0.7-1.3%).

About absorbption chiller configuration it can be noticed that both electrical output surplus, and efficiency delta (0.1-0.2%) , increase with cooling power. On the contrary, thermal energy output and thermal efficiency, decrease, as expected, with cooling power increasing. In particular way thermal efficiency decreases by 1.7-2.3 %and energy by 0.6-1%.

About exergetic analysis, exergetic efficiency has been evaluated, as ratio between output exergy and input one for the system:

$$\eta_{ex} = \frac{Ee + Et\left(1 - T_0 / T_{ml}\right)}{Ep} \qquad (7)$$

Exergy associated to electrical energy is equal to electrical energy itself, while exergy associated to thermal one is reduced by Carnot factor, calculated supposing that thermal energy is distributed at T_{ml} =130 °C. Input exergy is considered to be equal to fuel heat value.
From data reported it can be remarked that exergetic efficiency is lower with respect to reference configuration, especially for cooling system case and decreases with cooling power increasing.
About economic benefit derived from installation of such a system, from the analysis of data reported in Tab. 3, we can conclude that it depends strongly upon unit prices applied, once considered the investment cost. Anyway such a system is certainly to be well considered in case that a cooling machine is already available in the plant, with not so low COP efficiency.

ABSTRACT

In this paper, the thermoeconomic concept is applied to the optimization of a double-effect H_2O/LiBr VAR system, aimed at minimizing its overall product cost. Here, a simplified cost minimization methodology based on the Exergetic Cost Theory with negentropy concept is applied to calculate the economic costs of all the internal flows and products of the system. Once these costs are determined, an improved design configuration of the system is obtained through an iterative improvement procedure using sequential local optimization of the components of the system. Finally, sensitivity analysis shows that the optimal values of the decision variables are negligible with changes in the fuel cost.

INTRODUCTION

The refrigeration-based industries are facing challenges mainly from the ozone layer depletion and the global warming effects. It has directed the research trend towards the search for alternative refrigerants and alternative technologies [1]. In this regard, vapour-absorption refrigeration (VAR) systems appear to be a promising option. However, these systems still have lower COP with higher investment cost compared to their vapour-compression counterpart. This demands for performance enhancement along with reduction in investment cost. In this respect, the Exergetic Cost Theory (ECT) [2] is one of the better tools as it provides a common platform for both thermodynamics and economics. The research so far has put the thermoeconomic optimization methodologies to a maturity level. The works of Tsatsaronis and his coworkers [3], Valero and his coworkers [4,5], Frangopoulos [6], von Spakovsky [7], ect. have contributed towards this development. The applications are mainly focused on large cogeneration and combined power plants, chemical plants, etc. [3-7]. However, applications like refrigeration and air-conditioning have higher rates of energy consumption and poor efficiency, and therefore, deserve greater attention. Regarding the optimization of refrigeration systems, the notable contributions are seen from d'Accadia and de Rossi [8], and Wall [9] in compression refrigeration, Misra et al. [10,11] in single-effect H_2O/LiBr absorption refrigeration, and Sahoo et al. [12] in NH_3/H_2O absorption refrigeration system.

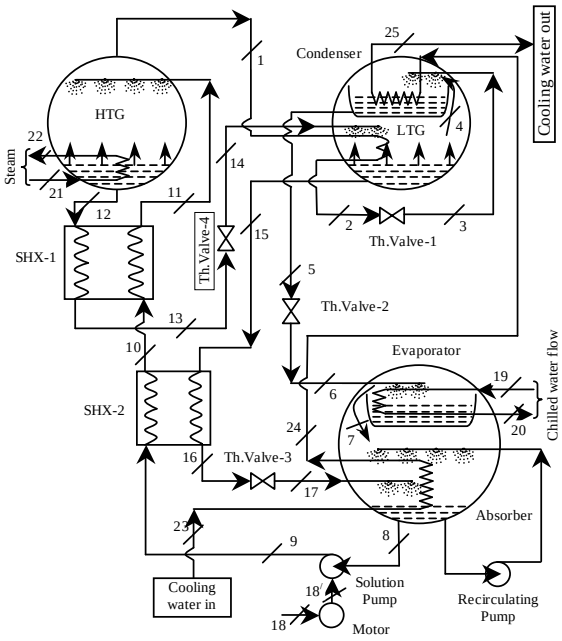

Figure 1: Schematic diagram of a double-effect H_2O/LiBr vapour absorption refrigeration system

ASSUMPTIONS USED IN THE ANALYSIS

Figure 1 shows the schematic diagram of a double-effect H_2O/LiBr VAR system having a cooling capacity of 2731 kW (about 780 TR). For the purpose of analysis the following assumptions are made:

- The system is in steady state.
- The refrigerant at the condenser and the evaporator exits are in saturated states.
- The refrigerant vapour and the weak solution of refrigerant leaving the LTG, and the strong solution of refrigerant leaving the absorber are in saturated states.
- Pressure losses in all the heat exchangers and the pipelines are negligible.
- The reference environmental state is 25^0C (T_0) and 1 atmospheric pressure (p_0).
- To avoid crystallization of the solution, the temperature of the solution entering the throttling valve should be at least 5^0C above crystallization temperature.

- The cooling water first enters the absorber at 27^0C, then passes through the condenser, and finally it is rejected by the system at 35^0C.
- The water to be chilled enters the evaporator at 20^0C and leaves at 10^0C.

Based on these assumptions, a workable initial design, referred as the Base Case, is developed for the system shown in Fig.1 with the following data: t_{htg}=157^{0}C, t_{ltg}=94^{0}C, t_c=40.3^{0}C, t_e=4.1^{0}C, t_a=39.4^{0}C, χ_{he1}=60%, χ_{he2}=60%, η_p=75%, and η_m=90%. In the analysis, the properties of water/steam are obtained from correlations provided by Irvine and Liley [13]. The properties of LiBr solution are taken from the work of Chua et al. [14].

THERMODYNAMIC ANALYSIS

Exergy measures the true thermodynamic losses of a system qualitatively as well as quantitatively. In the absence of magnetic, electrical, nuclear, surface tension effects, and considering the system is at rest relative to the environment, the total exergy of a system becomes:

$$B = B^{Ph} + B^{Ch} \quad (1)$$

The physical exergy component is calculated using the following relation:

$$B^{Ph} = \dot{m}\left[(h - h_0) - T_0(s - s_0)\right] \quad (2)$$

The calculation procedure of the chemical exergy of various substances based on standard chemical exergy values of respective species is widely discussed by Bejan et al. [15], Ahrendts [16], and Szargut et al. [17]. In the VAR system considered here, the chemical exergy of the flows for water can be calculated using the following relation:

$$B^{Ch}_{H_2O} = \dot{m}\left(z_{H_2O} / M_{H_2O}\right) e^0_{Ch,H_2O} \quad (3)$$

where e^0_{Ch,H_2O} is the standard chemical exergy of water and its value is taken from Ahrendts [16]. As there is no chemical reaction in the components of the VAR system, the chemical state of the absorbent remains constant throughout the absorber circuit. But, changes in chemical composition lead to changes in chemical exergies. In this analysis the change in chemical exergy of LiBr is not considered. This assumption, however, introduces a small error [10]. Using these, the exergy at various state points is calculated.

THERMOECONOMIC ANALYSIS

In order to analyze the system from thermoeconomic point of view, its productive structure must be considered by attributing a well defined role, i.e. fuel, product or loss, to each physical flow entering or leaving them [2-6]. This is quite easy for the HTG, LTG, evaporator, pump, solution heat exchanger-1 (SHX-1) and solution heat exchanger-2 (SHX-2), where exergy of the product stream is increased. Since the product cannot be defined readily for the heat dissipative devices, i.e. the four throttling valves, they are considered together with the components they serve. With regard to the condenser and the absorber, which reject heat to the environment, the concept of negentropy is used [8,11]. That is to consider the reduction of entropy induced for the outflow as product of the system. The negentropy flows do not have any significance as for real operation of the plant, nor appear in the energy and exergy balances. But, it represents a physical flow that can be introduced to which the cost of fuels entering these devices is attributed. This cost is then distributed among the remaining components of the system. These considerations lead to the 'Productive Structure' of the system as shown in Fig. 2. The system is considered to be composed of eight productive units and two fictitious units. In the two fictitious units, the homogeneous products are distributed among more than one unit.

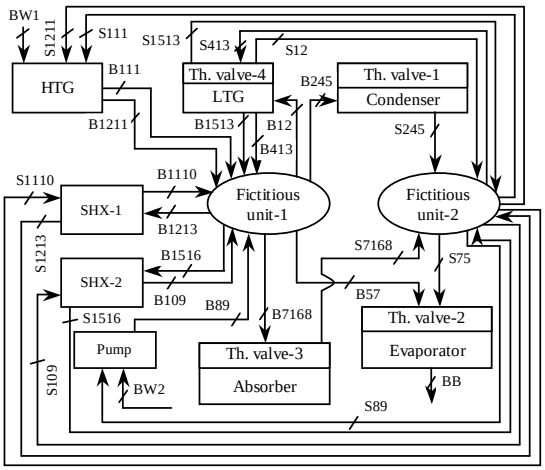

Figure 2: Productive structure of the system

Thus, the flows that interrelate the structure are either exergy flows (denoted by '*B*') or have same dimensions, in case of negentropy flows (denoted by '*S*'). In the fictitious unit-1, the increase of the exergy in the HTG, LTG, pump, and the two solution heat exchangers is divided into six flows (*B*12, *B*245, *B*57, *B*7168, *B*1213, and *B*1516) corresponding to the decrease in the exergy in the LTG, condenser, evaporator, absorber, SHX-1, and

SHX-2. As far as the negentropy flow is concerned, the negentropy produced in the LTG (*S*12 and *S*1315), condenser (*S*245), the absorber (*S*7168), and the two solution heat exchangers (*S*1213 and *S*1516) is distributed among the HTG, LTG, evaporator, pump, and the two solution heat exchangers through flows *S*111, *S*1211, *S*413, *S*75, *S*89, *S*1110, and *S*110 This distribution is done through the fictitious unit-2.

The annual levelized investment cost associated with the k[th] component is calculated as

$$\dot{Z}_k = \dot{Z}_k^{CI} + \dot{Z}_k^{OM} = \xi Z_k + \beta_k Z_k \quad (4)$$

where, ξ is the capital recovery factor and β_k is O&M costs associated with the total investment cost. The calculation of $\dot{Z}_k$ is shown in Appendix-A. For simplicity, we assume β_k =1.25% of total investment cost of each component [3,15].

According to the ECT [2], now it is possible to obtain the exergetic and thermoeconomic costs with their unit values of all the flows that appear in this structure. The exergetic cost, B^*, and the economic cost, $\dot{C}$, of an exergy flow (B) are defined, respectively, as the amount of exergy and the economic resources required to obtain that flow. For a flow, the unit exergetic cost (k^*) is the exergetic cost per unit of exergy and the unit thermoeconomic cost (c) is the thermoeconomic cost per unit of exergy of that flow. These costs are calculated by formulating respective balance equations for each productive unit of the system using the propositions formulated by Lozano and Valero [2]. For example, the exergetic cost balance equation along with other balance equations for the HTG are written as

$$B^*_{BW1} - B^*_{B111} - B^*_{B1211} + B^*_{S111} + B^*_{S1211} = 0 \quad (5)$$

$$B^*_{BW1} = BW1 \quad (6)$$

$$k^*_{B111} = k^*_{B1211} \Rightarrow B^*_{B111} - \left(\frac{B111}{B1211}\right) B^*_{B1211} = 0 \quad (7)$$

$$k^*_{S111} = k^*_{S1211} \Rightarrow B^*_{S111} - \left(\frac{S111}{S1211}\right) B^*_{S1211} = 0 \quad (8)$$

Similarly, the thermoeconomic cost balance equation along with other cost balance equations for the HTG are written as

$$\dot{C}_{BW1} - \dot{C}_{B111} - \dot{C}_{B1211} + \dot{C}_{S111} + \dot{C}_{S1211} = -\dot{Z}_{htg} \quad (9)$$

$$\dot{C}_{BW1} = \Pi_{BW1} \quad (10)$$

$$c_{B111} = c_{B1211} \Rightarrow \dot{C}_{B111} - \left(\frac{B111}{B1211}\right) \dot{C}_{B1211} = 0 \quad (11)$$

$$c_{S111} = c_{S1211} \Rightarrow \dot{C}_{S111} - \left(\frac{S111}{S1211}\right) \dot{C}_{S1211} = 0 \quad (12)$$

In this system, there are ten productive units including two fictitious units and 29 flows. Thus, a total of 10 cost equations are formulated from the cost balances, i.e. $\overline{A}\,\overline{B}^* = 0$ and $\overline{A}\,\overline{\dot{C}} = \overline{\dot{Z}}$. There are two flows entering the system, i.e. the fuels for the system: *BW*1 and *BW*2, which form two equations for the system, i.e. $\overline{\alpha}_f\,\overline{B}^* = \overline{\omega}$ and $\overline{\alpha}_f\,\overline{\dot{C}} = \overline{\Pi}$. The HTG, LTG, SHX-1, SHX-2, fictitious unit-1, and fictitious unit-2 have products composed of several flows, which provide the remaining 17 equations, i.e. $\overline{\alpha}_x\,\overline{B}^* = 0$ and $\overline{\alpha}_x\,\overline{\dot{C}} = 0$. The coefficients of the variables on the LHS of these equations form the coefficient matrix, i.e. $\overline{\overline{A}} = \left[\overline{A} : \overline{\alpha}_f : \overline{\alpha}_x\right]^t$. The terms on the RHS of these equations form the vectors $\overline{\overline{Y}}_B = \left[0 : \overline{\omega} : 0\right]^t$ and $\overline{\overline{Y}}_Z = \left[\overline{\dot{Z}} : \overline{\Pi} : 0\right]^t$ for exergetic cost and thermoeconomic cost, respectively. In matrix form, the exergetic and thermoeconomic cost balances, respectively, are expressed as:

$$\overline{B}^* = \overline{\overline{A}}^{-1}\,\overline{\overline{Y}}_B \quad (13)$$

$$\overline{\dot{C}} = \overline{\overline{A}}^{-1}\,\overline{\overline{Y}}_Z \quad (14)$$

By solving these two matrix equations, B^* and $\dot{C}$ for each flow are determined, which are summarized in Table 1 for the Base Case.

THERMOECONOMIC OPTIMIZATION

The objective function is to minimize the economic cost of the final product of the system. The initial values for the overall optimization can be obtained by means of sequential, local optimization of the individual productive units of the system, each one considered as if it were independent of others. The minimum thermoeconomic product cost of each individual units (say, unit *k*) of the system, with respect to the local decision variable x_k, can be expressed as:

$$\underset{\{x_k\}}{\text{Minimize}} \quad c_{P,k} = \sum_k \left(c_{F,k} \frac{B_{F,k}}{B_{P,k}} \right) + \frac{\dot{Z}_k}{B_{P,k}} = \sum_k \left(c_{F,k}\, k_k \right) + \frac{\dot{Z}_k}{B_{P,k}} \quad (15)$$

where, k_k is function of the decision variable x_k.

Table 1. Exergetic and thermoeconomic costs of flows of the system (base case).

The term, $\dot{Z}_k$, is expressed as function of the decision variable x_k and the exergetic product of the unit $B_{P,k}$ (Appendix-B). Considering $c_{F,k}$ and $B_{P,k}$ as constants, the cost $c_{P,k}$ becomes sole function of the decision variable x_k. Applying standard procedures, such as, golden section algorithm, polynomial approximation methods etc. Eq. (15) can be easily solved.

^ Rupees (*Rs.) is the Indian Currency. Equivalent approximate U.S. Dollar ($) value is Rs. 45.00*

The local decision variables considered for the double-effect VAR system are: t_{htg} for the HTG, t_{ltg} for the LTG, t_c for the condenser, t_e for the evaporator, t_a for the absorber, η_p for the solution pump, χ_{he1} for the SHX-1, and χ_{he2} for the SHX-2. Using Eq. (15), the objective functions for the local optimization of the components are formulated. For example, the local objective function for the HTG is formulated as

$$\begin{aligned} & c_{B111} \times (B111 + B1211) \\ & = c_{BW1} \times BW1 + c_{S111} \times (S111 + S1211) + \dot{Z}_{htg} \\ & \Rightarrow c_{B111} = c_{BW1} \times \frac{BW1}{B111 + B1211} \\ & + c_{S111} \times \frac{S111 + S1211}{B111 + B1211} + \left(\frac{\xi + \beta}{\tau} \right) a_{htg} \left(\frac{A_{hx,htg}}{A_{hx,tot}} \right)^{b_{htg}} \end{aligned} \quad (16)$$

Now for constant values of the exergetic product and the unit thermoeconomic cost of the fuel, the product cost (c_{B111}) of the HTG becomes sole function of its local decision variable, t_{htg}. Using the golden section algorithm, the optimum values of x_{htg}^{OPT} and $c_{P,htg}^{OPT}$ are found out. For other components same procedure is followed.

However, such one step optimization may not lead to near global optimum solution for the overall system. This is due to the complex interrelations of the various units of the system, such as variation of a local variable of one unit may have serious impact on the thermodynamic as well as economic behaviour of the other units of the system. Thus, an iterative procedure, which leads towards the minimum product cost, is used to find out an improved cost-effective design of the system. In this iterative procedure, the following parameters are evaluated in each iterative step to take necessary judgment regarding the changes in the decision variables from one iterative step to the next:

- The thermoeconomic variable, $\Delta c_{P,k}$, is defined to show the percentage variation of the product cost of a particular unit with its optimum value, i.e.
$$\Delta c_{P,k} = 100 \times \left(c_{P,k} - c_{P,k}^{OPT} \right) / c_{P,k}^{OPT} \quad (17)$$
- The product cost of the overall system, i.e.
$$\dot{C}_{P,tot} = \dot{C}_{F,tot} + \dot{Z}_{tot} \quad (18)$$

In the iterative procedure engineering judgments and critical evaluations are used in deciding on the changes made to the decision variables from one iterative step to the next. The criteria followed for this is as follows:

- Determination of the local optimum by formulating the objective functions for each productive unit.
- Calculation of $\Delta c_{P,k}$ and $\dot{C}_{P,tot}$ for a change in one decision variable in a certain step, while keeping all other decision variables constant.
- If the effect on the above parameter is positive, i.e. $\dot{C}_{P,tot}$ has reducing trend, then in the next iterative step this variable becomes a candidate for a similar change, otherwise, this variable remains unchanged in the next iterative step.
- Repetition of the above three steps for the other decision variables.

Table 2: Variables obtained during the optimization of the system from base case to the optimum case

Table 2 summarizes the stage-by-stage iteration results from the Base Case to the Optimum Case. With the study of the positive/negative effects of the changes in the decision variables, which is governed by $\Delta c_{P,k}$, on the product cost, the decision has been taken on the changes of these decision variables from one iterative case to the next. The process of iterations continues till the difference in the objective function, i.e. the product cost, between successive iterations becomes negligible.

Table 3: Comparative results between the base case and the optimum case of the system

Table 3 represents a comparative study of the final cost optimal configuration with the Base Case. The overall thermoeconomic cost of the product (chilled water) is decreased by about 12.0 % and the corresponding decrease in the fuel costs is 17.2%. Also, the results show a significant reduction in the exergy destruction cost (about 21.5%) and exergy loss cost (about 8.1%). The corresponding increase and decrease in the investment costs of the components are also shown in the same table. The greater investment is mainly in the LTG. Incidentally, the overall investment cost of the system almost remains same. It is because increase in investment cost of some components is compensated by reductions in investment cost of some other components. The exergetic efficiency and the COP are both increased by about 20.7%.

In order to remain competitive, it is crucial for any system to be robust with respect to the uncertainty pertaining to frequently changing parameters with time. In general, the economic parameters, such as the fuel costs and the capital investments, are the

uncertain terms as they vary with time. Therefore, it is necessary to investigate their effect on the decision variables and the product costs of the optimal solution. In this work, the variation with respect to capital investment cost is not considered, as once installed the system components are not supposed to alter in response to change in their capital investment. Hence, only the fuel cost is considered. To study the robustness of the optimal solution, analysis is carried out for 20%, 40%, 60%, 80%, and 100% increase in the fuel cost for the operating decision variables and the product costs of the system. Figure 3 shows the variation of the product cost with respect to the increase in the fuel cost. The trend of this increase in the product cost is same as that of the fuel cost variation and Table 4 presents the percentage change in the decision variables with respect to the present optimum. It is seen that the change in the decision variables with respect to the change in the fuel cost is very small; in fact, it is well within ± 1.5%. Therefore, it can be concluded that the decision variables of the system are not very sensitive to the changes in the fuel cost (uncertainty) in the close vicinity of the optimal solution space.

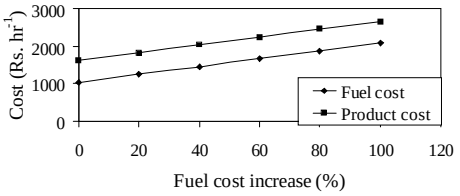

Figure 3: Sensitivity of the product cost (Rs. hr^{-1}) with respect to increased fuel cost (%)

		Changes in decision variables (%)							
		t_{htg}	t_{ltg}	t_c	t_e	t_a	χ_{shx1}	χ_{shx2}	η_p

CONCLUSIONS

The thermoeconomic optimization of the double-effect H_2O/LiBr VAR system, presented in this paper, provides one cost-effective design configuration. The results clearly show the performance improvement of the system with almost same investment cost to produce the cooling effect at a reduced cost. However, the application requires adequate attention to the following points:

- Proper definition of the productive structure of the system.
- Proper selection of local decision variables for various subsystems.
- Reliability of the cost information available.
- Proper engineering judgment to relate the costs with thermodynamic parameters.

APPENDIX-A

Calculations for the Investment Costs and Capital Recovery Factor

The investment cost of the double-effect system is taken the THERMAX Ltd., Pune, India [18]. For the purpose of analysis, the HTG, LTG, condenser, evaporator, absorber, SHX-1, and SHX-2 of the system are considered as simple heat exchangers. The costs of these heat exchangers are calculated based on their area-weighted average after duly deducting the investment costs of pump and motor and using the following relation [8]:

$$Z_k = Z_{R,k}.\left(\frac{A_k}{A_R}\right)^{0.6} \qquad \text{(A-1)}$$

where $k = htg, ltg, c, e, a, he1, he2$

The subscript 'R' represents the reference component of a particular type and size. The investment cost of the pump and the motor can be written respectively as [8,9]:

$$Z_p = Z_{R,p}\left(\frac{\dot{W}_P}{\dot{W}_{R,P}}\right)^{m_p}\left(\frac{1-\eta_{ip}}{\eta_{ip}}\right)^{n_p} \qquad \text{(A-2)}$$

$$Z_m = Z_{R,m}\left(\frac{\dot{W}_m}{\dot{W}_{R,m}}\right)^{m_m}\left(\frac{1-\eta_{im}}{\eta_{im}}\right) \qquad \text{(A-3)}$$

The cost of electric energy is taken as Rs. 5.0 per kWh, based on the commercial power tariffs in India (i.e. about $ 31.0 per GJ of energy). The capital recovery factor (ξ) is given by [8,15]:

$$\xi = \left(\frac{i_r.(1+i_r)^{N_y}}{(1+i_r)^{N_y}-1}\right) \text{ yr}^{-1} \qquad \text{(A-4)}$$

An interest rate of 8%, 20 years of life span and 1800 hours of operation per year are used in the analysis presented in this paper.

APPENDIX-B

Expression for investment cost as functions of exergetic product and local decision variable for Eq. (15)

In this work, since all the major components are heat exchangers, the decision variables are related to their areas. Thus, the effect of changing the decision variable can be registered not only in exergetic product of the component, but also in the investment cost of that component. Then by generating the investment cost data and corresponding exergetic product of a particular component for a range of x_k, Z_k of the component is expressed as

$$Z_k = a\left(\frac{A_{hx,k}}{A_{hx,tot}}\right)^b B_{P,k} \qquad \text{(B-1)}$$

By plotting the data between $\left(A_{hx,k}/A_{hx,tot}\right)$ and $\left(Z_k/B_{P,k}\right)$, the parameter '*a*' and the exponent '*b*' can be found out through curve fitting technique. For example, considering the case of HTG, the plot between $\left(A_{hx,htg}/A_{hx,tot}\right)$ and $\left(Z_{htg}/B_{P,htg}\right)$ for a given range of t_{htg} is presented in Fig. 4.

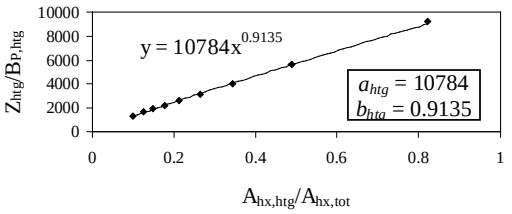

Figure 4: Plot of investment cost equation (Eq. 15) for the HTG ($148^0 \le t_{hta} < 160^0$C)

ABSTRACT

A cogeneration system based on a reciprocating natural gas engine, a heat recovery steam generator (HRSG), an absorption refrigeration system (ARS) and a cooling tower (CT) is presented as an alternative to the current UNICAMP University Hospital (HC) utility plant. The objective of this work is to do a thermoeconomic analysis of a cogeneration system proposed for HC. Three thermoeconomic methodologies were applied to the cogeneration system. Three methodologies were based in the Theory of the Exergetic Cost, Functional Analysis and Functional Analysis using negentropy. The results show that there are differences in the costs of power, steam and refrigeration (cold) production which result from application of the methodologies.
Keywords: Cogeneration, thermoeconomics

HC	UNICAMP University Hospital

INTRODUCTION

The cogeneration is defined as the simultaneously production of electric (or mechanic) power and thermal energy, starting from a same primary energy source. It improves the use of the fuel energy minimizing the effects of the second law of thermodynamics, which foresees an obligatory loss in the transformation of energy from one form into another. The cogeneration has the main intention of to obtain a better use of the primary fuels; this is why it is considered a fundamental alternative in the energy rational use programs.

In the last years, a market tendency is perceived in the direction to the development and implantation of technologies and processes less aggressive to the environment, tendencies motivated, many times, by environmental protection laws. The cogeneration is an alternative to accomplish these laws, once it reduces the emissions of greenhouse effect gases and contributes to reach the objectives of the Kyoto Protocol.

In Brazil, the cogeneration is used in very specific cases, due to the availability and low cost of hydro-power. In cogeneration projects, the electricity

represents the revenue for the investor, while natural gas is a cost. The economic viability of natural gas-fired cogeneration in Brazil has as major barrier the value of electricity and natural gas price. The ratio of these two values is considered low to be viable some cogeneration projects. In this work a cogeneration system is designed to use natural gas as an alternative to the UNICAMP University Hospital (HC) and a thermoeconomic analysis is performed. The assessment of this system for the HC is part of the ECOGERA project, which is realized by the NIPE (Interdisciplinary Center of Energy Planning).

COGENERATION SYSTEM DESCRIPTION

In this work the cogeneration system is basically composed by an internal combustion engine, a heat recovery steam generator (HRSG), an absorption refrigeration system (ARS) and a cooling tower (CT). The details are shown in Figure 1.

The internal combustion engine is a Waukesha - VHP9500G, and has 1075 kW of nominal capacity. The fuel supplied to the engine is natural gas. The water used for cooling the jacket and auxiliary circuit of the engine will be used later as thermal energy source in the ARS. The engine exhaust gas has high quality of thermal energy; it will be used later in the HRSG.

The HRSG is of two pressure level, it takes advantage of the thermal energy contained in the exhaust gas of the engine. It has two pre-heaters, one of low pressure for heating of water that will go to the de-aerator, and the other of high pressure, after the exit of the feeding bomb. A part of the produced steam is injected later in the de-aerator.

The ARS uses as a work fluid, LiBr-H_2O; it is of single effect. The heat of the engine cooling water is used as energy source. The condenser and evaporator work in a temperature of 40ºC and 5ºC respectively. The condenser and absorber need to be cooling; a current of water is used for this.

The CT is used for cooling the water that was used to cool the absorber and condenser of the ARS. Due to the evaporative cooling of the CT, it needs replacement water to compensate the water that evaporates and goes to atmosphere with the dry air.

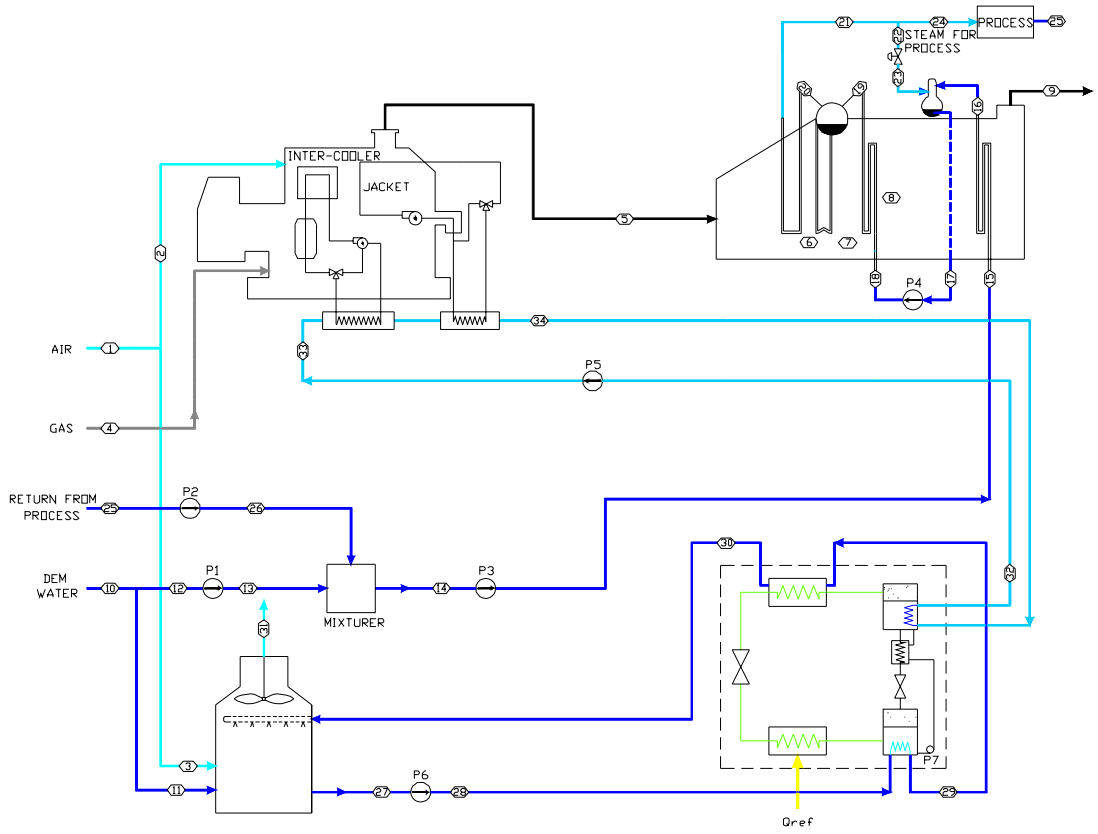

Figure 1: Sketch of proposed cogeneration system

ENERGETIC AND EXERGETIC ANALYSIS

Gonzales and Nebra [4] realized an energetic and exergetic analysis for the cogeneration system shows in Figure 1. The energetic analysis showed that at maximum load conditions, the cogeneration system produces 1052 kW of electricity, 1335 kg/h of process steam and 770 kW of refrigeration (cold production). Generally, the engine first law efficiency is 30% and the COP of the absorption refrigeration system is 0.7. The cogeneration system gets to save up to 28.5% of fuel in comparison with the separate production of heat and electricity. The Energy Utilization Factor reaches 88%. The exergetic analysis showed that the largest irreversibility happened in the system is due to the engine, this participates in the average with 78% of the total irreversibility. The other pieces of equipment that also contribute to the total irreversibility are the HRSG (13.5%), ARS (3%) and CT (4.7%). The optimization showed that the cogeneration system obtains its best performance with the smallest exhaust gas temperature of the HRSG (T9) and the maxim engine load percentage. The Table 1 presents the thermodynamic variable values at each system point (Figure 1), in the state for which the objective function presents a maximum.

THERMOECONOMIC ANALYSIS

Thermoeconomics combines exergy analysis and economic principles that provide information not available, but crucial to the design and operation of a cost-effective system [1].

The Exergeconomic methodology proposed by Tsatsaronis and Pisa [6], consists in the determination of the exergetic and energetic flows, capital and maintenance cost for each unit. An interesting concept introduced also by Tsatsaronis is that of the specific cost, where the cost of the addition of exergy to a current is determined and charged to the unit that make use of that exergy [2].

Cerqueira and Nebra [2] applied thermoeconomical analysis for gas turbine cogeneration problem. Besides, used four thermoeconomical methodologies, to compare the results of the power and heat cost, obtaining a significant difference of these costs for each applied methodology.

Flow	Composition	Temperature (ºC)	Pressure (kPa)	Mass flow (kg/s)
1	Air	25.00	101.30	33.1500
2	Air	25.00	101.30	1.3710
3	Air	25.00	101.30	31.7800

Table 1: Thermodynamics states

In this work, three methodologies based in the Theory of the Exergetic Cost, Functional Analysis and Functional Analysis using negentropy were applied for the HC cogeneration system.

The exergetic cost is defined by the following equation:

$$E^{*} = k.E_{X} \quad (1)$$

The exergetic cost balance in a control volume is given by the following equation:

$$\sum E^*_{e,i} = \sum E^*_{s,j} \quad (2)$$

The monetary cost is defined by the following equation:

$$C = c.E_X \quad (3)$$

The monetary cost balance in a control volume is given by the following equation:

$$\sum C_{e,i} + Z_k = \sum C_{s,j} \quad (4)$$

The theory of the Exergetic Cost

The Theory of the Exergetic Cost (TEC) proposed by Lozano and Valero [5] consists of dividing appropriately the system into sub-systems, identifying the input and output exergetic flows, classifying them in fuels and products. Other authors have also worked with this methodology, proposing different approaches.

Following this methodology the system was separated in 9 control volumes: engine, HRSG (including the de-aerator and the pump 4), absorption refrigeration system and cooling tower (including the pump 6 and 7), mixer, process, pump 1, pump 2, pump 3 and pump 5. The Figure 2 shows the layout used for this evaluation. The fuels, products and losses of the control volumes are presented in the Table 2.

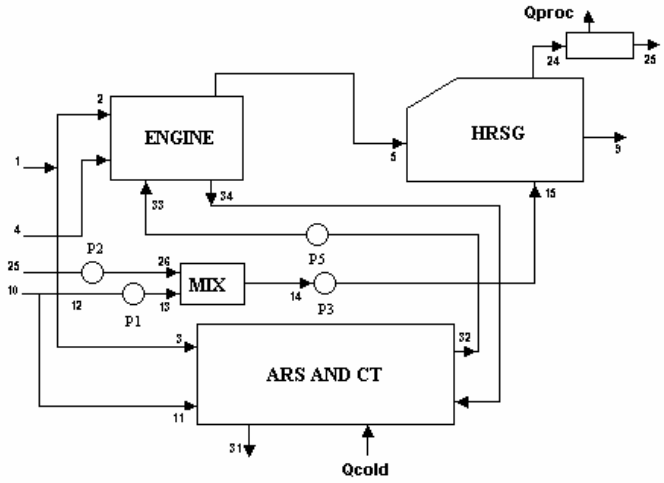

Figure 2: Layout for the Theory of the Exergetic Cost analysis

The exergetic and monetary cost balance in each control volume of the Figure 2 shows the following equations:

Engine

$$E^*_2 + E^*_4 + E^*_{33} = E^*_{em} + E^*_5 + E^*_{34} \quad (5)$$

$$C_2 + C_4 + C_{33} + Z_{motor} = C_{em} + C_5 + C_{34} \quad (6)$$

HRSG

$$E^*_5 + E^*_{15} + E^*_{B4} = E^*_{24} + E^*_9 \quad (7)$$

$$C_5 + C_{15} + C_{B4} + Z_{HRSG} = C_{24} + C_9 \quad (8)$$

ARS and CT

$$E^*_{34} + E^*_3 + E^*_{11} + E^*_{B6} + E^*_{B7} = E^*_{Qref} + E^*_{31} + E^*_{32} \quad (9)$$

$$C_{34} + C_3 + C_{11} + C_{B6} + C_{B7} + Z_{SRA+TER} = C_{Qref} + C_{31} + C_{32} \quad (10)$$

Control volume	Fuel	Product	Losses
Engine	$Ex_2+Ex_4-Ex_5-(Ex_{34}-Ex_{33})$	W_e	
HRSG	Ex_5+W_{B4}	$Ex_{24}-Ex_{15}$	Ex_9
ARS and CT	$(Ex_{34}-Ex_{32})+W_{B6}+W_{B7}+Ex_{11}+Ex_3$	Ex_{Qref}	Ex_{31}
Mixer	$Ex_{26}+Ex_{13}$	Ex_{14}	
Pump 1	W_{B1}	$(Ex_{13}-Ex_{12})$	
Pump 2	W_{B2}	$(Ex_{26}-Ex_{25})$	
Pump 3	W_{B3}	$(Ex_{15}-Ex_{14})$	
Pump 5	W_{B5}	$(Ex_{33}-Ex_{32})$	
Process	$(Ex_{24}-Ex_{25})$	$Ex_{Qprocesso}$	

Table 2: Fuels, products and losses for the Theory of the Exergetic Cost analysis

Process

$$E^*_{24} = E^*_{Qproc} + E^*_{25} \quad (11)$$

$$C_{24} + Z_{proc} = C_{Qproc} + C_{25} \quad (12)$$

Mixer

$$E^*_{13} + E^*_{26} = E^*_{14} \quad (13)$$

$$C_{13} + C_{26} + Z_{mist} = C_{14} \quad (14)$$

Pump 1

$$E^*_{B1} + E^*_{12} = E^*_{13} \quad (15)$$

$$C_{B1} + C_{12} + Z_{B1} = C_{13} \quad (16)$$

Pump 2

$$E^*_{B2} + E^*_{25} = E^*_{26} \quad (17)$$

$$C_{B2} + C_{25} + Z_{B2} = C_{26} \quad (18)$$

Pump 3

$$E^*_{B3} + E^*_{14} = E^*_{15} \quad (19)$$

$$C_{B3} + C_{14} + Z_{B3} = C_{15} \quad (20)$$

Pump 5

$$E^*_{B5} + E^*_{32} = E^*_{33} \quad (21)$$

$$C_{B5} + C_{32} + Z_{B5} = C_{33} \quad (22)$$

which Bi is used to indicate the bombs of the Figure 1.

These equations are not enough to determine all the exergetic and monetary costs. Then, to get a equation system with one solution is necessary to arbitrate the following equations:

For exergetic cost

$$k_1 = k_4 = k_{10} = 1 \quad (23)$$

$$k_9 = k_{31} = 0 \quad (24)$$

$$k_3 = k_2 = k_1 \quad (25)$$

$$k_{12} = k_{11} = k_{10} \quad (26)$$

$$k_{34} = k_5 = k_4 \quad (27)$$

$$k_{24} = k_{25} \quad (28)$$

$$k_{34} = k_{32} \quad (29)$$

For monetary cost

$$c_1 = c_9 = c_{31} = 0 \quad (30)$$

$$c_3 = c_2 = c_1 \quad (31)$$

$$c_{12} = c_{11} = c_{10} \quad (32)$$

$$c_{34} = c_{32} = c_4 \quad (33)$$

$$c_5 = c_4 \quad (34)$$

$$c_{24} = c_{25} \quad (35)$$

$$c_4 = 16{,}37854\ \text{US\$/MWh} \quad (36)$$

$$c_{10} = 1{,}5\ \text{US\$/MWh} \quad (37)$$

The results of this analysis are shown in the Table 3.

Table 3: Results with Theory of the Exergetic Cost analysis

Thermoeconomic Functional Analysis

The Thermoeconomic Functional Analysis in a complex thermal installation is understood as a system composed for connected units. Each unit has a unique function (or product) that determines its relation with the others units. This analysis was presented by Frangopoulos [3], it is based on the concept of junctions and distributors of exergy, and on the construction of the functional diagram.

The Figure 3 shows the functional diagram used to analyze the cogeneration system. In this analysis, the exergy hasn't been divided into pressure and thermal associated parts; it was taken as total exergy.

Following this methodology the system was separated in 15 control volumes: engine, HRSG (including the de-aerator and the pump 4), absorption refrigeration system and cooling tower (including the pump 6 and 7), mixer, pump 1, pump 2, pump 3 and pump 5, process, water distributor, air distributor, fuel distributor, electric power distributor, exergy junction and exergy distributor. Each unit generates a product through the consumption of a unique fuel; the fuels and products of the control volumes are presented in the Table 4.

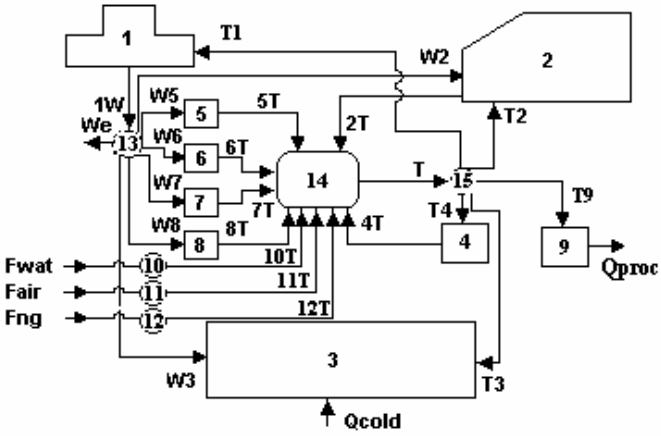

Figure 3 – Functional Diagram

Control volume	Fuels	Products
1. Engine	$T1=(Ex_2+Ex_4-Ex_5)-(Ex_{34}-Ex_{33})$	$1W=W_{engine}$
2. HRSG	$T2=Ex_5-Ex_9$; $W2=W_{B4}$	$2T=Ex_{24}-Ex_{15}$
3. ARS and CT	$T3=(Ex_{34}-Ex_{32})+(Ex_{11}+Ex_3-Ex_{31})$; $W3=W_{B6}+W_{B7}$	$E_{Qref}=Ex_{Qref}$
4. Mixer	$T4=Ex_{26}+Ex_{13}$	$4T=Ex_{14}$
5. Pump 1	$W5=W_{P1}$	$5T=(Ex_{13}-Ex_{12})$
6. Pump 2	$W6=W_{P2}$	$6T=(Ex_{26}-Ex_{25})$
7. Pump 3	$W7=W_{P3}$	$7T=(Ex_{15}-Ex_{14})$
8. Pump 5	$W8=W_{P5}$	$8T=(Ex_{33}-Ex_{32})$
9. Process	$T9=(Ex_{24}-Ex_{25})$	$E_{Qproc}=Ex_{Qprocess}$
10. Water distributor	$Fwat=Ex_{10}$	$10T=Ex_{10}$
11. Air distributor	$Fair=Ex_1$	$11T=Ex_1$
12. NG distributor	$Fng=Ex_4$	$12T=Ex_4$
13. Electric power allocation	1W	W2+W3+W5+W6+W7 +W8+We
14. Exergy junction	2T; 4T; 5T; 6T; 7T; 8T; 10T; 11T; 12T	T=2T+4T+5T+6T+7T+8T +10T+11T+12T
15. Exergy distributor	T	T1+T2+T3+T4+T9

Table 4 – Fuels and products for thermoeconomic functional analysis

The exergetic and monetary cost balance determines in each unit the fuels and products cost. The exergetic and monetary cost balance in each control volume of Figure 3 are performed through the following equations:

Engine

$$E^*_{T1} = E^*_{1W} \quad (38)$$

$$C_{T1} + Z_{engine} = C_{1W} \quad (39)$$

HRSG

$$E^*_{T2} + E^*_{W2} = E^*_{2T} \quad (40)$$

$$C_{T2} + C_{W2} + Z_{HRSG} = C_{2T} \quad (41)$$

ARS+CT

$$E^*_{T3} + E^*_{W3} = E^*_{Qcold} \quad (42)$$

$$C_{T3} + C_{W3} + Z_{ARS+CT} = C_{Qcold} \quad (43)$$

Mixer

$$E^*_{T4} = E^*_{4T} \quad (44)$$

$$C_{T4} + Z_{mixt} = C_{4T} \quad (45)$$

Pump 1

$$E^*_{W5} = E^*_{5T} \quad (46)$$

$$C_{W5} + Z_{P1} = C_{5T} \quad (47)$$

Pump 2

$$E^*_{W6} = E^*_{6T} \quad (48)$$

$$C_{W6} + Z_{P2} = C_{6T} \quad (49)$$

Pump 3

$$E^*_{W7} = E^*_{7T} \quad (50)$$

$$C_{W7} + Z_{P3} = C_{7T} \quad (51)$$

Pump 5

$$E^*_{W8} = E^*_{8T} \quad (52)$$

$$C_{W8} + Z_{P5} = C_{8T} \quad (53)$$

Process

$$E^*_{T9} = E^*_{Qproc} \quad (54)$$

$$C_{T9} + Z_{proc} = C_{Qproc} \quad (55)$$

Exergy Junction and distributor

$$E^*_{T1} + E^*_{T2} + E^*_{T3} + E^*_{T4} + E^*_{T9} = E^*_{2T} + E^*_{4T} + E^*_{5T} + E^*_{6T} + E^*_{7T} + E^*_{8T} + E^*_{Fng} + E^*_{Fair} + E^*_{Fwat} \quad (56)$$

$$C_{T1} + C_{T2} + C_{T3} + C_{T4} + C_{T9} = C_{2T} + C_{4T} + C_{5T} + C_{6T} + C_{7T} + C_{8T} + C_{Fng} + C_{Fair} + C_{Fwat} \quad (57)$$

These equations are not enough to determine all the exergetic and monetary costs. Then, to get an equation system with unique solution it is necessary to arbitrate the following equations:

For exergetic cost

$$k_{Fng} = k_{Fair} = k_{Fwat} = 1 \quad (58)$$

$$k_{T1} = k_{T2} \quad (59)$$

$$k_{T3} = k_{T4} \quad (60)$$

$$k_{T4} = k_{T9} \quad (61)$$

For monetary cost

$$c_{T1} = c_{T2} = c_{T3} = c_{T4} = c_{T9} \quad (62)$$

$$c_{Fng} = 16{,}37854 \text{ US\$/MWh} \quad (63)$$

$$c_{Fwat} = 1{,}5 \text{ US\$/MWh} \quad (64)$$

$$c_{Fair} = 0 \quad (65)$$

The Table 5 shows exergetic and monetary costs calculated for the cogeneration system using the Thermoeconomic Functional Analysis methodology. These results are different from that obtained with the Exergetic Cost Theory. With this methodology is keeping the trend in the unit exergetic cost of the products, however is observed that electricity unitary cost increased and the unitary costs of the steam and refrigeration (cold) production decreased.

Flow	Exergetic cost		Monetary cost	
	k	E*	c (US$/MWh)	C (US$/h)
Fwat	1.000	36.330	1.50	0.05

Qcold	3.757	208.900	182.40	10.14

Table 5: Results with thermoeconomic functional analysis

Thermoeconomic Functional using negentropy

In the Exergetic Cost Theory the cost of the external irreversibility is load to the last unit product, being thus its cost overestimate. The negentropy was used for the external irreversibility evaluation by Frangopoulos. The objective of the negentropy is the costs redistribution: it gives credit or pain the process when it decreases or increases the entropy, respectively.

The negentropy is defined by:

$$S = \dot{m}.T_o.(s - s_o) \quad (66)$$

The negentropy flow for each control volume is give by:

$$N_i = S_i - S_{i-1} \quad (67)$$

"i-1" is the negentropy flow that input into control volume. The negentropy cost is defined by:

$$N_i^* = k_{n,i}.N_i \quad (68)$$

$k_{n,i}$ is the unit negentropy cost

The Figure 4 shows the functional diagram, considering negentropy, used to analyze the cogeneration system. The fuels and products of the control volumes are shows in the Table 6.

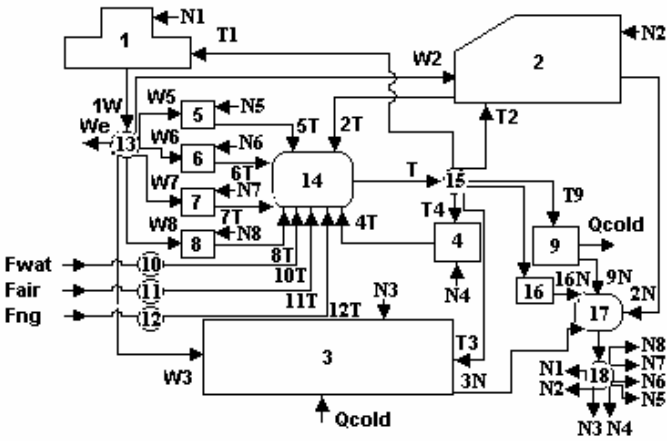

Figure 4: Functional diagram using negentropy for thermoeconomic analysis

Control volume	Fuel	Product
1. Engine	$T1=(Ex_2+Ex_4-Ex_5)-(Ex_{34}-Ex_{33})$ $N1=(S_5-S_4-S_2)+(S_{34}-S_{33})$	$1W=W_{engine}$
2. HRSG	$T2=Ex_5-Ex_9$; $W2=W_{B4}$ $N2=S_{24}-S_{15}$	$2T=Ex_{24}-Ex_{15}$ $2N=S_5-S_9$
3. ARS and CT	$T3=(Ex_{34}-Ex_{32})+(Ex_{11}+Ex_3-Ex_{31})$; $W3=W_{B6}+W_{B7}$ $N3=S_{31}-S_3-S_{11}$	$E_{Qcold}=Ex_{Qcold}$ $3N=S_{34}-S_{32}$
4. Mixturer	$T4=Ex_{26}+Ex_{13}$ $N4=S_{14}-S_{13}-S_{26}$	$4T=Ex_{14}$
5. Pump 1	$W5=W_{B1}$ $N5=S_{13}-S_{12}$	$5T=Ex_{13}-Ex_{12}$

Table 6 – fuels and products for thermoeconomic functional analysis using negentropy

For this methodology three new virtual units had been added: the chimney, the junction and the negentropy distributor. The chimney produces negentropy, necessary to carry the humid air and exhaust gases that leave the cooling tower and HRSG, respectively, until the equilibrium conditions with the environment. The absorption refrigeration system produces negentropy, since it diminishes the entropy of the hot water used in the engine cooling. The HRSG consumes negentropy when the entropy of the water is increased to produce steam, and it produces negentropy when the entropy of the engine exhaust gases is decreased. The engine, the pumps, the mixturer and the cooling tower are pieces of equipment that consumes negentropy.

The exergetic and monetary cost balance determines in each unit the fuels and products cost. The exergetic and monetary cost balance in each control volume of the Figure 4 shows the following equations:

Engine

$$E^*_{T1} + E^*_{N1} = E^*_{1W} \quad (69)$$

$$C_{T1} + C_{N1} + Z_{engine} = C_{1W} \quad (70)$$

HRSG

$$E^*_{T2} + E^*_{N2} + E^*_{W2} = E^*_{2T} + E^*_{2N} \quad (71)$$

$$C_{T2} + C_{N2} + C_{W2} + Z_{HRSG} = C_{2T} + C_{2N} \quad (72)$$

ARS+CT

$$E^*_{T3} + E^*_{N3} + E^*_{W3} = E^*_{Qcold} + E^*_{3N} \quad (73)$$

$$C_{T3} + C_{N3} + C_{W3} + Z_{ARS+CT} = C_{Qcold} + C_{3N} \quad (74)$$

Mixer

$$E^*_{T4} + E^*_{N4} = E^*_{4T} \quad (75)$$

$$C_{T4} + C_{N4} + Z_{mixt} = C_{4T} \quad (76)$$

Pump 1

$$E^*_{W5} + E^*_{N5} = E^*_{5T} \quad (77)$$

$$C_{W5} + C_{N5} + Z_{P1} = C_{5T} \quad (78)$$

Pump 2

$$E^*_{W6} + E^*_{N6} = E^*_{6T} \quad (79)$$

$$C_{W6} + C_{N6} + Z_{P2} = C_{6T} \quad (80)$$

Pump 3

$$E^*_{W7} + E^*_{N7} = E^*_{7T} \quad (81)$$

$$C_{W7} + C_{N7} + Z_{P3} = C_{7T} \quad (82)$$

Pump 5

$$E^*_{W8} + E^*_{N8} = E^*_{8T} \quad (83)$$

$$C_{W8} + C_{N8} + Z_{P5} = C_{8T} \quad (84)$$

Process

$$E^*_{T9} = E^*_{Qproc} + E^*_{9N} \quad (85)$$

$$C_{T9} + Z_{proc} = C_{Qproc} + C_{9N} \quad (86)$$

Chimney

$$E^*_{T16} = E^*_{16N} \quad (87)$$

$$C_{T16} = C_{16N} \quad (88)$$

Exergy Junction and distributor

$$E^*_{2T} + E^*_{4T} + E^*_{5T} + E^*_{6T} + E^*_{7T} + E^*_{8T} + E^*_{Fng} + E^*_{Fair} + E^*_{Fwat} = E^*_{T1} + E^*_{T2} + E^*_{T3} + E^*_{T4} + E^*_{T9} + E^*_{T16} \quad (89)$$

$$C_{2T} + C_{4T} + C_{5T} + C_{6T} + C_{7T} + C_{8T} + C_{Fng} + C_{Fair} + C_{Fwat} = C_{T1} + C_{T2} + C_{T3} + C_{T4} + C_{T9} + C_{T16} \quad (90)$$

These equations are not enough to determine all the exergetic and monetary costs. Then, to get an equation system with unique solution it is necessary to arbitrate the following equations:

For exergetic cost

$$k_{Fng} = k_{Fair} = k_{Fwat} = 1 \quad (91)$$

$$k_{T1} = k_{T2} = k_{T3} = k_{T4} = k_{T9} = k_{T16} \quad (92)$$

$$k_{N1} = k_{N2} = k_{N3} = k_{N4} = k_{N5} = k_{N6} = k_{N7} = k_{N8} \quad (93)$$

$$k_{2N} = k_{3N} = k_{9N} = k_{16N} \quad (94)$$

For monetary cost

$$c_{T1} = c_{T2} = c_{T3} = c_{T4} = c_{T9} = c_{T16} \quad (95)$$

$$c_{N1} = c_{N2} = c_{N3} = c_{N4} = c_{N5} = c_{N6} = c_{N7} = c_{N8} \quad (96)$$

$$c_{2N} = c_{3N} = c_{9N} = c_{16N} \quad (97)$$

$$c_{Fng} = 16{,}37854 \text{ US\$/MWh} \quad (98)$$

$$c_{Fwat} = 1{,}5 \text{ US\$/MWh} \quad (99)$$

$$c_{Fair} = 0 \quad (100)$$

The Table 7 shows exergetic and monetary costs calculated for the cogeneration system with Functional Analysis using Negentropy methodology. These results are different to these gotten with the Exergetic Cost Theory and Functional Analysis. It is observed that electricity unitary cost increased and the unitary costs of the steam and refrigeration (cold) production decreased.

Flow	Exergetic cost		Monetary cost

Table 7: Thermoeconomic functional analysis using negentropy

CONCLUSIONS

Three thermoeconomic methodologies were applied to a cogeneration system. There are differences in the costs of power, steam and refrigeration (cold) production which resulted from the application of the methodologies. The Theory of the Exergetic Cost showed that the unitary cost to produce refrigeration is more expensive than the electricity and the process heat. In the Functional Analysis the unit exergetic cost of the products have the same trends that with the Theory of the Exergetic Cost, however is observed that power unitary cost increased and the unitary costs of the steam and refrigeration (cold) production decreased. The difference between both methodologies is that in The Functional Analysis is not pain a unique piece of equipment (in ours case the exhaust gases of the HRSG and humid air that leaves the cooling tower) in the irreversibilities allocation. The exergy junction and distributor allow distributing the exergetic costs and irreversibility proportionally by the diverse piece of equipment. The Functional Analysis using Negentropy shows bigger differences in the costs allocation, because in this type of analysis the absorption refrigeration system would be acting as a condenser for engine cooling water.

ABSTRACT

Paulus and Tsatsaronis presented a method with which specific exergy *revenues* can be calculated, as opposed to specific exergy *costs*. In this paper, specific exergy revenues and costs are calculated for a hypothetical two-pressure combined cycle power plant. First, the plant-internal specific exergy revenues and associated exergoeconomic variables are calculated for the case when the product revenues are equal to the product costs. The exergoeconomic, revenue-based variables are then compared to those resulting from the traditional, cost-based methods. The good agreement of the exergoeconomic variables calculated by both methods provides evidence of the validity of the proposed auxiliary equations for calculating revenues. Then, a parametric study with varying product revenues is performed. The resulting exergoeconomic variables show that, for a fixed fuel input, increased capital investment is desired as the products become more valuable.

INTRODUCTION

Exergoeconomics is traditionally employed to find the specific cost of exergy associated with flows within a system, as well as the final product costs. In order to do this, monetary balances are written for each component, along with the appropriate auxiliary equations. When the cost of fuel is known, the resulting system of equations allows for the finding of the desired specific exergy costs, both within and at the boundaries of the system. The methodology for finding these auxiliary equations has been formulated by Lazzaretto and Tsatsaronis [1, 2, 3].

These costs can be used to calculate certain exergoeconomic variables, such as the f-factor. These variables are useful in the optimization of an energy system, when the goal is to minimize the total cost for a fixed output with the fuel and capi-

[1] corresponding author. e-mail: d.paulus@iet.tu-berlin.de

tal investment as the independent variables. (See, for example, [4])

There are times, however, when instead of specific exergy cost, it is desirable to find the specific revenue associated with the exergy flows of a system, and to calculate the other exergoeconomic variables therewith. As when calculating costs, monetary balances form part of the necessary set of equations to determine the revenues. However, the set of auxiliary equations will differ from that used for calculating costs, and the price of the products replaces the cost of the fuel as a boundary condition. Paulus and Tsatsaronis [5] developed a methodology for determining the auxiliary equations for finding specific exergy revenues, as well as explained the fundamental difference between specific exergy costs and revenues, and recommended when the latter should be used.

The purpose of this paper is to further examine the methodology given by Paulus and Tsatsaronis [5]. A comparison is made between exergoeconomic variables (cost rates of exergy destruction and f-factors) when calculated with costs and revenues for a hypothetical two-pressure combined cycle power plant (CCPP). When calculating specific exergy revenues, the specific revenue associated with electric power was set equal to its average cost. For this case, it was expected that the exergoeconomic variables should be in relatively good agreement when calculated from either revenue or cost data. It will be shown that, for most components, exergoeconomic variables calculated by both means have satisfactory agreement; the deviations will be elaborated upon.

One case where revenues are recommended for calculating exergoeconomic variables in lieu of costs is for the optimization of a system with a fixed fuel input. In this case, increased efficiency results in greater product revenue flow. In the optimization, capital costs are traded against the total product revenue flow. Therefore, components of the same system should show increased cost rates of exergy destruction with increasing product prices (specific revenue). The cost rate of exergy destruction here approximates the lost sales (lost product revenue) due to the exergy destruction in the component. As the cost rates of exergy destruction increase, the f-factors, which show the ratio of capital cost to total cost, decrease. A parametric study with varying product prices (revenues) has been performed on the sample CCPP, and it will be shown that the cost rates of exergy destruction and the f-factors behave as expected with varying product revenues.

THE AUXILIARY EQUATION RULES

Costs

The following two rules for formulating the auxiliary equations are valid when it is desired to find the specific costs of exergy associated with flows:

F-Principle: The total cost associated with the removal of exergy must be equal to the cost at which the removed exergy was supplied to the same stream in upstream components. [3]

P-Principle: Each exergy unit is supplied to any stream associated with the product at the same average cost. [3]

Revenues

The following two rules for formulating the auxiliary equations are valid when it is desired to find the specific revenues associated with exergy flows:

F-Principle (for revenues): Each exergy unit, of any type of exergy, which is supplied by any fuel stream to a device, has the same specific revenue associated with it. [5]

P-Principle (for revenues): The revenue associated with a unit of exergy, supplied to a stream, is the same as the revenue of a unit of exergy removed from the same stream in a downstream component. [5]

THE EXAMPLE SYSTEM

Description

The example system is a natural gas-fired, two-pressure CCPP, modeled in GateCycle. A system diagram is at the end of this article (Figure 2); the exergy flows are given in Table 1. Table 2 shows the capital costs for each component.

Fuel, Product and Efficiency Definitions

The definitions for the exergetic fuel and product are per Tsatsaronis et al. [1-3]. These definitions are independent of whether specific costs or revenues are being calculated.

Table 1: Exergy Flows

Stream	Exergy Flow [MW]	Stream	Exergy Flow [MW]
1	138.90	21	18.33
2	128.13	22	0.81

14	59.70	34	8.24
15	79.87	$\dot{W}_{el,\mathrm{GT1}}$	151.79
16	0.35	$\dot{W}_{el,\mathrm{ST1}}$	13.11
17	21.41	$\dot{W}_{el,\mathrm{ST2}}$	54.91
18	1.21	$\dot{W}_{el,\mathrm{PUMP1}}$	0.04
19	20.20	$\dot{W}_{el,\mathrm{PUMP2}}$	0.10
20	20.90	$\dot{W}_{el,\mathrm{PUMP3}}$	0.24

Auxiliary Equations

The auxiliary equations used for calculating both specific costs and revenues are given in Table 3. This table shows also the relevant rule used to formulate each auxiliary equation.

Boundary Conditions

Table 2 shows capital costs. Table 3 shows the fourteen auxiliary equations, which are used in conjunction with monetary balances on each component for the calculation of specific exergy costs. With forty unknown specific exergy costs, six boundary conditions are necessary to solve the resulting set of equations.

Table 2: Components, Capital Costs and Monetary Balances

Device	Capital Cost[2] [€/hr]	Device	Capital Cost[3] [€/hr]
CND1	16.2	PUMP2	6.0
DA1	1.6	PUMP3	12.3
ECON1	38.7	SP1	0
ECON2	42.6	SP2	0
EVAP1	125.3	SP3	0
EVAP2	258.8	SPHT1	38.9
GT1	1877.	SPHT2	64.7
M1	0	SPHT3	7.8
M2	0	ST1	296.6
PUMP1	2.6	ST2	712.6

The specific cost of the exergy of the natural gas is 5.539 €/GJ. The specific cost associated with both the intake air and the cooling water is zero. (The calculated exergy flow of this air is non-zero because Szargut's standard model [6] was used for chemical exergy, and the air was modeled with a chemical composition other than the reference state employed by the standard model.) The three remaining boundary conditions are given by setting the cost of electric power to the pumps equal to the average cost of power from the plant. For the calculation of revenues, there are again twenty balances and fourteen auxiliary equations; six boundary conditions are required. For the first calculation of specific revenues and exergoeconomic variables, the specific revenue associated with electric power was set equal to the average cost of the power:

$$r_{el} = \frac{c_{32}\dot{E}_{32} + \sum_j \dot{Z}_j}{\dot{W}_{el,net}} = 1.706\,€/\mathrm{MJ} \qquad (1)$$

Streams 8 and 33 are waste streams; they have zero revenue. Also, the revenue flow associated with the air at the gas turbine was set equal to zero.

[2] The capital costs associated with piping have been included with those of the primary components. Therefore, the capital costs of mixers and splitters are zero.

[3] The capital costs associated with piping have been included with those of the primary components. Therefore, the capital costs of mixers and splitters are zero.

For the parametric study, revenues and exergoeconomic values were additionally calculated at one half, three halves and twice the average cost of electric power:

$$r_{el} = (0.5, 1.0, 1.5, 2.0) \cdot 1.706\,€/\mathrm{MJ} \quad (2)$$

Specific Costs (Revenues) Associated with the Exergetic Fuel or Product, Costs of Exergy Destruction and F-Factors

The specific cost of the exergetic fuel (or product) is found by dividing the cost flow associated with the fuel (or product) by its exergy flow. For example, for the heat exchanger SPHT1:

$$c_{F,\mathrm{SPHT1}} = \frac{\dot{C}_1 - \dot{C}_2}{\dot{E}_1 - \dot{E}_2} = \frac{c_1\dot{E}_1 - c_2\dot{E}_2}{\dot{E}_1 - \dot{E}_2} \quad (3)$$

$$c_{P,\mathrm{SPHT1}} = \frac{\dot{C}_9 - \dot{C}_{12}}{\dot{E}_9 - \dot{E}_{12}} = \frac{c_9\dot{E}_9 - c_{12}\dot{E}_{12}}{\dot{E}_9 - \dot{E}_{12}} \quad (4)$$

The same equations are used to calculate the specific revenue of the fuel or product, with "$\dot{R}$" substituted for "$\dot{C}$" and "r" for "c".

When working with costs, the cost rate of exergy destruction is defined with [4]:

$$\dot{C}_{D,i} = c_{F,i}\dot{E}_{D,i} \quad (5)$$

Alternatively, when working with revenues, the cost rate of exergy destruction is defined with [5]:

$$\dot{C}_{D,i} = r_{P,i}\dot{E}_{D,i} \quad (6)$$

Instead of approximating the additional cost to the system, Eq. (6) approximates the lost revenue to the plant due to the exergy destruction in component *i*.

The f-factor represents the ratio of the capital cost of a component to its total cost, the sum of capital cost and the cost of exergy destruction, as defined in Eqs. (5) and (6).

$$f_i = \frac{\dot{Z}_i}{\dot{Z}_j + \dot{C}_{D,i}} \quad (7)$$

RESULTS

Specific Costs and Revenues

The resulting specific costs and revenues associated with the exergy flows are reported in Table 4. (The revenues reported therein are for the case of the revenue associated with electricity set equal to its average cost.)

Exergoeconomic Variables

The cost of exergy destruction in each component, as well as the component's f-factor, are reported in Table 5. These values are shown as calculated from (1) the specific exergy costs and (2) the specific exergy revenue when calculated with the revenue associated with electricity set equal to its average cost.

Both methods of calculating the costs of exergy destruction and the f-factors for the steam turbines show excellent agreement. (The difference in the cost of exergy destruction is less than ten percent for both turbines; the difference in f-factor is less than two percent.) The values for the heat exchangers differ more, with the cost of exergy destruction averaging about eighteen percent higher than the corresponding revenue; the resultant f-factors average fourteen percent higher.

While the values for the steam turbines and heat exchangers are reasonably close, there is substan-

tial deviation in the exergy destruction cost and the f-factor of the gas turbine.

Parametric Study

Table 6 shows the variation of the f-factor (as calculated with $\dot{C}_{D,i}=r_{P,i}\dot{E}_{D,i}$) with varying product revenue. For all components, the f-factor declines as the product revenue increases.

DISCUSSION

Exergoeconomic Variables

In the calculation of the specific costs and revenues, the combustion gas turbine was treated as a single component, as it is typically purchased as such. Therefore, it is not possible to calculate the specific exergy costs (or revenues) of the streams internal to the gas turbine. With this treatment of the gas turbine, there are two choices for auxiliary equations.

In the auxiliary equations used to calculate the specific exergy costs, the gas turbine was assumed to have two products, and the P-rule yields $c_1=c_{el,GT1}$. This results in the proportional assignment of gas turbine's capital costs to both the power output and the gas turbine's exhaust gas.

An alternative is to assume the gas turbine to have one product, electric power. With this assumption, all of the gas turbine's capital costs are assigned to the electricity, and the F-rule yields $c_1=c_{32}$. In

order to clarify why the f-factors of heat exchangers were consistently somewhat higher when calculated based on revenue data rather than cost data, the f-factors were recalculated. In this recalculation, the f-factors were calculated based on cost data with the assumption that the gas turbine had a single product.

ST2	0.778	0.636	0.538	0.467

When the f-factors of the heat exchangers, as calculated from revenue data, were compared to those from the recalculation, it was found that those calculated from revenue data were now somewhat lower than those calculated from cost data. That is, the f-factors of the heat exchangers, when calculated from revenue data, fell between the two sets of those calculated from costs. This is shown graphically in Figure 1. The lower calculated cost of exergy at stream 1 reduces the calculated costs of exergy destruction in the heat exchangers. This reduction results in higher calculated f-factors. (Not shown on the graph is the deaerator. Its f-factor, as calculated from revenue data, also falls between the f-factors from the two sets of cost data.)

If it were possible to split the combustion gas turbine into its components, the resulting specific exergy costs would fall between those calculated assuming (1) the gas turbine has one product and (2) the gas turbine has two products. This is because, when the gas turbine is split into components: (1) the generator's capital costs would be assigned entirely to the electric power, (2) the capital costs of the compressor and combustion chamber would be assigned proportionally to the exhaust gas and the electric power and (3) the expander's capital costs would be assigned directly to mechanical power; some of these costs (approximately half) flow back to the compressor, while the remainder are assigned to the electric power. As the *majority* of the capital costs would be assigned proportionally, the results would be expected to be closer to those from the assumption of two products. Because not *all* of the capital costs are assigned proportionally, the results must lay between those of the assumptions of one product and two products. Thus, if the gas turbine could be split into components, the authors would expect the f-factors calculated from both revenues and costs to match very closely.

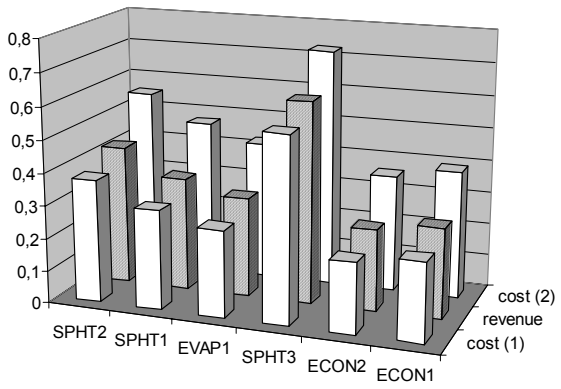

Figure 1: F-factors of the heat exchangers[5]

Calculations by the authors, estimating the internal parameters of the gas turbine, and estimating the capital costs as being equally split between the compressor, combustion chamber, turbine and generator, showed agreement in the f-factors of

[5] The set with the shaded bars was calculated from revenue data. The set cost(1) was calculated from cost data with $c_1=c_{el,GT1}$ and the set cost(2) with $c_1=c_{32}$.

these components within ten percent for all components except the combustion chamber (which had an f-factor of 0.15 and 0.092 calculated from costs and revenues, respectively).
This discussion reiterates that when a detailed cost breakdown of subassembly of an energy system is not available, even a rudimentary estimate of this breakdown may improve the accuracy of exergoeconomic calculations.

Parametric Study

The f-factor, representing the ratio of capital cost to total cost (capital cost and the cost of exergy destruction), is a tool useful in the iterative optimization of an energy system [4]. A very high f-factor is a sign that a reduction in efficiency should be accepted in order to reduce capital costs, and a very low value is a sign that additional capital should be invested in order to reduce exergy destruction. When calculated from cost data, the f-factor is in no way affected by the product price.
There are times, however, when it is desirable to have an f-factor that is influenced by price (the specific revenue associated with the product). Consider as an example a cogeneration system being designed for a company currently producing its own steam but purchasing all needed electricity. Assume that the plant will not completely meet the company's electric demand. Then, the specific revenue associated with the electricity is equal to the current purchase price of electricity for the company. Logically, if the fuel input to the plant is fixed (as it would be, for example, if the plant were fired by a gas turbine), the higher the purchase price of electricity, the more capital should be invested in the plant.
The results from the parametric study show that the f-factor, when calculated from revenue data, is strongly influenced by the product's specific revenue. As the specific revenue increases, the f-factors decrease, suggesting that more capital should be invested in each component. This is in agreement with logic and the expected behavior, and such behavior is nonexistent when the f-factors are calculated from cost data.
The authors suggest that when fuel input is fixed, exergoeconomic variables calculated from revenue data should be employed for any analysis.

CONCLUSION

Validity of the Auxiliary Equations for the Calculation of Specific Exergy Revenues

The generally good agreement between (1) the cost of exergy destruction in components and (2) the components' f-factors when calculated based on (a) costs and (b) revenues (the latter calculated with the revenue of electricity set to its average cost of production) provides evidence that the auxiliary equations for calculating the specific costs associated with exergy streams, as proposed by Paulus and Tsatsaronis [5], are valid. Although some discrepancies were initially noted, these were definitively attributed to the lumping of the individual components of the gas turbine.

Applicability of Revenues to Exergoeconomic Analysis

An exergoeconomic analysis in which specific exergy costs are used to calculate the exergoeconomic variables is unable to take into account product price information. For the case of a fixed system output, this is of no account to optimization. Minimizing product costs suffices as an optimization goal.
However, the design of some systems (including any system based on a commercially available combustion gas turbine) has the constraint of fixed fuel input. Then, capital costs are traded against additional output. In some cases (such as that of an additional power plant for a utility), minimizing the average costs likely suffices as an optimization goal. However, in other cases, such as the one where a proposed plant will offset the purchase of a currently commercially purchased commodity, it does not. In these latter cases, the economically optimal design of a plant will be strongly influenced by product price. Here, methods that take into account this price are necessary. The specific revenues associated with exergy flows should then be used to calculate exergoeconomic variables. This paper demonstrated that the use of revenues for these calculations provides price feedback to the exergoeconomic variables.

ACKNOWLEDGEMENT

The comments from Professor George Tsatsaronis are greatly appreciated.

Thermal and economic evaluation of Heat Recovery Steam Generators (HRSG)

Sepehr Sanaye **Omid Hamidkhani**

Energy Systems Improvement Laboratory
Mechanical Engineering Department
Iran University of Science and Technology (IUST)
Tehran, Iran

Abstract
One of the efficient power producing technologies is the combined cycle which includes both Brayton (topping) and Rankine (bottoming) cycles. Due to this fact, an optimal design of heat recovery steam generator (HRSG) as an important part of this system is a subject of interest. In this paper a thermoeconomic analysis has been used to optimally design HRSGs in a combined cycle power plant. The applied method and the results of the performed sensitivity analysis are explained.

Keywords: Heat Recovery Steam Generator, Thermoeconomy, Capital Investment, Exergy destruction, Optimization

f	flue gas

Introduction

Heat recovery steam generator (HRSG) is an important part of a combined cycle power plant by which the energy of turbine exhaust gases is being recovered. These systems include three main groups of heat exchangers or elements named economizer, evaporator and superheater. An HRSG may contain up to three pressure levels, named low pressure (LP), intermediate pressure (IP) and high pressure (HP). Each pressure level has its own three mentioned heat transfer elements. When the turbine exhaust gases pass over HRSG elements, by the recovered energy, steam is produced inside tubes. This steam will be used for driving a steam turbine and generating shaft power. While water preheats in economizer and evaporates in evaporator, it will be separated from steam in drum. Water returns to down comers of evaporator and steam will be sent for superheating (figure 1).

The optimal design of such a thermal system is of primary interest specially due to extensive use of combined cycles as a preferred method of producing electricity. These systems are designed mainly based on the gas turbine exhaust mass flow rate and temperature. The

results of changing parameters such as ambient temperature, condenser type and pressure (or inlet water temperature to economizer) shows that these parameters have a neglecting effect on HRSG design parameters and performance. Therefore HRSGs may be optimized as a subsystem separated from other equipment in a combined cycle power plant.

Due to the energy or exergy crisis [1], this optimal design method provides a cost effective system [2] with the minimum total cost [3].

This fact resulted in choosing a target (60%) for thermal efficiency of combined cycle power plants by the manufacturers [4]. The optimal design of heat recovery has certainly important effects on overall cycle efficiency, power output, and cost of the system [5].

In this present work simulation and optimal design of HRSGs with up to three pressure levels is performed. An objective function, which is the total cost, per unit of steam produced exergy, is introduced. The total cost includes the capital cost, operational cost (in case of using duct burners in HRSG) and the cost of exergy or availability destruction for the system. The design parameters are selected when the system total cost per unit of steam exergy is minimized. A typical optimal design is performed and the output design parameters are reported for a two pressure level system.

Thermodynamic Analysis

To find the optimum physical and thermal design parameters of the system a simulation program was developed. Temperature profile, input and output exergy, exergetic efficiency, heat transfer surface are a of each element were estimated by study of heat recovery performance. The following assumptions have been considered in HRSG simulation program:

- The outlet stream from the evaporator and economizer assumed to be saturated vapor and saturated liquid respectively.
- The HRSG consists of up to three pressure levels and each level contains three components: Economizer, Evaporator, and Superheater.
- Dominant heat transfer mechanism is convection.
- Variation of the specific heat of the hot gas due to the temperature variations can be neglected.
- The inlet water streams are at ambient temperature.

The energy balance equations for various parts of the system (figure 1) are:

High-pressure Superheater

$$\dot{M}_g C_p (T_1 - T_2) = \dot{m}_{HP} (h_{20} - h_{19}) \quad (1)$$

High-pressure Evaporator

$$\dot{M}_g C_p (T_2 - T_3) = \dot{m}_{HP} (h_{19} - h_{18}) \quad (2)$$

High-pressure Economizer

$$\dot{M}_g C_p (T_3 - T_4) = \dot{m}_{HP} (h_{18} - h_{11'}) \quad (3)$$

Intermediate-pressure Superheater

$$\dot{M}_g C_p (T_4 - T_5) = \dot{m}_{IP} (h_{17} - h_{16}) \quad (4)$$

Intermediate-pressure Evaporator

$$\dot{M}_g C_p (T_5 - T_6) = \dot{m}_{IP} (h_{16} - h_{15}) \quad (5)$$

Intermediate-pressure Economizer

$$\dot{M}_g C_p (T_6 - T_7) = \dot{m}_{IP} (h_{15} - h_{11'}) \quad (6)$$

Low- pressure Superheater

$$\dot{M}_g C_p (T_7 - T_8) = \dot{m}_{LP} (h_{14} - h_{13}) \quad (7)$$

Low- pressure Evaporator

$$\dot{M}_g C_p (T_8 - T_9) = \dot{m}_{LP} (h_{13} - h_{12}) \quad (8)$$

Low- pressure Economizer

$$\dot{M}_g C_p (T_9 - T_{10}) = \dot{m}_{LP} (h_{12} - h_{11}) \quad (9)$$

These combinations of energy and mass balance equations were numerically solved and the temperature profile in the gas and water/steam side of HRSG were predicted.

From the system exergy balance, the exergy destruction in HRSG was computed using the following equation:

$$\dot{I} = \dot{E}_{in} - \dot{E}_{out} \quad (10)$$

The inlet exergy to the HRSG is the corresponding exergy of gas turbine exhaust. The exergy of the inlet water streams, which were assumed to be at ambient temperature (dead state), is zero.
The output exergy from HRSG is in two forms of steam generated in evaporator that then has been superheated in superheaters as well as the flue gas leaving the stack, thus:

$$\dot{I} = \dot{E}_g - \dot{E}_s - \dot{E}_f \quad (11)$$

Based on the definition of the exergy, the following equations can be derived:

Inlet Hot Gas Exergy

$$\dot{E}_g = \dot{M}_g \left[C_p (T_1 - T_a) - T_0 (S_1 - S_0)\right] \quad (12)$$

Steam Exergy

$$\dot{E}_S = \Sigma \dot{m}_i \left[(h_i - T_0) - T_0 (S_i - S_0)\right] \quad (13)$$

Flue Gas Exergy

$$\dot{E}_f = \dot{M}_g \left[C_p (T_{10} - T_a) - T_0 (S_{10} - S_0)\right] \quad (14)$$

The heat transfer surface areas can be obtained by solving the heat transfer equation in form of:

$$Q = U A \ \Delta T \quad (15)$$

Where the total heat transfer coefficient was obtained from the developed software program [6]. It is worth mentioning that the results of the developed software and simulation program were checked and found to be correct in compare to results reported in literature.

Economic Considerations

A key design parameter in each pressure level of HRSG is the pinch point, which is the temperature difference of steam leaving the drum and hot gases leaving the evaporator section. A bigger pinch point corresponds to a smaller exchanger heat transfer surface area and the relative lower capital cost of the recovery system for the same rate of energy exchange. A small pinch point corresponds to a larger heat transfer surface area and more costly system.

The average investment cost of the each component is calculated based on the following coefficients [7]:

Economizer

$$K_E = 34.9 \ \$/m^2 \quad (16)$$

Evaporator

$$K_V = 45.7 \ \$/m^2 \quad (17)$$

Superheater

$$K_S = 96.2 \ \$/m^2 \quad (18)$$

Thus the capital cost of the HRSG can be written as follows:

$$\begin{aligned} C_c = & (K_V A_V + K_E A_E + K_S A_S)_{LP} \\ & + (K_V A_V + K_E A_E + K_S A_S)_{IP} \\ & + (K_V A_V + K_E A_E + K_S A_S)_{HP} \end{aligned} \quad (19)$$

Optimization, objective function and Constraints

In this paper the total annualized cost per unit of steam produced exergy, (C_T / E_S) is selected as the objective function. The total annualized cost of the plant is obtained from:

$$C_T = t_{op.} C_E \dot{I} + a C_C \quad (20)$$

This function contains decision variables that their optimum values are the optimum system design parameters. These values minimize the total cost per unit of produced steam exergy, i.e., the objective function. There are some constraints for decision variables in minimization procedure. These constraints are ranges of variations or typical values of design parameters of an HRSG system which may be listed as below:

$5 < P_H < 22$ Mpa (21)

$1 < P_I < 10$ Mpa (22)

$0.01 < P_L < 3$ Mpa (23)

$8 < PP_H < 20$ K (24)

$8 < PP_I < 20$ K (25)

$8 < PP_L < 20$ K (26)

$$0.1 < mr_H < 0.9 \quad (27)$$

$$0.1 < mr_L < 0.9 \quad (28)$$

The decision variables in this problem are the pressure levels, pinch temperatures, and the mass flow rates of steam in each pressure level.
The lowest value of hot gas temperature was also a constraint. This temperature (dew point) specifies a lower limit to prevent the condensation of water vapor and corrosion.
Therefore the goal of the optimization process is to find a set of the decision variables to minimize the objective function (C_T), subject to constraints mentioned.

Computer program

A Visual Basic code is developed for simulation and optimization of HRSG system.
This code contains the following main modules:
Thermal analysis:

This part solves the thermodynamic model and computes the gas temperature variations along the heat recovery. Input and output exergy, exergy destruction, heat transfer surface areas and exergetic efficiency are among the output parameters. Pinch temperature differences, pressure levels and mass flow rates are the input data to this module.
Economic computations:

This part computes the total cost of HRSG. Temperature profile, heat transfer surface areas and exergy destruction of HRSG are input data to this module.
Using the economic parameters presented earlier, this module computes the capital cost of the heat transfer surface areas, the cost of the exergy destruction, and the total annualized cost of the system.
Optimization procedure:

This module links to the other modules and finds the optimum set of the decision variables subjected to the mentioned constraints using the search optimization method.
Besides these modules, a database containing the thermodynamic properties of the steam is linked to the code. This database was developed in Dynamic Library Link (DLL) format and has been generated in IUST Energy Systems Improvement Laboratory.
Through the relation of these modules the developed code solves the optimization problem and finds the optimum set of the decision variables as well as other important parameters of the system such as heat transfer surface areas, gas and water/steam side temperature profile along HRSG, steam turbine power output, log mean temperature differences and exergy destruction rate. The input and output data of the program are listed in table (1).

Results and Discussion

For the given input data (table 1), the obtained results from simulation and optimization programs (i.e., the system optimum design parameters) are listed in table (2) for various gas temperatures entering HRSG. As is shown from table (2) the lowest values of C_T / E_S, belongs to $700\,^{\circ}K$ turbine exhaust temperature.
The values of mr_l, mr_h (the fraction of the steam mass flow rates of two pressure levels), η_{ex} (the exergetic efficiency, a non-dimensional index which is defined as the ratio of the steam exergy produced to the inlet gas exergy) and pinch points are also listed.
The pinch points in LP level were lower than the corresponding values in HP level for this arrangement of heat transfer elements (arrangement A).

One of the most effective parameters that play a key role in thermoeconomic optimization is the exergy unit price that specifies the effect of exegetic efficiency on the total cost. The higher exergy unit prices, the better exergy efficiency gained. In this case the effect of the first term in equation (20) increases. Then for the minimizing the objective function (C_T / E_S), the decision variables (design parameters) will be computed with more attempt on decreasing the first term of C_T, which means decreasing the exergy destruction or increasing exgrgetic efficiency.
There are several methods for estimating exergy unit price [7]. One method considers the ratio of fuel cost divided by the plant efficiency (which in combined cycles is about 0.55 and is approximately used for heat recovery system) as exergy unit price. In another method the ratio of the fuel cost divided by the common plant

efficiencies is being used for the value of this parameter (typically of the order of 0.35 ~ 0.4). The average value of the selling price of electricity can be considered in the third method (the one has been used in this paper).
Table (3) shows the effects of changing C_E on optimum design parameters (pressure levels, pinch points and steam mass flow rates) at $800^\circ K$ for HRSG inlet gas temperature. For the case of C_E = 0.02 \$/kWh (nearly the electricity price in Iran), the pinch points are higher than the case in which C_E = 0.068 \$/kWh (nearly the electricity price in Italy) [7].

Figure (2) shows another arrangement for heat transfer elements in HRSG. The goal was finding whether the arrangement of elements changes the design parameters (decision variables), and C_T / E_S. Table (4) shows the outputs for arrangement B shown in figure (2) and C_E = 0.02 \$/kWh.

In most cases, the C_T / E_S values at each inlet gas temperature, was also lower in arrangement B in compare to the corresponding values in arrangement A. Furthermore η_{ex} values in arrangement B were also bigger than those in arrangement A.

In this case with the exception of $700^\circ K$, the pinch temperatures in HP level were less than the corresponding values in LP level.
Table (5) compares the outputs including mass flow rates, pinch points, and C_T / E_S for arrangements A and B for HP and LP levels. This parameter is lower in arrangement B when inlet gas temperature is above $700^\circ K$.

Conclusion

A thermoeconomic optimization method was applied to obtain the optimum values of design parameters in a heat recovery steam generator. The objective function introduced was the total cost per unit of steam produced exergy including the capital, operational (fuel cost in case of using duct burners) and exergy destruction costs.

The estimated exergy unit price and the arrangements of heat transfer elements also effects the design parameters. A sensitivity analysis carried out to examine the effect of exergy unit price on the results.
It was found that the arrangement of heat transfer elements also affects the design parameters as well as the total cost per unit of steam exergy produced.

Thermal and Economic Evaluation of an Ice Thermal Storage System

Sepehr Sanaye[1] Abbasali Fardad[1] Hossein Babaie Touski[2]

Energy Systems Improvement Laboratory
Mechanical Engineering Department
Iran University of Science and Technology

Abstract
Gas turbine power output and efficiency, decrease with increasing the atmospheric temperature. This may be compensated by using compressor inlet cooling systems in forms of evaporative cooling, vapor compression and/or absorption, and thermal storage systems (TES). Thermal and economic evaluation of a latent TES system using ice storage is studied in this paper. The objective function is the capital and operational costs of the gas turbine plant with a vapor compression refrigeration system for producing ice in a storage tank. The system design parameters were obtained using the search method optimization technique.

Keywords: Thermal and Economic optimization, Inlet air cooling system, Thermal Storage System

Nomenclature:

$\dot{m}_a$	Air mass flow rate [kg/s]
$\dot{m}_g$	Turbine inlet mass flow rate [kg/s]
$\dot{m}_w$	Water mass flow rate [kg/s]
$\dot{m}_{fuel}$	Fuel mass flow rate [kg/s]
η_C	Compressor efficiency
η_T	Turbine efficiency
r_C	Compressor pressure ratio
r_T	Turbine pressure ratio
A_{AC}	Air cooler surface area [m^2]
A_{EV}	Evaporator surface area [m^2]
V_{ST}	Storage tank (Ice Bank) volume [m^3]
γ_g	Air specific heat ratio
γ_g	Gas specific heat ratio
Cp_a	Air specific heat at constant pressure [kJ/kg.K]
Cp_g	Gas specific heat at constant pressure [kJ/kg.K]
C_{fuel}	Cost per unit mass of fuel [$/Mj]
$\dot{W}_{net}$	Net power output [MW]
$\dot{W}_C$	Compressor power consumption [MW]
$\dot{W}_T$	Turbine power output [MW]
LHV	Lower heating value [kJ/kg]
Re_d	Inside tube flow Reynolds number
μ	Dynamic viscosity [$N.s/m^2$]
d	Pipe diameter [m]
h	Convection heat transfer coefficient [$W/m^2.K$]
U	Total heat transfer coefficient [$W/m^2.K$]
ΔT_{LMTD}	Mean logarithmic temperature difference [C]
NTU	Number of transfer units
i_{ph}	Melting latent heat [kJ/kg]
t_c	Charging time [sec]
t_h	Discharging time [sec]
$\dot{Q}_{AC}$	Air cooler heat rate [kW]
$\dot{Q}_{RC}$	Refrigeration heat rate [kW]
C_c	Cold water specific heat [kJ/kg.K]
Q_r	Reservoir available heat [kJ]
ρ_w	Density of water [kg/m^3]
C_r	Stored liquid specific heat [kJ/kg.K]

1- Assistant Professor
2- Researcher & M. Sc. Engineer

ΔT	The difference between the ambient temperature and liquid in thermal storage tank [$^\circ$C]
Z	Capital cost [$]
$\dot{Z}$	Capital cost rate [$/sec]
i	Interest rate [%]
n	Payback period [year]

Subscripts:

RC	Compression refrigeration system
AC	Air cooled heat exchanger
T	Turbine
C	Compressor
CC	Combustion chamber
EV	Evaporator
ST	Storage tank

Introduction

Gas turbine inlet air cooling by increasing the air density, increases the power output to about 20% of the nominal power and efficiency up to 6 percent. These systems satisfy the need for installing more gas turbines and therefore reduces capital and investment costs. The inlet cooling techniques include vapor or absorption refrigeration systems, evaporative cooling systems (inlet fogging, media and air washer), and thermal energy storage systems (TES).

In this paper the optimum design parameters of a TES system shown in figure (1) are predicted using a thermal and economic analysis and by minimizing the total cost as an objective function.

Thermal energy storage systems are in two major categories of sensible and latent heat types. In the first type, water and sand/stone are used to store the energy. The cost of the energy storage media (water or stone) is low in this case. In the second type, the phase of the energy storage media may change from solid to liquid when it receives energy and its phase shifts back to solid when it rejects energy. Considering the same volume, the latent type of energy storage systems can store more energy compared to the first type. In this paper thermal and economic optimization of ice storage tank is performed for gas turbines in 15 to 150 MW range of power output. By using ice storage tank and chilled water (25% Etylen Glycole and 75% water) the gas turbine inlet air temperature drops. This increases the inlet air density and gas turbine power output.

Consider a gas turbine (or combined cycle power plant) such as one shown in figure (1). The compressor inlet air cooling is performed by using a vapor compression refrigeration system to increase the power output. Inlet cooling might be necessary in time intervals with the maximum electricity consumption (on peak hours). On the other hand, running such a system consumes electricity (provided by the same or different power plant) in peak hours. This plan might not be economical since the electricity is the most expensive during peak hours. A better plan is to use the refrigeration system to make ice in off-peak hours in which the electricity consumption and its price is at the lowest values (usually after mid-night). Then the chilled water (25% Etylen Glycole and 75% water) inside tubes passes through the ice and will be pumped to an air cooler for cooling the inlet air and rejecting heat to the ice in storage tank in peak hours [1].

Thermal Analysis and Simulation of the System

The relations used for modeling the gas turbine sections such as compressor, combustion chamber and turbine are (figure 1):

$$r_T = p_3 / p_4 \tag{1}$$

$$T_2 = T_1 . \left[1 + \frac{r_C^{(\frac{\gamma_a - 1}{\gamma_a})} - 1}{\eta_C} \right] \tag{2}$$

$$T_4 = T_3 . \left[1 - \eta_T (1 - r_T^{(\frac{1-\gamma_g}{\gamma_g})}) \right] \tag{3}$$

$$\dot{W}_C = \dot{m}_a \, Cp_a \, (T_2 - T_1) \tag{4}$$

$$\dot{W}_T = \dot{m}_a \, Cp_a \, (T_2 - T_1) \tag{5}$$

For natural gas, the fuel lower heating value (LHV) was 45100 kJ/kg.

For cooling coil (air cooler) through which the chilled water (25% Ethylene Glycole and 75% water) passes, the following relations were used (figure1):

$$\dot{m}_W = \frac{\dot{m}_a\, Cp_a\, (T_0 - T_1)}{Cp_w\ (T_{h,i} - T_{h,o})} \quad (6)$$

$$Re_{d,i} = \frac{4\,\dot{m}_w}{10\,\pi\, d_i \mu_i} \quad (7)$$

$$(\Delta T_{LMTD})_{AC} = \frac{(T_1 - T_{h,i}) - (T_0 - T_{h,o})}{\ln[\frac{T_1 - T_{h,i}}{T_0 - T_{h,o}}]} \quad (8)$$

$$\dot{Q}_{AC} = \dot{m}\, Cp_a\, (T_0 - T_1) \quad (9)$$

$$A_{AC} = \frac{\dot{Q}_{AC}}{U\,(\Delta T_{LMTD})_{AC}} \quad (10)$$

The evaporator surface area of the refrigeration system and the ice storage tank volume are determined by [5]:

$$A_{EV} = \frac{(NTU)_c\, C_c}{U_{EV}} \quad (11)$$

$$Q_r = (\dot{Q}_{RC})\,(t_c) \quad (12)$$

$$V_{ST} = \frac{Q_r}{\rho_w\, C_r\, \Delta T + \rho_w\, i_{ph}} \quad (13)$$

Ten percent overestimation of the volume obtained from (13) was also considered due to expansion of water when it freezes in storage tank [8].

The Objective Function and Constraints

The objective function is the total cost including capital investment and operational costs in the form of:

$$\prod = \sum \dot{Z}_i\ (\$/s) + C_{fuel}\ (\$/Mj)\, LHV\, (Mj/kg)\, \dot{m}_{fuel}\, (kg/s) + Electricity\ cost\ rate\ (\$/s) \quad (14)$$

where the first term is the capital cost while the second and third terms are operational costs (including fuel and electricity). Due to the fact that the values of Z (capital cost) should be used in form of capital cost rate ($/sec), then:

$$\dot{Z} = Z \times \phi / 3600 \times 8000 \quad (15)$$

Where CRF is the capital recovery factor which is 18.2% in a 10 years period. ϕ is the operational and maintenance factor which was considered to be 1.06 [6].

The followings are the decision variables and the range of their variations. The mentioned ranges of values for variables are obtained based on the level of technologies present in the market.

$$273 \le T_1 \le T_0 \quad (16)$$

$$7 \le r_C \le 16 \quad (17)$$

(Pressure ratio of gas turbines for electricity production)

$$0.7 \le \eta_T \le 0.92 \quad (18)$$

$$0.7 \le \eta_C \le 0.9 \quad (19)$$

(The present level of technology in the market)

$$1000 \le T_3 \le 1550 \quad (20)$$

(Blade temperature limit)

$$0 \le t_c \le 86400 \quad (21)$$

(Seconds in a day)

$$273 \le T_2 \le T_4 \quad (22)$$

The followings are the system physical constraints:

$$T_4 \ge 400\ K \quad (23)$$

(To avoid water saturation and acid sulphoric formation)

$$T_{h,i} \ge T_{h,o} \quad (24)$$

$$T_3 \ge T_4 \quad (25)$$

$$(NTU)_c \ge 0 \quad (26)$$

$$\dot{Q}_{RC} \ge \dot{m}_w\, Cp_w\, (T_{h,i} - T_{h,o}) \quad (27)$$

The above objective function was minimized using search optimization method to get the design parameters (decision variables).

Economic Considerations

The capital cost of various components in the system (Z in equations (14) and (15)), are determined by equations (28) to (34) and

shown in figures (2) to (5) for gas turbine, inlet air cooler, refrigeration unit and TES system:
The capital cost equations for turbine, combustion chamber and compressor,are [4]:

$$Z_T = \frac{1094\,\dot{m}_g}{0.92-\eta_T}.\ln r_T \times\left[1+\exp(0.036\ T_3 - 54.4)\right] \quad (28)$$

$$Z_{CC} = \frac{102\,\dot{m}_g}{0.995-0.95}\times\left[1+\exp(0.018\ T_3 - 26.4)\right] \quad (29)$$

$$Z_C = \frac{16.53\,\dot{m}_g}{0.9-\eta_C}.r_C\ \log r_C \quad (30)$$

The capital cost equations for air cooler, refrigeration unit, evaporator and storage tank for the system operating conditions mentioned in this paper, were obtained in equation forms using graphical information provided in [3]:

$$Z_{AC} = 24202\ A_{AC}{}^{0.4162} \quad (31)$$

$$\begin{cases} Z_{RC} = 471.92(\dot{Q}_{RC}{}^{0.8198}) & (32) \\ Z_{EV} = 16648.3\ A_{EV}{}^{0.6123} & (33) \end{cases}$$

$$Z_{ST} = 5.7\times 10^{[2.9211\exp(0.1416\log V_{ST})]} \quad (34)$$

The electricity consumption of both compressor and condenser cooling water (cooling tower fan and cooling water pump) for vapor compression refrigeration system during the night and also the chilled water pumping during the peak hours were considered in the analysis. A simplified assumption uses 10% of the compressor electricity cost for all pumping services.
The electricity cost during the peak hours (TES discharging) was 0.08 $/kWh and during the off-peak hours (TES charging) was 0.05 $/kWh. C_{fuel} in relation (14) was 0.004 $/Mj [4]. It is apparent that these cost values may change in different locations and/or atmospheric conditions.

Discussion and Results

A computer program was developed to simulate and optimize the thermal system shown in figure (1). The inlet air temperature was changed from 280K to 320K for gas turbine nominal power outputs in range of 15 to 150 MW. The results are listed in tables (1) to (5). It is important to note that for gas turbine plants below 25 MW the use of thermal storage is logical only when the atmospheric temperature is higher than 320 K. For lower atmospheric temperatures, the results show that the use of thermal storage is not economical. This temperature limit decreases with increasing the gas turbine power output, i.e. for 25 MW at or more than 310 K, for 55MW at 290 K, and for 100 MW at 280 K ambient temperature.
It was found that for all inlet air temperatures, gas turbine power outputs, and decision variables such as r_C, η_C, η_T and T_3, the optimum charging period was about 40000 seconds (about 11 hours). The variations of this charging time with cost rate is shown in figure (6).
The payback period for thermal storage system has also been studied. If Ec is the capital cost of air cooler, refrigeration system and thermal energy storage (including operation and maintenance cost), the worth of this investment in n_{th} year later will be [7].

$$\begin{aligned} Ec_n &= (Ec)(1+i)^n \\ &= \left[Z_{AC}+Z_{RC}+Z_{EV}+Z_{ST}\right](1+i)^n \end{aligned} \quad (35)$$

Where i is the interest rate which was assumed to be equal to 0.1 (10%).
The payback period may be estimated for such a system by using the following formula:

$$\Delta EP_n = \left\{\begin{bmatrix}\text{Min cos t, without TES}\\ -\text{Min cos t, with TES}\end{bmatrix}\times 3600\times 24\times 365\right\} n \quad (36)$$
$$= Ec_n = (Ec)(1+i)^n$$

The payback period for a 25 MW gas turbine is about 2.5 years and this value decreases with increasing the gas turbine nominal power output (figure 7).
The percentage of increase in power output with the gas turbine nominal power when thermal energy storage and inlet cooling system are used is also shown in figure (8). The range of power output increase for 15 to 150 MW gas turbine nominal power is about 2.5 to 10 percent.

The variations of the cost rate with power output of a gas turbine power plant including thermal storage is also shown in figure (9). The cost rate changes from 0.0109 to 0.0091 $/Mj for 15 to 150 MW plants.

Conclusion

By performing thermal and economic assessment of an energy storage system, important physical or design parameters of the system were obtained at different ambient temperatures. Results show that the payback period and the cost rate per MW of using thermal storage system decrease with increasing the nominal power output. The net power increase shows a noticeable augmentation with increasing the power output.

ABSTRACT

The paper presents a model for thermoeconomic analysis of the biggest thermal system in Slovenia in which electric power and heat energy are produced in five units all operated by steam turbines, the main fuel being lignite. The prices of heat and electric energy from the plant were calculated. The calculations and the ratio between electric energy price and district heating price were based on an exergy analysis that considers the economics of the system.

INTRODUCTION

The biggest coal-fired power plant in Slovenia using lignite as fuel source consists of five units built over different periods of time. Each unit consists of a power plant run by a steam turbine. The main difference between units is in the power of each unit and in the temperature of steam used for district heating. Electric energy produced is sold to the public distribution system, while the heat energy is sold to a district heating company running two main heating substations. The first district heating substation is supplied from the first and second unit of the power plant and the second substation from the third, fourth and fifth unit. The goal of this study is to calculate prices of heat energy from each unit. On this basis it will be possible to determine in which time period it is best for one unit to produce heat and in this way optimize the system. Calculations of prices are based on an exergy analysis that considers the economics of the system. Calculations of this kind require the data on investment, maintenance and labor costs including depreciation. Incomes are from the electricity sold to the public electric energy distribution system where the price is determined by the government decree. So all other

costs have to be distributed on heat energy. This is the approach that is presently used. This study suggests recalculating the ratio between the electric energy and heat energy, considering also the incomes from the district heating. In the calculation the emphasis is on exergy approach.

Exergy analysis is based on the second law of thermodynamics. The second law states that, although energy cannot be created or destroyed, it can be degraded in quality. Exergy is the maximum work obtainable as a system comes to equilibrium with a reference environment or more simply, exergy is that part of energy which is available for performing useful tasks. While energy analysis is the conventional method of thermodynamic analysis, more recently exergy analysis has received a growing recognition. It gives engineers a tool for proper design and operation of such complex systems.

Exergy transfer associated with the transfer of energy of heat can be defined as [1]:

$$E_{12} = Q_{12} - T_o \cdot \int_1^2 \frac{dQ}{T} \quad (1)$$

Exergy losses at heat transfer can be defined as [1]:

$$E_{12} = T_o \cdot \sum \Delta S_i \quad (2)$$

According to the first law of thermodynamics, we can define energy efficiency of cogeneration system as [2]:

$$\eta_e = \frac{W_e + \dot{Q}_h}{\dot{Q}_f} \quad (3)$$

If we consider exergy as a measure of efficiency, equation 3 turns into [2]:

$$\eta_{ex} = \frac{W_e + \dot{E}_h}{\dot{E}_f} \quad (4)$$

Exergy as a measure of efficiency and further costs was applied to the biggest coal-fired power plant in Slovenia. Different levels of heat supply and the way this affects the heat price were identified. A comparison of energy prices from the coal-fired power plant was also done on the basis of energy and exergy.

DESCRIPTION OF THE COAL-FIRED POWER PLANT

The plant consists of five units each one producing electric energy and heat. The total installed power is 755 MW and an average yearly production is from 3.8 to 4.2 billion kWh of electric energy and 0.4 billion kWh of heat energy. For this production 4.4 million tons of lignite is spent.

The units of the power plant have been built gradually. The first three units produce electric energy heat being taken directly from boilers. In units 4 and 5 electric energy and heat are produced in cogeneration. The electric energy from all units is sold to the public network, while the heat is supplied to two main heat stations. The operation of each unit is adapted to current electric energy needs. The power production of units 1, 2 and 3 is changing on a daily basis, while the power production of unit 4 and 5 is regulated directly from the national power distributor. Heat production is therefore dependent on electricity production. The heat from heat stations is used for district heating, the temperature of feed water being 140 ^{0}C and of return water 90 ^{0}C. The objective was to find from which heat station, and consequently from which unit it is most appropriate to supply the heat stations. The analysis starts from the fuel source, which is in our case lignite, and concludes with the end product, which is electric power and heat. The first task is to find out the energy flow in the cogeneration system for each unit separately. Such analyses are mainly very complex and they demand numerical programming to optimize such a system.

Let us first present the energy production of each unit in the power station with simplified diagrams (Figures 1-4).

PRODUCTION OF HEAT ENERGY IN THE COAL-FIRED POWER PLANT

For district heating two heat stations are installed in the power plant. The first heat station located in unit 3 is supplied from units 1, 2, 3 and 4. The second heat station located in unit 5 is supplied from units 4 and 5 (Figure 5).

THERMOECONOMIC ANALYSIS

Thermoeconomics deals with exergy analysis in connection with economy. It gives us the information that cannot be obtained with a conventional energy/economic analysis. From the literature, different ways of establishing thermodynamic efficiencies of systems and exergy losses are known. To solve the problem for a particular power plant we need to know the values of these losses to improve the efficiency of the whole system and reduce the price of the product.
The steps in thermoeconomic analysis are:

- calculation of production costs for each product respectively,
- understanding development process of costs and cost flow in a system,
- optimization of certain variables in a particular component,
- optimization of the whole system.

A number of researcher have tried to apply thermoeconomic analysis to a combined production of energy with an exergy approach [3], [4], including a coal-fired power plant [5]. Some models and suggestions have also been done on concrete examples, but each power plant is different. To make a detailed thermoeconomic analysis, the first step is to do the cost balance. All the costs that occur in operation are needed to determine the cost flow through the plant and to determine the costs of the two energies produced. The cost of products (energies) c_p at constant operation consists of fuel costs c_f, investment costs c_i (yearly depreciation) and maintenance/operations costs c_m. It is often difficult to determine how big these costs are and even more difficult to determine what amount would go to electricity and what to heat. Our thermoenomic analysis based on exergy has shown how prices of heat energy could be determined according to heat supply from a specific unit. Heat taken away at higher temperatures would in such a way have a higher price than heat taken away at lower temperatures.
As the exergy method of costing is based on rational thermodynamic considerations, it encourages efficient production and is fair to consumers.
The cost is increasing in each next step of the system. The general balance equation would be [6]:

Cost input + cost generation – cost output = cost accumulation (5)

Cost generation corresponds to capital and all other maintenance costs.

In general in combined power plants four different methods for determining costs are known [2]. In the equality method, the generation of two products is considered to be equal. The prices of electric and heating energy would be in that case the same. In the extraction method, it is considered that production of power is the main purpose, and that every extraction of steam reduces the output power. Emphasis of costs is therefore given to electricity price. In the by-product work method, it is assumed that production of steam is essential, although no electricity is produced. A low pressure boiler is used and costs are mainly on steam production. This method is useful in some industrial facilities. And the last method is the by-product steam method where the main costs are on produced electricity.
However, none of these methods could be directly applied to our case. In the discussed coal-fired power plant electric power production is essential, but still the importance of steam production cannot be neglected. In the study an exergy analysis was done for the whole process of combined power production from the primary source (coal) to the end products (electricity and steam). Our main goal was to build a model that would serve as a basis for determining real prices of produced electricity and steam. Generally, we can say that input exergies must be equal to output exergies [2]:

$$\dot{E}_{in} \cdot c_{in} + (\dot{Z}_b + \dot{Z}_t + \dot{Z}_g) = \dot{E}_h \cdot c_h + \dot{W}_e \cdot c_e \quad (6)$$

This is just a general equation that does not consider exergy destructions through the process of combined production of the heat power process. The model that will also consider exergy destructions through the process is still being worked on.

A theoretical approach and basis for prediction of ratios between heat and electricity price is shown below. The exergy of electricity is 1, while the exergy of heat is calculated from equation 6 [6].

$$\dot{E}_h = \dot{Q}_h \cdot \left(\frac{T - T_0}{T} \right) \tag{7}$$

According to equation (6), we can calculate exergies of steam taken for each unit. Further we can compare prices of electricity and heat energy.

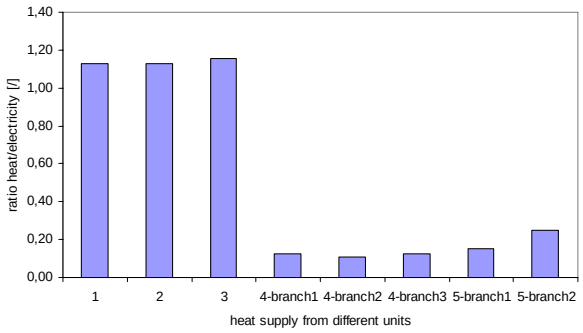

Figure 6: Ratio of heat to electricity prices regarding to heat supply

As we can see from Figure 6, heat from units 1, 2 and 3 should be even more expensive than electricity. The reason for this is the extraction of steam directly from the boiler and consecutively this steam does not produce mechanical work. The main exergy losses occur in this case at pressure reduction. The ratio of heat to electricity price for other units and branches ranges from 0.11 to 0.25. This means that the price from unit 4-branch 2 should be the cheapest. Regarding the different supplies of heat stations with heat (Figure 5) and considering different ratios of heat/electricity prices (Figure 6) we can calculate the ratio of heat/electricity prices for each station. The analysis has shown that this ratio is for the first station 0.25 and for the second 0.16. This means that the price of heating energy from heat station 1 and 2 should be respectively 4 and 6 times lower than the price of electricity.

CONCLUSIONS

In this paper we tried to identify prices of electricity and heat energy produced in a coal-fired power plant. Our main approach was exergy analysis. It is often difficult to get exact data for each step in the process of combined production of energies. One approach is to calculate exergy destruction in each part of the system, where energy (exergy) is changed. However, due to lack of exact data in the operation of the system and because of the complexity of the system, we have chosen a different approach. This approach is also based on exergy, because it considers different qualities of produced electricity and heating energy. Another difficulty was that we also could not set the exact prices of electricity and heating energy, because the operating devices are old and it was not possible to get the exact investment costs and the related depreciation. Our research was just aimed at defining which branch of heat supply is the optimal one to supply heating station 1 and heating station 2. It turned out as was expected that it was better to produce more electricity and to extract steam at lower temperatures for heating purposes. This is just a theoretical approach. However, it gives us a basis on which we can later calculate the exact price of heat from each unit. As it was mentioned in the paper, the coal-fired power plant was primarily set up for electricity production for Slovenian electricity network. Therefore the selling price of produced electricity from a coal power plant to public electricity network has already been determined by government decrees. Heat is in our case just a by- product and its price should be of course much lower.

The aim of the paper was to propose a method of determining the heating price from a coal-fired power plant. Units 1 and 2 have been planned to be replaced by new units, which will be based on a combined gas-steam process. It would be also interesting to see what in that case would be better to use for production of cooling energy: steam or electricity? An exergy approach would in this case certainly give interesting results.

ABSTRACT

A general model for the study and optimization of reversed cycle thermal machines with two heat reservoirs is presented. The mathematical model basically consists of the First and Second Laws of Thermodynamics applied to the cycle and machine, and the heat transfer equations at the source and sink considered non-linear laws, namely convective-like and radiative-like ones. The entropy generation terms consider internal and external irreversibilities of the cycle. Several constraints imposed to the system allow finding the optimum operating conditions, as well as the limited variation ranges of the system parameters. Some results generated by the model when applied to refrigeration machines are presented, pointing out two different operating regimes of the machine, namely maximum useful effect, respectively minimum dissipation. Some sensitive studies are also presented. These results are new and extensions of them we presently develop.
Keywords: Optimization, Irreversibilities, Non-linear heat transfer law, Operating regimes

NOMENCLATURE

COP	Coefficient of performance
c_p	Specific heat at constant pressure [J kg^{-1} K^{-1}]
K	Thermal conductance [W K^{-1}]

INTRODUCTION

During the 60s, a new direction in Thermodynamics appeared, namely the analysis of internally reversible heat engines considering finite heat transfer irreversibilities [1,2]. It was renewed during the 70s when an expression for the endoreversible efficiency at maximum power output was developed [3].

Since then, the so called Finite Time Thermodynamics has been developed for analyzing mostly endoreversible thermal engines, the main irreversibility considered being the heat transfer at finite temperature difference between the sources of the studied system and the working fluid [4,5]. Generally, the associated heat fluxes obeyed linear heat transfer laws (Newton's law of heat transfer) [5].

When applied to the study of heat pumps, the same method does not exhibit an optimum due to no theoretical limitation for gas temperature at the hot end [6]. Previously, an expression for the *COP* of a heat pump has been obtained corresponding to minimum power consumption for a required heating load [7]. Also, some complementary results have been obtained for a similar case, considering a given heat exchanger area to be allocated [8].

It followed an extensive study on the theory of irreversible heat transfer refrigeration systems [8]. Formulae for the *COP* and cooling rate of an endoreversible refrigerating machine were derived [9] and also for maximum specific cooling load [10]. All mentioned authors considered linear heat transfer laws.

A forward step was to introduce the internal irreversibilities, firstly represented by an irreversibility ratio [11], when maximum cooling load was determined for a required *COP*.

Recently, a review has been done [12] taking into account internal irreversibilities too, by introducing into the model the internal entropy generation term as parameter and also considering non-linear convective-like heat transfer laws, $\dot{Q} \sim (\Delta T)^n$. Two main non-linear heat transfer laws, convective and radiative-like ones ($\dot{Q} \sim (T_S^n - T^n)$), have further been explored extensively [13], the linear heat transfer law representing a particular case.

In the present paper we are analyzing general performance characteristics of an irreversible reversed cycle Carnot machine, applying the proposed model to such a refrigeration cycle.

We are considering a complete set of optimization procedures. The possible objective functions could be, not only maximum useful effect with imposed *COP*, but also minimum power consumption or minimum total dissipation. Also, the two main non-linear heat transfer laws stated above are analyzed, the convective-like one since in practice this case could represent natural convection or boiling, respectively the radiative-like one.

Internal and external irreversibilities of the cycle are taken into account too, by introducing two terms corresponding to internal and respectively, total entropy generation. The last mentioned one, which results by applying the Second Law of Thermodynamics to the whole system composed by the cycle and the two heat reservoirs, allows us to put emphasis on minimum dissipation operating regime. The entropy generation terms give the model a more general approach than the irreversibility ratio used in other papers [12,14,15]. More and more this approach concerning the entropic analysis of machines and processes [13,16-22] becomes an important tool for the design of real operating machines.

By applying this proposed model to a refrigeration cycle Carnot machine for which dimensional or performance constraints are imposed, one can notice the existence of different optimal operating regimes and also a limited range for the possible values of the system variables and parameters.

GENERAL MODEL MATHEMATICAL APPROACH FOR A REFRIGERATION CARNOT MACHINE

Machine Description

In Figure 1, the *T-S* diagram of an irreversible Carnot cycle machine is represented; therefore all processes are represented as irreversible ones. For the two adiabatic processes, the irreversibility is illustrated by entropy generation, while for the isothermal ones it is due to finite temperature heat transfer processes.

Generally, the internal irreversibility of the machine is represented by the corresponding internal entropy generation term, $\dot{S}_i$ as a model parameter. It takes into account the internal irreversibility generated on each cycle process, its value representing the sum of throttling losses, friction ones, etc. To this one an external irreversibility is added, being generated by finite

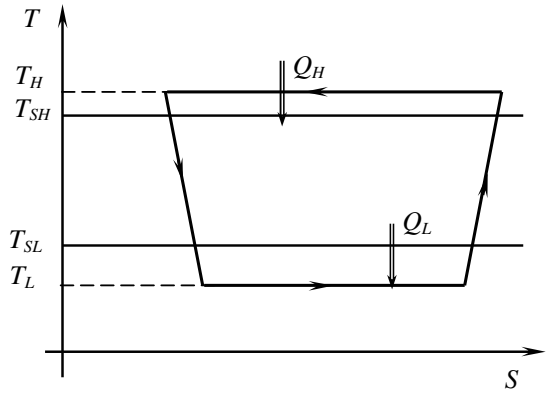

Figure 1: *T-S* diagram for an irreversible refrigeration Carnot cycle machine

temperature heat transfer process between the working fluid and the heat reservoirs. In this model, the two heat reservoirs are considered to be thermostats, of constant temperatures T_{SH} and T_{SL}, and also a steady state operating regime is considered.

Mathematical Equations

The proposed model is based on the most powerful and useful tools of Thermodynamics, namely the First and Second Laws of Thermodynamics, and also on the two heat transfer laws applied to the source and sink. For the considered hypotheses, the expression of the First Law of Thermodynamics is:

$$\dot{W} = \dot{Q}_H + \dot{Q}_L \tag{1}$$

The used sign convention is as follows: power consumption is considered negative and heat fluxes entering the cycle are considered positive, while leaving ones are negative.

The Second Law of Thermodynamics could be written in two different forms, function on the system to which it is applied. If it is applied to the endoirreversible machine, its expression is written taking into account the internal entropy generation term:

$$\frac{\dot{Q}_H}{T_H} + \frac{\dot{Q}_L}{T_L} + \dot{S}_i = 0 \tag{2}$$

If it is applied to the whole system (cycle and the two heat reservoirs), it is written taking into account the total entropy generation term:

$$\frac{\dot{Q}_H}{T_{SH}} + \frac{\dot{Q}_L}{T_{SL}} + \dot{S}_T = 0 \tag{3}$$

To these three above mentioned equations, the non-linear heat transfer laws between the heat reservoirs and working fluid are added:

$$\dot{Q}_H = K_{H,gen}\left(T_{SH} - T_H\right)^{n_H}\left(-1\right)^{n_H - 1} \text{ or}$$

$$\dot{Q}_H = K_{H,gen}\left(T_{SH}^{n_H} - T_H^{n_H}\right) \tag{4}$$

$$\dot{Q}_L = K_{L,gen}\left(T_{SL} - T_L\right)^{n_L} \text{ or}$$

$$\dot{Q}_L = K_{L,gen}\left(T_{SL}^{n_L} - T_L^{n_L}\right) \tag{5}$$

As in the present paper we apply the model to refrigeration machines, the expression of the corresponding coefficient of performance is:

$$COP = \frac{\dot{Q}_L}{\left|\dot{W}\right|} \tag{6}$$

Combining the two expressions of the Second Law, relations (2) and (3), we get:

$$\dot{S}_T = \dot{S}_i + \dot{Q}_H\left(\frac{1}{T_H} - \frac{1}{T_{SH}}\right) + \dot{Q}_L\left(\frac{1}{T_L} - \frac{1}{T_{SL}}\right) \tag{7}$$

One can notice that the total entropy generation is a sum of three positive terms each of them taking into account one type of irreversibility: the first term – internal, the last two ones – external irreversibilities due to finite temperature heat transfer processes between the heat reservoirs and working fluid.

Generally, it is difficult to establish a variation law for the internal entropy generation. We have chosen to consider the following approaches [23,24]:

a) constant: $\dot{S}_i = const$ (8a)

b) linear variation law with temperature:

$$\dot{S}_i = const \cdot \left(T_H - T_L\right) \tag{8b}$$

c) logarithmic variation law with temperature:

$$\dot{S}_i = const \cdot \ln\frac{T_H}{T_L} \tag{8c}$$

Dimensionless Model Equations

In order to avoid cumbersome computations and to make the model easy to apply to any machine, we preferred working non-dimensionally. Thus:

- dimensionless temperatures are expressed relative to the reference temperature T_{SH} which is the ambient temperature, too;
- dimensionless energy fluxes are expressed relative to the product $\dot{m}c_p T_{SH}$, where $\dot{m}c_p$ is the minimum heat rate capacity between those of the working gas and the heat reservoirs;
- non-linear thermal conductances are expressed relative to the product $\dot{m}c_p T_{SH}^{-(n-1)}$;

- entropy generation terms are expressed relative to the heat rate capacity, $\dot{m}c_p$.

According to a dimensionless constraint relative to a fixed heat exchanger area, we impose that:

$$NTU_T = NTU_H + NTU_L \quad (9)$$

which becomes a parameter of the model.

OPTIMISATION UNDER CONSTRAINTS

The dimensionless variables of the model are θ_L and NTU_L, while the considered parameters are: θ_{SL}, NTU_T, $\tilde{\dot{s}}_i$ and the imposed performance characteristics. In the present paper, we are studying the case when a certain value for *COP* is required. In this case, the objective functions could be: maximum refrigerating load, minimum power consumption or minimum total dissipation (minimum total entropy generation).

The analytical development for the optimization procedure is based on Lagrange Multipliers Method for which we wrote the Lagrangian function as:

$$L = FO + \lambda_1 C_1 + \lambda_2 C_2 \quad (10)$$

where: FO is one of the considered objective functions stated above; λ_1 and λ_2 are the corresponding Lagrange multipliers; C_1 and C_2 are the problem constraints represented by the First Law of Thermodynamics including the imposed performance characteristic restrictions and Second Law of Thermodynamics applied to the cycle including the internal entropy generation restriction.

After doing all necessary calculations, the above optimization procedure put in evidence the same system of non-linear equations no matter the considered objective function was.

It results that the optima of all objective functions (maxima and minima, respectively) correspond to the same values of the model variables.

GRAPHICAL RESULTS

By applying a numeric method for solving the system of non-linear equations for the present studied case (imposed *COP* and internal entropy generation), the proposed model put emphasis on two optimum operating regimes, namely maximum refrigerating load and minimum total dissipation.

No matter the variation law for internal entropy

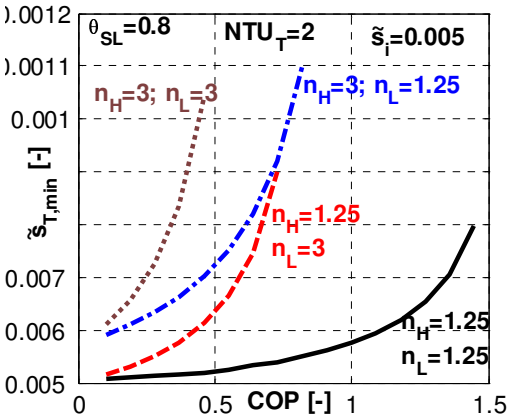

Figure 15: Minimum dimensionless total entropy generation; sensitivity studies with respect to the heat transfer law and *COP*

generation (relations (8)), the system of non-linear equations has two physical solutions corresponding to these two optimum regimes (Figure 2). This figure shows possible values for the model variables. It puts emphasis on the fact that for a chosen value of NTU_L (design stage), the machine can operate on two different regimes corresponding to solution 1 or 2, respectively. For reduced values of NTU_L (equivalent to a more important investment in the high temperature heat exchanger area), the heat transfer process is much better at the hot end, so is the temperature difference between the gas and the source (θ_H tends towards θ_{SH}=1). The opposite happens for high values of NTU_L.

The influence of these two solutions on the energy fluxes could be analyzed in Figure 3 for the first solution and Figure 4 for the second one. They also provide information about the optimal distribution of heat transfer areas between the two heat exchangers.

One can notice that the first solution corresponds to maximum refrigerating load regime, while the second one corresponds to minimum total dissipation regime. This is highlighted by the ordinate axis label, too. Once the machine parameters and desired operating regime are settled on, these two figures give us information about the future necessary distribution of total heat transfer area.

A sensitivity study with respect to *COP* values was made for the refrigerating load (Figure 5) and optimal energy fluxes corresponding to the above mentioned two operating regimes (Figures 6 and 7, respectively). We notice that an increase in *COP* value reduces the possible range values for the model variables (Figure 5). Also, higher required *COP* values determine simultaneously reductions in the refrigerating load and power consumption, for the maximum refrigerating load regime (Figure 6). For the minimum total dissipation regime (Figure 7), the higher *COP* is, the higher refrigerating load and power consumption are. This particular behavior of the system under the imposed constraints is explained by the gas temperature variation and heat exchanger inventory distribution, with respect to *COP* (Figures 8 and 9).

A second sensitivity study was made with respect to internal entropy generation values. In Figure 10, dimensionless refrigerating load for the two operating regimes in plotted for different values of imposed internal entropy generation. One can notice that higher values of $\tilde{\dot{s}}_i$ have a negative effect on the refrigerating load and also, the domain for possible values of the heat exchanger area (through NTU_L) is narrower. Of course, these limit values for the system variables depends, not only on $\tilde{\dot{s}}_i$, but also on the other imposed parameters (*COP*, θ_{SL} ,NTU_T, etc).

A third sensitivity study was made with respect to the nature of heat transfer laws at the source and sink (Figures 11-15), for which we have chosen symmetric and non-symmetric combinations of exponents (n_H and n_L).

When we compare the curves plotted in Figure 10 (representing dimensionless refrigerating load for the first operating regime), we notice different distributions of the heat transfer areas for maximum useful effect. The same conclusion is valid when comparing the curves in Figure 13. In this analysis, we have to take into account that the temperature difference between the two heat sources and the gas depends on the heat transfer law, too (Figure 11).

We also notice that the nature of the heat transfer law influences the domain for possible values of the system variables, especially the phase-change heat exchangers.

The sensitivity study with respect to *COP* and the nature of heat transfer laws (Figures 14-15) puts emphasis on the distribution of optimal values ($\tilde{\dot{q}}_{L,\max}$ and $\tilde{\dot{s}}_{T,\min}$) for the two operating regimes.

CONCLUSIONS AND PERSPECTIVES

In the present paper, we proposed a general model for the study and optimization of irreversible thermal machines, applied here to a Carnot refrigeration one.

The presented results confirm that this model is a very useful tool in spite of its simplicity. Also, they put emphasis on the limit ranges of model variables and parameters, optimal total surface distribution between the two heat exchangers of the studied machine and necessary conditions for achieving optimal operating regimes. Similar results were obtained when applying the model to the study and optimization of irreversible heat pumps.

Extension of this analysis to other cases of imposed parameters (e.g. refrigeration load and internal entropy generation, consumed mechanical

power and internal entropy generation) is under development. Also, in the near-by future, we are going to extend the model for the study of thermal machines with finite capacity heat reservoirs.

ABSTRACT

Recent work has revealed that the assumption regarding the behavior of gases (perfect, ideal, real) and, consequently, the way their properties are evaluated may alter critically the picture obtained about the performance of gas turbine systems. This fact prompted an investigation of how the aforementioned assumption may affect the optimal design point of gas turbine systems. Three systems have been selected for study and three optimization problems have been formulated and solved for each system: two thermodynamic and one thermoeconomic. The results demonstrate that the method (assumption) used for the evaluation of properties of gases has a very significant effect on the optimal point of each system.

Keywords: Gas properties, Gas turbine cycles, Optimization, Thermoeconomics.

NOMENCLATURE

C_n	Capital cost of component n (installed)
c_f	Unit cost of fuel
c_p	Specific heat capacity at constant pressure
$\tilde{c}_p$	Molar heat capacity at constant pressure
c_v	Specific heat capacity at constant volume
$\tilde{c}_v$	Molar heat capacity at constant volume
FCR	fixed charge rate
f	fuel to air ratio: $f = \dot{m}_f / \dot{m}_a$
H_u	Lower heating value of the fuel
k	Specific heat ratio: $k = c_p / c_v$
$\dot{m}_a$	air mass flow rate
$\dot{m}_f$	fuel mass flow rate
$\dot{m}_g$	exhaust gas mass flow rate
P	Pressure
r	Pressure ratio
$\dot{Q}$	Useful heat rate of the cogeneration system (production of steam)
$\tilde{R}$	Universal gas constant
T	Absolute temperature $[K]$
T_1	Compressor inlet temperature
T_3	Turbine inlet temperature (simple cycle)
t	period of operation during a year
$\dot{W}$	Net power to the load
w	Specific work, as defined by Eq. (17)
x	set of independent variables for optimization
x_i	molar fraction of species i in a mixture
Z	Annualized cost rate of a system, in \$ (including capital as well as operation and maintenance expenses)

Greek letters

γ	$\gamma = (k-1)/k$
η	Efficiency
η_B	Efficiency of the combustor
η_C	Isentropic efficiency of the compressor

1. INTRODUCTION

It is common knowledge that the efficiency of a simple gas turbine cycle increases monotonically with the maximum cycle temperature for constant pressure ratio [1]. In order to be more specific, the efficiency of the air standard cycle (assumption of perfect gas with no change of mass flow rate due to fuel addition and no pressure losses in the ducts and the combustion chamber) is given by the equation

$$\eta_A = \frac{\eta_C \eta_T \eta_J \tau_3 - \left(r^k - 1\right)}{\eta_C \left(\tau_3 - 1\right) - \left(r^k - 1\right)} \qquad (1)$$

where

$$\eta_J = 1 - \frac{1}{r^k} \qquad (2)$$

is the Joule cycle efficiency, i.e. the ideal cycle with isentropic compression and expansion and no losses. Starting with Eq. (1) it is easily proved that, if the turbine temperature is increased, keeping the pressure ratio constant, the thermal efficiency of the air standard cycle increases continuously and asymptotically it reaches the limit:

$$\lim_{\tau_3 \to \infty} \eta_A = \eta_T \eta_J \qquad (3)$$

It was tacitly assumed that the general trend was the same even if a change of specific heat capacity or of the mass flow rate due to fuel addition were considered. Thus, it was a surprise to read in Ref. [2] that, if the assumption of a working substance of constant quality and quantity is relaxed, then the behavior changes drastically: for a constant pressure ratio, the efficiency initially increases with the turbine-inlet temperature, it reaches a maximum value and then it decreases. Detailed studies of these effects appear in Refs. [3]-[5]. This remark prompted the investigation reported here.
Many publications on optimization of gas turbine cycles, including Refs. [6]-[9], are based on the assumption of perfect gas with different values for the specific heats of air and exhaust gases, in order to decrease the inaccuracy. After the aforementioned, the question arises: "how is the optimum point affected if the properties of gases are evaluated with a higher accuracy?" An answer to this question is attempted in the following, using as examples three different system configurations.

2. EVALUATION OF GAS PROPERTIES

A clarification of terminology is useful at this point. The specific heat capacities of a *real gas* are functions of both temperature and pressure:

$$c_p = c_p(p, T), \qquad c_v = c_v(p, T) \qquad (4)$$

For an *ideal gas*, they are functions of the temperature only:

$$c_p = c_p(T), \qquad c_v = c_v(T) \qquad (5)$$

For a *perfect gas*, they are constant:

$$c_p = \text{const.}, \qquad c_v = \text{const.} \qquad (6)$$

This 'textbook material' is repeated here because it is often written in related publications that 'real-gas' effects are studied, while in fact the gases are considered ideal. Thus, the reader should be careful.
In the present work, it is considered that air consisting of N_2, O_2, CO_2 and H_2O is compressed and then it reacts with a fuel having the general composition $C_\alpha H_\beta$ in a complete combustion to produce exhaust gases consisting of N_2, O_2, CO_2 and H_2O. For simplicity, minor constituents (such as CO, NO_x, etc) due to additional reactions, dissociation, impurities or other reasons are not considered here. The properties of each species are evaluated by the following equations obtained

from Refs. [10] and [11]:

$$\frac{\tilde{c}_{p0}}{\tilde{R}} = a_1 \cdot T^{-2} + a_2 \cdot T^{-1} + a_3 + a_4 \cdot T + a_5 \cdot T^2 + a_6 \cdot T^3 + a_7 \cdot T^4 \quad (7)$$

$$\frac{\tilde{h}_0}{\tilde{R}} = -a_1 \cdot T^{-1} + a_2 \cdot \ln(T) + a_3 \cdot T + \frac{1}{2} a_4 \cdot T^2 + \frac{1}{3} a_5 \cdot T^3 + \frac{1}{4} a_6 \cdot T^4 + \frac{1}{5} a_7 \cdot T^5 + b_1 \quad (8)$$

$$\frac{\tilde{s}_0}{\tilde{R}} = -\frac{1}{2} \cdot a_1 \cdot T^{-2} - a_2 \cdot T^{-1} + a_3 \cdot \ln(T) + a_4 \cdot T + \frac{1}{2} \cdot a_5 \cdot T^2 + \frac{1}{3} \cdot a_6 \cdot T^3 + \frac{1}{4} \cdot a_7 \cdot T^4 + b_2 - \ln(P) \quad (9)$$

The numerical values of the parameters a_i depend on the species and the temperature range, and they are given in Ref. [11].
The properties of air and exhaust gases are evaluated with the assumption that they are ideal mixtures; for example the molar heat capacity is calculated by the equation

$$\tilde{c}_p = \sum_i x_i \tilde{c}_{pi} \quad (10)$$

Thus, the perfect gas assumption of previous works has been replaced here with the ideal gas assumption. The effect of pressure is still considered negligible for the pressure ranges used in the systems that are studied here, as justified by values obtained for the compressibility factor.

3. SYSTEMS STUDIED

3.1 Description of the Systems

Three systems have been selected in order to study the effect of the method used for property evaluation on the optimal design point.
System I consists of a simple, open-cycle gas turbine (Figure 1). An approach for its thermodynamic and thermoeconomic optimization based on the perfect gas assumption has been presented in Refs. [6] and [7].
System II is a cogeneration plant consisting of a regenerative gas turbine with an exhaust gas boiler producing saturated steam (Figure 2) of a given quality and quantity; it is the system of the CGAM problem [8,9].
System III is an inter-cooled, regenerative gas turbine with a twin spool gas generator and a power turbine (Figure 3).

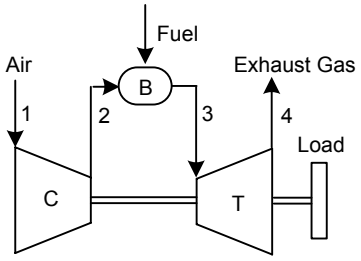

Figure 1: System I

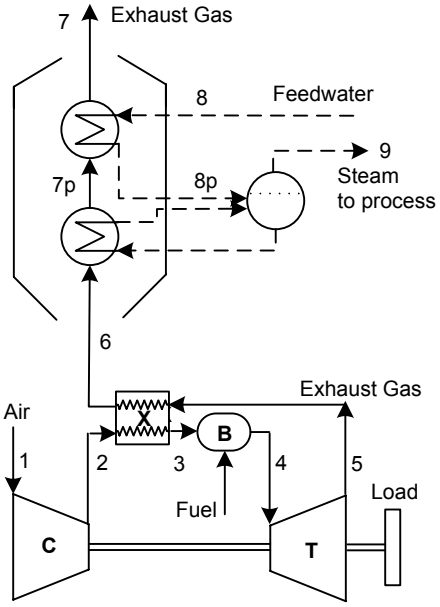

Figure 2: System II

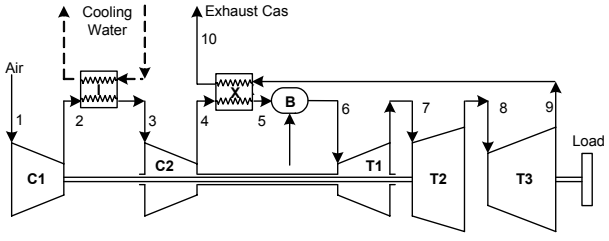

Figure 3: System III

3.2 Mathematical Models of the Systems

Thermodynamic model of System I

The air temperature at the exit of the compressor and the exhaust gas temperature at the exit of the turbine are evaluated by the equations

$$T_2 = T_1 \cdot \left[1 + \left(r_C^{\frac{k_{12}-1}{k_{12}}} - 1 \right) \cdot \frac{1}{\eta_C} \right] \qquad (11)$$

$$T_4 = T_3 \cdot \left[1 - \left(1 - r_T^{\frac{1-k_{34}}{k_{34}}} \right) \cdot \eta_T \right] \qquad (12)$$

where

$$k_{ij} = \frac{\tilde{c}_{pij}}{\tilde{c}_{pij} - \tilde{R}} \qquad (13)$$

$$\tilde{c}_{pij} = \frac{1}{T_j - T_i} \int_{T_i}^{T_j} \tilde{c}_p(T)\, dT \qquad (14)$$

Since k_{12} and k_{34} depend on the temperatures T_2 and T_4, respectively, Eqs. (11) and (12) are used in an iterative procedure in order to obtain the temperatures T_2 and T_4.

An energy balance in the combustion chamber gives the equation

$$f H_u \eta_B = (1+f)(h_3 - h_0) - (h_2 - h_0) \qquad (15)$$

which can be solved for f, if the temperature T_3 is given. The composition of the exhaust gases is determined by the reaction of combustion for any specified fuel. Since the temperature T_3 and the composition of exhaust gases are interrelated through the temperature-dependent properties of the constituents, an iterative procedure is applied also here.

The system efficiency is given by the equation

$$\eta_I = \frac{\dot{W}}{\dot{m}_f H_u} = \frac{(1+f)(h_3 - h_4) - (h_2 - h_1)}{f H_u} \qquad (16)$$

The specific work is also of interest:

$$w = \frac{\dot{W}}{\dot{m}_a} \qquad (17)$$

Thermodynamic model of System II

Equations (11)-(15) and (17) are valid for System II, with a proper adjustment of certain numerical indexes. The effectiveness of the air pre-heater is given by the equation

$$\varepsilon_X = \frac{h_3 - h_2}{h_{a5} - h_2} \qquad (18)$$

The subscript 'a5' is used in Eq. (18) in order to make it clear that h_{a5} is the enthalpy of air at temperature T_5. There is no ambiguity about h_2 and h_3. The following efficiencies are defined for this system.

Net shaft-power efficiency:

$$\eta_{II} = \frac{\dot{W}}{\dot{m}_f H_u} = \frac{(1+f)(h_4 - h_5) - (h_2 - h_1)}{f H_u} \qquad (19)$$

Efficiency of providing the useful heat:

$$\eta_{II,Q} = \frac{\dot{Q}}{\dot{m}_f H_u} = \frac{\dot{m}_s (h_9 - h_8)}{\dot{m}_f H_u} \qquad (20)$$

Total efficiency:

$$\eta_{II,tot} = \eta_{II} + \eta_{II,Q} = \frac{\dot{W} + \dot{Q}}{\dot{m}_f H_u} \qquad (21)$$

The model of System II consists of many more equations, which are given in Ref. [9], but they are not repeated here due to space limitations.

Thermodynamic model of System III

For the compression, combustion and expansion processes, equations similar to those of the System I are used. The effectiveness of the air pre-heater is given by an equation similar to Eq. (18), with proper adjustment of the numerical indexes. In addition, the following equalities are taken into consideration:

$$\dot{W}_{C1} = \dot{W}_{T2}, \qquad \dot{W}_{C2} = \dot{W}_{T1} \qquad (22)$$

The division of the pressure ratio between the low-pressure and high-pressure spool is determined by an iterative procedure so that Eqs. (22) are satisfied.

The system efficiency is given by the equation

$$\eta_{III} = \frac{\dot{W}}{\dot{m}_f H_u} = \frac{(1+f)(h_8 - h_9)}{f H_u} \qquad (23)$$

The specific work is given by Eq. (17).

Thermoeconomic models of the systems

The cost functions for Systems I and II appear in Refs. [6]-[9]. For System III, equations available for Systems I and II have been properly modified and used. Space limitations do not allow giving the complete set of equations here.

4. PERFORMANCE OF SYSTEMS WITH ALTERNATIVE METHODS FOR EVALUATION OF PROPERTIES

For the performance evaluation and for the optimization of the systems, certain values have been considered for the various parameters involved, which are given in Table 1.

System I	System II	System III
$r_B = 0.975$	$r_B = 0.975$	$r_{C1} = r_{C2}$
$\eta_B = 0.99$	$\eta_B = 0.99$	$r_I = 0.98$
$\eta_m = 0.99$	$r_{Xa} = 0.975$	$T_3 = T_1$
	$r_{Xg} = 0.965$	$r_B = 0.975$
Air	$\Delta T_{X\min} = 20\,K$	$\eta_B = 0.99$
N_2: 77.82%	$\eta_m = 0.99$	$r_{Xa} = 0.975$
O_2: 20.68%	$r_R = 0.95$	$r_{Xg} = 0.965$
CO_2: 0.03%	$\Delta T_{p\min} = 15\,K$	$\Delta T_{X\min} = 20\,K$
H_2O: 1.47%	$T_{7\min} = 373.15\,K$	$\eta_m = 0.99$
$T_{amb} = T_0$=25°C	$\dot{m}_{st} = 14\ kg/s$	$r_R = 0.95$
$P_{amb} = P_0$	$P_8 = 20\,bar$	
= 1.01325 bar	$T_8 = 298.15\,K$	
Fuel: CH_4	$T_{8P} = T_9 - 15\,K$	
$H_u = 50000 \frac{kJ}{kg}$	$P_9 = 20\,bar\,(sat.)$	

Table 1: Values of parameters

The first step in this investigation has been the study of the effect of properties evaluation on the simple cycle efficiency (System I). The results depicted in Figure 4 are revealing: the perfect gas assumption, as expected, gives an efficiency continuously increasing with the turbine inlet temperature. With the ideal gas assumption and properties evaluated by Eqs. (7)-(10), the efficiency exhibits a maximum at a temperature of about 1600 K (for the parameter values considered here). Thus, the related results of Ref. [5] are reproduced to a very close approximation (small differences are due to different values of parameters and to the different sources of equations for evaluation of gas properties).

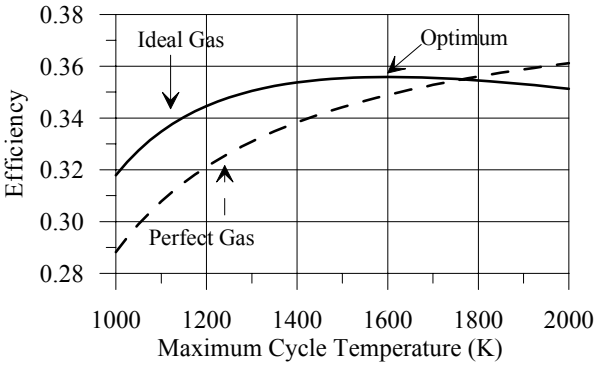

Figure 4: Efficiency of System I as a function of turbine inlet temperature with two gas models: perfect gas, ideal gas; η_C =0.90, η_T =0.92, r=10.

With the perfect gas model, the specific work increases continuously with turbine inlet temperature for a certain pressure ratio. This trend remains the same with the ideal gas model too.

In Figures 5 and 6, the effect of the gas model assumption on the system efficiency and specific work as functions of pressure ratio is shown. It is clarified that the graphs of Figures 5B and 6B correspond to the system of Figure 2 but without the exhaust gas boiler.

The coordinates of the optimum points in Figures 5 and 6 are given in Tables 2 and 3, respectively.

A change from perfect to ideal gas model changes the pressure ratio for maximum efficiency by +37.04%, –14.29% and –15.38% for the simple cycle, the regenerative cycle and the intercooled-regerenerative cycle, respectively. The optimum efficiency increases by 11.11%, 13.08% and 10.10%, respectively.

A change from perfect to ideal gas model increases the pressure ratio for maximum specific work by 16.67%, 28.57% and 50.00% for the simple cycle, the regenerative cycle and the intercooled-regerenerative cycle, respectively. The optimum specific work increases by 15.49%, 13.25% and 15.85%, respectively.

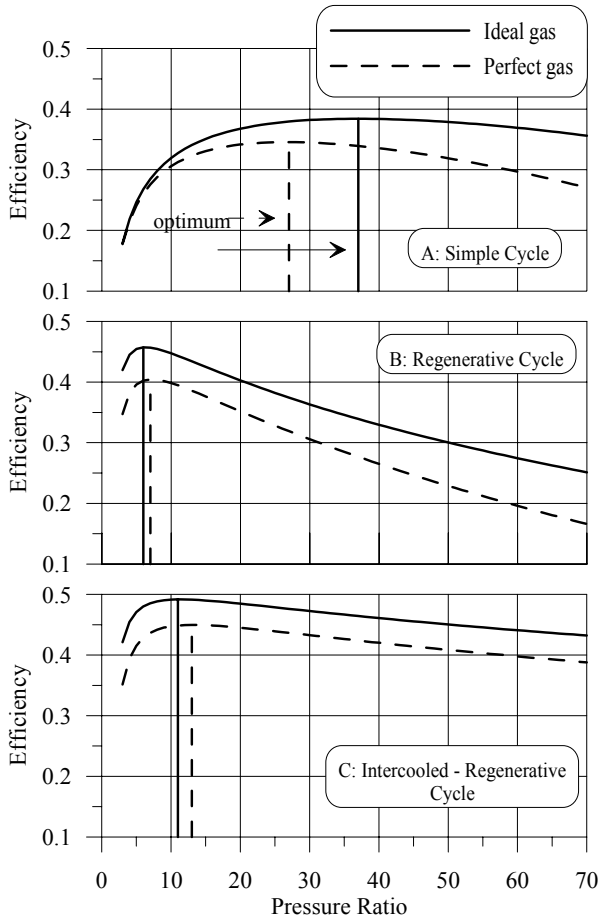

Figure 5: Efficiency as a function of pressure ratio with two gas models: perfect gas, ideal gas; η_C =0.85, η_T =0.88, τ_{max} =5.

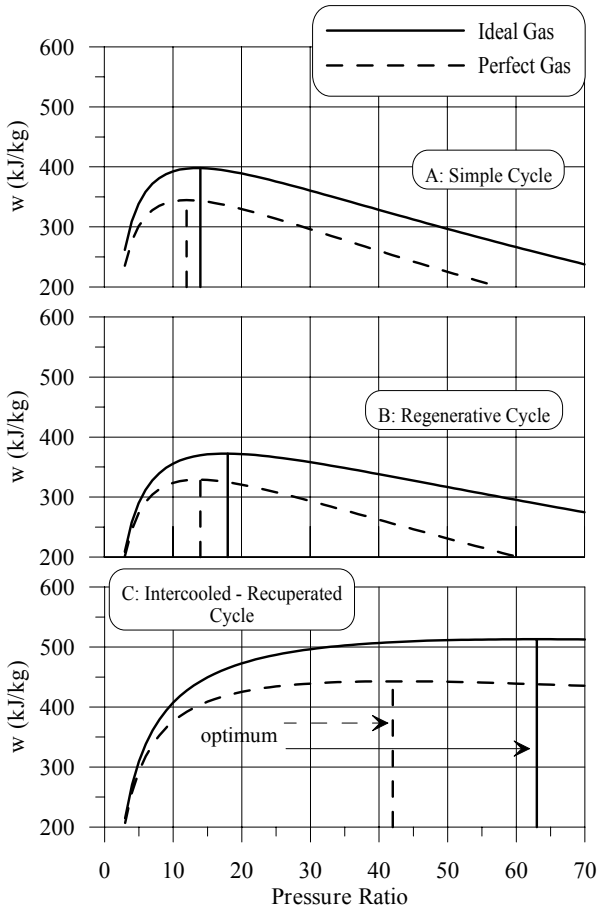

Figure 6: Specific work as a function of pressure ratio with two gas models: perfect gas, ideal gas; η_C =0.85, η_T =0.88, τ_{max} =5.

Cycle	Perfect gas		Ideal Gas	
	r*	η*	r*	η*
Simple	27	0.3457	37	0.3841
Regenerative	7	0.4045	6	0.4574
Intercooled Regenerative	13	0.4497	11	0.4918

Table 2: Coordinates of the optimum points of Figure 5.

Cycle	Perfect gas		Ideal Gas	
	r*	w*	r*	w*
Simple	12	344.64	14	398.04
Regenerative	14	328.93	18	372.50
Intercooled Regenerative	42	442.85	63	513.06

Table 3: Coordinates of the optimum points of Figure 6.

It is noted that for the Figures 5 and 6, component efficiencies more or less realistic have been used. For those values of efficiencies, the temperature of maximum cycle efficiency increases to an extremely unrealistic value. In order to keep the maximum point in a realistic temperature, we have considered more optimistic component efficiencies in Figure 4.

5. OPTIMIZATION OF SYSTEMS WITH ALTERNATIVE METHODS FOR EVALUATION OF PROPERTIES

Three distinct optimization problems have been formulated and solved for each system:

(a) Maximization of the cycle efficiency:

$$\max \eta_i , \qquad i = I, II, III \tag{24}$$

(b) Maximization of the specific work:

$$\max w_i, \qquad i = I, II, III \tag{25}$$

(c) Minimization of the annualized cost rate:

$$\min Z_i, \qquad i = I, II, III \tag{26}$$

$$Z = FCR \cdot \phi \cdot \sum_n C_n + c_f \cdot \dot{m}_f \cdot H_u \cdot t \qquad n = C, B, T, I, X, R \tag{27}$$

For the air standard cycle mentioned in the Introduction, the first two optimization problems have a well-known closed-form analytic solution [5-7]. Changing the model from constant to variable quantity and quality and simultaneously introducing pressure losses makes the analytic solution very difficult or impossible. An analytic solution for certain cases based on various simplifying assumptions has been attempted in Ref. [3] but, as mentioned in Ref. [5], the errors introduced by these assumptions may be critical. Therefore, the optimization problems are solved numerically here.

5.1 Optimization of System I

The following independent variables have been considered for the three optimization problems:

$$\mathbf{x}_{I,\eta} = (r), \quad \mathbf{x}_{I,w} = (r), \quad \mathbf{x}_{I,Z} = (\eta_C, r, \tau_3, \eta_T) \tag{28}$$

The problems (a) and (b) have been solved for the thermoeconomic optimum values of η_C^*, τ_3^*, and η_T^* obtained from the solution of problem (c). The results are given in Table 4, where the optimum values of the objective functions are written in bold numbers.

The most significant effects of the change from perfect to ideal gas are the following: The optimum pressure ratio for the problems (a), (b) and (c) increases by 34.48%, 9.69% and 21.05%, respectively. The optimum efficiency of problem (a) increases by 9.85%. The optimum specific work of problem (b) increases by 13.58%. The optimum annualised cost rate of problem (c) decreases by 7.78%.

5.2 Optimization of System II

The following independent variables have been considered for the three optimization problems:

$$\mathbf{x}_{II,\eta} = (r), \qquad \mathbf{x}_{II,w} = (r), \qquad \mathbf{x}_{II,Z} = (\eta_C, r, \tau_3, \eta_T, \varepsilon_X) \tag{29}$$

It is noted that the useful heat rate $\dot{Q}$ is fixed; consequently, maximization of η_{II} is equivalent to maximization of $\eta_{II,tot}$.

The problems (a) and (b) have been solved for the thermoeconomic optimum values of η_C^*, τ_3^*, η_T^* and ε_X^* obtained from the solution of problem (c). The results are given in Table 5.

The most significant effects of the change from perfect to ideal gas are the following: The optimum pressure ratio for the problems (a), (b) and (c) increases by 32.33%, 21.37% and 13.42%, respectively. The optimum efficiency of problem (a) increases by 3.72%. The optimum specific work of problem (b) increases by 12.41%. The optimum annualised cost rate of problem (c) decreases by 4.78%.

5.3 Optimization of System III

The following independent variables have been considered for the three optimization problems:

$$\mathbf{x}_{II,\eta} = (r, \varepsilon_X), \qquad \mathbf{x}_{II,w} = (r, \varepsilon_X), \qquad \mathbf{x}_{II,Z} = (\eta_C, r, \tau_6, \eta_T, \varepsilon_X) \tag{30}$$

The problems (a) and (b) have been solved for the thermoeconomic optimum values of η_C^*, τ_6^* and η_T^* obtained from the solution of problem (c).

The results are given in Table 6. The most significant effects of the change from perfect to ideal gas are the following: The optimum pressure ratio for the problems (a), (b) and (c) changes by –44.67%, +19.47% and –24.98%, respectively. The optimum efficiency of problem (a) increases by 12.24%. The optimum specific work of problem (b) increases by 15.89%. The optimum annualised cost rate of problem (c) decreases by 9.57%.

It is worth noting also that the maximization of the specific work results in elimination of the air pre-heater ($\varepsilon_X = 0$) in both cases (perfect and ideal gas).

5.4 Further remarks on system optimization

According to the analysis of Section 4, the optimization problem (a) of System I might be considered as having two independent variables:

	Perfect gas			Ideal gas

Z_{III}	$8.218 \cdot 10^6$	$1.116 \cdot 10^7$	$\mathbf{8.202 \cdot 10^6}$	$7.433 \cdot 10^6$	$1.077 \cdot 10^7$	$\mathbf{7.417 \cdot 10^6}$

Table 6: Optimization results for System II (intercooled regenerative cycle)

$$\mathbf{x}_{I,\eta} = (r, \tau_3) \quad (31)$$

The solution of this problem gives extremely and unrealistically high optimum values r* and τ_3^* for the values of η_C and η_T considered here. This is why only the pressure ratio has been considered as independent variable, while τ_3 is a parameter.

The effectiveness ε_X of the air pre-heater could be an independent variable for problems (a) and (b) of System II also. In such a case, maximization of the specific work would result in elimination of the air-pre-heater, changing the structure of the system. In order to keep the structure the same as in the CGAM problem, it was decided to treat ε_X as a fixed parameter for these problems.

It is interesting to note that, as we go from the simple cycle to the intercooled regenerative cycle, the optimum value of the annualized cost rate decreases by 25.22% (from $9.914 \cdot 10^6$\$ to $7.417 \cdot 10^6$\$), in spite of the fact that the system becomes more complex. The most important reasons for this decrease are the significant decrease of the pressure ratio (which decreases the capital cost of certain components) and the significant increase of the system efficiency (which decreases the fuel cost).

CONCLUSION

A preliminary performance evaluation followed by the solution of three optimization problems for each one of three different gas turbine system configurations has demonstrated that a change from the perfect gas to ideal gas model for evaluation of properties has a very significant effect on the results, which cannot be ignored. With the computing capabilities of today, the necessary calculations are conveniently performed.

ADDITIONAL FLOW RATE OF H_2 IN METHANOL PROCESS OPTIMIZATION USING NLP MODEL

Anita Kovač Kralj and Peter Glavič
Faculty of Chemistry and Chemical Engineering, University of Maribor,
2000 Maribor,
Slovenia

ABSTRACT

The opportunities for additional profit depend very much on the existing plant and energy system. Methanol plant was optimized using mathematical nonlinear programming (NLP) model by including an additional flow rate of hydrogen (H_2) in crude methanol recycle and increasing the methanol production by 2,5 %. The electricity can be generated in methanol recycle using gas turbine. The total additional profit is 2,5 MEUR/a.

Keywords: simultaneous optimisation, NLP, model, cogenerations, the product increase

INTRODUCTION

Heat and power integration can be performed by thermodynamic (pinch analysis) or by mathematical methods (nonlinear programming, NLP).

Pinch analysis is guiding heat and power integration using extended grand composite curve [1]. The pinch analysis does not guarantee the global optimal solution because it cannot be used simultaneously with material balances but it quickly proposes good ideas for process heat and power integration of complex processes. Combined heat and power integration adds degrees of freedom to the optimisation method [2]. The graphical representations of gas turbine using pinch analysis help us to better understand the integration [3]. A step-wise methodology of gas turbine integration combined with heat and power cogeneration developed by Axelsson and coauthors [4] is based on pinch analysis.

The NLP algorithm [5], which is based on mathematical programming can be used for rigorous process and power integration. Although simultaneous, it is difficult to converge for complex and energy intensive processes because the number of variables increases with the number of combinations.

In this paper, we are concerned with simultaneous NLP mathematical optimization techniques after including increased production by additional flow rate of hydrogen in recycle system by cogeneration of electricity using gas turbine.

ADDITIONAL FLOW RATE OF THE RAW MATERIAL

The opportunities for increasing the production depend very much on the reaction conversion and reaction kinetics. Thermodynamic and kinetic properties of chemical reactions (r = 1, …, R) give a good predicted aspects about: flow rate and compositions of raw material, conversion efficiency of product and parameter conditions. The method based on minimization of Gibbs free energy (ΔG) is used for the calculations of chemical equilibrium composition (n, y) of components (s = 1, …, S) and equilibrium constant of reactions r (K_r):

$$\mathrm{d}n_s/y_s = \mathrm{d}\, w_r \qquad s = 1, \ldots, \mathrm{S} \quad r = 1, \ldots, \mathrm{R} \qquad (1)$$

$$K_r = \mathrm{e}^{(-\Delta Gr/RT)} \qquad r = 1, \ldots, \mathrm{R} \qquad (2)$$

GAS TURBINE

Many chemical products are produced at high pressure and temperature, followed separation at lower pressure and temperature follows. This pressure change can be used to drive a turbine conpled to an electricity generator. The reactor is acting as a combustion chamber of a gas turbine plant. The turbine uses process gas as a working fluid [6]. Gas turbine can be used in the plant with a steady flow rate.

The designed medium pressure of the turbine can be varied [7]. Its power (P_{tur}) is a function of the outlet ($T_{\mathrm{tur,\ out}}$) temperature, molar heat capacity (C_{m}) and amount flow rate (F; eq. 3). The inlet temperature ($T_{\mathrm{tur,\ in}}$) is constant:

$$P_{\mathrm{tur}} = C_{\mathrm{m}} \cdot (T_{\mathrm{tur,\ in}} - T_{\mathrm{tur,\ out}}) \cdot F \cdot \eta_{\mathrm{tur}} \cdot \eta_{\mathrm{gen}} \qquad (3)$$

The thermodynamical efficiency of the medium pressure turbine (η_{tur}) and mehanical efficiency of the generator (η_{gen}) are supposed to be 85 % each.

CO_2 EMISSIONS

CO_2 shall be separated from the process for the following reasons:

- it is forming H_2CO_3 and
- it is mitigating the global climate conditions.

The simultaneous mathematical optimization method NLP model is presented containing the decreased CO_2 emissions by including taxes and costs of CO_2 emissions. The emissions can be reduced at the source. The CO_2 flow rate depends on [8]:

- the raw material inlet amount flow rate,
- the separation and reactor system and
- the fraction of the recycle exhaust flow rate.

CASE STUDY

We tested this ideas using a complex process of low-pressure Lurgi methanol production (Fig. 1). The methanol is produced from synthesis gas obtained from natural gas and steam in reactor (REA-1). The exothermal methanol reactor (REA-2) with three main reactions (r = R1, R2, R3):

$$\mathrm{CO} + 2\mathrm{H_2} \rightarrow \mathrm{CH_3OH} \qquad (\mathrm{R1})$$

$$\mathrm{CO_2} + 3\mathrm{H_2} \rightarrow \mathrm{CH_3OH} + \mathrm{H_2O} \qquad (\mathrm{R2})$$

$$\mathrm{CO_2} + \mathrm{H_2} \rightarrow \mathrm{CO} + \mathrm{H_2O} \qquad (\mathrm{R3})$$

is operated at high pressure and unconverted gas is recycled. The reactor is to be operated at the existing parameters. The high recycle ratio and operating pressure of the reactor are exploited to produce electricity, using gas turbine (TUR) placed downstream the reactor. The turbine is using process gas as a working fluid. The inlet stream of the reactor is heated by a process stream (HEPR) or by high pressure steam (HEST) or combining both of them. The stream leaving the turbine is cooled using air (HEA) and water (HEW) heat exchangers before entering the flash (SEP). The liquid stream of the separation is the product and the recycled gas stream is compressed to 51 bar in a two stage compressor (COMP1, 2) with intermediate water cooling (HEW1).

The simultaneous mathematical optimization method using the NLP model for methanol plant is presenting the effects of the:

- additional flow rate of H_2,
- decreased raw material rate (the high pressure steam),
- decreased CO_2 emissions,
- increased product production depending on the raw material flow rate (H_2 and steam), the separation (SEP) and reactor system (REA-2),
- electricity cogeneration
- integration of heat flows and
- reduced exhaust flow rate (purge gas).

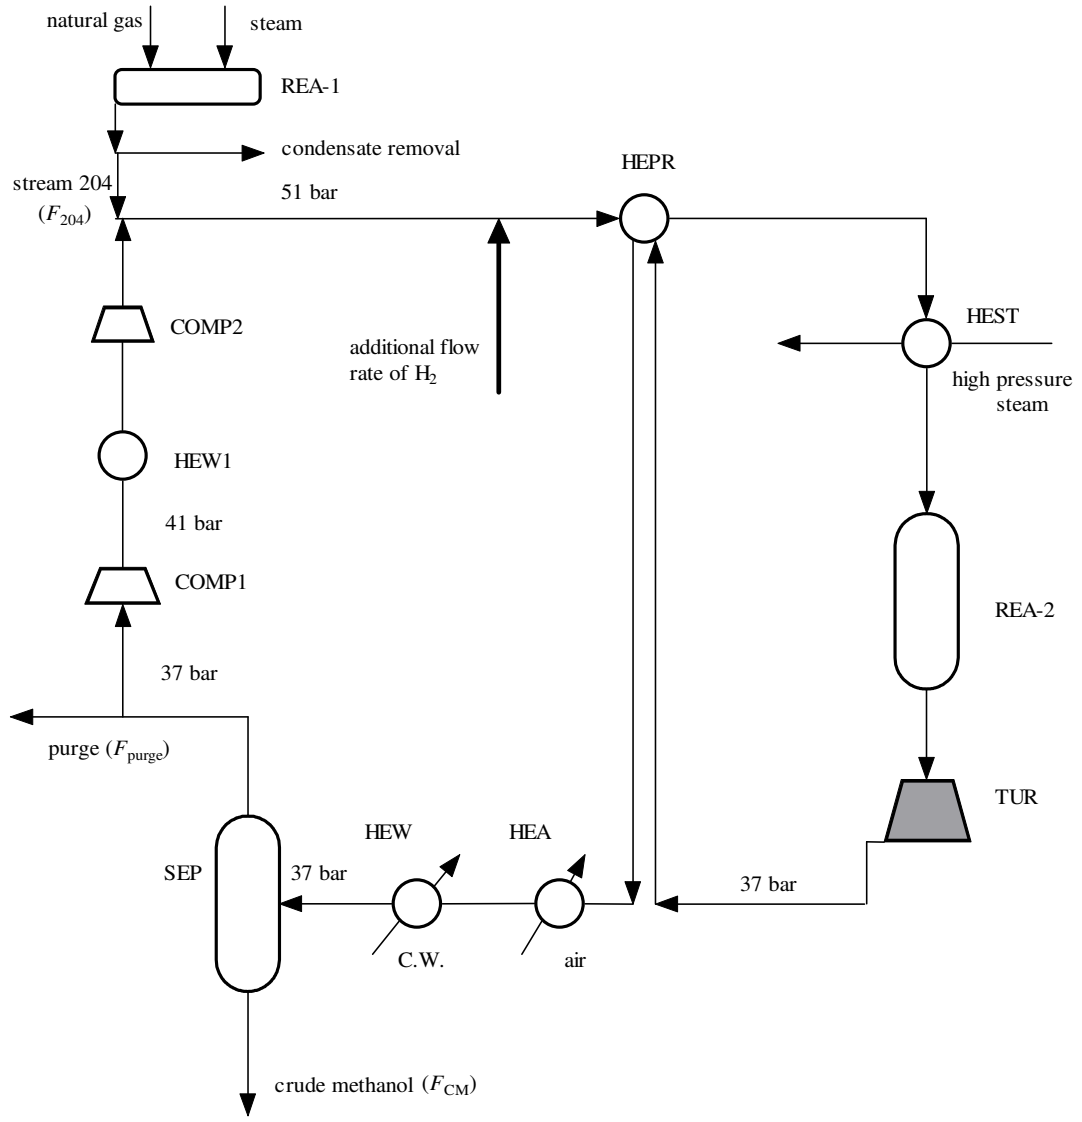

Figure 1: Simplified flow sheet of the methanol plant with gas turbine with additional H_2 flow rate.

Additional flow rate of H_2

Additional flow rate of hydrogen (H_2) in crude methanol recycle is increasing the methanol production. The methanol conversion is calculated with the equilibrium reaction system (eq. 1 and 2) depanding on raw material flow rate, the recycle flow rate and operating conditions.

H_2 shall be separated from the purge gas by an existing pressure swing adsorption (PSA) column. The purge gas is purified by the PSA column to

deliver hydrogen at the 90 % to 99,99 % level by removing N_2, CO, CO_2, CH_4 and H_2O. The pressure swing adsorption uses an adsorber packed with a molecular sieve adsorbent with 50 % efficiency. The PSA column is operated at the 26 bar pressure and the 35 ^oC temperature with maximal 488 kg/h capacity of H_2.

In the NLP model the additional flow rate of hydrogen in the reactor REA-2 can be varied from 0 kg/h to 488 kg/h (ΔF_H) and it can effect the optimal process structure and production rate. After start-up the PSA column will produce pure H_2 in 2 to 4 h. The purification system is competely automatic. The H_2 purification cost in the existing PSA column and inlet injection cost in recycle (with inlet parameters 51 bar and 60 ^oC) is 0,1 EUR/kg.

Synthesis gas is produced from natural gas using 33 100 kg/h of high pressure steam in the reactor (REA-1). The flow rate of high pressure steam (as the raw material) can be decreased to the lower operating bound constraint of 32 000 kg/h and the flow rate of the high pressure steam as reactant can be reduced by 9 192 t/a. All the other process units shall be operated at the existing parameters. The lower flow rate of high pressure steam influences the reaction equilibrium, as well as conversions in the synthesis gas and methanol synthesis reactors. The higher equilibrium conversion in the synthesis gas reactor is decreasing the flow rate of CO_2 and increasing the flow rate of CO. In the NLP model the flow rate of high pressure steam in the synthesis gas reactor can be varied from 0 t/a to 9 192 t/a (ΔF_{steam}) and with them the composition of stream 204 (F_{204}) is changing:

$$F_{204,\,i} = a_i + b_i\,\Delta F_{steam} \quad (4)$$

i = CO_2, CO, H_2, CH_4, N_2 and H_2O

$$F_{204} = \Sigma\, F_{204,\,i} \quad (5)$$

Decrease CO_2 emissions

The reduced flow rate of CO_2 is to decrease the corrosion of the gas turbine and the emissions.

Increase product production

Increased product production depends on the raw material flow rate (H_2 and steam), the separation (SEP), reactor system (REA-2) and exhaust flow rate.

Additional production of methanol can be calculated:

$$\Delta F_M = F_M - 138{,}97 \quad (6)$$

F_M being the optimized amount flow rate of methanol, and 138,97 mol/s the existing one.

Cogeneration of electricity in gas turbine

In methanol production the pressure drop can be used for electricity cogeneration.

Integration of heat flows

The model is including the heat integration between outlet and inlet streams.

Exhaust flow rate (purge gas)

The exhaust flow rate can be varied from 5,2 % to 5,9 %.

The equations for heat and mass balance of the process units shown in Fig. 1 were included [9]. The NLP model contains equations for structural and parametric optimisation. The goal of the optimization is to maximize additional annual income and minimize the additional annual depreciation (eq. 7). The additional annual income sums up:

- the additional cogeneration of electricity ($P_{tur} \cdot \eta_{tur} \cdot \eta_{gen}$),
- the additional production of methanol (ΔF_M) and
- saving obtained by decreasing the flow rate of high pressure steam (ΔF_{steam}) raw material.

The additional annual depreciation cost sums up (Table 1):

- the emission cost of outlet stream of crude methanol (F_{CM}),
- the gas turbine with power P_{tur},
- the compressors COMP1 and COMP2 and
- the enlarged and new areas of heat exchanger (A_{HE}).

The objective function is including:

- H_2 purification cost in existing PSA column and
- the buying the flow rate of high pressure steam in heat exchanger HEST.

Max. additional annual profit =

$$C_{el} \cdot P_{tur} \cdot \eta_{tur} \cdot \eta_{gen} + C_M \cdot \Delta F_M + C_{37} \cdot \Delta F_{steam} - C_{tax} \cdot F_{CM,CO2} - C_{37} \cdot \Phi_{HEST} - (22\,946 + 13{,}5 \cdot P_{tur}) \cdot 4 - [2\,605 \cdot P_{COMP1}^{0,82} - 2\,605 \cdot P_{COMP2}^{0,82} - \sum_{new} (8600 + 670 \cdot A_{HE,new}^{0,83}) \cdot 3{,}5 \cdot 2 - \sum_{add} 670 \cdot \Delta A_{HE,add}^{0,83} \cdot 3{,}5 \cdot 2] \cdot r - C_{H2} \cdot F_{H2} \quad (7)$$

new = HEST, HEW1
add = HEW, HEA, HEPR

Table 1: Cost items for example process.

Installed cost of heat exchanger*/EUR: $(8\,600 + 670\,A^{0,83}) \cdot 3{,}5 \cdot 2$ #
Cost of compressor, C_{com}&/EUR: $2\,605 \cdot P^{0,82}$
Cost of gas turbine, C_{tur}&/(EUR/a): $(22\,946 + 13{,}5\,P_{tur}) \cdot 4$ #
Cost of methanol $(C_M)^+$/(EUR/t): 115,0
Cost and taxes of CO_2 emissions $(C_{tax})^{++}$ /(EUR/t): 11,5
Cost of electricity $(C_{el})^{**}$/(EUR/(kW · a)): 435,4
Cost of H_2 purification in existing PSA column and inlet injection in recycle (C_{H2}) /(EUR/kg): 0,1
Cost of 37 bar steam $(C_{37})^{**}$/(EUR/(kW · a)): 106,3

* [11] A = area in m^2
** [12]
& [5] P = power in kW
++ [4]
\+ ten years average
\# the published cost equations for the equipment are adjusted to the real, higher industrial costs, by multiplier of 2 or 4.

The inlet stream of the reactor REA-2 can be heated by a process stream in heat exchanger (HEPR) or/and by high pressure steam (HEST) with varying heat flow rate.
In the model the existing areas can be used ($A_{HE,ex}$), enlarging them with additional areas ($\Delta A_{HE,add}$) if necessary. The additional annual depreciation of the enlarged and new areas ($A_{HE,new}$) of heat exchangers and compressors (Table 1) are multiplied by the payback multiplier (r = 0,216; [10]).

The simultaneous NLP of heat and power integration with 488 kg/h maximal additional flow rate of H_2 was selected with electricity generation using gas turbine pressure drop from 49,7 bar to 37 bar and outlet temperature, $T_{tur,out}$ = 110 °C. The existing PSA column for purification the H_2 can be used. The total additional annual methanol production (including all the effects of the additional flow rate of hydrogen, reduced the flow rate of steam and reaction kinetics) is 3,5 mol/s. The structure enables 17,5 MW of electricity to be generated. The steam exchanger (HEST) needs 22,85 MW of heat flow rate. The integrated process streams exchange 5,18 MW of heat flow rate in HEPR. The powers of the first and the second compressor are 2,9 MW and 4,0 MW, respectively. The HEW1 exchanges 3,0 MW. In the heat exchangers HEW and HEA 5,3 MW and 8 MW of heat flow rate are exchanged by cooling, respectively. The purge gas is decreasing outlet fraction flow rate from 5,9 % to 5,2 %.
The additional annual depreciation of the gas turbine, new heat exchangers (HEST, HEW1) having 730 m^2 and 324 m^2 area, respectively and the new two-stage compressor is 2,69 MEUR/a. The emission cost is 0,01 MEUR/a. The cost of high pressure steam used in HEST is 2,43 MEUR/a. The H_2 purification cost in the existing PSA column and inlet injection cost in recycle is 0,4 MEUR/a.
The annual income of the additional electricity produced is 7,6 MEUR/a and of the additional methanol produced 0,37 MEUR/a. The steam flow rate can be reduced to 9 192 t/a with

additional annual income of 0,06 MEUR/a. The additional profit of the process including cogeneration and additional methanol production is estimated to be 2,5 MEUR/a with 2,3 years of the payback time.
The NLP program is including 130 equations and 138 variables with computation time of 17 s on the VAX-3100 using the GAMS program.

CONCLUSIONS

The paper has presented efficient NLP model formulations for simultaneous cogeneration of electricity using gas turbine and process heat integration including additional equations for reaction conversion and the CO_2 emissions. The simultaneously optimized NLP model of low-pressure Lurgi methanol plant can include the effects of raw material flow rate (the additional flow rate of H_2 and reduced flow rate of steam as reactants), reactor conversion, temperature efficiency of flash, fraction of the exhaust flow rate and energy saving to decrease the CO_2 emissions in outlet stream of crude methanol by 900 t/a. The higher equilibrium conversion with all the effects in both reactors can increase the conversion of methanol by 2,5 %, producing 3 200 t/a of additional methanol. We have carried out simultaneous heat, power and emission optimization with a potential additional profit of 2,5 MEUR/a.

[2)] Department of Physics, Xiamen University, Xiamen 361005, P. R. China

ABSTRACT

The cyclic model of an irreversible three-source chemical pump is put forward, in which finite rate mass transfer and internal irreversibilities resulting from friction, eddy currents and other dissipation inside the cyclic working fluid are taken into account. The performance of the chemical pump is optimized by using the optimal control theory. The optimal relation between the coefficient of performance and the rate of energy pumping is derived. The bounds of some important performance parameters, such as the maximum rate of energy pumping and its corresponding coefficient of performance and so on, are obtained. The optimally operating region of the chemical pump is determined and evaluated. The optimal time distribution spent on the three mass transfer processes is also discussed. Moreover, the condition that the chemical pump has the maximum rate of energy pumping is analyzed in detail. The results obtained in the present paper can not only include some important conclusions relative to the endoreversible three-source chemical pump and the irreversible chemical engine which have been investigated in some literatures, but also provide some guidance for the optimal design and development of chemical pumps.

INTRODUCTION

In the last decades, the investigation on the optimal performance of thermodynamic cyclic systems has been extended to the cyclic devices driven by mass fluid [1-14]. For example, the optimal analysis on the performance of chemical engines [4-9] and the two- and three-source chemical pumps [10-14] are some of the successful applications of the theory of optimum thermodynamics. The three-source chemical pump is one of the typical mass transfer systems, which is operated among three mass reservoirs and is analogous to a heat transformer [15,16], which has a potential advantage of saving energy and reducing environmental pollution. Lin *et al.* [11,12] analyzed the optimal performance of an endoreversible chemical potential transformer. By using the optimal control theory, they studied the influence of the finite rate mass transfer on the performance of the chemical potential transformer. However, for real thermodynamic system, there often exist other sources of irreversibility besides the finite rate mass transfer. In the present paper, a general cycle model of a three-source chemical pump affected by finite rate mass transfer and other irreversiblities resulting from the internal dissipation of the working fluid is established and used to analyze the optimal performance of the three-source chemical pump. In particular, the optimized expressions for two key performance parameters, the coefficient of performance and the rate of energy pumping, of the chemical pump are calculated and the optimal relation between them is derived. Furthermore, the other optimal performances of the chemical pump are analyzed and evaluated. The results obtained can play a significant reference role for the development and optimal design of mass exchangers, electro-chemical, photochemical and solid state devices related to mass transfer processes.

THE CYCLIC MODEL OF IRREVERSIBLE THREE-SOURCE CHEMICAL PUMP

We consider a class of chemical pumps operating among the three mass reservoirs whose chemical potentials are, respectively, μ_h, μ_p and μ_O, as shown schematically in figure 1, where $\mu_p > \mu_h > \mu_O$ and μ_1, μ_2 and μ_3 are, respectively, the chemical potentials of the cyclic working fluid in the three iso-chemical-potential processes. They are different from the chemical potentials of the three mass reservoirs, so that mass transfer is carried out under a finite chemical potential difference. It is assumed that mass exchange obeys the mass-transfer law of linearized irreversible thermodynamics [1-14], i.e.,

$$\Delta N_1 = h_1(\mu_h - \mu_1)t_1 \tag{1}$$

$$\Delta N_2 = h_2(\mu_2 - \mu_p)t_2 \tag{2}$$

$$\Delta N_3 = h_3(\mu_3 - \mu_O)t_3 \tag{3}$$

where ΔN_1, ΔN_2 and ΔN_3 are, respectively, the exchanged mass between the working fluid

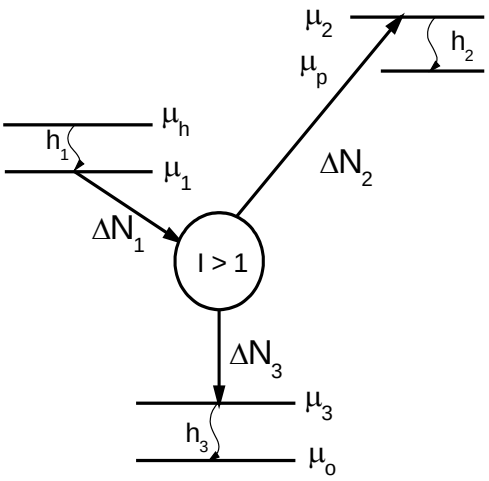

Figure 1: Schematic diagram of an irreversible three-source chemical pump cycle

and the three reservoirs at chemical potentials μ_h, μ_p and μ_O, h_1, h_2 and h_3 are, respectively, the coefficients of mass transfer between the working fluid and the three reservoirs, and t_1, t_2 and t_3 are the corresponding mass transfer times spent on the three mass transfer processes.

Except for three mass exchange branches between the working fluid and the three reservoirs, there exist other additional branches of the three-source chemical pump cycle that connect the three mass exchange branches. These branches may be regarded as instant because there is no mass exchange in these additional branches [6-14]. Therefore, the cyclic period τ of the chemical pump equals approximately the sum of t_1, t_2 and t_3, i.e.,

$$\tau = t_1 + t_2 + t_3 \qquad (4)$$

It should be pointed out that besides the mass-transfer irreversibility, the internal irreversibilities resulting from friction, eddy currents and other irreversible effects inside the cyclic working fluid are inevitable, such that the internal cycle of the chemical pump is irreversible. This implies that the sum of entropy flows flowing out from the iso-chemical-potential μ_2 and μ_3 processes are always larger than that flowing into the iso-chemical-potential μ_1 process. Therefore, according to the definition of entropy, one has

$$[(\Delta U_2 - \mu_2 \Delta N_2) + (\Delta U_3 - \mu_3 \Delta N_3)] - (\Delta U_1 - \mu_1 \Delta N_1) \geq 0 \qquad (5)$$

where ΔU_1 is the internal energy flow flowing into the iso-chemical-potential μ_1 process and $\Delta U_2, \Delta U_3$ are the internal energy flows flowing out from the iso-chemical-potential μ_2 , μ_3 processes, respectively. They satisfy $\Delta U_1 = \Delta U_2 + \Delta U_3$. According to above analysis, we have

$$\mu_1 \Delta N_1 - (\mu_2 \Delta N_2 + \mu_3 \Delta N_3) \geq 0 \qquad (6)$$

The equality in equations (5) and (6) is true only when the cycle is endoreversible.

Moreover, the consideration in this approach is limited to isothermal irreversible three- source chemical pump in order to isolate and more transparently illustrate results that are linked to the mechanism of mass transfer, rather than these effects combined with that of heat transfer across a temperature difference.

On the basis of equation (6), we can introduce an internal irreversibility parameter

$$I = \frac{\mu_1 \Delta N_1}{\mu_2 \Delta N_2 + \mu_3 \Delta N} \geq 1 \qquad (7)$$

to describe the internal irreversibilities resulting from friction, eddy currents and other irreversible effects inside the cyclic working fluid. The value of I is, in general, larger than 1. It is equal to 1 only when the internal irreversibility may be neglected. It is thus clear that the endoreversible cyclic model (I =1) of the three-source chemical pump [11,12] is just a special case of the cyclic model established in the present paper, so that the

optimal performance of an endoreversible three-source chemical pump can be directly derived from the results obtained in the present paper.

TWO KEY PERFORMANCE PARAMETERS AND THEIR OPTIMUM RELATION

According to the law of mass conservation and equation (7), one has

$$\Delta N_1 - \Delta N_2 - \Delta N_3 = 0 \tag{8}$$

$$\Delta N_1 \mu_1 - I(\Delta N_2 \mu_2 + \Delta N_3 \mu_3) = 0 \tag{9}$$

On the other hand, from the definitions of the coefficient of performance χ_{3P} and the rate of energy pumping Σ_{3P}, we have

$$\chi_{3P} = \Delta N_2 \mu_p / (\Delta N_1 \mu_h) \tag{10}$$

$$\Sigma_{3P} = \Delta N_2 \mu_p / \tau \tag{11}$$

Using equations (1)-(4), (8), (9), one can prove that the coefficient of performance and the rate of energy pumping are expresses as

$$\chi_{3P} = \mu_p(\mu_1 - I\mu_3)/[I\mu_h(\mu_2 - \mu_3)] \tag{12}$$

$$\Sigma_{3P} = \mu_p \left\{ \frac{I(\mu_2 - \mu_3)}{h_1(\mu_1 - I\mu_3)(\mu_h - \mu_1)} + \frac{1}{h_2(\mu_2 - \mu_p)} + \frac{I\mu_2 - \mu_1}{h_3(\mu_1 - I\mu_3)(\mu_3 - \mu_O)} \right\}^{-1} \tag{13}$$

For the optimal purpose, we introduce the Lagrangian function [2]

$$L = \chi_{3P} + \lambda \Sigma_{3P} = \frac{\mu_p(\mu_1 - I\mu_3)}{I\mu_h(\mu_2 - \mu_3)}$$

$$+\lambda\mu_p \left\{ \frac{I(\mu_2 - \mu_3)}{h_1(\mu_1 - I\mu_3)(\mu_h - \mu_1)} + \frac{1}{h_2(\mu_2 - \mu_p)} + \frac{I\mu_2 - \mu_1}{h_3(\mu_1 - I\mu_3)(\mu_3 - \mu_o)} \right\}^{-1} \tag{14}$$

where λ is the Lagrangian multiplier. From the Euler-Lagrange equations $\partial L/\partial \mu_1 = 0$, $\partial L/\partial \mu_2 = 0$ and $\partial L/\partial \mu_3 = 0$, we can find that when the chemical potentials of the cyclic working fluid in the three iso-chemical- potential processes

$$\mu_1 = \frac{(\sqrt{b_2} + \sqrt{Ib_1}\chi_{3P})\mu_h\mu_p - I(\sqrt{b_2} - 1)\mu_h^{\,2}\chi_{3P} - \sqrt{Ib_1}\chi_{3P}\mu_h\mu_o + \sqrt{Ib_1}\mu_p\mu_O}{(\sqrt{I^{-1}b_1} + \sqrt{b_2})\mu_p - (\sqrt{b_2} - 1)\mu_h\chi_{3P}} \tag{15}$$

$$\mu_2 = \frac{(\sqrt{b_1 I^{-1}} + \sqrt{b_2})\mu_p^{\,2} - \sqrt{b_2}\mu_h\mu_p\chi_{3P} + \mu_h\mu_o\chi_{3P} - \mu_p\mu_o + I^{-1}\mu_h\mu_p}{(\sqrt{b_1 I^{-1}} + \sqrt{b_2})\mu_p - (\sqrt{b_2} - 1)\mu_h\chi_{3P}} \tag{16}$$

and

$$\mu_3 = \frac{I^{-1}\sqrt{b_2}\mu_h\mu_p + \sqrt{I^{-1}b_1}\mu_p\mu_o + \mu_h\mu_o\chi_{3P} - \sqrt{b_2}\mu_h\mu_p\chi}{(\sqrt{I^{-1}b_1} + \sqrt{b_2})\mu_p - (\sqrt{b_2} - 1)\mu_h\chi_{3P}} \tag{17}$$

the relation between the optimal coefficient of performance χ_{3P} and the rate of energy pumping Σ_{3P} of the irreversible three-source chemical pump is given by

$$\Sigma_{3P} = H_I \chi_{3P} \frac{\mu_h^{\,2}\mu_p(\mu_p - \mu_o)[(\chi_{3P})_I - \chi_{3P}]}{(\mu_p - B_I\mu_h\chi_{3P})^2} \tag{18}$$

where $H_I = Ih_1h_3/(\sqrt{Ih_1} + \sqrt{h_3})^2$,

$B_I = (\sqrt{b_2} - 1)/(\sqrt{I^{-1}b_1} + \sqrt{b_2})$,

$(\chi_{3P})_I = \mu_p(\mu_h - I\mu_o)/(I\mu_h(\mu_p - \mu_o))$; and $b_1 = h_2/h_1$ and $b_2 = h_2/h_3$. Equation (18) is an important optimum relationship and the optimal performance of a class of three-source chemical pumps can be obtained from it.

SEVERAL IMPORTANT PERFORMANCE BOUNDS

It can be seen from equation (18) that when the coefficient of performance χ_{3P} equals some value, the rate of energy pumping Σ_{3P} has a maximum. Using equation (18) and the extreme condition $\partial\Sigma_{3P}/\partial\chi_{3P} = 0$, we can obtain the

maximum rate of energy pumping as

$$(\Sigma_{3P})_{\max} = \frac{H_I}{4} \frac{(I^{-1}\mu_h - \mu_o)^2 \mu_p}{[\mu_p - \mu_O - B_I(I^{-1}\mu_h - \mu_o)]} \quad (19)$$

with the corresponding coefficient of performance

$$\chi_{3P} = \frac{\mu_P(1 - I\mu_O/\mu_h)}{2(\mu_P - \mu_O) - B_I(I^{-1}\mu_h - \mu_O)} \equiv (\chi_{3P})_m \quad (20)$$

where $(\Sigma_{3P})_{\max}$ and $(\chi_{3P})_{\mathrm{m}}$ are two important performance bounds of the irreversible three-source chemical pump. In fact, the maximum rate of energy pumping $(\Sigma_{3P})_{\max}$ determines an upper bound for the rate of energy pumping, while the corresponding coefficient of performance $(\chi_{3P})_m$ determines the allowable value of the lower bound of the optimal coefficient of performance. Obviously, the optimal coefficient of performance should be located between $(\chi_{3P})_m$ and $(\chi_{3P})_I$.

It should be pointed out that there exists a maximum rate of energy pumping for the irreversible three-source chemical pump only when the following equation is satisfied, i.e.,

$$B_I < \frac{(\mu_P - \mu_O)}{I^{-1}\mu_h - \mu_O} \quad (21)$$

For example, when $\mu_h / \mu_O = 6, \mu_P / \mu_O = 10$, I = 1.1, the value of B_I should be less than 2.02 otherwise there doesn't exist a maximum rate of energy pumping. Notice that the value of B_I depends closely on the coefficients of mass transfer and the internal irreversibility parameter, and hence equation (21) determines the relation among the coefficients of mass transfer, the chemical potentials of the mass reservoirs and the

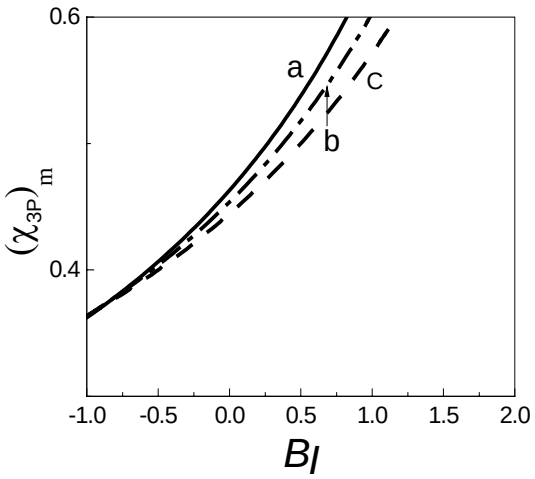

Figure 2: The $(\chi_{3P})_m$ versus B_I curves. Plots are presented for $\mu_h / \mu_O = 6, \mu_P / \mu_O = 10$. Curves *a*, *b* and *c* correspond to the case of *I*= 1, 1.1 and 1.2

internal irreversibility parameter. This indicates indirectly that the lower bound of the coefficient of performance depends closely on the internal irreversibility parameter besides the chemical potentials of the three reservoirs and the mass transfer coefficients.

It can be seen from equation (20) that when the internal irreversibility parameter I is given, the lower bound $(\chi_{3P})_{\mathrm{m}}$ of the coefficient of performance decreases as B_I decreases, as shown in figure 2. At the same time, it can be seen from figure 2 that the lower bound $(\chi_{3P})_{\mathrm{m}}$ of the coefficient of performance decreases as the internal irreversibility parameter I increases, especially when B_I is large. Therefore, we should

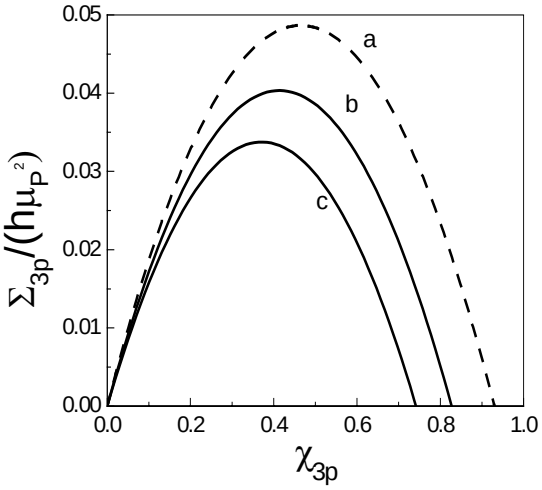

Figure 3: The Σ_{3P} versus χ_{3P} curves. Plots are presented for $\mu_h / \mu_O = 6, \mu_P / \mu_O = 10$ and $h_1 = h_2 = h_3$. Curves *a*, *b* and *c* correspond to the case of I = 1, 1.1 and 1.2

pay more attention to the internal irreversibility besides to the irreversibility of mass transfer in research into real chemical pumps and try to decrease the internal irreversibility as much as possible.

DISCUSSION

1) Using equation (18), we can easily generate the $\Sigma_{3P} \sim \chi_{3P}$ curves of the irreversible three-source chemical pump, as shown in figure 3, where $\mu_h / \mu_O = 6, \mu_P / \mu_O = 10$ and $h_1 = h_2 = h_3 = h$. From figure 3, we can see that as the internal irreversibility parameter I increases, the upper bound of the rate of energy pumping, $(\Sigma_{3P})_{\max}$, and the upper and lower bounds,

I	$(\chi_{3P})_m$	$(\chi_{3P})_I$	$(\Sigma_{3P})_{max}$*
1	0.467	0.929	0.049
1.1	0.416	0.822	0.040
1.2	0.373	0.736	0.034

Table 1: The value of $(\chi_{3P})_m$, $(\chi_{3P})_I$ and $(\Sigma_{3P})_{max}$* with different I

$(\chi_{3P})_I$ and $(\chi_{3P})_m$, of the coefficient of performance all decrease. Some values of the two important parameters with I =1、1.1 and 1.2 are listed in Table 1, where $h_1 = h_2 = h_3 = h$ and $(\Sigma_{3P})_{max}$* = $(\Sigma_{3P})_{max}/(h\ \mu_P^2)$ is the dimensionless maximum rate of energy pumping. Further analysis of equation (18) shows that when the other parameters are given, not only the lower bound $(\chi_{3P})_m$ but also the upper bound $(\chi_{3P})_I$ of the coefficient of performance decrease as μ_P increases; and $(\chi_{3P})_m$ decreases and $(\chi_{3P})_I$ is unchanged as B_I decreases, as shown in figure 4.

2）In order to make the chemical pump operate in the optimal states, the times of the mass transfer processes between the working fluid and the three mass reservoirs should satisfy certain conditions. From equations (1)-(3)，(4), (10), (11) and (18) , we can find that the optimal times spent on the three mass transfer processes are given by

$$t_1 = \frac{\sqrt{h_3}}{\sqrt{Ih_1} + \sqrt{h_3}} \frac{\mu_p}{(\mu_p - B_I \mu_h \chi_{3P})} \tau \qquad (22)$$

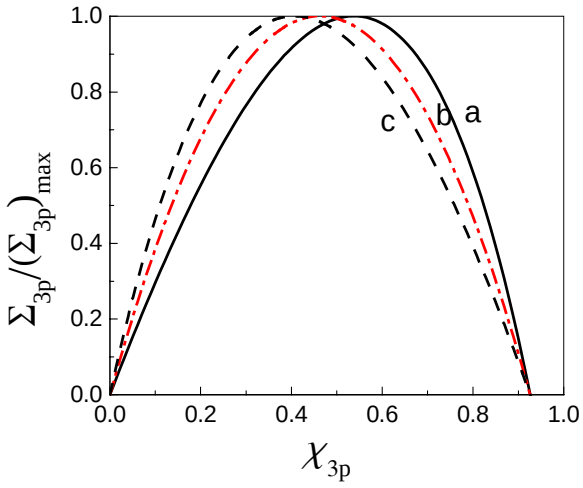

Figure 4: The rate of energy pumping versus the coefficient of performance curves. Plots are presented for $\mu_h/\mu_O = 6, \mu_P/\mu_O = 10$ and $I = 1$. Curves *a*, *b* and *c* correspond to the case of B_I = 0.5, 0 and -0.5

$$t_2 = \frac{\sqrt{Ih_1h_3}}{\sqrt{h_2}(\sqrt{Ih_1}+\sqrt{h_3})}\frac{\mu_h\chi_{3P}}{\mu_p - B_I\mu_h\chi_{3P}}\tau \qquad (23)$$

$$t_3 = \frac{\sqrt{Ih_1}}{\sqrt{Ih_1}+\sqrt{h_3}}\frac{\mu_p - \mu_h\chi_{3P}}{\mu_p - B_I\mu_h\chi_{3P}}\tau \qquad (24)$$

such that the optimal time distribution of the three mass transfer processes satisfies the following relation

$$\sqrt{Ih_1}t_1 = \sqrt{h_2}t_2 + \sqrt{h_3}t_3 \qquad (25)$$

For example, when $h_1 = h_2 = h_3$, equation (25) is simplified as $t_1 = (t_2 + t_3)/\sqrt{I}$。This implies that the mass transfer time t_1 decrease as the internal irreversibility parameter *I* increases. These results can play an instructive role for engineers to design the mass exchangers of real chemical pump.

3) When $\mu_P \to \infty$, equation (18) is simplified as

$$\Sigma_{3p} = \frac{Ih_1h_3}{(\sqrt{Ih_1}+\sqrt{h_3})^2}\mu_h{}^2\eta(\eta_I - \eta) \equiv P \qquad (26)$$

Equation (26) is just the optimal relation between the power output *P* and the efficiency η of the irreversible chemical engine [9], where h_1 and h_3 are the coefficients of mass transfer between the working fluid and the reservoirs μ_h and μ_O, respectively; and η_I is the maximum efficiency of the irreversible chemical engine. Furthermore, when *I* = 1, equations (15)、(17)、(19)、(22) become

$$\mu_1\Big|_{\eta=\eta_m^{ce}} = \mu_h - \frac{\mu_h - \mu_o}{2(1+\sqrt{h_1/h_3})} \qquad (27)$$

$$\mu_3\Big|_{\eta=\eta_m^{ce}} = \mu_o + \frac{\mu_h - \mu_o}{2(1+\sqrt{h_3/h_1})} \qquad (28)$$

$$(\Sigma_{3P})_{\max} = h_1\left(\frac{\mu_h - \mu_o}{2(1+\sqrt{h_1/h_3})}\right)^2 \equiv P_{\max} \qquad (29)$$

$$t_1 = \tau/(1+\sqrt{h_1/h_3}) \qquad (30)$$

where η_m^{ce} is the efficiency of the endoreversible chemical engine at the maximum power output $P_{max.}$ Equations (27)-(30) are just the important parameter equations of the endoreversible chemical engine. They are consistent with the related equations in the Ref. 6. This shows once again the results obtained in the present paper are more general and useful than those of the endoreversible three-source chemical pump, irreversible and endoreversible two-source chemical engines.

CONCLUSIONS

A cyclic model of a class of three-source chemical

pumps is set up, in which the external irreversibilities between the working fluid and the mass reservoirs and the internal irreversibilities inside the cyclic working fluid have been taken into account. Based on the optimal control theory, the fundamental optimal relation of the irreversible three-source chemical pump cycle is derived. The influence of finite rate mass transfer and the internal irreversibility on the cyclic performance of the chemical pump is revealed. Some new performance bounds are determined and evaluated. The results obtained here are more general and useful, and can not only play an instructive role for the optimal design and operation of a class of chemical pumps but also be directly used to derive the important results of some relevant cyclic models appeared in the existing literatures.

ABSTRACT

The general objective of the energy model described in this paper is to provide a powerful analysis tool to evaluate the market value of Swiss hydropower plants and to quantify the future value of hydropower on the background of a liberalised European electricity market considering various scenarios. The energy system analysis model PERSEUS-HYDRO is a technology-based modelling approach, employing linear programming algorithms with a focus on hydropower. Due to its detailed representation of the real energy supply system, including the specific techno-economic characteristics and constraints of this sector, the model permits an in-depth analysis of the interrelations between capacity development, power exchange volumes, plant dispatching, and price information. In order to assess the influence of alternative assumptions on future technological investment options, the model parameters include the projected techno-economic characteristic of future energy conversion technologies.
Keywords: Investment planning, energy system modelling, hydropower, electricity prices, power system reserve

INTRODUCTION

Investments in hydropower plants are characterised by high capital intensity and long project durations. In the liberalized energy markets, most independent power producers are not wiling to accept the risks connected with investments in hydropower plants. About one fourth of the prolongations of concessions (licenses) of hydropower plants in Switzerland are estimated not to be obviously cost-efficient. Thus, the long-term use of hydropower production is at risk [1]. On the other hand, hydropower plants are characterised by a high controllability for the provision of peak load and control energy and as a renewable energy carrier with good predictability, which can achieve high prices on liberalized energy markets.

Due to the high complexity of the real energy supply system, sophisticated analysis tools are required to support research and planning activities in order to evaluate the expected effects. Energy systems analysis models have been widely used in the past to support policy design or strategic planning issues within energy companies. Within this paper, the developed energy system model for a hydro-thermal generation system to analyse the long-range prospects for Swiss hydropower within the European electricity market will be presented.
The challenges faced to model hydropower will be shown too. With the developed model approach four questions are addressed: Will hydropower in the Alps be a competitive energy in the European energy system? What is the trend and absolute level of electricity prices in the next

three decades for base and peak load? Will hydropower in the Alps be a technological response to balance fluctuating wind energy (e.g. in Northern Germany) or are there other suitable responses? How will the interregional power exchange develop?

OBJECTIVES AND METHODOLOGY

The general objective for the development of the energy system model PERSEUS-HYDRO[1] was to provide an analysis tool to assess a hydro-thermal generation system with regard to the long-term competitiveness of alpine hydropower, electricity prices, technology choices, capacity development, and interregional power exchanges. In this long-term model approach for decision support related to investment planning also generation scheduling and dispatchability features are included[2]. PERSEUS-HYDRO is an energy and material flow model applying a multi-periodic mixed integer linear programming approach (MILP).

The modelling approach is based on a detailed representation of energy conversion technologies, including hydropower cascades and the interconnecting flows of energy and material (i. e. primary energy carriers, emissions of pollutants etc.). The structure of the model is equivalent to a directed graph: Energy and material flows represent the edges of the graph. Conversion technologies and their processes correspond to the nodes of the graph. The model follows a linear, mixed integer programming approach.

The target function is the minimization of all decision-relevant expenditures within the entire energy supply system. This basically comprises fuel supply and transport costs, transmission fees, fixed and variable costs of the physical assets (operation, maintenance, load variation costs etc.) and specific investments for new plants. The relevant techno-economic characteristics of the real supply system have been considered by implementing further equations covering technical, ecological (e.g. renewable energy targets) and political (e.g. nuclear phase out) restrictions. The most important technical restrictions are:

- *Physical energy balances*: Restrictions providing the balance of supply and demand taking into account the load curve of electricity demand.
- *Capacity restrictions*: transmission constraints, availability of installed capacities, hydro storage constraints, commissioning restrictions, technical lifetime of physical assets.
- *Plant operation*: maximal/minimal operating hours at full load, fuel options, cogeneration options, load variation restrictions.

The time horizon of the model is 30 years. As not every hour of a year can be optimized, so called characteristic days are used. Eight characteristic days represent one year - four seasons are considered, each characterised through a working day and a weekend day which are both represented by a simplified load curve of 6 (working day) respectively 3 time periods (weekend).

A detailed description of the basic modelling package can be found in [3]. Within this paper, we do not want to go more into detail on the general modelling approach, as similar approaches have been used in other energy models. We focus on the modelling of hydropower, power system reserve, the regional structure covering the alpine regions and neighbouring countries as well as the analysis options of the model.

POWER SYSTEMS RESERVE MODELLING

As electricity cannot be stored, the amounts of the electricity consumed and generated have to be in balance. The transmission system operator (TSO) is responsible for system balancing within a defined region and must guarantee to have enough excess reserve generation available for use at all times in order to ensure the reliable operation of the system. Reserve power and reserve energy have to be distinguished here. Reserve power (or reserve capacity) is necessary to balance unforeseen power fluctuation (e.g. station blackouts or fluctuating wind energy production) and load changes. Reserve energy is the energy

[1] **P**rogramme Package for **E**mission **R**eduction **S**trategies in **E**nergy **U**se and **S**upply – with focus on **Hydro**power;

[2] Within [2] is demonstrated that dispatchability features such as start-up costs and ramp rates are important for the economic profitability assessment of a project, especially in hydro-thermal systems.

effectively used for the balancing of the system. Depending on national and/or international regulations, different types of reserve have to be provided by the generators. In the UCTE, the following reserve qualities can be distinguished by the time horizon: primary reserve to be fully available within 30 seconds, secondary reserve replacing primary reserve within 5 minutes and tertiary reserve freeing secondary reserve within 15 minutes. In a simpler model, only spinning reserve (primary and secondary reserve) and non-spinning reserve (tertiary or minute reserve) is distinguished, the first being called automatically and the latter manually via rescheduling of generation.

Within the PERSEUS-HYDRO model several approaches to model power systems reserve are integrated.

Capacity reserve restriction (for spinning reserve): A capacity reserve factor is defined, guaranteeing that for each time interval the total installed capacity of one region plus a factor (1 + *capacity reserve factor*) exceeds the cumulated load of that particular region. The value of the capacity reserve factor can be calculated on the basis of the stipulated capacity reserve of the UCTE (first synchronous zone: 3000 MW [4]). In other words, this equation guarantees that the capacity used for production plus the reserve capacity exceeds the cumulated load in every time period of the model.

Energy reserve restriction (for non-spinning reserve): To ensure within the energy system model that also plants for (secondary and) tertiary reserve (e.g. hydropower plants and fast starting thermal plants like gas turbines) are needed within the generation portfolio, a reserve energy restriction is defined. This equation guarantees that the production of selected plants (hydropower plants and gas turbines) exceeds the necessary amount of energy for tertiary reserve. The energy for tertiary reserve is modelled as a share of the total energy demand.

The capacities and the energy supply by selected plants for the provision of reserve power are guaranteed with the two described equations. But as the model is deterministic, only the plant dispatch for the forecasted energy demand schedule is calculated within the optimization. This forecasted energy demand schedule is planned for the next day by the energy utility on the basis of the anticipated probable consumption of their consumers and can be traded at energy exchanges or arranged in bilateral contracts.

Simulation of the plant operation for tertiary reserve (energy reserve): To estimate the plant operation for tertiary reserve a second optimization is based on the results of the first optimization. For the provision of tertiary reserve all fast starting units are available because of their high flexibility. Consequently, only fast starting plants can provide tertiary energy within the second optimization of the model approach. Hence, a large part of variables are fixed namely these of the installed capacity and the plant dispatch of units, which can not provide tertiary reserve. Only the operation of fast starting units is optimized within the second optimization. Thus, a tertiary reserve energy demand has to be provided in the second optimisation step in order to be able to analyze the plant operation for tertiary reserve. This tertiary reserve energy demand is derived from forecast errors of the forecasted scheduled energy demand and the forecasted wind energy production.

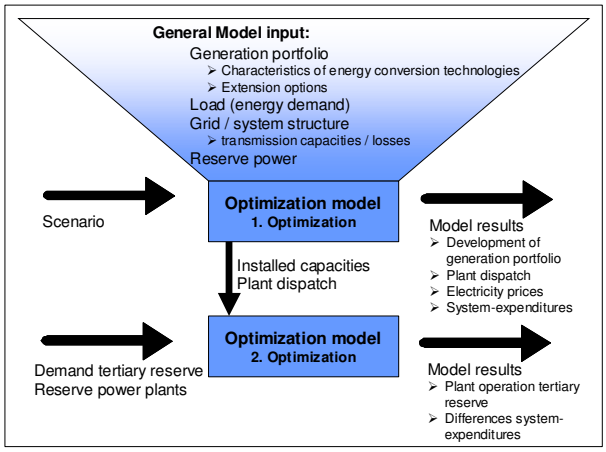

Figure 1: Model input and output

HYDROPOWER MODELLING

Beside thermal power plants, hydropower plants play a considerable role in many electric power systems. Three main types of hydropower plants can be classified:

Run-of-river plants do not have any storage possibilities and need to produce electricity

continuously depending on the water-flow of the river. They are used for base load production.

Hydro storage plants are able to store the water outflow of a catchments area in a reservoir. They can further be classified by the size of the storage in relation to the water inflow (day-, week or year-storage). Having the ability to store water allows shifting large parts of the average annual production into peak power times.

Pumped storage power plants have an additional capability to pump water from a lower reservoir to a higher one which means they can also consume energy. This designates pumped storage plants for providing ancillary services, especially (negative) balancing power.

Hydro storage plants are far more complicated to model than base-load producing run-of-river plants since through the storage, several time periods in the model are linked. This requires the introduction of nodes for storage purposes in the energy system model. The energy and material balance equation for storage nodes has to be extended to a storage equation and storage level variables have to be introduced. The storage equation is also used for the pumped storage plants where a second process (pump process) has to be integrated within the model too. In order to consider hydropower cascades, the cross linking of turbines has to be modelled. As the same hydro flow rate generates a different amount of electricity in each hydropower plant, the head of the turbines have to be taken into account. In particular, for the detailed modelling of individual hydropower plants the following data is crucial:

Hydro inflow (Pardé coefficient) to the reservoirs needs to be modelled to represent the seasonal variability of the hydropower energy production. For all reservoirs and run-of-river plants the seasonal inflow shares on monthly basis (Pardé coefficient) for an average hydrological year have been determined using data from [5], [6]. Due to the missing storage capacities the run-of-river plants are very sensitive to inflow variations and have usually a significantly higher energy production in summer. Even though storage and pumped storage plants are to some extent disconnected from the seasonal water inflow and try to collect water in summer to produce in winter they are still dependent on regional inflow characteristics. Modelling additional natural water inflow to lower reservoirs of hydropower cascade systems accounts for the flexibility of the lower plants to produce energy without using water from an upper reservoir. By multiplying the average annual energy production on half-year basis with the Pardé coefficients for every plant's reservoir, the monthly inflow can be expressed in energy units, which is necessary for modelling purposes.

Energy volumes of reservoirs have been calculated using both geographic information system data from the Swiss Federal Office of Water and Geology on reservoir area and perimeter as well as technical literature data on reservoir water volumes and maximum reservoir level fluctuations [7]. The energy volumes in relation to the average annual production give insight into the plants capability to shift potential energy from summer to winter or generally from base load to peak load times. Energy volumes of reservoirs are always calculated in relation to the maximal and minimal head of the turbine they feed, not over the whole cascade system. Further, the storage capacity at the reservoirs limits production and pumping possibilities of the plant as these depend strongly on the relation of water inflow, reservoir volume, and maximal turbine flow. By taking into account all three factors, an exact model of the hydropower plants can be constructed.

The head of the turbines have been looked up in the technical literature for all power plants in a thorough data collection and then used to express the water flow within cascade systems in energy units. Because the energy potential of the turbined water depends on the head of the connected plant, the energy inflows into a plant node are not the same as the outflows. To keep the energy balance in the system right the energy inflow to every plant node is multiplied by the ratio 'gross head of the lower plant / gross head of the upper plant' to obtain the energy outflow. This calculated outflow and the possibly joining natural inflow on that particular level of the cascade system sum up to the inflow of the following plant in the system.

Maximal installed power of every hydropower plant is the crucial variable used to integrate the plant into the model. Depending on the restrictions from water availability and storage

possibility this installed power can be used to cover part of the exogenously given load. On average, for run-of-river plants maximum installed power is available for about 4'000-8'000 hours a year depending on the ratio of the maximum turbine flow and the minimum flow of the river. In the case of storage plants in Switzerland it is about 2'500 hours a year. Pumped storage plants are usually stronger focused on peak load times and are producing power during about 1'500 hours.
Cross linking hydropower plants to cascade systems is crucial because the single power plants cannot in all cases be operated independently.

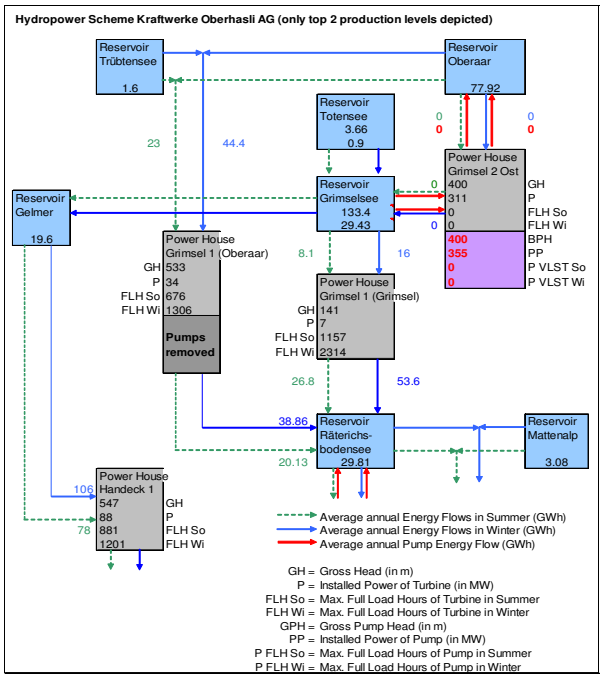

Figure 2: Cascade System with Energy Flows

All the larger storage hydropower plants in Switzerland are part of cascade systems where the classical scheme comprises two reservoirs and two plants. Based on the characteristics of the cascade system, the degree to which the lower plant can be operated independently from the upper one can vary a lot and needs to be considered in detail. Therefore, all cascade systems were analysed, their hydraulic schemes described and plotted with all relevant technical details including pumping possibilities. A simple example is depicted in Figure 2. A mathematical model description including equations for the hydropower modelling and the representation of reservoirs can be found in [8].
Within the PERSEUS-HYDRO model about 180 Swiss hydropower plants have been modelled in detail. Another 340 plants larger than 300 kW installed power are integrated on an aggregate basis divided into typical subgroups considering their production characteristics. Of course the 5 nuclear plants providing 40 % of the Swiss electricity production are contained in the model too.

APPLICATION AREA AND TRANSMISSION CAPACITIES

To analyse the Swiss energy system within a European context, the neighbouring countries Austria, France, Germany and Italy, as well as Belgium, Luxemburg, the Netherlands, and Slovenia are modelled on an aggregated level. All power generators within one region compete on a free market for the national electricity demand that has to be satisfied. However, at the same time there is also direct competition between the different regions given that neighbouring countries are connected by interconnection lines. The consideration of transmission capacities and losses as well as transmission fees ensures a realistic representation of the real power exchange characteristics within the model. The transmission capacities of the interconnection lines are modelled as upper limits of the energy flows. Figure 3 gives an overview about the modelled transmission capacities.
Interconnection lines between modelled and non-modelled countries, e.g. Germany - Poland, are modelled as fixed energy amounts with load flow characteristics.

IMPLEMENTATION OF THE MODEL

The model described above has been implemented as a PC version that can be run on commercial PCs. However, due to their high complexity and the resulting large problem size, they require state-of-the-art hardware components.
The PERSEUS models are equipped with an MS Access based data management system that permits easy data handling and a fully automated link to the mathematical module. The mathematical model is programmed in GAMS (c.p. [11]). In order to solve the problem,

commercial solvers like CPLEX can be applied. Formatted and structured results become available in MS Excel spreadsheets.

The resulting optimising model consists of roughly 610'000 continuous and 1'300 integer variables and about 410'000 restrictions with approximately 2'200'000 non-zero elements. Solving the model on a PC with Pentium 4 - 3 GHz and about 1.6 GB main memory results in calculation times of about 20 minutes to 4 hours with the commercial solver CPLEX 9.0.

ANALYSIS OPTIONS

The PERSEUS-HYDRO model has been implemented within a project for a Swiss energy utility. At present, due to the confidential nature of results achieved, no quantitative results will be shown, instead the quantitative analysis options of the model will be presented. However, the results of the model give interesting insights on the interactions of investments in hydropower, investments in conventional power plants and electricity prices, and show similar tendencies as estimations of energy experts.

Electricity price projections: The basic idea of fundamental models, like the one constructed, is to explain electricity prices from the fundamental generation costs, which is based on the assumption that the market price of a homogeneous good in an open and fully competitive market is set by its marginal costs. We therefore use the marginal costs (shadow prices) of the mathematical model to indicate the resulting electricity prices that can be analysed for every time period of a day (as already mentioned before, a year is represented by eight characteristic days). Electricity prices can be derived on a national/regional level. The exact derivation of price information based on system-marginal-costs is described in more detail in [8].

Structural changes: Energy technologies show significant differences in their relevant parameters like cost structure, emission factors and load variation abilities. Plant dispatch depends on the merit-order of all available power plants established on cost categories. However, these decision-relevant costs and also the merit-order depend on fuel prices, possibly CO_2-certificate prices, and load profiles which all may vary over time. Given that the optimization algorithm used in this model results in a simultaneously optimized plant dispatch and (dis)investment strategy, expected structural adaptations of the entire system to external market conditions can be analysed in detail.

The most obvious structural changes are the shares different technologies cover within the total installed capacity and/or the total electricity generation. New investment options can be added or modified in order to study the impact of a modification within the plant characteristics (e.g. improved efficiency with consequently higher specific investment, or different fuel options) on the future market penetration of this technology.

Interregional power exchanges: Given that every regional supply system is characterised by a different set of available power generation technologies with varying cost characteristics and emission data, any modification of the generation structure from one region/player to another will directly affect power generation structures and/or power exchange characteristics between the two regions. Hence, the influence on the Swiss energy system by a massive growth of wind use in neighbouring countries or the phasing out of nuclear energy can be analysed.

Furthermore, planned projects of common interest

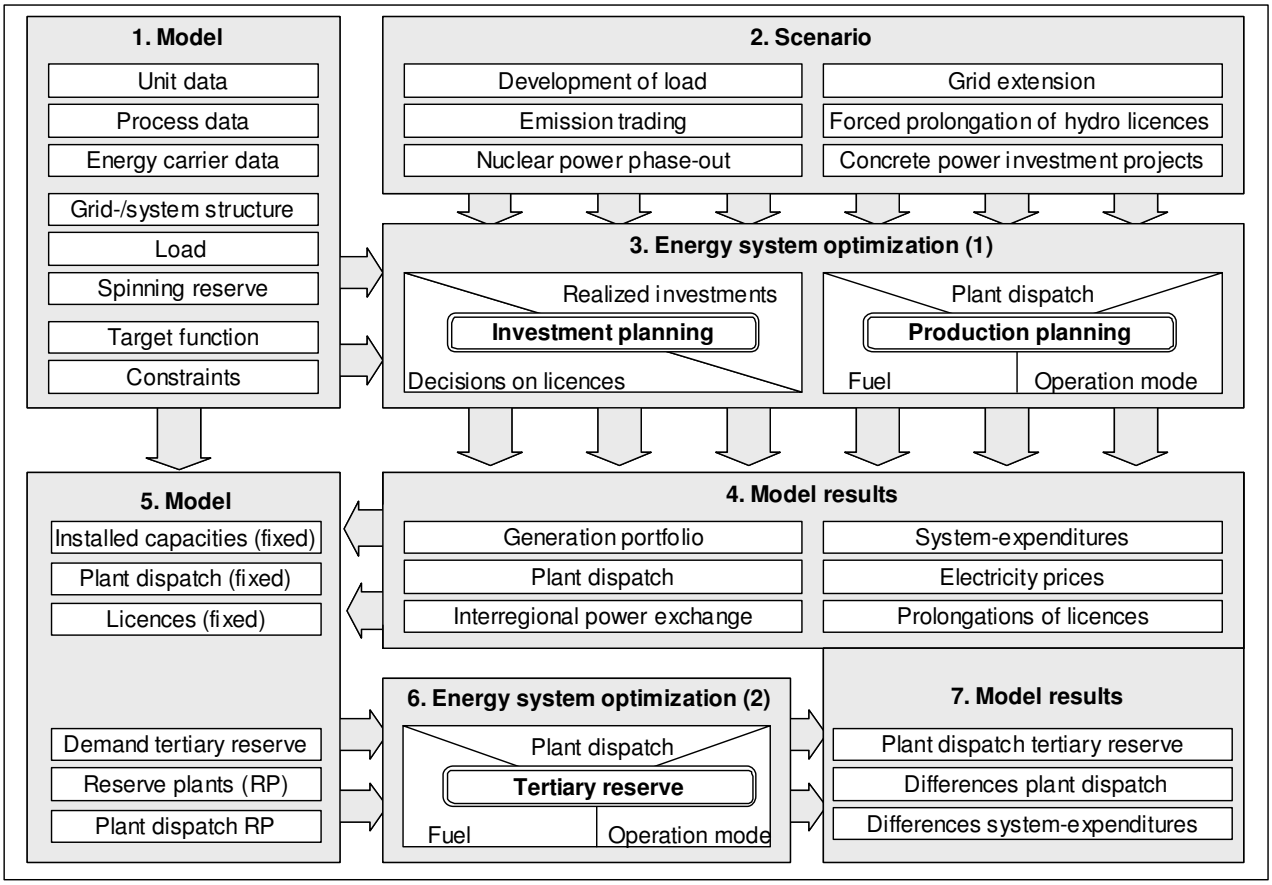

Figure 4: Steps of model-based scenario analysis

in the sector of the trans-European energy networks [12] and their influence on electricity prices and the interregional power exchanges can be quantified. For example, transmission capacities between Switzerland and Italy show a high utilization ratio. Within the model, the effects of an increase of transmission capacities can be used to analyse their influence on investment decisions and electricity prices.

Financial valuation of specific investment projects: Due to the detailed modelling of hydropower plants it is possible to valuate license and investment decisions for current hydropower projects. New investment options of concrete projects (e.g. license decisions of water power plants or (pumped) storage extensions) can be added, and their cash flow can be analysed taking interrelations within the European energy market into account. Hence, an added decision support can be given to strategic planners in energy utilities and to power plant operators.

Tertiary reserve energy: The plant operation for tertiary reserve is analysed within the second step of the optimization. With this approach, it is possible to quantify the value of selected plants for the generation portfolio. E.g. the influence of hydropower plants on the provision of tertiary reserve can be analysed by computing two scenarios: one with and one without the possibility to provide tertiary reserve.

In Figure 4 the steps of the model based scenario analysis are summarized. In a first step, the model has to be built up including modelling data, system structure and mathematical equations. Second, various scenario options have to be defined before the energy system is optimized. Model results are the plant dispatch, investment planning, development of generation portfolios, interregional power exchanges, electricity prices and the total system expenditures. The second optimization process is built up on the basis of these results (Step 5). Within the second

optimization, the plant operation for tertiary reserve is estimated and the results calculated are the plant dispatch for tertiary reserve and differences in the system-expenditures.

CONCLUSIONS

Energy system analysis models have been widely and successfully used in the past supporting energy system development projections under different external circumstances. Within this paper it has been shown how such an energy model can be amended in order to provide an analysis tool for a generation system with a high share of hydropower. The detailed modelling of hydropower plants is a crucial step in order to be able to evaluate the long-term competitiveness of hydropower and the re-licensing decisions of existing capacities in liberalised electricity markets. The model has been successfully tested for the Swiss energy system under non-flexible connections with neighbouring countries. Assessed dispatching results of the various hydropower plant types, especially of the pumped storage plants, show that the Swiss hydropower production is modelled accurately.
Furthermore, a novel approach to model power system reserve requirements within an energy system model has been developed and presented. The various analysis options of the presented model cover most relevant aspects that decision makers may need in order to get an indication on what are the most likely developments of the Swiss electricity park under different scenarios: price information, energy system structures, technology choice and power exchange characteristics.

ACKNOWLEDGEMENT

The development and application of the described model have been the topic of a research project together with the Centre for Energy Policy and Economics (CEPE) at the ETH Zürich, the BKW Energie AG, the Kraftwerke Oberhasli AG, and ETRANS. In this context we would like to thank our project partners for providing all the necessary data and for the fruitful discussions and meetings. Moreover, we would like to thank PSEL (Projekt- und Studienfonds der Elektrizitätsswirtschaft) and BKW Energie AG for financing.

ABSTRACT

This paper summarizes a series of works on thermodynamic optimization of heat exchanger area allocation for power and refrigeration plants. It is shown that the thermodynamic optimum is pinpointed by an optimal distribution of the heat exchanger area inventory among the heat exchangers of the installation. Hot-stream-driven power producing devices, solar-driven refrigerators and a combined[1] power and refrigeration systems are discussed. The optimal allocation of heat exchanger area appears as a common result for all the installations.

Keywords: Heat exchangers, thermodynamic optimization, power plants, refrigerators

Nomenclature

A	heat transfer area, m^2
c_p	specific heat at constant pressure, $J/kg\ K$
C	thermal conductance, W/K
M	mass flow rate ratio
$\dot{m}$	mass flow rate, kg/s
$\dot{m}_h$	hot water mass flow rate, kg/s
N	number of heat transfer units
$\hat{N}$	conductance ratio
$\hat{q}_0, \hat{q}_L$	dimensionless heat transfer rates
$\dot{Q}$	heat transfer rate
r	absorbent mass flow rate fraction
R	relative refrigeration load, $\dot{Q}_L/\dot{W}$
$\dot{S}_{gen}$	entropy generation rate, W/K
T	temperature, K
$\dot{W}$	power, W
w	dimensionless power
x, y	allocation ratios

Greek Symbols

ε	heat exchanger effectiveness
μ_w	dimensionless collector's physical and operating parameter [8]
η_{II}	second law efficiency

1. Introduction

Thermodynamically, the maximum limit to the power that is available from a single-phase hot stream with mass flow rate $\dot{m}$ and initial temperature T_H is given by the flow exergy [1],

$$\dot{W}_{rev} = \dot{m} c_p T_0 \left(\frac{T_H}{T_0} - 1 - \ln \frac{T_H}{T_0} \right) \qquad (1)$$

Equation 1 is based on the assumption that the stream behaves as an ideal gas with nearly constant c_p and it is in contact only with the atmospheric temperature reservoir.

The maximum power is not reached in practice due to entropy generation. For example, the stream-to-stream temperature difference, the thermal mixing of the hot stream being discharged into the environment, and the pressure drop experienced by the hot stream constitute main sources of irreversibility and as such a departure from Equation (1).

The problem of optimizing heat transfer area allocation is relevant to power and refrigeration applications ([2], [3]). In the effort of minimizing the irreversibilities and maximizing power output or refrigeration capacity, it is possible to identify an optimal heat exchanger area allocation for a given heat exchanger inventory. In this paper some results that illustrate the existence of such optimum are summarized.

2. Power Extraction

2.1. Phase change in the collecting stream

Consider the system of Figure 1. The left side of Figure 1 illustrates the extraction of power from a hot exhaust, the right side illustrates the isolation of the irreversible component that receives the heat input. Given is the single-phase stream of hot exhaust, which has the mass flow rate $\dot{m}$ and the initial temperature T_H. This fluid behaves as an ideal gas with nearly constant c_p. The temperature of this stream decreases as it serves as heat input to a power plant. The objective is to maximize the power output $\dot{W}$, or to minimize the total rate of entropy generation of the plant subject to the area constraint,

$$A = constant \qquad (2)$$

The mass flow rate of the collecting stream, $\dot{m}_w$, is not fixed and represents a degree of freedom.

In [4], it was shown that when the collecting stream remains in a single phase, the power extracted from

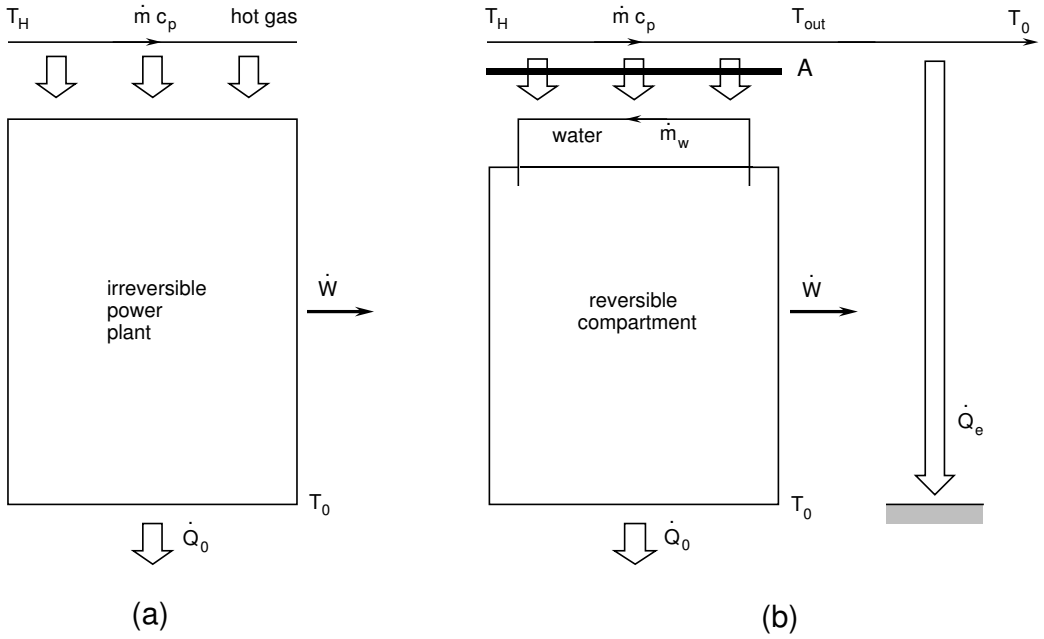

Figure 1: (a) Power extraction from a hot exhaust stream. (b) Isolation of the irreversible component that receives the heat input.

the hot stream, can be maximized by using a counterflow heat exchanger whose degree of imbalance can be determined from thermodynamic optimization.

The configuration shown in Figure 2 was studied in [5]. The counterflow configuration was selected following the results in [4]. The available heat transfer surface splits itself into three sections: a preheating region, a boiling region and a superheating region. It was pointed out the existence of an optimal mass flow rate ratio of the hot stream to the collecting stream. Figure 3 illustrates the allocation of heat exchanger inventory for different mass flow rate ratios ($M = \dot{m}_w/\dot{m}$). The mass flow rate ratio (indicated with dashed lines) maximizes the second law efficiency of the installation.

2.2. Phase change in contact with hottest gases

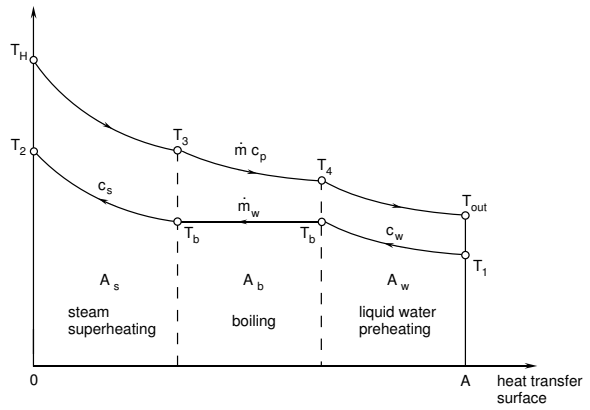

Figure 2: Temperature distribution for the counterflow configuration.

Limitations imposed by the materials used in the construction of the heat exchangers may require a departure from the configuration of Figure 2. Placing the boiling section in contact with the hottest

gases will prevent pipe overheating due to the higher heat transfer coefficient associated with phase change [6]. In [7] the best 'match' between $\dot{m}$ and $\dot{m}_w$, across A, when the boiling section is in contact with the highest temperature section of the hot stream was studied (Figure 4).

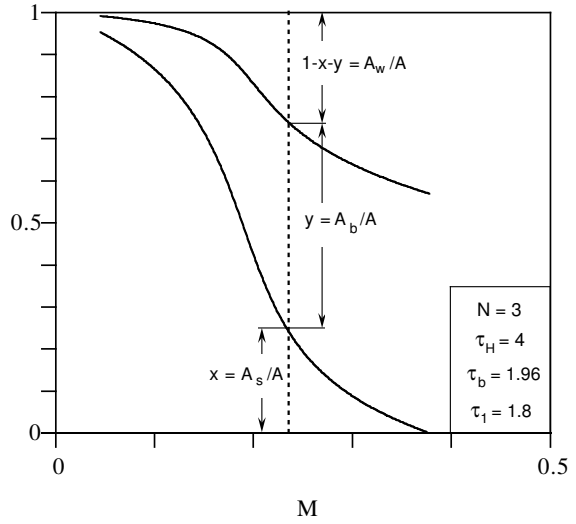

Figure 3: Optimal allocation of heat exchanger area for the counterflow configuration.

It can be anticipated that due to larger stream-to-stream temperature differences the maximum power that can be extracted using the configuration of Figure 4 would be smaller than the one that could be extracted using the optimal configuration of Figure 2. In spite of this, the former configuration is more commonly implemented in power plants, where the hot gases leaving the burners are placed in contact with the boiling section, then with the superheating and finally the pre-heating section.

Figure 5 illustrates, for this new configuration, the heat exchanger area allocation for different mass

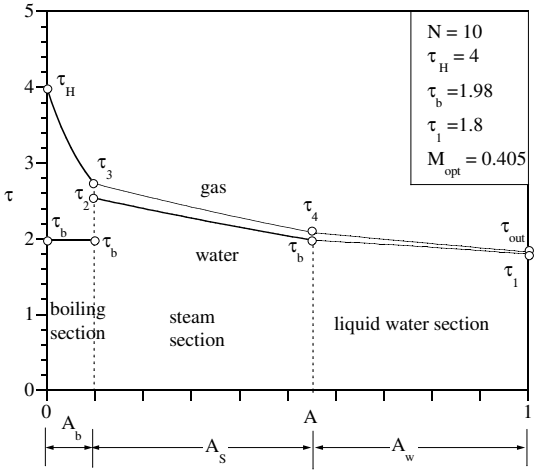

Figure 4: Temperature distribution for the configuration with the boiling section in contact with hottest gases.

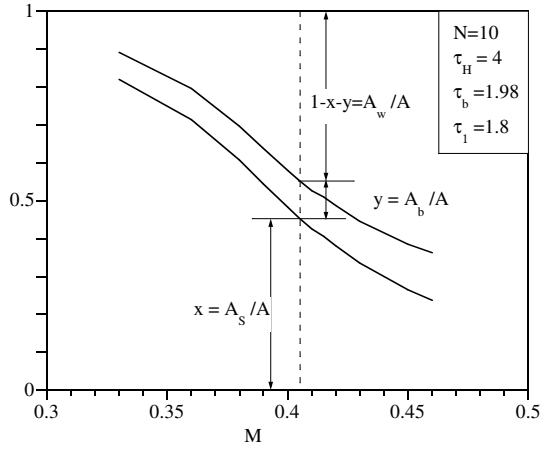

Figure 5: Optimal allocation of heat exchanger area for the system of Figure 2.

flow rate ratios of the collecting stream to the hot stream. Each vertical gap corresponds to an area allocation: the lower gap, x, represents the fraction of the total area, A, allocated to the superheating section, the middle gap, y, corresponds to the fraction of the total area allocated to the boiling section, and the upper gap, 1-x-y, corresponds to the fraction of the total area allocated to the preheating section. In [7], it was shown that there is a mass flow rate ratio $(M = \dot{m}_w/\dot{m})$ that maximizes the second law efficiency, η_{II} (and the power extraction from the hot stream). The optimal value of M is associated to an optimal heat exchanger area allocation (indicated with dashed lines in Figure 5).

3. Solar driven refrigerators

Figure 6 illustrates a solar-driven refrigerator [8]. The transfer of heat from the hot water to the solution stream occurs across a surface of area A, which is considered to be constrained. The solution refrigerant/absorbent experiences a change of phase, i.e., it vaporizes over an intermediate section of the heat exchanger, at constant temperature. Therefore, the temperature of the working fluid stream shows abrupt changes in slope.

With respect to the heat transfer surface A, on the water side the fluid is single-phase, and the heat transfer coefficient is well documented by the technical literature and fairly uniform along the surface. On the refrigerant side, however, the heat transfer coefficient differs considerably from one section to the next, i.e., surface A_l over which the liquid refrigerant is heated to the boiling point, surface A_b over which the refrigerant stream boils, and, surface A_s where the refrigerant is superheated.

The heat transfer surface constraint is expressed as

$$A = A_l + A_b + A_s \tag{3}$$

Each section is characterized by distinct overall heat transfer coefficients. The optimization problem focuses on determining the solution refrigerant/absorbent mass flow rate, an important operating parameter for the equipment, that maximizes the refrigeration rate. Just like in the power producing systems considered previously, there is an associated optimal heat exchanger area allocation.

Figure 7 shows the allocation of heat exchanger area and the corresponding to the thermodynamic optimum (M_{opt}).

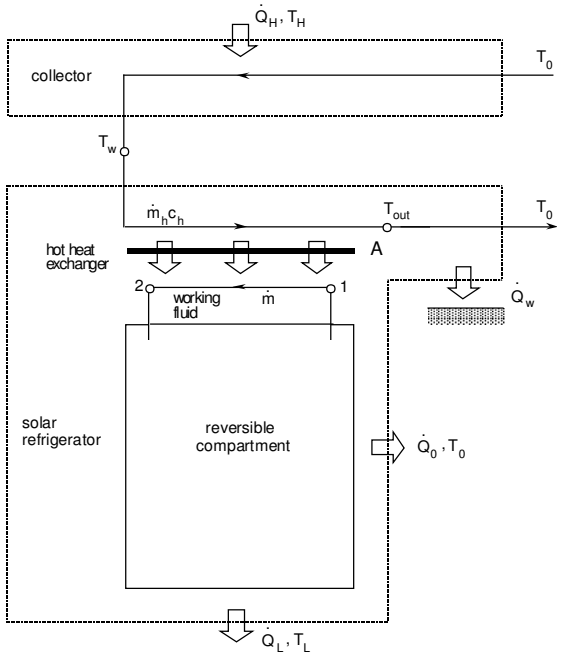

Figure 6: Sketch of a solar driven refrigerator

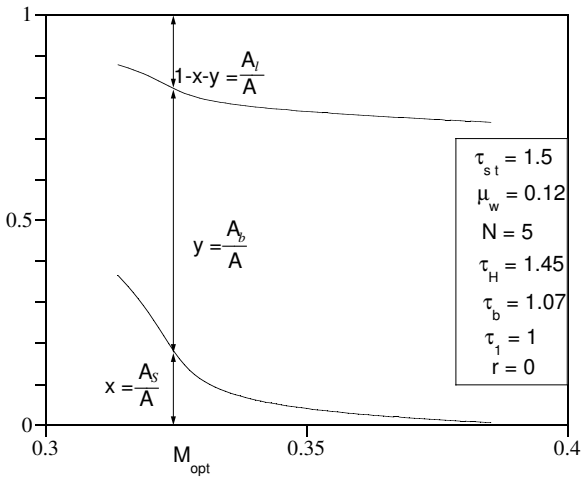

Figure 7: Allocation of heat exchanger area for the system of Figure 6.

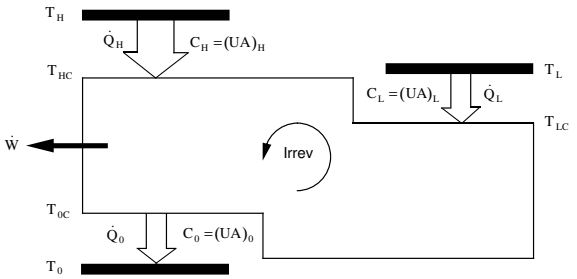

Figure 8: Model of combined power and refrigeration system with internal irreversibility.

4. Combined power and refrigeration

In the model of Figure 8 we propose to examine a combined power and refrigeration system with internal irreversibility. The generated power is used for generating the refrigeration effect Q_L, and the remaining fraction is delivered as net power $\dot{W}$ to an external user. The operation of the combined system may span the entire spectrum from pure refrigeration to pure power production, and its position on this scale is marked by the ratio $R = \dot{Q}_L/\dot{W}$.

The irreversibility of the system characterizes the interior of the power and refrigeration installation. This feature can be accounted for by means of the exergetic efficiency η_{II} of the system defined by the solid line in Figure 8. The specified parameter η_{II} is less than 1, and is defined as the ratio of the net exergy flow rate out of the system divided by the net flow of exergy into the system.

The heat input rate Q_H is a fixed (given) parameter. The region of lower temperature T_{HC} on the solid-line boundary receives the heat transfer interaction Q_H,

$$\dot{Q}_H = C_H(T_H - T_{HC}) \tag{4}$$

From the first and second laws of thermodynamics,

$$\dot{Q}_H + \dot{Q}_L - \dot{Q}_0 - \dot{W} = 0 \tag{5}$$

$$\dot{S}_{gen} = \frac{\dot{Q}_0}{T_{0C}} - \frac{\dot{Q}_L}{T_{LC}} - \frac{\dot{Q}_H}{T_{HC}} \geq 0 \tag{6}$$

The heat interactions with the environment and the low temperature space are modelled as

$$\dot{Q}_0 = C_0(T_{0C} - T_0) \tag{7}$$

$$\dot{Q}_L = C_L(T_L - T_{LC}) \tag{8}$$

For the nondimensionalization of these equations, T_0 was used as temperature scale, $\tau = T/T_0$, $C = C_H + C_L + C_0$, and

$$\hat{q}_0 = \frac{\dot{Q}_0}{\dot{Q}_H} \quad \hat{q}_L = \frac{\dot{Q}_L}{\dot{Q}_H} \quad w = \frac{\dot{W}}{\dot{Q}_H} \tag{9}$$

$$\left(\hat{N}_H, \hat{N}_0, \hat{N}_L, \hat{N}\right) = \frac{T_0}{\dot{Q}_H}\left(C_H, C_0, C_L, C\right) \tag{10}$$

$$x = \hat{N}_H/\hat{N} \quad y = \hat{N}_L/\hat{N} \quad 1-x-y = \hat{N}_0/\hat{N} \qquad (11)$$

In summary, the dimensionless equations that govern the functioning of the the model of Figure 8 are

$$1 - \hat{q}_L - \hat{q}_0 - w = 0 \qquad (12)$$

$$\eta_{II} = \frac{\hat{q}_0(1-\tau_{0C}^{-1}) + w}{1 - \tau_{HC}^{-1} + \hat{q}_L(1-\tau_{LC}^{-1})} \leq 1 \qquad (13)$$

$$1 = x\hat{N}(\tau_H - \tau_{HC}) \qquad (14)$$

$$\hat{q}_0 = (1-x-y)\hat{N}(\tau_{0C} - 1) \qquad (15)$$

$$\hat{q}_L = y\hat{N}(\tau_L - \tau_{LC}) \qquad (16)$$

$$\hat{q}_L = Rw \qquad (17)$$

where the second-law efficiency statement, Equation (13) accounts for the second law, Equation (6). The system of six equations (12) - (17) was solved numerically for the six unknowns: $w, \hat{q}_0, \hat{q}_L, \tau_{HC}, \tau_{0C}$, and τ_{LC}. These were developed numerically as function of the remaining parameters: x, y, $\tau_H, \hat{N}, \eta_{II}$ and R.

The specific work output with respect to the spatial distribution of heat exchanger inventory, x and y, was maximized. The impact of the internal irreversibility,(η_{II}), was also investigated.

Figure 9 shows how the distribution of heat exchanger equipment responds to changes in the internal second-law efficiency, when the operating mode ratio is set at $R = 1$. The sizes of the three heat exchangers are plotted in relative terms, so that the three sizes always add up to 1. The Figure shows that the size of the hot-end heat exchanger (x_{opt}) is relatively insensitive to changes in η_{II}. The other two heat exchangers respond together: the refrigeration-load heat exchanger decreases in size as η_{II} decreases, and vanishes entirely at approximately $\eta_{II} = 0.3$. The power output and refrigeration effect also vanish at this point, as shown by the corresponding dashed line in Fig. 10. This behavior has its source in the irreversibility of the combined system. When η_{II} is too low, all the exergy available based on Q_H [namely $Q_H(1 - T_0/T_H)$], is destroyed through the irreversibility of the power and refrigeration installation.

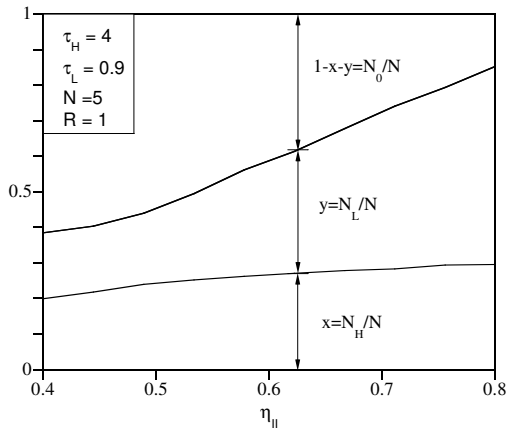

Figure 9: The optimal distribution of heat exchanger inventory, as a function of the second-law efficiency of the power and refrigeration system.

5.Concluding remarks

The existence of an optimal allocation of heat exchanger area resulting from maximization of the thermodynamic performance of both power and refrigeration systems has been documented. When the total heat transfer area available is given, the cases studied have shown two basic results: first, that in one heat exchanger where a hot stream transfers energy to a phase-changing working fluid, there

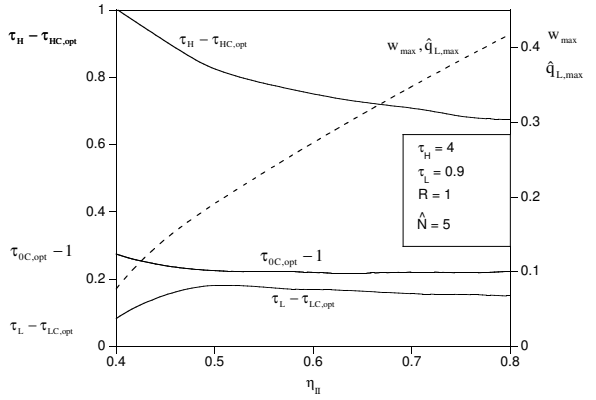

Figure 10: The maximized power and refrigeration, and the three temperature gaps that correspond to the system optimized in Figure. 9.

is an optimal heat transfer area splitting among the three sections (pre-heating, boiling and superheating). This has been documented for two configurations in the case of power generation (sections 2.1 and 2.2) and for solar-driven refrigerators (section 3); second, that when a combined power and refrigeration system is in contact with three temperature reservoirs by means of three heat exchangers, there is an optimal allocation of the total heat exchanger area available for the installation between the heat exchangers (section 4).

Finally, the results summarized in this paper came from thermodynamic optimization and should be complemented with a thermoeconomic analysis.

ABSTRACT

A newly expanded expression of the First Law of Thermodynamics for Processes with Finite Speed is presented. This expression includes three principal sources of internal irreversibility. It is used to develop equations that relate properties for each of the five commonly encountered irreversible processes that may occur with finite speed. Using these equations applied to the particular process involved, equations are developed for calculating the heat and work of the system. This paper includes entropy generation calculations as a function of the finite speed of the process and other parameters. They can then be used to optimize any finite speed cycle. An example is presented to illustrate how the power and efficiency of any cycle can be optimized when the effects of both external and internal irreversibility due to finite speed are considered.
Keywords: Optimization, Finite speed processes, Irreversibilities, Entropy generation calculation

INTRODUCTION

A recently model for the optimization of a Carnot cycle engine based on the "Direct Method" and the First Law of Thermodynamics for processes with Finite Speed was developed [1-2]. In that model a closed system has been studied. Therefore, no internal irreversibilities generated by throttling process were involved. In the present paper we study an irreversible Carnot cycle executed in four separate machines (an isothermal expansion machine at T_H, an adiabatic expansion machine, an isothermal compression machine at T_L and an adiabatic compression machine) that are connected through tubes and valves. Another difference is that in the previously papers [1-2] we kept the compression ratio of the low temperature isothermal compression constant. Now we keep the expansion ratio during the isothermal expansion at the high temperature constant.

This "Direct Method" analytic model will now be extended to include the effect of the internal irreversibility generated by throttling processes through the valves and also the adiabatic irreversibility generated by finite speed, during the adiabatic compression and adiabatic expansion. As in paper [2], this analysis includes the temperature differences between the engine and both the heat source and sink that generate the heat losses. In addition, the method for optimizing the temperatures of the cycle gas with respect to the source and sink temperatures as a function of the speed of the piston [2] is used. The resulting optimization predicts different optimum speeds for maximum efficiency and for maximum output power, as expected from the results of the previous research [2].

Optimum cycle temperatures and the resulting efficiency and power are computed using both the "Direct Method" analysis [3-4] and the analysis of Chambadal [5] and Curzon-Ahlborn [6] and the results predicted by the two methods of analysis are compared. Under conditions corresponding to maximum engine power, the Curzon-Ahlborn optimization technique was found to predict results that were more favorable than those predicted by the "Direct Method" analysis presented here. Also, computations of Carnot cycle efficiency and entropy generation per cycle that are based on a "Finite Speed" analysis indicate that both the maximum efficiency and minimum entropy generation per cycle occur at the same optimal piston speed. At maximum engine power, however, the entropy generation per unit time (entropy source) is greater than when the engine operates at maximum efficiency.

There are other models for the study and optimization of the Carnot Cycle that take into account the speed of the cycle (as frequency or number of rotations per minute) [7-8] but in those papers only external irreversibility is included. The present model is much more general and closer to engineering applications because it takes into account the internal irreversibility generated by the finite speed of the pistons, in addition to the external irreversibility with finite speed.

There are some models that take into account internal irreversibilities that are not based on the finite speed of the processes in the cycle, but are based on certain assumptions regarding the internal entropy generation [9-10]. The present model has the advantage, in comparison with those models, that it correlates the efficiency and power directly with the internal and external losses generated by the same essential parameter, the finite speed. In addition it also makes possible to calculate the entropy generation as a function of speed and to correlate it with the efficiency or power. It is important to note that all of these correlations are made possible through use of the “Direct Method”, based on the First Law of Thermodynamics for processes with finite speed. This method is proven to be very powerful in the analyses and optimization of all irreversible cycles, not only Carnot cycles but also, for example, practical machines that work on the Stirling cycle [11] and it is useful in engineering applications such as design and optimization [11-13].

THERMODYNAMICS OF PROCESSES WITH FINITE SPEED APPLIED TO AN IRREVERSIBLE CARNOT CYCLE ACHIEVED WITH 4 MACHINES, USING "THE DIRECT METHOD"

The efficiency, output power, entropy generation per cycle and entropy generation per unit time for the Carnot engine with irreversible processes is computed using the First Law of Thermodynamics for processes with "Finite Speed" [13-14]. The various forms of irreversibility that occur in a Carnot cycle are considered and their effect on the performance of the cycle is presented.

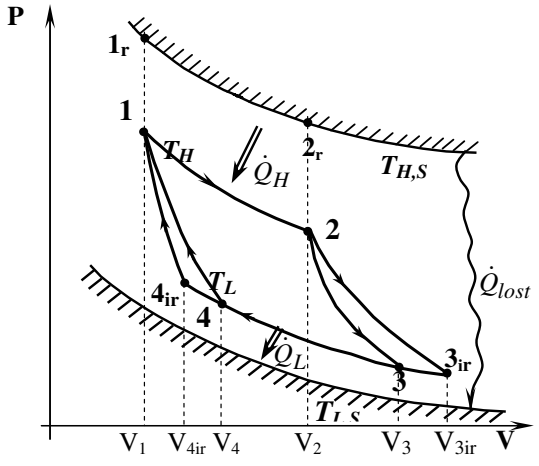

Figure 1: A comparison on p-V coordinates of the Carnot cycle with internal and external irreversibilities (1-2-3ir-4ir-1) with the Carnot cycle only with external irreversibilities (1-2-3-4-1)

The First Law of Thermodynamics for Processes with Finite Speed is [13-14]:

$$dU = \delta Q - p\left(1 \pm \frac{aw}{c} \pm \frac{\Delta p_f}{p} \pm \frac{\Delta p_{thr}}{p}\right) dV \quad (1)$$

where each term in parenthesis takes into account one type of irreversibility:

$\frac{aw}{c}$ = contribution of finite speed;

with $c = \sqrt{3RT}$; $a = \sqrt{3\gamma}$;

$\Delta p_f / p$ = contribution of mechanical friction between mechanical parts;

$\Delta p_{thr} / p$ = contribution of throttling processes (for example, through the valves).

The sign (+) is for compression and the sign (–) is for expansion.

The terms Δp_f and Δp_{thr} can be expressed as a function of speed and stroke based on experimental data [2]:

$$\Delta p_f = \left(0.97 + 0.45\frac{w}{100 \cdot y}\right) \cdot 10^5 \quad [\mathrm{N/m^2}] \quad (2)$$

$$\Delta p_{thr} = 0.45\left(\frac{w}{100 \cdot y}\right)^2 \cdot 10^5 \quad [\mathrm{N/m^2}] \quad (3)$$

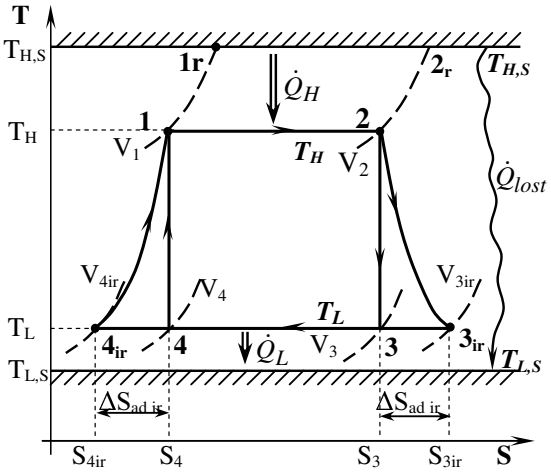

Figure 2: Representation of the irreversible Carnot cycles on T-S coordinates

Each process in the Carnot cycles shown in Figs. 1 and 2 occurs in a separate machine. The resulting four machines are assumed to be connected by tubes and valves as needed.

Note that the expression of the First Low for processes with finite speed has been derived taking into account the irreversibilities introduced by the Second Law of Thermodynamics, caused by finite speed, friction and throttling processes.

Equation (1) can be integrated for various processes with finite speed, to obtain the process equations and also the resulting expressions for the irreversible work and heat.

Adiabatic Process with Finite Speed

For an adiabatic compression or expansion of an ideal gas, we get from (1):

$$m c_v\, dT = -\frac{mRT}{V} \cdot z_{ad} \cdot dV \; ; \quad c_v = \frac{R}{\gamma - 1} \quad (4)$$

where:

$$z_{ad} = \left(1 \pm \frac{aw}{c} \pm \frac{\Delta p_f}{p} \pm \frac{\Delta p_{thr}}{p}\right) \quad (5)$$

By integrating eq. (4) we get the following expression for the adiabatic process with finite speed:

$$T_1\, V_1^{z_{ad}(\gamma-1)} = T_2\, V_2^{z_{ad}(\gamma-1)} \tag{6}$$

where:

$$z_{ad} = \left[1 \pm \frac{aw}{\sqrt{3R(T_1+T_2)/2}} \pm \frac{\Delta p_f}{(p_1+p_2)/2} \pm \frac{\Delta p_{thr}}{(p_1+p_2)/2}\right] \tag{7}$$

$$p_{12}{}_{av.ad} = \frac{p_1+p_2}{2} = \frac{p_1}{2}\left(1+\frac{p_2}{p_1}\right) = \frac{p_1}{2}\left[1+\left(\frac{T_2}{T_1}\right)^{\frac{\gamma}{\gamma-1}}\right] \tag{8}$$

Upon substitution of eq. (2). (3) and (8) in (7):

$$z_{ad} = \left[1 \pm \frac{w\sqrt{3k}}{\sqrt{3R(T_1+T_2)/2}} \pm \frac{2\left(0.97+\frac{0.45w}{100y}\right)\cdot 10^5}{p_1\left[1+(T_2/T_1)^{\gamma/(\gamma-1)}\right]} \pm \right.$$
$$\left. \pm \frac{0.9\left(\frac{w}{100y}\right)^2 \cdot 10^5}{p_1\left[1+(T_2/T_1)^{\gamma/(\gamma-1)}\right]}\right] \tag{9}$$

When eq. (9) is used with the two adiabatic processes in the irreversible Carnot cycle, (1-2-3_{ir}-4_{ir}-1), the result is:

$$z_{ad}{}_{2-3_{ir}} = \left[1 - \frac{w\sqrt{2\gamma}}{\sqrt{R(T_H+T_L)}} - \frac{(1.94+0.009w/y)\cdot 10^5}{p_2\left[1+(T_L/T_H)^{\gamma/(\gamma-1)}\right]} - \right.$$
$$\left. - \frac{(3w/y)^2}{p_2\left[1+(T_L/T_H)^{\gamma/(\gamma-1)}\right]}\right] \tag{10}$$

$$z_{ad}{}_{4_{ir}-1} = \left[1 + \frac{w\sqrt{2\gamma}}{\sqrt{R(T_H+T_L)}} + \frac{(1.94+0.009w/y)\cdot 10^5}{p_1\left[1+(T_L/T_H)^{\gamma/(\gamma-1)}\right]} + \right.$$
$$\left. + \frac{(3w/y)^2}{p_1\left[1+(T_L/T_H)^{\gamma/(\gamma-1)}\right]}\right] \tag{11}$$

Expressions for the pressures p_1 and p_2 are as follows:

$$p_{1r} V_1 = mRT_{HS} \quad \text{and} \quad p_1 V_1 = mRT_H$$

It results:

$$p_1 = p_{1r}\frac{T_H}{T_{HS}} \tag{12}$$

The value of p_{1r} is imposed by material resistance considerations. A high value of p_{1r} is not recommended.

$$p_2 = p_1/\varepsilon_H = \frac{p_{1r}}{\varepsilon_H}\frac{T_H}{T_{HS}} \tag{13}$$

where

$$\varepsilon_H = \frac{V_2}{V_1} \tag{14}$$

Upon using eq. (6), the irreversible adiabatic expansion with finite speed 2–3_{ir} becomes:

$$T_2\, V_2^{(\gamma-1)z_{ad,2-3_{ir}}} = T_{3_{ir}}\, V_{3_{ir}}^{(\gamma-1)z_{ad,2-3_{ir}}} \tag{15}$$

which upon solving for V_{3ir} becomes:

$$V_{3_{ir}} = V_2 \cdot \left(\frac{T_H}{T_L}\right)^{\frac{1}{(\gamma-1)z_{ad,2-3_{ir}}}} \tag{16}$$

Similarly, for the irreversible adiabatic compression with finite speed 4_{ir}–1, we get:

$$V_{4_{ir}} = V_1 \cdot \left(\frac{T_H}{T_L}\right)^{\frac{1}{(\gamma-1)z_{ad,4_{ir}-1}}} \tag{17}$$

The duration time of the isothermal processes is:

$$\tau_H = \frac{V_2 - V_1}{A_p \cdot w} = \frac{V_1}{A_p \cdot w}(\varepsilon_H - 1) \tag{18}$$

$$\tau_L = \frac{V_{3_{ir}} - V_{4_{ir}}}{A_p \cdot w} = \frac{V_{3_{ir}}}{A_p \cdot w}\left(1 - \frac{1}{\varepsilon_{L_{ir}}}\right) \tag{19}$$

where

$$\varepsilon_{L_{ir}} = \frac{V_{3_{ir}}}{V_{4_{ir}}} = \frac{V_2}{V_1}\cdot\left(\frac{T_H}{T_L}\right)^{\alpha} \tag{20}$$

and

$$\alpha = \frac{1}{\gamma-1}\left(\frac{1}{z_{ad,2-3_{ir}}} - \frac{1}{z_{ad,4_{ir}-1}}\right) \tag{21}$$

Upon substituting eq. (16) into eq. (19):

$$\tau_L = \frac{V_2}{A_p \cdot w}\cdot\left(\frac{T_H}{T_L}\right)^{\frac{1}{(\gamma-1)z_{ad,2-3_{ir}}}} \cdot \left(1 - \frac{1}{\varepsilon_{L,ir}}\right) \tag{22}$$

We denote:

$$\frac{T_H}{T_L} = t \qquad \frac{1}{(\gamma-1)z_{ad,2-3_{ir}}} = \beta \tag{23}$$

Upon substituting eqs. (14),(20),(23) into eq. (22):

$$\tau_L = \frac{V_2}{A_p \cdot w}\cdot t^{\beta}\cdot\left[1 - \frac{1}{\varepsilon_H \cdot t^{\alpha}}\right] \quad \text{with} \quad \frac{V_2}{A_p} = L_2 \tag{24}$$

The heat exchanger area of the hot and cold end of the machine respectively is expressed by:

$$A_H = \pi D \cdot \frac{V_2 - V_1}{A_p}\,; \quad A_L = \pi D \cdot \frac{V_{3_{ir}} - V_{4_{ir}}}{A_p} \tag{25}$$

Isothermal Processes with Finite Speed

The isothermal compression and the isothermal expansion process with finite speed of the Carnot cycle will be considered in the present section. From eq. (1), the expression for the heat exchange for an ideal gas in an isothermal process with finite speed is:

$$\delta Q = p\left(1 \pm \frac{aw}{c} \pm \frac{\Delta p_f}{p} \pm \frac{\Delta p_{thr}}{p}\right) dV \qquad (26)$$

Upon integrating eq. (26) for a isothermal irreversible process 1-2 with finite speed w,

$$W_{1-2,T,ir} = Q_{1-2,T,ir} = z_{T,1-2} \cdot m R T_1 \ln \frac{V_2}{V_1} \qquad (27)$$

is obtained, where:

$$z_{T,1-2} = 1 \pm \frac{aw}{\sqrt{3RT}} \pm \frac{2\Delta p_f}{p_1(1+p_2/p_1)} \pm \frac{2\Delta p_{thr}}{p_1(1+p_2/p_1)} \qquad (28)$$

with $\frac{P_2}{p_1} = \frac{V_1}{V_2} = \frac{1}{\varepsilon_e}$ (expansion) = ε_c (compression)

However, considering the isothermal processes:

$$\varepsilon_H = \frac{V_2}{V_1} \qquad \varepsilon_L = \frac{V_3}{V_4} \qquad (29)$$

Expressions for the isothermal work/heat result in:

$$W_H = W_{1-2,T,ir} = Q_{1-2,T,ir} = Q_H = z_{T,H} \cdot mRT_H \ln \varepsilon_H \quad (30)$$

When eq. (28) is used with the two isothermal processes in the irreversible Carnot cycle, (1 – 2 – 3_{ir} – 4_{ir} – 1), the result is:

$$z_{T,H} = 1 - \frac{w\sqrt{3\gamma}}{\sqrt{3RT_H}} - \frac{(1.94 + 0.009\, w/y)\cdot 10^5}{p_1(1+1/\varepsilon_H)} - \frac{(3w/y)^2}{p_1(1+1/\varepsilon_H)} \qquad (31)$$

$$z_{T,L} = 1 + \frac{w\sqrt{\gamma}}{\sqrt{RT_L}} + \frac{(1.94 + 0.009\, w/y)\cdot 10^5}{p_3(1+\varepsilon_L)} + \frac{(3w/y)^2}{p_3(1+\varepsilon_L)} \qquad (32)$$

where $$p_3 = p_2\left(\frac{T_3}{T_2}\right)^{\frac{\gamma}{\gamma-1}} = p_2\left(\frac{T_L}{T_H}\right)^{\frac{\gamma}{\gamma-1}} \qquad (33)$$

The isothermal heat transfer from the source, Q_H at temperature T_H, for a process at finite speed is:

$$Q_H = h_H \cdot A_H \cdot (T_{HS} - T_H) \cdot \tau_H \qquad (34)$$

where:

$$A_H \cdot \tau_H = \left(\pi D \cdot \frac{V_2 - V_1}{A_p}\right) \cdot \frac{V_2 - V_1}{A_p \cdot w} = \left(\frac{V_2 - V_1}{A_p}\right)^2 \frac{\pi D}{w} = \frac{V_1^2}{A_p^2}(\varepsilon_H - 1)^2 \cdot \frac{\pi D}{w} \quad \text{with } V_1 = A_p \cdot L \qquad (35)$$

Upon substituting eq. (35) into eq. (34):

$$Q_H = h_H \cdot L_1^2 \cdot (\varepsilon_H - 1)^2 \cdot \frac{\pi D}{w} \cdot (T_{HS} - T_H) \qquad (36)$$

The irreversible Carnot engine with finite speed operating in steady state must satisfy eqs. (36) and (30). Therefore:

$$z_{T,H} \cdot mRT_H \ln \varepsilon_H = h_H \cdot (A_H \cdot \tau_H) \cdot (T_{HS} - T_H) \qquad (37)$$

Upon solving the eq. (37) for T_H :

$$T_H = T_{HS}\left[1 + \frac{z_{T,H} \cdot mR \ln \varepsilon_H}{h_H \cdot (A_H \cdot \tau_H)}\right]^{-1} \qquad (38)$$

where $z_{T,H}$ is given by eq. (31) and ($A_H \cdot \tau_H$) by eq. (35).

The term $z_{T,H}$ contains T_H. Therefore the value of T_H results from an iterative calculation.

The isothermal heat transfer at the sink, Q_L at the sink temperature T_L, for a process at finite speed using eq. (27) for the process 3_{ir} –4_{ir} is:

$$|W_L| = |Q_L| = z_{T,L} \cdot mRT_L \ln \frac{V_{3_{ir}}}{V_{4_{ir}}} = z_{T,L} \cdot mRT_L \ln \varepsilon_L \qquad (39)$$

where $z_{T,L}$ is given by eq. (32).

The isothermal heat transfer from the sink, Q_L at temperature T_L for a process at finite speed is:

$$Q_L = h_L \cdot A_L \cdot (T_L - T_{LS}) \cdot \tau_L \qquad (40)$$

which in steady-state equals Q_L as expressed by eq. (39) for thermodynamics with finite speed:

$$h_L \cdot A_L \cdot (T_L - T_{LS}) \cdot \tau_L = z_{T,L} \cdot mRT_L \ln \varepsilon_L \qquad (41)$$

Upon solving eq. (41) for T_L :

$$T_L = T_{LS}\left[1 - \frac{z_{T,L} \cdot mR \ln \varepsilon_L}{h_L \cdot A_L \cdot \tau_L}\right]^{-1} \qquad (42)$$

Since the terms $z_{T,L}$, ε_L, A_L, and τ_L all depend on T_L, the solution requires iterative calculations. The iterated value of T_L that is sufficiently close to the value of the previous iteration is then used to calculate the efficiency, power, and entropy generations.

CALCULATION OF THE EFFICIENCY, POWER, ENTROPY GENERATION PER UNIT TIME AND ENTROPY GENERATION PER CYCLE

The efficiency of the Carnot cycle with internal

and external irreversibility is:

$$\eta_{C,ir} = 1 - \frac{Q_L}{Q_H} = 1 - \frac{z_{T,L} \cdot mR\,T_L \ln\varepsilon_L}{z_{T,H} \cdot mR\,T_H \ln\varepsilon_H} = 1 - \frac{z_{T,L} \cdot T_L \ln\varepsilon_L}{z_{T,H} \cdot T_H \ln\varepsilon_H} \quad (43)$$

The power output of the Carnot irreversible engine is:

$$Power = \frac{Q_H \cdot \eta_{C,ir}}{\tau_{cycle}} = \frac{Q_H - Q_L}{\tau_{cycle}} \quad (44)$$

The total entropy generation per cycle is:

$$S_t = -\frac{Q_H}{T_{HS}} + \frac{Q_L}{T_{LS}} = -\frac{z_{T,H} \cdot mR\,T_H \ln\varepsilon_H}{T_{HS}} + \frac{z_{T,L} \cdot mR\,T_L \ln\varepsilon_L}{T_{LS}} \quad (45)$$

The total entropy generation per unit time is:

$$\dot{S}_t = S_t / \tau_{cycle} \quad (46)$$

The internal entropy generation per cycle is:

$$S_i = -\frac{Q_H}{T_H} + \frac{Q_L}{T_L} = -\frac{z_{T,H} \cdot mR\,T_H \ln\varepsilon_H}{T_H} + \frac{z_{T,L} \cdot mR\,T_L \ln\varepsilon_L}{T_L}$$

$$S_i = m\,R\left(-z_{T,H} \cdot \ln\varepsilon_H + z_{T,L} \cdot \ln\varepsilon_L\right) \quad (47)$$

The internal entropy generation per unit time is:

$$\dot{S}_i = S_i / \tau_{cycle} \quad (48)$$

The effect on the Carnot Cycle of including the heat loss that could occur between the cycle and the heat reservoirs

The equations in the above section are changed when the external and internal losses are included in the analysis. An expression for the heat loss, between the cycle and the heat reservoirs, $\dot{Q}_{lost}$, is:

$$\dot{Q}_{lost\cdot} = \pi D\left(L_2 - L_1\right) \cdot \frac{\lambda_{ins}}{g_{ins}}\left(T_{HS} - T_{LS}\right) \quad (49)$$

$$Q_{lost\cdot} = \dot{Q}_{lost\cdot} \cdot \tau_{cycle} \quad (50)$$

The effect of the heat loss is to reduce the efficiency:

$$\eta_{C,lost} = 1 - \frac{Q_L + Q_{lost}}{Q_H + Q_{lost}} \quad (51)$$

The power output is not affected by the heat losses, as shown below:

$$Power = \frac{\left(Q_H + Q_{lost}\right) - \left(Q_L + Q_{lost}\right)}{\tau_{cycle}} = \frac{Q_H - Q_L}{\tau_{cycle}} \quad (52)$$

The total entropy generation per cycle with heat loss is:

$$S_t = -\frac{Q_H + Q_{lost}}{T_{HS}} + \frac{Q_L + Q_{lost}}{T_{LS}} \quad (53)$$

The total entropy generation per unit time is:

$$\dot{S}_t = S_t / \tau_{cycle} \quad (54)$$

The internal entropy remains the same.

DISCUSSION

A "Finite Speed" analysis of a Carnot cycle engine achieved in four machines was performed. Air modeled as an ideal gas with constant specific heat is the working gas in the cycle. Losses due to heat transfer between the cycle and the heat source and sink were included as was the effect of variation in the area for heat transfer and in the dwell time for heat transfer due to the movement of the piston during the isothermal expansion and compression processes. Irreversibility during the adiabatic compression and expansion with finite speed also has been taken into account. The results of these calculations are presented in Figs. 3 to 9.

Figures 3, 4, 5 and 6 illustrate the effect on the power output, the cycle efficiency, the entropy generation and the temperatures in the gas, as a function of piston speed for a Carnot engine with internal and external irreversibilities, generated by the Finite Speed of the pistons in each of the 4 machines, for $V_2/V_1 = 8$. Figures 3 and 4 illustrate the power output and cycle efficiency including all irreversibilities, respectively internal and external ones. Also the Curzon-Ahlborn efficiency is included in Figure 4. These results are based on the following fixed parameters: D = 0.1m; L_2 = 1 m; $\varepsilon = 8$; P_{1r} = 1 bar (pressure of the gas in state 1r); T_{HS} = 600 K; T_{LS} = 300 K; γ = 1.4; g_{ins} = 0.03 m; λ_{ins} = 0.04 W m^{-1}K^{-1}.

As illustrated in Fig. 4, the optimum piston speed for maximum efficiency is only 3 m/sec. At this speed the rate of entropy generation (per unit time) is a very low 0.25. However, the optimum piston speed for maximum power is 8.5 m/sec and the rate of entropy generation per unit time at this speed is significantly higher, 0.7. The expectation is that, the maximum power output and the efficiency would decrease, as would the optimum speed for maximum power if additional irreversibilities were included in the analysis.

The efficiency of the Carnot cycle as determined by the "Finite Speed" analysis for any piston speed is less than the efficiency based on the Chambadal-Curzon–Ahlborn analysis when both internal and external irreversibilities are included in the analysis, but it is close to the maximum efficiency.

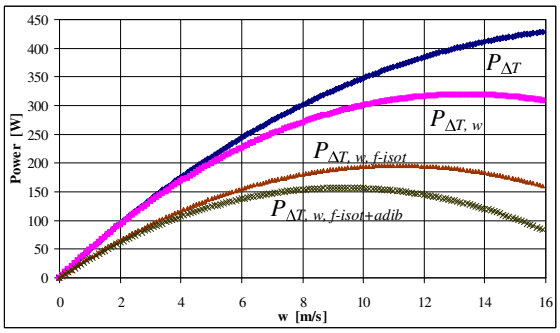

Figure 3: Power output versus the piston speed

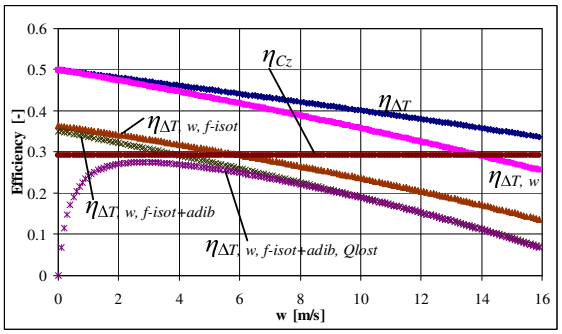

Figure 4: Cycle efficiency versus the piston speed

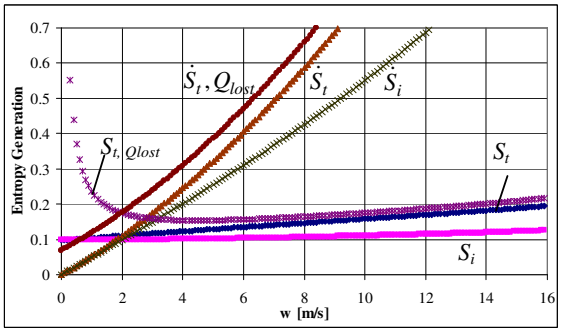

Figure 5: Entropy generation versus the piston speed

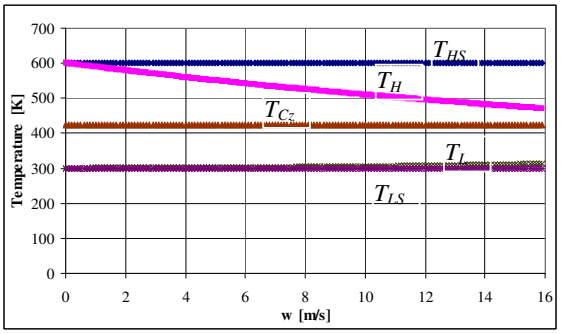

Figure 6: Temperature versus the piston speed

This difference is illustrated in Fig. 4. In addition, the efficiency of the Carnot cycle at maximum power as determined by the "Finite Speed" analysis is less than the efficiency based on the Curzon-Ahlborn analysis. The Carnot cycle efficiency based on a "Finite Speed" analysis, at the speed corresponding to Maximum Power, is 0.43, when only external irreversibilities are included and is 0.22, when both internal and external irreversibilities are included in the analysis.

The hot and cold heat reservoir temperatures, the hot and cold side engine gas temperatures, and the Chambadal-Curzon-Ahlborn optimized temperature are shown in Fig. 6 as a function of the piston speed. The hot side gas temperature optimized for maximum power is shown to be higher (530 K compared to 420 K), over the full range of piston speeds investigated, than the Chambadal–Curzon–Ahlborn optimized temperature. Also, the predicted temperature difference between the high and low gas temperature is shown to increase as the piston speed decreases and to be especially great at piston speeds less than the speed for maximum efficiency.

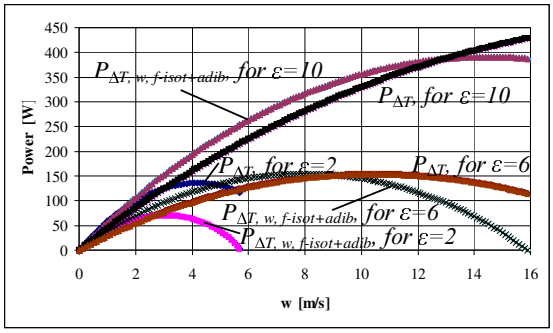

Figure 7: Sensitivity study of the power output with respect to the ε_H

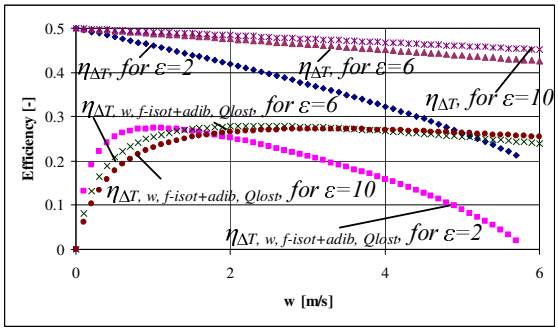

Figure 8: Sensitivity study of the cycle efficiency with respect to the ε_H

It is important to note, in Fig. 4, that the piston speed for maximum efficiency (3 m/s) is the same as the piston speed for the minimum entropy generation on a per cycle basis. As piston speeds decrease to the optimum speed (3 m/s) for maximum efficiency, the entropy generation on a per cycle basis continually decreases to a minimum. If the piston speed is decreased beyond that, the entropy generation per cycle will increase dramatically, because of heat losses between the heat sources. This implies that optimization of the piston speed for minimum entropy generation per cycle is equivalent to optimization the piston speed for maximum efficiency, when the isothermal expansion ratio V_2/V_1 is held constant.

It should be pointed out however that the time rate of entropy generation at maximum efficiency is much lower compared to the corresponding value at maximum power.

Figures 7 and 8 illustrate the same conclusions for values of V_2/V_1 of 10, 6 and 2. The shape of the curves for efficiency and power are very similar, but they shift with the maximum at lower speeds. Also the maximum power and the maximum efficiency will decrease as V_2/V_1 decreases.

CONCLUSION

Important performance parameters of a Carnot engine achieved in a 4 cylinders machine, based on a "Finite Speed" analysis have been presented. The optimum piston speed for maximum power and optimum speed for maximum efficiency has been found for a particular set of engine parameters and it has been shown that minimum entropy generation per cycle occurs at maximum efficiency. This study produces a more realistic model for the design of Carnot cycle engines since it includes many of the various internal and external irreversible processes that occur in the actual operation of these engines and correlates them with the finite speed of the piston.

Thermodynamic analysis based on the "Direct Method" and "Finite Speed" is shown to be especially effective for engineering optimizations since the efficiency and power can each be optimized based on gas temperatures and process speed. Based on these engineering optimizations, there is hope that industry soon will choose to build quasi-Carnot machines. To hasten that day it would be very useful to use this method to evaluate the optimum values for other parameters such as piston diameter, compression ratio, piston stroke.

A SECOND LAW AID IN POWER PLANT REPOWERING IMPROVEMENT

Joseph EA Roy-Aikins

Durban 4000
South Africa

ABSTRACT

Exergy analysis is a technique that embodies the second law of thermodynamics, and when combined with costs analysis forms that branch of energy system analysis known as thermoeconomics. Thermoeconomics can be used to aid the design and analysis of power plants, with regard to costs, by giving either an optimised solution or an improved design.
With this in mind, an investigation was carried out to find out if it would be feasible to repower the steam turbine plants at a power station in South Africa. This was looked at with a view to adding capacity, in order to alleviate the shortfall in capacity that is about to be experienced. Parallel repowering was the repowering option chosen, as it was identified as the most appropriate, in view of the company's business strategy and in line with the national energy plan. A base case design was formulated and a thermoeconomic analysis was carried out to improve on the design. An improved design was arrived at, but the cost of the power was higher than what it was for the existing plant. It was concluded that in the light of the present power situation repowering of old steam turbine plants is an option that should be considered to help manage the capacity problem, in the short to medium term.
Keywords: combined cycle plants, exergy analysis, power plant design optimisation, repowering, second law analysis, thermoeconomics.

INTRODUCTION

The electric utility company Eskom generates about 92 percent of the electrical power produced in South Africa. Eskom is the fourth largest power company in the world, with regard to capacity, and has for a number of years been producing the lowest cost electricity in the world, as a result of the abundance of cheaply priced coal in the country, which has resulted in the coal-fired steam turbine being the primary power generation plant. Eskom has announced that it will run out of excess peaking capacity in 2007, and of excess baseload capacity in 2010.
Several options are being looked at to determine strategies that will enable the company meet the growth in power demand in the short to medium term. No new coal-fired power stations are being planned for construction during this time frame, as considerable time is required to get such large central power generation facilities up and running. The only type of power plant that is being considered, and which is for long-term application, is the Pebble Bed Modular Reactor, which is a nuclear plant operating on the closed-cycle gas turbine. Work on the development of the technology is at an advanced stage. The company has embarked on some demand-side management initiatives in all three sectors, i.e. industrial, commercial, and residential, to encourage consumers to reduce their electricity consumption and to be more energy efficient. However, more

needs to be done to manage the problem, and alternatives are to be investigated to find the correct mix of solutions.

The Integrated Energy Plan published by the government in 2004 for comments stipulates that energy supply will remain reliant on coal for the next two decades, and that energy supply should be diversified through increased use of gas and new and renewable energies. With natural gas arriving in the country in 2005 from Mozambican gas fields, new opportunities for the use of gas turbines in meeting the country's energy needs will arise.

One alternative that could provide a temporary fix of the problem of diminishing generation capacity is that of steam turbine repowering, where a gas turbine (and in some cases a heat recovery steam generator (HRSG) as well) is added as a topping plant to an existing steam turbine either to increase capacity or improve heat rate, or both. In some cases, the objective of repowering is to reduce emissions, and this could result in a loss of capacity [1]. Old power plants, especially those with boilers coming to the end of their useful lives, are good candidates for repowering. There are a few such plants in the arsenal of power stations owned by Eskom, and they present an opportunity for increasing generation capacity through repowering.

This paper investigates the thermoeconomic benefits of repowering the steam turbines at an Eskom power station. The repowering exercise is carried out in line with the company's business strategy in view of the national Integrated Energy Plan. An exergy analysis of the repowered cycle is carried out to obtain improvements to the design until the cost of plant output is minimised. The Arnot power station is taken as an example.

THE STEAM TURBINE PLANT

The Arnot power station consists of six steam turbine plants in base load application. The average age of the plants is 31 years. Each unit is fired on pulverised coal and operates on the reheat Rankine cycle with six stages of feed water heating. At the design point, the boiler generates 316.5 kg/s superheated steam at 167 bar and 516 ^{o}C. After expansion in the high pressure (HP) turbine the steam is reheated to the same temperature as the main steam before being fed to the intermediate pressure (IP) turbine, and upon leaving the IP turbine the steam is fed to a double-flow low pressure (LP) turbine that exhausts to a condenser pressure of 0.075 bar. The plant generates 350 MW at a heat rate of 9557 Btu/kWh, at the design point, based on a lower heating value of 21.353 MJ/kg for coal. A schematic of the plant is shown in Fig. 1, and the thermodynamic data at the major stations are shown in Tab. 1.

Table 1: Steam turbine performance data

THE REPOWERED PLANT

As mentioned earlier, repowering of the steam turbine plants is to be carried out in line with the company's business strategy and in view of the national energy plan. Consequently, a number of practical issues are to be taken into consideration, which in turn impact technical matters. The main practical consideration is the use of coal as (primary) fuel. A direct impact of this on technical matters is the repowering option, i.e. full or

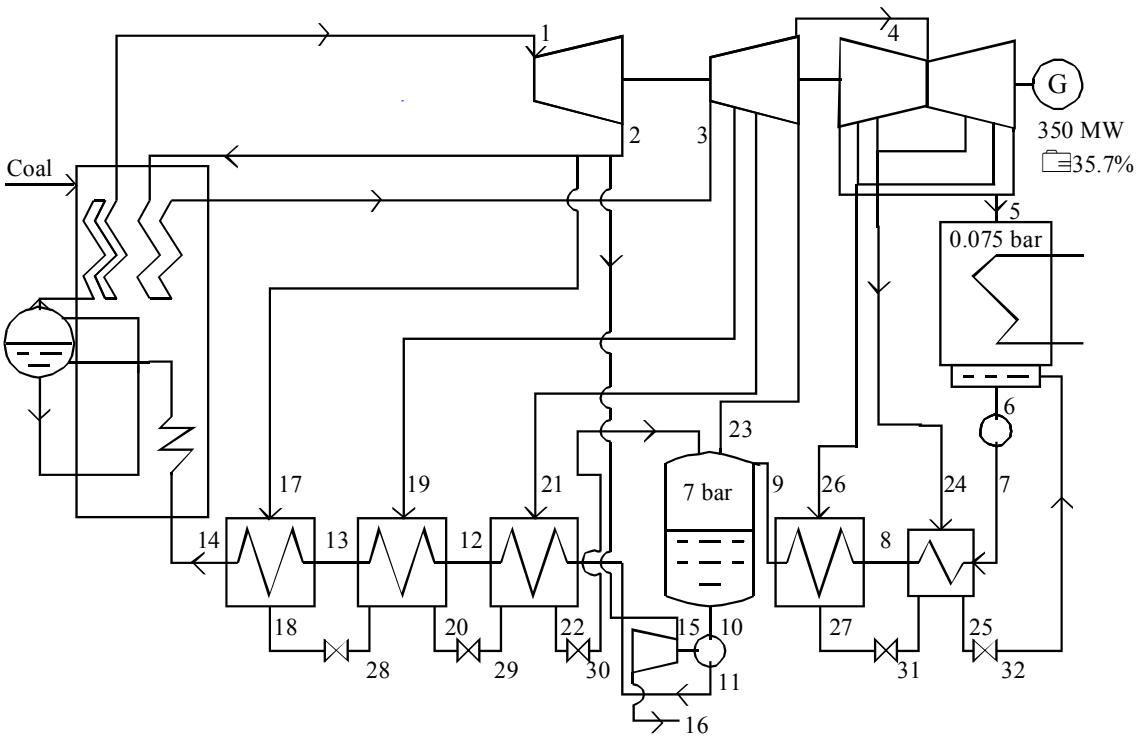

Fig.1 Schematic of the Steam Turbine Plant

parallel repowering. Joyce [2] describes these repowering options.

The first step in the repowering process is to determine the structure and performance of the repowered plant. As the preferred fuel for gas turbines is natural gas, and as coal is taken to be the dominant energy resource, it was decided to use both gas and fuel in the repowered plant. Consequently, parallel repowering was the repowering option that was chosen, and a decision must then be made on whether the topping or straight option is selected. In both options the existing boiler is kept and steam is raised independently of the operation of the gas turbine. However, in the former, the exhaust gas from the gas turbine is used as vitiated air in the boiler, whereas in the latter, an HRSG is incorporated, in addition.

	°C	°C	MW	Btu/kWh
11.0	1100	543	156	9977

Basis: ISO conditions, LHV = 50057 KJ/kg

Table 2: Gas turbine performance

Taking into consideration on the one hand technical issues [3], which include the capacity of the existing steam turbine, the matching of the HRSG and the steam turbine, and fuel handling, and on the other, financial issues, notably the need for low capital investment, the straight option was chosen. The gas turbine chosen for the topping cycle is the Siemens V94.2, whose performance at the design point is shown in Tab. 2, for an exhaust mass flow of 514 kg/s. In repowering the steam turbine with this gas turbine, the repowered plant has an output of 506 MW and a heat rate of 7921 Btu/kWh. The station output has increased by 45%, while the heat rate has improved by 17%. The basis of the re-design is that the existing steam turbine components are refurbished and kept. The computer software BRAKINE [4] was used to analyse the performance of the combined plant. Because of the age of the steam turbine, it is necessary to refurbish the boiler to extend its life. To avoid huge refurbishment costs, it was decided to de-rate the steam turbine. As a result, the superheater and reheater outputs were reduced to lower the steam turbine output to 280 MW, thereby reducing the output of the combined plant to 436

Table 4: Project economic data

ECONOMIC EVALUATION

The next step in the analysis procedure is to carry out an economic analysis to determine the overall costs associated with owning and operating the plant. The investment made in the equipment must be recovered during the life of the plant, and an acceptable rate of return must be obtained. In addition, provision must be made to recoup the cost of the fuel and the operation and maintenance charge. To effect these calculations, costs and economic data, load duration curves and plant overall performance are required. The data used are shown in Tab. 4. The bare equipment cost includes the cost of refurbishing the steam turbine plant. The cost of the gas turbine was estimated with the aid of [5].

The economic analysis was carried out by using the computer program PEACES [6]. The levelised net present value was obtained as $34.2 million, and the levelised cost of electricity was 5.06 ¢/kWh.

THERMOECONOMIC ANALYSIS

As mentioned earlier, thermoeconomics is a technique that combines economic analysis with exergy analysis, to aid the design of thermal energy systems. Exergy analysis (or second law analysis) helps to pinpoint the sources of inefficiency in an energy system, and when combined with economic analysis has the potential to minimise or reduce costs. Hence, the objective of thermoeconomic analysis is to minimise the cost of the product of the plant. A few authors have proposed techniques for carrying out cost optimisation of thermal energy systems [7–10]. The method proposed by Tsatsaronis [11] is used here, because of the manner in which BRAKINE and PEACES work, which allows the method of Tsatsaronis to lend itself to easy adaptation. A computer program XAG [12] was developed to carry out thermoeconomic analyses of energy systems; it complements BRAKINE and PEACES. The three software were used to analyse the performance of the combined cycle plant, with a view to improving on the design.

Improving on the design of the repowered plant involves altering those decision variables that alter the overall performance of the plant. Hence, the third and final step of the design process is to determine the thermoeconomic variables that define the improvement process. Usually, each component of the plant is looked at and its thermodynamic and cost data examined to find out the impact of the performance of the component on the overall performance of the plant. The structure

of the plant could change during the improvement exercise, but in this case the structure of the plant is fixed, comprising of the gas turbine, the HRSG, and the steam turbine. The performance of the gas turbine is fixed and so nothing changes in this unit. The performance of the HRSG changes in line with the steam requirements of the steam turbine, hence improvement to the design of the combined plant comes primarily from improving the performance of the steam turbine cycle, by modifying the cycle performance variables.
The variables that determine the overall performance of the steam turbine plant are:

1. the main steam pressure and temperature
2. the reheat steam pressure and temperature
3. the condenser pressure
4. the deaerator pressure

The pressures of the bleed steam affect the overall performance of the plant as well, but to a lesser extent. These decision variables are all not completely independent, since the structure is fixed and since the existing components are not replaced. In general, the decision variables affect directly the thermodynamic performance of the plant and, indirectly, the sizes of the components. Component size affects the cost of the plant, which in turn affects the economic performance of the system. With regard to the above variables, the main and reheat steam temperatures are set the same, as the reheat steam is heated to the temperature of the main steam. The pressure of the reheat steam is controlled by the performance of the HP turbine.
The design improvement exercise requires the calculation of certain thermoeconomic variables for each component. Following the method of Tsatsaronis [11], these variables are the exergetic efficiency ε, rate of exergy destruction $\dot{E}_D$, exergy destruction ratio y_D, the cost rate of exergy destruction $\dot{C}_D$, capital investment and operating and maintenance cost rates, $\dot{Z}^{CI}$ and $\dot{Z}^{OM}$, and their sum $\dot{Z}$, the relative cost difference r, and the exergoeconomic factor f. The definitions and significance of these variables are explained by Bejan, Tsatsaronis, and Moran [13], and the authors also explain the thermoeconomic optimisation process in detail.
Briefly speaking, the design improvement exercise is carried out iteratively, wherein a cost balance is formulated for each component, to determine the cost of each exergy stream. The cost balance is affected by the performance of the component, which in turn is influenced by the value of one or more decision variables. Hence, by altering the values of the decision variables progressively, where necessary, a localised optimal solution representing an improved design can be arrived at.

RESULTS

The values of the decision variables for the base case design are given in Tab. 3, and the values of the critical variables required for the thermoeconomic analysis are shown in Tab. 5 for the base case design, and for the important plant components. The components are listed in decreasing order of $\dot{C}_D+\dot{Z}$ values.

To start off the iterative process, the values of the decision variables given in Tab. 3 are altered in a logical manner, and the whole process is repeated all over again by first analysing the thermodynamic performance of the plant, and then carrying out an economic analysis, and thereafter performing a thermoeconomic analysis.

Component	ε (%)	$\dot{C}_D + \dot{Z}$ ($/h)	r (%)	f (%)
Gas turbine	37.8	21637	261.6	12.1
Boiler	81.6	4899	27.1	9.2
HRSG	72.1	4082	85.5	41.6

LP Turbine	85.3	2980	38.6	81.4
HP Turbine	86.9	2449	28.0	87.3
Deaerator	85.8	1634	34.9	46.4

Overall product cost $\dot{C}_P$= 49031 $/h

Table 5: Base case thermoeconomic data

The analysis of the data in Tab. 5 was carried out by inspection and by applying logic. This is the shortfall in iterative thermoeconomic analysis that has not yet been addressed. It requires the attention of the experienced performance analyst. In [14], the author explained in detail how the thermoeconomic data presented for the case examined there was analysed to alter the decision variables until a cost optimal solution was reached. A similar process is followed here. After an analysis of the data in Tab. 5, the decision variables were changed to the following:

Superheater pressure = 110 bar

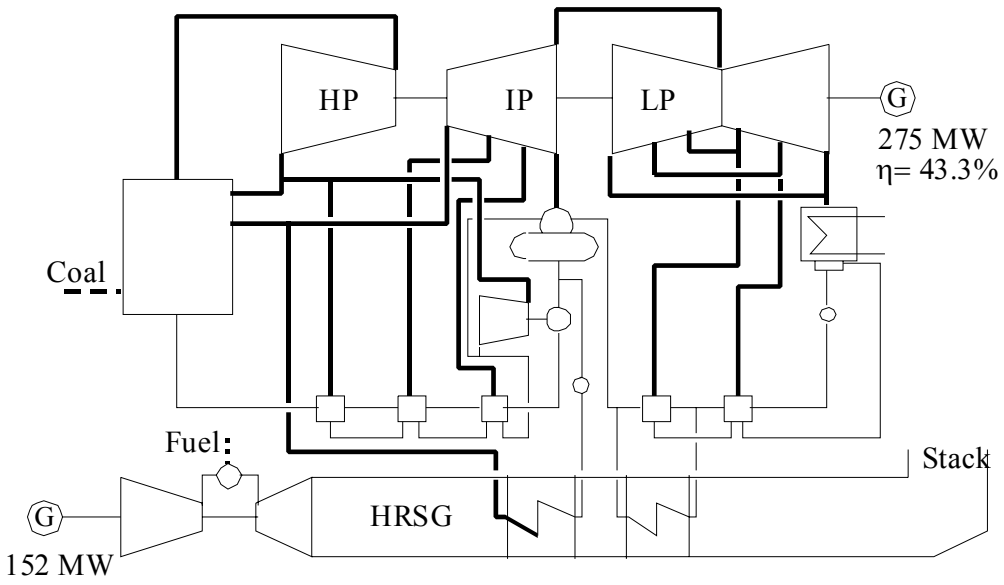

Fig. 6 Schematic of the Repowered plant

Superheater temperature = 480 °C
Reheat pressure = 25 bar
Deaerator pressure = 8 bar
Condenser Pressure = 0.078 bar

Component	ε (%)	$\dot{C}_D + \dot{Z}$ ($/h)	r (%)	f (%)
Gas turbine	37.7	21636	261.7	12.1

Deaerator	86.0	1552	35.8	48.0

Overall product cost $\dot{C}_P$= 45398 $/h

Table 6: Thermoeconomic data after Iteration 1

The thermoeconomic data after the first iteration is shown in Tab. 6. The iterative process continued, and after seven iterations it was believed that the cost optimal solution had been obtained. The thermoeconomic data at the cost-optimal point is shown in Tab. 7 and the performance of the plant at this point is shown in Tab. 8. The output of the plant is 427 MW at a heat rate of 7880 Btu/kWh, which was obtained at an overall product cost of 40046 $/h. The schematic of the plant is shown in Fig. 2.

Component	ε (%)	$\dot{C}_D + \dot{Z}$ ($/h)	r (%)	f (%)
Gas turbine	37.7	21635	261.7	12.1
Boiler	82.4	4213	25.4	8.6

HP Turbine	87.0	1559	22.9	72.6
Deaerator	86.0	1391	32.9	59.3

Overall product cost $\dot{C}_P$= 40046 $/h

Table 7: Cost-optimal data of repowered cycle

CONCLUSION

A steam turbine plant was repowered by adding a gas turbine and a HRSG as a topping cycle. A thermoeconomic analysis of the repowered cycle was carried out in an attempt to optimise the performance of the plant with regard to costs, i.e. to minimise the cost of the product of the plant. The analysis was restricted to the fixed structure obtained by combining a particular gas turbine with a given steam turbine. No changes could be

Throttle Conditions		Reheat Conditions		Output		Heat Rate
Pressure (bar)	Temp. (^oC)	Pressure (bar)	Temp. (^oC)	GT (MW)	ST (MW)	(Btu/kWh)
112	490	27	490	152	275	7880

$P_{deaerator}$ = 9 bar, $P_{condenser}$ = 0.08 bar

Table 8: Performance of the optimised repowered cycle

made to the decision variables that impact the performance of the gas turbine, as the gas turbine was employed to operate at its design point at the optimum performance point of the repowered cycle.

A very large portion of the investment cost went into purchasing the gas turbo set and HRSG equipment, leaving a small amount for refurbishing the steam turbine plant. As a result, the thermoeconomic optimisation process centered around reducing the cost of refurbishment of or the cost due to exergy destruction in the steam turbine components. The capacity of the repowered plant increased by 22% while the heat rate improved by 17.5%. An overall product cost of 40046 $/h was obtained for the plant, and the levellised cost of the electricity produced was obtained as 4.81 ¢/kWh, which is higher than the 2.99 ¢/kWh for that produced by the steam turbine plant. The higher cost is due primarily to the use of natural gas, in addition to coal, the sole fuel used in the existing plant. There are, however, environmental benefits to be gained by the use of natural gas, which benefit was not quantified in the analysis.

Repowering is feasible, and though the cost of electricity is increased, repowering of old steam turbine plants with gas turbines is a viable option that could be used to manage the looming capacity problem, in the short to medium term.

MINIMIZING THE ENTROPY PRODUCTION IN A CHEMICAL PROCESS FOR DEHYDROGENATION OF PROPANE

Abstract

We minimize the total entropy production of a process designed for dehydrogenation of propane. The process consists of 21 units, including a plug-flow reactor, a partial condenser, two tray distillation columns and a handful of heat exchangers and compressors. The units were modeled in a manner that made them little sensitive to changes in the molar flow rates, to make the optimization more flexible. The operating conditions, and to some degree the design of selected units, which minimized the total entropy production of the process, were found. The most important variables were the amount of recycled propane and propylene, conversion and selectivity in the reactor, as well as the number of tubes in the reactor. The optimal conversion, selectivity and recycle flows were results of a very clear trade-off among the entropy produced in the reactor, the partial condenser and the two distillation columns. Although several simplifying assumptions were made for computational reasons, this shows for the first time that it is also meaningful to use the entropy production as an objective function in chemical engineering process optimization studies.

Keywords: Entropy production rate, propane dehydrogenation, optimization.

INTRODUCTION

Large amounts of high quality energy are spent in the chemical process industry to convert raw materials into desired products. The art of process design and optimization is continuously being developed [1, 2]. In this paper we study the energy efficiency of a chemical process, a topic that so far has received little attention.

We have previously studied the state of minimum entropy production in several process units [3, 4, 5, 6, 7]. These studies gave insight in the design of the particular units with more or less fixed boundary conditions. In a process, each unit has few or no boundary conditions; the boundary conditions are placed on the process itself. Optimization of a process, the topic of the present work, may thus likely give very different results from optimization of single units.

In a chemical process, the aim is to convert a feedstock into products of certain purities. Typically, this is done with a reactor(s) that transforms the raw materials, followed by a separation to obtain the desired purity. One particularly important question in such chemical processes is: How does the selectivity and conversion in the reactor affect the downstream separation section? We shall see that the composition and flow rate of the recycle streams, as well as the operation of reactors and separation equipment, will have a large influence on the overall energy efficiency of the process.

We study the production of a fixed amount and quality of propylene from propane. Propylene is mostly used for production of polypropylene, a polymer with numerous applications. An emerging technology is the dehydrogenation of propane, which presently accounts for a small share of the total propylene production in the World. This share is expected to increase due to higher demands for propylene and because the dehydrogenation process uses propane instead of higher alkanes as feed [8].

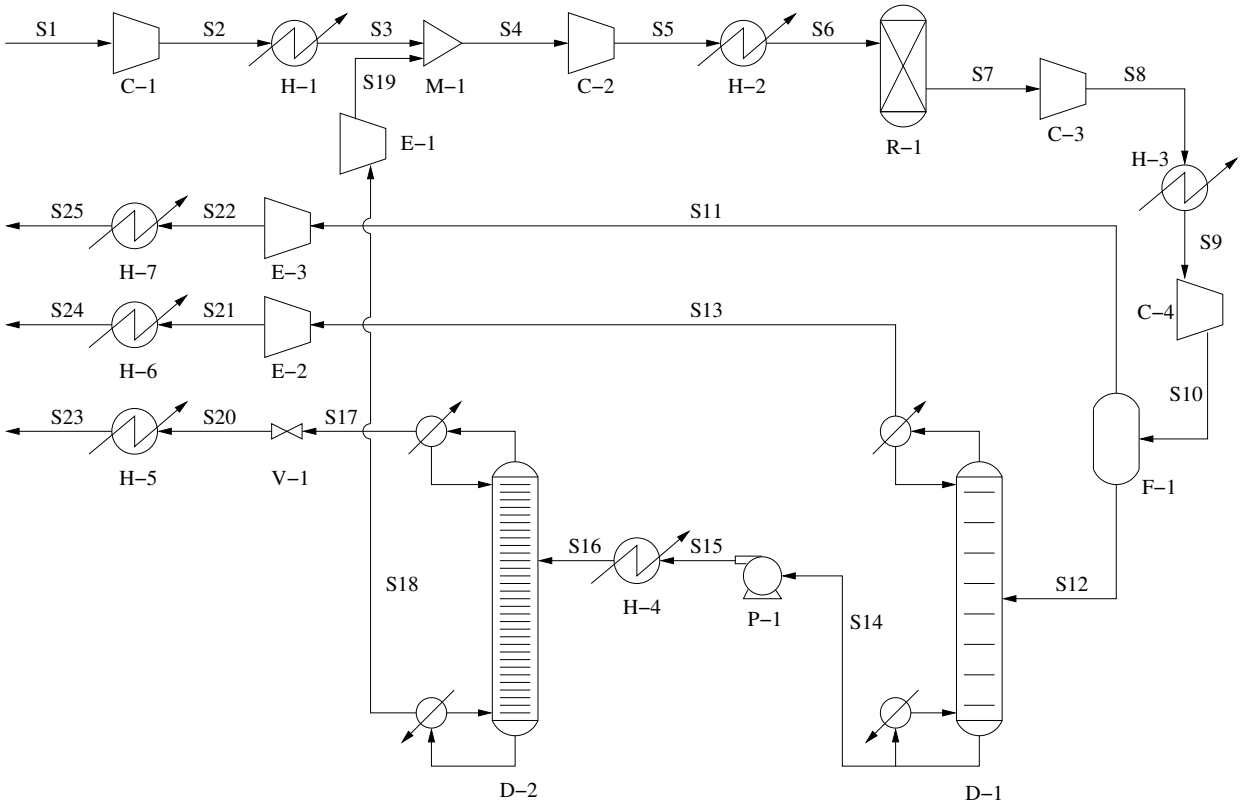

Figure 1: Flow sheet showing the propane dehydrogenation process. Symbols are explained in the text.

We have here chosen to minimize the entropy produced in the propane dehydrogenation process inspired by Linde's design [9]. The complete process consists of hundreds of units, but we study a simplified version where the main features are preserved. We concentrate our effort on finding the operating conditions of the process that give the least entropy production, without changing the structure of the process.

The most important result from this study is that there exists a meaningful trade-off in the energy efficiency among a handful of units, and that it may be found by minimizing the total entropy production of the process. The exact numerical values for operating conditions are of less importance, because of the assumptions that are used.

THE PROPANE DEHYDROGENATION PROCESS

The process we study in this work, is a simplified version of the propane dehydrogenation process designed by Linde [9]. One of the central process units is the dehydrogenation reactor in which the following two reactions are the dominating ones [10]:

$$C_3H_8 = C_3H_6 + H_2 \quad \text{(I)}$$

$$C_3H_8 = C_2H_4 + CH_4 \quad \text{(II)}$$

The expression for the reaction kinetics of reaction (I) was given by [11]. No expression that included the backward reaction of reaction (II) was found, so we guessed an expression [12].

According to the two reactions, the system contains five components: Hydrogen (H_2), methane (CH_4), ethylene (C_2H_4), propylene (C_3H_6) and propane (C_3H_8). We neglect other species that normally would be present in a real dehydrogenation process, among them water.

A flow sheet of the dehydrogenation process is shown in Fig. 1. The process consists of 21 units, and the chosen superstructure is an attempt to keep the main features of a real dehydrogenation process [13, 9, 8, 14]. Fresh feed enters the process and is mixed with a recycle stream before entering the reactor (R-1).

Equal amounts of hydrogen and propylene are formed in the reactor, along with some methane and ethylene. In order to separate the hydrogen from the main process stream, the pressure is increased and the temperature lowered before the stream enters a condenser (F-1), after which mostly hydrogen still is in the vapor phase. The remaining products are fed to two distillation columns in series (D-1 and D-2). The distillation column D-1 separates C_2-components from C_3-components. The distillate of the propane-propylene splitter (D-2) contains most of the propylene product, while the bottom stream is used as recycle to the reactor.

In at least three positions, heat exchangers must remove heat at cryogenic conditions (the temperature of the cooling fluid is then lower than the environmental temperature). First, the condenser (F-1) must operate under high pressure (15-25 atm), but also at very low temperatures (ca. 230 K) to ensure that a liquid phase of the heaviest components is present. Second, the top condenser in D-1 must work under quite similar conditions as those of F-1. Third, the required temperature of the cooling medium in the top condenser in D-2, may be below 298 K if the pressure is low. A refrigeration cycle consisting of four units is used to supply these cold heat exchanger fluids [13]. Using propane as the working fluid, temperatures no lower than 230 K could be obtained.

CALCULATIONS

We did two kinds of calculations: First, we found a set of initial operating conditions for the process by using a numerical solver. Second, we used this information as the initial guess in a minimization of the total entropy production, using a numerical optimization routine.

Every unit in the process under consideration had several design parameters that determined how that unit changed the process stream (for instance length of reactor, etc.). We chose to keep most of these parameters fixed during this study and did only allow to vary the *load* , or in a few cases other parameters, on each unit. With the load, we mean the amount of heat transferred in a heat exchanger, the work input to a compressor, the fractional recovery of a distillation column, etc. The values of the fixed unit parameters are given in Tab. 1.

Each unit were modeled according to widely used textbooks [17, 18].

Table 1: Process unit parameters. Reactor and catalyst parameters taken from [15] and compressor efficiency from [16].

Unit	Parameter	Value
Reactor	Length [m]	8.0
	Diameter [m]	0.2
	Heat transfer number [W/m^{2}K]	56.784
	Catalyst dens. [kg cat./m^3]	984.4
	Void of catalyst bed	0.45
	Catalyst particle diameter [m]	$4.572{\cdot}10^{-3}$
	Gas viscosity [kg/sm]	$3.7204{\cdot}10^{-5}$
	Residence time [s]	5
Heat ex.	Pinch, ΔT [K]	50
Comp./exp.	Efficiency, $\eta_{c/e}$	0.8
Dist. D-1	Number of trays, N	8
	Feed tray, N_F	6
	Light key, LK	3
	Heavy key, HK	4
Dist. D-2	Number of trays, N	100
	Distillate comp., $x_{D,LK}$	0.99

The following properties were chosen for the fresh feed stream to the process [13]: T_1 = 275 K, P_1 = 1 atm, F = [1, 1, 1, 1, 96] mol/s. The components in this vector are ranged from the lightest to the heaviest. We use this notation to describe the composition of the process stream from now on. The temperature and pressure of the three process streams exiting the process, were set to 310 K and 1 atm, respectively. The environmental temperature, T_0, was set to 298 K. All physical and thermodynamical properties were taken from [19] and [20]. The molar enthalpy, entropy and fugacity coefficients were derived from the Soave-Redlich-Kwong equation of state with the binary interaction parameters equal to 0 [21].

Modeling the process

For a given temperature, pressure and flow rates of the five components at the inlet of the process, we calculated sequentially the change each unit did to the process stream. All parameters in Tab. 2, except T_{19}, F_{19,C_3H_6} and F_{19,C_3H_8}, were fixed to a set of reasonable values. Initially, the state of the recycle stream was not known, and it was necessary to solve the following three equations to find the right values

of T_{19}, F_{19,C_3H_6} and F_{19,C_3H_8}:

$$\hat{T}_{19} - T_{19} = 0 \quad (1)$$

$$\hat{F}_{19,C_3H_6} - F_{19,C_3H_6} = 0 \quad (2)$$

$$\hat{F}_{19,C_3H_8} - F_{19,C_3H_8} = 0 \quad (3)$$

where the variables with a hat symbol represent the guessed values and those without represent the values found after calculating through the whole process. The numerical solver *fsolve* from the Optimization Toolbox in Matlab R13, MathWorks Inc. was used to find the solution to the above nonlinear problem.

With the correct values of the recycle stream (given in Tab. 2) we calculated all properties of the process like duties of heat exchangers, work of compressors, entropy production of each unit etc. The set of values for the properties given in Tab. 2 were used as initial guess in the optimization problem. We will therefore refer to this process as the *initial* process.

Optimizing the process

To find the state of minimum entropy production of the propane dehydrogenation process, we used the sum of the entropy produced by each of the 21 units as the objective function:

$$\left(\frac{dS}{dt}\right)^{\text{irr}}_{\text{process}} = \sum_{i=1}^{21} \left(\frac{dS}{dt}\right)^{\text{irr}}_{i} \quad (4)$$

where $(\frac{dS}{dt})^{\text{irr}}_i$ was the entropy production of unit i.

The variables we used in this optimization problem are listed in Tab. 2, along with their initial values. Table 2 gives also the fractional recovery, FR, of the two distillation columns, defined as [17]:

$$FR = \frac{Dx_{\text{D,LK}}}{Fx_{\text{F,LK}}} \quad (5)$$

where D and F are the molar flow rate of distillate and feed stream, respectively. Furthermore, $x_{\text{D,LK}}$ and $x_{\text{F,LK}}$ are the mole fractions of the light key component in the distillate and feed stream, respectively. The light (LK) and heavy (HK) key components are the components that we wish to separate in distillate and bottom product of the distillation column, respectively.

Upper and lower boundaries were set for the variables in order to avoid breakdown of the models (i.e negative pressures in reactor).

Table 2: Variables in the optimization: Initial and optimal values.

Unit	Variable	Init./opt.
Compressor (C-1)	P_2 / atm	3.0 / 2.3
Heat exchanger (H-1)	T_3 / K	500 / 494
Mixer (M-1)	T_{19} / K	261 / 250
	F_{19,C_3H_6} / mol/s	0.72 / 10.5
	F_{19,C_3H_8} / mol/s	99.4 / 27.9
Compressor (C-2)	P_5 / atm	5.0 / 2.0
Heat exchanger (H-2)	T_6 / K	1100 / 1099
PFR reactor (R-1)	T_a / K	1300 / 1343
Compressor (C-3)	P_8 / atm	10.0 / 25.0
Heat exchanger (H-3)	T_9 / K	500 / 460
Compressor (C-4)	P_{10} / atm	15.0 / 19.0
Condenser (F-1)	T_{12} / K	230 / 251
Distillation (D-1)	RR	10.0 / 9.8
	FR	0.99 / 0.986
Pump (P-1)	P_{15} / atm	15.0 / 18.0
Heat exchanger (H-4)	T_{16} / K	300 / 310
Distillation (D-2)	FR	0.99 / 0.87

As equality constraints we used the three Eqs. (1)-(3) in addition to the following demand on the production of propylene:

$$F^{\text{init}}_{17,C_3H_6} - F_{17,C_3H_6} = 0 \quad (6)$$

where $F^{\text{init}}_{17,C_3H_6}$ was the flow of propylene out of the propane-propylene splitter (and thus out of the process) in the initial process. A constant purity of the propylene product was ensured by always enforcing $x_{\text{D,LK}} = 0.99$ in D-2.

To find the minimum of Eq. (4) we used the function *fmincon* from the Optimization Toolbox in Matlab. This function solves numerically constrained nonlinear optimization problems by employing a sequential quadratic programming algorithm.

To reduce the required computational time needed to find the optimum, we made the additional assumption that the process stream entering the propane-propylene splitter (D-2) consisted of propylene and propane only. This means that traces of the three lightest components were technically removed before D-2, making it a binary distillation. Since any components that are lighter than propylene will almost exclusively end up in the distillate of D-2, we added the following inequality constraint on the content of C_2H_4 in the bottom stream from D-1 (and thus the feed stream to D-2):

$$F_{14,C_2H_4} - F^{\text{init}}_{14,C_2H_4} \leq 0 \quad (7)$$

By keeping the amount of ethylene at least as low as in the initial process, we reduced the error associated with the assumption of a binary distillation in D-2.
To further reduce the required computational time, we compiled a table with the entropy production, product temperatures etc., for different combinations of variables in D-2, before we did the process optimization. For four values of the feed mole fraction, fractional recovery, feed temperature and pressure, we carried out 256 simulations of D-2. We used this four-dimensional table instead of solving the distillation model itself when we optimized and modeled the process.

RESULTS

By solving Eqs. (1)-(3) we found the properties of the recycle stream that corresponded to the operating conditions chosen as in the initial process.
The residence time of 5 seconds was fulfilled with a number of tubes in the reactor equal to 72, giving a conversion of propane and selectivity toward propylene of 0.47 and 0.82, respectively.
The total entropy production of the initial process was 95.21 kW/K. Most of this entropy was produced in the reactor (R-1) and the three separation units (F-1, D-1, D-2). Around 24% of the total entropy production was due to the presence of cryogenic heat exchange in the three separation units. In Tab. 3 we have given the net work and heat added to the process.
By minimizing the entropy production as described in Calculations, we found a new set of operating conditions that gave the same product flow rate as the initial process (due to the constraints Eqs. (6) and (7)). The most important results can be summarized in three points:

- The amount of recycle was reduced from 100.1 mol/s to 38.4 mol/s.
- The conversion of propane increased from 0.47 to 0.74, while the selectivity toward propylene increased from 0.82 to 0.92.
- The pressure in the separation section attained the highest allowed value, thus reducing the need for cryogenic heat exchange.

The number of tubes in the reactor in the optimized process was calculated to be 124. A conversion and a selectivity of 0.74 and 0.92, respectively, was found in the reactor. Detailed values of the optimization variables are given in Tab.2.

The optimal process had an entropy production of 44.66 kW/K of which 12% was due to cryogenic heat transfer. The net work and heat added to the process is shown in Tab. 3.

As a consequence of the optimization, the total entropy production of the propane dehydrogenation process was reduced with 53%, or 50.6 kW/K. Six units produced the majority of the total entropy in both the initial and optimal process: H-2, R-1, C-3, F-1, D-1 and D-2. Each of these contributions, from both processes, is shown in Fig. 2.

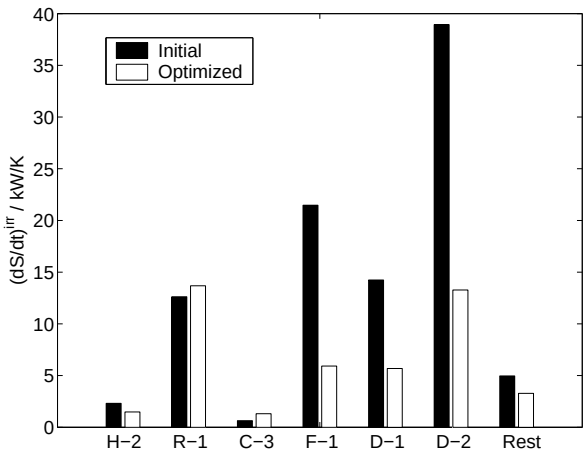

Figure 2: Entropy production in the 6 most significant units and the rest of the process, both in the initial and optimal process.

The entropy production due to the cryogenic process units, all of these located in the separation part (F-1, D-1 and D-2), decreased with 75% or 16.8 kW/K. This lead to a large reduction in the net work added, as shown in Tab. 3.

Table 3: Net work and heat added to the initial and optimal process.

	Net work [kW]	Net heat [kW]
Initial	21140	-11350
Optimal	13100	-2840
Change	-8040	8510

DISCUSSION

The most important result of this study is that we were able to formulate and solve an optimization problem using the entropy production of a chemical process as the objective function.

From the initial process, we know the variables that have the greatest impact on the entropy production of the process. There is little knowledge of whether the initial process is reasonable, however. The operating conditions of the initial process were not taken from a real, existing process, but were rather obtained through qualified guesses. The results from the optimization must be understood with this perspective in mind.

The great reduction of the total entropy production of the process, was due to the three major changes listed in the end of Results. It is apparent that the reduced recycle flow reduced the flow through most parts of the process with 30-40%. This translates almost directly into equivalent reductions in the entropy production. In other words: 55-75% of the demonstrated reduction in entropy production was caused by the reduced recycle flow. Furthermore, a simple estimate shows that the reduction in entropy production due to cryogenic heat exchange was partly due to the reduced process flow, but mainly due to higher temperatures for heat exchange. Approximately 20% of the decrease in total entropy production can be traced back to the increased heat exchange temperatures in F-1, D-1 and D-2. The last 5-25% of the reduction is likely to come from the increased selectivity toward propylene in the reactor, which lead to less work needed in the separation section.

The reduced entropy production translated into changes in the work and heat added to the process. When adding the work needed in all units, the results show that 8040 kW less work was needed to operate the optimal process. An approximately equal decrease in the released heat was found. As expected, the general tendency was that heat was supplied to the process at lower temperatures (except those with cryogenic conditions), while heat was released at higher temperatures.

To obtain further improvements in the entropy production, more variables could be added to the optimization (unit design), the process could be more integrated, and units could be upgraded. The design and operation of the heat exchanger network [22] may be included in the optimization. This requires, however, a very different mathematical treatment.

The reactor was modeled as a one-dimensional plug-flow reactor with side firing. Of the two reactions, only one reaction rate was founded on experimental results. The predictive ability of the reactor was thus probably low. The rate of the second reaction was chosen to never dominate the first reaction, since the purpose of including the second reaction was to introduce impurities.

Both distillation columns were modeled assuming equilibrium between the vapor and liquid that left each tray. This assumption gave a too high performance of the columns. No fluid dynamics were accounted for inside the columns and this also contributed to make the separation too efficient compared to a real column.

In general, most of the units were lacking the level of detail necessary to predict the detailed behavior of the real process. Some simplifications were done in order to make the optimization converge fast, while other, more critical assumptions were done due to lack of better models (i.e. the reaction rate expression). Most of the models of the units seem to have underestimated the entropy production. However, it was not the absolute value of the entropy production, but rather how it varied, that was of principal interest.

In order to find the solution of the optimization problem in a reasonable amount of time, several limitations and simplifications were introduced. This was partly due to the choice of numerical solver and partly due to a desire to use less than a few days of computational time to find the optimum. A fixed superstructure of the process was the most serious limitation in the optimization. To include the different interconnections and alternative units as variables gives a highly complex optimization problem. At the present stage in the method development this was not seen as necessary. We concentrated instead on the effect of finding the best operating conditions.

To develop the methodology based on minimization of the entropy production, it seems necessary to include both a heat exchanger network (see e.g. [22]) and allow the superstructure of the process to vary

(see e.g. [23]). Furthermore, a very interesting possibility is to perform entropy production minimizations with additional constraints on the operating or capital cost. Several of these optimizations would give valuable information of the additional cost associated with increasing the energy efficiency of a process, as recently demonstrated by [24].

To the authors' knowledge, this is the first time a minimization of the entropy production has been carried out for a chemical process. It is difficult to extract general knowledge from this kind of optimization but the questions answered is a classical chemical engineering question: How far does it pay to operate the reactor to avoid to pay in the separation section? It is interesting to see that there is a possibility for larger gains, to be found through optimization. This illustrates that there is a potential for similar optimizations to ensure high energy efficiency of chemical processes.

CONCLUSION

We have shown in this work that it is meaningful to use the entropy production in a chemical process as objective function in an optimization that aims to find the most energy efficient state of operation and, in some aspects, design. A process where propylene was produced in a dehydrogenation reactor from propane was studied. A plausible initial process was chosen as reference, inspired by Linde's design. The optimal process gave a large reduction in entropy production, for feasible new operating conditions. In both the initial and optimal process, the units with the largest entropy productions were the reactor, partial condenser and the two distillation columns. The results show that there was a large gain possible in the separation part of the process, by reducing the recycle stream. A higher conversion of propane and selectivity toward propylene in the reactor also contributed to reduce the entropy produced in the distillation column separating propylene from propane. Finally, we found that a higher operating pressure in parts of the process reduced the need for cryogenic heat exchange.

Assumptions and models, introduced to have reasonable computational times in the initial phase, can now be improved. Most important is to include water among the species in the process and implement the corresponding expressions for the reaction rates in the two reactions. To improve the energy efficiency of the process further, a reasonable strategy will be to include a heat exchanger network and a variable superstructure in the optimization. Future stages in the development of these procedures should include economic optimizations.

ABSTRACT

An irreversible cycle model of a combined chemical pump is set up, in which mass transfer irreversibility between the cyclic working fluid and the mass reservoirs and mass leak between the two mass reservoirs are taken into account. On the basis of the new cycle model, by using the optimal control theory method, the optimal relationship between the coefficient of performance and the rate of energy pumping is derived. Furthermore, the maximum coefficient of performance and the corresponding rate of energy pumping, the optimal chemical potentials in the iso-chemical-potential processes, the minimum power input and some other performance parameters are analyzed and discussed. The results obtained provide insight into the design of combined chemical pumps to achieve their optimum performance. The conclusions are of practical values to mass exchangers, chemical reactive devices, electrochemical, photochemical and solid state devices.

INTRODUCTION

In recent years, the theory of the optimum thermodynamics and the entropy generation minimization [1,2] have been extended to the chemical reaction, the chemical engine and chemical pump. De Vos [3], Gordon *et al*. [4,5], Chen *et al*. [6,7] and Lin *et al* [8] analyzed the

optimal performance characteristics of chemical engines. Lin *et al* [9-11] investigated the general performance characteristics of the two-source and three-source chemical pumps. Chen *et al* [6] explored the optimal cycle performance of the combined chemical engine. These works are of practical value for many chemical cycle devices and have provided us a good overview of possible developments and applications of chemical engines and chemical pumps. Similar to the combined heat pump [12,13], when the span of the chemical potentials of the two mass reservoirs is very large, a combined chemical pump is needed in order that we can upgrade some substance located in a low chemical potential region to a higher chemical potential region so that they can be more effectively utilized. So far the investigation on the cyclic performance of combined chemical pump has not been made. For this reason, it is a new and significant work to study the optimal performance characteristics of a combined chemical pump cycle. In the present paper, the general performance characteristics of the combined chemical pump cycle are studied and the influence of finite rate mass transfer and mass leak on the cyclic performance of the combined chemical pump is revealed. Furthermore, some important performance parameters are discussed and evaluated. The results obtained can provide some theoretical guidance for mass exchanger, electrochemical, photochemical and solid-state devices as well as development of some new type of chemical pumps.

A COMBINED CHEMICAL PUMP CYCLE MODEL

An irreversible combined chemical pump, which is operated between two mass reservoirs at

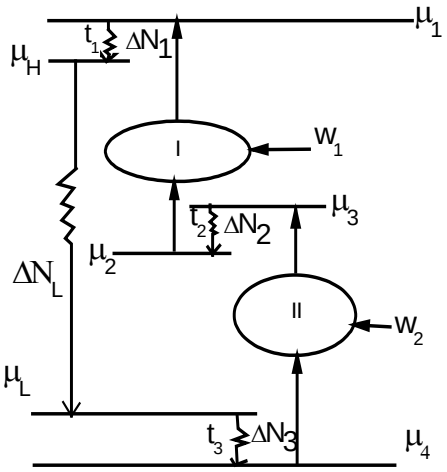

Figure 1: Schematic diagram of an irreversible combined chemical pump cycle

constant chemical potential μ_H and μ_L, consists of the chemical pumps I and II, as shown in figure 1, where μ_1, μ_2 and μ_3, μ_4 are, respectively, the chemical potentials of the working fluid in two iso-chemical-potential processes of chemical pump cycles I and II. It should be pointed out that the iso-chemical-potential processes result from linearized mass transfer law [4-11]. And, $\mu_1 > \mu_H > \mu_3 > \mu_2 > \mu_L > \mu_4$; W_1 and W_2 are the work input of chemical pump cycles I and II; ΔN_1 and ΔN_3 are the exchanged mass between the cyclic working fluid and the reservoirs μ_H and μ_L; t_1 and t_3 are the corresponding mass transfer times; Moreover, ΔN_2 is the exchanged mass between the two iso-chemical -potential processes μ_3 and μ_2 and the corresponding time of mass exchange is t_2. As the combined heat pump, t_2 in the combined chemical pump cycle is the public mass exchange time of chemical pumps I and II. Therefore, it is natural to assume $t_1 = t_3$ in order to make the combined chemical pump operate

normally [6,13,14].

In order to isolate and more transparently illustrate the results that are uniquely related to the process of mass transfer across a difference in chemical potentials, our consideration is restricted to an isothermal combined chemical pump. On the other hand, it is assumed that mass exchange obeys the mass transfer law of linearized irreversible thermodynamics [3-11], i.e.,

$$\Delta N_1 = h_1(\mu_1 - \mu_H)t_1 \qquad (1)$$

$$\Delta N_2 = h_2(\mu_3 - \mu_2)t_2 \qquad (2)$$

$$\Delta N_3 = h_3(\mu_L - \mu_4)t_3 \qquad (3)$$

where h_1, h_3 and h_2 are the mass transfer coefficients between the working fluid and the two reservoirs and between the iso-chemical-potential processes μ_3 and μ_2, respectively. In addition, it is inevitable that there exists mass leak in the combined chemical pump and it is assumed that the mass leak is proportional to the chemical potential difference of the two reservoirs, i.e.,

$$\Delta N_L = h_L(\mu_H - \mu_L)\tau \qquad (4)$$

where τ is the cycle period of the combined chemical pump. It should be pointed out that except for the mass exchange branches, there exist other additional branches of the cycle that connect the mass exchange branches. These branches may be regarded as instant**.** Although instantaneous change is clearly impossible in a real cyclic device, the time spent on the connecting branches without mass exchange is sufficiently short compared with the time spent on the mass exchange branches so that it can be treated as negligible for analytic purpose. Therefore, based on $t_1=t_3$ and above analysis, the cycle period of the combined chemical pump may be written as

$$\tau = t_1 + t_2 \qquad (5)$$

This implies that the processes of mass transfer between the working fluid and the two reservoirs is carried out synchronously [14].

THE FUNDAMENTAL OPTIMAL RELATIONSHIP

Based on figure 1, one has the total work input of the combined chemical pump cycle

$$W = W_1 + W_2 \qquad (6a)$$

where

$$W_1 = \Delta N_1(\mu_1 - \mu_2) \qquad (6b)$$

$$W_2 = \Delta N_2(\mu_3 - \mu_4) \qquad (6c)$$

From the law of mass conservation, it yields

$$\Delta N_1 = \Delta N_2 = \Delta N_3 \equiv \Delta N \qquad (7)$$

Thus, according to the definition of rate of energy pumping[9-11] , we have

$$\sum = \frac{\mu_H(\Delta N - \Delta N_L)}{\tau} \qquad (8)$$

Substituting equations (5), (6), (7) and (8) into the definition of coefficient of performance [9-11] yields

$$\chi = \frac{\Sigma}{W/\tau} = \frac{\mu_H(\Delta N - \Delta N_L)}{[(\mu_1 - \mu_2) + (\mu_3 - \mu_4)]\Delta N} \qquad (9)$$

By substituting equations (1)-(3) into equations (8) and (9), the rate of energy pumping and the coefficient of performance are expressed as

$$\Sigma = \frac{\mu_H(\beta - \mu_H\chi_r^{-1})}{\alpha} - h_L\mu_H^{\,2}\chi_r^{-1} \qquad (10)$$

$$\chi = \frac{\mu_H(\beta - \mu_H\chi_r^{-1}) - h_L\mu_H^{\,2}\chi_r^{-1}\alpha}{\beta(\beta - \mu_H\chi_r^{-1})} \qquad (11)$$

where $\alpha = (1+\lambda)/h_0 + (1+\lambda^{-1})/h$, $\lambda = t_2/t_1$ is a dimensionless parameter, $h_0 = h_1h_3/(h_1+h_3)$, $h = h_0h_2/(\sqrt{h_0}+\sqrt{h_2})^2$. $\chi_r = \mu_H/(\mu_H - \mu_L)$ is the coefficient of performance of the reversible two-source chemical pump [9] operating between

μ_H and μ_L and $\beta=\mu_1-\mu_2+\mu_3-\mu_4$. In view of equations (10) and (11), we can see that both the rate of energy pumping Σ and the coefficient of performance χ are functions of λ and β when other parameters are given. And our objective is to find out the maximum coefficient of performance for the combined chemical pump cycle. For this reason, by using the optimal control theory and the extreme condition $\partial\chi/\partial\lambda=0$ or $\partial\Sigma/\partial\lambda=0$, one can obtain when

$$\lambda=\sqrt{h_0/h_2} \quad , \tag{12}$$

the coefficient of performance χ attains its extremum. By substituting equation (12) into equations (10) and (11), the rate of energy pumping Σ and the coefficient of performance χ are rewritten as

$$\Sigma=h\mu_H(\beta-\mu_H/\chi_r)-h_L{\mu_H}^2/\chi_r \tag{13}$$

$$\chi=\frac{\mu_H(\beta-\mu_H/\chi_r)-h_L{\mu_H}^2/(h\chi_r)}{\beta(\beta-\mu_H/\chi_r)} \tag{14}$$

Furthermore, combining equations (13) with (14), one can obtain the relationship between the optimal coefficient of performance and the rate of energy pumping is given by

$$\chi=\frac{1}{[\Sigma/(h{\mu_H}^2)+(1+h_L/h)/\chi_r][1+h_L{\mu_H}^2/(\chi_r\Sigma)]} \tag{15}$$

Equation (15) is the optimal relationship between the rate of energy pumping and the coefficient of performance and also called as the fundamental optimal relationship of the irreversible combined chemical pump cycle. From it, the optimal performance characteristics of the combined chemical pump affected by the mass transfer irreversibility and mass leak can be revealed. Using equation (15), we can generate the Σ^*-χ characteristic curves, as shown in figure 2, where $\Sigma^*=\Sigma/(h_1{\mu_H}^2)$ is the dimensionless rate of energy pumping. Figure 2(a), 2(b) and 2(c) show, respectively, the coefficient of performance χ versus the rate of energy pumping Σ characteristics under different mass transfer coefficients ratio h_2/h_1, different mass leak coefficient h_L and different chemical potentials ratio μ_H/μ_L. Based on figure 2 and the above analysis, the optimal performance characteristics of the combined chemical pump will be discussed further in the following sections.

DISCUSSION

Maximum coefficient of performance

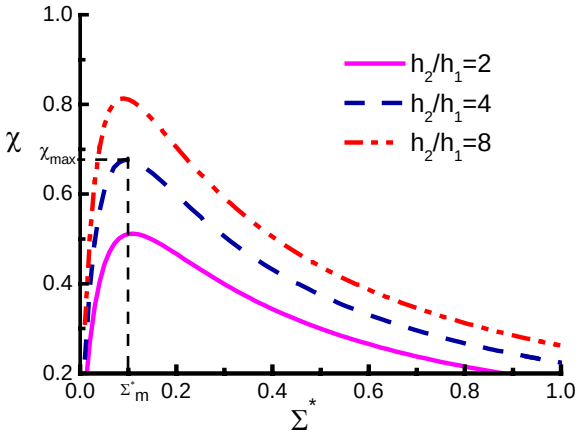
For the irreversible combined chemical pump, there exists a maximum coefficient of performance. In fact, substituting equation (15) into the extreme condition $\partial\chi/\partial\Sigma=0$, we can find that when

$$\Sigma=\Sigma_m={\mu_H}^2\chi_r^{-1}\sqrt{h_L(h_L+h)}\,, \tag{16}$$

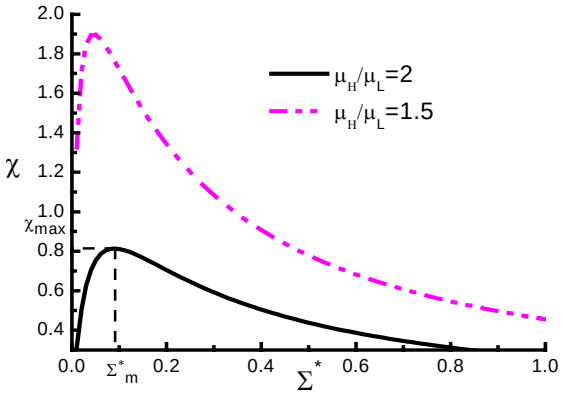
the maximum coefficient of performance

$$\chi_{\max}=\{[1+\frac{h_L}{\sqrt{h_L(h_L+h)}}]\frac{1}{\chi_r}+[(h_L(h+h_L))^{1/4}+\frac{h_L}{[h_L(h+h_L)]^{1/4}}]^2\frac{1}{h\chi_r}\}^{-1} \tag{17}$$

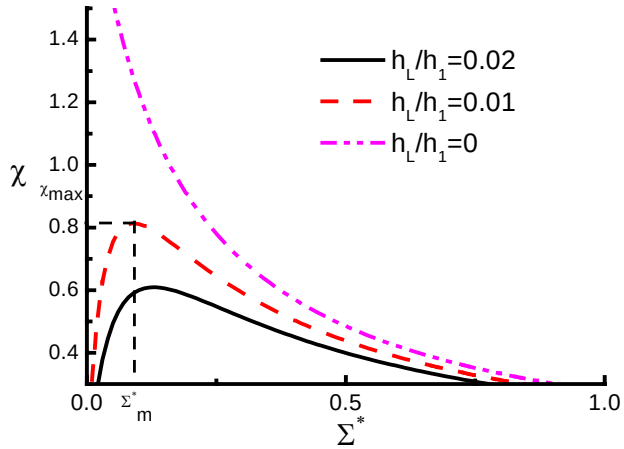
Equations (16) and (17) determine the two important performance bounds. Σ_m is not only the rate of energy pumping at the condition of the maximum coefficient of performance but also the allowable values of the lower bounds of the optimum rate of energy pumping. $\chi_{\max}$ is the upper bound of the coefficient of performance. It is clear that these bounds are more realistic and useful than those of classical and endoreversible thermodynamics. As mentioned last section, the coefficient of performance versus the rate of energy pumping characteristics depends closely on



(a)



(c)



(b)

Figure 2: The coefficient of performance χ versus the dimensionless rate of energy pumping Σ^* curves. Plots are presented for $h_1 = h_3$ and (a) $\mu_H/\mu_L = 2$, h_L/h_1 =0.01 (b) $\mu_H/\mu_L = 2$, $h_2/h_1 = 8$ (c) $h_2/h_1 = 8$, h_L/h_1 =0.01

the mass transfer coefficients, the mass leak coefficient and the chemical potentials of the two reservoirs. Figure 2(a) shows clearly that the coefficient of performance χ increases as the value of h_2/h_1 increases. For example, when h_2/h_1=2, 4 and 8, χ_{max} =0.51, 0.68 and 0.82. It is clear that increasing h_2 or decreasing h_1 is beneficial to increase of the coefficient of performance. On the other hand, we can see from figure 2(b) that the influence of mass leak on the coefficient of performance is obvious. The larger the mass leak coefficient, the smaller the coefficient of performance becomes. For example, when h_L/h_1 = 0.01, χ_{max} =0.82; when h_L/h_1 = 0.02, χ_{max} =0.61. And when the mass leak coefficient, compared with the mass transfer coefficient h_1, is small enough that it can be ignored, there hardly exists any extremum of the coefficient of performance, as shown in figure 2(b). Moreover, the chemical potentials ratio μ_H/μ_L of the two mass reservoirs has also obvious effect on the optimal performance of the combined chemical pump, as shown in figure 2(c). In view of figure 2(c), we can see the coefficient of performance χ decreases as the value of μ_H/μ_L increases, whereas the rate of energy pumping Σ_m at the maximum coefficient of performance hardly changes. As an example, when μ_H/μ_L=2, χ_{max} =0.82, and when μ_H/μ_L=1.5, χ_{max} =1.91. It is clear because increasing the value of μ_H/μ_L will result in the increase of mass leak quantity.

Optimal chemical potentials

From equations (1), (2), (3), (12) and (15), one can obtain

$$\Delta N = (\beta - \mu_H \chi_r^{-1})\tau / h \qquad (18)$$

$$\beta - \mu_H \chi_r^{-1} = \frac{\mu_H (\chi^{-1} - \chi_r^{-1}) + \mu_H A}{2} \qquad (19)$$

When the combined chemical pump is operated in the optimal operating state, we can find the chemical potentials of iso-chemical-potential processes should satisfy

$$\mu_1 = \mu_H + \frac{\mu_H (\chi^{-1} - \chi_r^{-1}) + \mu_H A}{2h_3\sqrt{h_2}/[h(\sqrt{h_0} + \sqrt{h_2})}, \qquad (20)$$

$$\mu_3 - \mu_2 = \frac{\mu_H (\chi^{-1} - \chi_r^{-1}) + \mu_H A}{2h_2\sqrt{h_0}/[h(\sqrt{h_0} + \sqrt{h_2})]}, \qquad (21)$$

$$\mu_4 = \mu_L - \frac{\mu_H (\chi^{-1} - \chi_r^{-1}) + \mu_H A}{2h_1\sqrt{h_2}/[h(\sqrt{h_0} + \sqrt{h_2})]}, \qquad (22)$$

where $A = \sqrt{(\chi^{-1} - \chi_r^{-1})^2 - 4h_L(h\chi_r\chi)^{-1}}$. Obviously, when the coefficient of performance, the mass transfer coefficients and the chemical potentials of the reservoirs are given, as the mass leak coefficient increases, μ_1 and $\mu_3 - \mu_2$ should decrease, whereas μ_4 should increase, otherwise the combined chemical pump can't attain its expected optimum performance.

Minimum power input

For a combined chemical pump, when the rate of energy pumping is given, the minimum total power input is an important performance parameter. Substituting equations (6) into $P = W/\tau$, we find the minimum power input of the combined chemical pump affected by mass transfer irreversibility and mass leak may be expressed as

$$P = h\,\mu_H^{\,2}/4\{[\chi^{-1} + A]^2 - \chi_r^{-2}\} \qquad (23)$$

Then, the minimum power input versus the coefficient of performance curves are shown in figure 3, where $P^* = P/(h\mu_H^{\,2})$ is the dimensionless minimum power input. We can see from equation (23) and figure 3 that the minimum power input decrease with increasing coefficient of performance. As the mass leak coefficient increases, the minimum power input decreases under same coefficient of performance. In other words, as long as the coefficient of performance is same, the larger the mass leak coefficient, the smaller the minimum power input becomes. Because, for the combined chemical pump cycle, the larger the mass leak, the smaller the rate of energy pumping becomes, such that the minimum power input should decrease under same coefficient of performance. Of course, if we want the larger rate of energy pumping and the larger coefficient of performance, increasing the power input becomes necessary.

Optimization of mass transfer times

In order to make the combined chemical pump operate in the optimum operating states, the distribution of the mass transfer times should satisfy certain condition. By using equations (5) and (12), the optimal mass transfer times spent in the mass transfer processes are given by

$$t_1 = \tau/[1 + (h_0/h_2)^{1/2}] \qquad (24)$$

$$t_2 = \tau/[1 + (h_2/h_0)^{1/2}] \qquad (25)$$

In view of equations (24) and (25), we find the optimal distribution of the mass transfer times is

$$\sqrt{h_2}\,t_2 = \sqrt{h_1 h_3/(h_1 + h_3)}\,t_1 \qquad (26)$$

Especially, when $h_1 = h_3$, $t_2/t_1 = \sqrt{h_1/2h_2}$; Furthermore, when $h_2 = 2h_1$, $t_1 = 2t_2$; when $h_1 = 2h_2$, $t_1 = t_2$. These results provide some theoretical guidance for the optimal design of the mass exchanger in the combined chemical pump.

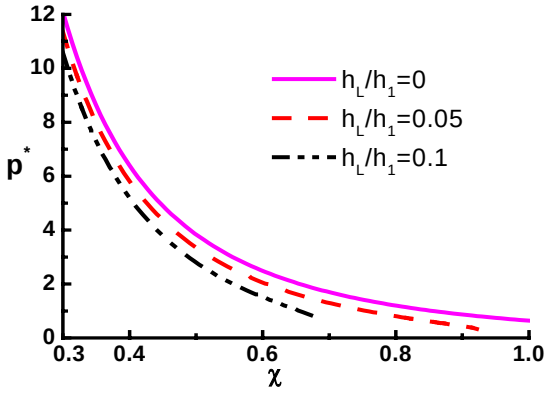


Figure 3: The dimensionless power input P^* versus the coefficient of performance χ curves of the combined chemical pump. Plots are presented for μ_H/μ_L=2, h_1=h_3 and h_2/h_1=8

Special cases

When the mass leak is small enough that it can be neglected, i.e., $h_L \to 0$, equation (15) is simplified as

$$\chi = \frac{1}{\Sigma(h\mu_H{}^2)^{-1} + \chi_r{}^{-1}} \qquad (27)$$

Equation (27) is the fundamental optimal equation of the endoreversible combined chemical pump in which only mass transfer irreversibilities between the working fluid and the two reservoirs and between the iso-chemical-potential processes μ_3 and μ_2 are taken into account. Moreover, if the mass transfer coefficient $h_2 \to \infty$, equation (27) is expressed as

$$\Sigma = \frac{h_1 h_3}{h_1 + h_3}\mu_H{}^2(\chi^{-1} - \chi_r{}^{-1}) \qquad (28)$$

Equation (28) is the optimal relationship between the rate of energy pumping and the coefficient of performance for the two-source endoreversible chemical pump, in which only the mass transfer irreversibility between the cyclic working fluid and the two reservoirs is taken into account.

CONCLUSIONS

A new cyclic model of irreversible combined chemical pump is established. Based on the model, the optimal relationship between the coefficient of performance and the rate of energy pumping is derived. Some important performance bounds are obtained and evaluated. The influence of finite rate mass transfer and the mass leak on the performance of the combined chemical pump cycle is revealed. The optimal chemical potentials in the iso-chemical-potential processes, the minimum power input and the optimal distribution of the mass transfer times are also analyzed and discussed. The results obtained are more general and useful than those of classical and endoreversible thermodynamics and can provide some instructions for the development and optimal design of a combined chemical pump.

PREDICTION OF ENERGY DEMANDS USING NEURAL NETWORK BY A GLOBAL OPTIMIZATION METHOD

Ryohei Yokoyama*, Makoto Inui, and Koichi Ito
Osaka Prefecture University
Department of Mechanical Engineering
Sakai, Osaka, Japan

ABSTRACT

To operate energy supply systems optimally from the viewpoints of energy and cost savings, it is important to predict energy demands accurately as basic conditions. Several methods of predicting energy demands have been proposed, and one of them is to use multi-layered neural network models. Although gradient methods have conventionally been adopted in the back propagation procedure to identify the values of model parameters, they have the significant drawback that they can derive only local optimal solutions. In this paper, a global optimization method named "Modal Trimming Method" for nonlinear programming problems is adopted in the back propagation procedure to derive global quasi-optimal solutions. The multi-layered neural network model is applied to the prediction of the cooling demand in a building used for a bench mark test of a variety of prediction methods, and its validity and effectiveness are clarified.

INTRODUCTION

Distributed energy supply systems have conventionally been operated based on experiences and intuitions of operators for stable energy supply. However, energy and cost savings have recently been required to operators in addition to stable energy supply. Therefore, it has become difficult for operators to operate the systems properly in consideration of energy demands which change with season and time as well as corresponding energy consumptions and costs.

Under these situations, advisory systems which assist operators in operating energy supply systems in real-time manner are required. The basic functions for the advisory systems are to predict energy demands accurately as basic conditions for the operational planning, and to conduct the operational planning properly based on the predicted energy demands from the viewpoints of stable energy supply, and energy and cost savings.

Several methods of predicting energy demands have been proposed, and typical examples are time series analysis and neural network [1–3]. In addition, an optimal operational planning method for the real-time operation of energy supply systems has also been proposed [4], and case studies have been conducted on the operation based on predicted energy demands [5]. Moreover, an effort to coadunate the energy demand prediction and operational planning has been made [3].

In this paper, a multi-layered neural network model is adopted to predict energy demands [6]. The values of model parameters are identified in the back propagation procedure. Local optimization methods such as gradient methods have conventionally been adopted for this purpose. However, they have the significant drawback that they can derive only local optimal solutions. Some global optimization methods have also been proposed [7–9]. Here, a global optimization method named "Modal Trimming Method" is adopted, which has been proposed to derive global quasi-optimal solutions for constrained nonlinear programming problems [10]. The multi-layered neural network model is applied to the prediction of the cooling demand in a building used for a bench mark test of a variety of prediction methods. The results obtained by the global optimization method are compared with those by a conventional gradient method.

PREDICTION MODEL

Removal of trend and periodic change

Before the application of the multi-layered neural network model, the trend and periodic change are removed in time series data on energy demand. Especially, since the energy demand changes periodically with a period of 24 hours, the removal of the periodic change will improve the accuracy of the prediction. Here, the time series data on energy demand is designated by z_t $(t = 1, 2, \cdots)$ with a sampling time interval of Δt.

First, the ordinary differential operation is conducted to remove the trend, and the first order ordinary difference is obtained as follows:

$$\nabla z_t = z_t - z_{t-1} \tag{1}$$

where ∇ is the ordinary differential operator. By conducting this operation d times, the dth order ordinary difference y_t is obtained as follows:

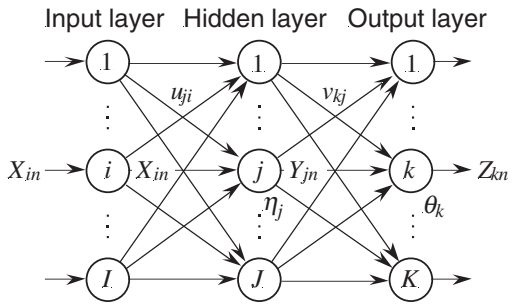

Figure 1: Three-layered neural network model

$$y_t = \nabla^d z_t = \begin{cases} z_t & (d=0) \\ \sum_{e=0}^{d} (-1)^e {}_dC_e z_{t-e} & (d \geq 1) \end{cases} \quad (2)$$

where ${}_dC_e$ is the binomial coefficient which expresses the number of combinations for selecting e elements among d ones.

Second, the periodic differential operation is conducted to remove the periodic change, and the first order periodic difference is obtained as follows:

$$\nabla_s y_t = y_t - y_{t-s} \quad (3)$$

where ∇_s is the periodic differential operator with a period of $s\Delta t$, and s is the number of sampling times for the periodic differential operation. By conducting this operation D times, the Dth order periodic difference w_t is obtained as follows:

$$w_t = \nabla_s^D y_t = \begin{cases} y_t & (D=0) \\ \sum_{e=0}^{D} (-1)^e {}_DC_e y_{t-es} & (D \geq 1) \end{cases} \quad (4)$$

Three-layered neural network model

As shown in Figure 1, a three-layered neural network model is considered. This neural network model is composed of I, J, and K neurons of the input, hidden, and output layers, respectively. To apply this model to the energy demand prediction, the number of neurons of the output layer is set at $K=1$.

Input and output. As output from the model, the value $\breve{w}_{t+l|t}$ at the sampling times $t+l$ ($l = 1, 2, \cdots, L$) predicted at the sampling time t is adopted, where $\breve{(\,)}_{t'|t}$ means the value at the sampling time t' predicted at the sampling time t. Here, it is assumed that $L \leq s$. As input to the model, the p measured or predicted values $\hat{w}_{t+l-1}$, $\hat{w}_{t+l-2}$, $\cdots$, $\hat{w}_{t+l-p}$ at the sampling times $t+l-1$, $t+l-2$, $\cdots$, $t+l-p$, respectively, are adopted. Here, $\hat{w}_{t'}$ is evaluated as the measured value $w_{t'}$ if it can be evaluated, otherwise as the predicted value $\breve{w}_{t'|t}$. Here, it is assumed that $p < s$. In addition, the q errors between the measured and predicted values $\hat{a}_{t+l-1}$, $\hat{a}_{t+l-2}$, $\cdots$, $\hat{a}_{t+l-q}$ at the sampling times $t+l-1$, $t+l-2$, $\cdots$, $t+l-q$, respectively, are adopted. Here, $\hat{a}_{t'}$ is evaluated as

$$\hat{a}_{t'} = w_{t'} - \breve{w}_{t'|t'-1} \quad (5)$$

if $w_{t'}$ can be evaluated, otherwise as zero. Here, it is assumed that $q < s$. This is similar to the autoregressive moving average model for time series analysis. Therefore, the number of the neurons of the input layer is $I=p+q$.

Input-output relationships. The input-output relationships for the jth neuron of the hidden layer and the kth neuron of the output layer are expressed as follows:

$$Y_{jn} = g\left(\sum_{i=1}^{I} u_{ji} X_{in} + \eta_j \right) \quad (n = 1, 2, \cdots, N; j = 1, 2, \cdots, J) \quad (6)$$

$$Z_{kn} = h\left(\sum_{j=1}^{J} v_{kj} Y_{jn} + \theta_k \right) \quad (n = 1, 2, \cdots, N; k = 1, 2, \cdots, K) \quad (7)$$

respectively. Here, X_{in} is the input to and output from the ith neuron of the input layer for the nth pattern, Y_{jn} is the output from the jth neuron of the hidden layer for the nth pattern, Z_{kn} is the output from the kth neuron of the output layer for the nth pattern, u_{ji} is the weight for the connection between the ith neuron of the input layer and the jth neuron of the hidden layer, η_j is the threshold for the jth neuron of the hidden layer, v_{kj} is the weight for the connection between the jth neuron of the hidden layer and the kth neuron of the output layer, and θ_k is the threshold for the kth neuron of the output layer.

In Eqs. (6) and (7), N is the number of patterns, which is equal to the number of the predicted values $\breve{w}_{t+l|t}$, or the number of the sets of the measured or predicted values $\hat{w}_{t+l-1}$, $\hat{w}_{t+l-2}$, $\cdots$, $\hat{w}_{t+l-p}$ and the errors between the measured and predicted values $\hat{a}_{t+l-1}$, $\hat{a}_{t+l-2}$, $\cdots$, $\hat{a}_{t+l-q}$.

In Eqs. (6) and (7), $g(x)$ and $h(x)$ are the functions which convert input into output in the neurons of the hidden and output layers, respectively. The sigmoid function has conventionally been adopted as these conversion functions. However, the predicted value $\breve{w}_{t+l|t}$ can be negative and

larger than unity in the problem under consideration. Therefore, the following functions are adopted here:

$$g(x) = \tanh x \tag{8}$$

$$h(x) = \alpha \tanh x \tag{9}$$

where α is a constant coefficient.

Conversion from output to energy demand

The relationship between the predicted values $\hat{w}_{t+l\,|\,t}$ and $\hat{y}_{t+l\,|\,t}$ is expressed as follows:

$$\hat{y}_{t+l\,|\,t} = \begin{cases} \hat{w}_{t+l\,|\,t} & (D = 0) \\ \hat{w}_{t+l\,|\,t} - \displaystyle\sum_{e=1}^{D} (-1)^e {}_D\mathrm{C}_e y_{t+l-es} & \\ & (D \geq 1) \end{cases}$$
$$(l = 1, 2, \cdots, L) \tag{10}$$

In addition, the relationship between the predicted values $\hat{y}_{t+l\,|\,t}$ and $\hat{z}_{t+l\,|\,t}$ is expressed as follows:

$$\hat{z}_{t+l\,|\,t} = \begin{cases} \hat{y}_{t+l\,|\,t} & (d = 0) \\ \hat{y}_{t+l\,|\,t} - \displaystyle\sum_{e=1}^{l-1} (-1)^e {}_d\mathrm{C}_e \hat{z}_{t+l-e\,|\,t} & \\ \quad - \displaystyle\sum_{e=l}^{d} (-1)^e {}_d\mathrm{C}_e z_{t+l-e} & \\ & (d \geq 1,\ l \leq d) \\ \hat{y}_{t+l\,|\,t} - \displaystyle\sum_{e=1}^{d} (-1)^e {}_d\mathrm{C}_e \hat{z}_{t+l-e\,|\,t} & \\ & (d \geq 1,\ l > d) \end{cases}$$
$$(l = 1, 2, \cdots, L) \tag{11}$$

MODEL IDENTIFICATION

Optimization problem for back propagation

Generally, the squared error between the output from the kth neuron of the output layer Z_{kn} and the corresponding teaching data is evaluated for the nth pattern, and its summation for the K outputs and N patterns is minimized as the objective function. In the problem under consideration, the output Z_{kn} and the corresponding teaching data are replaced by the predicted and measured energy demands, $\hat{z}_{t+l\,|\,t}$ and z_{t+l}, respectively. Therefore, the objective function is defined as follows:

$$f = \sum_{l=1}^{L} \sum_{t=R}^{M-l} (\hat{z}_{t+l\,|\,t} - z_{t+l})^2 \tag{12}$$

The number of patterns N is replaced by $L\{(M - R) - (L-1)/2\}$, where M is the number of sampling times for the measured energy demand, and R is the number of sampling times reduced for the predicted value $\hat{w}_{t+l\,|\,t}$ and is expressed as follows:

$$R = Ds + d + \max(p, q) \tag{13}$$

The variable vector composed of the weights and thresholds whose values are to be determined is defined as follows:

$$\boldsymbol{x} = \big(u_{11}, \cdots, u_{JI}, v_{11}, \cdots, v_{KJ}, \eta_1, \cdots, \eta_J, \theta_1, \cdots, \theta_K\big)^{\mathrm{T}} \tag{14}$$

where the superscript T means a transposition.

In the back propagation approach, the error function for each pattern in Eq. (12) is minimized sequentially. Here, to secure the local optimality of solutions and make the convergence faster, the total error function for all the patterns of Eq. (12) is minimized simultaneously.

Search for local optimal solutions

The search for local optimal solutions can be conducted by a gradient method for unconstrained nonlinear programming problems. For example, the simplest gradient method is the steepest descent one, and the renewal of the values of the variables $\boldsymbol{x}$ is expressed as follows:

$$\boldsymbol{x}_{(m+1)} = \boldsymbol{x}_{(m)} - \beta \big[\partial f(\boldsymbol{x}_{(m)}) / \partial \boldsymbol{x}\big]^{\mathrm{T}} \tag{15}$$

where the subscript (m) is the number of the renewal of the values of the variables $\boldsymbol{x}$, and β is the step width. However, the steepest descent method has the drawback of slow convergence. Therefore, the conjugate gradient and quasi-Newton methods with faster convergence are often adopted instead of the steepest descent method.

Nevertheless, as aforementioned, these methods have the significant drawback that they cannot derive global optimal solutions. Therefore, the modal trimming method is adopted as a global optimization one.

Global optimization by modal trimming method

Basic concept. The concept of the modal trimming method is shown in Figure 2. This method is composed of the following two procedures: A local optimal solution is searched to obtain a tentative global quasi-optimal one; A feasible solution with the value of the objective function equal to that for the tentative global quasi-

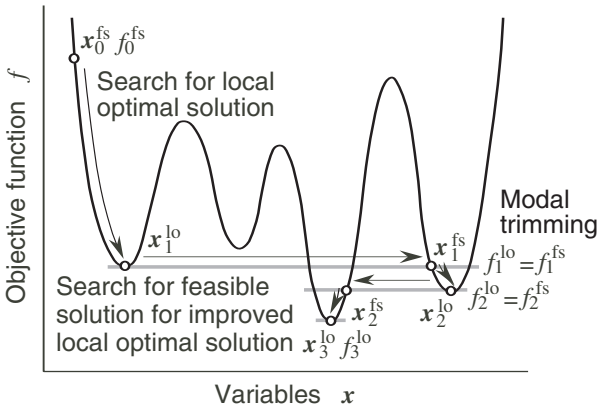

Figure 2: Concept of modal trimming method

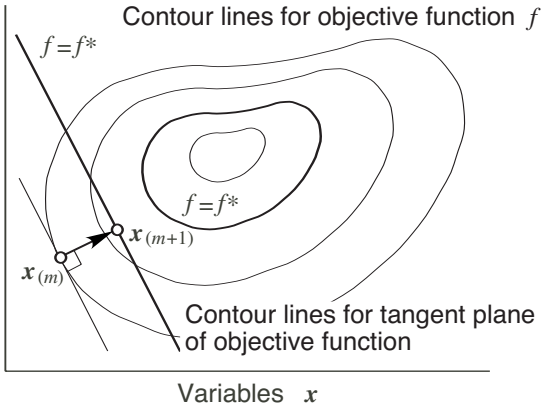

Figure 3: Renewal of values of variables

optimal one is searched to obtain an initial point for finding a better local optimal one. These procedures are repeated until a feasible solution with the value of the objective function equal to that for the tentative global quasi-optimal one cannot be found, and the tentative global quasi-optimal one is adopted as the global quasi-optimal one.

The aforementioned idea is similar to that of the tunneling algorithm, which has also been proposed to derive global quasi-optimal solutions [11]. In the tunneling algorithm, a feasible solution is searched by a conventional gradient method. However, in the modal trimming method, a feasible solution is searched by an extended Newton-Raphson method based on the Moore-Penrose generalized inverse of the Jacobi matrix of the objective function and constraints. The method can have a high possibility of deriving global optimal solutions, if it has the capability of global search for feasible ones.

Search for feasible solutions. An extended Newton-Raphson method is applied to search a feasible solution with the value of the objective function equal to that for the tentative global quasi-optimal one. Namely, the function composed of the objective function

$$F(\boldsymbol{x}) = f(\boldsymbol{x}) - f^* \tag{16}$$

is defined, and the values of the variables $\boldsymbol{x}$ are renewed to satisfy $F(\boldsymbol{x}) = 0$ by the following equation:

$$\boldsymbol{x}_{(m+1)} = \boldsymbol{x}_{(m)} - \gamma \left[\partial F(\boldsymbol{x}_{(m)}) / \partial \boldsymbol{x}\right]^+ F(\boldsymbol{x}_{(m)}) \tag{17}$$

In Eq. (16), f^* is the value of the objective function for the tentative global quasi-optimal solution. In Eq. (17), $[\ ]^+$ means the Moore-Penrose generalized inverse and is applied to the Jacobi matrix $\partial F(\boldsymbol{x}) / \partial \boldsymbol{x}$ of the function $F(\boldsymbol{x})$, and γ is the decelerating parameter whose value is between 0 and 1.

The application of the Moore-Penrose generalized inverse is because of the multiple variables $\boldsymbol{x}$ produce numerous solutions which satisfy $F(\boldsymbol{x}) = 0$. For the problem under consideration, the Moore-Penrose generalized inverse is reduced to the right inverse as follows:

$$\begin{aligned}\left[\partial F(\boldsymbol{x}_{(m)}) / \partial \boldsymbol{x}\right]^+ &= \left[\partial F(\boldsymbol{x}_{(m)}) / \partial \boldsymbol{x}\right]^{\mathrm{T}} \\ &\quad \times \left(\left[\partial F(\boldsymbol{x}_{(m)}) / \partial \boldsymbol{x}\right] \left[\partial F(\boldsymbol{x}_{(m)}) / \partial \boldsymbol{x}\right]^{\mathrm{T}} \right)^{-1} \\ &= \left[\partial f(\boldsymbol{x}_{(m)}) / \partial \boldsymbol{x}\right]^{\mathrm{T}} / \left\| \partial f(\boldsymbol{x}_{(m)}) / \partial \boldsymbol{x} \right\|_2^2 \end{aligned} \tag{18}$$

where $\| \ \|_2$ means the Euclidean norm of a vector. Therefore, Eq. (17) is reduced to

$$\begin{aligned}\boldsymbol{x}_{(m+1)} = \boldsymbol{x}_{(m)} &- \gamma \{ f(\boldsymbol{x}_{(m)}) - f^* \} \\ &\times \left[\partial f(\boldsymbol{x}_{(m)}) / \partial \boldsymbol{x}\right]^{\mathrm{T}} / \left\| \partial f(\boldsymbol{x}_{(m)}) / \partial \boldsymbol{x} \right\|_2^2 \end{aligned} \tag{19}$$

For example, in an unconstrained nonlinear programming problem with two variables, Eq. (19) means that the values of $\boldsymbol{x}_{(m+1)}$ are determined as the point where the line on the tangent of the objective function drawn from the point $\boldsymbol{x}_{(m)}$ toward the direction with the steepest descent gradient crosses the plane $f(\boldsymbol{x}) = f^*$, as shown in Fig. 3.

The renewal of the values of the variables $\boldsymbol{x}$ based on the extended Newton-Raphson method has the following features: In the region with a feasible solution, the renewal can have the convergence to it; In the region with no feasible solution, the renewal can create a chaotic behavior and has the capability of global search; In the region with no feasible solution, the renewal can also create a cyclically vibrating behavior and has the possibility of trap into a local optimal solution. To prevent

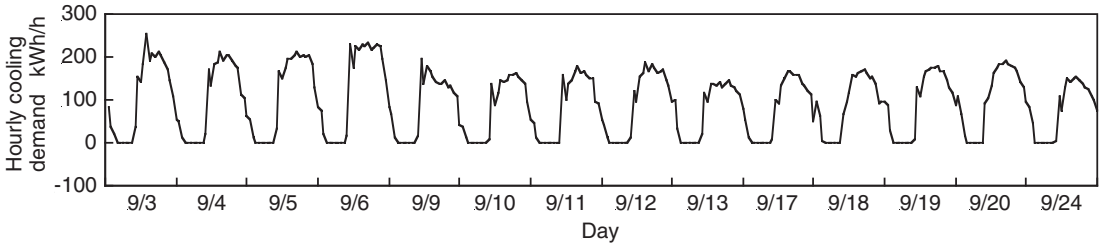

Figure 4: Measured cooling demand for identification

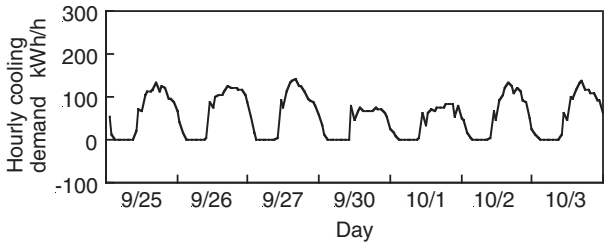

Figure 5: Measured cooling demand for prediction

the trap, the decelerating parameter γ is changed randomly in the range $0 < \gamma \leq 1$ at each renewal.

NUMERICAL STUDY

The aforementioned neural network model is applied to the prediction of the cooling demand in a building used for a bench mark test of a variety of prediction methods.

Calculation conditions

The cooling demand is for a commercial building with nine floors, a parking space on the first floor, and a total floor area of 5400 m^2.

The measured cooling demand on the 14 weekdays from Sept. 3 to Sept. 24, 1996 is used to identify the values of model parameters, or weights and thresholds. Figure 4 shows the measured cooling demand for identification. Here, a day is defined as the period from 22:00 on the previous day to 22:00 on the corresponding day. The sampling time interval is set at Δt = 1 h. Therefore, the number of sampling times for the measured cooling demand is $M = 14 \times 24 = 336$. The prediction of the cooling demand is conducted using the identified values of model parameters on the 7 weekdays from Sept. 25 to Oct. 3, 1996. Figure 5 shows the measured cooling demand for prediction.

The order of the ordinary difference is set at $d = 0$. On the other hand, the number of sampling times for the periodic differential operation and the order of the periodic difference are set at $s = 24$ and $D = 1$, respectively. The number of sampling times for prediction is set at $L = 3$. The numbers of measured or predicted values and errors are set at $p = 3$ and $q = 3$, respectively. Consequently, the number of sampling times reduced is $R = 27$.

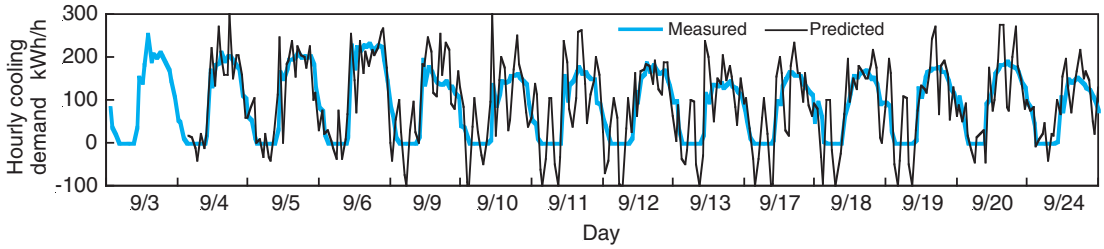
From the aforementioned conditions, the number of patterns is $N = 924$. The number of neurons of the input layer is $I = p + q = 6$. On the other hand, the number of neurons of the hidden layer is set at $J = 6$. Therefore, the number of model parameters is $(I + 1)J + (J + 1)K = 49$. The constant coefficient α in Eq. (9) is set at 200.0 in consideration of the magnitude of the periodic difference of the cooling demand.

The quasi-Newton method is adopted as a conventional gradient method, and the Broyden-Fletcher-Goldfarb-Shanno (BFGS) formula is applied to express the inverse of the Hessian matrix approximately.

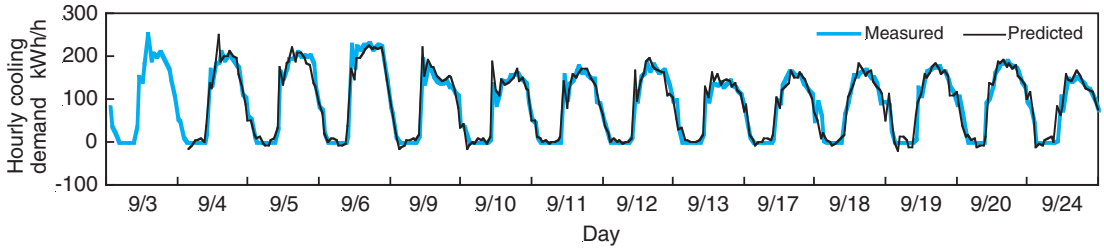
Basic study

First, the quasi-Newton method is applied to the identification of the values of model parameters. Figure 6 (a) compares the measured and predicted cooling demands. Here, the predicted cooling demand is based on the values of model parameters corresponding to a local optimal solution obtained by the quasi-Newton method. The predicted cooling demand fluctuates widely, and the errors between the measured and predicted cooling demands are too large. Therefore, this result cannot be validated.

Next, the modal trimming method is applied to the identification of the values of model parameters. Figure 6 (b) compares the measured and predicted cooling demands. Here, the predicted cooling demand is based on the values of model parameters corresponding to the global quasi-optimal solution obtained by the modal trimming method. This solution is obtained through some local optimal solutions. The measured and predicted cooling demands are in good agreement.



(a) Local optimal solution by quasi-Newton method



(b) Global quasi-optimal solution by modal trimming method

Figure 6: Comparison of measured and predicted cooling demands for identification

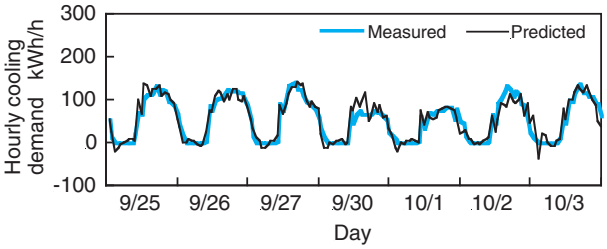


Figure 7: Comparison of measured and predicted cooling demands for prediction

Finally, the prediction is conducted using the values of model parameters corresponding to the global quasi-optimal solution obtained by the modal trimming method. Figure 7 compares the measured and predicted cooling demands. Although the cooling demand for prediction is smaller than that for identification, the measured and predicted cooling demands are also in good agreement.

These results show that the identification of the values of model parameters for the neural network model needs a global optimization method, and that the modal trimming method can find appropriate values as the global quasi-optimal solution.

Extended study

An extended study is conducted in consideration not only of the cooling demand but also of the air temperature as the inputs to the neural network model. In this study, a neuron is added to the input layer, and the air temperature is assigned to this neuron. Two types of air temperature are considered: One is the maximum air temperature of each day; The other is the hourly air temperature. As an initial study, the measured values are used in place of the predicted ones for all the air temperatures. Since the air temperature also changes periodically with a period of 24 hours, the 1st order periodic differential operation is conducted on the air temperature. In this case, the number of neurons of the input layer is $I = p + q + 1 = 7$, and the number of model parameters is $(I+1)J + (J+1)K = 55$.

Table 1: Average errors between measured and predicted cooling demands

(Unit: kWh/h)

Case	Identification	Prediction	Identification and prediction
A	18.09	17.60	17.90
B	17.59	16.91	17.35
C	16.51	16.27	16.43

Table 1 compares the average errors between the measured and predicted cooling demands in the following three cases:

Case A: without consideration of air temperature
Case B: in consideration of maximum air temperature
Case C: in consideration of hourly air temperature

It appears that the consideration of the air temperature, especially the hourly air temperature, can

improve the accuracy of the prediction. This is because the cooling demand is affected significantly by the air temperature.

CONCLUSIONS

A multi-layered neural network model has been adopted to predict energy demands. To identify the values of model parameters in the back propagation procedure, the modal trimming method has been applied as a global optimization one. The multi-layered neural network model has been applied to the prediction of the cooling demand in a building used for a bench mark test of a variety of prediction methods.

It has turned out that the identification of the values of model parameters needs a global optimization method, and that the modal trimming method can find appropriate values as the global quasi-optimal solution. It has also turned out that the consideration of the air temperature, especially the hourly air temperature, can improve the accuracy of the prediction.

THE SECOND LAW OPTIMAL OPERATION OF A NEWSPRINT PAPER DRYING MACHINE

Anita Zvolinschi*, Eivind Johannessen and Signe Kjelstrup
Norwegian University of Science and Technology
Department of Chemistry
N-7491 Trondheim, Norway

Abstract

Paper drying is an exergy costly operation, so also a few percent saving may be of importance. The entropy production for the paper drying process was derived for the newsprint paper drying machine at Norske Skog ASA in Skogn, Norway. The machine has 51 cylinders grouped in three drying groups. The cylinders are heated from the inside by steam, unheated or operated under vacuum conditions. The inlet drying air is supplied with same parameters in all air-pockets of the machine. The entropy production of the total process was calculated for actual operating conditions (i.e. reference conditions) and then optimised subject to a defined outlet paper moisture content (i.e. 0.07 kg H_2O/ kg dry paper). Inlet air humidity and cylinder group conditions were varied. Optimum conditions were obtained for a range of inlet air humidities, and for different cylinder groupings. We found that it was very favorable to increase the inlet air humidity. The realisation of such a change is probably hampered by unwanted condensation. Other changes had a negligible effect on the entropy production. The results pointed to the need for a revision of the current model of heat and mass transfer, as the second law was violated at high air humidities with this model.

INTRODUCTION

All industrial paper drying techniques require high temperatures, high heat fluxes and large partial pressure differences. They are thus sources of considerable exergy loss. Significant losses occur not only in the drying machine itself, but also in the connected steam generation and heat recovery system. Therefore, when one discusses paper drying techniques it is not sufficient to evaluate the specific heat requirement, like literature proposes [1]. Also the exergy loss has to be considered. The exergy loss is defined as the entropy production in the process times the temperature of the surroundings.

The purpose of this paper is to formulate, calculate and optimise the entropy production of a multi-cylinder Valmet newsprint paper drying machine, which uses saturated steam as heating agent inside the cylinders. This machine dries paper as it travels over three drying groups of heated and un-heated cylinders, cf. Table 1. Additional cylinders are operated under vacuum. Although new paper drying techniques such as impingement and impulse drying have been introduced [2], the conventional steam-heated cylinder drying technique is still widely used in the paper industry, and can serve as a reference for the others.

The entropy production for the system shall be formulated. Then, a constrained optimization method shall be applied. The same method was used to minimize the entropy production in a chemical reactor [3]. In this study, the temperatures of the saturated steam supplied to each drying group shall be used as optimization variables, and the dryness of the paper sheet at the end of the machine as the constraint. A varying inlet air humidity and a re-grouping the drying groups shall also be studied. The outcome of the calculation is thus knowledge about the second-law optimal operation of the drying machine, and a recommendation for a more energy efficient process.

THE PAPER DRYING MACHINE

The machine that we study, the Valmet Paper Machine PM2 at Norske Skog, Skogn, Norway, manufactures newsprint (540 tonn paper/ day). It consists of 51 cylinders that are assembled in three drying groups, see Table 1.

There are two types of felt configuration in the machine; the single-felt configuration in the first group and the double-felt one in the last groups, see Fig. 1.

Table 1: Drying groups. Cylinders that are not mentioned, are operated under vacuum.

Drying Group	Un-heated cyl.	Heated cyl.
1st (1-8)	1	3,5,7
2nd (9-23)	16,18,20,22	9,11,13,15,17 19,21,23
3rd (24-51)	31,51	24-30,32-50

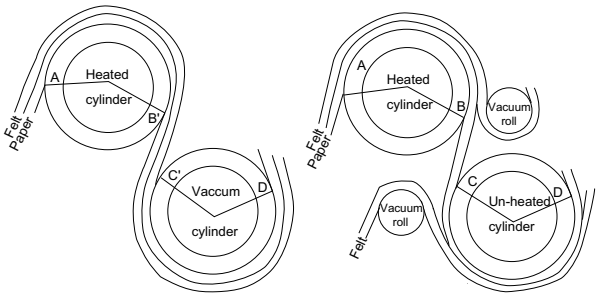

Figure 1: Drying modes with single- (*left*) and double-felt (*right*) configurations.

Table 2: Drying mode specifications. See also Fig. 1

Mode	Specification	n
A	Paper in contact with a heated cylinder surface on one side and felt on the other (A-B, B')	1
B	Paper in contact with air on both sides (B-C)	2
C	Paper in contact with an un-heated cylinder surface on one side and felt on the other (C-D)	1
D	Paper in contact with air on one side and felt on the other (B'-C')	2
E	Paper in contact with air and felt on a cylinder under vaccum (C'-D)	1

The machine has five types of drying modes; identified by the letters given in Table 2, (see also Fig. 1). The whole machine is a combination of 102 drying modes. Figure 1 (*left*) and (*right*) gives as examples the following combinations: **ADE** and **ABC**, respectively. This change of drying modes throughout the machine lead to a discontinuous variation in the paper temperature. Near heated cylinders, the

paper temperature is high, away from them it is low. Inlet and outlet conditions of the paper, air and steam, as well as other parameters of the machine, are given in Table 3.

CONSERVATION EQUATIONS

The paper travels from the wet to the dry-end of the paper drying machine; we defined this direction as the z-direction. We consider transport of mass and heat at a given moment in the direction normal to the paper sheet. Gradients within the paper are neglected. Conservation of mass gives:

$$\frac{dw}{dz} = -\frac{n}{V\,B}\,J \tag{1}$$

while conservation of internal energy gives

$$\frac{dT_p}{dz} = \frac{n}{V\,B\,Cp,p}\left(J_{q,cyl} + J_{q,air} - J\frac{\partial(w\Delta H)}{\partial w}\right) \tag{2}$$

Here J is the flux of water evaporating from the paper sheet, $J_{q,cyl}$ and $J_{q,air}$ are heat fluxes from cylinder to the paper sheet, and from the air to the paper sheet, respectively, and n equals 1 or 2 depending on the type of drying mode (see Table 2).

LOCAL ENTROPY PRODUCTION

The local entropy production, σ, was found from the entropy balance over a small element dz of the total length of paper sheet. The entropy balance gives

$$\sigma = nb\left(VB\frac{\partial s_p}{\partial z} - \frac{J_{q,cyl}}{T_{cyl}} - \frac{J_{q,air}}{T_{air}} + Js^{\text{in air}}_{H_2O}(T_{air})\right) \tag{3}$$

where s_p is the entropy of the paper, given by

$$s_p = s_{\text{dry-p}}(T_p) + ws^{\text{in paper}}_{H_2O}(T_p, w) \tag{4}$$

Derivation of Eq. (4) with respect to dz gives

$$\frac{\partial s_p}{\partial z} = \frac{C_{p,p}}{T_p}\frac{\partial T_p}{\partial z} - \frac{J}{VB}s^{\text{in air}}_{H_2O}(T_{air}) + \frac{J}{VB}\frac{\partial(w\Delta S)}{\partial w} \tag{5}$$

Introducing Eq. (5) into Eq. (3) gives

$$\sigma = nb\left[J_{q,cyl}\left(\frac{1}{T_p} - \frac{1}{T_{cyl}}\right) + J_{q,air}\left(\frac{1}{T_p} - \frac{1}{T_{air}}\right) + J\left(-\frac{1}{T_p}\frac{\partial(w\Delta H)}{\partial w} + \frac{\partial(w\Delta S)}{\partial w}\right)\right] \tag{6}$$

where ΔH and ΔS are the enthalpy and entropy change, respectively, for water between states in the paper sheet and the surrounding air (see the Appendix: *Thermodynamic relations*).

The first two terms on the right-hand side of Eq. (6) give the contributions from heat transport, while the last term gives the contribution from mass transport. Integration of Eq. (6) over the paper travelling through the whole machine, was the objective function:

$$\left(\frac{dS}{dt}\right)_{\text{irr}} = \int_0^L \sigma\,dz \tag{7}$$

As constraint in the optimisation, a defined outlet paper moisture content (w_{out}) was used, see Table 3.

Fluxes and forces

The heat and mass transport forces are defined by Eq. (6), where $\left(\frac{1}{T_p} - \frac{1}{T_{cyl}}\right)$ and $\left(\frac{1}{T_p} - \frac{1}{T_{air}}\right)$ are the forces for the heat transport, and $\left(-\frac{1}{T_p}\frac{\partial(w\Delta H)}{\partial w} + \frac{\partial(w\Delta S)}{\partial w}\right)$ is the force for the mass transport.

The literature [4, 5] gives the evaporation flux from the paper to the air as

$$J = \frac{1}{C_{p,dry-air} + X^*\,C_{p,H_2O}}h_{p-air}(X^* - X_{in,air}) \tag{8}$$

where h_{p-air} is the heat transfer coefficient between paper sheet and air, $C_{p,dry-air}$ and C_{p,H_2O} are the heat capacities of dry air and of vapour water, respectively, X^* is the saturation humidity above the paper, and $X_{in,air}$ is the inlet air humidity.
The heat flux from the cylinder to the paper is

$$J_{q,cyl} = h_{cyl-p}(T_{cyl} - T_p) \tag{9}$$

while that from the air to the paper is

$$J_{q,air} = h_{p-air}(T_{air} - T_p) \tag{10}$$

The heat transfer coefficients in Eqs. (9) and (10) were taken from literature [6] (see the Appendix: *Heat transfer coefficients*).
The evaporation flux equation, Eq. (8), shall be used here, despite the fact that the driving force in Eq. 8) it is not according to that defined by Eq. (6). We shall see that this mismatch leads to a violation of the second law for some conditions, which means that the Eq. (8) proposed in literature cannot correctly predict the evaporation flux for the entire range of operating conditions of the machine.

CALCULATIONS

We calculated first the reference system, i.e. the actual paper drying machine, which is the starting point of the analysis. The distribution of the paper moisture and temperature was found by numerical integration of Eq. (1) and (2), respectively, over the total length of the paper within the machine. The drying groups are given in Table 1, and the operating conditions in Table 3. Physical properties, heat capacities, and thermal conductivities of air and water vapour were taken from [7].
The optimization was performed numerically using the *Matlab® 6.1.0 (R12.1) Optimization Toolbox* function *fmincon*. This function uses a sequential quadratic programming method to find a minimum of the objective function [8]. The temperatures of the saturated steam supplied to the drying groups were the optimization variables, and the paper moisture content at the outlet of the machine was the constraint (w_{out}= 0.07 kg H_2O/ kg dry paper). The following lower and upper bounds were applied to the saturated steam temperature: 338 and 393 K in the 1st drying group, and 358 and 403 K in the 2nd drying group.
We studied the effect of different inlet air humidities and the effect of re-grouping of the drying groups on the optimal solution.

RESULTS AND DISCUSSION

The reference system

Figure 2 presents the variation in the paper temperature and moisture content in the reference system.
The temperature profile shows clearly the increase and decrease in temperature as the drying mode is changing; it has a *zig-zag* pattern. All temperature rises correspond to drying mode **A**. This is common for all drying groups. In the 1st drying group, the cooling effect is caused first by drying mode **D** then by **E**. The cooling of the paper sheet is about 7 °C in the 1st drying group, but it is 16 °C in the 2nd drying group. In the 3rd drying group, the presence of an un-heated cylinder is the reason for the big shift in the temperature profile at cylinder 36, at z = 139 m. The gradually increase in the heat required for the evaporation of sorbed water in the 3rd drying group, causes an overall decrease in paper temperature of about 13 °C until the paper sheet reaches cylinder 31. After this location, the paper sheet temperature increases with few degrees, and then it decreases to about 50 °C when the paper sheet reaches the end of the drying machine.

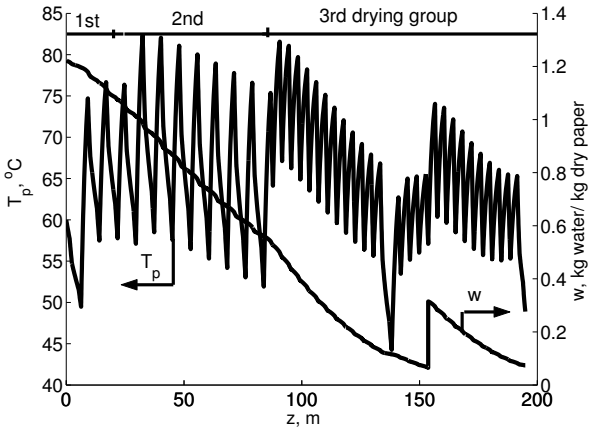

Figure 2: The temperature and moisture profile along the paper sheet in the reference system. The top line shows the three drying groups.

The paper moisture profile in Fig. 2 gives an approximately constant rate of paper drying in the 1st and 2nd drying groups. The falling drying rate regime

starts at the begining of the 3rd drying group. The presence of a moisture control device (i.e. steam box that shower the paper sheet) after cylinder 40, at z= 155 m, explains the jump in the paper moisture profile at this location in Fig. 2. This device controls the smoothness and moisture distribution of the paper surface in the width direction of the machine.

Entropy production in the reference system

The local entropy production along the machine is shown in Fig. 3. Its detailed contributions from the drying modes are given in Fig. 4, while the result of the integration is given in Table 4.
We see from Fig. 3 that σ reaches the largest values at the begining of each drying group. Similar to the paper temperature profile, σ has a *zig-zag* pattern. In the 3rd drying group, when the falling drying rate regime develops, the value of σ is falling steadily towards the end of the machine.

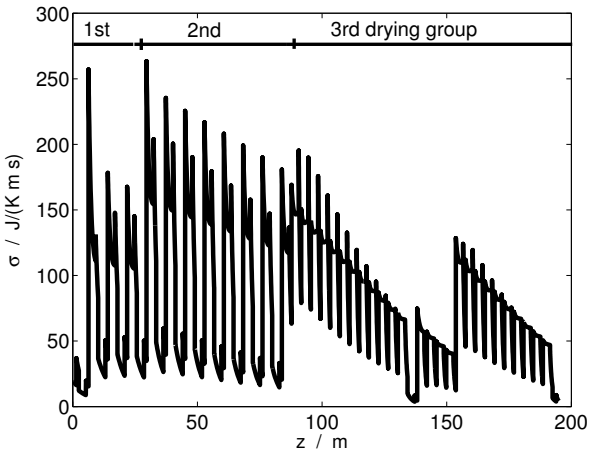

Figure 3: Local entropy production in the reference system. The top line shows the three drying groups.

Heat and mass transport contributions account almost equally to the entropy production in the paper drying process (see Table 4, first column).
The contributions from the drying modes to σ are also interesting, see Fig. 4. The highest driving force for heat and mass transport is found at the heated cylinders (mode **A**). We therefore find the highest values of the entropy production here. Un-heated cylinders (mode **C**) and cylinders operated under vacuum (mode **E**) have a smaller entropy production. When the paper travels between two cylinders (mode **B** and **D**), the contributions are among the lowest ones

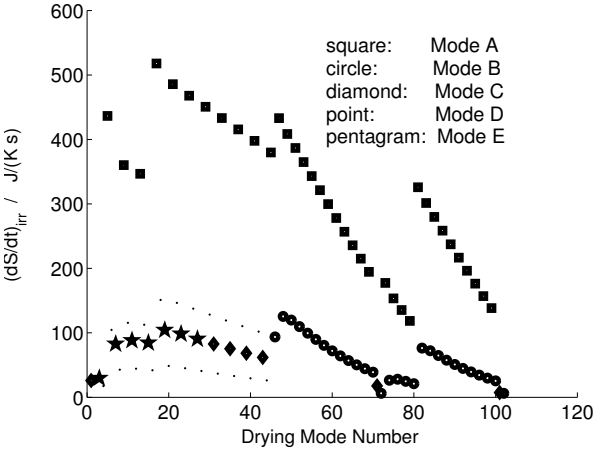

Figure 4: Entropy production per drying mode in the reference system.

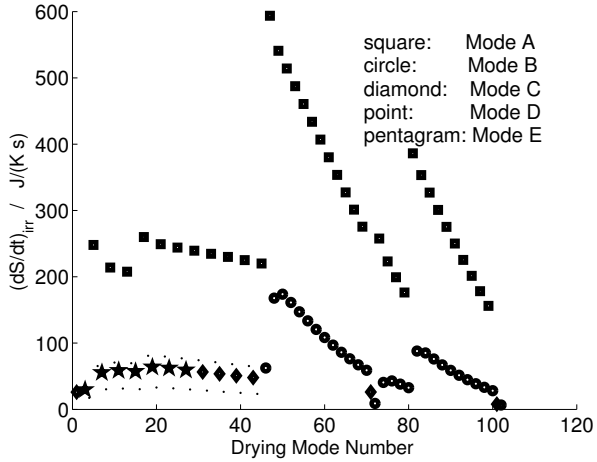

Figure 5: Entropy production per drying mode in the optimal system.

(point and filled circle symbols, respectively). There is still an evaporation taking place over the cylinders under vaccum (star symbols) and un-heated cylinders (diamond symbols), giving a positive contribution also at these locations.

The impact of cylinder temperatures

The results for the total entropy production and the optimal drying group temperatures are shown in Table 4 for three inlet air humidities. Figure 5 gives the entropy production per drying mode in the optimal system, for an inlet air humidity of 0.026 kg H_2O/ kg dry air. The corresponding results are summarized in the second column of Table 4.

Table 4: Total entropy production, $(dS/dt)_{irr}$, contributions from the heat and mass transport, and the saturated steam temperatures in the reference (*ref*) and optimal (*opt*) system for different inlet air humidities, $X_{in,air}$.

$X_{in,air}$, kg/kg	0.026	0.026	0.065	0.13
System	*ref*	*opt*	*opt*	*opt*
$\left(\frac{dS}{dt}\right)_{\text{irr}}$,$10^3$ J/ Ks	15.5	15.0	12.5	10.0
Contributions:				
Heat transport	7.9	7.5	7.7	6.8
Mass transport	7.6	7.5	4.7	3.2
Reduction, %	-	3	19	35
$T_{cyl,1}$, °C	98	84	88	94
$T_{cyl,2}$, °C	111	89	94	99
$T_{cyl,3}$, °C	121	126	131	133

The first optimization was done with an inlet air humidity of 0.026 kg H_2O/ kg dry air, to investigate the effect of the saturated steam temperature on the total entropy production. The reduction in entropy production from the reference state to the state of minimum entropy production was 3%. This improvement is achieved if the saturated steam temperature is reduced with 14 °C and with 22 °C in the 1st and 2nd drying group, respectively, while it is increased with 5 °C in the 3 rd drying group.

Figure 5 shows that the optimal solution occurs when entropy production of the modes **A** in the 1st and 2nd drying groups is halved compared with that in the reference solution. This happens as a response to the changes in the saturated steam temperature.

The impact of air conditions

Furthermore, the impact of changing the inlet air conditions was studied. Figure 6 shows the minimum entropy production as a function of inlet air humidity. The final paper moisture content was the same in all cases (w_{out}= 0.07 kg H_2O/ kg dry paper). The reference system is shown as the point (square symbol) in the Fig. 6. This point lies very near the curve for optimal solutions, according to the results described in the previous section.

Table 4 gives details of the optimal solution for the three selected inlet air humidities. The curve (Fig. 6) gives a clear message: It is possible to reduce the total entropy production up to 35 % by increasing the inlet air humidity, and changing the cylinder temperatures accordingly to the values given in the last column of Table 4. As the inlet air humidity sets out higher and higher, the cylinder temperatures in the 1st and 2nd drying groups get closer and closer to the corresponding values in the reference system. This results can be understood from the fact that the heat transport has almost the same contribution to the entropy production in all cases, while the mass transport contribution decreases when higher inlet air humidity is used.

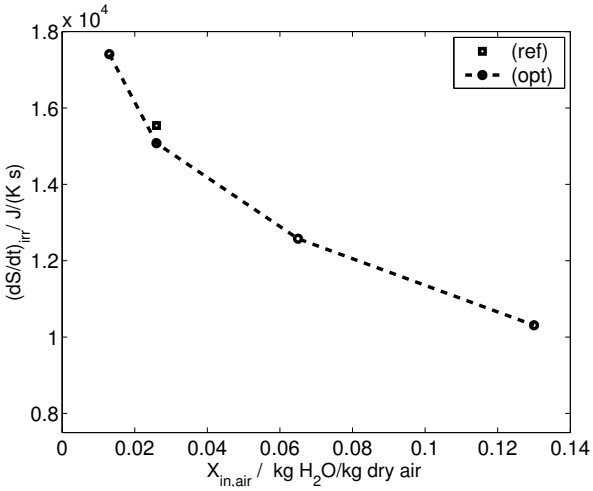

Figure 6: Total entropy production rate of the optimal (*opt*) systems vs different inlet air humidities, including the reference (*ref*) system.

The highest inlet air humidity shown in the Table 4 $X_{in,air}$= 0.13 kg H_2O/ kg dry air, is near to the saturation limit for the air in the machine's air-pockets. This means that it may be difficult to realise in practice. An high inlet air humidity means an increased likelihood for condensation, and condensation must be avoided everywhere in the machine's hood. A high humidity is, however, an advantage for the heat recovery process, which is located upstream of the paper drying process.

The curve in Fig. 6 was not drawn beyond the point given by $X_{in,air}$= 0.13 kg H_2O/ kg dry air. For higher values of inlet air humidity, the entropy production given by the mass transport contribution became negative in some points of the machine. This is of course an unphysical situation. It arose because the driving force for mass transport was not the thermodynamic one, compare Eq. (6) and Eq. (8). Another reason is that the coupling between mass and heat transport was not proper described as it is required

in the irreversible thermodynamics [13]. Therefore, whitout having a coupling effect taken into account, we can not admit entropy production to be negative. We conclude that there is a potential for an improved model at this point. This is a topic for the future, however.

The impact of drying groups conditions

A possible effect of opening the un-heatead cylinders and of re-grouping the drying groups was investigated, without any significant effect of the total entropy production. When the 2^{nd} drying group was extended from 15 to 17 cylinders, or it was contracted from 15 to 13 cylinders, the total entropy production was reduced by only 0.1% compared to the reference. A small gain was also obtained when less cylinders were used in the 1^{st} drying group, and when un-heated cylinders 1, 36 and 51 were set on.

CONCLUSION

We have analyzed a Valmet newsprint drying machine, and found that its total entropy production can be reduced with 3% when the conditions for the minimum entropy production are followed. These new operation conditions concern the temperature of the steam used in the drying groups. We found that low temperatures should be used in the first two drying groups, while high temperature should be used in the last group.

The total entropy production rate can be drastically reduced by increasing the inlet air humidity. How far it is possible to go in this direction remains to be studied. The physical model for the system should first be improved, to give possitive entropy production everywhere in the paper drying machine.

ACKNOWLEDGEMENTS

The Research Council of Norway funded this research. Norske Skog ASA, Skogn, made data available. We wish to thank Mr. Sadeghi for valuable suggestions.

APPENDIX
Thermodynamic relations

The enthalpy change for water between states in the paper sheet and the surrounding air is

$$\Delta H = \Delta_{sor}H + \Delta_{vap}H + \int_{T_p}^{T_{air}} C_{p,H_2O}^{\text{in air}}\, dT \qquad (11)$$

where $\Delta_{sorp}H$ is the sorption enthalpy of water from the paper, and $\Delta_{vap}H$ is the vaporisation enthalpy of free water.
The entropy change for water between states in the paper sheet and the surrounding air is

$$\Delta S = -\frac{\Delta_{sor}H}{T_p} - \frac{R}{M_{H_2O}} ln\left(\Theta(w,T_p)\right) + \frac{\Delta_{vap}H}{T_p} - \frac{R}{M_{H_2O}} ln\left(\frac{p_{H_2O}^{\text{in air}}}{p^*}\right) + \int_{T_p}^{T_{air}} \frac{C_{p,H_2O}^{\text{in air}}}{T}\, dT \qquad (12)$$

The sorption enthalpy is derived from the desorption isotherm for liquid water to paper, $\Theta(w,T_p)$;

$$\Delta_{sor}H = -R\frac{\partial ln\Theta(w,T_p)}{\partial(1/T_p)} \qquad (13)$$

The desorption isotherm was measured by [9] as a function of temperature and water content

$$\Theta(w,T_p) = \frac{p_{\text{p}}^*}{p^*} = \exp(\beta_1 T_p - \beta_2) \qquad (14)$$

The coefficients β_1 and β_2 in Eq. (14) were determined by [10]

$$\beta_1 = \exp(-15.03w - 1.37\sqrt{w} - 3.14) \qquad (15)$$

$$\beta_2 = \exp(-13.53w - 2.90\sqrt{w} + 2.9) \qquad (16)$$

Using Clausius-Clapeyron's relation, we find $\Delta_{vap}H$ from the equilibrium vapour pressure (p^*), as

$$\Delta_{vap}H = -R\frac{\partial ln(p^*/p^{\ominus})}{\partial(1/T_p)} \qquad (17)$$

where $p^{\ominus}$ is the standard pressure. An empirical relation for the equilibrium vapour pressure was given by [7]:

$$p^*(T_p) = 0.133\times 10^3 \exp(18.303 - \frac{3816.44}{T_p - 46.13}) \qquad (18)$$

The heat capacity of paper, $C_{p,p}$, is estimated from

$$C_{p,p} = C_{p,dry-p} + wC_{p,H_2O} \qquad (19)$$

where $C_{p,dry-p}$ = 1256 J/ K kg for newsprint [11].

Heat transfer coefficients

The heat transfer coefficient between cylinder and paper at the contact side with cylinder was calculated by [12]

$$h_{cyl-p} = 1556.6w + 52.87 \qquad (20)$$

The heat transfer coefficient between paper and air at non-contact side with cylinder was calculated by [6]

$$h_{p-air} = \frac{\kappa}{D_{cyl}}\left\{ 0.3 + \frac{0.62Re_D^{1/2}Pr^{1/3}}{\left[1+\left(\frac{0.4}{Pr}\right)^{2/3}\right]^{1/4}} \left[1+\left(\frac{Re_D}{282000}\right)^{5/8}\right]^{4/5} \right\} \qquad (21)$$

The heat transfer coefficient between paper and air when the paper sheet travels between two cylinders was calculated by [6]

$$h_{p-air} = \frac{\kappa}{l}\left(0.664Re_l^{1/2}Pr^{1/3}\right) \qquad (22)$$

when $Re_l < 5\times 10^{\,5}$.

$$h_{p-air} = \frac{\kappa}{l}Pr^{1/3}\left(0.037Re_l^{4/5} - 871\right) \qquad (23)$$

when $Re_l > 5\times 10^5$.
The Reynolds (Eqs. (24) and (25)) and Prandtl (Eq. (26)) numbers were determined by

$$Re_D = \frac{V\, D_{cyl}}{\nu} \qquad (24)$$

$$Re_l = \frac{V\, l}{\nu} \qquad (25)$$

$$Pr = \frac{C_p\, \mu}{\kappa} \qquad (26)$$

All physical properties of the gas phase (C_p, κ, μ and ν) are calculated at the film temperature (average of T_{air} and T_p).

ABSTRACT

Rational energy use in industry decreases costs, environmental pollution and depletion of resources. Since energy costs are often in the magnitude of the profit, a reduced energy use considerably affects the company-results. Yet, a systematic and profound analysis and optimization of the energetic processes is seldom conducted. In order to reduce the effort and increase the quality of energy system analysis, a computer aided method is being developed in a research project called TOP-Energy (Toolkit for Optimization of Industrial Energy Systems). The main goal of TOP-Energy is to support energy consultants in analyzing and optimizing industrial energy supply systems by supplying modules for documentation, simulation and evaluation of energy systems in respect to energetic, economic and environmental aspects. TOP-Energy consists of two major parts, a unifying framework and a set of modules: The former supplies the services of a modern GUI-application like module-sensitive dialogs and presentations, flow sheet editing and report generation. The latter are technical modules addressing particular aspects of energy system analysis like economical analysis or system simulation. An outstanding module of TOP-Energy is the supply system simulator called eSim, tailored to the consultant's needs. It evaluates energy supply concepts by means of historical or estimated demand data. In contrast to other simulator packages eSim supersedes costly modelling of control systems at an early stage of concept development by automatic optimization of component use. In order to model temperature sensitive components like chillers or heat pumps the conventional MILP-method was modified by employing evolutionary algorithms.
The article briefly presents the basic concepts of TOP-Energy including the framework's capabilities and then puts the focus on the simulator module, discussing its foundations and the solver numeric.

INTRODUCTION

Today, energy savings and efficient use of energy are important means of sustainable development. Particularly in industry, an appreciable amount of primary energy can be saved by enhancing the existing energy supply and transformation systems. Apart from the possibility of avoiding energy losses due to deteriorated equipment and insufficient system con-

trol, a considerable amount of primary energy can be saved by designing optimized energy systems on the basis of techniques such as cogeneration, heat pumps and heat integration. For cogeneration, for example, this has been surveyed in [1]. Unfortunately, methods and supporting tools to find such potentials, for example exergy analysis and system simulation, are well known in science but rarely used in practice.

Since the costs of energy are frequently of the same magnitude as the company's profits, reducing energy costs can lead to an appreciable effect on the profitability of the company. On the other hand, any investment in the energy system of a company competes against investments in new products or production equipment. It has to be profitable over a short payback period, even though it is a long term investment. Furthermore, the high costs of expert advice with the risk of uncertain results are usually avoided. This leads to a situation in which significant potentials for saving primary energy and money are not employed.

For these reasons, it is desirable to take steps to reduce the efforts and costs of an analysis and subsequent improvement of industrial energy systems. The use of computer aided methods seems favorable for this task, as an integrated tool can speed up work and offer effective methods for system analysis and optimization. In addition, aspects usually neglected in decision processes, like environmental protection can easily be incorporated by an automated evaluation of appropriate coefficients.

These considerations lead to the development of a new modular designed software called TOP-Energy (Toolkit for Optimization of Industrial Energy Systems), which is developed by a cooperation of several partners from universities and industry.

OBJECTIVES

The main objective of TOP-Energy is to provide an application that supports the process of energy system optimization for small- and middle-sized industrial sites. This work is usually done by smaller energy engineering companies that can not afford expensive custom developments. Contrary to numerous computational tools focusing on a specific technical problem, TOP-Energy integrates all steps of the typical work flow in one application, supplying a seamless flow of information from the first step of a project to the last. Apart from the support of computational methods like system simulation, special attention was paid to combining pure scientific methods with services such as comfortable user I/O and report generation. It is expected that this approach enhances working results by allocating appropriate computational methods, as well as reducing routine work by the automation of standard calculations and integrated project management.

BASIC CONCEPTS OF TOP-ENERGY

The approach taken for the design of TOP-Energy is outlined by the a number of basic concepts incorporated into the application. The main objective of these concepts is to supply an abstract description of the processes and elements involved in order to transform the multiplicity of engineering requirements to a consistent and coherent application. The most important of them are briefly described below.

Business Process Model

A business process model was defined in order to describe a standard work-flow for industrial energy system analysis and enhancement. It was derived from the German guideline, VDI 3922 (energy advisory for industry and trade) [2]. It describes a typical process for problem solution and is divided into three phases: problem analysis, solution development and decision. In accordance with this guideline a set of modules is defined each covering a major step in the work flow: A preliminary analysis module serves to give an overview of the energetic and energy-economic situation of the examined site.

This is followed by a detailed analysis where the goal is to document the energy supply system and identify its weak points in order to develop measures which enhance rational energy use.

In the solution development phase, a concept for an optimized system is found. For this purpose, TOP-Energy offers a system simulator designed for fast composition and simulation of energy supply system models. The result of the simulation contains various energetic, economic and ecological coefficients helping to evaluate the effects of the improvement measures planned.

Finally, to assist decision making, the developed variants are evaluated comparatively using one as a reference. For economical aspects, this is performed

by an economy module capable of computing a variety of key figures directly from the simulation results.

System Boundary Model

While VDI 3922 describes the engineer's workflow very well, it lacks a precise definition for system boundaries, especially the distinction between the energy supply system and energy utilizing systems. As this is vital for the interpretation of balance results and system coefficients, an appropriate definition is introduced in TOP-Energy. Basically, it distinguishes between four subsystems: First, the public energy market which represents the economic boundary conditions, supplying various forms of end energy to the examined site. Second, an environment based on the definition of a thermodynamical environment capable of exchanging energy and matter with the remaining two subsystems covering the examined site itself: The energy supply system and the systems of energy end users (usually the production site). The former converts the available forms of end energy into forms required by the end users. The latter employs the delivered energy in all kinds of technical processes, possibly rejecting waste heat or production residues to the energy supply system.

Framework Approach

Analyzing the basic use cases of the application, it became apparent that every technical module requires certain functionalities that are non-specific to the technical problem it addresses: Basically, these are the persistent data storage and data exchange, user interface functionality like I/O-dialogs and flow sheeting, managing projects and report generation. In case these services are outsourced to a generic framework which exposes appropriate interfaces, the development of a module is reduced to the implementation of its technical contents. On the one hand, the availability of such a framework simplifies the transfer of a scientific program code to an engineering application tremendously. On the other hand, cooperation on the level of technical contents between framework, modules and component models, makes high demands on interface specifications and the underlying object model.

Application Object Model

As the framework supplies services for persistent data storage and data manipulation on the user interface to the modules and model components, sophisticated interface specifications are needed. The foundation for these definitions is an object model describing the structure and semantics of data to be exchanged. Its central element – the component – is used to map real-world units, as well as to represent the usage of a module within the project tree.
A component can aggregate a set of different elements in order to store information about technical data, GUI appearance, network structures and report generation. First of all, components can contain other components and thus are able to build tree structures or collections. However, depending on the component sub-class, the aggregation of components is restricted. In order to map network structures like they occur in schematic representation of energy systems, components can contain connection points (*pins*) that can be connected to internal or external networks.
Components are not restricted to mapping real world objects to the data space, they may represent any configurable element of the application as long as it forms a complete and autonomous unit.

Content Database

Closely related to the object model, a content database was developed in order to support the development of technical data structures: Using well defined technical terms when requesting user input or presenting results is vital to the usefulness of the application. Furthermore, developing a set of cooperating modules and component models requires a method to guarantee identical semantic interpretation of data by all communicating elements.
This is achieved by setting up a global dictionary of technical terms. In order to set up component data structures based on this dictionary, every definition of a technical term is attached to a pre-defined basic data type (such as *number* or *characteristic diagram*) including appropriate template data like units and value boundaries. These atomic data units – called *primitives* – can then be assembled to tree like data structures and be imported to a component template and thereby defining its data space. The unique definition of technical terms allows the save

exchange of data between different modules even without exact knowledge of their data structures.

THE TOP-ENERGY FRAMEWORK

Based on the concepts described above, an application framework was implemented, using the Computer Aided Schematics Toolbox (CASTool) developed by the R&D Department for Graph-based Engineering Systems of the Society for the Promotion of Applied Informatics (GFaI), Berlin.
