We used the parameter values in Table 2 in all calculations. The feed temperature and the feed composition in the table correspond to a liquid feed ($q = 1$). The number of the feed tray, N_F, the number of trays, N, and the total heat transfer area, A_{total}, varied. The numbers of the feed trays in the adiabatic, optimal and EoEP columns were chosen such that the entropy productions of the columns were minimised. We studied the effects of varying the number of trays between 14 and 40 and the total heat transfer area between 2 and 20 m^2.

Table 3: Thermodynamic properties

Component	1	2
T_{boil}/K	351.45	373.15
$C_p^V/(J/K\,mol)$	65.6	33.60
$C_p^L/(J/K\,mol)$	112.3	75.35
$\Delta_f H^{\ominus,L}/(kJ/mol)$	-277.6	-285.830
$\Delta_f H^{\ominus,V}/(kJ/mol)$	-234.8	-241.826
$S^{\ominus,L}/(J/K\,mol)$	161.0	69.95
$S^{\ominus,V}/(J/K\,mol)$[a]	283.3	188.836

[a] These entropies were adjusted so that $\Delta_{vap}G = 0$ at T_{boil} for each component.

We assumed that the liquid is an ideal mixture, and that the vapour is an ideal gas. We used pure component thermodynamic data for ethanol (component 1) and water (component 2), given in Table 3 [20]. The enthalpies and entropies in Table 3 are the values at 1 atm and 298 K. Enthalpies and entropies at other temperatures were found by integration of C_p and C_p/T, respectively, from 298 K to the temperature in question.

RESULTS AND DISCUSSION

We compare the EoEP column to the other columns. The focus shall be on how good the EoEP column approximates the optimal column. The adiabatic column is added as a reference. First, we discuss the total entropy production. Then, we discuss the characteristics of the columns.

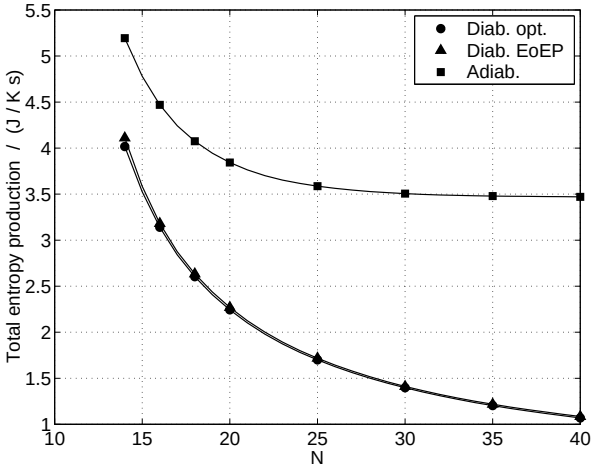

Figure 2: The total entropy production vs. the number of trays when the total heat transfer area is $20\,m^2$.

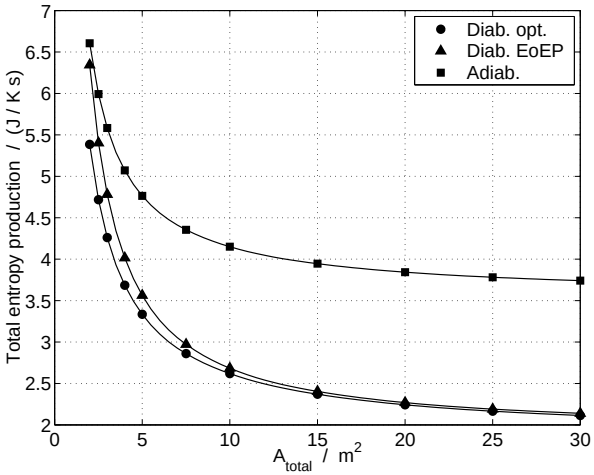

Figure 3: The total entropy production vs. the total heat transfer area when there is 20 trays.

The effects of varying the number of trays and the total heat transfer area on the total entropy production of the adiabatic, optimal and EoEP columns are shown in Figs. 2 and 3, respectively. The figures show, as expected, that the total entropy production increases when the number of trays and/or the total heat transfer area decrease. The adiabatic column has the highest entropy production, and the optimal column has the lowest entropy production. The EoEP column has approximately the same en-

tropy production as the optimal column, except for low heat transfer areas. For low heat transfer areas, the entropy production of the EoEP column is significantly higher than the entropy production of the optimal column. The agreement between the optimal and the EoEP column gets better and better as both the number of trays and/or the total heat transfer area increase.

The characteristics of the adiabatic, the optimal and the EoEP columns are presented in Figs. 4 - 9. In all the figures, tray 0 is the condenser, and tray 21 is the reboiler.

Figures 4 - 6 present the characteristics of column A. This is a column with 20 trays and a heat transfer area of 20 m^2. For this column, the total entropy production of the optimal and the EoEP columns are approximately the same (cf. Fig. 3).

The vapour flows and the heat duties on each tray in column A are shown in Figs. 4 and 5, respectively. The characteristics of the adiabatic and the optimal columns are the same as discussed earlier [7, 8, 11, 12]. The important point here is that the agreement between the optimal column and the EoEP column is very good. The vapour flow on each tray in the EoEP column is shifted slightly down in the rectifying section and slightly up in the stripping section compared the optimal column, but the differences are not substantial. The differences in the heat duties are barely visible, except on trays 8 and 20. Even smaller differences exist between the temperature profiles of the two columns (not shown). The liquid flows on each tray (not shown) differ approximately as much as the vapour flows do, see Fig. 4.

Figure 6 shows the entropy production on each tray in column A. This figure shows small differences between the optimal and the EoEP columns. The entropy production on each tray in the optimal column varies slightly in the rectifying and the stripping sections. In the EoEP columns, the entropy production is as required constant in each section.

Figures 7 - 9 present the characteristics of column B. This is a column with 20 trays and a heat transfer area of 2 m^2. For this column, the total entropy production of the optimal and the EoEP columns are significantly different (cf. Fig. 3).

The differences between the optimal column B and the EoEP column B are thus also significant. This is visible in Figs. 7 - 9. Figure 7 shows that the vapour flow is too low to be optimal in most of the EoEP

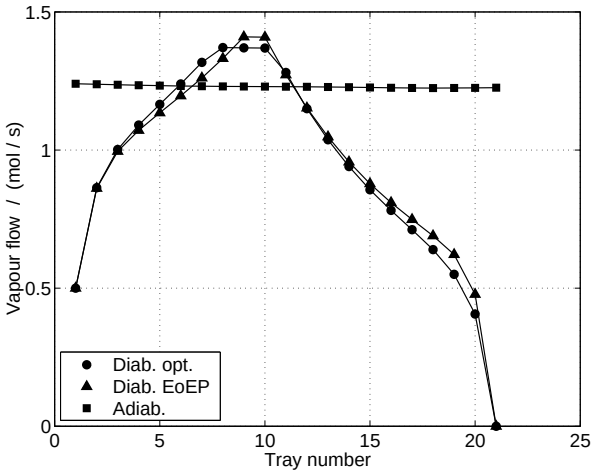

Figure 4: The vapour flow on each tray in column A.

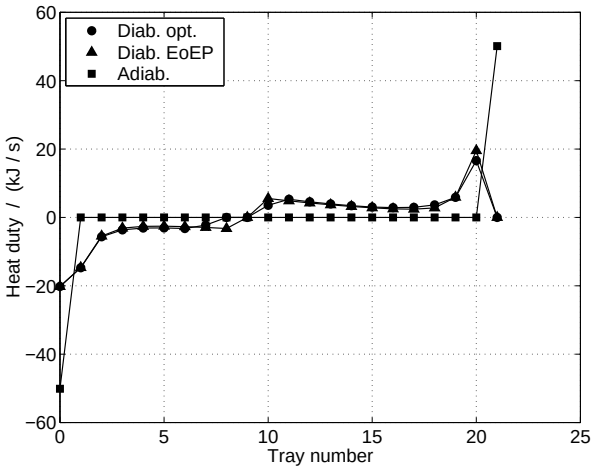

Figure 5: The heat duty on each tray in column A.

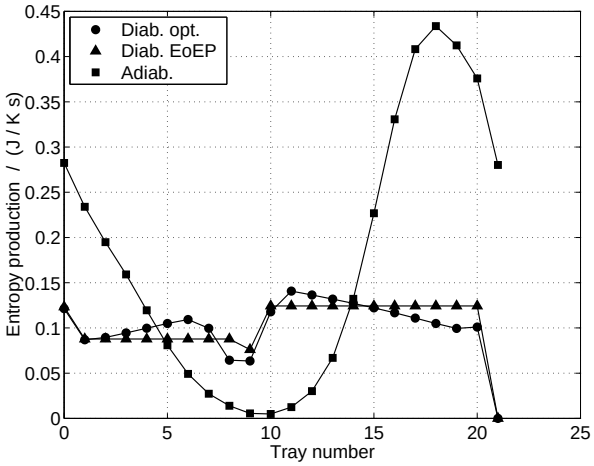

Figure 6: The entropy production on each tray in column A.

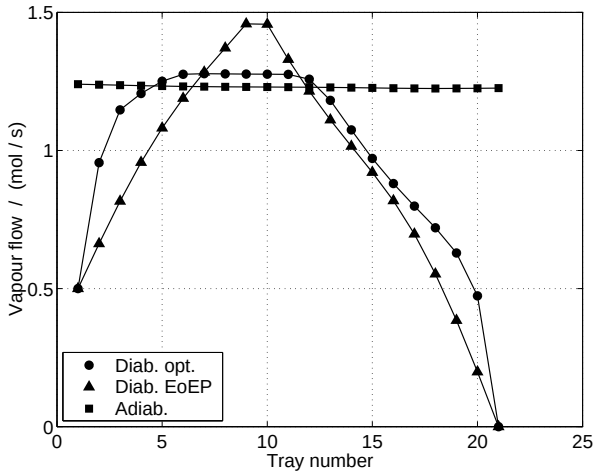

Figure 7: The vapour flow on each tray in column B.

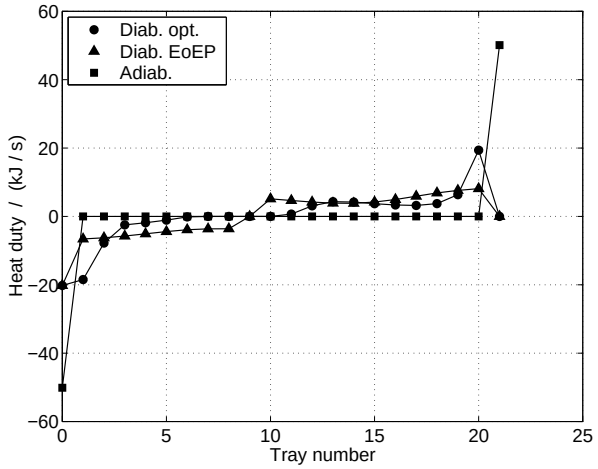

Figure 8: The heat duty on each tray in column B.

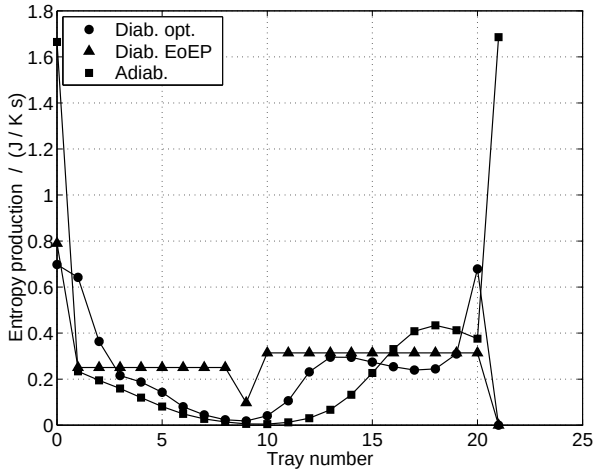

Figure 9: The entropy production on each tray in column B.

column, except close to the feed tray ($n = 9$) where it is too high. The heat duty on each tray in the EoEP column is higher than in the optimal column, especially in the rectifying section (cf. Fig. 8). The differences between the optimal column and the EoEP column, are also visible in the entropy production on each tray (cf. Fig. 9). The entropy production in the optimal column is far from constant in the rectifying section. The difference between the two columns is smaller in the stripping section.

The results show that the EoEP column is a good approximation to the optimal column, except when the heat transfer area is low. Moreover, the EoEP column approximates the optimal column best for long columns with a large heat transfer area. These results support the hypothesis put forward by [13]. Using column A and column B as examples, it is clear that there is sufficient freedom to adjust in column A, but not in column B. The fact that the total heat transfer area in column B is one tenth of that in column A, restricts the system's freedom to adjust.

As discussed earlier, the model of distillation that we have used in this paper, is not consistent with the kind of model for which EoEP (and EoF) has been derived. We therefore had to use the properties of a continuous distillation model to explain why EoEP is a good approximation to the optimum in diabatic distillation. In order to be completely sure that "EoEP, but also EoF are good approximations to the state of minimum entropy production in the parts of an optimally controlled system that has sufficient freedom" [13], we need to study continuous distillation in more detail. This is therefore an important next topic.

CONCLUSION

We have studied EoEP as an approximation to the state of minimum entropy production in diabatic tray distillation. A column with constant tray entropy production in the rectifying section and in the stripping section was a good approximation to the optimal column, except when the total heat transfer area was low. The agreement between the two columns became better and better as the total heat transfer area and the number of trays increased. The condenser, the reboiler and the tray(s) where the feed stream is mixed with the internal streams were left out in the equipartitioning.

We predicted these results using the hypothesis formulated by [13] on a continuous diabatic distillation

column. We explained why, when and in what sense EoEP applies. The properties of the optimal state in the tray column were deduced from the similarities with the continuous column. The numerical results supported the validity of the hypothesis, since the agreement with the predictions was very good.

ABSTRACT

Although internal heat integration within a distillation column can be effective in reducing energy consumption, it needs generally much more expenditure on capital investment due to the necessity of an expensive compressor and the diminishing of mass transfer driving force. A novel method for intensification of distillation processes through external heat integration is proposed in this paper. The external heat integration signifies heat integration between a rectifying section and a stripping section of different distillation columns here. It can work as an alternative means for reducing not only energy consumption, but also capital investment through accommodation of the relevant distillation columns within one shell. Through examination on a distillation system separating a hypothetical ternary mixture, the advantages of external heat integration are demonstrated thoroughly. Sensitivity analysis is also conducted with respect to feed composition and product specifications. The results obtained indicate the inherent characteristics of the design procedure proposed. However, it must be pointed out that external heat integration can present negative effect to process dynamics and process operation and it is therefore necessary to exercise a careful trade-off between process economics and process operation during process development.

INTRODUCTION

Process intensification has now gained increasingly importance in the chemical and petrochemical process industries, for instance, the development of membrane reactor and reactive distillation columns, etc. The major driving force behind this tendency is the dramatic reduction in not only energy consumption but also the capital investment (Stankiewicz and Moulijn, 2000, 2002, 2003; Luyben and Hendershot, 2004). Other benefit includes, for example, the reduction of plant size and the improvement of risk management. For the intensification of distillation processes, the progress is rather unsatisfactory. Although reactive distillation offers an effective alterative for process intensification, its applications are quite limited due to the strict requirement on the match of reaction and separation operating conditions (Stankiewicz, 2003). As distillation process still represents the major means of separation operation currently, it appears therefore imperative to develop an effective way for the intensification of distillation processes.

Distillation columns have been well known for their low energy efficiency. For effecting a separation heat has to be given at a high temperature in the reboiler and simply drawn off at a low temperature in the condenser. For dealing with this deficiency, a considerable amount of research has been conducted and the earliest work can even be dated back to the beginning of 1920s, where the studies were concentrated primarily on the low-temperature air separation. Since then, heat pump principle has frequently been used in improving distillation efficiency. Freshwater (1961) ones proposed a very rough idea for pumping heat from a stage in the rectifying section and then apply it to a stage in the stripping section for multi-component distillation columns. Petlyuk and his coworkers (1965) developed a method for the design of multi-component distillation columns with intermediate condensers and/or reboilers through minimization of entropy production. The potential drawback, however, is the exceedingly complexities in problem formulations and their solutions, especially when highly non-ideal systems have been considered. Later, Fonyo (1974) derived in more detail a reversible model for multi-component distillation columns and displayed the necessity of simultaneously withdrawing heat from the rectifying section and supplying heat to the stripping section in order to achieve a more efficient process operation. Mah and his coworkers (1980) evolved a different process configuration, which was later called by them the secondary reflux and vaporization (SRV) distillation column. Instead of the heat integration between a pair of stages, SRV distillation column actually included internal heat integration between part of the rectifying and part of the stripping sections. Our research laboratory has been continuing the research work on this subject both theoretically and experimentally since 1980 and confirmed for the first time by large-scale pilot-plant evaluations the high advantages of internal heat integration to the separation of binary close-boiling mixtures (Nakaiwa et al., 2003). One of our principal contributions is the exploit of full degree of heat integration between the whole rectifying and whole stripping sections of a distillation column, by which a more perfect way can be realized to approximate the reversible distillation operation. Recently, our studies demonstrated that through internal heat integration between the whole rectifying and whole stripping sections, considerable reduction in energy consumption could also be achieved for some multi-component systems (Iwakabe et al., 2004).

However, it should be pointed out here that large investment has to be expensed for the internal heat integration due to, for instance, the necessity of an expensive compressor and the resultant very large distillation column (cf. Figure 1). These factors pose certainly severe constraints on the application of internal heat integration to distillation processes. The purpose of the present work is therefore to explore the feasibility of intensifying distillation columns through external heat integration between different distillation columns. The current work is organized as follows: The comparison of internal heat integration and external heat integration is conducted in the next section, followed by the description of a new method for intensification of distillation processes. The design method is then evaluated through separation a hypothetical ternary mixture. Comparative studies are conducted in both steady and dynamic states between distillation columns with and without external heat integration. Some concluding remarks on the intensification of distillation processes are given in the last section of

the paper.

INTERNAL HEAT INTEGRATION VS EXTERNAL HEAT INTEGRATION

Although internal heat integration within a distillation column can be effective in reducing energy consumption, it needs generally much more expenditure on capital investment due to the necessity of an expensive compressor and the diminishing of mass transfer driving force. Figure 1 shows a schematic of an internally heat-integrated distillation column. As can be seen, a compressor must be incorporated to realize the temperature rise between rectifying section and stripping section. Moreover, two column shells are needed for one distillation column, worsening further the process economics. To avoid these negative factors of internal heat integration, external heat integration appears to be an effective way to realize intensification of distillation processes. In Figure 2 the principle of external heat integration is illustrated between two distillation columns. It is not difficult to understand that external heat integration needs no expensive compressors and offers the possibility of reduction in capital investment by arrangement of two distillation columns in one shell.

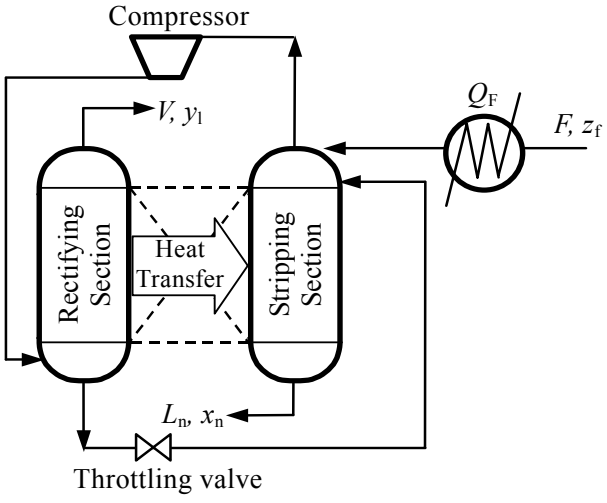

Figure 1: The schematic of an internal heat integrated distillation column

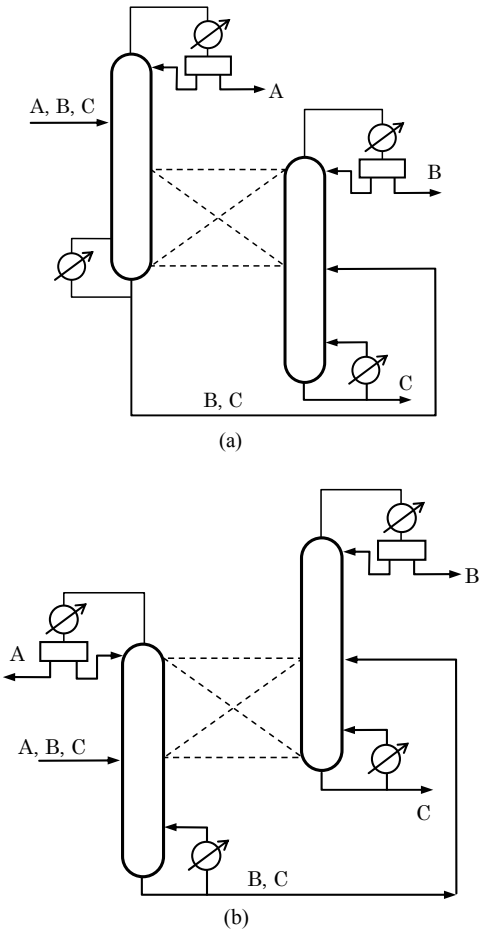

Figure 2: The direct sequence of distillation columns with external heat integration

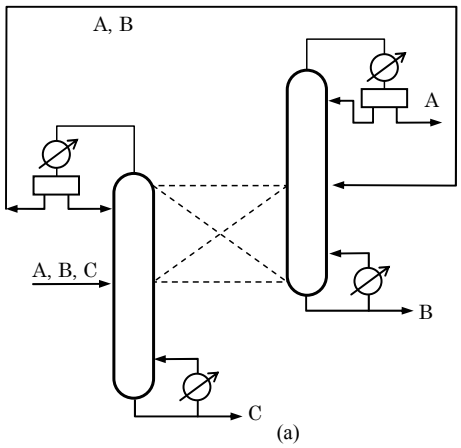

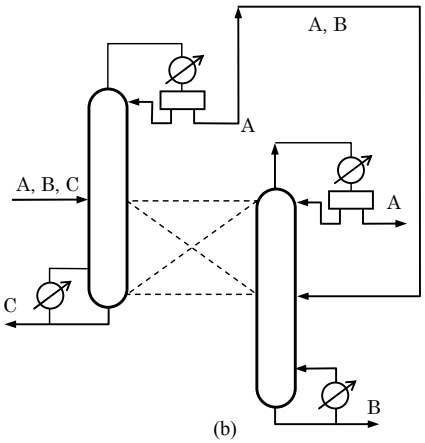

Figure 3: The indirect sequence of distillation columns with external heat integration

INTENSIFICATION OF DISTILLATION PROCESSES BY EXTERNAL HEAT INTGRATION

Although the distribution of heating and cooling sections are very complicated especially for multi-component distillation columns, it is reasonable to simply take the rectifying section as cooling section and stripping section a heating section in most cases. With this interpretation, the external heat integration can be exploited for any pair of distillation columns, provided the economical feasibility can be justified. Figure 2 illustrates the two schemes for the intensification of the direct sequence (DCS) of distillation systems separating a ternary mixture. The two schemes differ mainly in the magnitudes of pressure elevation between the two heat integrated distillation columns. Depending upon the detailed operating conditions, each of them can be effective for intensification of distillation processes. However, scheme (a) is generally superior to scheme (b), because relative small elevation of pressure is needed. Analogously, the two possible schemes for the intensification of indirect sequence (ICS) of distillation systems are illustrated in Figure 3. In this work, the process schemes of (a) in Figures 2 and 3 are mainly examined, because they represent the potentials of external heat integration.

It should be reminded here that external heat integration narrows also the driving forces in mass transfer within the two distillation columns and it is therefore still necessary to compensate these losses in the process development by adding additional stages in the corresponding sections of the two distillation columns.

AN ILLUSTRATIVE EXAMPLE: SEPARATION OF AN HYPOTHETICAL TERNARY MIXTURE

The Example System

A distillation system has been selected for the evaluation of the proposed design method of intensifying distillation processes by means of external heat integration. Table 1 tabulates the specification of process design, which includes the separation of an ideal liquid saturated ternary mixture into 0.9 pure products. For simplification, constant relative volatility and constant latent heat is assumed for the mixture to be separated.

Process Design for Distillation Processes with External Heat Integration

A general procedure for the design of distillation systems with external heat integration is presented in Appendix II and Table 2 shows the economical basis of the process design. The minimization of total annual cost (TAC) is taken as the design objective. Figure 4 shows the relationship between TAC and total stage numbers of distillation columns. The comparison against conventional distillation trains has been tabulated in Table 3 for the case of the direct sequence of distillation columns and Table 4 for the indirect sequence of distillation columns. As can be seen, external heat integration leads to a reduction of capital investment by 3.47% for the direct sequence of columns, and by 3.33% for the indirect sequence of columns. In the meanwhile, external heat integration gives also rise of reduction of operating cost by 11.43% for the direct sequence of distillation columns, and by 16.22% for the indirect sequence of distillation columns. These results are very striking; confirming that even without additional capital investment, the improvement of system performance can still be obtained. They also demonstrate that external heat integration can work as an alternative way for the intensification of distillation trains.

Table 4: Comparisons of indirect sequence of columns with and without heat integration

Sensitivity Analysis

Sensitivity analysis is conducted with respect to changes in feed composition. Tables 5 and 6 compare the performance of direct and indirect sequence of distillation columns with and without external heat integration for three feed compositions. It has been found that external heat integration appears to be relative insensitive to operating condition changes. In comparison with conventional process design, it can secure a

reduction of energy consumption from 9.09**%** to 15.38% for the direct sequence of columns and from 12.5% to 20% for the indirect sequence of columns.

Sensitivity analysis is also conducted with respect to changes in product specifications. Figure 5 illustrates the changing tendency of the effectiveness of external heat integration against the product specifications. As can be seen, the higher the product specifications are, the more effectiveness of the external heat integration. The phenomenon is due to the fact that high reflux ratio is needed to achieve high degree of separation. A similar observation can also been observed for the case of the indirect sequence of columns.

Table 6: Comparisons between direct sequence of columns with and without external heat integration

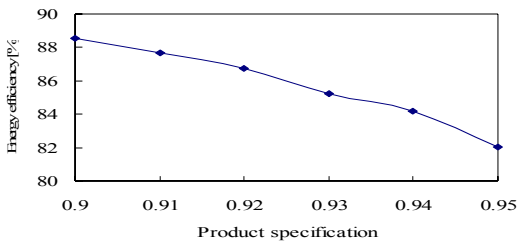

Figure 5: The effectiveness of external heat integration vs product specifications

Controllability Analysis

One of the major concerns in external heat integration of distillation columns is the influence to the process dynamics and process operation. The regulatory responses are illustrated in Figure 6 when the processes have been disturbed by a +10% step change, respectively, in feed flow rate of DSC and IDSC. Here, the levels of reflux drums and reboilers are controlled by the manipulation of top and bottom product flow rates and the purity of top and bottom products is controlled by the manipulation of reflux flow rates and boilup rates. It is readily to see that IDSC displays larger deviations and longer setting time than DSC. These realities indicates that external heat integration strengthens the interaction between the two distillation columns involved and thus poses additional difficulties to process operation.

Likewise, the regulatory responses are illustrated in Figure 7 when the processes have been disturbed by a -10% step change, respectively, in feed flow rate of ISC and IISC. Again, it can be found that external heat integration presents negative effects to the process dynamics and process operation.

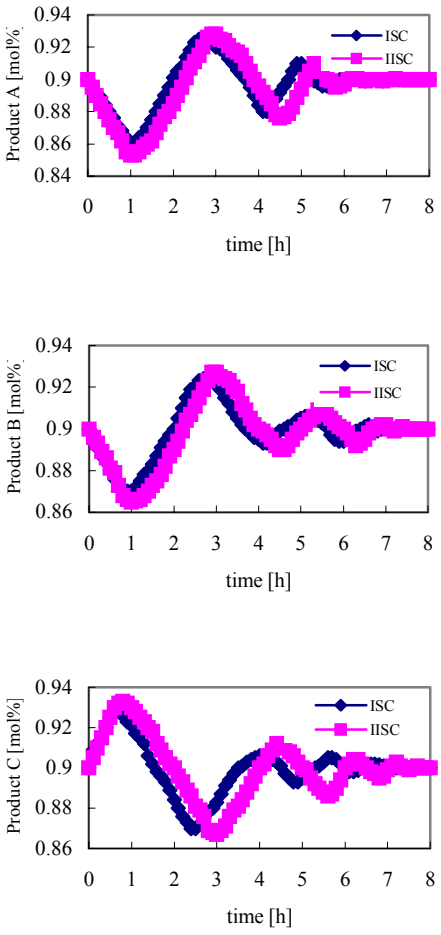

Figure 7: The comparison of dynamic performance between ISC and IISC

DISCUSSIONS

It is worth mentioning here that external heat integration offers more freedoms in process design than internal heat integration for the reduction of energy consumption of distillation systems. Provided it is economically feasible, it can be applied to any pair of distillation columns, which may even belong to different process systems. Internal heat integration can, however, only be used within the one distillation column. In addition to its high investment requirement, whether it can be used or not depends heavily on the mixture to be separated, for instance, the relative volatility, thereby limiting severely its application opportunities.

On the other hand, external heat integration has frequently been found to worsen process dynamics and introduce extra difficulties to process operation. It is thus of great significance to make a careful balance between process economics and process operation during process development.

CONCLUSIONS

In terms of the principle of external heat integration, a novel method for intensification of distillation processes is proposed in this paper. In contrast to internal heat integration, it includes heat integration between two different distillation columns and can allow accommodation of these two distillation columns within one shell. These characteristics permit it to work as an alternative way to reducing not only energy consumption, but also capital investment in the same time. Simulation studies are conducted for the separation of a hypothetical ternary mixture. Through comparison with conventional distillation schemes, the effectiveness of the external heat integration has been ascertained. It has also been found that external heat integration appears not so sensitive to changes in feed composition and product specifications.

However, it must be pointed out that external heat integration can strongly influence process dynamics and give additional difficulties to process operation. It is therefore necessary to make a careful balance between process economics and process operation during process development.

Appendix I: Sizing and Economic Basis

The capital costs of distillation columns and the energy cost are estimated using the following equations

$$\text{Column cost} = 17640 D_C^{1.066} L_C^{0.802}$$
$$\text{Tray cost} = 229 D_C^{1.55} N_T$$
$$\text{Heat exchanger cost} = 7296 S_R^{0.65} + 7296 S_C^{0.65}$$
$$\text{Energy cost} = 0.6206\, \Delta H_V^{0.65} V_S$$

Assuming an F factor of 1 in engineering units, the diameter of the column is calculated from the equation

$$D_C = 173.5 (M_W T/P)^{0.25} V_{NT}^{0.5}$$

The column height is calculated assuming a 0.61-m (2 ft) tray spacing and allowing 20% more height for base level volume.

$$L_C = 0.73152\, N_T$$

The heat-transfer areas of the reboiler and condenser are calculated using the steady-state vapor flow rates and the heat of vaporization.

$$S_R = 0.0042 \Delta H_V^{0.65} V_S/(U_R T_R)$$
$$S_C = 0.0042 \Delta H_V^{0.65} V_S/(U_C T_C)$$

Appendix II: The Procedures for Design of Distillation Systems Separating a Ternary Mixture

The following rule of thumb method is used in the process design of ternary distillation systems. They include direct sequence of column (DSC), indirect sequence of column (ISC), direct sequence of column with external heat integration (IDSC), and indirect sequence of column with external heat integration (IDSC).

[1] Set the pressures of each column and determine the pressure difference at the same time.

[2] Given the recovery of the first distillation column.

[3] In each column, the reflux ratio is 1.2 times the minimum reflux ratio, which is calculated via the Underwood equations.

[4] In each column, the number of stage is twice the minimum number of stages, which is calculated via the Fenske equations.

[5] Kirkbride`s method is used to find the optimal feed location, N_F.

[6] Determine the number of stages that is heat integrated.

[7] Using these data, calculate the total annual cost (TAC) by combining the energy cost with the annual capital cost, using a payback period given.

[8] Vary the value of the recovery of the first distillation column and repeat steps iii–vi. Select the minimum in the TAC as the economically optimum steady state design for the given process.

Laboratory for Process Equipment, TU Delft
Leeghwaterstraat 44, 2628 CA Delft, The Netherlands

ABSTRACT

In this paper a procedure is described to come to an optimal (in economic and exergetic sense) fluid based separation device and configuration. It consists of two steps: first the best device is determined with the help of a design tool and secondly for heat integrated distillation column (HIDiC) the optimal configuration is determined (for other devices this is known). To test this approach, rigorous models of conventional distillation (CD), vapor recompression (VR) and HIDiC have been built and the PP-splitter was used as case study. The design tool used in the first step predicted operational costs and exergetic losses within an error of 10 % for the PP-case. The HIDiC configuration has been optimized and the results have been explained with a force-flow analysis. HIDiC is shown to be more advantageous than VR both economically and exergetically for the PP-splitter case.
Keywords: HIDiC, design tool, force-flow analysis

INTRODUCTION

The increasing importance of sustainability and stronger competition has caused a renewed interest in improving the distillation processes. At present a number of alternatives exist for separating components in a fluid state. Of the many configurations [3] we will focus on a conventional distillation column (CD), the vapor recompression (VR) and the heat-integrated distillation column (HIDiC).

Other alternatives such as the diabatic column have been studied by among others Rivero and Le Goff [12], Rivero [11] and experimentally by de Koeijer and Rivero [4]. In particular recent efforts of Jimenez et al. [2] where only two independent heat exchange streams are used, are promising from an exergetic point of view. A disadvantage of the diabatic column besides the increased capital investment is the heat exchange fluid: if only sensible heat is used large flows are needed, if latent heat is used finding the appropriate mixture is difficult. In HIDiC it is the process fluid that is used for heat-exchange.

HIDiC has first been suggested by Mah and Wodnik [5] (introduced as secondary reflux vaporization) to improve the energy efficiency of distillation. HIDiC has a rectifying section at elevated pressure inside the stripping section as to allow for internal heat transfer (from the rectifying to the stripping section). A good overview of the results that can be achieved with HIDiC can be found in Nakaiwa et al. [6]. Olujić et al. [7] describe the conceptual design of HIDiC and Pritchard et al. [8] a continuation approach to get from CD to HIDiC.

In this paper we will use exergy as a sustainability indicator and annualized cost as competitiveness indicator. To get to optimal exergetic and economic operation we can divide the problem in two: 1) screen the different devices to see which is most optimal. Since conventional distillation can be considered a special case of HIDiC (mathematically by no heat-transfer area and no compressor duty), we only need to consider VR and HIDiC. 2) optimize the configuration of the device.

First we develop a design tool that allows us to quickly screen the devices. The optimization of the configuration is discussed next and the theory of irreversible thermodynamics is used to explain the optimization results. To test the design tool and the proposed optimization approach we explore the propylene propane splitter as a case study.

DESIGN TOOL

The design tool should allow us to choose the most optimal device HIDiC (CD is special case of HIDiC) or VR without having to model both devices rigorously. The approach we have used consists of investigating the changes from CD to either VR or HIDiC, since the conceptual design of CD has been well developed.

At present the design tool uses the following assumptions (always looking from the perspective of CD):

- same top and feed flow, i.e. T, P, x, F are the same (T_{bot}, P_{bot} different)
- Redlich-Kwong equation of state
- total condensor only
- Raoult's law (activity coefficients neglected in present version)

We would like to stress that constant molar overflow is **not** assumed in the design tool calculations. The tool needs information on:

- physical properties: $T_c, P_c, V_c, Cp(l), T_b$
- design variables:
  - purities: $x_{top}, x_{feed}, x_{bot}$
  - reflux rate
  - flows: top, feed and bottom
- Standard values: $T_{ref}, \Delta T_{htx}, \Delta T_{vr}, \Delta T_{hid}$
- cost data: electricity, steam and cooling water

A dimensional analysis of the differences in exergy loss (see appendix for derivation difference exergy loss) resulted in the following set of dimensionless variables:

$$PH_{aa} = \frac{\int \hat{V} dP}{\eta_{comp} \Delta H_{vap}^{reb}} \qquad VF = \frac{V_{feed}}{V_{bot}} \qquad \Delta T_{ho} = \frac{\Delta T_{htx}}{T_{ref}}$$

$$\Delta Ex_{i-j} = \frac{Ex_{loss}^{i} - Ex_{loss}^{j}}{V_{bot} \Delta H_{vap}^{reb}} \qquad T_{ro} = \frac{T_{reb}}{T_{ref}} \qquad \Delta H_{ft} = \frac{\Delta H_{vap}^{feed}}{\Delta H_{vap}^{top}}$$

$$DV = \frac{D}{V_{bot}} \qquad T_{co} = \frac{T_{cond}}{T_{ref}} \qquad \Delta H_{rt} = \frac{\Delta H_{vap}^{reb}}{\Delta H_{vap}^{top}}$$

$$BV = \frac{B}{V_{bot}} \qquad \Delta T_{vo} = \frac{\Delta T_{vr}}{T_{ref}} \qquad CH_a = \frac{Cp_a T_{ref}}{\Delta H_{vap}^{reb}}$$

It is interesting to see that all variables can best be scaled by the energy needed to generate the vapor boil-up (in CD) rather than the more intuitive reflux rate. The vapor boil-up is the "driving" engine in

CD, which makes the result understandable. Furthermore we introduce for reasons of brevity:

$$\alpha = \left(1 - \frac{1}{T_{co} - \Delta T_{ho}}\right) \tag{1}$$

The differences in exergy loss of VR and HIDiC with respect to CD in dimensionless variables is given by:

$$\begin{aligned}
\Delta Ex_{hid-cd} &= BV(T_{ro} - T_{co})CH_{bot}(1 - \frac{1}{T_{ro}}) \\
+(\frac{\Delta H_{rt}}{\Delta H_{ft}} &+ VF)PH + (VF\frac{\Delta H_{ft}}{\Delta H_{rt}} - \frac{DV}{\Delta H_{rt}})\alpha \\
&+ \left(\frac{1}{T_{ro} + \Delta T_{ho}} - \frac{1}{T_{co} - \Delta T_{ho}}\right) \qquad (2) \\
\Delta Ex_{vr-cd} &= \left(\frac{1}{T_{ro} + \Delta T_{ho}} - \frac{1}{T_{co} - \Delta T_{ho}}\right) \\
&+ \left(\frac{\Delta H_{rt}}{\Delta H_{ft}} + VF\right)PH_{vr} \\
-(\Delta H_{rt} &+ VF\Delta H_{ft})CH_{top}(T_{ro} + \Delta T_{vo} - T_{co})\alpha \qquad (3) \\
\Delta Ex_{hid-vr} &= BV(T_{ro} - T_{co})CH_{bot}(1 - \frac{1}{T_{ro}}) \\
&+ \left(VF\frac{\Delta H_{ft}}{\Delta H_{rt}} - \frac{DV}{\Delta H_{rt}}\right)\left(1 - \frac{1}{T_{co} - \Delta T_{ho}}\right) \\
+(\Delta H_{rt} &+ VF\Delta H_{ft})CH_{top}(T_{ro} + \Delta T_{vo} - T_{co})\alpha \\
&- (1 + \frac{\Delta H_{ft}}{\Delta H_{rt}}VF)\frac{\Delta T_{vo}}{T_{ro}} \qquad (4)
\end{aligned}$$

Some of the terms are generally in a certain range. For example in the first term in equation 2, BV usually increases when relative volatility gets closer to one, but in general $(T_{ro} - T_{co})$ reduces, changing ΔEx_{hid-cd} possibly only slightly. The relative heat of vaporization, $(\frac{\Delta H_{rt}}{\Delta H_{ft}})$, decreases when the relative volatility gets closer to one, reducing ΔEx_{hid-cd}, but the last term in equation 2 decreases, increasing ΔEx_{hid-cd} (last term is always smaller than zero).

These effects can be understood if one realizes that if the separation gets more easy less reflux and vaporboilup is needed (reducing flows) on the one hand, but the difference in quality of energy needed in reboiler and extracted from the condensor increases. Since exergy is flow times the quality of energy it is in principle not easy to say what happens. Finally, we would like to stress that in general we are interested in both the exergy flow as well as the exergy density (a large exergy flow at low exergy density is not that valuable).

CONFIGURATION OPTIMIZATION

The configuration can be optimized with respect to construction materials (amount, type and its actual geometrical lay-out) as well as its internal flows (e.g. by means of utility streams). To optimize the geometrical layout a very detailed model would be needed (e.g. CFD [10]). Since optimal configurations of both CD and VR have been reported abundantly (e.g. [3]), we will focus on optimization of HIDiC.

Internal flows could also be optimized by means of CFD calculations, but here we assume we have a model that has no spatial dependencies. We focus on two variables that are specific to HIDiC: the heat exchange area, A, and the pressure ratio over the compressor, PR. The optimization problem can now be stated as:

$$\begin{aligned}
\min_{A,PR} \quad & EC \\
s.t. \quad : \quad & f(y;PR,A) = 0 \qquad (5) \\
& g(y;PR,A) \leq 0
\end{aligned}$$

The function f is the model that will be described briefly in the next section, y are the model variables and g are all inequality constraints.

The objective, EC, can either be 1) economic: annualized costs (operation + capital) or exergetic: exergy loss. The heat-exchange area, A, can be considered in many ways:

- one total area: area is evenly distributed over all heat-exchange trays
- a distribution of area: a function is used to describe the form of the area distribution over the trays
- every area: every area on each heat-exchange tray is an optimization variable

In fact we have another degree of freedom: which tray exchanges heat with which other tray? Including this degree of freedom in the optimization would make it a MINLP. Let us designate trays in the rectifying section by Ri and in the stripping section by Si (counting from top to bottom). In that case R1 is located next to S1, or Ri is located next to Si. Now physically (from a construction and temperature profile point of view) it would be unwise to have a coupling like: R1-S8, R2-S1, R3-S12, etc.

Although it is possible to achieve this, it seems unlikely this would yield an optimum solution.
For analysis we use the theory of irreversible thermodynamics [1]:

$$J_i = \sum_j L_{ij} X_j \quad (6)$$

$$\theta = \sum_i J_i X_i = \sum_i \sum_j L_{ij} X_j X_i \quad (7)$$

In particular we will do a flow-force analysis [15, 14]. The heat exchange area's will be part of the L_{ih} (i being components and h is the heat flow at that tray trough the wall). Furthermore, PR has a direct influence on the $X's$. So we can rewrite the optimization problem (5) in irreversible theory as:

$$\begin{aligned} \min_{X,L} \quad & EC \\ s.t. \quad : \quad & f_s(J,X,L) = 0 \\ & g_s(J,X,L) \leq 0 \end{aligned} \quad (8)$$

The internal entropy production part of EC is now given by:

$$EC = \Theta = \sum_{k=1}^{N} \sum_i \sum_j L_{ij}^k X_j^k X_i^k \quad (9)$$

(X_j^k means force j on tray k) PR and A both influences both L and X, hence L and X cannot be varied independently. It is therefore to be expected that the principle of equipartition of forces will not hold in this case.

CASE STUDY

In this paper the PP-splitter is taken as a case study. A feed of 52 mole% propylene (110 ton/hr) is purified to 99.5 mole% in the top and 1.1 mol% in the bottom. The column consisted of 211 theoretical trays, 154 of which where in the rectifying section, i.e. 57 trays of the stripping section are connected with an equivalent number of trays in the upper part of the rectifying section [7].
Models of a conventional distillation, vapor recompression and HIDiC column were built in gPROMS, an equation oriented software package [9]. The model contains mass, energy and momentum balances as well as economic, exergetic and design (tray and column) equations. Main assumptions concern:

Table 1: Results design tool

	VR		HIDiC	
	Rig.	Des.	Rig.	Des.
Wcomp(MW)	7.55	7.80	6.87	6.20
Qreb (MW)	4.06	4.80	0.02	0
Qcond (MW)	14.45	14.99	8.63	8.37
Oper. cost(M$/yr)	7.4	7.7	5.9	5.35

Table 2: Comparison of exergy loss

	Abs. (MW)		Rel. (%)	
Exergy loss	Rig.	Des.	Rig.	Des.
CD-HIDiC	10.14	9.34	60	60
VR-HIDiC	1.80	1.24	21	17

- equilibrium tray
- Peng-Robinson EOS and Wilson activity model
- Constant heat transfer coefficient (800 $W/m^2/K$, has been verified by experimental data in a HIDiC column to be a safe estimate)

The results could be confirmed by literature data (equilibrium and saturation pressure data) and actual plant data from the Borealis group. The results agreed well with both literature and plant data.
The model size in combination with the MINLP size for theoretically 211 trays results in a problem that at present cannot be handled on a conventional PC. gPROMS was used for the numerical optimization of HIDiC. We started by optimizing the total area, next we optimized a (linear) function, which was increased in complexity. The optimization turned out to move to its maximum area for a large part of the column. Therefore in the last optimization we optimized a linear function describing the area profile of the bottom 45 heat-exchanging trays and simultaneously the top 12 area's were optimized. The following constraints were used in the optimization (function g in equation 5): 1) Maximum area on a stage : 500 m^2 and 2)A flow of 0.1 kmole/s is needed for proper operation.

RESULTS AND DISCUSSION

Design tool

First we look at the results of the design tool in comparison with the rigorous model. The results can be

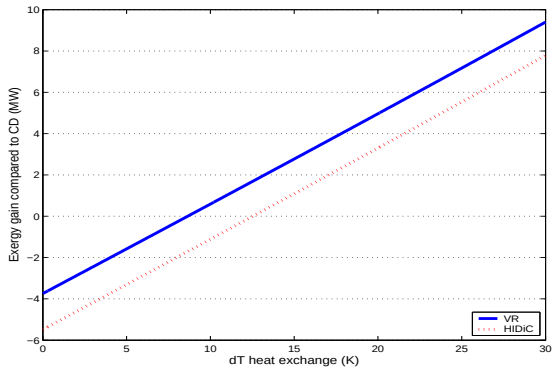

Figure 1: Exergy loss difference compared to CD

found in tables 1 and 2. The design tool correctly predicts that HIDiC is more favourable from an exergetic and operational cost point of view. Given the fact that the rigorous calculations contained in the order of 100.000 equations and the design tool in the order of 100, while the relative error found is below 10% means the tool is quite effective.

It has to be stressed that the choice of the device is sensitive to the used temperature difference for heating and cooling, ΔT_{htx} (figure 1). The break-even point for HIDiC lies at a temperature difference of 8 K and for VR at 16 K, i.e. CD is exergetically competitive with VR and HIDiC at those points.

Configuration optimization

The optimization results can be found in table 3. For the case study we verified that HIDiC was more optimal than VR. The fixed area means that during the optimization every tray had the same area and the optimized area means all areas were optimized as described in the case-study. An annual cost reduction of 0.67 M$ per year and 0.49 MW less exergy loss could be achieved within HIDiC if the tray area profile was optimized in comparison to the optimized case where every tray had the same area.

An idea of the objective surface for the fixed area case is given in figure 2. The lines are contours indicating the same exergy loss, the gray area is physically infeasible. The point Area=0 and Pressure ratio ≈ 1 corresponds to the CD case. From figure 2 we see that (as was remarked by [13]) the optimum is not flat which means two things: 1) we need to choose the area and pressure ratio smartly and 2) we can reduce the exergy loss substantially.

Table 3: HIDiC configuration optimization results

	VR	HIDiC fixed area	opt. Area
Wcomp (MW)	7.55	6.60	6.87
Qcond (MW)	-14.45	-12.64	-8.63
Qreb (MW)	4.06	4.22	0.02
Annual (M$/yr)	11.73	10.86	10.19
Capital (M$/yr)	4.33	4.28	4.30
Oper. (M$/yr)	7.40	6.58	5.90
Exloss (MW)	8.46	7.15	6.66

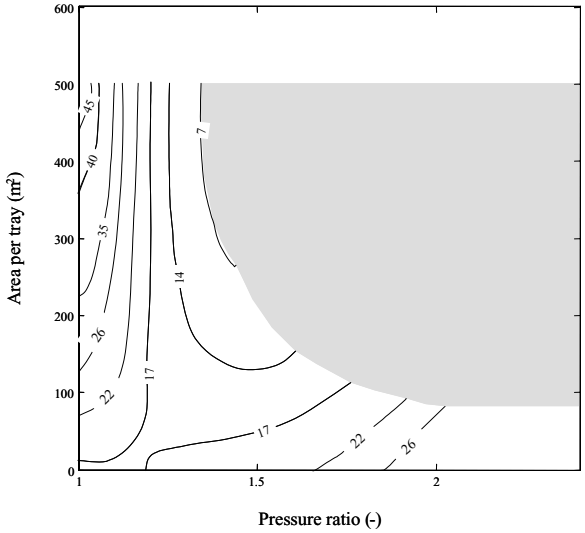

Figure 2: Exergy loss contours (MW)

Force-flow analysis

Now we will use the theory of irreversible thermodynamics to explain the results. In figure 3 we compare the local entropy production profiles in the column for VR and HIDiC (note that since HIDiC is heat integrated it is locally possible to have negative entropy production). Entropy production at the ends of the column is reduced (smaller flows) and at the same time entropy production is more concentrated around the feed.

To understand the profile we will analyze the thermodynamic flows and forces (figure 4 and 5). From the figures it is clear that the chemical forces are increased in the rectifying section and reduced in the stripping section for HIDiC compared to VR. The first is in contrast with a reduction in exergy loss (see equation 7).

If we look at the flows (figure 5) and local entropy

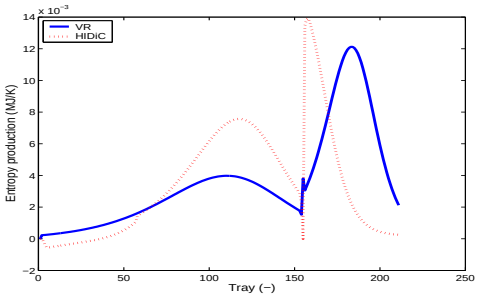

Figure 3: Local entropy production profile

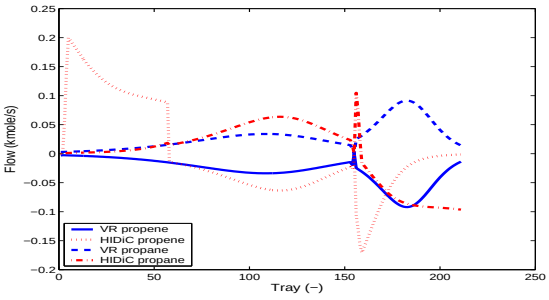

Figure 5: Flow overview

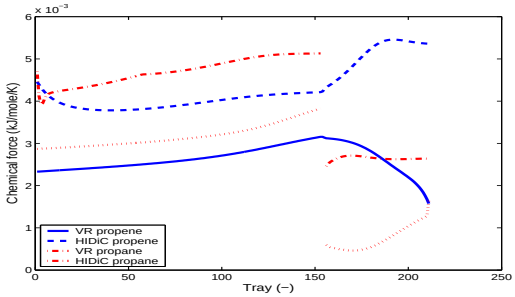

Figure 4: Chemical force overview

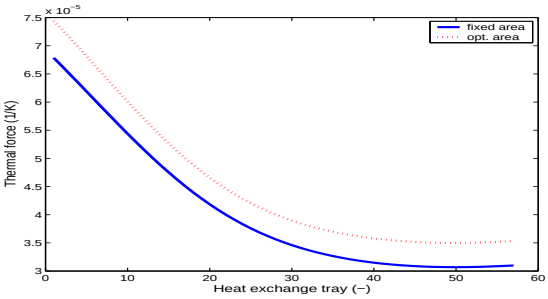

Figure 6: Thermal force heat integration

production (figure 3) however, we see that apparently it is beneficial to increase the entropy production at some points, which eventually results in a lower overall entropy production. A clear clue is given by the propylene flow in HIDiC (figure 5) compared to VR, here we see the influence of heat transfer through the wall, implying that L_{1h} (1 for propylene and h for heat through wall) plays a dominant role (as expected).

Another interesting phenomenon could be observed by looking at the differences in the optimization results for HIDiC for fixed area and optimized (=variable) area. The exergy loss, as shown in table 3, can be reduced by an increase in the thermal force as shown in figure 6. At the same time in figure 7 we see that the flow is also increased over the largest part of the column (increasing the internally generated reflux and vapor boil-up flows).

However, the flow is reduced at the place where the force is highest. This is caused by manipulation of the L's via the heat transfer area (see figure 8). Physically this can be understood since the reboiler and condensor duties do not cancel out (there is some remaining condensor duty, see table 3). This means that the at the top an "external" reflux already enters the column, reducing the need for an internally generated reflux. Also note that the area is increased gradually, i.e. not from a minimum to a maximum from one tray to the next.

CONCLUSIONS

We have developed a framework that helps to find the best (in economic and exergetic sense) device (CD, VR or HIDiC) and configuration for fluid based separation. It consists of two steps: 1) a screening tool that determines which device (HIDiC, CD or VR) is optimal and 2) numerical optimization to find the optimal configuration of HIDiC. We did not consider diabatic columns in this paper, because of the disadvantages mentioned in the introduction.

The theory of irreversible thermodynamics, in particular the flow-force analysis, was used to explain the results. Optimization was shown not just to be a matter of reducing all the forces, the complete picture has to be taken into account. The force-flow analysis helped to uncover the complex behavior and helped to explain what happened.

For the pp-splitter used in the case study HIDiC was correctly indicated to be the best device by the de-

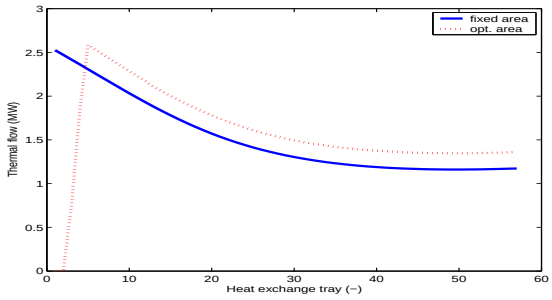

Figure 7: Thermal flow heat integration

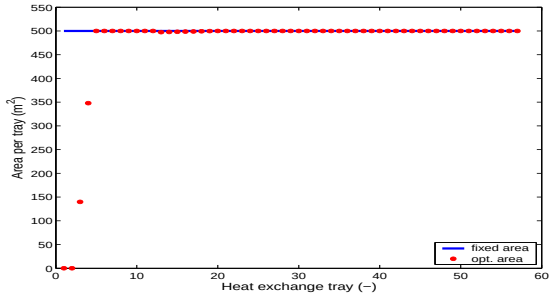

Figure 8: Heat exchange area profile

sign tool, which was verified by rigorous simulations. Optimization of HIDiC resulted in a reduction of exergy loss of 1.8 MW and a reduction in annualized cost of 1.5 M$ compared to state of the art VR.

From these results it is clear that particularly in devices where phenomena are coupled, like in HIDiC, optimization needs to be done globally, since local entropy production may well increase at some place while the over-all entropy production is reduced.

It is expected that the accuracy and overall usability of the design tool will improve if we: 1) improve estimate of Z, 2) possibly incorporate activity coefficients 3) incorporate a temperature profile matching check to assure no reversed heat-flow occurs, 4) incorporate capital cost and 5) incorporate tray efficiencies.

ACKNOWLEDGEMENT

This work was part of an EET project (EETK01025) with ECN, ABB-Lummus, Akzo Nobel, BP, DSM, Shell GS and Sulzer Chemtech. We are grateful to Ir. R. Cousaert from the BOREALIS Group (Antwerp) for providing actual plant data used in this work.

APPENDIX
DESIGN TOOL EQUATIONS

We start with (feed and distillate flow HIDiC is identical to CD in this derivation and assuming $Q_{reb} > Q_{cond}$ to keep equations clear):

$$\begin{aligned} & Ex^{hid}_{loss} - Ex^{cd}_{loss} = -B\left(H^{hid}_{bot} - T_{ref}S^{hid}_{bot}\right) \\ + \quad & B\left(H^{cd}_{bot} - T_{ref}S^{cd}_{bot}\right) + W_{comp} \\ + \quad & Q_{cond}\left(1 - \frac{T_{ref}}{T_{cond} - \Delta T_{htx}}\right) - Q_{reb}\left(1 - \frac{T_{ref}}{T_{reb} + \Delta T_{htx}}\right) \\ - \quad & Q^{hid}_{cond}\left(1 - \frac{T_{ref}}{T_{cond} - \Delta T_{htx}}\right) \end{aligned} \tag{10}$$

In which ΔT_{htx} represents the temperature difference used for heat transfer. Now if CD is a bottom temperature of T_{bot} and a pressure P_{bot} than HIDiC has a "bottom" temperature $T_{bot} - \Delta T$ and a pressure $p_{bot} - \Delta p$. In that case we may write:

$$H^{hid}_{bot} = H_{bot}(p_{bot} - \Delta p, T_{bot} - \Delta T) \tag{11}$$

$$S^{hid}_{bot} = S_{bot}(p_{bot} - \Delta p, T_{bot} - \Delta T) \tag{12}$$

Since pressure dependence of a liquid enthalpy is limited we may write (assuming Cp is constant over ΔT):

$$\begin{aligned} - \quad & B \quad \left(H^{hid}_{bot} - T_{ref}S^{hid}_{bot}\right) + B\left(H^{cd}_{bot} - T_{ref}S^{cd}_{bot}\right) \\ = - \quad & B \quad \left[-Cp_{bot}\Delta T - T_{ref}Cp_{bot}\ln\left(\frac{T_{bot} - \Delta T}{T_{bot}}\right)\right] \end{aligned} \tag{13}$$

Now since $\Delta T << T_{bot}$ we have:

$$\ln\left(1 - \frac{\Delta T}{T_{bot}}\right) \approx -\frac{\Delta T}{T_{bot}} \tag{14}$$

Assuming we may use the ideal mixing rule for the heat of vaporization of a mixture we can write:

$$V_{bot} = \frac{Q_{reb}}{\Delta H^{reb}_{vap}} \tag{15}$$

$$V_{top} = \frac{V_{bot}\Delta H^{reb}_{vap}}{\Delta H^{cond}_{vap}} + \frac{V_{feed}\Delta H^{feed}_{vap}}{\Delta H^{cond}_{vap}} \tag{16}$$

$$V_{comp} = \frac{V_{bot}\Delta H^{reb}_{vap}}{\Delta H^{feed}_{vap}} + V_{feed} \tag{17}$$

Using 13 and equations 14 in equation 10 gives us ($Q^{Hid}_{cond} = \frac{D}{V_{top}}Q_{cond}$):

$$\begin{aligned} Ex^{hid}_{loss} \quad & -Ex^{cd}_{loss} = B\Delta TCp_{bot}\left(1 - \frac{T_{ref}}{T_{bot}}\right) \\ + \quad & \frac{V_{top} - D}{V_{top}}Q_{cond}\left(1 - \frac{T_{ref}}{T_{cond} - \Delta T_h}\right) \\ - \quad & Q_{reb}\left(1 - \frac{T_{ref}}{T_{reb} + \Delta T_{htx}}\right) + W_{comp} \end{aligned} \tag{18}$$

If we now assume that $W_{comp} = V_{comp} \int \hat{V} dP / \eta_{comp}$ ($\hat{V}$ is the molar volume, V_{comp} is the flow at the location of the compressor in CD column), we can write ($Q_{cond} = \Delta H_{vap}^{top} V_{top}$):

$$\begin{aligned} Ex_{loss}^{hid} &- Ex_{loss}^{cd} = B\Delta T C p_{bot} \left(1 - \frac{T_{ref}}{T_{bot}}\right) \\ +(V_{top} &- D)\Delta H_{vap}^{top} \left(1 - \frac{T_{ref}}{T_{cond} - \Delta T_{htx}}\right) \\ -V_{bot}\Delta H_{vap}^{reb}(1 &- \frac{T_{ref}}{T_{reb} + \Delta T_{htx}}) + \frac{V_{comp} \int \hat{V} dP}{\eta_{comp}} \end{aligned} \quad (19)$$

Looking at the temperature profile we can see that ΔT above is close to the temperature difference in reboiler and condensor (as a safe guess).
Similar derivations can be made for CD compared to VR. The simplest way to find the difference between HIDiC compared to VR is than to subtract the results of the other differences ((HIDiC-CD) - (VR-CD)= (HIDiC-VR)).

ABSTRACT

The separation performances of ideal mixture (n-hexane and n-heptane) were evaluated by using the commercial software simulator called HYSYS in the conventional distillation column and the feed splitting column. The optimum conditions of stage number and reflux ratio can be pointed out from the simulation results. To obtain a better separation performance, the stage number should be increased while having a low reflux or vice versa. From the result of conventional column, the condition of minimum reflux ratio was visualized. Moreover, the composition profiles of those two columns were performed with the variations of stage number, reflux ratio and the second feed location in feed splitting column in order to find the proper criteria.

Keywords: Binary Distillation, HYSYS, Simulation, Feed splitting column

INTRODUCTION

Distillation has been one of the most popular separation units being applied in many engineering fields. Since it is a major energy consuming, a lot of efforts to reduce energy consumption in distillation have been evolved throughout the world. One of the efforts is to introduce the intermediate heater/cooler to the column in order to reduce the amount of heat duty at the reboiler as well as at condenser [1, 2, 3]. Some studies have emphasized on the use of waste heat as a heat source to preheat and partially vaporize the feed before entering the column [4, 5]. Other approaches for energy saving or optimization in distillation unit are exergy analysis and entropy production of the column [6, 7, 8]. Although, the above mentioned efforts were done and still have been under investigated even it was proclaimed to be a dead end as mentioned by Soave and Feliu [4]. Nevertheless, calculation of distillation by using commercial software will be another approach for studying the performance of column [8].

In the operating problem, the separation of the mixture by distillation depends on the difference of volatility between components. The greater the relative volatility is, the easier the separation will be. For binary component, the profile of separation can be represented as the mole fraction of one component (usually light component in distillate) or as its equilibrium temperature of the column. Nowadays, some commercial simulators such as ASPEN PLUS and HYSYS are available and

become popular as the tool for process simulation. In some circumstance, those simulators can be used as the tool to study process control since they are rather reliable and less-time consuming [9, 10].

In this study, binary component of n-hexane and n-heptane will be selected as a case study and using commercial software HYSYS to simulate the conventional column and feed-splitting column in order to visualize the separation performance. Some conditions such as different reflux ratio, different feed location were investigated in this study as well.

CASE STUDY WITH SIMULATOR: HYSYS

Scheme of distillation column

Figure 1 (a) shows the schematic of conventional column. In binary component distillation, the McCabe-Thiele diagram can be used as a tool in design problem. By assuming the equimolal flow and equimolal latent heat both in the rectifying section and the stripping section, the operating lines of these two sections can be drawn as straight line on xy diagram. Then, the number of stages can be achieved by drawing the steps between the equilibrium line and the operating line. If the two operating lines intersect with the equilibrium curve, the minimum reflux condition will be reached as shown in Figure 1(b). At this intersect point, the number of stage will be infinity or in other word, there is no separation. Similar manner can be found in multicomponent as well by having the constant component concentration along the column [11]. In practical, the column should not be operated at this condition. It should be at the condition in between the minimum reflux and the total reflux. In the case of total reflux condition, the operating line will be shifted to the diagonal line. Figure 1 (c) shows the schematic of feed splitting column. The F2-feed is called the second feed whereas the F1-feed is the first feed. If the second feed is fed in the rectifying section and its temperature is lower than the first one, there will be two lines of feed making three operating lines of column because of the second feed as shown in Figure 1 (d). In this study, we would like to look at the separation profile of two type columns.

Separation performance of conventional distillation column

The HYSYS simulator was used to examine several operation cases of binary distillation column. The ideal mixture of n - hexane and n - heptane was selected for this study. The feed mixture of 50 % of each component was fed at stage number 10 with the flow rate 100 kmol/hr. The total number of stage in the column is 22 including total condenser and reboiler. The hypothesis UNIQUAC is used in this case. The column is operated at the atmospheric pressure. The simulator is run at steady state. Firstly, we will examine the case of conventional distillation column with manipulating reflux ratio. Secondly, the variation of thermal condition of feed will be examined. The column stage is fixed and distillate flow rate is 50 kmol/hr while the reflux ratio is varied. Figure 2 shows the composition profile of n-hexane with different reflux ratios. The ordinate is mole fraction of n-hexane along the column while the abscissa is the stage number of the column. When the reflux ratio is decreased, the obtained component in the distillate is decreased as well. Here, the smallest of reflux ratio is 0.5 whereas the highest is 1.4. It reveals that when the reflux ratio becomes large, the separation performance is improved and the composition profile is changed drastically along the column. When the reflux ratio is decreased, the profile is changed abruptly in the rectifying section. Similar manner can be seen also in the stripping section. The composition profile in the middle of column becomes constant when the small reflux is performed. It means the minimum condition of reflux is reached. Theoretically, the minimum reflux ratio can be observed from the composition profile along the column, if the composition appears constantly [11]. In binary component, this condition will appear at around feed stage as seen in Figure 2. Figure 3 shows the result of the temperature profile along the column which is the mirror image of the mole fraction. When we examine further if the thermal condition of feed is varied but keeping the reflux ratio fixed at 0.8. The other conditions of the column are kept the same. Figure 4 shows the temperature profile at each stage at the different feed condition. The higher temperature of feed is, the poorer of separation

performance is. This result supports the theory saying that when the feed temperature is low, it gives the internal reflux to encourage more condensation of the component resulting in having a better separation. However, having a low temperature of feed will enhance the heat duty at reboiler as shown in Figure 5.

Figure 6 shows the simulation result of the conventional column. When the reflux ratio is varied, the number of stages in the column will be varied as well. The y-axis is mole fraction of n-hexane in the distillate (X_{Hx}) and the x-axis is the number of stage in the column (excluding reboiler and condenser). At the stage number 11, the separation performance is poor at each value of reflux ratio comparing with the higher amount of stage number. The separation performance of n-hexane is improved by increasing the reflux ratio. At the stage number 20 with reflux ratio 2.5, the separation performance is about the same with the stage number 30 and reflux ratio at 1.5. The result of HYSYS program will give us a choice to obtain the suitable value of stage number or adjusted reflux ratio. We can say that the requirement of stage number is essential around 30-40 and reflux ratio 1.45-1.55 in order to obtain 100% separation of this mixture.

Separation performance of feed-splitting distillation column

In Figure 1(c), the feed will be split into two streams but keeping the same composition. The first feed is fed at the middle of column while the second is at different stage in the rectifying section. By doing that, the operating line of this column will be three lines since the internal flow is changed due to the second feed condition.

Figure 7 (a) shows the simulation result when the column has the feed splitting at ratio 10/90. The 10% of feed (the second feed) is fed at some certain stage (at stage 3, 5 and 7) while the 90 % (the first feed) is unchanged and fed at the middle of the column (at stage 10). It shows that the case with the second feed at stage 3 gives rather poor separation whereas the second feed at stage 5 and 7 give the insignificant result. Figure 7(b) shows the result when the stage number is 30 and the first feed is fed at stage 15 and the second feed is at stage 7, 9 and 12. The separation performances of each case are about the same but the profile of hexane can reach 100 % at reflux around 2. When we check the stage number from 40 up to 60 shown in Figure 7 (c)-(e), the separations show the same result. It implies that when the amount of stage increases up to 40 or more, it is not necessary to have such a huge number. Figure 7 (f) shows the result of separation of this feed splitting column. When the feed is split into 50/50 and fed at different stage similar to previous case. We observed that the separation performance of this splitting case gives the significant result as shown in Figure 8. Note that when the feed splitting ratio is great, the separation performance is affected at the small value of reflux ratio.

CONCLUSION

Commercial simulation program HYSYS has been used in this study to visualize the separation performance of n-hexane and n-heptane mixture. The conventional distillation column has given the better separation when the feed has a lower temperature. However, the heat duty at the reboiler will be increased as a consequence. Regarding the feed splitting column, the separation performance is partly affected at high value of reflux ratio.

Abstract

The effect of form with corrugated packing on mass transfer and pressure drop characteristics in atmospheric cooling towers has been studied experimentally. The results showed that the mass transfer coefficient decreased with increase in packing pitch and increase in the ratio of rib pitch to rib height. Friction factors were expressed by a dimensional equation which included pitch and distance between the packings, for both smooth and rough surface. From these results, the relationship between packing mass transfer coefficient and pressure drop was deduced. The correlations were verified with additional experimental data taken with $1.1< P/D <1.70$ and $1 \leq p/e \leq 5$. This provides a useful semi experimental relation, in the area generally lacking in design and performance data.

Introduction

In general, the design of an efficient, compact mass transfer pack for gas/liquid applications is based on the optimisation of the passage diameter and passage length. Also from a number of recent studies it is apparent that the choice of material plays a major role in packing design, the ideal material being highly formable in order to provide a high specific surface area.(Egberongbe 1990). Heat and mass transfer between a falling liquid film along a vertical wall and upward flowing air contacting directly with the film is an important and interesting phenomenon in industrial apparatus such as cooling towers. While 96% of the cooling towers use PVC packing with smooth and cross ribbing, no data on the flow of liquid over a flat vertical wall with cross ribbing have been published. Only some of the features of their operation in contact heat exchangers have been investigated. (Bukowski 1995, Nabhan 1994, Kranc 1993, Marselle 1991). Major aspects that remain to be studied include: the geometry and layout of the main corrugation with and without the cross ribbings, the pattern of flow of the liquid film and interaction between phases. In this paper the mass transfer and pressure drop characteristics of many types of corrugated packing, including smooth and rough surface corrugated packings, are investigated, and the relationship between packing mass transfer coefficients and pressure drops are discussed. Mass transfer performance of rough corrugated packing is increased by 1.5 to 2.5 times the smooth packing values, but the pressure drop of packings also increases with the increase in heat transfer performance.

Experimental Apparatus and Procedure

The experimental apparatus for the heat transfer experiments, consisted of a counterflow forced draft cooling tower, as shown in Fig. 1. Water stored in a tank at the base was pumped into the spray nozzles. The supply water velocity was regulated by a valve. The cross sectional test area was A= 0.15 x 0.15 m. Inlet and outlet air and water temperatures were measured by mercury in glass thermometers with a range of 0-50°C and an accuracy of 0.2 K. Packing pressure drop was measured by an APM 2000 (0 to 2000 Pa) micromanometer with an accuracy of ±1% FSD (i. e. maximum of 1.2 Pa error in our measurements). Measurements of mass transfer and pressure drop were carried out in the steady state. The mass transfer coefficients and pressure drops were measured for a range of L/A (L') from 0.45 to 2.22 kg/m^{2}s and G/A (G') 0.20 to 1.50 kg/m^{2}s. A series of perimeter deflector plates as shown in Fig 1 was installed around the inner perimeter of the column, made in the laboratory of clear Poly Carbonate plastic to allow observation of the water flow. These deflector plates removed the water film from the wall of the tower's column and redistributed the water in the packing zone. As a result of deflection, most of the water was transferred to the packing surface from the outer wall, forming descending thin films, while air was blown vertically upward, counter current to the water by a fan at the base.

The packings tested were of two types, smooth and ribbed, both of PVC. The smooth packing had horizontal corrugations and the ribbed had horizontal corrugations with ribbing set at an angle to the main corrugations. The cross ribs were separated by distance p, ranging from 2 mm to 10 mm, for the six sample packings, and the height e of the ribs ranged from 1 mm to 3 mm. The main corrugation pitch, P, ranged from 30 mm to 70 mm. The thickness of packing was negligible. The forms of corrugated packings used in the experiments are listed in Table 1, and typical shapes are shown in Figs. 3 and 4. The column packed height, Z, was 160 cm and the water level in the sump was about 1.2 m below the top of the packing. Water inlet and outlet temperatures were 37 °C and 27 °C respectively.

Table 1: shapes of corrugated packing used for experiments

Test Group	Type of corrugation	Surface area per unit volume (m^{-1})	Pitch (mm)	Spacing (mm)	P/D	Type of surface	p/e	θ deg)
C1	sinusoidal	200	70	50	1.40	rough	1	45
C2	sinusoidal	250	65	40	1.65	rough	3	0

Experimental Results

Heat Transfer Characteristics

Cooling tower packings typically have quite complex surface geometries, for which the mass transfer co-efficient, k, cannot be analytically predicted. Because manufacturers treat such data as proprietary, the k relation should be derived from test data, specific to the packing geometry.

Fig. 6 shows values of measured mass transfer coefficient k, plotted against the ratio of water flow rate to air flow rate (L/G) for existing packings. The values of k for corrugated packing were 1.5 to 2.5 times higher than comparable smooth packing k values when the water to air ratio was 1.0. The k values for rough and smooth corrugated packings decreased with the increase in pitch, and had a maximum value when P/D = 1.5 and the ratio of distance between repeated ribs to height of rib was 4, and the angle, θ, 45°. (Packing C6)

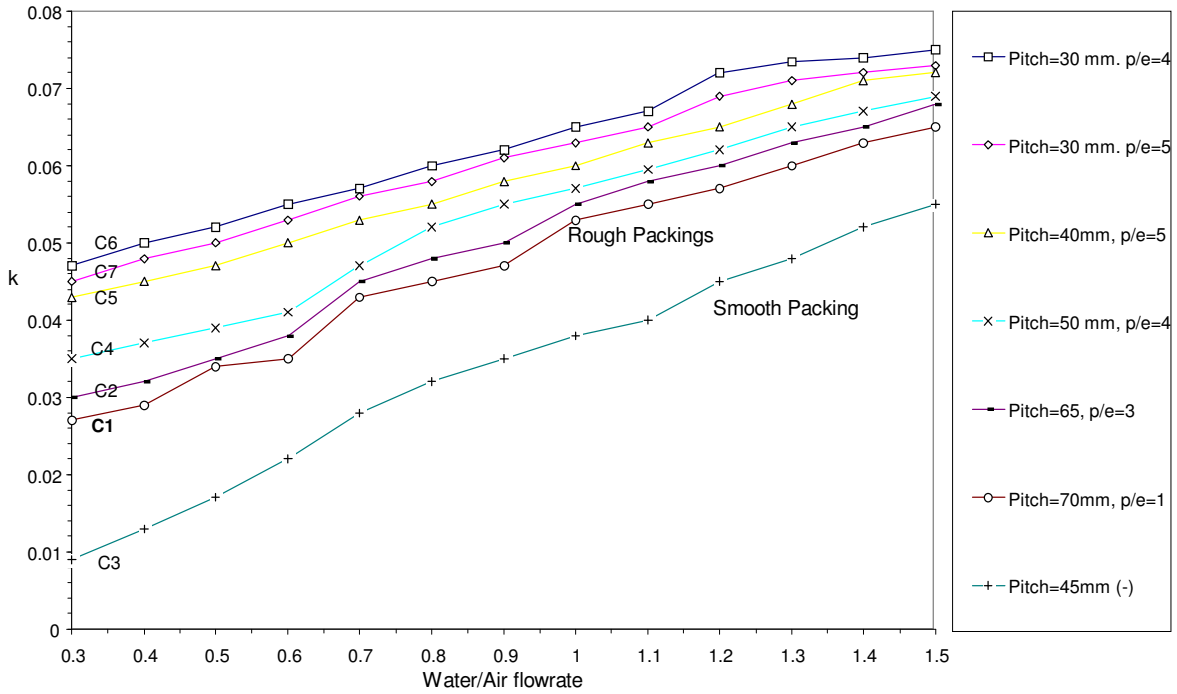

Fig. 6 Heat transfer characteristic of packing with different spacing and surface roughness.

As it can be seen from Fig. 6, k increases with

(i) decrease of the spacing between the sheets, all other parameters being constant.
(ii) increase in the value of L', for G' = constant.
(iii) increase in the ratio of the pitch of the corrugation to the of the spacing. P/D should be of the order of 1.5 and p/e should be of the order 5 to have maximum heat transfer.
(iv) decrease of the ratio of distance between repeated ribs and height of the rib.
(v) decrease in θ.

It can see that mass transfer increases with the decrease in spacing, but higher mass transfer in packing C6 compared with C7 and C5 is likely to be due mainly to the difference in the effect of the packing wall roughness[factors (iv and v) above].

The volumetric overall mass transfer coefficient based on enthalpy difference, which expresses the thermodynamic performance of a cooling tower, changes not only with the mass flow rate of air and water and temperature conditions but also with the dimensions, shape and arrangement of the cooling tower packing. Since the air and water flow in a cooling tower is complicated, the relationships between k, G and L have been found only by individual experiments for each cooling tower.
The resultant correlation k of the Nos 1 to 7 was determined from these experiments with the

most susceptible to error of ±4% by;

$$\mathbf{k = c_1 (L')^{0.45} (G')^{0.6}} \qquad \mathbf{(1)}$$

c_1 is an experimental constant. The constant for type No. 3, (smooth surface), is 1.20 while for type Nos 1, 2, 4, 5, 6, 7 the constant is 1.75, 1.83, 190, 1.98, 2.20, 2.10 respectively. Using the smooth sample, No 3 as reference, the relative increases due to ribbing were, for No. 1 = 1.45, for No. 2 = 1.52, for No. 4 = 1.58, for No. 5 = 1.65, for No. 6 = 1.83, and for No. 7 = 1.75 respectively.
Convective heat transfer data are usually correlated by an equation of the Dittus Boelter type; (Grigule 1969)

$$\mathbf{Nu_w = A\, Re_w^{\,m}\, Pr_w^{\,n}} \qquad \mathbf{(2)}$$

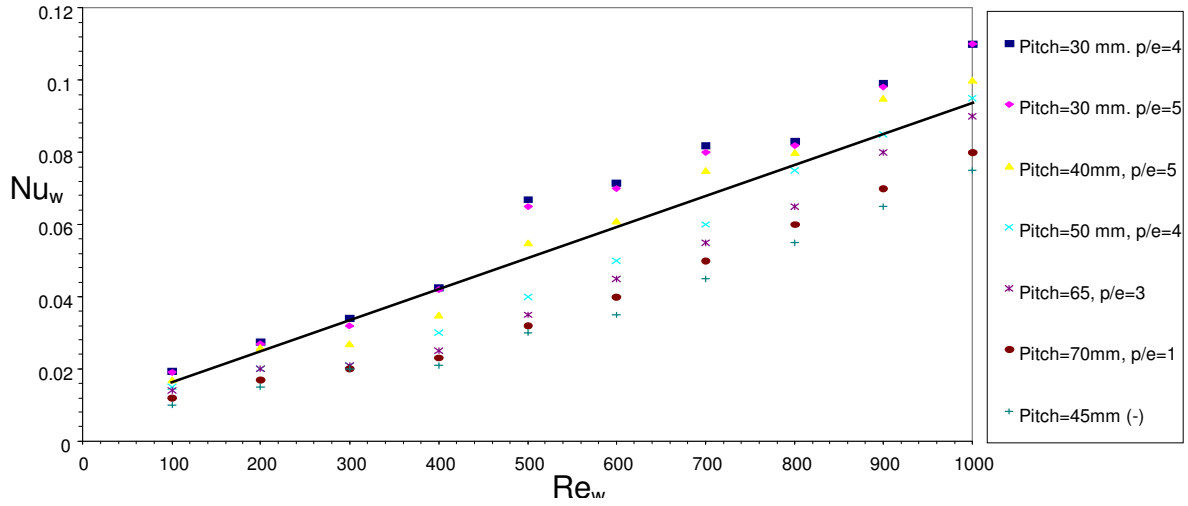

Fig. 7 Correlation of liquid phase heat transfer data.

The value of Nu_w can be evaluated based on empirical correlations found in the literature. In this paper, the value of Nu_w is evaluated using the Dittus - Boelter equation.(Bernier 1995)
Thereafter the dimensionless correlation of data is shown in Fig. 7, where a solid line gives approximations to Nu_w.

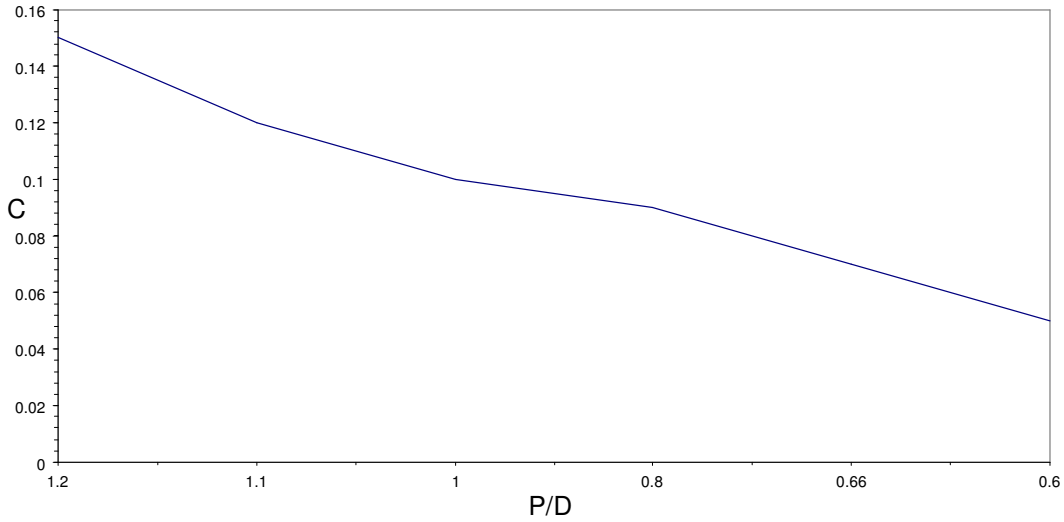

Fig. 8 Plots of C against the ratio of pitch to diameter.

From Fig.7 and 8 packing heat transfer coefficients were finally expressed as follows;

$$\mathbf{Nu_w = C\,(P/D)^{-0.15}\,Re_w^{0.8}\,Pr_w^{0.4}} \qquad \mathbf{(3)}$$

The constant C is a function of surface roughness and varies with ratio of distance between repeated ribs and height of roughness element.

Pressure drop characteristics

Another aspect of the investigation of the performance of packings concerned pressure drop characteristics.
As it can be seen from Fig. 9 ΔP increases with
(i) decrease in spacing between the sheets when all the other parameters being constant.
(ii) increase in L', for G' = constant.
(iii) increase of the ratio of distance between repeated ribs and height of rib.
(iv) decrease in θ.
The resultant of pressure drop for the packing No. 1 to No.7 is expressed with the most susceptible to error of ±3% by;

$$\mathbf{\Delta P = c_2\,(L')^{0.35}\,(G')^{0.55}} \qquad \mathbf{(4)}$$

c_2 is an experimental constant. The constant for type No. 3 having a smooth surface is 17.7 while those for types Nos. 1, 2, 4, 5, 6, 7, are 20.5, 22.6, 25.6, 27.8, 30.7, 32.5, 35.2, respectively.
The result in figure 9 shows that the pressure drop of packing C7 is about 70% higher than that of C1. This difference appears to be caused by difference in the height of the corrugations and the different surface created by the ribs.
The only exception is for C6 of the present investigation (spacing of 20 mm). The pressure drop is lower by about 15% than the pressure drop for the C7 (spacing of 20mm). This difference can be attributed to the difference of the turbulent flow condition caused by the wall roughness of the packing created by the lower distance between the plates.

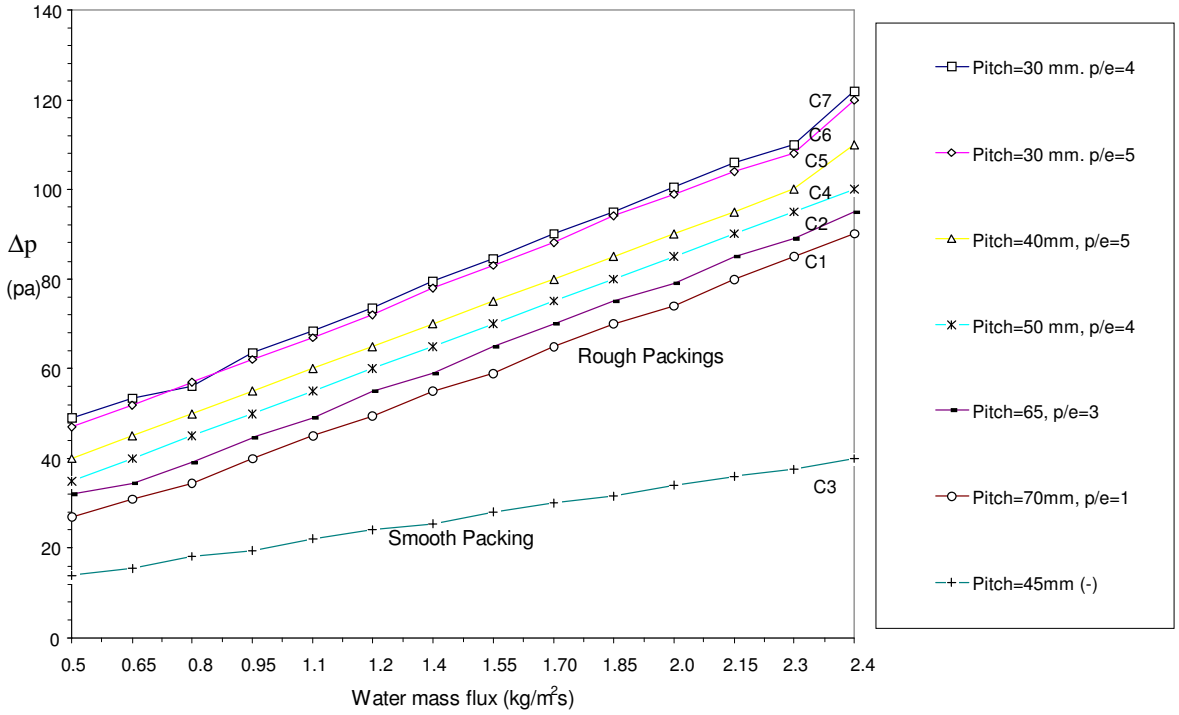

Fig. 9 Pressure drop characteristic with different spacing and surface roughness.

Friction factor f was derived using the following equation (Tezuka 1980)

$$f = \frac{1}{4}\,\frac{D}{Z}\,\frac{\Delta P}{\rho_a \left(\frac{u_a + u_w}{2}\right)^2} \qquad (5)$$

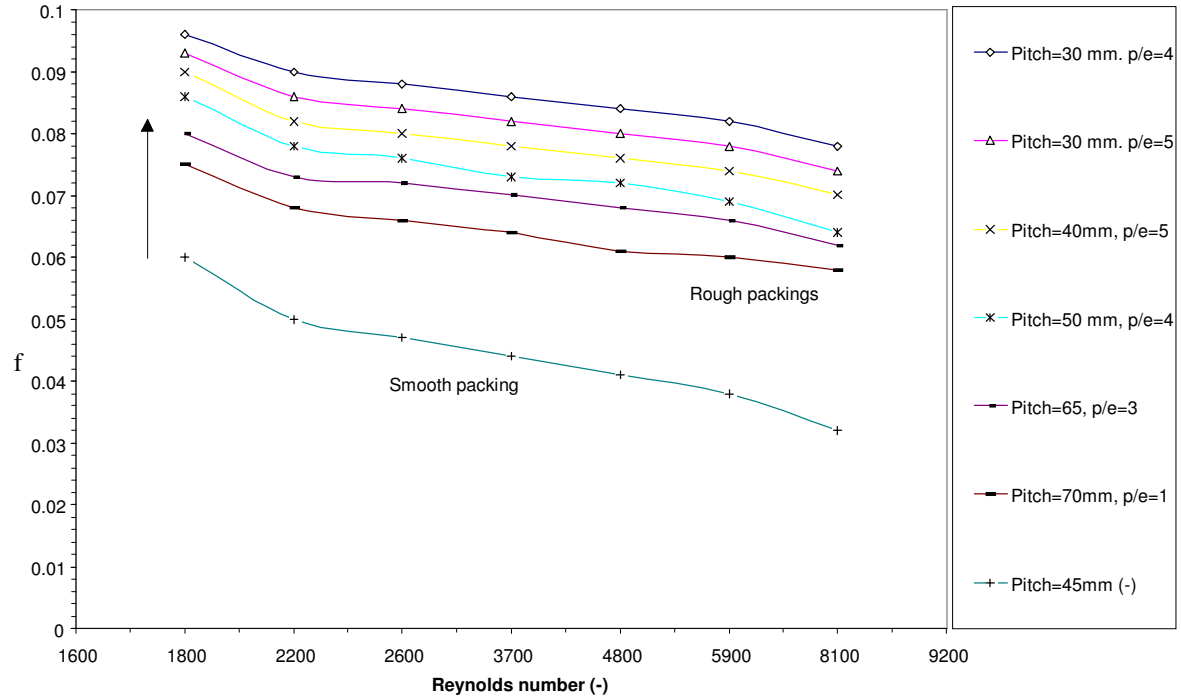

Fig. 10 Typical friction factor

Fig. 10 shows typical plots of friction factor f against the Reynolds Number Re. As it can seen from the graph, the friction factor of corrugated packing was affected by pitch, depth and also surface roughness.
The friction factor curve for packing C3 investigated in the present test, lies below the curves for packing C1 to C7. This can be expected because the height of the corrugation and the condition of the surface are dominating, the mean overall height of corrugations for packing C3 is 2.0 cm.

Therefore friction factors f was expressed by the following equation for the smooth packing;

$$f_{smooth} = C_f (P/D)^m \qquad (6)$$

And friction factor for the rough packings were expressed by the following equation;

$$f_{rough} = C_f (P/D)^m (p/e)^n \qquad (7)$$

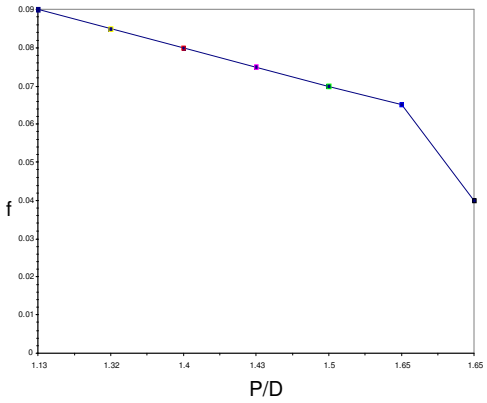

Fig. 11 Friction factor against P/D

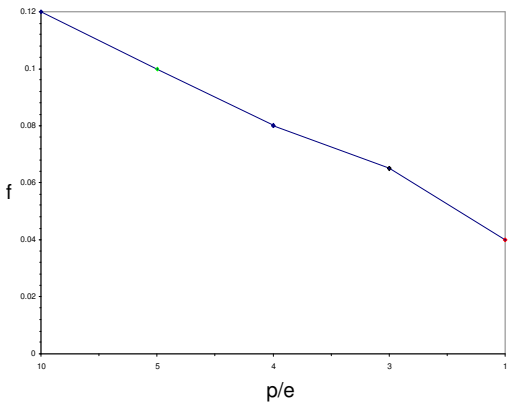

Fig. 12 Friction Factor against p/e

Fig 11 and 12 show plots of friction factor of packing against P/D and p/e respectively. From these figures the exponents m and n were obtained and friction factors of smooth and rough packings were expressed by the following equations;

$$f_{smooth} = C_f (P/D)^{-1.32} \qquad (8)$$

&

$$f_{rough} = C_f (P/D)^{-1.52} (p/e)^{-0.94} \qquad (9)$$

As an example, if m = -1.52 and n = -0.94, $C_f = 1.48$ is obtained for P = 30mm and D = 35 mm.

Discussion

When a fluid flows through a channel containing a solid system, various resistances to fluid flow (or friction factors) occur, according to the shape of the solid system. The conditions, which result in high friction factors, produce strong eddies in the fluid and thereby increase the rate at which heat may be transmitted from the fluid to the solid system. In other words, the friction and heat transfer properties of the system are correlated, so that it is generally impossible to achieve high heat transfer properties with low friction factor.

In relatively wide packings, the fluid stream is almost completely separated from the walls, and a large proportion of the packing is filled with recirculating fluid. (e.g. Packing C1)

In relatively narrow, corrugated packings flow separation takes place near the ridge of every corrugation, and flow re-attachment takes place upstream of the next ridge in the flow directions. The troughs of the corrugations are partly filled with re-circulating fluid. It was found that a packing of particular interest was the packing C6, which has a vertical main corrugation with the cross ribbing making an angle of 45°. Flow separation enhances the turbulence of the flow (compared with corresponding flow between smooth, straight wall) and thereby increases mass transfer rate and pressure drop. (e.g. Packing C6)

A packing with high turbulence in combination with a relatively low fluid velocity is more economic than a fairly smooth and straight packing in combination with a high fluid velocity. The results showed that mass transfer performance of the corrugated packing is increased by up to 1.5 to 2.5 times compared to the smooth packing, C3. In order to have the maximum mass transfer, the ratio of the pitch to spacing of the corrugation, P/D should be of the order of 1.36 to 1.50.

In this study packing mass transfer coefficients, k, of corrugated packings were expressed by Eq. (1). It was found that, for the effect of pitch on the Nusselt number, the value C was approximated to by $(P/D)^{-0.15}$. In fact the value C decreased with increase in P/D. Eq (3).

Finally, in order to compare the mass transfer performance of smooth packing with that of rough corrugated packing, the packing mass transfer coefficient (k) was correlated to pressure drop per unit length (ΔP/L) from experimental results (see Fig 13). It was found that at a given pressure drop, the maximum mass transfer coefficient for the corrugated packing can be obtained when $\frac{P}{D}$ = 1.5 and $\frac{p}{e}$ = 4 with an angle of 45° to the horizontal. For all corrugated packings, (ΔP/L) and k were correlated by the following equation;

$$\mathbf{k \propto (\Delta P/L)^{0.41}} \qquad \mathbf{(10)}$$

It has been found that mass transfer coefficients of rough corrugated packing are in proportion to the pressure drop raised to the power 0.41. This value of 0.41 is smaller than the value for smooth packing, 0.46.

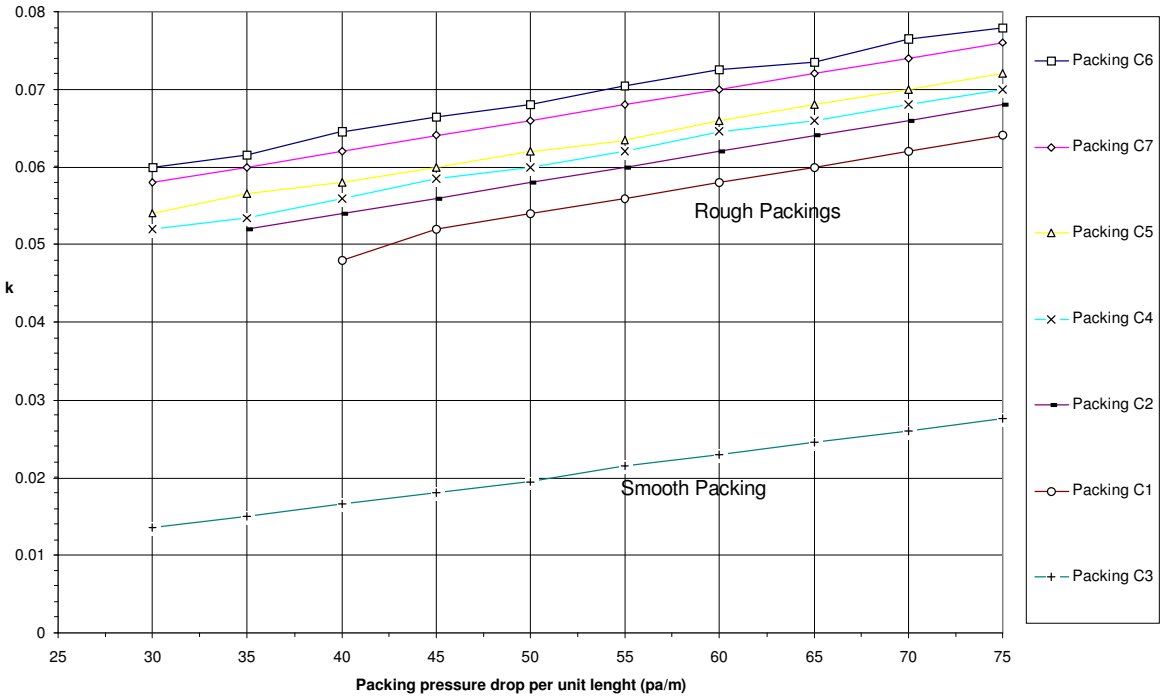

Fig. 13 Relation between packing mass transfer and pressure drop per unit length

Conclusions

Experiments were conducted to investigate the effect of the spacing and surface roughness on the mass transfer and pressure drop in PVC packing for which no comprehensive investigations had previously been reported. The experiments were carried out for comparative types of packing in a counterflow cooling tower. From the experimental results and discussion on the performance characteristic of seven vertical parallel packings arrangement in forced draft counterflow cooling tower the following conclusions may be drawn;

(1) Overall mass transfer coefficients and pressure drops of ribbed corrugated packings increase considerably compared with smooth packing and are affected by spacing of the packing and the distance between the ribs.

(2) It was found that the shape and configuration of the roughness projections are as important as the height of those projections in determining their effect on Fanning friction factor and mass transfer coefficient. It was found that a packing of particular interest was the packing C6 , which had maximum mass transfer value at P/D = 1.5 and the ratio 4 for the ratio of distance between repeated ribs to height of rib with the cross ribbing making an angle of 45°.

(3) Packing mass transfer coefficients vary in proportion to $(P/D)^{-0.15}$ and C the value decreased with increase in P/D.

(4) Friction factors of corrugated packings vary in proportion to $(P/D)^{-0.94}$ and $(p/e)^{-1.52}$.

(5) Mass transfer coefficients of corrugated packing vary in proportion to the 0.41 power of pressure drop per unit height. This value of 0.41 is smaller than smooth packing value 0.46.

ABSTRACT

The potential to liberate steam production capacity for power generation has been assessed using actual energy consumption data and the recorded seasonal consumption fluctuations for a kraft pulp mill. The revenues from power production are compared with possible energy savings, achieved through enhancement of the process efficiency using an absorption heat pump (AHP). Bunker oil, wood bark and black liquor, the fuels used, have very different costs and heating values. The net present value was used with a simple pay back time for the comparison of three cases, i) power production from liberated steam capacity using a cogeneration unit, ii) maximized energy savings using an AHP and iii) power production combined with heat upgrading and cold production using a trigeneration unit. The results show economic viability of all options investigated. The stand alone AHP achieves the shortest simple pay back time, whereas the trigeneration option reaches the highest net present value and therefore the best overall economics.
Keywords: absorption, heat pump, cogeneration, trigeneration, green power, heat recovery, pinch analysis, greenhouse gas emissions, kraft pulping, economic assessment.

INTRODUCTION

The pulp and paper industry is very energy intensive. Major advances have been made in the last two decades towards lower energy costs in the Canadian pulp and paper industry. However, enhanced energy efficiency measures implemented in pulp and paper mills have been mostly limited to low-investment, high-return projects, except for the revamping and up-grading of boilers [1]. Advanced engineering techniques, such as pinch analysis® [2], are now routinely used and with success to maximise internal heat recovery [3-4]. Process integration combining several approaches such as water system closure, production of power by cogeneration and heat exchange networks optimisation has paved the way for new and

[1] Corresponding author: Phone: +1 514 3404711
Fax +1 514 3405795 E-mail andrea.costa@polymtl.ca

innovative solutions [5-7]. These efforts have been induced by steadily increasing energy prices and the drive for energy savings on a large scale in the framework of the Kyoto protocol. It is becoming evident that low-investment measures will not suffice to meet these more ambitious goals. The perspective for future action is changing.

This work considers a new promising approach which combines waste heat upgrading and power production. Waste heat upgrading with simultaneous cooling of the waste heat stream can be achieved by absorption heat pumps (AHP) [8]; power production can be achieved by cogeneration. The coupling of both technologies is usually referred to as trigeneration [9]. The objective of the work was to perform a preliminary economic assessment of the retrofit implementation of AHP-based trigeneration in the pulp and paper industry.

The energy consumption pattern is studied and three cases are compared: a cogeneration unit, a stand-alone absorption heat pump and a trigeneration unit. The energy savings and CO_2 emission reduction are compared. The economics of the options are analysed in terms of simple pay back time and present net value to assess both the investment risk and the overall return on the retrofit installation of the required equipment.

THE PULP MILL

A kraft pulp mill can be seen for the purpose of this work as an energy producing facility delivering steam from different energy carriers. These are bunker oil, bark (a waste product of the lumber industry) which is bought by other industries as a low cost biomass fuel and black liquor (a by-product of the chemical digesting process which transforms wood chips into pulp). Black liquor is burned in specially designed recovery boilers after having been concentrated. Bark is burned in separate furnaces with an overall efficiency of about 67%. Oil is burned in conventional back-up boilers with about 80 % efficiency to cover steam demand fluctuations. An exhaustive description of the kraft process is given in [10]. Figure 1 shows the high pressure steam demand and the relative consumption of the two purchased fuels (oil and bark) for the year 2003 in an actual Canadian mill. Figure 1 clearly shows that whereas steam production and bark consumption are relatively constant throughout the year, the oil consumption varies by a factor of

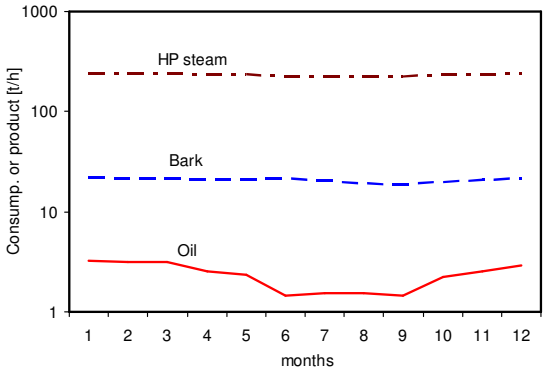

Figure 1: Yearly consumption patterns of purchased fuels and steam production.

nearly 2 between summer and winter periods. This is related to process independent parameters like temperature of make-up water and of ambient air. The yearly mill operational time has been divided in three equal periods – winter, summer and intermediate seasons – in order to analyse the technical and economic impacts of turbine and heat pumps under representative conditions. In the reference mill high pressure (HP) steam is produced at 3034 kPa (3160 kJ/kg). Roughly 20 % of it is used directly, 20 % is throttled down to medium pressure (MP) at 965 kPa (2779 kJ/kg) and 50 % to low pressure (LP) at 345 kPa (2743 kJ/kg).

ASSUMPTIONS

It was assumed that in all cases analysed the process had already been pre-optimised from the stand point of internal recovery using a state-of-the-art engineering approach. Based on previous experience in the P&P industry it has been assumed that this optimisation would achieve 5 % energy savings with a simple return on investment of 1 year [11]. This cost-efficient pre-optimization reduces the size of the new equipment to be installed and increases the economic profitability of the process changes. The energy savings cannot be entirely achieved through reduced consumption of bunker oil, which is always needed to ensure efficient combustion in the boilers. Therefore a ratio of 80/20 for the oil/bark savings was assumed. Moreover, a minimal hourly oil consumption of 25 GJ was set as baseline for the same reasons. Furthermore, the savings were assumed to be made on MP and LP steam, as this is more likely to be achieved with heat exchanger network optimization than HP steam savings.

These measures have been set as a baseline in all options analysed.

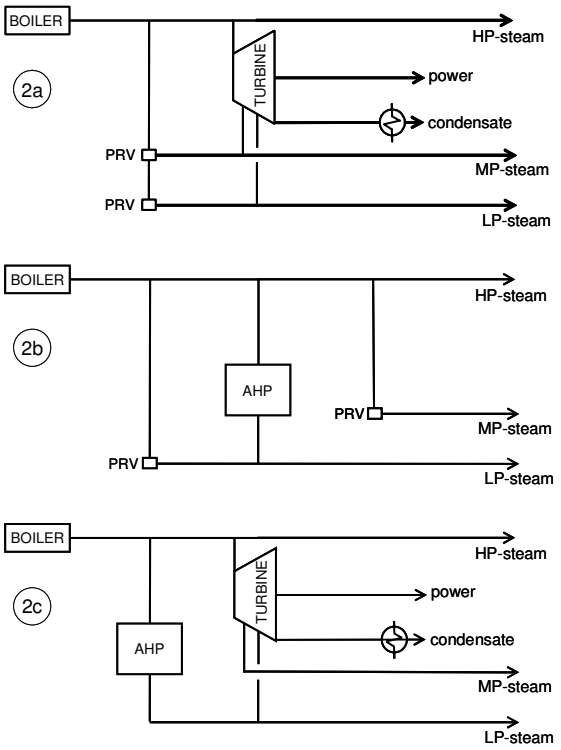

Figure 2: Schematic of the three options. 2a) Extraction and condensing turbine. 2b) Stand alone absorption heat pump. 2c) Combined turbine and heat pump.

THE THREE OPTIONS

Three options have been envisaged to enhance the process thermal efficiency beyond the maximum achievable by internal heat recovery. Two of them aim at liberating steam from the process allowing its use in a condensation turbine for power production. The third option targets a maximal reduction of the energy consumption without power production, for comparison.

Option I: cogeneration

This option consists of a steam turbine and a condensing unit installed as shown on figure 2a. The retrofit implementation of cogeneration in pulp and paper mills is not new, though not yet common practice in Canada. The turbine is normally fed by HP steam and delivers MP and LP steam (extraction operation mode) or condensate (condensing mode). Pressure retention valves (PRV) are situated on parallel lines balancing the steam production to follow demand fluctuations. The efficiencies were realistically set at 10 % for extraction and 30 % for condensation; condensation increases the turbine output considerably and consequently the power production. However, this operation is only economically feasible when steam is produced by bark combustion, assuming a mean bark price of 0.60 CAN$/GJ and a market price of 50 $/MWh for the power sold. In contrast, oil with an average price of 8 $/GJ would require a resale price of at least 120 $/MWh to be profitable (assuming efficiencies of 80 % for the burner and 30 % for the turbine) [11]. For these reasons a two-step strategy was considered in which the oil consumption is first minimised and subsequently surplus bark is burned for power production in a condensing turbine.

Option II: absorption heat pump

In this second option an absorption heat pump driven by heat from the HP steam delivers LP steam (figure 2b) [8]. Depending on the process temperatures a single effect cycle using water/lithium-bromide or ammonia/water as working pairs could be implemented. The coefficient of performance (COP) for heating would be between 1.4 and 1.8 [12]; a COP of 1.7 was used. It must be noted that a single heat pump would probably not be a practicable solution because of the very large capacity required to meet the needs of the whole process; smaller heat pumps distributed in the process are a more realistic option. However, in the context of a preliminary assessment without the benefit of detailed process data, this hypothetical case can provide a reliable benchmark. Since the steam pressure levels do not change between manifold and process, the thermodynamic properties and consequently the economic results of peripheral devices would not change, compared to a centrally installed device. It must be noted that the heat pump also delivers a cooling capacity that in this case is released at 80 to 90 °C. This could find advantageous uses in the process. Cooling possibilities were not taken into account in this work. The operation of the heat pump has been computed as a function of the percentage of the total LP steam required by the process which is supplied by the heat pump. For example, 40 %

heat pump coverage means that 40 % of the LP steam load is delivered by the heat pump output, while the remaining 60 % is supplied by PRV-depressurised steam. The threshold for profitability is given by the heat pump capacity leading to maximum oil savings. Beyond that point, savings of bark would not justify the high equipment investment.

Option III: trigeneration

The third option is the combination of a steam turbine and an absorption heat pump in parallel, as shown in figure 2c. The turbine delivers, by extraction, the total MP steam load and the fraction of LP steam not produced by the heat pump. The condensing mode is assumed. The parallel arrangement chosen reduces the HP steam available for the turbine; therefore, the load of the turbine is decreased while the heat pump capacity is increased. This drawback could be avoided by installing the heat pump in series with the turbine on the MP steam line. In this manner all the HP steam would become available for the turbine. However, the driving force for the heat pump would be lower and require the use of a double lift instead of a single effect cycle. The increased power output of the turbine would not compensate for the increased cost and lower efficiency of a double lift device. Therefore this last arrangement is not advantageous for this application; however, it could be under other steam pressure conditions.

ANALYSIS

The oil and bark savings exceeding the heat recovery benchmark were estimated for the three periods of the year defined earlier. The results are shown for the three strategies in table 1. It must be noted that savings of 5 % of the total steam

consumption through internal heat recovery, used in the computations constitute the threshold for an even yearly distribution of the oil savings. However, higher heat recovery savings would result in increased bark savings in the summer months, which in turn could be converted in higher condensing capacity and higher turbine output in the summer months. Thus, this should be targeted especially to old mills with high savings potential by heat exchanger network optimisation.

Option II has been analysed for six different heat pump coverage capacities of the LP steam demand ranging from 0 to 100 %. The results are shown in figure 3. The full lines represent winter, the dotted lines intermediate and the dashed lines summer operation. Since the periods of the year significantly affect oil consumption, the impact of the heat pump varies broadly with the seasons (figure 3a). The oil savings reach a plateau between 0 and 40 % of heat pump coverage, while bark savings on the contrary start to increase at that point. Whereas in the winter oil savings would steadily increase up to a heat pump output of about 40 MW (40 %), in the intermediate seasons they would stop growing at a heat pump coverage of 20 %. In summertime the heat pump contribution to oil savings would be almost zero. The implementation of heat pump capacities higher than 40 MW would result in wood bark savings, which have no energetic or economic advantage.

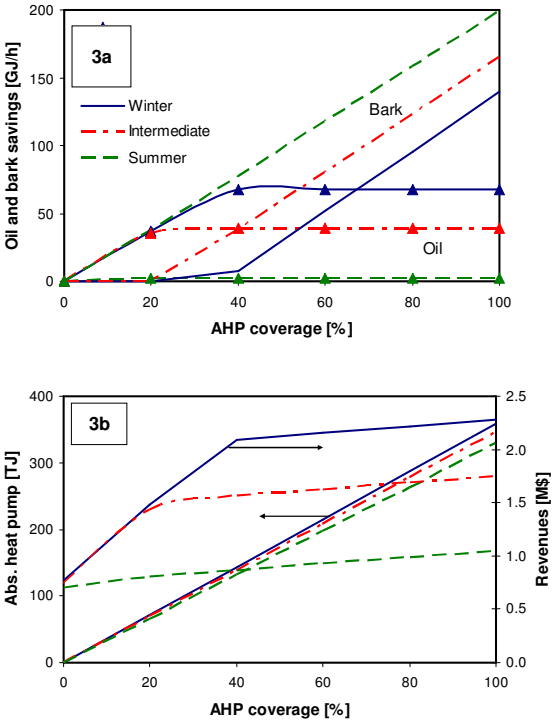

Figure 3. Effects of heat pump coverage. 3a) Oil (triangles) and bark savings. 3b) Heat pump savings and revenues.

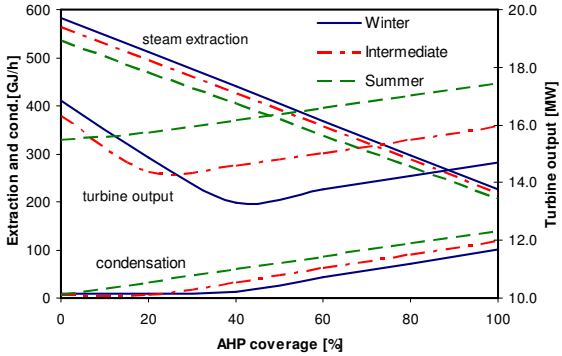

Figure 4: Extraction, condensing mode and turbine output.

Figure 3b shows how absorption heat pump savings increase steadily with increasing heat pump coverage whereas the revenues come to a plateau for high capacities. The CO_2 emission reductions which are dependant of oil consumption also do not increase proportionally to the size of the heat pump. The contribution of the heat pump could become substantial in summer if a seasonal application is found, for example for process or building cooling where electrical chillers or other equipment could be replaced. However, this application would require equipment capable of switching from heating to cooling modes.

The third option, trigeneration, is the combination of the two previous ones. Two main effects characterize this system: the trend of the oil savings and the performance of the turbine with increasing heat pump capacities. Increased process efficiency due to heat pump use lowers the oil consumption down to the baseline as in the first option. This affects the turbine operation in two ways: as oil is increasingly saved, the input to the boilers steadily decreases and so does the turbine output. Figure 4 shows the trends for the three periods. At the point where steam from bark is no longer needed in the process, thus becoming available for condensation, the net output of the turbine starts to increase steadily, despite the continuously decreasing output in the extraction

mode. This is especially pronounced in winter with a threshold for 40 % of heat pump coverage. Accordingly, a heat pump of about 40 MW (40 %) achieves the highest oil savings possible as shown in Table 1 (67 GJ/h, 39 GJ/h and 3 GJ/h in winter, intermediate and summer, respectively). On the other hand with this heat pump coverage the turbine is being operated at part load in winter compared to summer conditions (13.3 MW vs. 16.2 MW). Hence, 20 % heat pump coverage is probably the best economic choice, since the oil savings are still 50 % of the maximum achievable in winter (37 GJ/h out of 67 GJ/h) and they reach 100 % during intermediate seasons and summer, while the turbine utilisation ratio (14.4 MW vs. 15.7 MW) is more even than at 40 % coverage.

ECONOMIC COMPARISON

Two indicators of economic performance have been used, the simple payback time (SPB) and the net present value (NPV). It must be noted that this study considered only the incremental cost of the system. Therefore the investment only consists of the retrofit cost of internal heat recovery measures, a new heat pump and a turbine. Revenues are the sold power and the oil saved, even if oil savings are in reality expenses not incurred rather than received revenue. For the purpose of this work, the installed capacities of the equipment were determined for maximum impact on energy consumption and CO_2 emissions achievable in the course of a year. Accordingly, these equipments operate at partial load during important periods. An economic optimised design would be based on minimal required capacities, which could not be determined with the data available.

Simple payback time

The economic calculation was performed on the basis of the yearly revenues during the aggregate of the three seasonal periods. The results are summarised in Table 2 and presented graphically on figure 5. All financial information is given in Canadian dollars. The oil savings achieved by heat

recovery pre-optimisation are evenly distributed and account for M$ 0.7 per season. The cogeneration option is characterised by an even utilisation of the turbine throughout the year with average revenue of M$ 2 per period. The total revenues add up to 8.1 M$/a. The total investment for the optimisation of the heat exchanger network and the installation of a new turbine (1000 $/kW) amounts to M$ 19.1. The simple payback time is 2.4 years.

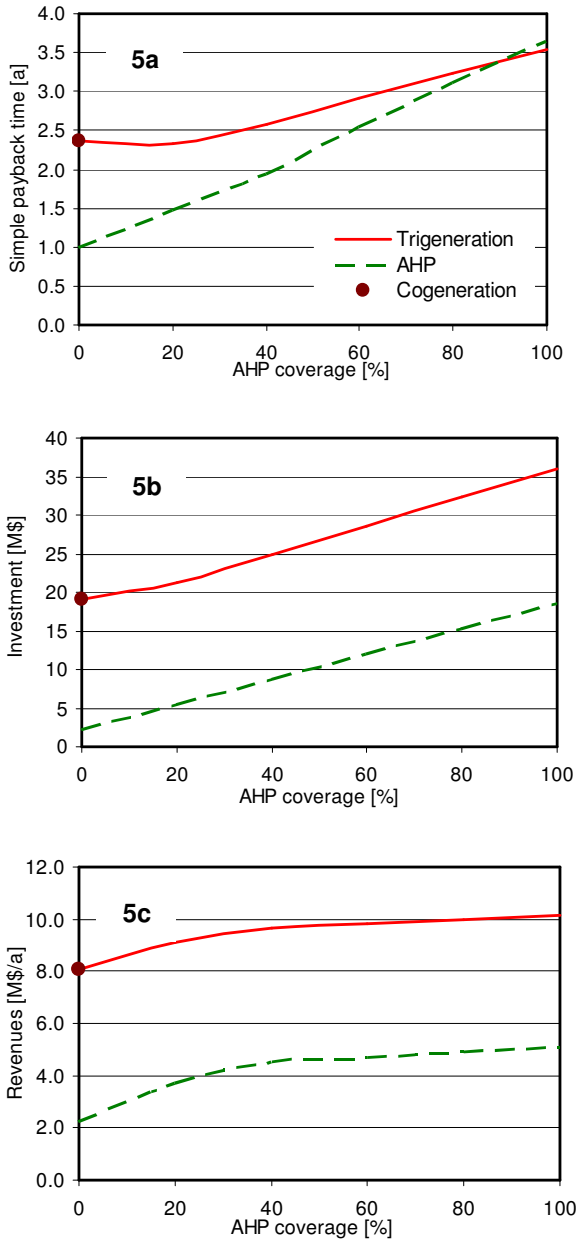

Figure 5: Profitability of three options as a function of the AHP coverage. a) Simple pay back time. b) Investment. c) Revenues.

The heat pump option has a less even pattern, especially for high coverage percentages. From 40 % coverage upwards the summer revenues become less than half that for the rest of the year (Table 2). Moreover, at high coverage the revenues do not increase proportionally to the investment necessary for the heat pump (165 $/kW heating) producing higher pay back times. Since the CO_2 emission reductions do not decrease either over 40 % coverage, the threshold for both economic viability and maximum environmental benefits is between 20 % and 40 % coverage.

Finally, the trigeneration option shows opposite trends for heat pump and turbine, which lead to a plateau of the SPB between 0 % and 40 % coverage. This is caused by the increasing revenues from oil savings which largely offset the loss in power produced, both in winter and intermediate season (Table 2). After 40 % heat pump coverage the increase in total revenues is very flat and does not compensate for the steady increase of the heat pump cost, with a resulting linear growth of the SPB.

Net present value

For this analysis an operational time of 20 years has been set for all equipment. An internal yearly interest rate of 7 %, which is usual for energy projects, and a yearly escalation rate of 4 % for fuel and power prices have been used [13]. The stand alone heat pump and trigeneration options were first analysed to determine the optimum percentage of heat pump coverage. The results are presented on figure 6. There is a maximum at 40 % coverage because of the non-linear relationship between revenue and investment. This value was used in the subsequent comparative analysis. Figure 6b shows the evolution of the NPV over 20 years. The abscissa shows the time elapsed from the date of investment. The cut through $0-value shows the time required by the projects to become cost-effective. The initial investment for the heat pump option has a clear advantage. Nevertheless the systems with high yearly outputs perform best in long-term comparison, even if the initial investment is higher. After 4 to 5 years the co- and tri-generation options become more advantageous than the stand alone heat pump. Trigeneration has 16 % higher initial revenue than cogeneration (M$ 9.7 against M$ 8.1) for a comparable investment burden

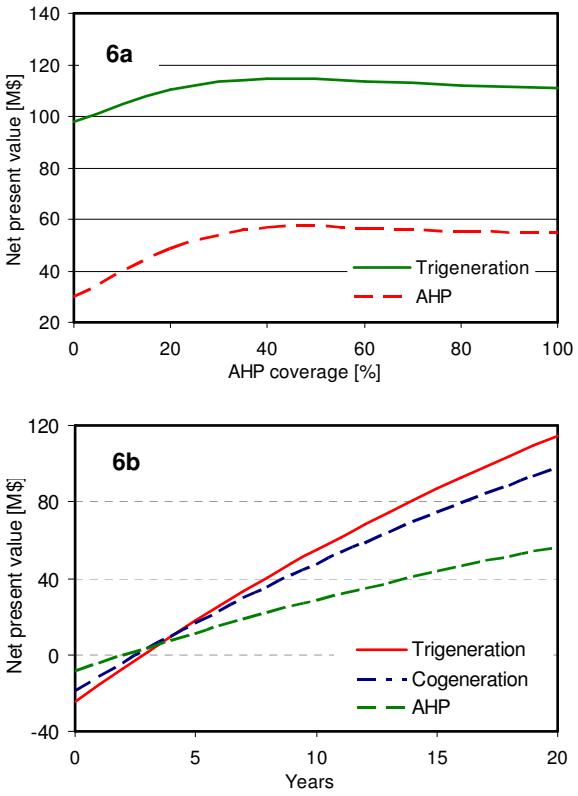

Figure 6: Net present value. a) Optimum NPV as function of AHP coverage. b) Overall NPV evolution.

(M$ 24.9 against M$ 19.1). This explains its better performance in the long term.

CONCLUSION

The energetic and economic incremental impacts of the retrofit implementation of three technological options, cogeneration, absorption heat pump and, trigeneration, have been analysed. The simple pay back time and the net present value of the options have been calculated. The results show an economic viability for all options investigated. Their simple pay back time ranges between 1 year for a single heat pump and 2.5 years for a trigeneration system including a heat pump covering 40 % of the low-pressure steam demand in the process. Moreover, the net present value is in all cases positive, which indicates that the equipment is viable. The options with high yearly revenues coming from power sales show the highest net present values, between M$ 100 and M$ 120. This supports the feasibility of the envisaged technologies.

ABSTRACT

Energy carriers needed for chemical technologies are produced in a network of mutually connected energy processes. Some part of these connections is of feedback character. A change in the balance of one energy carrier affects the production processes in all the other energy carriers. Hence, it becomes necessary to apply the system approach in the energy, exergy and ecological analysis of the energy management of a chemical plant. The mathematical model of the energy management of a chemical plant is based on the *input-output analysis*. Besides already known applications of the mathematical model in the system analysis of the balances of direct energy consumption, algorithms have been suggested for the calculation of the indices of cumulative energy consumption and the cumulative emission of noxious substances. This paper presents merely the fundamentals of methodology. An example of its application in nitrogen plant is foreseen to be presented at the next ECOS'06.
Keywords: energy management, system analysis, mathematical modeling, input-output analysis

NOMENCLATURE

$a_{ij,}\ \overline{a_{ik}}$ - coefficients of the direct consumption of energy carriers concerning energy processes and chemical processes, respectively,

$\hat{a}_{kl}$ - coefficient of the direct consumption of technological product or raw material in the technological subsystem,

$\mathbf{A},\ \overline{\mathbf{A}}$ - matrices of the coefficients of the direct consumption of energy carriers concerning the energy and technological subsystem, respectively,

$\hat{\mathbf{A}}$ - matrix of the coefficients of the direct consumption of technological semiproducts and raw materials,

$D_{ij,}\ \overline{D_k}$ - external supplies of energy carriers and technological raw materials or semiproducts,

* Corresponding author: Phone +48 32 237 16 61 Fax: +48 32 237 28 72 E-mail: ziebik@itc.polsl.pl

$\mathbf{D}, \overline{\mathbf{D}}$ - vectors of external supplies of energy carriers and technological raw materials or semiproducts, respectively,

e_i^* - index of cumulative energy consumption,

$\mathbf{e}^*$ - vector of indices of cumulative energy consumption,

$\mathbf{E}$ - unit matrix,

$f_{ij,} \overline{f_{ik}}$ - coefficients of the by-production of energy carriers in energy processes and chemical processes, respectively,

$\mathbf{F}, \overline{\mathbf{F}}$ - matrices of the coefficients of the by-production of energy carriers concerning energy and technological subsystem, respectively,

$\mathbf{G}$ - peak part of the main production of energy carriers in the case of the existence of a peak and basic installation; otherwise global main production of energy carriers,

$K_i, \overline{K_k}$ - sale of energy carrier and chemical products, respectively,

$\mathbf{K}, \overline{\mathbf{K}}$ - vectors of sale of energy carriers and chemical products, respectively,

P_i - basic part of the main production of energy carrier,

$\mathbf{P}$ - vector of the basic part of the main production of energy carriers,

Y_{ij}, Y_{ik} - consumption of energy carriers for general needs concerning energy and technological processes, respectively,

$\mathbf{Y}$ - matrix of general needs of energy carriers,

$\varepsilon_{si}, \varepsilon_{sk}$ - index of direct harmful emission concerning an energy process and chemical process, respectively,

$\boldsymbol{\varepsilon}_s$ - matrix of indices of direct harmful emissions,

ε_{si}^* - index of cumulative harmful emissions,

$\boldsymbol{\varepsilon}_s^*$ - matrix of indices of cumulative harmful emissions.

Subscripts and superscripts

d - diagonal matrix,

D - external supply,

E - energy carrier,

F - by-product,

G - peak part of the main production,

GD - external supply and peak part of production,

GG - peak part of production and peak installation,

i,j - current number of the energy carrier (energy branch),

k,l - current number of the chemical product (technological branch),

m - number of energy carriers,

n - number of energy carriers produced in chemical plant,

P - basic part of main production,

PD - external supply and basic part of production,

PP - basic part of production and basic installation,

p - number of chemical (technological) products,

r - number of chemical products and raw materials,

R - raw materials,

s - harmful emission of s-th kind,

T - transpose of a matrix,

t - technological (chemical) product.

1. SYSTEM APPROACH TO THE ENERGY ANALYSIS OF A CHEMICAL PLANT

System production of a chemical plant can be divided into two subsystems: the technological subsystem – a set of chemical processes (chemical branches) and the energy subsystem (energy management – a set of energy processes). The production of energy carriers is intended, first of all, to cover the needs of the chemical processes and partially also to cover the own consumption in the energy subsystem. Some part of the energy carrier production can be sold to external consumers (e.g. heat for district heating). The complex of connections between energy and chemical processes, as well as the interdependences between the energy processes cause that the energy management of a chemical plant is a system defined as a set of energy processes and internal relations between them and the external relations between energy management and the environment. Due to these relations the energy management of a chemical plant, treated as a complex, has attributes which its respective parts

(the particular energy processes considered separately) do not possess [1,2].
No energy process operates separately but is an element of a comprehensive energy system. The production and consumption of energy carriers take place within the network of interconnected energy processes. Therefore, both the direct consumption of energy carriers in the investigated process and the indirect consumption occurring in other processes must be analysed if we want to know the overall consumption of primary energy burdening the production of final energy carrier in a chemical plant. The same concerns the final chemical products which are also formed within the network of interconnected chemical processes.

Thus, energy is consumed not only in the last stage of production, but also in the preceding stages. Therefore the total energy consumption must be taken into consideration. In both cases, energy carriers and chemical products, the energy analysis should be based on system approach [4,5,6]. A convenient mathematical tool proved in this case to be *input-output analysis* [3].

2. LINEAR MATHEMATICAL MODEL OF THE ENERGY MANAGEMENT OF A CHEMICAL PLANT

The set of equations resulting from the balances of energy carriers is a mathematical model of the energy management of a chemical plant. This model comprises a network of interdependences existing in a real chemical plant between the technological and energy subsystems and inner relations between the respective energy processes. The algorithm of this model is a development of the *input-output analysis* applied to the energy management of a chemical plant [7,8]. In this method of analysis the production system is divided into branches (chemical and energy processes), and the set of balance equations is treated as a whole.

The chemical or energy process existing in the considered plant (e.g. nitrogen plant) is characterized by the production of one main product, as well as an optional number of by-products. If there are more than one source of the energy carrier produced as the main product, the production must be divided into its basic part and peak part (e.g. process steam from the co-generation system and steam from the pressure reducing valve). In some cases the own production of energy carriers must be supplemented by external supply (e.g. electricity). Some energy carriers are only provided from outside (mainly fuels). If a given energy carrier is the main product in one process and the by-product in another, it should be considered as a whole in one balance equation. Sometimes a part of the production of energy carriers is sold to external consumers (e.g. municipal district heating). Table 1 presents a set of equations of energy balance in compliance with "input-output analysis".

Table 1 " Input – output" balance table of energy carriers

Input part

Energy carrier	Main production		By-production		External supply
	Peak part	Basic part	Energy subsystem	Technological subsystem	
1	...	...	...	...	...
...					
i	G_i	P_i	$\sum_{j=1}^{n}(f_{ij}^{G}G_j + f_{ij}^{P}P_j)$	$\sum_{k=1}^{p}\overline{f}_{ik}\overline{G_k}$	D_{Gi}
...					
n	...	...	...	...	...
n+1	...	...	...	...	...
...					
i	*0*	*0*	*0*	*0*	D_{Di}
...					
m	...	...	...	...	...

Output part

Energy carrier	Interbranch flows		General needs	Sale
	Energy subsystem	Technological subsystem		
1	...	...	...	...
...				
i	$\sum_{j=1}^{n}(a_{ij}^{G}G_j + a_{ij}^{P}P_j)$	$\sum_{k=1}^{p}\overline{a}_{ik}^{G}\ \overline{G_k}$	$\sum_{j=1}^{n}\left(Y_{ij}^{GD} + Y_{ij}^{PD}\right) + \sum_{k=1}^{p}\overline{Y}_{ik}^{G}$	K_i
...				
n	...	...	...	...
n+1	...	...	...	...
...				
i	$\sum_{j=1}^{n}(a_{ij}^{GD}G_j + a_{ij}^{PD}P_j)$	$\sum_{k=1}^{p}\overline{a}_{ik}^{D}\ \overline{G_k}$	$\sum_{j=1}^{n}\left(Y_{ij}^{GD} + Y_{ij}^{PD}\right) + \sum_{k=1}^{p}\overline{Y}_{ik}^{D}$	*0*
...				
m	...	...	...	...

First part of equations concern energy carriers produced in chemical plant *(i,j=1, ..., n).* Second part deals with energy carriers supplied only from outside *(i =n+1, ..., m).*

Subset of balance equations concerning energy carriers produced in the energy subsystem of a chemical plant is as follows:

$$\mathbf{G} + \mathbf{P} + \mathbf{F}_{\mathbf{G}}\mathbf{G} + \mathbf{F}_{\mathbf{P}}\mathbf{P} + \overline{\mathbf{F}}\,\overline{\mathbf{G}} + \mathbf{D}_{\mathbf{G}} = \mathbf{A}_{\mathbf{GG}}\mathbf{G} + \mathbf{A}_{\mathbf{PP}}\mathbf{P} + \overline{\mathbf{A}}_{\mathbf{G}}\mathbf{G} + \mathbf{Y}_{\mathbf{GG}} + \mathbf{Y}_{\mathbf{PP}} + \overline{\mathbf{Y}}_{\mathbf{G}} + \mathbf{K} \qquad (1)$$

where the additional indices G or P denote submatrices concerning the by-production and consumption of energy carriers produced in the energy subsystem of chemical plant.

Equation (1 is usually employed to compute the elements of the vector **G**:

$$\mathbf{G} = \left(\mathbf{E} - \mathbf{A}_{\mathbf{GG}} + \mathbf{F}_{\mathbf{G}}\right)^{-1}\left[\left(\mathbf{A}_{\mathbf{PP}} - \mathbf{F}_{\mathbf{P}} - \mathbf{E}\right)\mathbf{P} + \left(\overline{\mathbf{A}}_{\mathbf{G}} - \overline{\mathbf{F}}\right)\overline{\mathbf{G}} + \mathbf{Y}_{\mathbf{GG}} + \mathbf{Y}_{\mathbf{PP}} + \overline{\mathbf{Y}_{\mathbf{G}}} + \mathbf{K} - \mathbf{D}_{\mathbf{G}}\right] \qquad (2)$$

The inverse matrix facilitates calculations particularly in the case of feedback character connections. Relation (2 is supplemented by a subset of balance equations concerning energy carriers only supplied from outside (mainly fuels):

$$\mathbf{D}_{\mathbf{D}} = \mathbf{A}_{\mathbf{GD}}\mathbf{G} + \mathbf{A}_{\mathbf{PD}}\mathbf{P} + \overline{\mathbf{A}}_{\mathbf{D}}\,\overline{\mathbf{G}} + \mathbf{Y}_{\mathbf{GD}} + \mathbf{Y}_{\mathbf{PD}} + \overline{\mathbf{Y}_{\mathbf{D}}} \qquad (3)$$

where the index D denotes submatrices concerning the consumption of energy carriers only brought from outside.

Eqs. (2) and (3) describe the simulation mathematical model of the energy management of a chemical plant. As input data there are given first of all: $\mathbf{A}_{\mathbf{G}}, \mathbf{A}_{\mathbf{P}}, \mathbf{F}_{\mathbf{G}}, \mathbf{F}_{\mathbf{P}}, \overline{\mathbf{A}}, \overline{\mathbf{F}}, \mathbf{Y}, \overline{\mathbf{G}}$. In the simulation model the vectors $\mathbf{P}, \mathbf{D}$ and $\mathbf{K}$ are given a priori, too. In the case of an optimization model these vectors are treated as decision values [8]. Yet, the presented model can be used only to analyse the direct energy consumption.

3. MATHEMATICAL MODEL OF CUMULATIVE ENERGY CONSUMPTION

The analysis of direct energy consumption is not a sufficient tool for the evaluation of the energy utilization effectiveness, because the consumption of energy in previous production and transportation processes leading to a given final energy carrier is not included. The same remark can refer to products of chemical processes. It is not enough to analyse only the direct consumption of energy, but

more important is the analysis both the direct and indirect energy consumption, that means cumulative energy consumption.

In order to determine the relation describing the indices of cumulative energy consumption, the balances of cumulative energy consumption were applied according to the balance equations of a linear mathematical model of the energy management of the chemical plant. In general, an energy carrier may be produced as the main product (basic and peak production) or be by-product of the energy or technological subsystem. It can also be an energy carrier from outside (external supply). Therefore the average index of cumulative energy consumption concerning the given i-th energy carrier ought to be taken into account:

$$e_{Ei}^{*} = \frac{G_i e_{Gi}^{*} + P_i e_{Pi}^{*} + F_i e_{Fi}^{*} + D_i e_{Di}^{*}}{G_i + P_i + F_i + D_i} \tag{4}$$

and

$$F_i = \sum_{j=1}^{n} \left(f_{ij}^{G} G_j + f_{ij}^{P} P_j \right) + \sum_{k=1}^{p} \overline{f}_{ik} \overline{G}_k \tag{5}$$

Vector $\mathbf{e}_{\mathbf{E}}^{*}$ of the average indices of cumulative energy consumption takes the following form:

$$\mathbf{e}_{\mathbf{E}}^{*} = \mathbf{H}^{-1} \left(\mathbf{G}^{\mathbf{d}} \mathbf{e}_{\mathbf{G}}^{*} + \mathbf{P}^{\mathbf{d}} \mathbf{e}_{\mathbf{P}}^{*} + \mathbf{L}^{\mathbf{d}} \mathbf{e}_{\mathbf{F}}^{*} + \mathbf{D}^{\mathbf{d}} \mathbf{e}_{\mathbf{D}}^{*} \right) \tag{6}$$

and

$$\mathbf{L} = \mathbf{F}_{\mathbf{G}} \mathbf{G} + \mathbf{F}_{\mathbf{P}} \mathbf{P} + \overline{\mathbf{F}}\,\overline{\mathbf{G}} \tag{7}$$

$$\mathbf{H} = \mathbf{G}^{\mathbf{d}} + \mathbf{P}^{\mathbf{d}} + \mathbf{L}^{\mathbf{d}} + \mathbf{D}^{\mathbf{d}} \tag{8}$$

where the index **d** denotes the diagonal matrix after the transformation column vector.

The indices of cumulative energy cunsumption e_{Gi}^{*} and e_{Pi}^{*} are determined basing on the cumulative energy balances. Fig. 1 presents a calculation scheme concerning the j-th energy branch in the general case when the basic and the peak part of main production are taken into account. Basing on this scheme the balance equations of the cumulative energy consumption can be set up for the peak part and basis part of the main production.

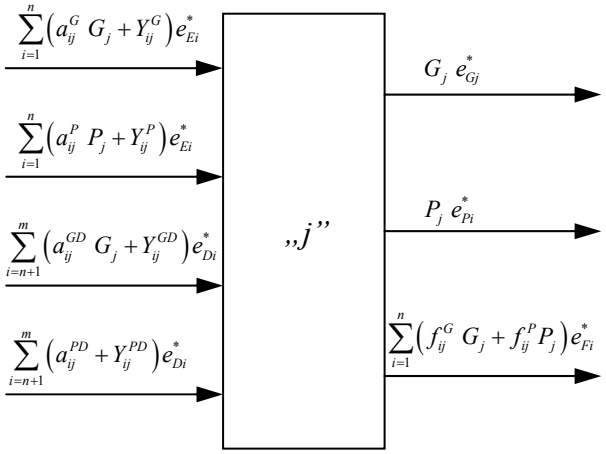

Fig. 1. Calculation scheme of cumulative energy balance of energy branch

$$\left[\mathbf{A}_{\mathbf{G}}^{\mathbf{T}} + \left(\mathbf{G}^{\mathbf{d}} \right)^{-1} \mathbf{Y}_{\mathbf{GG}}^{\mathbf{T}} \right] \mathbf{e}_{\mathbf{E}}^{*} + \left[\mathbf{A}_{\mathbf{GD}}^{\mathbf{T}} + \left(\mathbf{G}^{\mathbf{d}} \right)^{-1} \mathbf{Y}_{\mathbf{GD}}^{\mathbf{T}} \right] \mathbf{e}_{\mathbf{D}}^{*} = \mathbf{e}_{\mathbf{G}}^{*} + \mathbf{F}_{\mathbf{G}}^{\mathbf{T}} \mathbf{e}_{\mathbf{F}}^{*} \tag{9}$$

$$\left[\mathbf{A}_{\mathbf{P}}^{\mathbf{T}} + \left(\mathbf{P}^{\mathbf{d}} \right)^{-1} \mathbf{Y}_{\mathbf{P}}^{\mathbf{T}} \right] \mathbf{e}_{\mathbf{E}}^{*} + \left[\mathbf{A}_{\mathbf{PD}}^{\mathbf{T}} + \left(\mathbf{G}^{\mathbf{d}} \right)^{-1} \mathbf{Y}_{\mathbf{PD}}^{\mathbf{T}} \right] \mathbf{e}_{\mathbf{D}}^{*} = \mathbf{e}_{\mathbf{P}}^{*} + \mathbf{F}_{\mathbf{P}}^{\mathbf{T}} \mathbf{e}_{\mathbf{F}}^{*} \tag{10}$$

In the Eqs. (9) and (10) the vector of indices of cumulative energy consumption burdening the energy carriers supplied from outside $\mathbf{e}_{\mathbf{D}}^{*}$ is given a priori. These are average values of the indices of cumulative energy consumption concerning mainly fuels. The aforesaid equations contain also the vector $\mathbf{e}_{\mathbf{F}}^{*}$ concerning the indices of cumulative energy consumption burdening the by-products. Apparently it is an additional set of unknown values. In such a case, however, the principle of avoided energy expenditures should be applied (similarly as the principle of avoided costs). This means, that the by-products should be burdened by such a cumulative energy consumption as in the case of the specialistic (single-aimed) process which is substituted by the by-production of energy carrier [6]. For instance, in the heat and power co-generation process the electricity (by-product) should be assigned by the index of

cumulative energy consumption like in the power plants.

4. MATRIX METHOD OF CALCULATING THE INDICES OF CUMULATIVE ENERGY CONSUMPTION OF CHEMICAL PRODUCTS

From the point of view of investigating the energy consumption in chemical processes the system method of calculating the indices of cumulative energy consumption is still more interesting than previous application concerning energy carriers They are determined similarly as presented before basing on the set equations of the balances of cumulative energy consumption. The balance of technological subsystem can be also described by means of the *input-output table*. The balance equations concerning k-th technological products and technological raw material or semi-products have the following form:

$$\overline{G}_k = \sum_{l=1}^{p} \hat{a}_{kl}^{G}\, \overline{G}_k + \overline{K}_k \tag{11}$$

$$\overline{D}_k = \sum_{l=1}^{p} \hat{a}_{kl}^{D}\, \overline{G}_K \tag{12}$$

The set of balance equations of technological products, as well as raw materials and semiproducts in matrix notation have the following forms:

$$\overline{\mathbf{G}} = \hat{\mathbf{A}}_{\mathbf{G}}\overline{\mathbf{G}} + \overline{\mathbf{K}} \tag{13}$$

or

$$\overline{\mathbf{G}} = \left(\mathbf{E} - \hat{\mathbf{A}}_{\mathbf{G}}\right)^{-1}\overline{\mathbf{K}} \tag{14}$$

and

$$\overline{\mathbf{D}} = \hat{\mathbf{A}}_{\mathbf{D}}\overline{\mathbf{G}} \tag{15}$$

Fig. 2 presents a calculation scheme concerning the k-th chemical process (technological branch). Basing on this scheme a balance equation of the cumulated energy consumption can be set up.

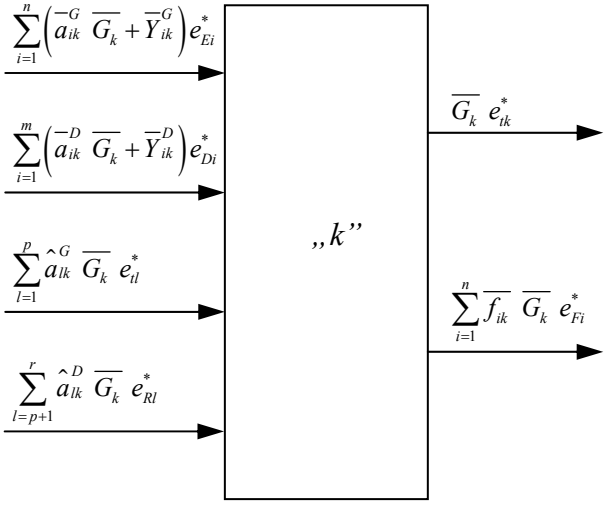

Fig. 2. Calculation scheme of cumulative energy balance of chemical process

The set of equations of the cumulative energy balance concerning the technological subsystem takes the following form:

$$\left[\overline{\mathbf{A}}_G^T + \left(\overline{\mathbf{G}}^d\right)^{-1}\mathbf{Y}_G^T\right]\mathbf{e}_E^* + \left[\overline{\mathbf{A}}_D^T + \left(\overline{\mathbf{G}}^d\right)^{-1}\overline{\mathbf{Y}}_D^T\right]\mathbf{e}_D^* + \hat{\mathbf{A}}_G^T\,\mathbf{e}_t^* + \hat{\mathbf{A}}_D^T\,\mathbf{e}_R^* = \mathbf{e}_t^* + \overline{\mathbf{F}}^T\,\mathbf{e}_F^* \tag{16}$$

In the algorithm of calculating the indices of cumulative energy consumption burdening the chemical products the input data comprise column vector $\overline{\mathbf{e}}_{\mathbf{R}}^{*}$ determining the average indices of cumulative energy consumption burdening chemical raw materials and semiproducts, as well as the previously determined vector $\mathbf{e}_{\mathbf{E}}^{*}$ (described in the previous chapter). Similarly as in chapter 3 the vector $\mathbf{e}_{\mathbf{F}}^{*}$ is determined basing on the principle of avoided energy expenditures.

5. SYSTEM ANALYSIS OF ECOLOGICAL INDICES

The production of energy carriers and chemical products is accompanied by the emission of noxious gaseous, liquid and solid substances, as well as surplus heat passed into the environment. The direct consumption of energy carriers (mainly fuels), as well as raw materials and technological semiproducts leads to the direct emission related to the production of the given carrier or chemical

product. The energy carriers, raw materials and technological semiproducts are, however, already burdened with harmful emissions resulting from earlier production and transporting processes. Similarly as in the case of the analysis of cumulative energy consumption this is the result of the production energy carriers and chemical products within the interconnected processes. The ecological burden of energy carriers or chemical products do not depend on the direct noxious emissions but on the global emission including also the indirect negative ecological effects occurring in previous stages of the network of energy and chemical processes. Thus, similarly as in the case of cumulative energy consumption we must take into account the indices of the cumulative harmful emissions burdening the production of energy carriers and chemical products.

In the case of energy carriers we must apply the average emission for the i-th energy carrier, because it can be obtain in basic or peak installations and can also be a by-product and external supply. Analogically to eg. (4) we can express the average index of cumulative harmful emissions concerning the i-th energy carrier as follows;

$$\varepsilon^*_{sEi} = \frac{G_i \varepsilon^*_{sGi} + P_i \varepsilon^*_{sPi} + F_i \varepsilon^*_{stui} + D_i \varepsilon^*_{sDi}}{G_i + P_i + F_i + D_i} \tag{17}$$

Similarly as in the case of cumulative energy consumption the vector $\boldsymbol{\varepsilon}^*_{\mathbf{sE}}$ of the average indices of cumulative harmful emissions takes the following form:

$$\boldsymbol{\varepsilon}^*_{\mathbf{sE}} = \mathbf{H}^{-1}\left(\mathbf{G}^{\mathbf{d}}\boldsymbol{\varepsilon}^*_{s\mathbf{G}} + \mathbf{P}^{\mathbf{d}}\boldsymbol{\varepsilon}^*_{s\mathbf{P}} + \mathbf{L}^{\mathbf{d}}\boldsymbol{\varepsilon}^*_{s\mathbf{F}} + \mathbf{D}^{\mathbf{d}}\boldsymbol{\varepsilon}^*_{s\mathbf{D}}\right) \tag{18}$$

The indices of the cumulative emission $\boldsymbol{\varepsilon}^*_{\mathbf{sGi}}$ and $\boldsymbol{\varepsilon}^*_{\mathbf{sPi}}$ are determined basing on the cumulative balance of emissions. Fig. 3 presents a calculation scheme concerning the j-th energy branch. Basing on this scheme we can express the set of balance equations used to calculate the indices of the s0th cumulative emission burdening the production of energy carriers:

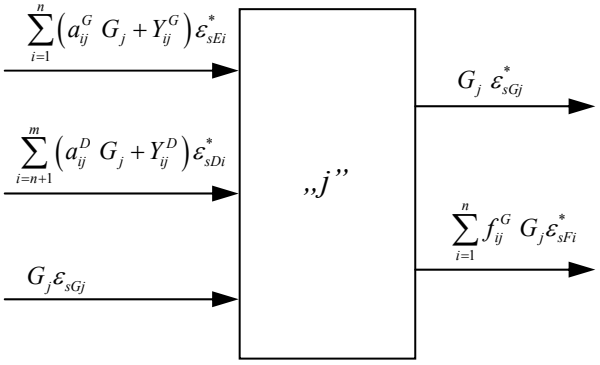

Fig. 3. Calculation scheme of cumulative emission of energy process

$$\left[\mathbf{A}_{\mathbf{G}}^{\mathbf{T}} + \left(\mathbf{G}^{\mathbf{d}}\right)^{-1}\mathbf{Y}_{\mathbf{G}}^{\mathbf{T}}\right]\boldsymbol{\varepsilon}^*_{\mathbf{sE}} + \left[\mathbf{A}_{\mathbf{GD}}^{\mathbf{T}} + \left(\mathbf{G}^{\mathbf{d}}\right)^{-1}\mathbf{Y}_{\mathbf{GD}}^{\mathbf{T}}\right]\boldsymbol{\varepsilon}^*_{\mathbf{sD}} + \boldsymbol{\varepsilon}_{\mathbf{sG}} = \boldsymbol{\varepsilon}^*_{\mathbf{sG}} + \mathbf{F}_{\mathbf{G}}^{\mathbf{T}}\boldsymbol{\varepsilon}^*_{\mathbf{sF}} \tag{19}$$

In Eq. 19 the unknown value is the vector $\boldsymbol{\varepsilon}^*_{\mathbf{sG}}$ of the cumulative emission burdening the peak part of the main production of energy carriers. The vector $\boldsymbol{\varepsilon}^*_{\mathbf{sE}}$ of the average emission of the s-th noxiouses substance being determined by means of Eq. (10). The analogical equation as (19) we can write in the case of basic part of main production of energy carriers. The input data (known a priori) are the vectors $\boldsymbol{\varepsilon}^*_{\mathbf{sD}}$ and $\boldsymbol{\varepsilon}_{\mathbf{sG}}$, the former of which denotes the indices of cumulative s-th harmful emission burdening the supply of energy carriers from outside. The latter one determines the direct s-th harmful emission resulting from the peak part production. The vector $\boldsymbol{\varepsilon}^*_{\mathbf{sF}}$ concerning the cumulative emission burdening the by-production of energy carriers is determined basing on the principle of avoided harmful emissions. That means that the by-product should be burned by such a cumulative harmful emission as in the case of a specialistic process, which is substituted by the by-production of energy carrier.

An analogical approach ought to be applied in calculations of the indices of cumulative harmful emissions concerning chemical products. The scheme of calculations is similar to that presented in Figs. 2 and 3.The set of equations applied in calculations of the indices of cumulative harmful emissions burdening chemical products takes the form:

$$\left[\overline{\mathbf{A}}_{\mathbf{G}}^{\mathbf{T}}+\left(\overline{\mathbf{G}}^{\mathbf{d}}\right)^{-1}\overline{\mathbf{Y}}_{\mathbf{G}}^{\mathbf{T}}\right]\boldsymbol{\varepsilon}_{\mathbf{sE}}^{*}+\left[\overline{\mathbf{A}}_{\mathbf{D}}^{\mathbf{T}}+\left(\overline{\mathbf{G}}^{\mathbf{d}}\right)^{-1}\overline{\mathbf{Y}}_{\mathbf{D}}^{\mathbf{T}}\right]\boldsymbol{\varepsilon}_{\mathbf{sD}}^{*}$$
$$+\widehat{\mathbf{A}}_{\mathbf{G}}^{\mathbf{T}}\,\boldsymbol{\varepsilon}_{\mathbf{st}}^{*}+\widehat{\mathbf{A}}_{\mathbf{D}}^{\mathbf{T}}\,\boldsymbol{\varepsilon}_{\mathbf{sR}}^{*}+\boldsymbol{\varepsilon}_{\mathbf{st}}=\boldsymbol{\varepsilon}_{\mathbf{st}}^{*}+\overline{\mathbf{F}}^{\mathbf{T}}\boldsymbol{\varepsilon}_{\mathbf{sF}}^{*} \qquad (20)$$

In the algorithm of calculating the indices of cumulative harmful emissions burdening the chemical products the input data comprise the vector $\boldsymbol{\varepsilon}_{\mathbf{sR}}^{*}$ determining the average indices of cumulative harmful emissions burdening chemical raw materials and semiproducts, the vector $\boldsymbol{\varepsilon}_{\mathbf{sD}}^{*}$ and the vector $\boldsymbol{\varepsilon}_{\mathbf{st}}$ determining the direct s-th harmful emission resulting from the chemical processes. The vector $\boldsymbol{\varepsilon}_{\mathbf{sE}}^{*}$ is previously determined basing on Eqs. 18 and 19 and vector $\boldsymbol{\varepsilon}_{\mathbf{sF}}^{*}$ results from the principle of avoided harmful emissions.

6. CONCLUSIONS

The system of production in a chemical plant consists of two subsystems, namely the energy and technological one. In the former subsystems energy carriers are produced, mainly for the needs of the technological subsystem. They are produced in networks of mutually connected processes. Some of them are of feedback character, which complicates the reconciliation of the balances of energy carriers by means of the traditional method applying partial balances.

The technological subsystem is also a network of interconnected chemical processes, additionally connected with the energy subsystem. In a modern chemical plant the technological subsystem is not only the consumer of energy carriers but also produces some energy carriers (e.g. steam and hot water from waste-heat boilers, technological fuel gases) by means of waste energy recovery.

Therefore, it is quite obvious that both energy and chemical processes realized in a chemical plant cannot be considered separately from each other because of the relations existing between them. For this reason the system approach is inevitable. In this paper a system approach to the energy management of a chemical plant by means of the *input-output analysis* has been applied.

Basing on the linear mathematical model of energy management in chemical plants algorithms have been suggested to be used in calculations of the indices of cumulative energy consumption, concerning both energy carriers and chemical products. Such a procedure was applied to construct a model for the calculation of the indices of cumulative emissions of harmful substances burdening energy carriers and chemical products.

The models presented in this paper are being implemented in practical calculations in one of the Polish chemical plant. The results of these investigations will be presented at the next ECOS'06.

ABSTRACT

An evaluation was performed on the efficiency and emissions from an engine fuelled with CNG and a mixture of natural gas and hydrogen, respectively. The mixtures of CNG and hydrogen were named HCNG.
Two different mixtures were investigated; pure compressed natural gas (CNG), and 29 vol% H_2 in CNG (named HCNG). For each mixture, four engine speeds were tested under full load conditions, namely 1300 rpm, 1500 rpm, 1800 rpm and 2200 rpm. For each mixture and each engine speed four different excess air ratios (λ [-]) were chosen, in the range of λ= 1.1– 2.0 [-]. It is very important to note that the spark advance chosen for each of the mixtures is a major test parameter in this kind of study where hydrogen is involved, as the flame speed of hydrogen is much higher than the flame speed for CNG. This implies that the spark advance resulting in the maximum break mean effective pressure ($BMEP_{max}$) is closer to top dead centre (TDC) for the HCNG than for the pure CNG. This is taken into consideration in these tests, so the spark advance is optimized for each of the mixtures tested.
The full load curves (P_e=f(Engine speed)) for the two mixtures at different excess air ratio coincide at λ=1.4 [-] and λ=1.6 [-]. When the mixtures are leaned out to λ=1.8 [-] the HCNG gives more power than the equivalent CNG. The explanation for this is that the CNG is approaching the limit where the engine starts to misfire, i.e. it is too close to the limit on the lean side. This is also seen on the emissions of unburned hydrocarbons.
The emissions of total unburned hydrocarbons (in g/kWh) were also measured. From the plots of HC emissions as a function of lambda, one may see that at a certain excess air ratio, the emissions of unburned hydrocarbons start to increase considerably. This indicates that the lean limit is approached. The lean limit for the pure CNG tested in this engine is approximately λ=1.8[-], and the lean limit for the HCNG is even leaner, i.e. at about λ=2.0 [-]. This is as expected, and in accordance with the literature. It is also important to note that the level of the unburned hydrocarbons emitted at certain excess air ratio are considerably lower for the HCNG than for the pure CNG. On the other hand, comparing the emissions of nitrogen oxides, the HCNG is emitting more than the CNG at the same excess air ratio. This difference is decreasing as the λ increases from 1.4 [-] to 2.0 [-], where the level of NO_x are equal for the two mixtures investigated. However, it is important to note that the NO_x emissions is significantly reduced by increasing the excess air ratio, and by using HCNG this leaning out is easily achieved without any substantial HC penalty.
Considering the total emissions of unburned hydrocarbons and nitrogen oxides, it is easily seen that the positive effect of adding hydrogen to the CNG increases as a function of lambda. The results also indicate that the amount of hydrogen addition to the CNG needs to be varied as a function of engine load, in order to optimise engine efficiency and power.

Key words: Hydrogen, natural gas, SI Engine, emissions, performance.

INTRODUCTION

Global warming and the need for a stable energy market world wide have resulted in an increased focus on hydrogen as an energy source. A transition solution to the use of pure hydrogen may be the use of mixtures of hydrogen and hydrocarbons, based on both the availability and low cost of petroleum supply within the next decades. For comparison, most IC engines running on gasoline operate with a spark advance of approximately 35 degrees BTDC, while a CNG engine would require approximately 50 degrees BTDC. This slower burn rate results in reduced thermal efficiency and poor lean burn characteristics.

The reason for the increasing interest in the use of internal combustion engines operating on alternative gaseous fuels, is mainly the demand for reduced exhaust emissions combined with improvements in efficiency. The lean burn approach with addition of hydrogen offers a number of positive features that makes it attractive. Lean mixtures in general may provide both high thermal efficiency, reduced tendency of knocking, reduced emissions (especially NO_x) and less heat transfer.

On this background, the use of hydrogen as an additive to hydrocarbon fuels is interesting for many reasons, such as extended lean limit. The reactivity and diffusivity of hydrogen are responsible for potential explosions hazards due to either slow leakage or puncturing of the storage tank. In order to reveal the behaviour of CNG-H_2 mixtures, both fundamental and more applied research have been conducted on the combustion characteristics of hydrocarbon-air mixtures with hydrogen addition ([1], [2], [3]).

The addition of hydrogen to methane-air mixtures in SI engines will move the lean limit to leaner mixtures, increasing the combustion speed and the combustion temperatures. An increase in the combustion temperatures may result in increased NO_x emissions compared to pure natural gas (CNG) at the same excess air ratio.

Law and Kwon ([1]) have investigated the substitution of hydrogen with hydrocarbons up to C3 in hydrogen-air flames. Their results indicate that these hydrocarbons are all capable of reducing the temperatures and burning velocities of hydrogen-air flames significantly. A reduction of the flame temperature would most probably lead to a lower NO_x formation rate, although a slower burning rate could promote it. When it comes to knocking, the increased energy density of the fuel could obviate the need for supercharging, which promotes knocking, but the slower burning rate on the other hand favours knocking through auto-ignition.

An optimised combustion chamber design is an important parameter when CNG-hydrogen blends are considered. The reason for this is the fact that hydrogen will have most impact on the combustion process in a “slow” combustion chamber, and the potential for a simultaneous reduction of NO_x and HC is therefore highest for such a combustion chamber geometry.

Karim et al. ([3]) have reviewed the effects of some hydrogen addition to methane on the main combustion characteristics of the fuel for engine applications. Some of the parameters tested were flame propagation rate, optimum spark timing and average combustion duration.

Raman et al. ([4]) performed a comprehensive study on HCNG in lean burn SI engines, using 0, 5, 15 and 30 vol% H_2 on a GM 5.7l, V8 engine. With 15 and 30 vol% H_2 substantial reductions in NO_x with some HC penalty were observed as a result of very lean combustion. Above λ=1.4 [-] the BMEP was increased due to improvements in the lean combustion characteristics.

In the studies reported by Hoekstra et al. ([5] and [6]), experiments were employed with up to 50 vol% H_2 in CNG on a 4.6 l SI V8. Using 20-30 vol% hydrogen, the NO_x emissions were reduced below 0.5 g/kWh, but increasing the H_2 addition above 30 vol% did not result in a further NO_x benefit.

Fotache et al. ([7]) found that the hydrogen has a catalyzing effect in the ignition of hydrocarbons with only a few percent addition of hydrogen by volume.

The objectives of this work are to compare compressed natural gas (CNG) and HCNG under various steady-state conditions in order to supplement the research performed to date (see the reference list).

EXPERIMENTAL SET- UP

Two fuel gas mixtures were investigated in this work, namely Compressed Natural Gas (CNG), (which in this work consisted of about 99,5 vol % CH_4), and a mixture of 29 vol% hydrogen in this CNG/methane (HCNG).

The engine used for the experiments was three-cylinder, single spark plug, 2.7l Zetor Z4901 originally used for stationary applications. It was rebuilt for natural gas use, reducing the compression ratio form 17:1 [-] down to 11:1 [-]. The most important engine data is presented in Table 1.

Engine:	Zetor Z4901 (D)
Displaced volume:	2,7 dm^3
Bore:	102 mm
Stroke:	110 mm
Original compression ratio:	17:1
Compression ratio after rebuilding:	11:1
Power at 2200 rpm:	32,4 kW
Torque at 1500 rpm:	150 Nm
Brake specific fuel consumption BSFC [g/kWh]:	245 +/- 10%

Table 1: Engine data

The test engine was equipped with K-type thermo elements in the intake manifold, in the cooling water system and in the exhaust. A hydraulic water brake was employed in the engine set-up, and a coriolis device measured the mass rate of fuel entering the engine. The spark timing needed to be adjusted manually during the tests, based on MBT (Maximum Brake Torque) timings found in preliminary investigations. The sensitivity in spark timings for the fuels and the engine were studied in the range of 5-25 degrees BTDC.

The control and data logging system for the engine was written using National Instruments program LabView. It is also important to note that the HCNG mixture used in these tests was premixed outside the intake manifold, and not mixed within the manifold. But there is no reason to believe that this layout should be of any significant influence on the results obtained.

In order to design the experimental matrix for comparison of CNG and HCNG, operating values for engine speed, engine load, excess air ratio (λ [-]) and spark timing were chosen. The HCNG calibration included operation at retarded spark timings.

An experimental matrix comprised of these two fuel mixtures (CNG and HCNG), four different engine speeds and five excess air ratios. This test matrix is presented in Table 2.

As a result of practical considerations concerning the engine control system, lower values of air-fuel ratio for the HCNG tests were not performed.

The spark advance chosen for each of the mixtures is a major test parameter in this kind of study where hydrogen is involved, as the flame speed of hydrogen is much higher than the flame speed for CNG. This implies that the spark advance resulting in the maximum break mean effective pressure ($BMEP_{max}$) is closer to top dead centre (TDC) for the HCNG than for the pure CNG. This is taken into consideration in these tests, so the spark advance is optimized for each of the mixtures tested.

The experimental uncertainty in the spark timing is assumed to be about ± 2°.

RESULTS

Brake thermal efficiency is a measure of how much available power that is produced with respect to the chemical input rate. The brake thermal efficiency $\eta_{th,brake}$ is calculated for all the test points in the test matrix, with the efficiency defined as follows:

$\eta_{th,brake}$ = ENGINE POWER/ FUEL ENERGY =

$$= \frac{2p}{60} \frac{n \cdot M}{m \cdot \left(LHV_{H_2} \cdot x_{H_2} + LHV_{CNG} \left(1 - x_{H_2}\right)\right)} \quad (1)$$

Figure 1 shows the brake thermal efficiency versus engine power for tests with constant engine speed. For a given engine power, the brake thermal efficiency $\eta_{th,brake}$ is considerably higher using HCNG than using pure NG. This effect is most pronounced for the highest engine speeds.

In Figure 2 the engine power is plotted as a function of engine speed with each iso-line representing constant excess air ratio. It is important to note that the NG-air blends range from λ=1.1 – 1.8 [-], but the HCNG blends range form λ=1.4 – 2.0 [-] in this test series.

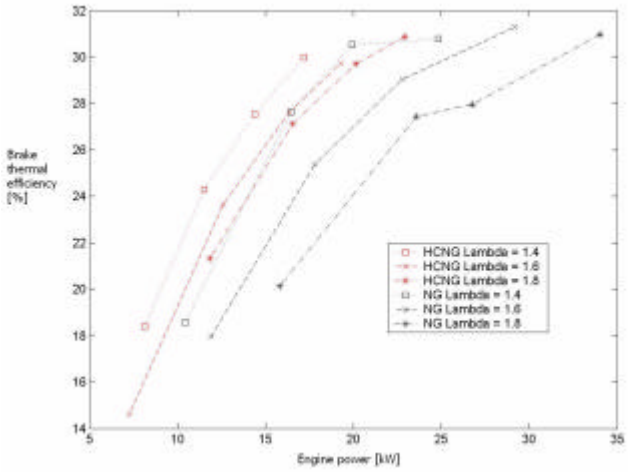

Figure 1: Brake thermal efficiency $\eta_{th,brake}$ as a function of engine power for test points with constant engine speed

Nagalingam et al. ([8]) noted that the power of HCNG compared to CNG was reduced due to the lower heating value of H_2 compared to methane. However, since the flame speed of hydrogen is so much higher than that of CNG, less spark advance is required to produce MBT (Maximum Brake Torque).

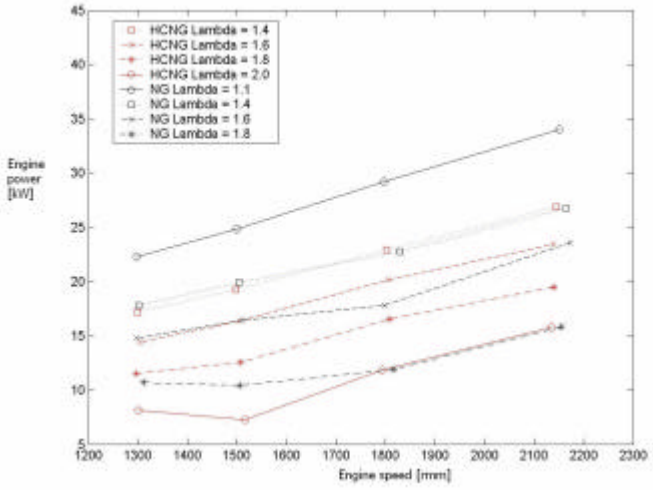

Figure 2: Engine power as a function of engine speed for constant excess air ratios λ [-]

The differences in engine power between CNG and HCNG increases while leaning out the excess air mixture, as expected. The difference is minor for λ=1.4 [-] and λ=1.6 [-], but a further increase in λ to λ=1.8 [-] results in a considerable deviation in the engine power using CNG and HCNG, respectively. This is the same effect that was seen in [9] when the lean limit is approached; that the positive effect of adding hydrogen to the methane-air mixture is most pronounced close to the lean limit.

The engine-out emissions of unburned hydrocarbons HC are plotted in Figure **3** and as a function of excess air ratio λ [-]. In general, the production of unburned hydrocarbons seem to be reduced when adding hydrogen to the CNG for a given excess air ratio. This is in accordance with the literature ([10], [11], [12], [13] and [14]), and the fact that the lean limit for pure methane-air mixtures is much richer then the lean limit for hydrogen-enriched methane-air mixtures. With H_2 addition, a smaller quenching zone results, enabling the flame to propagate closer to the walls, in addition to a reduction in the partial burning in the case of HCNG compared to CNG. For the CNG-air blends, the HC emissions increase considerably when increasing the lambda from 1.6 [-] to 1.8 [-]. On the other hand, the HC emissions form the HCNG blends experience the same trend when leaning out form λ=1.8 [-] to 2.0 [-].

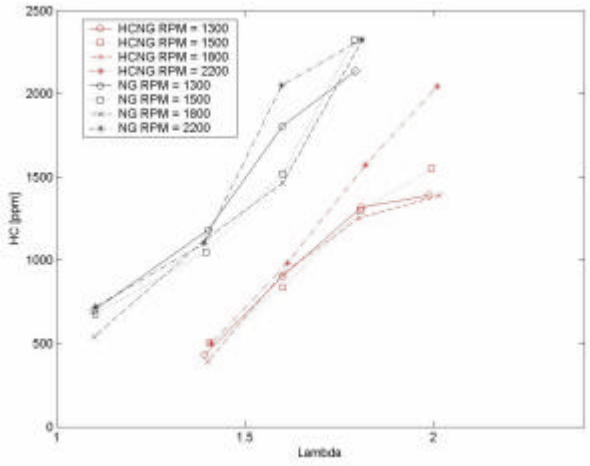

Figure 3: Emissions of unburned hydrocarbons (HC) ([ppm]) versus the excess air ratio λ [-]

In Figure 4 the specific concentrations of HC (g/kWh) for both the NG and the HCNG blends are shown as a function of λ.

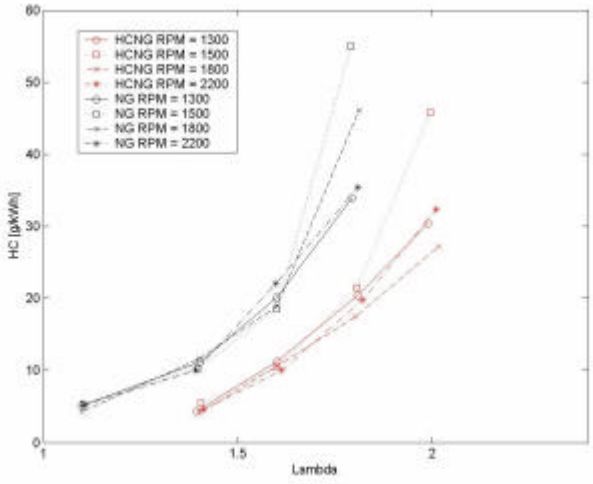

Figure 4: Specific HC emissions [g/kWh] as a function of excess air ratio λ [-]

In Figure 5 and Figure 6 the NO_x concentrations in the engine-out exhaust are shown as a function of the excess air ratio for all the air-fuel blends investigated. The addition of hydrogen to methane-air mixtures will increase the combustion speed

and the combustion temperatures, leading to increased NOx emissions compared to pure natural gas (CNG) at the same excess air ratio. This is as stated in [11], [17], [15], [12], [13] and [14].

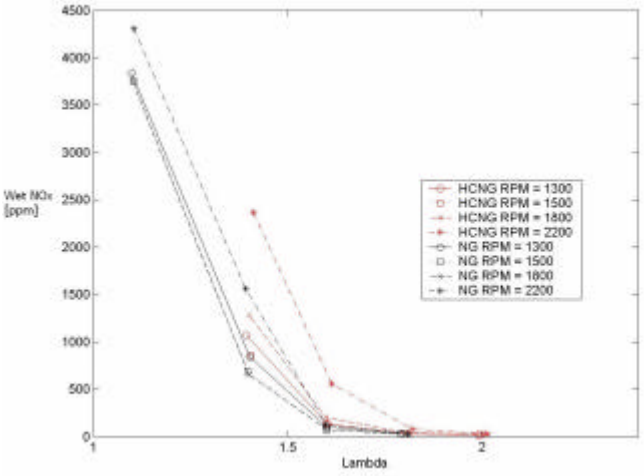

Figure 5: Emissions of nitrogen oxides NO_x ([ppm]) versus the excess air ratio λ [-]

Figure 7 presents both the NO_x and HC emissions (in ppm) for the CNG tests, while Figure 8 shows the corresponding results for all the HCNG tests.

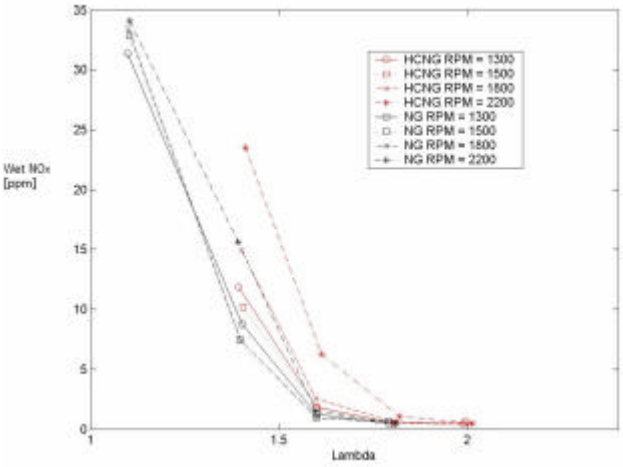

Figure 6: Specific NO_x emissions (wet) [g/kWh] as a function of excess air ratio λ [-]

The most obvious difference in the NOx emissions in these two figures is the higher NO_x emissions at the highest engine speed for HCNG for a given excess air ratio. This is as expected taking into consideration the deviations in laminar flame speeds between CNG and HCNG, which affect the flame temperatures most at higher engine speeds where the time available for reaching these temperatures is the shortest. Concerning the emissions of unburned hydrocarbons, these are higher for the pure CNG case compared to the HCNG cases for given excess air ratios, as expected. The measured engine out concentrations of HC is comparable between the CNG cases for λ=1.1 [-] with the HCNG cases for λ=1.4 [-], for the CNG cases with λ=1.4 [-] with the HCNG cases for λ=1.6 [-], and finally – for CNG cases with λ=1.6 [-] with the HCNG cases for λ=1.8 [-]. It is important to note the main trend in these NO_x results, that the NO_x emissions is significantly reduced by increasing the excess air ratio, and that the use of hydrogen addition to the CNG this leaning out may easily be achieved without any substantial HC penalty.

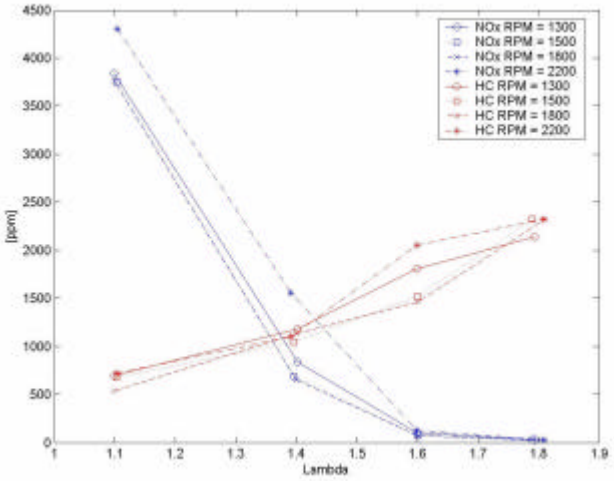

Figure 7: Emissions of nitrogen oxides (NO_x) and unburned hydrocarbons (HC) ([ppm]) versus the excess air ratio λ [-] for the pure natural gas (CNG) tests

Figure **3** – Figure 8 illustrate the fact that it is possible to reduce the emissions of both NO_x and HC by combustion of HCNG by leaning out the air-fuel mixture. This will be a trade-off against engine power and efficiency. In order to illustrate this fact, results form experiments using a constant engine speed of 1800 rpm will be used as an example in the following figures.

Figure 9 is another example of the trends discussed earlier when it comes to the effect of adding hydrogen to methane-air mixtures for spark ignition engines. The HC emissions increase rapidly as the lean limit is approached, and it is obvious that CNG at λ=1.8 [-] is very close to its

lean limit, and that by extrapolating the results for HCNG one may assume that the lean limit for the HCNG mixture is somewhat leaner than λ=2.0 [-].

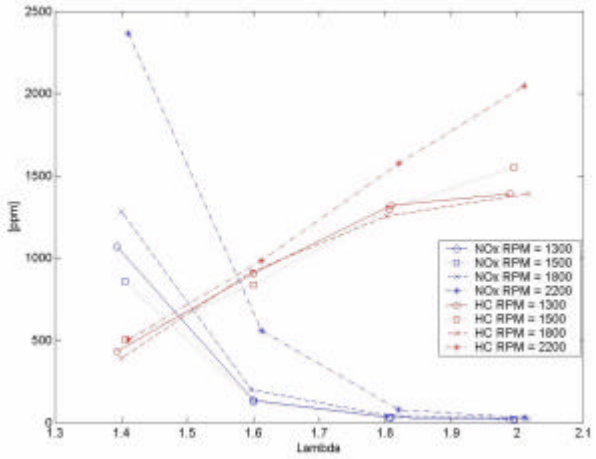

Figure 8: Emissions of nitrogen oxides (NO_x) and unburned hydrocarbons (HC) in [ppm] versus the excess air ratio λ [-] for the hydrogen enriched natural gas (HCNG) tests

As a result of the increase in flame speed and flame temperature, the NO_x emissions from the HCNG is higher than the CNG, and the CNG experiences a major increase in NO_x emissions for λ=1.1 [-]. It is a well known fact from the literature that the maximum NO_x emissions will be produced slightly lean of stoichiometric.

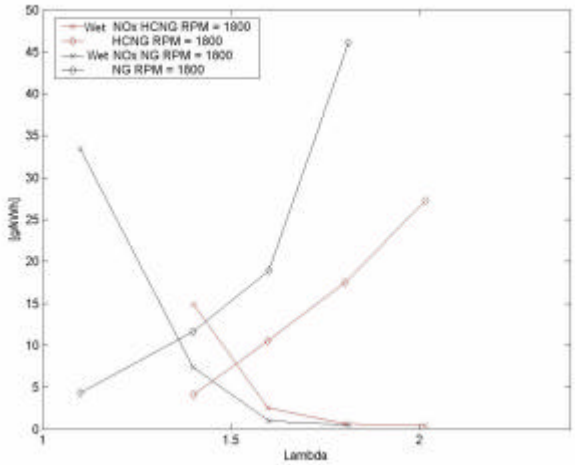

Figure 9: Specific HC and NO_x emissions [g/kWh] as a function of excess air ratio λ [-] at an engine speed of 1800 rpm

Figure 10 shows a typical trend in engine power as a function of excess air ratio for the CNG and the HCNG mixture. It is obvious from this figure that by adding hydrogen, an increase in power will result in the λ range investigated.

Figure 11 shows that the brake thermal efficiency $\eta_{th,brake}$ will decrease significantly with increasing excess air ratio as the lean limit is approached for both CNG and HCNG. This is in agreement with [14], [15] and [16]. The reason for this is the fact that addition of hydrogen to lean-burning methane-air mixtures solves the challenge of slower flame speed of lean methane-air mixtures, less complete combustion and increased cyclic variability ([9] and [16]).

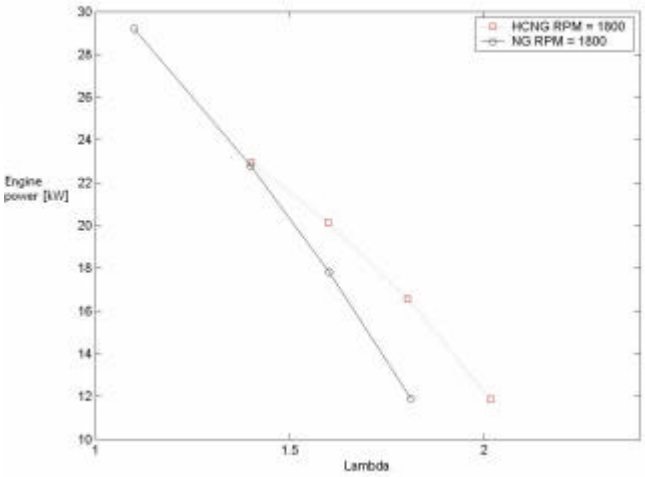

Figure 10: Engine power as a function of engine speed for tests at constant air-fuel ratio λ [-] at an engine speed of 1800 rpm

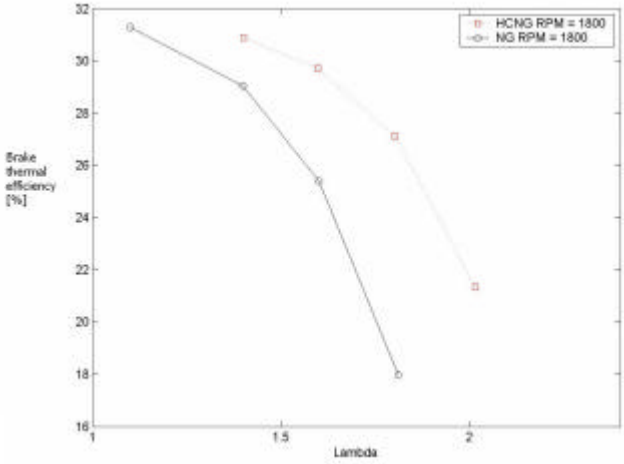

Figure 11: Brake thermal efficiency $\eta_{th,brake}$ as a function of excess air ratio λ [-] at an engine speed of 1800 rpm

The efficiency for HCNG is greater than for NG for the same λ, and the difference in $\eta_{th, brake}$ between HCNG and CNG for the same λ increases with increasing excess air ratio. In [16] an optimum in $\eta_{th,brake}$ was found around λ=1.3 [-] for CNG, and at λ=1.4 [-] for HCNG. In [12] it is found that the engine efficiency depends more on the excess air ratio than on the composition of the hydrogen-methane mixture.

The cylinder pressure development for the pure natural gas blends is presented in Figure 12. A reduction in the maximum combustion pressure developed results as the mixture is leaned out. For λ=1.8 [-] the combustion is very poor, and a very low efficiency results, as seen in Figure 10.

The accumulated Rate-Of-Heat-Release (ROHR) for the CNG blends is presented in Figure 13. The results in this figure correspond to the cylinder pressure curves in Figure 12.

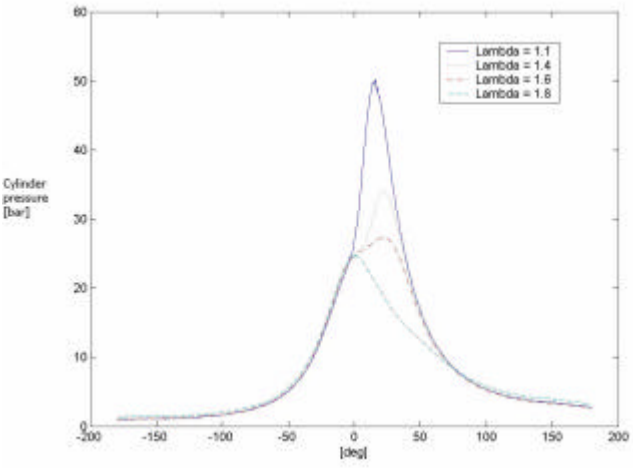

Figure 12: Cylinder pressure development using pure natural gas (CNG) at 1800 rpm

In Figure 14 the cylinder pressure curves for the HCNG blends are presented. The same trend as for CNG, a reduction in the maximum combustion pressure, occurs when the λ is increased. Comparing with the results in Figure 12, a higher p_{max} is measured at a certain excess air ratio for HCNG than for CNG. A shorter ignition delay is also found for HCNG than for the CNG blends.

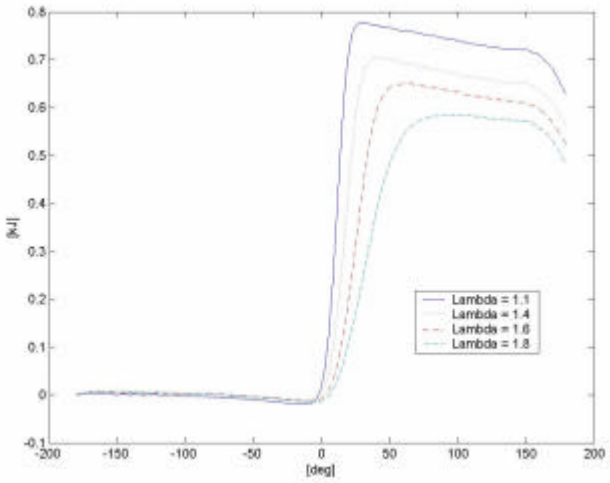

Figure 13: Accumulated Rate Of Heat Release (ROHR) using pure natural gas (CNG) at an engine speed of 1800 rpm

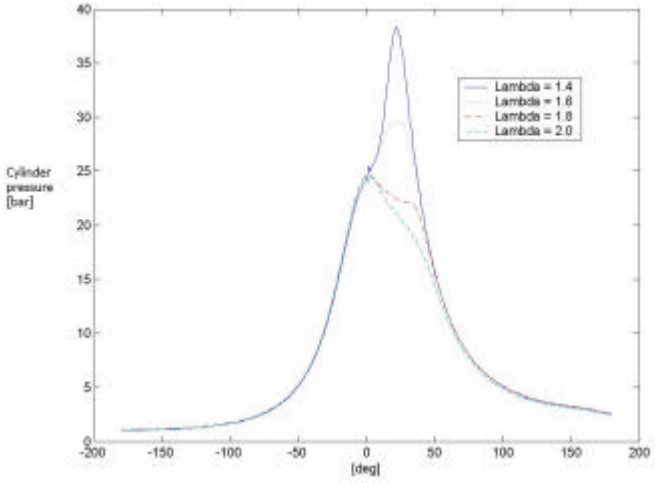

Figure 14: Cylinder pressure development of hydrogen enriched natural gas (HCNG) at an engine speed of 1800 rpm

The accumulated Rate-Of-Heat-Release for the HCNG blends is presented in Figure 15 . The results in this figure correspond to the cylinder pressure curves in Figure 14.

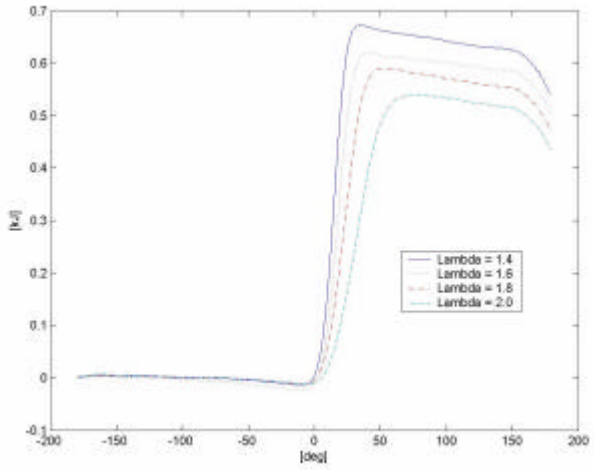

Figure 15: Accumulated Rate Of Heat Release (ROHR) using hydrogen enriched natural gas (HCNG)

CONCLUSIONS

The addition of hydrogen to Compressed Natural Gas (CNG) as a fuel in a SI engine has a significant, positive impact on the efficiency, especially close to the lean limit.

Pure compressed natural cas (CNG) and 29 vol% H_2 in CNG (named HCNG) were investigated at four engine speeds under full load conditions, namely 1300 rpm, 1500 rpm, 1800 rpm and 2200 rpm. For each mixture and each engine speed four different excess air ratios (λ) were chosen, in the range of λ= 1.1. – 2.0 [-].

Addition of H_2 to CNG makes it possible to run the engine leaner, resulting in lower emissions of CO_2, CO and HC at a certain λ [-], and higher NO_x emissions at constant excess air ratio. However, it is very important to note the fact that increasing the excess air ratio reduces NO_x significantly, and that the use of HCNG results in a major extension of the lean limit.

The full load curves (P_e=f(Engine speed)) for the two mixtures at different excess air ratio is coincides at λ=1.4 [-] and λ=1.6 [-]. When the mixtures are leaned out to λ=1.8 [-] the HCNG gives more power than the equivalent CNG. The explanation for this is that CNG approaches the limit where the engine starts to misfire, i.e. it is too close to the limit on the lean side. This is also seen on the emissions of unburned hydrocarbons.

The emissions of total unburned hydrocarbons were also measured. From the plots of HC–emissions as a function of lambda, one may see that at a certain excess air ratio, the emissions of unburned hydrocarbons start to increase considerably. This indicates that the lean limit is approached. The lean limit for the pure CNG tested in this engine is approximately λ=1.8[-], and the lean limit for the HCNG is even leaner, i.e. at about λ=2.0 [-]. This is as expected, and in accordance with the literature. It is also important to note, that the level of the unburned hydrocarbons emitted at certain air-fuel ratio is considerably lower for the HCNG than for the pure CNG.

at an engine s

On the other hand, comparing the emissions of nitrogen oxides, the HCNG is emitting more than the CNG at the same excess air ratio. This difference decreases as the λ increases from 1.4 [-] to 2.0 [-], where the level of NO_x is equal for the two mixtures investigated.

Considering the total emissions of unburned hydrocarbons and nitrogen oxides, it is easily seen that the positive effect of adding hydrogen to the CNG increases as a function of lambda.

ABSTRACT

This work shows a methodology for analysis and management of hot water generation for industrial utilization from solar energy and cogeneration, the latter involving usage of a gas turbine or a natural gas fuelled engine. The methodology presented uses criteria that allow for evaluation of the power/heat ratio in the project of a water heating system. A computer program was developed to furnish a complete analysis of the energy system. A case study in an automotive industry is presented. The results show that solar energy and cogeneration using a natural gas fuelled engine are the most economic options.

Keywords: cogeneration, internal combustion engines, solar energy, gas turbines, natural gas

NOMENCLATURE

A_{col}	solar plate area [m^2]
c_p	constant pressure specific heat of water [kJ/kg ^oC]
c_{pcomb}	fuel specific heat [kJ/kg ^oC]
c_{pg}	constant pressure specific heat of combustion gases [kJ/kg ^oC]
E_{mes}	monthly energy [kWh/day]
FC_j	cash flow values of the order j = 1,2,3,...,n
FC_0	initial cash flow [dimensionless]
F_u	shower utilization factor [dimensionless]
H_2	hydrogen concentration in the fuel [%]
h_{ar}	water enthalpy [kJ/kg]
h_d	outlet steam enthalpy [kJ/kg]
h_{gs}	boiler outlet steam enthalpy [kJ/kg]
h_s	boiler inlet water enthalpy [kJ/kg]
h_v	steam enthalpy [kJ/kg]
LHV	fuel low heating value [kJ/kg_{comb}]
$\dot{m}_c$	burned fuel mass flow rate [kg_{comb}/s]
$\dot{m}_d$	outlet steam mass flow rate [kg/s]
$\dot{m}_f$	cold water mass flow rate [kg/s]
$\dot{m}_g$	gas mass flow rate [kg/s]
$\dot{m}_{gs}$	dry gas mass flow rate [kg/s]
$\dot{m}_q$	hot water mass flow rate [kg/s]
$\dot{m}_v$	steam mass flow rate [kg/s]
N	number of daily equipment utilization [dimensionless]
Nb	number of daily showers [dimensionless]
P_{gs}	thermal loss through the dry gas [dimensionless]
P_{H2O}	thermal loss due to water formation in the fuel [dimensionless]
P_i	power of equipment i [kW]
P_{nm}	non-measured losses [dimensionless]
P_r	thermal loss by radiation [dimensionless]
P_u	loss associated to fuel humidity [dimensionless]
Q	total heat energy consumed [kWh/day]

*Corresponding author: Phone/Fax +55-31-3319-4910
E-mail ricardo@pucminas.br

$\dot{Q}_{cc}$	combustion heat transfer rate [kW]
Q_i	energy required for water heating in equipment i [kWh/day]
Q^*_{real}	energy given by Eq. [12] [kW]
$\dot{Q}_{th}$	thermal energy [kW]
r	loss by radiation [kJ/kg]
T	Thermal viability [dimensionless]
T_{ar}	air temperature [ºC]
T_{ef}	cold fluid inlet temperature [ºC]
T_{eq}	hot fluid inlet temperature [ºC]
T_{gs}	dry gas temperature [ºC]
$T_{máx}$	maximum water temperature [ºC]
$T_{mín}$	minimum water temperature [ºC]
T_{rede}	feed water temperature [ºC]
T_s	exhaust gas outlet temperature [ºC]
T_{sf}	cold fluid outlet temperature [ºC]
t	interest rate [dimensionless]
u	fuel humidity [%]
V_{ch}	changing room hot water consumption [liter/day]
V_i	hot water consumption in equipment i [liter/day]
vv_{ch}	shower volumetric flow rate [dimensionless]
vv_i	hot water consumption in each equipment per operation [liter/day]
x	unmeasured loss [kJ/kg]
ΔTi	temperature difference between water in equipment i and feed water [^oC]
h_e	exhaust thermal efficiency [dimensionless]
η_{eq}	equipment efficiency [dimensionless]
h_{hrsg}	recovery boiler efficiency [dimensionless]
η_{tc}	heat exchanger effectiveness [dimensionless]
$h_{tg}\|_{cog}$	overall thermal efficiency of cogeneration system with gas turbine [dimensionless]
θ	shower average time [dimensionless]
ρ	water density [kg/m^3]

INTRODUCTION

The Brazilian energy system, predominantly based on hydroelectric power plants, has been evaluated under the light of economic and ambient impact, and the need to diversify the energy source. The increase on natural gas availability will probably alter the present situation in the near future. To guarantee continuous economic growth, it is necessary to increase the energy efficiency of industrial processes, to reduce the environmental impact, and to guarantee energy delivery. In this case, utilization of cogeneration turns to be a very attractive option. Its use in Brazil is still low, being concentrated in some areas like sugar, alcohol, steel, paper and cellulose industries.

This work presents a methodology of energy analysis and management, with emphasis on hot water generation. The alternatives evaluated were natural gas-fuelled engines and gas turbines, and solar heating. A case study was applied to an automotive industry, which shows a daily demand of 250 m^3 of hot water to feed its refectories and changing rooms, with the need of 10% reduction of specific energy consumption under a strict environment control.

LITERATURE REVIEW

The growing energy demand and the potential use of cogeneration in Brazil have been evaluated by Janson *et al* [1], Nascimento *et al* [2] and Coelho *et al* [3], among others.

Hilbert *et al* [4] studied combined cycles, typical fuels and costs, and concluded that this alternative is economically attractive to be applied in Brazil.

Barreto *et al* [5] proposed a minimum agenda for critical evaluation of viability studies of thermal energy generation in combined cycles.

El-Masri [6], Torres and Gallo [7], and Tuma *et al* [8] evaluated the combined cycle under the first and second laws of thermodynamics. System losses and internal irreversibilities were identified, including reduction of the net power produced due to use of the thermal energy in the cogeneration process.

Feng *et al* [9] described a simple methodology that allows for evaluation of costs of implementation of cogeneration systems.

Bicalho [10] developed a study on the utilization of gas turbines in the Brazilian energy system, emphasizing the role of natural gas for energy generation and the technological challenges, based on energy systems worldwide.

Céspedes and Júnior [11] performed an exergy and thermal-economy analysis of cogeneration application in the tertiary sector. The authors pointed out utilization of natural gas in cogeneration processes applying gas turbines or internal combustion engines as an answer for the growing energy demand in the expanding sectors.

Ramalho [12] evaluated the payment of exceeding energy production by sugar and alcohol industries, and discussed the modification occurred in the national energy system.

Fernandes Filho [13] evaluated the application of cogeneration in steel industries, using the exhaust

gas from the high oven and integrating systems with the air blower or the steam generator. Among the advantages, the authors mentioned costs reduction between 15 to 25%.

Muniz and Andrade [14] evaluated the potentiality of cogeneration application to paper and cellulose industries. Implementation of gas turbines and boiler for heat recovery of combustion gases was studied, with a forecast of cogeneration use in case of substitution of conventional boilers.

López *et al* [15] discussed the application of cogeneration to paper and cellulose industries, emphasizing economic issues.

Methodologies for thermal-economy applied to cogeneration systems, according to studies by Cerqueira and Nebra [16] and Monteiro [17], showed the economic viability of self generation and cogeneration for several configurations of heat and electric power production.

METHODOLOGY OF ANALYSIS

Hot Water and Energy Demands

For determination of the daily hot water demand one must consider the industry working periods, the number of employees and daily showers, the number of meals served and hot water need in the industrial processes, with typical flow rates and temperatures. In the case of operating industries, measurements in the field are recommended. Hot water flow rate and temperature data are required. For changing rooms, hot water consumption is given by:

$$V_{ch} = Fu \cdot Nb \cdot q \cdot vv_{ch} \quad (1)$$

In the case of industrial kitchens and refectories, the number of daily utilization and hot water consumption must be measured or estimated for each equipment i. The volume of hot water consumed is given by:

$$V_i = N_i \cdot vv_i \quad (2)$$

The total consumption is given by the sum of Eqs. (1) and (2). For new plants, typical values are estimated from standards and catalogues. The estimated hot water consumption in industrial changing rooms and refectories in this wok were based on the ABNT – NBR 7198 standard [18]. The total energy consumed is the sum of the daily consumption, given by:

$$Q = \sum_i Q_i = \sum_i \frac{r.V_{i.}c_p \cdot \Delta T_i}{3{,}6} \quad (3)$$

Thermal Efficiency of the Equipment

In the case study of this work, water heating is provided through heat exchangers, which hot fluid is vapor originated from a gas boiler. Thus, calculation of thermal efficiency in this section will be restricted to this equipment. Incropera [19] shows a complete discussion on the effectiveness of heat exchangers, which can be written as:

$$h_{tc} = \frac{[\dot{m}_f \cdot c_p \cdot (T_{sf} - T_{ef})]}{[(\dot{m}_q \cdot c_p \cdot (T_{eq} - T_e f)]} \quad (4)$$

The efficiency of a steam generator is defined by the ratio between the heat transferred to the water during the process, $\dot{Q}_{útil}$, and the heat liberated by combustion, $\dot{Q}_{cc}$. Two different methods are used to calculate the boiler efficiency, one direct and one indirect. Dukelow [20] evaluates that the indirect method, also called method of losses, gives more precise results; however, the direct method is the most used due to ease of use, higher speed and lower costs. The efficiency calculated by the direct method is given by:

$$h_{DIR} = 100 \cdot \frac{\dot{m}_v (h_v - h_s) + \dot{m}_d (h_d - h_s)}{\dot{m}_c \cdot LHV} \quad (5)$$

Dukelow [20] emphasizes that, as this method uses three distinctive mass flow rates, a more precise evaluation requires utilization of measuring devices with maximum uncertainties between 1 and 2%. The uncertainty of industrial sensors have been estimated between 3 to 5%, being a major limitation to the application of this method, together with the uncertainty associated to the determination of the fuel heating value. The thermal efficiency calculated by the indirect method is given by [20]:

$$h_{IND} = 100 - (P_{gs} + P_u + P_{H_2O} + P_r + P_{nm}) \quad (6)$$

Calculation of the thermal losses must obey the procedures established by ASME PTC 4.1a and 4.1b standard [21]. The thermal loss through the dry gas is given by:

$$P_{gs} = \frac{\dot{m}_{gs} \cdot cp_{comb} \cdot (T_{gs} - T_{ar}) \cdot 100}{LHV} \quad (7)$$

The thermal loss due to fuel humidity is so calculated:

$$P_u = \frac{u \cdot (h_{gs} - h_{ar})}{LHV} \quad (8)$$

The loss due to H_2O formation from the fuel is calculated by:

$$P_{H_2O} = \frac{9 \cdot H_2 \cdot (h_{gs} - h_{ar})}{LHV} \quad (9)$$

The loss by radiation is thus calculated:

$$P_r = \frac{100 \cdot r}{LHV} \quad (10)$$

Finally, the non-measurable losses are evaluated:

$$P_{nm} = \frac{100 \cdot x}{LHV} \quad (11)$$

The calculation procedure described was developed considering only the losses related to utilization of natural gas as fuel.

Energy Consumption

The energy released by the natural gas associated to water heating is calculated as a function of the thermal efficiency of the equipment:

$$Q_{real} = \frac{Q}{\prod \cdot h_i} \quad (12)$$

The denominator represents the product of the efficiencies of all equipments used. The daily consumption of natural gas is given by:

$$NGC = \frac{3600 \cdot Q_{real}}{LHV} \quad (13)$$

where the LHV value is 61.500 kJ/kg_{comb} [18].

System Selection

- Solar Heating System

To define the solar system, the solar plate area is first calculated:

$$A_{col} = \frac{30 \cdot Q}{E_{mês}} \quad (14)$$

The hot water volume to be stored is the sum of the volume of each equipment i, multiplied by a safety factor f_{saf}:

$$V_{RT} = f_{saf} \cdot \sum_i V_i \quad (15)$$

It is also necessary to establish the local geographic coordinates, weather conditions and the presence of shadows for installation of the solar plates. The energy required by the equipment is calculated by Eq. (3), where $\Delta T_i = T_{máx} - T_{rede}$.

- Cogeneration Systems

To attend the hot water demand, small cogeneration systems using natural gas-fuelled internal combustion engines and gas turbines are considered. The cogeneration is defined by adjusting the thermal load. The heat transfer rate required for water heating is calculated by:

$$\dot{Q}_{cc} = \frac{P_i}{h_{eq}} \quad (16)$$

The energy released through the exhaust gas is so given:

$$\dot{Q}_{rec} = \dot{m}_g \cdot c_{pg} \cdot (T_s - 150) \quad (17)$$

The minimum boiler outlet temperature is set to 150 ºC, to avoid acid formation and corrosion [18]. Natural gas consumption for the new water heating configuration is calculated as:

$$NGC_i = \frac{3600 \cdot \dot{Q}_{cc}}{LHV} [kg\,NG/h] \quad (18)$$

The efficiency of the exhaust gases is calculated as a function of the power, number of equipments and the energy produced in the combustion chamber:

$$h_e = 1 - \frac{P_i + Q^*_{real}}{\dot{Q}_{cc}} \quad (19)$$

For an internal combustion engine in cogeneration systems, the power/heat ratio is calculated by:

$$PHR = \frac{h_{eq}}{h_e \cdot h_{hrsg}} \quad (20)$$

The equipment is thermally viable when:

$$T = P_i / PHR > (Q_{real} \cdot h_{cald}) \quad (21)$$

For gas turbines the calculation is analogous as for internal combustion engines, considering the typical losses in the equipment.

- Economical Analysis

The economical analysis of a project is done through the net present value (NPV) and internal return tax (IRT) methods. These methods are based on comparison of the sum of values in each future cash flow (payments and incomes) with the value of initial cash flow (income and payment) in the current period.
The cash flow analysis technique (NPV) is based on calculation of the present value of a series of equal or different payments at a known tax, discarding the initial flow value, which can be from borrowing, financing or investment:

$$NPV = \sum_{j=1}^{n} \frac{FC_j}{(1+t)^j} - FC_0 = \frac{FC_1}{(1+t)^1} + \ldots + \frac{FC_n}{(1+t)^n} - FC_0 \quad (22)$$

The internal return tax, IRT, equalizes the present value of one or more equipment (cash outcome) to the value of one or more income (cash income):

$$FC_0 - \sum_{j=1}^{n} \frac{FC_j}{(1+t)^j} = 0 \quad (23)$$

The net present value (NPV) and the internal return tax (IRT) are used for decision making between alternatives. A project is considered economically viable if NPV is, at least, equal to zero. As higher is NPV, as more attractive is the project. Besides, the internal return tax (IRT) turns a project attractive if it is higher than the minimum acceptable investment return tax.
The invested amount differs for each alternative, being necessary the knowledge of the equipment cost. In the construction period, the time for implementation of a project and the expenditure chronogram are considered. During the working period, operation and maintenance costs and the depreciation factor are considered. In this work, the annual depreciation factor presented by ANEEL resolution 044/99 [24] was considered. The income of the energy generated or saved must also be taken into account.

RESULTS - CASE STUDY

For the industry studied in this work, Table 1 shows the main data for the refectory and Table 2 shows the data for the changing room. Data for the efficiency of the equipment and the energy released are shown in Table 3.

Table 1 – Main data for the refectory.

PARAMETER	VALUE
Hot water temperature	70 ºC
Daily hot water consumption	117.6 m^3
Ambient temperature	21.7 ºC
Energy consumption	6595 kWh/day

Table 2 – Main data for the changing room.

PARAMETER	VALUE
Hot water temperature	45 ºC
Daily hot water consumption	122.4 m^3
Ambient temperature	21.7 ºC
Energy consumption	3311 kWh/day

Table 3 – Data of efficiency and released energy.

PARAMETER	VALUE
Thermal efficiency of heat exchanger	0.8
Thermal efficiency of boiler	0.8
Energy released (Eq. (12))	15479 kWh/day
Natural gas consumption	906 kg/day

Due to the dimensions and temperature requirements of this project, the solar heating system was divided into two parts, one for the refectory and the other for the changing room. The thermal reservoir for each system was subdivided into eight tanks of 15 m^3. For the system simulation, the minimum and the maximum average temperature were considered to be 18.9 ºC and 23.9 ºC, respectively, according to DNMET [25]. The efficiency of the simulated solar plate was 49.7%, with area of 1.99 m^2, and an average monthly energy production of 66.37 kWh/m^2. Tables 4 and 5 show the simulated results for the refectory and changing room, respectively. For the changing room two configurations were proposed.
Tables 6 and 7 present results for seven gas engine models and with the recovery boiler efficiency of 80%. The parameters Q_{cc}, Q_{rec}, NGC_i, η_e, PHR, and T were calculated through Eqs. (16) to (21), respectively. This simulation considered engine efficiencies of 35% (Tab. 6) and 45% (Tab. 7). From Tables 6 and 7, it is observed that the power-to-heat ratio is inversely proportional to the engine efficiency. As the engine efficiency is increased, PHR decreases, reaching, for the engines of 318

and 400 kW of power (Tabs. 6 and 7) and for the engine of 636 kW of power (Tab. 7), values that indicate the project to be thermally inadequate, as the parameter T (Eq. (21)) turns to be lower than Q_{th}.

Table 4 – Simulated results for the refectory.

PARAMETER	VALUE
Maximum hot water temperature	70 ºC
Minimum hot water temperature	65 ºC
Feed water temperature	20 ºC
Daily hot water consumption	117.6 m^3
Number of reservoirs	8
Reservoir capacity	15 m^3
Number of solar plates	1490
Total solar plate area	2965.1 m^2
Solar fraction	70%
Auxiliary heating	30%
Volume-to-area ratio	0.0413 m

Table 5 – Simulated results for the changing room.

PARAMETER	CONF. 1	CONF. 2
Maximum hot water temperature	50 ºC	50 ºC
Minimum hot water temperature	45 ºC	45 ºC
Feed water temperature	20 ºC	20 ºC
Daily hot water consumption	122.4 m^3	122.4 m^3
Number of solar plates	1496	820
Total solar plate area	2977 m^2	1631.8 m^2
Solar fraction	89.8%	68.8%
Auxiliary heating	10.2%	31.2%
Volume-to-area ratio	0.0411 m	0.0750 m

Table 6 – Simulated results for gas engines (η_{eq} = 35%, Q_{th}= 516 kW).

P [kW]	Q_{cc} [kW]	Q_{rec} [kW]	NGCi [kg/h]	η_e	PHR	T
400	1142	112	84	0,56	0,78	512
318	908	137	66	0,51	0,86	369
636	1817	279	133	0,51	0,86	738
748	2137	298	156	0,53	0,83	904
776[1]	2217	305	162	0,53	0,82	947
776[2]	2217	323	162	0,53	0,82	947
912	2605	395	191	0,55	0,79	1149

Simulation of gas turbines involved eight models (Tab. 8). Analysis of the results shows that the PHR parameter behaves in a similar way as for gas engines. Gas turbines allows for higher energy recovery than internal combustion engines due to higher exhaust gas temperature and mass flow rate. Thus, it is necessary to use a higher number of engines to furnish the thermal energy required for water heating, Q_{th}. The thermal viability was verified for all models, as $T > Q_{th}$.

Table 7 - Simulated results for gas engines (η_{eq} = 45%, Q_{th}= 516 kW).

P [kW]	Q_{cc} [kW]	Q_{rec} [kW]	NGCi [kg/h]	η_e	PHR	T

Economy Analysis

For the economy analysis of the three alternatives presented, electric power and natural gas were considered to have the same adjustment rate. The economy analysis for the solar energy considered two configurations: the first with the solar plate area of 5942.1 m^2 and auxiliary heating of 20.1%; the second with the solar plate area of 4596.9 m^2 and 30.8% of auxiliary heating. From Fig. 1 it can be observed that the first configuration requires a higher initial investment, but lower operational costs due to less dependence on auxiliary heating. This way, the net present value in the period of twenty years is higher for the first configuration with respect to the second one to the order of US$ 250000. The investment return for the first and the second configuration were after 40 and 41 months, respectively.

For the economy analysis of the cogeneration system using internal combustion engines, 8760

working hours per year, installation costs of 3% of the investment, operation and maintenance costs of 2% a year, and major maintenance costs at each five years of 4% of the investment were considered. From Fig. 1 it is noticed that the engine of 776 kW of power, simulated at an attractiveness rate of 1%, shows an investment return period of 49 months at the efficiency of 0.35, against 40 months when its efficiency is 0.45. The same initial investment was considered in both cases. Comparing the cogeneration system with internal combustion engines to the solar configurations proposed at the same attractiveness rate, the first option is the most economically attractive, accumulating higher incomes throughout an estimated thirty years lifetime.

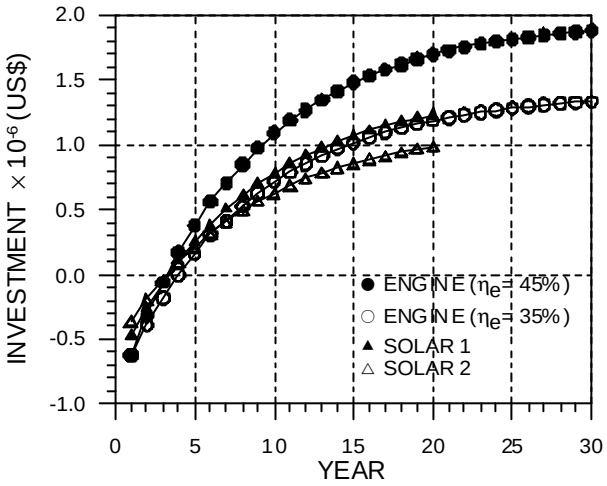

Figure 1 – Economy analysis of the 776 kW gas engine versus solar energy.

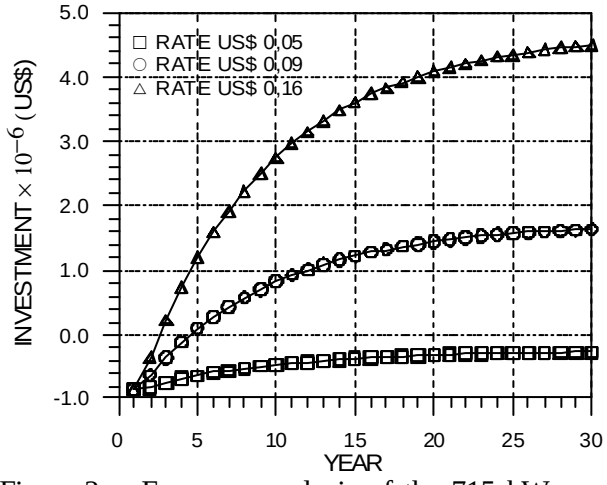

Figure 2 – Economy analysis of the 715 kW gas turbine.

For the economy analysis of the cogeneration system with gas turbine, 8760 working hours per year, installation cost of 3% of the investment, operation and maintenance costs of 1% a year and major maintenance costs of 2% of the investment were considered. Figure 2 shows that the gas turbine turns to be economically attractive only if the electric power rate is higher than US$ 0.09/kWh. If the electric power rate is the same as the natural gas, of US$ 0.16/kWh, the period for return of the investment would be 32 months and, after a lifetime of 30 years, would accumulate a total income of about US$ 4500000.

CONCLUSIONS

- A methodology of energy analysis and management was developed.
- The methodology was applied to an automotive industry for hot water generation using solar energy and cogeneration using gas turbines or internal combustion engines with a recovery boiler.
- The investment return period for two different solar energy systems, of distinct solar fraction and plate area, varied between 40 to 41 months.
- A cogeneration system with the internal combustion engine efficiency of 35% or 45% was simulated, for which the higher the system efficiency, the lower the power-to-heat ratio, and the investment return periods were 49 and 40 months, respectively.
- The cogeneration system with internal combustion engines showed higher income throughout a 30-year lifetime than the solar energy system, which lifetime is 20 years.
- The cogeneration system using gas turbine showed higher energy recovery, comparable to that produced by a higher number of engines to attend the thermal energy requirements for hot water generation.
- The cogeneration system with a 715 kW gas turbine showed economic disadvantages, being estimated an investment return period of up to 55 months, against lower investment return periods estimated for the solar heating system and for the cogeneration system using natural gas-fuelled 776 kW engines.

ABSTRACT

This paper reports a simple technique to perform simulations of Diesel engines, taking into account the discrete variation of engine power load under constant speed. This simulation technique was developed to be used in cogeneration systems simulation. To perform the model, some assumptions were made: the combustion reaction was supposed to have only four combustion products and the heat loss were treated through a bulk simple modeling. Some technical information introduced was taken from manufacturer's data spreadsheet.
Key-words: Engine simulation, Diesel engines, partial load.

INTRODUCTION

Power generation by internal combustion engines is particularly dependent on fuel consumption level, by environmental or economical reasons, as it influences operational costs and gas emissions. In the context of the present lack of fossil energy resources, internal combustion engines are evolving towards the reduction of this parameter.
In the Amazon region, Diesel engines are responsible for power generation at villages and towns. The fuel cost, including transportation, is a very important factor. With these conditions, the analysis should attempt to the additional problem of the variation of engine power as a response to the electric power demand, which usually happens in autonomous power grids. A simple methodology to simulate the engine performance is helpful for energy generation planning and also to simulate cogeneration systems. To get these objectives, in this paper is presented a simple engine modeling under variable load.

ENGINE BALANCES

To perform the energy and mass balances under permanent conditions, a control volume surrounding the engine and its admission system and exhaust system is defined, see Figure 1:

$$(\dot{m}_f h_f)+(\dot{m}_{air} h_{air})-[\dot{W}_b+\dot{Q}_{irrad.}+(\dot{m}_{exh.} h_{exh.})+$$

$$+(\dot{m}_{refr.}\Delta h_{refr.})+(\dot{m}_{lubr.}\Delta h_{lubr.})]=0 \quad (1)$$

$$\dot{m}_{exh.}=\dot{m}_{air}+\dot{m}_f \quad (2)$$

Manufacturers give data spreadsheets for brake power upon load discrete values, usually set at 25 [%], 50 [%], 75 [%] and 100 [%]. The heat loss to lubricant $(\dot{m}_{lubr.}\Delta h_{lubr.})$ is small ([1], [2], [3], [4]), so it can be summed up to that of the cooling fluid $(\dot{m}_{refr.}\Delta h_{refr.})$.

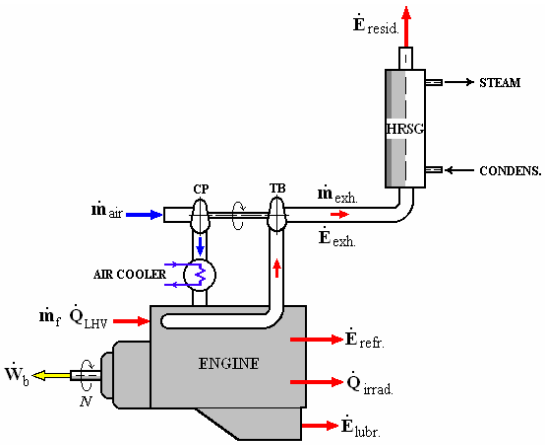

Figure 1: Engine energy balance

The above mentioned energy balance terms are related to the variable load, which is herein defined by the relation:

$$q \equiv \frac{\dot{W}_{b|q}}{\dot{W}_{b|100}} \quad (3)$$

Energy from Fuel under Variable Load

In Equation (1) the sum $(\dot{m}_f h_f)+(\dot{m}_{air} h_{air})$ is the fuel energy furnished by unit time $\dot{E}_f$. Taking into account a reaction balance where only the four main combustion products, enough for energy balance purpose, H_2O, CO_2, N_2 and O_2, are considered. The above mentioned sum may be written as:

$$\dot{E}_f=\dot{n}_f\left[\sum_P \nu_i\left(\tilde{h}^o_{f,i}+\Delta\tilde{h}_i\right)-\sum_R \nu_j\left(\tilde{h}^o_{f,j}+\Delta\tilde{h}_j\right)\right]=$$

$$=\dot{m}_f Q_{LHV} \quad (4)$$

where $\Delta\tilde{h}=\tilde{h}(T)-\tilde{h}(T_0)$ is the sensible enthalpy above the reference temperature (T_0 = 298.15 [K]) of reactants (fuel and air) at T_R and products at T_P.

And then the fuel conversion efficiency may be determined as:

$$\eta_f = \frac{1}{bsfc\, Q_{LHV}} \quad (5)$$

Where the brake specific fuel consumption is defined as:

$$bsfc \equiv \frac{\dot{m}_f}{\dot{W}_b} \quad (6)$$

The exhausted gas flux may be evaluated from the air-to-fuel ratio:

$$AF \equiv \frac{\dot{m}_{air}}{\dot{m}_f} = \frac{\dot{m}_{air}}{bsfc\, \dot{W}_b} \quad (7)$$

In general, AF is given by the manufacturers' spreadsheets, frequently only at 100 [%] load. Assuming the engine running at its nominal speed and that in fuel injected engines the air mass flux remains constant as load varies (full throttle), for discrete loads ranging from, say, 25 [%] to 100 [%], other air-to-fuel ratios may be inferred by:

$$\frac{AF_{|q}}{AF_{|100}} = \frac{\dot{m}_{air|q} / \dot{m}_{f|q}}{\dot{m}_{air|100} / \dot{m}_{f|100}} = \frac{\dot{m}_{f|100}}{\dot{m}_{f|q}} \quad (8)$$

Radiation Heat Loss under Variable Load

This effect is a markedly small part of the energy balance. The manufacturers provide data for 100 [%] load. Ferguson [4] reports values from 7% to 9% of $\dot{E}_f$, for every engine load for medium speed engines at constant speed. So it may be assumed that the relation $\varsigma \equiv \dot{Q}_{irrad.|100} / \dot{E}_{f|100}$ remains constant for every engine load. It can be avaluated from manufacturer's data spreadsheet. For loads others than 100 [%], the radiation heat loss can be inferred by:

$$\dot{Q}_{irrad.|q} = \varsigma \dot{E}_{f|q} \quad (9)$$

Cooling Fluid Heat Loss under Variable Load

The reciprocating nature of the internal combustion engines makes evaluating the heat loss to the cooling fluid and lubricant extremely difficult, by any practical method. In general, as reported by Ramos [5], even modern zero to multidimensional simulation methods demand empirical and not precise regressions for space averaged heat loss, such as proposed by Annand and Whoschnnis. In late fifties, Taylor [2] established one of the first methods for estimating the average bulk cylinder heat loss, to perform that, the author collected data from a wide range of engine types, speeds and conceptions, relating empirical parameters. Taylor's method at least explains this complex phenomenon. However, Taylor's methodology does not approach satisfactorily the behavior of Diesel engines under variable load.

A simpler method is reported by Stone [1], as a correlation developed by Alcock et al. based on extensive experiments, established as a exponential correlation between the cylinder bulk heat loss and the mass fuel consumption, which is:

$$\dot{E}_{refr.|q} = \xi \left(\dot{m}_{f|q} \right)^{\alpha} \quad (10)$$

It is obvious that this model should be viewed as a curve regression, where the coefficients ξ and α must be searched for any particular engine, as these are dependent upon engine's fuel injection conception, pressure, velocity, geometric parameters, etc. Stone [1] reports also that Alcock et al. got the value $\alpha = 0.6$ for a direct injected 1.8 litter Diesel engine. Equation (17) is Equation (10) applied to the practical example of this paper.

Energy and Temperature of the Gases under Variable Load

The heat rate exhausted by the combustion gases is given by solving the balance Equation (1). The exhausted gases energy must attempt to the following equation:

$$\dot{E}_{exh.|q} = \dot{m}_{gas|q} \left(h_{exh.} - h_0 \right) \quad (11)$$

The solution of Equation (11), joined to the energy balance, returns the exhaust gas temperature $T_{exh.|q}(h_{exh.|q})$. Many algorithms may solve such an iterative calculation which takes into account that the gas enthalpy data may be adjusted to polynomials, such as $h = B_6 T^6 + B_5 T^5 + ... + B_0$.

The available *residual energy* can be calculated from the date of allowable minimum exhaustion

temperature, which is established in order to avoid the formation of liquid sulfuric acid by Diesel oil. See equation (12).

$$\dot{E}_{residlq} = \dot{m}_{gaslq}\left(h_{resid.} - h_0\right) \qquad (12)$$

It is usually assumed for this minimum temperature, under Amazon weather conditions, the value $T_{resid.} = 413.15$ [K] (140 [C]). In such a case, the available energy of the exhaust gases is:

$$\dot{E}_{netlq} = \dot{m}_{gaslq}\left(h_{exh.} - h_{resid.}\right) \qquad (13)$$

A PRACTICAL EXAMPLE

The equations were applied to a supercharged Diesel engine of a national manufacturer working on continuous basis, whose most important technical data are related on the table bellow, Table 1.

q	**10^{-8} *bsfc*** [6]	**AF** [6]
25	6 841	89.92
50	6 034	50.97
75	5 688	36.05
100	5 592	27.50
Performance at rated speed		
Brake power [6]	1 200 [kW]	
Heat rejected to cooling fluid and lubricant [6]	618 [kW]	
Environment Radiation Loss [6]	150 [kW]	
Engine speed [6]	1 800 [rpm]	
Diesel oil Q_{LHV} [7]	40 270 [kJ/kg]	
Diesel oil molecular mass [7]	198,10 [kmol/kg]	
Diesel oil density [7]	850,0 [kg/m³]	
Average Diesel oil molecular composition [4]	$C_{14,4}H_{24,9}$	

Table 1: Diesel engine data.

For the above mentioned *bsfc* and AF data, the following polynomial regressions, equations (14) and (15), can be obtained. In both cases, the statistic parameters R^2 are 100%:

$$bsfc_{lq} = 8{,}320\,8\cdot10^{-5} - 7{,}545\,7\cdot10^{-7}\,q + 7{,}071\,7\cdot10^{-9}\,q^2 - 2{,}254\,7\cdot10^{-11}\,q^3 \qquad (14)$$

$$AF_{lq} = 1{,}705\,2\cdot10^{2} - 4{,}292\,9\,q + 4{,}744\,6\cdot10^{-2}\,q^2 - 1{,}882\,0\cdot10^{-4}\,q^3 \qquad (15)$$

In particular for the Diesel engine of the example, Equations (9) and (10) were adjusted to the values presented in equations (16) and (17):

$$\dot{Q}_{irradlq} = \dot{E}_{flq}\left(\frac{150}{\dot{E}_{fll00}}\right) \qquad (16)$$

$$\dot{E}_{refr.lq} = 3\,871\left(\dot{m}_{flq}\right)^{0,68} \qquad (17)$$

In Equation (17), ξ and α were found by equaling Equation (10) to 'environment radiation loss', see value on Table 1.

Figure 2 shows the energy balance. Figure 3 shows the energy balance ratios $\dot{E}/\dot{E}_f$. Figure 4 reports the combustion products exhaust temperature, obtained by solving Equation (11) as explained above. All of them are in function of the engine load. The solutions were obtained by solving the precedent equations with the aid of the software EES® [8].

For the purpose of comparison from the simulated results to actual data, in Figure 5, statistical data from ASHRAE [10] are reported, compiled from many types and sizes of supercharged Diesel engines. Note how similar Figures 3 and 5 are, despite the obvious statistical differences on each discrete power load points.

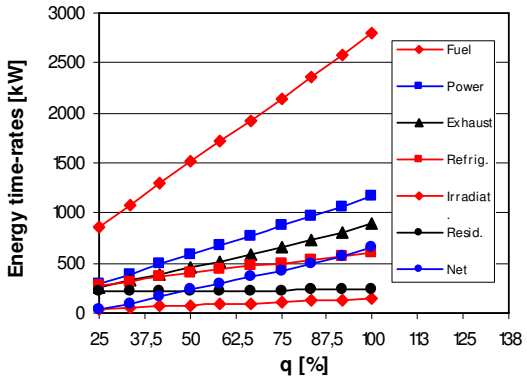

Figure 2: Simulated energy balance for the Diesel engine of the example [9].

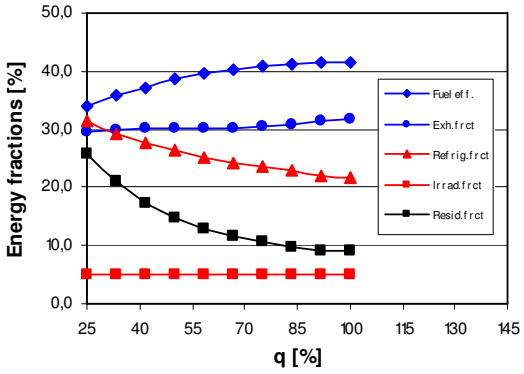

Figure 3: Simulated energy balance fractions for the Diesel engine of the example [9].

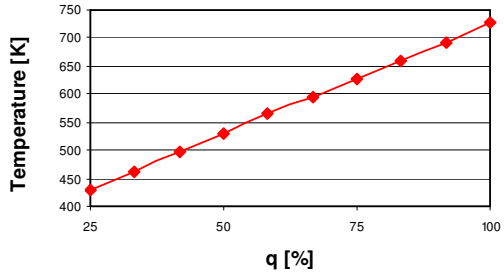

Figure 4: Simulated temperature of the exhausted gases for the Diesel engine of the example [9].

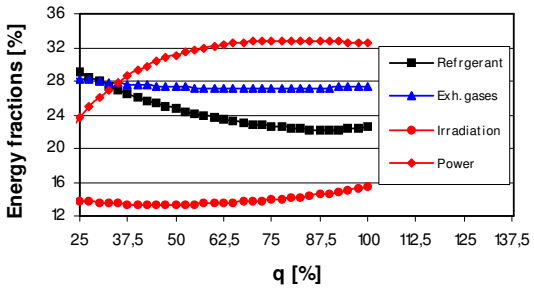

Figure 5: Supercharged Diesel engines energy fractions from ASHRAE [10]).

Figure 2 shows that the exhaust gases available energy increases with the load, at a higher rate than the cooling fluid available energy. Considering the energy fractions, both, Figure 3 and 5, show that the available heat fraction of the exhaust gases remain almost constant as the power load enhances.. Moreover, despite of its higher energy content, at low power loads, the combustion products do not support high temperature levels at that point, as shown in Figure 4. As the cooling fluid temperature do not vary as extensively as gases do, with the power load variation; it should be noted that most of rejected heat at low loads is concerning to the cooling fluid. At low power loads, cogeneration cycles should attempt to the low temperature of the combustion products.

CONCLUSIONS

The problem of simulating the performance of internal combustion engines under variable load is satisfactorily attempted by the simple procedure presented in this paper. If it is taken into account that most of the theoretical simulation procedures are difficult, to not say unpractical, to be implemented by daily engineering, the main calculation difficulties related to the present procedure may be promptly attained nowadays. These difficulties are mainly to obtaining performance data from engine manufacturers, thermo-physical data for gases, fuel and water. To facilitate the calculation, it is recommended the use of a computer software package as, for instance, EES® [8], whose thermo-physical data bank and equations solving algorithm can fully satisfy the computational efforts demanded.

ABSTRACT

The purpose of this work is the evaluation of the feasibility of an Oxy-Fuel retrofit on a 660 MWe coal-fired boiler in order to obtain CO_2-rich flue gases and avoid post combustion CO_2 capture technologies. In order to achieve this goal, a GateCycle ® simulation model of a typical existing ENEL power station has been developed in detail and tested under normal operating conditions. Then, off-design conditions using pure O_2 and CO_2-rich flue gas recirculation have been explored. In particular, four plant configurations have been evaluated, both from the performance and plant complexity points of view. Some interesting results have been obtained, especially for what concerns parameters and configuration quantitative influence to the boiler performances.

INTRODUCTION

Carbon dioxide (CO_2) is emitted into the atmosphere mainly through fossil fuel combustion in power plants, automotive engines and for heating purposes. The CO_2 emissions are the major contribution to the greenhouse effect resulting in a global warming of the earth's surface. Moreover, the world energy demand is increasing strongly and the fossil fuel use for energy supply will continue for a long time [1]-[2]. At present in the energy sector the main options in order to reduce the CO_2 emissions from fossil fuels are the following [1]-[3]:

- Increasing the fuel conversion efficiency;
- Increasing the use of fuels with a lower fossil carbon content and of renewable energies;
- Capturing and storing the CO_2 emitted in the fossil fuel fired power plants;

On the market today the use of renewable energies is available but limited to small scale energy production. Moreover, the cost to avoid CO_2 emissions using the renewable energies is very high. As discussed in [3], it is reasonable to think that only in the very long period the large scale energy production based on renewable and/or sustainable energy will have an important development. Therefore, in the middle and near period the study of innovative combustion technologies of fossil fuels (mainly bituminous coal and lignite) in large steam boiler power plants will have a strong development to reduce the CO_2 emissions and the greenhouse effect [2]-[7]. The most promising technologies use systems for the CO_2 capture from the flue gas together with its

*Corresponding author: Phone +39 050 6185971, Fax +39 050 6185585, E-mail juri.riccardi@enel.it

re-circulation to the boiler [1]-[7]. As well known, it is difficult to remove CO_2 efficiently because the CO_2 concentration in the flue gases exiting from a conventional fossil fuel power plant is only between 10 to 15% by volume. An efficient way to make the CO_2 capture easier is to increase the CO_2 concentration in the flue gas up to 95% using high purity oxygen rather than air as oxidant. In this case the flue gas consists mainly of CO_2 ad H_2O, from which CO_2 is easily separated, for example, by H_2O condensation, without the use of extra devices, like MEA scrubber, reducing strongly both the energy consumption and the plant cost. Then a fraction of the flue gas, after addition with a nearly stoichiometric amount of pure O_2, is re-circulated into the boiler. Oxy-fuel combustion is not a new concept because is already routinely employed in metallurgical and glass industries [2]-[3]. This technology for the capture and subsequent storage of the CO_2 is potentially attractive because the resulting mixture O_2/CO_2 provides a high flexibility for the temperature and flow rate control inside the boiler. Nevertheless the number of scientific papers concerning the applications of the oxy-fuel combustion in large conventional retrofit coal power plant is still small. Some limited research activities on the specific field have been mainly carried out in Japan, Canada and Sweden, especially at the Chalmers University of Technology [8]-[9].

The main goal of this paper is hence to investigate intensively the feasibility of the oxy-fuel combustion on a retrofit conventional 660 MWe coal fired boiler power station. Off-design conditions of the retrofit boiler have been studied using four possible plant engineering configurations, both from the performance variations and plant complexity point of view. The simulations has been carried out using Gate Cycle Version 5.2 commercial code.

The outline of this paper is as follows. In Section I the main characteristics of the reference boiler are described. The development of simulation model of the power station together with the its validation is also discussed. In section II the performance analysis of four oxy-fired boiler power plants in off-design conditions is described. At the end, some conclusions are reported.

I SIMULATION MODEL OF THE REFERENCE PLANT

Description of the ENEL's reference 660 MWe coal fired steam power plant

The ENEL's reference 660 MWe pulverised coal fired power station is constituted by a typical supercritical boiler and the main characteristics are reported in Table 1. The steam-cycle of the boiler is shown in Figure 1. The steam produced in the superheater (SH) is fed to the high pressure stage of the steam turbine (HP). Then, the steam goes through the re-heater (RH) and expands in middle pressure stage (MP) of the steam turbine. At the end, the MP outlet is connected to low pressure stage (LP) of the steam turbine. Six regenerative steam bleedings, from 77.4 bar to 1.2 bar of pressure, and a further auxiliary steam bleeding at 0.6 bar, are applied to the steam turbine (Figure 1). The mass flow of the regenerative steam bleedings varies in the range from 218 t/h to 56 t/h, while the mass flow of the auxiliary steam bleeding is about 121 t/h.

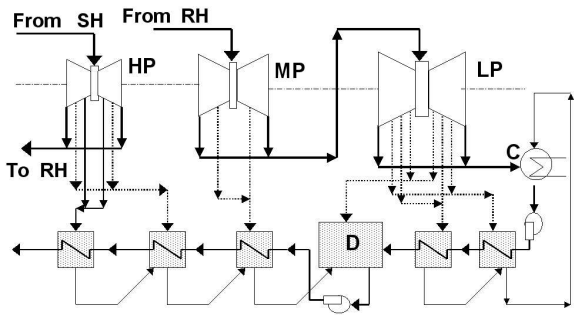

Figure 1: Scheme of the steam-cycle.

Modeling of the boiler and steam-cycle

The simulation model of the whole power station (boiler + steam-cycle) has been made using Gate Cycle Version 5.2 commercial code. In order to simplify the complexity of the real equipments that constitute the boiler and the steam-cycle, the following assumptions have been adopted:

1. the boiler has been divided in three independent sections: evaporative section, superheating section (SH) and re-heating section (RH). The SH section has been further subdivided in two subsections: SH1 and SH2, respectively. While SH2 subsection is undergoes to the convective and radiative heat transfer, for SH1 subsection the main contribution to heat transfer with the flue gases is due to convective processes. The SH2 outlet is connected to HP. The pressure loss between SH and HP has been included in the simulation model. Also RH section has been subdivide in two subsections: RH1 and RH2, respectively. Both these subsections are submitted to only convective heat transfer. Inside the boiler, the RH2 subsection is located between SH2 and SH1 subsection and the RH2 outlet is connected to MP. The pressure loss between RH and MP has been included in the model, too;

2. the economizer (ECO) has been simulated using a heat exchanger outside the boiler;

3. the Coal Lower Heating Value (LHV) has been assumed equal to 26.3 MJ/kg, corresponding to that of a typical Indonesian coal with the following chemical composition (as received): C=67.2%, H=5.9%, N=1.2%, S=0.6% and O=11.6% (by difference). Moreover, the coal moisture and ash contents have been assumed equal to 6.1% and 7,5%, respectively. The coal mass flow inside the boiler has been fixed equal to 212.2 t/h;

4. the excess of comburent air has been fixed equal to 17% with respect to the stoichiometric value. The air preheating takes place first in a steam exchanger using the auxiliary steam extraction and after in the Ljungstrom (LJ). The latter has been simulated using a general heat exchanger; for the heat transfer coefficient has been used a typical value of a heat exchanger gas/gas [10];

5. the steam turbine has been subdivided in three independent sections, as shown in Figure 1. For each sections a reasonable values for the isoentropic expansion coefficients, which have calculated using plant's nominal thermal data have been assumed. During the simulations, the values of these coefficients have been lightly adjusted in order to assure a good and a rapid convergence of the simulator to the plant working effective conditions. The steam leakages inside the turbines due to, for example, the steam seals, have been also taken into account in the model;

6. the heat regenerative exchangers (feedwater heaters) have been supposed adiabatic and composed by three independent sections: desuperheating section, condensing section and bleeding section. For each section a reasonable value for the heat transfer coefficient [10] has been defined;

7. the pressure of the condenser and the temperature of the cooling water have been fixed equal to 0.05 bar and 15^{o}C, respectively. Moreover, the inlet water mass flow has been established imposing on it a thermal increase equal to 10^{o}C;

In the simulation model the following aspects have been also included:

- the fans for the circulation of the comburent air and of the combustion gases;

- the condensated extraction pump and the feed-water pump (Figure 1).

On the basis of the assumptions reported above, the simulation model has been realized and the convergence has been checked by a detailed comparison between the simulation results and the nominal operating conditions of the plant (reference case). The main results of this comparison are reported in Table 2. The agreement between the simulation results and the nominal conditions of the reference case is good.

	Reference Case	Reference Case Simulation
Nominal Gross Power Output (MWe)	660	662
Gross Efficiency (-)	0.427	0.427

II OXY-FUEL COMBUSTION

Modeling of the oxy-fuel combustion

The off-design conditions of the developed simulation model have been explored in order to study pure O_2 and CO_2 enriched flue gases re-circulation. Four plant engineering configurations have been evaluated, both from performance variations and retrofit plant complexity points of view. In every simulation the SH1 inlet steam temperature has been fixed equal to 433^oC, according to the reference case. This choice allows an effective control of the heat exchanged inside the RH and SH sections. The following retrofit plant configurations have been examined:

Plant engineering configuration A

In this plant configuration (Figure 2), pure oxygen, produced in an air separation unit (ASU), is pre-heated in the LJ via flue gases cooling. The mixing and re-recirculation of a part of the flue gas (mainly constituted by CO_2 and H_2O) with pure oxygen take place downstream the ECO outlet. In the condenser C the remaining part of flue gas is cooled down to the water condensation in order to make it possible the CO_2 separation.

Plant engineering configuration B

As shown in Figure 3 the pure oxygen is preheated in the LJ and the mixing and re-recirculation of a part of the flue gases with the oxygen take place downstream the LJ.

Plant engineering configuration C

In this configuration (Figure 4) the pure O_2 is added to a part of the CO_2 separated in the condenser C. The mixture O_2/CO_2 is then preheated in the LJ via the flue gas cooling.

Plant engineering configuration D

As shown in Figure 5, this plant solution is very similar to the configuration C. The O_2/CO_2 mixture O_2/CO_2 is, at first, preheated in an adjunctive heat exchanger and then in the LJ via the flue gas cooling. The adjunctive heat exchanger (AUX) allows to improve the thermal exchange overall efficiency between flue gas and CO_2/O_2 mixture. The AUX thermal exchange surface has been calculated using a heat transfer coefficient of about 30 $W/m^2/K$, obtaining a value of about 150000 m^2, which is about

1.5 times the LJ's one.

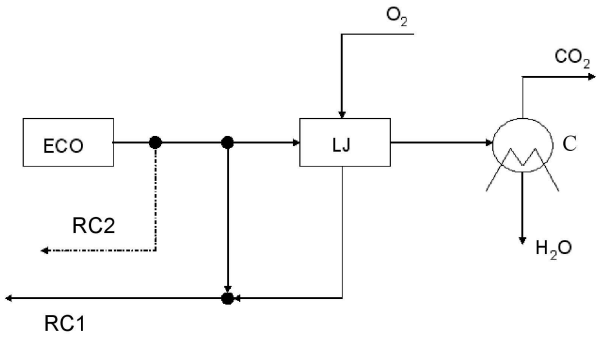

Figure 2: Plant engineering configuration A.

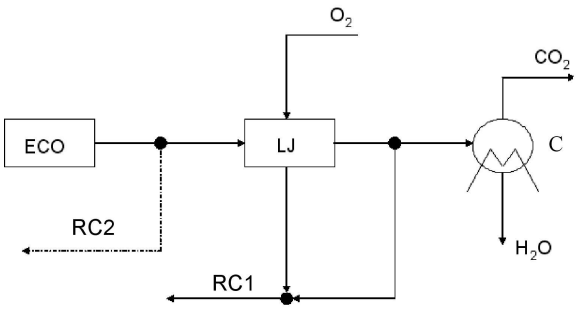

Figure 3: Plant engineering configuration B.

For each configuration a specific simulation model has been realised, tuning the reference model described in section I in order to take into account both the adjunctive equipments introduced and the modification to piping systems. Moreover, it has been supposed to use pure oxygen in order to emphasised the main effect of the oxy-fuel combustion. The excess of O_2 has been fixed equal to 10% of the stoichiometric value. In the simulations the coal mass flow has been fixed equal to 212.2 t/h, according to the reference case. The condenser H_2O/CO_2 has been simulated using a Flash Tank apparatus, fixing equal to 30^{o}C the water outlet temperature.

Oxy-fuel combustion simulation results

The simulation results for the configurations A, B, C and D are summarised in Table 3, where the symbol named Δ represents the percentage variation of the

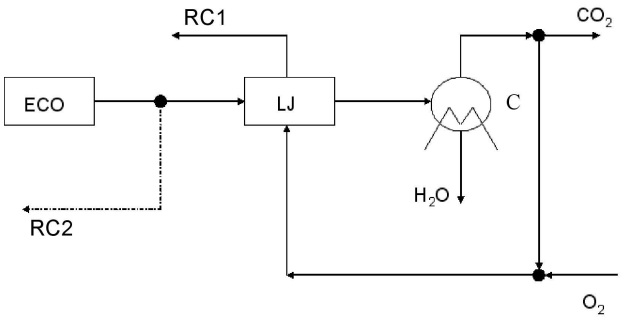

Figure 4: Plant engineering configuration C.

Table 3: Summary of the main simulation results.

plant operating conditions with respect to the reference case. Using the data of Table 3 it is possible to point out the following considerations:

- only the configurations A and D make it possible to obtain consistent increases both of the plant power output and of the plant efficiency. This result is mainly due to the increase of the steam production with the same coal thermal power input;

- although the simulation results for the configuration A and D are very similar, it should be stressed that the latter requires the adjunctive heat exchanger with the increase of the plant cost;

- in the configuration A, the production of superheated steam reaches the maximum value;

- for the configurations B and C, the power plant output is slightly greater of that of the reference case, while it decreases the steam production. For these configurations the power output increase is mainly due to the simultaneous increment of the HP and MP steam temperature;

- the temperature of the O_2/CO_2 mixture recirculated to the boiler reaches the highest value in the configuration A (about 380^oC against 300^oC for the reference case). This fact allows to obtain the highest value of the gross plant efficiency.

In Table 4 the values of the thermal power recovered in the condenser C during the separation process of the flue gases, together with the condensed water mass flow, are also reported. Figures 6 and 7 show the temperature-exchanged heat diagram for the steam/water and flue gas inside RH1, RH2, SH1, SH2 and ECO in reference case and configuration A, respectively. The same diagram for the LJ is shown in Figure 8. From the comparison of Figure 6 with Figure 7 it is evident that flue gas temperature is higher in the configuration A with respect to the reference case; this fact is due to an increase of the flue gas thermal capacity. Moreover, it is possible to affirm that every plant pressure and temperature values calculated by the simulations are within the technological constraints.
Finally, a preliminary estimate of the power consumption for O_2 production is reported in Table 5, assuming to use a cryogenic air separation unit

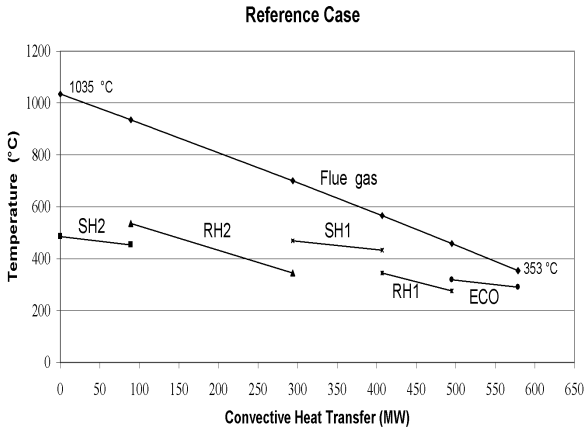

Figure 6: Temperature-exchanged heat diagram for steam/water and flue gas inside RH1, RH2, SH1, SH2 and ECO in the reference case.

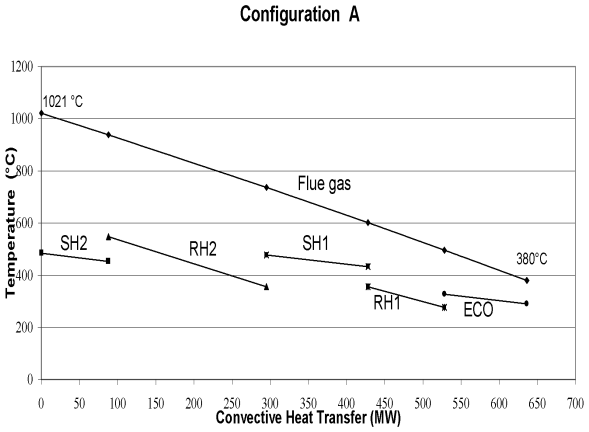

Figure 7: Temperature-exchanged heat diagram for steam/water and flue gas inside RH1, RH2, SH1, SH2 and ECO in the configuration A.

(cryo-ASU). At present, the O_2 production by cryo-ASU is the only available large scale technology for oxygen separation from air [2], [4], [6], although membranes and chemical looping technologies are sometime mentioned as possibile alternative to cryogenic air separation. According to Ref [11], it has been assumed that oxygen is produced (atmospheric pressure) at 0,25 kWh/kgO_2. Moreover, in Table 5 the plant net efficiency, which has been calculated assuming that the gross power output is partly consumed in the cryo-ASU is also reported: the plant auxiliary energy consumptions (fans, feedwater, pumps, etc.) and the thermal power recovered in the condenser C (see Table 4) are not included in the plant net efficiency calculation. It is evident from Table 5's data that the Cryo-ASU energy consumption severely penalizes the plant net efficiency.

Plant Configuration	Thermal Power *MWt*	H_2O Mass Flow t/h
A	111	113
B	139	112

CONCLUDING REMARKS

A feasibility study of an Oxy-Fuel combustion in a 660 MWe pulverized coal fired steam power station has been carried out on four possible plant configurations. These have been evaluated both from the point of view of the performance variations and of the plant complexity. Some interesting results have been obtained, especially for what concerns parameters and configuration quantitative influence to boiler performances. In particular, in the configuration A the increase of power output and plant efficiency (about 2%) with respect to the base case assumes the highest value. It should be stressed that the overall evaluation of the simulation results is still in progress. In particular the energetic consumptions of the entire auxiliary equipments used to retrofit the reference plant for oxy-fuel combustion application will be analyzed in depth. From point of view of the energetic consumptions the air separation unit constitute certainly the most critical aspects. For the

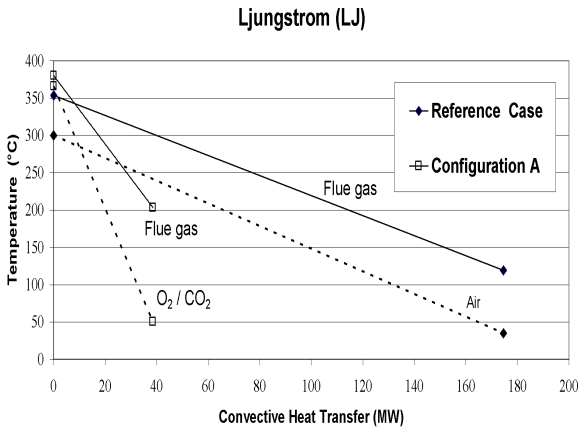

Figure 8: Temperature-exchanged heat diagram in the LJ for the reference case and the configurations A, respecively.

purposes of this paper, the power consumed in the cryo-ASU has been estimated in about 113 MWe, and the gross plant efficiency undergoes un decreasing of about 6-7 point per cent.

PREDICTION OF S.I. ENGINE PERFORMANCE IN STEADY AND TRANSIENT CONDITIONS

Giancarlo Ferrari*, Angelo Onorati
Dipartimento di Energetica - Politecnico di Milano
20133 Milano
Italy

ABSTRACT

The 1D thermo-fluid dynamic code GASDYN has been used to optimize the new configuration of a Fiat Fire 1.4 L automotive s.i. engine. The complete system formed by the engine together with its intake and exhaust groups have been modeled to predict its main performance parameters not only in steady state conditions, but also during the first transient part of the ECE cycle. Meanwhile the same quantities were measured in a test room to check the predictive ability of the code. The satisfactory agreement found between predictions and measurements proved the good accuracy of the code in predicting the gas composition at the exhaust valves. Relevant are the results given by the code modeling the complete engine system during the during the first 90 seconds of the new European driving cycle, to predict the effects of both engine parameters as well as catalyst geometry and position on the pollutant conversion efficiency.

Keywords: fluid-dynamic modeling, internal combustion engines, pollutant emission control.

INTRODUCTION

To-day the development and optimization procedure of the main components of a new I.C. engine requires a good synergy between experimental techniques and computational models, so that the actual engine testing may begin from a prototype close to its optimum design. In fact, computer models [1-10] are now able to simulate in a satisfactory way the main characteristics of the technical components introduced in the current generation of engines (i.e. variable valve timing, internal and external EGR, secondary air injection, advanced catalytic converters, etc..). So, once the numerical codes have been sufficiently validated by comparison with experimental measurements, they can be used as predictive tools in the optimization processes of main design variables of the whole engine system. Moreover, among numerical codes of different complexity, the 1D fluid dynamic models are generally the most widely used for evident reasons of times and costs.

Also the authors during last decades have continuously developed a 1D fluid dynamic model, called GASDYN, to simulate the whole system: engine plus intake and exhaust groups. In fact, the computer code has been continuously improved in its ability to predict the unsteady flows with the transport of reacting chemical species through more and more complex components of intake and exhaust systems [7-10]. At first comparing predicted results with experimental data accurately validated each part of the model. Then the authors have used GASDYN to predict the performance of complete different engines and to optimize the main components of the hole system, as well as manifold, silencer and catalytic converter shapes and locations.

In order to show the main features and the accuracy level reached by the code at the moment, this paper reports some results of an optimization work recently carried out on a Fiat Fire 1.4 L S.I. engine. In particular they will be discussed some

meaningful comparison between predicted and measured engine parameters, suitable to describe the in-cylinder combustion process, the related pollutant formation and the evolution of the unsteady reacting flows in the manifolds during steady and transient engine operating conditions.

ENGINE CHARACTERISTICS

The simulated engine is the new Fiat Fire 1.4 L automotive engine, installed on the Fiat "Punto" vehicle and complying with Euro IV limits. The main geometric and performance parameters, as well as reference valve timings and lifts, are reported in Table I.

Engine type	4 strokes, S.I., 16 valves
Swept vol., compr. ratio	1368 cm^3; 11.0
Bore, stroke	72 mm; 84 mm
Max. power	72 kW at 6000 rpm
Max. torque	127 Nm at 4000 rpm
Ref.Int.valve AVO/AVC	16° BTDC / 64° ABDC
Ref.Exh.valve EVO/EVC	55° BBDC / 19° ATDC
Intake / exhaust valve lift	8.0 mm; 6.5 mm

Table I – Main data of the simulated Fiat Fire 1.4 L automotive engine.

Peculiarity of this engine is an hydraulic device which allows the rotation of the camshaft relatively to the driving mechanism. This results in a typical variation of the intake and exhaust valve timings, which can retard both the intake and exhaust valve openings and closings from 0°(no delay) to 50°(maximum delay) of crank angles. This retard is useful to achieve significant internal EGR rates at partial load, because of the late exhaust valve closing, whereas the late intake valve closing determines a partial back flow of fresh charge during the initial part of the compression stroke. At partial load, both effects causes a reduction of pumping losses, while the high internal EGR rates gives an important reduction of NO_x emissions.
Moreover the two intake valves are fed by ducts of different shapes and functions. One of them directs the flow straight toward the cylinder with low fluid dynamic resistance, resulting in a tumble port able to give high air mass flow at full load and high rpm. The second one has a strong helical shape, resulting in a tangential port suitable to impose an effective swirl on the flow, even with small mass flow rates. A moving slider closes the tumble port at low engine loads, forcing all the air to go trough the tangential port and notably increasing the turbulence intensity in the combustion chamber. Therefore this port-deactivation system greatly helps in sustaining the burning speed, when the engine is fed by high EGR rates at partial load running condition.
The engine exhaust after-treatment system is characterized by a compact design of the exhaust manifold and a close-coupled catalyst. Recently the complete system formed by this engine together with its intake and exhaust groups (shown schematically in Figure 1) have been modeled by GASDYN, to predict its main performance parameters in steady and transient (first 90 seconds of the ECE cycle) running conditions.

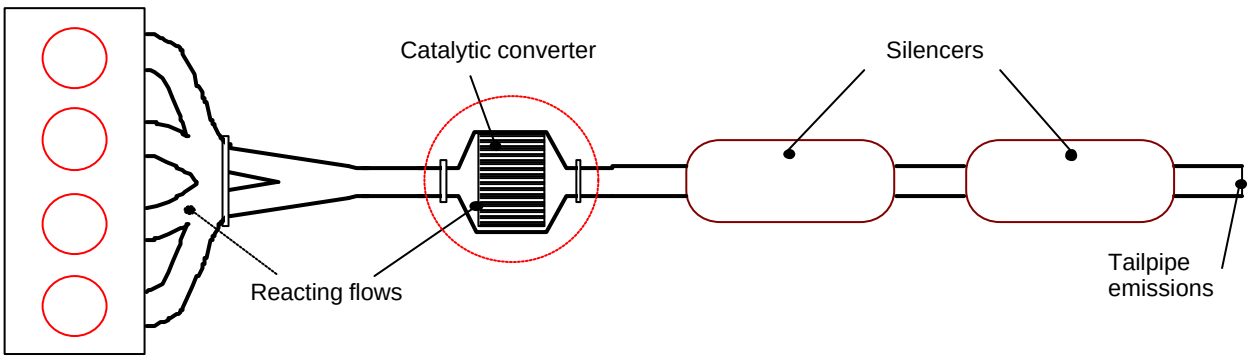

Figure 1 - Sketch of the four-cylinder spark ignition automotive engine simulated by GASDYN, in steady and transient (first 90 seconds of the ECE cycle) running conditions.

To validate the computer predictions with detailed experimental measurements, an extensive experimental work has been carried out on the engine test bench in ELASIS , in order to get a large set of measured data concerning: cylinder pollutant emissions, tailpipe emissions, gas and wall temperatures both in steady state engine running conditions and in transient conditions during the NEDC driving cycle. In particular, the attention has been focused on the first 90 seconds of the ECE cycle, which are quite critical during the global pollutant emission test.

STEADY CONDITION TESTS

First of all we recall that the initial composition of the exhaust gas discharged by the cylinders in the GASDYN code are predicted by means of a multi-zone thermodynamic combustion model, which includes dedicated kinetic emission sub-models described in detail in [9]. In fact the propagation of the flame front is calculated by means of an advanced fractal model [9-12] and an equilibrium approach is followed to evaluate the concentrations of the major species (H2O, H, H2, CO, CO2, O, O2, OH, N2, NO). However, CO, NO and HC cannot be satisfactorily calculated on the basis of the equilibrium assumption, but they have to be more properly evaluated by kinetic sub-models.

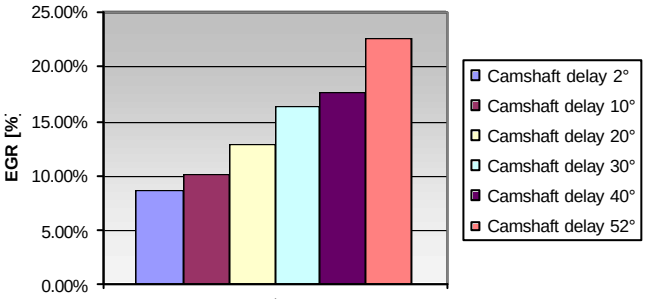

Figure 2 – Mass fraction of burned gases, trapped into the cylinder from the previous cycle, for different camshaft delays (engine conditions: n = 3000 rmp, bmep = 3 bar; slider closed).

The classical six-reaction extended Zeldovich model can be used for the calculation of NO, but also the super-extended Zeldovich model, based on 67 reactions, can be applied [13]. The CO concentration is evaluated on the basis of a kinetically controlled formation process [9]. Unburned HC are predicted by a dedicated sub-model, considering the different contributions due to crevices, to oil film layer and to incomplete combustion (partial burning and misfire) [14-18].
First of all the fractal combustion model, implemented within the thermo-fluid dynamic code GSDYN, can be tuned for the specific engine, to get a practical superposition of predicted and measured in-cylinder pressure history versus crank angle. In fact a good prediction of in-cylinder pressure is fundamental to correctly describe the physical action of the variable valve timing device and the wave actions in the intake and exhaust systems.

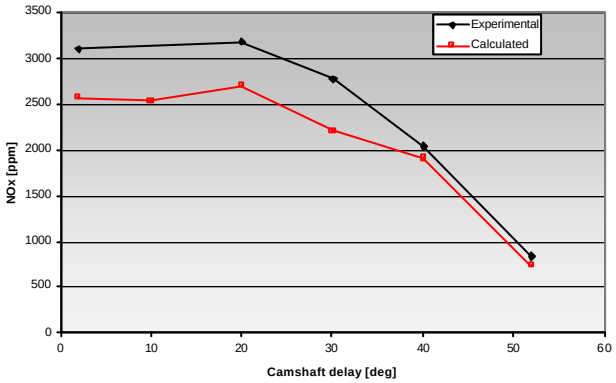

Figure 3 – Variation of NO_x concentration in gases exhausted by the cylinder, versus different camshaft delays (engine conditions: n = 3000 rmp, bmep = 3 bar; slider closed).

The model allows to follow in details the movement of different masses trough the valves and into the inlet and exhaust ducts, giving an important help in optimizing the effective valve timings. Finally it is possible to predict the total mass fraction of burned gases, trapped into the cylinder from the previous cycle (Figure 2), that is the internal EGR.
The burned gases act as a diluent in the new cylinder charge, reducing the combustion rate and the temperature reached after combustion. To keep the combustion rate at an acceptable level, in this engine the turbulence intensity is increased, closing the tumble port and forcing all the charge to flow trough the tangential port. On the other hand, because of the strong dependence of NO_x formation rate on the maximum temperature value

reached during combustion, the internal EGR effectively reduces NO_x emission levels.
The data in Figure 3 prove that the kinetic sub-model used to predict NO_x emissions from the cylinder, correctly catch the primary effect of EGR on NO_x formation process, given by a reduction of flame temperatures because of the increased heat capacity of cylinder charge, per unit mass of fuel burnt.

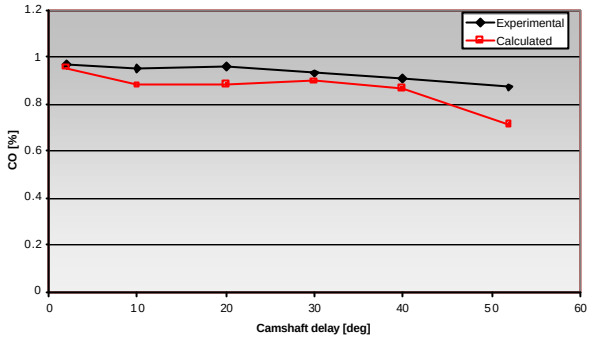

Figure 4 – Variation of CO concentration in gases exhausted by the cylinder, versus different camshaft delays (engine conditions: n = 3000 rmp, bmep = 3 bar; slider closed).

In fact the satisfactory agreement between predicted and measured values is the result of a correct simulation of both chemical and fluid dynamic processes.
Finally Figures 4 and 5 show that also the kinetic controlled sub-models for prediction of CO and HC emissions are strong enough, to be able to properly predict CO and HC concentration variation at the exhaust valves, with increasing camshaft delays and consequent masses of exhaust gas recycled.
Then, the main original feature of GSDYN is given by its ability in following the evolution of the gas composition along the exhaust ducts, taking account of possible chemical reactions that can occur node by node of the simulated system. In fact in the upper part of the exhaust system, where temperature is still high for many engine running condition, unburned HC and CO can be further oxidize, specially if secondary air is injected near the exhaust valve [10]. In any case the burned gases, whit their detailed chemical composition, are transported by the model through unsteady and reacting flows, until to the catalyst substrate, where catalytic reactions occur.

The prediction of the conversion characteristics of the catalysts is carried out on the basis of a specific sub-model that take into account in an integrated way the fluid dynamic, chemical and thermal processes typical of a catalytic converter [7,9]. A 1D approach is used to simulate the unsteady, laminar flow in the channels of the substrate. In this case only a single thin pipe, representing one channel, is considered for the simulation of the unsteady, reacting laminar flow in the monolith. The overall number of channels is important for the calculation of the substrate boundary conditions, i.e. the junctions (of several pipes) between the inlet/outlet cones and the monolith.
From the thermal point of view, in the converter is considered the heat released in solid phase by exothermic reactions and the thermal gradients due to the layer of insulating material. The multi-layer structure of the converter is taken into account, considering heat conduction in the system in the radial and axial direction. In this way the axial heat conduction from the metallic shell to the adjacent divergent and convergent ducts (and so to the rest of the exhaust system) can be calculated.

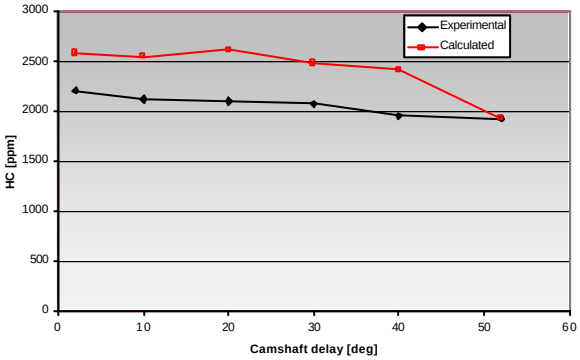

Figure 5 – Variation of HC concentration in gases exhausted by the cylinder, versus different camshaft delays (engine conditions: n = 3000 rmp, bmep = 3 bar; slider closed).

The main chemical reactions (oxidation of CO, C_3H_6, C_3H_8, H_2 and reduction of NO) occurring in the solid phase, within the wash-coat, are considered, by mean of appropriate kinetic expressions for the evaluation of the reaction rates on the basis of the catalyst temperature and species concentration in solid phase [19,20].

Moreover, the endothermic steam reforming reactions of the fast and slow oxidizing hydrocarbons have been introduced, which probably have a significant role in the conversion of HC for rich mixtures, providing some CO useful for the NO reduction. The water-gas shift reaction of CO with H_2O has been included, which is influenced by the oxidation state of Rhodium active sites. Finally an oxygen storage sub-model has been added to the chemical scheme, to describe the transient behavior of the system. The oxidation and processes of Cerium oxides are useful to store and release oxygen when the converter is fed with an oscillating gas composition. Typical mass transfer between gas and solid phase is taken into account. The predicted reaction rates are used to determine the specie source terms to be included in the fluid dynamic conservation equations, to allow for the modeling of chemical specie transport with reactions in the unsteady flow. The heat released by the exothermic reactions is accounted for as a source term in the heat transfer equations, to calculate the thermal transient of the catalyst and the consequent wall and gas temperature.

Comparisons between predicted and measured pollutant emissions at the catalyst inlet and outlet prove that a satisfactory modeling of the catalytic converter behavior can be achieved after an initial calibration of the kinetic constants which are needed to calculate the reaction rates, depending on the catalyst formulation. With an appropriate set of kinetic parameters the chemical model is able to properly catch the influence of the main operating parameters, in agreement with the experimental measurements.

TRANSIENT CONDITION TESTS

Moreover recently the code has been used to simulate the behavior of the complete engine system during the during the first part (first 90 seconds) of the new European driving cycle, to study the emission production related to the successive engine operating points (in transient conditions) and the consequent downstream action of the catalytic converter and to predict the effects of both engine parameters and catalyst geometry and position on the conversion efficiency.

In order to simulate the ECE driving cycle, coupling the engine to the vehicle, a simple one degree of freedom model has been developed, to evaluate the torque required by the vehicle to follow the prescribed velocity trend. A closed-loop control algorithm has been introduced in the simulation model to control the throttle valve opening angle and regulate the engine torque, in order to match the required vehicle torque. Moreover, a simplified modeling of the engine thermal transient from cold start has been considered, since the temperature of piston, cylinder head, cylinder liner, coolant have a significant influence on the production of unburned HC, originated from the crevices and the oil film layer. Similarly, possible partial burn and misfire during the combustion process of the first engine cycles have been taken into account. The variation of A/F ratio, spark timing, valve timing during the first 90 seconds of the ECE driving cycle have been considered as input data, assigned every second (or less) on the basis of the known engine operating points.

The simulation of the first part of the NEDC cycle, including the engine combustion, the vehicle, the transport of reacting species along the ducts and the catalyst conversion process, certainly requires a significant computational effort, since about a thousand of engine thermodynamic cycles must be calculated. On a Pentium IV 2 GHz PC the simulation requires about six hours, but the results provided are certainly important to investigate the key-issues of the engine + exhaust + vehicle system optimization, aiming at a reduction of pollutant emissions during the first seconds after the cold start.

Figure 6 shows the calculated emissions downstream of the engine, after the four-into-one manifold junction, and downstream of the catalytic converter, during the first 90 seconds of the ECE cycle. The predicted results are compared with the experimental measurements of NO, HC (as hexane, C_6H_{14}), CO and CO_2. These data prove that, with an appropriate set of kinetic parameters, the catalyst model can satisfactorily predict the conversion efficiency of the system as a function of the A/F values and other main engine parameters.

It can be noted that the overall agreement between predicted and measured emissions in Figure 6 is rather good in every case, both upstream and downstream of the catalyst, quantitatively and

qualitatively. In Figure 6(a) it is evident that the two peaks of emitted NO are related to the increase of load during the ECE cycle, corresponding to the accelerations of the vehicle.
Both of them are well predicted by the model. With regard to the unburned HC, the predicted trend is satisfactory, thanks to the sub-models embedded in the simulation code which take into account the different contributions due to the crevices, the oil film layer, the partial burn and some misfire during the engine cold running .

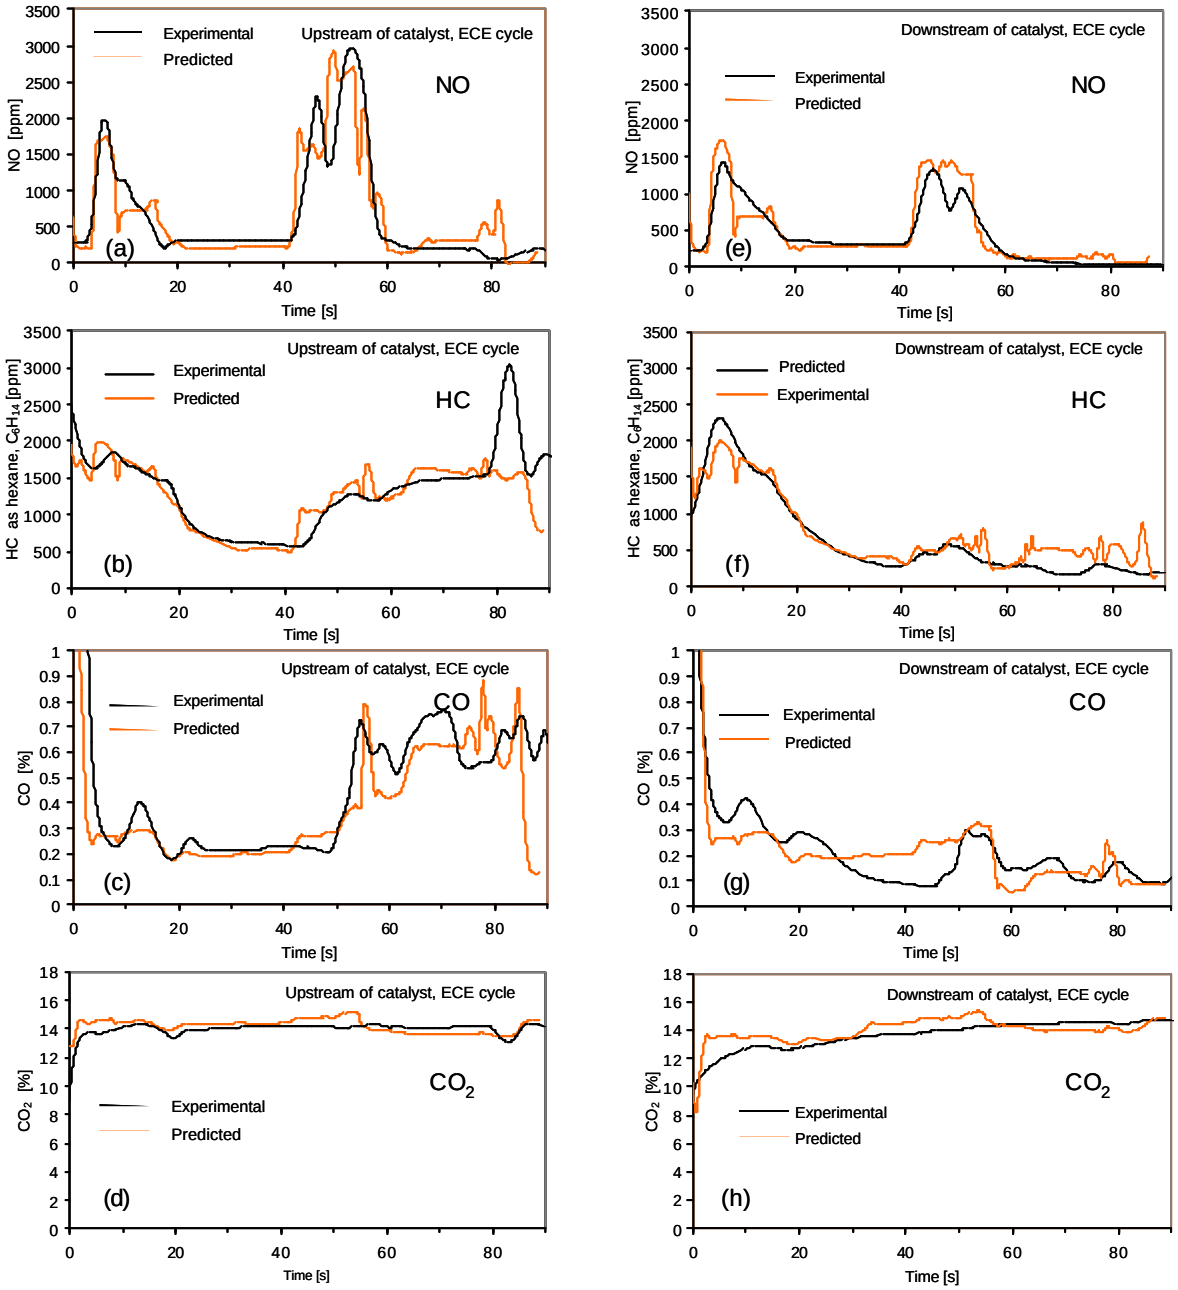

Figure 6 – Comparison between predicted and measured emissions upstream and downstream of the close-coupled catalyst, during the first 90 seconds of the ECE European cycle. Figures 6 (a), (b), (c), (d) refer to NO, HC, CO, CO_2 calculated and measured upstream of the catalyst, just downstream the exhaust manifold junction, while Figures 6 (e), (f), (g), (h) refer to NO, HC, CO, CO_2 calculated and measured downstream of the catalyst.

Also the agreement between predicted and measured CO and CO2 is fairly good, depending mostly on the A/F ratio values of the mixture fed to the engine during the ECE cycle. Some discrepancies can be noted in each diagram, which can be due both to some approximations in the modeling of engine emissions formation or of catalyst behaviour, as well as to inaccuracies in the experimental measurements.

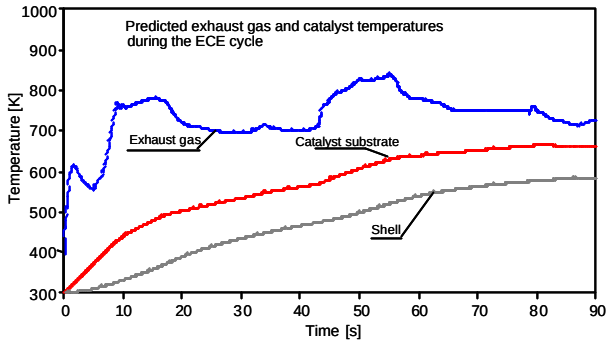

Figure 7 – Predicted exhaust gas temperature (upstream of the catalyst), catalyst substrate and shell temperatures during the first 90 s of the ECE cycle.

Figure 7 shows the predicted results concerning the exhaust gas temperature at the catalyst inlet (just downstream of the four-into one junction), the catalyst monolith temperature and shell temperature during the first 90 seconds of the ECE cycle. Two exhaust gas temperature peaks can be noted, related to the two vehicle accelerations (and consequent engine load increases) in this part of the ECE cycle. Moreover, the warm-up of the catalyst substrate (and consequently of the catalyst shell) is evident, starting from the ambient temperature of 300 K. The calculation points out a gradual heat-up from 300 K to about 650 K in 90 seconds.

CONCLUSIONS

The results achieved by the authors, using the GASDYN code to optimize different engine configurations, and particularly the Fiat Fire 1.4 L automotive s.i. engine presented in this paper, allow to draw the following conclusions:

- the code is able to simulate the fluid dynamic, thermal and chemical interactions between the engine and each intake and exhaust system component, predicting the exhaust gas composition from the cylinder to the tailpipe outlet and taking into account the effects of chemical reactions in the exhaust ducts and catalytic converters;
- the comparison between the simulation results and experimental measurements carried out on a new configuration of a Fiat Fire 1.4 L automotive S.I. engine, has pointed out that GASDYN can be used to calculate the behavior of the exhaust after-treatment system coupled to the engine not only in steady state conditions, but also during the real engine working conditions of the ECE cycle, considering the vehicle dynamics and the corresponding thermal transient of the system;
- therefore the influence of the engine parameters (A/F ratio, spark timing, valve timing, port-deactivation) and of the exhaust system design (geometry and position of the catalytic converter, monolith precious metal loading, etc..) can be usefully investigated during an important part of the effective test conditions, with a fundamental help in optimizing the manifold geometry as well as the silencers and converters shapes and locations.

Turkey

ABSTRACT

It is important to determine the effect of operational parameters in CFB combustors via a simulation study instead of expensive and time consuming experimental studies. From this point of view, in this study a model for a CFB combustor, which can be employed to simulate under a wide range of operating conditions, has been developed. The developed model includes coal volatilization, attrition and combustion of a char particle. In the modeling, the combustor riser is analyzed in two regions: bottom zone considering as a bubbling fluidized bed and upper zone core-annulus solids flow structure is established. In the model, solids return cycle has been considered. Simulation model calculates the axial and radial distribution of voidage, velocity, particle size, pressure drop, gas emissions and temperature at each time interval for gas and solid phases. The simulation results are compared with test results obtained from various CFBC test rigs at different size and developed model has been validated.

***Keywords*:** Modeling CFB, combustion, pressure distribution, temperature distribution, velocity distribution, voidage distribution.

NOMENCLATURE

AFR	Air to fuel ratio [-]
C	Gas concentration [kmol/m^3]
C_D	Drag coefficient [-]
c_v	Specific heat of gas [kj/kmol K]
d_p	Mean particle diameter [m]
d_{pi}	Particle dimension interval [m]
E	Emissivity [-]
D	Riser diameter [m]
D_g	Diffusion coefficient for oxygen [m^2/s]
G	Mass flux [kg/m^{2}s]
$G(\varepsilon)$	Solids stress modulus [N/m^2]
H	Riser height [m]
h_t	Overall heat transfer coefficient [W/m^{2}K]
$\dot{J}$	Mass transfer rate via density difference per unit volume [kmol/ m^{3}s]
k_a	Attrition constant [-]
k_c	Char combustion reaction rate [kg/s]
k_{cr}	Kinetic rate [1/s]
k_{cd}	Diffusion rate [1/s]
k_L	Reaction rate [1/s]
P	Pressure [kPa]
R	Radius of riser [m]
R_a	Particle attrition rate [kg/s]
R_u	Universal gas constant [kJ/kmol K]
R'''	Total heat generated/consumed per unit volume [W/m^3]
$\dot{R}$	Mass flow rate generated/consumed from chemical processes per unit volume [kmol/ m^{3}s]
Re	Reynolds number [-]
T	Temperature [K]
U_0	Superficial gas velocity [m/s]
u	Gas velocity [m/s]
u_b	Absolute rise velocity of bubble [m/s]
v	Particle velocity [m/s]
W_b	Mass of particle in the furnace [kg]
X_k	Char weight fraction [-]
x_i	Weight fractions of particles [-]
z	Distance from top of the riser [m]
z_i	Height of inflection point [m]
Z_0	Bed characteristic height [m]

τ	Shear stress [N/m^2]

1. INTRODUCTION

Increasing energy requirements and necessity of saving environment, Circulating Fluidized Bed Combustors (CFBC) are gaining importance when compared to other solid-fuel fired combustors. The advantages of CFBCs are; the ability to burn a wide variety of solid fuels with low pollutant emissions, high combustion efficiency, having smaller combustor cross section, fewer feed points, good turndown and load capability.

Modeling of coal combustion in the CFB is rather difficult. The fluid dynamics of this gas-solid two-phase flow is very complex and strongly dominated by particle to particle interactions. Furthermore, the numerous homogeneous and heterogeneous catalytic gas-phase reactions and their kinetics for the description of the combustion phenomena and the emission formation and destruction are not completely known. Therefore, it is necessary to develop simplified modeling approaches, which can describe both the gas-solid flow structure and the combustion process with sufficient accuracy. The main goal of the modeling of CFBCs is to constitute a system that maximizes combustion efficiency, and minimizes operating and investment costs and air pollutant emissions. It is also important to determine the effects of operational parameters in CFB combustors via simulation study instead of expensive and time-consuming experimental studies.

The publications in the literature about the CFB modeling may be subdivided into those that consider the hydrodynamic behavior [1-7,10,13-16], and others that investigate the combustion phenomena [1,2,17,18]. Although published models, have a similar structure, significant differences are found in the sub-models.

In the present study, a dynamic two dimensional CFBC model is developed. The model is applicable to different applications of CFBCs. The scheme of the combustor used in the model is shown in Fig.1. Simulation model calculates the axial and radial distribution of voidage, velocity, particle size, pressure drop, gas emissions and temperature at each time interval for gas and solid phase. The simulation results are compared with test results obtained from various CFBC test rigs at different size in the literature [6-10] and developed model has been validated.

2. CFB COMBUSTOR MODEL

This model includes the following constraints:

a) Although the physical and chemical processes occurring in the combustor are described, they include empirical correlations for less identified processes. b) The model should be flexible enough in order to be used in different applications of CFBCs. c) The computer code should be modular to allow users to update component modules easily as new findings become available.

Hydrodynamic Model: The flow structure of CFBs is known to exhibit axial nonuniformities [11,16]. In order to characterize this behavior, the riser is subdivided vertically into zones with different properties. According to Schoenfelder et.al.[12], four axial zones, bottom zone, splash zone, upper dilute zone and exit zone, are sufficient to give a reasonable description of the CFB flow structure.

According to the axial solid volume concentration profile, the riser is axially divided into two different zones: The bottom zone including splash zone and the upper zone including exit zone.

Bottom Zone: Experimental evidence has been reported by Svensson et.al. [13] and Werther and Wein [14] that, the fluid-dynamical behavior of the bottom zone is similar to that of bubbling fluidized beds. In generally lumped formulation is used for this zone in the literature. In this model, the bottom zone is simulated as a bubbling fluidized bed in fast bubbling fluidization regime. The flow domain is subdivided into a suspension phase and a bubble phase. The bubble rise velocity, the bubble size, the bubble volume fraction and the suspension porosity were calculated by extrapolating the Eskin [15] bubbling-bed model to the high gas velocities

used in the CFB. A single-phase back-flow cell model is used to represent the solid mixing in the bottom zone. Solids exchange, between the bubble phase and the suspension phase is a function of the bubble diameter and varies along the axis of the riser. The flow direction in the gas phase is considered upward; back mixing of gas is neglected.

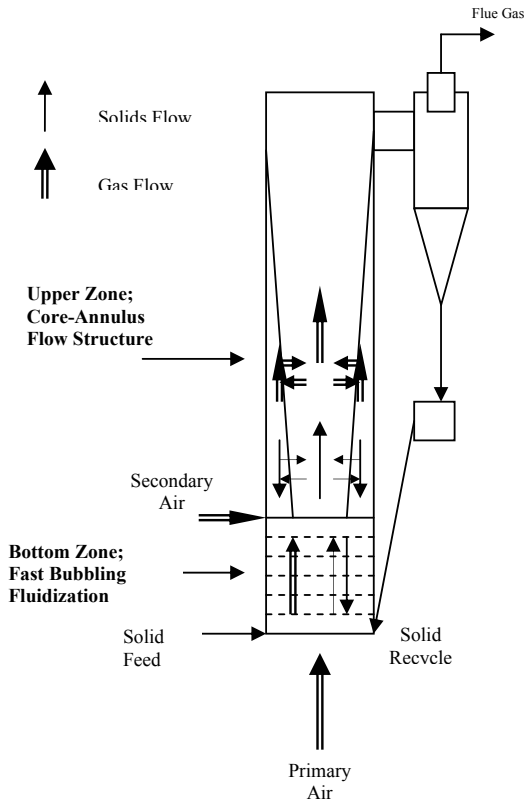

Figure 1. The scheme of the CFBC.

Upper Zone: Between the bottom zone and the riser exit the upper zone is located. Usually, most of the riser height is occupied by this zone, which is characterized by countercurrent-flow situation of dense clusters of particles (dense phase) moving downwards and upflowing lean suspension (lean phase) [1]. In this study, on the basis of the previous researchers [2,3,5], core-annulus flow structure in a CFBC is used. Particles move upward in the core and downward in the annulus. Thickness of the annulus varies according to the combustor height h. δ is given by Werther [14] as,

$$\frac{\delta}{D} = 0.55 \cdot \mathrm{Re}^{-0.22} \left(\frac{H}{D}\right)^{0.21} \left(\frac{H-h}{H}\right)^{0.73} \qquad (1)$$

Smolders et. al. [4] proposed a model in which the bed density was described as an exponential function of the bed height. In this paper, the model proposed by was used:

$$\frac{\varepsilon - \varepsilon_{mf}}{1-\varepsilon} = \exp\left(\frac{z - z_i}{Z_0}\right) \qquad (2)$$

In a conventional fluidized bed, the pressure drop through the bed is just equal to the weight of the solids in the bed. In the model, pressure drop in the riser consider as follows:

$$\nabla P = \rho g \nabla\left(z\left(1-\varepsilon\right)\right) + \frac{1}{2}\rho \nabla\left(v^2\left(1-\varepsilon\right)\right) \qquad (3)$$

where, the first term on the right hand side is pressure drop due to hydrostatic head of solids and second term is pressure drop due to solids acceleration.

In the fluidized beds, particle attrition takes place by surface abrasion, i.e. particles of a much smaller break away from the original particle. The upper limit size of the fines produced is in the range 50-100 μm [2,11,16]. The attrition rate is given as follows [2];

$$R_a = k_a \left(U_0 - u_{mf}\right) \frac{W_b}{d_p} \qquad (4)$$

For the upper zone, attrition rate is used as follows;

$$R_a = k_a \left(u - v\right) \frac{W_b}{d_p} \qquad (5)$$

Particles in the model are divided into n size groups in the model and mean particle diameter of different-sized particles considers as follows:

$$d_p = \frac{1}{\sum_{i=1}^{n}\left(x_i / d_{pi}\right)} \qquad (6)$$

Kinetic Model: While moving in the combustor, the char particle burns and undergoes attrition. The bed material in the combustor consists of coal, inert particles and limestone. Volatiles are entering the combustor with the fed coal particles. It is assumed that the volatiles are released in the bottom region of the CFB only. Volatiles are released at a rate proportional to the solid mixing rate. Volatile nitrogen and sulfur increases a function of bed temperature. The combustor model takes into account, the devolatilization of coal, subsequent combustion of volatiles followed by residual char, sulfur dioxide capture by limestone particles, reduction of NO_x by the char in the combustor.

Coal particles' behavior during the gas-solid reaction is assumed to be described in terms of shrinking core with attiring shell i.e. the dual shrinking-core model. Therefore the changes in particle diameter are taken into consideration in the model. The rate at which particles of size r_i shrink as follows;

$$r(r_i) = -\frac{dr_i}{dr} = \frac{12C_{O_2}}{\rho_c X_k (1/k_c + d_p / ShD_g)} \quad (7)$$

where D_g is the diffusion coefficient for oxygen, X_k is the char weight fraction.

The char combustion at each control volume is considered according to the reaction.

$$C + \frac{1}{\Phi} O_2 \rightarrow \left(2 - \frac{2}{\Phi}\right) CO + \left(\frac{2}{\Phi} - 1\right) CO_2 \quad (8)$$

and the combustion rate is calculated as follows:

$$r_c = \pi d_c^{\,2} k_c C_{O_2} \quad (9)$$

where k_c combustion reaction rate;

$$k_c = \frac{R_u T_b}{\frac{1}{k_{cr}} + \frac{1}{k_{cd}}} \quad (10)$$

During coal combustion, the sulphur compounds are oxidized and resultant sulphur dioxide is reduced by calcium oxide particles (produced by the limestone calcinations), forming calcium sulfate according to the reaction:

$$CaO + SO_2 + \tfrac{1}{2} O_2 \rightarrow CaSO_4 \quad (11)$$

The reaction rate of a limestone particle can be expressed as [19]:

$$k_L = \frac{\pi}{6} d_s^3 k_{vL} C_{SO_2} \quad (12)$$

where, k_{vL} presents the overall volumetric reaction rate constant and C_{SO_2} is the SO_2 concentration in the combustion gases.

Heat Transfer: Heat transfer model based on cluster renewal process[2]. The dilute phase is comprised of a continuous upflowing gas phase with thinly dispersed solids and relatively denser phase moving downward along the wall. Therefore some parts of the wall come in contact with the clusters and the dilute phase. If ε_{cl} is the average fraction of the wall area covered by the clusters, the time-averaged overall heat transfer coefficient, h_t, may be written as the sum of convective and radiative heat transfer coefficients,

$$h_t = \varepsilon_d h_{cl} + (1-\varepsilon_{cl}) h_d + \varepsilon_{cl} h_r + (1-\varepsilon_{cl}) h_{rd} \quad (13)$$

where h_{cl} and h_d are the convective heat transfer coefficient for the cluster and the dispersed phase respectively. Similarly h_r and h_{rd} stand for the radiative heat transfer coefficient for the cluster or the dispersed phase respectively. The radiative component is determined from the following equation:

$$h_r = \frac{\sigma \left(T_p^4 - T_b^4\right)}{\left\{\left(e_p^{-1} - e_b^{-1}\right) - 1\right\} \left(T_p - T_b\right)} \quad (14)$$

for gray particles. It is fairly accurate to estimate the bed emissivity from the particle emissivity.

$$e_b = 0.5\left(1 + e_p\right) \quad (15)$$

The external heat transfer coefficient h_o is calculated to be 17 W/m^{2}K, which is consistent with surface temperature measurements and experimental heat balances [9].

3. NUMERICAL SOLUTION

Table 1. shows the conservation of mass, momentum and energy equations for each phase and the constitutive relations used for the model. The calculation domain is divided into $m \times n$ grid nodes, in the radial and the axial directions respectively. With the cylindrical system of coordinates, a symmetry boundary condition is assumed at the column axis. The set of differential equations governing mass and momentum are solved using the Gauss-Seidel iteration method. At the walls, a partial slip condition is assumed for the solid and the gas phases. Then, the simulated results are obtained by using a combined Relaxation Newton-Raphson method.

4. RESULTS AND DISCUSSION

The developed simulation model is used for the simulation of the CFBC. In order to validate the developed model, simulation results are compared with the experimental data obtained from various CFBC test rigs at different size in the literature [6-10]. The information of experimental data used for comparison is shown in Table 2.

Continuity Equation

$$\frac{d\left(C_j\varepsilon_i\right)}{dt}=\sum_{\text{in}}\dot{C}_j\varepsilon_i-\sum_{\text{out}}\dot{C}_j\varepsilon_i+\dot{R}_j+\dot{J}_j$$

$$\left(j=O_2,CO,CO_2,NO,N_2O,N_2,HCN,CNO,NH_3,H_2O,SO_2,CH_4\right)$$

Momentum Equation

Radial direction

$$\frac{\partial\left(Cu\varepsilon_i\right)}{\partial t}+\frac{\partial\left(Cu\varepsilon_i u\right)}{\partial r}=-\frac{\partial\left(\tau_{rr}\varepsilon_i\right)}{\partial r}-\frac{\partial\left(\tau_{rz}\varepsilon_i\right)}{\partial z}-\beta\left(u-v\right)$$

Axial direction

$$\frac{\partial\left(Cu\varepsilon_i\right)}{\partial t}+\frac{\partial\left(Cu\varepsilon_i u\right)}{\partial z}=-\frac{\partial\left(\tau_{zz}\varepsilon_i\right)}{\partial z}-\frac{\partial\left(\tau_{zr}\varepsilon_i\right)}{\partial r}-\beta\left(u-v\right)$$

$$\tau_{rr}=2\mu\frac{\partial u}{\partial r}-\frac{2}{3}\mu\left(\frac{\partial u}{\partial r}+\frac{\partial u}{\partial z}\right)$$

$$\tau_{zz}=2\mu\frac{\partial u}{\partial z}-\frac{2}{3}\mu\left(\frac{\partial u}{\partial z}+\frac{\partial u}{\partial r}\right)$$

$$\tau_{rz}=\tau_{zr}=\mu\left(\frac{\partial u}{\partial z}+\frac{\partial u}{\partial r}\right)$$

Gas-solid friction coefficient [18];

$$\beta=\frac{3}{4}C_D\frac{C\varepsilon_i\left(1-\varepsilon_i\right)}{\varepsilon_i^{2.65}}\frac{1}{d_p}\left|u-v\right|$$

$$C_D=\frac{24}{\mathrm{Re}_p}\left(1+0.15\mathrm{Re}_p^{\,0.687}\right)\qquad \mathrm{Re_p}<1000$$

$$C_D=0.44\qquad \mathrm{Re_p}\geq 1000$$

İdeal gas equation

$$C=\frac{1}{R_u}\frac{P}{T_b}$$

Solids stress modulus

$$G\left(\varepsilon\right)=\frac{\partial\tau}{\partial\left(1-\varepsilon_i\right)}=10^{-8.76\cdot\varepsilon_i+5.43}$$

Energy Equation

$$C\varepsilon_i c_v\frac{\partial T_b}{\partial t}-uC\varepsilon_i c_v\frac{\partial T_b}{\partial x}-uC\varepsilon_i c_v\frac{\partial T_b}{\partial y}=R'''+\mu\varepsilon_i\left\{2\left[\left(\frac{\partial u}{\partial x}\right)^2+\left(\frac{\partial u}{\partial y}\right)^2\right]+\frac{1}{3}\left(\frac{\partial u}{\partial x}+\frac{\partial u}{\partial y}\right)^2\right\}$$

Table 1. The conservation of mass, momentum and energy equations for each phase and the constitutive relations for gas phase.

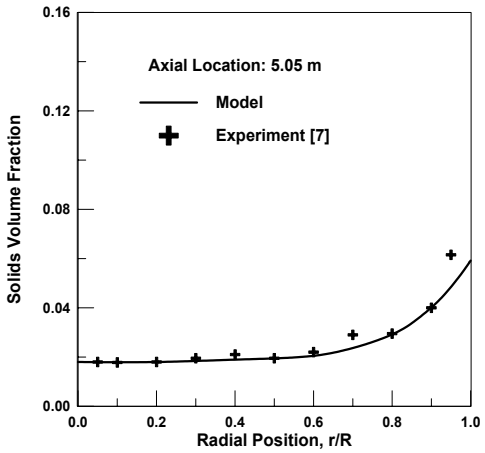

Figure 3. Comparison of model solids volume fraction values with Zheng et.al.[7]'s experimental data.

The solids particles are entrained up the column, against gravity, by the upflowing gas flow. The comparison of the radial profiles of local solids volume fraction with model predictions and experimental results are shown in Fig.3-4.

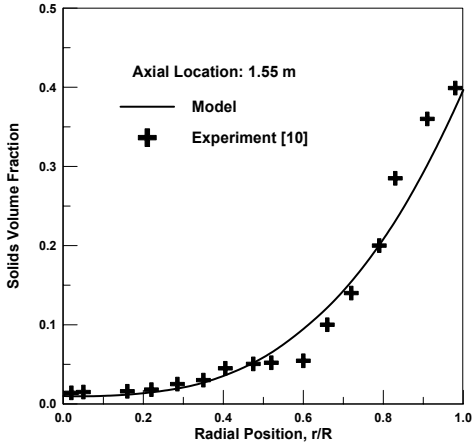

Figure 4. Comparison of model solids volume fraction values with Malcus and Pugsley[10]'s experimental data.

	Bed Temp. T(℃)	*Bed Diameter D(m)*	*Bed Height H(m)*	*Superficial Velocity U_0(m/s)*	*Particle Diameter d_p(μm)*	*Density ρ_p(kg/m^3)*	*Mass Flux G_p(kg/m^{2}s)*

Malcus and Pugsley [10]	25	0.14	7	4.7	89	1740	264

Table 2. Data comparing model results.

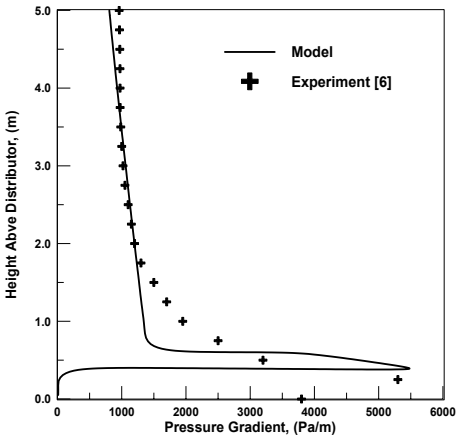

Figure 5. Comparison of model pressure gradient and Pugsley and Berruti [6]'s experimental data along the bed.

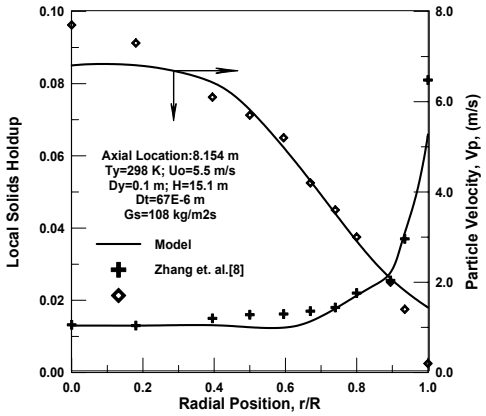

Figure 6.a. Comparison of model solids volume fraction and particle velocity values with Zhang et.al.[8]'s experimental data.

Generally, the change in the pressure gradient with height in CFBC is small. Figure 5 shows the axial profiles of pressure gradient predicted and obtained from experimental data. In the riser, the pressure gradient is always negative because the gas phase losses pressure head to accelerate and to suspend the particles. The absolute values of pressure gradient decrease monotonically with increasing distance from the riser entrance and then gradually approach a constant value.

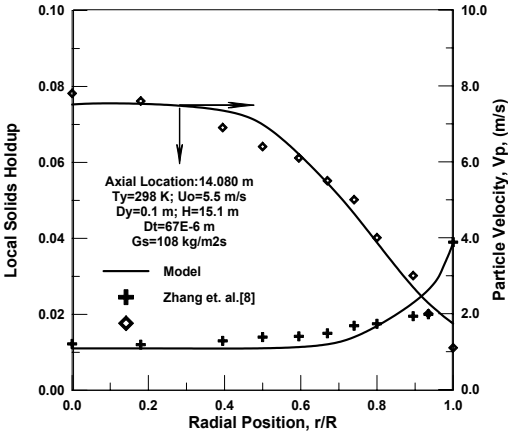

Figure 6.b. Comparison of model solids volume fraction and particle velocity values with Zhang et.al.[8]'s experimental data.

The overall radial structure generally shows a nonuniform solids volume fraction distribution with a dilute core and a dense annulus.

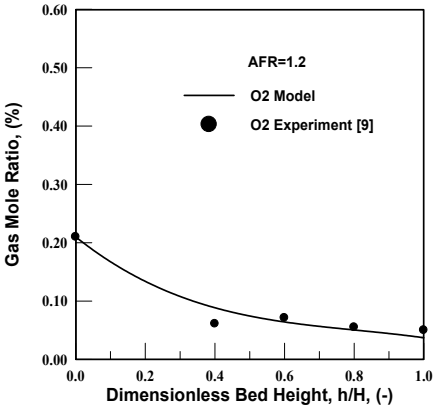

Figure 7. Comparison of model oxigen mol ratio with Topal[9]'s experimental data.

The radial profile is relatively flat in the core and solids volume fraction increases sharply toward the wall in the annulus with the highest solids volume

fraction right at the wall. The same trends above are observed in Fig.6 a-b. at two different bed heights corresponding to solids volume fraction profiles for test rig [8] which has smaller combustor diameter.

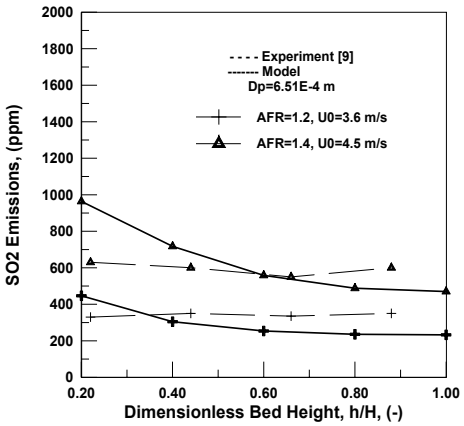

Figure 8. Comparison of model SO_2 emissions with Topal[9]'s experimental data.

To validate the hot bed model presented in this study, the molar ratio of oxygen, nitrogen oxide and sulfur dioxide emissions along the combustor height was obtained for the pilot CFBC using the same test data as the simulation program input Figs 7-9.

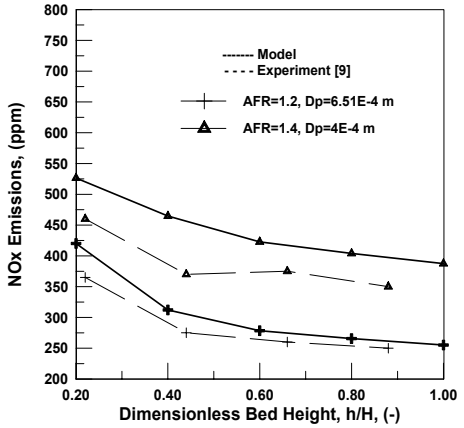

Figure 9. Comparison of model NO_x emissions with Topal[9]'s experimental data.

Mole ratio of oxygen along the combustor height in suspension phase in the bottom zone and dense phase in the upper zone is reasonably predicted by the model as shown in Fig. 7. As it is shown from the Figs.8-9., the simulated results are in good agreement with experimental ones.

The maximum deviation is about 5% for SO_2 and NO_x emissions at the bed height of 20 cm, which is at the coal feed point. This is due to the assumption that the great amount of the volatile matters is released at the feed point in the combustor.

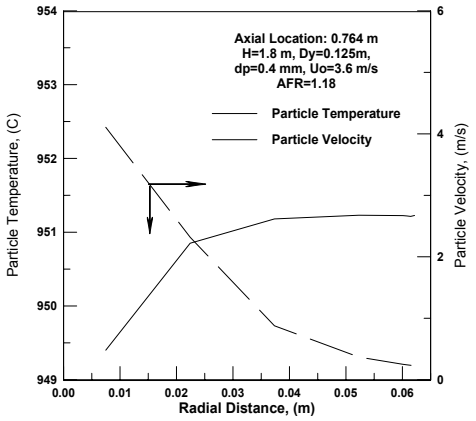

Figure 10. Radial profiles of bed temperature and particle velocity according to Topal[9]'s conditions.

Hot bed model results are shown in Figs.10-11. Particle temperature is increasing with increasing solids volume fraction toward the wall. Pressure gradient has an increasing trend along the radial distance as solids volume fraction increases and particle velocity decreases.

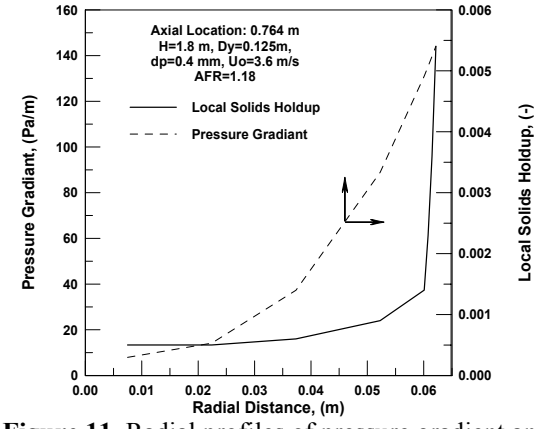

Figure 11. Radial profiles of pressure gradient and local solids hold up according to Topal[9]'s conditions.

5. CONCLUSION

In this study a dynamic two dimensional model for a CFB combustor is developed. The model is applicable to different applications of CFBCs. The

developed model includes coal volatilization, attrition and combustion of a char particle. In the modeling, the combustor riser is analyzed in two regions: bottom zone considering as a bubbling fluidized bed and upper zone core-annulus solids flow structure is established. In the model, solids return cycle has been considered. Simulation model calculates the axial and radial distribution of voidage, velocity, particle size, pressure drop, gas emissions and temperature at each time interval for gas and solid phase. The simulation results are compared with test results obtained from various CFBC test rigs at different size and developed model has been validated.

ABSTRACT

In this work, the effect of alcohol addition on the performance and emissions of a diesel engine fuelled with animal fat emulsions is studied. A single cylinder air-cooled, direct injection diesel engine is used. Tests are conducted using animal fat emulsions with water and alcohols. Methanol and ethanol are used to improve the physical properties of emulsions. Results show significant improvement in performance and emissions with animal fat emulsions as compared to neat animal fat. Smoke levels are drastically reduced with both the emulsions. Ethanol animal fat emulsion shows more reduction in smoke levels than methanol emulsion. No significant difference in NO emission is noted between the two emulsions. However, the values are very low as compared to neat fat and neat diesel. Hydrocarbon and carbon monoxide emissions are found as higher with ethanol emulsions as compared to methanol. However, these emissions are still lower than neat fat and neat diesel. On the whole it is concluded that animal fat emulsions with methanol and ethanol can be used as fuel in a compression ignition engine with improved performance as compared to neat animal fat.

Keywords: Diesel engine, Alternatives fuels, Alcohols, Animal fat, Emulsions, Emissions.

INTRODUCTION

The fast depletion of fossil reserve causes a renewal interest in renewable energy like biofuels based on vegetable oil or animal fat. In addition, since the European order dated on 14th November 2000 forbids to use animal fat in animal foods, the European feedstock has not found new applications. From its creation in 1909, compression ignition engines can run with vegetable oils as fuel. Studies of Elsbett's group on engine research very well proved that diesel engines can be directly run with vegetable oils as fuel [1,2]. Animal fats and vegetable oils are potential alternatives biofuels for diesel engines because their Lower Heating Value (LHV) and cetane number are close to standard diesel [3,4]. Moreover, animal fats and vegetable oils are composed of great molecules which are rich in oxygen as compared to standard diesel (cf. table 1). Contrary to fossil fuels, animal fats and vegetable oils are free from sulphur and heavy metals. But animal fat and vegetable oils have high viscosity and cause some injection problems if they are used without modifications in a compression ignition engine [5,6]. Transesterification is considered as one of the effective methods of improving the performance and reducing emissions of diesel engines using vegetable oils and fats as fuel. However, transesterification is a complex and time consuming process. It also produces certain products like glycerine and fatty acids which can not be used as fuel. The other effective solution to improve the combustion of heavy fuel is by

making stable emulsion with a water fraction [7,8]. Combustion of this kind of fuel leads to the well known “microexplosion” phenomenon [9,10].

Microexplosion occurs when a liquid droplet is trapped in an other liquid droplet with different volatility property. With temperature influence, the trapped droplet enters in a metastable state as far as homogeneous nucleation occurs violently. The resulting expansion causes the explosion of the second droplet leading to its fine atomisation. But in case of viscous liquid as emulsion formation increases the initial viscosity, the resulting emulsion is too viscous to be use in a C.I engine. The emulsion viscosity can be improved by the addition of alcohols with the animal fat while preparing the emulsions. Alcohols can also act as co-surfactants and improve emulsions stability. It has been reported that the animal fat emulsions with water and alcohol (ethanol and methanol) showed enhancement in physical properties of the emulsions and resulted in reduced emissions and improved performance of a diesel engine [11,12]. However, methanol has limited miscibility with diesel and heavy fuels. Contrary to methanol, ethanol is entirely miscible with animal fat. These alcohols are renewable fuels which can be obtained by fermenting agricultural waste containing sugar (ethanol) or by gasification of wood and coal (methanol) [13].

Properties	Diesel	Animal fat	Vegetable oil
Density (kg/m^3)	840	918	904
LHV (kJ/kg)	42490	39774	37000
Viscosity (cst)	4.59	49.93	40
Cetane number	45-55	40-45	35-40
Flash Point (°C)	75	96	120
Carbon (%w)	84-87	73	77.6
Hydrogen (%w)	33-16	12.3	11.6
Oxygen (%w)	0	12.5	10.8
Sulphur (%w)	0.29	0	0

Table 1 : Properties of Diesel, Animal fat and Vegetable oil [3-5]

In this study, the use of methanol and ethanol in making stable animal fat emulsion are compared. Performances and emissions with the two alcohols are studied and confront with base data obtained by using neat animal fat and standard diesel in compression ignition engine. The tested emulsions are the optima (cf. Table 3) from previous studies regarding in one hand: stability, fluidity and economical aspects [14,15], and in the second hand: performance and emission [3,11,13,16]. Experiments are conducted on a single cylinder diesel engine at the rated speed of 1500 rev/min with variable load conditions. Performance parameters like specific energy consumption, exhaust gas temperature and emission parameters like smoke, unburned hydrocarbon, carbon monoxide and nitric oxide emissions are evaluated. Finally, the efficiency of the added alcohol is discussed.

Best Emulsion	Water fraction	Animal fat fraction	Alcohol fraction
Methanol emulsion	10 %	80 %	10 %
Ethanol emulsion	10 %	50 %	36 %

Table 2 : Formulations of best animal fat emulsions with alcohol addition.

EXPERIMENTAL DETAILS

Emulsion process

An emulsion is obtained by mixing two immiscible liquids in presence of a stabiliser often called surfactant. The surfactant permits the emulsion to be well stable even if it is composed of a dispersed (the water) and a continuous (the fat) phase. The surfactant reduces the interfacial tension of the fat and allows the water droplets to be formed. The choice of surfactant is very important because it influences the emulsion stability and its nature. Referring to the bancroft law [17] , to make an indirect (water-in-oil) emulsion, the emulsifier must be more lipophilic than hydrophilic. Consequently the non-ionic surfactant SPAN 83 is used to stabilise the mixture because it has a HLB (Hydrophilic-Lipophilic-Balance) number equal to 3.7 [18]. According to the Davies’ scale, this emulsifier is appropriate for making water-in-oil

emulsions. Specified amounts of animal fat, water, alcohol and surfactant are taken in a container. The mixture is stirred vigorously since the fat and water are immiscible until a homogeneous phase is obtained. The emulsions are prepared by using a stirrer (Janker and Kunkel model RW 20 DZN) which rotates at maximum 2000 rpm. Since the fat is in solid form at temperatures lower than 60°C, a heater is used to give enough heat to maintain its liquid state. The heat energy is also used to enhance mixing rate and the emulsion formation. The animal fat container is kept in water bath and the emulsification process is carried out at a constant temperature of 30°C during mixing. This method has resulted in very stable emulsions. When the emulsion is ready, the heater is stopped and the emulsion can be used at ambient temperature (more than 20 °C).

Engine Set-up

A Single cylinder 4-Stroke air-cooled, direct injection open combustion chamber (bowl in piston) diesel engine developing a power output of 2.8 kW is used. Engine details are given in Table 3.

Make	LISTER – PETTER TS1
General Details	4-S, CI, Air cooled, DI, open chamber, NA, Single cylinder engine
Bore & Stroke	95.3 mm ×88.9 mm
Compression Ratio	18:1
Rated power output	2.8 kW at 1500 rev/min
Injector opening Pressure	250 bar
Displacement Volume	633 cc
Connecting rod length	165.3 mm
Fuel Injection Timing	20° BTDC

Table 3 : Engine Details

The Schematic of the experimental set up is shown in Fig.1. An electrical dynamometer is used for loading the engine. An orifice meter connected to a large tank is attached to the engine to make air flow measurements. An optical shaft position encoder is used to give signals at TDC. The fuel flow rate is measured on the volumetric basis using a burette. Chromel alumel thermocouple in conjunction with a slow speed digital data acquisition system is used for measuring the exhaust gas temperature. An infrared exhaust analyser is used for measuring HC/CO emissions. NO in the exhaust is measured by using a Beckman chemiluminascence analyser. Black carbon smoke levels are obtained by using a standard Hartridge smoke meter which works on light absorption technique (passing a light beam through the exhaust sample and the fraction of light is absorbed by the exhaust gas). Standard SAE J1667 procedure is followed for the measurement of smoke [19]. Light extinction coefficient K is used as the measure of smoke density per meter. It uses the following relationship:

$$K = (-1/L) * \ln (1-N/100),$$

Where, K = Smoke density (m^{-1}),
L = Optical path length of the smoke measurement (m) and
N = Smoke Opacity (%).

During the entire investigation the injection timing is optimized and set at 20^{o} before TDC. The engine is thermally stabilized before taking all measurements. Readings for engine speed, fuel flow, air flow, exhaust gas temperature etc. are recorded for obtaining performance parameters. Exhaust gas analyzers are calibrated before making measurements. Observations are made for smoke, NO, HC and CO to analyze the emission characteristics. Uncertainty analysis may be found in previous papers [3,12].

OBSERVATIONS AND RESULTS

As the quality of the fat vary according to the period, the results are influenced by its quality.

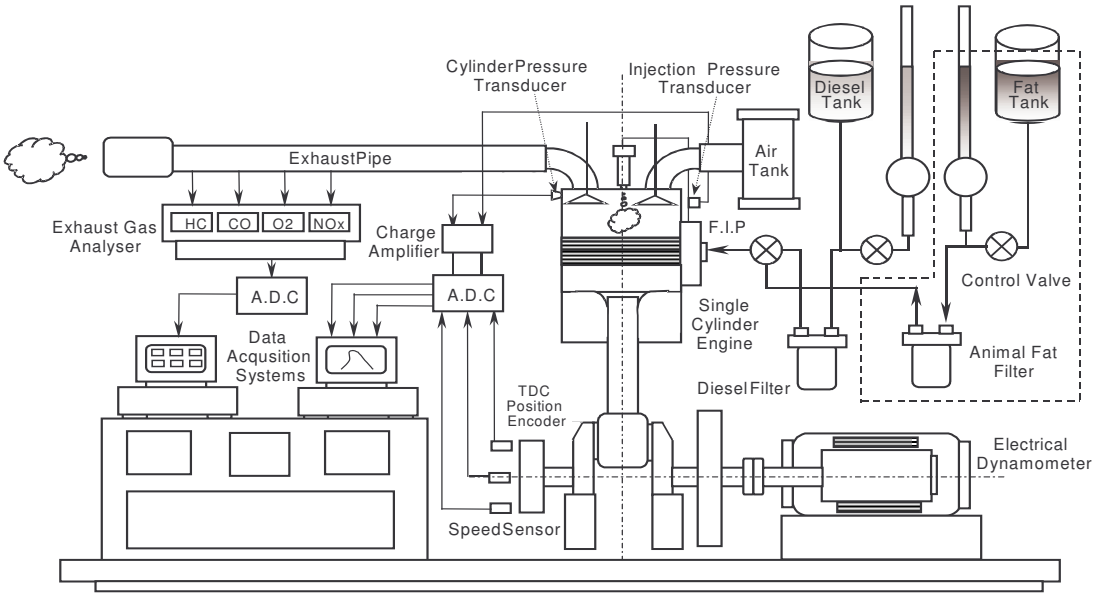

Figure 1 :Experimental setup

Thus on the obtained graphs neat fat results are represented by an interval drawn in dot lines instead of unique value.

Performance Parameters

The performance parameters are important because they permit to know the fuel ability to be used in a C.I engine. As shown in Fig. 2, Specific Energy Consumption (SEC) is estimated for neat diesel, neat fat and the best emulsions using methanol and ethanol at maximum power output.

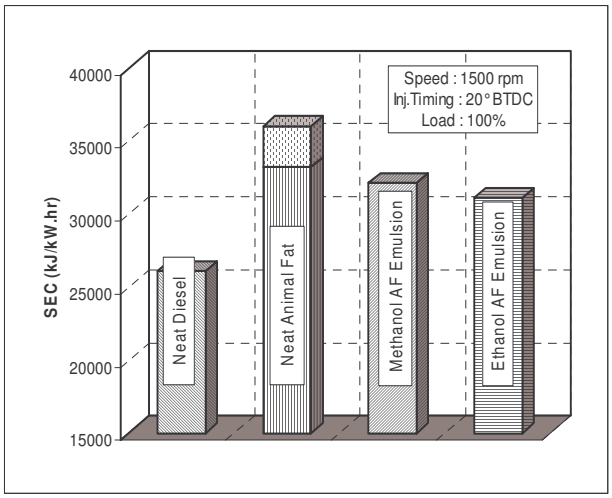

Figure 2 : Specific energy consumption estimated for the tested fuels(P =2.8 kW)

As compared to neat diesel, neat fat results in higher SEC that is due to its high viscosity. Viscous fuels suffer from bad atomisation which causes an increase in the SEC. In fact, mechanical efficiency is reduced as compared to standard diesel. As noted in Fig 2, emulsification of animal fat permits to reduce the SEC by decreasing the

mean diameter of injected fuel caused by the second atomisation (micro-explosion). In addition, the presence of surface agent in emulsions contributes to better atomisation characteristics of the fuel on leaving the injection nozzle. Ethanol emulsion reaches the minimum SEC of the emulsified fuels because ethanol is more miscible with animal fat than methanol that results in a lower viscosity.

The effects of substituting emulsified fuels for diesel oil on the exhaust temperature of the engine are shown in the Fig. 3.

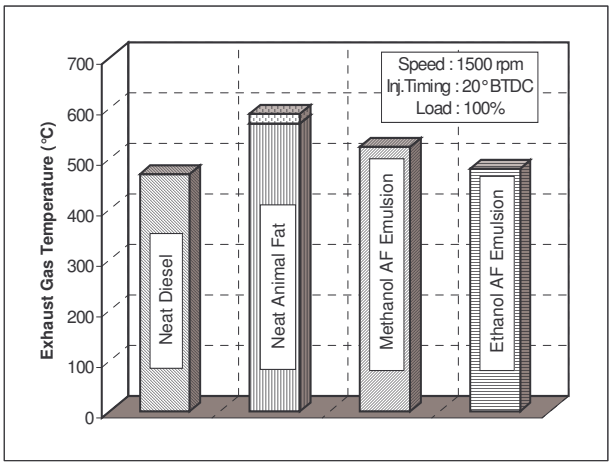

Figure 3 : Exhaust gas temperature measured for the tested fuels (P =2.8 kW)

The exhaust gas temperature in case of neat animal fat is higher than neat diesel. This result finds explanations in the facts that neat animal fat has longer ignition delay than standard diesel and is atomised in coarse droplets that take longer time to be entirely burned. Thus it is understandable that emulsified animal fat leads to a reduction of this temperature caused by a better atomisation. This result is the consequence of the microexplosion phenomenon. Ethanol animal fat emulsion yields to the minimum exhaust gas temperature as compared to methanol one. The obtained temperature is close to the temperature reached with neat diesel. Ethanol animal fat emulsion results in lower exhaust gas temperature as compared to methanol one due to the bigger quantity of high latent heat of vaporisation (alcohol + water) introduced in the fat (46 % by volume).

Emission Parameters

As shown in Fig. 4a and 4b, Carbon monoxide emission is measured for the different tested fuels at peak power output. Neat animal fat combustion yields to higher values as compared to neat diesel (cf. Fig. 4a).

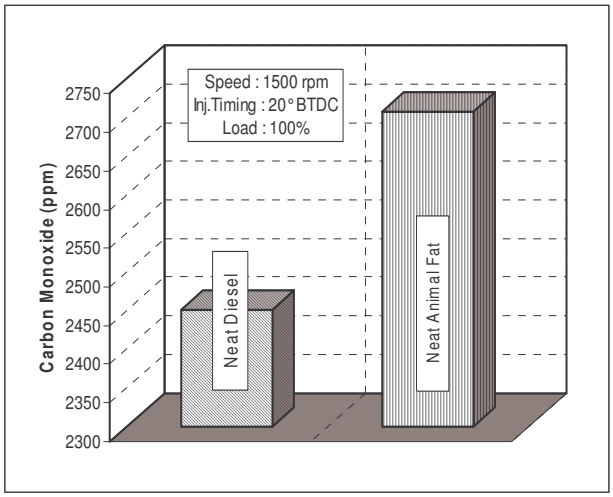

Figure 4a : Carbon monoxide emission measured for neat diesel and neat animal fat (P =2.8 kW)

The high viscosity of neat animal fat resulting in lean mixture can explain this value because this pollutant is mainly controlled by fuel/air ratio. However, animal fat emulsions drastically reduce this emission by improving the fuel/air mixture (cf. Fig. 4b). The two emulsions results in closed reduction but the methanol animal fat shows lower reduction than ethanol one.

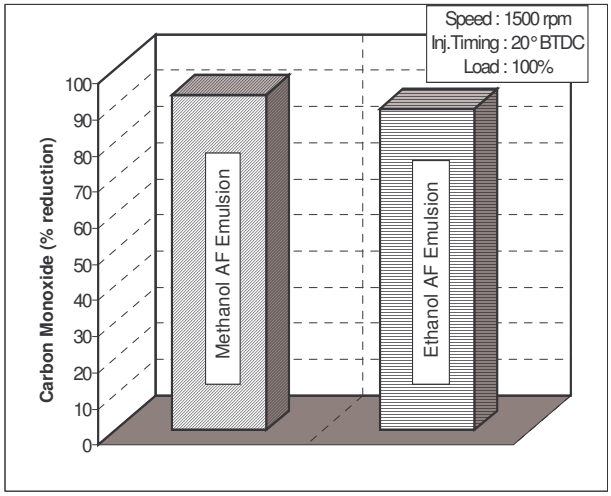

Figure 4b : Percentage reduction of carbon monoxide emission with animal fat emulsification (P =2.8 kW)

Figure 5a shows the measured unburned hydrocarbons at full power for standard diesel and neat animal fat. As unburned hydrocarbons are present in the exhaust gas for mainly the same reason than carbon monoxide, the same trend is observed.

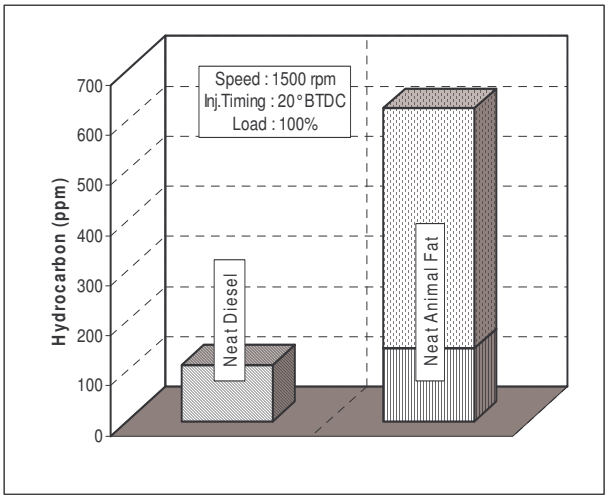

Figure 5a : Hydrocarbon emission measured for neat diesel and neat animal fat (P =2.8 kW)

Neat animal fat combustion yields to higher emission than standard diesel and its emulsification leads to a drastic reduction (cf. Fig 5b). Nevertheless ethanol animal fat emulsion results in lower reduction as compared to methanol one. This phenomenon find explanation in the bigger alcohol quantities in case of ethanol animal fat emulsion.

Thus the temperature of combustion is lower with ethanol than methanol and leads to partial combustion.

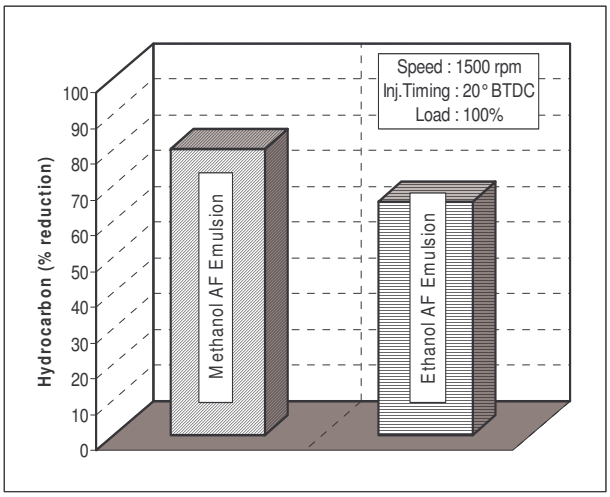

Figure 5b : Percentage reduction of hydrocarbon emission with animal fat emulsification (P =2.8 kW)

Nitric oxide emission is measured at peak power for the different tested fuels. The formation of NO is principally governed by high temperature and availability of oxygen. Neat animal fat yields to lower NO emission than standard diesel (cf. Fig. 6a). As previously noticed, neat animal fat is not well vaporised in the cylinder due to its high viscosity. Thus the resulting cylinder temperature is low. Emulsions further reduce NO emission because their alcohol + water content considerably decrease the flame temperature. Emulsions results are similar (cf. Fig. 6b).

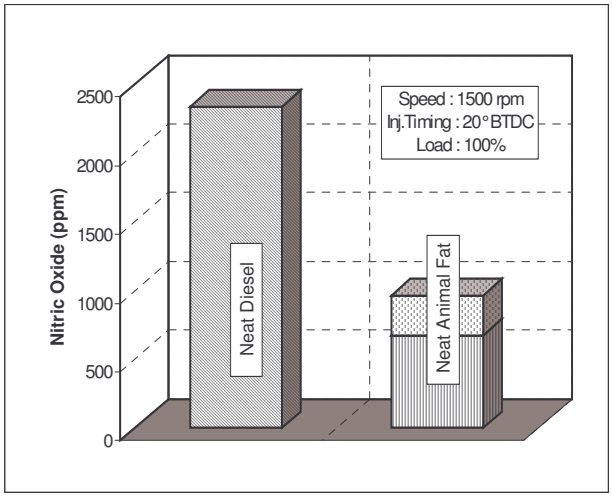

Figure 6a : Nitric oxide emission measured for neat diesel and neat animal fat (P =2.8 kW)

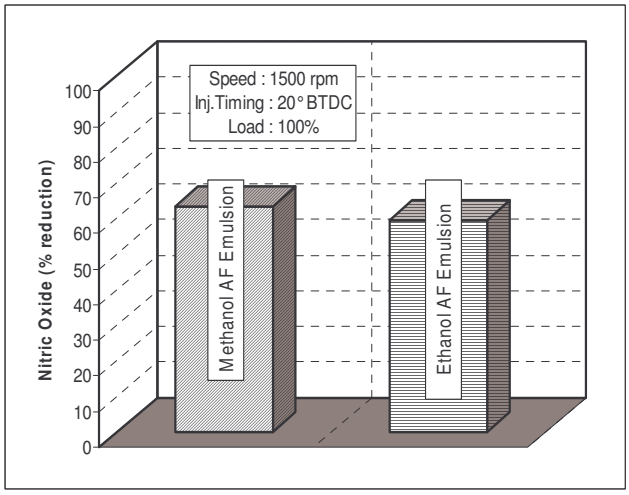

Figure 6b : Percentage reduction of nitric oxide emission with animal fat emulsification (P =2.8 kW)

Figure 7a illustrates the estimations of carbonaceous materials emission at full power output for standard diesel and neat animal fat. Neat animal fat results in lower smoke density than standard diesel. The high oxygen content of animal fat (cf. Tab. 1) permits to improve soot oxidation and to reduce its concentration in the exhaust gas.

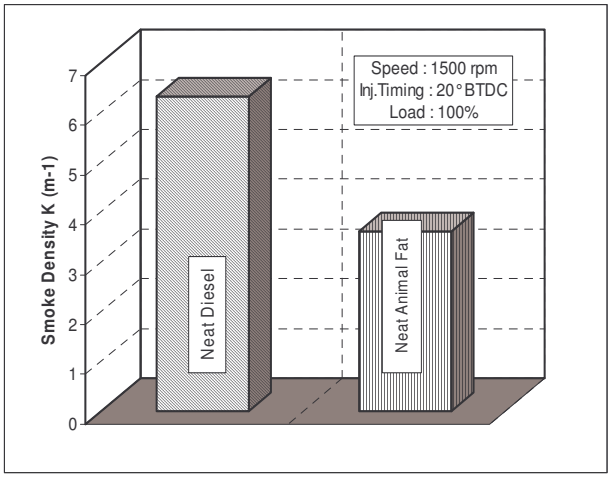

Figure 7a : Smoke density emission measured for neat diesel and neat animal fat(P =2.8 kW)

The emulsification of animal fat further promotes this reduction due to alcohol content which are well known oxidizers (cf. Fig 7b). In addition, the appearance of microexplosion that leads to a second atomisation permits to obtain a better fuel/air mixture. Hence smoke density reaches very low values with animal fat emulsions. The combustion of ethanol animal fat emulsion

produces the minimum soot emission because this emulsion has a higher alcohol content as compared to methanol one.

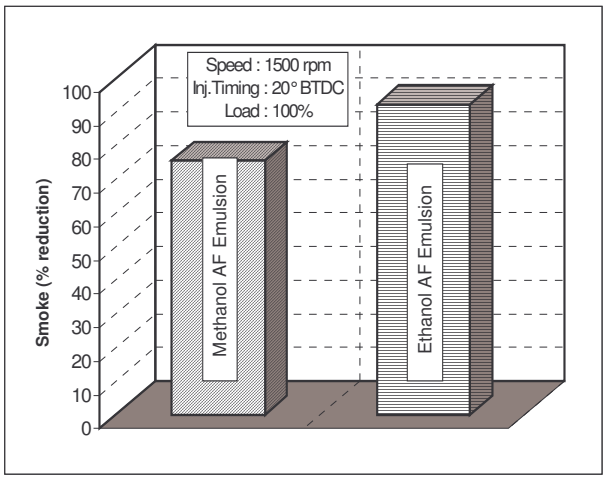

Figure 7b : Percentage reduction of smoke density emission with animal fat emulsification (P =2.8 kW)

Figure 8 shows the reduction percentage as compared to neat fat of pollutants emission at peak power output for animal fat emulsions. Emulsification of animal fat is a very efficient process to drastically reduce pollutants emission.

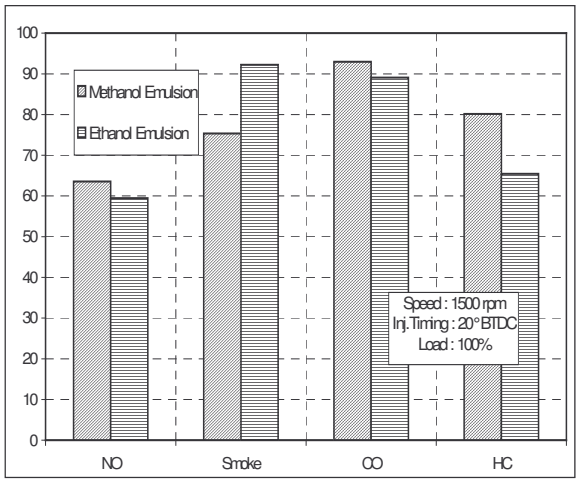

Figure 8 : Effect of the different animal fat emulsions on pollutants emission(P =2.8 kW)

As previously noticed, methanol and ethanol emulsions leads to similar results. Pollutants emission are reduced to more than 50 % and the reduction can reach 90 % for smoke or CO emission.

CONCLUSIONS

The use of animal fat in a compression ignition engine was achieved in this study. Neat animal fat and its emulsification with water via methanol and ethanol addition were tested. Performances and exhaust emission was analysed for this three different fuels and for standard diesel. From this experimental investigation several conclusions can be done :

- Engine performance by observing SEC and Exhaust gas temperature is lower with neat animal fat and its emulsions as compared to neat diesel. However, animal fat emulsions improve the performance as compared to neat fat. Ethanol animal fat results in best performance.
- Animal fat as a fuel yields to high emissions of hydrocarbons and carbon monoxides because of its high viscosity. Thus the fuel/air mixing is not well done. Nevertheless animal fat emulsions drastically reduce these emissions.
- Nitric oxide emission with animal fat is considerably decreased as compared to standard diesel. This phenomenon is amplified by its emulsification with methanol and ethanol which lead to closed values.
- Combustion of neat animal fat results in a decreased of smoke density as compared to standard diesel. In case of animal fat emulsions this emission is further reduced.

On the whole the percentage reduction of pollutant emission with animal fat emulsions are similar with the two alcohol added at peak load. This study can be extend by a partial load comparison.

SIMULATION OF IN-CYLINDER PROCESSES AND EMISSION FORMATION IN INTERNAL COMBUSTION ENGINES

Ugur Kesgin and Aykut Safa*
Yildiz Technical University
Department of Naval Architecture
TR 34 349 Besiktas – ISTANBUL

ABSTRACT

In order to obtain the effects of design and operational parameters on the engine performance and exhaust gas emissions, i.e. NO_x and HC, in-cylinder processes are modeled and evaluated using one-, two- and three zone combustion models for the high pressure part of the engine process and filling and emptying model for the gas exchange part of the engine process. The results are evaluated and compared to the experimental data of a gas engine operating on natural gas displays agreement. The effects of charge pressure and temperature, excess air ratio, start of combustion, combustion duration and form of combustion on the engine performance and on the emissions are investigated and optimum fields of the engine operation regarding engine efficiency and emissions are investigated.

INTRODUCTION

The goal in development of engines is to optimize engine performance within the reduced emission levels. Studies on NO and HC formation mechanisms for internal combustion engines using one-, two-, and three- zone models are widely available in the literature [1-12]. NO_x emissions are composed of NO and NO_2 emissions. In cylinder NO_x emissions are, in particular, NO gases. Atmospheric nitrogen is the main NO emission source. The other sources of NO emission are oxidation of molecular nitrogen and behind the flame front, NO formation in the flame front and oxidation of fuel bound nitrogen. HC emission formation processes in SI engines are: quenching of flame on the cylinder wall, crevice based HC emission formation, absorbed HCs by oil layer on the cylinder wall and lean combustion [13]. In this study, in cylinder processes are modeled and engine performance is analyzed, considering emissions released.

IN-CYLINDER PROCESS MODELING

In cylinder processes are modeled using zero dimensional process models in a computer program. In cylinder combustion models, one-, two- and three zone models are explained in Figure 1. The assumptions and the main equations of these models and the differences of the models can be seen from this Figure. The main difference between one-zone and multi-zone model is that the multi-zone models require dividing the combustion chamber in unburned and burned zones. In two zone model, combustion chamber consists of burned and unburned zones. In three zone model, the combustion chamber is divided into two zones, namely, burned and unburned zones, and an additional crevice volume. The crevice volume surrounded by cylinder liner, piston and piston ring is considered as the third zone, all the crevices are modeled as a single crevice with a volume equal to the total crevice volume. In three-zone model temperature of gas leaving crevice volume is equal to the liner temperature.

The heat is transferred through surfaces of the piston, cylinder head and cylinder liner. For the heat transfer areas of the unburned and burned zones some empirical relationships considering mass-burned fraction can be used [15]. By using this acceptation the heat transfer from the unburned and burned zones can be represented as follows:

$$\frac{dQ_u}{d\theta} = (1 - x^{1/2}) \sum_{i=1}^{3} A_i \alpha_u (T_u - T_{w_i})$$

$$\frac{dQ_b}{d\theta} = x^{1/2} \sum_{i=1}^{3} A_i \alpha_b (T_b - T_{w_i})$$

i=1 piston, *i=2* cylinder head, *i=3* cylinder liner

Detailed information about the two zone combustion model can be found in Pischinger [14] and Ferguson [15]. The combustion is modelled by using a VIBE function, which is defined by the start of combustion, the combustion duration, a shape parameter m, also called the form factor [14].

CALCULATION of NO_x and HC EMISSIONS

For the calculation of the NO_x and HC formation in internal combustion engines a computational program was developed. The NO_x model is based on a reaction-kinetic model developed by Pattas and Haefner [16] and calculates the NO_x formation with the input of engine speed and fuel data as well as the following: zero dimensionally determined pressure, temperature, air excess ratio, volume and mass depending on time in the burned zone. The latter is necessary because the theory for NO_x formation is based on the dissociation of N_2 and O_2 molecules following the high temperature of the gas in the front of flame. The reactions used for the calculation of the NO_x formation are represented in Table 1 [16]. The calculation of the NO_x formation is begun at the combustion start. In this reaction kinetic model the chemical equilibrium of 19 different concentrations is used, which are calculated with the help of a program developed at the Institute for Internal Combustion Engines and Thermodynamics of Technical University of Graz [56]. These concentrations are: CO_2, O_2, H_2O, N_2, Ar, CO, CH_4, C, O, O_3, OH, H, H_2, N, NO, NO_2, NH_3, HNO_3, HCN. During the calculation it was also necessary to calculate the concentration of N_2O. This is computed with the help of the statically averaged equilibrium constants, as partial pressure relation, obtained as follows [16].

$$\frac{N_2O}{N_2\sqrt{O_2}} = 1.1802.10^{-6}.T_1^{0.6125}.\exp\left[\frac{-18.71}{R.T}\right]$$

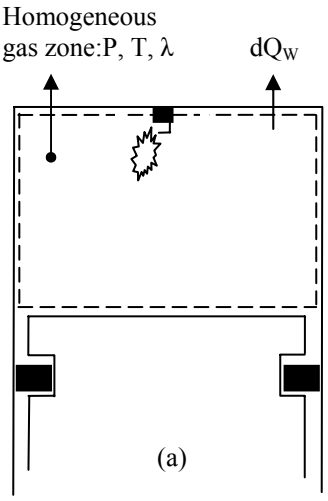
Table 1: Reactions for NO_x formation

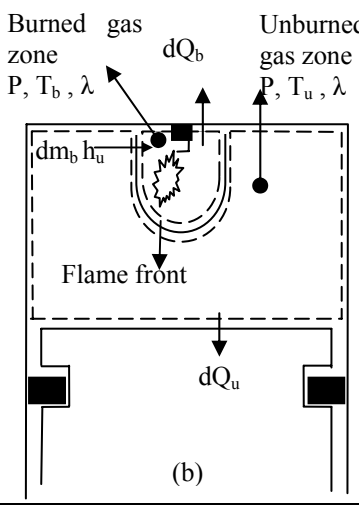
$$N_2 + O \leftrightarrow NO + N$$
$$O_2 + N \leftrightarrow NO + O$$
$$OH + N \leftrightarrow NO + H$$
$$N_2O + O \leftrightarrow NO + NO$$
$$O_2 + N_2 \leftrightarrow N_2O + O$$
$$OH + N_2 \leftrightarrow N_2O + H$$

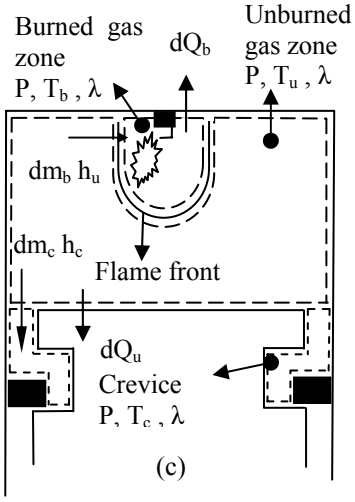
The HC formation mechanism for hydrocarbon fuels is so complex that it is usually not feasible to consider all the chemically reacting species and their reaction rates when analysing practical combustion systems. To simplify the chemistry it is useful to use a global reaction scheme. Therefore, to calculate the HC formation a post-flame oxidation with a one-step global reaction in cylinder is used. The Arrhenius equation for methane is taken from Borman and Ragland [17].

$$\frac{d[CH_4]}{dt} = -8.3 \cdot 10^5 \exp\left(\frac{-15098}{T}\right)[CH_4]^{-0.3}[O_2]^{1.3}$$

Post-flame oxidation in the cylinder is assumed to occur in a boundary layer near the cylinder wall, where the temperature is equal to the average of







ASSUMPTIONS

1) The pressure in the combustion chamber is uniform at any instant of time.
2) Blow-by does not occur.
3) The mixture of residual gas, fuel and air is perfect.

$$\frac{dm}{d\theta}=\frac{dm_i}{d\theta}+\frac{dm_f}{d\theta}-\frac{dm_e}{d\theta}$$

Energy equation:

$$\frac{d(mu)}{d\theta}=-p\frac{dV}{d\theta}+\frac{dQ_f}{d\theta}-\sum\frac{dQ_W}{d\theta}+\sum\frac{dm_i}{d\theta}h_i-\sum\frac{dm_e}{d\theta}h_e$$

$\frac{d(mu)}{d\theta}$ change of the internal energy in the cylinder

$-p\frac{dV}{d\theta}$ piston work

$\frac{dQ_f}{d\theta}$ fuel heat input

$\sum\frac{dQ_W}{d\theta}$ wall heat losses,

$\sum\frac{dm_i}{d\theta}h_i$ energy input into the cylinder through inlet valve,

$\sum\frac{dm_e}{d\theta}h_e$ energy output from the cylinder through exhaust valve

ASSUMPTIONS

Assumptions 1-3 from one-zone model:
4) No heat transfer between zones.
5) The flame front between the burned and the unburned zones is very thin.
6) Each zone is assumed to be in thermodynamically and chemically equilibrium.
7) For the compression the cylinder contents occupy only the unburned zone. The burned zone forms after combustion starts.

EQUATIONS

Total mass in cylinder:

$$m=m_u+m_b$$

$$\frac{dm_u}{d\theta}+\frac{dm_b}{d\theta}=0$$

Energy equation

$$m\frac{du}{d\theta}+u\frac{dm}{d\theta}=-p\frac{dV}{d\theta}+\frac{dQ_f}{d\theta}-\frac{dQ_W}{d\theta}+\sum\frac{dm_i}{d\theta}h_i-\sum\frac{dm_e}{d\theta}h_e$$

$p\frac{dV}{d\theta}$ = the piston work = W

Cylinder volume

$$V=V_u+V_b$$

V=f (Cylinder geometry, crank angle)

Energy of the cylinder content

$$u=\frac{U}{m}=xu_b+(1-x)u_u$$

Specific volume of the system

$$v=\frac{V}{m}=xv_b+(1-x)v_u$$

ASSUMPTIONS

Assumptions 1-6 from two-zone model:
4) The crevices in the combustion chamber are modelled as one crevice, which's volume is equal to the total volume of all crevices.
5) The temperature of the gas discharged from the crevices is the same as the cylinder liner temperature.
6) For the compression the cylinder contents occupy two zones, namely unburned zone and crevice zone, and each zone is spatially homogenous. The burned zone exists first after combustion start.

EQUATIONS

Total mass in cylinder:

$$m=m_u+m_b+m_c$$

$$\frac{dm_u}{d\theta}+\frac{dm_b}{d\theta}+\frac{dm_c}{d\theta}=0$$

The mass in the crevice volume:

$$m_c=\frac{pV_c}{RT_c},\quad \frac{dm_c}{d\theta}=\frac{V_c}{RT_c}\frac{dp}{d\theta}$$

The differentiation of the mass in the unburned zone:

$$\frac{dm_u}{d\theta}=-m_b\frac{dx}{d\theta}-\frac{V_c}{RT_c}\frac{dp}{d\theta}$$

Energy equation:

$$m\frac{du}{d\theta}+u\frac{dm}{d\theta}=-p\frac{dV}{d\theta}+\frac{dQ_f}{d\theta}-\frac{dQ_W}{d\theta}-h_c\frac{dm_c}{d\theta}+\sum\frac{dm_i}{d\theta}h_i-\sum\frac{dm_e}{d\theta}h_e$$

The enthalpy of the mass transferred between the cylinder and the crevice volume:

$$h_c=h_c(p,T_c),\quad \frac{dm_c}{d\theta}<0$$

$$h_c=h_u(p,T_u),\quad \frac{dm_c}{d\theta}>0$$

Figure 1: (a) One-, (b) two- and (c) three-zone models.

the wall and burned gas temperature in cylinder. This assumption is used also by Dent and Lakshminarayanan [18] and Schramm and Sorenson [19].

MODEL VERIFICATION

By adapting the calculation of combustion models to different engine operating conditions, the three-zone model presented here allows the prediction of the change in NO emission as well as HC emissions depending on engine load, engine speed, charge air pressure, charge air temperature, humidity of the combustion air, fuel type, combustion characteristics (start, duration and form of combustion). In the Figures 2 and 3, data measured on the test engine and computed values are shown. Test engine is a turbocharged lean burn gas engine working on natural gas. Its specifications are stroke/bore ratio of 220/190 mm/mm, engine speed of 1500 rpm, excess air ratio of over 1.7 and compression ratio of 11. The pressure data, measured and computed, shows a remarkably well agreement (Figure 2a). The changes in mass of three zones during combustion period can be seen in Figure 2b. Before the combustion starts, burned zone has not evolved, but unburned zone and crevice volume exist. With the start of combustion, burned gas region develops. As the combustion starts, burned gases prevail in the cylinder. However, the change in crevice volume mass is very small. Since the zones are fictitious, mass data are computed. Under eight different conditions of excess air ratio, charge pressure, ignition timing for the test engine, measured and calculated emissions data are shown in Figure 3. The results show a good proximity.

EFFECT OF ENGINE DESIGN AND OPERATION PARAMETERS ON ENGINE EFFICIENCY AND EMISSIONS

One of the primary optimisation targets in engine development is maximisation of the efficiency while, at the same time, producing minimum NO_x and HC emissions. The effects of combustion-start and duration, excess air ratio, charge temperature, charge pressure and crevice volume were investigated by using the three-zone combustion model described above. The results of these investigations are summarised in Table 2.

Effect of Combustion- Start and Duration

In order to execute parametric studies and to examine basic relations, application of the zero dimensional process calculation is particularly helpful and efficient. Thus, under the specification of the VIBE form factors derived by using heat release calculated from the three dimensional combustion model, variation calculations were also executed for different combustion starts and combustion durations. The results are represented via isolines for constant indicated efficiency and for constant emissions (Figure 4). From these results, basic information about the efficiency and emissions of the respective concepts can be determined immediately.

Table 2: Effect of excess air ratio, charge temperature and pressure and crevice volume

Engine Parameter	Change in the Parameter	Change in		
		Efficiency [%]	NO_x [%]	HC [%]
Excess Air Ratio	+ 0.1	+ 0.3	- 55	- 0.5
Charge Temperature	- 10 K	+ 0.6	- 14	- 1
Charge Pressure	+ 0.1 bar	+ 0.08	1	0
Crevice Volume	- % 50	+ 0.05	+ (5-8)	- 47 %

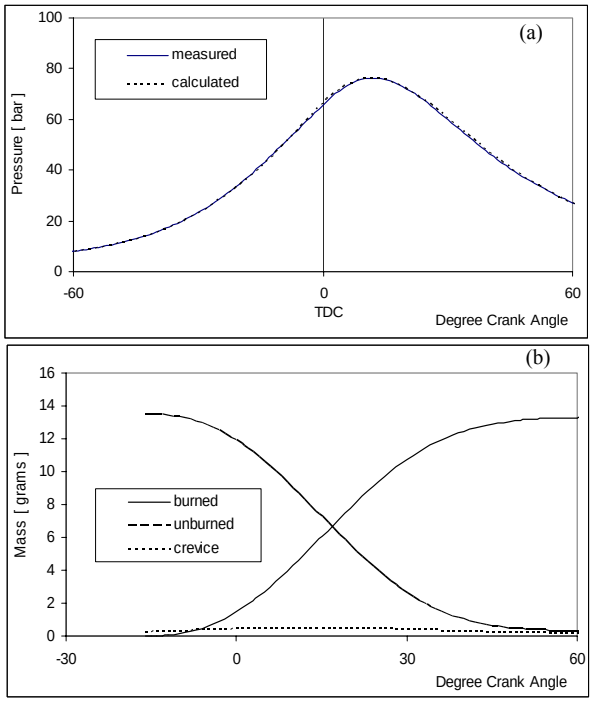

Figure 2: Comparison of computed and measured in cylinder pressure data (a) and of computed burned, unburned and crevice mass data (b) on crank angle basis.

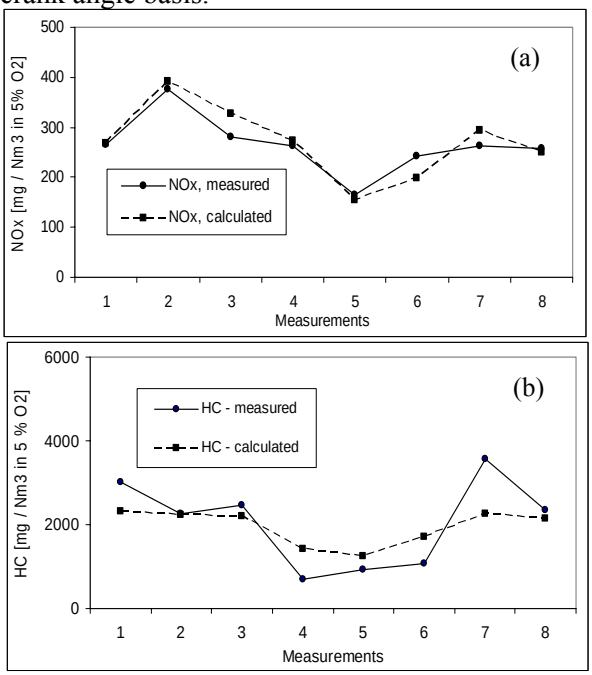

Figure 3: A Comparison of emissions from calculation and measurement
(a) NO_x emission, (b) HC emission

Spark timing significantly affects NO and HC emissions levels. Advancing the timing so that combustion occurs earlier in the cycle increases the peak cylinder pressure (because more fuel is burned before top dead centre (TDC) and the peak pressure moves closer to TDC where cylinder volume is smaller), while retarding the timing decreases the peak cylinder pressure (because more of the fuel burns after TDC). Higher peak cylinder pressures result in higher peak burned gas temperatures and, hence, higher NO formation rates. For lower peak cylinder pressures, lower NO formation results [20]. Naturally, the highest efficiency occurs at the maximum brake torque, hence retarding the timing moves away from this point and increases the specific fuel consumption. [17].

The same effects mentioned above for combustion start on the rate of NO_x emissions and on the engine efficiency for these engine concepts can be determined from Fig. 4a. As it can be seen from these Figures, the longer combustion durations result in a lower amount of NO_x emissions. Also as it can be seen from Fig. 4b, the same effect of combustion- start and duration on HC emission occurs as it is on NO_x emission.

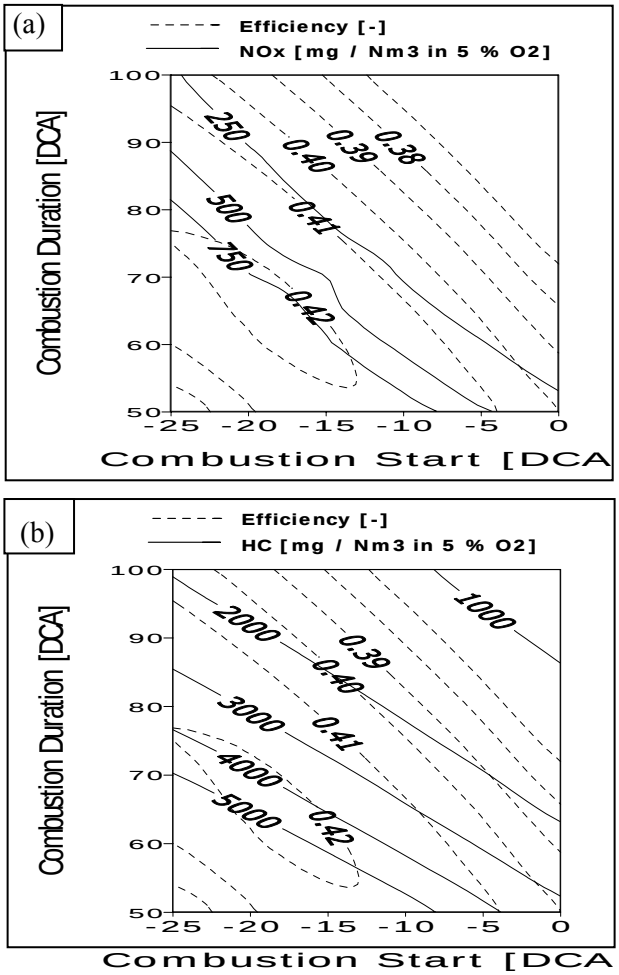

Figure 4: (a) Efficiency – NO_x Trade-Off,
(b)Efficiency –HC Trade-Off

Effect of Excess Air Ratio

The effect of excess air ratio and also leaner operation of the base engine, on emissions is shown in Fig. 5. The excess air ratio was varied from 1.5 to 2. Reduction of the fuel–air ratio to leaner and leaner conditions reduces CO and HC emissions as long as the flame speed and ignitability do not become a problem. Lean operation needs extra air. This results in greater cooling of the cylinder charge. Lower flame temperatures are produced during the cylinder processes, which reduce the NO formation. Not only are emissions reduced, but also fuel economy is improved by lean operation. However, lower flame speed creates drivability problems and, in the limit, partial burning of the charge. The partial burning takes place because the slow moving

flame burns during the rapid expansion stroke of the piston, which causes a lowering of the temperature to a point where the flame will no longer propagate. A second effect of lean operation is to lower the exhaust gas temperature, which is very important for the efficiency of the catalyst, if it exists [17].

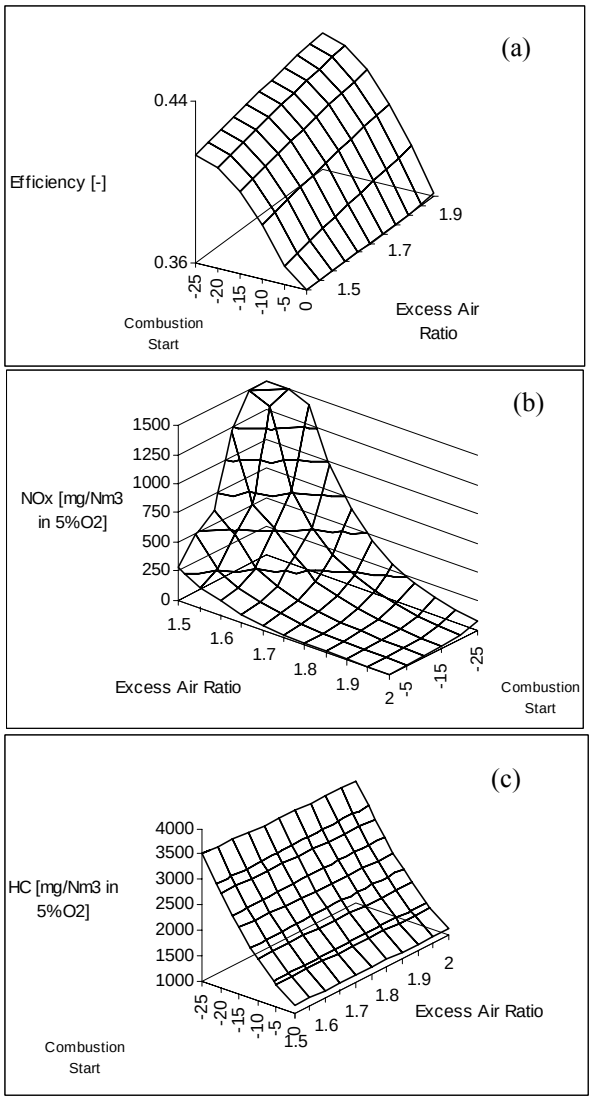

Figure 5: Effect of excess air ratio and combustion start on (a) Efficiency (b) NO_x (c) HC Emissions

Effect of Charge Temperature

The NO_x and HC emission production is very sensitive to the temperature of the charge. In order to clarify the effect of charge temperature on emissions, the temperature at the time of inlet valve closing was varied from 320 to 370 K, which is in the temperature range for stationary natural gas engines. Fig. 6 shows the effect of charge temperature on the engine efficiency and NO_x and HC formation for various excess air ratios. Because the reactions are slow, the amount of NO and HC produced is controlled by the rate of reaction. Thus, lower temperatures, which greatly reduce the reaction rate, lower the amount of NO produced before expansion lowers the temperature to about 800 K, where the reactions freeze [17].

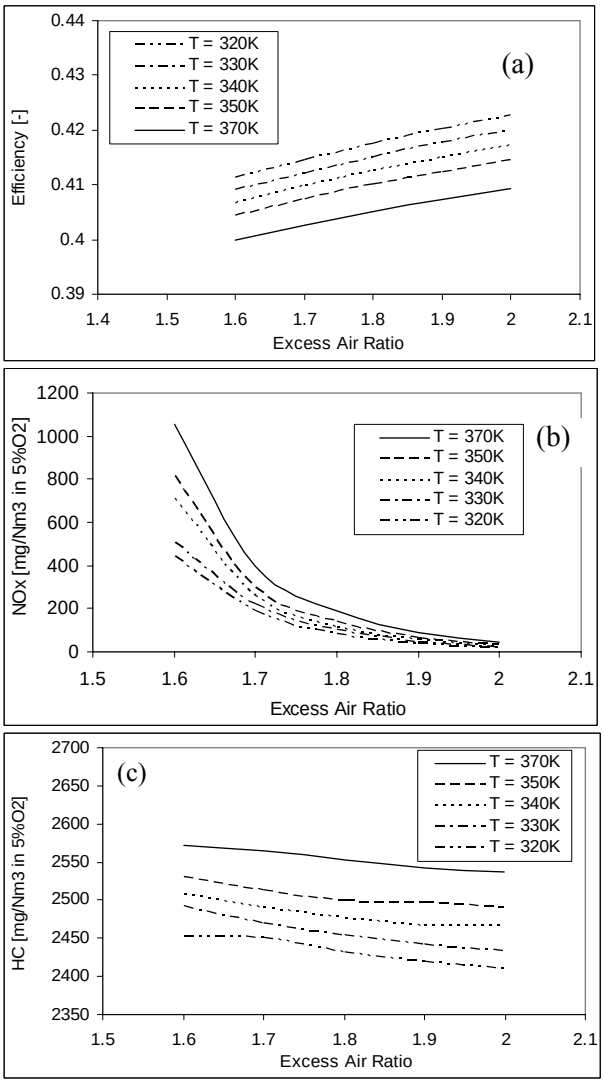

Figure 6: Effect of excess air ratio and charge temperature on (a) Efficiency (b) NO_x (c) HC Emissions

Effect of Crevice Volume

Many studies are being made about the influence of the crevice volume on HC emissions [21-23]. Reducing the crevice volume has a significant effect on the amount of HC returning to the combustion chamber [24]. Their investigations showed also that the crevice gas flow represents a significant power and efficiency loss. Depending

on the degree and rate of in-cylinder oxidation, and design and operating details, these losses are at least 2 to 7 percent.
In order to obtain the effect of crevice volume on the engine performance and emissions for the natural gas engine optimised here, the crevice volume is varied from 4.5 cm^3 to 22.5 cm^3.

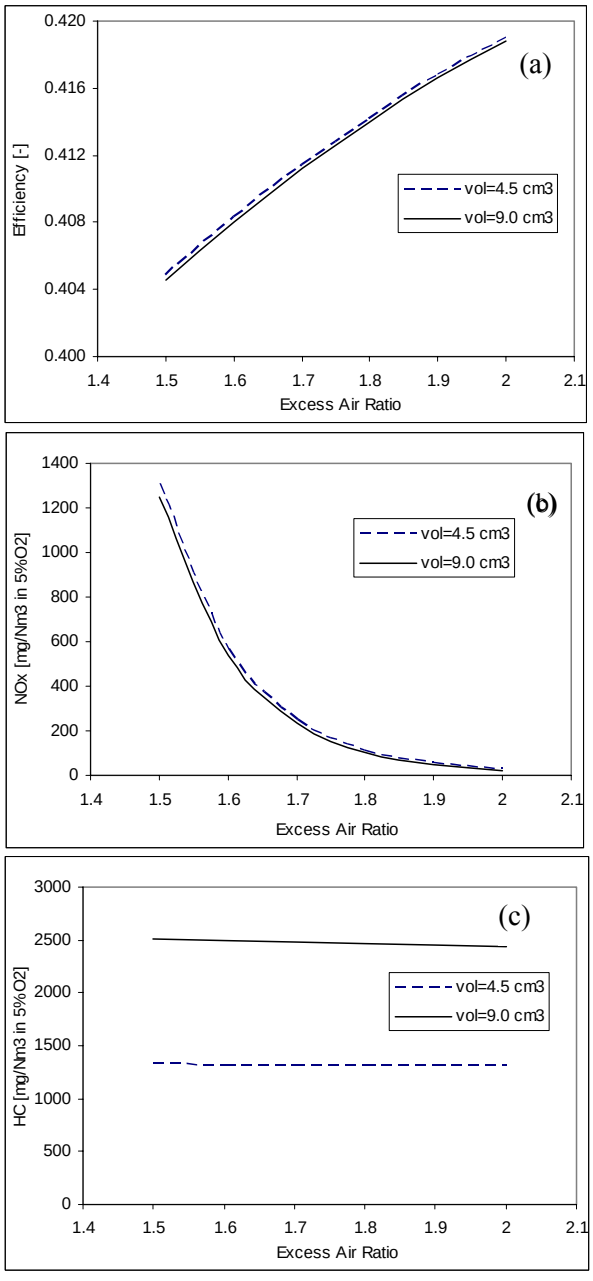

Figure 7: Effect of crevice volume on (a) Efficiency (b) NO_x (c) HC Emissions

As it can be seen from Figure 7 the engine efficiency and emissions decrease with decreasing of the crevice volume. The engine efficiency and NO_x emission increase with decreasing of the crevice volume. A reduction in crevice volume of 50% results in HC emissions of 48% because less unburned fuel-air mixture is stored within crevice volume during compression stroke and in the early stage of combustion. These results are comparable to that previous investigations mentioned above.

CONCLUSIONS

A computer program to calculate the engine process and the amount of NO_x and HC emissions based on a reaction kinetic model was developed. The model uses six reactions for NO_x formation and a global reaction scheme for HC formation. To do this totally 19 species are utilised. It calculates the NO_x and HC emissions with the input of engine speed and fuel data as well as the following data: zero dimensionally determined pressure, temperature, excess air ratio, volume and mass depending on time in the burned zone, resulting from a two zone engine cycle simulation program.

The validity of the program presented here was verified by measurements from a turbocharged, leanburn, natural gas engine. The results are represented via isolines for constant indicated engine efficiency and for constant emissions. From this, basic information about the efficiency and emissions of the respective concepts can be readily determined. Further, the effects of engine parameters were investigated. The results show a wide improvement potential from an emission point of view and are very useful for developing new engines, which must fulfil stricter emission limitations.
The following important conclusions can be drawn from the results of this study:
• The characteristics of the combustion have great influence on NO formation. The combustion- start and duration highly affect the level of NO and HC emissions. The natural gas engines investigated here produce very little NO emissions with a combustion start after TDC, but operating the engines with a combustion start after TDC is not realistic from an efficiency point of view.
• As expected, an increase in the excess air ratio causes a significant decrease in NO emissions.
• The effect of the pressure and temperature of the cylinder charge shows a wide potential from an emission point of view. Especially charge temperature highly affects the level of NO emissions, as expected. By reducing the charge temperature, the amount of emissions can be

decreased to a level sufficient to meet standards determined by international, national or other societies.

• The volume of crevices has a significant effect on the engine efficiency and emissions. A smaller crevice volume results in a decrease of HC emissions and an increase of the engine efficiency as well as NO_x emissions.

ABSTRACT

This work presents a numerical analysis of the thermo-hydraulic performance of secondary surfaces for compact heat exchangers of the plate and fin type. The study resulted in the determination of the film heat transfer coefficient and its variation with the distance from the exchanger inlet. The numerical results obtained provide a thorough description of the performance of the flow inside the exchanger and the heat transfer coefficient shows a similar behaviour compared with analytical models.

INTRODUCTION

A fundamental aspect in the design of compact heat exchangers of the plate and fin type is the prediction of the heat transfer coefficients and friction factor as a function of the Reynolds number. This information is available as experimental data for a number of surfaces or fins in Kays and London [1]. A number of researchers have used this information in the form of fitted potential expressions as a function of the Reynolds number and the resulting equations have been extensively used to develop design methodologies for this type of exchangers [2-6].

The data presented by Kays and London [1], assumes average values on the axial direction of the exchanger, this means that the heat transfer coefficient is not a function of the distance along the length of the unit in the flow direction. In a recent work, Polley and Abu-Khader [7], have developed a generalised model to predict the variation of the heat transfer coefficient as a function of the fluid velocity and the distance for rectangular plain fin surfaces. These findings lead us to conclude that current sizing methods must be modified to account for the variation of the heat transfer coefficient with the distance.

One way of predicting the thermo-hydraulic performance of secondary surfaces is through the simultaneous solution of the fundamental equations of mass, momentum and energy between two fluids separated by a solid surface. This system of equations can be solved using CFD software (Computational Fluid Dynamics). In this work, Fluent ® is used to determine the thermo-hydraulic performance of two plain fin surfaces. The methodology applied is as follows: 1.- A counter-current plate fin heat exchanger is designed using the approach presented by Picon et al. [6]; 2.- The heat transfer coefficient is determined using the generalised expressions introduced by Polley and Abu-Khader [7]; 3.- The thermal performance of the heat exchanger is simulated using CFD software and the heat transfer coefficient along the length of the exchanger is determined.

EXCHANGER DESIGN

One way of sizing a plate and fin heat exchanger is through the concept of full pressure drop utilization. This leads to the development of a thermo-hydraulic model that aids in achieving this objective [6]. The model relates the allowable pressure drop with the exchanger volume and the heat transfer coefficient.

The heat transfer performance for a number of compact surfaces can be expressed in terms of the Reynolds number in the following way:

$$j = aRe^{-b} \quad (1)$$

Where the term *j* represents the Colburn factor which is defined as:

$$j = StPr^{2/3} \quad (2)$$

Where *Pr* is the Prandtl number and *St* is the Stanton number.

The equation for the design of heat exchangers,

$$Q = UAF\Delta T_{LM} \quad (3)$$

can be combined with the expression that defines the overall heat transfer coefficient to give:

$$A_1 = \frac{Q}{F\Delta T_{LM}}\left[\frac{1}{\eta_1}\left(\frac{1}{h_1}+R_1\right)+\frac{1}{\eta_2}\left(\frac{A_1}{A_2}\frac{1}{h_2}+R_2\right)\right] \quad (4)$$

The terms A_1 and A_2 are the heat transfer area on sides 1 and 2 respectively. The exchanger volume and the surface area of one side are related through:

$$A_1 = \alpha_1 V_T \quad (5)$$

After substitution of A for sides 1 and 2 and rearranging we obtain:

$$V_T = \frac{Q}{F\Delta T_{LM}}\left[\frac{1}{\eta_1\alpha_1}\left(\frac{1}{h_1}+R_1\right)+\frac{1}{\eta_2\alpha_2}\left(\frac{1}{h_2}+R_2\right)\right] \quad (6)$$

Equation (6) represents the total exchanger volume as a function of the heat load, the heat transfer surfaces y the heat transfer coefficients. In this design method the heat transfer coefficient is assumed to be constant along the length of the exchanger for a given Reynolds number.

The total exchanger volume, heat transfer coefficient and pressure are related by:

$$\Delta P = \left(\frac{K_p}{K_h}\right)^{\frac{3-y}{1-b}} V_T h^2 \quad (7)$$

Where K_p and K_h are respectively:

$$K_p = \frac{xm^{2-y}\mu\alpha}{2\rho d_h^y} \quad (8)$$

and

$$K_h = \frac{am^{1-b}\mu^b C_p}{d_h^b \,\mathrm{Pr}^{2/3}} \quad (9)$$

Equation (7) represents the thermo-hydraulic model that relates the pressure drop with the exchanger volume and the heat transfer coefficient.

ANALYTICAL MODEL

Polley and Abu-Khader [7] present a generalised model to predict the variation of the heat transfer along the length of the exchanger based on the expression proposed by Churchill [8]. The equation for the heat transfer performance is:

$$\mathrm{Nu} = \left(\mathrm{Nu}_{\mathrm{lam}}^{10} + \left(\frac{1}{\mathrm{Nu}_{\mathrm{i}}^2}+\frac{1}{\mathrm{Nu}_{\mathrm{turb}}^2}\right)^{-5}\right)^{0.1} \quad (10)$$

Where the heat transfer for laminar flow under thermally developing conditions as well as fully developed flow can be estimated from [7]:

$$\mathrm{Nu}_{\mathrm{lam}} = \left[3.66^3 + 0.7^3 + \left(1.77\mathrm{Gz}^{1/3} - 0.7\right)^3\right]^{1/3} \quad (11)$$

and the Grazt number is given by

$$\mathrm{Gz} = \mathrm{RePr}\left(\frac{\mathrm{d_h}}{\mathrm{l}}\right) \quad (12)$$

The heat transfer rate for the turbulent region can be expressed by [9]:

$$\mathrm{Nu}_{\mathrm{turb}} = \frac{\left(\frac{\mathrm{f}}{2}\right)\mathrm{RePr}}{\left(1.07+12.7\left(\frac{\mathrm{f}}{2}\right)^{1/2}\left(\mathrm{Pr}^{2/3}-1\right)\right)} \quad (13)$$

In the above equations the tube diameter has been replaced by the surface hydraulic diameter.

Now, the term $\mathrm{Nu_i}$ can be calculated as:

$$\mathrm{Nu_i} = \mathrm{Nu}_{\mathrm{lam,Re_{critical}}}\exp\left(\frac{\mathrm{Re}-\mathrm{Re_{critical}}}{730}\right) \quad (14)$$

In the following case study a plate and fin exchanger is sized and the thermo-hydraulic performance of the geometry is simulated in Fluent®. The numerical performance is compared with the results obtained using the generalised model proposed by Polley and Abu-Khader [7].

CASE STUDY

A plate fin heat exchanger is designed using the following surfaces according to the nomenclature introduced by Kays and London [1]: Plain plate-fin surface 5.3 and Plain plate-fin surface 6.2. The operating conditions and fluid data for the problem are shown in Table 1. Using the design method presented above, the geometry of the exchanger is determined and the results are given in Table 2.

Table 1: Operating conditions and fluid physical properties for case study.

	Plain -fin surface 6.2 Gas side	**Plain -fin surface 5.3 Air side**
Inlet temperature [°C]	430	175
Outlet temperature [°C]	338.5	270.5
Mass flow rate [kg/s]	2.466	2.43
Pressure drop [kPa]	0.672	0.0477
Fin thermal conductivity[W/m°C]	20.8	20.8
Density [kg/m³]	0.58	5.7
Heat capacity [J/kg k]	1040	1050
Viscosity [kg/m s]	0.0000302	0.0000285
Fluid thermal conductivity [W/m °C]	0.047	0.044

Table 2: Geometry of the exchanger.

Exchanger volume	0.137 m^3
Length	0.38 m
Width	0.603 m
Height	0.599 m
No. of passages per stream	26
Air side heat transfer coefficient	94.72 W/m^2 °C
Gas side heat transfer coefficient	80.27 W/m^2 °C
Air side pressure drop	47.77 Pa
Gas side pressure drop	671.96 Pa
Reynolds number on gas side	2,952
Reynolds number on air side	3,024

The numerical study of the flow inside the passages of the exchanger requires the mathematical representation of the movement of the fluid. This representation is summarised by a set of equations of mass, momentum and energy conservation together with the equation that describes the turbulence phenomenon present.
A single passage of the exchanger was used to simulate the whole unit. It is assumed that the heat transfer coefficient varies only in the direction of the flow and that the flow distribution among the passages is uniform. Figure 1 shows the geometry of the passages and Figure 2 the control volume chosen for the simulation.

The whole exchanger length was simulated in sections of 0.05 m each until the total length of 0.38 m was covered.

The turbulent condition was modelled using the standard k-epsilon model. As for the boundary conditions, periodic conditions were chosen on the left and right walls; on the upper and lower planes, symmetrical conditions were chosen. The inlet and outlet conditions for the fluids are given in Table 3.

From the numerical results, the heat transfer coefficient is calculated as:

$$h = \frac{q}{T_{wall} - T_{ref}} \qquad (15)$$

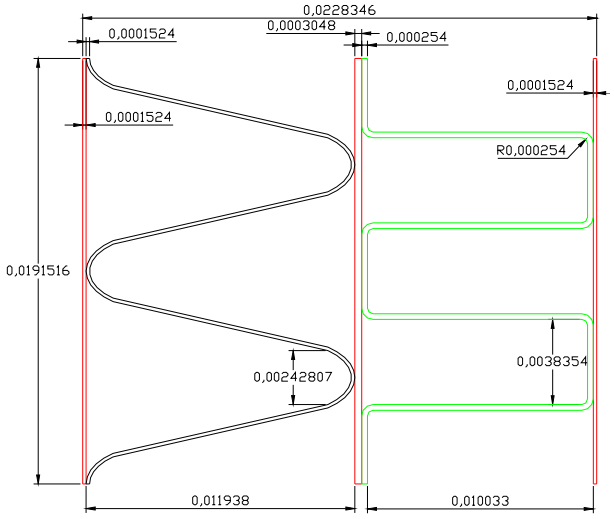

Figure 1: Cross sectional view of the hot and cold passages.

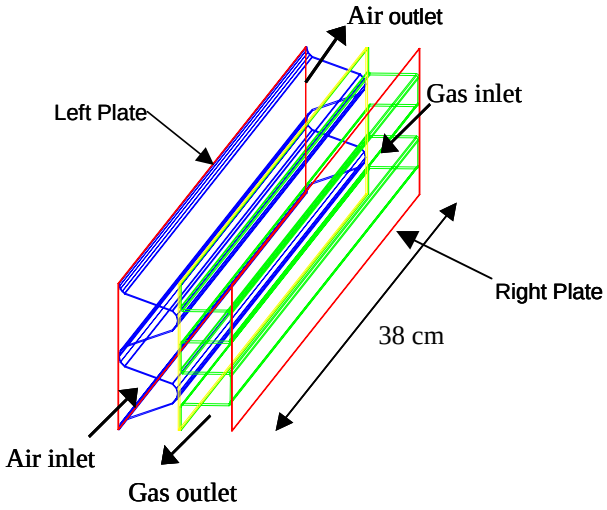

Figure 2: Control volume.

Table 3: Inlet and outlet conditions for hot and cold fluids.

Inlet	Outlet
Air side (Plain-fin surface 5.3)	
d_h = 0.006147 m	d_h = 0.006147 m
I = 6%	I = 6 %
v = 2.2929 m/s	P = 161 Pa
T = 175°C	
Gas side (Plain -fin surface 6.2)	
d_h = 0.00554 m	d_h = 0.00554 m
I = 6%	I = 6 %
v = 26.5384 m/s	P= 1453 Pa
T = 430°C	

Where q is the local heat flux; T_{wall} is the temperature of the wall and T_{ref} is the reference temperature. In this work the reference temperature is calculated in two ways:

1.- Fixed temperature. This can either be a fixed value or an average between the inlet and outlet temperature of the fluid.
2.- Variable temperature. Average fluid temperatures are calculated locally along the exchanger and are considered the reference value. Readings of temperature can be taken as nodal points or average values per cell.

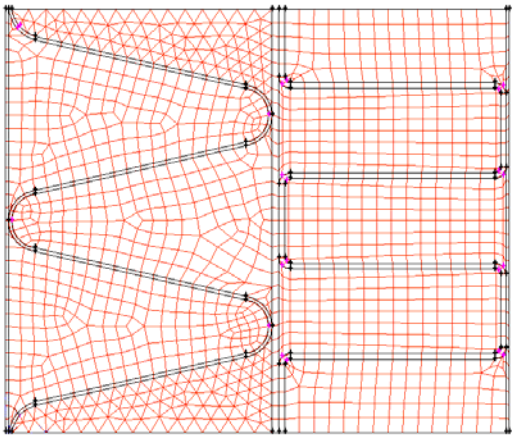

Figure 3: Computational domain.

RESULTS

The computational domain and mesh distribution for the numerical analysis of the exchanger are shown in Figure 3. The mesh size is of 0.7x0.7 mm.

Temperature readings were taken on various points as shown in Figure 4. The points close to the wall are separated 0.0001 m from it. For the inlet and outlet temperatures on the air side, a line was drawn between point a_4 and a_2 whereas for the gas side, a line was drawn between g_2 and g_5.

Figure 5 shows the outlet temperatures on the air side on positions a_1, a_2, a_4 and Figure 7 the outlet temperatures for the gas side on positions g_1, g_2, g_7, g_{10}, g_{11}, g_{12} and g_{19}. The temperatures along the exchanger on the same positions for the air and gas side are shown in Figures 6 and 8 respectively.

The temperatures calculated numerically (Figures 5 and 7) and the temperatures calculated along the exchanger (Figures 6 and 8) are consistent and close to the ones calculated with the analytical model. Similar consistent results are obtained for the case of the pressure drop as shown in Figures 9 and 10.

The average heat transfer coefficient between points a_1, a_2 and a_3 for the air side and between g_1, g_2 and g_3 for the gas side are calculated in three different ways: 1.- using the average fluid temperature as reference value, 2.- using fixed temperature as a reference value and 3.- using a variable reference temperature. The numerical results are compared to the analytical results in Figures 11 and 12 for the gas and air side respectively. Both results are consistent and show the same behaviour: larger heat transfer coefficients are found in the region near the exchanger inlet and tend to asymptotic values as the flow regime develops. The asymptotic value being close to the one predicted with the traditional fully developed flow model which is constant throughout the exchanger.

CONCLUSIONS

The experimental data for heat transfer performance of plain fin surfaces have been reported for conditions of non developed flow. In this region, values are greater than the ones found in the fully developed flow region. One of the most critical parameters for the numerical determination of heat transfer coefficients is the specification of the reference temperature. From the various ways of determining it, the condition where this temperature corresponds to the stream inlet temperature gives results which are closer to the values reported experimentally.

In this work, a model has been developed for the analysis of plain fins. The model can be applied to other geometries to predict the heat transfer coefficient as a function of the distance and the Reynolds number. In the case of new surfaces where the thermo-hydraulic performance is normally obtained experimentally, the model can be used to numerically determine their performance thus saving the long time required to produce the experimental data.

SINGLE-COMPONENT OPTIMAL HEAT EXCHANGER EFFECTIVENESS USING SPECIFIC EXERGY COSTS AND REVENUES

David Paulus[1]
Technical University of Berlin
Institute for Energy Engineering
Marchstrasse 18
10587 Berlin, Germany

ABSTRACT

It has been observed that in a heat recovery steam generator of a combined cycle power plant (CCPP) optimized to minimize its cost of electricity, the ratios of capital costs rates to the total cost rate (capital costs plus the cost rate of exergy destruction) of downstream (with reference to the hot gas) components often are greater than those of upstream components. In order to understand this relationship, the economic optimum design of a heat exchanger considered as a single component is explored. Expressions for time rates of profit are written using specific exergy revenues and costs. These expressions are non-dimensionalized, and their derivatives are taken to find the optimum heat exchanger effectiveness. This optimum is shown to be a function of several dimensionless groups. Three of the variables contained within these groups are both of the stream inlet temperatures and the reference temperature. Results of numeric optimization of heat exchangers confirm the validity of the dimensionless groups.
Keywords: exergoeconomics, specific exergy revenue, heat exchanger optimization

NOMENCLATURE

c	specific exergy cost
c_A	average heat exchange area cost
C	heat capacity of a stream
C_{min}	heat capacity of the stream with the smaller heat capacity
C_r	heat capacity ratio
$\dot{C}_D$	cost rate of exergy destruction
$\dot{E}$	rate of exergy flow/destruction
f	f-factor
NTU	number of transfer units
$\dot{P}$	profit per unit time
$\dot{Q}$	heat transfer rate
r	specific exergy revenue
$\dot{S}_\pi$	rate of entropy production
T	temperature
U	overall heat transfer coefficient
$\dot{Z}$	capital cost per unit time

Greek Variables

χ_A	dimensionless specific cost of area
χ_F	fuel cost/product revenue ratio

INTRODUCTION

The f-factor is defined as

$$f = \frac{\dot{Z}}{\dot{Z} + \dot{C}_D} \quad (1)$$

It expresses the ratio of the capital cost rate of the component to its total cost, the sum of its capital cost rate and its cost rate of exergy destruction [1]. The capital cost rate is found by amortizing the component's capital cost, for example through the use of a capital recovery factor or by proportionally assigning the carrying charges calculated through the revenue-required method [1]. The f-factor can serve as a tool during iterative optimization by helping to judge whether it is desirable to reduce exergy destruction at the expense of additional capital, or to save capital at the expense of increased exergy destruction.

A complication to the use of the f-factor in the optimization of a heat exchanger network , such as a heat recovery steam generator (HRSG), was observed by Paulus and Tsatsaronis [2]. The capital costs in order to achieve a given heat exchanger efficiency tend to increase as hot stream temperatures decrease. For example, in a HRSG, the f-values of the heat exchangers in a CCPP optimized for minimal product costs often noticeably rise as the hot stream temperatures decrease (assuming that the hot stream is the fuel stream). This temperature dependency can make it very difficult to judge if an f-factor shows a good balance between capital and total costs, i.e. if the relative capital investment in the heat exchanger is correct for the system. For example, the author has encountered instances where the product costs of a two-pressure CCPP were decreased by lowering the pinch temperature (and *increasing* the capital investment) of the low pressure evaporator, although the f-factor of this component was judged quite high (which would suggest *decreasing* the capital investment). The author has similarly observed the opposite behavior with respect to the high-pressure evaporator.

The following work originated as an attempt to quantify the influence of temperatures on the f-factors in a HRSG. Initially, a heat exchanger, specifically an evaporator in a HRSG, was numerically optimized as a single component, with the goal of maximizing the time rate of profit (for that single component), as defined by[2]:

$$\dot{P} = r_P \dot{E}_P - c_F \dot{E}_F - \dot{Z} \quad (2)$$

Observation of the f-factors at the optimal single-component efficiency showed temperature influences, but the exact relationship was not readily quantifiable. Therefore, the expression for profit was rewritten as a function of the inlet stream temperatures and mass flows, along with the cost of heat exchanger area. As the resulting expression was a function of many variables, it was non-dimensionalized. This was done for an evaporator, where it was assumed that the exergy increase in the cold stream was the product, and for a heat exchanger without a phase change, again with the cold stream as the product. All calculations assumed a constant overall heat transfer coefficient, constant stream heat capacities and no occurrence of pressure drop in either stream.

NONDIMENSIONAL PROFIT FOR AN EVAPORATOR

If the product of an evaporator (see Figure 1) is the exergy increase of the cold stream, and it is assumed that no pressure drop occurs in the hot stream, the exergetic fuel can be expressed as

$$\dot{E}_F = C_h \left(T_{hi} - T_{hii}\right) - T_0 C_h \ln\left(T_{hi}/T_{hii}\right) \quad (3)$$

The term $C_h \left(T_{hi} - T_{hii}\right)$ is equal to the duty of the heat exchanger, $\dot{Q}$. The duty, in turn, is equal to the effectiveness times the maximum possible heat transfer with the given inlet conditions, $\dot{Q}_{max} = C_h \left(T_{hi} - T_{sat}\right)$. Equation (3) can thus be rewritten as

$$\dot{E}_F = \varepsilon \dot{Q}_{max} - T_0 C_h \ln\left(\frac{T_{hi}}{T_{hi} - \varepsilon \dot{Q}_{max}/C_h}\right) \quad (4)$$

If the cold stream enters as a saturated liquid, and leaves in a saturated state at the pressure with which it enters, the exergetic product is

$$\dot{E}_P = \left(1 - T_0/T_{sat}\right)\dot{Q} = \left(1 - T_0/T_{sat}\right)\varepsilon \dot{Q}_{max} \quad (5)$$

[2] See [2] for the methodology of calculation of specific exergy revenue. Lazzaretto and Tsatsaronis [3] provide an comprehensive reference on the definitions of exergetic fuel and product, as well as the calculation of specific exergy costs.

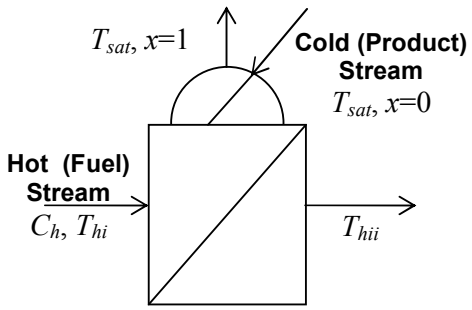

Figure 1: An evaporator

With the assumption that the cost of the heat exchanger varies linearly with its area (or that the average cost per unit area is known), the capital cost of the heat exchanger is given by

$$\dot{Z} = c_A A \tag{6}$$

From the definition[3] of *NTU*, $A = NTU \cdot C_h / U$ and $NTU = -\ln(1-\varepsilon)$. Equation (6) may be expressed as

$$\dot{Z} = -c_A \frac{C_h}{U} \ln(1-\varepsilon) \tag{7}$$

With the given assumptions, Eq. (2), after manipulation, can be rewritten as

$$\frac{\dot{P}}{r_P T_0 C_h} = \varepsilon\left[\left(\frac{T_{hi}-T_{sat}}{T_0}\right) - \left(\frac{T_{hi}}{T_{sat}} - 1\right)\right] - \frac{c_F}{r_P}\left[\varepsilon\left(\frac{T_{hi}-T_{sat}}{T_0}\right) + \ln\left(1+\varepsilon\left(\frac{T_{sat}}{T_{hi}}+1\right)\right)\right] + \frac{c_A}{r_P U T_0}\ln(1-\varepsilon) \tag{8}$$

Inspection of Eq. (8) shows that all of the variable groups are now dimensionless, and the following dimensionless variables may be defined[4]:

Dimensionless profit:

$$\Pi = \dot{P} / r_P T_0 C_h \tag{9}$$

Fuel cost-product revenue ratio:

$$\chi_F = c_F / r_P \tag{10}$$

Dimensionless entrance temperature difference:

$$\theta = (T_{hi} - T_{sat}) / T_0 \tag{11}$$

Entrance temperature ratio:

$$\tau = T_{hi} / T_{sat} \tag{12}$$

Dimensionless heat exchanger area cost:

$$\chi_A = c_A / r_P U T_0 \tag{13}$$

Equation (8) becomes

$$\Pi = \varepsilon[\theta - (\tau - 1)] - \chi_F\left[\varepsilon\theta + \ln\left(1+\varepsilon\left(1/\tau - 1\right)\right)\right] + \chi_A \ln(1-\varepsilon) \tag{14}$$

and the profit is now a function of four variables instead of nine.

The first derivative of Eq. (14) with respect to effectiveness is

$$\frac{\partial \Pi}{\partial \varepsilon} = \theta - (\tau - 1) - \chi_F\left(\theta + \frac{1/\tau - 1}{1+\varepsilon\left(1/\tau - 1\right)}\right) - \frac{\chi_A}{1-\varepsilon} \tag{15}$$

Equation (15), when solved for effectiveness when set equal to zero may have no solution, or it may yield either a local or global maximum in the range from ε=0 to 1. Figure 2 illustrates this with plots of Π as a function of ε at several values of θ. When it yields a global maximum, Eq. (15) allows the optimal effectiveness to be expressed as a function of four variables instead of eight.

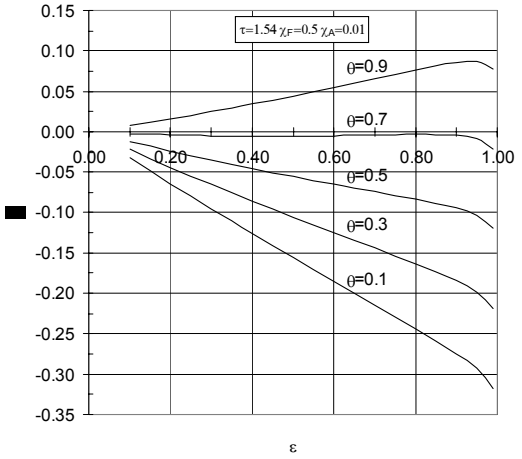

Figure 2: Nondimensional profit Π as a function of effectiveness and the nondimensionless temperature difference θ

[3] See [4] as a reference on the effectiveness-NTU method.

[4] It is worth noting that the ratio τ also appears in the equations for dimensionless entropy production in heat exchangers as defined by Sekulic [5]. The dimensionless entropy production is given the symbol σ and is equal to $\dot{S}_\pi / C_{min}$.

Figure 3 shows the effect of dimensionless variables containing temperature on the optimal effectiveness for one set of χ_A and χ_F. Interestingly, while a greater inlet temperature *ratio* favors a smaller heat exchanger, a greater inlet temperature *difference* favors a larger. (Not shown in the figures is that the optimal effectiveness decreases linearly with increasing χ_A and decreases approximately parabolically with increasing χ_F.)

Equation (1), after substitution of appropriate expressions for the capital cost and heat exchanger area, becomes

$$f = \frac{-c_A \dfrac{C_h}{U} \ln(1-\varepsilon)}{-c_A \dfrac{C_h}{U} \ln(1-\varepsilon) + r_P \dot{E}_D} \tag{16}$$

The exergy destruction can be found with $\dot{E}_F - \dot{E}_P$, and with Eqs. (4) and (5) is found to be

$$\dot{E}_D = \varepsilon \dot{Q}_{max} - T_0 C_h \ln\left(\frac{T_{hi}}{T_{hi} - \varepsilon \dot{Q}_{max}/C_h}\right) - \left(1 - T_0/T_{sat}\right)\varepsilon \dot{Q}_{max} \tag{17}$$

Equation (17) may then be substituted into Eq. (16). The resulting expression can be written in terms of the non-dimensional groups above:

$$f = \frac{-\chi_A \ln(1-\varepsilon)}{-\chi_A \ln(1-\varepsilon) + \ln\left[1 + \varepsilon\left(\dfrac{1}{\tau} - 1\right)\right] - \varepsilon(1-\tau)} \tag{18}$$

This is equivalent to

$$f = \frac{\chi_A NTU}{\chi_A NTU + \sigma} \tag{19}$$

where σ is the dimensionless entropy production, $\dot{S}_\pi / C_{min}$.

The f-factor itself is thus a function of NTU, dimensionless heat exchanger area cost and dimensionless entropy production (itself also a function of the inlet temperature ratio and effectiveness). Because the optimal effectiveness of an evaporator is a function of χ_A, χ_F, θ and τ, and the f-factor is a function of χ_A, effectiveness and τ, it follows that the optimal f-factor is dependent on the same dimensionless groups upon which the optimal effectiveness is dependent. Thus, it would be expected that the f-factors in a good design would vary with temperature along the gas path of the hot stream through the HRSG. Figure 4 shows the f-factor at optimal effectiveness for various τ and θ differences at fixed values of χ_A and χ_F. The inlet temperature ratio shows a decided effect on the f-factor at the optimal single-component effectiveness; the dimensionless inlet temperature difference has a much smaller effect.

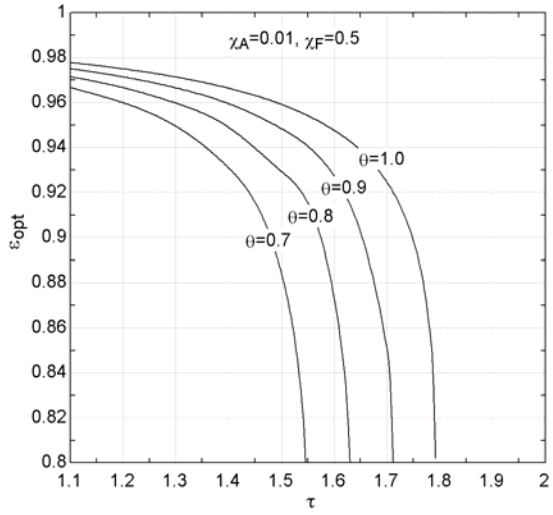

Figure 3: Influence of τ and θ on optimal effectiveness for an evaporator, constant χ_A and χ_F

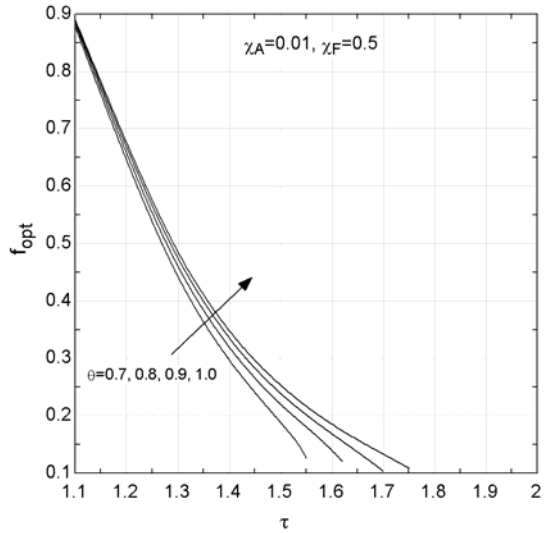

Figure 4: Influence of τ and θ on the f-factor at optimal effectiveness for an evaporator, constant χ_A and χ_F

NONDIMENSIONAL PROFIT FOR A HEAT EXCHANGER WITH NO PHASE CHANGE

For an economizer or a superheater (see Figure 5), Eq. (5) does not describe the exergetic product. This is instead given by

$$\dot{E}_P = C_C\left(T_{cii} - T_{ci}\right) - T_0 C_C \ln\left(\frac{T_{cii}}{T_{ci}}\right) \tag{20}$$

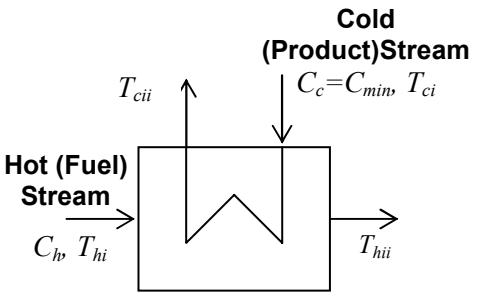

Figure 5: A heat exchanger

The introduction of the effectiveness and maximum heat transfer, $\dot{Q}_{max} = C_C\left(T_{hi} - T_{ci}\right)$, yields:

$$\dot{E}_P = \varepsilon\dot{Q}_{\max} - T_0 \ln\left(\left(T_{ci} + \frac{\varepsilon\dot{Q}_{\max}}{C_c}\right)\Big/ T_{ci}\right) \tag{21}$$

In order to express the maximum heat transfer as a function of the entrance temperatures, it is necessary to specify which stream has the smaller heat capacity, C_{min}. In a HRSG, the cold stream commonly has the lower heat capacity (when no phase change is present), so this derivation will proceed from this assumption. Moreover, in order to express it, it is necessary to specify the geometry of the heat exchanger. Because of the many tube passes in one of the HRSG's superheaters or economizers, counterflow geometry will be assumed. With these two assumptions, and using $NTU = UA/C_{min}$ along with the appropriate effectiveness-NTU relation for a counterflow heat exchanger, $NTU = \ln\left(\frac{\varepsilon - 1}{\varepsilon C_r - 1}\right)\Big/\left(C_r - 1\right)$, the heat exchange area may be expressed as

$$A = \frac{C_c \ln\left(\frac{\varepsilon - 1}{\varepsilon C_r - 1}\right)}{U\left(C_r - 1\right)} \tag{22}$$

where, for this case, $C_r = C_c/C_h$.

Now, Eq. (2) may be rewritten as

$$\dot{P} = r_P\left[\varepsilon\dot{Q}_{\max} - T_0 \ln\left(\frac{T_{ci} + \frac{\varepsilon\dot{Q}_{\max}}{C_c}}{T_{ci}}\right)\right] - c_F\left[\varepsilon\dot{Q}_{max} - T_0 C_h \ln\left(\frac{T_{hi}}{T_{hi} - \varepsilon\dot{Q}_{max}/C_h}\right)\right] - c_A\frac{C_c \ln\left(\frac{\varepsilon - 1}{\varepsilon C_r - 1}\right)}{U\left(C_r - 1\right)} \tag{23}$$

with $\dot{Q}_{\max} = C_c\left(T_{hi} - T_{ci}\right)$. This can be nondimensionalized, reducing an expression with ten independent variables to one with six:

$$\Pi = \left(1 - \chi_F\right)\varepsilon C_r\theta - \chi_F \ln\left[1 - \varepsilon C_r\left(1 - \frac{1}{\tau}\right)\right] - C_r \ln\left[1 + \varepsilon\left(\tau - 1\right)\right] - \chi_A\frac{C_r \ln\left(\frac{\varepsilon - 1}{\varepsilon C_r - 1}\right)}{C_r - 1} \tag{24}$$

The dimensionless groups remain defined as before with the exception that T_{ci} replaces T_{sat} and the addition of C_r[5].

The derivative of Eq. (24) with respect to ε is

$$\frac{\partial\Pi}{\partial\varepsilon} = \left(1 - \chi_F\right)C_r\theta + \chi_F C_r\frac{1 - \frac{1}{\tau}}{1 - \varepsilon C_r\left(1 - \frac{1}{\tau}\right)} - C_r\frac{\tau - 1}{1 + \varepsilon\left(\tau - 1\right)} - \chi_A C_r\frac{\frac{1}{\varepsilon C_r - 1} - \frac{\varepsilon - 1}{\left(\varepsilon C_r - 1\right)^2}C_r}{\varepsilon - 1}\frac{\varepsilon C_r - 1}{C_r - 1} \tag{25}$$

Graphing of Eq. (24) shows that setting Eq. (25) to zero and solving for ε will either yield no solu-

[5] In this expression, τ is the inverse of that defined by Sekulic [5]. A decision was made to be consistent between the case of an evaporator and that of an economizer or superheater, rather than Sekulic's of the ratio of temperature of the stream with the smaller heat capacity to the temperature of the stream with the larger capacity. Sekulic retained consistency between the heat capacity ratio and the temperature ratio, which was the logical choice for his work.

tion, or a local or global maximum for Π for rational values of effectiveness. (Graphs are similar in appearance to the example given for an evaporator in Figure 2.) The number of variables upon which the optimal effectiveness depends is reduced to five. The influence of τ and θ at constant χ_A , χ_F, and C_r for a heat exchanger is similar to that of an evaporator at constant χ_A and χ_F. Again, while a greater inlet temperature *ratio* favors a smaller heat exchanger, a greater inlet temperature *difference* favors a larger. Figure 6 shows the influence of C_r over a typical range for the economizers and superheaters of a HRSG. The dimensionless variables χ_A and χ_F have similar effects as for the case of an evaporator.

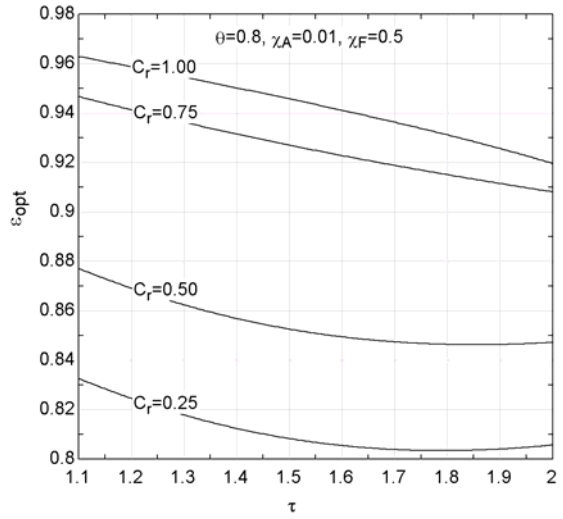

Figure 6: Influence of τ and C_r on the optimal effectiveness for a heat exchanger with the cold stream as product and having minimum *C*, constant θ, χ_A and χ_F

The f-factor is related to the effectiveness and other dimensionless groups with

$$f = \frac{\chi_A \ln\left(\frac{\varepsilon - 1}{\varepsilon C_r - 1}\right) \Big/ \left(C_r - 1\right)}{\chi_A \ln\left(\frac{\varepsilon - 1}{\varepsilon C_r - 1}\right) \Big/ \left(C_r - 1\right) + \frac{1}{C_r} \ln\left(1 - \varepsilon C_r \left(1 - \frac{1}{\tau}\right)\right) + \ln\left(1 + \varepsilon\left(\tau - 1\right)\right)} \quad (26)$$

This is again equivalent[6] to

$$f = \frac{\chi_A NTU}{\chi_A NTU + \sigma} \quad (27)$$

The optimal f-factor for an evaporator or economizer is thus not only dependent on the inlet stream temperatures, but also on the ratio of heat capacities of the streams. The graph of optimal f-factor at constant χ_A , χ_F, and C_r appears similar to that of an evaporator at constant χ_A and χ_F,.

These derivations are straightforward to repeat for other cases (i.e. different geometry, the case where the hot stream has the lower heat capacity, etc.).

NUMERICAL TESTING

In order to test the validity of the dimensionless groups, numerical optimization was undertaken. First, for an evaporator, the component profit was maximized for several different hot stream entrance temperatures. The pressure of the cold stream and the reference temperature were varied to keep the inlet temperature ratio, τ, and the dimensionless inlet temperature difference, θ, constant. This was done for a variety of values for τ and θ. The hot stream was modeled as air, using ideal gas property relations with varying specific heat. The cold stream was modeled using real properties.

It was found that (a) the resulting optimal effectiveness remained nearly constant when the relevant dimensionless groups remained constant and (b) the resulting optimal effectiveness matched the optimal effectiveness predicted by setting Eq. (15) equal to zero. The maximum discrepancy between the two calculated values over a range of hot stream entrance temperatures from 550 to 800K was 0.2%.

The calculations were repeated for a heat exchanger without a phase change. To maximize any possible effects of real fluid behavior, the heat exchanger was modeled as a superheater with the cold stream entering as a saturated liquid. The same observations were made as for an evaporator – nearly constant effectiveness resulted from the numerical optimization, and it agreed well with

[6] The difference between the term for dimensionless entropy production σ in Eq. (26) and that of Sekulic [5] is due to the inverse of definitions of τ.

the theoretical, in this case predicted by setting Eq. (25) to zero and solving for effectiveness. The maximum discrepancy in this test was 0.4%. When the calculations were repeated at lower pressures and away from the saturation point, the optimal effectiveness remained even more constant and matched the predicted value to three significant figures.

DISCUSSION

The F-Factor along the Gas Path of a HRSG

Typically, in a HRSG far more heat transfer occurs in the higher pressure evaporators than in the lower pressure units. This typically results in the lower pressure evaporators, located in areas of lower hot stream temperature, having lesser temperature inlet ratios and dimensionless inlet temperature differences. It was shown before that greater inlet temperature ratios favor lower values for the f-factors, while greater inlet temperature differences favor higher values. However, at least for a HRSG, the differences in dimensionless inlet temperature differences between high and lower-pressure evaporators are far less significant than differences in ratios, and areas of high exergetic fuel potential (temperature) favor less relative capital investment. Pinch temperatures are greater in the high pressure section than in the lower pressure sections. This matches the observations of Paulus and Tsatsaronis.

For a superheater, the situation is complicated by the effect of the heat capacity ratio, and it is difficult to state any trends of the f-factors based solely on hot-stream temperatures. The effect for the economizers is even more difficult to assess, as these are often constrained by either the maximum cold stream exit temperature (below the saturation temperature) or the hot stream exit temperature (to prevent condensation).

The work contained in this paper shows that the optimal capital investment in a heat exchanger, when investigated as a single component, depends on more than just the hot stream entrance temperature. The cold stream inlet temperature, the ratio of heat capacities and even the dead state temperatures play roles as well. And, if these variables influence the optimal size of a heat exchanger considered as a single component, they are extremely likely to play a role in the optimum sizing of a heat exchanger within a system.

The Optimal Effectiveness and Optimization

Most types of energy system components show a common relationship between exergetic efficiency and exergy destruction. As the efficiency increases, the exergy destruction *decreases*. The increased efficiency comes at the price of a greater capital investment in the component. With such components, the f-factor is a valuable tool for iterative optimization. For components showing this relationship between efficiency and exergy destruction, the f-factor will increase as the capital investment is increased and the component's efficiency improves.

Heat exchangers are unique in that an increase in efficiency can be accompanied by an *increase* in exergy destruction. When the inlet conditions are fixed, it is only possible to increase the efficiency of a heat exchanger by changing the *UA* value. Consider the case when the cold stream has the lower heat capacity: Because additional heat is transferred across a smaller temperature difference than the average for the heat exchanger, to cold stream temperatures higher than the average, the efficiency of the heat exchanger increases. However, because additional heat transfer occurs, the total exergy destruction *can* increase. This could lead to problems with the use of f-factors for optimization of a heat exchanger network: depending on the relative costs of heat transfer area and exergy destruction, the f-factor may actually decrease with increasing efficiency. Moreover, if the inlet conditions are even partially fixed, given the fact that increased efficiency comes with increased fuel exergy use, product exergy delivery and exergy destruction renders the assumption made when calculating the cost of exergy destruction – the assumption that either the exergetic fuel or product remains constant – incorrect.

The resulting dimensionless expressions derived here for optimal effectiveness might well serve as a replacement for the f-factor. Indeed, it would not be unreasonable to hypothesize that an optimally designed heat exchanger network would find all heat exchangers at their optimal component effectiveness (unless constrained by other design parameters), *as long as the fuel costs and*

product revenues were properly calculated. If this hypothesis is correct, the designer could move stepwise towards the optimum, by observing if the effectiveness of any given heat exchanger in the current iteration is greater or less than the optimum, and by making changes accordingly. The procedure would have to be iterative, and it would be unwise to make too large of a change to any heat exchanger's effectiveness in a single iteration, because (a) changes in upstream heat exchangers affect temperature ratios, etc. in the downstream heat exchangers, (b) costs and revenues will change between iterations and (c) in reality, the cost of heat exchanger area does not necessarily remain constant with varying heat exchanger size. The greatest difficulty in employing such a method would be the proper choice of exergetic costs and revenues – the average specific costs and revenues may not be the proper costs in such an optimization scheme.

The question might arise, "Why not use exergetic efficiency instead of effectiveness?" It is clear that just as the f-factor is fixed at optimal effectiveness, so is the exergetic efficiency. The advantage of the effectiveness, in the eyes of the system designer, is that it quickly specifies the heat exchanger without having to (again) resort to the use of calculations involving the inlet temperatures.

CONCLUSION

By non-dimensionalizing the expressions for component profit of two types of heat exchangers, the number of independent variables upon which these expressions depend was dramatically reduced. It was then possible to take the derivative of these expressions for dimensionless profit with respect to effectiveness, and from these derivatives the optimal heat exchanger effectiveness, considering the heat exchanger as a single component, could be found. It was found that, among other dimensionless groups, the dimensionless profit and optimal effectiveness depend on the inlet temperature ratio and the dimensionless inlet temperature difference.

Subsequently, the f-factor for the investigated heat exchanger was related to its effectiveness, the dimensionless cost of heat exchanger area and the inlet temperature ratio. Therefore, the optimal f-factor for a heat exchanger depends upon the same groups as the optimal effectiveness. As two of these groups contain the stream inlet temperatures, it is clear that the f-factor of heat exchangers in a HRSG of a cost-optimized system will vary with these temperatures. The analysis points to a situation more complicated than just a dependency of thermodynamic fuel potential, as not only the hot stream temperature, but also the cold stream inlet temperature and the ratio of heat capacities influence at least the optimal capital investment for a heat exchanger.

Beyond temperature dependency, other shortcomings in the use of the f-factor for optimizing heat exchanger networks were highlighted. These difficulties suggest that optimal effectiveness might well be an improvement on the f-factor in the iterative optimization of a heat exchanger network. Future work will center on this application.

University of Roma 1 "La Sapienza"

Italy

ABSTRACT

A numerical simulation of the heat exchange process within a car radiator has been performed with a CFD commercial code.
The heat exchanger is of the cross flow type, with elements composed of flattened tubes surrounded by a finned matrix; each fin has louvered surfaces, and the geometry is modular.
The fluids involved in the heat exchange are air on the cold side and a water/ethylene-glycol mixture (40%) on the hot side.
The numerical simulation was carried out on a 3D reduced model that includes a single module, consisting of one corrugation of finned matrix connected with two shells representing the upper and the lower sections of the flattened tubes respectively. The exchanger is considered to be operating in a steady-state mode. The difficulty of theoretically deriving the heat transfer coefficients on the external finned surface is overcome by imposing only a convective heat transfer boundary condition on the tube shells internal surfaces. The longitudinal variability of the heat transfer coefficient along the channels internal surfaces is accounted for by considering the hydraulic and thermal development of the flow inside of the glycol tubes: the relevant heat transfer formulae are derived by the existing literature. The external air flow is assumed to be laminar.
All results are in a good agreement with experimental data provided by tests conducted on an industrial prototype.

Keywords: Compact heat exchangers, conjugate heat transfer, louvered fins.

INTRODUCTION

During the last decade, commercial CFD codes employing numerical methods for the solution of the Navier-Stokes equations have reached a high degree of reliability. Such an improvement, coupled with an exponential improvement in the hardware performance, has greatly increased the capability of numerical simulations to reproduce the details of real physical phenomena.

This capability makes it possible to substantially shorten the material prototyping phase with an important reduction of the extent of laboratory tests, and brings about corresponding monetary savings. The study reported in this paper was aimed to a verification of the accuracy of the numerical determination of the performance of the latest generation of car radiators.

Conventional design methods [8] for compact heat exchangers are based on a preliminary definition of the economical and performance requirements of the device. The so-called Mason flow chart [9], reported in figure 1, synthesizes this first stage (only the first block of the Mason diagram is reported here because economic factors or shipping problems, included in its second part, are not relevant to the present study).

According to this scheme, the "problem specification" branch represents the definition of the radiator foreseen application field: i.e., the radiator application field determines the configuration of the device.

The most common configurations for compact heat exchangers are:

1. Direct transfer heat exchangers;
2. Liquid-coupled indirect transfer h.e.;
3. Periodic flow type h.e.

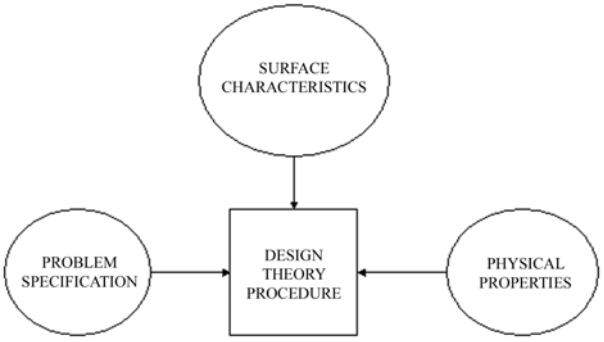

Figure 1: General methodology for heat exchanger design (first part of Mason's original chart [9])

Car radiators fall into class 2. However, in this work we are not interested in the heat exchanged inside of the engine block, and therefore we can introduce a simplification, assuming our exchanger belongs to class 1 instead. In addition, we assume that the best configuration for a car radiator is the "cross-flow finned-tube bundle".

To increase the surface-to-volume ratio, it is customary to employ low-aspect ratio (flattened) channels on the water-glycol mixture hot side and to combine them with large finned surfaces on the cold side. For what the actual (i.e., local) heat exchange coefficient is concerned, there is still a substantial lack of generally valid correlations: from an engineering design point of view the correct sizing can be easily attained by means of graphs like the one reported in figure 2.

The frontal dimensions of a compact heat exchanger result from a compromise between two contrasting requirements: an increase of the active heat exchange surface in contact with the cold fluid and the reduction of the related friction power. The friction power losses display a quadratic

dependency on the flow velocity, while the heat exchanged varies with a linear law[2].

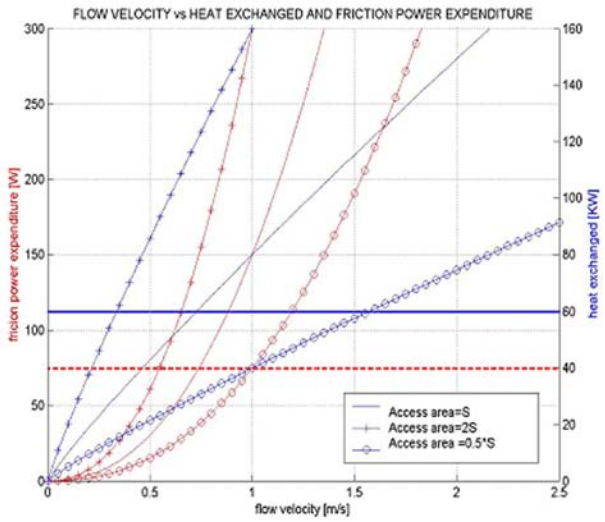

Figure 2: Radiator sizing curves

As an example, consider the situation of figure 2, where for a heat flux of 60kW (continuous horizontal thick line) and a fluid velocity of 1m/s we impose an upper limit to the pumping power of -say- 75W (dashed thick horizontal line). A radiator having an access area of 0.5 S ("o" marks) would not satisfy the thermal requirements but would instead abide by the friction power limitations. A radiator with an access area of S, on the other side, would satisfy the thermal requirements but not the friction power. The final solution consists in simultaneously reducing the fluid velocity, by changing the radiator placement within the engine compartment (for example placing it just downstream a diverging air intake) and adjusting its frontal area.

The curves displayed in figure 2 are plotted on the basis of experimental data, as compact heat exchanger performance cannot be derived with pure analytical methods: car radiator external surfaces are provided with "baroquely shaped" fins to induce boundary layer discontinuities and to improve the thermal performance on the air side; the experimental literature on louvered fins does not (and cannot) cover all existing geometries and small variations in louver inclination result in non negligible changes in radiator performance. Therefore, it is unreliable to extrapolate available data even to slightly different geometries.

This is the reason why radiator constructors must assemble a new prototype for each fin matrix geometry and for each radiator configuration.

Goal of the present work is to eliminate or strongly reduce the number of radiator prototypes to be tested. Particular attention was devoted to the modeling of the entry length development in flattened channels, that exerts a strong influence on heat transfer coefficients, especially in the case of laminar flow [12], and consequently on the overall heat exchange. Fully developed flows and turbulent flows were treated according with basic textbook literature [2,12].

THE GEOMETRIC MODEL

The radiator we will refer to hereafter is a Magneti Marelli brazed aluminium (Nocolock technology) device, with dimensions (height*width*thickness) 391.8*500*2.8 mm, a fin density of 200 fin/500mm and consisting of 40 flat parallel channels.

For the numerical simulation we considered a single element of the matrix constituting the whole radiator, figure 3.

The actual dimensions of the tubes are shown in figure 4; a frontal view of a single fin corrugation is given in figure 5.

Fin louvers belonging to adjacent corrugations are arranged at an alternate angle w.r.t. the air stream main velocity, figure 6. The fluid region surrounding the above described solid element was chosen as small as possible, to reduce the extension of the computational domain. A couple of regular volumes was added in front and behind the fin.

The downstream "plenum" is larger than the upstream one, to capture possible turbulent phenomena deriving by the interaction of the air with the fin wave. The detailed element dimensions are reported in figure 7.

To account for the presence of the solid connections due to the weldings between the corrugated fin wave and the tubes, we created small solid blocks running all along the extension of the fin-tubes contacts. The dimensions of those blocks were taken to be approximately representative of the real welding lines.

[2] Actually, the lines representing the heat exchanged in Figure 2 are not straight: the experimental evidence suggests a correlation of the type $P_f=k*V^n$, with n slightly smaller than 1.

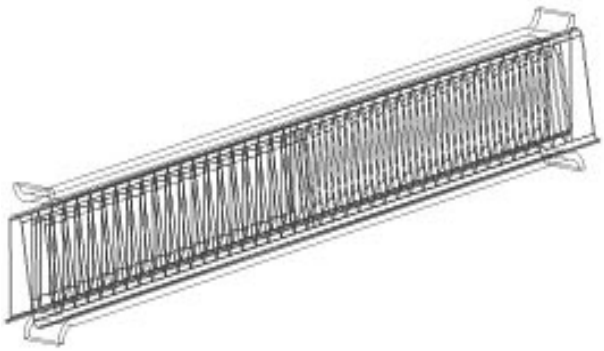

Figure 3: Geometric element for the CFD simulation

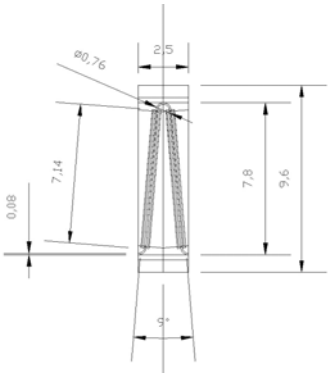

Figure 5: A single fin wave front view (mm)

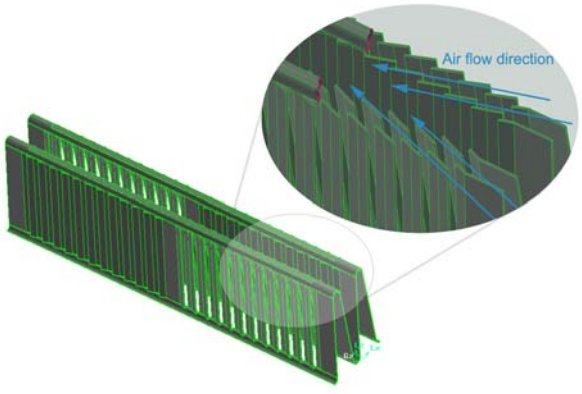

Figure 6: Detail of a pair couple of adjacent fins

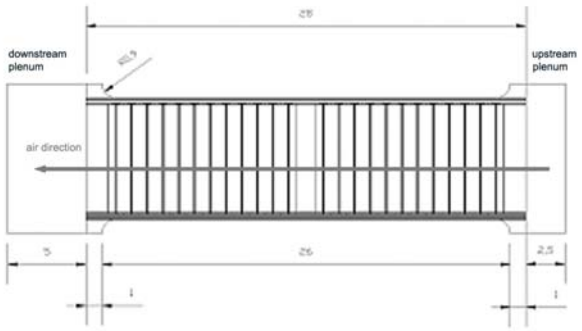

Figure 7: A complete louvered element side view (dimensions in mm)

THE FINAL MESH, THE SOLUTION PROCEDURE AND THE MATERIAL PROPERTIES

The entire domain shown in figure 3 (both solid and fluid regions) was discretised. On a hybrid-type mesh that and alternates Cooper meshing scheme zones and unstructured tetrahedral regions. Initial tests, run on a completely unstructured mesh evidenced the need for a refinement in the regions included between louvers, to adequately take into account the boundary layer development on the fin walls, allowing at the same time for a consistent reduction of cell density in less sensitive regions. The final mesh is described in table 1.

Number of Cells	Number of Faces	Number of Nodes	Number of Partitions
1860920	4210589	620440	1

Table 1: Mesh elements summary

The small hydraulic radius of the finned volumes and the relatively small air velocities result in low Reynolds numbers on the cold side, which justifies the choice of the model summarized in Table 2:

Model	Settings
Space	3D
Time	Steady
Viscous	Laminar
Wall treatment	Standard wall functions. No-slip condition
Heat Transfer	Enabled

Table 2: Model characteristics

The simulation was run using FLUENT, version5.6, the convergence of the iterative non-linear solver was accelerated (both for pressure and

for momentum) by means of the under-relaxation factors shown in Table 3:

Variable	Relaxation Factor
Pressure	0.03
Density	1
Body Forces	1
Momentum	0.07
Energy	1

Table 3: Relaxation factors

The solution scheme was:

Variable	Scheme
Pressure	Standard
Pressure-Velocity Coupling	SIMPLE algorithm
Momentum	First Order Upwind
Energy	First Order Upwind

Table 4: Solver description

For the water/ethylene-glycol mixture, temperature variable properties were assumed as shown in Table 5.

Temperature	Density [kg/m3]	Thermal conductivity [W/(mK)]	Viscosity [mPa s]	cp [KJ/(kgK)]
273	1065,00	0,396	6,50	3,36
293	1055,00	0,414	3,10	3,45
313	1042,00	0,428	1,80	3,56
333	1030,00	0,44	1,13	3,64
353	1018,00	0,45	0,80	3,71
363	1009,00	0,454	0,60	3,74
373	1002,00	0,458	0,56	3,76

Table 5: Properties of 40% vol. Water/Ethylene-Glycol mixture (adapted from[11])

BOUNDARY AND OPERATING CONDITIONS

The face through which the air impinges on the finned volume was defined "*velocity inlet*" and a single component velocity vector was assigned to it. An "outflow condition" is imposed on the downstream surface. "*Simmetry*" boundary conditions are imposed on the side walls, while adiabatic conditions are imposed on the surfaces representing the longitudinal (YZ) tube sections.

A graphical summary of the imposed boundary conditions is provided in figure 8. Planes delimiting the air volumes on the XY sections are considered to be periodic, to take into account possible vertical mass transport. The treatment of the internal tube surface ("ITS" in the following) deserves a more detailed discussion, provided in the next paragraph.

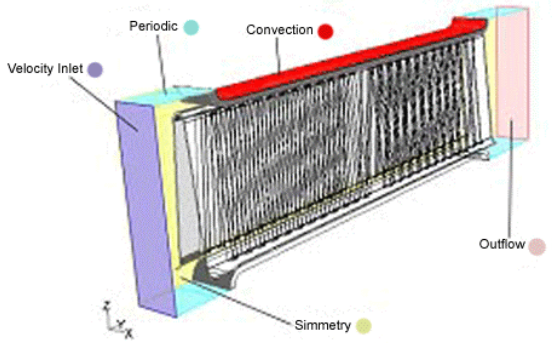

Figure 8: Boundary conditions

THERMAL BOUNDARY CONDITIONS ON THE INTERNAL TUBE SURFACE

The calculation of the temperature field established by the thermal exchange between two fluids separated by a solid matrix requires the solution of a double-conjugated problem. Each conjugate problem involves the definition of the thermal field both for fluid and solid elements. Both the temperature and heat flux at the interface between solid and fluid fields are considered continuous. The use of a numerical model with a cross flow heat exchange including both fluids results though in an extremely high CPU consumption.

To simplify this model and to reduce the physical problem to a single-conjugated one, we resolved to adopt a mathematical law to describe the behavior of the heat transfer coefficient on the internal tube surface. The existence of several concurring thermal effects on the internal tube surface, like the perturbations induced by the external fin welding, or the influence of the variation of the inlet velocity profile caused by the geometrical configuration of the water box, make though the definition of a single thermal boundary condition difficult. For these surfaces, Shah and London [12] suggest a constant temperature boundary condition, remarking that this is a valid assumption only for very high liquid flow rates. We performed some preliminary simulations with such a temperature condition on the internal duct surface, taking as "wall value" the local mixing cup temperature of the water/GE solution: the results showed an excessive thermal exchange and overestimated air-side heating; this agrees with Garimella et al. [5] experimental tests performed on a simplified tube geometry very similar to ours (α=0.05, hydraulic diameter=2.21 and Pr=10). We finally assumed a

heat transfer coefficient that is constant on the duct transversal section and varies along the tube (in the x direction, figure 9) depending on the thermal/hydraulic internal flow boundary layer development.
Neglecting the influence of the duct inlet configuration and of externally induced vibrations, we will thus assume that the laminar-to-turbulent transition takes place approximately at Re=2300: a very extensive literature of experimental data exists on this topic and shows the extreme variability of the transition Reynolds number (Pfenninger [10] pushed the laminar to turbulent transition Reynolds number value up to $1.005*10^5$), but the 2300 value is well accepted for most common cases where the tube length is much longer than the hydraulic entry length.

Laminar flow

For Re<2300, the peripheral heat transfer coefficient on the inside of the tubes is strongly influenced by the development of the temperature profile inside of the ducts and by the thermal boundary conditions. The heat transfer coefficient decreases as the velocity and thermal profiles develop and its variation affects a large portion of the tube.
To define the extension of the hydrodynamic entrance length we used Chen's equation [4] for developing flow between parallel plates:

$$\frac{L}{D} = \frac{0.315}{0.0175 * \mathrm{Re} + 1} + 0.011 * \mathrm{Re} \qquad (1)$$

The analytical definition of the dimensionless thermal entrance length shows its dependence on the Péclet number

$$L_{th}^{*} = L_{th} / (D_h Pe) \qquad (2)$$

The thermal entrance length increases with the fluid axial heat conduction (i.e. as the Pe number decreases); the lateral short walls of our almost rectangular ducts should therefore give origin to longer L_{th}^{*} higher values than a parallel plates configuration. Since the aspect ratio of the tubes is here extremely low, the parallel plates value of $L_{th}^{*} \approx 0.012$ can be regarded though as a good approximation.
For the evaluation of the heat transfer coefficient, the tube was divided into three zones:

A. Hydrodynamically-thermally developing flow
B. Hydrodynamically developed, thermally developing boundary layer
C. Completely developed thermal-hydrodynamic boundary layer

A. Hydrodynamically-thermally developing flow

A great amount of data about the values of the heat transfer coefficient is available for square and round tubes geometries; few studies exist about flattened tubes. Wibulswas [14] provides interesting analytical results about similar geometries but considers only flows with Pr=0.72. Chandrupatla [3] considers simultaneously developing flow but treats only square ducts. We used the Hwang and Fan [7] heat exchange coefficients over a simultaneously developing flow obtained for a value of Pr=10. These results are in good agreement with Garimella and al. [5] experimental data for flat tubes, for different tube lengths, different hot fluid composition (30, 40, 50% GE) and several values of the Prandtl number. Defining an axial dimensionless coordinate x* Hang and Fan's [10] experimental data provide:

x*	5*10e-5	1,25*10e-4	4,38*10e-4	7,5*10e-4
$Nu_{x,h}$	50,74	34,07	20,66	17,03

0,0015116	0,002	0,00625	0,01
14	12,6	9,5	8,8

Table 6: $Nu_{x,h}$ as a function of x* for simultaneous developing flows between parallel plates [10]

B. Thermally developing region

Adopting the same symbolism as in Table 6, and denoting by x* the distance from the duct inlet, Shah and London [12] provide the following results:

X*	0,001	0,0015	0,002	0,003
$Nu_{x,h}$	15,42	13,68	12,6	11,29

0,004	0,005	0,006	0,007
10,51	99,87	9,6	9,32

X*	0,008	0,009	0,01	0.015
$Nu_{x,h}$	9,1	8,93	8,8	8,43

0.02	0.03	0.04	0.05
8,31	8,24	8,23	8,23

Table 7: $Nu_{x,h}$ as a function of x* for fully developed velocity profile, thermally developing flow within parallel plates

Figure 9 shows the variation of the heat transfer coefficient on the internal tube surfaces for a hydraulically and thermally simultaneously developing entry length.

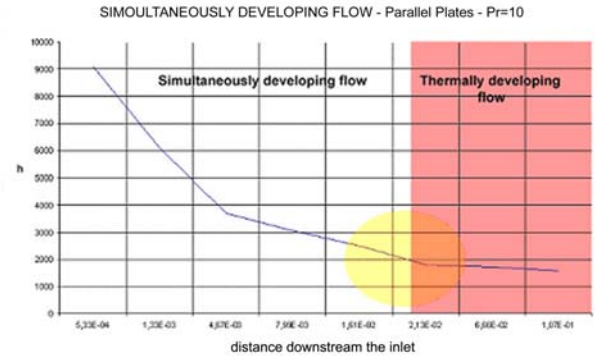

Figure 9: Heat transfer coefficient vs tube lenght along simultaneously developing entry lengths

Figure 10 clearly identifies the heat transfer coefficient for a completely developed and for thermally developing entry length.

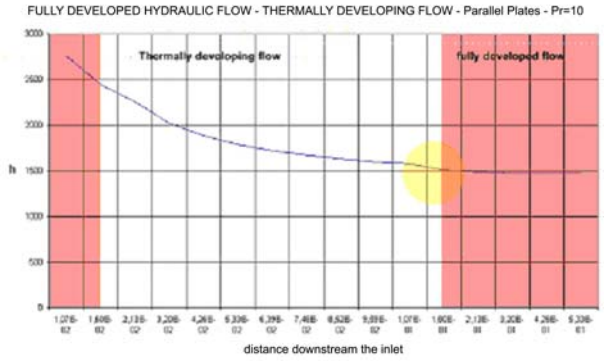

Figure 10: Heat transfer coefficient vs tube lenght along thermal developing entry length

The variation of the slopes of both curves is evidenced by the shaded areas in figure 9 and 10; such change in slope implies a variation in the thermal boundary layer configuration and confirms the results for the entry length extensions obtained with the above mentioned Chen law.
As a first step, we matched the results obtained for the simultaneously developing entry length and for the hydraulic completely developed/thermally developing entry length. Table 8 reports the values of the heat transfer coefficients calculated for real (non dimensionless) extensions of tube length along the complete boundary layer development.

x[m] 1000kg/h l	x[m] 2000kg/h l	x[m] 3000kg/h l	h [W/(m²°C)]	zone (fig.5,3)

0,106	0,249	0,3374	1480	13

Table 8: Entry length real extension with corresponding heat transfer coefficient and zone identification marker

We then divided the domain in zones (Table 8, last column) with constant “h”, thus somewhat grossly approximating the heat transfer coefficient variation. Figure 11 shows, by means of different shading, the distribution of piecewise constant heat transfer coefficient regions along the tube entry length for a 1000 kg/h hot fluid flow rate

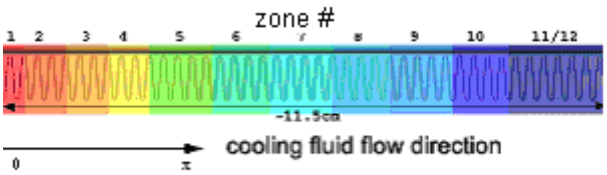

Figure 11: Zones with constant heat transfer coefficient

Turbulent region

For Re>2300 the motion transitions into turbulence.The hydraulic radius of the tubes (2.21 mm) sufficiently exceeds the 2 mm indicative value beneath which the suppression of turbulent eddy mechanism causes a reduction in the heat transfer coefficient. Bhatti and Shah [2] suggest that for practical computations of the fully developed Nusselt numbers in rectangular ducts it is possible to use the same correlations obtained for circular channels. We therefore used the Hausen [6] formula to obtain the Nusselt number for turbulent fully developed flow:

$$Nu = 0.116\left(\mathrm{Re}^{2/3} - 125\right) * \mathrm{Pr}^{1/3}\left[1 + \left(\frac{x}{D}\right)^{-2/3}\right] \qquad (3)$$

This formula takes into account the thermal entrance length effect embodied in the last bracketed factor. Figure 16 reports a comparison between the heat exchange coefficient obtained with Hausen formula and some experimental values. There is a sufficiently good agreement over the entire turbulent region.

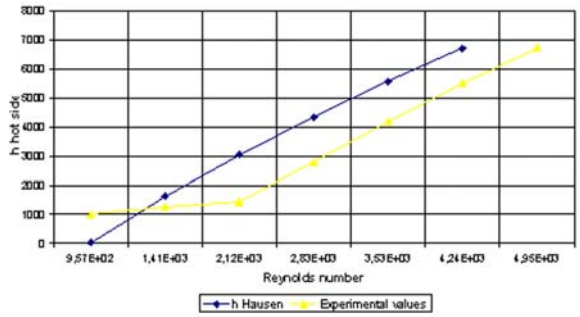

Figure 12: Cold side heat transfer coefficient vs. Reynolds number

RESULTS

Scope of the simulation was to compute the heat power exchanged in a full length (500mm) tubes radiator. Tables 9 and 10 compare the results of our Fluent® simulations with experimental data [1]. The error, defined as:

$$\frac{\varphi_{CFD} - \varphi_{EXP}}{\varphi_{EXP}} \qquad (4)$$

is reported in Table 11: it never exceeds 8% for any relevant variable.

Q [kW]		Coolant flow rate [kg/h]					
		1000	2000	3000	4000	5000	6000

	4000	23,1	28,2	30,9	37,7	41,3	49,7
	5000	24,7	30,6	33,7	42,1	46,8	51,4
	6000	25,8	32,3	36,1	45,2	50,9	56,5

Table 10: Heat exchanged for a 500mm radiator length- Experimental data

		m-liq [kg/h]					
		1000	2000	3000	4000	5000	6000
Air flow rate [kg/h]	1000	4.50	3.36	1.99	1.55	7.14	1.50
	2000	2.76	2.13	0.97	7.25	3.39	7.71
	3000	3.19	2.71	2.86	3.59	4.67	1.90
	4000	4.14	4.53	3.31	2.83	3.95	3.12
	5000	5.00	1.29	0.88	2.09	2.70	4.42
	6000	5.14	2.41	0.82	4.03	1.35	3.55

Table 11: Heat exchange % error for a 500mm radiator length

To validate the theoretical required by our discrete model for the first zone of entrance length, we can consider experimental data derived for a 250mm radiator with the same fin geometry as the previous one.

Q [kW]		Coolant flow rate [kg/h]		
		1000	2000	3000
Air flow rate [kg/h]	1000	10,10	11.17	11,54
	2000	14,10	16,61	17,55
	3000	16,10	19,21	20,60

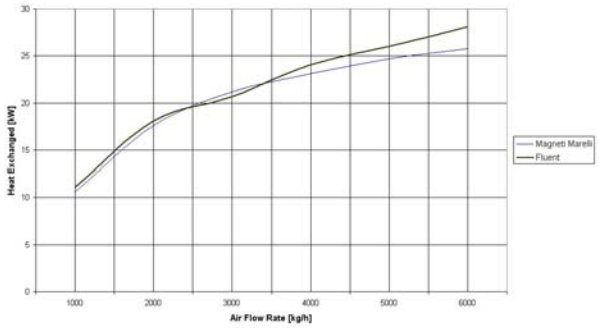
Table 12: Heat exchanged for a 250mm radiator - Fluent simulation

Q [kW]		Coolant flow rate [kg/h]		
		1000	2000	3000
Air flow rate [kg/h]	1000	0	0.63	0.34
	2000	0	1.33519	0.9
	3000	0	0.57	0.09

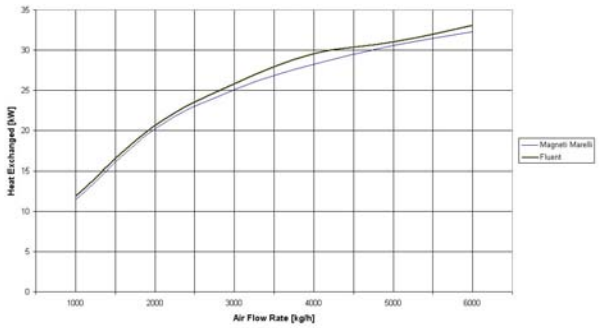
Table 13: 250 mm radiator heat exchange % error

From Tables 12 and 13 we observe that the shorter radiator exchanges a heat power much higher than the half of that exchanged by the 500mm one: this confirms that thermal transfer efficiency decreases as the entry length develops.

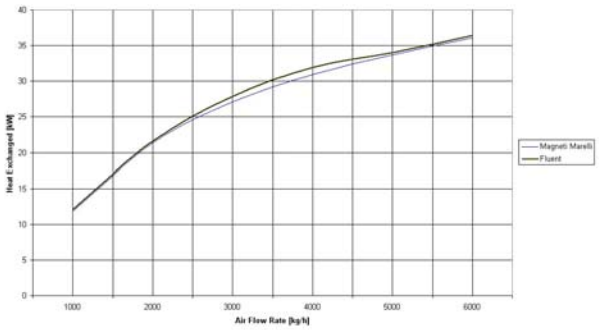
The graphs in figure 13 a through h report a graphic comparison between experimental and simulated results; each graph is for a single coolant flow rate over a range of air flow rates.



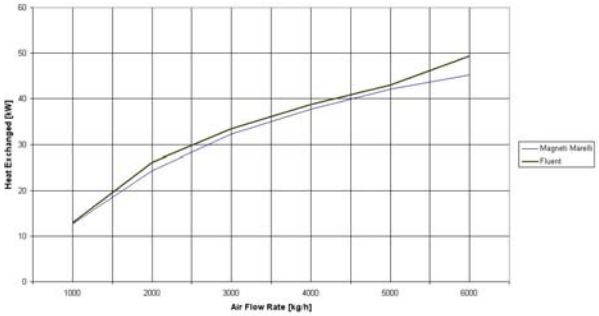
13 a: Heat exchanged within a radiator for 1000 [kg/h] hot fluid mass flow



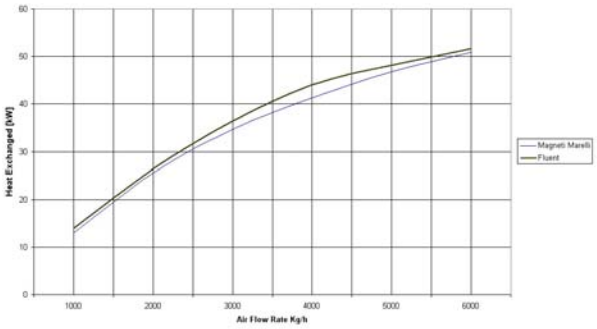
13 b: Heat exchanged within a radiator for 2000 [kg/h] hot fluid mass flow



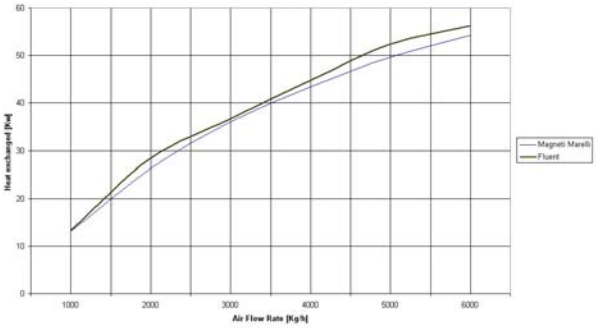
13 c: Heat exchanged within a radiator for 3000 [kg/h] hot fluid mass flow



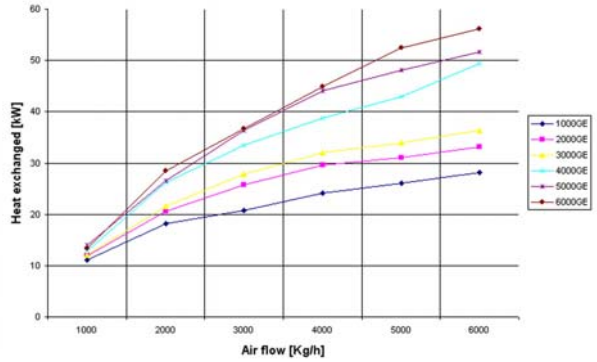
13 d: Heat exchanged within a radiator for 4000 [kg/h] hot fluid mass flow



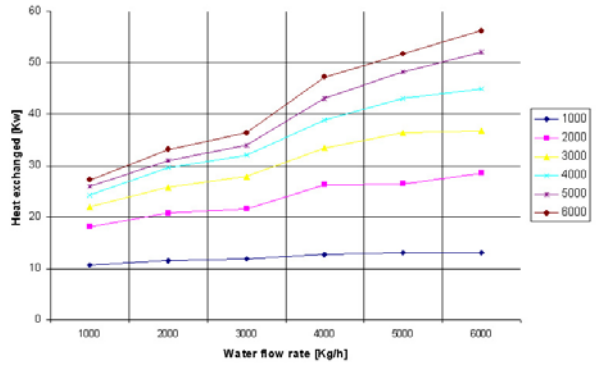
13 e: Heat exchanged within a radiator for 5000 [kg/h] hot fluid mass flow



13 f: Heat exchanged within a radiator for 6000 [kg/h] hot fluid mass flow



13 g: Heat exchanged vs air flow for different water flow rates



13 h: Heat exchanged vs water flow for different air flow rates

It is useful at this point to show the final temperature field on the single corrugation of the fin (figure 14) and the temperature of the cooling air for three different sections ordered according with the predominant air flow direction (figure 15): a fully three-dimensional thermal boundary development is observed, as expected. Of particular interest is the progressive reduction of the cold air core in the axial (y) direction: its asymptotic behavior suggests the existence of a practical upper limit to the axial thickness of the radiator. In correspondence of three sections of the fin like those shown in figure 15, the mean temperatures of the fin and the fluid free stream temperature were calculated. An averaged value of those ΔT was used to obtain the heat transfer coefficient for a single fin:

$$\overline{h} * A * \overline{\Delta T} = \overline{q} \qquad (5)$$

A graphical comparison between the values of global cold side heat transfer coefficient obtained with the above described method and those provided by experiments [1] are shown in figure 16.

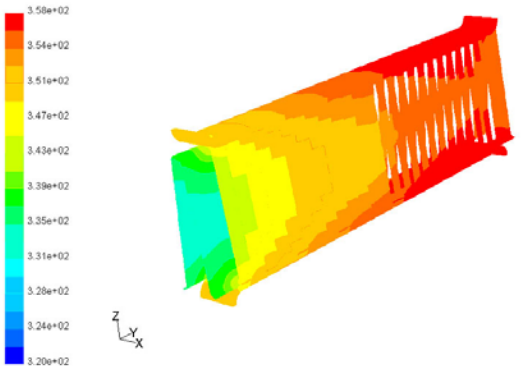


Figure 14: Temperature distribution on the single fin corrugation

SUMMARY AND CONCLUSIONS

This work presents a general procedure for predicting a compact heat exchanger performance by means of a numerical code.

As a workaround to the lack of literature data on coefficients and parameters necessary to the device performance evaluation, all simulations were performed on *ad hoc* model that implicitly calculated hard-to-predict unknown values.

A semi-empirical correlation accounting for Nusselt number variation along the hot fluid side was imposed on the internal tubes surfaces.

Values for the thermal entrance length were deduced from the parallel plates case, and this resulted in a possible underestimate of the thermal exchange.

The heat transfer coefficient was assumed to be piecewise constant for each longitudinal region of the tube, its value being calculated on the first elemental element of each slice: this caused an overestimate of the heat exchange performance. The two effects seem to balance and the numerical results agree very well with experimental data (within 8% error). The longer the slices of tubes on which the heat exchange coefficients are considered constant, the higher the error affecting the results. This is confirmed by comparisons with the results of a simulation of a 250mm lengh radiator, for which the numerical results were affected by a maximum error of 1.5%.

The values of the heat transfer coefficient on the finned surface result in good agreement with experimental data.

AKNOWLEDGMENTS

EXHAUST GAS RECIRCULATION IN GAS TURBINES FOR REDUCTION OF CO_2 EMISSIONS. COMBUSTION TESTING WITH FOCUS ON STABILITY AND EMISSIONS.

Petter E. Røkke and Johan E. Hustad
Norwegian University of Science and Technology
Department of Energy and Process Engineering

ABSTRACT

Exhaust gas recirculation can be applied with the intention to reduce the CO_2 emissions. When a fraction of the exhaust gas is injected in the entry of a gas turbine, the amount of CO_2 in the exhaust gas not being recirculated will be higher and less complicated to capture. However, with this change in combustion air composition, especially the reduced concentration of oxygen, the combustion process will be affected. The lower oxygen concentration decreases the stability and the increased amount of CO_2, H_2O and N_2 will decrease the combustion temperature and thus, the NO_x emissions. Testing has been performed on a 65 kW gas turbine combustor, to investigate the effect of adding N_2, CO_2 and O_2 in the combustion process, with focus on stability and emissions of NO_x. Results show that adding N_2 and CO_2 decrease the NO_x emissions, whereas O_2 addition increases the NO_x emissions. The tests have been performed both in a diffusion flame (pilot burner) and a premixed flame (main burner), and for additives being injected with the fuel or with the air stream. Addition into the fuel stream is proven to affect the NO_x emissions most. The stability limits of the flames are indicated with respect to massbased additive-to-fuel ratios.

INTRODUCTION

Natural gas fired power generation facilities have always been considered as an environmental friendly power source, when compared to other fossil fuel based power sources such as for instance coal-fired power plants. The NO_x and CO emissions from natural gas fired power plants are significantly lower than when coal is applied as fuel. More recent focus has turned onto CO_2 emissions and the effect CO_2 has on the atmosphere. An increased greenhouse effect is proved to have a source in the higher concentration of CO_2 in the atmosphere. CO_2 stems from multiple human generated sources, along with more natural sources such as the photosynthesis. Combustion engines in cars, boats and planes contribute significantly, but the CO_2 from these distributed sources is difficult to handle. CO_2 from larger stationary combustion facilities, such as power plants can be handled with a CO_2 clean-up system. Several different technologies for CO_2 capture processes are being developed, as described in [1]. Especially the power demanding oil industry is interested in the development of so-called CO_2 free power generation sources. The CO_2-tax is a significant motivation for decreasing the CO_2 emissions into the atmosphere.

An alternative technology for CO_2 mitigation is to recirculate the exhaust gas of a simple cycle gas

turbine. A part of the exhaust gas can be recirculated to the entry of the gas turbine and mixed with the air. This will change the composition of the combustion air and thus, affect the combustion process. Most important with respect to NO_x emissions, the recirculated exhaust gas will decrease the O_2 concentration in the combustion air. With regards to CO_2 mitigation, the exhaust gas that is not recirculated will have a higher CO_2 concentration. One of the problems for post-combustion CO_2 separation, where the CO_2 is separated with an amine-process, is the low concentration of CO_2 in the exhaust gas. Thus, the exhaust gas from a recirculation process can give a higher CO_2 capture than for a regular gas turbine exhaust gas.

As mentioned, the combustion process is affected due to the change in combustion air composition. For gas turbines today that are operated with low emission combustion systems, most commonly so-called lean premixed systems, the flame stability will be affected by the lower O_2 concentration in the combustion air. Premixed combustion systems are highly dependent on the flame velocity of the mixture and a decrease in the O_2 concentration of the mixture lowers the flame velocity [2]. A decrease in the O_2 concentration, without further modifications of the system may then cause blowout of the flame. More conventional combustion systems that are operated with diffusion flames are less sensitive to variations in combustion air composition with regards to flame stability. NO_x emissions for such flames, however, are significantly higher than for lean premix combustion systems.

In gas burners so-called flue gas recirculation (FGR) is widely applied for reduction of NO_x emissions. Gas burners refer to 3 vol% O_2 in the exhaust gas in contrast to gas turbines that refer to 15 vol% O_2. In this paper, a gas turbine combustor has been applied for experiments on both a premixed and a diffusion flame with focus on NO_x emissions and how the addition of O_2, N_2 and CO_2 affects the NO_x emissions. O_2, N_2, CO_2 and H_2O are the main components in a hydrocarbon combustion process. Steam injection has not been applied in these experiments due to the available equipment in the laboratory, preheating to temperatures above 100ºC for the air supply has not been possible. The effect of steam is thus based on the literature. These experiments will also investigate the importance of O_2 concentration in the recirculated exhaust gas with respect to NO_x emissions.

EXPERIMENTAL SETUP

A gas turbine combustor is applied for combustion testing. The combustor has the possibility for both diffusion flame (pilot burner) and premixed flame operation (main burner).

A schematic of the rig is shown in Figure 1.

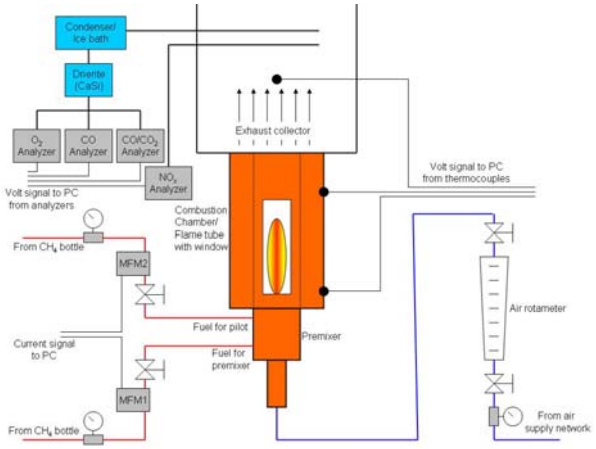

Figure 1. Experimental schematic.

Two mass flow meters are applied for the addition of two different components (fuel + additive). The additive can either be injected into the air stream or it can be premixed with the fuel. For premixing with the fuel, a mixing chamber with a fine metal grid inside it is built for efficient mixing.

A more detailed view on the premixer is shown in Figure 2. The combustion air enters vertically at (1), and flows through a section of 12 airfoil vanes (2) that creates a high swirl (tangential velocity/axial velocity~9). Premixed fuel injection is done through these vanes that are hollow and have four fuel injection holes on the pressure side of each vane. The fuel is distributed in the premix fuel manifold (5). About 2 % of the air flows through the center hollow reverse cone (3) for cooling of the perforated bluff-body (4) inside the combustor. The fuel manifold for the diffusion flame (6) distributes the fuel into the combustor through 12 holes.

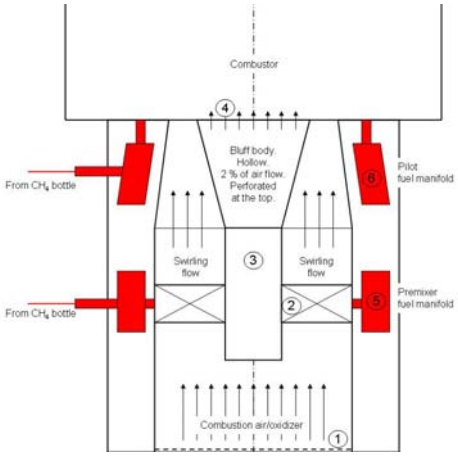

Figure 2. Premixer schematic.

A photo of the premixer and bluff-body is shown in Figure 3.

Figure 3. Premixer and bluff-body.

Measurements are performed on surface temperatures of the combustor, and the combustion gas. The concentrations of the species in the exhaust gas are measured as indicated in Figure 1. The mass flows of fuel and additive are controlled with needle valves and measured with mass flow meters, whereas the supply of air is controlled by a rotameter. The measured O_2 concentration in the exhaust gas is applied for calculation of exact air-excess ratios. As methane (CH_4) is the main component of natural gas it is applied as fuel.

EXPERIMENTAL RESULTS

First, stability limits for operation in diffusion and premixed mode is checked. In Figure 4, the indicated equivalence ratios where the flame becomes unstable is shown for operation in diffusion and premixed mode. The air supply is kept constant for each test, and the fuel supply is gradually decreased until the flame becomes unstable. The premixed flame LBO limit occurs at a 0.6 equivalence ratio, whereas the diffusion flame becomes unstable at an equivalence ratio below 0.25.

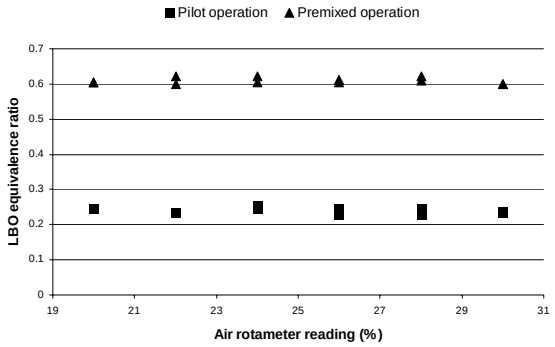

Figure 4. Lean Blowout (LBO) limits for diffusion and premixed operation.

Further, the emissions of CO and NO_x are measured for the two operation modes. The NO_x emissions are shown in Figure 5. The diffusion flame operation is a swirling co-flow flame, and the air supply to the flame is controlled. Usually, the equivalence ratio is not applied as a measure for diffusion flames, but since this is a confined system, it is an important parameter.

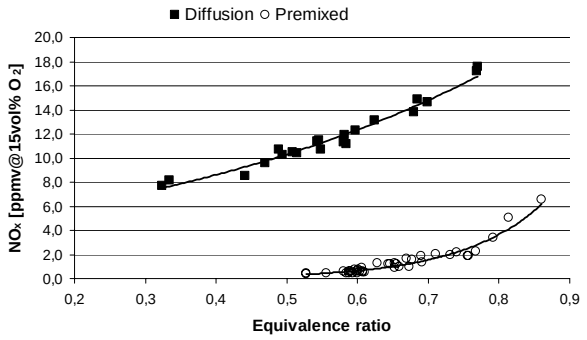

Figure 5. NO_x emissions measured for operation in diffusion and premixed mode.

The CO emissions measured were in general very low, especially for the premixed flame where the measured CO was below 3 ppmv for all equivalence ratios. For diffusion operation, the CO emissions increased significantly when approaching equivalence ratios below 0.5, as shown in Figure 6.

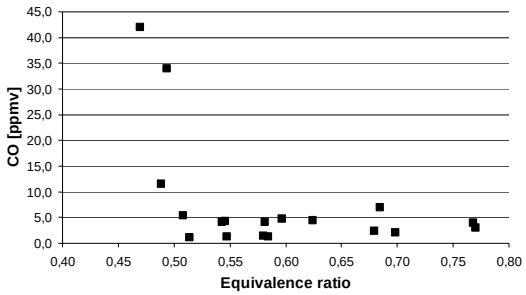

Figure 6. CO emissions for operation in diffusion mode.

Thus, the points for NO_x emissions below 0.5 equivalence ratio for diffusion operation are doubtful due to the high amounts of CO in the exhaust products. However, the higher NO_x emissions for diffusion operation than for premixed operation are not to be questioned.

The increase in NO_x emissions at higher equivalence ratios are as expected. Increasing the equivalence ratio gives a more fuel rich flame with higher flame temperature. Higher temperature affects the NO_x formation mainly through the thermal mechanism [3]. The increase in CO emissions at lean condition is caused by lower reaction ratios at lower flame temperatures.

A diffusion flame will always have a flame surface with a stoichiometric fuel-air composition. Thus, at the flame surface the temperature will be significantly higher than in a premixed flame where the overall equivalence ratio is leaner than stoichiometry. The NO_x emissions in a diffusion flame will thus be higher than in a lean premixed flame, just as the results here prove.

In the case of exhaust gas recirculation, an interesting issue is to see if the diffusion operation NO_x emissions can be reduced down to premixed operation levels.

The results given in Figure 7 show how the different additives affect the NO_x emissions in diffusion operation. The points with the highest additive-to-fuel ratio indicate stability limits where the flame becomes unstable due to the amount of additive being injected (not the actual blow-out limits). It is seen that the unstable flame occurs at lower ratios when the additive is premixed with the fuel than with the air stream. Even for O_2 enrichment of the flame, a stability limit is approached, already before an additive-to-fuel ratio at unity.

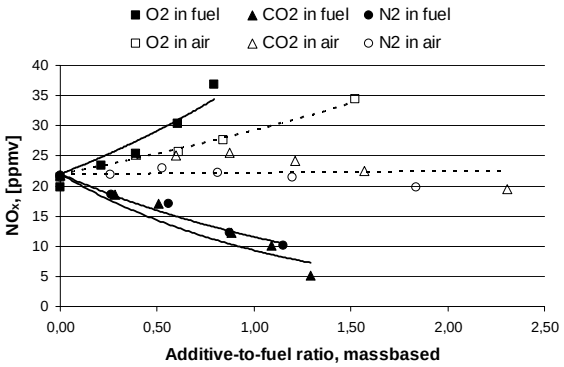

Figure 7. Additives effect on NO_x emissions in diffusion operation.

For additives being injected into the fuel stream, the flame is lifted when more additive is injected. This is due to the increased jet velocity out of the fuel nozzles. Also, the different additives have different molar weights, and thus, the molar additive-to-fuel ratio must be considered. Table 1 shows the values for the stability limits referred to Figure 7 for the massbased values.

	Mass	Molar
O_2/CH_4	0.79	0.40
CO_2/CH_4	1.29	0.47
N_2/CH_4	1.15	0.66

Table 1. Comparison of mass- and molar based stability limit additive-to-fuel ratios.

Premixing the additive with the fuel affects the NO_x emissions more than when injected with the air stream. Oxygen enrichment of the flame increases the NO_x emissions, both when injected with the fuel stream and with the air stream. When premixed with the fuel, the NO_x emissions are doubled already at an oxygen-fuel ratio below unity. CO_2 and N_2 injection seem to have quite similar effects on the NO_x emissions. A significant decrease is seen when premixed with the fuel, whereas addition into the air stream has less effect on the NO_x emissions. If steam could have been applied for the experiments, a more significant decrease in NO_x emissions would have been expected, due to a higher specific heat that would reduce the flame temperature more.

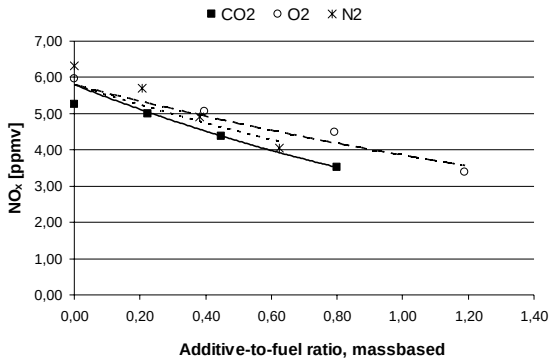

Figure 8. Additives effect on NO_x emissions in premixed operation.

The results from the experiments where the additives were injected into the flame in premixed operation are shown in Figure 8. Injection of additives into premixed operation of the flame is not affected by the injection point of the additive. The fuel and air mixture is well mixed. For all additives, the NO_x emissions decrease similarly. Even for oxygen addition to the fuel stream a decrease is seen. This is explained by the fact that for a well mixed premixed flame, operating lean, extra oxygen addition will only make the flame leaner, and the NO_x emissions will thus decrease.
The specific heat for the components of an exhaust gas is shown in Table 2.

T [K]	H_2O	CO_2	N_2	O_2
250 K	liquid	0.782	1.044	0.910
1000 K	2.267	1.232	1.167	1.085
2000 K	2.832	1.371	1.287	1.180

Table 2. Specific heat (C_p) values for H_2O, CO_2, N_2 and O_2 for different temperatures [kJ/kgK].

Steam has significantly higher specific heat than the other components and will surely affect the flame temperature in a larger degree than the other additives if evaluating only the thermal effect. The evaluation of the NO_x chemistry is similarly important. The thermal mechanism is often described by the following reaction as the rate determining step [3];

$$O + N_2 \underset{k_{1b}}{\overset{k_{1f}}{\Leftrightarrow}} NO + N \qquad (1)$$

Thus, the N_2 concentration in the flame is of main importance. It is referred to as the thermal NO_x formation mechanism because it is highly dependent on the temperature, especially at temperatures above 1850 K [4]. The prompt mechanism is determined by the sudden cracking of hydrocarbons in the flame, with the following reaction as the main [5]:

$$CH + N_2 \underset{k_{4b}}{\overset{k_{4f}}{\Leftrightarrow}} HCN + N \qquad (2)$$

The radical (CH) concentration is dependent on the temperature, and as for the thermal mechanism, the N_2 concentration is important. The principal reaction of the nitrous oxide mechanism is;

$$O + N_2 + M \underset{k_{5b}}{\overset{k_{5f}}{\rightleftharpoons}} N_2O + M \qquad (3)$$

Due to the third body dependence, this mechanism has more influence at increased pressure [6].
The results indicate that the flame being analyzed here is affected by the thermal effect when CO_2 or N_2 is added, since both have quite similar effect on the NO_x emissions. It is indicated in [7] that CO_2 may affect the NO_x formation mechanism. The CO_2 added will change the equilibrium of the $CO+OH \leftrightarrow CO_2+H$ reaction to the left, and thus compete with the $H+O_2 \leftrightarrow O+OH$ reaction for the H-atom. Fewer radicals in the flame are due to the lower temperatures, and thus less NO_x emissions. The specific heats are quite similar for the two components and thus the chemical effect is indicated to be less important for such a flame. The oxygen enrichment of the diffusion flame affects the chemical kinetics through the increased oxygen content in the flame, and also that the mixture turns towards a fuel-oxygen mixture rather than a fuel-air mixture. The properties of a CH_4-O_2 flame is significantly different than 0f a CH_4-air flame as described in Table 3.

Stoichiometric	CH_4-O_2	CH_4-Air
Flame temperature (K)	~3800	~2600
Flame velocity (cm/s)	330	40

Table 3. Different flame properties for CH_4 combustion in oxygen or in air.

The flame temperatures are calculated for atmospheric conditions [8] and the flame velocities from [2]. Thus, the thermal NO_x formation mechanism gives higher NO_x emissions with increased amount of oxygen enrichment. As

mentioned, the oxygen addition in the lean premixed flame, however, acts as a diluent.

EXHAUST GAS RECIRCULATION

The experiments performed here are with addition of the components in an exhaust gas separately. Limitations in the laboratory have excluded the possibility for injection of all components of an exhaust gas to simulate the actual combustion environment in such a process. The effect the reduction of O_2 concentration in the combustion air has on the blowout limits have been tested in [9], indicating that blow out for combustion air with less than 13.5 vol % O_2. In [10], it is said that 16-18 vol% O_2 is required for stability. The reduction in the flame velocity for some hydrocarbon fuels as a function of the oxygen concentration (in an oxygen-nitrogen mixture) is shown in [11], indicating a significant reduction when the oxygen concentration is reduced. The temperature change in the flame will also affect the combustion stability; lower temperature reduces the reaction rates and the reaction may become too slow to maintain stability. This is, however, not likely to affect the stability as much as the oxygen concentration and the flame velocity. The change in temperature is more likely to affect the NO_x emissions. As mentioned, the temperature affects both the prompt and (especially) the thermal NO_x formation mechanisms. The composition of the combustion air will have different bulk specific heats and specific heat ratio, which will give a change in the combustor inlet temperature and pressure. A change in the inlet temperature gives approximately half the change in flame temperature. This, along with the flame temperature change due to the additives, will influence the NO_x emissions.

The experiments performed with the additives being injected separately can be applied for correlating the recirculation of an exhaust gas. The trendlines can be extracted from the curves shown above and correlated in a single equation. The correlated trendlines for the different additives are as follows, based on the effect on NO_x emissions when the additive is premixed with the fuel:

$$\frac{NO_{x,O_2}}{NO_{x,0}} = e^{0.56\cdot(O_2/CH_4)_m} \quad (4)$$

$$\frac{NO_{x,N_2}}{NO_{x,0}} = e^{-0.64\cdot(N_2/CH_4)_m} \quad (5)$$

$$\frac{NO_{x,CO_2}}{NO_{x,0}} = e^{-0.86\cdot(CO_2/CH_4)_m} \quad (6)$$

Steam injection into the combustor, premixed with the fuel, has been investigated in the Cheng Low NO_x process [12]. With emphasis on homogeneity in the fuel-steam mixture, NO_x reduction has been proven without increasing the CO emissions. A decrease in the homogeneity of the fuel-steam mixture would increase the CO emissions significantly. From the results shown for NO_x emissions as a function of steam injection in [12], a trendline can be extracted as follows;

$$\frac{NO_{x,H_2O}}{NO_{x,0}} = e^{-0.90(H_2O/CH_4)} \quad (7)$$

Now, these four equations - (4), (5), (6) and (7) – can be combined into one expression for modelling of an exhaust gas recirculation process. This can be done as shown here;

$$NO_{x,total} = w_{CO_2} NO_{x,CO_2} + w_{H_2O} NO_{x,H_2O} + w_{O_2} NO_{x,O_2} + w_{N_2} NO_{x,N_2} \quad (8)$$

where w_i are coefficients for the different additives that may be adjusted due to the influence of the additives. The denominator ($NO_{x,0}$) is already eliminated since it is the same for all additives, and also for the total exhaust gas recirculation process. The w_i coefficient can be set as 0.25 if similar influence from the additives is assumed. If the recirculated exhaust gas is free of oxygen (from a stoichiometric combustion process), the coefficients for CO_2, H_2O and N_2 are set as 0.33, and the coefficient for O_2 as zero. In the case of air addition (partially premixed flame), the coefficients for O_2 and N_2 are set as 0.5 and the rest as zero.

The composition of the exhaust gas will vary due to the air excess ratio (lambda = 1/equivalence ratio) in the combustion process. Figure 9 shows how the O_2 concentration in the exhaust gas varies as a function of the air excess ratio. Gas turbines operate with an overall air excess ratio in the

range from 3-4 which gives 13-15 vol% O_2 in the exhaust gas. For the recirculation of exhaust gas the concentrations of O_2, N_2, CO_2 and H_2O are calculated, which is required for predictions based on equation (8).

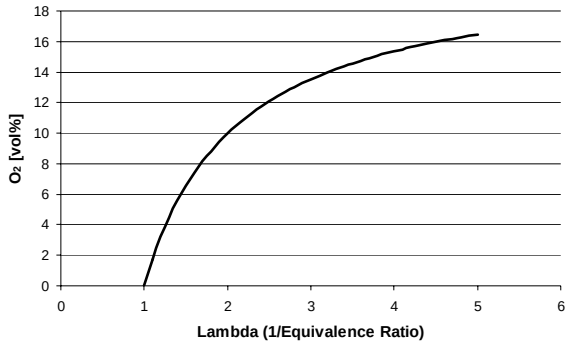

Figure 9. O_2 concentration in the exhaust gas as a function of the air excess ratio.

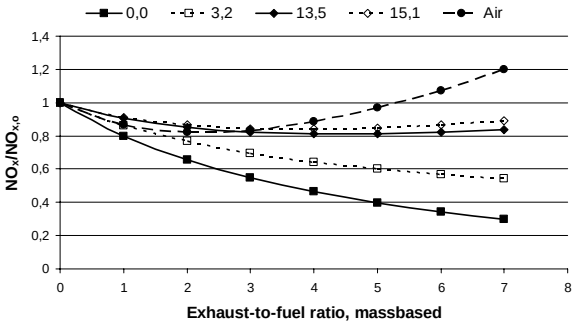

Figure 10. NO_x emissions as function of exhaust-to-fuel ratio in the combustion process. The different curves describe exhaust gas with the specified concentration of oxygen.

Applying equation (8) for varying amounts of exhaust gas being recirculated, the NO_x emissions varies as shown in Figure 10, dependent on the amount of oxygen in the recirculated gas. The lower line, with the most efficient NO_x reduction, is with exhaust gas from a complete combustion process (no oxygen). On the opposite side, applying pure air, with 20.9 vol % oxygen, gives an optimum "additional air"-to-fuel ratio (exhaust-to-fuel ratio in the figure) around 3. This is then the case for a partially premixed combustion process. The curves indicate that for the cases with higher oxygen concentrations, an optimum exhaust-to-fuel ratio can be found, approaching 3 for the partially premixed case. It is seen that for 15 vol % O_2 content in the exhaust gas, which is reference for gas turbine processes, a 20 % decrease in NO_x emissions can be achieved. A 20 % decrease in NO_x emissions in the diffusion operation mode is far from the levels achieved in premixed operation. In the case of gas burners, 3 vol % O_2 is the reference value. Thus, it is seen that a 40 % decrease in NO_x emissions can be achieved with an exhaust-to-fuel ratio at 7 for such applications. For gas turbines, the improvement potential points towards methods that can reduce the oxygen content of the recirculated exhaust gas, which will reduce the NO_x emissions further. O_2 can for instance be separated from the exhaust gas, which is a costly process. A less costly alternative is to supply additional fuel for afterburning, which then will reduce the oxygen content further.

The advantage for NO_x emissions in diffusion flames with exhaust gas recirculation is not comparable to premixed flames NO_x levels. But with the emphasis to increase the CO_2 concentration in the exhaust gas, the 20 % reduction in NO_x emissions is a positive side-effect. Post combustion CO_2 capture processes may be suited to absorb the NO_x in the exhaust gas, and thus the NO_x emissions can be avoided for such a process.

CONCLUSIONS

Experiments have been performed on a gas turbine combustor with the emphasis on stability and NO_x emissions. The combustor has been operated both in diffusion mode and premixed mode, proving that lean premixed operation is significantly more advantageous for low NO_x emissions.

To simulate the effect the components of an exhaust gas has on stability and NO_x emissions, experiments have been performed with addition of O_2, N_2 or CO_2 injected either into the fuel or into the air stream. Steam injection has been referenced from the literature. Oxygen enrichment of the diffusion flame increases the NO_x emissions, both when injected into the fuel and into the air stream, whereas N_2 and CO_2 act as diluents. For injection with the fuel on the diffusion flame, a decrease in NO_x emissions is

seen, whereas a negligible change in NO_x is seen when injected into the air stream. All additives act as diluents when injected into a lean premixed flame.

Modeling of exhaust gas recirculation has been done, based on the experiments with the additives injected separately. This indicates that the amount of O_2 in the exhaust gas plays an important role, concerning the NO_x emissions with the change in composition of the combustion air.

ABSTRACT

Scale-invariant forms of mass, energy, and linear momentum conservation equations in chemically reactive fields are described. The modified equation of motion is then solved for the classical problem of axisymmetric laminar rotating free jet. The results are shown to be in agreement with the classical theories of *Loitsianskii* and *Görtler*. The problem of turbulent axisymmetric rotating jet is shown to have solutions identical to those of laminar jet. Temperature distributions of axisymmetric and two-dimensional turbulent jets are determined and the latter results are found to be in agreement with the observations of *Reichardt*.

Keywords: Theory of laminar and turbulent cylindrically symmetric rotating jets. Decay of swirl.

INTRODUCTION

The universality of turbulent phenomena from stochastic quantum fields to classical hydrodynamic fields [1-26] resulted in recent introduction of a scale-invariant model of statistical mechanics and its application to the field of thermodynamics [27]. The implications of the model to the study of transport phenomena and invariant forms of conservation equations have also been addressed [28, 29]. In the present study, following the classical studies of *Loitsianskii* [39] and *Görtler* [40], the modified equation of motion is solved for the classical problem of laminar axisymmetric rotating jet. The predicted analytical solutions are found to reduce to the approximate solutions obtains from the classical form of the equation of motion. The solutions of the modified forms of the equation of motion and energy at the larger scale of laminar eddy-dynamics LED representing turbulent axi-symmetric rotating jet are also discussed.

SCALE-INVARIANT FORMS OF THE CONSERVATION EQUATIONS FOR REACTIVE FIELDS

Following the classical methods [30-32], the invariant definitions of the density ρ_β, and the velocity of *atom* $\mathbf{u}_\beta$, *element* $\mathbf{v}_\beta$, and *system* $\mathbf{w}_\beta$ at the scale β are given as [29]

$$\rho_\beta = n_\beta m_\beta = m_\beta \int f_\beta du_\beta \quad , \quad \mathbf{u}_\beta = \mathbf{v}_{\beta-1} \tag{1}$$

$$\mathbf{v}_\beta = \rho_\beta^{-1} m_\beta \int \mathbf{u}_\beta f_\beta d\mathbf{u}_\beta \quad , \quad \mathbf{w}_\beta = \mathbf{v}_{\beta+1} \tag{2}$$

Also, the invariant definitions of the peculiar and the diffusion velocities are given as [29]

$$\mathbf{V}'_\beta = \mathbf{u}_\beta - \mathbf{v}_\beta \quad , \quad \mathbf{V}_\beta = \mathbf{v}_\beta - \mathbf{w}_\beta = \mathbf{V}'_{\beta+1} \tag{3}$$

Next, following the classical methods [30-32], the scale-invariant forms of mass, thermal energy, and linear momentum conservation equations at scale β are given as [29]

$$\frac{\partial \rho_\beta}{\partial t} + \nabla.\left(\rho_\beta \mathbf{v}_\beta\right) = \Omega_\beta \tag{4}$$

$$\frac{\partial \varepsilon_\beta}{\partial t} + \nabla.\left(\varepsilon_\beta \mathbf{v}_\beta\right) = 0 \tag{5}$$

$$\frac{\partial \mathbf{p}_\beta}{\partial t} + \nabla.\left(\mathbf{p}_\beta \mathbf{v}_\beta\right) = 0 \tag{6}$$

involving the *volumetric density* of thermal energy $\varepsilon_\beta = \rho_\beta h_\beta$ and linear momentum

$\mathbf{p}_\beta = \rho_\beta \mathbf{v}_\beta$. Also, Ω_β is the chemical reaction rate and h_β is the absolute enthalpy [28].

The local velocity $\mathbf{v}_\beta$ in (4)-(6) is expressed in terms of the convective $\mathbf{w}_\beta = \langle \mathbf{v}_\beta \rangle$ and the diffusive $\mathbf{V}_\beta$ velocities [29]

$$\mathbf{v}_\beta = \mathbf{w}_\beta + \mathbf{V}_{\beta g} \quad , \quad \mathbf{V}_{\beta g} = -D_\beta \nabla \ln(\rho_\beta) \qquad (7a)$$

$$\mathbf{v}_\beta = \mathbf{w}_\beta + \mathbf{V}_{\beta tg} \quad , \quad \mathbf{V}_{\beta tg} = -\alpha_\beta \nabla \ln(\varepsilon_\beta) \qquad (7b)$$

$$\mathbf{v}_\beta = \mathbf{w}_\beta + \mathbf{V}_{\beta hg} \quad , \quad \mathbf{V}_{\beta hg} = -\nu_\beta \nabla \ln(\mathbf{p}_\beta) \qquad (7c)$$

where ($\mathbf{V}_{\beta g}$, $\mathbf{V}_{\beta tg}$, $\mathbf{V}_{\beta hg}$) are respectively the diffusive, the thermo-diffusive, and the linear hydro-diffusive velocities.

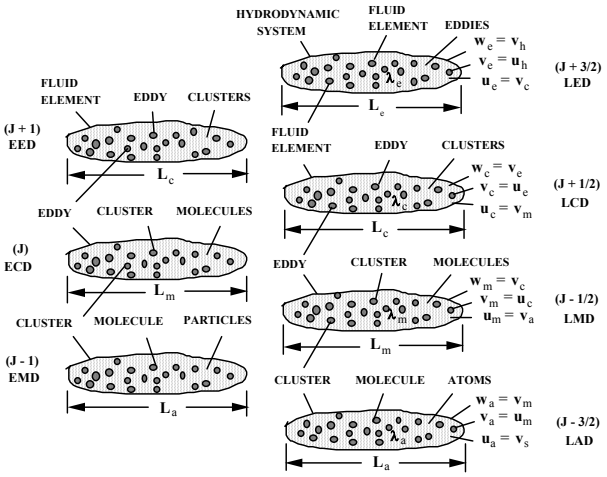

Figure 1: Hierarchy of statistical fields for equilibrium eddy-, cluster-, and molecular-dynamic scales and the associated laminar flow fields.

For unity *Schmidt* and *Prandtl* numbers, one may express

$$\mathbf{V}_{\beta tg} = \mathbf{V}_{\beta g} + \mathbf{V}_{\beta t} \quad , \quad \mathbf{V}_{\beta t} = -\alpha_\beta \nabla \ln(h_\beta) \qquad (8a)$$

$$\mathbf{V}_{\beta hg} = \mathbf{V}_{\beta g} + \mathbf{V}_{\beta h} \quad , \quad \mathbf{V}_{\beta h} = -\nu_\beta \nabla \ln(\mathbf{v}_\beta) \qquad (8b)$$

that involve the thermal $\mathbf{V}_{\beta t}$, and linear hydrodynamic $\mathbf{V}_{\beta h}$ diffusion velocities [29]. Since for an ideal gas $h_\beta = c_{p\beta} T_\beta$, when $c_{p\beta}$ is constant and $T = T_\beta$, Eq.(8a) reduces to the *Fourier* law of heat conduction

$$\mathbf{q}_\beta = \rho_\beta h_\beta \mathbf{V}_{\beta t} = -\kappa_\beta \nabla T \qquad (9)$$

where κ_β and $\alpha_\beta = \kappa_\beta / (\rho_\beta c_{p\beta})$ are the thermal conductivity and diffusivity. Similarly, (8b) may be identified as the shear stress associated with diffusional flux of linear momentum and expressed by the generalized *Newton* law of viscosity [29]

$$\boldsymbol{\tau}_{ij\beta} = \rho_\beta \mathbf{v}_{j\beta} \mathbf{V}_{ij\beta h} = -\mu_\beta \partial \mathbf{v}_{j\beta} / \partial \mathbf{x}_i \qquad (10)$$

Substitutions from (7a)-(7c) into (4)-(6), neglecting cross-diffusion terms and assuming constant transport coefficients with $Sc_\beta = Pr_\beta = 1$, result in [29]

$$\frac{\partial \rho_\beta}{\partial t} + \mathbf{w}_\beta . \nabla \rho_\beta - D_\beta \nabla^2 \rho_\beta = \Omega_\beta \qquad (11)$$

$$h_\beta \left[\frac{\partial \rho_\beta}{\partial t} + \mathbf{w}_\beta . \nabla \rho_\beta - D_\beta \nabla^2 \rho_\beta \right] + \rho_\beta \left[\frac{\partial h_\beta}{\partial t} + \mathbf{w}_\beta . \nabla h_\beta - \alpha_\beta \nabla^2 h_\beta \right] = 0 \qquad (12)$$

$$\mathbf{v}_\beta \left[\frac{\partial \rho_\beta}{\partial t} + \mathbf{w}_\beta . \nabla \rho_\beta - D_\beta \nabla^2 \rho_\beta \right] + \rho_\beta \left[\frac{\partial \mathbf{v}_\beta}{\partial t} + \mathbf{w}_\beta . \nabla \mathbf{v}_\beta - \nu_\beta \nabla^2 \mathbf{v}_\beta \right] = 0 \qquad (13)$$

In the first and second parts of (12) and (13), the *gravitational* versus the *inertial* contributions to the change in energy and momentum density are apparent. Substitutions from (11) into (12)-(13) result in the invariant forms of conservation equations in chemically reactive fields [29]

$$\frac{\partial \rho_\beta}{\partial t} + \mathbf{w}_\beta . \nabla \rho_\beta - D_\beta \nabla^2 \rho_\beta = \Omega_\beta \qquad (14)$$

$$\frac{\partial T_\beta}{\partial t} + \mathbf{w}_\beta . \nabla T_\beta - \alpha_\beta \nabla^2 T_\beta = -h_\beta \Omega_\beta / (\rho_\beta c_{p\beta}) \qquad (15)$$

$$\frac{\partial \mathbf{v}_\beta}{\partial t} + \mathbf{w}_\beta . \nabla \mathbf{v}_\beta - \nu_\beta \nabla^2 \mathbf{v}_\beta = -\mathbf{v}_\beta \Omega_\beta / \rho_\beta \qquad (16)$$

An investigation of the system (14)-(16) in the presence of chemical reactions Ω resulted in a modified hydro-thermo-diffusive theory of laminar flames presented earlier [29]. It is emphasized here that in (16) the convective velocity $\mathbf{w}_\beta$ is different from the local fluid velocity $\mathbf{v}_\beta$.

SOLUTION OF THE MODIFIED EQUATION OF MOTION FOR LAMINAR AXI-SYMMETRIC ROTATING JET

As examples of exact solutions of the modified equation of motion (16), the classical problems [32-41] of laminar [42] and turbulent [43] flow in axisymmetric and two-dimensional jets were investigated. In the present study, the modified equation of motion is solved for the classical problem of axi-symmetric laminar rotating jet investigated by *Loitsianskii* [39] and *Görtler* [40]. Therefore, one looks for the local axial, radial and azimuthal velocities (v'_x, v'_r, v'_θ) along the corresponding coordinates (x', r', θ) and introduces the dimensionless quantities

$$(v_x,\ v_r, w_x,\ w_r) = (v'_x,\ v'_r, w'_x,\ w'_r)/w'_o$$

$$v_\theta = \frac{v'_\theta}{\sqrt{\nu\omega_o}} \quad , \quad w_\theta = \frac{w'_\theta}{\sqrt{\nu\omega_o}} \quad , \quad \theta = \frac{T - T_\infty}{T_o - T_\infty}$$

$$r = \frac{r'}{l_H} \quad , \quad x = \frac{x'}{l_H} \quad , \quad l_H = l_T = \frac{\nu}{w'_o} = \frac{\alpha}{w'_o} \tag{21}$$

The initial axial convective velocity w'_o at the origin of the jet is assumed to be known and signifies the strength of the jet. Also, the initial angular frequency ω_o at the origin of the jet is known and signifies the strength of the jet angular momentum. Hence, in (21) both the local and the convective dimensionless azimuthal velocities (v_θ, w_θ) involve this initial jet angular frequency. The parameters ν and α are the kinematic viscosity and thermal diffusivity and l_H and l_T are the characteristic hydrodynamic and thermal lengths. The steady dimensionless forms of the modified equation of motion (16), energy (15), and the continuity equation (4) for incompressible fluid with the usual boundary layer assumptions and in the absence of chemical reactions Ω = 0 reduce to

$$w_x \frac{\partial \mathbf{v}_x}{\partial x} + w_r \frac{\partial \mathbf{v}_x}{\partial r} = \frac{\partial^2 \mathbf{v}_x}{\partial r^2} + \frac{1}{r}\frac{\partial \mathbf{v}_x}{\partial r} \tag{22}$$

$$w_x \frac{\partial \mathbf{v}_\theta}{\partial x} + w_r \frac{\partial \mathbf{v}_\theta}{\partial r} + \frac{w_\theta \mathbf{v}_r}{r} = \frac{\partial^2 \mathbf{v}_\theta}{\partial r^2} + \frac{1}{r}\frac{\partial \mathbf{v}_\theta}{\partial r} - \frac{\mathbf{v}_\theta}{r^2} \tag{23}$$

$$w_x \frac{\partial \theta}{\partial x} + w_r \frac{\partial \theta}{\partial r} = \frac{\partial^2 \theta}{\partial r^2} + \frac{1}{r}\frac{\partial \theta}{\partial r} \tag{24}$$

$$\frac{\partial v_x}{\partial x} + \frac{\partial v_r}{\partial r} + \frac{v_r}{r} = 0 \tag{25}$$

subject to the boundary conditions

$$r = 0 \qquad \frac{\partial v_x}{\partial r} = \frac{\partial \theta}{\partial r} = v_r = 0 \tag{26a}$$

$$r \to \infty \qquad v_r = v_\theta = v_x = \theta = 0 \tag{26b}$$

To solve equation (22), the convective velocities (w_x, w_r) that are the average of the local axial and radial velocities (v_x, v_r) are needed. Because the jet momentum is initially only in the axial direction, the radial dispersion of the jet is entirely caused by diffusion of axial momentum in the radial direction. Therefore, the jet diameter d' at any axial position will be given by the radial diffusion length

$$d'^2 = 2\nu t' \tag{27}$$

where the local diffusion time t' is related to the axial position x' and the local convective velocity w'_x by

$$t' = x'/w'_x \tag{28}$$

The dimensionless jet cross sectional area A' is given by

$$A = A'/(\nu/\omega_o) = \pi d^2/4 = \\ = (\pi/2)\, t = (\pi/2)\, x/w_x \tag{29}$$

Hence, the mass flow rate at any axial position will vary as

$$Q = \rho A' w'_x \propto \rho A w_x \propto x \tag{30}$$

where the symbol (∝) in (30) denotes proportionality. On the other hand, the total axial momentum along the jet must remain constant [32] and hence

$$J = Q w'_x \propto x\, w_x = \text{constant} \tag{31}$$

leading to the dimensionless convective velocity [35]

$$w_x = \frac{1}{2x} \tag{32}$$

Solving the global continuity equation

$$\frac{\partial w_x}{\partial x}+\frac{\partial w_r}{\partial r}+\frac{w_r}{r}=0 \tag{33}$$

after substitution from (32) results in

$$w_r=\frac{r}{4x^2} \tag{34}$$

Following *Schlichting* [32], one introduces the stream function Ψ and the similarity variable η

$$\Psi = x\,F(\eta) \qquad , \qquad \eta=\frac{r}{x} \tag{35}$$

leading to the axial velocity

$$v_x=\frac{F'(\eta)}{x} \tag{36}$$

Substitutions from (32), (34), (35), and (36) into (22) results in [42]

$$zF'''+(z^2+1)F''+2zF'=0 \tag{37}$$

$$z=0 \qquad F''=0 \tag{38}$$

$$z\to\infty \qquad F'=0 \tag{39}$$

where $z=\eta/2$ and primes denote differentiation with respect to z. The bounded solution of (37)-(39) is

$$F'=\exp(-z^2/2)]=\exp(-\eta^2/8)] \tag{40}$$

that by (36) gives

$$v_x=\frac{\exp(-\eta^2/8)}{x} \tag{41}$$

From (35) and (41), the stream function that satisfies $\Psi = 0$ at $\eta = 0$ is obtained as

$$\Psi=4x[1-\exp(-\eta^2/8)] \tag{42}$$

that in turn gives the radial velocity

$$v_r=\frac{1}{x}\left[\eta\exp(-\eta^2/8)-\frac{4}{\eta}\left(1-\exp(-\eta^2/8)\right)\right] \tag{43}$$

Since (24, 26) are similar to (22, 26), the distribution of temperature θ is similar to that of the axial velocity (41) and given by

$$\theta=\frac{\exp(-\eta^2/8)}{x} \tag{44}$$

Therefore, the ratio of the axial velocity v_x (temperature θ) to the centerline velocity v_{xc} (temperature θ_c) becomes

$$\frac{v_x}{v_{xc}}=\exp(-\eta^2/8) \tag{45}$$

$$\frac{\theta}{\theta_c}=\exp(-\eta^2/8) \tag{46}$$

The mass flow rate Q is given by [42]

$$Q=2\pi\rho\int_0^\infty v_x' r'dr'=8\pi\rho\nu x' \tag{47}$$

in exact agreement with the classical result of *Schlichting* [32]. Also, the axial momentum J

$$J=2\pi\rho\int_0^\infty v_x'^2 r'dr'=4\pi\rho\nu^2 \tag{48}$$

is a constant independent of the jet strength w'_o in accordance with the classical results [32].

At large values of x for which the present similarity solution is valid, i.e. for small values of $z=\eta/2$, (41) can be expressed as

$$v_x=\frac{\exp(-z^2/2)}{x}=\frac{1}{x}\frac{1}{\exp(-z^2/2)}$$

$$=\frac{1}{x}\frac{1}{\exp(-z^2/2)}\approx\frac{1}{x}\frac{1}{\left(1+z^2/4\right)^2} \tag{49}$$

that is in exact agreement with the classical solution [32] except for some multiplicative constants. Therefore, it is expected that the excellent agreement of the classical theory of *Schlichting* [32] with the experimental observations also extend to the modified theory [42].

The above results are now used in the azimuthal momentum conservation equation (23) to determine the angular velocity. The radial velocity can be approximated as

$$v_r=\frac{1}{x}\left[\eta\exp(-\eta^2/8)-\frac{4}{\eta}\left(1-\exp(-\eta^2/8)\right)\right]$$

$$\approx\frac{1}{x}\eta\exp(-\eta^2/8) \tag{50}$$

since under the assumption $x >>1$ ($\eta<<1$) valid for the similarity solution being considered, the second term can be neglected. Substituting (50) along with the similarity form

$$v_\theta = \frac{H(\eta)}{x^2} \tag{51}$$

and the convective velocities (32), (34), and

$$w_\theta = \frac{\eta}{4x^2} \tag{52}$$

into (23) results in

$$\eta^2 H'' + \eta(1+\eta^2/4)H' + (\eta^2 - 1)H - (\eta^3/4)\exp(-\eta^2/8) = 0 \tag{53}$$

$$\eta = 0 \qquad H = 0 \tag{54a}$$

$$\eta \to \infty \qquad H = 0 \tag{54b}$$

The solution of (53)-(54) is

$$H = \eta \exp(-\eta^2/8) \tag{55}$$

that by (51) leads to the angular velocity

$$v_\theta = \frac{\eta \exp(-\eta^2/8)}{x^2} \tag{56}$$

The rapid decay of the angular velocity with axial position in (56) is in accordance with the classical results [39-41].

The predictions of the modified theory are next compared with the classical results. As shown in (49), for z<<1 the axial velocity can be approximated as

$$v_x \approx \frac{1}{x\left(1+z^2/4\right)^2} \tag{57}$$

By substitution of (57) in the continuity equation (25) one obtains the approximate radial velocity

$$v_r \approx \frac{z(1-z^2/4)}{x(1+z^2/4)^2} \tag{58}$$

Finally, for z<<1 the angular velocity in (56) may be approximated by

$$v_\theta \approx \frac{2z}{x^2(1+z^2/4)^2} \tag{59}$$

Except for some multiplicative constants, the results (57)-(59) are in exact agreement with the classical solutions of *Loitsianskii* [39] and *Görtler* [40] discussed by *Crabtree* , *Kuchemann*, and *Sowerby* [41].

According to the classical results [39-41], the jet rotation has negligible influence on the axial and radial velocities. The weak effects occur indirectly through the pressure term that is in the parameter M signifying the total axial momentum. That is, the angular velocity v_θ in the angular momentum parameter L influences the pressure field p, that in turn influences linear momentum parameter M, thereby affecting (v_x, v_r) [41]. However, because of the small factor of 2^{-11} appearing in the expression for the dimensionless pressure in the classical theory [41], the effects of rotation on velocities (v_x, v_r) will be exceedingly small. According to the modified theory presented herein, the jet rotation does not influence either the axial or the radial velocity profiles.

SOLUTION OF THE MODIFIED EQUATION OF MOTION FOR TURBULENT AX--SYMMETRIC ROTATING JET

The scale-invariant nature of the conservation equations (14)-(16) suggests that the problem of turbulent rotating jet will be governed by the same equations (14)-(16) except at the next larger scale of laminar-eddy-dynamics LED $\beta = e$. However, the transport properties such as the momentum diffusivity ν and the thermal diffusivity α will now correspond to eddy-diffusivity for momentum ν_e and heat α_e. Therefore, as discussed in a recent study [43], the solution to the problem of turbulent rotating jet will be identical to those already found for laminar jet (41)-(43). In particular, from (45), the ratio of the axial velocity to the centerline value v_{xc} for turbulent rotating jet will be [43]

$$\frac{v_x}{v_{cx}} = \exp(-\eta^2/8) \tag{60}$$

Therefore, the transverse position where v_x is half its maximum, i.e. centerline value v_{xc} becomes

$$\eta^* = \eta(v_{cx}/2) = [-8\ln(0.5)]^{1/2} \tag{61}$$

such that (60) may be expressed as

$$\frac{v_x}{v_{cx}} = \exp[\ln(0.5)\xi^2] \quad , \quad \xi = \frac{\eta}{\eta^*} \tag{62}$$

Similarly, from (46) one obtains

$$\frac{\theta}{\theta_c} = \exp[\ln(0.5)\xi^2] \tag{63}$$

where θ_c is the temperature at the jet centerline.

The predicted axial velocity profile calculated from (62) using *Mathematica* [44] is in

excellent agreement with the experimental data of *Reichardt* [37-38] as shown in Fig.2.

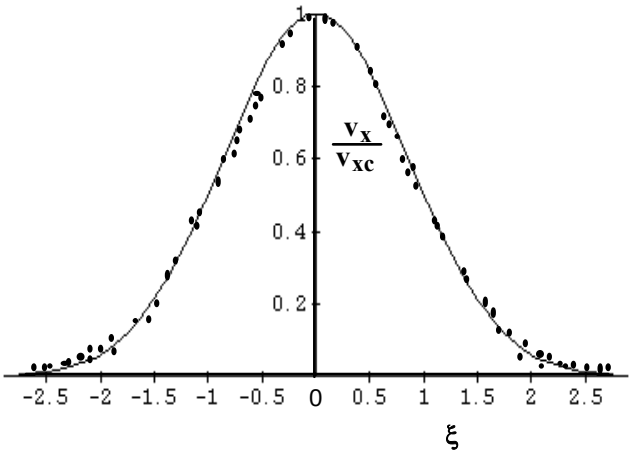

Figure 2: Comparisons of predicted velocity profile with the data of Reichardt [37] for turbulent axisymmetric jet.

It is important to note that, as opposed to the classical theories discussed in [32], the agreement with experimental data shown in Fig.2 is achieved without any empirically adjustable constants.

Comparisons between the predicted temperature profile and experiments performed on turbulent jets will be discussed next. Because the experimental data on temperature distribution in turbulent jets performed by *Reichardt* [38] involve two-dimensional jets, the problem of turbulent two-dimensional jet [43] will also be considered. Following steps parallel to (21)-(25), one arrives at the conservation equations

$$w_x \frac{\partial v_x}{\partial x} + w_y \frac{\partial v_x}{\partial y} = \frac{\partial^2 v_x}{\partial y^2} \tag{64}$$

$$w_x \frac{\partial \theta}{\partial x} + w_y \frac{\partial \theta}{\partial y} = \frac{\partial^2 \theta}{\partial y^2} \tag{65}$$

$$\frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} = 0 \tag{66}$$

that are subject to the boundary conditions

$$y = 0 \qquad \frac{\partial v_x}{\partial y} = \frac{\partial \theta}{\partial y} = v_y = 0 \tag{67a}$$

$$y \to \infty \quad v_x = v_y = \theta = 0 \tag{67b}$$

Similar to the treatment of axisymmetric jet in (27)-(34) one obtains the convective field

$$w_x = \frac{1}{6x^{1/3}} \quad , \quad w_y = \frac{y}{18x^{4/3}} \tag{68}$$

Following the classical studies [32, 36], one introduces for the two-dimensional laminar jet the stream function Ψ and a similarity variable ζ as

$$\Psi \equiv x^{1/3} G(\varsigma) \quad , \quad \varsigma \equiv \frac{y}{3x^{2/3}} \tag{69}$$

that lead to the stream function

$$\Psi = \sqrt{\pi} x^{1/3} \mathrm{erf}(\varsigma / 2) \tag{70}$$

and hence the velocity components [43]

$$v_x = \frac{\exp(-\varsigma^2/4)}{x} \tag{71}$$

$$v_y = \frac{\sqrt{\pi}}{3x^{2/3}} \left[(2\varsigma/\sqrt{\pi}) \exp(-\varsigma^2/4) - \mathrm{erf}(\varsigma/2) \right] \tag{72}$$

Since under the assumption $\nu_e = \alpha_e$, the momentum and temperature equations (64) and (65) are identical and subject to identical boundary conditions (67), the temperature distribution is similar to the axial velocity (71) and given by

$$\theta = \frac{\exp(-\varsigma^2/4)}{x} \tag{73}$$

The results (71) and (73) lead to

$$\frac{v_x}{v_{xc}} = \exp(-\varsigma^2/4) \tag{74}$$

$$\frac{\theta}{\theta_c} = \exp(-\varsigma^2/4) \tag{75}$$

The predicted velocity profile (74) is in excellent agreement with the experimental observations of *Förthmann* [35, 43]. Also, the result (75) has exactly the same form as the classical solution presented by *Reichardt* [32, 38] on the basis of an entirely different theory. The classical theory is based on the assumption that the eddy diffusivity for heat is twice that for momentum

$$\alpha_e = 2\nu_e \tag{76}$$

This assumption results in the square root relation between the temperature and the axial velocity ratios [32, 38]

$$\frac{\theta}{\theta_c}=\left(\frac{v_x}{v_{xc}}\right)^{1/2}=\exp(-\eta^2/4) \qquad (77)$$

However, according to the simplified kinetic theory of ideal gas [45], (α_e,ν_e) are expected to be identical [28]

$$\alpha_e=\nu_e=l_e u_e/3=\lambda_c v_c/3 \qquad (78)$$

Of course, (α_e,ν_e) are expected to be variables in the non-equilibrium region of transition from one scale to another (Fig.1).

Because of the close agreement between the theory and experimental data achieved by the classical theory [32, 38], it is interesting to examine other possible reasons for the occurrence of the factor 2 in the classical model. According to the classical theory of *Reichardt* [32, 38], rather than solving the equation of motion directly, the first integral of this equation is considered in the form

$$\frac{\partial}{\partial x}\left(\frac{\overline{p}}{\rho}+v_x^2\right)+\frac{\partial}{\partial y}(\overline{u_x u_y})=0 \qquad (79)$$

It is suggested here that rather than (79), the integral of the equation of motion should lead to the energy, i.e. *Bernoulli* equation in the presence of turbulent diffusion expressed as

$$\frac{\partial}{\partial x}\left(\frac{\overline{p}}{\rho}+\frac{1}{2}v_x^2\right)+\frac{\partial}{\partial y}(\overline{u_x u_y})=0 \qquad (80)$$

With the *Boussinesq-Reynolds* stress expressed as

$$\overline{u_x u_y}=-\nu_e\frac{\partial v_x^2}{\partial y} \qquad (81)$$

and the assumption $\overline{p}=0$ for the free turbulent jet one obtains from (80)

$$\frac{\partial v_x^2}{\partial x}=2\nu_e\frac{\partial v_x^2}{\partial y^2} \qquad (82)$$

It is therefore suggested that the factor of 2 leading to (77) in the classical theory [32, 38] should be attributed to difference of factor ½ between (79) and (80) rather than the difference between the eddy-diffusivity for heat versus momentum (76). Another words, the factor of 2 in (82) leads to the occurrence of $1/\sqrt{2}$ in the similarity variable $\eta=y/\sqrt{2x}$ used in the analysis of the momentum as compared to the temperature field thus leading to the square root relation in (77). According to the present theory, on the other hand, the velocity and temperature ratios for axisymmetric (45)-(46) and two-dimensional (74)-(75) turbulent jets are identical.

The characteristic lengths for "atom", element, and system (l_e, λ_e, L_e) for the scales of laminar molecular-, cluster-, and eddy-dynamics (Fig.1) will be about

$$\begin{aligned}&\text{LMD} \quad (l_m=10^{-9},\ \lambda_m=10^{-7},\ L_m=10^{-5}\ \text{m})\\ &\text{LCD} \quad (l_c=10^{-7},\ \lambda_c=10^{-5},\ L_c=10^{-3}\ \text{m})\\ &\text{LED} \quad (l_e=10^{-5},\ \lambda_e=10^{-3},\ L_e=10^{-1}\ \text{m})\end{aligned} \qquad (83)$$

The field of conventional fluid mechanics will be identified as ECD scale β = c, composed of a spectrum of cluster sizes moving with Brownian motion with velocities $\mathbf{u}_c$ [29]. In a stationary fluid, molecular-clusters will be in equilibrium with suspended particles within the fluid that also undergo *Brownian* motions [28].

For LED field (Fig.1), the *Kolmogoroff* length and velocity, and the dissipation rate will be associated with the "atomic" scale and hence identified as [21-23, 26, 46, 47]

$$\eta_k=l_e=\lambda_c \quad , \quad v_k=u_e=v_c \qquad (85)$$

and

$$\varepsilon\propto\frac{u_e^3}{l_e} \qquad (85)$$

The stationary field of isotropic turbulence is identified as equilibrium-eddy-dynamic EED field shown in Fig.1 and its temperature will be expressed as [27]

$$3kT_e=m_e<u_e^2> \qquad (86)$$

Therefore, in an isolated system, as the convective and the local velocities (w_e, v_e) vanish, their kinetic energy will be dissipated into the "atomic" scales and hence manifested as heat at the temperature defined in (86).

CONCLUDING REMARKS

The solution of the modified equation of motion for the classical problem of laminar axisymmetric rotating jet studied by *Loitsianskii* and *Görtler* was determined. The analysis was also extended to velocity and temperature distributions in turbulent rotating jets as well as two-dimensional turbulent jet. The predicted velocity profiles were found to be in close agreement with the experimental observations of *Reichardt*. Also, the predicted temperature profile of two-dimensional

turbulent jet was found to be in agreement with the observations of *Reichardt.*

Via per Arnesano – 73100 Lecce (Italy)

ABSTRACT

Ground source heat pump (GSHP) systems have a good environmental compatibility and low impact on rooms reserved to heating and cooling systems in buildings. The choice of the GSHP has to be justified in many applications, such commercial and industrial buildings, by cost advantages.

The key feature of this kind of systems is the ground heat exchanger (GHX) whose more likely configurations are vertical or horizontal. The latter can represent a good compromise solution between the cost and the effectiveness, as it can benefit to face with a heat source at quasi-constant temperature and to ask for low installation costs as can be mounted in trenches in areas adjacent to the building.

This work verifies numerically, with the help of the CFD code Fluent (Release 6.1.22), the operating conditions for horizontal heat exchangers, placed under the ground level areas of the South of Italy, that had to be provided with an air conditioning system for both winter and summer. The real operating temperatures and the heat fluxes to and from the ground have been considered in order to evaluate the environmental impact and the real advantages of this kind of heat transfer strategy compared to traditional heat pump (HP) systems, using air as heat sources and sinks. The CFD calculations showed the influence of the heat transfer process to the soil, so estimating the annual net energy flux to the ground.

A cost/benefit analysis in three different scenarios was then performed, to evaluate both GSHP vertical and horizontal GHX solutions applied to different cases. The results showed the convenience times for three different applications.

Keywords: Ground Source Heat Pump, Horizontal Heat Exchanger, Geothermal.

NOMENCLATURE

Symbol	Definition
a	Half min-max temperature difference on soil surface
b	Phase constant
c_p	Specific heat capacity
D_T	Ground thermal diffusivity
EWT	Entering water temperature
OWT	Outlet water temperature
Pr	Prandtl Number
t	Time
T(z,t)	Ground temperature
T_{2m}	Ground temperature at two meter depth
T_{cond}	Condenser operating temperature
T_{ev}	Evaporator operating temperature
T_M	Mean temperature in the period
t_M	Time needed to reach the maximum temperature on the surface
z	Depth
ν	Cinematic viscosity

ρ	Density
τ	Period
ω	Angular velocity
λ	Thermal conductivity

INTRODUCTION

The needs to reduce pollutant emissions and the energy consumption, due to the growing energy demand, to the increased environmental consciousness of people in the world and to the increased price of crude oil, have been the fundamental engine for the development of innovative technologies in the field of heating and cooling systems in large buildings.

In the last decade the development of GSHP technology has registered a great interest worldwide. The first working GSHP prototype was installed in the USA in 1945 as a demonstration device, and it succeeded in showing clearly the big advantages of such an innovative solution [1]. USA is nowadays the country with the highest concentration of installed GSHPs.

For this kind of heat pumps the underground is used as heat reservoir: heat source in winter seasons and heat sink in summer. The highest number of GSHPs are located in the countries of North America and North Europe [2].

This technology gives advantages in many different fields, even if with a higher initial investment.

The main goals reached by GSHPs compared to traditional solutions can be summarized as follows:

- lower energy and overall operating costs;
- significantly reduced greenhouse emissions;
- high reliability with low maintenance;
- lower life-cycle costs;
- easier modular design that facilitates a zone-controlled approach in heating and cooling, reaches a greater comfort and increases energy efficiency;
- compactness of the equipment that reduces room reserved to heating and cooling systems;
- one single system existence that can provide heating and cooling;
- improved exterior aesthetics and environmental friendliness, as the need for external noisy units or ugly cooling towers is eliminated [3], [4].

There are different kinds of GSHPs provided with heat exchanger open or closed, ground coupled or direct expansion loop configurations, using vertical or horizontal heat exchangers.

Each solution has its own pros and cons, but the most spread ones are closed loop, ground coupled with vertical heat exchangers.

Vertical heat exchangers (borehole heat exchangers), are very efficient but expensive and the drilling costs depend on ground composition [5]. Horizontal ground heat exchangers are an alternative solution and represent a good compromise between efficiency and costs [6]. The ground coupled horizontal heat exchangers are long piping buried at a depth of 1.5-2.5 m, where the thermal vector (usually water with glycol) transfers the thermal power to and from the soil.

In North America the most common arrangements, for ground horizontal heat exchangers are linear with a single-tube or a multi-tube layouts. The most frequent solution in Europe is the one with tubes in series or parallel.

Other possible arrangements and solution enhancements are:

- ground heat exchanger spirally shaped yielding a wide surface of tubes, for heat transfer, with a compact overall volume;
- parallel tubes in trenches filled with sand or other filling material;
- providing the tubes with copper fins.

Horizontal heat exchangers are particularly suitable for use in commercial buildings heating and cooling systems, where there is the availability of a car parking or a large free open space (i.e. an open storage), where the long piping can be buried.

The lower efficiency of the horizontal heat exchangers, compared to the vertical ones, is due to the higher variability of the ground temperature. The lower the temperature daily and seasonal variations in the ground are (very smaller than the ambient air temperature variations) the better is for the ground system efficiency. Ground temperature variations are damped and phase delayed, compared to the air temperature ones, because of the ground thermal inertia and heat capacity.

The seasonal delay, that depends on the depth and the ground composition, can be as long as some weeks, so that the lowest possible temperature is encountered at the end of the cold season. This behaviour of the ground is exploited by the GSHPs for the fluid refrigeration at the beginning of the hot season with low energy consumption.

This study shows the thermal impact of a GSHP equipped with a horizontal heat exchanger on the soil interfacing the ground system. Some topics

are discussed about the energety fluxes transferred to and from the soil and the thermal modifications of the ground due to the system operation both in cold and hot seasons [7], [8].

GENERAL CONSIDERATIONS ABOUT THE USE OF GSHP IN SOUTH OF ITALY

The GSHP is mostly used in North America (USA and Canada) and North Europe (Germany, Sweden and Switzerland) [1], [9], where this devices are active in buildings mainly in the cold seasons for heating. In Italy such systems have not yet a strategic role even if some energetic, economic and geographic considerations would show they might be convenient both in cold and hot seasons with good reduction of energy consumptions and pollutant emissions. The position of the Italian peninsula, placed in a temperate climate, assures low variation of ground temperature in the year, and this is the key to success of GSHPs.

The air mean temperature variation between the cold and the hot seasons are in the order of 30-40°C; particularly in the Southern regions, heating in winter and cooling in summer are always needed. The GSHP collects the thermal power from the ground in winter rejecting heat inside the building; in summer it pumps the thermal power coming from the building into the ground.

The use in both hot and cold seasons must be guaranteed in order to keep an annual ground thermal balance not with a heat flux in one direction only. The use heating of the GSHP system all over the year is also the key feature to make it competitive as an investment. In this way, the heat pump is exploited for a longer period in the year [10].

These considerations make the GSHPs suitable for the South of Italy, where a good know-how of drilling wells made for water suction from water tables is present. Despite of that, this systems are not popular and a big effort has to be done by the Government to promote the utilization of these devices for energy and money savings. Both in winter and summer, the use of GSHP could assure savings of energy costs, if compared to traditional methane heating systems or standard air-conditioning ones, with lower pollutant emissions.

CFD SIMULATIONS OF A HORIZONTAL HEAT EXCHANGER FOR GSHPs

The numerical analysis was carried out according to the following two steps:

a) unsteady annual 2D analysis for mathematical model of temperature underground distribution validation; the boundary conditions for the simulations were experimental values at 0.1m deep and temperature at 7m deep calculated with Eq.(1). The side vertical boundary surfaces were set adiabatic as the thermal flux through them was null. A ground region smaller than the calculation domain was involved in the heat transfer process. By small changes, coefficients *a* and *b* of Eq.(1) were found for optimal fitting both in time and space, i.e. in amplitude and phase response at several depths (figure 1 and figure 2). The thermal fluxes and temperatures at different depths (from 0.2m to 7m) were also calculated for the next steps input and for the estimation of the actual involved fluxes transferred to and from the ground (figure 3);

b) unsteady annual optimized 3D analysis for the unit length pipe heat flux transferred to water in the horizontal ground heat exchanger simulated portion. Set boundary conditions were coherent with the results of previous 2D step, in terms of temperatures at two different depth level. In particular, temperatures at depth of 1m and 3m calculated by the first analysis have been used. Entering water temperatures were supposed variable with a hourly constant 7°C difference from the temperature of the ground around the pipe.

The water mass flow rate was 5.88 kg/s (with a mean velocity of 3 m/s).

Geometry and properties of materials used

The 2D analysis was made with a simple rectangle of 1m x 6.9m [length x depth]. The 3D analysis used a parallelepiped of 1m x 0.5m x 2m [length x width x depth] with a 0.05m diameter polyethylene (PE) pipe at the depth of 2m, length of 1m and thickness of 2mm. In tab.1 the main parameters of the material properties are shown, supposing a homogeneous material at all depths.

Table 1: Materials properties

	Pipe (PE)	Ground	Water
ρ [kg/m^3]	946	2723.23	998.2
λ [W/(mK)]	0.35	2.94151	0.582
c_p [J/(kgK)]	1920	837.338	4182
ν [m^2/s]			1.4E-06
Pr			10.4

Numerical model

The geometric model was created with the Gambit Preprocessor 2.1.2 with a rectangular grid. The numerical analysis was carried out using the CFD code Fluent, release 6.1.22. Tab.2 shows the input calculation parameters.

Table 2: Settings of numerical simulations

	2D	3D
Elements	Quadrangles	Tetrahedral and hexahedral elements
Cell dimension	0.01 m	0.01-0.05 m
Number of cells	69000 – 1000	30789
Solver	2D unsteady	3D unsteady
Numerical Scheme:	Segregated	Segregated
Linearization:	Implicit	Implicit
Discretizat7ion Scheme:	Second order upwind	Second order upwind

Experimental data

The experimental climatic data were temperature and velocity of the air, temperature of the underground soil at two depth (0.1 and 0.2 m) and solar radiation of the year 2002. Data were averaged hour after hour and have been recorded by an automatic station, located in Lecce (Italy), at the coordinates: Latitude 40°26'16" North and Longitude 18°14'42" East.

Ground temperature distribution

The energy balance of the ground is really complex because of the presence of all the heat transfer processes: conduction, convection and radiation [11]. The only part that concerns the soil in its depth is the conduction one, moving up and down in the surface layers depending on the instantaneous differences imposed by air temperature, sunlight, soil temperature memory, fluxes transferred to and from heat sources or sinks. The frequencies typical of the air-sun-soil interactions are the day and the annual ones (the former more influenced by casual events, the latter much more repetitive). Both can be schematized by a Fourier series with a high number of harmonics, but a schematization sufficient for the analysis of this work is that of the following equation

$$T(z,t) = T_M + a \cdot e^{-z\sqrt{\frac{\omega}{2D_T}}} sin\left(\omega t - z\sqrt{\frac{\omega}{2D_T}} + b\right) \quad \text{Eq.(1)}$$

where

$\omega = 2\pi / \tau$

$b = (\tau - 4t_M)\pi / 2\tau$

Table 3: Eq.(1) parameters values

Coefficient	Value
T_M	16.84°C
a	16.95°C
τ	1 year
t_M	218th day

Figure 1 shows the hourly average temperatures at a depth of 0.02m experimentally measured (black line) and the ones (grey line) calculated by the numerical simulation. The comparison between the two lines confirmed a good choice of the boundary condition for the numerical simulations.

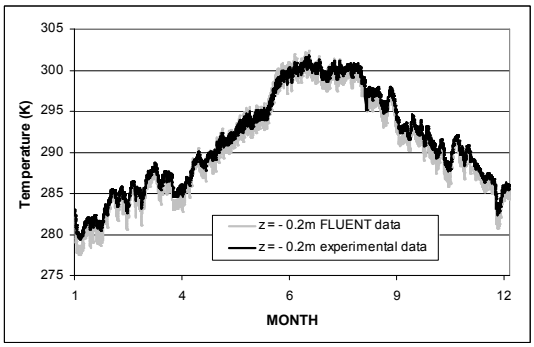

Figure 1: Comparison with the experimental data

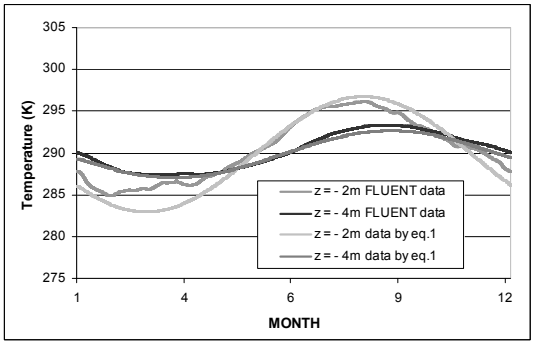

Figure 2: Comparison between data by FLUENT and Eq. 1

Figure 2 shows the correspondence between the temperature distribution at two different depths calculated both by the numerical simulations and by the Eq.1. This result underlines that the Eq.(1) can be used with a good accuracy at depths not less than 1m.

Figure 3 shows the temperature distributions at depths from 0.1m to 7m. Different considerations can be made. Moving down from the surface the temperature daily oscillations get completely dumped after 1m, the year ones disappear deeper and a phase shift due to the thermal inertia of the ground can be observed.

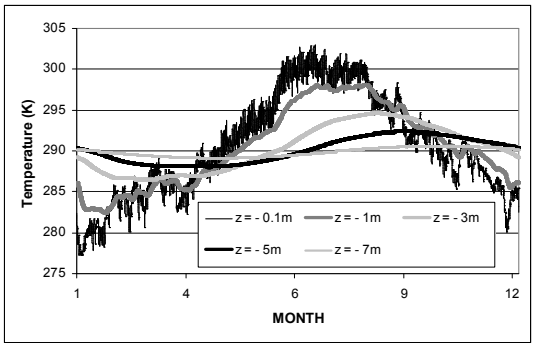

Figure 3 Temperature distribution at all depths

CFD output

No difference were taken into consideration for systems comparison about the distribution of thermal energy to the building as they were supposed the same for all the analyzed solutions. In table 4 the max and min average temperature levels of the soil, entering water, refrigerant are depicted both for winter and summer. Here the real temperature differences imposed for calculations can be observed.

Table 4: Temperature level [°C] for the CFD with a water flow rate of a 100m of pipe length at a depth of 2m

	WINTER		SUMMER	
	Min	**Max**	**Min**	**Max**
T_{2m}	12	18	17	23
EWT	5	11	24	30
OWT	5	11	24	30
T_{ev}	10	10		
T_{cond}			50	50

Refrigerant condensing temperature in winter was set at 50°C while refrigerant evaporating temperature in summer was set at 10°C.
For cost calculations and compressor efficiencies a subcooling of 5°C and a slight protection overheating were considered.
In this step a good visualization of the significant interaction pattern between pipe and ground can be observed (figure 4). In particular, the figure shows that the pipe influence is on a cylinder region around it with a diameter five times the pipe's one.

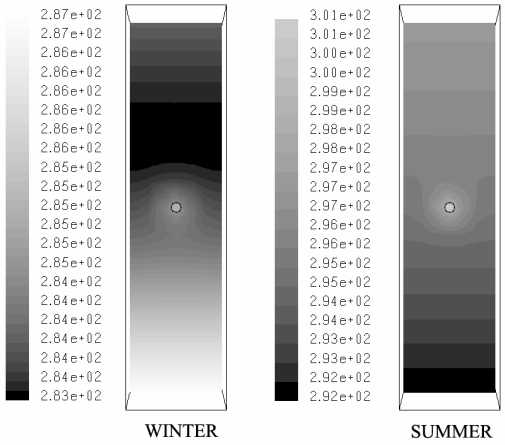

Figure 4 Examples of temperature (K) distribution around the pipe and region of influence.

In figure 5 and figure 6 the typical winter and summer heat fluxes per unit length to and from the water are shown for few days, respectively.

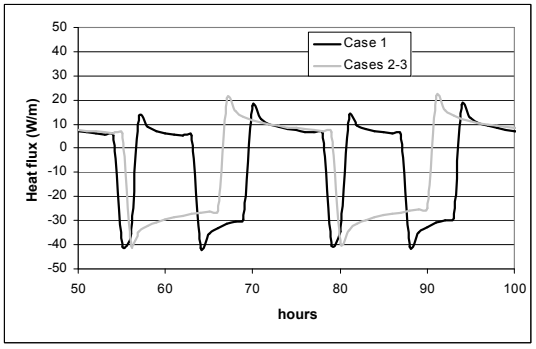

Figure 5 Typical heat flux per length unit exchanged by the water during the winter.

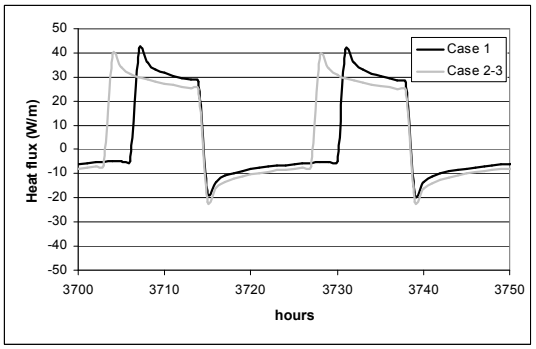

Figure 6 Typical heat flux per length unit exchanged by the water during the summer.

Environmental effects

The environmental effects of the installation of a GSHP are mainly due to the global energy balance of the ground coupled heat exchanger. The main issue of this kind of system is the heat subtraction from the ground in winter. This energy flux could be so high to cool progressively the ground till an unacceptable level, that is the origin for system performance decay and unwanted freezing effects. This problem is particularly felt in those region (North of America and Europe), where the GSHPs are used in winter only ([12], [13]). The summer use of these devices makes possible to restore to the ground a part of the heat subtracted in winter, and so, indirectly, to improve the system performance and the freezing effect. In this work it has been performed a calculation to predict the total amount of energy balance in one year between the analyzed GSHPs and the ground. The results obtained from the analyzed cases (see table 5) show that the effect of summer utilization of the horizontal GSHP, guarantee a return of energy from 21% to 28% to the ground.

Table 5: Annual ground energy [kWh] balance for a horizontal GSHP

	Winter	Summer	Net
Case 1	-5040	1416	-3624.71
Case 2	-141718	30377	-111341
Case 3	-1771470	379709	-1391761

COST EVALUATION IN DIFFERENT SCENARIOS

It is not easy to evaluate exactly the economic convenience of the GSHPs, because it depends on several variable factors such as: the geographic location, the materials price, the maintenance costs, the concurrent alternative technologies and so on [14]. In this paper a cost analysis is performed to evaluate the economic convenience for the installation of a GSHP located in South of Italy, equipped with a horizontal ground heat exchanger. This evaluation is made by comparing this solution with a vertical ground heat exchanger and a traditional air coupled heat exchanger. The main cost voices can be divided in: Capital Costs, Operating Costs and Maintenance Costs. The Capital Costs for the GSHPs are considerably higher than the equivalent traditional heat pump. In fact for the GSHPs many additional cost issues have to be taken into account apart from the particular external heat exchanger. However this cost depends on the type of GSHP. The Operating Costs are referred to estimated energy consumptions of the compared systems during winter and summer. They depend on different variable parameters such as: building type and use, duration of system working, efficiency and heat dispersion, control mode. The Maintenance Costs, on the other hand, have been considered to be the same for all the compared system. This hypothesis is not completely exact, but it comes from two main considerations: a) the Maintenance Costs for GSHPs are often lower than those referred to traditional heat pumps and so the convenience of the GSHPs is a bit better than that calculated in this paper; b) it depends on too many random parameters.

Three main cases have been analyzed to perform a consumption prevision: small, medium and large size cases.

The first system analyzed, namely Case 1, is a small size system that yields a 10 kW of thermal power in the worst design condition. This is a typical system used for a small flat or villa.

The second system analyzed, Case 2, that is medium size system, is able to generate 200 kW of thermal power. This is a system to be installed in a building hosting offices.

The last analyzed case, Case 3, is a large size system. This is able to produce 2500 kW of thermal power to be used for a commercial building.

Each case has been analyzed in three different scenarios of energy costs dynamics. In the first scenario it has been considered a constant cost of energy. The second has been built considering the hypothesis that the electricity cost in the future will have a constant growing rate equal to the present Italian average inflation rate: 2.5%. In the third scenario it is considered that the electricity cost will increase with an average constant rate of 6% per year, that is an assessment of the actual trend.

Primary overall energy consumptions (reported in table 7), seasonal efficiency, thermal energy transferred to and from buildings respectively in summer and in winter evaluations were based on a hour by hour year calculation. The used data were:

- air temperature;
- underground temperature at 2m and 7m deep;
- peak heating and cooling power respectively for winter and summer;

- mean temperature difference for water to water, soil to water, air to water, refrigerant to water heat exchangers for all the systems taken into consideration (see tab. 4);
- estimated losses due to defrosting for air-water traditional heat pump;
- on-off periods of the system and strategies of switching it on during the whole year based on a hour by hour resolution and depending on the application and size.

The calculations of the electricity consumptions and of heating and cooling energies have been carried out proportionally to the peak power data taken from the characteristic curves of popular compressors of appropriate capacity depending on the chosen working temperatures. Traditional heat pumps compressor capacity at the same input power was set higher than the GSHP one because of the former's lower efficiency. The mean temperature difference between the refrigerant and the external source (air or ground) has been set to 10°C for the traditional heat pump and to 7°C for the GSHPs. For the traditional heat pump it has also been taken into account a fraction of energy consumption due to defrosting of the external evaporator in winter. This problem, not present in the GSHPs, has been evaluated increasing the electric energy consumption for heating of 5%. The design conditions are those indicated by the Italian regulations for the design of heating and cooling system for the place where the system has been supposed to be installed. In the Case 1 the activation period in winter was from 15th November to 31st March and each day from 7.00am to 9.00am and from 4.00pm to 10.00pm (typical of flats, apartments, etc.). For the Case 2 and 3 in winter it has been set, instead, from 8.00am to 7.00pm, because of their different use (typical of offices, farms, etc.). The activation period in summer was from 1st June to 31st August and each day from 11.00am to 7.00pm for the Case 1 and from 8.00am to 7.00pm for Case 2 and 3.

Table 6: Annual electric energy consumption [kWh] for heating

	Traditional HP	Vertical GSHP	Horizontal GSHP
Case 1	2263	1553	1651
Case 2	63069	43699	46505
Case 3	785926	546232	581311

Table 7: Annual electric energy consumption [kWh] for cooling

	Traditional HP	Vertical GSHP	Horizontal GSHP
Case 1	270	132	197
Case 2	5779	2832	4209
Case 3	72237	35402	52612

The evaluation of the capital and installation costs for the GSHPs was made by evaluating the main cost voices: central unit, ground heat exchanger, circulation pump, antifreeze fluid, fittings, digging, drilling and so on. The electric energy cost was supposed to be € 0.14 per kWh, that is an average value for Italy in 2004. The cost evaluations show that the convenience of the horizontal GSHPs versus traditional air-coupled heat pump systems (shown in figure 7) is possible after 10 years for the Case 1, 6 years for Case 2 and 3 years for case 3 for the conditions considered in scenario 3. For the scenarios 1 and 2 results show that the convenience comes later, even if it remains acceptable the no. 2. The more the energy price grows, the better is the convenience of the horizontal GSHPs. Even if the vertical GSHPs guarantee higher energy savings than the horizontal ones (see table 8), on the other hand the Capital and Installation Costs are so high to double or to treble the convenience time.

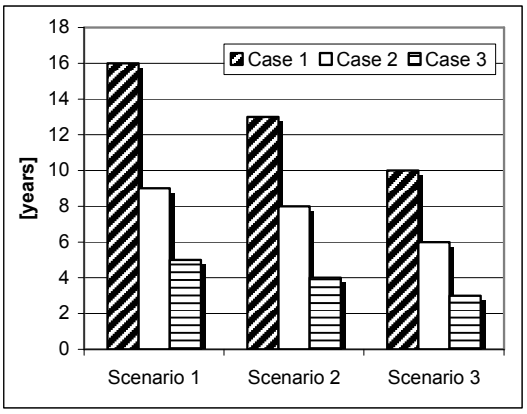

Figure 7: Convenience time of Horizontal GSHPs vs. traditional HP

Table 8: Annual electric energy savings with reference to the conventional HP

	Vertical GSHP [%]	Horizontal GSHP [%]
Case 1	33.46	27.05
Case 2	32.41	26.33
Case 3	32.22	26.13

CONCLUSIONS

An investigation on horizontal GSHPs was performed in terms of CFD simulations based on experimental data and cost comparison. Small differences between Entering and Outlet Water Temperatures assure a good exploitation of the ground heat reservoir. The area of the soil thermally influenced by the pipe presence is small enough to let the designers count on high specific heat power per square meter. The depth of 2m seems to be a good compromise between costs and increased efficiency compared to traditional solutions.

This GSHPs solution showed its convenience especially for systems of medium and big size (minimum 3.5 years) and advantages could be much more, considering that the horizontal GSHPs installation can exploit other building works, involving digging.

ACKNOWLEDGMENTS

The experimental data of the climatic conditions and ground temperature have been provided by the OCFGA group of University of Lecce and a special thanks goes to Prof. L. Ruggiero and Mr. G. Rispoli.

Abstract

HTAC (**H**igh **T**emperature **A**ir **C** ombustion) is one of the most important progress which has been done in combustion technology in recent years. It was invented about ten years ago and has been successfully applied in hundreds industrial furnaces all over the world. Authors of the present paper considered possibility of applying this technology in industrial boilers. In the paper it has been pointed out application of this technology in industrial boilers may lead to increase of thermal efficiency of power generation. Moreover possibility of gas turbines thermal efficiency improvement by has been described.
Keywords: combustion, gas turbines

INTRODUCTION

Industrial furnaces are widely used for heating, melting and in many other industrial processes. To improve thermal efficiency of the furnace usually recuperative heat exchanger is used which is presented in Fig.1. In such exchanger energy of flue gases is used for heating combustion air. Thermal efficiency

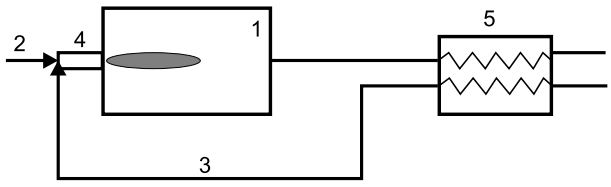

Figure 1: Scheme of the industrial furnace with recuperative heat exchanger. 1-furnace, 2-fuel supply, 3-combustion air, 4-burner, 5-recuperative heat exchanger

of such installation increases with increasing combustion air temperature [4]. Unfortunately with increasing air temperature emission of NO rises very rapidly, which is formed via thermal mechanism [8].

For many years environmental impact of NO in flue gases limited the maximal combustion air temperature. However about ten years ago it was discovered that it is possible to increase air temperature without increasing NO emission. This can be achieved when the air and fuel nozzles are separated and when sufficient in-furnace recirculation of combustion gases is present. Moreover, temperature of the air should exceed ignition temperature of fuel [2], which is about 1000^oC for the natural gas. Under such conditions combustion takes place in whole volume of combustion chamber and no visible flame can be observed. For this reason this technology is named flameless combustion or High Temperature Air Combustion (HTAC).

Today HTAC has been successfully applied in many industrial furnaces [1], [7]. In all these furnaces reduction of both specific fuel consumption and harmful species emission have been observed. Reduction of fuel consumption is the result of decreasion of

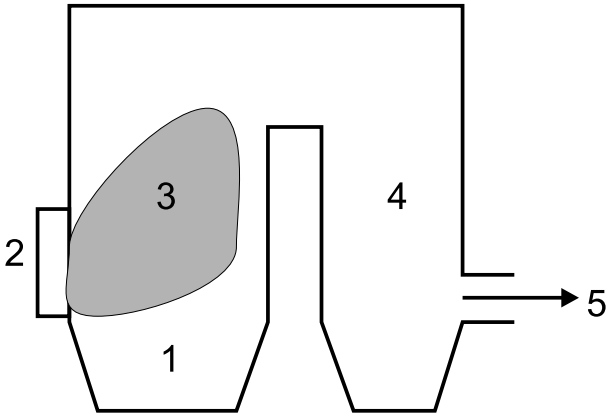

Figure 2: Classical industrial boiler. 1-combustion chamber, 2-burners, 3-flame, 4-convective section, 5-flue gas exit

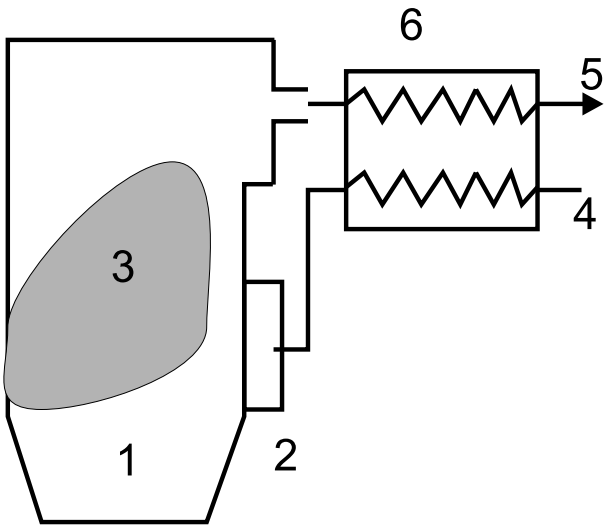

Figure 3: HTAC boiler. 1-combustion chamber, 2-burners, 3-flame, 4-air supply, 5-flue gas exit, 6 - regenerative heat exchanger

flue gas temperature and shortening of process time due to the increased radiative heat fluxes. Industrial experiences showed that thanks to HTAC technology specific fuel consumption can be reduced up to 30% comparing with conventional combustion techniques. Emission of NO is reduced due to the very uniform temperature profiles inside the combustion chamber with no peaks characteristic for classical combustion. Also emission of CO is very low which is probably result of long residence time of combustion products in the high temperature zone.
Authors of the present paper considered application of this technology in industrial boilers and in gas turbines cycles. In both cases HTAC seems to be very promising technology.

HTAC FOR INDUSTRIAL BOILERS

Combustion process and heat transfer inside the combustion chamber of boiler is different to the one taking place in furnace. First of all temperature of medium absorbing heat (water or steam) in boilers is lower than in case of furnaces (heated charge). This allows to reduce flue gas temperature in industrial boilers down to about 150^oC (limit of water condensation) which corresponds with about 8% of energy loss. For this reason introducing HTAC technology to the boiler will cause no increasion of thermal efficiency of the boiler. Nevertheless authors of the paper tried to consider what would happen if the classical boiler construction presented in Fig.2 would be replaced by the construction presented in Fig.3. In this case radiative part of the boiler is substituted by the regenerative heat exchanger preheating combustion air to the temperature high enough to run HTAC combustion. First of all heat transfer area in new boiler would be significantly reduced. This is because of increased radiative fluxes characteristic for the HTAC technology. Secondly emissions of both NO and CO would be reduced significantly. Thirdly char burn-out ratio should be increased because of the higher residence time of the combustible matter in the area of high temperatures inside the combustion chamber. Fourthly moderated combustion temperature would open possibility of dry desulphurization inside the chamber.
It was mentioned above that required air temperature for the natural gas combustion under HTAC technology is about 1000^oC. Such temperature would be very difficult to be achieved in recuperative heat exchanger. Fortunately minimal air temperature for coal combustion is significantly lower than for natural gas. It was found [5] that light fuel oil can be successfully used in HTAC boiler with air temperature equal to about 400^oC. The same result is expected for coal combustion since the minimal temperature requirements are related to fuel ignition temperature which is almost the same for oil and coal.
Reduced heat transfer area of the boiler means lower investment costs. Thus it may be reasonable to built the boiler of more expensive, heat-resistant steel.

Consequently superheated steam temperature, produced by the boiler, can be increased leading to increase in steam cycle efficiency [4]. In other words energy efficiency of the classical and HTAC boiler is almost the same, but exergy efficiency of the HTAC boiler is higher. This allows to improve thermal efficiency of the power plant. Problem of applying HTAC in boilers was discussed more widely in [5].

HTAC APPLICATION IN GAS TURBINES

The simplest gas turbine cycle consists of two isentropes and two adiabates (Fig.4. cycle A) and differs from the Carnot cycle (Fig.4. - cycle B) [3]. Energy efficiency of Carnot cycle is the highest one. Unfortunately Carnot cycle can not be applied in gas turbines because it is not possible to perform isothermal expansion of gases. In fact pseudo-isothermal expansion can be performed in multi-stage turbines with additional combustion chambers between stages.

Authors of the present paper proposed quite new method of isothermal expansion in gas turbines which is described below.

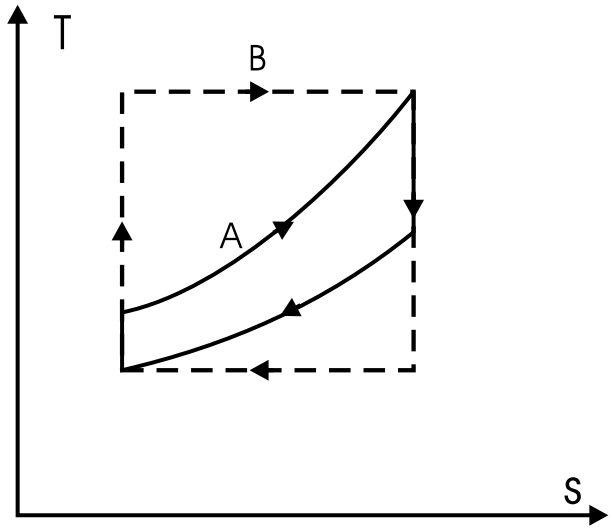

Figure 4: The simplest gas turbine cycle (A) and Carnot cycle (B)

In the HTAC industrial furnaces temperature along whole combustion chamber is almost constant, although chemical energy of the fuel is released. It is because thermal energy generated during combustion is, with almost the same intensity, radiated to the chamber walls by radiation. Gas turbines are thermally isolated and no heat can be transferred outside the turbine. But it is possible to achieve isothermal expansion of gases if heat released during combustion of gas is equal to mechanical work of expansion. In other words if mechanical energy stream transferred to the turbine's blades is equal to heat released than expansion is isothermal.

The question is how to control amount of heat released in combustion. According to authors idea it is possible by continuous supply of fuel during the expansion process. It can be done for example by introducing gas through the channels inside the blades of turbine (in such case gas can also play a cooling role for blades). Gas can be also introduced to the turbine by the nozzles located in the turbine housing.

To guarantee complete combustion of fuel and avoid stabilization problems, air temperature should be higher than self ignition temperature of the fuel. For this reason combustion air supplied to the new concept turbine should be much higher than it is used nowadays.

The idea of new turbine is presented in Fig.5. Ambient air (1) is supplied to the compressor (C) and than put to the regenerative heat exchanger (E). In the exchanger air is heated up to the temperature (3) which must be above the ignition temperature of fuel. Compressed and hot air (3) is supplied to the turbine where it expands. Fuel (6) through the channels in the rotating blades of turbine is delivered into the turbine where it mixes with hot air. Proper gas distribution along the turbine can be achieved by appropriate sizes of gas injectors located in turbine's blades. Decompressed, but hot combustion gases (4), are supplied to the heat exchanger where are cooled to the temperature (5).

Example parameters of gas in the characteristic points are listed in Table.1.

Table.1 Example parameters of the cycle

point No	pressure, bar	temperature,^oC
1	1	20
2	10	400
3	10	1150
4	1	1200
5	1	450

For the parameters listed in Tab.1 thermal efficiency of the cycle is above 65% which is much higher than the efficiency achievable by nowadays turbines. In

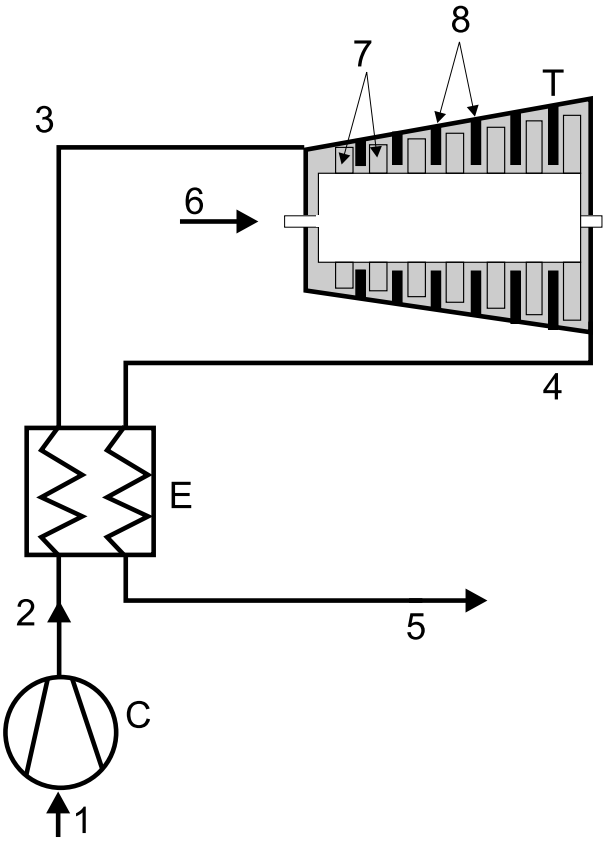

Figure 5: Scheme of the new concept of turbine. 1-air intake, 2-compressed air, 3-high temperature air, 5-flue gas exit, 6-fuel supply (through the schaft), 7-rotating blades, 8- stationary blades, C-compressor, T-turbine, E-heat exchanger)

the T-s coordinates system described turbine cycle is presented in Fig.6. This cycle is very close to the Ericson [4] cycle of the same efficiency as Carnot cycle. Described idea is protected by the international patent [6].

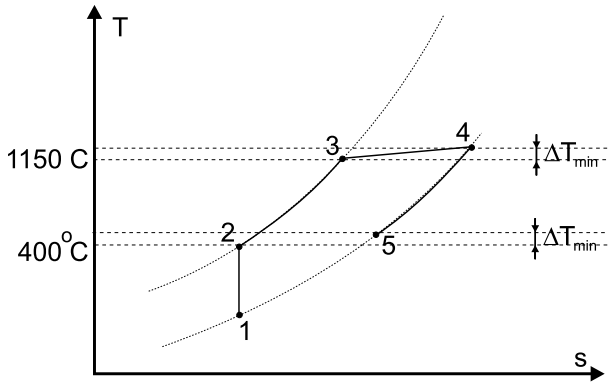

Figure 6: New turbine cycle presented in T-s coordinates

Of course this is only the idea - a lot of theoretical and experimental work has to be done before technical application. Nevertheless it indicate that by introducing combustion process into the turbine body isothermal expansion of gas can be achieved and thus Ericson or Carnot cycle performed. Consequently thermal efficiency of the cycle can be very significantly improved.

SUMMARY

High Temperature Air Combustion is one of the most important and significant progress in combustion technologies in recent years. It has developed from the laboratory scale to industrial furnaces application in only ten years which is extremely fast progress as for energy technologies. This fast progress is forced by reduction of fuel consumption and harmful species emission achievable by using HTAC technology. Authors of this paper performed preliminary considerations on using the technology in the power generation sector.

Considering application of the HTAC in industrial boilers authors pointed out that no increase in thermal efficiency is expected. Nevertheless, by reducing the boiler size increase of overheated steam parameters may be economically reasonable and thus exergy efficiency of the boiler would be achieved. As the consequence thermal efficiency of whole

power plant can be improved. Moreover reduction of harmful species emission can be achieved since the HTAC is more environment friendly technology than conventional one.
More interesting is the possibility of HTAC application in gas turbines. By introducing combustion process into the turbine body isothermal expansion can be achieved. Thus Ericson or Carnot cycle can be performed. Consequently thermal efficiency of the gas turbine cycle can be significantly improved.
Paper presents preliminary study and a lot of additional theoretical and experimental work have to be done before industrial application of presented ideas.

Thermoeconomic Diagnosis of Energy Systems with Measured Data

Vittorio Verda*, Romano Borchiellini

Department of Energy Engineering
Politecnico di Torino
ITALY

ABSTRACT

The use of thermoeconomics for the diagnosis of efficiency reductions in energy systems has been widely discussed in the literature. Several procedures based on thermoeconomic analysis aiming at locating and quantifying the malfunctions have been proposed and applied to operating plants.
The correct location of anomalies is made difficult by the effects that the anomalies induce throughout the system, not only in the component where they take place. A possible approach for the correct diagnosis consists of a successive filtration of the effects induced. Diagnosis procedures are often tested on data obtained through simulators. In real applications, an additional difficulty is represented by the errors in measurements.
This paper aims at analyzing the effect of these errors on the results of the diagnosis, in particular whether the procedure still allows one identifying the malfunctioning components.
In addition, the accuracy of results is evaluated and represented through error bars associated with the indicators adopted for the diagnosis.

Keywords: Thermoeconomics, diagnosis, measurement accuracy.

INTRODUCTION

Diagnosis of power plants consists in detecting anomalous behaviours of the components while the system is operating and understanding their causes. This is a relevant task because of the high economic impact of failures and efficiency drops on the overall management.
Failures are generally prevented through prescriptions that include:
- avoid operating conditions outside a safe range;
- periodic check of quantities such as vibrations, metal temperatures, oil pressures, cooling fluid temperatures, etc.;
- variation in the plant load operated by following pre-determined ramps.

These prescriptions are generally integrated within a control and monitoring system that directly

* Corresponding author: Phone (+39) 011 564 44 78, Fax. (+39) 011 564 44 99, e-mail: vittorio.verda@polito.it

intervenes on the plant or signals possible problems to the operator.
Reductions in performances can be evaluated through deductive procedures. Several procedures have been proposed in the last decades and applied too gas and steam turbines; some examples are represented by: the *fault matrix* [1], the *gas path analysis* [2], the *ASME PTC-PM* [3]. Thermoeconomic analysis has been also proposed as a general tool for the diagnosis of the plant performances [4]. This tool presents several advantages: 1) it can be used not only for detecting and locating anomalies, but also for quantifying their effects, i.e. for the calculation of possible technical energy savings obtained by removing each of the anomalies [5-8]; 2) it can be applied to whatever plant, such as steam turbines [9,10], gas turbines [11,12], combined cycles [13,14], desalination plants [15], etc.
Some applications of the diagnosis procedures to real plants have been performed, providing satisfactory results [9, 14, 16]
Localization of malfunctioning components is obtained by calculating one of more indicators for all the components. These indicators are obtained by comparing some thermodynamic quantities calculated in the actual operating condition and a proper reference condition.
Diagnosis procedures need to be tested before their application to real plants can be performed. Tests are usually performed on data obtained by means of a simulator. This is the only way for testing several cases, obtained by varying the components where the anomalies are located as well as their magnitude. One of the main differences between theoretical and real applications is that, in the latter, data are affected by errors.
When diagnosis is performed by using theoretical data, the indicators are expected to assume the highest values in correspondence of the components where the anomalies have taken place.
This paper deals with the impact of measurements on the results of diagnosis. In particular, the main objective consists in investigating whether a thermoeconomic diagnosis procedure is able to detect the components where the anomalies have occurred in spite of data are affected by errors.
This topic has been tackled in some of the works available in the scientific literature (see for example, [14, 17, 18]). The approach adopted in this work allows one determining the error bars associated with the indicators.

THE DIAGNOSIS PROCEDURE

In this paragraph the diagnosis procedure is summarized. With respect to the procedure presented in a previous paper [19], some new features are introduced.
In pure thermoeconomic approaches, the physical structure of the system is substituted by a productive structure. This means that the components are represented in terms of resources required for the process and products supplied to other components or made available to the users (overall plant product). Resources and products are generally expressed in terms of exergy flows.
The concept of exergy presents several advantages in this application: 1) the objective of diagnosis consists in identifying the components where efficiency is decreased as the direct effect of the anomalies; exergy intrinsically includes the concept of performance degradation; 2) once the malfunctioning components are identified, it is likely to quantify the effects of each anomaly occurred in the system, i.e. to discriminate between the anomalies causing large impact on the fuel consumption and those not. Such evaluation, called *prognosis*, can be performed by using the concept of *fuel impact*, which is based on exergy and exergetic cost [5,6]. This aspect is not developed in this paper. Authors would like to highlight that it makes sense to use the same variables to perform diagnosis and prognosis.
Figure 1 shows the physical structure and a possible productive structure for the high pressure evaporator of the plant considered in this paper.

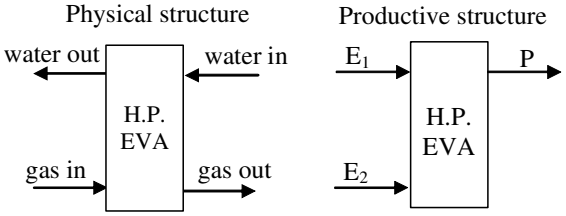

Figure 1 – Physical and productive structure of the HPSH

Resource E_1 is defined as the difference between the exergy flows of the gas entering and exiting the evaporator, while E_2 is defined as the exergy flow of the water entering the evaporator, namely:

$$E_1 = G_{gas} \cdot \left(b_{gas,in} - b_{gas,out}\right) \quad (1)$$

$$E_2 = G_{water} \cdot b_{water,in} \quad (2)$$

The product is defined as the exergy flow of the

exiting steam:

$$P = G_{water} \cdot b_{water,out} \quad (3)$$

At this point, a productive model can be built for the components. The model expresses the component product as the function of its resources, namely:

$$P_j = P_j\left(E_{1j}, E_{2j}, \mathrm{K}, E_{mj}\right) \quad (4)$$

The productive model for a component is not unique: it depends on the choice of resources and products. Some additional details related to the use of productive models instead of physical models are provided in the appendix.

A linear model is considered in this paper:

$$P_j = P_{j,ref} + \sum_{i=1}^{m} \lambda_{ij} \cdot \left(E_{ij} - E_{ij,ref}\right) \quad (5)$$

where subscript *ref* indicates a reference condition. Coefficients λ must be calculated by using plant data, measured when the plant is supposed to operate without anomalies, i.e. when it is new. At this point of the paper, errors in measurements have been still not considered; plant data are generated through a simulator by varying ambient conditions and plant load.

Equation (5) can be rewritten:

$$\Delta P_j = \sum_{i=1}^{m} \lambda_{ij} \cdot \Delta E_{ij} \quad (6)$$

Figure 2 shows the relation between ΔP and ΔE_1 ΔE_2 in the case of the high pressure evaporator. The operating conditions considered for plotting this graph refer to different values of mass flow rate, temperature and pressure of gas and water entering the component. Results show that a linear productive model is acceptable.

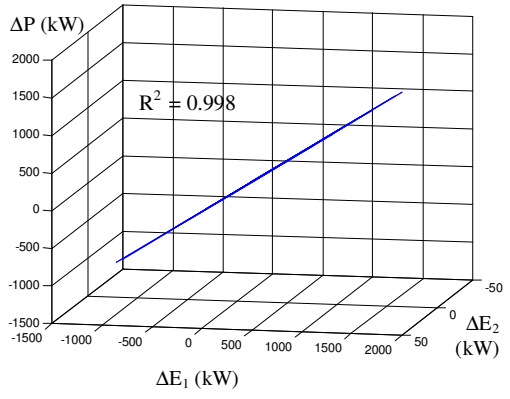

Figure 2 – Relation between resources and product of the high pressure evaporator

Curves such as the one shown in Figure 2 are sort of productive maps of the components. Non linear models can be considered as well; in particular, neural network models are suitable for the application to measured data [20].

The third step of the diagnosis procedure consists in considering two operating conditions of the plant: a reference condition (plant without anomalies) and the actual operating condition to be analyzed. For both conditions, the productive flows (resources and products) are calculated for all the components. Then, for each component, the ratio between each resource and the product is calculated. This quantity is called the unit exergy consumption:

$$k_{ij} = \frac{E_{ij}}{P_j} \quad (7)$$

Using this quantity, some performance parameters providing information about the status of the components can be calculated

1) *variation in the unit exergy consumption* between the actual operating condition and the reference condition, namely

$$\Delta k_j = k_{j\,op} - k_{j\,ref} = \frac{\sum_{i=1}^{m_j} E_{ij,op}}{P_{j,op}} - \frac{\sum_{i=1}^{m_j} E_{ij,ref}}{P_{j,ref}} \quad (8)$$

where m_j indicates the number of resources of the component j.

2) *malfunction* [7]:

$$MF_j = \sum_{i=1}^{m_j} \left(k_{ij,op} - k_{ij,ref}\right) \cdot P_{j_{ref}} \quad (9)$$

This quantity accounts for the different impact that the same anomaly would produce if it occurred in the different components, in fact, the efficiency reduction in a component has a larger overall impact in the additional fuel consumption if the component production is large.

If these parameters are different from zero for a component, it means that its performances are changed.

Before completing the analysis, it is necessary an additional step, which consists in the elimination of the induced effects. When one or more anomalies take place in the system, all components change their operating condition; for instance some of the components have to produce more since the malfunctioning component requires more resources to keep its production constant. The efficiency of components generally depends on their operating

condition, so it is possible that the two parameters introduced through equations (8) and (9) are sensibly different from zero also if in the components no anomalies have taken place. The model introduced in the second step of this procedure can be used in order to eliminate these induced effects. A possible way to reach this result consists in calculating through equation (5) the component product that would be obtained if the resources were moved from the value assumed in the operating condition to the value assumed in the reference condition (expected product). In the case of the high pressure evaporator, this component is characterized by a set of productive flows in the reference condition $\{E_1, E_2, P\}_{ref}$ and a set in the operating condition $\{E_1, E_2, P\}_{op}$. The expected production $\hat{P}$ is calculated as:

$$\hat{P} = P_{op} + \lambda_1 \cdot \left(E_{1,ref} - E_{1,op}\right) + \lambda_2 \cdot \left(E_{2,ref} - E_{2,op}\right) \quad (10)$$

If the expected production is different from the reference production, this is a symptom of anomaly in the component.
A new definition of unit exergy consumption can be introduced:

$$\hat{k}_{ij} = \frac{E_{ij,ref}}{\hat{P}_j} \quad (11)$$

This term is introduced in equations (8) and (9) in order to obtain evaluation parameters that are not affected by the induced effects:

$$\Delta\hat{k}_j = \hat{k}_j - k_{j\,ref} = \frac{\sum_{i=1}^{m_j} E_{ij,ref}}{\hat{P}_j} - \frac{\sum_{i=1}^{m_j} E_{ij,ref}}{P_{j,ref}} \quad (12)$$

$$M\hat{F}_j = \sum_{i=1}^{m_j} \left(\hat{k}_{ij} - k_{ij,ref}\right) \cdot P_{j_{ref}} \quad (13)$$

These parameters can be used for locating the anomalies.

APPLICATION TO A HEAT RECOVERY SYSTEM

In this section, the application of the diagnosis procedure to a heat recovery system is proposed. The objective of this part also consists in presenting the thermodynamic variables measured in the plant. Figure 3 shows the plant, constituted by a heat recovery steam generator and a steam turbine that are placed downstream a gas turbine. The gas turbine is not considered in this analysis.

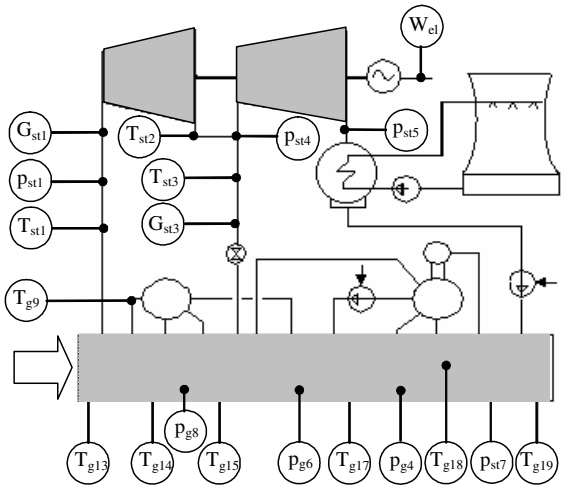

Figure 3 – Schematic of the plant with the measured thermodynamic variables

Table 1 shows the values assumed by the variables that are measured. Both the reference condition and in the actual operating condition are indicated. These values have been obtained through a simulator, without any error in the measurements. In the operating condition, the fouling in the high pressure evaporator has been simulated by reducing the heat transfer coefficient of 10%.

p_{st1}	52.36	bar	52.14	bar

Table 1 – Plant data

Using these data, the simulator allows one calculating all the thermodynamic data, by expressing energy and mass balances for all the components. In addition, some assumptions are made: fluid at the exit of the condenser is assumed as saturated liquid, while the fluid exiting the evaporators is assumed as saturated vapour (quality X=1). The number of measured data is in excess. In the model this fact is used in order to calculate the gas mass flow as the average value of the mass flow rates calculated in three heat exchangers.
The results obtained by applying the procedure introduced in the previous section are shown in table 2. No diagnosis can be performed for the condenser for the lack of data at cooling fluid side.
The results show that the diagnosis operated without filtering off the induced effects does not allow one to locate the anomaly correctly; in fact the largest positive variation in the unit exergy consumption takes place in the low pressure evaporator. Instead, the elimination of the induced effects through the linear model of the components highlights the high pressure evaporator as malfunctioning component, since both evaluation parameters assume the highest value in this component.

Table 2 – Diagnosis of the system without errors

THE PROBLEM OF ERRORS IN MEASUREMENTS

In this section the whole diagnosis procedure is repeated by using operating data affected by errors. These data have been also simulated, as explained hereafter. This choice has been taken in order to have complete control of the information about the anomalies occurred in the plant. The use of a simulator makes it possible to vary the number of anomalies, their location and their value, while this is not possible when real data are used. Nevertheless, the analysis has been developed in a way that makes it close to an analysis performed with real data. Only the variables actually measured in the plant have been considered. Errors have been estimated by considering real data.
A set of operating data (almost 2000 for each variable) measured in a period of about two months has been considered. These data have been first classified into groups, provided that two criteria are both satisfied: 1) the data in each group refer to operating conditions in a sufficiently short period of time; 2) the operating conditions must be characterized by close values of the gas turbine pressure ratio and its net power. Groups with abundant number of elements have been considered. After having verified the normal distribution of data for all the variables, the standard deviation has been calculated. Figure 4 shows the distribution of data for three different variables: high pressure steam pressure, outlet turbine temperature, low pressure steam mass flow rate. In the figure the normal distribution is also shown.

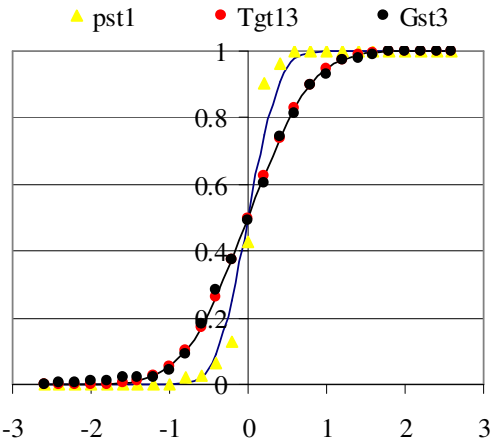

Figure 4 – Distribution of some of the measured data.

This information has been added to the simulator, so that its output is constituted by operating data affected by errors, generated according with a normal distribution. For each variable, the calculated standard deviation has been considered for generating the errors. These values are shown in Table 3.

T_{st2}	0.35	°C	p_{st1}	0.29	bar

Table 3 – standard deviation obtained for the different measured variables

The first step of the diagnosis procedure consists in determining the coefficients λ_{ij} of the linear model. For this goal, 200 data of the plant operating at different load and different ambient conditions have been generated. These data refer to the plant operating without any performance degradation. For the systems components, the accuracy of the linear models, evaluated by considering the whole set of 200 data, is shown in table 4. The average percent errors are shown as well. Errors refer to the estimation of the plant product; they account for possible non-linear behaviour and errors in measurements.

LP T	0.992	0.06	0.28
LP P	0.992	0.11	0.47
HP P	0.999	0.09	0.25

Table 4 – Performance of the linear model with errors in measures.

Using this model it is also possible to simulate the reference and actual operating conditions. The approach used for the diagnosis consists in simulating several times these conditions. In figure 5, the resource E1 of the high pressure evaporator in the reference and operating conditions are shown.

The number of points for the operating condition is sensibly less than for the reference condition. The reason is that some sets of the measurements do not comply the thermal balance of the components. In these cases the whole set of measures has been erased. This also means that the data distribution in the operating condition is not a normal distribution anymore.

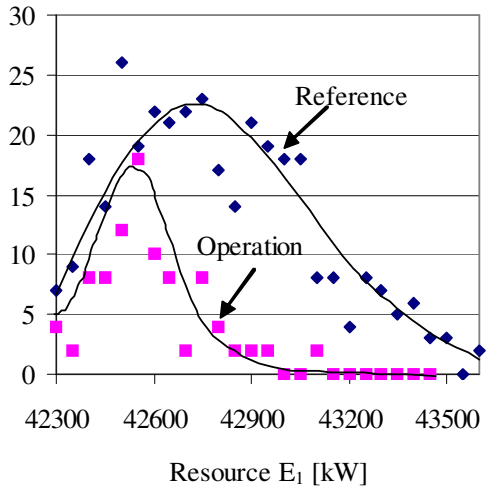

Figure 5 – Distribution of the productive resource E_1 of the high pressure evaporator.

Diagnosis is then performed by calculating the expected product and, then, the evaluation parameters for all the components. For each evaluation parameter, the average value and the error bar can be determined. Figure 5 shows the evaluation parameters obtained by considering the average values of the productive flows.

Table 5 – Diagnosis of the system with errors

It is possible to notice that the first parameter, the variation in the unit exergy consumption does not allow one to locate correctly the anomaly. The malfunction, instead, presents the highest value in the high pressure evaporator. This behavior is characteristic of the evaluation parameter, i.e. the malfunction is, in the authors' opinion, more suitable for the location of anomalies. A simple example can be considered in order to clarify this concept and to highlight another feature of the malfunction as an evaluation parameter.

As an example, it is possible to consider the high pressure turbine and the circulation pump of a steam power plant. The expansion is assumed between 140 bar, 450 °C and 32 bar, 262 °C and the pumping between 6 bar, 157 °C and 160 bar, 159.5 °C, while the mass flow rate is considered 1kg/s. If an error of 0.5% were committed in measuring the temperature of the flow exiting both components, it would cause a difference between calculated and expected value in the unit exergy consumption and consequently in the malfunction of both components, although no anomaly has occurred in the system. Numerical results are shown in table 6.

	Turbine	Pump
Δk [kW/kW]	0.015	0.105
MF [kW]	4.49	3.43

Table 6 – Sensitivity of the evaluation parameters to an error in measurements.

The results show that the variation in the unit exergy consumption is very different in the two components, in particular the variation occurred in the pump is larger. This different response to a similar impulse can be the origin of erroneous interpretations while diagnosing the presence of anomalies, i.e. the variation in the unit exergy consumption of the pump could be confused with an anomaly or it could impede to detect other anomalies. The malfunction seams to be less dependent on the errors in measures, in fact similar values of this parameter are obtained for both components.

A second aspect of the same problem is now considered. A general component whose productive structure is constituted by one resource and one product is considered. Once again, an error on a intensive property (pressure or temperature) is considered. An extensive quantity (e.g. mass flow rate) is made vary from 100% to 50%. Two hypotheses are made: 1) this variation just slightly affects the intensive properties required for the definition of resources and products; 2) the unit exergy consumption for this component does not depend on the resource. The variation in the unit exergy consumption and the malfunction associated with the error in measurement is computed in nominal condition (100% of the mass flow rate). These indicators are also calculated when the mass flow rate is reduced.

Figure 6 shows how the indicators vary depending on the component production; the values of the indicators are referred to the value assumed in the nominal condition. The malfunctions does not depend on the variation in the mass flow rate, while the variation in the unit exergy consumption increases as the product decreases.

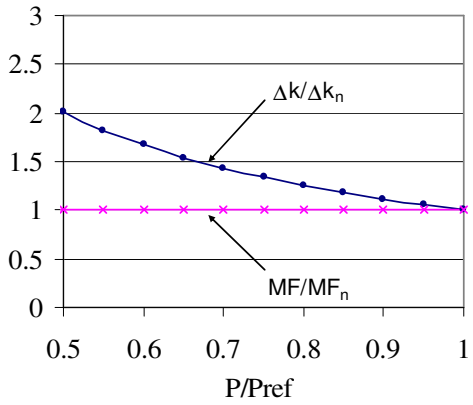

Figure 6 – Effect of the error on a intensive quantity.

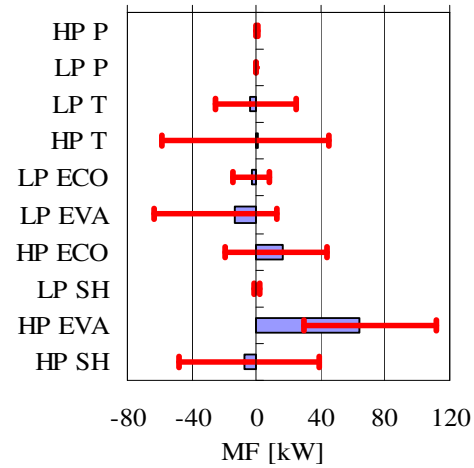

Figure 7 – Error bars associated with the corrected malfunctions.

If the error is associated with an extensive quantity, both indicators behaves in the same way, showing small variations.

At this point, an analysis of the deviation of the evaluation parameters can be performed. This analysis is conducted by considering the corrected malfunctions $M\hat{F}$ only. Figure 7 shows the average values and the error bars obtained by considering the set of data corresponding to the operating and the reference conditions.

The figure highlights that the errors induce important effects that cannot be neglected. In any case it is possible to notice that the error bar associated with the anomaly is only slightly superimposed to the error bars of the induced effects, thus the anomaly can be correctly located.

CONCLUSION

In this paper, the problems associated with the errors in measures and their impact on the results of thermoeconomic diagnosis are tackled.

Several results have been achieved. The application of a diagnosis procedure to a particular case of anomaly, occurred in the high pressure evaporator of a HRSG, shows that the impact of the errors is not negligible but it does not impede to locate correctly the anomaly, provided that a sufficiently large set of data is considered.

With respect to other diagnosis techniques, thermoeconomic diagnosis leaves to the analyst more freedom to chose among the performance indicators to use. The application here proposed highlights that the parameter called *malfunction* is less sensible to the effects of errors in measurements. In contrast, parameters such as efficiencies and unit exergy consumptions seam to be more sensitive to errors, thus less indicated for the diagnosis with real operating data.

APPENDIX. Use of productive model.

The use of a productive structure instead of the physical structure seams to involve a reduction in the number of thermodynamic variables that are used to simulate the component's behavior.

In this section, authors would like to discuss some of the effects related to the use of a productive structure to model the components in off-design conditions as well as its use in diagnosis.

All the considerations refer to the heat exchanger in figure 1, but they can be easily extended to whatever component.

The physical model is characterized by 12 variables, since there are 4 streams; for each stream the mass flow rate, pressure and enthalpy are defined. Six of these variables are independent (boundary conditions). The other variables are obtained through continuity equation, momentum equation and energy equation applied to both fluids.

If the productive structure defined by equations (1)-(3) is assumed, only two boundary conditions are imposed, i.e. the two resources. In the case of a heat exchanger, this basically means that only the thermal problem is solved. Consequently, the thermal behavior of the heat exchanger is independent on the mass flow rate of the two fluids and on their pressures.

This productive model provides the same details as a physical model with the following characteristics: 1) the transformations of the two fluids are assumed as isobaric; 2) heat transfer is expressed by using the effectiveness-NTU model with constant heat transfer coefficient.

Both physical and productive models are suitable to be expressed through linear functions. The productive model is just more compact.

Such model is expected to correctly detect anomalies affecting the heat transfer, provided that fluid dynamic and thermal behaviors are decoupled in the component. When the linear regression analysis is performed, this hypothesis is verified together with the hypothesis of linearity. The model is expected not to work properly for the diagnosis of anomalies affecting the pressure drops.

A more accurate model could be needed, both in case fluid dynamic and thermal problems are coupled, or in order to detect anomalies affecting the pressure drops. A physical model can be obtained by expressing for each flow, the outlet pressures as the function of inlet pressure and mass flow rate. A corresponding productive model can be obtained by splitting exergy flows into mechanical and thermal components.

It is also possible to obtain a productive model characterized by 6 independent resources, which is equivalent to the most possible zero-dimension physical model (it can be obtained though a change in the independent variables). For such model, the independent resources are:

$$E_1 = G_{gas} \cdot b_{Tgas,in} \tag{14}$$

$$E_2 = G_{gas} \cdot b_{Mgas,in} \tag{15}$$

$$E_3 = G_{gas} \cdot b_{Tgas,out} \tag{16}$$

$$E_4 = G_{gas} \cdot b_{Mgas,out} \tag{17}$$

$$E_5 = G_{water} \cdot b_{Twater,in} \tag{18}$$

$$E_6 = G_{water} \cdot b_{Mwater,in} \tag{19}$$

University of Guanajuato, MEXICO

ABSTRACT

The thermoeconomic diagnosis in operating power plants is more and more being demanded by the users of the same ones. Nevertheless, in spite of the efforts to unify the techniques or tactics of diagnosis, it seemed that we are even far from standardizing the analytical procedures to do it. Recently, a series of papers have been considered to compare different ways to solve a concrete problem to diagnose a power plants TADEUS part 1 to 7. In this paper, we look for to establish the minimum requirements that must fulfill the three fundamental aspects in an on-line thermoeconomic diagnosis and monitoring. Such as: *Dynamic Reference Operating State, an Acceptable Performance Test State, and an Equalized Reconciliation Method.* Where the Dynamic Reference Operating State, talks about to create a reference on the basis of the atmosphere conditions, fuel quality and present load of the plant in operation; in the Acceptable Operating State Test, we will describe to the minimum requirements of data acquisition and filtrate to have an acceptable tests and comparable with the reference; and an Equalized Reconciliation Method, talks about to the comparison of states (reference versus proves) to conditions of equal load and atmosphere, solved by a module of equation systems; respectively. An example of development and results applied to a plant of combined cycle 240 MW of third generation is presented.

Keywords: Thermoeconomic diagnosis, Anomalies, malfunctions, reconciliation.

INTRODUCTION

The diagnosis in real time in existing power plants, has received in the last 10 years a special interest. Every time is clearer that the effective potential of energy saving is in the opportune detection and correction of the anomalies. The users of the plants have demonstrated that the loss of efficiency dragged during the time, creates an accumulated burst of fuel of tremendously high orders of economic magnitude. In the last decades where the operation strategy was the maximum production, without having special well-taken care of the efficiency, it seemed that this changed to always have the maximum efficiency and the maximum availability. The strategies of maintenance and control also are changing, every time that it is had better systems of data acquisition, software and hardware, and it is possible to detect the losses of efficiency or impact in the production, almost in real time. Nevertheless, it does not even exist a standardization and normalization (for example of the type ASME PTC or others) of the procedures of thermoeconomic diagnosis in operation, so that they are applicable for any power plant and can offer a clear idea of where these greater deviations and whichever time take some anomaly. A series of referring articles to the thermoeconomic diagnosis of power systems has appeared, with the intention of presenting to the scientific community the different currents to solve an example of diagnose of a case of study, call TADEUS [1-6]. The results of this series of articles have revealed the great diversity of points of view and methods of solution. In part 3 of the TADEU'S series [4], we presented the concepts of the reconciliation of a Test *versus* a Reference State, for the case described in TADEUS, based on a module of reconciliation of anomalies. Nevertheless, taking the methodology to a case in real-time (a combined cycle of third generation of 240MW), we have been new approaches in the methodology that will serve as the base to standardize the procedures of diagnose. In this sense, the objective of this work is to deepen in the foundations that a thermoeconomic diagnosis in real-time must be, and redefining the concepts of reference state *(of how it would have to be)* and test condition *(of how it is);* as well as the method reconciliation *(of how it is going to be compared).*

With the objective to give a immediately and precise answer in the diagnosis of operational thermoelectric plants, this work presents a methodology that permits opportunely inform and value Heat Rate's deviations, defined as $\left(\Delta HR = {}^{\Delta Fuel\,[kW]}\!/_{Net\ Power\,[kW]}\right)$ and Power's deviations by separated causes, in order to the user only see the anomalies of subsystems or control deviations, discriminating environment and load effects.

DYNAMIC REFERENCE OPERATING STATE

The manufacturers of power plants give to the owners the ***thermal balance*** at ISO conditions or site conditions (before project or after acceptance test), as a guarantee (reference) to the optimal state of the plant, leaving in addition a series of correction curves (by environmental conditions, fuel quality, load or degradation). Nevertheless, actually there are a few plants that have systematized this form to obtain the reference, and those that already have done; they have chosen to turn them by using parametric models (polynomials) for obtaining a reference state, losing precision and accuracy in the reference data. Moreover by considering that environment properties, fuel quality and load, change every time, it is more difficult to ensure a specific reference. For example in Figure 1, we can show a typical month of average (10 minutes) data of LHV, IGV, and environment properties, in the plant (case of study).

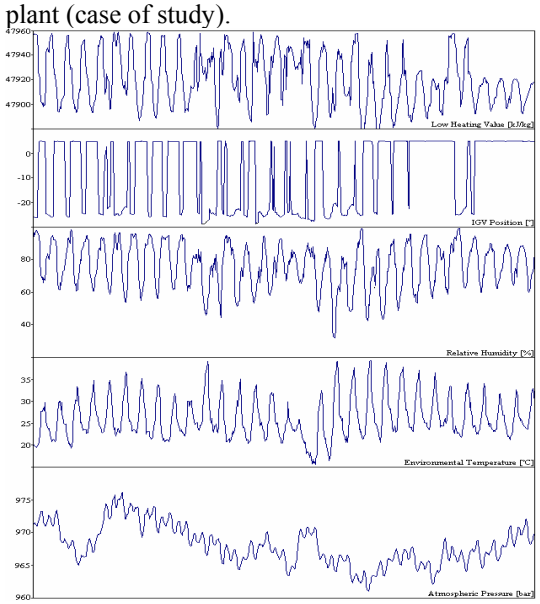

Figure 1: A typical tendency in real-time of the environmental properties, fuel quality, and IGV position (load).

Simulator Validation and a real time reference

From our point of view, the *Reference Operating State* must be based on a **simulator** able to respond to the environmental conditions, fuel quality, load and (optionally) the control of the process, with the objective to establish a (real time) dynamic and optimal reference of the systems with respect to its present operating condition, including factors like partial loads and control set-point. In this way, the ***thermal balance*** at the acceptance tests condition can serve to validate and to fit us the mathematical model (Fig. 2) of a simulator by computer, the simulator has been developed using a mathematic model based in mass and energy balances, compressor map, IGV model, model to predict steam turbine efficiencies, Stodola model to predict admission pressures. The simulator can reproduce a determinate number of thermodynamic conditions in each point of the plant (Fig. 1), the inlet independent variables are: *environmental conditions, fuel quality, IGV (Inlet Guide Vanes), temperature and pressure points control* (the objective of this paper is not show the developed of one simulator, it had been discussed in previous work [2,4]).

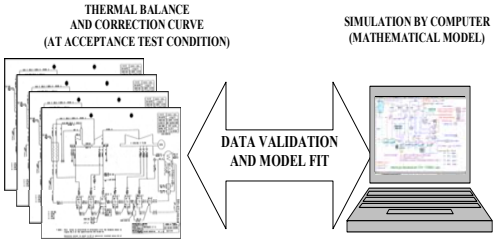

Figure 2: Comparison process and data validation of between Thermal Balance and Simulator by computer

Once validated the simulator, it is possible to execute at real time load and environmental conditions, obtaining reference thermal balances in the time (Fig. 3). In Fig. 4, it is possible to see the importance to have a dynamic variable behavior, because with this simulator any change in a specific variable represents one change for evaluating a Reference Heat Rate and Net Power. Also Fig. 4 shows a references value of Heat Rate and Power at environmental condition, fuel quality and present load, shown in Fig. 1.

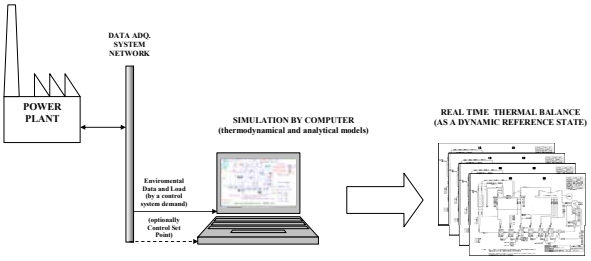

Figure 3: Scheme of data process in order to obtain a Dynamic Reference State

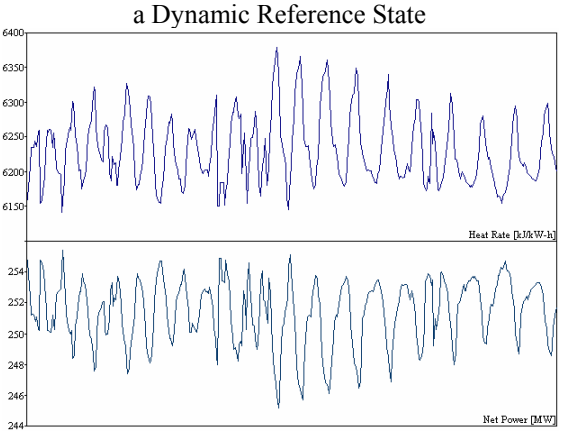

Figure 4: Reference Heat Rate and Power by Adapting in the simulator at the real-time conditions

ACCEPTABLE (DYNAMIC) PERFORMANCE TEST STATE

A performance test is defined as the data collection at determinate operation condition. The codes ASME PTC – 4, 6 and 22 *(Performance Test Code)* defined the conditions and measure points for gas turbines, steam turbine and HRSG tests. The measure data is referred to the information that can be obtained from the instrumentation in a strategic points into the plant (described in Table 1). With the objective to reproduce the same thermodynamic conditions in the reference state it is necessary additional operations using mass and energy balances, then efficiencies, heat rate and admission coefficients (Fig 5).

MEASURE POINTS	DATA
Environmental condition and compressor admition	P, T, T_w
IGV	%α
Compressor exit and air extractions	P, T
Fuel admission in the	P, T,

combustor	HHV,LHV,ρ, $\dot{m}$
Combustor (TG admission)	P

Steam generated by HRSG	P, T, $\dot{m}$
Steam admission at AP-TV Y BP-TV	P, T
Steam exit at AP-TV and steam admission at BP-TV.	P, T
Exhaust steam	P
Condenser exit conditions and feet water.	P, T, $\dot{m}$
Suction and exit condenser and feet pumps.	P, T
Electric generator, pumps, fans and auxiliary.	Volt. and Amp.

Table 1: Measure variables (directly or indirectly) in plant

For *operating (performance) tests* state aspects like the need to data validation by a dynamic min., max., avg. values, and thermodynamic filtrate, interchange and dynamic replacement of data with the reference state, calculation of thermodynamic conditions of the test and determination of the free variables (anomalies) are necessary. First before any operation with the data, it needs a validation passing through filtrate with two limits max. and min., those limits are established by the plant operation, maxim and minimum charge. After this filter it is necessary a thermodynamic validation, that is a data compare between inlet an exit of a component, like pressure in air filters, the inlet pressure never can be less than exit pressure; with this filters it can reject any mistake. If any signal after the filter is wrong, the simulator will be replace by an optimal value for the same variable (signal). The system chose the data replace from the data base, where is update every minute by a polynomial equation.

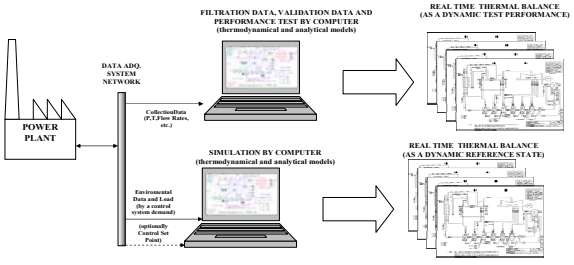

Figure 5: Scheme of data process in order to obtain an *Acceptable (dynamic) Performance Test State*

EQUALIZED RECONCILIATION METHOD

The method of diagnosis is based on reconciliation data; in other words, a comparison between test and reference; we described this method at TADEUS´ series [4]. However, this included one long list of anomalies from the external ones to the internal ones (Fig 6). In this sense, at the time of evaluating in real time the impacts to the Heat Rate and Power, the external causes can impact very strong, but they are irremediable, the question is: *is it worth really the trouble to evaluate them?.* In addition, as we discussed above, the reference must be to the same load, it is with the intention of having comparable efficiencies and operation conditions. It is the concept that we call ***Equalized Reconciliation Method,*** means a comparison of reference and test, at the same extern conditions with the intention of isolating the intrinsic effects of the components.

Anomalies Classification

The anomalies that impact to Heat Rate and Net Power are defined as internal and external (Fig. 6).

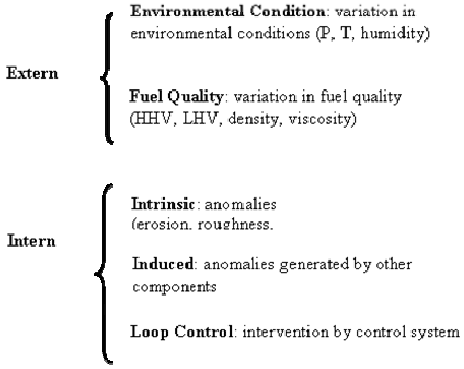

Figure 6: Anomalies Classification in Power Cycles.

In order to do reconciliation, first is necessary create one module (Figure 7), where it is determinate the Heat Rate and Net Power by mathematic models used in the simulator. Once created the module, beginning one call to evaluate in first time the test state, after every test parameter is changed by a reference parameter, until all the anomalies have been substituted. An example of a module declaration and callings of 4 anomalies (2 of control and 2 intrinsic) are shown in Fig. 7; where with a sequential replace, has been calculated ΔHR y $\Delta\dot{W}$ for each anomaly. Obtained

ΔHR is possible determinate the economic cost by every anomaly.

On – Line Implementation

The use of this methodology has been tested by manual data acquisition, however exits the necessary to know the impact by anomaly in the moment that it occurs, so the implementation of this methodology result indispensable to offer "in real – time" diagnosis. In the actual data acquisition systems allowed the developed of "on – line" monitoring procedures, with the possibility to show the Impact of components that operate out of nominal conditions, control deviations and environment conditions.

CASE OF APPLICATION

The case of study is a combined cycle (Figure 8) with sequential combustor, two compressor stages, a steam turbine with three stages: high, intermediate and low pressure; one HRSG, one electric generator and one aerocondenser. The Table 2 shows a detail description of the plant and its principal points in the analysis.

Analysis point	Description

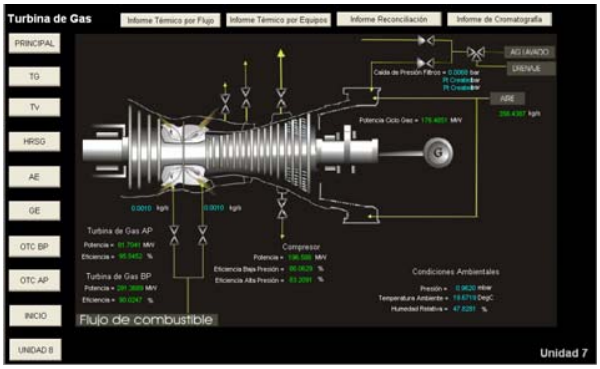

Figure 10: Gas Turbine - Interface

CONCLUSION

The opportunity knowledge of the causes that impact the efficiency in an energetic process and its economic costs, allow take decisions and corrective actions in plant, from low cost (calibration of loop control) until predictive or corrective maintenance. This actions permit save energy sources and recovery efficiency until optimal state. The "on – line" implementation of this methodology allow the detection of substantial saves in energy and the immediately correction, then avoid raise fuel consumptions and environment pollution.

ABSTRACT

A cyclic model of irreversible Diesel heat engine is presented. The influences of heat transfer and irreversibility of the adiabatic processes on the net work output and the efficiency of the Diesel heat engine cycle are explored. The heat losses through cylinder walls are considered and the expansion and compression isentropic efficiencies are put forward in the present paper. The optimal relationships between the net work output or the efficiency and the isentropic efficiencies, the pressure ratio, and other parameters are derived. The optimum operating range of the pressure ratio is determined and the other optimal performance characteristics are discussed and evaluated. The conclusions obtained may provide some theoretical guidance for the optimal design of a class of internal combustion engines.

INTRODUCTION

The optimum thermodynamics method has been applied successfully to a large number of engineering problems in recent decades [1-8]. Mozurkewich *et al*. [3] applied the optimal control theory to optimize piston movement for the ideal Otto cycle. Angulo-Brown *et al.* [4] optimized a non-endoreversible Otto cycle to improve power output and efficiency. Aragón-González *et al.* [5] considered the irreversible adiabatic processes in the Otto cycle. Chen *et al* [6] studied the effect of heat transfer in cylinder wall on the Otto cycle. Bhattacharyya [7] investigated the effect of compression ratio and cut-off ratio on an irreversible Diesel cycle. Akash [8] presented the effect of heat transfer on the net work output and the indicated thermal efficiency of the Diesel cycle. These research results are closer to the reality than the classical thermodynamic theory. It is significant and of practical value to investigate further the influence of the irreversibilities in the expansion and compression processes, combustion and heat transfer parameters on the performance of the Diesel heat engine cycle. In this paper, a new irreversible Diesel cycle model is established, in which the irreversibilities resulting from the non-isentropic compression and expansion processes and heat losses through the cylinder walls are taken into account. The expansion and compression isentropic efficiencies are introduced. On the basis of thermodynamic theory, the analytical expressions of the net work output and the thermal efficiency of the Diesel heat engine cycle are derived. The effects of combination parameter, heat transfer coefficient, pressure ratio on the performance of the cycle are analyzed and evaluated. Several important performance bounds are determined and discussed. The conclusions obtained may provide some theoretical instruction in the optimal design of Diesel heat engines.

THE MODEL

Figure 1 presents a pressure-volume diagram for an Diesel cycle. The process 1-2-3-4-1 is a reversible cycle while 1-2i-3-4i-1 is an irreversible one. Considering two adiabatic processes as irreversible, we define the expansion and compression isentropic efficiencies as [5]

$$\eta_1 = \frac{T_3 - T_{4i}}{T_3 - T_4} \tag{1}$$

$$\eta_2 = \frac{T_2 - T_1}{T_{2i} - T_1} \tag{2}$$

where $0 < \eta_1, \eta_2 \le 1$, and $T_1, T_2, T_{2i}, T_3, T_4$ and T_{4i} are the absolute temperatures at states 1, 2, 2i, 3, 4 and 4i, respectively. It is clear that if two adiabatic processes are reversible, $\eta_1 = \eta_2 = 1$. Moreover, the air-standard Diesel cycle is considered in the present model.

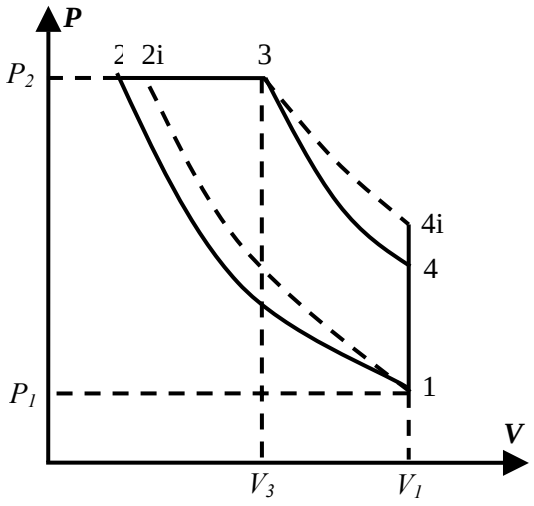

Figure 1: Schematic diagram of an irreversible Diesel cycle

According to the above model, the net work output and the efficiency are given by the following equations:

$$w = kc_v(T_3 - T_{2i}) - c_v(T_{4i} - T_1) \qquad (3)$$

$$\eta = 1 - \frac{T_{4i} - T_1}{k(T_3 - T_{2i})} \qquad (4)$$

where $k = c_p / c_v$, c_p and c_v are the constant-pressure and volume specific heats respectively and they are assumed as constant.

For the reversible processes 1-2, 3-4 and states 1 , 3 in the cycle, one has

$$T_2 / T_1 = r_p^{(k-1)/k} \qquad (5)$$

$$T_3 / T_4 = r_e^{k-1} \qquad (6)$$

$$\frac{P_1 V_1}{T_1} = \frac{P_2 V_3}{T_3} \qquad (7)$$

where $r_p = P_2/P_1$ and $r_e = V_1/V_3$ are the pressure and expansion ratios, P_1 and P_2 are the pressures at state 1 and the process 2-3, V_1 and V_3 are the volumes at the process 4i-1 and state 3.

During process 2i-3, the heat input is

$$q_{in} = c_p(T_3 - T_{2i}) \qquad (8)$$

and the heat is provided by combustion. For a real Diesel engine, heat loss between the working fluid and the cylinder wall during combustion is not negligible, and it is often assumed that the heat loss through the cylinder wall is proportional to the average temperatures of both working fluid and cylinder wall and that the cylinder wall temperature is a constant. Hence, the heat added to per unit mass of working fluid is given by [6,8-11]

$$q_{in} = \alpha - \beta(T_{2i} + T_3) \qquad (9)$$

where α and β are two parameters related to combustion and heat transfer.

By combining equations (8) with (9), it yields

$$T_3 = \frac{\alpha + (kc_v - \beta)T_{2i}}{kc_v + \beta} \qquad (10)$$

Using equations (1), (2), (5)-(7) and (10), one has

$$T_{2i} = [1 + \frac{r_p^{(k-1)/k} - 1}{\eta_2}]T_1 \qquad (11)$$

$$T_3 = A/(kc_v + \beta) \qquad (12)$$

$$T_4 = [A/(kc_v + \beta)]^k / (r_p T_1)^{k-1} \qquad (13)$$

$$T_{4i} = \frac{1 - \eta_1 + \eta_1\{A/[r_p T_1(kc_v + \beta)]\}^{k-1}}{(kc_v + \beta)/A} \qquad (14)$$

where

$$A = \alpha + (kc_v - \beta)\{1 + [r_p^{(k-1)/k} - 1]/\eta_2\}T_1 \qquad (15)$$

Then substituting equations (11), (12) and (14) into equations (3) and (4), we have

$$w = \frac{\alpha - 2\beta T_1\{1 + [r_p^{(k-1)/k} - 1]/\eta_2\}}{(kc_v + \beta)/[c_v(k - B)]} \qquad (16)$$

$$\eta = 1 - \frac{B}{k} \qquad (17)$$

where

$$B=\frac{1-\eta_1+\eta_1\{A/[r_pT_1(kc_v+\beta)]\}^{k-1}}{\{\alpha-2\beta T_1[1+(r_p{}^{(k-1)/k}-1)/\eta_2]\}/A}-\frac{(kc_v+\beta)T_1}{\alpha-2\beta T_1[1+(r_p{}^{(k-1)/k}-1)/\eta_2]} \quad (18)$$

Equations (16) and (17) are two important results in the present paper and they show clearly that the net work output and the efficiency of an irreversible Diesel heat engine cycle are dependent on not only the parameters η_1 and η_2 but also the parameters α, β and r_p. The influences of these parameters on the net work output and the efficiency will be discussed in the following sections.

NUMERICAL RESULTS AND DISCUSSION

It can be seen that both equation (16) and equation (17) are transcendental ones of the pressure ratio r_p, one can solve them by a numerical or graphical method. For example, letting $c_v=0.4372kJ/kg.K$, $k=1.4$, $T_1=300K$, $\alpha=3000kJ/kg$ and $\beta=1.5kJ/kg.K$, one can obtain that the net work output w and the efficiency η versus the pressure ratio r_p curves, as shown in figures 2 and 3. Figures 2 and 3 show clearly that when pressure ratio equal to r_{pw} and $r_{p\eta}$, the net work output and the efficiency of the Diesel heat engine cycle attain their maximum,

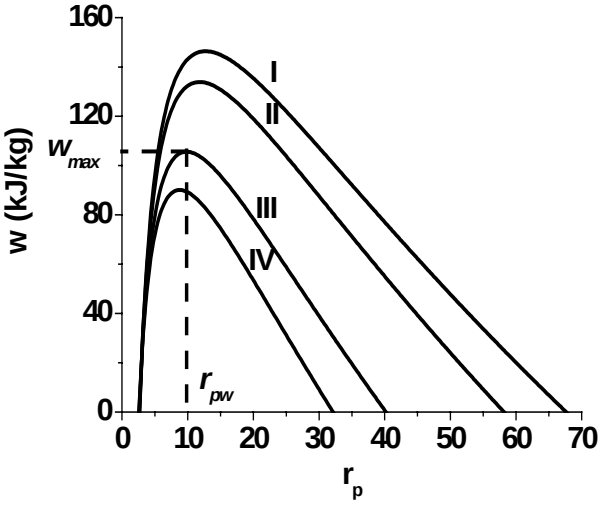

Figure 2: The net work output w versus the pressure ratio r_p curves. Curves *I, II, III* and *IV* correspond to the cases of $\eta_1=\eta_2=1$, 0.97, 0.90 and 0.86, respectively.

$w_{\max}$ and $\eta_{\max}$, respectively. Figure 2 or 3 also shows that when $r_p < r_{pw}$ or $r_{p\eta}$, both the net work output and the efficiency decreases as the pressure ratio decreases, when $r_p > r_{pw}$ or $r_{p\eta}$, the net work output or the efficiency decreases as the pressure ratio increases. It should be pointed out that the regions that the pressure ratios are located in $r_p < r_{pw}$ or $r_p > r_{p\eta}$ are not the optimal operating ones. Thus, the optimal operating range of the pressure ratio for the Diesel heat engine cycle should be

$$r_{pw} \le r_p \le r_{p\eta} \quad (19)$$

As an example, letting $\alpha=3000kJ/kg$, $\beta=1.5kJ/kg.K$ and $\eta_1=\eta_2=0.90$, we can

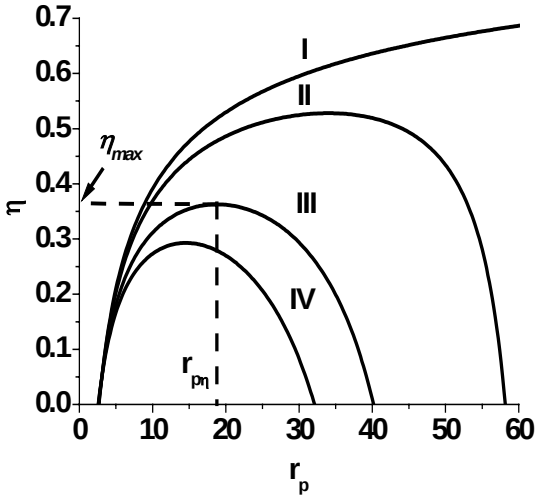

Figure 3: The efficiency η versus the pressure ratio r_p curves. Plots are presented for the same conditions as in figure 2. Curves I, II, III and IV correspond to the cases of $\eta_1 = \eta_2 = 1$, 0.97, 0.90 and 0.86, respectively.

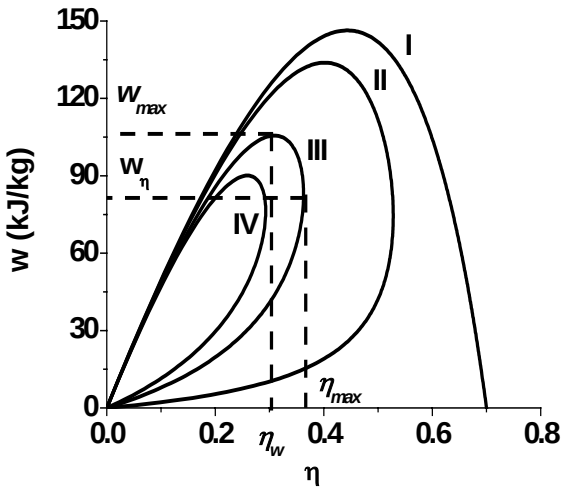

Figure 4(a): The net work output w versus the efficiency η curves. Plots are presented for the same conditions as in figure 2. Curves I, II, III and IV correspond to the cases of $\eta_1 = \eta_2 = 1$, 0.97, 0.90 and 0.86, respectively.

obtain the optimal operating range of the pressure ratio for the Diesel heat engine cycle should be $9.8 \le r_p \le 18.8$. It can be also seen from figures 2, 3 and 4(a) that the effect of parameters η_1 and η_2 on the net work output and the efficiency of the Diesel heat engine cycle is evident and they decrease with decreasing η_1 and η_2. This is natural. Because decrease of values of η_1 and η_2 implies increase of the irreversibility of the two adiabatic processes, such that the cyclic performance of the Diesel heat engine gets worse. As an example, letting $\alpha = 3000 kJ/kg$, $\beta = 1.5 kJ/kg.K$ and $\eta_1 = \eta_2 = 0.90$, we can obtain that the maximum net work output and the maximum efficiency of the cycle are, respectively, $w_{\max}$ = 105.59 kJ/kg and $\eta_{\max}$ = 0.36, and when $\alpha = 3000 kJ/kg$, $\beta = 1.5 kJ/kg.K$, $\eta_1 = \eta_2 = 0.97$, the maximum net work output and the maximum efficiency of the cycle are, respectively, $w_{\max} = 133.85$ kJ/kg and $\eta_{\max} = 0.53$.

Therefore, it is significantly important to pay great attention to the influence of irreversibilities of the adiabatic compression and expansion processes besides to heat transfer irreversibility between the working fluid and the cylinder walls on the net work output and the efficiency of the Diesel heat engine.

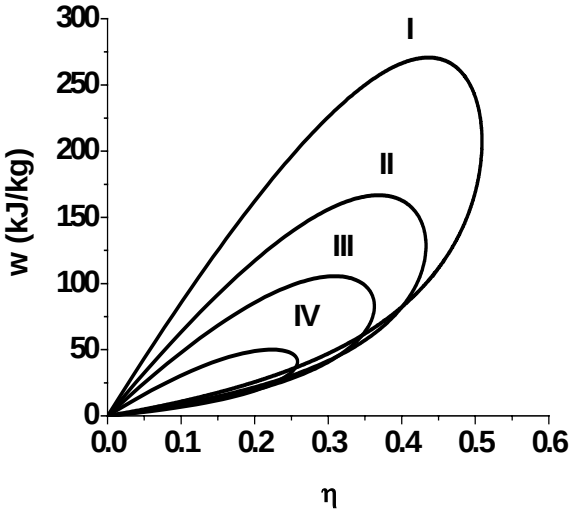

Figure 4(b): The net work output w versus the efficiency η curves. Plots are presented for the same conditions as in figure 2 except $\eta_1 = \eta_2 = 0.90$. Curves I, II, III and IV correspond to the cases of $\beta = 0.9$, 1.2, 1.5 and 2.0 $kJ/kg.K$, respectively.

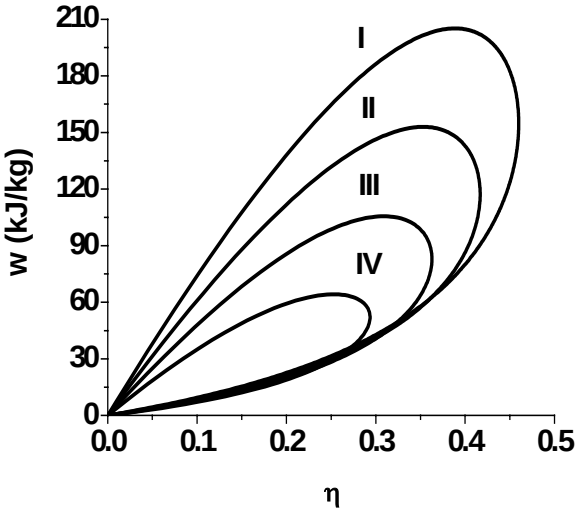

Figure 4(c): The net work output w versus the efficiency η curves. Plots are presented for the same conditions as in figure 2 except $\eta_1 = \eta_2 = 0.90$ and $\beta = 1.5 kJ/kg.K$. Curves I, II, III and IV correspond to the cases of $\alpha = 4000$, 3500, 3000 and 2500 kJ/kg, respectively.

When the Diesel heat engine is operated in those regions of the $w \sim \eta$ curves which have a positive slope, the net work output decreases with decreasing efficiency. Thus, these regions are not the optimal operating regions. Obviously, the optimal operating region of the Diesel heat engine cycle should be situated in the part of the $w \sim \eta$ curves which have a negative slope, as shown in figures 4(a), 4(b) and 4(c). When the Diesel heat engine is operated in the optimal operating region, the net work output increases with decreasing efficiency, and vice versa. Therefore, the optimal ranges of the net work output and the efficiency should satisfy the following equations:

$$w_{\max} \geq w \geq w_{\eta} \tag{20}$$

$$\eta_w \leq \eta \leq \eta_{\max} \tag{21}$$

where η_w and w_η are the efficiency at the maximum work output and the work output at the maximum efficiency. As an example, when $\alpha = 3000 kJ/kg$, $\beta = 1.5 kJ/kg.K$ and $\eta_1 = \eta_2 = 0.90$ are given, the optimal ranges of the work output and the efficiency should be 105.59kJ/kg $\geq w \geq$ 82.82kJ/kg and $0.31 \leq \eta \leq 0.36$. Similarly, using equations (11), (14) and (19), we can obtain the optimal regions of the cycle temperatures at state points 2i and 4i as

$$T_{2iw} \leq T_{2i} \leq T_{2i\eta} \tag{22}$$

and

$$T_{4iw} \geq T_{4i} \geq T_{4i\eta} \tag{23}$$

where T_{2iw} , $T_{2i\eta}$ and T_{4iw} , $T_{4i\eta}$ are the temperatures of the working fluid at state points 2i and 4i for the maximum work output or the maximum efficiency.

The heat transfer irreversibility between the working fluid and the cylinder walls during combustion has been taken into the cyclic model in the present paper and the parameter β embodies the characteristic of the irreversibility. For this reason, it is necessary to investigate the influence of parameter β on the cyclic performance of the Diesel heat engine cycle. Figure 4(b) indicates that the work output and the efficiency decrease as increase of the values of β. For example, when β =0.9, the maximum work output is about 275kJ/kg, and when β =1.2, the maximum work output is about 165kJ/kg whose value is much less than the former. Similarly, the effect of parameter α on the work output and the efficiency is plotted in figure 4(c). Evidently, the work output and efficiency increase rapidly as the values of α increase.

CONCLUSIONS

In the present paper, the effects of multi-parameters, such as combustion parameter, heat transfer parameter and irreversible adiabatic efficiencies and so on, on the performance characteristics of the Diesel heat engine cycle are investigated. Based on the obtained analytic expressions, the detailed analysis and evaluation of the optimal performance for the Diesel heat engine cycle are carried out by means of the numerical calculation and graphical method. The results obtained can provide some significant guidance for the optimal design and performance improvement of real Diesel heat engines.

ABSTRACT

Air conditioning is spread all over the world, even more in countries like Spain where summer weather reaches temperatures above 35 ºC. That causes the increase, not only of electricity consumption, but also organic refrigerants pollution.
Experimental research is being focused on air conditioning systems able to supply the thermal load requirements of a typical house using solar thermal energy. In Spain, this load is around 6 to 8 kW, for an 80 m^2 housing, according to Spanish INE (Instituto Nacional de Estadística). An aditional advantage of the studied system is the use of refrigerants that are not organic and have no ozone deplection activity
Research has been carried out at *Universidad Carlos III de Madrid*. The facility is based on a field of 50m^2 flat-plate solar collectors and a single-effect LiBr absorption chiller. Because of this technology CO_2 emissions are greatly reduced and lessen environmental danger risks, trying to achieve Kyoto Protocol, Spain signed in 1997.
This work includes results on system performance, instantaneous thermal load calculations, economic invest, energy and economic saving and environmental impact reduction. Paper offers experimental results obtained during 2004 summer season. Absorption machine cooling power outputs about 6–10 kW have been recorded, with a required generator power input of 10-15 kW, achieving a mean time-period of 6,5 hours of complete solar autonomy on an average day.
Keywords: Solar energy. Absorption cooling. Environmental impact reduction.

t_{pb}: Redemption period [year].

U: Overall heat transfer coefficient [W/(m^2·K)].

U_w: External wall overall heat transfer coefficient [W/(m^2·K)].

INTRODUCTION

In the past century, researchers have spent decades searching for new ways to make houses completely autonomous, working only by means of renewable energies. In the effort to reduce house electricity demand and to make "living" more environmental friendly, solar resources are gaining popularity because of its availability and its nearly zero impact to the environment.

In Spain, there is a peak in electricity consumption in summer time. This peak is due to the use of air conditioning electrically powered in most of Spanish houses, which impacts the grid and sometimes leads to black outs.

A partial solution could be found, using solar thermal panels to feed a H_2O/BrLi absorption machine [1]*. One of its advantages is that air conditioning demand is generally coupled with solar radiation. It is also a solution to the maintenance of solar installations devices during summer time, when there is no need of heating, and hot water supply demand diminishes.

Among all possible facilities, the chosen one is a 50m^2 field of flat plate solar thermal collectors and a 35kW single effect H_2O/BrLi absorption system. This kind of setup shows the lowest cost and is one of the most used accordingly to [2]. The extension of this solar collector field is able to supply a significant percentage of a typical Spanish single family house requirements [1]. Experimental set-up is located at the UC3M in Madrid.

Although H_2O/BrLi systems show the best performance in absorption machines, single effect system has a thermal COP in the range of 0.5-0.73 [2]. This value is not competitive with conventional systems, so there has to be a minimum threshold of renewable energy supply for it to be worthwhile [3].

Local climate characteristics have a significant influence not only on collector's performance but on its energy requirements, thus, it is important to use local weather conditions in order to design the system and not to over/underestimate its thermal conversion efficiency. As solar irradiation varies considerably from year to year, a large variation in the solar collector heat supply has to be expected [4]. This reason gives relevance to a detailed study on a real installation during a representative time period of use. It is useful either for daily or seasonal periods. This study takes into account that the normalized operation parameters will change along their working life.

This paper sets out an experimental approach to domestic's system operation and performance. To do that, experimental operating parameters have

* Numbers between square brackets [] are relatives to the references listed at the end of the paper.

been collected; not only the inlet and outlet collectors, heat exchangers and storage tank instantaneous temperatures, but also absorption machine components ones have been recorded during 2004 summer time in periods of 10 minutes. Weather conditions like external wet and dry bulb temperatures, solar radiation, wind velocity and direction, are also averaged over 10 minutes intervals.

FACILITY DESCRIPTION

- **Overview**

The solar facility at *Universidad Carlos III de Madrid* has the same components of an ordinary solar installation, with the difference of the incorporation of an absorption machine for cold water production for AC purposes.

The facility consists of 20 *Vitosol 100* flat-plate solar thermal collectors by Viessman, each one having 2,5 m^2 collecting surface, making a total collection surface of 50 m^2. Water is pumped from collectors to two *Alfa Laval* plate heat exchangers in a closed loop, one heat exchanger being of 22 plates and the other one of 20 plates. The heat exchagers are needed because the water flowing inside collectors incorporates antifreeze fluid for winter operating purposes. In the other side of the heat exchangers the water pumped from the thermal storage tank (tank capacity of 2,000 liters) is heated and sent to the absorption machine as the energy input into the generator. This water then comes back to the thermal storage tank to be heated again. The absorption machine is a *Yazaki LiBr-H_2O* (WFC10 model) of 35 kW cooling capacity. The condensator and absorber of this machine are cooled by a cooling tower and the cold water produced at the evaporator of the absorption machine is pumped to a fan coil to have the desired final output of cool air.

Figure 1: Configuration of the Solar Facility at Universidad Carlos III de Madrid.[1]

The facility includes an independent meteorological station which records data from solar radiation, air temperature, wind velocity, relative humidity, etc. This information and the one gathered by the Solar Facility are used as input to an in-house developed data acquisition computer software (see Figure 2).

- **Monitoring and Instrumentation**

On both facilities, solar and meteorological, data have to be processed and recorded to become a functional facility. A data acquisition program developed using *Labview* serves for this purpose.

First, calibration of instruments has been performed (thermocouples, pressure sensors, flowmeters, etc.) to record reliable measurements. Data acquisition software takes all sensor signals every 2 seconds and calculates the mean value of these signals each 10 minutes. These mean values are the ones recorded and used for off-line calculations as experimental data. Then data are processed and results are obtained for each day of summer time.

Real time experimental data from facility are available “on line” at the following web site: http://pc-134-222.uc3m.es/solar.htm

- **Interesting Details**

Following preliminary researches, the thermal storage tank was configured to work under stratification regime, thinking that this would be the best for the application, but this was not the case. Hot water was enough to feed the generator of the absorption machine but the period of time achieved producing cold water was not satisfactory. Eliminating stratification, by forcing hot water to enter at the bottom of the tank, a nearly homogeneous temperature was achieved. This behavior has given best results for the AC application because a larger autonomous working-time was recorded. Nevertheless, a lower collector

[1] Numbers in the figure refers to components of the facility. 1-Solar Collectors, 2- Heat Exchangers, 3-Storage Tank, 4-Absorption Chiller, 5-Cooling Tower, 6-Fancoil

efficiency has been detected using this configuration.

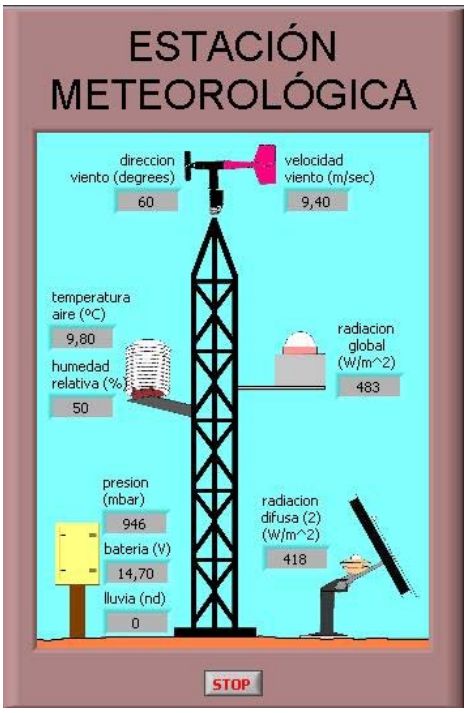

Figure 2: Meteorological Station at Universidad Carlos III de Madrid

Solar facility components at a glance (see Figure 1):

- 20 Vitosol 100 flat-plate collectors.
- 2 Alfa Laval plate heat exchangers.
- Thermal Storage Tank (2000 Liters).
- Cooling Tower.
- Yazaki 35 kW Absorption Chiller.
- 1 Fan coil.
- Pumps:
  - 1 (0.50 l / s)
  - 1 (0.68 l / s)
  - 1 (0.30 l / s)
  - 1 (0.46 l / s)

EXPERIMENTAL DATA RESULTS

Data gathered from the solar facility during the 2004 summer season are exposed to be compared with the house thermal load, evaluated in the next section. As an example, results corresponding to a typical day are shown in Figure 4.

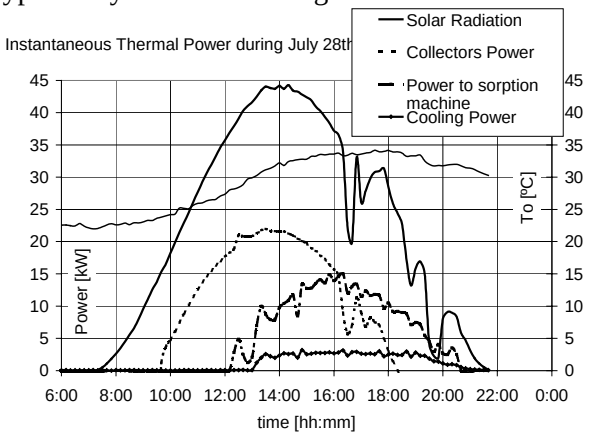

Figure 4: Instantaneous thermal power and ambient temperature corresponding to July 28th.

As it can be seen in Figure 4, due to the thermal storage tank effect, there is a delay between the collector's power and the cooling power curves. In the day shown, a significant cooling power value can be obtained for more than 2 hours in the afternoon, after the collector power is null (time between 18:00 h to 20:00 h). Accordingly to the observation of external air temperature curve, it can be concluded that this is an useful and necessary delay. During the operating period corresponding to the day shown, an averaged value of near 3 kW of cooling power has been obtained. Figures 5 to 7, show summer period (June 16th to October 14th) results. In Figures 5 and 6, daily values of total energy supplied and cooling period are shown. Summer period averaged cooling energy obtained was of 23 kWh per day; when the averaged period of useful daily cooling was of 6

hours and 30 minutes. During this time, the system was producing cooled air at a mean temperature of 15 ºC, using one fan-coil unit for this purpose.

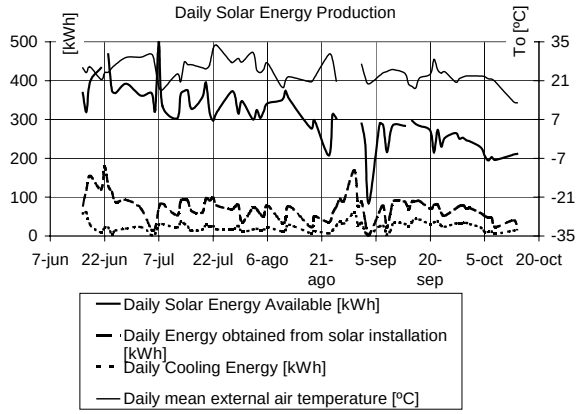

Figure 5: Daily Solar Energy Production during summer period of year 2004. Daily mean external air temperature is shown as a reference.

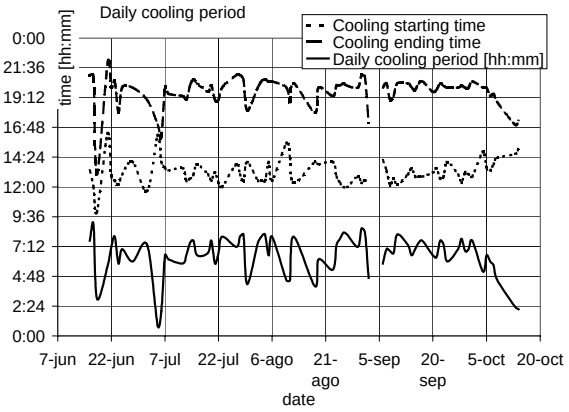

Figure 6: Daily cooling period during de summer period of year 2004.

In Figure 7, daily averaged efficiency parameters of cooling system, powered exclusively by solar energy, are shown. Definitions of those parameters are as follows:

$$COP = \frac{Q_{cool}}{Q_{panel}} \quad (1)$$

$$SCOP = \frac{Q_{cool}}{Q_{solar}} \quad (2)$$

Where:

$$Q_{cool} = \dot{m}_{cw} \cdot c_w \cdot \left(T_{icw} - T_{ocw}\right) \quad (3)$$

$$Q_{panel} = \dot{m}_{wp} \cdot c_w \cdot \left(T_{wpo} - T_{wpi}\right) \quad (4)$$

$$Q_{solar} = I \cdot A_p \quad (5)$$

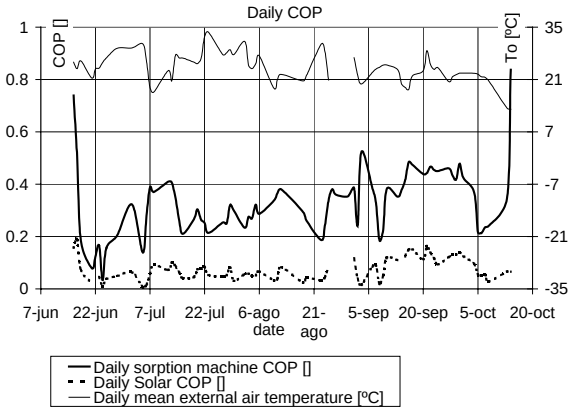

Figure 7: Daily averaged efficiency parameters of solar cooling system. Daily mean external air temperature is shown as a reference.

Averaged values of those parameters for summer time are 0,33 for *COP* and 0,07 for *SCOP*; when the averaged value of η_{si}, defined as follows, is of 0,224.

$$\eta_{si} = \frac{Q_{panel}}{Q_{solar}} \quad (6)$$

This parameter takes into account not only collector's efficiency (i.e. thermal losses in the collector itself) but also thermal losses in the solar facility (piping, pumps, thermal storage tank & heat exchangers).

THERMAL LOAD CALCULATIONS

In order to evaluate the application of solar cooling technology as previously described to a Spanish home air conditioning, its instantaneous thermal load has been calculated. That has been done using an environmental database available from UC3M meteorological installation .

House thermal load has been calculated taking into account the Spanish regulation [9] which gives an overall heat transfer coefficient U for each house wall, floor and roof.

The studied house is a single-family one, all construction element properties are well known: thickness and thermal resistances for conduction and convection and also solar radiation through the different four oriented walls, floor and roof. The latest one receives no solar radiation because of solar panels are installed there.

Regarding to thermal load calculation, it has been taken into account, radiation on wall surfaces,

accordingly to [8]. It is needed to define sunny wall temperature, different from air temperature.

$$Q_w = A_w \cdot U_w \cdot \left(T_a + \frac{\alpha \cdot I_w}{h_e} - T_{in} \right) \qquad (7)$$

where $T_a + \frac{\alpha \cdot I_w}{h_o}$ is the wall temperature under the sun radiation, and $\alpha = 0{,}6$ is the absorption wall coefficient.

The calculation process of external wall overall heat transfer coefficient is as follow:

$$U_w = \frac{1}{\frac{1}{h_e} + \sum_i \frac{e_i}{\lambda_i} + \frac{1}{h_i}} \qquad (8)$$

Repeating the process for every one of the house enclosure's walls, an overall heat transfer coefficient can be obtained for the enclosure; thus a total thermal load can be computed depending on the temperature difference ΔT:

$$Q = U \cdot A \cdot \Delta T \qquad (9)$$

Where:

$$\Delta T = T_{in} - T_a \qquad (10)$$

The calculated value for the overall house *UA* parameter was of 141 W/ºC.

The following environmental data are applied to the thermal load computation:

- Instantaneous Solar radiation on a tilted surface [W/m^2].
- Instantaneous external air temperature [ºC].
- Wind velocity [m/s] & direction.

Due to people living in the house, there are several additional thermal loads, such as, people sensitive and latent heat, about 100 W by person (4 people), thermal load from house lighting, internal air renovation (one renovation per hour), and infiltrations (considered as a 10% of total thermal load).

A constant, homogeneous indoor air temperature of 24ºC has been applied to thermal load calculations according to [10].

As an example, daily thermal load evolution, results corresponding to July 28th are shown in Figures 8 & 9.

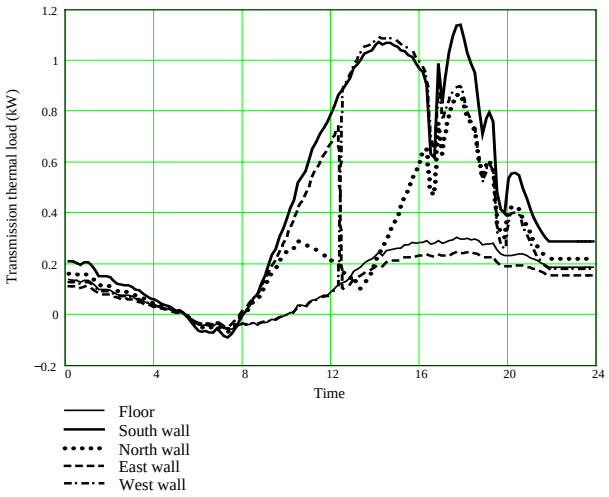

Figure 8: Instantaneous thermal load components of a single-family Spanish house corresponding to July 28th.

By integration of this instantaneous thermal load during the day, a daily thermal load has been obtained for each day of the season, giving the results shown in Figure 10.

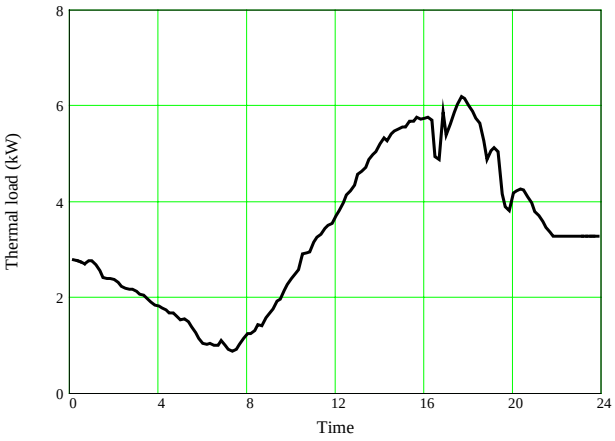

Figure 9: Total Instantaneous thermal load of a single-family Spanish house corresponding to July 28th.

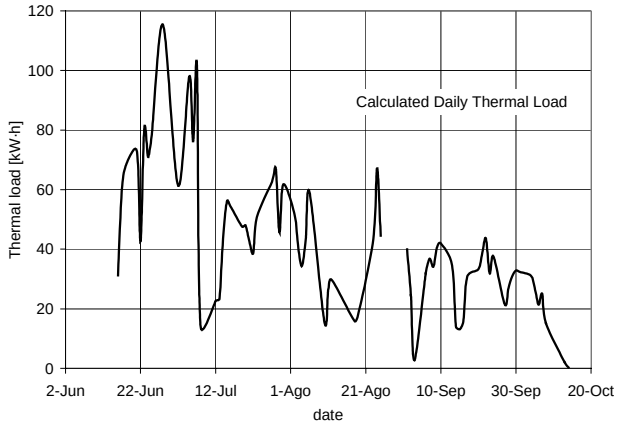

Figure 10: Daily thermal load of a single-family Spanish house corresponding to the summer season of 2004.

ECONOMIC AND ENVIRONMENTAL IMPACT

- **Economic Impact**

- Absorption chiller:

Data gathered for the study about the behaviour of the facility during summer 2004 shows that 53,6% of the total thermal load for the proposed house was delivered by renewable energy. This is 1398 kWh of the total 2938 kWh. Total thermal energy needed to supply the remaining load is 1947 kWh estimating a *COP* of 0,7 for the absorption chiller (when powered by a boiler supplying hot water at 90 ºC). Natural gas cost is estimated at 0,034 €/kWh, having a total expense of 66,20 €.

- Vapour-compression chiller:

Supplying the total thermal load with conventional vapour-compressor chiller, estimating an averaged COP of 2,4, electric energy needed reaches 1440 kWh. Total expense, estimating 0,13523 €/kWh, reaches 194,75 €.

Comparing vapour-compression chiller vs. absorption chiller, economic savings reaches 66%, i.e. 128,55 € for the totality of summer period.

- **Facility Cost**

Advantages on using equipment fed by renewable energy are noticeable. But reality is that this equipment is expensive. Nowadays, the main economical disadvantage of the facility is its initial amount. But in the future, overall costs can be lowered by means of mass production of facility components and integration. In addition to that, there are government incentives and subventions on using equipment that depends on renewable energies, and, still to come with the Kyoto agreement, savings on CO_2 emissions that can be estimated around 25 € per ton of CO_2 for the upcoming period of application 2008-2012. This is just an average between the current 6 €/t to the maximum estimated of 50 €/t for 2012.

To evaluate an estimated time of redemption for the facility, prices of main components are presented. Budget for the facility installed at UC3M is not applicable because this facility is an experimental prototype and some components are over engineered and in some cases oversized. Using gathered data, oversized components can be redesigned to the needs of a house, according to its thermal load. Another important aspect to take into account is that, to amortize the facility cost, it has to be functional around the year, not only during summer time. Because experimental data for domestic hot water and space heating are not yet available using the facility, time of redemption has to be calculated multiplying by a factor of 4/12, 4 month of summer time for the 12 month of the year. This period corresponds to that in which the air conditioning is working in a meteorologically typical Spanish summer.

Collectors	8.710 €
Heat Exchangers	500 €
Hot Water Storage Tank	2.000 €
Absorption Chiller 10kW	5.000 €
Cooling Tower	1.000 €
Fan-coil	200 €
Total	17.410 €

$$t_{pb} = \frac{17.410}{128,55}\left(\frac{4}{12}\right) = 45 years \qquad (11)$$

Resuming, facility cost reaches 17.410 € with an estimated redemption time (payback period) of 45 years, not applying any interest rates, inflation nor external subsidies for environmental protection.

- **Environmental Impact**

- Absorption chiller:

For summer 2004 total natural gas consumption to supply the remaining load would be of 125,9 kg. Estimating 0,22 kg CO_2/kWh for natural gas, total emissions, using renewable energy, reaches 428,41 kg of CO_2.

- Vapour-compression chiller:

Estimating in 0,6 kg of CO_2 by kWh of electric energy produced in the Spanish electric park during a representative year, CO_2 emission would be around 2.618,4 kg of CO_2 to supply the house thermal load.

Comparing vapour-compression chiller vs. absorption chiller, savings on natural gas consumption are of 45% and savings on CO_2 emissions are around 84% using renewable energy.

CONCLUSIONS

- An experimental facility with 50 m^2 of flat plate solar thermal collectors has been developed and fully monitored for cooling applications using absorption technologies.
- Facility has been working during 2004 summer period, producing a daily averaged cooling power of 3 kW for 6 hours and 30 minutes everyday.
- A lower value of *SCOP* has been obtained. New work has to be done in order to reduce facility thermal losses and to increase absorption cooling machine *COP*.
- Instantaneous thermal load of a single-family Spanish house has been calculated using local meteorological data. Results show that a 53,6% of summer air conditioning thermal load could be supplied by renewable source using 50 m^2 of flat plate solar thermal collectors and a 3 kW of cooling power absorption chiller.
- Thermal storage tank allows to adjust daily cooling period to the home air conditioning needs, especially later in the afternoon.
- Due to the high cost of several facility components as solar collectors and absorption chiller, the payback period for solar air conditioning applications has been estimated in 45 years.
- Compared with a conventional vapour – compression chiller, the system analyzed would provide a saving in CO_2 emissions of 84%, due to the use of a renewable energy source.

ACKNOWLEDGMENTS

This work has been partially funded by the Spanish government research grant M. C. y T. CLIMABCAR project DPI 2003-01567 & TRANSMACA project DPI 2002-02439. Their contribution is greatly appreciated.

RENEWABLE ENERGY IN BRAZIL

Mario Oscar Cencig*
Núcleo Interdisciplinar de Planejamento Energético (NIPE)
State University of Campinas (UNICAMP)
Campinas – São Paulo
Brazil

ABSTRACT

The Brazilian primary energy supply has a significant proportion of renewable energy (40.9 %). Brazilian Alcohol Program (PROALCOOL, started in 1975) is the major program on renewable energy in Brazil and the biggest ethanol program in the World. Growing programs: the Program for Renewable Energy – *PROINFA* (wind, biomass and small hydroelectric stations), the Probiodiesel Program (a blend of diesel with a vegetable oil), hydrogen as a fuel and fuel cells, Flex-Fuel Vehicles (with free mixing of gasoline and ethanol); also, about 22 MW from wind energy. Other issues: Brazil and the Kyoto Protocol; the Brazilian emissions of CO_2; projects concerning the Clean Development Mechanism (CDM).

THE BRAZILIAN ENERGY MATRIX

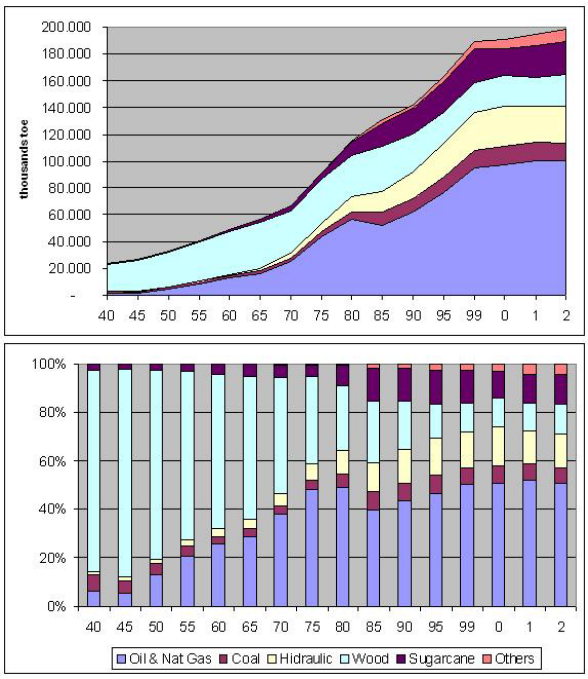

Figure 1: Brazilian energy matrix (1940-2002)

The Brazilian primary energy supply is shown for the period 1940-2002 (last data published, [1]) in the Figure 1.

It is clear the shift from biomass (wood) to oil, and an increase in hydro and sugarcane in the last 30 years. Looking in more detail, in the period 80-85 was verified an increase in renewable energies, followed by a decrease, until now. The actual situation is as Figure 2.

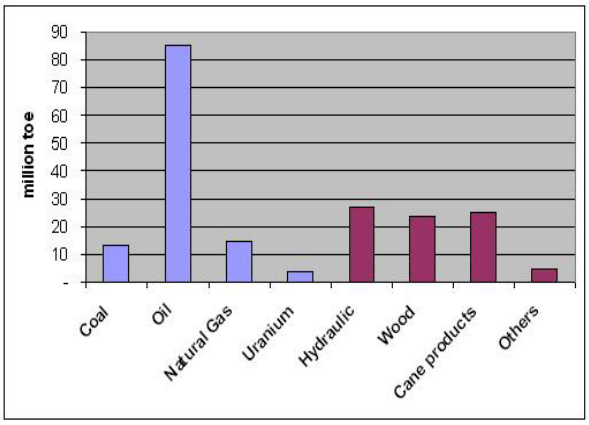

Figure 2: Brazilian primary energy supply (2002)

* Corresponding author: Phone / fax: +(55 19) 3289-3125 / 5499; e-mail: cencig@unicamp.br

The consumption (2002) was 197.9 million tons of oil equivalent, leading to 1.13 toe per capita, lower than world consumption that is about 1.65 toe per capita.
It is clear in Figure 2 the importance of renewable energy in the Brazilian case: a) non-renewable energy 59.1 % (oil 43.1 %, natural gas 7.5 %, coal 6.6 %, uranium 1.9 %), b) renewable energy 40.9 % (hydraulic 13.9 %, wood 11.9 %, products of cane 12.6 %, other 2.5 %).
Table 2 compares the Brazilian situation with selected data from the IEA data source for 2002.

	Brazil	Latin America	World	OEC countries	Non-OECD countries
Coal	6.6	4.5	23.0	20.8	26.3
Oil	43.1	47.6	35.8	40.8	28.3
Natural gas	7.5	18.8	20.9	21.3	21.0
Nuclear	1.9	1.2	6.8	11.2	2.0
Hydro	13.9	9.9	2.2	2.0	2.5
Renewable & waste	24.5	17.6	10.8	3.3	19.6
Geoth / solar / wind	2.5	0.4	0.5	0.7	0.3

Table 2: Selected IEA data [2] (in %)

Concerning the structure of electricity generation, Figure 3 shows the importance of hydro-electricity in Brazil (about 75 %), comparing with the world situation: hydraulic 17,1 %, oil 7,9 %, natural gas 17,4 %, nuclear 16,9 %, coal 39,1 %, others 1,6 %. This hydro power is mainly obtained from large plants, as for instance Itaipu, Xingó, Furnas, Ilha Solteira, between others.

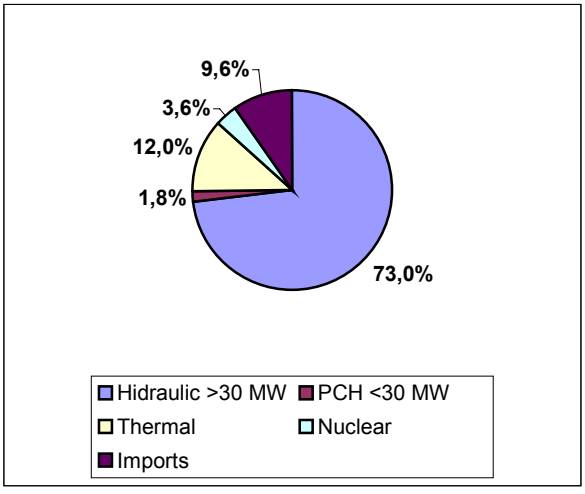

Figure 3: Electricity (Brazil, 2002)

RENEWABLE ENERGIES

Biomass programmes, ethanol and bagasse from sugarcane, biodiesel, (a blend of diesel with vegetal oil), wind power, solar and photovoltaics are at different stages of development in Brazil.

The Ethanol Program

The Brazilian Alcohol Program (PROALCOOL), started in 1975 is the major program on renewable energy in Brazil and the biggest ethanol program in the World [3], see Table 3.

Country	Million m^3
Brazil	12.50
USA	6.50
China	3.00
EU	2.00
India	1.70
Russia	1.30
Saudi Arábia	0.40
South África	0.38
Others	5.22
Total	**33.00**

Table 3: Ethanol world production (2000)

The raw sugar-cane production in Brazil was about 350 million tons in 2003 (in 5 million ha, productivity about 70 ton/ha). Production: sugar 24.82 million tons (2003/2004) and ethanol 14.28 x 10^9 liters (2003/2004). Export: sugar 14.0 million tons (2003/2004) and ethanol 1.120 x 10^9 liters (2003/2004). Figure 4 shows the situation [4].

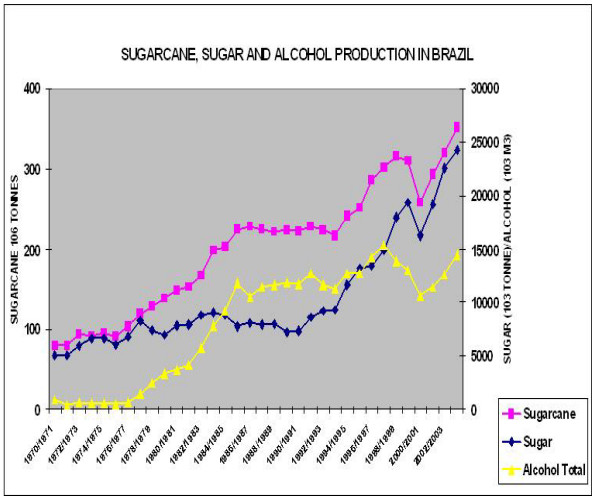

Figure 4: Sugarcane in Brazil

In Brazil, ethanol is used in one of two ways [5]:

- As octane enhancer in gasoline in the form of 22 % *anhydrous ethanol* at at 99.6 Gay-Lussac (GL) and 0.4 % water (a mixture called gasohol) or
- In neat-ethanol engines in the form of *hydrated ethanol* at 95.5 GL.

The structure of the Brazilian market of cars is shown in Figure 5.

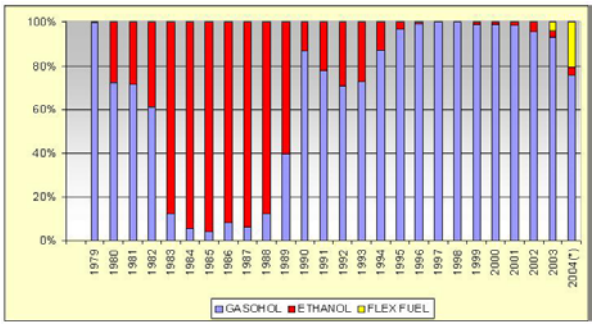

Figure 5: Sales of automobiles

Flex-Fuel Vehicles, with free mixing of gasoline and ethanol was started in March 2003. Four car makers: Fiat, Volkswagen, Ford, General Motors. Sales are growing: 11.444 units (2003), 55.346 units (January to march 2004). Figure 6 shows the actual situation for the market-share in Brazil [6].

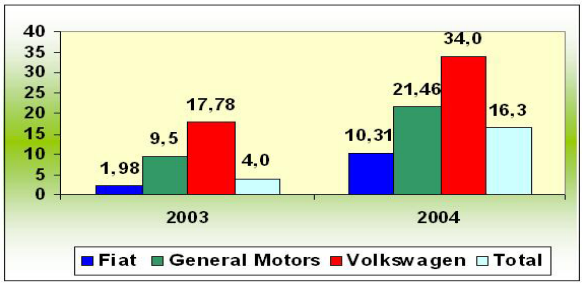

Figure 6: Flex fuel/ethanol vehicles sales (%)

A life cycle analysis of cane and ethanol production [7] show the following relationship for the energy balance: output (renewable energy) /input (non-renewable energy) = 8.3; also, there is a carbon sequestration highly significant.

The generation of electricity (cogeneration) with products of sugarcane industry (bagasse and black-liquor) is very important, the sugar and alcohol producers are auto sufficient, and the potential for fuel and electricity generation is very impressive (see Brazilian Biomass Reference Center – *CENBIO*).

The Biodiesel Program

There are several opportunities for replacing diesel fuel by vegetal oils, as is shown in Figure 7 [8]. For every region, was indicated the fuel consume (in %) and the species existent with possibilities for replacing diesel fuel.

Figure 7: Diesel fuel x vegetal oils

Nowadays, the Green Fuel Program (*Programa Combustível Verde*) expanded the concept to bio-fuel, including ethanol (PROALCOOL Program) and biodiesel (Probiodiesel Program, started October 2002), a blend of diesel with a vegetable oil, such as from soybeans, corn, *babaçu* and *dendê* palm nuts, castor beans and sugarcane. The latest program, conducted by the Ministry of Science and Technology (*Ministério da Ciência e Tecnologia – MCT*) has a target of 5% (v/v) biodiesel /conventional diesel.

The situation may be summarized as follow:

- Patent CENPES / Petrobrás (*Khalil, C.N. Processo de produção de biodiesel a partir de sementes de mamona, 2001*)
- Biodiesel plant at Charqueda (SP) looking for production 100 million liter/year
- Pilot plants at Bahia, Para, Paraná, Piauí and Natal
- University of São Paulo (Ribeirão Preto) is building the first biodiesel station of the country
- Tests are running with bus, automobiles Peugeot 206 and Xsara Picasso, truks Valtra and locomotives América Latina Logística (ALL).

Wind Energy

Brazil has a significant potential for wind energy, fundamentally at the coastal zones, research is running for a more precise determination (preliminary estimations are of 6,000 MW for the

northeast region). Figure 8 shows this potential [9].

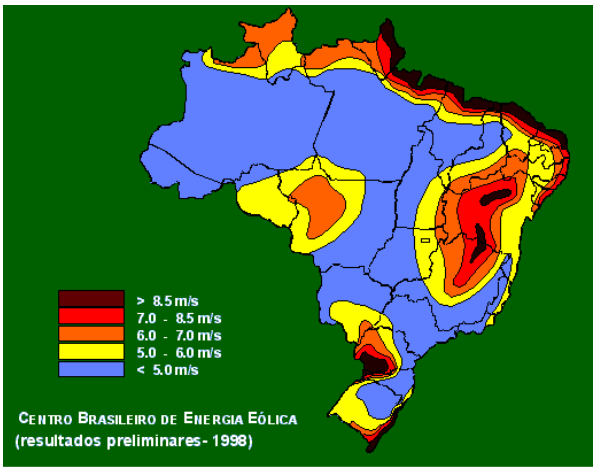

Figure 8: Brazilian wind potential

Presently, there is an electric generation (about 22 MW) at several places, in different technological stages. The most important include: Fernando de Noronha, in the State of Pernambuco, with 75 kW (started 1992); Morro do Carmelinho, with 1 MW (4 units), in the State of Minas Gerais (started 1994); Mucuripe (photo), with 2.4 MW (4 units), in the city of Fortaleza (started 1996); Palmas, with 2.5 MW (5 units) and 5,000 MWh/y, in the State of Paraná (started 1999); Taíba, with 5 MW (10 units) and 17.5 MWh/y and Prainha, with 10 MW (20 units) and 35,000 MWh/y, both in the State of Ceará (started 1999); Horizonte, with 4.8 MW, in the State of Santa Catarina (8 units, started 2003); Macau, with 1.8 MW (under construction, in the State of Rio Grande do Norte).

Figure 9: Brazilian wind projects

So, the utilization of the wind energy for electric generation purposes is more recent. The manufacturing processes are developed and there is a process of building up local capacity for manufacture. The relevant issues for expanding the wind utilization are market regulations, prices for the electricity, connection to the electric grid, so are necessary public (energy) policies for including this source in the national planning, financial questions involving financing agencies, government and private agents.

The Brazilian Wind Energy Center (*Centro Brasileiro de Energia Eólica – CBEE*) is the national reference for projects on wind energy.

Hydrogen and Fuel Cell Programs

Projects in Brazil with hydrogen as a fuel are in progress from middle of the 70´s: electrolysis of water, reforming with vapor of ethanol (from 80´s), biomass gasification (from end 90´s). The research with fuel cells (*Células a Combustível*) is more recent. In 2001 Sectorial Funds from the Science and Technology (MCT) and the Development, Industry and Trade (MDIC) Ministries and from private institutions UNICA, BALLARD, OMG and BASF for ethanol reform. In 2002, the MCT – CGEE Brazilian Fuel Cell Program (PBCaC). In 2004, the SOFC Brazilian network.

Automotive research includes the Vega, a prototype under test at the Brazilian Reference Center for Hydrogen Energy (*Centro Nacional de Referência em Energia do Hidrogênio – CENEH*), at UNICAMP.

Besides, AGRENER GD 2004 supported the organization of the 2nd International Workshop on Fuel Cells – 2nd WICaC, held on October 21st and 22nd. Although it is in its second edition, the 2nd WICaC is already the most important event about fuel cells and hydrogen in Latin America. It brought together more than 20 experts from all over the world to expose and debate the state of the art in research, development and demonstration (R&D&D) of fuel cell systems and hydrogen related technologies. Its public has reached 250 people from research centers, universities (professors and students), private companies and public organizations. In addition to the 20 conference papers, there were 15 oral presentations about the recent R&D&D activities in Brazil.

Some conclusions [10]: SOFC research in Brazil is still rather limited, about 70 people are engaged now in SOFC research; even though still limited, current skilled personnel and facilities are sufficient to head start the development of innovative solutions and bring about technological breakthroughs. Few papers are published in technological aspects, less than 70 papers in total including basic research. Even for more advanced research SOFC groups reproducibility and choice of new materials still remain a challenge.

Solar

Solar thermal has an interesting application to heating water for residential utilization. Figure 10 shows the consumption of electricity during a "typical" day at the State of São Paulo [11]; the peak of consume occurs around 7-8 pm, people take a bath and the water is mainly heated electrically.

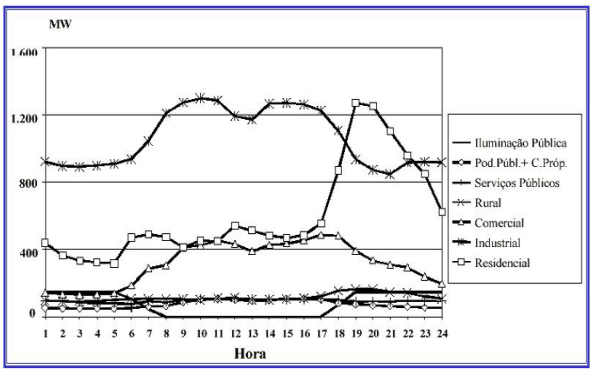

Figure 10: "Typical" day in São Paulo

There is not precise figures about the thermal utilization of solar energy, it is something like 2 million m^2 of solar collectors installed.
Concerning photovoltaic, there are thousands of units installed all over the country, basically at isolated communities (small manufacturers, schools, etc). Examples (Amazonian): Vila Campinas (124 houses), hybrid system (diesel – photovoltaic), 800 units of 64 Wp and 120 batteries; Ilha de Marajó, 10 kWp photovoltaic and 40 kW wind (hybrid system).

Brazilian Energy Policy

Several governmental programs are described. The National Electricity Conservation Program (*Programa para a Conservação de Energia Elétrica - PROCEL*) achieved savings of more than 10 TWh in electricity consumption (US$ 318 million in authorized investments between 1995 and 2000), for more details see Figure 11 [12].

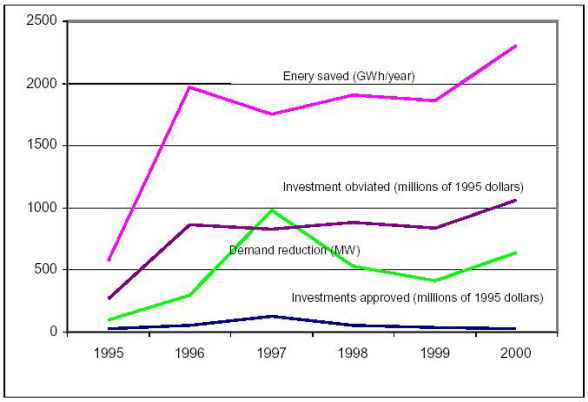

Figure 11: Performance of PROCEL

In Brazil, the PROCEL program was launched by the Federal Government in 1985 and has been run since 1991 by Eletrobrás, in coordination with the public-sector electricity companies. The current role of PROCEL is unclear.
Solar, thermal and photovoltaic are included in the Program for Energetic Development of States and Cities (*Programa para o Desenvolvimento Energético dos Estados e Municípios – PRODEEM*) from December 1994 at the Ministry of Energy (*Ministério das Minas e Energia – MME*). PCH-COM program for small hydroelectric stations (under 30 MW) is a specific program for energy policy. The Program of Incentives for Alternative Electricity Sources (*Programa de Incentivo às Fontes Alternativas de Energia Elétrica – PROINFA*) is the most recent and is a major step looking for the promotion of renewable energy sources. The potential generation for biomass is as follow: for the sugarcane sector 4,000 MW, paper and cellulose sector 1,000 MW, rise processing sector 300 MW. Two stages for the program: stage I, provides for 3,300 MW of renewable energy (wind, biomass and small hydroelectric stations) to be brought on stream before the end of 2007; stage II, once the target of 3,300 MW has been met, PROINFA will be developed with a view to increasing the share of electricity produced by the three renewable sources to 10 % of annual consumption, a target that is to be met within 20 years.

Presently, in Brazil, there are ten research centers (*Centros Nacionais de Referência em Energias Renováveis*) considered as national references for the different renewable sources that coordinate the R&D activities on renewable energies.
One general problem is the constraint on the programs by short-term priorities to the detriment of long-term priorities, as well as, the lack of national integration of different policies.

Environmental Issues

Concerning environmental issues, the Brazilian scenery has the following characteristics: Brazil is a ´Non-Annex I´ country of the Kyoto Protocol; the Brazilian emission of CO_2 (2002, estimated) is 1.7 tCO_2/tonne of oil equivalent, lower then world average, about 2.36 tCO_2/toe; about 70 % of the GHG emissions came from land use and deforestation, indicating the existence of negative questions related to the expansion of economic activities; introduction of fossil fuel-based thermoelectric power plants; several projects (ca 19 presently) concerning the Clean Development Mechanism (CDM) are under study (ranging from 95.5 to 172.5 MW, 53 million tCO_2eq for CO_2 and 38 million tCO_2eq for CH_4); also, among other initiatives, the MaB Program of Biosphere Reserves, conducted from 1993 by the Ministry of Environment (*Ministério do Meio Ambiente – MMA*) that includes the following biosphere reserves: Atlantic Rainforest (*Mata Atlântica*), Central Amazonian, *Cerrado*, *Caatinga*, *Pantanal*, the total extension of the five biosphere reserves is approximately 1.3 million km^2 (about 15 % of the territory), looking for sustainable development.
The current position of the Federal Government was explained by the Minister of Energy, Dilma Roussef, during the International Conference for Renewable Energy, which took place at Bonn (Germany, June 2004), representing the position of the Latin American and Caribbean Initiative for Sustainable Development (May 2002): a target (2010) of at least 10 % of total energy consumption with renewable energy.
The fundamental for this proposal - The Brazilian Energy Initiative – calls for expanded use of alternative sources (solar, wind, geothermal, tidal, "modern" biomass and small hydroelectric facilities), its goal is to rise the share of these sources in the total amount of world energy generated from 2.2 % today to 10 % by 2010.

COMPRESSED AIR ENERGY STORAGE (CAES) - POSSIBILITIES IN DENMARK

Brian Elmegaard[1], Nicklas Szameitat and Wiebke Brix
Technical University of Denmark
Department of Mechanical Engineering
2800 Lyngby
Denmark

ABSTRACT

Through a systematic development of the Danish electrical supply system with wind power and Combined Heat and Power, problems with stability and electricity surplus have appeared. Therefore, the possibilities for profitably implementing a CAES plant for energy storage, peak shaving and electricity surplus reduction are investigated. Based on existing plants and the latest technology a simulation model of a 360 MW plant with an efficiency of 35 % has been developed and optimized to Danish conditions. An analysis of the economics in the plant, operating under market conditions, shows a growing potential, but the allocated investment costs require investigation of more competitive operation. The regulating-power market could be a solution.
Keywords: Energy storage, compressed air, CAES, simulation, economic analysis.

NOMENCLATURE

W_T	Turbine work [MWh]
W_C	Compression work [MWh]
Q_{in}	Energy supplied in natural gas burner [MWh]
EP	Energy price [€/MWh]
η	Thermodynamic efficiency
$\dot{C}$	Cost rate [€/s]
$\dot{Z}$	Investment cost rate [€/s]
$\dot{E}$	Exergy flow [MJ/s]
c	Exergy unit cost [€/MJ]

INTRODUCTION

Compressed air energy storage, CAES, is a method for storing power using gas turbine technology. In principle the components are the same as in an ordinary Brayton-cycle gas turbine and the configuration is nearly the same. The difference is that the compression and expansion processes do not take place at the same time, which introduces the possibility to exploit diurnal variations in electricity prices. Air is compressed and stored in a cavern while electricity is cheap, and when the electricity prices rise, the stored air is heated and expanded through a turbine, which drives a generator to produce electricity.

Today two plants operating according to this principle exist worldwide, one in Huntorf, Germany, and one in Alabama, USA. A third plant is planned in Ohio, USA [4].

The storage cavern

Construction of a CAES plant requires suitable geological conditions for the construction of a storage cavern. Air storage caverns can be constructed in rock, limestone or salt domes. Denmark does not have rocks in the underground, but in Jutland salt domes can be found. These domes are today already used as sites for natural gas storage caverns.

ELECTRICAL SYSTEM IN DENMARK

The Danish electrical supply system is unique with its large percentage of wind power and combined heat and power (CHP) plants. In the western part of Denmark, which is electrically separated from the eastern part, the total installed electrical capacity is around 7500 MW. The amount of wind

[1] Corresponding author: Phone: +45 4525 4169 Fax: +45 4593 5215 E-mail:be@mek.dtu.dk

power today is around 2400 MW (30% of the total capacity). The installed combined heat and power capacity is furthermore around 1600 MW (20% of total capacity), which means that approximately 50% of the installed capacity in western Denmark is bound production (production rates are not dictated by the grid operators).

Over the last few years the occurrence of electricity surplus has become an increasing challenge. Electricity surplus happens, when the bound production exceeds the electricity consumption, and actions have to be taken, to protect the system against overload. Electricity surplus is separated in two branches: Exportable electricity surplus and critical electricity surplus.

Exportable means that surplus electricity can be exported through cable connections with Norway, Sweden and Germany. These cable connections have a total capacity of app. 2900 MW (38% of the total installed capacity).

Critical means that the electricity cannot be exported because of physical restrictions, and may lead to shutdown of CHP plants or wind turbines.

In 2001 The Danish Energy Agency established a commission to investigate the problems with electricity surplus and the different possibilities of reducing the difficulties in an electrical system with an increasing share of wind power and CHP [3]. The investigation predicted that the electricity surplus problems would be an increasing problem for the system stability in the near future since wind power and CHP are expanding and the export options are limited.

The commission suggested a series of initiatives that would contribute to the reduction of the electricity surplus, and a long term flexible electricity storage solution was one of the options. CAES is such a long term storage initiative.

Furthermore, if the initiative can be used profitably as a flexible component in addition to the electricity surplus reduction potential, the investment is beneficial.

If the starting point is that a CAES plant will be operating under market conditions, the driving force is price variations. Charge of the storage takes place when the price is low, and discharge when the price is high. An analysis of the price variations in today's deregulated market and a preparation of these prices to use for simulations are required. As basis the system price in Denmark from the last five years is used.

DESIGN OF A CAES PLANT

In order to develop an appropriate design for a CAES plant, operating under the conditions given by the Danish electricity market, different models have been proposed using the simulation tool DNA [10]. Both static and dynamic simulations and experience from existing plants are used during the design process. A component outline of the design is shown in Figure 1.

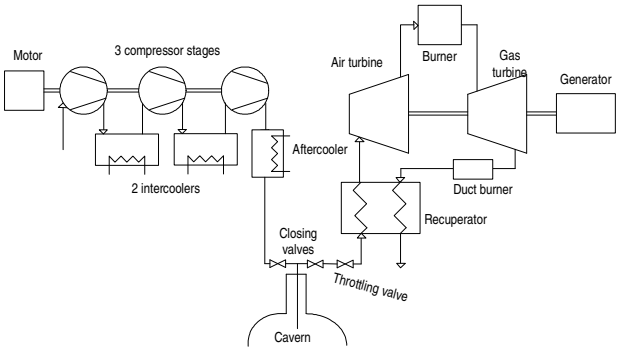

Figure 1: Component outline of the designed plant.

The three major branches, compression, storage and expansion are considered in the following.

The expansion train

The turbine required for expansion is a modified industrial gas turbine, where no compressor is needed since the compressor train has its own power shaft. Alstom Power produces such a modified gas turbine, the ET11 NM [2], and the design of the expansion train is based on the use of this turbine. The mass flow rate in the turbine is 400 kg/s, which corresponds to a power production of 360 MW.

The total expansion process is composed of the following processes: Air leaving the cavern is throttled to 56 bar to ensure constant turbine inlet conditions. Afterwards the air is heated in a regenerator and at a temperature of 550°C the air enters an air turbine, where it is expanded to 13,7 bar. In the combustion chamber natural gas is injected and ignited. The temperature is raised to 1027°C and afterwards the flue gas is expanded to atmospheric pressure. At atmospheric pressure the flue gas is reheated in a duct burner to ensure the turbine inlet temperature for the air turbine reaches 550°C in the recuperator. A T-s diagram of the expansion process is shown in Figure 2.

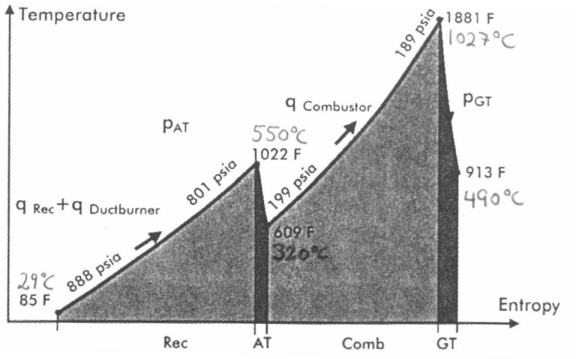

Figure 2: T-s diagram of the expansion process in the ET11 NM turbine [2].

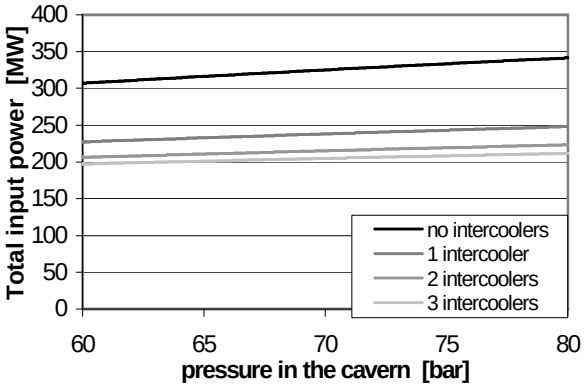

Figure 3: Power input to compressors with different numbers of intercoolers.

Pressure level in the cavern

The pressure level in the storage is an important parameter considering the thermodynamic efficiency of the plant. For gas turbines in general a large pressure ratio ensures a high thermodynamic efficiency, but since the entrance temperature into the cavern in salty environment is restricted to 35°C, an increased pressure ratio also would result in a raised heat loss in the aftercooler.

Considering a balance between efficiency improvements due to raised pressure and efficiency drop due to increased heat loss in the aftercooler at high pressure in the cavern, together with an estimate of the amount of energy, which needs to be stored, the optimal working pressure in the cavern is estimated to be 60-80 bar. Under normal operating conditions the plant will compress air up to a pressure of 80 bar in the cavern, and a full discharge of the cavern will reduce the pressure to 60 bar. To guarantee a greater flexibility the storage should be designed to be able to allow a maximum pressure of 85 bar. The depth of the cavern is chosen according to these pressure requirements.

The compression train

The compression is carried out by axial compressors. Air is compressed from atmospheric pressure to cavern pressure, which means that the compressor has to work against a varying pressure in the cavern and the power input increases during compression.

To reduce the power input to the compressor a number of intercoolers are inserted in the compressor train. Simulations of the compression with different numbers of intercoolers are carried out, and the needed power input is shown in Figure 3.

The design with two intercoolers has been chosen. The pressure ratio over each of the compressor stages varies between 3.9 and 4.3. A lower pressure ratio would not be profitable for the compressors. An additional third intercooler would not be worth the investment, taking into account the relatively low input reduction, which could be achieved.

Dimensioning

By using the ET11 NM the mass flow rate and power production is fixed to 400kg/s, 360MW for the expansion process, which is expected to be a suitable power output regarding peak-load periods in the Danish electricity system.

Running the compression with a mass flow rate of 400kg/s results in equally long compression and expansion periods. The input power for a compressor train working between 60 and 80 bar varies from 207 MW to 223 MW with an average of 216 MW as seen in Figure 3.

Taking into consideration that the plant is meant to reduce electricity surplus, a possible compression time of 10 hours would be appropriate regarding the predicted electricity surplus in the next 10 years, according to The Danish Energy Authority [3]

Dynamic simulations of the compression process running 10 hours with a mass flow rate of 400 kg/s and raising the pressure from 60 to 80 bar show that a storage capacity of 700,000 m^3 is required to suit the mentioned conditions. These simulations account for part load of the compressors and heat loss from the compressed air to cavern surroundings.

Compressing to the maximum cavern pressure of 85 bar would give the possibility to compress for

12 hours and 40 minutes. In Table 1 the optimal dimensions of the plant are listed.

Storage volume	700,000 m^3
Mass flow, compression	400 kg/s
Mass flow, expansion	400 kg/s
Power input to compressor	216 MW (avg.)
Power output from turbines	360 MW
Natural gas consumption (LHV)	416 MJ/s
Compression time	10 hours
Expansion time	9.2 hours

Table 1: Dimensions for CAES power plant in Denmark.

Operating the plant

Under normal operating conditions the plant is designed to run 10 hours of compression followed by 10 hours of expansion, with a little extra margin if necessary. In reality the plant will operate when it is economically advantageous. In Figure 4 simulation results of pressure and temperature variations in the storage cavern during a total charge/discharge period are shown. Due to a heat loss from the cavern the discharge period will be a little shorter than the charge period. Figure 5 shows the power input and output as well as the natural gas consumption.

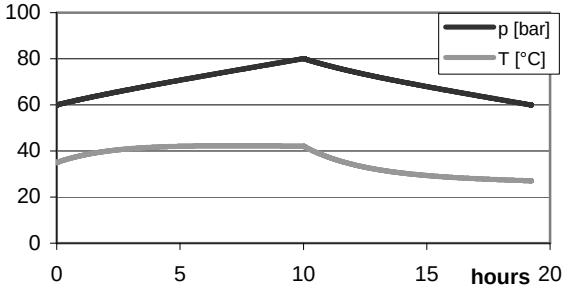

Figure 4: Pressure and temperature developments during an operating period consisting of 10 hours compression and 9.2 hours expansion.

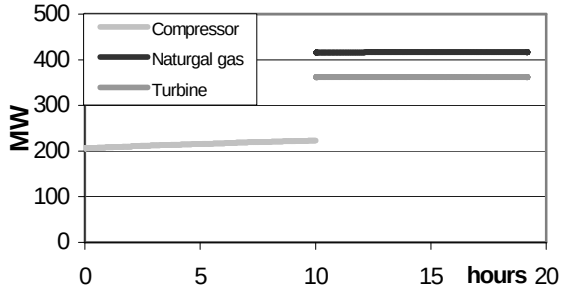

Figure 5: Compressor power input, turbine power output and natural gas consumption during a total charge/discharge period.

Thermodynamic efficiency

The efficiency of a CAES plant can be defined in different ways. The normal thermodynamic efficiency for a gas turbine process is defined by

$$\eta = \frac{W_T - W_C}{Q_{in}}. \quad (1)$$

Calculating the efficiency according to (1), where the power input and output and the natural gas energy supply is summarized over time, an efficiency of $\eta = 35.1\%$ is obtained.

Compared to this a gas turbine working under the same conditions, but without aftercooler and storage, has a thermodynamic efficiency of $\eta = 38.9\%$, this decrease in efficiency in the CAES plant occurs mainly because of heat loss in the aftercooler.

Another way of defining the efficiency for the CAES plant is based on the fact that the power used to compress is produced somewhere else, lets say in a CHP plant, which has an efficiency of 35%. The efficiency of the CAES plant can then be defined as

$$\eta_e = \frac{W_T}{Q_{in} + \frac{W_C}{0.35}} \quad (2)$$

Calculated for the designed CAES plant this efficiency is $\eta_e = 35.1\%$.

Compared to simulations of the existing plants the efficiency is increased significantly, mainly due to changes in the design and higher turbine inlet temperatures. For the Huntorf plant, which runs without recuperator, an efficiency of $\eta = 10.7$ % is found, and for the Alabama plant simulations give an efficiency of $\eta = 28.8$ %.

An exergy analysis of the system shows that exergy losses mainly occur in the burners, as expected for a gas turbine. The burner in front of the gas turbine accounts for 44 % of all losses, while the rest of the losses are quite equally distributed in the other components. The loss in the cavern with aftercooler and throttling valve accounts for 12,4% of the total losses. This is an additional loss for a CAES plant compared to a conventional gas turbine.

ALTERNATIVE DESIGNS

HP gas turbine instead of air turbine

Instead of placing a duct burner after the gas turbine in front of the recuperator a high-pressure burner could be placed in front of the first turbine,

as it is done in existing plants in Huntorf and Alabama. This would give a higher efficiency because the burner would not have to compensate for losses in the recuperator. Simulations show efficiencies of η = 36.3% and η_e = 35.5% using a high-pressure burner instead of the atmosphere-pressure duct burner.
Although a slightly better efficiency can be obtained using the high-pressure burner, the duct burner is to prefer, since NOx emissions are reduced significantly [4]. Also a high-pressure burner could require extra equipment to compress natural gas.

Throttling after the cavern
In the designed CAES plant the air exiting from the cavern is throttled, to ensure constant turbine inlet conditions. A throttling is accompanied by an exergy loss, therefore an investigation of a system working without throttle valve has been made. The varying turbine inlet temperature results in a varying mass flow and therefore a varying turbine power. The expansion time is extended to 11 hours, because of the lower mass flow.
The efficiency is 3% higher than the efficiency of the original design, but the varying turbine output is a disadvantage. Furthermore it is economically profitable to produce as much power as possible while the electricity prices are high, and this makes a throttle valve an advantage.

Higher turbine inlet temperatures
In the CAES-model the turbine inlet temperatures are 550°C and 1030°C. These temperatures are the most important parameters influencing the efficiency, and usually material properties set a limit for the maximum temperature. If both turbine inlet temperatures are raised by 20% to 660°C and 1236°C the efficiency is η = 41.8%, which is 20% higher than the original design. Higher temperatures also result in a higher turbine power output (242 MW) and higher natural gas consumption (494 MJ/s), but the ET11 NM turbine could not be used.

ECONOMIC ANALYSIS OF THE CAES PLANT

In order to evaluate the potential of the CAES concept in Denmark an analysis of the economics of the plant based on simulations with the designed model has been done. The charging and discharging intervals will at market conditions be based on the price variations of electricity. Which intervals are profitable will be investigated in the following.
On The Nordic Power Exchange – Nordpool – electrical power is traded and prices are determined for each hour of the day. The prices are fixed a day before production, and it is possible to plan the daily operation of the CAES plant based on these prices. It is assumed that the plant can start and stop quickly, so that charging or discharging can be scheduled for each hour. The electricity surplus situations are in this study assumed to be contained in the system prices.
The plant should be operating as long as it is profitable, and for simplicity the cavern has the same pressure at the end of each day. Since the mass flows in and out are equal, 12 hours of compression and 12 hours of expansion are possible on a daily basis. Each expansion hour and corresponding compression hour must respond in a positive profit contribution. Otherwise the plant has to be shut down. The equation looks like this:
Profit contribution =
$W_T \cdot EP_{HIGH} - Q_{in} \cdot EP_{GAS} - W_C \cdot EP_{LOW}$

With this method every hour in the day is arranged after price level. Then the most expensive hour is paired with the cheapest hour and the profit contribution for these two is calculated and so on. Pairs of hours with negative profit contribution mean that the plant is not in operation.
This method has been implemented in MatLab, and with input prices from the last four years, daily, monthly and annual profit contributions are calculated as well as an operating plan is worked out.
As an example the working plan for a week is shown in Figure 6. A natural gas price of app. 18€/MWh is likely in Denmark [7]

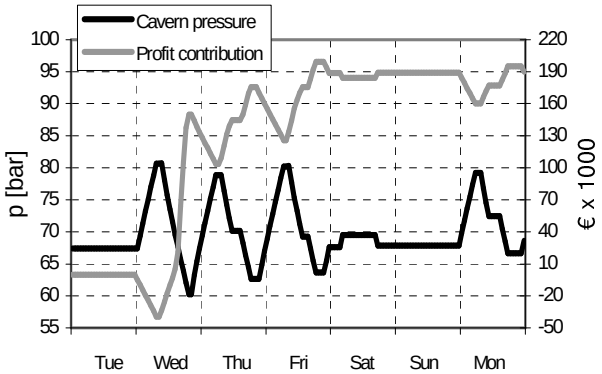

Figure 6: Seven days working plan example. Pressure and profit contribution is shown.

In this example it is seen that every day of operation leads to an increase in profit contribution. A summary of the number of operating hours over the four whole years is seen in Table 2.

Year	Production hours	Production hours /operating days
2000	49	3,5
2001	152	4,2
2002	460	8,4
2003	483	5,5
2004	27	2,3

Table 2: Number of hours with expansion with positive profit contribution.

The CAES plant can be seen as a gas turbine as well, and it is a fact that high level electricity prices make operation more profitable. A critical price that allows simultaneous compression and expansion as a normal gas turbine can be calculated from a given natural gas price. A gas price of 18€/MWh gives a critical electricity price of 52 €/MWh. Consequently, an electricity price at a general high level makes CAES very profitable. The option of operating the plant as a gas turbine also means that there should be no loss in the aftercooler. On the other hand the economics of the plant is very sensitive to variations in gas price. Regarding the system in the long term the development of the gas prices has to be considered.
For a complete evaluation of the plant knowledge of prices of the components and installation is necessary. The nature of the project is a design situation, which makes such prices hard to estimate, and furthermore only two plants of this type exist in the world.
Based on personal communication we present following price estimates:

Compression = 53 mio. € [8]
Expansion = 101 mio. € [8]
Cavern = 30 mio. € [7]
Total = 184 mio. €

These investment costs are to be paid off, and we expect that a lifetime of 20 years and an interest rate of 4% are realistic. This gives an annual payment of app. 13 Mio. Euro, which has to be subtracted from the annual profit contribution from operating the plant. The annual payment is linearly dependent on the investment cost.

The annual results from the historical prices are given in Figure 7. Maintenance costs are not included.

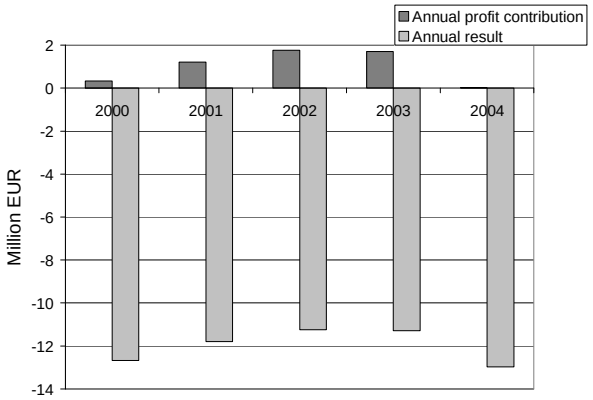

Figure 7: Annual profit contribution and result. Natural gas price is 18 €/MWh [7].

As can be seen from Figure 7 with the given prices, investing in a CAES plant and operating it on a daily basis with the system prices as the driving potential is not profitable. Even considering that installation costs are very uncertain, the profit contributions are just too small to support the high investment.

For the CAES principle to become a profitable business, other factors than operation based on the system price will have to be considered.
1) Since the CAES plant is a very flexible component in the electrical supply system, it can act as backup during power blackouts and help stabilize the grid during both surplus and demand situations.
2) There may be a subsidy to power plants, which stand by with regulating power for the grid. This is another option that has to be considered.
3) If the owners of the CAES plant are power plant companies, CAES could supplement the base load plants, and compensate for expensive regulations of the power plant.

Exergy considerations
A relationship between electricity price and operating hours can be investigated using a thermoeconomic approach. This is a more general method than using historical price data.
For each component in a system cost rates must balance [6].

$$\sum_e \dot{C}_e + \dot{C}_W = \sum_i \dot{C}_i + \dot{C}_Q + \dot{Z} \qquad (3)$$

The cost rates associated with exergy streams are calculated: $\dot{C} = \dot{E} \cdot c$

The components in the system are grouped after information about prices, and the three groups are: Compression, Cavern and Expansion. Equation (3) is applied to each group and the system of equations solved for the whole system.
With this approach it is necessary to give the investment costs as €/s, and the operating time is therefore an input. The investment is still considered to last for 20 years. The required electricity price during expansion can then be calculated with a gas price of 18 €/MWh. The compression electricity price chosen for the calculations is 21,6 €/MWh based on an average from the profit contribution calculations for 2001. For 3 compression and 3 expansion hours the cost rates through the system are seen in Figure 8. It is seen that the necessary electricity price for expansion is 7 €/s which corresponds to 69 €/MWh.

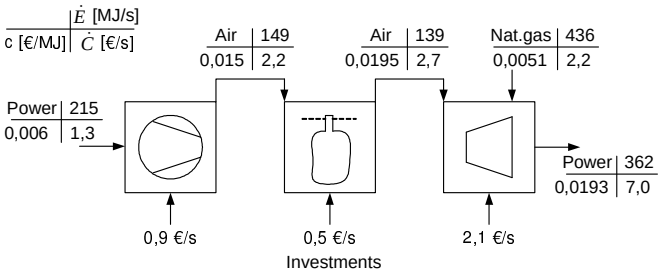

Figure 8: Cost rates in the CAES plant. Exergy streams without cost are neglected.

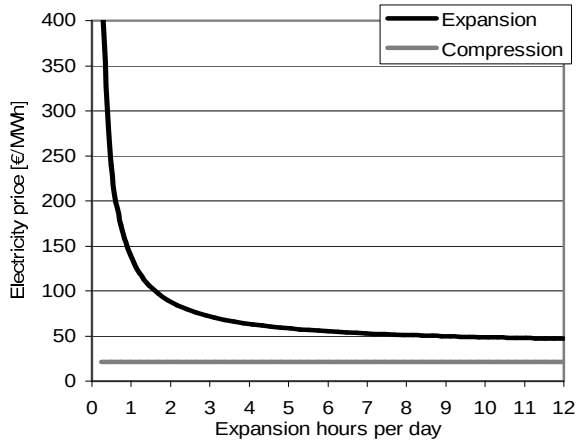

Figure 9: Required expansion price for profitable operation depending on number of operating hours.

As the investment cost rates [€/s] are highly dependent on the operating time, the important results of the thermoeconomic analysis are given as a function of this time as seen in Figure 9. A large number of operating hours is desirable to keep the needed price difference between compression and expansion electricity prices down. This requires a compromise between the needed electricity price and the number of operating hours.

PRELIMENARY ANALYSIS OF RESERVE MARKET OPERATION

If the CAES plant is operated in the reserve power market preliminary calculations show that a significantly higher annual income would be possible. The Nordpool reserve power market and production is divided into two: manual/voluntary reserve and automatic reserve.
In the automatic reserve market the plant operators obtain three income contributions. The monetary values are based on tenders of the last three quarters of 2004 [11]:
The contributions are:
Availability (annually): 8.5 mio € for 100 MW
Upward regulation: 53 €/MWh
Downward regulation: 10 €/MWh

One plant may at most contribute with 50 MW for automatic and 50 MW for manual regulation. The manual reserve market contributes about 3000 €/MW/month and plants operates at an increased power price for produced power and a decreased price for consumed power.
Only data for the reserve power market of May and June 2004 are available [9]. It is assumed that the size of the storage cavern does not give any limitations during up and down regulations, and the pressure in the cavern will be balanced when needed.
Based on calculations of the air standard cycle it is assumed that 50% of the output power comes from pressurized air and the rest is generated by the natural gas.
Based on data from May and June 2004 the annual income for automatic and manual regulation including income for availability is calculated:

Automatic regulation	14.2 mio €
Manual regulation	21.7 mio €
Total income	35.9 mio €

It seems that a CAES plant may be profitable if operated as a regulating power plant. However, it is a condition for this that the plant is able to operate under the very strong requirements for startup and load changes prescribed by Eltra.

DISCUSSION

The idea of storing power is a relevant subject in Denmark, especially because of the relatively high part of the electricity produced by wind turbines. As Denmark does not have any rivers or mountains, CAES is a solution, which is possible with existing technology.

The economical analysis shows that the development of the electricity and natural gas markets have great influence on the economical situation of a CAES plant. Based on prices from the last four years a positive profit contribution is seen for 2000-2004, but the high investment costs result in negative annual outcome. The economical analysis has been carried out from the assumption that the plant has to operate under normal market conditions, but other possibilities could exist. Letting the CAES plant operate in the regulating power market seems much more promising than operating under market conditions, but this option should be investigated further.

CONCLUSION

The possibilities of designing and operating a large scale Compressed Air Energy Storage plant for peak load support and reduction of electricity surplus in Denmark has been investigated.

A dynamic simulation model of the CAES plant has been developed, and optimization and adjustment to Danish conditions has resulted in a simulation model, which has a thermodynamic efficiency of 35,1%, can produce 360 MW of electricity during expansion, and consume 210 MW during compression. A corresponding gas turbine of the same size without the storage cavern has a thermodynamic efficiency of 38,9%.

The thermodynamic analysis is supplemented by an economic estimation of the plant as a component on market conditions in the Danish power supply. The conditions are based on the electricity price from the last four years and the estimated cost of a plant with an underground cavern. It is concluded that in Denmark this plant does not represent a profitable investment yet. The main reasons are that the investment costs are very high, and the plant is quite sensitive to natural gas price fluctuations.

If the electricity surplus increases as predicted by The Danish Energy Agency [3] it is possible that CAES can become a profitable solution in the deregulated market. On the other hand preliminary calculations show that the market for regulating power may be a more profitable alternative.

ABSTRACT

In this work, a possible way for partial CO_2 emissions reduction from gas turbine exhausts by linking with biomass gasification was investigated. The basic principle is the recirculation of a fraction of the exhausts (still rich in oxygen) to a gasifier, in order to have the production of a syngas to be mixed with natural gas fuel. As biomass is a CO_2 neutral fuel, the fraction of natural gas replaced with it is a measure of the CO_2 removal potential of the system.
Two solutions were investigated, the first of which only considers the gasifier, whilst the second one inquires the possibility of adding a pyrolyzer upstream the gasifier, in order to exploit the heat release of the exhausts for biomass pyrolisis to char, which is subsequently sent to the gasification section.
The produced syngas is thus sent to the cold cleaning system, recompressed and mixed with natural gas fuel. Due to the low calorific value of syngas, only a relatively reduced fraction of it should be mixed with natural gas. Encouraging results were obtained within the 10 – 30% range, with the same levels of CO_2 removal. The calculations on a target 10 MWe GT model showed only a modest reduction in efficiency, at the price of almost null modifications in machine design, which might make the solution attractive for powerplant management when carbon tax will be introduced, allowing to save 10 to 30% of energy production taxes, as well as the access to green certificates.

NOMENCLATURE

α	Moles of H per mole of biomass
β	Moles of O per mole of biomass
η_{GT}	GT efficiency
C_{tax}	Carbon tax per ton of CO_2 emission
ER	Equivalence ratio
f	Fraction of exhausts recirculated to the gasifier
F_{ren}	Fraction of syngas fuel replacing natural gas
H_P	Total energy of products
H_R	Total energy of reactants
LHV	Lower heating value
LHV_{pyr}	Lower heating value of pyrolysis gas
LHV_{syn}	Lower heating value of syngas
m_{bio}	Biomass flowrate
m_{char}	Mass flow of pyrolysis produced char
m_{pyr}	Mass flow of pyrolysis gas
m_{syn}	Syngas flowrate
PBT	Payback time
Q	Heat added or released to gasifier
R	Powerplant size scale coefficient
R_{save}	Ratio between the yearly savings due to carbon tax and that due to reduced fuel price
R_{vol}	Ratio between inlet turbine volumetric flow of gasifier integrated GT and standard GT
T_0	Reference temperature

T_g	Gasification temperature
T_{in}	Gasifier inlet temperature
T_{inpyr}	Temperature at pyrolyzer inlet
T_{outpyr}	Temperature at pyrolyzer outlet
W_{csyn}	Power demand for syngas fuel recompression

INTRODUCTION

The Kyoto Protocol subscription leaded many countries to study and propose systems and techniques for CO_2 capture and sequestration from powerplants. The major of these studies investigates in the field of very large amounts of CO_2 emissions capture (more than 80%), by applying pre or post combustion technologies [1 – 10]. Anyway, the proposed solutions often imply relevant changes in existing turbomachinery equipment, which are highly expensive and generally discourage the electricity providers in taking some measures against the growing CO_2 emissions [10]. Even the cheapest solutions, aimed to limit the existing equipment modifications (i.e. semi closed gas turbine cycles SCGT), have shown increases in the cost of electricity around 60 – 70% compared to traditional layouts with no CO_2 removal [12, 13]. Further unknowns related to costs of transportation and storage of liquid compressed CO_2 and the related environmental safety made application of CO_2 capture systems unattended [14].

It is well known that renewable fuels are globally zero CO_2 emissions to the environment, thus they might be an interesting approach to the greenhouse trouble. On the other hand, their extensive application to existing powerplants often involves deep and expensive modifications to current technologies. The most mature are those involving IGCC, which are not excessively complex to be converted to biomass fuels, even if they are applicable in the field of large power generation.

The upcoming 2006 EU carbon tax should encourage all Member States to do substantial investments in the direction of CO_2 abatement. In this way, systems with even partial CO_2 emissions reduction potential (15 to 50%) might lead to a consistent reduction in electricity production costs and encourage companies to introduce some measures to tackle CO_2 production. The partial integration of biomass fuels with natural gas may lead to the reduction of CO_2 emissions by the same proportion. Moreover, if the integration is not so high, reduced off design problems on existing turbomachinery equipment may be achieved and limited additional costs would be expectable. The present proposal deals with the possibility of an "internal" capture of CO_2 emissions, by integrating biomass fuel with natural gas fuel to a current production gas turbine: a small fraction of the exhausts, typically reach in fresh air, is recycled as the oxidizer of a gasification process, which should produce the amount of gas to replace the saved fraction of natural gas.

DESCRIPTION OF THE POWER CYCLE

The basic scheme of the proposed power cycle is shown on figure 1: The turbine exhaust gas is partially recirculated into the gasifier, in order to produce a syngas to be mixed with natural gas fuel, in a proportion which is closely related to the fraction of replaced natural gas, thus, finally, to the removed CO_2. Two options have proposed here: the first one only considers the gasifier, whereas in the second one a pyrolyzer upstream the gasifier is added (dotted lines on figure 1). The pyrolyzer takes a fraction of the exhausts heat content to do the initial pyrolysis of the entering biomass, producing char and mean LHV pyrolysis syngas. Successively, the char is sent to the downstream gasifier, where the final syngas is produced, cleaned and mixed with the pyrolysis gas, thus recompressed into the GT combustor.

Without entailed CO_2 removal systems, the saved CO_2 emission with respect to a standard turbogas corresponds to that which would be emitted by the primary replaced natural gas amount. In fact, the energy production from renewables like biomass, leads to globally zero CO_2 emission to the environment. The addiction of a downstream CO_2 removal system might further increase the biogas production (by the re-injection of a fraction of pure CO_2 into the gasifier in order to enhance

Bouduard reaction) and favour a higher CO_2 abatement, but it has not been investigated here.
The analysis was carried out referring to a biogas/natural gas integration ranging from 10 to 50%. The upper limit is very hard to exceed due to the extremely low syngas heat value, so that the gas turbine would undergo serious off design problems.

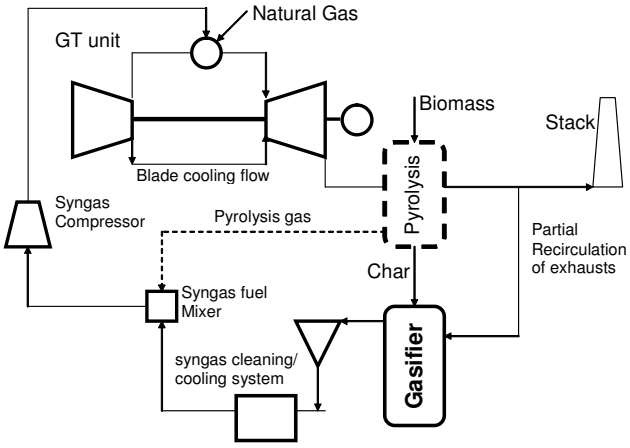

Figure 1 – Basic power cycle scheme

MODELLING GASIFIER AND POWERPLANT

Two different modules, developed with EES software, modelled the gasifier and the whole powerplant:

1 – ***gasifier/pyrolyzer***, which follows a chemical equilibrium approach for the evaluation of syngas composition, once the inlet biomass, oxidant/reducer composition and equivalence ratio (ER) are fixed. The general chemical equation, referred to one mole of biomass, is the following:

$$CH_\alpha O_\beta + a(O_2 + \frac{79}{21}N_2) + bH_2O + cCO_2 \Rightarrow$$
$$\Rightarrow n_1O_2 + n_2N_2 + n_3CO_2 + n_4CO + n_5H_2O + \quad (1)$$
$$+ n_6H_2 + n_7OH + n_8NO + n_9NO_2 + n_{10}CH_4$$

Where $CH_\alpha O_\beta$ is the chemical composition of the biomass, resulting from the ultimate analysis.
Two calculation approaches may be followed:

- Adiabatic, by fixing ER and calculating the outlet syngas equilibrium temperature T_g and composition, which follows the energy balance:
  $$H_R = H_P + Q$$
  Where H_R and H_P are the total energies of reactants and products respectively at the related temperatures, defined as:

$$H_R = LHV_{CH\alpha O\beta} + a\int_{T_0}^{T_{in}} cp_{O2}dT + \frac{79}{21}a\int_{T_0}^{T_{in}} cp_{N2}dT \quad (2)$$

$$H_P = \sum_i (n_i \int_{T_0}^{Tg} cp_i dT) + n_4 LHV_{co} + n_6 LHV_{H_2} + \quad (3)$$
$$+ n_{10} LHV_C + n_{11} LHV_{CH_4}$$

  Where LHV are the lower heating values of the combustible species; Q is the heat needed or released by the gasification process, which is set to zero in the adiabatic process.
- With fixed gasification temperature T_g and ER, by the same heat balance, determining the heat Q to be released/provided from/to the gasifier.

The number of moles of products n_1, …, n_{10} of eq. (1) is found by minimizing the Gibbs' free energy. The pyrolysis was modelled by the same module, with the addition of a semi empirical model, which is able to predict the gas composition and char production, as functions of the inlet biomass composition and the temperature of pyrolyzer.

2 – ***Gas Turbine (GT)***, which is modelled by the means of a well tested software developed at Energy Engineering Dept. of Florence (Fiaschi and Lombardi, 2001, Fiaschi and Tapinassi, 2003) with EES software, including the blade cooling.

The two modules are joined together in two different sections:

1. fuel section: the syngas coming from the gasifier may be mixed up with the natural gas and the related fuel mixture is sent to the GT combustion chamber.
2. exhausts section, where the GT exhausts are partially recirculated and sent to the gasifier as oxidisers for the gasification process.

EFFECTS OF GT EXHAUSTS ADDITION ON THE GASIFICATION REACTIONS

The basic idea of recirculating a fraction of GT exhausts to the gasifier allows the exploitation of their considerable heat content to the gasifier, where endothermic reduction reactions take place. This fraction of exhausts is mainly determined by the working conditions of the gasifier (i.e. ER). In fact, the large excess air of gas turbines makes the oxygen content of the exhausts more than enough for sustaining the gasification process. Moreover, the related CO_2 content should favour the Bouduard reaction:

$$C + CO_2 = 2CO.$$

The reference composition and temperature of exhaust gas is shown on table 1, together with the main working data of GE-5 GT, which is the reference machine here considered.

Table 1 – GE-5 gas turbine design working data

Net electric power output [kW]	5400
Compressor pressure ratio	14.8
Inlet compressor flowrate [kg/s]	19.8
Exhausts flowrate [kg/s]	20.2
Exhausts temperature [°C]	574
Heat rate [kJ/kWh]	11990
Inlet turbine volumetric flowrate [m^3/s]	4.80
Exhausts composition	
Mass fraction O_2	0.1473
Mass fraction N_2	0.735
Mass fraction CO_2	0.06868
Mass fraction H_2O	0.04902

The volumetric syngas composition vs. ER, related to the gasification with air and GT exhausts, are shown on figure 2. The gasification with exhausts leads to a syngas, which is more diluted with nitrogen for a fixed ER, due to the lower oxygen concentration of the exhausts (around 8-9%). It leads to a lower heating value of syngas (LHV_{syn}) when the exhausts are used, in spite of the higher adiabatic temperature T_g, see figure 3. On the other hand, the adoption of the hot gas stream as oxidiser suggests the possibility of working at lower equivalence ratios, as a consistent fraction of the heat needed for the endothermic gasification reactions is provided by the hot stream itself. Actually, the conversion ratios (moles of gas species per mole of inlet biomass) of the main syngas combustible species (H_2 and CO) increase in gasification with hot exhausts, as shown on figure 4. It is mainly due to the higher inlet temperature and to content of steam and CO_2 of the exhausts.

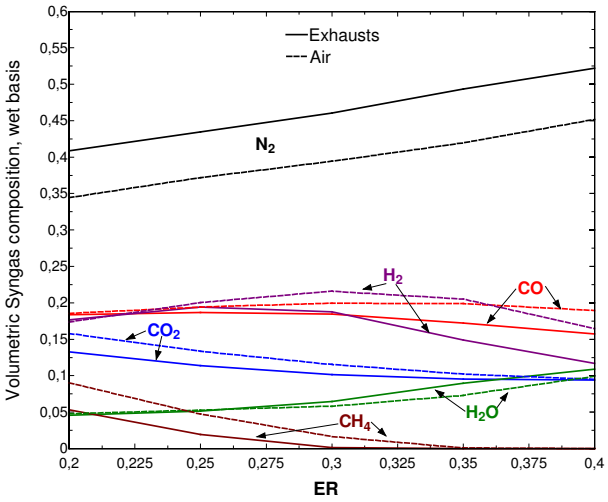

Figure 2 – syngas composition vs. ER for air and exhausts oxidisers

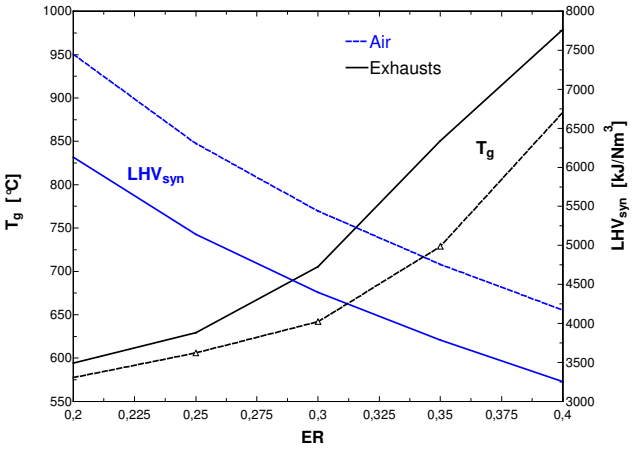

Figure 3 – syngas LHV and adiabatic gasification temperature vs. ER for air and exhausts oxidizers

PERFORMANCE ANALYSIS OF THE GT POWER CYCLE WITH INTEGRATED GASIFICATION

The proposed powerplant configuration aims to reduce part of its CO_2 emissions by replacing a

fixed fraction of natural gas fuel with biomass derived syngas. The recirculation of a fraction of the exhausts to the gasifier is advantageous because it is a hot stream, which gives an important contribution to sustain the endothermic gasification reactions, thus increasing the conversion ratio of the solid fuel. Moreover, recirculation represents a sort of "internal recycling" of a fraction of produced CO_2. In fact, an important feature of the proposed powerplant is that no additional recompression of the CO_2 and/or disposal is needed.

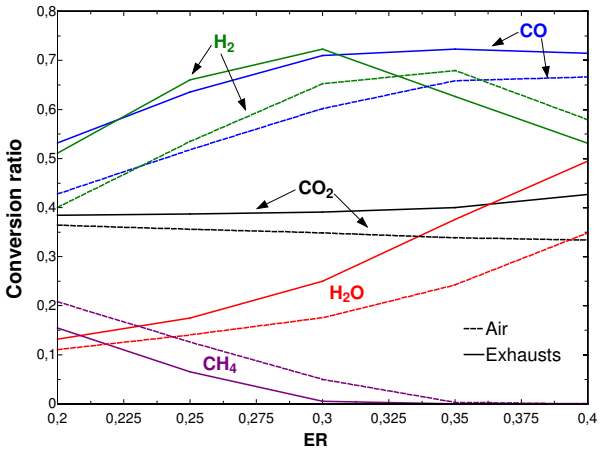

Figure 4 – conversion ratio vs. ER for air and exhausts oxidizers

The objective of this work was to assess the chances of applying this technique to remove a fraction of the CO_2 emissions from the traditional natural gas fuelled GT cycle.

The analysis was carried out referring to an integration of syngas into natural gas ranging from 10 to 50%. The upper limit is very hard to exceed, due to the extremely low heating value of the produced syngas, which would lead to a deep redesign of the GT combustor. As the main objective of this proposal is a moderate reduction of CO_2 emissions at the price of limited modifications to the existing plant with minimisation of the additional costs, the solutions involving deep modifications to the existing equipment were not considered here.

In the case of powerplant with only gasifier and no pyrolyzer, the gasification temperature is fixed at 800 °C, as well as the fraction of syngas fuel replacing natural gas (F_{ren}), which also represents the saved fraction of CO_2 emissions with respect to the standard GT, as syngas is derived from renewables, which are typically CO_2 neutral. These parameters allow the determination of the required ER and thus the fraction f of exhausts to be recirculated to the gasifier. The behaviours of f, biomass and syngas flowrates (m_{bio} and m_{syn} respectively), GT efficiency (η_{GT}) and specific CO_2 emissions are shown on figures 5 and 6 vs. F_{ren}.

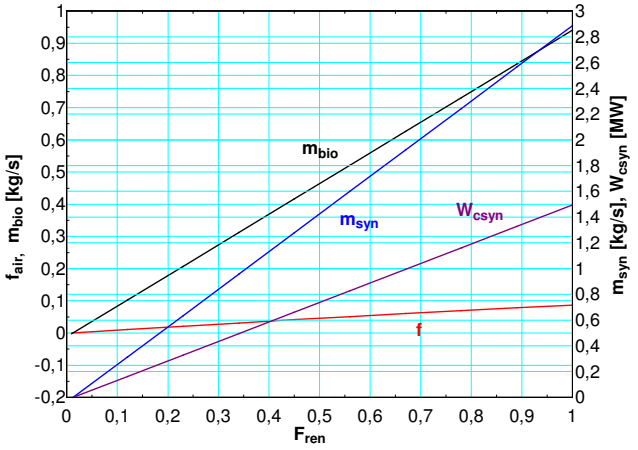

Figure 5 – syngas flowrate, biomass flowrate and fraction of exhausts recirculated to gasifier vs. ratio of renewables to natural gas fuel

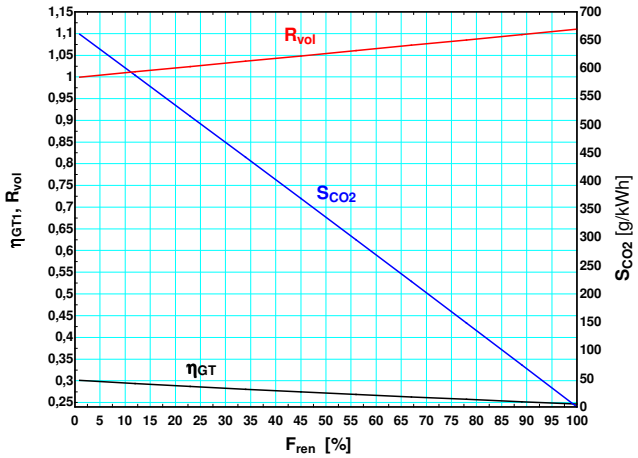

Figure 6 – GT efficiency, specific CO_2 emissions and inlet turbine volumetric ratio vs. ratio of renewables to natural gas fuel

As it is seen on figure 6, the fraction f of recirculated exhausts to the gasifier is very low, below 10%, even working with total biomass fuel (F_{ren} = 100%). The modest syngas heating value

(LHV_{syn} = 4837 kJ/Nm^3) leads to a consistent increase of fuel mass flow (m_{syn} is 6 to 10 times higher than natural gas in fuel mixture, see figure 5). It leads the expander to off design conditions, due to the higher volumetric flowrate of fuel gas mixture, which may become 10% higher than the design value at full renewable F_{ren} = 100% (see R_{vol} on figure 6). It suggests an integration of biofuel not exceeding 40 – 50%, in order to avoid high off design levels, thus maintaining the same expander and minimising the costs of modification of the existing powerplant. In this range, the CO_2 emissions of the proposed cycle may be reduced down to 350 gCO_2/kWh, which is a very interesting result for simple GT cycles. Moreover, this powerplant eliminates the problems and costs related to the CO_2 sequestration and disposal. One drawback of this powerplant is the relatively high power demand for syngas recompression (W_{csyn}, figure 5) which may reach around 20% of GT power output at F_{ren}=0.5. Anyway, it seems convenient to recompress the syngas fuel after the cleaning process and keep atmospheric gasifier to contain its costs, especially when dealing with small size plants like the one here proposed.

PERFORMANCE ANALYSIS OF THE GT POWER CYCLE WITH INTEGRATED PYROLYSIS AND GASIFICATION

The possibility of adding a pyrolyzer, downstream the gas turbine, which exploits the heat content of the exhausts to produce pyrolysis gas and char to be successively converted to syngas into the downstream gasifier, was another investigated option. Once again, the analysis was carried out versus variable ratio of biofuel to natural gas (F_{ren}), having fixed the outlet char gasification temperature at 800 °C. The main results are summarised on figures 7 and 8.

When compared to the plant with gasification only, it is evident the larger efficiency decay with F_{ren}, which is due to the higher biomass consumption (figure 7). The exhausts recirculation ratio f is reduced with respect to the case with no pyrolyzer, while an amount (m_{pyr} around 25%) of pyrolysis gas is produced and mixed with the amounts coming from the gasifier and natural gas. It leads to an increase in fuel gas heating value, due to the larger heating value (LHV_{pyr}) of pyrolysis gas (see figure 8). As a direct consequence, the volumetric flow ratio at the expander inlet of the biomass integrated GT to the standard GT (R_{vol}) is consistently reduced. It does not exceed 5% even at full biomass fuelling. It should greatly reduce the off design level of turbomachinery equipment, especially when the biomass integration level does not exceed 50%.

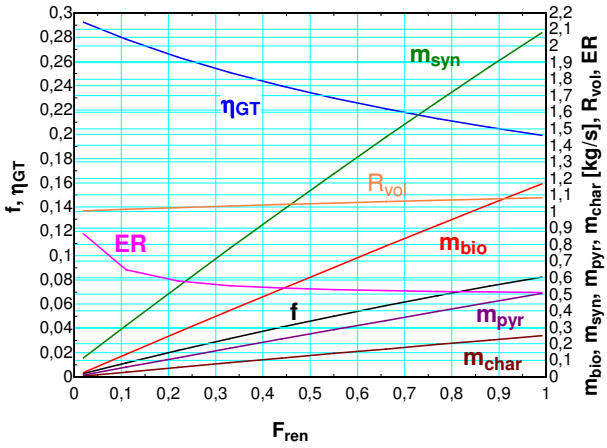

Figure 7 – GT efficiency, exhausts recirculation ratio, pyrolysis and gasification syngas flowrates, biomass and char flowrates and inlet turbine volumetric ratio vs. ratio of renewables to natural gas fuel

The temperature at pyrolyzer inlet (T_{inpyr}) is that of turbine's exhausts and is almost constant with F_{ren}, while the outlet pyrolyzer temperature T_{outpyr} decreases with increasing F_{ren}, due to the increased biomass pyrolysis level. The increase of F_{ren} also entails a slight decrease of ER, due to the larger difference between inlet biomass (m_{bio}) and produced char (m_{char}). In other words, the fraction of biomass converted by pyrolysis grows with increasing the biomass integration level. The larger extent of pyrolysis process is also responsible for the higher heat consumption. Thus, the exhausts are cooler when reach the gasifier inlet (see the behaviour of outlet pyrolyzer temperature T_{outpyr} on figure 8). It makes necessary the adoption of higher equivalence ratios to sustain the endothermic gasification reactions with respect to the plant with no pyrolyzer.

The CO_2 specific emissions may be reduced according to the fraction of natural gas replacement.

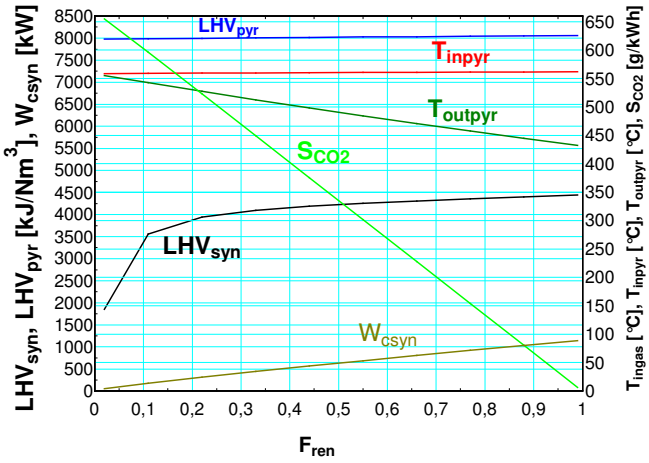

Figure 8 – Syngas and pyrolysis gas heating values, gasifier and pyrolyzer inlet temperatures, outlet pyrolyzer temperature and specific CO_2 emissions of the powerplant vs. ratio of renewables to natural gas fuel

Due to the higher heating value of syngas mixture, the additional power demand for syngas recompression is 1.5 times reduced.

EVALUATION OF ADDITIONAL COSTS DUE TO THE GASIFICATION SYSTEM

This analysis was carried out on the basis of literature data, which are referred to a nominal 30 MW powerplant size [15, 16] and later rescaled down by the following relationship:

$$cost_{size\ 2}/cost_{size\ 1} = (size_2/size_1)^R$$

where R is a scale coefficient, variable in the 0.6 - 0.85 range and depending on the specific components considered.

The costs of the main additional components required for the integration of biogas to the standard natural gas fuelled GT are reported on table 2. The analysis of costs was done at two levels of biomass fuel integration: F_{ren}=0.2 and F_{ren}=0.5. Thus, referring to the nominal 5 MWe, the power capacity of gasification system and the related devices are reduced by a factor ranging between 12 and 30 respectively.

Considering that the current cost of powerplants is around 600 €/kW, referring to the 5 MW GE5 here proposed, the cost of gasification equipment to achieve 50% natural gas replacement represents around 100% the total cost of the GT powerplant. With only 20% renewables integration level, the additional costs of gasification island are reduced to about 50% of standard powerplant cost.

Table 2 – Estimation of gasification island costs [M€]

	R	F_{ren}=0.5	F_{ren}=0.2

OVERALL		**2.54**	**1.34**

The evaluation of investment profitability was carried out referring to the payback time (PBT) of the initial investment. Considering an average price of natural gas and biomass fuel of 20 c€/kg and 5 c€/kg respectively, the yearly savings due to the integration of the biofuel are closely related to the price of carbon tax and to the natural gas saving. Figure 9 shows the PBT vs. carbon tax (C_{tax}), which has been varied from current values (5 to 10 €/t) to possible future long term values (25 – 50 €/t) [17, 18], having supposed a discount rate of 10% and a plant working time of 8000 hrs/year. At current levels of carbon tax (10 €/t) the PBT is around 12 years, which is not very attractive, but even a moderate increase of C_{tax} would greatly improve the PBT of the plant with only gasifier (at 20 €/t PBT is halved to 6 years).

The ratio between the yearly saving due to carbon tax and that due to reduced fuel price, R_{save}, is

lower than one only at the lowest values of C_{tax}. The PBT here evaluated might have further consistent margins of improvement, if the contributions for use of renewable fuel (green certificates) were accounted.
In the case with pyrolyzer and gasifier, the costs of pyrolyzer plus char gasifier were supposed, at least in a first approach, the same as biomass gasifier only. It is evident that the lower efficiency of this solution, with respect to the one with gasifier only (see figure 8) leads to definitely prohibitive PBT if carbon tax is maintained below 20 €/t. For C_{tax} higher than 35 €/t, the PBT of the two proposed solutions are comparable.

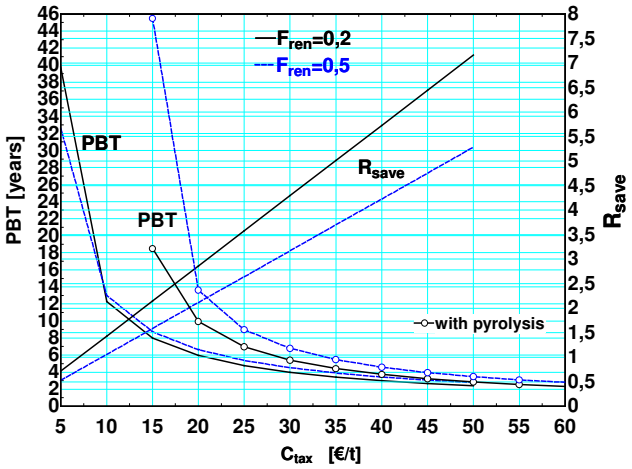

Figure 9 – PBT and R_{save} (for plant with gasifier only) vs. carbon tax price

CONCLUSIONS

A relatively simple solution for reducing a fraction ranging from 10 to 50% of CO_2 emissions from gas turbine based powerplants has been proposed. It adopts an integrated gasification/pyrolysis system, which recirculates a small fraction of the oxygen rich exhausts to the gasifier, in order to exploit their heat content and partially sustain the endothermic reduction reactions. In spite of the higher amount of gas flow required with respect to air gasification due to the lower oxygen concentration, the related heat content and, partially, the larger reducing capacity of fluegas due to presence of CO_2, lead to an increase of biomass to syngas fuel conversion ratio.

Comparing the two proposed solutions, with and without pyrolysis, the second one showed lower efficiency penalties with respect to the standard GT, but even higher volumetric flowrate to the expander, due to the lower syngas fuel heating value, which should increase the off design level of the gas turbine and the related efficiency losses. The economic analysis showed that the solution with only gasifier might be proposed in the very short time, as it allows the recuperation of the initial investment within 4 to 8 years, provided that the carbon tax was set in the range 15 – 25 €/t. The solution with pyrolyzer showed economic attractiveness only in the field of high carbon tax level (higher than 25 €/t).

ABSTRACT

A company holding a license to build a wind farm has the right, but not the obligation, to build a certain capacity of wind power. This postponement flexibility has value when electricity prices and/or the wind speed distribution are uncertain. Assuming that long term electricity prices follow a Brownian motion dynamics, with parameters estimated by considering forward prices of the Nordic electricity market, the value of the postponement flexibility is estimated. Since this value is lost when investing, the decision rule is to invest when the value of the revenue stream from the wind farm exceeds both investment cost and flexibility value. Investment decisions and wind power values are discussed in terms of a case study from Norway. Although net present value is positive, the value of waiting is higher, so the recommendation is to postpone the investment.

NOMENCLATURE

INTRODUCTION

Large areas with sparse population and relatively high yearly average wind speeds make the Norwegian coastline a favorable place to site new wind farms. The Norwegian government aims for 3 TWh yearly windpower within 2010. A new market for green certificates, and increasing electricity prices, have spurred a large number of applications for licenses to build wind farms.

Such licenses are granted freely on a first come, first served basis. Getting a license is not costless however, since formal requirements for license applications include a feasibility report, a report on environmental effects, and a duty of public consultation. We consider the case of a company holding a license to build a wind farm.

In the case considered, the regional electricity company TrønderEnergi holds a license, i.e. a deferrable right, to build a 50 MW farm on Bessakerfjellet in Nord-Trøndelag county. The profitability of this investment depends on electricity prices, green certificate prices or other subsidies, wind distribution, investment costs and operation/maintenance costs. All of these factors are uncertain, and we explicitly take into account price uncertainty by calculating the long term price level at which it is optimal to invest. Investment is optimal when the present value of revenues equal the sum of 1) investment and present value of O&M costs, and 2) the costs associated with losing the opportunity to defer investment further.

This work is an application of the theory of investment under uncertainty [1]. It is an adaptation of the model in [2]. The status of wind power in Europe is discussed in [3]. Whereas this paper considers a particular wind farm project, a related paper [4] considers choice of renewable power plant capacity under uncertainty. Also related is [5], which performs an economic analysis of the license to build a gas fired power plant.

The paper is structured as follows. Section 2 discusses technical issues surrounding the wind farm. In Section 3, the model for electricity price uncertainty is explained. Then follows two sections on subsidies and other project data. The investment decision is analysed in Section 6, followed by a discussion and a conclusion.

CAPACITY AND COST OF WIND FARM

It is common practice to measure wind speeds at the farm location over a year, and to model the uncertainty of wind speeds using a Weibull distribution. This was done also for Bessakerfjellet, based on wind measurements between June 2002 and December 2003. In addition, we used historical wind measurements for nearby locations, dating back to 1980 (a more advanced method for incorporating information from neighboring measuring stations is given in [6]). This gave us an average wind speed of 8.44 m/s, and form and scale factors of k = 1.74 and A = 9.47. These parameters enter the density function of the Weibull distribution as follows:

$$f(u) = \frac{k}{A}\left(\frac{u}{A}\right)^{k-1} \exp\left(-\left(\frac{u}{A}\right)^{k}\right) \qquad (1)$$

where u is wind speed. Form and scale factors were also found per week.

There is an economy of scale in producing, transporting, erecting and maintaining wind mills. The largest commercially available are 3 MW. The wind mills must not be located too close to each other, otherwise there will be losses due to wind shadow effects. In Norway, the license to build a wind farm is usually given with an upper bound on the total MW capacity, and for a specified geographical area. If large capacity mills are chosen, fewer mills can be bought, but at a higher cost per mill. If smaller capacity mills are chosen, more mills can be bought giving possibly a high

total cost. The optimal choice of mill type depends on their power curve, i.e. how much power they deliver given different wind speeds. A wind mill is usually operating between 4 m/s and 25 m/s, at larger speeds the mill is shut down. A power curve of a 2 MW Vestas turbine is shown in Figure 1:

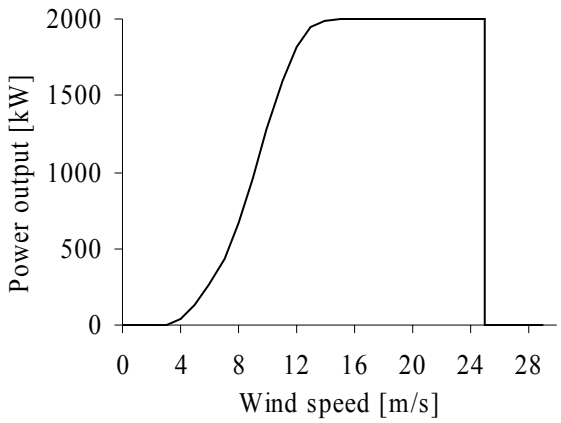

Figure 1. Power curve, showing power output as a function of wind speed.

We do not know the exact per MW cost of different turbine types before going into extensive negotiations with turbine manufacturers. For this reason we assume that the investment cost of the wind farm is independent of the type/size of turbine chosen. Thus, the optimal choice of turbine is the type/size that maximizes the yearly energy generation for the park. The expected yearly energy generated per turbine is given by

$$E = 8.76\int_{4}^{25} f(u)P(u)du \qquad (2)$$

The size of the Bessakerfjellet wind farm is set to 50 MW. Table 1 shows the annual expected energy generation per turbine, and annual expected energy generated for the whole farm, for turbines ranging from 2 MW to 3 MW. These sizes are the commercially most attractive at the time of analysis.

The calculations indicate that the Vestas 2 MW mill is a good choice. If the license holder decides to go ahead with the wind farm, an effort will be made to get more accurate investment cost data, as well as wind data. More wind data is needed for micrositing of wind mills, i.e. the exact location of the mills in the terrain and in height.

Table 1. Comparing different wind mill types. The farm can be up to 50 MW, e.g. 25 Vestas mills or 20 Nordex mills.

Manufacturer	Capacity	Energy per turbine [MWh]	Energy for farm [GWh]
Vestas	2 MW	7096	177
Bonus	2 MW	6826	171
Bonus	2,3 MW	7976	173
Nordex	2,5 MW	7898	158

ELECTRICITY PRICES

Electricity is used for heating in the Nordic area, leading to greater electricity demand in winter than in summer. Furthermore, the large share of hydropower in the region, with most inflow coming in the summer, makes for seasonality in electricity prices, with high expected prices in the winter and low summer prices. This profile is favorable for wind power, since wind speeds are greater in winter than in summer. What matters for the investment decision regarding electricity prices, is the expected future electricity prices during the lifetime of the wind farm, at the time of investment. There is uncertainty about long-term price levels, thus there is uncertainty about wind farm revenues (price times generated energy). Short term electricity prices are even more uncertain, but this does not matter for the investment decision, since such uncertainty does not influence the value of the wind farm. For the same reasons, we ignore the possibility of price spikes, price extremes, and seasonality over the day.

Another issue regarding electricity prices is their riskiness. Revenues with a high degree of systematic risk have lower value than revenues with a lower riskiness. One way of finding the present value of risky revenues is to use the information in electricity futures and forward

prices. Such contracts are traded actively in the Nordic market, and a forward curve can be constructed, based on information available in the market, revealing directly the value of future delivery of electricity. See Figure 3.

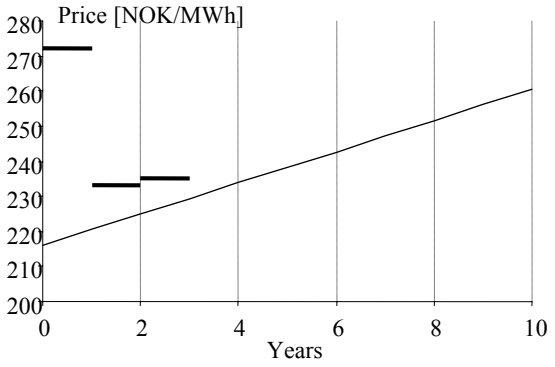

Figure 2. Forward prices on Nord Pool electricity, at the time of analysis (fall 2003). Actual market prices in bold lines, and estimated long-term relationship below.

Forward prices represent the risk-adjusted expected future electricity prices. The appropriate discount interest rate for electricity revenues, if generated energy is constant, is the risk free rate. We use the following stochastic model for long-term risk-adjusted electricity prices:

$$dS = \alpha dt + \sigma dz \qquad (3)$$

Equation (3) says that the current value of the long term price S is known, but future values of S are unknown, and are normally distributed with a variance that grows with the time horizon. Thus even though information arrives over time, with changes in market prices on forwards, future prices are always uncertain. This particular model choice is based in part on its simplicity, and in part on the empirical behavior of long-term electricity prices at Nord Pool, the Nordic power exchange. See e.g. [7] and [8] for estimation of energy price processes in this market.

This model does not account for seasonality in prices over the year. To correct for this, a correction factor h is defined. This is necessary because if expected future revenues from a wind farm is to be calculated from expected annual production, and an electricity price that does not exhibit seasonality, the revenues need to be scaled up. The power plant generates much of its annual output in the winter months, when prices usually are higher than in the summer. The correction factor h is written as

$$h = \sum_t \frac{P_t G_t}{\bar{P}} \qquad (4)$$

where $\bar{P}$ is the yearly average price. With our data it is estimated to $h = 1.046$.

Figure 3 shows how weekly local electricity prices have varied over the year, based on the average of 1996-2003. The Figure also shows weekly expected generation over the year, as a share of annual production.

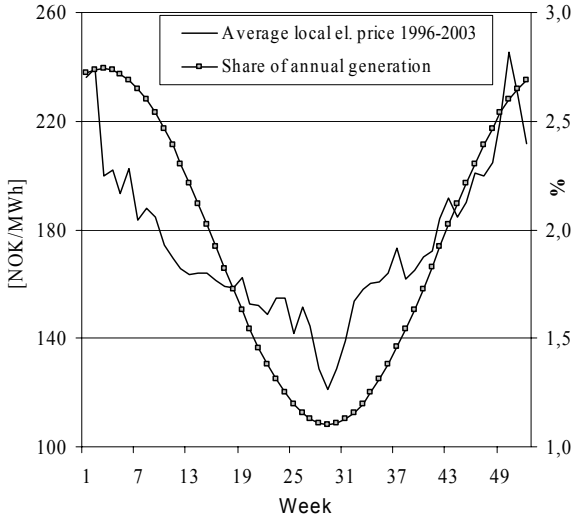

Figure 3. The relationship between expected generation and electricity price.

Based on data from Nord Pool, we estimated the current long term price to S = 216 NOK/MWh, yearly growth α = 4.4 NOK/MWh, and volatility to σ = 10.1 NOK/MWh.

SUBSIDIES

Windpower needs subsidies to be competitive. Norway has decided to adopt the Swedish model using green certificates, a market in which new renewable producers can issue certificates, and electricity retailers must buy certificates according

to certain rules. Typically, retailers must have certificates for a certain percentage of what they sell, or else they will be fined. In Sweden, there is a government-set upper and lower bound on prices, providing insurance to buyers and sellers. There is uncertainty in the future level of certificate prices, and expected price level can not be predicted with much precision. We have chosen to assume a level of 150 NOK/MWh, which is somewhat lower than average Swedish prices. This reflects the large potential Norway has for new renewable generation, particularly regarding small hydro.

As a temporary subsidy, the governmental energy fund Enova is supporting new wind power projects with up to 25% of the investment cost. The receiver of this subsidy has the option to pay it back if they find it more profitable to enter the green certificate market. We have chosen to ignore this feature of the subsidies issue since it is temporary, and instead focus on the green certificate market.

PROJECT DATA

The minimum acceptable nominal rate of return on comparable power projects has been 7-8% after tax. We choose to use $r = 8\%$, most of which is not compensation for the time value of money, but a risk premium. Above we argued that the electricity price risk in the project cash flows should not require any risk premium in the discount interest rate. We stick to that, however, there are other risks requiring a premium. We have already mentioned subsidy risk, which probably is the most important factor. Other factors include the risks in operation and maintenance cost, the level of unforeseen outage time, the exact distribution of wind speeds, and investment cost. Annual generation will vary by roughly +/- 20%. Although the mill manufacturers provide guarantees for some of the technical factors, there is no functioning market for hedging these risks. Other risks such as interest rate risk, currency risk and inflation risk, also affect profitability, but can be hedged to some extent.

The investment cost is estimated to 8 million NOK/MWh, giving a total of 400 million NOK for the 50 MW farm. Investment cost components are explained in Table 2.

Table 2. Breakdown of investment costs.

Cost component	%
Complete windmills 50 MW	83.1
Foundation	7.9
Transformer substation	2.6
Internal cables and switching station	1.6
External cabling/distribution	1.3
Access and service roads	2.6
Engineering	0.8
Total	100

The governmental license is granted for a period of 20-25 years, after which the wind mills are to be removed and the landscape restored to a natural state. However, wind mill components are designed to have a very low probability of failure within the first 20 years, and the mills can probably still be used beyond that time. We set the economic lifetime to 20 years, assuming the cost of restoring the landscape is cancelled out by the remaining value of the wind mills.

Operation and maintenance (OM) cost consist of insurance cost, periodic inspection and maintenance, damage repairs, revenue losses when units are down, and energy used in the electric motors that make the wind mill face the wind at any time. Considering experience from Denmark, we estimate the OM cost to 2% of investment cost initially, increasing with inflation thereafter. We assume inflation is 2.5%, consistent with the target for the central bank of Norway. This means the OM cost is 47.5 NOK/MWh.

Wind farms are subject to company tax and property tax, but are exempt from tax on economic rent and natural resource tax. Company tax is 28% of profit, and the investment is activated and depreciation is tax deductible. Durable assets has a depreciation rate of 4% using the balance method, except electrical equipment which is depreciated at 5%. However, the generators and other particular components are depreciated linearly over 40 years. We assume

the wind farm owner is in a tax-paying position. Yearly property tax is approximated to 0.7% of taxable value, which is 70% of investment cost.

Cost of balancing services are approximated to 10 NOK/MWh. Transmission tariffs depend on expected generation. We approximate this to 6 NOK per MWh produced, and 4% of revenues. Further, the original property owner is assumed compensated by 4 million NOK up front, and by 2.9 NOK per produced MWh. All per MWh costs are assumed to grow with inflation. The local municipality is assumed paid up front by 3 million NOK, to compensate for negative consequences e.g. connected to reduced weekend cottage building.

PROJECT ANALYSIS

The present value of revenues less costs is a function of long-term electricity prices, and is written $V(S)$. The license owner gets this value when paying investment cost I, and the net present value is $V - I$. The present value of revenues can be expressed as

$$\sum_{t=c}^{c+L} \frac{(S+\alpha t)h\bar{G}}{(1+r)^t}$$

From this we see that V is a linear function of S. We write this as

$$V(S) = a\,S + b, \qquad (5)$$

where a and b are known constants (note that the present value of costs are imbedded in b).

The value of the license equals the value of the opportunity to invest in the wind farm. We assume that the license does not expire in order to facilitate easy calculation of an upper bound on the value of the license. We assume further that holding this license is free. In this situation, the expected return on the value of the license, F, can be expressed in two ways. On the one hand this return depends on the minimum required rate of return, the value, and the size of the time interval. On the other hand, this return must equal the expected change in the value of F during the same time interval:

$$rFdt = E[dF] \qquad (6)$$

This is the Bellman equation for the value of the license [1]. We assume that long-term electricity prices are the only significant factor driving changes in F. The license value is then a function of long-term electricity prices, and the change dF can be found using Ito's lemma [1]:

$$dF = \left(\tfrac{1}{2}\sigma^2 F''(S) + \alpha F'(S)\right)dt + \sigma F'(S)dz \qquad (7)$$

By taking expectation of Eq. (7) and inserting it into Eq. (6), and dividing each term by dt, we get

$$\tfrac{1}{2}\sigma^2 F''(S) + \alpha F'(S) - rF(S) = 0 \qquad (8)$$

This is an ordinary differential equation whose solution in general is

$$F(S) = A_1 e^{\beta_1 S} + A_2 e^{\beta_2 S} \qquad (9)$$

where β_1 and β_2 are the positive and negative roots of the following quadratic expression:

$$\tfrac{1}{2}\sigma^2\beta^2 + \alpha\beta - r = 0 \qquad (10)$$

When long-term electricity prices are high enough, investment is triggered. The triggering price is denoted S^*. To determine S^*, A_1 and A_2, we use the boundary conditions associated with eq. (6):

1. Should long-term electricity prices become very low, the value of the license should approach zero. To ensure this, we must have that $A_2 = 0$. Eq. (9) now becomes

$$F(S) = A_1 e^{\beta_1 S}. \qquad (9')$$

2. When it is optimal to invest, the license is lost, but the license owner gets the net present value of the wind mill instead.

$$F(S^*) = V(S^*) - I \qquad (11)$$

By inserting Eq. (5) and (9') into Eq. (11) we obtain an equation in S^* and A_1:

$$A_1 e^{\beta_1 S^*} = aS^* + b$$

Solving that equation with respect to A_1 and substituting that expression into Eq. (9'), we obtain the value of the license as a function of the trigger price level S^*:

$$F(S, S^*) = A_1 e^{\beta_1 S} = e^{-\beta_1 S^*}(aS^* + b - I)e^{\beta_1 S} \qquad (12)$$

3. The trigger price level should be chosen to maximize the value of the license. The value of S^* maximizing the right hand side of Eq. (12) is

$$S^* = \frac{1}{\beta_1} - \frac{(b-I)}{a} \qquad (13)$$

Using Eq. (12) and (13), an approximate trigger price and value of wind farm opportunity can be calculated.

RESULTS

Net present value

The net present value depends to a large degree on the current level of long-term electricity prices, and on the price of green certificates which can be sold based on certified generation from the wind farm. Table 3 shows the net present value of the wind farm, with varying levels of electricity and certificate prices.

Table 3. Sensitivity of net present value of wind farm in million NOK, with respect to prices of green certificates in NOK/MWh and electricity prices in NOK/MWh.

	Certificate prices					
El. price	0	50	100	150	200	250
200	-192	-121	-49	22	94	165
220	-170	-98	-27	44	116	187
240	-148	-76	-5	66	138	209
260	-126	-54	17	89	160	231
280	-103	-32	39	111	182	254

Increased revenues lead to increased net present value. Given the current level of electricity prices (base case), 216 NOK/MWh, the break-even price of green certificates is 122 NOK/MWh. Given a price of green certificates of 150 NOK/MWh (base case), the break-even price of electricity is 180 NOK/MWh. The base case net present value is 40 million NOK, i.e. 800 NOK/kW or 236 NOK per annual MWh generated.

License value

The value of the license, Eq. (12), as a function of long-term electricity price level, is shown in Figure 4. Recall that the long-term electricity price level is the start level (year 0) for the forward price, i.e. 216 NOK/MWh in Figure 3. This level is stochastic and varies according to Eq. (3). As a result of an upward (downward) change in this level, the entire forward curve moves upward (downward), affecting the profitability of the investment over the whole plant lifetime[2]. As can be seen from the figure, the lower the price, the lower is the marginal value of the license – the license value tends to zero at very low prices. The base case (S = 216 NOK/MWh) license value is 47 million NOK. If the electricity price should increase enough (to S^* = 247 NOK/MWh), so that the license value becomes 75 million NOK, the license should be given up in favor of a wind farm.

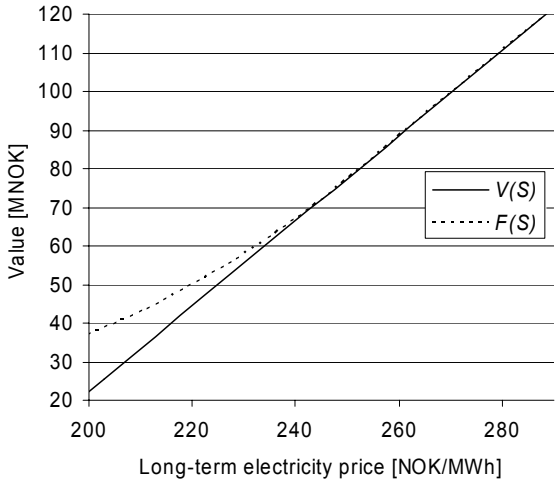

Figure 4. Net present value and license value as functions of electricity price level. Investment is optimal when net present value has reached 75 million NOK.

Trigger price

The long-term wholesale electricity price level that is high enough to trigger the investment is around 247 NOK/MWh. This is higher than the current long-term electricity price level of 216 NOK/MWh, so the conclusion is to wait for better price information. Table 4 shows how the trigger price level varies with the real price on green certificates.

[2] The forward curve from Eq. (3) is: $S + \alpha T$.

Table 4. Sensitivity of triggering electricity price level in NOK/MWh on green certificate prices in NOK/MWh.

Certificate price [NOK/MWh]	Trigger price [NOK/MWh]
0	441
50	376
100	312
150	247
200	183
250	118

The internal rate of return at the trigger level is 10.2%. This can be interpreted as a form of required rate of return, adjusted for electricity price risk.

DISCUSSION

The least realistic aspect of this model is the assumption that the license does not expire. In reality, the license is granted for around two years. At the end of this period, the license holder has a now-or-never opportunity to build a wind farm, and in that case the correct decision rule is to build the farm if the net present value is positive. The fact that the license expires, makes the trigger price level lower than with our calculations.

The cost of wind mills is constantly decreasing [9]. We have not taken this into account, but this would lead to a larger trigger price level, since it would be beneficial to wait for lower investment cost.

Long-term price uncertainty is usually modeled as having a log-normal distribution, i.e. proportional changes in price, not NOK/MWh price changes, are normally distributed. We also did the analysis with such a price model, but the main conclusion is the same, namely that it appears best to wait for better information.

CONCLUSION

We have applied the theory of investment under uncertainty to the case of an exclusive license to build a 50 MW wind power farm in Norway. Wind farms need subsidies to be viable, and Norwegian subsidies are not expected to be very high; we used a price of green certificates of 150 NOK/MWh in our analyses, or a third of expected real revenues. Given the current expected level of wholesale electricity prices, this subsidy is not enough to trigger immediate investment in the wind farm, although the net present value is around 236 NOK per generated MWh. The uncertainty in prices makes it optimal to wait and see if profitability improves.

ABSTRACT

The partial combustion in a two-stage downdraft gasifier is critical for the process optimisation. Flame temperature and residence time of gas in the hot zone are indeed determining for tar cracking, the major issue in gasification. This paper presents a CFD model of the oxidation zone. Chemical reactions, including tar cracking, are treated by the "EDC" model (homogeneous reactions). Fluid flows are turbulent and simulated by the k-ε RNG turbulence model.
The validation of the model is done with the DTU 100 kW two-stage gasifier. Results fit satisfactory the data, regarding the temperature profile.
Keywords: Two-stage downdraft gasifier; partial oxidation; tar; modelling.

INTRODUCTION

The energy crisis of the 1970s sparked a renewed interest in biomass gasification systems. Nowadays environmental concerns are questioning the continued use of fossil fuels and the need for sustainable energy production has prompted new research into the possibility of gasification as a key source of energy production.
Gasification is a thermal process converting biomass feedstock into a mixture of gases that can be burnt in boilers, internal combustion engines and gas turbines.
If well designed, gasification allows an environmentally friendly energy production. Furthermore, it can help reducing the "waste disposal" constraints by using it as a feedstock to convert it into useful and valued product.
Biomass is indeed a particular kind of fuel. Its price is fixed by the collecting expenses. That is why small-scale installations are well adapted to this market. They allow valorising wastes directly on their production location.
In these perspectives downdraft gasifiers present indisputable advantages [1]. A traditional example is presented in *Figure 1* [2]. In current pilots called two-stage, drying/pyrolysis and combustion/reduction zones are physically separated. This low tar level technology only requires a small gas-cleaning unit to prevent engine fouling problems [3]. Furthermore it is well adapted to turnover and biomass diversity. Finally its utilisation is relatively easy and can be highly automated.
However available kinetics data and the theoretical comprehension of the physical phenomena remain still insufficient to build a general accurate model.

This paper presents a tool for validating two-stage downdraft gasifier design. In this type of installation, temperature field in the partial oxidation zone is crucial. Indeed gas produced during pyrolysis must pass through a hot uniform zone to crack satisfactorily tar, the main issue of gasifier. As a result, reactor diameter, throat shape and nozzle geometry have to be well designed in order to ensure an optimum process.
A CFD model is used to simulate the complex phenomena occurring in the partial oxidation zone. It includes detailed chemical mechanism with tar cracking, heat transfer with radiation and turbulent fluid flow.

Vijeu's pyrolysis model [4] is used to determine input pyrolysis gas composition, given in *Table 1* at a temperature of 650°C.
Results are then validated with the experimental data get from the DTU 100 kW_{th} two-stage gasifier [5,6]. They are finally discussed.

Table 1: *Pyrolysis gas composition (mass %)*

MODEL

The model is divided into three parts: fluid flow, chemical mechanism and heat transfer. Model equations are listed in *Table 2*. *Figure 2* shows model geometry and boundary conditions.

Fluid flow

Air is injected into the reactor through three injectors with five nozzles each. Reynolds number is around 2,000 at the air injector nozzles. The flow may thus be turbulent in this zone. Moreover velocity pattern is complex as recirculation may occur.
A detailed turbulence model is thus required to simulate these phenomena. After a preliminary sensitivity study, the RNG k-ε model was chosen

Pyrolysis gas + steam inlet
u = 0.52 m/s, turbulence intensity: 3%, T=650°C, hydraulic diameter: ϕ =0.26 m.

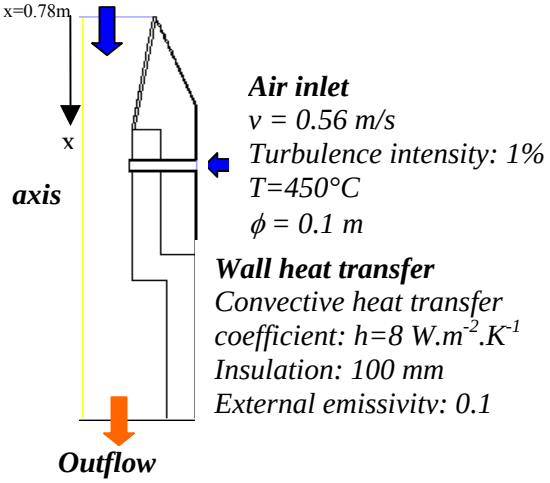

Figure 2: *Model geometry*

as the best compromise between accuracy and efficiency. It is also adequate for laminar flow that may develop inside the gasifier.
Wall boundary conditions are simulated by a low Reynolds number approach [8]. Solid phase is modelled by a Lagrangian particles tracking.

Chemical mechanism

The chemical mechanism consists in five oxidation reactions (1-5) and the water-gas shift reaction (6).

$$CO + 0.5\ O_2 \longrightarrow CO_2 \quad (1)$$
$$CH_4 + 1.5\ O_2 \longrightarrow CO + 2\ H_2O \quad (2)$$
$$H_2 + 0.5\ O_2 \longrightarrow H_2O \quad (3)$$
$$C_6H_6 + 4.5\ O_2 \longrightarrow 6\ CO + 3\ H_2O \quad (4)$$
$$C_{10}H_8 + 7\ O_2 \longrightarrow 10\ CO + 4\ H_2O \quad (5)$$
$$CO + H_2O \longleftrightarrow CO_2 + H_2 \quad (6)$$

Arrhenius rate is calculated from equation (7).

$$k_c = k_s e^{-\frac{E_a}{RT}} [A]^a [B]^b \quad (7)$$

Constants are taken from literature. They are listed in *Table 3*. The reverse term of (6) is obtained by a free Gibbs energy variation method.

Tars are modelled as a simplification of Jess works [9]. Pyrolysis, as it is slow and long, is considered to produce only secondary tar compounds, represented by benzene, and tertiary tar compounds, represented by naphthalene.
Naphthalene is indeed one of the main component of tar and 6C ring hydrocarbons are considered as the key component of thermal decomposition of aromatic hydrocarbon [9].
Further model development should include oxygenated hydrocarbons as phenol, whose concentration is not negligible particularly in steam gasification [10].
Initial tar concentration is extrapolated from literature data [3,7]. Methane includes C_2 compounds as ethane and ethylene. Tars are considered to be thermally cracked and to form soot. *Figure 2* shows the tar evolution mechanism. The kinetics constants of the five reactions are taken from Jess [9,11].

As flow is turbulent, it must be taken in consideration in the chemical reaction model. The chosen model, called "Eddy Dissipation Concept" model [12], calculates also Arrhenius rate at the turbulence time scale (18). It seems to suit well to this kind of reactive flow [13].

Besides it is observed that particles residence time is relatively short (<1s) in a two-stage downdraft gasifier. As a consequence heterogeneous reactions are negligible in the oxidation zone, as oxygen reacts far quicker with gas phase.

Heat transfer

As temperature exceeds 1000°C in the reactor core, heat transfer by radiation is predominant. They are simulated by the Discrete Ordinates model [14], a four-flux method. It integrates the Radiative Transfer Equation (13). As a result a source term S_f due to radiative transfer is included in the energy equation (12). S_f also includes the heat of the chemical reactions from equation (8).

$$S_{f,r} = -\sum_j \left(\frac{h_j^0}{M_j} + \int_{T_{ref,j}}^{T} c_{p,j} dT \right) R_{j,r} \quad (8)$$

The absorption coefficient of the fluid phase is computed by the cell-based Weighted-Sum-of-Gray-Gases model [15]. It only takes into account the concentration of CO_2 and H_2O.

Heat transfer from fluid to solid phase is calculated by equation (9).

$$m_p Cp_p \frac{dT_p}{dt} = hA_p\left(T_\infty - T_p\right) - \frac{dm_p}{dt} H_r + A_p \varepsilon_p \sigma (T_\infty^4 - T_p^4) \qquad (9)$$

Numerical solution

A segregated solver solves sequentially the continuity, momentum (Navier-Stokes equations), energy, radiation and species equations (N-1 equations for N species).

Governing equations are converted to algebraic equations that can be solved numerically by a control-volume-based technique through a power-law scheme [16]. SIMPLE algorithm couples velocity and pressure [17].

Simulation is 2D axisymmetric. In this purpose, the air injector, which is composed of five cylinders with three nozzles each, is considered as annular. Flowrate and injection surface area are conserved. Thus momentum is also conserved. Previous studies showed that this analogy was correct in this kind of problem [18].

However swirl neglecting may be a source of error.

The unstructured grid is composed of 20,000 cells. Meshing tests have been performed from 5,000 to 30,000 cells to insure independence of results.

Simulation is considered as converged when residuals remain constant at a value below 10^{-5} (10^{-4} for momentum). The calculation time is approximately fifty hours on a 3.2 GHz computer.

Mass $$\frac{\partial \rho}{\partial t} + \nabla.(\rho \vec{v}) = \mathrm{S_m} \qquad (10)$$

Momentum $$\frac{\partial}{\partial t}(\rho \vec{v}) + \nabla.(\rho \vec{v}\vec{v}) = -\nabla p + \nabla.(\bar{\bar{\tau}}) + \rho \vec{g} + \vec{F} \qquad (11)$$

Energy $$\frac{\partial}{\partial t}(\rho E) + \nabla.(\vec{v}(\rho E + p)) = \nabla.\left[k_{eff} \nabla T - (\sum_j h_h \vec{J}_j) + (\bar{\bar{\tau}}.\vec{v})\right] + S_f \qquad (12)$$

with $k_{eff} = \alpha_{\mathrm{Pr}} \mu_{eff} Cp$ [8]

Radiative transfer

$$\nabla.(I(\vec{r},\vec{s})\vec{s}) + (\alpha + \sigma_S) I(\vec{r},\vec{s}) = \alpha n^2 \frac{\sigma T^4}{\pi} + E_p + \frac{\sigma_S}{4\pi} \int_0^{4\pi} I(\vec{r},\vec{s}) \Phi(\vec{s}.\vec{s}') d\Omega' \quad) \qquad (13)$$

Turbulence $$\frac{\partial\left(\rho U_j k\right)}{\partial x_j} = \frac{\partial}{\partial x_j}\left[\rho \alpha_k \nu_{eff} \frac{\partial k}{\partial x_j}\right] + \rho \nu_t \left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right)\frac{\partial U_i}{\partial x_j} - \rho\varepsilon \qquad (14)$$

$$\frac{\partial\left(\rho U_j \varepsilon\right)}{\partial x_j} = \frac{\partial}{\partial x_j}\left(\rho \alpha_\varepsilon \nu_{eff} \frac{\partial \varepsilon}{\partial x_j}\right) + C_{\varepsilon 1} \frac{\varepsilon}{k} \rho \nu_t \left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right)\frac{\partial U_i}{\partial x_j} - C_{\varepsilon 2} \rho \frac{\varepsilon^2}{k} - R \qquad (15)$$

with $\nu_{eff} = \nu\left(1 + \sqrt{\frac{C_\mu}{\nu}} \frac{k}{\sqrt{\varepsilon}}\right)^2 = \nu\left(1 + \sqrt{\nu_t / \nu}\right)^2$

$C_\mu = 0.0845$; $C_{\varepsilon 1} = 1.42$ and $C_{\varepsilon 2} = 1.68$. α_k and α_ε are the inverse of turbulent Prandtl number for k and ε.

Species transport $$\frac{\partial}{\partial t}(\rho Y_i) + \nabla.(\rho \vec{v} Y_i) = -\nabla.\left(-\left(\rho D_{0,i} + \frac{\mu_t}{Sc_t}\right)\nabla Y_i\right) + R_i \qquad (16)$$

Homogeneous reaction rate $$R_{i,r} = \frac{(\xi^*)^2 \chi}{\tau^*}(Y_i^* - Y_i) \qquad (17)$$

With $\xi^* = C_\xi \left(\frac{\upsilon\varepsilon}{k^2}\right)^{\frac{3}{4}}$; $\tau^* = C_\tau \left(\frac{\upsilon}{\varepsilon}\right)^{\frac{1}{2}}$; $\chi = \frac{\rho}{[1 - (\xi^*)^3]}$; $C_\xi = 2{,}1377$; $C_\tau = 0{,}4082$.

EXPERIMENTAL

Facilities

The plant is a two-stage gasifier built at DTU with a thermal input of 100 kW. It consists of following components: propane heated pyrolysis unit, partial oxidation zone, air preheater, steam feeder and char bed lying on a movable grate [6]. It is showed in *Figure 3*.

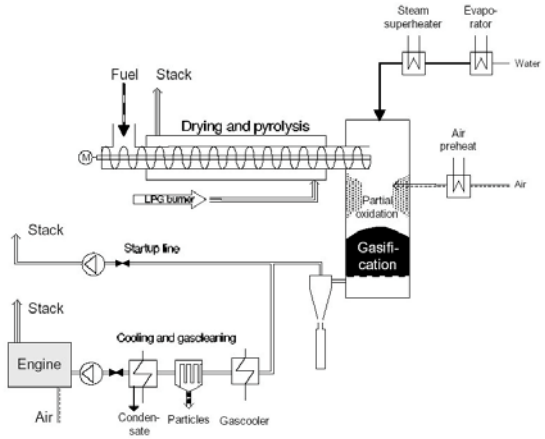

Figure 3: *100 kW_{th} two—stage gasifier*

Operating conditions

Experiments are performed with wood chips. Wood moisture is 26.5% of the total mass and the wood elementary formula is $CH_{1.4515}O_{0.66}$. Operating conditions are reported in *Table 4*.

	Wood	Air	Steam
Flowrate	24.8 kg/h	25 kg/h	7 kg/h
Initial temperature	600°C	≈450°C	600°C

Table 4: *Operating conditions*

Method of investigation

Temperature field inside the reactor was investigated through two different techniques.
A rod equipped with nine thermocouples measures the temperature along the vertical axis. It is movable and thus can inspect the radial temperature profile.
Secondly an infra red detector and a suction pyrometer are used to measure axial temperature in the symmetry axis.
Gas was analysed at the end of the process, i.e. after the reduction zone. Tar level is below 25 mg/Nm^3. The final dry gas composition is in volume-%: 17 CO, 17 CO_2, 2 CH_4 32 H_2 and 32 N_2. The soot particles concentration is around 450 mg/Nm^3 at the exit.

RESULTS & DISCUSSION

Temperature field

The *Figure 4* shows the comparison of the temperature profile along the vertical axis between the infrared measurement and the simulation

results. It fits satisfactorily the experimental data, although temperature is slightly overestimated. It may be partially due to an overestimation of the gas pyrolysis heating value.

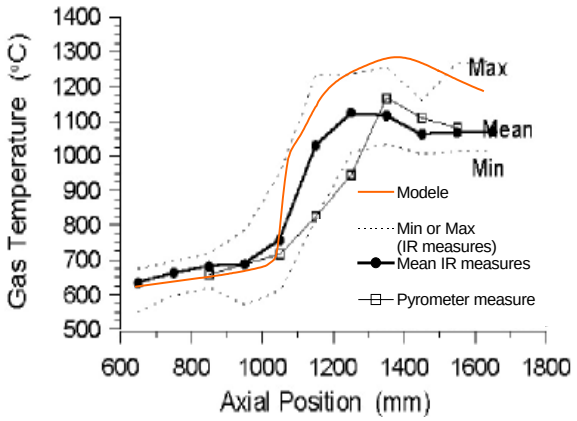

Figure 4: *Comparison modele/experiences results*

Temperature field is shown in *Figure 5*. The reaction heat is released mainly close to the injector. It induces a very hot zone in this area.

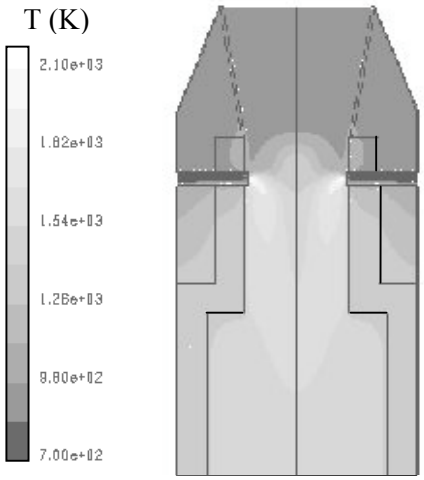

Figure 5: *Temperature field inside the reactor*

The uncertainties of measure and the operating conditions make the comparisons between experience and simulation difficult.
Indeed gasification is not a totally steady-state process. Inlet gas composition may for example vary strongly with time, as pyrolysis is also not fully stable. The effects of pyrolysis unsteadiness are studied later.

Flow pattern

The air velocity at the nozzle outlet is around 48 m/s, as the constriction accelerates the air. It implies fully developed turbulence in the flow and recirculations. These latter are shown in *Figure 6*.

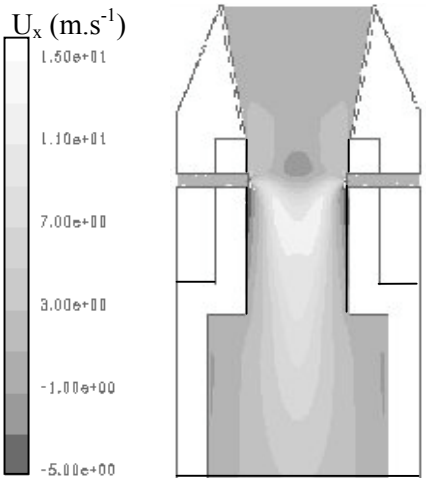

Figure 6: *Axial velocity inside the reactor*

Effect of the injection surface area

The injection surface area influences strongly the flow. Smaller nozzles induce higher air radial velocity but also higher axial gas velocity. As a result air penetrates deeper in the reactor, temperature is thus more uniform than with bigger nozzles. In the latter case the very hot zone located close to the wall is bigger. Temperature along the axis is shown in *Figure 7*.

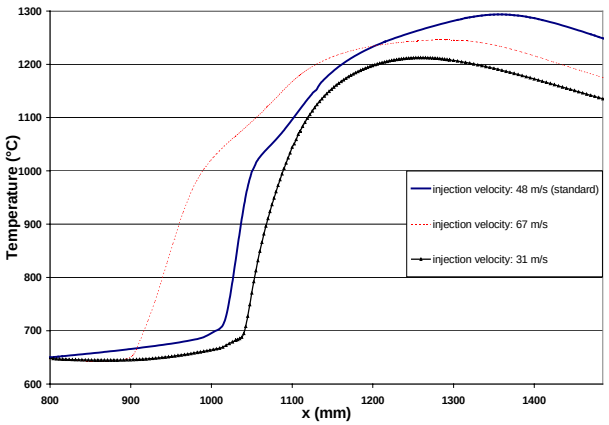

Figure 7: *Axial temperature with different nozzles*

The injector should also be carefully designed. A low opening area will induce better mixing and higher turbulence rate, necessary for a good combustion, but high gas velocity and thus smaller residence time too. This tool is also useful to find the best compromise to optimise the process.

Unsteady-state effects

The pyrolysis unsteady effects on temperature profile have been studied with the model. *Figure 8* shows a comparison of the axial temperature in the standard case, with 10% lower pyrolysis gas flowrate and with two different pyrolysis gas compositions – poorer and richer, respectively -/+ 20% [CO], [H_2], [CH_4], +/- the difference [CO_2].
It is observed that instabilities influence significantly the process. They should also be taken into account during a gasifier conception.

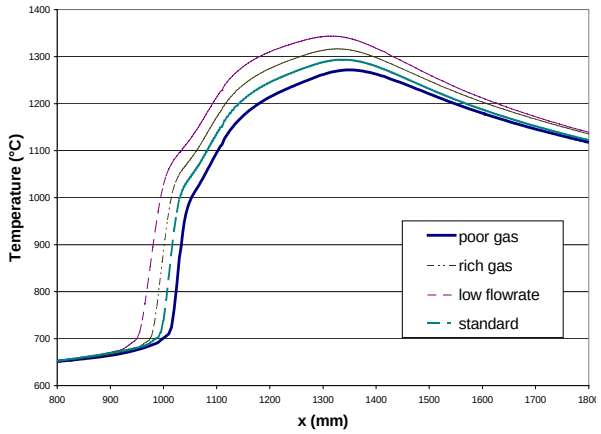

Figure 8: *Effect of pyrolysis unsteadiness on vertical axial temperature*

Chemical model discussion

The simulated final gas composition, summarised in *Table 5*, is in good agreement with experimental observations. Reduction reactions indeed convert water and char to hydrogen and carbon monoxide, diluting the mixture. Moreover the water-gas shift reaction, catalysed by the char bed, modifies the mixture composition.
It will be used in a future study as input for a reduction model to obtain a complete gasification model and then to compare numerical and experimental gas composition.

Conditions	CO	CO_2	H_2	CH_4	N_2
Standard	17.9	14.1	11.4	6.6	50
Poor gas	16.2	17.9	9.6	5.5	50.8
Rich gas	19.3	10.5	12.9	7.6	49.7
Low flowrate	16.9	13.9	10.1	6	53.1

Table 5: *Final gas dry composition (volume %)*

The modelling of competitive combustion reactions in an oxygen-limiting environment presents two main difficulties.
Firstly kinetic data are often determined for complete oxidation. Uniform sources have thus to be find or adaptations to be made.
That is why the –0.1 coefficient for benzene in its oxidation reaction (5) has been switched to 1. It implied furthermore heavy problems of solution convergence. Moreover the mechanism is very stiff and it is difficult to make it converged. It requires much time and precautions.
Besides the attempt of tar modelling is not a complete success. Naphthalene is reduced by a 5 factor during the process. It is far from the experimental results in similar case, which shows a decrease by a 100 factor. This difference can be partially explained by the neglecting of swirl effects. Residence time in simulation is thus lower than in reality.
The kinetic constants appear also to be uncertain. As already observed by Morf [10], naphthalene conversion to soot is negligible with rate of [5] used in this study. It means that either different pathways to produce soot exist or that the kinetic constants, calculated for coke-oven gas, are not adapted to biomass gasification.
To verify the later hypothesis, a try with a first order rate from Diesel combustion [23] has been performed. Naphthalene conversion to soot is then complete, whereas it was negligible with previous rate. Further kinetic study is thus required.

CONCLUSION

The oxidation zone of a two-stage downdraft gasifier has been simulated by a 2D CFD model. It takes into account turbulence, detailed chemical mechanism including tars and heat transfer.
Results fit satisfactorily to the experimental data regarding temperature pattern. However tar model requires further investigation.
Simulations enlightened several crucial point of the process:

- injector design is fundamental in gasification;
- pyrolysis unsteadiness influences significantly the process;
- kinetic data adapted to the process should be determined to ensure the tar model precision.

ABSTRACT

Black liquor constitutes a huge energy potential. In order to improve the efficiency of a pulp mill, this study is focussed on borate autocausticizing, which has proved to work efficiently in recovery boilers. The leading idea is to complete an overloaded recovery boiler with a booster gasifier. In this configuration, the black liquor is gasified with air at low overpressure. Results regarding conventional black liquor gasification are close to the reality and very promising. Regarding black liquor gasification with borate, lack of data for orthoborate, like the Gibbs free energy, did not enable good results. The model so far is a good starting point for black liquor gasification studies, and needs to be improved as soon as new data on borates will be available.
Keywords: Black liquor, borate, orthoborate, caustisation, booster gasifier, ASPENplus.

NOMENCLATURE

BL	Black liquor
DHFORM-DH	Standard enthalpy of formation at 25˚C
DGFORM-DG	Standard free energy of formation at 25˚C

INTRODUCTION

Background

Black liquor gasification has been studied, developed and simulated by a large number of research organisations and universities during the past 25 years. A number of processes and gasification media have been proposed. One process configuration has gone from the laboratory experiments to the edge of commercialization. According to this solution, the black liquor is gasified with air or oxygen in a ceramic reactor. The smelt and the raw gas of the process are separated in a quench cooler under the gasification reactor (Figure 1). Gasification of this type is marketed by the Chemrec company (earlier Kvaerner Chemrec).

Two different alternatives exist for this technology: Booster gasification relieves overloaded recovery boilers. This configuration is sold on commercial

basis by Chemrec. The leading idea is to complete an overloaded recovery boiler with a small gasifier. In this configuration the black liquor is gasified with air at low overpressure. The focus lies on chemical recovery and simple design.
Another alternative of this technology is the pressurized gasification of black liquor with a gas turbine. In this configuration, all the black liquor from the pulp mill is gasified at high pressure and with oxygen. The cleaned syngas is used to drive a gas turbine to maximize power production. The gasification part has been demonstrated in laboratory experiments. The complete system with gasification integrated with a gas turbine has not yet been demonstrated anywhere on the world.
The use of sodium borates to causticize the black liquor recovery boiler smelt directly in the furnace was first suggested by Jansson in 1977 [1]. This so called autocausticizing process by Jansson involved the reaction between the sodium carbonate in the bed and the added sodium meta-borate ($NaBO_2$), to form disodium metaborate, ($Na_4B_2O_5$).The disodium borate would hydrolyze in water to sodium hydroxide (NaOH), and to the original meta-borate. This process would produce sodium hydroxide directly in the green liquor and thus eliminate the need for the recaust plant including the lime kiln.
It was demonstrated that the addition of borate to the black liquor had the potential to increase the black liquor viscosity and decrease its heating value, thus rendering the process unattractive [2].
Trans et al., 1997 [3], showed that the key borate formed in the furnace is trisodium borate, also known as orthoborate (Na_3BO_3), instead of the disodium borate as originally suggested by Jansson. In water the trisodium borate hydrolyzes to form sodium hydroxide and sodium metaborate.
The finding implies that only half a mole of boron metaborate is required to produce one mole of sodium hydroxide in the green liquor, as opposed to one mole of metaborate per mole of sodium hydroxide as in the Jansson concept. This 50% reduction in borate requirement has made the borate autocausticizing process much more attractive than previously. Especially interesting is the possibility to partially convert the carbonate in the smelt to borate with a small amount of metaborate, and then complete the causticizing of the remaining sodium carbonate in the recaust plant with a reduced amount of lime. This partial autocausticizing technology is an attractive alternative for kraft mills where the capacity of the recausticizing plant or the lime kiln is limiting the total production.
The partial borate-autocausticizing technology uses a small quantity of sodium borate to causticize a portion of sodium carbonate (Na_2CO_3), in a recovery boiler, and then completes the causticization of the remaining sodium carbonate in a conventional recaust plant with a reduced quantity of lime.

Borate autocausticizing reactions

The principal reaction that occurs in recovery boilers is the reaction between sodium meta-borate, and sodium carbonate, Na_2CO_3, in molten smelt to form tri-sodium borate (Reaction (1)).

$$NaBO_2 + Na_2CO_3 \rightarrow Na_3BO_3 + CO_2 \qquad (1)$$

In the dissolving tank, trisodium borate reacts with water to form sodium hydroxide, and regenerate sodium meta-borate (Reaction (2)).

$$Na_3BO_3 + H_2O \rightarrow NaBO_2 + 2NaOH \qquad (2)$$

If the borate make-up chemical, sodium tetraborate pentahydrate, $Na_2B_4O_7\ 5H_2O$, is introduced into the recovery cycle through mixing with green liquor or white liquor, it will react with sodium hydroxide to form sodium meta-borate in the liquor.
If the borate makeup is carried out through addition to black liquor, it will also react with residual sodium hydroxide in the liquor to form sodium meta-borate before entering the boiler. However, if the amount of $Na_2B_4O_7$ added is stoichiometrically larger than that of the residual sodium hydroxide in the black liquor, the excess $Na_2B_4O_7$ will react with sodium carbonate in molten smelt to form trisodium borate (Reaction (3), (4) and (5)).

$$Na_2B_4O_7 + Na_2CO_3 \rightarrow 4NaBO_2 + CO_2 \qquad (3)$$
$$4NaBO_2 + 2Na_2CO_3 \rightarrow 2Na_4B_2O_5 + 2CO_2 \qquad (4)$$
$$2Na_4B_2O_5 + Na_2CO_3 \rightarrow 2Na_3BO_3 + CO_2 \qquad (5)$$

Thus, several different sodium borate compounds can be formed and the overall autocausticizing efficiency depends strongly on the type of borate compounds formed in the boiler. Trisodium borate yields twice as much sodium hydroxide compared to $Na_4B_2O_5$ when hydrolysed in water (Reactions (2) and (6)).

$$Na_4B_2O_5 + H_2O \rightarrow 2NaBO_2 + 2NaOH \quad (6)$$

Sodium meta-borate does not yield any sodium hydroxide, while $Na_2B_4O_7$, if still exits in the boiler, would react with sodium hydroxide from the weak wash to form sodium meta-borate (Reaction (7)).

$$Na_2B_4O_7 + 2NaOH \rightarrow 4NaBO_2 + H_2O \quad (7)$$

Thus, if the make-up chemical is not well mixed in the liquor, or if the autocausticizing reaction in the boiler does not occur uniformly over the char bed, or if the bed temperature is not sufficiently high, the resulting smelt would contain not only trisodium borate, disodium metaborate, and sodium meta-borate, but also $Na_2B_4O_7$ which consumes sodium hydroxide. This would lower the overall autocausticizing reaction efficiency in the dissolving tank.

Recent studies from Tran et al, 2001 [4], and Cameron et al, 2001 [5], suggested a different stoichiometry and reaction product (Reaction (8) and (9)):

$$NaBO_2 + Na_2CO_3 \rightarrow Na_3BO_3 + CO_2 \quad (8)$$

$$5Na_2B_4O_7 + 2Na_2CO_3 \rightarrow 5Na_3BO_3 + 5CO_2 \quad (9)$$

The tri-sodium borate, formed by these reactions in the recovery boiler, dissolves in the smelt dissolving tank and forms caustic and metaborate (Reaction 2). Sodium metaborate remains dissolved in the liquor cycle to continue performing its autocausticizing function. No additional equipment is necessary for borate autocausticizing and the major cost involved is only the addition of makeup borate to compensate for the loss in the liquor cycle.

The major side effect is the increase in the inorganic content of the liquor due to the presence of sodium borate. This would complicate the use of borate in 100 % autocausticizing application. As a result, the initial focus of the technology was concentrated on the development of partial borate autocausticizing application, which is especially suitable in pulp mills that are recausticizing limited. By this manner the chemical species have regenerated without causticizing.

Regarding the black liquor gasification, the borate autocausticizing process is really interesting, since it is possible to avoid the immediate problem of increasing causticizing need. Black liquor gasification together with borate autocausticizing has some advantages:

The rotary kiln is the part of the process which still is dependent in many cases of fossil fuel. There are several alternative methods for heating the rotary kiln. This has proved to give either a decrease of the operating reliability, or give unwanted side-effects. With borate causticizing the production of the pulp in the mill can be totally free from fossil fuel. There are indications that the borate contributes to the delignification. This has not yet been able to be shown with experiments.

SIMULATION MODEL

Description of the system

The layout of the studied configuration represents the classical Chemrec-concept and is shown in Figure 1.

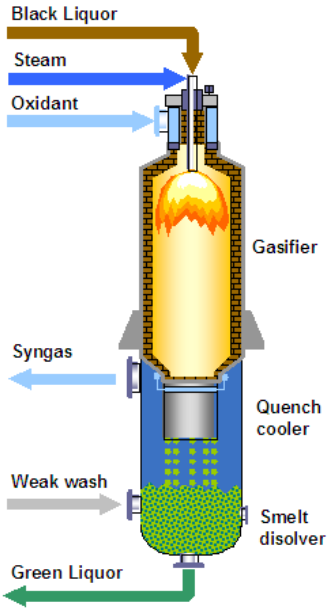

Figure 1: Basic plant configuration [6].

The gasifier is a vertically oriented entrained flow, operated at 1.3 bar, and 1000°C. Black liquor is introduced at the top, together with atomizing steam and oxidant, in this case air. The black liquor is atomized into a fine spray of droplets that undergo partial oxidation to form a combustible fuel gas and a smelt similar to that from a recovery boiler. The smelt and gas flow downwards in to the reactor and exit to the quench system.

The quench system is situated directly underneath the gasifier and is responsible for cooling the products as well as separating the smelt from the

fuel gas. The smelt falls into the quench sump, well mixed and fed with water or weak wash, to form green liquor. The fuel gas is saturated with water vapor, and passes through condensers to remove particulate matter and recover the latent heat. It then reaches a scrubber, where the gas temperature has reached 40°C. At this point, some chemical species are separated from the gas. The clean syngas is then ready to be combusted in a gas fired boiler. This gasifier has been simulated with the system process engineering software, ASPENplus. Simulations of the gasifier with usual black liquor have been studied in a first step, and with addition of borate in a second step.

Input data

The composition for black liquor and borate black liquor entering the combustor is shown in Table 1.

Elements	Without Borate [7]	With Borate[8]
C	37.18	34.71
H	3.55	3.31
O	35.09	32.77
N	0.09	0.08
S	4.86	9.07
Na	19.02	17.76
Cl	0.22	0.20
B	0	2.09

Table 1: Composition of the black liquor in mass % in dry solid.

Three different streams are needed in ASPENplus, for each stream, the flow rate of each component are as detailed on Table 2, with and without borate.

Stream	Comp.	Ordinary black liquor	Borate black liquor
Black Liquor	C	8.118	7.991
	Na	4.154	3.067
	O_2	7.663	6.121
	Cl_2	0.047	0.047
	N_2	0.019	0.019
	S	1.061	2.088
	B		2.925
H_2O	H_2O	5.557	5.499
	H_2	0.775	0.7620
Air		30	30

Table 2: Flow data in Aspen in (kg/s).

The pressure of the system is atmospheric pressure, and of the gasifier, 1.3 bar. The amount of air injected in the gasifier (30 kg/s) represents 45 % of the stoichiometric need. Dry solids content of the black liquor is 74.8%. The composition of the weak wash injected in the gasifier is shown in Table3 below.

Comp.	Min		Max	
	g/l water	kg/s	g/l water	kg/s
NaOH	5	0.20	15	0.59
Na_2CO_3	1.5	0.06	10	0.39
NaCl	0.1	0.00	0.5	0.02
Na_2S	0.5	0.02	5	0.20
Na_2SO_4	2	0.08	5	0.20
$Na_2S_2O_3$	2	0.08	5	0.20
PFG	0.1	0.00	5	0.20

Table3: Composition of the weak wash [9].

The B/Na mol ratio is over 3, which corresponds to the lower limit of complete reaction. Below this weigh ratio, the degree of completion decreases and appears to level off about 50–60 % completion [10].

Thermodynamical data

The base method used is the Redlich-Kwong-Soave equation of state with Boston-Mathias modifications (RKS-BM). ASPEN needs several input data which are not included in its data bank.
Standard enthalpy of formation at 25°C: DHFORM, and the standard free energy of formation at 25°C: DGFORM.

T (°C)	700	800	900	1000
NaCl	s	s	l	l
NaOH	l	l	l	l
Na_2SO_4	s	s	l	l
Na_2CO_3	s	s	l	l
Na_2S	s	s	s	s
$NaBO_2$	s	s	s	l
Na_3BO_3	l	l	l	l

Table 4: State of each compounds according to the temperature; (s=solid state, l=liquid state) [11].

Comp	DH (s)	DG(s)	DH(l)	DG(l)
NaCl	-411.2	-432.1	-385.2	-414.5
NaOH	-425.3	-445.39	-416.8	-439.
Na_2SO4	-1387.6	-1432.6	-1356.8	-1410.7
Na_2CO_3	-1130.7	-1172.3	-1108.1	-1155.2
Na_2S	-366.	-394.8	-323.4	-393
$NaBO_2$	-975.1	-1000.3	-960.2	-981.3
Na_3BO_3			-1966	-1700

Table 5: Enthalpy and free energy for different species [11].

For some species, such as Na_2S, $NaBO_2$, Na_3BO_3, The following parameters were estimated:

The critical temperature: for pure inorganic compounds, the method of Gambill was modified and requires only the boiling point as input [12]:

$$T_c=1,4T_b \qquad (1)$$

The acentric Pitzer coefficient (ω) is primarily a measure of the shape of a molecule. It is calculated from the reduced vapor pressure (P_r^{sat}) at a reduced temperature of 0.7 by the definition [12]:

$$\omega= -\log(P_r^{sat})_{(Tr=0.7)} -1 \qquad (2)$$

The acentric factor is used as a third parameter with the critical temperature, T_c, and the critical pressure, P_c, in cubic equations of state such as the Peng-Robinson equations. For simple spherical molecules, the acentric factor is essentially zero. For compounds of similar size and shape, the acentric factor increases slightly with increasing polarity [12].

The critical compressibility factor Z_c of a compound is calculated from the experimental or predicted values of the critical properties by the definition [12]:

$$Z_c=P_cV_c/RT_c \qquad (3)$$

The critical volume of a compound is the volume occupied by a set mass of a compound at its critical temperature and pressure [12].

$$V_c=RT_c/P_c(3,72+0,26*(4,919\omega-1,199) \qquad (4)$$

The data required in ASPEN are presented in the table below.

Data set	Unit	Na_2S	$NaBO_2$	Na_3BO_3
T_C	K	6888	2799.48	2864.4
P_C	atm	5	60	60
OMEGA		2.6	0.34746	0.70758
Z_C		0.293	0.259	0.232
V_C	m^3/kmol	3357.966	100.620	91.967
VLSTD	ml/mol	22400	22400	22400
T_b[11]	K	4200	1707	1848
T_r		0.7	0.7	0.7

Table 6: Thermodynamic data required in ASPEN. (T_c = critical temperature, P_c = critical pressure, OMEGA = acentric Pitzer coefficient, Z_c=compressibility coefficient, V_c=critical volume, VLSTD=standard liquid molar volume at 60F, T_b=boiling temperature, T_r=reduced temperature).

RESULTS

To establish a base case, the model was used to simulate gasification of non-borate black liquor. This has been done experimentally by several other authors and the results from this simulation model was compared with the results of Consonni et al., (1997) [13], see Table 7.

Components	ASPENplus	Consonni et al., 1997. [13]
Gas		
H_2O	14,632	13.100
H_2	13,977	19.200
CO	11,231	11.700
CO_2	18,646	12.500
H_2S	0,000	0.640
N_2	41,448	42.000
CH_4	0,066	0.913
COS	0,000	0.019
Smelt		
Na_2SO_4	0,677	0.000
Na_2CO_3	54,080	88.459
Na_2S	36,224	11.300
NaCl	1,100	0.000
NaOH	7,920	0.241

Table 7: Comparison of standard black liquor gasification with other reported results in mol%.

The results of the composition for the gas at the outlet of the gasifier are close to the results from Consonni et al. (1997) [13]. Species of

concentrations below 1E-3 % have been ignored, as they are considered as negligible. The reduction degree for the smelt is 100%. The results for borate gasification are shown in Table 8 and Table 9. The results were calculated with a Gibbs free energy of -1700 J/kmol.

Components	Mol %
H_2O	0.588
H_2	0.006
CO	0.007
CO_2	0.015
N_2	0.011
NaOH	39.297
NaCl	0.976
Na_2S	20.808
Na_2CO_3	2.363
Na_2SO_4	0.838
$NaBO_2$	35.092
Total	100

Table 8: Molar composition of borate green liquor flow in mol %.

Components	Rawgas	Syngas
H_2O	10.858	0.493
H_2	21.302	23.779
CO	22.836	25.491
CO_2	6.921	7.726
N_2	38.083	42.512
Total	100	100

Table 9: Mol composition of the syngas before and after gas cleaning in mol %.

From the results, it appears that autocausticizing does happen, Reactions (1) and (2). The molar fraction of CO_2 and NaOH are indeed higher for gasification with metaborate than for the case with conventional gasification. There is also sodium meta-borate in the smelt, indicating that Reaction (6) takes place in the gas phase, before the quench. This has to be verified by experiments, however. Also, effects of retention time on the completeness of Reactions (1) and (2) are still largely unexplored.

DISCUSSION

The model without borate worked properly and gave results close to the reality.

Regarding the simulation with borate, and based on the data available, it seems that an autocausticizing reaction happens in the gasifier. These results were obtained with a thermodynamic equilibrium calculation. Reaction kinetics and other reaction restraints are not considered. For simplicity, only orthoborate, has been included in the autocausticizing reactions. Other sodium borate species may well be equally important, like $Na_2B_4O_7$ and Na_3BO_3.

Recent experimental data by Sinquefield et al (2004) [14] point out that for a high temperature, low pressure gasifier, the retention time needs to be above 3 seconds.

These results have been calculated from an estimated Gibbs free energy of -1700 J/kmol for metaborate. With more data for the borate compounds that is slowly emerging, the model can be refined and improved.

The raw gas which is produced from the black liquor will contain more carbon dioxide than the usual gasified black liquor. There are some advantages and drawbacks. The concentration of CO_2 in the gas flow increases and it will be easier to separate it before the combustion. This has been chosen as a cost effective mean to decrease the CO_2 emission. Extracted CO_2 can also be used in pulp production. The drawback is that the raw gas can be less energetic and therefore will be harder to be used in a gas turbine.

The negative effects that have been identified with borate autocaustization are a possible increase of steam need in the process and possible increase of the viscosity of the black liquor at a high concentration of borate. The autocausticizing reaction is endothermic, which will influence the energy exchange for the gasification. An aspect that is not well investigated is the effect on the environment from the borate black liquor.

These calculations are based on thermodymical equilibrium and no considerations have been taken to the reaction kinetics.

CONCLUSION

The simulations concerning the gasification of black liquor without borate gave reasonable results, in line with results from other researchers, and were thus very promising.

Concerning the gasification of black liquor with borate, the model presented here is a first approximation of a thermochemical equilibrium model. Due to the lack of data for orthoborate, only a first approximation of autocausticization in a gasifier environment can be presented. Other borate compounds can also play an important part in the autocausticizing process. As soon as some data are

available, the model can be refined, for more accurate results.

SPECIAL PURPOSE SOLAR THERMAL SYSTEM AS A CLEAN DEVELOPMENT MECHANISM CANDIDATE IN GHG EMISSION REDUCTION

Paritosh Nandi*
School of Energy Studies
Jadavpur University
Calcutta-700032, India

ABSTRACT

A Solar Thermal system comprising of the concentrator, heat exchanger and the heat transfer fluid has been fabricated and an estimate has also been done of the saving in fuel and the reduction of emission. The payback period is being kept low through reduction in the initial cost outlay for setting up the system through improved designing for its better acceptability in small scale sector. With a very large number of such production units run with good profitability in the country, the reduction in emission will be appreciable and introduction of the system in numbers for regular use can be supported by Clean Development Mechanism.

Keywords: Sweetmeat, Clean Development Mechanism (CDM), Solar Parabolic Concentrator, Green House Gases (GHGs)

INTRODUCTION

Sweetmeat is a very common and popular item of the Indian sub-continental dishes. These palatable items are consumed by almost every section of people in India. As the sweetmeats are produced mainly in small-scale industries all over the country, its quantum of production generally goes unnoticed. However, the industry's annual turnover is, according to insiders, around Rs. 200 billion (more than $ 4 billion) and it provides employment, both direct and indirect, to about 1.5 million people. In the cost of production, energy, almost exclusively thermal, accounts for15% to 20% of the total and traditionally cheaper fuels like coal, fuelwood, etc. are used. Old traditional methods are still being followed and most of the items are based on milk. It needs mention here that the milk comes from semi-urban and rural areas for the urban outlets. A part of the processing is done at the milk diaries where milk is boiled to drive out a good part of water in it. There are two principal types of Indian sweetmeats: (a) Soft and semi hard products mostly from milks, and (b) Fried and crispy mostly made from flour and ground wheat and lentil. The second type has lesser shelf-life and forms a relatively small share of about twenty five per cent. This implies that most of the sweetmeats

*Corresponding author. Phone: +91 94333 19184
Email: paritoshnandy@yahoo.com
Fax: +91-33-24146853

are produced from milk. In the rural and semi-urban areas cheap traditional fuel coal and fuelwood are extensively used. In urban manufacturing units LPG and furnace oil are the major fuels, the latter having the natural preference because of its lower price.

TECHNICAL STUDY

The area of the concentrator which is made of anodized aluminium is 2.97 sq.m. and on the base of this the collector and the receiver tube is kept at an inclination of local latitude for the same purpose [1]. Tracking is employed in case of solar concentrating systems due to the movement of the sun in the sky with diurnal and seasonal position changes. For outdoor systems automatic tracking arrangement not only adds to capital cost but also requires skilled maintenance support. Essentially because of these two reasons fixed systems are preferred. However, manual and semi-automatic tracking results in an improved functioning of the system with marginal cost addition. Where grid electricity is not available automatic or semi-automatic tracking demanding interruption free electricity supply will be considerably expensive if the electricity is to be locally generated through photovoltaics or other renewable devices with storage. The concentrator and heat exchanger specifications are given here in below.

Concentrator material:	Anodized aluminium
Concentrator aperture:	1.20 m
Length of the concentrator	2.4 m
Collection area	2.88 sq.m
Reflectivity of the concentrator:	0.85
Receiver tube material:	Copper with black chrome coating
Receiver tube diameter:	40mm
Outer Glass tube (jacket) diameter:	65 mm
Amount of thermic fluid (in pipeline):	24 litre
Concentration ratio:	32

Four temperature sensors (including one sensor for recording ambient temperature) have been installed to measure the temperature at different points as given in Figure.1. For large scale application, multiplication of the same system is needed. An average temperature distribution in November 2004 of three installed RTDs on the fabricated system is shown in Figure 2.

Technological Risk

This is a supplementary system. With an average 250 sunny days in most of the regions of the country on more than two thirds of the total sunshine hours in a year the system can be put to use. With hardly any moving system the downtime will also be low.

BENEFICIAL FEATURES OF THE SYSTEM

Compared to the high cost of oil that is likely to be in future, energy conversion systems based on renewable energy technologies are much cost

effective. Renewable energy systems also have a positive impact on the various environmental, economic and political issues of the world. Benefits accruing from installation and operation of renewable energy systems can be classified into three categories, viz., saving of energy, generation of new working posts and reduction of environmental pollution [5]. Energy is saved by reduction in consumption of electricity and LPG which are the conventional energy sources. This benefit can be expressed in terms of money having regard to the corresponding production or the capital expenditure for the purchase of imported fossil fuels avoided. Further, various countries also take interest in the potential for economic development of exporting renewable energy technology expertise. The amount of emissions from solar thermal systems depends on the type of fuel used as auxiliary. In using electricity or Diesel backup in solar thermal systems, the percentage saving obtained is about 80% whereas if both electricity and Diesel are employed, the saving is 75% [6].

Electricity is uneconomical and is almost never used in the manufacturing stage. The Solar Thermal system will definitely cut down the demand of the fossil fuels like coal, oil and gas and also fuelwood. This will lead to emission reduction. The use of solar energy for heating purposes results in the reduction of emission of GHGs released through the burning of fossil fuels to produce the required thermal energy. In process industries inter-fuel substitution is often adopted for efficient system operation like replacement of coal by oil or gas. However, a substantial reduction in CO_2 emission can be achieved by utilizing solar thermal energy. A typical case of utilisation of solar thermal system and the reduction of CO_2 emission thereby can be more or less correctly estimated as shown below.

1.Emission Reduction Potential – GHG mitigation

LPG burner replaced

1kg of LPG emits 3.20 kg of CO_2, and 0.0056kg of CO in the atmosphere [2].

No of cylinders used (per day)	LPG content per cylinder (Kg)	LPG used per day (Kg)
4	17	68

Considering 250 days of operation in a year

LPG used (Kg/yr)	CO_2 emitted (yr)
17000	54.4 tons

2. Economic Analysis

LPG used per Day (Kg)	No. of pieces sweets produced (per day)	Average price (Rs.)	Daily turnover (Rs.)	Yearly turnover (Million rupees)
68	10000	2	20000	7.2

Considering total turnover is Rs. 200 billion in sweetmeat industry

Yearly turnover (Million rupees)	**CO_2 mitigated (Ton)**
7.2	54.4
200000	1510000

3. Economic Benefits:

Electrical heating system replaced [3]

Collection area	4.88 m^2
Solar insolation available	5.5 Kwh/sq.m/day
Temperature of hot milk	100 °C
Ambient temperature	25 °C
Cost of electricity	Rs.3.50 /kWh
Efficiency of electrical heater	80% ~ 90%
Efficiency of solar hot water system	50%
Life of the system	15 yrs
Heat available from Solar System	5.5×4.88×0.5 kcal/day
Saving in electricity consumption per day	13.42/0.9= 14.91
Cost of electricity saved	15×250×3.5 = Rs.13125.00
Cost of the solar system	Rs.20000.00
Pay back period	1.52 years

BARRIERS IN APPLICATION

i) Manual operation is necessary for tracking of the system which may be considered as a disadvantage in its application. Automatic tracking will deliver more energy or heat but automatic tracking is not only expensive but electric power required for tracking may also not be available in the rural areas

ii) This system is supplementary. It can not work alone throughout the year as the required amount of solar radiation that is 5.5 kWh/sq.m/ day on an average is available for 250 days only in a year. During the rainy season and for cloudy days other heating arrangements are required.

iii) As it is a new technology obviously there are some psychological barriers in its acceptance. However, adaptation of a system is better when smooth running of the system is ensured. Therefore, care is to be taken in the training of the skilled hands for its maintenance.

DESIRED PROMOTIONAL SUPPORT

It is obvious that the system cost will not be low. It is true that fuel costs are avoided but a large system cost will not make it attractive to small scale producers. Convinced of the beneficial features of such a system in eliminating to a good extent the use of oil/coal/wood and emission of CO_2, it is submitted that promotion of such systems should receive due support from government and the other agencies. Creating awareness regarding the long term benefit of the system is of course important but more important is to provide the due financial support in the form of soft loans to enable the processed food producers to invest for the installation of such

system in their work. Soft loans are to be introduced and other fiscal incentives/reliefs can be thought of. CDM is considered to be a powerful market mechanism in the emission reduction of GHGs and the extension of CDM for the application of such systems is to be seriously considered.

ELIGIBILITY FOR CDM

As per the UNFCCC the eligibility set for CDM [4] are the followings:

Baseline

In all sweetmeat manufacturing units heating is done by coal oil gas or fuel wood. If solar energy is employed the reduction in fuel consumption will surely mean a reduction in the emission of GHGs. If we start with the baseline of fuel based systems, introduction of solar thermal systems in large numbers would result in adequate emission reduction and such large deployment will qualify as a CDM candidate. As has been stated earlier it is a completely new technology and its proliferation will result in a significant reduction of emission. The system itself and its operation do not have wide variation. Amount of saving of fuel in a single day can be computed with knowledge of number of units in use in different locations/zones and an estimate of average available solar radiation in these zones from radiation measurements and thus the total fuel saving in a year can be computed. According to our computation based on recorded solar data each system can account for a reduction of emission of 50 tonnes per year. If hundreds and thousands of such systems are installed in a country it will result in a saving of around 50 MT of emission per year.

Additionalities

Additionality means to the projects which would not have taken place in absence of the crediting procedure or trading scheme. The proposed solar thermal system necessarily comes with an investment without an attractive payback period. The systems will not be used in larger numbers without any incentive. If a support comes through CDM the cost of installation will be lesser and the proposal of deployment in large number will be more realistic. It is to be admitted that there is a general reluctance in absorbing a new technology and the prices matter. It will be extremely difficult in the current volatile market of oil and gas to predict the future of solar thermal systems. However, if the systems can be made more reliable and user friendly, it will definitely be accepted by the industry. The project is yet to finalise the system design and as a result prospective customer response is yet to be had. Among the additionalities mentioned the three main additionalities are Emission, Financial and Technological additionalities. It is well clear from this case study that firstly the real measurable long term GHG mitigation is quite possible as it has already been shown. Secondly the funding for

CDM in case of solar thermal system application will not lead to diversion of official development. Thirdly it is obvious that the technology of such a solar heating system is environmentally safe and sound.

Sustainable Development Indicators:

The report is an attempt to bring to the kind notice of the policy makers in the use of a solar energy device in an industry which employ a large number of people and fairly expanding.

- ♣ It will generate employment
- ♣ It would have wider application in rural areas
- ♣ The system is as such based on the solar energy utilization and therefore sustainable in character.

A concrete evidence will demand an extensive survey in semi-urban and rural areas on the adoption of solar thermal system by the sweetmeat industries. Conduction of awareness programmes and successful demonstration will help in the desired wide-spread use. The Ministry of Non-conventional Energy Sources (MNES),

Government of India has withdrawn subsidies offered to solar thermal systems assuming that solar thermal industry can now be fully market driven. But the Ministry has taken a massive programme on the popularization of solar/renewable energy devices and solar thermal system is one. National level specifications are being framed for the purpose of standardization only in case of established products like solar cookers, solar flat plate collectors etc. Some fiscal incentives are being offered at the state level (West Bengal) but the quantum has not been fully specified. The overall policy of the government is in general highly supportive of such devices.

iv) With the introduction of this new system improvement of the quality of life of the poor people in rural areas is expected as this sweetmeat industry is mainly confined to the cottage and small scale sector employing a large number of people. Alleviation of poverty is also ensured as with the introduction of the new system in the sweetmeat industry additional employment will be generated for manufacturing of the solar systems. The introduction of the new system will not lead to any retrenchment as labour intensity will remain the same. Direct benefit from no-smoke condition with the introduction of solar heating system instead of burning conventional fuel also results in reduction of level of pollution in general.

The solar energy systems have certain negative environmental impact such as land displacement, possible air and water pollution resulting from manufacturing, normal maintenance operations and demolition of the systems. However, the limitation of land use can be done away with by mounting collectors on the roof of a building. The maintenance required is so less here that the pollution caused by demolition is not greater than the pollution caused from demolition of a conventional system of similar capacity. Similarly, in case of consumption of insignificant quantities of materials by the solar thermal system, the only potential environmental pollutant arises from the

coolant change and it can be easily controlled by good working practice. The accidental leakage of the heat transfer fluid can cause hazards to the workers' health and safety but the large-scale use of solar thermal systems would lead to significantly reduction in the burning of fossil fuels and will thus; reduce the environmental impacts associated with those.

Financial Indicators

Under the heading BENEFICIAL FEATURES OF THE SYSTEM in the paper in point (2) and point (3) it has been clearly shown that the payback period is low and the cost effectiveness of energy saving is ensured.

Manpower

In the fabrication, installation, erection and commissioning and testing of the system the following manpower will be required.

i) Skilled manpower indicates the jobs of mechanical fitter, welder, marker, mason and plumber etc. The total working hour required is around 70.

ii) Total unskilled manpower required is around 100 hours.

CONCLUSION

The governments at the centre and in the state are supportive of the development of such solar thermal system. Popularisation of the same with eventual reduction of carbon dioxide will be an humble step in meeting the objectives of the Kyoto Protocol. CDM support will mean an enormous boost to the healthy induction of a new technology in a traditional industry.

ACKNOWLEDGEMENTS

The author gratefully acknowledges the support received from the Department of Science and Technology and the CSIR, Government of India The author is also grateful to Prof. Sujay Basu and Ms. Rupanjana De for their help and encouragement.

ABSTRACT

The problem of the improving efficiency is very important in the design and operation of energy intensive systems. The main way for solving this problem is an optimization. This paper describes the general approach for the thermoeconomical optimization of the system with linear structure. The suggested method is based on the creation and analysis of the special thermoeconomical expenditure graphs. This method is illustrated by an example of solar heat pump systems with season heat storage optimization.

INTRODUCTION

Processes that are taking place in the complex energy intensive systems are characterized by mutual transformation of quantitatively different power resources. The fast growth and development of the modern technologies requests a thermodynamic analysis and optimization of these systems, based on combined application of both thermodynamics laws which request an exergy approach [1]. Exergetic methods are universal and make it possible to estimate the energy fluxes and to build up the energy balances for every element of the system using a common criterion of efficiency. Therefore, the exergetic methods are meaningful in the analysis and calculations.
Despite its usefulness, the benefits of the exergetic approach were not fully realized until recent years.
One reason for this situation is the underestimation of exergetic functions for mathematical modeling, synthesis, and optimization of the flow sheets. Another reason is the mathematical difficulty of the exergetic approach in thermodynamic analysis. Meanwhile, the increase in the complexity of optimization problems requires more effective and powerful mathematical methods. Hence, many papers have been published during the last few years, with the different applications of the exergetic methods [2,3,4].
Above mentioned papers, as well as the author's earlier investigations [5-10] show that one of the most effective mathematical methods used for exergetic analysis and optimization is the method of graph theory [8]. The benefit of the graph models can also be demonstrated by its flexibility and its wide varieties of possible applications.
Exergy topological methods include the sole use or the combination of the exergy flow graphs, exergy loss graphs, and thermoeconomical graphs [5-9].
Systems with linear structure are often used in energy technology as well as in other branches of industry. For that reason it is necessary to study the problem of linear structures systems optimization separately from the systems with arbitrary structure.

METHOD OPTIMIZATION OF LINEAR SYSTEMS

First, let us consider a homogeneous system that contains n different elements of one type (as shown in Fig. 1.)
In this system one flow h_j, j=1 interacts successively with flows C_i , i=1,2,…n.
In the problem of optimal synthesis, it could be reformulated in such a way:
It is necessary to distribute the multitude of flows
$C = \{C_1, C_2, ..., C_i, ..., C_n\}$
along the flow h_j (j=1) and the result of the interaction of these parameters of flow h_j in outlet of system will be in interval of required constrains and thermoeconomical criteria will be minimized

$$\sum_i \sum_j Z_{ij} = Z_\Sigma^{\min} \qquad (1)$$

where
Z_{ij} -thermoeconomical expenditure at i-element (j=1).
For solving this type of problem, it is necessary to build the graph of thermoeconomical expenditure as it was shown in [8]. In our case this graph will be a tree $Z = (N, D)$. The multitude of nodes N displays the possibility of distribution of flows in the system, the multitude of arcs D ,

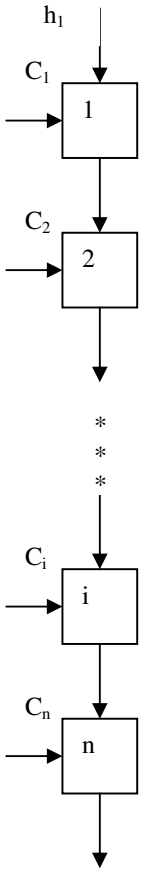

Figure1: Linear system

displays the possible meanings of thermoeconomical expenditures.

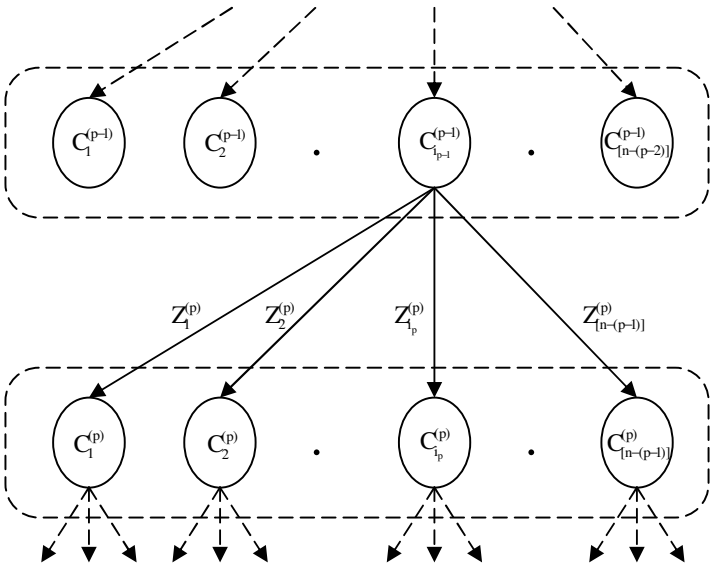

Fig.2. (P-1) and P - levels tree of thermoeconomical expenditure

The governing equation which are representing these levels are:

$$N = N_0 \mathbf{Y} N_1 \mathbf{Y} N_2 \mathbf{Y} .... \mathbf{Y} N_p ... \mathbf{Y} N_k$$

$$N_p = \left\{ C_1^{(p)}, C_2^{(p)}, ..., C_{i_p}^{(p)}, ..., C_{[n-(p-1)]}^{(p)} \right\} \quad (2)$$

$$p = 1,2,...,k; i_p = 1,2,...,\left[n - (p-1) \right]$$

where

$$N_p \subset C,\ p = 1,2,...,k,$$

$$p = 0 \Rightarrow \left| N_0 \right| = 1$$

$$p = 1 \Rightarrow \left| N_p \right| = \left| C \right|, C - N_p = \varnothing \quad (3)$$

$$1 \le p \le k \Rightarrow \left| N_p \right| \le \left| C \right|$$

$$\forall \left(C_{i_{p-1}}^{(p-1)}, C_{i_p}^{(p)} \right) \in D \Rightarrow \left(C_{i_{p-1}}^{(p-1)}, C_{i_p}^{(p)} \right) = Z_{i_p}^{(p)} \quad (4)$$

$$\forall \left(C_{i_{p-1}}^{(p-1)}, C_{i_p}^{(p)} \right) \notin D \Rightarrow \left(C_{i_{p-1}}^{(p-1)}, C_{i_p}^{(p)} \right) = \infty \quad (5)$$

where symbol ∞ shows that arcs of this type are absent.

The flow hj in graph $Z(N, D)$ is described as node $C_0^{(0)}$. Then for obtaining conditions (1) it is necessary to find an optimal way $\overline{C} \subset N$,

$$\overline{C} = \left(C_0^{(0)}, C_1^{(1)}, ..., C_{i_p}^{(p)}, ..., C_{[n-(p-1)]}^{(k)} \right) \quad (6)$$

so that

$$\sum_{i_p} \sum_{p} Z_{i_p}^{(p)} = Z_{\Sigma}^{\min} \quad (7)$$

The algorithm of Belmann-Kalaba is usually used for seeking the optimal way in graphs without contours. This algorithm is based on the matrix of expenditures analyses [8].

In our case the graph of thermoeconomical expenditure is following:

$$\Gamma_p N_p = N_{p+1} \quad (8)$$

where Γ_p is display of set N_p, and condition of Eq. (4) will be valid for elements of matrix which are located in the intersection of columns $C_{i_p}^{(p)}$ and lines

$C_{i_{p-1}}^{(p-1)}, p = 1,2,...,k;\ \ i_p = 1,2,...,\left[n - (p-1) \right]$.

This feature of graph of thermoeconomical expenditure allows one to simplify the matrix of expenditure and to reduce the number of analyzed variants in **n** times [8].

Based on features of the thermoeconomical expenditure graph, we recommend the algorithm of searching optimal variant.

Each step of seeking an optimal variant is successively compared with thermoeconomical expenditure $Z_{i_p}^{(p)}$ and $Z_{\min}^{(p)}$. In result, the flow corresponded equation (7) can be found. Then applying the procedure of seeking $Z_{\min}^{(p)}$ to all k steps, we will find the optimal flow distribution that corresponds to the condition in Eq. (1).

In case of inhomogeneous linear systems optimization, the main idea of this approach will retain.

Since inhomogeneous elements are able to change the different characteristics of flow h_j, it is necessary to consider not only the p th-step but also previous steps of the system's optimization. Consequently the method of dynamic programming has to be changed to branch- and -bound method. On this approach at each step we seek and then save expenditure $Z_{\Sigma}^{(p)\min}$, where $Z_{\Sigma}^{(p)}$ is the sum of thermoeconomical expenditure for all p steps of considered variant. Then expenditure $Z_{\Sigma}^{(p)\min}$ will be compared with the analogous sums for the previous steps $(p-1),(p-2),...,1$.

Then the variant corresponding to the following equation has to be developed

$$Z_{\Sigma}^{\min} = \min\left[Z_{\Sigma}^{(l)\min} \right], l = 1,2,..., p \qquad (9)$$

The elements for the next step of optimization have to be taken from the multitude N_{p+1}, which corresponds to equation (8).

OPTIMIZATION OF A SOLAR-HEAT PUMP SYSTEMS WITH SEASON HEAT STORAGE

The described above approach was applied to the optimization of a solar- heat pump systems with season heat storage (SHPS) with total heat productivity of 0.5 MW (see Fig. 3.) detailed description of which is given in [5].

The main difference of a SHPS from others energy intensive systems with conventional energy sources is the presence of a "charge-free" source -the sun.

However, the use of the thermoeconomical approach allows to take into account real exergy losses in the subsystem: a solar collector - the heat exchangers and to find the certain cost of the SHPS as a whole.

As it was shown above the application of the suggested method of optimization requests the presentation of the system's structure in "linear view".

For the SHPS it is possible to present this scheme as a four-sequence levels (zones) graph of thermoeconomical expenditures as it is shown in Fig.4.

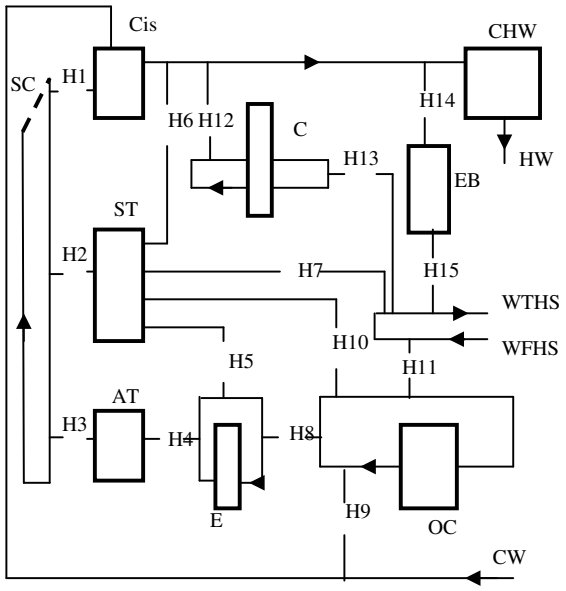

Fig. 3. Solar- heat pump systems with season heat storage.

Flows: CW - cold water; HW- hot water; WTHS - water to heating system; WFHS- water from heating system. Elements: H1-H15 - heat exchangers; SC- solar collector; Cis - cistern; ST - season storage tank; AT - antifreezes tank; E- evaporator of heat pump; C - condenser of heat pump; OC - oil cooler of heat pump; EB - electric boiler; CHW - cistern of hot water.

Numbers of indexes "i" coincide numbers of heat exchangers of the scheme in Fig.3. (e.g., Z_V - thermoeconomical expenditures the heat exchanger H5). For the other elements the correspondence of nodes of thermoeconomical graph and elements are following: solar collector (SC)- Z_{XVI}; cistern (Cis)- Z_{VII}; season storage tank (ST)- Z_{VIII}; antifreese tank (AT) - Z_{XIX}; evaporator of heat pump (E)- Z_{XX}; condenser of heat pump (C) - Z_{XXIV}; oil cooler of heat pump (OC)- Z_{XXI}; EB - electric boiler (EB)- Z_{XXII}; cistern of hot water (CHW) - Z_{XXIII}.

After transforming the initial scheme SHPS (Fig.3.) to a view of graph of thermoeconomical expenditures (Fig.4.) it is easy to build the tree of thermoeconomical expenditure shown in Fig.5.
The tree of thermoeconomical expenditure will also contain four levels ss it follows from the analysis of the graph in Fig.4.
Further consideration will be presented on an example of SHPS with a total heat production of 0.5 MW.
This system was analyzed in [5] for 64 variants:

- area of Solar Collector: A_{SK}= 1000 м^2; 2000 м^2; 3000 м^2; 4000 м^2;
- volume of Season Storage Tank :V_{ST}=3000 м^3; 4000 м^3; 11000 м^3; 15000 м^3;
- use factor for Heat Pump: n=0.2, 0.4, 0.6, 1;
- use factor for Electric Boiler Heat: s=0.2, 0.4, 0.6, 1;

with an appropriate economical estimation for each of analyzed variant.
The advantages of the suggested approach are described by solving this optimization problem.
Level I (Fig. 5.) contains four trailing tops reflecting possible thermoeconomical expenditure in a zone I (Fig.4). Zone I includes one solar collector and three heat exchangers H1, H2, H3.
The number of tops in level I is equal to four pursuant to four sizes of solar collector area A_{SK}= 1000 м^2; 2000 м^2; 3000 м^2; 4000 м^2;
Accordingly, a possible thermoeconomical expenditure at level I is:

$$Z^I_k = Z^k_I + Z^k_{II} + Z^k_{III} + Z^k_{XVI},$$

With k = 1,2,3,4 - displays four sizes of Solar Collector and correspondent heat exchangers H1, H2, H3.
With the growth of the area of solar collector not only its cost will grow, but also the cost of the heat exchangers H1, H2, H3,so $Z_1^I < Z_2^I < Z_3^I < Z_4^I$
Level II also contains four trailing tops reflecting possible thermoeconomical expenditure in a zone 2 (see Fig.4.) which includes tanks Cis, ST, AT, and heat exchangers H4, H5, H6.
As the size of the season storage tank - accumulator varies (V_{ST}=3000 м^3; 4000 м^3; 11000 м^3; 15000 м^3) different Cis, AT and heat exchangers H4, H5, H6 of correspondent size are needed. Analogically to level I:

$$Z_l^{II} = Z^l_{IV} + Z^l_V + Z^l_{VI} + Z^l_{VII} + Z^l_{VIII} + Z^l_{IX},$$

l = 1,2,3,4.

With growth of a volume V_{ST} the indispensable costs of other tanks and heat exchangers will also increase, so $Z_1^{II} < Z_2^{II} < Z_3^{II} < Z_4^{II}$.
Level III is reflecting possible thermoeconomical expenditure in a zone 3 (see Fig.4) including the heat pump and the supplementary heat exchangers. It contains 4 tops displaying the use-factor of the heat pump.
The main difference to the previous two levels is the invariable cost of the equipment, the essential factor is the costs of the electric power consumption, depending on use-factor of the heat pump n = 0,2; 0,4; 0,6; 1:

$$Z_m^{III} = Z^m_{VII} + Z^m_{IX} + Z^m_X + Z^m_{XI} + Z^m_{XII} + Z^m_{XIII} + Z^m_{IX} + Z^m_{XX} + Z^m_{XXI} + Z^m_{XXIV},$$

m = 1,2,3,4.

With growth "n" the thermoeconomical expenditure also grows in this zone, so $Z_1^{III} < Z_2^{III} < Z_3^{III} < Z_4^{III}$
Level IV reflects the possible thermoeconomical expenditure in a zone 4 (see Fig.4) including the electric boiler, heat exchangers H14 and H15, and also cistern with hot water.
This level contains the water heating after level III that increases the thermoeconomical expenditure.
Accordingly level IV also contains four tops, that increases the thermoeconomical expenditure:

$$Z_1^{IV} < Z_2^{IV} < Z_3^{IV} < Z_4^{IV},$$

Where:

$$Z_r^{IV} = Z^r_{XIV} + Z^r_{XV} + Z^r_{XXII} + Z^r_{XXIII},$$

r = 1,2,3,4.

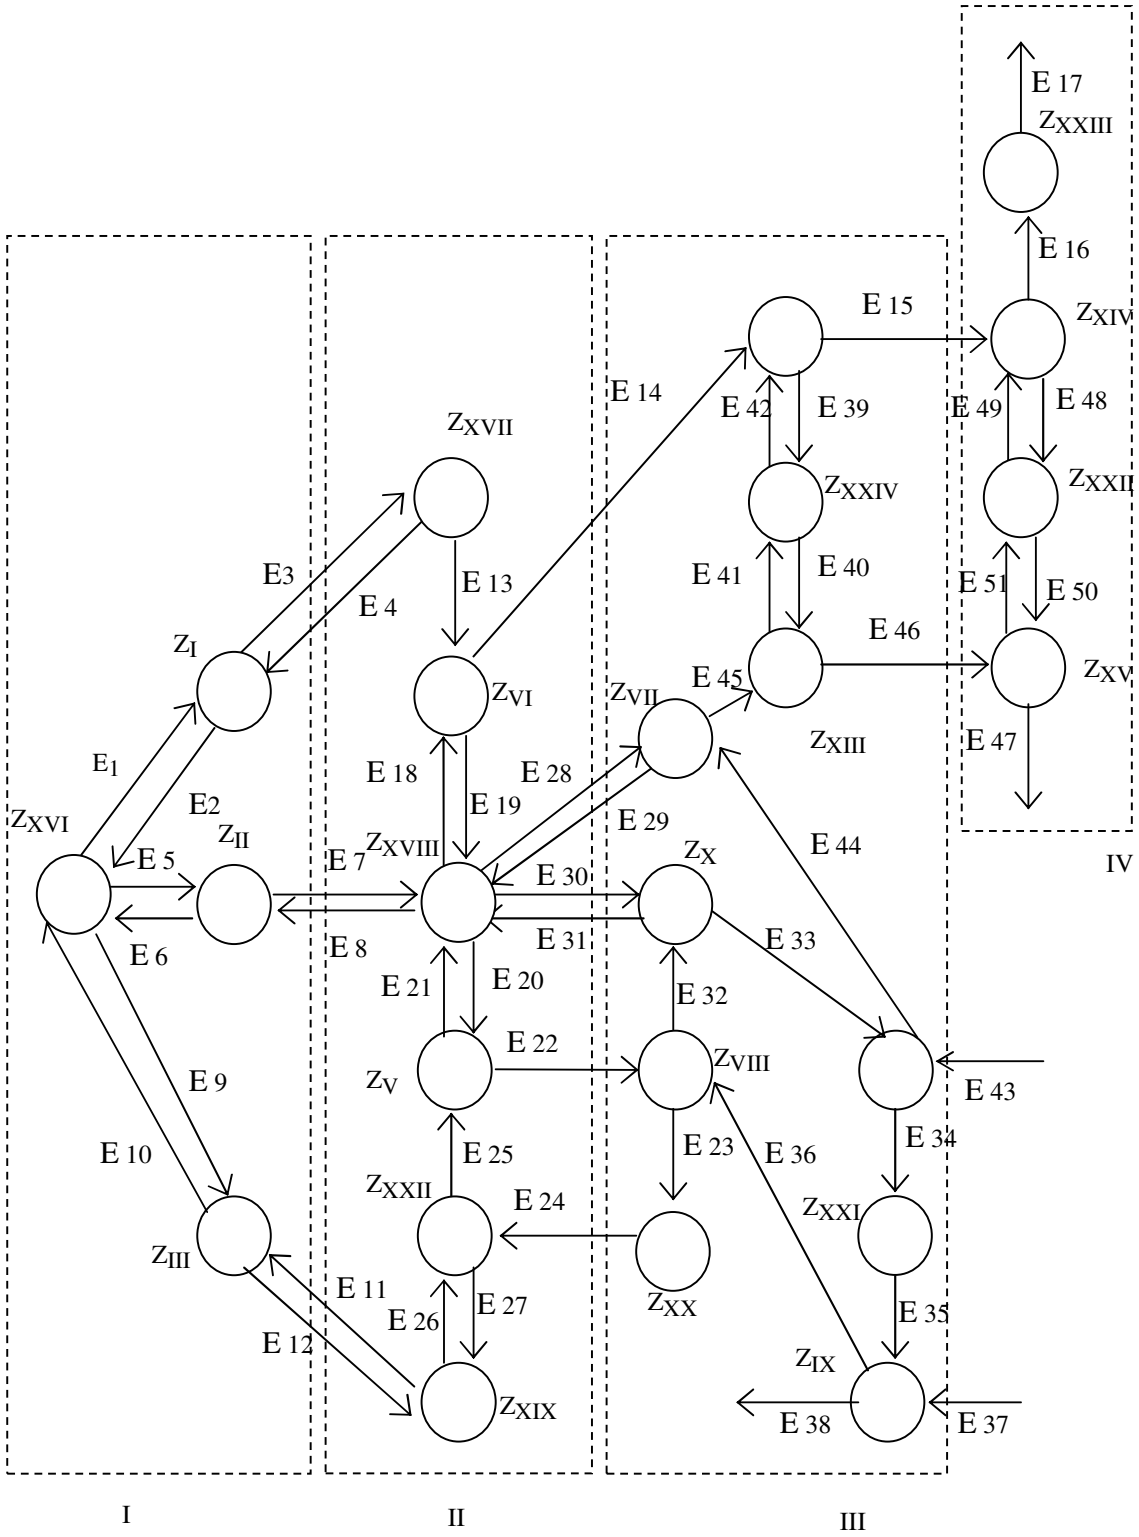

Fig.4. Graph of thermoeconomical expenditures the system shown in Fig.3.

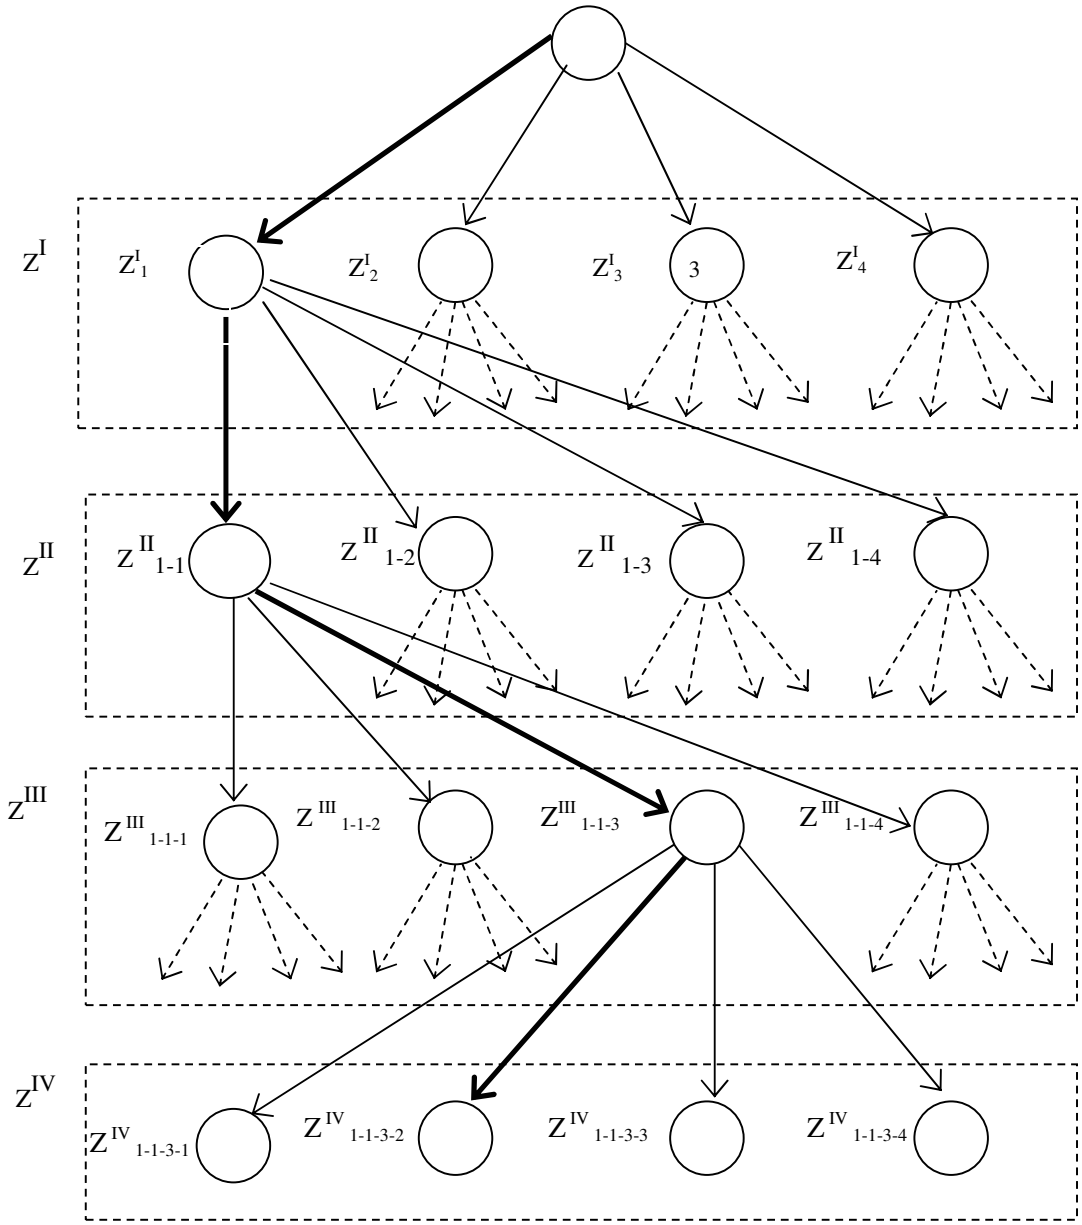

Fig.5. Tree of possible thermoeconomical expenditures

In the tree of possible thermoeconomical expenditure (Fig.5) each trailing top corresponds to the total thermoeconomical expenditure in the subsystem of the SHPS for given and the previous levels. The number of bottom indexes for trailing tops corresponds to the number of levels in the tree and also reflects the previous way to this trailing top.

For example the top $Z^{III}_{1\text{-}1\text{-}3}$ reflects the thermoeconomical expenditure of selected version 1 in a zone I, version 1 - in a zone II and version 3 - in a zone III.

The application of the described approach allows to receive the minimum value of thermoeconomical expenditures for trailing top $Z_{1\text{-}1\text{-}3\text{-}2}$. So, the optimal variant for the SHPS with total heat production of 0.5 MW is the system with a Solar Collector A_{SK}= 1000 м^2 , Season Storage Tank V_{ST}=3000 м^3 , use- - factor for the Heat Pump n=0.6, use factor for the Electric Boiler Heat s = 0.4.

So the correspondent minimum of the thermoeconomical expenditures in the system:

$$Z_{\Sigma}^{opt} = Z_{1\text{-}1\text{-}3\text{-}2} = 2502 \text{ USD/year}$$

The optimal variant is shown by bold arcs on the tree of the possible thermoeconomical expenditures (Fig.5)

It is easy to see, that in contrast to a method of direct enumeration [5] which requests the calculation of full 64 versions of a system, the suggested by us procedure of a "tree search" requests for optimization only 8 full calculations of SHPS (zone IV), 8 calculations up to a zone III and 16 calculations of zones I and II.

In result the total time for seeking an optimal variant decreased more than in 6 times.

CONCLUSION

The problem of developing the modern technologies based on optimization of linear systems has to be solved separately from the problem of optimization of systems with arbitrary structure. On the basis of features of linear systems it is possible to build the effective procedure of optimization. The suggested method based on development and analysis of the thermoeconomical expenditure graph. It allows to find the optimal variant for homogeneous systems as well as for systems with different types of elements. The method is illustrated by an example of optimization for the solar-heat pump systems with the season heat storage.

ABSTRACT

The steam-reforming of CH_4 and LPG using concentrated solar power as the source of process heat is thermodynamically examined in the temperature range 300-1300 K, pressure range 1-20 bar, and steam to hydrocarbon molar ratios range 1-3. The solar-driven process increases their LHV by over 20%. A steady state process model that includes mass and energy conservation coupled to equilibrium thermodynamic composition is formulated to predict the system performance of an idealized and a 400 kW-demonstration solar reforming plants. Process optimization predicts a peak solar-to-chemical exergy efficiency of 60%.

INTRODUCTION

The advantages of using concentrated solar power to drive the endothermic reforming of hydrocar-

bons are three-folded: a) the discharge of pollutants is avoided; b) the gaseous products are not contaminated; and c) the calorific value of the fuel is upgraded. The solar reforming using either steam or CO_2 as partial oxidant has been extensively studied in solar concentrating facilities with small-scale solar reactor prototypes using Rh-based catalyst [1-7] Fe-based catalysts [8,9]. Recently, it has been demonstrated to proceed without added catalysis [10]. The solar reforming process has been scaled-up to power levels of 300-400 kW and tested at 1100 K and 8-10 bars in a solar tower concentrating system using two solar reforming reactor concepts: an indirect-irradiation tubular reactor [11] and a direct-irradiation volumetric reactor [12,13]. The latter is being further developed within the EU-project SOLREF [14]

This paper examines the chemical thermodynamics and process engineering of the solar reforming under the operating conditions of the 400 kW demonstration plant [15]. The chemical equilibrium compositions of methane-steam and LPG-steam systems are calculated for various stoichiometries in the pressure range 1-20 bar and temperature range 300-1300 K. Special attention is devoted to identifying the conditions that favor coking, as these will have to be avoided for preventing catalyst deactivation and carbon deposition on the reactor window. Two steady-state plant models are examined: 1) an idealized plant with theoretically minimum losses; and 2) the actual demonstration plant with measured operating parameters. Both models are compared in terms of their energy efficiency and chemical conversion for identifying irreversibility sources and optimization potential.

CHEMICAL THERMODYNAMICS

The chemical equilibrium compositions and enthalpy changes are computed using the HSC code [15] by Gibbs free enthalpy minimization. The solar steam-reforming of CH_4, represented by the overall stoichiometry reaction

$$CH_4 + H_2O = CO + 3\,H_2 \qquad (1)$$

has the potential of increasing the LHV of the feedstock (LHV_{CH4} = 797.5 kJ/mol) by 25.6 %. If CO is further water-gas shifted, 4 moles of H_2 may be obtained per mol CH_4 fed. In practice, however, a significant amount of CO_2 is co-produced while excess steam is used for avoiding coking, which decreases the energy efficiency. Further complication arises when other hydrocarbons are used as feedstock, as in the case of liquid petroleum gas (LPG) in the 400 kW solar demo plant. Typical LPG composition is listed in the Appendix. Its average C molar content per mole of the mixture is 3.682, its average molar ratio H:C is 2.54, and its average molecular mass is 53.5 g/mol. The solar steam-reforming of LPG, represented by the overall stoichiometry reaction

$$1\,LPG + 3.682\,H_2O = 3.682\,CO + 8.358\,H_2 \qquad (2)$$

has the potential of increasing the LHV of the feedstock (LHV_{LPG} = 2448 kJ/mol) by 24.3%. Table 1 shows the equilibrium composition of the CH_4-H_2O and LPG-H_2O systems at 1100 K and 1 bar, and for H_2O:CH_4 and H_2O:C molar ratios of 1, 2, and 3, respectively. For example, for a H_2O:CH_4 = 1, the solar steam-reforming of CH_4 increases its LHV by 23.1%. For H_2O:C = 1, the solar steam-reforming of LPG increases its LHV by 22.3%.

Table 1 Equilibrium molar composition of the CH_4-H_2O and LPG-H_2O systems at 1100 K and 1 bar, and for H_2O:CH_4 and H_2O:C molar ratios of 1, 2, and 3, respectively.

Figure 1 shows the variation of the equilibrium composition of the CH_4-H_2O system as a function of temperature at a total pressure of 1, 10, and 20 bars. The parameter is the H_2O:CH_4 molar ratio: 1, 2, and 3. For H_2O:CH_4 = 1, carbon formation is thermodynamically favorable in the range 700 - 1100 K. Elevated pressures inhibit carbon formation, but at the expense of shifting the equilibrium to higher temperatures, according to Le Chatelier's principle. For H_2O:$CH_4 \geq 2$, carbon is not present in equilibrium.

The variation equilibrium composition of the LPG-H_2O system as a function of temperature at a total pressure of 1, 10, and 20 bars is shown in Figure 2. The parameter is the H_2O:C molar ratio: 1, 2, and 3. As expected carbon formation is more pronounced than in the CH_4-H_2O system because the H/C ratio is lower. For example, for H_2O:C = 1, carbon formation is thermodynamically favorable throughout the whole temperature and pressure range. Similar to the CH_4-H_2O system, the

equilibrium is shifted to higher temperatures with increasing pressure. For H_2O:C ≥ 3, carbon is not present in equilibrium.

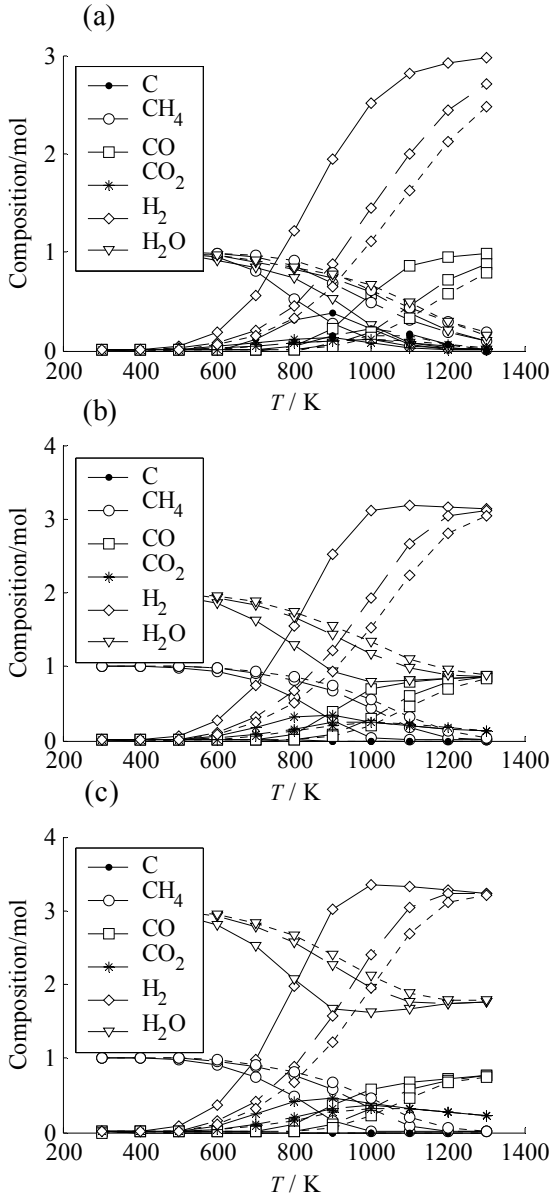

Figure 1 Equilibrium composition of the CH_4-H_2O system vs. temperature at a total pressure of 1 (solid curves), 10 (dashed curves) and 20 bars (dotted curves), for 1 mol CH_4. The parameter is the H_2O:CH_4 molar ratio: (a) H_2O:CH_4 = 1, (b) H_2O:CH_4 = 2, (c) H_2O:CH_4 = 3.

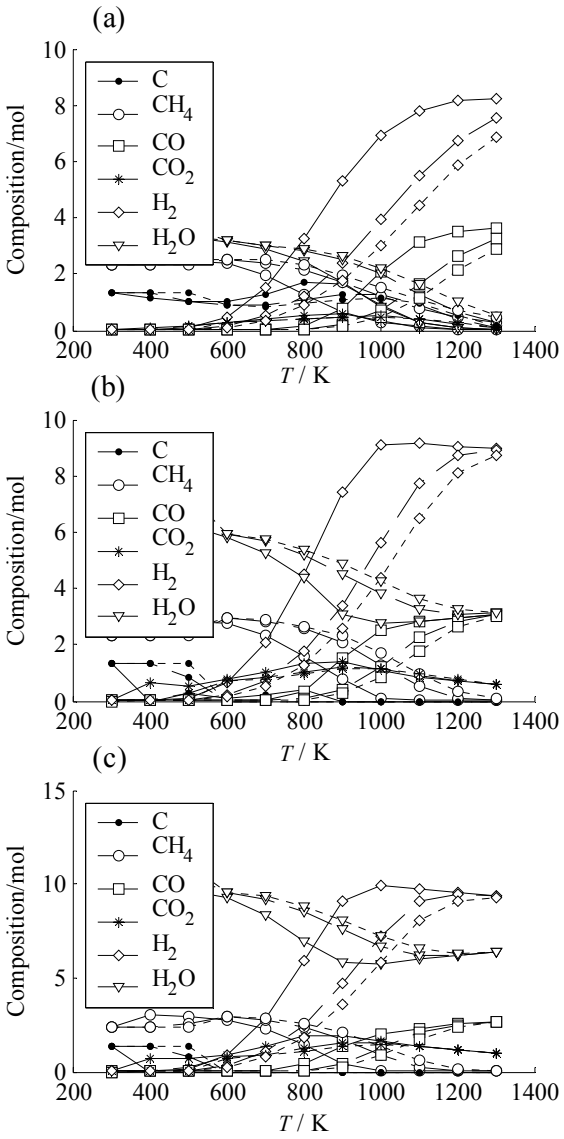

Figure 2 Equilibrium composition of the LPG-H_2O system at 1100 K and a total pressure of 1 (solid curves), 10 (dashed curves) and 20 bars (dotted curves) for 1 mol of LPG. The parameter is the H_2O:C molar ratio: (a) H_2O:C = 1, (b) H_2O:C = 2, (c) H_2O:C = 3.

STEADY STATE SYSTEM MODEL

ASPEN Plus™ [17] is applied to simulate the steady-state operation of the complete solar reforming process. Two plant models are considered: 1) an idealized plant with theoretically minimum losses, and 2) the actual demonstration plant with measured operating parameters. The methodology has been outlined elsewhere [18-19].

Idealized Plant Model

Figure 3 depicts the layout of an idealized solar reforming plant, encompassing a solar chemical reactor, a solar steam generator, and two heat exchangers: a pre-heater and a super-heater. It is assumed that Eq. (1) proceeds to completion at 1100 K and 1 bar with no excess steam, all components are perfectly insulated (no conduction or convection losses), and pumping work is negligible (no pressure drops throughout the system).

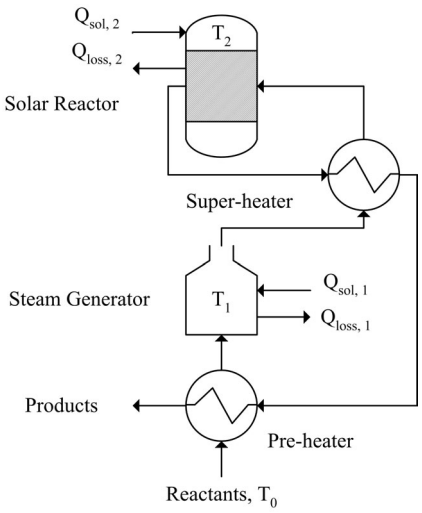

Figure 3 Scheme of idealized solar reforming plant.

Since the energy necessary for heating the reactants from 300 to 1110 K ($\Delta\bar{h}_{T_0-T_2}$ = 120.3 kJ/mol) is more than half the reaction enthalpy at 1110 K ($\Delta\bar{h}_{react}$ = 225.4 kJ/mol), heat recovery is essential. Reactants are first pre-heated to 373 K, flow through a solar-powered steam generator, and finally are super-heated using the sensible heat of the products. The solar chemical reactor and the solar steam generator are assumed to be perfectly insulated blackbody solar cavity-receivers (cavity's absorptivity and emissivity equal to 1). Their solar energy absorption efficiency, η_{abs}, is defined as the net rate at which energy is being absorbed divided by the solar power coming from the concentrator. Thus, for the solar reactor and steam generator:

$$\eta_{abs,1} = \frac{Q_{sol,1} - Q_{loss,1}}{Q_{sol,1}} = 1 - \left(\frac{\sigma T_1^4}{IC_1}\right) \quad (3)$$

$$\eta_{abs,2} = \frac{Q_{sol,2} - Q_{loss,2}}{Q_{sol,2}} = 1 - \left(\frac{\sigma T_2^4}{IC_2}\right) \quad (4)$$

where T_1 and T_2 are the nominal temperatures, $Q_{sol,1}$ and $Q_{sol,2}$ are the solar power inputs, $Q_{loss,1}$ and $Q_{loss,2}$ are the re-radiation losses, and C_1 and C_2 are the mean solar flux concentration ratios for the steam generator and reactor, respectively. η_{abs} expresses the capability of the solar receiver to absorb incoming concentrated solar energy but does not include the losses incurred in collecting and concentrating solar energy. For the solar reactor, the net energy absorbed matches the enthalpy change of the reaction,

$$\dot{Q}_{sol,1} - \dot{Q}_{loss,1} = \dot{n}\,\Delta\bar{h}_{react} = \dot{n}_{out}\,\bar{h}_{out}(T_2) - \dot{n}_{in}\,\bar{h}_{in}(T_2) \quad (5)$$

Similarly, for the steam generator, the net energy delivered to the steam generator matches the evaporation enthalpy of water:

$$\dot{Q}_{sol,2} - \dot{Q}_{loss,2} = \dot{n}\,\Delta\bar{h}_{sg} = \dot{n}\left(\bar{h}_{pinch} - \bar{h}_l(373K)\right) \quad (6)$$

where $\bar{h}_{pinch}$ is evaluated at the super-heater pinch point, since both pre-heaters and super-heaters are assumed ideal countercurrent flow heat exchangers. The overall energy conversion efficiency of the process is

$$\eta_{en} = \frac{\dot{n}_{out}\,\bar{h}_{out}(T_0) - \dot{n}_{in}\,\bar{h}_{in}(T_0)}{Q_{sol,1} + Q_{sol,2}} = \frac{\dot{n}\Delta\bar{h}_{tot}}{Q_{sol,1} + Q_{sol,2}} \quad (7)$$

The exergy efficiency is defined as

$$\eta_{ex} = \frac{\dot{n}_{out}\,\bar{g}_{out}(T_0) - \dot{n}_{in}\,\bar{g}_{in}(T_0)}{\eta_{carnot}(T_{sol})Q_{sol,1} + \eta_{carnot}(T_{sol})Q_{sol,2}} \quad (8)$$

Figure 4 shows the enthalpy change of the reaction for the system CH_4-H_2O and LPG-H_2O, with H_2O:CH_4 and H_2O:C molar ratios equal 1, respectively. Reactants are fed at T_0 = 298 K, products are obtained at 1100K. The net energy required to drive the solar reforming of CH_4 and LPG is $2.501 \cdot 10^5$ J/mol and $2.0768 \cdot 10^5$ J/mol (per mol of C), respectively.

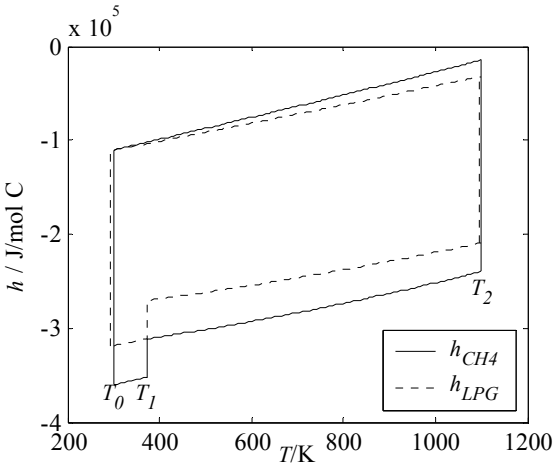

Figure 4 Enthalpy change of the reaction for the systems CH_4-H_2O and LPG-H_2O, with H_2O:CH_4 and H_2O:C molar ratios equal 1, respectively. Reactants are fed at 298 K, products are obtained at 1100 K.

Table 2 lists the baseline operating conditions and energy balances of the idealized plant, employing either CH_4 or LPG as feedstock, and for H_2O:CH_4 and H_2O:C molar ratios equal 1, respectively. η_{en} approaches 1 for both CH_4 and LPG feedstock because the only heat losses are due to re-radiation. In contrast, η_{ex} for LPG-reforming is lower than the one for CH_4-reforming because of the lower H/C ratio for LPG.

Feedstock	CH_4	LPG
Reactant stoichiometry	$H_2O:CH_4 = 1$	$H_2O:C = 1$
I	1000 W/m^2	1000 W/m^2

C_2	1500	1500
Δh_{react} @ T_{react}	$2.254 \cdot 10^5$ J/mol C	$1.776 \cdot 10^5$ J/mol C
Δh_{sg}	$2.468 \cdot 10^4$ J/mol C	$3.0129 \cdot 10^4$ J/mol C
Δh_{tot} @ T_0	$2.501 \cdot 10^5$ J/mol C	$2.0768 \cdot 10^5$ J/mol C
Δg_{tot} @ T_0	$1.499 \cdot 10^5$ J/mol C	$1.0474 \cdot 10^5$ J/mol C
$\eta_{abs,1}$	0.948	0.948
$\eta_{abs,2}$	0.996	0.996
η_{en}	0.949	0.951
η_{ex}	0.600	0.506

Table 2 Baseline operating conditions of the idealized plant.

Demonstration Plant Model

Figure 5 depicts the layout of the 400 kW solar reforming demonstration plant, erected at the solar tower of the Weizmann Institute. It encompasses a solar chemical reactor, a pre-reformer, a steam generator, a LPG/steam pumping system, a jet-pump for product recirculation, multiple electrical heaters for steam and reactants, and two heat exchangers. Main assumptions are: expansions in valves are adiabatic; LPG compressors operate with an isentropic efficiency 0.72; heat-exchangers are countercurrent-flow with constant overall heat-transfer coefficient times area ($U \cdot A$); and the reaction reaches chemical equilibrium in the pre-reformer and solar reactor. The solar reactor consists of a cavity-receiver with a quartz dome to enable operation at 9 bar. The reactant gas is fed through porous ceramic foam coated with Rh-catalyst directly exposed to high-flux solar irradiation, augmenting heat transfer and reaction surface [15].

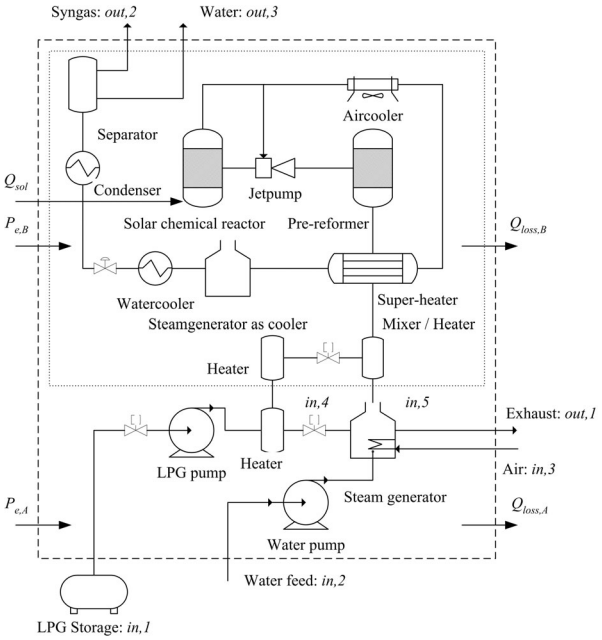

Figure 5 Scheme of the 400 kW solar reforming demonstration plant. Boundaries for system A (dashed) include steam generation; boundaries for system B (dotted) exclude steam generation and LPG preheating.

A similar reactor concept has been demonstrated for CO_2 reforming [7]. Equilibrium composition is assumed for the reactor model, as corroborated experimentally for high catalyst loading [20]. Further, the reactor is modeled as a well-insulated gray body, with an emissivity of 0.95.

LPG, at a nominal mass flow rate of 120 kg/h, is pumped to the system pressure of 17 bar, and electrically heated and evaporated to 378 K. Afterwards, the LPG-stream is splitted. 16.6% is burned to supply heat to the steam generator. The remainder is re-heated to avoid condensation and finally mixed with steam, which is electrically superheated to 498 K. The mixture undergoes a 2-stage pre-heating before entering the pre-reformer: first to 503 K by means of electrical heating, and secondly to 773 K by means of a 3.1

m^2 shell-and-tube heat exchanger. After pre-reforming to mainly CH_4, CO, and steam, the mixture flows through a jet-pump for product re-circulation at a volume ratio products-to-reactants of 3. This feature, although inefficient, is necessary for assuring stable operations conditions. The solar reactor operates at design conditions of 1100 K, 9 bar, and input solar power of 400 kW. After exiting the solar reactor, products are cooled, their sensible heat is recovered via heat exchanges, and excess steam is separated by condensation.

Steady state mass and energy conservation is applied to each of the components of Figure 5. Potential and kinetic effects are neglected. Thus,

$$0 = \sum_{i=1}^{N} \dot{m}_{in,i} - \sum_{j=1}^{M} \dot{m}_{out,j} \tag{9}$$

$$0 = \dot{Q} - P + \sum_{i=1}^{N} \dot{m}_{in,i} h_{in,i} - \sum_{j=1}^{M} \dot{m}_{out,j} h_{out,j} \tag{10}$$

The system of equations (7) and (8) are solved iteratively. Efficiencies are newly defined to account for several sources of heat loss, especially parasitical losses:

$$\eta_{en,A} = \frac{\sum_{i=1}^{3} \dot{m}_{out,i} h_{out,i} - \sum_{i=1}^{3} \dot{m}_{in,i} h_{in,i}}{Q_{sol} + P_{el,A} + P_{el,B}} \tag{11}$$

$$\eta_{en,B} = \frac{\sum_{i=1}^{3} \dot{m}_{out,i} h_{out,i} - \sum_{i=1}^{3} \dot{m}_{in,i} h_{in,i}}{Q_{sol} + P_{el,B}} \tag{12}$$

$$\eta_{ex,A} = \frac{\sum_{i=1}^{3} \dot{m}_{out,i} g_{out,i} - \sum_{i=1}^{3} \dot{m}_{in,i} g_{in,i}}{\eta_{carnot}(T_{sol}) Q_{sol} + P_{el,A} + P_{el,B}} \tag{13}$$

$$\eta_{ex,B} = \frac{\sum_{i=2}^{3} \dot{m}_{out,i} g_{out,i} - \sum_{i=4}^{5} \dot{m}_{in,i} g_{in,i}}{\eta_{carnot}(T_{sol}) Q_{sol} + P_{el,B}} \tag{14}$$

Equations (11) and (13) are valid for system *A* (Figure 5). Equations (12) and (14) are valid for system *B* (Figure 5).

Table 3 lists the baseline operating conditions and energy balances of the demonstration plant. For the baseline conditions, the exergy efficiencies of both systems A and B are negative because of the burning of LPG for supplying heat to the steam generator. Thus, fore large-scale applications, steam generation must use solar energy.

Table 4 shows the comparison between the numerically calculated temperatures and the experimentally measured ones.

Feedstock	LPG	LPG

Table 3 Baseline operating conditions of the 400 kW demonstration plant.

The agreement at the solar reactor outlet is within 5%. Differences in the heat exchangers' temperatures are principally due to heat losses in the tubing, which are not modeled.

Location	T_{model} / K	$T_{measured}$ / K	Relative Error
Solar reactor outlet	1077	1018	0.055
Reactants at heat exchanger outlet	757	735	0.029
Products at heat exchanger outlet	554	618	0.116

Table 4 Comparison of the numerically calculated and experimentally measured temperatures

The effect of the solar power input and steam-to-LPG mass-ratio is examined for both systems A and B.

The variation of the efficiencies, reactor temperature, and the product composition as a function of the solar power input is shown in Figs. 6, 7, and 8, respectively. As expected the efficiencies and reactor temperature increase with Q_{sol} because of the higher product yield and reduced re-radiation losses for a higher solar concentration. Consequently, the product composition shifts towards CO and H_2.

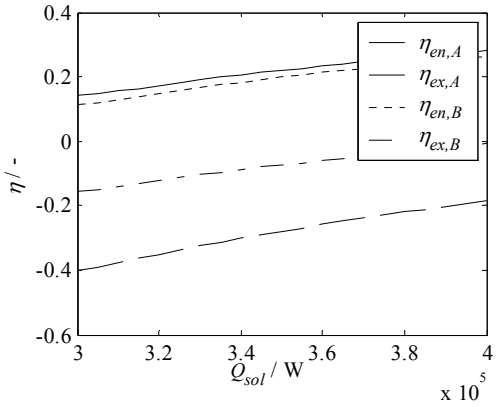

Figure 6 Variation of the energy and exergy efficiencies of systems A and B as a function of the solar power input.

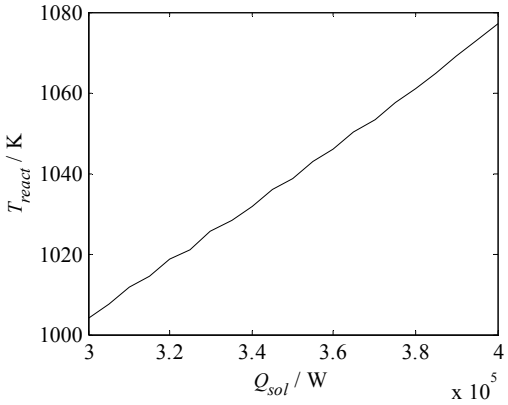

Figure 7 Variation of the reactor temperature as a function of the solar power input.

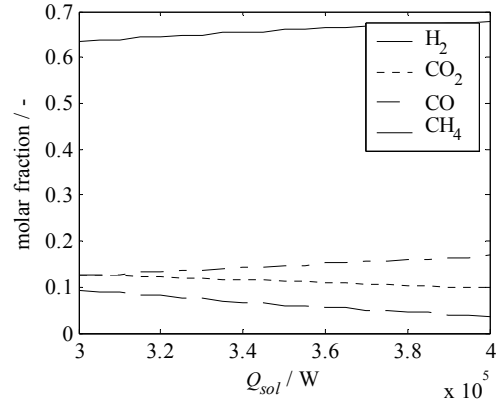

Figure 8 Variation of the molar product composition as a function of the solar power input.

The variation of the efficiencies, reactor temperature, and the product composition as a function of the steam mass flow rate is shown in Figs. 9, 10, and 11, respectively. All efficiencies decrease with increasing steam mass flow rate, except the exergy efficiency of system A. This is because the difference in Gibbs free enthalpy remains about constant (almost all LPG reacts in any case) while the parasitical losses increase (for example, more energy needed to produce and pump excess steam). As expected, the reactor temperature decreases as the steam mass flow rate increases for a given Q_{sol}. The product composition shifts towards H_2 and CO_2, because the combined effects of reduced temperature and higher steam content.

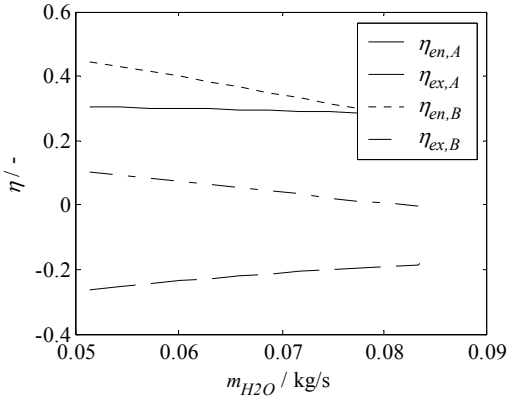

Figure 9 Variation of the energy and exergy efficiencies of systems A and B as a function of the steam mass flow rate.

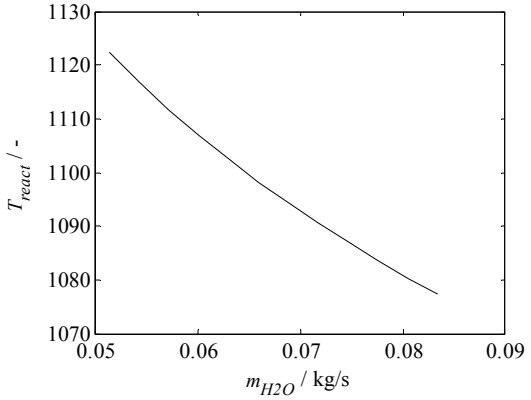

Figure 10 Variation of the reactor temperature as a function of the steam mass flow rate.

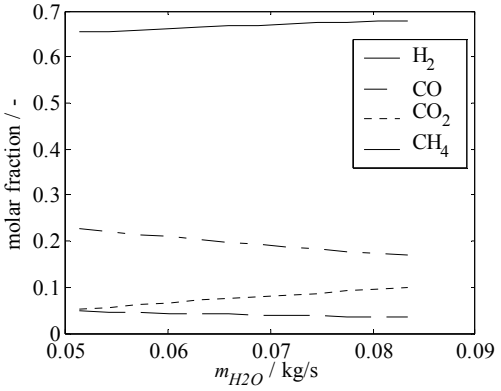

Figure 11 Variation of the product composition as a function of the steam mass flow rate.

SUMMARY AND OUTLOOK

We have computed the chemical equilibrium composition of the systems CH_4-H_2O and LPG-H_2O as a function of temperature, pressure, and

steam to hydrocarbon molar ratios. The reforming reaction proceeds in the 900-1300 K range. Low pressures and high steam to hydrocarbon molar ratios shift the equilibrium towards H_2. For CH_4-reforming using a reactant molar stoichiometry of $H_2O:CH_4 = 1$, carbon formation is thermodynamically favorable at 700 K < T < 1100 K and p < 8 bars. In contrast, for $H_2O:C \geq 2$, carbon is absent in equilibrium in the range 300-1300 K and 1-20 bar. For LPG-reforming using $H_2O:C = 1$, carbon formation is thermodynamically favorable at T < 1200 K for the whole pressure range (p < 20 bar). In contrast, for $H_2O:C \geq 3$, carbon is absent in equilibrium in the range 300-1300 K and 1-20 bar. The theoretical maximum exergy conversion efficiencies for the solar steam-reforming of CH_4 (with $H_2O:CH_4 = 1$) and LPG ($H_2O:C = 1$) are 60.0% and 50.8%, respectively. Their LHV is increased by 25.6% and 24.3%, respectively.

The model is being employed for system optimization, and will be further expanded to include dynamic behavior during transient operation such as start-ups, shut-downs, and varying solar irradiation.

RENEWABLE ENERGY IN RUSSIA: APPROPRIATE TECHNOLOGIES AND DEVOPMENT PERSPECTIVES

Irina Proshkina
Publishing House "Great Russian Encyclopedia",
Department of Physics
Russia

ABSTRACT

A brief review of renewable energy technologies in Russia is presented. High efficiency of hybrid energy systems is underlined. Minimal damage to environment is recognized as a main advantage of renewable energy technologies. Application of renewable energy technologies in Russian remote areas and hardly accessible regions is motivated now socially and economically. According to Federal Program "Energy Effective Economy", substitution of fossil fuel by local fuels and renewables will save 1 million tons of equivalent fuel annually supplied at North regions. New economic situation and increasing the environmental requirements give a new chance to renewable energy development. Some conditions for successful future of renewable energy technologies are discussed, among them the effective interaction of research institutes, developers and production companies.

INTRODUCTION

Now electric power and liquid fuel have paramount importance for life of civilisation, as these two sources represent free energy, which (in view of efficiency) can be transformed into work. Limitation of hydrocarbon fuel resources and strengthening the nature protection requirements stimulate search for alternative sources of energy in many countries.

The mankind is not threatened with an energy crisis connected to an exhaustion of stocks of petroleum, gas, coal, if it will develop technologies of use renewable energy sources (RES). In this case problems caused by harmful emissions connected with burning fuel for energy and transport will be solved, and consequently quality of life will rise. The application of RES in Russia is expedient by three reasons: inexhaustible nature, ecological acceptability and economic benefit in the removed regions of Russia. In conditions of prices growth on the organic fuel it is economically favourable for developing RES in removed areas already today. 20 millions of Russians live in regions not connected to the centralized networks of power supply. Therefore development of the renewable energy programs has the large social importance. In cities and settlements with bad ecological conditions the introduction RES in power balance helps to improve the situation.

The environmental acceptability of renewable energy can be illustrated with the following example. One RES system (wind turbine, solar photovoltaic elements, small hydroelectric power station) with capacity of 500 kW produces not less than 1 million kWh per one year. Hence it prevents emissions of equivalent coal station: carbon dioxide - 750-1250 tons, sulfur dioxide – 5-8 tons, nitrogen oxides - 3-6 tons.

Huge potential of renewable power in Russia is used unsufficiently. The share of manufacture of a thermal energy from RES (by different assessment) is 4-6 % from general ounput. The data on manufacture of the electric power from RES indicate that their share is no more than 1 %, including small hydroelectric power station. Development of renewable energy is a field of interest for many Russian

scientific institutes and industrial companies. Despite of problems with financing, the essentially new power technologies based on renewable energy sources are created in Russia.

SOLAR THERMAL SYSTEMS

After disintegration of the Soviet Union Russia began to consider as northern country, where the resources of a solar energy are unsufficient. However, last researches of Institute of high temperatures of the Russian academy of sciences (IHT RAS) prove an inconsistency of such point of view.

In laboratory of renewable energy sources of IHT RAS the Atlas of distribution of solar energy resources on Russian territory was maped, the climatic database is created especially assigned for research in the field of solar power. The laboratory specialists make cards of receipt of solar radiation on variously focused surfaces. The highest arrival of energy on a horizontal surface is characteristic for southern areas of the country (Northern Caucasus, for example). However, the resources of a solar energy are great enough also in other regions of Russia.

According to the received results the rather perspective areas are the south of Siberia and Far East. And parameters for Krasnodar region, that is rather unexpected, is the same, as for Yakutsk. As a barrier to a wide dissemination of solar termal systems serves its high cost. Therefore developers all over the world, as well as in Russia, aim to create effective solar collectors, whose use is economically competitive in different regions. Specialists of IHT RAS work actively at new models of solar collectors with application of heatproof polymeric and composit materials, that will allow to lower their cost not to the detriment of quality.

Research and development on perfection of solar collectors and concentrators are carried out in Russian Institute of electrification of an agriculture. The engineers create two essentially new solar concentrators: quasistationary and stationary types. The correction connected to change of declination of the Sun is made in quasistationary concentrator once per day; the concentrated solar radiation from separate concentrators is summarized and is directed to the receiver by optical waveguide. If the area of concentrators will reach several square kilometres, the total capacity of the concentrated solar radiation would be up to million kilowatt.

Application of solar elements with a bilaterial working surface were created in Russia in 1970s, has allowed to increase factor of concentration of stationary concentrators up to 5. Use of new stationary solar modules with concentrators for facades both roofs of buildings and reception of electrical energy and heat is especially effective.

New type of solar concentrators was offer Recently by Institute of electrification of an agriculture. Its main feature - combination of positive qualities of solar power stations to the central receiver of a modular type and opportunity of use as the receiver both traditional steam heater, and solar elements on the basis of silicon.

Application of solar concentrators makes realisable a creation of solar photo-photovoltaic systems of megawatt level of capacity at two – five reduction of their cost.

SOLAR PHOTOVOLTAIC SYSTEMS

One of the most perspective technologies of solar energy is of photovoltaic systems with solar elements on the basis of silicon. World manufacture of solar elements is increasing (up to 30 % annually) at continuous reduction of cost. Photovoltaic modules, produced in Russia, transform solar radiation to electrical energy with efficiency 11-15 %. Laboratory samples provide efficiency 23 %.

For manufacturing solar batteries the silicon is used being one of the most widespread elements of the earth's crust from firm substances. Some experts named silicon as petroleum of 21 century. The contents of silicon in the earth's crust is 29,5 % , it exceeds the contents of aluminium 3,35 times. The Russian scientists have developed new chlorine-free technology of silicon manufacture for solar photovoltaic modules. The production of “solar quality” silicon by a method of direct restoration from pure natural quartzite allows to reach an output of silicon 80-85 % of cost USD 5-15 kg. In case of wide application of this technology cost of the electric power generated by photovoltaic

modules decline to USD 0,10-0,12 kWh. In new technology the chemical methods are replaced with ecologically acceptable electrophysical methods.

There are now some enterprises in Russia having technology and capacities for manufacturing solar elements and modules up to 2 MW per year.

One more technology offered by Institute of electrification of an agriculture - technology of polymeric-free hermetic sealing of solar modules, developed together with electronic industry. It allows to doubling operational life time of solar stations from 20 to 40 years, that exceeds operation life of traditional thermal power stations.

WIND ENERGY

Russia has significant resources of wind energy in many regions, including those, where there is no electricity network (coast of Northern Ice Ocean, Kamchatka, Sakhalin, Chukotka, Yakutia). Naturally, Russia has good prospects for development of wind energy, however powerful turbines are not manufactured by domestic enterprises, and the large-scale development of this energy sector is difficult without government support. The major consumers of wind energy systems are residential users (the gardeners, vocational home owners, farmers) who require an independent provider of electric energy with the power consumption up to 1.5 — 2 kW. Other category of the consumers is the remote small technical services and automatic posts (beacons, supervision and communication, meteorological service). The smallest group of consumers includes small industrial customers (autonomous lighting, heating, water cleaning systems etc.).

Russian enterprises produce trial versions of wind turbines in very small quantities resulting in their high cost. Organization of commercial production of wind turbines and certification process requires significant investments. Wind energy systems with the capacity of 8 kW and 16 kW are commercially produced now for the individual consumers.

Manufacturers of renewable energy equipment increasingly come to a conclusion that only combined utilization of various renewable energy sources can create economically feasible alternative to traditional power sources and encourage wider use of renewable energy.

The so-called "solar" houses, getting energy from renewable sources, were built as a pilot project. For example, the first "solar" apartment building has been recently constructed in Sverdlovsk area (Ural region). Wind turbine even at a wind speed of 5 m/s can produce about 4 kW of electricity that is used to power up electrical pump in the house to get water from a well. Photovoltaic panels installed on a facade of a building have accumulators, which provide people with light and heat in case of failure on a network or during periods of increased power consumption.

Hybrid power stations (utilizing wind and diesel) seems to be most perspective for private consumers as well as for oil and gas companies at remote wells. The stations like Russian hybrid power system “Musson” can be used for lighting and household needs of the log personnel at reduced expenses for diesel fuel.

Despite a lack in demand for wind turbines and funding problem, Russian engineers continue working on improvement wind energy systems. Recently, ecologically safe wind system with no fans has been developed in the Institute of electrification of agriculture. This installation is in essence a tower, inside which air whirlwind rotates the turbine. The system is characterized by the absence of noise and vibrations.

One more way for development of wind energy in Russia is creation of joint ventures. Wind energy turbines, replaced in Europe for more powerful and modern ones, can still be at good service in Russia. For example, a wind system "Bonus-150" was set up in operation recently in the Pskov region. This turbine (having operational life time of 25 years) has already been in operation in Denmark for 10 years. This system output is about 60-70 kW. It works in an automatic mode, and does not require supporting personnel. Similar units successfully operate in Kaliningrad region.

SMALL HYDROELECTRIC POWER STATIONS

At present time a small and micro hydroelectric power stations are the most environmentally friendly systems.

In Russia, economic potential of small and micro- hydroelectric power stations is significantly underutilized. A number of small hydropower plants decreased from 5000 in 50s to 300 in 90s of the 20th century. Lately an interest to small hydroelectric power stations has been brought back to life. A process of restoration of previously destroyed and construction of new small and micro-hydroelectric power stations is on its way. During the last years, more than 20 power plants were constructed and restored in Northern Caucasus and Northwest of Russia. Micro-hydroelectric power plants can be used by small businesses, also at geological, meteorological station etc. As opposed to pressure-head hydroelectric power stations, small and micro- hydroelectric flow-through systems do not obstruct navigation, do not require deployment of expensive dams, and do not disturb the environment.

The recent product of Moscow engineers is micro-hydroelectric power station «Raduga» with capacity of 400 W, which can be used all year round, and also under ice. This station is developed for operation primarily in a channel of the flat rivers having flow speed from 0,8 m/s up to 5 m/s. Distance between a reservoir bottom and ice cover is not less than 1,5 m. The maximum submerge depth is 5 m. Such an energy unit, having a diameter of the water-wheel of 0,98 m provides electricity with capacity of 80 - 400 W (220 V, 50 Hz) with the quality comparable to standard network output.

According to market analysis micro-hydroelectric units with capacity 5-30 kW will find a market nearest time, but then small hydroelectric units with capacity 200-400 kW will be also in requisition.

BIOFUEL

The important component of renewable energy will be stations working on biomass. Biomass is pure enough as a source of energy from the ecological point of view. A process of burning biomass (as compared to coal) is not accompanied by emissions of sulphur. Also, emissions of nitrogen oxides can be reduced due to optimum technology of burning.

In Russia 20 % of the world wood resources are located. Forests cover about 40% of Russian land territory. Forest industry is an important sector of Russian economy, and utilization of the biomass (wood waste) products generated during preparation and processing of wood as an energy resource is very attractive. At present, this resource is only being minimally utilized. Alongside with valuable coniferous breeds and birch that have steady demand in traditional wood processing businesses, there are big quantities of bad quality, unusable aspens and alder.

For example, Leningrad area alone produces annually about 1100 -1200 thousand m^3 of bad quality wood that does not have any selling value, is unprofitable for business and is harmful to an environment. At the same time, this wood has significant calorie content. If this wood is effectively processed, total calorific value of this fuel will be more than 2.3 millions of GC. It is enough for operation of 750 boiler with thermal capacity 1.2 MWh. Just a single boiler is capable to provide heat to a standard 100-120 apartments building.

In case of wide spread of boiler-heated houses utilizing biofuel, there will be a replacement of oil and coal and will be a solution to a problem of wood recycling and allocation of waste. Local ecological situation will improve, due to a reduced level of environment pollution associated with acidification of ground and water, and also with methane emission, being a product of wood rotting.

Biomass can be effectively utilized in power plants as wood chips or as processed wood bio fuel (briquettes, pellets). The most perspective technology is not a direct burning (its efficiency is about 25 %), but biomass gasification using gas-vapour cycles with efficiency up to 50 %.

Russian scientists develop technology of fast pyrolysis of biomass which allow up to 80 % of organic substance to be transformed into liquid or gas fuel. From one ton of wood sawdust it is possible to obtain more than 700 kg of liquid fuel. Combining this technology with technology of cultivation of quickly

growing plants, yielding up to 40 ton of biomass in dry weight from hectare, it is possible to decentralize liquid fuel production. To supply each rural area by liquid fuel it is required less than 5 % of cultivated grounds. This technology can effectively be used in the countries importing petroleum, where today gas and oil price is high enough.

GEOTHERMAL POWER

Geothermal power is strictly not a renewable source of energy, its methods are traditional and impact on environment is essential. However, especially significant growth is observed in this sector, due to take-off of two geothermal power stations on Kamchatka with capacity 12 MW and 50 MW.

RENEABLE ENERGY TOMORROW

A decisive promotion of renewable energy sources during last years is caused in many countries by obligations to reduce GHG emissions. Russia has also acceded to Kyoto protocol. Russian government approved the Federal Target Program “Energy Efficiency Economy”. A chapter of this document named “Energy supply of remote areas, Northern and hardly accessible regions on the base of renewable energy sources and local sources of fuels” underlined a regional importance of RES. To realize great potential of renewable energy sources some problems should be solved, including lack of funds, weak coordination between researchers, providers and consumers, underestimation of RES as most appropriate energy alternative from ecological and social point of view.

ABSTRACT

Biomass has great potential as a clean, renewable feedstock for producing modern energy carriers. This paper focuses on the process of biomass gasification, where the producer gas may subsequently be used for the production of electricity, fuels and chemicals. The gasifier is one of the least efficient unit operations in the whole biomass-to-energy technology chain and an analysis of the efficiency of the gasifier alone can substantially contribute to the efficiency improvement of this chain. The purpose of this paper is to compare different types of biofuels for their gasification efficiency and benchmark this against gasification of coal. In order to quantify the real value of the gasification process exergy-based efficiencies, defined as the ratio of chemical and physical exergy of the producer gas to chemical exergy of a biofuel, are proposed in this paper. Biofuels considered include various types of wood, vegetable oil, sludge, and manure. The gasification efficiencies are evaluated at the carbon boundary point, where exactly enough air is added to avoid carbon formation and achieve complete gasification. The cold gas efficiency of biofuels was found to be comparable to that of coal. It is shown that the exergy efficiencies of biofuels are lower than the corresponding energetic efficiencies. For liquid biofuels, such as sludge and manure, gasification at the optimum point is not possible, and exergy efficiency can be improved by drying the biomass using the enthalpy of producer gas.
Keywords: Biomass, Biofuels, Gasification, Exergy analysis, Process efficiency.

NOMENCLATURE

C_S	calorific value of sulfur [kJ/kg]
ΔH	enthalpy of reaction [kJ/mol]
LHV	lower heating value [kJ/kg]
LHV_{org}	LHV of organic fraction in biomass per kg of organic fraction [kJ/kg org.fr.]
LHV_{org}	LHV of organic fraction in biomass per kg of wet biomass [kJ/kg biomass]
T	temperature [^oC]
z	mass fraction [-]
β	ratio of the chemical exergy to the LHV of dry organic substances [-]
ε_{ch}	chemical exergy [kJ/kg]
ε_{ph}	physical exergy [kJ/kg]

INTRODUCTION

Biomass has great potential as a renewable and relatively clean feedstock for producing modern energy carriers, such as electricity and transportation fuels. In order to compete with fossil energy sources an optimal utilization of biomass resources is desired. For biomass-based systems, a key challenge is thus to develop efficient conversion technologies. This paper focuses on the process of biomass gasification, a technology that converts biomass into gaseous products. The gas may subsequently be used for the production of electricity, fuels and chemicals.

The complete technology from solid fuel to final application involves several unit operations including grinding of fuel, drying, gasification, gas cooling, gas cleaning and final utilization of the

gas. It was previously demonstrated by Vlaswinkel [1] for gasification of coal and recently by Ptasinski et al. [2] for gasification of organic sludge that the gasifier is one of the least efficient unit operations in the whole gasification technology. Therefore an analysis of the gasifier alone can substantially contribute to the efficiency improvement of the whole gasification technology.

The main purpose of this paper is to compare different types of biofuels for their gasification efficiency and benchmark this against gasification of coal. A wide range of biomass sources, such as traditional agricultural crops, dedicated energy crops, residues from agriculture and foresting as well as organic wastes can be gasified. This is generally regarded as a real advantage, because it means that the best available and usually economically most attractive feedstock can be selected. However, these biomass types differ in chemical composition, heating value, ash and moisture content. The question is whether all the biomass types can be converted with comparable efficiencies. Biomass is not a well-defined and often inhomogeneous feedstock, whose composition may vary depending on origin, physical location, age, season and other factors. The composition of the organic matter in biomass does not vary much, e.g. wood typically contains cellulose: hemicellulose: lignin in 2:1:1 ratio. However, variations in moisture content and ash content are especially large. In this study various fuels, comprising wood, grass and vegetable oils and including wet biomass sources such as manure and sludge are studied. Coal was also chosen as a reference point for fossil fuel gasification.

The change in composition from biomass to coal can be illustrated using a diagram developed by Van Krevelen [3]. Figure 1 shows the change in atomic ratios H/C and O/C from biomass to peat, lignite, coal and anthracite. As it can be observed from this figure, biomass, e.g. wood, contains more oxygen with respect to carbon than in coal. This influences the gasification process, as gasification is a partial oxidation.

This paper starts with an evaluation of exergetic efficiencies. Focusing thereafter on biomass gasification, the question is under which gasification conditions the gasification efficiencies should be evaluated. It was shown by Desrosiers [4] and Double and Bridgwater [5] that energy-based efficiencies reach a sharp maximum at the so-called carbon boundary point where exactly the right amount of oxygen is added to the gasifier in order to achieve complete gasification. Prins et al. [6] have shown that the carbon boundary point is also the optimum for exergy-based efficiencies. The locations of the carbon boundary points with corresponding carbon boundary temperatures and gas phase compositions are calculated for a variety of biofuels. Results are presented for gasification efficiencies of these fuels, based on energy and exergy. Finally, the effect of improving gasification of wet biomass by prior drying using the enthalpy of the product gas is evaluated.

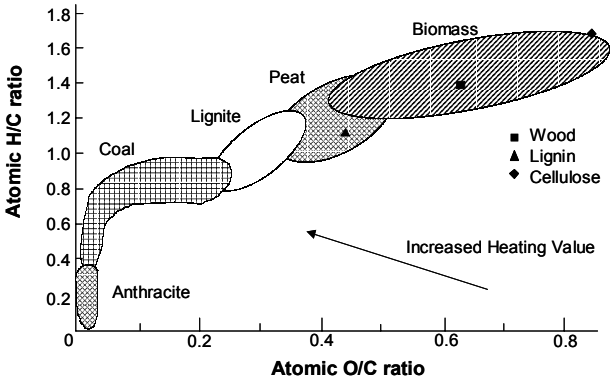

Figure 1: Van Krevelen diagram

EVALUATION OF EXERGY EFFICIENCY

The gasification process considered in this paper is schematically presented in Fig. 2. Biomass enters the gasifier at environmental temperature T_0, air at the same temperature is used as a gasifying medium. The gaseous products leave the gasifier at the reactor temperature T_R. It is assumed that the gasifier operates as adiabatic and pseudo homogeneous reactor at atmospheric pressure. Gasification entails partial oxidation of the feedstock so chemical energy of biomass is converted into that of gas and also heat.

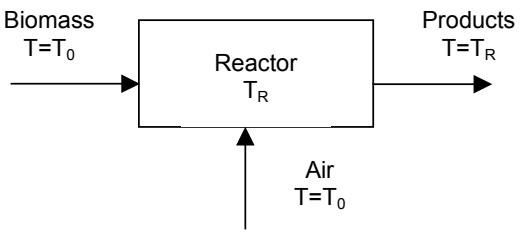

Figure 2: Schematic diagram of the gasifier

The energetic efficiency of a gasification process, generally known as the cold-gas efficiency, can be determined as:

$$\Psi_1 = \frac{LHV_{gas}}{LHV_{biomass}} \quad (1)$$

where LHV_{gas} and $LHV_{biomass}$ are the net heats of combustion (lower heating values) of gas and biomass, respectively. The lower heating values for the organic fraction of the biomass were calculated from the higher heating values, present in the Phyllis database, maintained by the Energy Research Centre of the Netherlands, ECN [7].
The exergetic efficiency may be defined as the ratio between chemical exergy of product gas and biomass feed:

$$\Psi_2 = \frac{\varepsilon_{ch,gas}}{\varepsilon_{ch,biomass}} \quad (2)$$

Both definitions have a drawback: they disregard the sensible heat contained in the product gases. Producer gas at elevated temperature is preferred over environmental temperature and therefore the calculated efficiency should be higher. However, if the sensible heat were to be added to the energetic efficiency, this efficiency would always be 100% because the gasifier operates adiabatically. This problem can be overcome by using exergetic efficiency based on chemical as well as physical exergy:

$$\Psi_3 = \frac{\varepsilon_{ch,gas} + \varepsilon_{ph,gas}}{\varepsilon_{ch,biomass}} \quad (3)$$

Exergy analysis is performed according to the method proposed by Szargut et al. [8]. Chemical exergy of the biomass is calculated from the correlations for technical fuels using the LHV, and mass fractions of organic material, sulfur, water and ash in the biomass:

$$\varepsilon_{0,total} = z_{org} \cdot (\beta \cdot LHV_{org}) + \\ + z_S(\varepsilon_{0,S} - C_S) + z_{water} \cdot \varepsilon_{0,water} + z_{ash}\varepsilon_{0,ash} \quad (4)$$

The factor β is the ratio of the chemical exergy to the LHV of the organic fraction of biomass. This factor is calculated from statistical correlations developed by Szargut and Styrylska [9]. The following correlation are used:

- for solid biofuels:

$$\beta = \frac{1.044 + 0.0160 \cdot \frac{H}{C} - 0.3493 \cdot \frac{O}{C} \cdot \left[1 + 0.0531 \cdot \frac{H}{C}\right] + 0.0493 \cdot \frac{N}{C}}{1 - 0.4124 \cdot \frac{O}{C}} \quad (5)$$

- for liquid vegetable oils:

$$\beta = 1.0374 + 0.0159 \cdot \frac{H}{C} + 0.0567 \cdot \frac{O}{C} \quad (6)$$

- for coal:

$$\beta = 1.0437 + 0.1869 \cdot \frac{z_{H_2}}{z_C} + 0.0617 \cdot \frac{z_{O_2}}{z_C} + 0.0428 \cdot \frac{z_{N_2}}{z_C} \quad (7)$$

where H/C, O/C, and N/C represent atomic ratios in the fuel.

GASIFICATION OF VARIOUS BIOFUELS AT THE CARBON BOUNDARY POINT

Table 1 shows proximate and ultimate analyses for the fossil fuel and the biofuels that were considered. The presented data were obtained from the Phyllis database [7]. Since biomass and (to a lesser degree) coal contain mainly carbon, hydrogen and oxygen, the compositions of the fuels can be indicated in a molar ternary C-H-O-diagram as shown in Fig. 3. The equilibrium composition at any point in the diagram can be computed at a given temperature and pressure by minimization of the Gibbs free energy of the system. In this work only thermodynamically stable components at temperatures above 600°C were considered, i.e. CO, CO_2, H_2, H_2O, CH_4, C(s), N_2 and H_2S. The main chemical reactions taking place in the gasifier are:

$$C + CO_2 = 2\ CO \qquad \Delta H = 172{,}6\ kJ/mol \quad (8)$$

Table 1: Proximate and ultimate analysis of various fuels

Fuel	Proximate analysis (wt%)			Ultimate analysis (wt% of organic fraction)				
	Mois-ture	Ash	Organic fraction	C	H	O	N	S
Coal	11.5	8.50	80.0	78.2	4.93	13.3	1.45	1.69
Vegetable oils	0	0	100	75.4	11.7	12.9	0	0
Straw	12.7	6.37	80.9	48.9	5.97	43.9	0.82	0.15
Treated wood	14.6	4.44	81.0	51.5	6.03	41.3	1.22	0.09
Untreated wood	19.8	1.84	78.4	50.8	6.06	42.7	0.36	0.07
Grass/plants	24.2	5.46	70.3	49.7	6.00	42.7	1.32	0.18
Sludge	32.5	25.72	41.8	50.2	7.09	34.9	5.63	1.77
Manure	43.6	17.20	39.2	50.2	6.50	34.6	5.19	0.85

Note: Ultimate analysis does not add up to exactly 100% due to presence of trace elements (e.g. chlorine).

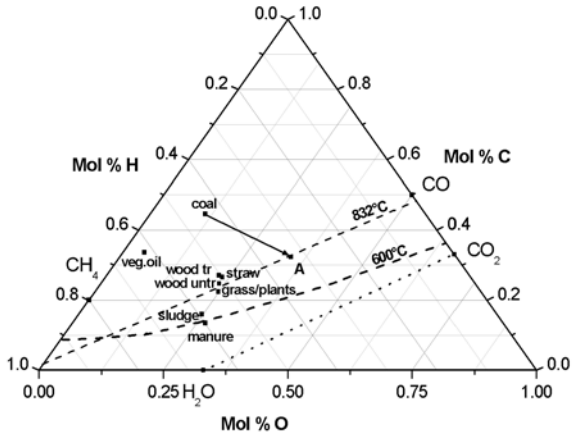

Figure 3: Location of biofuels in ternary C-H-O diagram.

$C + H_2O = CO + H_2$ $\Delta H = 131{,}4$ kJ/mol (9)

$C + 2\ H_2 = CH_4$ $\Delta H = -74{,}9$ kJ/mol (10)

$C + O_2 = CO_2$ $\Delta H = -393{,}5$ kJ/mol (11)

In Fig. 3 the indicated isotherms are the solid carbon-boundary lines (at a temperature of 600°C and 832°C). Above the carbon boundary line, solid carbon exists in heterogeneous equilibrium with gaseous components; below this line, only gaseous components are present in homogeneous equilibrium. Gasification of fuel implies adding so much oxygen until the solid carbon boundary is reached. This is indicated for coal by the arrow in Fig. 3, which points in the direction of oxygen; when point A is reached, all carbon has been gasified. The carbon-boundary point is the optimum point of the gasifier operation because exactly enough oxygen is added to achieve complete gasification. If more oxygen is added than required, the produced gas loses its heating value, until eventually the line from CO_2 to H_2O is crossed and complete combustion has taken place.

For the various biofuels considered, the optimum point of gasifier operation was calculated by the software programme Aspen Plus assuming that chemical equilibrium is attained. Table 2 shows the corresponding air/biomass ratios and carbon boundary temperatures for the optimum gasification points for the fuels. From these data, it can be observed that the solid biofuels require much less addition of air than coal or vegetable oil. The reason for this is that they already contain a large amount of oxygen in their organic matter. Since relatively little oxygen has to be added to the biomass, less oxidation reactions take place and the corresponding carbon boundary temperatures for gasification of biomass are lower than for coal and vegetable oil.

The compositions of sludge and manure lie already very close to the carbon boundary isotherm of 600°C. Because sludge and manure are very moist, they already contain a large amount of oxygen, so that oxygen addition is limited, and carbon boundary temperatures were found to be below 600°C. However, at such low temperatures, the gasification reactions become very slow and it

Table 2: Optimum gasification operating points and gas compositions for various fuels

Fuel type	T (°C)	Air flow (kg/kg biomass)	Product gas composition (mole fraction) H_2O	N_2	H_2	CO	CO_2	CH_4	H_2S
Coal	832	2.836	0.005	0.500	0.158	0.324	0.009	0.001	0.003
Vegetable oils	875	3.837	0.003	0.467	0.251	0.275	0.003	0.001	0.000

Treated wood	655	1.628	0.062	0.409	0.213	0.194	0.112	0.010	0.000
Untreated wood	642	1.452	0.076	0.380	0.227	0.177	0.126	0.013	0.000
Grass/plants	621	1.240	0.097	0.363	0.232	0.146	0.145	0.018	0.000
Sludge*	600	1.237	0.186	0.412	0.192	0.056	0.147	0.004	0.003
Manure*	600	1.247	0.246	0.395	0.171	0.038	0.147	0.002	0.001

* For this feedstock. the carbon boundary temperature is below 600°C. A minimum gasification temperature of 600°C was used.

would be difficult to attain chemical equilibrium in practice. A gasification temperature of at least 600°C was considered as being required in order to reach equilibrium within a reasonable reaction time. This criterion dictated the amount of air for gasification of sludge and manure, which means that these fuels are over-oxidized in order to evaporate all the moisture present.

Table 2 shows the composition of the products formed by the gasification process. As a result of the higher gasification temperature for coal and vegetable oil, more carbon monoxide and hydrogen are formed, while gasification of the other biofuels takes place at lower temperatures and the gas contains more carbon dioxide and methane. From the table, it is apparent that very moist gas streams result from gasification of sludge and manure.

RESULTS OF EXERGY ANALYSIS

Table 3 shows lower heating values, the ratio beta, and total chemical exergy of the various fuels. It is remarkable that for biomass containing a lot of oxygen, the values of beta are higher (above 1.10) than for coal and vegetable oils (around 1.07) with much lower oxygen content. This may be explained by the fact that polymers such as cellulose and hemi-cellulose are highly ordered structures, and work can be delivered if these are decomposed.

Fig. 4 shows the exergy distribution for gasification of various biofuels. The exergy contained in the biomass is converted by gasification into chemical exergy of the product gas, physical exergy of the product gas, and part of

Table 3: Lower heating value and chemical exergy of various fuels

Fuel	LHV_{org} (kJ/kg organic)	LHV_{org} (kJ/kg biomass)	β (-)	ε_{ch} (kJ/kg biomass)
Coal	31047	24839	1.067	26638
Vegetable oils	37558	37558	1.074	40338
Straw	18064	14619	1.128	16506
Treated wood	18886	15290	1.119	17129
Untreated wood	18904	14812	1.122	16634
Grass/plants	18624	13101	1.125	14760
Sludge	19617	8197	1.118	9249
Manure	19148	7506	1.116	8427

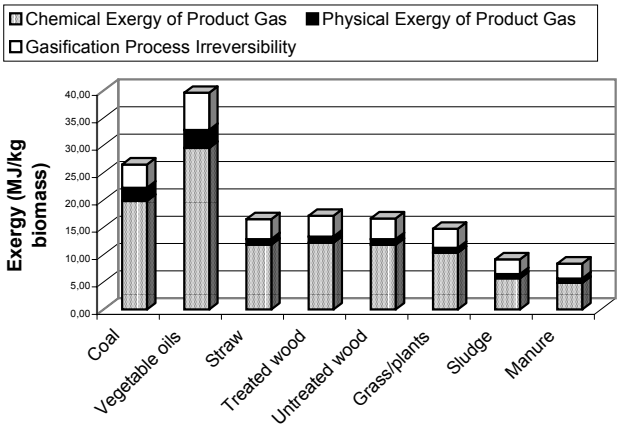

Figure 4: Exergy distribution for gasification of various fuels

the exergy of biomass is lost due to process irreversibilities. It can be seen that the largest irreversibility occurs for vegetable oil and coal gasification, which is related to the large amount of oxygen that needs to be added to vegetable oil and coal gasifiers. However, rather than the absolute irreversibility, it is more meaningful to focus on relative irreversibility, i.e. to compare the biofuels due to exergetic efficiencies.

Figure 5 shows the energetic and exergetic efficiencies for the gasification of different biofuels. The energetic efficiencies of vegetable oil, straw, treated wood, untreated wood and grass are very comparable with coal, whereas efficiencies for sludge and manure are considerably lower. This was to be expected, because gasification at the optimum operating point was not possible for these streams. In sludge and manure gasification, oxygen is added mainly to generate heat and evaporate moisture present in

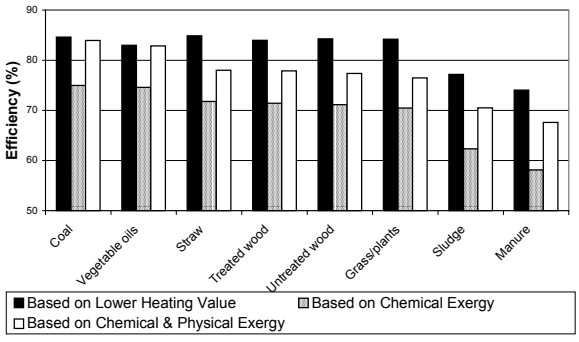

Figure 5: Comparison of gasification efficiency for various fuels

the fuel. If the exothermic oxidation reactions could drive endothermic gasification reactions, rather than endothermic evaporation of water, the gasifier would work much more efficiently.

Fig. 5 shows that the efficiency based on chemical exergy is higher for coal and vegetable oil than for the other biomass streams, i.e. around 75% versus 70-72%. This may be explained because large molecules are broken up into smaller ones. For some of the small molecules contained in the product gas, the chemical exergy is less than their lower heating value e.g. 97.6% for hydrogen and 97.2% for carbon monoxide. On the contrary, the chemical exergy for coal and biomass is higher than their heating value. Therefore, the difference in chemical exergy between feed and product is larger than the difference in lower value. This difference is smaller for coal and vegetable oils, because their chemical exergy is only 107% of their lower heating value, while for solid biomass this is 111-113%. Also, exergetic efficiencies of gasification are lower than energetic efficiencies.

Gasification efficiencies based on chemical and physical exergy are also shown in Fig. 5. The same trends are observed as before: gasification of vegetable oil and coal is better than biomass such as wood, straw or grass, while gasification of manure and sludge is much less efficient. Because coal and vegetable oil are gasified at higher temperatures, their gasification efficiencies are improved relatively much by inclusion of the physical exergy. Drier biomass such as treated wood or straw may be slightly preferred over fresh biomass such as untreated wood and grass.

Finally, it is very interesting to note that gasification of vegetable oils, which are moisture and ash-free, is comparable to gasification of coal, despite containing moisture and ash. It can be noted that chemical exergy of vegetable oils and coal is higher than that of remaining fuels (see Table 3).

IMPROVING GASIFICATION OF WET BIOMASS

It was concluded that gasification of sludge and manure is not very efficient because these contain a substantial amount of water, so that operation at the optimal gasification conditions is not possible. This is caused because extra heat must be generated at the gasification temperature (> 600°C) in order to evaporate the water at a much lower

temperature, leading to exergetic losses. In order to improve the gasification efficiency, moisture should be removed prior to the gasifier. It is possible to use the enthalpy of the gasifier product gas for drying the biomass (in the absence of alternative, external sources of heat). We have assumed that water is evaporated in the dryer at a temperature of 100°C by exchanging heat with the product stream, as shown in Fig. 6. Modeling of drier and gasifier was restricted to sludge, as this was one of the two streams containing relatively much moisture. In this new situation, the temperature of the products is lower than the temperature of the gasifier, due to the fact that heat is removed for the vaporization of the water.

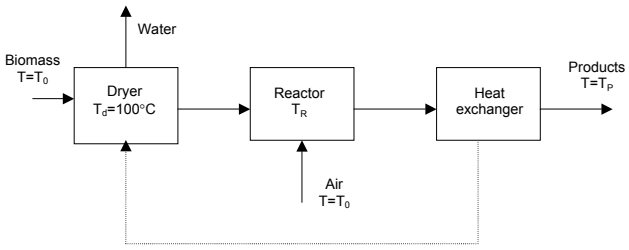

Figure 6: Process scheme for drying of biomass prior to the gasification process

Calculations were performed using Aspen Plus, and the sludge was dried from its initial moisture content of 32.5% to water percentages varying from 30% to 11%. This decreases the final temperature of the product gas from 600°C to temperatures between 514°C and 297°C. It was found that gasification of dried sludge containing 19 wt% moisture corresponded to a carbon boundary temperature of 600°C. Therefore, by drying the sludge from 32.5 wt% moisture to 19 wt% using product gas, it was possible to enable gasification at the point where not more oxygen is added than required for gasification of the carbon. This is demonstrated in the ternary C-H-O diagram in Fig. 7. By gasification of the original wet biomass at 600°C, point B is reached which is below the carbon boundary isotherm. If water is removed from the sludge by prior drying, gasification at the carbon boundary becomes possible, indicated by moving from the point indicated with 19% moisture to point A on the carbon boundary line.

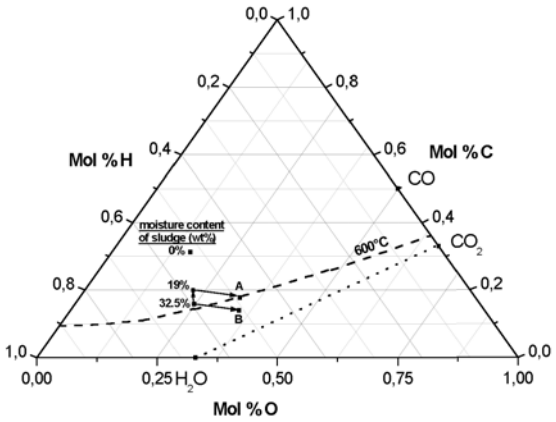

Figure 7: Drying and gasification of sludge illustrated in ternary C-H-O diagram

Figure 8 shows the effect of drying the biomass on the overall efficiency of the gasification system, including the dryer. It is obvious that the efficiency improvement by drying is less for the efficiency based on the total exergy compared to the efficiencies based on the lower heating value or the chemical exergy. The reason is that this definition takes the temperature decrease of the products into account. As the moisture content decreases, higher amounts of water have to be evaporated in the dryer. Because the heat needed to vaporize this water is removed from the hot gases leaving the gasifier, the temperature of the products decrease, thus lowering the value of the physical exergy.

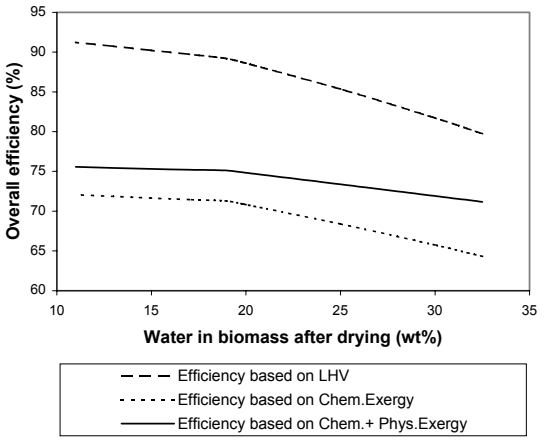

Figure 8: Improvement of gasification efficiency by drying using enthalpy of product gas

As expected, decreasing the moisture content of the biomass entering the gasifier increases the efficiencies of the process. The largest benefit is obtained when the sludge is dried from 32.5% to 19% moisture. Further drying hardly increases the chemical exergy of the product gas, but the physical exergy of the product gas is slightly increased because carbon boundary temperatures higher than 600°C can be achieved. Therefore, at increased drying levels (that is for water content in the biomass leaving the dryer lower than 19%), the efficiency based on chemical and physical exergy has the same slope as the efficiency based only on chemical exergy. Moreover, at this range the efficiency based on the total exergy (chemical and physical exergy) is only slightly higher than the efficiency based only on the chemical exergy. The reason is that the chemical exergy of the biomass is the main constituent of the total exergy and the contribution of physical exergy is much smaller.

CONCLUSIONS

In order to substitute fossil fuels by renewable fuels, solid biofuels (straw, untreated wood, treated wood, grass/plants) or liquid biofuels (vegetable oil) could replace coal as a gasification feedstock. The optimum gasification efficiencies of these fuels based on lower heating values are comparable, i.e. around 84%. However, if the efficiencies are based on chemical exergy, the solid biofuels with high oxygen content are regarded as high-quality fuels, for which a penalty is paid when decomposing them into small gaseous components. Also, the gas produced from solid biomass gasification has a lower temperature so that it contains less physical exergy. As a result of these two factors, gasification based on chemical and physical exergy shows higher efficiencies for coal than for solid biomass, i.e. almost 84% vs. 76-78%. It is interesting to note that gasification of vegetable oils is similar to the gasification of coal, and both these fuels can be considered as high quality fuels.

ACKNOWLEDGEMENT

This research project was conducted within the scope of the Incentives Programme for Energy Research, founded by NWO (Netherlands Organization for Scientific Research) and Novem (Netherlands Agency for Energy and Environment).

ABSTRACT

The paper is a result of an EU-funded project, focusing on the feasibility study of 1 MWe biomass-fuelled power plant concentrating on using a fluidized bed gasifier coupled with a micro turbine. In total 8 technical solutions from biomass to electricity are discussed here, covering gas turbine, gasifier, pyrolyser, gas cleaning and conditioning, gas engine, Stirling engine and steam boiler. The referred biomass feedstock is local cotton stalk and sometimes rice stalk. The result indicates that, for 1 MWe power plant, fluidised bed gasifier coupled with a 500 kWe gas turbine and 500 kWe gas engine is a promising choice. The work related to environmental assessment will be of the future research.

Keywords: Biomass, Electricity, Biomass-derived gas, Micro turbine, Gasifier

INTRODUCTION

The rapid growth of the economy gives a quick increase of consumption of energy which leads meanwhile to serious pollution. Biomass is a renewable source and also a clean energy carrier thereby its extensive utilisation contributing to the national energy supply security and environmental protection. The Chinese government is therefore paying particular attention to it. Biomass can be converted into energy products (usually electricity or heating and sometimes gaseous fuel, liquid fuel, and solid fuels) through many options [1,2]. Biomass to electricity is currently mostly concerned in China and Europe as it is justified economically viable [3,4]. However, if the availability of local biomass resource is concerned and furthermore the size of biomass power plant is limited, different technical solutions for biomass to electricity may result in totally different economic advantages, even if the uncertainty regarding the technical implementation and operation of such power plant is neglected. In addition, some newly emerging technologies may be suitable for biomass-to-electricity solution, but not evidently proven. Therefore, a research addressing technical and economic aspects of biomass-to-electricity solution is necessary.

This paper is a short technical analysis of different systems, which can be used for the generation of bioelectricity from biomass in China. The work is a duty of combined EU and China funded project, targeting on a small size (around 1 MWe) biomass power plant in the vicinity of Tianjin, mainly fuelled with rice straw/cotton stalk. Different

systems are being researched here and compared on efficiency, economics and emissions.

BIOMASS RESOURCE AND BIOELECTRICITY IN CHINA

Biomass resource in China is very abundant with the annual production of 3000Mt in total [5]. Table 1 and 2 illustrate the yearly yield of several typical biomass feedstocks in China in 2002 [6]. So much biomass feedstock is a strong driving force for developing biomass-to-energy conversion technologies in China. Up to now, a number of such technologies in terms of biomass to electricity have been developed, including a circulating fluidized bed (CFB) coupled with downstream gas engines (small scale under operation for 3 years), moving-bed pyrolyser combined with gas engines (on demonstration as of the end of 2004), fluidised bed gasifier coupled with the gas engine (on demonstration), fluidised bed boiler combined with steam turbine (under development) , fluidised bed gasifier with Stirling engine (under preparation) [7-11]. However, those technologies are usually concentrating on sawdust or rice husk and more or less being subjected to problems, such as, tar contamination, non-reliable and bad operation, less cost benefit, seriously secondary pollution, low efficiency of electricity generation.

Biomass Types	Quantity Mt	Mtce[1]	Estimated (2010)
Stalks/ straws	600	280	700
Firewood	140	80	210.5[12]
Rice husks	50	25	58
Industrial wastes	24	12	26
Bagasse	12	6	14
Total	826	403	

Table 1: Several biomass yields in China (2002)

The first CFB biomass gasification power plant using rice husk as feedstock was constructed in Putian, Fujian Province and has been continuously operated since August of 1998. The system consists of a CFB gasifier, a gas cleaner (including an inertial separator, a cyclone separator, a venturi and two water scrubbers) and power generation system, which consists of 5 x 200 kWe gas engines [7]. However this system has a total efficiency of about 17% [7]. The reliability of such system has been proven through two years of operation (about 10,000 h). The total investment is 510, 000 US$. The pay-back time for the system is no more than two years. Later another Demo-plant of 1.2MWe output was funded jointly by the Sanya Timber Factory and Guangzhou Institute of Energy Conversion [8]. The plant is based on an atmospheric circulating fluidized bed gasifier (CFBG) using wood powder as fuel in combination with a gas engine [8]. Due to the low efficiency and handing of liquid streams resulting from gas scrubbing the technology is complicated and costly.

Straw/stalk types	Quantity, Mt
Rice straw	201.8
Corn stalk	217.6
Wheat straw	102.4
Cotton stalk	18.2
Bean stalk	18.7
Others	35.7
Total	~600

Table 2: Stalk and straw output in China (2002)

The planned 1MWe Demo plant is going to be established in Tianjin. Tianjin region is available to supply rice straw and cotton stalk up to 100 MWe. Therefore, the target feedstocks here are Tianjin-origin rice straw and cotton stalk. Table 3 shows their elemental analysis under air dry basis.

Ultimate analysis	Rice straw wt %	Rice straw wt %	Cotton stalk wt%	Cotton branch[2] wt%
C	43.8	48.1	50.2	39.5
H	5.9	5.9	7.1	5.7
N	0.88	1.7	0.64	1.25
O[3]	49.1	43.6	41.9	38.1
S	0.22	0.14	0.11	0.02
Cl	-	0.58	-	-
Ash	10.6	19.1	4.6	15.43
Moisture	10	10	10	10
LHV, MJ/kg	14.5	18.4	19.3	14.7

TECHNICAL SOLUTIONS TO BIOELECTRICITY

Different options for generating electricity from biomass are: Ranking Cycle, Gas engine, Micro (Gas) turbine, a combination of a turbine and an engine, Stirling engine. Further next to the base system there should always be a waste heat recovery system to increase the efficiency of the plant. In this paper all these variants will be discussed except for the Fuel Cell as fuel cell at this moment is in the early developing phase for bioelectricity. However, in the coming years it would be an option.

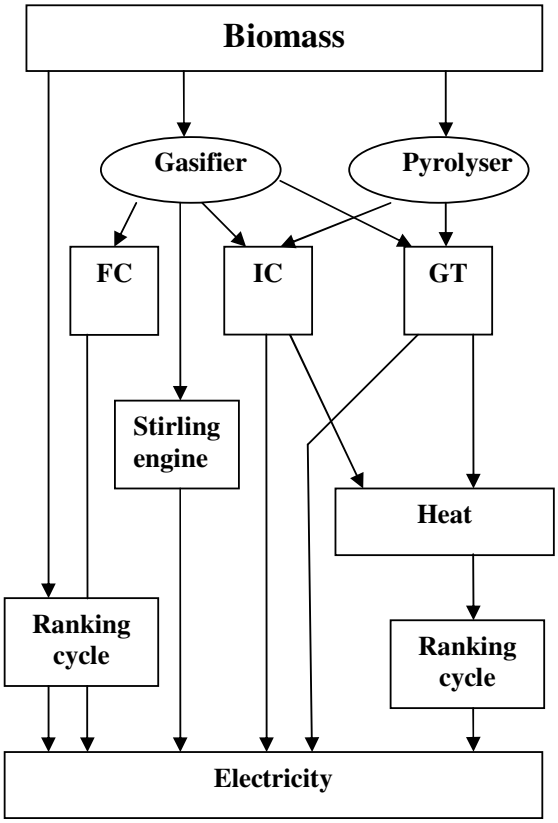

Figure 1: different solutions for electricity production from biomass

Biomass-derived gases

Biomass can first be converted to gaseous fuels and then burned in the engine or turbine to produce bioelectricity. The performances of different technical solutions are mostly dependent on the quality of gaseous fuels derived from gasification or pyrolysis of biomass. Table 4 lists the comparison of the composition of gasified and pyrolysed fuel gases. Both the gases out of the gasifiers have an approximately LHV of 3.5 to 4 MJ/kg, or 3.7~4.5MJ/Nm^3, however, the heating value of pyrolytic gas has a value of 14MJ/kg.

Gas composition at the outlet of gasifiers / pyrolysers			
Gas composition (vol. %)	AFBG	PFBG	AFBP[1]
H_2	8.55	9.30	25.50
CO	11.10	11.70	39.50
CO_2	14.95	14.50	15.55
CH_4	2.50	2.20	12.45
C_2H_n	0.82	0.43	3.50
N_2[2]	52.10	51.92	3.50
H_2O	9.98	9.95	12.63

Table 4: Gas composition at the outlet of gasifier / pyrolyser (ash and tar free)

Ranking cycle

This cycle is actually a basic steam cycle, which is being extensively used in China for producing electricity from coal for many years. The Ranking cycle fuelled by biomass is just under development now in China, and is deemed to have a few disadvantages compared to the case of coal. The lower energy density and the lower maximum temperature give a lower steam quality compared to the coal-fired case. Furthermore the scale of the plant is limited due to the availability of biomass feedstock's supply thereby resulting in a lower efficient steam turbine cycle. In addition, if rice straw and cotton stalk used as fuels, the cooling of the condenser/heat exchangers may lead to serious deposition and corrosion arising from the high content of alkali materials originated. This will reduce the system efficiency even more. In the worst case it leads to the shutdown of plant. Due to these problems the steam cycle gives an overall efficiency of around 19 to 21%, depending on the condenser values. However the system is simple in use and cheaper in cost compared to the micro (gas) turbine and even to gas engines in the middle to large scale. Further study must give a better view to this system.

Gas engine

[1] dry basis.
[2] by difference

The gas engine system used at present in China has an efficiency of nearby 17%. The problem is the low LHV and the arrangement of the different engines (5 * 200kWe). With a larger engine (1MWe) the efficiency can be further increased. For example the theoretical efficiency of the system can reach as far as 22 % to 25 % if the propoer modification to engine can be made. Another significant advantage is the local availability of the gas engine. This wouldn't increase a technical value, but significantly decrease the investment capital.

(Micro) Gas turbines

The known gas turbine, which are set to use LHV gas is the ABB Typhoon (used in Värnamo, Sweden) [13]. The Volvo VT 600, TURBEC and the Capstone gas turbines have been already designed to burn pyrolytic gas [14]. However these gas turbines are assumed that they can be rebuilt suiting for the biomass-derived gases. This involves however a higher investment than the usual gas turbine.

The main problem of a gas turbine with biomass-derived gases is that the inlet pressure of the fuel must be in comparison with the inlet pressure of the compressed air after the compressor. In normal case the natural gas or the Methane (ISO norm) is compressed in a small compressor at the inlet of the fuel. Due to the low LHV of biomass-derived gases the electricity needed for the compressor would sincerely decrease the efficiency of the total system. For example the Volvo VT 600 with a normal efficiency would go from 21.2 % around to approximately 20 %, which is a decrease in the total efficiency [14]. However due to the use of biomass-derived gas the total output of a gas turbine is increased. Due to the increase in power need of the fuel compressor the extra power output is almost totally consumed by this compressor.

There are different ways to encounter this problem. The following 2 are promising systems. The first system is a gas turbine coupled with a pressurized gasifier. This system has the advantage that the fuel gas doesn't have to be pressurized before burned in the combustion chamber of gas turbine. The intake air of the gasifier is pressurized, which, compared to the gasified fuel gas, is lower in the mass flow thereby leading to a lower electricity demand of the compressor. The advantage would be a total increase in efficiency of 2 to 3 percent. This system is already realised in Värnamo, Sweden [13]. The latter system has a pressurized system of 18 bars and uses a ABB Typhoon gas turbine with the output of 4.2 MWe.

The second option could be a gas turbine with a pyrolyser system. This system has 2 advantages compared to the former one. It could be an atmospheric system, because of the higher LHV and the need of a wet scrubber due to high ash and tar concentrations. Further the changes to the (micro) gas turbine wouldn't be significant as with the gasifier option, because of the higher LHV. However the wet scrubber invokes a series of other problems like the cleaning of the polluted waste water and the loss of sensible heat, which gives a chance to a higher environmental risk.

Combination of the gas engine and micro (gas) turbine

This combination might be slightly less efficient, because of the 2 different demanded pressures. Since the gas turbine needs a higher pressure than the gas engine, there will be a loss in energy in pressurizing the biomass-derived gases before the gas turbine or pressurizing the total air inflow of the gasifier. However this system has a few advantages that the other systems could not have. Firstly the system has the capability to be used in partial load, without lowering the efficiency when using only one gas turbine or gas engine. However further research has to be done to verify these ideas.

Stirling engine

Another option is the Stirling engine. This option has been researched at the Technical University of Denmark [15]. The electric efficiency of the system is 17.7%. Due to this low efficiency and the size of the system (35 kWe), this system can not be used in our project. However the low concentration of exhaust particles of the gasifier resulted in only the need of a bag filter, which is a huge advantage over any other gas cleaning system. The Stirling engine can also endure a larger dust and tar concentration than for example a gas engine or a gas turbine. Due to this advantage this system can be used in smaller project, which can tolerate a lower gas cleaning level not the more advanced systems.

Waste heat recovery

Most of the pilot plants in China use the waste heat only for heating the intake air of the gasifier. The waste heat (from gas cooling and flue gas) can be used in various systems. These systems can increase the efficiency of the total system substantially. The next solutions can be used in the gas turbine and gas engine variants, making them more efficient then the basic solutions.

The heat can be used to create steam in a combined cycle system. The heat of the flue gas and gas cooling can create steam of approximately 40 bars and 400 Celsius degree. Such steam can be used to drive a steam turbine, which has the potential to an additional 5 to 8 percent point of electricity. The latter value depends mostly on the condenser. Cooling water in China is not as common as in Europe where the cooling options can be more easily found for this scale. There are places in Chinese countryside where there is no open freshwater. Furthermore the temperature varies in the tropics from 20 to 40 degrees Centigrade and in the north from – 20 to 20 Celsius. These values give a not stable environment for the condenser. Combining the low isentropic efficiency of the steam turbine (due to a low power output) and the uncertain cooling option for the condenser, this option may not be as useful as in western countries.

The next option for the upgrade of the flue gas usage is the usage of a central heating system. This can be a small village or an industrial complex. Basically the heat from cooling the flue gas and the gas cooling system is the final product. It can be used for industrial steam generation, for heating or both. This option can increase the system with 60 % extra of heat efficiency. This system has some advantages in China because of the lower water dependence. The only water it needs is the water from the city heating or steam generation. It is clear this system cannot be used in the summer or in southern China because of no need for heating.

Another waste heat system can be a combination of the systems mentioned above. Using a backpressure system, this generates a lower amount of electricity, but gives the condenser a reliable cooling water supply. The last sensible option could be a seasonable use of the system. In the northern part of China the steam turbine option can be used at times when the biomass is available and electricity and heat is required. This period is the beginning of autumn and ending of spring. This leaves time for maintenance in the summer.

The usage of the waste heat is a sensible and more efficient way than the pilot plants operated at this moment. The two main disadvantages are that the capital investment is higher and the right solution for one place is not the right solution for the other. This system increases all the systems efficiencies, but it creates additional problems, which have to be solved from place to place

EMISSIONS

In contrast to woody biomass 1 year-rotation biomass like rice straw and cotton stalk have higher ash content. The ash can also contain elements like Chloride, which can be highly corrosive. Next to the efficiency and the technique the different kinds of elements have to be categorized and if needed measures have to be taken in the systems to prevent damage to the system and the environment. In addition, the N-containing pollutants should be highlighted considering the high N content of biomass feedstock.

The environmental benefit in terms of reducing carbon dioxide emission will be further investigated in later work.

CONCLUSIONS

The state of the art in the BGPG (biomass gasification power generation) in China is summarized. The size of the project is smaller compared to projects in Europe and USA. However because of lower operational cost of the gasifiers the systems can be more cost efficient at a lower level. Different systems have been selected to be researched, including gas turbines, gas engines, Ranking cycle, waste heat options and even the Stirling engine.

Different systems are being researched here and compared on efficiency, economics and emissions based on 1MWe capacity. From the technical point of view, those systems are feasible. The project is still ongoing now and therefore final results will be commissioned in the second half of 2005. The paper shows the most promising systems and interesting results in the research done so far.

Increase of efficiency compared to the 2 Pilot plants in China can certainly be done. A better cooling system or the use of a gas turbine could increase the efficiency with a few percents. A larger increase in efficiency can be created by use of a waste heat recovering system. However all these improvements will have a higher investment capital, which can make the system less economical. However further research on the relationship of efficiency and economical cost will be done in the later work.

ACKNOWLEDGMENTS

The financial support from European Commission through Asia-Pro-Eco programme is highly appreciated. The support from Jose Corella at University "Complutense" Madrid in terms of experimental results of using rice straw and cotton stalk in his test-rig should be also greatly grateful. In addition, the authors would like to thank Mohsen Assadi, Xuesong Bai, Tord Torrsion (Lund University), Umberto Desideri, Francesco Fantozi (University of Perugia), Li Sun (Energy Research Institute, Shandong Academy of Sciences) for their contribution. The support from Mengxiang Fang (Zhejiang University) should be finally acknowledged.

MODEL-BASED ANALYSIS OF EFFECTS FROM LARGE-SCALE WIND POWER PRODUCTION

Johannes Rosen[1], Ingela Tietze-Stöckinger, Otto Rentz
French-German Institute for Environmental Research (DFIU)
University of Karlsruhe (TH)
Germany

ABSTRACT

For an economically and ecologically optimised integration of fluctuating renewable power generation (especially wind power) into electricity generation, a detailed consideration of fluctuation-induced effects on the existing power system is essential. A model-based approach is introduced in this paper, which comprehensively analyses the impact of such effects on power plant scheduling and facilitates their integration into the development of strategies for an optimised evolution of the future power system structure. The newly developed AEOLIUS tool for the simulation of power plant scheduling is described. In a combined analysis of long- and short-term effects it is used together with the multi-periodic cost-optimising energy system model PERSEUS-CERT. Based on the MATLAB/Simulink® package, AEOLIUS considers the challenges for plant scheduling down to a time scale of 10 minutes. Special attention is paid to the provision of stand-by capacities and control power, as well as intermediate storage. Thus, a sophisticated quantification of the actual (net) benefits of wind power feed-in is achieved. Model results for Germany show that wind mainly substitutes power from intermediate-load and base-load plants (coal-, lignite-, and nuclear-fired). However, the required provision of stand-by capacities and control power does not only limit the substitution of conventional capacities, but also the achievable net savings of fuel and emissions in conventional power generation.
Keywords: Wind power, PERSEUS-CERT, Matlab, Simulink, energy system optimisation, simulation, power plant scheduling

INTRODUCTION

To date, more than 15.000 MW of wind turbines have already been installed in Germany, able to produce roughly 30 TWh/a of electricity [1]. All of this capacity is onshore, but the German Wind Energy Institute (DEWI) estimates that in addition about 15% of electricity production could be covered by offshore wind energy in the medium term [2]. Such large amounts of fluctuating electricity feed-in, which cannot be planned in advance, are of special relevance in the context of power production planning. The fluctuations occur in a random pattern and have to be compensated by the production of the schedulable, (mostly) conventional capacities in the power system. Fluctuations in wind speed can occur quite fast [3] and the resulting problems increase with the amount of installed wind turbine capacity. Critical cases are high wind speed gradients as well as excessively high total wind speeds (as e.g. in a storm). The latter may cause that turbines producing power at their nominal capacity have to be turned out of the wind in order to prevent structural damage. This can result in a steep negative gradient of wind power production, which has to be compensated by other power plants. Sufficient amounts of reserve capacities have to be provided for this case. These can be either conventional or renewable capacities, which can be dispatched on demand. Steep positive wind power gradients can occur as well,

[1] Corresponding author: e-mail: johannes.rosen@wiwi.uni-karlsruhe.de, phone: +49 721 608-4690, fax: +49 721 758909

for which the other currently operating capacities must be prepared to reduce their production appropriately.
An increasing scale of the fluctuations is thus a challenging phenomenon and the resulting effects cannot be ignored[2], neither in power system operation, nor in long-term energy system (expansion) planning. Consequently, this requires the development of methodologies that enable an appropriate consideration of these short-term effects in long-term energy system modelling.
In the following paragraph, a brief overview of such a methodology will be given. It is based on a long-term energy system model, which is coupled with a short-term model for power plant scheduling. After explaining this context, the rest of the paper will focus on the development and application of the short-term model for power plant scheduling.

COUPLING OF LONG- AND SHORT-TERM MODELLING APPROACH

At DFIU the long-term optimising energy system model PERSEUS-CERT[3] is used for strategic energy system analysis. This multi-periodic bottom-up model of the European electricity sector has been modified to represent renewable electricity sources in a considerably more detailed way. Further, existing plants and future expansion options based on conventional technologies are modelled. The adapted version of the PERSEUS-CERT model currently covers 21 European countries, represented by 25 regions, and determines the cost-optimised development in the time period between 2000 and 2020. In addition to the installed renewable capacities in all countries, a set of detailed potential and related cost data for 15 renewable energy technologies was adapted and integrated into the model data-base for each of the EU15 countries. The realisable renewable power production options and the costs for the development and operation of the related capacities are currently represented by about 1500 new units and the same number of processes in PERSEUS, all of them with their individual technical and economic parameters (capacity, operating hours, costs, etc.). While the most important potentials are included in greater detail, smaller and less significant potentials are considered in an aggregated way to maintain an acceptable computation efficiency.
Due to the large model size and complexity, the load curve in PERSEUS-CERT is represented by eight characteristic days per year, with a total of 36 individual time slots. This temporal resolution is sufficient for the low shares of wind energy in the system that result from the model calculations when no financial incentives are taken into account. In this case, the current and expected future cost situation in the electricity sector does not allow renewable sources of electricity to become a favourable economic solution, even if CO_2 restrictions are introduced. However, the incentive mechanisms currently in place have been shown to be extremely powerful tools to stimulate a long-term growth of renewable electricity use. In this context (and in accordance with the actual developments), first model results indicate that wind energy will play a key role.

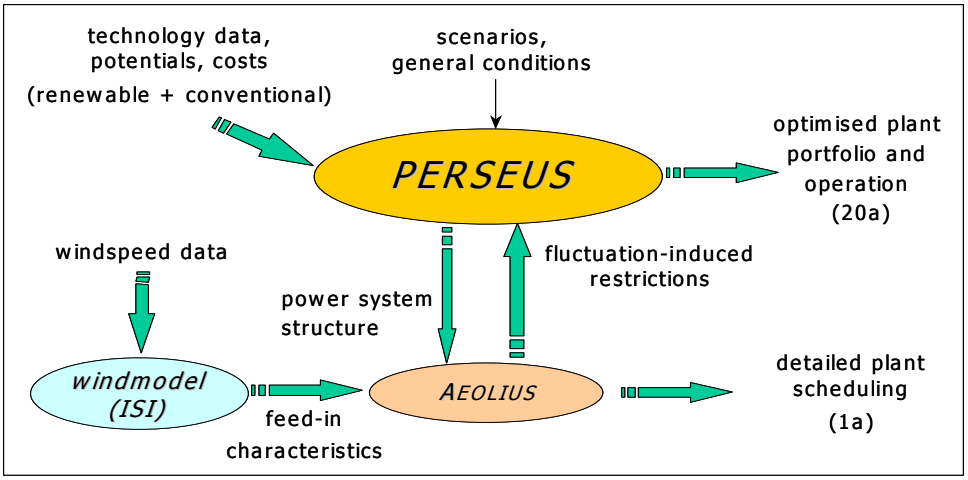

Figure 1: Interaction of models and data

[2] The interaction of large-scale wind power production with the power system, including the value of wind power in terms of fuel savings and CO_2-reductions, has been the subject of several studies, see e.g. [4], [5], [11], [14], [15].
[3] Programme-package for Emission Reduction Strategies in Energy Use and Supply – Certificate Trading. For a detailed description of the underlying PERSEUS-CERT linear optimisation approach, please refer to [6].

In order to ensure a consistent calculation of the capacity mix in future time periods also for the high wind energy shares encountered in this case, it is desirable to take into account the system requirements and interactions caused by a large-scale wind power production. This includes the secured wind turbine capacity, additional reserve capacities required, and the actual amount of fuel and emission savings. However, the temporal resolution in PERSEUS is not sufficient to represent the influence of the large resulting wind energy fluctuations, which occur randomly and do not follow a characteristic diurnal pattern. To overcome this limitation of the long-term modelling approach, it is combined with AEOLIUS, a newly developed and temporally highly resolved dynamic simulation model for power plant scheduling. It is designed to characterise the effects of an increasing contribution of fluctuating renewable electricity production on the conventional power production system, focusing especially on wind power.

The resulting complementary modelling approach is visualised in Figure 1. The future energy system structure determined by PERSEUS (without the consideration of fluctuation-induced effects) acts as input for AEOLIUS. In an iterative procedure, restrictions resulting from fluctuation-induced interdependencies between large-scale renewable power production and conventional power production are derived from AEOLIUS for individual periods of the intertemporal PERSEUS-CERT model. These restrictions can be generalised and subsequently used for an improved representation of renewable power production in PERSEUS, helping it to derive optimised long-term (20 years) energy system expansion and operation strategies on a more realistic basis.

In the following paragraphs, the newly developed dynamic AEOLIUS model is introduced in more detail.

SHORT-TERM MODELLING APPROACH

The AEOLIUS model was designed to simulate the combined medium- and short-term production planning for the entire power plant portfolio in a grid-area or a country, with the ability to account for an increasing feed-in of fluctuating renewable electricity generation. In the first model version, the German power sector is simulated for the duration of one year. Under the current market regulations, power plant schedules have to be announced 24 hours in advance (day-ahead scheduling). Beyond this, the model allows the introduction of short-term forecasts (intra-day) with better forecast quality due to the shorter forecast horizon.

AEOLIUS has been implemented in the MATLAB/Simulink® developing environment [7]. Figure 2 shows a rough overview of the simulation process with AEOLIUS. The driving force of the model is an interpolated load curve based on 8760 hourly mean values based on UCTE data for Germany [8]. For each month the weekdays are represented by the data given for the third Wednesday of this month, while the Saturdays and Sundays of each month are represented by the according data for two characteristic weekend days of the same month.

The Simulink signal corresponding to the load characteristic is depicted in the upper right of Figure 2.

The second important endogenous model variable is the feed-in of renewable electricity.

Wind power feed-in data is provided as a one-year set of hourly mean values as well. The AEOLIUS user can choose from wind power production data for good (1990), medium (1995), and bad (1996) wind years. These data sets result from the ISI wind model [9], which calculates the output of the current and the predicted future composition of wind parks in scenarios for the years 2000-2020 in 5-year intervals. The ISI model uses wind speed measurements obtained from the German meteorological service (DWD) for 22 characteristic sites in different regions on-shore (mountain, hill, near coast, coast) and off-shore. Also hydropower production data is fed into the model, but as it is much less subject to short-term fluctuations, it is easier to integrate into power production planning beforehand. Interpolated monthly mean values are thus provided as input to the model [10], which seems to be sufficiently accurate. Solar power is another type of fluctuating renewable electricity production. However, in the medium term its low efficiency and operating hours per year, resulting in a low production share, do not cause fluctuations large enough to affect the operation of the rest of the power system. Solar power production has thus not been included in the model. The same applies to schedulable renewable power sources, such as e.g. biomass or geothermal. In the simulation of future power system structures, where these

technologies can play a more important role, they can be considered in the forecasting and scheduling modules (see below) along with the conventional plant portfolio.

The level of renewable electricity feed-in determines how much of the original total demand remains to be covered by conventional power plants (Simulink signal in the middle of Figure 2). Based on this curve, load forecast simulations are conducted and a production schedule for each plant is derived. The cumulated schedule of all plants is graphically shown in the lower right Simulink signal in Figure 2. Scheduling is carried out on three different time-horizons, based on long-, medium-, and short-term forecasts. The costs and emissions resulting from the simulated schedule are computed along with further calculations and results, which all are made available for graphical and numerical analyses.

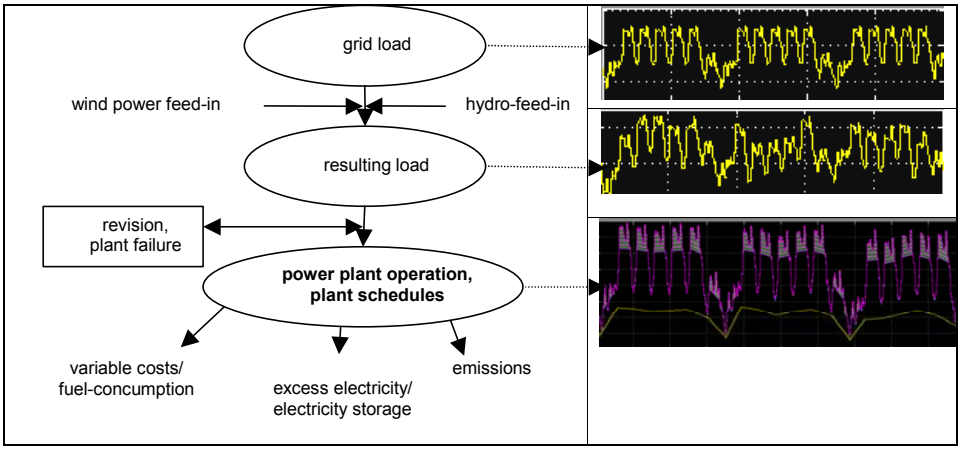

Figure 2: Schematic overview of the Aeolius fluctuation model approach

The AEOLIUS model structure is easily adaptable to the power sectors of other countries with a prospected high growth of wind energy use, as the model allows for an automated import of energy system parameters (e.g. from Excel sheets) and thus offers great flexibility for amending or changing the underlying power system specifications. This is especially advantageous with regard to the coupling with the PERSEUS-CERT model, where the parameters of future energy system structures are used to define the power plant portfolio in the short-term model.

In the following, the key aspects of the AEOLIUS simulation approach are explained in more detail.

Forecast module

The function of the forecast module is to calculate forecast data for the scheduling of the conventional plant portfolio (plus the schedulable renewable resources) for three different time horizons (24 h, 4 h, and 1 h). To account for insecurities in the forecast of the data for renewable energy production and also in electricity demand, the respective time series are varied randomly around the actual values with a Gaussian noise. This noise is more pronounced for the longer forecast horizons and decreases for the shorter forecast horizons, as the predictability for both the fluctuations in renewable energy production and demand increases for shorter time periods. While the longest forecast horizon is used to schedule the base load capacities, the medium term forecast is used to schedule intermediate load capacities. The one-hour forecast is used to schedule peak capacities and control power reserves of the other plant types currently in operation. Remaining load imbalances can be compensated by pumped storage plants, which are also modelled.

Heuristic approach for power plant scheduling

Different plant types were modelled, and in order to maintain an adequate level of technical detail, the block availability (blocks are unavailable in the case of stochastic plant failure or revision) as well as technical restrictions (e.g. start-up time, minimum times of operation and standstill, load-change characteristics, and partial load operation) were included. Besides the revision of individual blocks there are no other overall restrictions.

Similar to the approach of Krämer [11], ten different power plant types are considered (five fuel-categories, each with two different block sizes). The power plants modelled are geared to meet the technical parameters and the number of typical plants, thus creating a representative set of power stations. The pre-scheduling is based on heuristic procedures, for base, intermediate, and peak load power stations. The remaining difference between scheduled load and actual load

are balanced by stand-by capacities and pumped-storage reserves. A compensation of the arising fluctuations can thus be compensated by a sufficient supply of conventional stand-by capacities.
So-called "must-run" capacities like nuclear and lignite power plants with low specific production costs have been modelled in the base load category. They are technologically restricted to slow and relatively small changes of their output, in order to keep plant operation economical and prevent excessive material wear. In the intermediate load category, hard-coal capacities are included, with better load following characteristics and higher specific production costs than base load plants. Oil- and gas-fired plants (gas turbines and combined cycle plants), as well as pumped storage plants, all with the ability to start up and realise load changes very quickly, are considered in the peak load category. Their flexibility is, however, associated with the highest specific production costs.
Any combination of types and numbers of these plants can be combined to form a given power plant portfolio.

Capacity reserves and balancing power for security of supply

In order to provide sufficient security of supply under inherently inaccurate load forecasts or incidental power plant failures, the system must contain enough reserve capacities. Control (balancing) power in the model is provided by the activation of reserves and in order to allow for a clear and comparable quantification of fluctuation-induced effects on the scheduling of conventional capacities, it cannot be obtained from outside the system boundaries (e.g. interregional power exchange, EEX).
Basically, three different types of control power can be distinguished. They are characterised by differences in the time needed to activate the reserve and their maximum duration of deployment: primary, secondary, and tertiary reserve. Primary reserve is mainly used for an immediate correction of small power and frequency imbalances resulting from the fluctuation of electricity demand and grid operation by opening or closing turbine valves. Secondary and tertiary reserve are necessary to cover fluctuations on the power production side (wind, pv) and require the activation of additional capacity. Secondary reserve, which the grid operator must be able to activate fully within 15 minutes [12], should be taking over after 3-5 minutes. Its deployment duration is limited by technical and economic reasons to about 30 minutes. For continuing imbalances tertiary reserve must be manually activated. Gas turbines or even more quickly reacting pumped-storage plants, which can activate their full capacity within a few minutes, are counted as standing tertiary reserve, while the spinning tertiary reserve is constituted by the unused capacity margin of power plants already operating. Providing spinning reserve thus means plant operation at partial load with a reduced efficiency.
At any time, the amount of tertiary reserve is determined by the following requirements:

- coverage of possible plant failures,
- coverage of demand forecast errors, and
- compensation of output variations from fluctuating renewable power sources.

For the standing tertiary reserve, the amount necessary for the coverage of plant failures and demand forecast errors is taken into account in the model, while spinning tertiary reserve is required to balance the fluctuations from renewable electricity generation. The risk of plant failures is compensated by providing standing reserve equal to the power of the biggest block currently operated in the system. This simplification is regarded as an acceptable substitute for a probabilistic quantification of plant failures [13]. Forecast errors on the demand side are taken into account by increasing the simulated demand curve with a safety factor, which is set to 3.5% of the forecasted average load for each day.
The minimum requirement for spinning tertiary reserve is 2.5% of synchronised net plant capacity [11]. With maximum fluctuations of individual wind turbines between 75% (1 minute) up to 90% (5 minutes) of their nominal capacity, the safest solution would be to cover all capacity above the secured capacity of wind power plants by tertiary reserves. However, with an increasing penetration of wind power in electricity production, this is not an economically reasonable solution.
For the AEOLIUS simulations the probability function (frequency distribution) of hourly fluctuations is used instead to determine the required amount of tertiary reserve. As described by Sontow [14], the maximum amplitude of fluctuations expected with a 97% probability is

used as a minimum target value for the spinning reserve, which is equally distributed among all intermediate-load blocks.

Calculation of costs and emissions

Due to the limited time horizon of AEOLIUS (one year), and due to the rather long lead times for the construction of new plants, it is legitimate to assume that - unlike in the long-term PERSEUS model - the structure of the power generation system remains unchanged during this period. Thus, the amount of fixed costs (investments, interests, insurances and fixed operating costs, e.g. for staff wages, and revisions) to be accounted for is a constant figure for the time horizon of the model and does not have any influence on the scheduling of power plants. That makes it sufficient to consider only the variable costs of power generation (fuel costs and other variable operating costs, e.g. flue gas cleaning). Fuel costs depend on (world)market prices and the specific heat-demand of the plant, which varies with power output. Generally, an average specific heat demand would be sufficient, but with a growing wind power feed-in and the connected increase in necessary reserves it can be expected that plants will operate at partial load more often. Thus, load-dependent efficiency curves were used to adequately account for partial load situations. Fuel costs are calculated from the resulting thermal energy consumption of the plant and the specific fuel costs [ct/kWh]. For the fuel-prices and other variable costs fuel- and/or technology-specific values from DFIU's power plant database were used. CO_2-emissions of the plants are calculated from their respective fuel consumption using fuel-specific CO_2-emission coefficients [kg CO_2/MWh].

Simulation results

This paragraph gives an overview of how the AEOLIUS simulation model can be used to quantify the effects and the actual (net) benefits of wind power feed-in in terms of costs and emissions. In the following example, the conventional power plant portfolio installed in Germany in the year 2000 and the electricity demand are taken as a reference. Wind power is introduced into the model in three different stages based on the expansion of wind power use in Germany as anticipated by Fraunhofer ISI. While 6 GW were installed in 2000, 17.3 GW and 22.4 GW are introduced as the expected values for 2005 and 2010, respectively. A wind power production of 12 TWh, 34.9 TWh, and 50.4 TWh is introduced for the shares expected in the different years, assuming a good wind year with otherwise unchanged framework conditions in order to have a comparable basis.

Actual power production data from the year 2000 and the corresponding simulated power

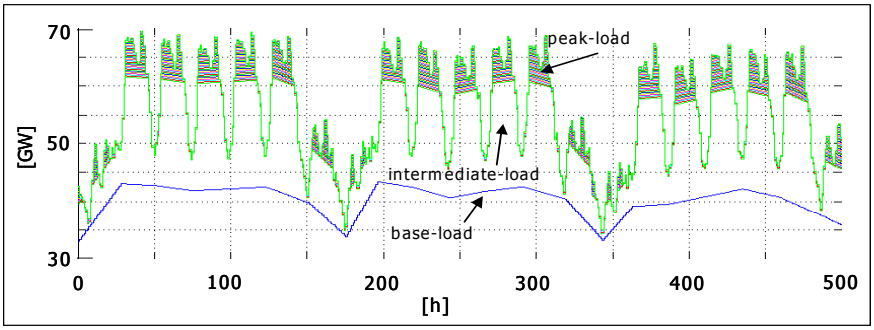

Figure 3: Load coverage by base, intermediate, and peak load during a three-week time period

production shares are in good accordance. Depending on the wind penetration results show a substitution mainly of coal-fired (about 4% in 2005 and 7% in 2010), lignite-fired (5% in 2005 up to 9.5% in 2010), as well as of nuclear production (4.5% in 2005 and nearly 10% in 2010). As quickly reacting gas-fired power plants are needed to compensate for the short-term fluctuations of wind power, the amount of gas-fired electricity displaced is negligible and, in contrast to the results above, decreases for higher shares of wind energy (from 2% in 2005 to a bit above 1% in 2010). Thus, intermediate-load generation and base-load generation are most affected. This effect can also be directly observed in the varying characteristics of base-load generation in the three-week period depicted in Figure 3.

The overall costs and CO_2-emissions of the three wind power expansion stages were compared to the costs and emissions of a reference case with the same conventional power plant structure, but without any wind power feed-in. This comparison with a purely conventional electricity system allows to calculate the average values of costs and emissions avoided per one kilowatt-hour of wind energy feed-in. This is done by relating the differences between the total costs and emissions of the reference case and those of each expansion stage to the wind power feed-in of the respective expansion stage. The calculated cost savings are used to determine the actual additional costs of wind energy feed-in, which are visualised in Figure 4. An average of 7.45 cent/kWh is paid for wind energy feed-in in Germany. Assuming that conventionally generated electricity can be replaced without efficiency losses, this would mean that about 4.3 cents/kWh could be saved by replacing electricity generated from hard coal, with remaining additional costs for wind power feed-in of 3.15 cents/kWh. However, the net cost savings resulting from AEOLIUS are much lower, for the expected wind energy feed-in in 2010, for example, only 1.14 cents/kWh of operating costs can be saved[4] in the conventional power plants, resulting in additional costs of 6.31 cents/kWh. This is due to the fact that the increasing reserve and control power requirements have to be fulfilled primarily by fossil-fuelled plants, causing losses in fuel efficiency and increased thermal wear. In addition to the reduced efficiency at partial load, the model also accounts for the emissions and fuel consumption related to plant upstarts, depending on the preceding downtime of the specific plant. Figure 4 also shows that these net savings decrease with growing shares of wind power production, with rising specific additional costs as a result. It has to be kept in mind that

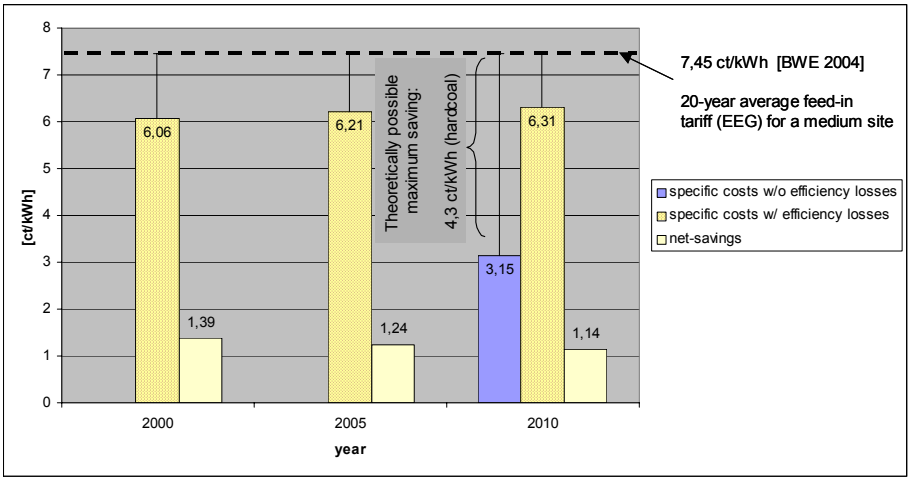

Figure 4: Theoretic and actual (net) specific costs of wind power feed-in

costs for most probably unavoidable grid expansions are not accounted for in these calculations. Along with fuel efficiency, the ecologic benefits (i.e. emission reductions) decrease with the growing share of wind energy[5]. Here the effect is even more pronounced than the influence on the costs. The reason is that in addition to the reduced fuel efficiency, wind energy does not only substitute fossil fuels, but also nearly CO_2-free electricity production from nuclear power plants, which does not save any significant amounts of emissions. The combination of these two effects causes a drastic decrease in specific emission savings.

Depending on the share of wind power in the system, only 32% (2000) down to 27% (2010) of cost savings, and between 86% (2000) and 46% (2010) of the theoretically possible emission savings can be realised. The results also depend very much on the structure of the conventional power generation capacities, whose production is partly replaced.

SUMMARY AND OUTLOOK

The aim of the newly developed AEOLIUS modelling approach was to provide a model structure for the simulation of interdependencies between increasing amounts of fluctuating electricity production (especially wind power) and the operation of the conventional plant portfolio.

[4] On the liberalised Nordic electricity market, Holttinen [4] and Nielsen [5] have calculated higher values of about 2 cents/kWh for wind power, depending on prediction accuracy and the amount of hydro power available.

[5] Similar effects have also been described by Liik [15], who modelled wind power in a unit commitment model of the Estonian electricity system, which is dominated by conventional thermal generation.

With its MATLAB/Simulink based calculation approach, the AEOLIUS model has been successfully applied to the German power sector using 60-minute average values of wind power feed-in data. The realised model allows a time-efficient plant scheduling, which accounts for the effects of a further expanding utilisation of wind energy. Typical interdependencies can be reproduced and analysed with the model, despite some simplifications. Simulations with AEOLIUS have shown that an increasing use of wind energy leads to a decrease of CO_2-emissions and lower fuel costs by substituting conventional fuels mainly in base-load and intermediate-load power production (coal, lignite, and nuclear). However, due to the increased requirements for spinning reserve (i.e. operation at reduced output level with lower plant efficiency) and more frequent load changes and/or plant upstarts, a unit of wind energy can neither avoid the entire emissions, nor the entire fuel costs associated with a unit of fossil-generated energy. Another effect limiting the achievable mitigation of greenhouse gases is the replacement of nearly CO_2-free power sources (e.g. nuclear energy) in the electricity mix.

In the further development of AEOLIUS, the modelling approach will be refined with regard to the feed-back routines between forecast horizons used for plant dispatching and the provision of control power, as well as the integration of alternative options for intermediate energy storage (e.g. hydrogen in addition to the existing pumped-storage plants). Both improvements are of special interest for the utilisation of temporally higher resolved 10 minute average values for wind power feed-in, which are currently used in a test version.

ABSTRACT

This paper describes the simulation of wave motion over a wave energy device known as the WavePlane. A general purpose computational fluid dynamics (CFD) code has been employed and modified in order to capture the physics of deep water ocean waves as well as the geometry of the WavePlane device itself. The paper describes in detail the modelling parameters employed in dealing with such a flow scenario and the results of the numerical simulation are presented which depict the flow patterns predicted and the possible energy output from the device. The results show that the CFD study has the potential to simulate such a complex scenario and can give a useful insight into possible design modifications for product improvement.
Keywords: Waves, numerical, CFD, energy conversion

INTRODUCTION

Waves, particularly those of large amplitude, contain large amounts of energy. Wave energy is in effect a stored and concentrated form of solar energy, since the winds that produce waves are caused by pressure differences in the atmosphere arising from solar heating.
The purpose of a wave energy device is to harvest the energy in the waves. Since wave energy is a renewable resource, the environmental impact is limited to the resources used for production, set-up and dismantling.
The first wave-power patent proposal was issued in 1799 by Girard, to use direct mechanical action to drive pumps, saws, mills, or other heavy machinery. Installations have been built or are under construction in a number of countries, including Scotland, Portugal, Norway, the U.S.A., China, Japan, Australia and India. The world's first

commercial wave energy plant (0.5 MW capacity) developed by WaveGen is located in Isle of Islay in Scotland.
Several studies have investigated the wave energy resource aiming to identify the best sites to deploy wave energy devices and estimate the size of the resource, including:

- 120 GW located on the west and north coasts of the United Kingdom [1]
- 320 GW around Europe [2]
- 2 TW globally [3]

Previous numerical work in this field is scarce. Dugan *et al* [4] have analysed both experimentally and numerically sloshing of water waves in a rectangular enclosure while Asavanant and van den Broeck [5] considered free surface, splashless potential flow over a two-dimensional body. It is evident that there appears to be no literature on three-dimensional, transient flow over complex bodies such as the device described in this work.
The goal of this paper is to outline some of the issues and challenges associated with CFD modelling for such a scenario and to reflect on the potential of such analyses to provide useful information in the field of wave energy generation.

WAVEPLANE BACKGROUND

The WavePlane machine was conceived in 1989 and patented in 1991 by Danish inventor Erik Skaarup. It has no moving parts except for the turbine and the generator. It is a floating device anchored to the bottom of the sea and set to face the oncoming waves. The device is equipped with large horizontal damping plates positioned under the sea surface in order to reduce as much as possible its vertical motion.
The aim of the WavePlane is to absorb the volume and the speed of the water generated by the waves and transform it into a smooth rotating flow within a tube whose energy can be converted by a turbine. A beach located at the front of the device raises the upstream wave then a series of inlet laminae collect the water and inject it tangentially in the tube in order to induce a rotating flow or vortex. The irregular motion of the waves is thus transformed into a virtually constant motion without any mechanical moving parts. Figures 1 and 2 show the design principles behind the WavePlane.

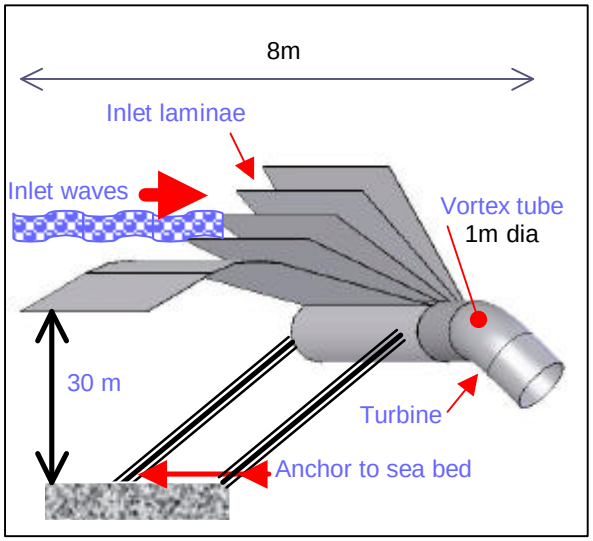

Figure 1: The WavePlane device

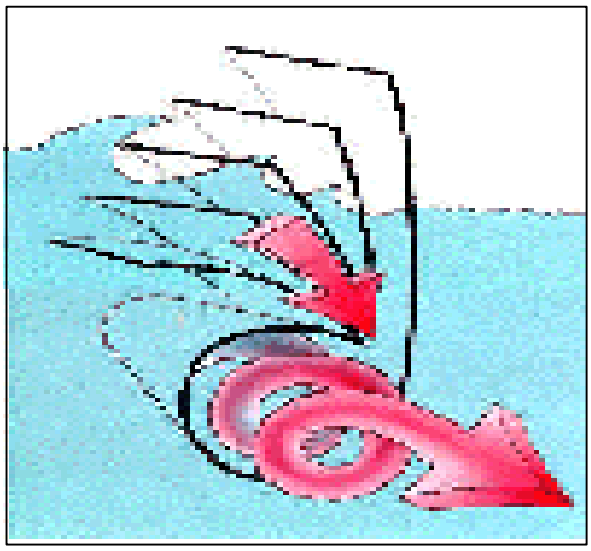

Figure 2: Vortex generation

COMPUTATIONAL FLUID DYNAMICS (CFD)

Various experiments have been performed on small-size physical models and these have improved the efficiency of the WavePlane device through the modification of the overall design. However, great care must be taken when attempting to scale up the efficiency figures for small-scale to industrial size. Physical experimentation has found that the efficiency of the energy conversion depends on numerous factors that do not behave similarly when

scaling up the problem. Amongst them are the wave height, period and speed, the movement of the WavePlane on the sea surface, the size of the tube containing the vortex and the number and the shape of the lamellas collecting the waves.

Numerical simulations using computational fluid dynamics (CFD) can produce more rapid answers to specific issues. Even if the results have to be interpreted with care, CFD is a convenient tool to obtain an idea of what will happen under real conditions. In the case of the WavePlane, CFD could then give an order of magnitude analysis of the efficiency expected for the full-size WavePlane. The main advantages of CFD are the speed of analysis and the large variety and number of results it can generate. Therefore simulating the flow in the WavePlane may provide useful information not only about its efficiency but also about the shape and the manner in which the vortex is created, the way the waves are harvested and the forces exerted by the water on the mechanical parts. Various solution parameters may also be tested in order to assess their influence on the device efficiency.

NUMERICAL MODELLING

The simulated linear wave model is based on Airy wave theory. The wave's shape is assumed to be sinusoidal, the velocities decrease with depth and the flow is taken to be irrotational and inviscid. In the physical environment of the ocean 85% of waves are of the order of 125m long or less and the ratio of wave length to height falls within that of Airy wave theory. The energy in the wave is both kinetic and potential.

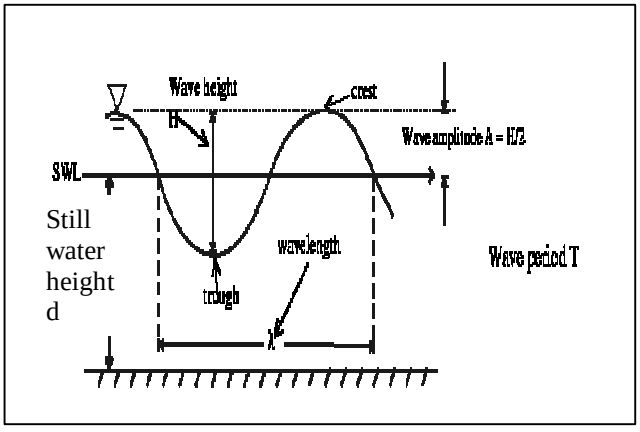

Figure 3: Theoretical Airy wave

The physical parameters involved in this numerical study were as follows:

d : still water height
L : wave length
A : wave amplitude
H : wave height
T : wave period
g : acceleration due to gravity
k : wave number

where:

$$k = 2p / L$$

and w is radian frequency where:

$$w = 2p / T$$

$$w^2 = g.k.tanh(k.d)$$

Usually, Airy waves are characterized by the ratio:

$$\frac{L}{H} \approx 25$$

The results of theory require the water surface elevation to be in the form of:

$$h(x,t) = d + \frac{H}{2}.cos(k.x - w.t)$$

and the velocity potential to be:

$$\Phi(x,y,t) = \frac{g.H}{2w}\frac{cosh(k.y)}{cosh(k.d)}sin(k.x - w.t)$$

thus giving the general form of the velocity field:

$$V_x(x,y,t) = \frac{\partial \Phi}{\partial x}(x,y,t) = \frac{H.p}{T}\frac{cosh(k.y)}{sinh(k.d)}cos(k.x - w.t)$$

$$V_y(x,y,t) = \frac{\partial \Phi}{\partial y}(x,y,t) = \frac{H.p}{T}\frac{sinh(k.y)}{sinh(k.d)}sin(k.x - w.t)$$

The average energy per meter wave width is given by:

$$E_w = \frac{r.g.H^2}{8}$$

The average mass flow rate per meter wave width is given by:

$$Q_{mw} = \frac{p.r.H^2}{4.T}$$

The average power per meter wave width is given by:

$$P_w = \frac{1}{32.p}.r.g^2.H^2.T$$

The simulated waves possess the following values:

$$H = 2m$$
$$T = 6s$$
$$L = 50m$$

The waves propagate in water of about half the wavelength in depth:

$$d \approx \frac{L}{2}$$

Therefore, to simulate open sea conditions, the computational domains in which the simulations are carried out are 30m deep, thus setting:

$$d = 30m$$

The commercially available CFD code Fluent has been employed in this study. User coding has been written by the authors to adapt the code to capture the physics of Airy waves as described above. This entails coding which describes boundary conditions for the initial, inlet and outlet conditions. The upper and lower boundary conditions for the model were assumed to be symmetric. For the inlet boundary the transient conditions of the x and y components of velocity were provided. The volume of fluid (VOF) method was used to capture the ocean-atmosphere interface so the time-dependent water surface elevation level was also prescribed at the inlet in terms of the volume fraction of water. For the outlet boundary a condition was provided that described the transient hydrostatic pressure as a wave passed through the outlet of the flow domain (at L = 50 m). A numerical grid of 220,000 unstructured cells was used to discretise space and time steps of the order of 0.1s were employed. This led to a total computational time of approximately 8 days for a simulation of 5 wave periods over the WavePlane using a PC with a P4 2.5GHz chip and 512Mb RAM.

RESULTS AND COMMENTS

Figure 4 shows the volume fraction of water as the wave encounters the WavePlane device:

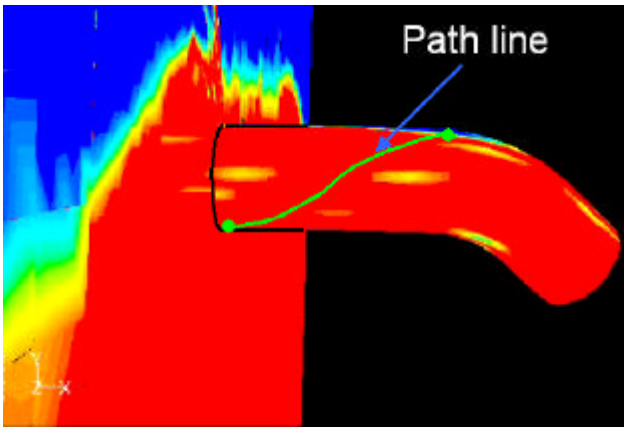

Figure 4: Contours of volume fraction and pathline in vortex tube

This figure also shows the pathline taken by a fluid element during the transient solution. This demonstrates that there exists a rotational element to the fluid flow as it passes through the vortex tube. Such a flow pattern is desirable as this will aid the rotation of the turbine.

Figure 5 shows the vortex tube outlet mass flow rate as a function of time. The average mass flow rate (horizontal line) is approximately 1500 kg/s and the flow within the tube is unconditionally positive. There is no back flow into the tube and even though the inlet conditions of the wave are periodic the CFD results predict a relatively smooth, continuous flow within the vortex tube which passes through the turbine.

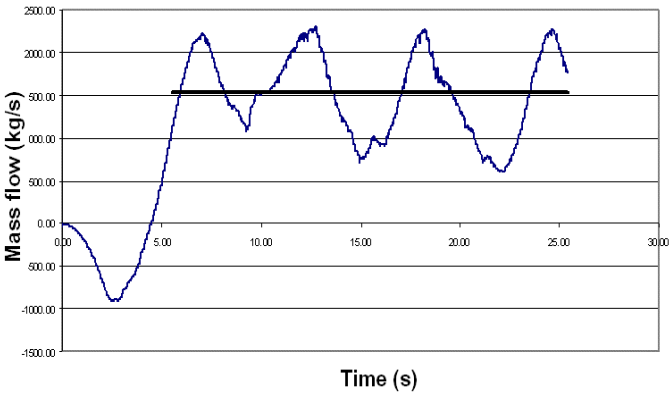

Figure 5 : Mass flow rate (kg/s) against time (s) at the outlet of the vortex tube

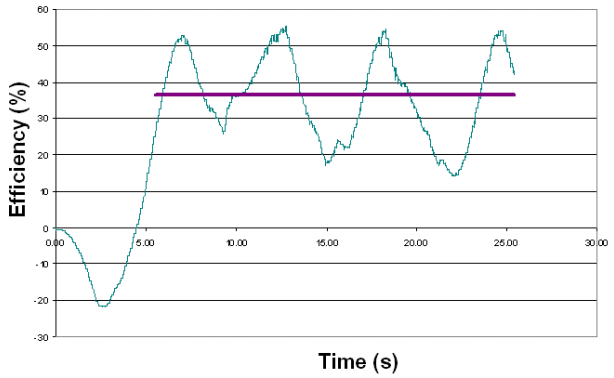

Figure 6 : Mass flow capture efficiency versus time

Figure 6 details the mass flow rate capture effeiciency which is defined as the actual mass captured by the WavePlane divided by the theoretical maximum mass flow in the oncoming wave (4181 kg/s). The results predict an average capture efficiency of 36 %.

Figure 7 shows the flow total power at the turbine location. The flow total power is the summation of the kinetic and potential energies according to:

$$P_{kin} = \int_{surf} \frac{1}{2} V^2 \times (r\vec{V}.d\vec{a})$$

$$P_{tot} = P_{kin} + \int_{surf} \frac{p}{r} \times (r\vec{V}.d\vec{a})$$

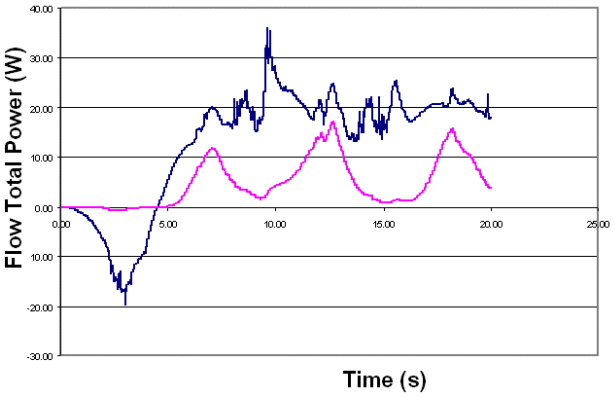

Figure 7 Transient kinetic (lower) and total (upper) powers at a plane coresponding to the turbine

The average total power is determined as 20 kW and in comparison with the maximum power available in the theoretical wave of 8m width (half of the WavePlane width – maximum power available = 184 kW) the power efficiency is calculated as 11 %.

One limiting factor of the model as it stands currently is the fact that no turbulence model has yet been incorporated in order to account for viscous losses through and over the device. This will be included in the next stage of the work. A further limitation of the model is that in order for the VOF free surface model to remain stable then very small time step sizes are necessary (0.1 s). As a results of this large computation times are required (8 days) on a high specification PC in order to obtain a solution over a reasonable time period.

CONCLUSIONS

A computational fluid dynamic (CFD) investigation of the WavePlane device has been carried out. The output shows that some useful results may be determined from such a study given that the correct physics are carefully incorporated into the model. Results from the numerical study include the flow patterns encountered and an indication of the possible efficiencies that may be generated by such a device. Further work will necessitate incorporating a turbulence model and implementing a parallel version of the code in order to reduce run times.

ABSTRACT

This work is a study of the meat and bone meal production processes. It covers the most interesting points of the legislation that regulates the animal wastes manipulation and the different MBM production technologies. These technologies are different in the way that the cooking and sterilization stages are made, therefore there are three methods for MBM production. In this paper the productive operations are described and energy balance and processing time are calculated for them.

Keywords: Meat and bone meal, production process, energy balance

INTRODUCTION

Animal by-products are defined as the entire bodies or parts of bodies of animals or products of animal origin not intended for human consumption, including ova, embryos and sperm. They represent more than 10 million tonnes of meat. These materials are then disposed of or processed and re-used in human food (meat-and-bone meal, fats, gelatine), the cosmetics or pharmaceuticals sectors and for other technical purposes.

Following the food crises of the 1990s, such as the bovine spongiform encephalopathy (BSE) epidemic, the role of these by-products in propagating transmissible animal diseases was brought to light. Those products derived from animals declared unfit for human consumption must not enter the food chain. Moreover, the

administration to any animal of proteins obtained by processing carcasses of the same species - or cannibalism - may constitute an additional risk of disease propagation.

Meat and Bone Meal (MBM) is produced in rendering plants where animal offal and bones are mixed, crushed and cooked together. During cooling process, tallow is extracted and the remaining material which is dried and crushed further is known as MBM. Tallow is used as a replacement for fossil fuels such as oil, or is sold to the oleochemical industry for recycling into useful products. MBM was previously a commercial product and was sold to the animal feedstuff industry, but since November 2000 the use of it in this way is no longer permitted.

Nowadays, European legislation (Regulation (EC) nº1774/2002) has established the health and surveillance rules applicable to the collection, transport, storage, handling, processing and use or disposal of animal by-products; the placing on the market and, in certain specific cases, the export and transit of animal by-products and products derived therefrom. [1].

It is necessary the development of new technologies or improved present ones in order to eliminate, in a secure way, specific risk materials and meat and bone meal.

This work is part of a project which purpose is the development of suitable technologies for secure MBM elimination whatever its origin (by-products of slaughter houses or specific risk materials). In the elimination MBM is mixed with residual biomass or mining industrial wastes of low value. This residual material will be used as a source of energy in an efficient way in order to promote energetic conversion facilities of small or average size.

This report describes briefly Spanish MBM production processes and the most interesting points of the legislation that regulates animal wastes manipulation.

Three alternative production processes are used. The purpose of this work is to chose the best production process in order to use MBM as fuel in thermoconversion plants. The study includes the composition of the raw material and a complete chemical and energetic characterization of the product (MBM): proximate analysis, ultimate analysis, lower and higher heating values and ash composition. These data are the basis for the performance of different technologies for elimination. Finally, energy balance and processing time are calculated for the three methods described.

PROCESSING PLANTS

The raw material (animal by-products), as it has been pointed out before, is very heterogeneous in composition, therefore the composition of MBM varies significantly too.

Table 1 presents some characteristics of raw material and MBM [2]:

Raw Material (30% bones)			
Moisture	Non fat-solids	Fat	
60%	24%	16%	
Meat and Bone Meal			
Moisture	Total solids	Proteins	Fat
4-8 %	92 – 96 %	80 – 86 %	8 – 12 %

Table 1: Composition of raw material and MBM

In order to study the behaviour of MBM as fuel, it has been characterized and these results are shown on the next table.

Moisture (%)		7.88
Density (kg/m^3)		178
Proximate Analysis (% db)	Fixed carbon	0.1
	Volatile	77.14
	Ash (550°C)	22.76
Ultimate Analysis (%db)	Carbon	49.5
	Hydrogen	6.36
	Nitrogen	10.75
	Sulfur	0.25
	Oxygen	9.87
	Chlorine	0.51
Heating values (kJ/kg)	HHV (dry)	20607
	HHV	19019
	LHV (dry)	19186
	LHV	17305
Analysis of ash at 550°C (% db)	Al	0.13

	P	8.2

Table 2: Characterization of MBM

Table 2 summarizes proximate and ultimate analysis, lower and higher heating values, and ash composition. They have been determined by conventional methods. It can be seen that MBM from a thermal point of view is a good fuel because of its high calorific value, however MBM's nitrogen content may lead to high NO_x emissions, while its high ash content will require an efficient ash off-take system, so that those drawbacks involve a well-controlled destruction as other wastes. On the other hand, a granulometrical distribution study shows that the particle size is between 0.1 and 1mm. Its small size is good for a better combustion.

The production of MBM always requires two stages: sterilization and cooking. Sterilization consists of a thermal treatment at a temperature of 133°C and 3 bars absolute pressure for 20 minutes with a maximum particle size of 50 mm [3] to destroy infection agents.

During cooking stage at atmospheric pressure tallow melts and proteins denature and coagulate.

In Spain, three alternative production processes are used and they are different in the moment and in the way of cooking and sterilization stages. These three methods are: Sterilization and cooking in a discontinuous digester; continuous cooker and later discontinuous sterilizer and, the third, discontinuous sterilizer and continuous cooker. Now a brief description of these processes is done.

Batch Digester (Method 1)

The raw material is stored in steal hoppers and feeding screws are used. From the reception hopper the raw material is conveyed into a pre-breaker and then to a fine crusher. This reduces the particle size to 50 mm. The crushed material is again stored until its thermal treatment.

Sterilization and cooking of animal by-products are done by means of a discontinuous digester. The digester is a cylindrical vessel around 20 m^3 volume with a stirring rod. It is externally heated using a steam jacket. The steam water is produced in a conventional boiler. In a first step, digester is pressurized and sterilization takes place, raw material is treated at 133°C and a total pressure of 3-bar for 20 minutes in accordance with requirements. It produces not only the destruction of infection agents, also fat is melted and the water content of the material is vaporized. Then the system is depressurised and the steam produced in the digester is lost by evaporation. This steam is condensed and treat as waste water. Cooking process continues at atmospheric pressure and the final moisture of the material is around 6%. After cooking the tallow is separated first gravimetrically and then it is pressed. The tallow obtained is recycled as fuel in the plant or is sold for recycling into useful products. After tallow is decanted, it is filtered and pumped to a tallow storage tank. The cake of meat and bone meal, and the solid obtain in the purification of tallow are cooled and conditioned in a hammer mill. After milling MBM is re-sieved and any larger particles are then re-milled. The product is finally stored.

Continuous cooker and batch sterilization of MBM (Method 2)

In this second method, crushed raw material, is first cooked at 100°C in a continuous way. In this stage, the material is cooked and residence time is about one hour, moisture is reduced to 16%, the digestor is quite similar to the discontinuous one, it is also heated with a steam jacket but it is not closed.

One advantage of this continuous system is that it can be easily automatized and controlled and therefore energy consumption could be optimised, in addition, energy lost in feeding and discharging operations is reduced. Next the cooked product is pressed to extract the tallow and the cake is sent to a discontinuous sterilizer, where it is treated at 133°C and a steam pressure of 3-bar for 20 minutes. Before storage MBM is cooled and milled properly. A diagram of the plant is shown in Figure 1.

Batch sterilizer and continuous cooker (Method 3)

The third process, consist of a discontinuous sterilization of the crushed raw material in a tank where it is directly heated with steam water that it is in contact with the animal by-products, there is not mechanical agitation and injection of steam is also used for mixing the material to assure that all the material is kept at the desired conditions. The residence time is not enough for a good cooking and then the sterilized product is further cooked in an open continuous system, externally heated, which operates at atmospheric pressure and 100°C during one hour.

Tallow and MBM are separated by decantation and in a mechanical screw press and, finally, both are treated to be stored.

RESULTS

Energy balance and operation time have been estimated for sterilization and cooking processes. The main energy consumption is steam water whereas electric energy for stirring, crushing, pressing or feeding is neglected. It is assumed the same conditions for entering raw material and exit product, in the three methods described. It enters at 20°C with a composition of 60% water and 40% non-fat dry extract, whereas MBM produced contains 6% moisture and 94% non-fat dry extract.

The stages considered in the three methods are:

Method 1: Sterilization (heating from 20°C to 133°C); cooking at 100°C with a moisture reduction 60% to 6%.

Method 2: Heating 20°C to 100°C, cooking at 100°C, moisture reduction 60% to 16%. Intermediated stages of filtering, pressing and storing. Batch sterilization (heating 50°C to 133°C) and moisture reduction 16% to 6%.

Method 3: Sterilization (heating from 20°C to 133°C); heating 80°C to 100°C; cooking at 100°C and moisture reduction 60% to 6%. Between both treatments the material is transported and it is slight cooled.

The parameters used in the calculations and the results of energy balance are shown on Table 3, where t is the average temperature and q is the amount of heat required per kilogram treated.

The heat capacity of the material c has been estimated as:

$$c = c_{pw} \cdot w + c_m \cdot (1 - w) \quad (1)$$

where c_{pw} is the specific heat capacity of the water at the average temperature, w is the specific humidity and c_m is the specific heat capacity of the non-fat dry extract (kJ/kgK) and its temperature dependence [4] is calculated by:

$$c_m = 1.465 + 0.0067 \cdot t \quad (2)$$

where t is the temperature in °C.

Process	t (°C)	c_{pw} (kJ/kgK)	c (kJ/kgK)	q (kJ/kg)
Method 1	76.5	4.192	3.306	1589
Method 2	60	4.186	3.258	1677
	91.5	4.205	2.418	
Method 3	76.5	4.192	3.306	1656
	90	4.203	3.349	

Table 3: Results of energy balance

Energy balance indicates that method 1, where sterilization and cooking stages take place in the same batch equipment requires less energy (about 5.6%) than the other two methods per kg of raw material processed .

9: Batch steriliser
10: MBM storage
11: Pumps
12: Sedimentation
13: Decanter
14: Boiler

In order to complete the study, processing time and plant dimension are evaluated for a better comparison of the three methods described.
Processing times estimated for the different stages on the three methods are:
Method 1: Feeding and preheating (10 min), sterilization (20 min) and final treatment (1 h 30 min). The typical capacity of these digesters is about 8000 kg of raw material per batch, it means that the plant processes about 4000kg/h of animal by-products.
Method 2: Cooking process takes 1 hour, and 8000 kg/h are treated. For sterilization (30 min), the capacity of this part of the plant could be reduced to 2000-2500kg/h because tallow has been separated and other part of the raw material has been lost by evaporation.
Method 3: Sterilization (30 min) and cooking (1 h). For a capacity of 8000kg/h of animal by-products in cooking stage, the capacity of the sterilizer could be reduced to 4000 kg.
These data indicate that methods 2 and 3, with a continuous cooker, can process twice animal by-products as much as batch digestor but it does not mean double the plant cost.
On the other hand, the sterilization of the MBM instead of the raw material decreases significantly the size of the sterilizer.
Therefore, the recommended process is method 2, which can be seen in detail on Figure 1.

ABSTRACT

The trend for material and energy recovery from wastes along with the need for greenhouse-gases reduction resulted in increased interest for biomass and / or wastes thermal exploitation. Combustion and pyrolysis seem to be the main route towards that direction. In this work the pyrolysis and combustion behaviour of ten biomass and waste materials was investigated. Samples tested included agricultural residues, wood processing by-products, straw and MBM (meat and bone meals). All biomass/waste species were subjected to standard proximate, ultimate and ash analyses. Both pyrolysis and combustion tests were conducted non-isothermally in a thermogravimetric analyser (TA Q600) at ambient pressure and 150-250μm particles size. The effect of the heating rate was also considered. The independent parallel, first order, reactions model was elaborated for the kinetic analysis of the pyrolysis results. The thermal degradation of the biomass/waste samples was modeled assuming three of four parallel reactions, corresponding to the decomposition of cellulose, hemicellulose and lignin for the biogenic fraction.
All samples were proven good fuels, reflection of their high volatiles and low ash content. At increased heating rates, the fuel sample reached faster higher temperatures, while enhanced pyrolysis rates were achieved. As a result, a slight decrease in total weight loss was observed accompanied with a systematic increase in pyrolysis starting temperature, and an almost linear increase in maximum pyrolysis rate. Increased combustion reactivity was found for olive kernel and willow followed by forest residue. The catalytic effect of mineral matter on char oxidation was pronounced in the MBM sample, leading to a reaction rate decrease and shifting the DTG curve to lower temperatures.

α = conversion (reacted fraction)

INTRODUCTION

The need for energy recovery from renewable sources along with the necessity for emissions reduction resulted in increased interest for biomass and / or wastes thermal conversion. Combustion constitutes one of the most important thermal treatment methods for biomasses and / or wastes. It combines the anticipation to replace the landfilling option along with energy recovery. Thus, the factors that affect the combustion procedure should be well known and studied in detail, towards the design and effective performance of industrial applications. The effect of mineral matter content in combustion and pyrolysis processes has also been investigated and identified as one of the key research areas [1].

Numerous separate studies have dealt with pyrolysis of biomass and lignocellulosic materials, while other researchers have investigated the pyrolysis of waste components. Madorsky et al, Kilzer and Broido and Chaterjje and Conrad have set the basis of the modern kinetic models [2]. Heikkinen et al studied the devolatilisation behaviour of about 50 different wastes. In order to calculate the devolatilisation of the samples, they assumed that the thermal degradation curve is obtained as a sum of the contributions of the corresponding pseudo components and found that this assumption holds for cellulosic samples [3]. Many different mechanisms have been considered, for instance the model proposed by Manya et al [4], who studied waste wood and sugarcane bagasse samples for kinetic evaluation. Waste wood pyrolysis was modeled assuming three independent parallel reactions, corresponding to the decomposition of three pseudocomponents linked hemicellulose, cellulose and lignin. In the same line, Caballero [2] tested two biomass samples including olive kernel and almond shell. He found that with three independent parallel reactions model, the agreement between calculated and experimental data is excellent. More recently, Gronly et al [5] investigated the devolatilisation behaviour of several hardwoods and softwoods. They found that devolatilisation dynamics of the wood species of the study can be described well by a simple model consisted of five parallel, first order reactions for the amounts of the volatile fractions associated with the two extractive components.

As Fisher et al [6] and Gronly et al [5] report all these derived kinetic parameters depend on the specific pyrolysis conditions that include temperature, heating rate, pressure, particle size, ambient gas environment, and the presence of ash or mineral matter deposits. Therefore, the presence of several components and the catalytic role of the inorganic matter affect the kinetic parameters. In the last two decades, extensive studies have been performed in this field of investigation by many researchers. Raveendran et al [7] examined the mineral matter of various biomass samples and reported that their main elements are Si, Ca, K, Na, and Mg followed in percentages by S, P, Fe, Mn and Al.

Serious number of research efforts has also been performed on the combustion procedure, indicating that the presence of oxygen causes many complexities. Bilbao et al [8] studied the thermal decomposition of cellulose and pine saw dust in oxidative atmosphere and found that the degradation of the material at low temperatures, causes the appearance of gas – phase reactions between the released volatiles and oxygen, and promotes the combustion of the char generated in the early stages of the solid degradation. In this line, Conesa at al [9] support that a later decomposition stage exists only when oxygen is present, maintained also by Zheng et al [10] who extensively investigated the combustion procedure.

Since, alternative fuels i.e. biomass, wastes etc. are at great importance nowadays, it is vital to understand deeply their behaviour under pyrolysis and combustion. However, there are not sufficient data available, particularly for non-conventional fuels such as MBM and wastes. To cover this need, the pyrolysis and combustion behaviour of agricultural residues, wood processing by-products, straw and MBM (meat and bone meals) was examined by thermogravimetry. The behaviour of the biomass / waste components in inert and oxidative atmosphere is compared. Kinetic parameters are calculated by using the independent parallel, first order, reactions model and the pyrolytic behaviour in the various heating rates is simulated according to the determined parameters.

The effect of mineral matter present in biomass and waste is studied and the role of feedstock properties in pyrolysis is also examined.

EXPERIMENTAL

Materials

Materials tested include two agricultural residues referred as almond shell and olive kernel, six woodprocessing by-products named as MDF, saw dust, willow, waste wood, forest residue and demolition wood. Meat and bone meal and straw were also added in the test matrix. The initial samples were milled and sieved and the selected particle size fraction was in the range of 150-250μm. Prior to the thermogravimetric experiments, samples were dried in the oven at 105°C in N_2 atmosphere for 3 hours. Aiming to investigate the influence of mineral matter on the thermal degradation of MBM, the specific sample was washed with three different acid solutions (5N HCl, 22N HF and 12N HCl). 18gr of sample was added in 120mL of each acid and the mixture was stirred for 1 h at 25 ± 2°C. Samples were then washed with distilled water, filtered and dried. The selected fuels were subjected to proximate analysis according to the standard ASTM D 3172-89 method. Ultimate analyses for all samples including calorific values were carried out in a Flash 1112 Series EA Thermo Finnigan CHNS elemental analyser. Proximate and ultimate analyses results are presented in Table 1. The analysis of heavy metals in the ash sample is performed by an Inductively Coupled Plasma – Atomic Emission Spectroscopy (ICP-AES) spectrophotometer.

Apparatus and Procedure

Thermogravimetric tests were performed in a TA Instruments Q600 simultaneous TGA-DSC apparatus. The weight precision of instrument is 0.1μg. Small sample weights, about 10 or occasionally 20mg were placed in an open alumina sample pan, in order to reduce the effects of eventual side reactions such as heat- and mass-transfer limitations. High purity helium and respal air (80 / 20 in N_2 / O_2) were used in the constant flow rate of 100 mL/min. Prior the heating program, system was purged for 10 min at 400 mL/min to ensure that the desired environment was established. Weight loss and the rate of weight loss were continuously recorded in a linear temperature increase from 30°C to 1000°C. Devolatilisation tests were conducted in three and in some cases in four heating regimes, i.e. 5, 20, 50 and 100°C/min.

KINETIC MODELING

The biomass and / or waste pyrolysis is a complex phenomenon and proceeds through multiple parallel or even competitive reactions. Thus, it is not possible to describe the whole process with a single reaction. Whereas that fact, DTG curves obtained by pyrolysis of biomass and waste samples can be essentially described by the relatively simple model of independent parallel reactions. More specifically, it is assumed that each component reacts independently and thus, the thermal behaviour of the sample could be described by the sum of its individual components. This approach has been successfully applied by many authors in earlier studies [4-5, 11-16]. In this work, pyrolysis of biomass and waste samples was modeled by assuming three or four independent, first order, parallel reactions.

The individual conversion rate for N reactions is described by:

$$\frac{da_i}{dt} = A_i \cdot \exp(-E_i/RT) \cdot f(a_i), \quad i=1, ..,N \qquad (1)$$

where a_i is the separate conversion, which is expressed as follows:

$$a_i = \frac{m_{0,i} - m_i}{m_{0,i} - m_{char,i}} \quad (2)$$

Assuming a first order reaction then:

$$f(a) = 1 - a \quad (3)$$

The overall conversion rate is described by

$$-\frac{dm}{dt} = \sum_i c_i \frac{da_i}{dt}, \quad i=1,..,N \quad (4)$$

The contribution of each partial process to the overall mass loss is expressed by the coefficient c_i:

$$c_i = m_{0,i} - m_{char,i} \quad (5)$$

The minimization of the objective function is used to identify the optimum kinetic parameters, as given below:

$$OF_{DTG} = \sum_{i=1}^{N} \left[\left(\frac{dm}{dt} \right)_i^{exp} - \left(\frac{dm}{dt} \right)_i^{calc} \right]^2 \quad (6)$$

The estimation of the best fitting kinetic parameters is achieved through the deviation between the experimental and calculated DTG curves, as a percentage of the maximum experimental value (dm/dt):

$$DEV_1(\%) = \frac{\sqrt{OF_{DTG}/(Z-M)}}{\max\left[\left(-dm/dt \right)_{calc} \right]} \cdot 100 \quad (7)$$

where M is the number of the model parameters (A_i, E_i, and c_i) and Z is the number of the measured data points. Also, the deviation between the observed and calculated char fraction can be used

$$DEV_2 = abs\left[\frac{(m_{char})^{exp} - (m_{char})^{calc}}{(m_{char})^{exp}} \right] \cdot 100 \quad (8)$$

where $(m_{char})^{exp}$ and $(m_{char})^{calc}$ are the experimental and calculated values of the residual mass. The latter as already reported, arise from the optimized pre-exponential factor and activation energy values computed.

RESULTS AND DISCUSSION

Pyrolysis of samples

Several characteristics of the thermal degradation of samples were used in order to evaluate its behaviour, such as the initial pyrolysis

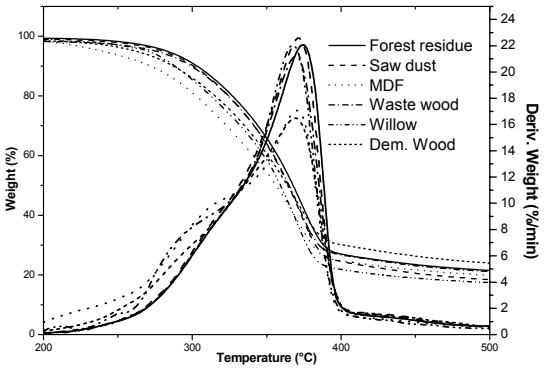

Figure 1: Weight loss and rate of weight loss as a function of temperature for several biomass samples.

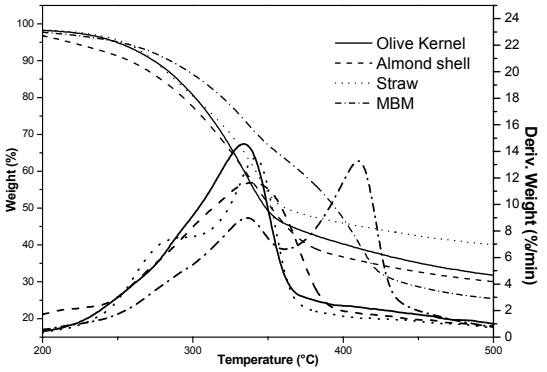

Figure 2: Weight loss and rate of weight loss as a function of temperature for several biomass and waste sample.

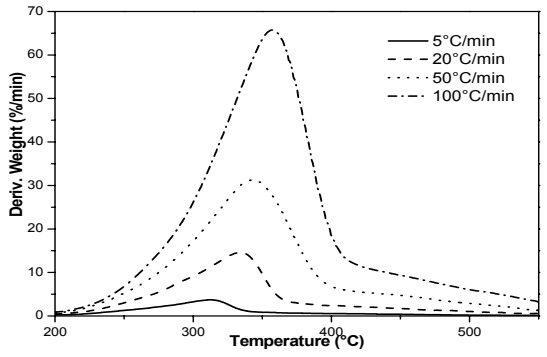

Figure 3: Effect of heating rate on the devolatilisation of olive kernel.

temperature, maximum pyrolysis rate and corresponding temperature, total conversion and contribution of various temperature intervals in total weight loss. The mass loss and the rate of mass loss are presented in figures 1 and 2 for wood based biomasses and waste samples, respectively. From the TG curves, it can be seen that pyrolysis starts at about 200°C and is essentially completed at 500°C. DTG curves of biomass and waste present a narrow peak between 330-375°C which is similar to that found by other authors [3]. Exceptional to this behaviour, MBM sample presents a maximum pyrolysis rate at 410°C. Taking into account that the reactivity is inversely proportional to the temperature corresponding to peak height, olive kernel seems to be the most reactive among the samples. In contrary, straw and MBM present the lowest peak heights and the highest peak temperature. The main devolatilisation occurs between 250-400°C in all test cases, with the exception of MBM, where the main degradation stage is completed at approximately 450°C. Significant variations of the total weight loss are observed, which are approximately between 65-85% and are in accordance with previous studies [17].
The derivatives of the weight loss for the pyrolysis of olive kernel in specific heating regimes (5, 20, 50 and 100°C/min) are presented in Figure 3. As it is obviously illustrated by the DTG curves, pyrolysis is completed at approximately the same

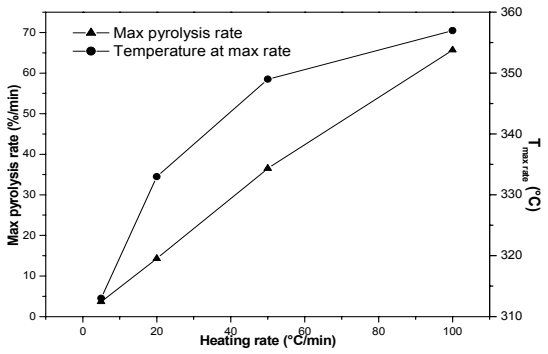

Figure 4: The maximum pyrolysis rate of olive kernel and temperature at max pyrolysis rate as function of the heating rate.

temperature region for all the heating rates. At higher heating rates a slight increase in the char yield was observed in previous studies. This has been cited to the competitive reactions that are affected by the increased heating rate [15]. An increase of the residual char between 1.3- 5.7% is obtained and thus, it is as small as it can be assumed to be practically unaffected by the heating rate. Figure 4 clearly shows that an almost linear increase in maximum pyrolysis rate is observed. At increased heating rates, sample particles reach faster higher temperatures, resulting in significantly higher DTG peaks, shifted at higher temperatures. This could be ascribed not only to the effect of the heat transfer phenomena occur at different heating histories, but also to the temperature lag of the sample.

Kinetics

Detailed reaction mechanisms are available for the kinetic evaluation of biomass and / or wastes pyrolysis. It is also adequate to take into account only the basic characteristics of the degradation process with a simplified mechanism. A relative simple approximation to determine the kinetics of the thermal decomposition consists in assuming that TG-DTG curves can be divided into three or more zones, each of them considered independently. Biomass samples can be modeled by assuming a three-step mechanism for each pseudo-component. The first pseudo-component constitutes hemicellulose, the second cellulose and lignin corresponds to the third reaction. A fourth reaction is necessary to simulate the hemicellulose decomposition. As Heikkinen et al [3] proposed lignin and xylan start decomposing at lower temperatures compared to cellulose. Lignin decomposes over a wide temperature range having

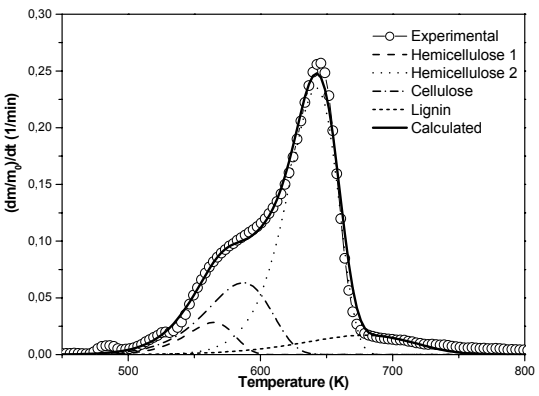

Figure 5: Modeling of the pyrolysis of willow by using four independent parallel reactions.

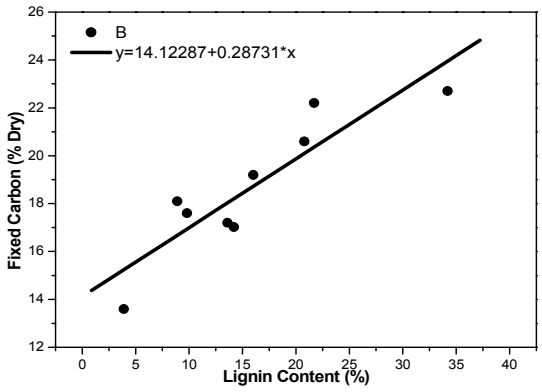

Figure 6: Fixed carbon content of lignocellulosic samples as a function of lignin content, calculated for the devolatilisation tests at 20°C/min.

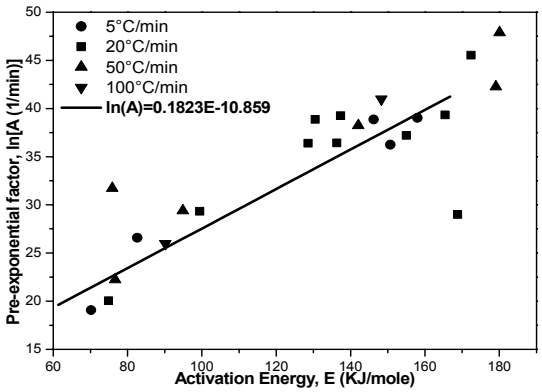

Figure 7: Kinetic parameters correlation.

a long tailing section. In literature, xylan is used instead of hemicellulose. Since many of the significant errors in kinetic estimations are derived from this assumption, hemicellulose was applied to evaluate the kinetics of the biomass samples.

Figure 5 shows the pathway that willow pyrolysis has been modeled by assuming four independent parallel reactions and using the DTG curve. The calculated kinetic parameters are listed in Table 2. MBM and four biomass samples were modeled by assuming four reactions, while the rest of the samples were efficiently modeled through three pseudo-components. It is worth mentioning that hemicellulose contributes in higher percentages, when two hemicellulose peaks are used to model accurately the thermal degradation of samples. On the other hand, cellulose is higher in samples where three independent parallel reactions are used, while lignin presents the lowest value. The average value of activation energy for the hemicellulose decomposition of biomass is 103.7 KJ/mol. This is in accordance but still lower than the values calculated by Gronly et al [16] and Sorum et al [11], being 133.5 KJ/mol and 110.3 KJ/mol, respectively. In correspondence, first reaction for meat and bone meals present a lower value (57.9 KJ/mol). The activation energy for the thermal degradation of lignin was calculated at 53 KJ/mol for the lignocellulosic materials and 31.7 KJ/mol for MBM. As resulted from the kinetic attributions pre- exponential factor values depend on the heating rate. An increase of the heating rate results in increased A values as was also shown by Bilbao et al [8].

Calculated lignin content was evaluated with respect to the fixed carbon content. Previous studies referenced to charcoal production from biomass [18, 19, 20] suggested that a correlation between lignin and fixed carbon content exists. Figure 6 shows that interrelation for the biomass samples tested. In evidence, lignin and fixed carbon content are proportional in all biomass samples. Antal et al [19] proposed a statistical **t-test** to ascertain the calculated trend of the substrates. They suggest that a **p-value** lower than 0.05 is significant for the trend existence. The calculated values for R^2 and p-value, which are 0.8 and 1.6 10^{-6} respectively, are within the margins, reflecting the linear correlation between fixed carbon and lignin content. Experimental conditions like the heating rate and sample size affect the kinetic parameters. For this reason a number of different activation energies and pre-exponential factors have been calculated in previous studies. It is important however to notice that the combined effect of kinetics in the rate constants is coherent and is known as compensation effect [16, 21]. It means that pre-exponential factor and activation energy are linearly correlated as follows:

$$\ln(A)=m\cdot E+\ln(k_0) \quad (9)$$

where the constant $m=1/RT_i$ is the slope of the linear plot. At the isokinetic temperature, T_i, all the reactions of the group proceed at the same rate k_0. Earlier research [21] suggested that this behaviour of the biomasses based on the experimental temperature measurement imprecision. In the present work kinetic data obtained for the pyrolysis

Sample	Hemicellulose 1			Hemicellulose 2			Cellulose			Lignin

at various heating rates was implemented in order to calculate the isokinetic temperature value. As illustrated in Figure 7, the constant m value is 0.1823 corresponding to 387°C (660K). In this line, k_0 value is calculated at $1.9\ 10^{-5}$.

Mineral matter effect

Meat and bone meals sample is characterized by its high-ash content followed by straw as shown in Table 1. These two samples seem to be less reactive among the rest of the biomasses tested (Figures 1 and 2) and, thus, showed the lowest reaction rate. It is well known that the decomposition of cellulose in biomass is catalyzed from the mineral matter contained in the raw material [22]. Therefore, the MBM sample was demineralised in order to investigate the effect of mineral matter on the pyrolysis of the specific sample. Table 1 presents the significant effect of demineralisation on the mineral matter content. Thus, almost complete ash removal is achieved when the previously described three-stage demineralisation procedure is applied. The remaining ash in the MBM sample is too low (0.29%). Lower initial pyrolysis temperature and a decrease in maximum reaction rate were observed during the test of demineralised MBM, Figure 8.

The main elements that form biomass ashes are presented in the samples as oxides, silicates, carbonates, sulfates, chlorides and phosphates. Sample pyrolysis is mainly affected by alkali metals (K, Na), alkaline earth metals (Ca, Mg), silicon, chlorine and sulfur [1]. Ash analysis results from the ICP-AES are given in Table 3. All biomass ashes are characterized by high CaO content, which ranges from 1.2% in straw to 18.62% in the forest residue and waste wood samples. Al_2O_3 has the highest concentration in olive kernel and Fe_2O_3 in saw dust. Increased contents of MgO, Na_2O and Mn_3O_4 are present in MDF and saw dust. It is worth noting that MBM has the highest content of calcium oxide (36.7%) along with phosphorous and potassium (47.5% and 2.77%). In general, the presence of potassium is considered to increase the char yield [7]. This is also true for demineralised MBM, which has the highest total conversion. It is well established that Ca concentration increases the gasification rate [23]. This trend is also observed in pyrolysis experiments presented here. As can be seen in Figure 8 demineralised MBM present significantly lower pyrolysis rate than raw fuel. DTG curves of raw and demineralised MBM follow the same shape in the temperature region of 300-500°C, but the peak heights are reduced and shifted to lower temperatures. By noting Figure 8, a peak between 200-300 °C in demineralised MBM is presented. This could be attributed to the fact that pretreatment methods might cause affection to the chemical structure of the sample, as suggested by earlier research [11, 22].

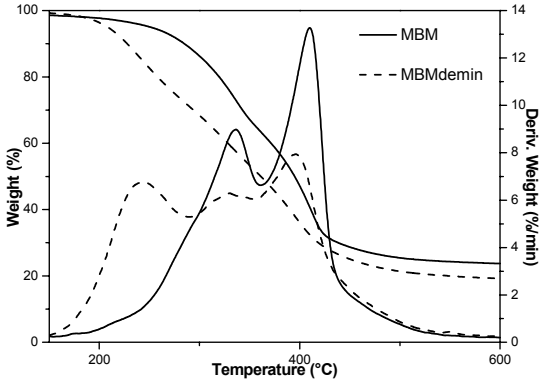

Figure 8: Comparative TG/DTG curves for the pyrolysis of MBM and demineralised MBM samples at 20°C/min.

Samples	CaO	Al_2O_3	Fe_2O_3	MgO	TiO_2	Na_2O	Mn_3O_4	K_2O	P_4O_6

Demol. wood	221	23	332	97.9
MBM	206	16.3	378	86.2

Table 4: Combustion characteristics of biomass samples and MBM.

Combustion of samples

The main combustion characteristic of biomass samples and MBM, i.e. the initial combustion temperature, maximum combustion rate and temperature at that rate along with the total conversion are presented in Table 4. Willow and olive kernel have the highest combustion rates at the lowest temperatures, reflecting their increased reactivity. Below 400°C, pyrolysis and combustion curves seem to follow the same behaviour with a shift of the later to lower temperatures [24], Figure 9. This behaviour indicates that mainly pyrolysis reactions take place and the presence of oxygen slightly affected the procedure actualized in the specific temperature region. The initial temperatures in all pyrolysis and combustion tests coincide. The second combustion peak represents the combustion of the generated char. Accessional attention should devote to the fact that the total conversion of MBM in pyrolysis differs in low percentage (about 6%) compared with the respective value of combustion. This fact can be explained of the low fixed carbon and high volatile content of MBM (Table 1).

Conclusions

All samples were proven good fuels, reflection of their high volatiles and low ash content. Olive kernel is most reactive among the samples. Increased heating rate results in slightly higher char yields, which are quite small. Pyrolysis is completed at approximately the same temperature region for all the heating rates. A linear increase of maximum pyrolysis rate and the corresponding temperature has been observed for all the samples. The independent parallel reactions model was employed to evaluate the kinetic parameters and was found quite effective. Three or occasionally four reactions were used to simulate the devolatilisation process. An increase of the heating rate results in increased A values, while fixed carbon content and lignin are proportionally correlated. The "compensation effect" was also examined and the isokinetic temperature was calculated at 387°C.

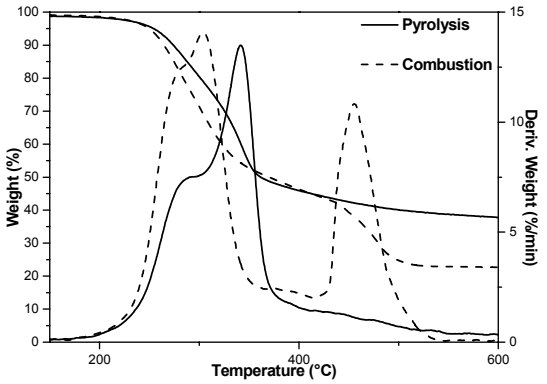

Figure 9: Comparison of pyrolysis and combustion of straw at the heating rate of 20°C/min.

MBM is the less reactive among the tested samples. Demineralization affects the pyrolysis of MBM by reducing the reaction rate and shifting the curve in lower temperatures. Demineralised MBM appears to have higher total conversion due to the reduced potassium content of the raw material. The second peak of DTG curve in the combustion test represents the incineration of the generated char. It is worth noting that the total conversion of MBM slightly differs compared to the pyrolysis char yield.

Thermo-ecological optimization of a solar collector

Jan SZARGUT* **and Wojciech STANEK**
Silesian University of Technology
Institute of Thermal Technology
44 100 Gliwice, Poland

ABSTRACT

The depletion of non-renewable natural exergy resources (the thermo-ecological cost) has been accepted as the objective function for thermo-ecological optimization. Its general formulation has been cited. The detailed form of the objective function has been formulated for a solar collector producing the hot water for home needs. Following design parameters have been accepted as the decision variables: the collector area per unit of the heat demand, the diameter of collector pipes, the distance of the pipe axes in the collector plate. The design parameters of the internal installation (the pipes, the hot water receiver) have not been taken into account, because they are very individual. The accumulation ability of hot water comprising one day has been assumed. The objective function contains following components: the thermo-ecological cost of copper plate, copper pipes, glass plate, steel box, thermal insulation, heat transfer liquid, electricity for driving the pump of liquid, fuel for the peak boiler. The duration curves of the flux of solar radiation and absorbed heat have been elaborated according to the meteorological data and used in the calculations. The objective function for economic optimization may have a similar form, only the cost values would be different.
Keywords: Exergy, Optimization, Non-renewable Resources, Solar Collector.

NOMENCLATURE

A — active area of the collector, m^2
b — distance between the axes of the pipes of the collector, m
c — specific thermal capacity, J/(kg K)
d — diameter of the pipes of the collector, m
$\dot{e}_r$ — energy flux of the solar radiation reaching the collector, W/m^2
E_{el} — consumption of electricity, J
G — amount of the material used to fabricate the collector, kg
K_{TE} — annual thermo-ecological cost of the useful heat, J
L — length of the pipes of the collector, m
m — coefficient characterizing the effect of the fin, m^{-1}
p — pressure, Pa
Q — amount of heat, J
Re — Reynolds number
T — temperature, K
u — coefficient of recovery of the material
U — coefficient of heat losses of the collector, $W/(m^2 K)$
$\dot{V}$ — volumetric flow rate of the liquid, m^3/s
$\dot{W}$ — driving power, W
w — flow velocity of the liquid, m/s
γ — density of the material, kg/m^3
δ — thickness of the wall, m
δp — pressure loss, Pa
ΔT_l — temperature increase of the intermediate liquid, K
ζ — correction expressing the fin effect
$\varepsilon_1, \varepsilon_2, \varepsilon_3$ — coefficient characterizing the energy efficiency of the collector, —, $W/(m^2 K)$, $W2/(m^4 K^2)$
η — energy efficiency
λ — coefficient of heat conduction, W/(m K)
λ_f — coefficient of hydraulic friction
ξ — coefficient characterizing the consumption of steel
ρ — specific thermo-ecological cost, J/kg, J/W, J/J_{el}
τ — time, s

φ — power of the absorbed heat stream, per area unit, W/m^2
χ — annual amount of the absorbed heat, J/a

Indices
A — annual demand
c — collector
Cu — copper
D — related to one day
el — electricity
f — fuel
g — glass
i — order number of the most hot day
is — thermal insulation
l — intermediate liquid
m — medium value
n — surplus over the demand
P — pump with driving electric motor
p — collector plate
s — steel
wh — peak water heater
0 — ambient value
Dot above the symbol denotes the quantity related to the time unit.

INTRODUCTION

In the field of ecological applications of exergy very important is the determination and reduction of the depletion of non-renewable natural resources. The quality of these resources may be expressed by means of exergy. The cumulative consumption of non-renewable exergy, connected with all the steps of fabrication of the considered useful product has been termed "the thermo-ecological cost" [1,2,3]. It is expressed not in monetary units, but in energy (exergy) units. An example of minimization of the thermo-ecological cost, by means of the selection of design parameters, has been presented in [4].
Sometimes an optimization of the design parameters based upon the minimization of entropy generation is recommended [5]. That method is not consequent, because it does not take into account the entropy generation in the preceding processes delivering energy carriers and semi-finished products to the considered process. On the other hand the entropy generation in the processes of extraction of the renewable exergy from the natural resources should not be taken into account, because the irreversibility of that processes has not any deleterious impact on the environment or on other fabrication processes.

The utilization of the solar energy represents a typical example of the extraction of renewable energy from the nature. Therefore, the optimization of the solar collector has been taken into account in the present paper.
The optimization problem of the solar collector has been considered, for example, in [6]. The authors apply the principle of minimization of entropy generation, including also the
irreversibility of the absorption of solar radiation. Additionally they do not take into account the changes of the energy flux of solar radiation and ambient temperature.

ASSUMPTIONS

A solar collector delivering hot water for the home use has been taken into account. It has been assumed that the annual demand for useful heat is known and the considered installation has the ability to accumulate the hot water in the scope of one day. The collector is filled with a non freezing liquid (glycol), which transports heat to the container of hot water installed inside the house. The circulation pump may be switched off when the temperature of the intermediate liquid is too low. The peak heat demand is covered by means of peak boiler fed with natural gas. The peak boiler ensures a required temperature of the hot water in the container. The collector is built of copper pipes connected in coil shape and welded to the copper plate on its bottom side [7]. The collector is covered with glass plate. The bottom wall and the side walls are made of steel and thermally insulated (Fig 1).

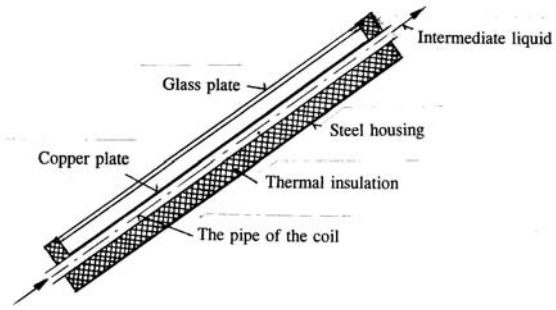

Figure 1. Scheme of the solar collector

Every optimization is partial, because it is no possible to take into account all the interactions with other processes. The considered optimization is also partial. It takes into account only the collector without the internal installation which is very individual. It has been assumed that at given heat demand the installed thermal power of the peak boiler is known because some days in winter can appear when the weather is very not friendly and the useful thermal power of the collector equals zero. On the other hand in summer very hot days can appear when the production ability of the collector is larger than the demand. The excess production should be deduced from the yearly production ability in order to determine the fuel demand in the peak boiler.

Two operation modes of the circulation pump may be applied. In the first case the flow rate of the liquid may be proportional to the heat stream absorbed in the collector. The rotation frequency of the pump should be changeable. Constant values of the liquid entering the collector and flowing out may be assumed. In the second case the flow rate of the liquid may be constant, adapted to the most warm days. The first mode of operation, accepted in the present considerations, ensures a lower consumption of electricity

Three decision variables have been accepted:

1) the active area of the collector per unit of the annual heat demand,

2) the diameter of the pipes of the collector,

3) the distance of he pipe axes of the collector.

It has been assumed that the thickness of the copper plate is determine by the required degree of its rigidity.

An optimal choice of the decision variable is possible, if the change of its value evokes opposite results. For example, an increase of the active area increases the consumption of materials, but decreases the demand of fuel in the peak boiler. The increase of diameter of pipes leads to an increase of the material consumption but decreases the flow resistance of the intermediate liquid. The increase of the distance between the axes of pipes reduces the total length of the pipes, but decreases the efficiency of the collector. The collector plate between the pipes transports the heat similarly to a fin. Its maximum temperature (in the middle between the pipes) becomes higher when the distance of pipes increases.

The total length of the pipe forming the coil results from the dependence:

$$L = \frac{A}{b} \tag{1}$$

The value of L decides about the necessary number of collectors for a given yearly heat demand.

OBJECTIVE FUNCTION

The yearly thermo-ecological cost of useful heat produced in the installation equipped in a solar collector may be expressed as follows:

$$\begin{aligned} K_{TE} = \frac{1}{\tau}\Big[& G_{\mathrm{Cu}}\,\rho_{\mathrm{Cu}}\,(1-u_{\mathrm{Cu}}) + G_g\,\rho_g + G_{is}\,\rho_{is} + \\ & G_s\,\rho_s\,(1-\mu_s) + G_l\rho_l + \dot{W}_{P\max}\rho_P + \dot{Q}_{wh\max}\rho_{wh}\Big] \\ & + \frac{\rho_{\mathrm{el}}}{\eta_{\mathrm{P}}}\int_0^{\tau_{\mathrm{P}}} \dot{V}_1 \delta p \,\mathrm{d}\tau + (Q_A - Q_c)\,\frac{\rho_{\mathrm{f}}}{\eta_{\mathrm{wh}}} \end{aligned} \tag{2}$$

The formula (2) contains two main components:

1) the investment component containing the thermo-ecological cost of the materials used for the construction of the collector and the thermo-ecological cost of the additional equipment (pump, peak boiler),

2) the operational components expressing the consumption of electricity in the circulation pump and the fuel consumption in the peak boiler.

The investment component takes into account the life time τ of the installation and the possibility to utilize copper and steel after the wear of the installation. The operational components take into account the yearly operation time τ_P of the pump, the annual demand Q_A for heat and the annual production Q_c of useful heat in the collector. The thermo-ecological cost of the peak boiler may be omitted in optimization calculations because that boiler should be able to cover the total demand for useful heat. Hence, the mentioned value is constant.

When calculating the annual production of heat in the collector, the possibility appears of some excess Q_n of the absorbed heat, which cannot be accumulated because of the assumed ability of accumulation only in the scope of one day. Hence the annual production of useful heat in the collector may be expressed as follows:

$$\begin{aligned} Q_c &= A\,\zeta \int_0^{\tau_P} \eta_c\,\dot{e}_r \,\mathrm{d}\tau - Q_n = A\,\zeta \int_0^{\tau_P} \varphi \,\mathrm{d}\tau - Q_n = \\ &= A\,\zeta\,\chi - Q_n \end{aligned} \tag{3}$$

where: η_c = energy efficiency of the collector

$\varphi = \eta_c \dot{e}_r$ = momentary thermal power per area unit of the collector

ζ (b) = correction expressing the effect of fin (efficiency of fin).

According to [8] the energy efficiency of the collector depends on its type, on the energy stream of the falling solar radiation, the mean temperature T_{lm} of the intermediate liquid and the ambient temperature:

$$\eta_c = \varepsilon_0 - \varepsilon_1 \frac{T_{lm} - T_0}{\dot{e}_r} - \varepsilon_2 \left(\frac{T_{lm} - T_0}{\dot{e}_r} \right)^2 \qquad (4)$$

Figure 2 presents after [8] the dependence (4) for some types of the collector. When the energy stream of falling solar radiation is too small, the energy efficiency has a value zero.

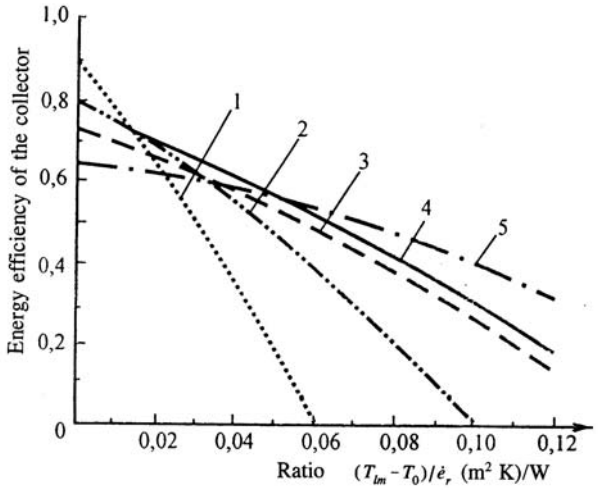

Figure 2: Energy efficiency of some types of the solar collector, after [8]

1— collector without any glass cover plate, 2 — absorber with single non-selective glass plate, 3 — absorber covered with double non-selective glass plate, 4 — absorber covered with single selective glass plate, 5 — vacuum absorber.

It has been assumed that Eq. (4) expresses the efficiency of the collector at fin efficiency near 100%. The pipes are welded to the bottom surface of the collector plate. Therefore, the correction taking into account the fin effect may be expressed more simply than in [9]:

$$\zeta = \frac{\text{tgh}\,(0{,}5\, m\, b)}{0{,}5\, m\, b} \qquad (5)$$

where:

$$m = \sqrt{\frac{U_L}{\lambda_p \delta_p}} \qquad (6)$$

where: U_L = coefficient of heat losses of the collector.

According to (4) one may introduce into (3):

$$\chi = \int_0^{\tau_P} \left[\varepsilon_0 \dot{e}_r - \varepsilon_1 (T_{lm} - T_0) - \varepsilon_2 \frac{(T_{lm} - T_0)^2}{\dot{e}_r} \right] \mathrm{d}\tau \qquad (7)$$

Only positive values of the integrated function should be taken into account. The components of that function are mutually dependent, because the ambient temperature depends on the intensity of falling solar radiation. However, that dependence is disturbed by the meteorological factors.

In order to determine the annual excess of absorbed heat, not accumulated in the system one should consider the most hot days and draw the duration curves of the absorbed heat during every of those days. Taking into account the planed heat demand per one day and the considered active area of the collector:

$$\begin{aligned} Q_n &= \sum_i Q_{ni} = \sum_i (A\zeta \int_0^{\tau_{Di}} \varphi_i \, d\tau - Q_D) = \\ &= \sum_i (A\zeta \chi_{Di} - Q_D);\ A\zeta \chi_{Di} > Q_D \end{aligned} \qquad (8)$$

where: i = order number of the hottest days

Q_D = heat demand per day

τ_{Di} = operation time of the collector in the i-th day.

The consumption of copper is expressed by following formula:

$$G_{Cu} = A \left(\frac{\pi d}{b} \delta + \delta_p \right) \gamma_{Cu} \qquad (9)$$

Similarly can be expressed other components of Eq. (2). After including also Eq. (8) the objective function takes the form:

$$K_{TE} = \frac{l}{\tau}\Big[A[(\pi \frac{d}{b}\delta + \delta_p)\gamma_{\mathrm{Cu}}\rho_{\mathrm{Cu}}(1-u_{\mathrm{Cu}}) \\ \delta_g\gamma_g\rho_g + \delta_{is}\gamma_{is}\rho_{is} + \delta_s\gamma_s(1+\xi_s)\rho_s(1-u_s) + \\ + \frac{\pi d^2}{4\,\mathrm{b}}\gamma_{\mathrm{l}}\rho_{\mathrm{l}}] + \dot{W}_{P\max}\rho_P \Big] + \\ + \frac{\rho_{\mathrm{el}}}{\eta_{\mathrm{P}}}\int_0^{\tau_P}\dot{V}_1\,\delta p\,\mathrm{d}\tau + (Q_A - A\chi\zeta + Q_n)\frac{\rho_{\mathrm{f}}}{\eta_{\mathrm{wh}}} \quad (10)$$

where ξ_s denotes the relative increase of steel consumption for side walls and supplementing parts of the collector.

The pressure loss of the intermediate liquid within the collector comprises the hydraulic resistance inside the pipes and local resistance at the inlet and outlet of the pipe. It has been assumed that the sum of local resistances equals to the dynamic pressure of the liquid:

$$\delta p = \frac{1}{2}\gamma_l w_l^2\left(\lambda_f\frac{L}{d}+1\right) = \frac{1}{2}\gamma_l w_l^2\left(\lambda_f\frac{A}{b\,d}+1\right) \quad (11)$$

Assuming:

$$\lambda_f = 0.046\,\mathrm{Re}^{-0.2} \quad (12)$$

one obtains the annual thermo-ecological cost of the consumed electricity:

$$E_{el}\rho_{el} = \frac{\rho_{el}}{\eta_P}\frac{8A^3}{\pi^2 d^4\gamma_l^2 c_l^3\Delta T_l^3}\times \\ \times\int_0^{\tau_P}\left(0.046\,\mathrm{Re}^{-0.2}\frac{A}{bd}+1\right)\varphi^3\,\mathrm{d}\tau \quad (13)$$

The Reynolds number is expressed as follows:

$$\mathrm{Re} = \frac{4\dot{V}_1\gamma_1}{\pi\, d\,\eta_l} = \frac{4\varphi A}{\pi\, dc_l\,\Delta T_1\eta_l} \quad (14)$$

The maximum driving power of the circulation pump results of (14) and maximum value $\varphi_{\max}$:

$$W_{P\max} = \frac{8A^3}{\pi^2 d^4\gamma_l^2 c_l^3\Delta T_l^3}\times \\ \times\left(0.046\,\mathrm{Re}_{\max}^{-0.2}\frac{\mathrm{A}}{bd}+1\right)\varphi_{\max}^3 \quad (15)$$

CALCULATIONS

In exemplary calculations it has been assumed that the collector is covered with single selective glass plate. Following data have been assumed :

The life time of the collector τ = 15 years

Thermo-ecological cost of the pump with driving motor ρ_P = 0.6 MJ/W

Electro-mechanical efficiency of the pump set η_P =0.7

Temperature of the intermediate liquid at the inlet and outlet of the collector T_{in} = 40 °C, T_{out} = 55 °C.

Specific thermal capacity of glycol c_l = 2.5 kJ/(kg K),

Exemplary yearly demand for useful heat Q_A = 2000 MJ/a,

Energy efficiency of the peak water heater η_{wh} = 0.8.

Coefficient of heat losses of the collector according to [9] U_L = 4.6 W/(m^2.K), coefficient of heat conductivity of copper λ_{Cu} = 372 W/(m K).

Coefficients of Eq. (4) characterizing the collector with a selective single glass plate, after Fig. 2:

$\varepsilon_0 = 0.8,\ \varepsilon_1 = 3.53\ W/(m^2K),\ \varepsilon_2 = 13.7\,W^2/(m^4K^2)$

From (5) and (6) it results m = 3.93 1/m.

Exemplary values of the correction ζ are cited in Table 1. The material parameters are given in Table 2.

RESULTS OF CALCULATIONS

Figure 3 presents the graphical interpretation of Eq. (7), according to the data taken from [10,11].

electricity	—	—	3.13 J/J$_{th}$	—
fuel	—	—	1.04 J/J$_{th}$	—

Table 2. Material parameters

Figure 4 shows the optimization results of the pipe diameter for various values of the active collector area and constant fin effect. The optimum diameter (9 mm) does not practically depend on the active area. The nearest diameter of the produced pipes is 10 mm and, therefore, that value has been accepted for furher calculations.

Fig. 5 presents the optimization of the distance of pipe axes and the active area at a optimum active area at optimum diameter of pipes. The determined optimum parameters of the collector at giver yearly heat demand are: A_{opt} = 7.5 m^2, d_{opt} = 10 mm, b_{opt} = 0.13 m.

CONCLUSIONS

1. The optimization of the solar collector requires large meteorological data, determining the yearly duration curve of the energy stream of the falling solar radiation and the duration curves of falling energy streams during the hottest days. The meteorological data are probabilistic but deterministic. Hence the considered problem belongs to the area of deterministic optimization with probabilistic information set.

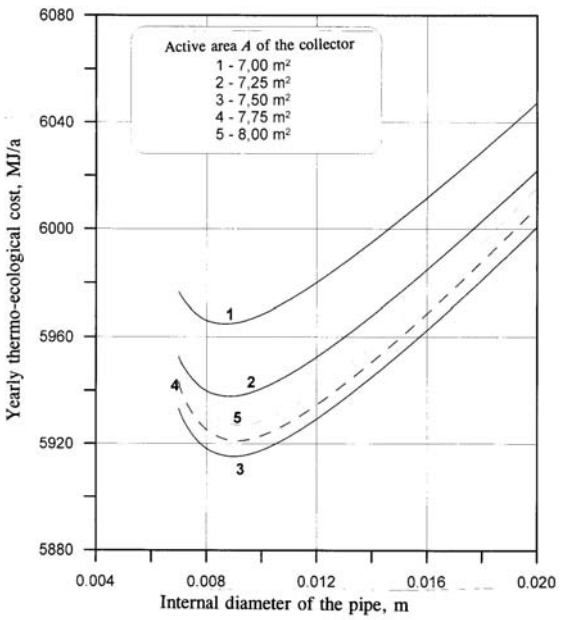

Figure 4: Optimization of pipe diameter at constant fin effect

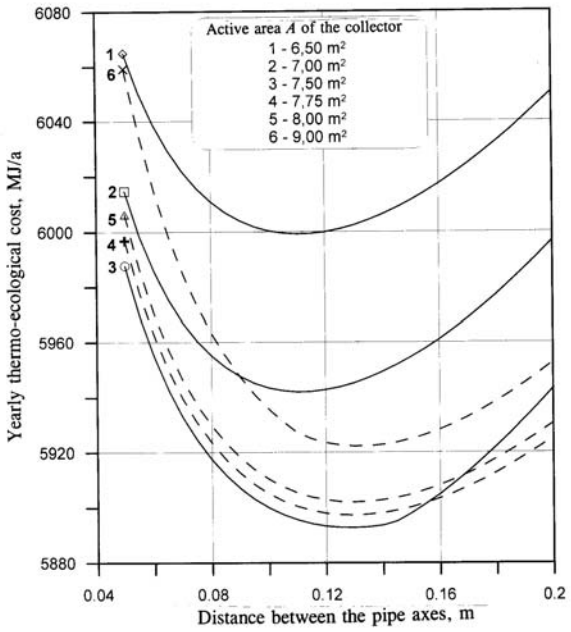

Figure 5: Optimization of the active area and distance between the pipe axes

2. The solution could be more exact when assuming an additional decision variable, namely the volume of the hot water receiver.

3. Exemplary calculations demonstrate that the optimum diameter of the collector pipe practically does not depend on the values of other decision variables.

4. The formulated objective function and the determined duration curves could be used also in an economic optimization after introducing the purchase prices instead of the values of the thermo-ecological cost.

ABSTRACT

In this study our aim is to reach high yields of bio-oil in a fixed bed tubular reactor at various pyrolysis temperatures, sweeping gas velocities, and heating rates. In these experiments, to improve heat and mass transfer, a stainless steel basket was used. Effects of different sweeping gas velocities, heating rates were examined on product yields.

Keywords: Fast Pyrolysis, Synthetic Fuels

INTRODUCTION

Fast pyrolysis of biomass is a moderate temperature process in which the feedstock is rapidly heated in the absence of oxygen [1]. While the conventional pyrolysis of wood and biomass is used essentially for making charcoal, fast pyrolysis can be controlled to give high yields of liquids (bio-oils), which can be readily stored and transported. Bio-oils can be used for the production of chemicals (food flavorings, resins, fertilizers and emission control agents) and can also substitute for fuel oils in many static applications for heat or electricity generation (boilers, furnaces, engines and turbines) [2]. For the development of effective combustion techniques, a detailed knowledge of the physico-chemical properties and the combustion characteristics are needed.

The main goal of fast pyrolysis is to convert the solid biomass into liquid bio-oil. In practice about 40-75% of the (dry) biomass is converted into oil vapour, which yields the liquid bio-oil after condensation. About 10-20% of the biomass is converted into char (solid porous carbon particles) and 10-30% is converted into an uncondensable gas.

The water content of the fuel usually is limited to about 15 wt-%. Present fast pyrolysis reactors are based on fluidized bed, entrained flow, ablative vortex, and rotating cone technology [3].

Fast pyrolysis requires high heating rates, moderate temperatures and short residence times for liquids. Feed drying, particle size, pretreatment, reactor configuration, heat supply, heat transfer, reaction temperature, vapor residence time, secondary cracking, char and ash separation and liquid collection are very important for the creative and innovative designs. These designs are based on high heat and mass transfer rates. Heat transfer in a pyrolysis reactor occurs firstly to the reactor heat transfer medium (solid reactor wall in ablative reactors, gas and solid in fluid and transport bed reactors, gas in entrained flow reactors), secondly, from the heat transfer medium to the pyrolysing biomass. Heat is transferred from hot gas to the pyrolysing biomass particle by primarily convection and solid-solid transfer with mostly conductive heat transfer. Some radiation occurs in all reactors [4].

Particle size, sweeping gas velocity, heating rates and reactor configuration are essential for mass transfer. Since thermal conductivity of biomass is very poor, biomass particles have to be very small to fulfill the

requirements of rapid heating to give high liquid yields. As particle size increases, liquid yields reduce as secondary reactions within the particle become increasingly significant. Char removal is an essential requirement for large particle sizes. It has a catalytic activity and cracks organic vapors to secondary char. High heating rates and high heat fluxes along the reactor is important. Long vapor residence times and high temperatures cause secondary cracking of primary products reducing yields of organic liquids [5].

In the present investigation, laboratory scale results are reported about the fast pyrolytic behaviour of olive residues. The main aim of our study is to get the biofuel from olive residues. Pyrolysis experiments were conducted at pyrolysis temperature of 400-700^{o}C. In the previous study, the effects of pyrolysis temperature and reaction times on pyrolysis product yields were observed [6]. The 2.5 cm diameter of the reactor caused insufficient heat and mass transfer for the low reaction times, although it had enough space to place higher amount of raw material. Therefore some of raw material was not reacted sufficiently. For this reason, in the second part of the experiments, a stainless steel mesh basket was used to get good contact between the material and reactor walls (Figure 1.). Pyrolysis experiments were performed for various pyrolysis temperatures with using the basket. Effects of various sweeping gas velocities and heating rates were also examined.

EXPERIMENTAL

The fast pyrolysis experiments were conducted under nitrogen atmosphere in a well-swept resistively fixed-bed reactor with a length of 90 cm and an inner diameter of 2.5 cm. Experimental set-up is given in Figure 2. Heating rate and pyrolysis temperature were controlled with a PID controller. The flow of the gas released was measured by using a soap film meter, for the duration of the experiments.

The experiments were carried out placing the olive residue among a deep basket (upside down) and reactor wall, like a thin layer. In the first part of the experiments, 10g of the air-dried sample, sieved to average particle size of 1.22 mm was placed in the reactor with a sweep gas velocity of 100 cm^3min^{-1} which was controlled and measured with a rotameter and then heated with a rate of 300 ^{0}C min^{-1} to the pyrolysis temperature range of either 400,500,550 and 700 ^{o}C within a reaction time of 5 min. Released gas was collected in a gas tight Tedlar bag. The liquid phase was collected in a cold trap maintained at about 0 ^{o}C. The liquid phase consisted of aqueous and oil phases, which were separated and weighed. Particularly water was separated in a Dean &Stark apparatus. After pyrolysis, char yield was determined from weight of remained carbon residue in the reactor after pyrolysis. The gas yield was then calculated by difference.

In the second part of the experiments, various sweeping gas flow rates (50, 200, 400, and 800 cm^3 min^{-1}) were performed at optimum pyrolysis temperature (500 ^{o}C) and constant heating rate (300 ^{o}C min^{-1}) and reaction time (5min.).

At the third part of the experiments, different heating rates (5,100,500 and 1000 ^{o}C min^{-1}) were studied at optimum pyrolysis temperature (500^{o}C) and sweeping gas flow rate (400 cm^3 min^{-1}) and reaction time (5min.).

In this study, all the yields are expressed on a dry, ash-free (d.a.f) basis and the average yields from at least three experiments. All of the experimental results (product yields) were calculated according to formulas given below:

$$\text{Yield (wt.\%)} = \frac{\text{Weight of obtained product}}{\text{Weight of raw material (d.a.f.)}} \times 100 \quad (2)$$

Conversion (%)= 100 %-Char yield (%)

d.a.f. represents dry and ash free.

RESULTS AND DISCUSSION

Raw Material

The sample of olive residue investigated in this study has been taken from an olive oil factory around Ayvalık located in Aegean region, western part of Turkey. The properties of raw material and proximate are given in Table 1.

Analysis	**Percentage (%)(As received)**
Moisture	8.83
Volatiles	68.75
Ash	5.12
Fixed carbon	17.30
Cellulose	66.96
Oil	5.46

Table 1. Proximate analysis and properties of olive oil residue

Product Yields

Pyrolysis experiments were conducted at pyrolysis temperature range of 400-700 ^{o}C within a constant reaction time of 5 minute. A stainless steel basket was designed to increase mass and heat transfer along the reactor walls and material. All the yields were expressed on a dry, ash-free basis and the average yields of at least three experimental errors of less then ±0.5%.

The yields of conversion were determined in relation to final temperature at 400, 500, 550 and 700 ^{o}C for the average particle size of taken 1.22 mm with a heating rate of 300 ^{o}Cmin^{-1} with sweeping gas velocity of 100 cm^{3}min^{-1}. As it is seen in Fig. 3., increasing pyrolysis temperature increases the pyrolysis conversion efficiency. Maximum oil yield was attained as 41.34% at the pyrolysis temperature of 500^{o}C. In previous study, maximum oil yield was attained at the pyrolysis temperature of 550^{o}C as 38.12% [6]. Usage of basket resulted with an increase of bio-oil 8.45%. Due to better mass and heat transfer, there is an increase of liquid yields. Experimental results are given in Fig. 3 and 4.

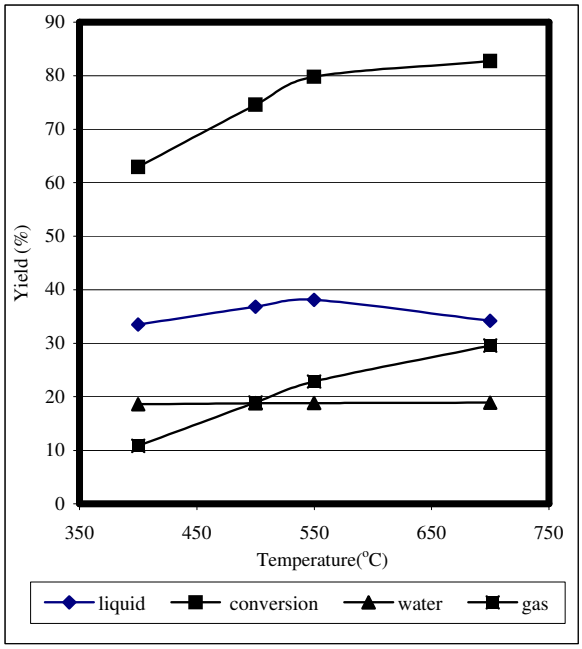

Figure 3: Pyrolysis yields of fast pyrolysis with out basket

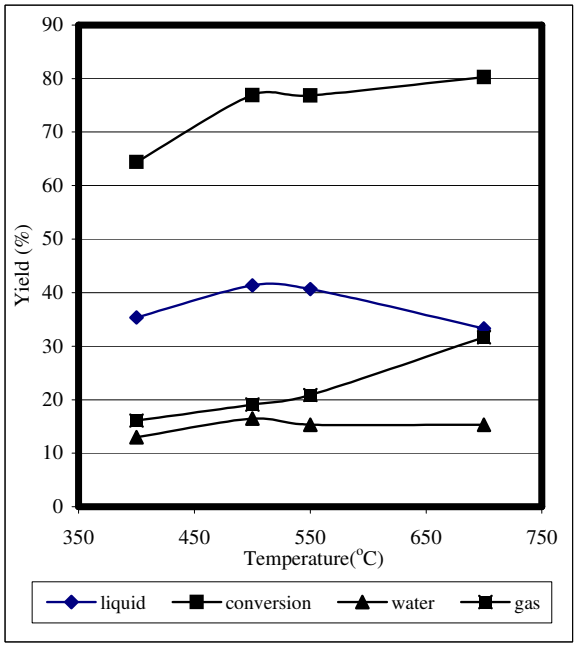

Figure 4: Pyrolysis yields of fast pyrolysis with using basket

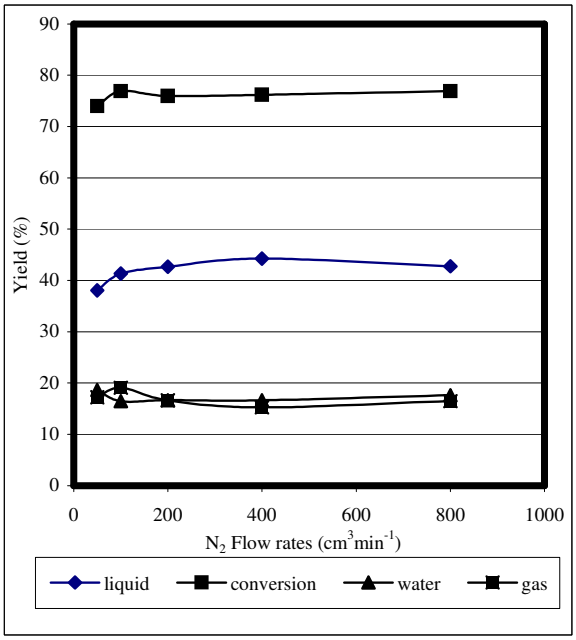

Figure 5. Effect of sweeping gas flow rates on pyrolysis yields

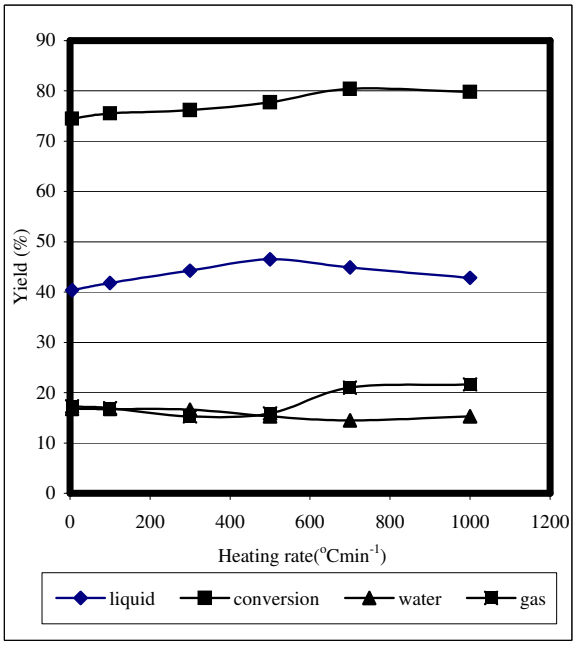

Figure 6: Effect of heating rates on pyrolysis yields

In the second set of experiments, various sweeping gas flow rates were investigated. Experimental results are given in Fig.5. According to the experimental results, 400 cm^3 min^{-1} is the most suitable flow rate to obtain maximum oil yields, due to shorten the residence times of volatiles and reduce forming secondary reactions. Liquid yields were increased from 41.34 to 44.27% (Fig. 5). As reported in the literature, the sweeping gas removed the products from the hot zone to minimize secondary reactions such as thermal cracking, repolymerization, and recondensation and to maximize the liquid yield [5]. Rapid quenching stops the chemical reactions before the valuble initial reaction products can be degraded [6]. Pyrolysis vapors are removed instantly by higher sweeping gas flow rates and if vapors are quenched sufficiently, the liquid yield has to be high. Because of sweeping gas effect, mass transfer rate is getting higher.

Experimental results of effect of heating rate are given in Fig. 6. Higher heating rates cause higher liquid yields. As it is seen, maximum oil yield was achieved as 46.52% with the heating rate of 500^oCmin^{-1}.

Comparing this study with our previous work, the main differences are in the reactor types, pyrolysis atmospheres and heating rates [7]. In the study mentioned, the maximum oil yield was found to be 32.72 % under static atmosphere, while the maximum oil yield attained was 38.98 % under nitrogen atmosphere at pyrolysis temperature of 500^oC with a sweeping gas flow rate of $200cm^3min^{-1}$ and heating rate of 7^oCmin^{-1}in Heinze retort. In that study, steam pyrolysis of olive residue in Heinze retort was also studied. The maximum oil yield was attained as 42.12% at the same pyrolysis temperature with a steam flow rate of 1.3 $cmsec^{-1}$. In this study, maximum oil yield was achieved as 46.52%. This result is better than previous results due to the reactor configuration, high heating rate and better mass and heat transfer [7].

CONCLUSION

Olive residue can be a promising candidate for the near future bio-fuel applications. Biomass decomposition rates and extents depend on the process parameters of reactor temperature, configuration, heating rate, sweeping gas velocity. Mass transfer limitations are very important for design and optimisation. In this study, for better heat and mass transfer from the reactor wall to biomass sample a stainless steel basket was used. Optimum parameters for getting maximum bio-oil in for our experimental condition were found. Maximum bio-oil was attained at pyrolysis temperature of 46.52%, with a heating rate of 500 ^oC min^{-1} and sweeping gas velocity of 400 cm^3min^{-1}. Heat and mass transfer conditions determine the selectivity of primary solid degradation reactions and thus the characteristics of pyrolysis. Therefore these affect pyrolysis yields.

ABSTRACT

Biomass and energy crops are the renewable energy sources, which is often believed to have the highest potential to contribute to a future sustainable energy supply to world's energy. Bioenergy is expected to become one of the best option energy sources to cope with global warming and exhaustion of fossil fuel resources. A wide range of process and routes are available for power generation. Pyrolysis is another emerging technology to convert solid wastes to char, gases and liquid fuels. In this study, our aim is to evaluate the pyrolytic behaviour of *Euphorbia rigida* known as a plant abundantly grown in arid lands by comparing the results of the previous studies at different pyrolysis conditions.

Key words: Euphorbia rigida, energy crops, bio-fuels

INTRODUCTION

Thermochemical conversion of organic residues constitutes an important way to recover energy and prepare chemicals and activated carbon. Turkey has a great potential of agricultural and forest residues. Two third of renewable energy use is provided by biomass. When thinking that more than 26 millions of people living in urban areas in Turkey, biomass energy is very important for heating and cooking [1].

The main advantages of using biomass are that it has negligible sulfur, nitrogen, and metal content and is also CO_2 neutral. Combustion is the most common way to employ biomass sources in Turkey. There are different ways to obtain heat and electricity from biomass such as liquefaction, gasification, and pyrolysis. Due to the easy application, Pyrolysis is a recommended process to convert biomass into heat, bio-oil and fine chemicals [1,2].

There is a number of biomass species can be considered as an alternative energy resource. The economics of biomass pyrolysis are generally considered to be most favorable for plant that grow abundantly and require little cultivation in arid lands. One group of plants is Euphorbiaceae, which are characterized by their ability to produce a milky latex, an emulsion of 30wt% terpenoids in water. *Euphorbia rigida* (Euphorbiaceae family) is found around the Mediterranean from Morocco through Portugal to Turkey and Iran. It is known that 80 species of Euphorbia are found in Turkey. Some species of this family have been investigated and identified as promising candidates for renewable fuels and chemical feedstocks by some researchers [3,4,5]. Also, there have been found some studies to obtain liquid products could be replaced petroleum, from *Euphorbia rigida*. Pütün et al. investigated the production of bio-fuel by pyrolysis of *Euphorbia rigida* for the first time. Further, various types of pyrolytic reactors and catalysts examined on pyrolysis of *Euphorbia rigida* by the other workers of our team. The main objective of the present study is to evaluate the aspects of Euphorbia rigida as a potential energy source, including major properties,

pyrolytic behaviours and efficiencies of different types of pyrolytic reactors to obtain bio-fuels. For this reason the results of our previous studies were put together and compared with each other for a review study.

Proximate Analysis:

Proximate analysis was performed on the *Euphorbia rigida* sample to determine the weight fraction of volatile, ash, and fixed carbon contents. The ASTM Standart Test Method For Proximate analysis of Wood Fuels (D 870-82) was used. Then, the fixed carbon content was obtained by substracting from 100% the sum of volatile matter and ash contents in percentage.
The ultimate analysis was performed in a elementel analyzer (Carlo Erba, EA 1108). The heating values are very important thermal properties for design and evaluation of thermal conversion systems. The gross calorific values of biomass samples and bio-oils are calculated by Dulong Formula:

$$Q_{GCV}\,(MJ/kg)=33.83C+144.3(H-O/8) \quad (1)$$

Where C, H, O are respectively, the mass fraction of carbon, hydrogen, and oxygen.

Experimental Discussion:

Our previous pyrolysis experiments were performed at various pyrolysis temperatures, heating rates, with different types of atmospheres and reactors. Details of the experimental set-up were given in related papers. The general experimental procedure is given in Figure 1. In this study, due to discuss the effect of reactor configuration, experimental results of slow pyrolysis in tubular and Heinze reactors are given in Table 2 [4,5].

After that, experimental result of catalytic pyrolysis is also compared [3]. Optimum experimental results of these catalytic and non-catalytic works are discussed. These optimum results are selected for this study those obtained in maximum bio-oil yields. For slow pyrolysis in a tubular reactor, maximum oil yield was achieved at the pyrolysis temperature of 500 ^{o}C, with sweeping gas velocity of 400 cm^3 min^{-1} and heating rate of 7 ^{o}C min^{-1}. Optimum results of slow pyrolysis experiments in Heinze retort were obtained at pyrolysis temperature of 550 ^{o}C and heating rate of 7 ^{o}C min^{-1}. In catalytic study, under the same experimental conditions, Maximum oil yield was obtained with Criterion-534 (20% weight of raw material) as catalyst under static atmosphere.
After all, results of fast pyrolysis experiments performed at various pyrolysis temperatures, heating rates, and pyrolysis atmospheres such as nitrogen and pressurized hydrogen are given in Table 4. In fast pyrolysis experiments, optimum results were performed at pyrolysis temperature of 550 ^{o}C, with a sweeping gas velocity 100 $cm^3min^{-1}$of and heating rate of 300 ^{o}Cmin^{-1}[6]. In hydropyrolysis, maximum oil yield was reached at pyrolysis temperature of 550 ^{o}C, hydrogen gas velocity of 10Lmin^{-1}, 150 bar hydrogen pressure and heating rate of 300 ^{o}C min^{-1}[5]. All of the experimental results (product yields) were calculated according to formula:

$$\text{Yield (wt.\%)} = \frac{\text{Weight of obtained bio-oil}}{\text{Weight of raw material (d.a.f.)}} \times 100 \quad (2)$$

d.a.f. represents dry and ash free.

An important characteristic of the pyrolysis is residence time. Residence time of vapours mainly depend on reactor geometry and sweeping gas flow rate.

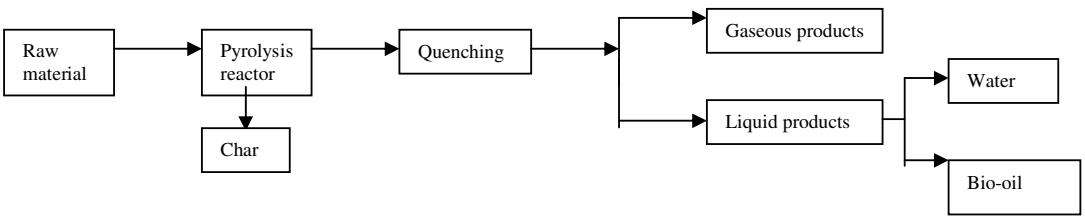

Figure 1. Pyrolysis procedure

Result of proximate analysis of Euphorbia rigida collected from Southwestern Anatolia is given in Table 1. Prior to the experiments the sample was dried and ground in a high speed rotary cutting mill 0,55mm. is found mean particle. Our sample has 3.0% moisture content.

Analysis	**Percentage (As received)**
Moisture	3.0
Volatiles	78.9
Ash	6.5
Fixed carbon	11.6

Table 1. Results of proximate analysis [3]

Elementel analysis of raw material is given in Table 2. H/C ratio of Euphorbia Rigida was found as 1.43. There was no sulphur content in this material.

Component	**(%)**
C	49.08
H	5.86
N	1.23
O*	43.83
H/C	1.43
O/C	0.67

Table 2. Results of elementel analysis [3]

In this study, our aim is to indicate maximum bio-oil yields. Optimum experimental results of Heinze retort, both catalytic and non catalytic works are given in Table 3. Whereas maximum oil yield was 31.46% for tubular reactor, Bio-oil yield was found 22.69% for Heinze retort. Selection of reactor geometry design is very important to reach desired product yields. Catalytic pyrolysis is very beneficial for product selectivity. There is a significant effect of catalyst (Criterion-534) was seen. Because of reactor geometry and sweeping gas, tubular reactor gives the highest biofuel yields among the experimental results given in Table 3.

	Slow Pyrolysis in tubular reactor [5]	**Slow Pyrolysis in Heinze reactor [4]**	**Catalytic Pyrolysis in Heinze reactor [3]**
Bio-oil(%)	31.46	22.69	30.98
Char (%)	27.98	20.40	21.38
Water(%)	16.94	24.13	26.79
Gas (%)	23.62	32.78	20.85

Table 3. Product yields of slow pyrolysis experiments

In Table 4, Experimental results of tubular reactor both nitrogen and pressurized hydrogen atmospheres are given with high heating rates. As it is expected, maximum oil yields were achieved by hydropyrolysis. Direct hydrogenation causes an increase of liquid fraction. There was a sharp decrease of char yield. Conversions of liquid and gaseous products were increased compared with fast pyrolysis results.

	Fast Pyrolysis [6]	**Hydropyrolysis [4]**
Bio-oil (%)	32.78	41.10
Char (%)	27.63	9.40
Water (%)	13.26	12.70

	C	**H**	**N**	**O**	**H/C**
Bio-oil [1]	75.50	11.10	2.80	10.60	1.76
Bio-oil [2]	74.14	9.31	2.20	14.40	1.48
Bio-oil [3]	66.24	8.95	2.10	22.71	1.62
Bio-oil [4]	68.81	8.74	1.85	20.60	1.52
Bio-oil [5]	77.30	11.70	1.80	9.20	1.82

Table 5. Elementel analysis of bio-oils

Bio-oil [1]: obtained from slow pyrolysis in a tubular reactor [5]
Bio-oil [2]: obtained from slow pyrolysis in a Heinze reactor [4]
Bio-oil [3]: obtained from catalytic pyrolysis in a Heinze reactor [3]
Bio-oil [4]: obtained from fast pyrolysis [6]
Bio-oil [5]: obtained from hydropyrolysis [4]

In Table 5, Elementel analyses of obtained bio-oils under different experimental conditions were given in Table 5. The greatest H/C was reached from bio-oil[5] obtained by Hydropyrolysis. It was found

1.82. The minimum H/C value was 1.48 from the bio-oil obtained by slow pyrolysis in Heinze retort. The heating values are very important thermal properties for the design and evaluation of thermochemical conversion systems. Gross heating values of raw material and bio-oils were calculated by Dulong formula and given in Table 6. Pyrolysis causes a double fold of heating value of raw material by converting it into liquid. Average calorific value of bituminous coal is 30 MJ/kg. While the biomass sample presents energy content nearly half of the energy content of coal. Due to abundance and content of milky latex, Euphorbia is an important energy source with the maximum calorific values of the obtained bio-oils

Material	**Gross Calorific Value (MJ/kg)**
Euphorbia Rigida	17.15
Bio-oil [1]	39.65
Bio-oil [2]	37.70
Bio-oil [3]	31.23
Bio-oil [4]	32.17
Bio-oil [5]	41.00

Table 6. Calorific values of raw material obtained bio-oils

Bio-oil [1]: obtained from slow pyrolysis in a tubular reactor
Bio-oil [2]: obtained from slow pyrolysis in a Heinze reactor
Bio-oil [3]: obtained from catalyticpyrolysis in a Heinze reactor
Bio-oil [4]: obtained from fast pyrolysis
Bio-oil [5]: obtained from hydropyrolysis

CONCLUSION

- Euphorbia Rigida can be a good candidate to produce biofuels. Because of ability to produce milky latex which is an emulsion of 30 wt.% terpenoids in water. Euphorbia species have a high potential to produce hydrocarbons by thermochemical methods. Obtained bio-oils have high energy content compared with raw material.
- After considering the experimental results hydropyrolysis seems to be the most advantageous method because of giving the maximum oil yields. Although it is a difficult and expensive process due to depending on hydrogen atmospheres with high pressures.
- While discussing the reactor geometry, selection of tubular reactor instead of Heinze retort has an advantage to reach maximum oil-yields.
- Catalytic pyrolysis in Heinze retort causes a 36.5 % increase of bio-oil yield compare with non-catalytic pyrolysis under static atmosphere. Economic feasibility depends on selection of catalyst and process.
- Selection of tubular reactor instead of Heinze retort has an advantage to reach maximum oil yields, by providing the fast pyrolysis processes, Heinze retort is more beneficial for slow pyrolysis applications. On the contrary, Fast pyrolysis is more important to reach maximum bio-oil yields in few seconds. Nevertheless cost of fast pyrolysis process is more than slow pyrolysis. Reaching higher heating rates and mass transfer rates may be feasible for optimum process parameters and reactor designs.

ENERGY ANALYSIS OF TECHNOLOGICAL SYSTEMS OF COMBINED HEAT AND POWER PLANTS INTEGRATED WITH BIOMASS GASIFICATION

Bolesław Zaporowski *
Poznan University of Technology, Poznan, Poland

ABSTRACT

This paper presents a complex energy analysis of technological systems of gas and gas-steam combined heat and power (CHP) plants integrated with biomass gasification. The analysis is based on elaborated mathematical models of main elements of the technological systems of these CHP plants. The mathematical model of biomass gasification includes a system of equations, which describes chemical, physical and energy phenomena occurring in gas generator. The solution of mathematical model of gasification process allows one to determine the following quantities: the composition and lower heating value of produced gas, the gasifying agent consumption and excess ratio, the volume of gas obtained from 1 kg of biomass, and the chemical and energy efficiency of the process. In equations which describe energy processes in gas generator, heat recovery steam generator (HRSG) and gas turbine block, the physical enthalpies of the produced gas, the gasifying agent, the oxidizer (air) and the combustion gases are determined with the help of statistical physics. The paper presents the results of a computer simulation of gasification of biomass with the help of various kinds of gasifying agent and the results of simulation of the energy utilization factor, efficiency of electric energy generation and power to heat ratio for the following technological systems of gas and gas-steam CHP plants integrated with biomass gasification: gas CHP plant using simple gas turbine cycle, gas CHP plants using steam injected gas turbine (STIG) cycle, and gas-steam CHP plant using gas turbine and extraction-condensing steam turbine.
Key words: biomass gasification, gas turbine, combined heat and power (CHP) plant

NOMENCLATURE

a, b, c, d	numerical coefficients determining mass fractions of biomass, gasifying agent, steam and slag related to 1 kg of gaseous fuel
e, f, g, h	numerical coefficients determining mass fractions of gaseous fuel, oxidizer (air), nitrogen and water steam, related to 1 kg of combustion gases
B	CHP plant biomass consumption [kg/s]
M_i	molar mass of particular components of combustion gases, gaseous fuel, gasifying agent and oxidizer [kg/kmol]
n	number of components of the gasifying agent (air or oxygen)
p_{cgi}, p_{gi}, p_{gai},p_{oxi}	partial pressures of particular components of the combustion gases, gaseous fuel, gasifying agent and oxidizer
P_{elgt} , P_{elst}	electric power of the gas and steam turbine generator respectively [kW]
P_{ox}	electric power consumption of gasifying agent compressor [kW]
q_{H2O}	steam consumption per 1 kg of biomass
Q_h^g	lower heating value of gaseous fuel [kJ/Nm^3]
Q_h^b	lower heating value of biomass [kJ/kg]

* Boleslaw Zaporowski, Phone : +48 61 6652525 Fax: +48 61 6652280 E-mail: bzap@sol.put.poznan.pl

Q_c	thermal power of gas or gas-steam CHP plant produced in cogeneration [kW]
Q_{gi}	molar heating value of particular components of gaseous fuel [kJ/kmol]
$T_{cg,} T_g,$ $T_{ga,} T_{ox}$	temperature of combustion gases, gaseous fuel, gasifying agent, and oxidizer (air) [K]
T_o	reference temperature (288,15 [K])
v_g	volume of gaseous fuel obtained from 1 kg of biomass [Nm^3/kg]
v_{ga}	gasifying agent consumption per 1 kg of biomass [Nm^3/kg]
$\Delta h_{b(T_0)}$	chemical enthalpy of biomass at the reference temperature To [kJ/kg]
$\Delta h_{H_2O(T_0)}$	chemical enthalpy of water (or steam) at the reference temperature To [kJ/kg]
$\Delta H_{gi(T_0)}$	molar chemical enthalpy of particular components of gaseous fuel at the reference temperature To [kJ/kmol]
$\Delta H_{(T_0,T_g)},$ $\Delta H_{(T_0,Tga)}$	increments of molar physical enthalpy of gaseous fuel and gasifying agent related to the temperature T_0 [kJ/kmol]
$\Delta h_{A(T_0,T_g)}$	
$\Delta h_{(T_0,T_{N_2})}$	
$\Delta h_{(T_0,T_{H_2O})}$	increment of physical enthalpy of ash, nitrogen and water (or steam) related to the temperature T_0 [kJ/kg]
$\Delta H_{i(T_0,T_{cg})},$ $\Delta H_{i(T_0,T_g)},$ $\Delta H_{i(T_0,Tga)},$ $\Delta H_{i(T_0,T_{0X})}$	increments of molar physical enthalpy of particular components of combustion gases, gaseous fuel, gasifying agent and oxidizer (air) related to the temperature T_0 [kJ/kmol]
ΔQ	heat losses to the environment [kW/s]
η_{ch}	chemical efficiency of biomass gasification process
η_T	energy efficiency of biomass gasification process

INTRODUCTION

There exists a problem of the choice of energy technology from the point of view of the effective utilization of biomass chemical energy, and in terms of its impact on environment [1-12]. An energy effective and environmentally friendly technology may involve the use of biomass for cogeneration of electric energy and heat in gas combined heat and power (CHP) plants integrated with biomass gasification. In CHP plants integrated with biomass gasification there are two new elements as compared with conventional (steam) CHP plants: the application of biomass gasification instead of biomass combustion and the application of gas cycle instead of steam cycle. The technology applied in gas CHP plants integrated with biomass gasification is advantageous from the point of view of energy effectiveness and ecology.

The paper presents the analysis of four technological systems of CHP plants integrated with biomass gasification: a) gas CHP plant using simple gas turbine cycle (Fig. 1), b) two gas CHP plants using steam injected gas turbine (STIG) cycle (Fig. 2 and 3), and c) gas-steam CHP plant (Fig. 4).

The main scientific innovations of the paper are elaborated models of gas generator and of the other energy facilities of CHP plants integrated with biomass gasification with the use of statistical physics and carry out on this basis the simulation investigations of energy effectiveness of the systems of gas and gas-steam CHP plants.

MODELLING OF THE BIOMASS GASIFICATION POCESS

The mathematical model of the process of complete biomass gasification was elaborated perform multivariant calculations of energy aspects of this process with changeable parameters such as: the temperature and pressure of the process, and the kind, the excess ratio and the temperature of gasifying agent. This model allows for numerical simulation of various methods of complete, pressure gasification of various kinds of biomass, with the help of various gasifying agents.

The number of equations of the model depends on the assumed number of components of gas. The kind and the number of gas components were determined on the basis of the analysis of chemical reactions proceeding in gas generator. As a result of carried out investigations it was assumed that in

produced gas the following components were present: CH_4, NH_3, CO_2, H_2O, N_2O, NO_2, SO_2, COS, H_2S, HCN, CS_2, CO, CN, OH, NO, CS, SO, C_2, H_2, O_2, N_2, S_2, C, H, O, N, S and Ar, which means 28 components, composed of 6 elements. It was, therefore, necessary to formulate a mathematical model in the form of the system composed of 28 non-linear algebraic equations:

- 22 equations, which describe chemical reactions proceeding in gas generator,
- 5 equations of the balance of elements,
- 1 equation of the balance of partial pressures of the components of gas.

The additional 29th equation which complements the system of equations, is the equation of the balance of energy of gas generator. This equation, related to 1kg of gas, is formulated in the following form:

$$\frac{1}{\sum_{i=1}^{i=28} M_i p_{gi}} \sum_{i=1}^{i=28} p_{gi}\left(\Delta H_{i(T_0,T_g)} + \Delta H_{gi(T_0)}\right) - a\Delta h_{b(T_0)} - b\frac{1}{\sum_{i=1}^{i=n} M_i p_{gai}} \sum_{i=1}^{i=n} p_{gai}\Delta H_{i(T_o,T_{ga})} - c\left(\Delta h_{(T_0,T_{H_2O})} + \Delta h_{H_2O(T_0)}\right) + d\Delta h_{A(T_0,T_g)} + \Delta Q = 0 \quad (1)$$

The biomass gasification process may be characterized by chemical efficiency and energy efficiency of the process. The chemical efficiency of biomass gasification process is defined as the ratio of chemical energy of gaseous fuel produced in the process of gasification to chemical energy of gasified biomass. It can be determined with the help of the formula:

$$\eta_{ch} = \frac{v_g Q_h^g}{Q_h^b} \quad (2)$$

Energy efficiency of biomass gasification was defined with the help of the formula:

$$\eta_T = \frac{v_g\left(Q_h^g + \frac{1}{22{,}4136}\Delta H_{(T_0,T_g)}\right)}{Q_h^b} - \frac{v_{ga}\frac{1}{22{,}4136}\Delta H_{(T_0,T_{ga})} + q_{H_2O}\Delta h_{(T_0,T_{H_2O})}}{Q_h^b} \quad (3)$$

Gaseous fuel produced in the process of biomass gasification is cooled to the temperature required by the cleaning process. Two technologies of gaseous fuel cleaning were considered – cold gas cleanup (383K) and hot gas cleanup (811K).

ENERGY ANALYSIS OF TECHNOLOGICAL SYSTEMS OF CHP PLANTS

For the evaluation of energy effectiveness of analyzed technological systems of gas CHP plant integrated with biomass gasification there were determined: energy efficiency (energy utilization factor), efficiency of electric energy generation and cogeneration index (power to heat ratio). These quantities were determined with the help of the following relations:

- energy efficiency of gas CHP plant:

$$\eta_e = \frac{P_{elgt} + Q_c - \Delta P_{OX}}{B * Q_h^b} \quad (4)$$

- energy efficiency of gas-steam CHP plant:

$$\eta_e = \frac{P_{elgt} + P_{elst} + Q_c - \Delta P_{OX}}{B * Q_h^b} \quad (5)$$

- efficiency of electric energy generation in gas CHP plant:

$$\eta_{el} = \frac{P_{elgt} - \Delta P_{OX}}{B * Q_h^b} \quad (6)$$

- efficiency of electric energy generation in gas-steam CHP plant:

$$\eta_{el} = \frac{P_{elgt} + P_{est} - \Delta P_{OX}}{B * Q_h^b} \quad (7)$$

- cogeneration index of gas CHP plant

$$\sigma_c = \frac{P_{elgt}}{Q_c} \quad (8)$$

- cogeneration index of gas-steam CHP plant

$$\sigma_c = \frac{P_{elgt} + P_{elst}}{Q_c} \quad (9)$$

For calculations of these quantities it was very important to formulate the equation of energy balance of combustion chamber of gas turbine,

related to 1 kg of combustion gases, in the following form:

$$\frac{1}{\sum_{i=1}^{i=6} M_i p_{cgi}} \sum_{i=1}^{i=6} p_{cgi} \Delta H_{i(T_O, T_{cg})} - e \frac{1}{\sum_{i=1}^{i=28} M_i p_{gi}} \sum_{i=1}^{i=28} p_{gi} \left(Q_{gi} + \Delta H_{i(T_O, T_g)} \right) - f \frac{1}{\sum_{i=1}^{i=3} M_i p_{oxi}} \sum_{i=1}^{i=3} p_{oxi} \Delta H_{i(T_O, T_{ox})} - g \Delta h_{(T_O, T_{N_2})} + h \Delta h_{(T_O, T_{H_2O})} + \Delta Q = 0 \quad (10)$$

The formulas describing temperature functions of increments of molar physical enthalpy of particular components of combustion gases $\Delta H_{i(T_0, Tcg)}$, gaseous fuel $\Delta H_{i(T_0, T_g)}$, gasifying agent $\Delta H_{i(T_0, Tga)}$, and oxidizer $\Delta H_{i(T_0, Tox)}$ and equilibrium constants of the particular chemical reactions proceeding in gas generator have been determined with the help of the sums of states of particular components of gaseous fuel and of gasifying agent [12].

SIMULATION OF BIOMASS GASIFICATION

The simulation of biomass gasification process has been conducted for six variants (methods of biomass gasification), where the changing parameters were the temperature of gasification process and the kind of gasifying agent. The following composition of biomass: C=46.5%,

Number of biomass gasification method		1	2	3	4	5	6
Gasification pressure [MPa]		1.8	1.8	1.8	1.8	1.8	1.8
Gasification temperature [K]		1100	1100	1100	1100	1200	1000
Gasifying agent		air	air+ H_2O	oxygen	air heated to 1000 K	air	air
Gasifying agent excess ratio		0.3300	0.3417	0.2678	0.2923	0.3805	0.2286
Gasifying agent temperature [K]		695	695	695	1000	695	695
Gasifying agent consumption per 1 kg of biomass [Nm^3/kg]		1.4441	1.4953	0.2455	1.2791	1.6651	1.004
Volume of gas obtained from 1 kg of biomass [Nm^3/kg]		2.6328	3.0839	1.3751	2.4726	2.8920	2.0053
Main components of produced gas [%]	CO	22.73	16.16	40.51	24.71	22.34	21.47
	H2	16.56	19.08	25.62	17.46	16.11	11.65

Table 1. The results of simulation of biomass gasification process

H=5.70%, S=0.03%, O=40.2%, N=0.19%, W=6.0% and A=0.38% was assumed in calculations. The following quantities were calculated: the composition of gas, the gasifying agent excess ratio, the gasifying agent consumption per 1 kg of biomass, the volume of gas obtained from 1 kg of biomass, the lower heating value of produced gas, the and chemical and energy efficiency of the gasification process. The results of carried out simulation of the biomass gasification process are presented in Table 1.

SIMULATION OF ENERGY EFFECTIVENESS OF CHP PLANTS INTEGRATED WITH BIOMASS GASIFICATION

Basing on the elaborated mathematical models of energy conversion processes, which take place in particular elements of the technological systems of gas CHP plant integrated with biomass gasification, and on the computer program developed on the basis of it a multivariant simulation for four elaborated technological systems of gas and gas-steam CHP plants (Fig. 1 to 4) was made. In particular variants of the simulation, cold (383 K) and hot (811 K) methods of gas cleaning were assumed. All the variants of simulation calculations were carried out for the same gas turbine with the following parameters: inlet gas temperature T_{cg1} = 1333 K, outlet gas temperature T_{cg2}=763 K The results of the simulation of energy processes in gas and gas - steam CHP plants integrated with biomass gasification are shown in Table 2 and 3.

Table 3. The results of energy calculations of technological systems of gas and gas-steam CHP plants integrated with biomass gasification for hot gas cleaning method

CONCLUSIONS

The results of the simulations allow one to formulate the following conclusions:

- The kind of gasifying agent has a significant impact on the chemical efficiency of the biomass gasification process and on the lower heating value of the produced gas. Water steam added to gas generator decreases the energy efficiency.
- The kind of gaseous fuel cleaning technology has a significant impact on the efficiency of electric energy generation. The replacement of the cold gas cleaning method with the hot gas
- Cleaning method allows the efficiency of electric energy generation to increase by around 3% in simple gas turbine cycle (Figure 1), and by around 5% in STIG cycle (Figure 3).
- Interesting simulation results were obtained for the technological system using steam injection to combustion chamber of gas turbine (STIG cycle). When the content of water steam in combustion gases is 20% (in this cycle), the efficiency of electric energy generation increases to 37.46% for cold gas cleaning method, and to 42.24% for hot gas cleaning method. However, the energy efficiency of the CHP plant decreases to 64.63% and 59.44%, respectively (Table 2).
- Among the investigated technological systems of CHP plants integrated with biomass gasification, the highest electric energy generation efficiency and a high energy efficiency is being obtained in technological systems of gas steam CHP plants (Figure 4). However, on the small scale this system has the highest investment cost.

ABSTRACT

A numerical study is carried out for a thermodynamic cycle — solar energy powered Rankine cycle using supercritical carbon dioxide as the working fluid for combine power and heat production. The system consists of a solar heating system, a power generating turbine, a heat recovery system, and a feed pump. A model has been developed to predict the cycle performance. The experimental data is used to verify the numerical formulation. The effects of the governing parameters on the performance are investigated numerically. The results show that the Rankine cycle has a reasonable power generation efficiency of somewhat above 20.0% and heat recovery efficiency of 68.0%, respectively. It is seen that the cycle performance is strongly dependent on the governing parameters and they can be optimized to provide maximum power, maximum heat recovery or a combination of both. The power generation and heat recovery are found to be increased with solar collector area. The power generation is also increased with water temperature of the heat recovery system, but decreased with heat exchanging area of the heat recovery system. It is also seen that the effect of the water flow rate in the heat recovery system on the cycle performance can be negligible.

Key words: Rankine Cycle, Solar Energy, Super-critical Carbon Dioxide, Power Generation, Heat Production

INTRODUCTION

Exhausting the fossil fuel leads to serious energy crisis we are about to face. Solar energy is a kind of inexhaustible energy supply. The application of solar energy to power/heat or power/refrigeration thermodynamic cycles has a potential to make solar energy competitive with fossil fuels [1−3]. Based on Kyoto Protocol, collective emissions of greenhouse gases (the period of 2008~2012) will be reduced by 5.2% compared to the year 1990. The interests in CO_2 as a working fluid increased considerably from 1990s [4, 5]. In this paper, we numerically investigate a thermodynamic cycle [6], in which both solar energy and CO_2 are used to form a Rankine cycle of power generation and heat production. Figure 1 shows a schematic diagram of the CO_2-based thermodynamic cycle.

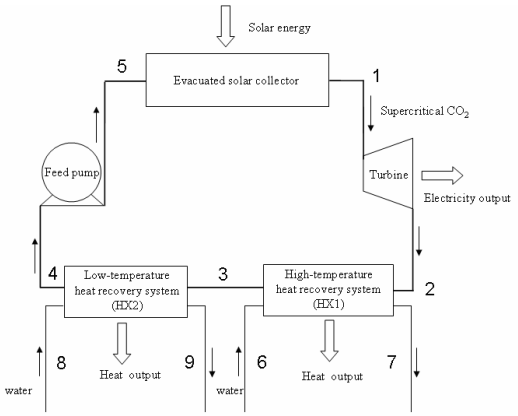

Fig. 1. A CO_2-based solar Rankine cycle for power generation and heat recovery

THEORETICAL ANALYSIS

As the first step of a basic estimation and understanding of the performance of the Rankine cycle, in this paper, a thermodynamic analysis considering a steady state is presented. It is supposed that an all-glass evacuated solar collector with a U-tube heat removal system is used in the Rankine cycle. Figure 2 shows a sketch of the solar collectors. The solar radiation passes through both the glass tubes to be absorbed by the selective surface. The surface

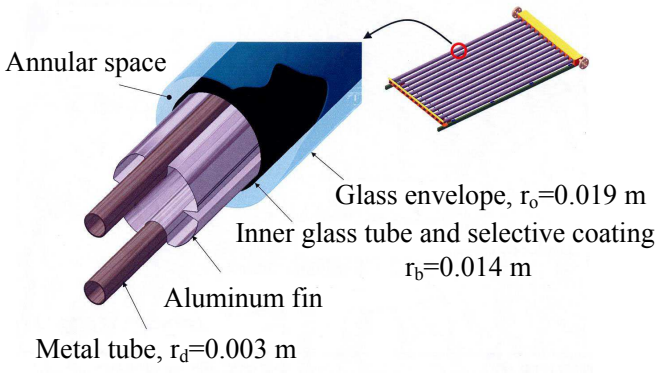

Fig. 2. A sketch of the evacuated solar collector used in the Rankine cycle

heats up and the heat is transferred by conduction to the metal tube and then by convection to the working fluid. The properties of glass are assumed to be 1.25, 0.09, and 0.05 for thermal conductivity, solar transmittance and solar absorbance, respectively. The properties of selective coating are 0.02 and 0.927 for solar transmittance and solar absorbance.

The several assumptions are made for the cycle analysis. 1. In the solar collector, thermal resistance among the selective surface, metal tube and fin is neglected. 2. In the solar collector, supercritical CO_2 is distributed uniformly in all heat removal tubes. 3. The friction loss and pressure change due to the heating or cooling processes in the collector and CO_2/water heat exchangers are neglected. 4. The CO_2 pressure at the pump outlet mainly varies with CO_2 flow rate. But the detailed relationship of this pressure and CO_2 flow rate is not clear until now. For convenience, in this study, this pressure is set as a constant value of 9.0 MPa, which may be not an optimal value, but close to the experimental value [6,7]. The pressure drop in the turbine is a constant value of 2.5 MPa. 5. The thermal loss from the CO_2 loop is neglected.

Figure 3 shows each of the differential control volumes, which is an annular region of length dx, the x axis indicating the direction of flow of the fluid inside the tube. Applying the first law of thermodynamics to each one of the differential

control volumes and assuming steady state with constant thermophysical properties except CO_2, we obtain the following equations.

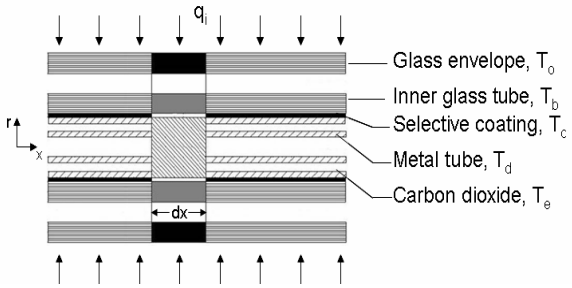

Fig. 3. The differential control volume of the solar collector used in the analysis of the model.

Solar collector

$$\alpha_g r_o q_i + r_b k_b (T_b - T_o) + \frac{r_b \sigma (T_b^4 - T_o^4)}{\frac{1}{\varepsilon_g} + (\frac{r_b}{r_o})(\frac{1}{\varepsilon_g} - 1)}$$

$$= r_o k_a (T_o - T_a) + r_o \sigma \varepsilon_o (T_o^4 - T_a^4) \quad (1)$$

$$\tau_g \alpha_g r_b q_i + \frac{\lambda_g (T_c - T_b)}{\ln\left[1 + \left(\frac{\delta}{2r_b}\right)\right]}$$

$$= r_b k_b (T_b - T_o) + \frac{r_b \sigma \left(T_b^4 - T_o^4\right)}{\frac{1}{\varepsilon_g} + \left(\frac{r_b}{r_o}\right)\left(\frac{1}{\varepsilon_g} - 1\right)} \quad (2)$$

$$\tau_g^2 \alpha_f r_b q_i = \frac{\lambda_g (T_c - T_b)}{\ln\left[1 + \left(\frac{\delta}{2r_b}\right)\right]} + 2 r_d k_c (T_c - T_e) \quad (3)$$

$$m_c C_p \frac{dT_e}{d\chi} = r_d k_c (T_c - T_e) \quad (4)$$

Turbine

$$T_2 = f1(s_2, P_1 - \Delta P) \quad (5)$$

$$P_T = m_c (h_2 - h_1) \quad (6)$$

Heat recovery system

$$Q_{H1} = m_c (h_3 - h_2) \quad (7)$$

$$Q_{H2} = m_c (h_4 - h_3) \quad (8)$$

Feed pump

$$T_5 = f3(P_5, h_5) \quad (9)$$

$$P_P = m_c (h_5 - h_4) \quad (10)$$

where, $h_2 = f2(s_2, P_1 - \Delta P)$, $h_5 = f2(s_5, P_5)$.

In this paper, a Program Package for Thermophysical Properties of Fluids database version 12.1 (PROPATH 12.1) is used in order to estimate the thermodynamic properties of CO_2. $f1$, $f2$ and $f3$ are function used in PROPATH 12.1 to calculate thermodynamic parameters of CO_2. With the available thermodynamic properties data, we modeled the components of the CO_2-based Rankine cycle. In the CO_2/water heat exchangers, the heat capacity of CO_2 is calculated based on the average temperature of CO_2-side of the heat exchangers. The outlet temperatures for CO_2 loop (T_3, T_4) and water loop (T_7, T_9) in the CO_2/water heat exchangers and heat-exchanging quantity are calculated based on the heat transfer equations and computations of heat balance [8]. The performance of the cycle is determined by solving this set of equations simultaneously. Convergent solutions are obtained based on the method of successive loops iterations in a logic manner. The convective heat transfer coefficient k_c of supercritical CO_2 in the Rankine cycle is calculated from the relations given by Hashimoto and Saikawa [9]. The heat transfer coefficient k_a (glass envelope to ambience) is calculated with expressions reported in the reference [10]. For the heat transfer coefficient between the two glass (k_b), we used the value 0.026 $W/(m^2 \cdot K)$ for very good vacuum.

The following efficiencies are defined to describe the performance of the Rankine cycle, power generation efficiency η_{power} (i.e. thermal efficiency of the Rankine cycle) and heat recovery efficiency η_{heat}:

$$\eta_{power} = \frac{P_T - P_P}{m_c (h_1 - h_5)} \quad (11)$$

$$\eta_{heat} = \frac{Q_{H1} + Q_{H2} - P_P}{m_c (h_1 - h_5)} \qquad (12)$$

RESULTS AND DISCUSSION

An examination of the problem under consideration shows that the governing parameters for the CO_2-based Rankine cycle are the climate conditions, the efficient solar collector area A_s, heat exchange area of HX1 and HX2 (A_{HX1} and A_{HX2}), inlet water temperature of HX1 and HX2 (T_6 and T_8), and water flow rate of HX1 and HX2 (m_{w1} and m_{w2}). For all simulations (in Table 1), the CO_2 flow rate m_c is assumed to be 0.0066 kg/s, which is chosen to be close to the value achieved in the experiment [6, 7].

Table 1 shows the simulated results for the typical climate of four seasons in Osaka of Japan in a year. It can be seen that during one year, the CO_2 temperatures increase with the season-averaged solar radiation and air temperature. The temperature of supercritical CO_2 at the outlet of the solar collector (T_1) can reach about 217.4 ℃ in the summer condition (from July to September), and under the winter climate (from January to March) the temperature of T_1 is about 137.0 ℃. The annual average value of T_1 is about 177.4 ℃. It can also be seen that there is about a temperature difference of 30～40 ℃ between the inlet and outlet of the turbine. At the outlet of the turbine, in the summer, CO_2 temperature T_2 is about 181.6 ℃ and the annual average value of T_2 is about 143.1 ℃, which can easily be used as a useful heat resource.

It is seen from the table 1 that the useful outputs of the Rankine cycle vary obviously with the incident solar radiation and air temperature. Contrary to the influences of the climate on the useful outputs, the higher power generation efficiency η_{power} and heat recovery efficiency η_{heat} are obtained in winter conditions. This means that in the summer conditions, the larger

Seasons	Jan-March	April-June	July-Sept	Oct-Dec
Air temp. T_a(℃)	6.6	18.9	26.5	13.0
Solar radiation. q_t(W/m^2)	510.2	773.3	851.7	593.3
CO_2 temp. T_1 (℃)	137.0	199.8	217.4	155.2
CO_2 temp. T_2 (℃)	104.1	164.9	181.6	121.8
CO_2 temp. T_3 (℃)	83.7	128.2	140.5	96.7

Heat Output (W)	1007.3	1384.4	1494.4	1115.1
Power generation efficiency η_{power}	0.2552	0.2020	0.1906	0.2406
Heat recovery efficiency η_{heat}	0.7330	0.6516	0.6368	0.6958

Table 1 Simulated results of the Rankine cycle for the whole year (Osaka, Japan)

cycle outputs and a little lower efficiencies are obtained. It can be explained that although the electric power and heat output increase for the summer condition, the heat quantity absorbed into CO_2 in the collector also increases. Furthermore the increasing amplitude of the heat quantity is larger than that of the power output. In addition, the temperature difference between the solar collector surface and the surrounding air become greater in the summer than in winter, and then the thermal loss of the solar collector to the ambient also increases, which may also contribute to the occurrence of this phenomena. It is found that the annual averaged power generation efficiency and heat recovery efficiency are 0.222 and 0.680, respectively. It should be mentioned here that the data in Table 1 can be optimized by using variable pressures.

The formulation of numerical model in the study is expected to have a capability of reasonably dealing with the CO_2-based Rankine cycle. Therefore, for validation of the numerical model, the measured data in the reference [6] is used. The experiment was conducted under a typical summer condition in Osaka area, and the power generation efficiency η_{power} and heat output efficiency η_{heat} were measured at 0.25 and 0.65, respectively. A comparison between the experimental data and the present prediction show that the present predictions are close to the measurement values. The difference between the experimental data and numerical predictions may be due to the assumptions and simplifications made in the steady state analysis. The measured

η_{power} is 0.25, higher than the calculated value of 0.222. The reason given to this phenomena may be that the averaged CO_2 flow rate in the experiment is a little higher than the value used in the simulation, and this value of 0.25 was obtained under the summer. But to a certain extent, the agreement is found and therefore the present model can be used with confidence.

Figure 4 shows the dependence of the cycle temperatures as a function of area of evacuated solar collector for the annual-averaged incident solar radiation of 682.0 W/m^2. It is clear from the curves of Fig. 4 that the cycle temperatures increase with the area of solar collector. The reason given here is that the heat quantity absorbed into CO_2 in the solar collector greatly increases when the area of solar collector is enlarged. So when other parameters are fixed, the CO_2 temperatures increase if the collector area is increased. From Fig. 5, which shows the effect of the solar collector area on the cycle performance, it is obvious that the electric power output and heat output increases with the collector area. The reason given is that the CO_2 temperatures can be effectively raised by the increase of the collector area (from Fig. 4). It can also be seen from Fig. 5 that enlarging collector area can increase the heat output more efficiently than the electric power output. Further, from Fig. 5, it is seen that the power generation efficiency decreases with the

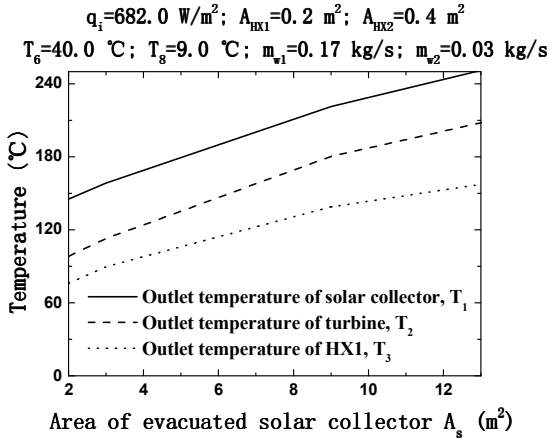

Fig. 4. Effect of area of evacuated solar collector on the CO_2 temperatures in the cycle

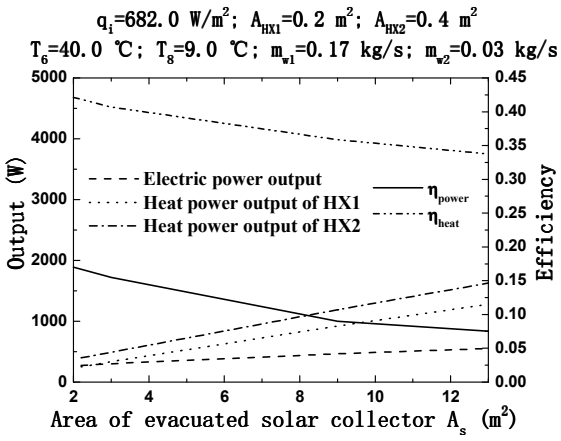

Fig. 5. Effect of collector area on the useful cycle outputs and efficiencies

increase of the collector area. It is because enlarging the collector area increases the overall quantity of heat absorbed into CO_2 in the collector. Although the electric power output is also increased by enlarging the collector area, the power generation efficiency decreases with the collector area. Another important reason is that the heat loss to the ambient environment is increased if the collector area is enlarged.

In the heat recovery systems, the heat exchanging areas (A_{HX1} and A_{HX2}), the inlet water temperature (T_6 and T_8) and the water flow rates (m_{w1} and m_{w2}) are also the governing parameters for the Rankine system. In this paper, the effect of these parameters is studied taken HX1 as an example. The effect of the heat exchanging area of HX1 A_{HX1} is shown in Figs 6 to 7 at the solar radiation of 682.0 W/m^2.

It is seen that the cycle temperature decrease with A_{HX1} increase. When the other parameters are fixed, the area increase means the more heat quantity is recovered from the cycle, which leads to the decreases of the CO_2 temperatures in the cycle. The decreases of the CO_2 temperatures result in a drop of the electric power output and heat output from the HX2, shown in Fig. 7. The heat output from the HX1 increase with the heat exchanging area A_{HX1}. The power generation efficiency η_{power} decreases with A_{HX1} increase, due to the decrease of the electric power

output. It is also sent that the heat output efficiency is almost not influenced by the heat-exchanging area A_{HX1}, since the variations of the heat outputs from HX1 and HX2, due to A_{HX1}, almost cancel each other.

Figures 8 and 9 show the variation of the cycle performance with the inlet water temperature of HX1 (T_6). Figure 8 shows that the CO_2 temperatures in the cycle go almost linearly up as the inlet water temperature of T_6 increase. It is known that heat exchanging quantity is decreased as the temperature difference drops, hence the CO_2 temperatures increase and the heat output in HX1 decrease (shown in Fig. 9). However, the heat output in HX2 increase due to the increase of the CO_2 temperature of T_3. It is obvious from Fig. 9 that the heat output efficiency is decreased with T_6 increase. It is also seen that the electric power output and power generation efficiency increase a little with T_6, which may be contributed to the CO_2 temperature increase with T_6, shown in Fig. 8.

Figures 10 to 11 show the effect of the water flow rate m_{w1} on the cycle performance. It is seen from Fig. 10 to 11 that there is no an obvious effect of m_{w1} on the CO_2 temperatures, the useful outputs from the cycle and the efficiency η_{power} and η_{heat}. It may be explained physically that although the heat exchanging process in the heat recovery system is influenced by m_{w1}, the influence is smaller and more indirect compared to those of varying heat exchanging area and inlet water temperature, since the variation of m_{w1} only can have an influence on the heat transfer coefficient, which is not only dependent on the water flow rate, but also the CO_2 flow rate etc. It should be mentioned here that the efficiencies in Fig.4～Fig.11 are somewhat lower than the efficiencies obtained in Table 1, because the CO_2 flow rate of 0.058 kg/s

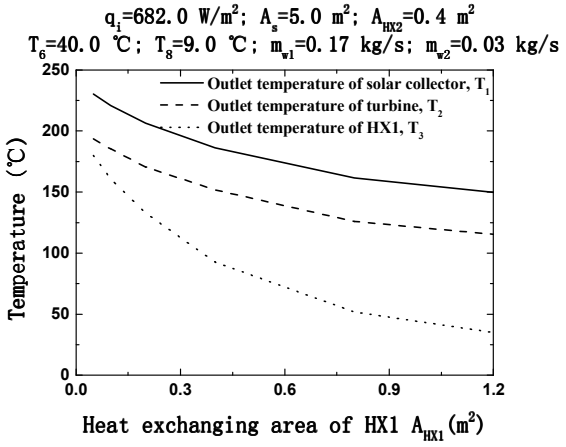

Fig. 6. Effect of heat exchanging area of HX1 on the CO_2 temperatures in the cycle

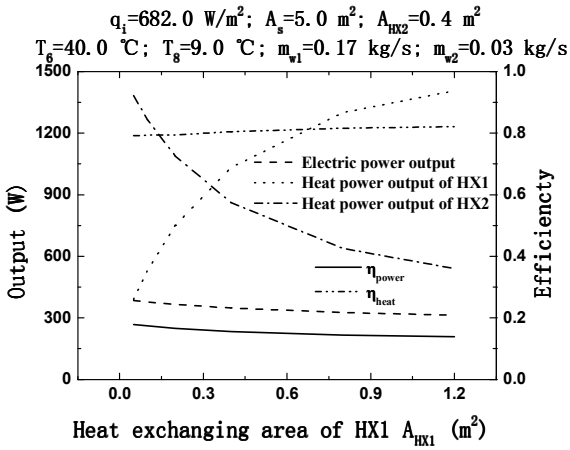

Fig. 7. Effect of heat exchanging area of HX1 on the useful cycle outputs and efficiencies

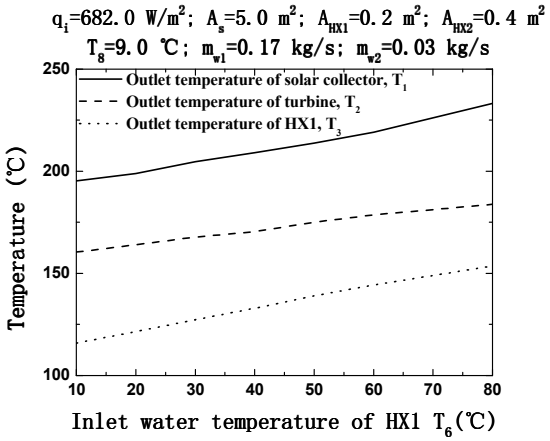

Fig. 8. Effect of inlet water temperature of HX1 on the CO_2 temperatures in the cycle

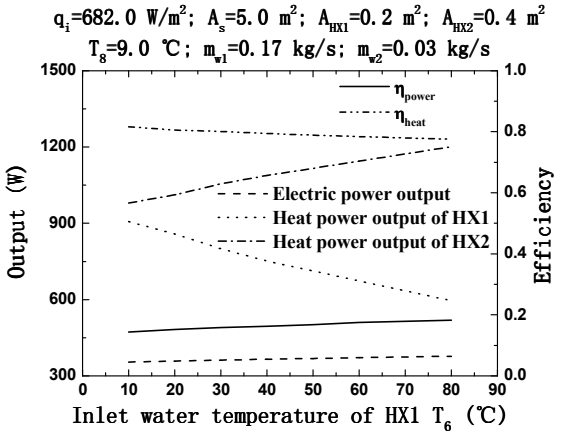

Fig. 9. Effect of inlet water temperature of HX1 on the useful cycle outputs and efficiencies

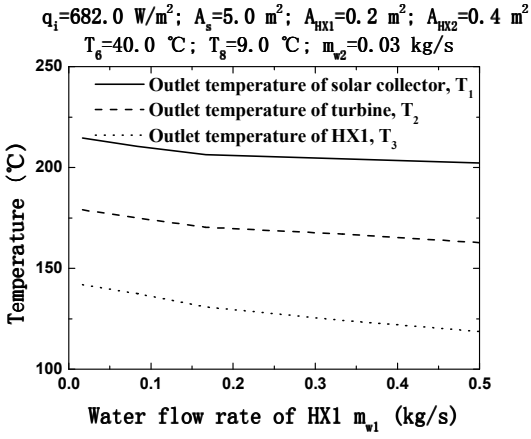

Fig. 10. Effect of water flow rate of HX1 on the CO_2 temperatures in the cycle

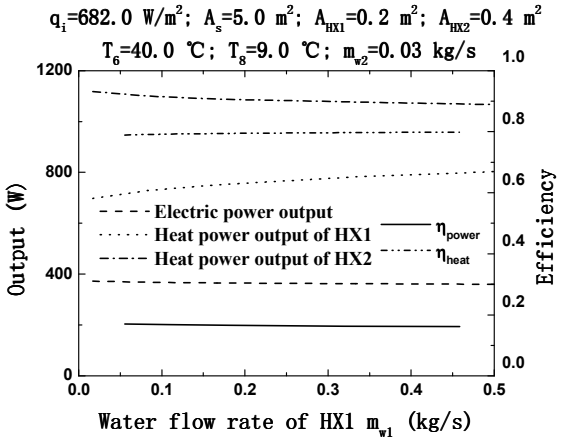

Fig. 11. Effect of water flow rate of HX1 on the useful cycle outputs and efficiencies

is used in the calculation of Fig. 4～Fig.11, which is a little lower than that used in Table 1. Furthermore, a constant pressure is assumed at the pump outlet in the present study. The pressure optimization is also needed in the future.

CONCLUSIONS

A numerical study has been made of a thermodynamic cycle — solar energy powered Rankine cycle using supercritical CO_2 as the working fluid. The following remarks are made from the results of this study:

(1) A numerical formulation of the problem considered in the study has been established and comparison of the experimental data and model prediction validates the model for predicting the cycle performance.

(2) The results show the CO_2-based Rankine cycle has a power generation efficiency and heat recovery efficiency of somewhat above 20.0 % and 68.0%, respectively.

(3) The problem considered is governed by the following independent parameters, the climate, the collector area and the heat-exchanging area, the inlet water temperature, the water flow rate of the heat recovery system. The results reveal that the electric power output is increased with the solar radiation and air temperature, the collector area and the inlet water temperature, but decreased with the increase of the heat-exchanging area. It is also seen that the influence of the water flow rate on the cycle performance can be neglected.

(4) It is recognized that a more detailed transient simulation and pressure optimization is needed to further estimate and understand the cycle performance and establish the practical usefulness of this cycle.

ABSTRACT

Present paper is aimed at describing a "closed cycle" power plant schematics(SOFT, Solar Oxygen Fuel Turbine) with macroalgae (seaweed) cultivation in a pond, combustion of its organic matter in a fluidized bed boiler of Rankine cycle and return the combustion products to the pond to feed algae. Used for combustion oxygen is released to atmosphere in photosynthesis.

Energy efficiency is less than in Photovoltaics but energy expenditures to construct pond as solar energy receiver are much less, it gives some economic benefits. For a power unit of 100 kW the pond surface is about 3 hectare.

The cultivation of seaweeds in sea water ponds is well developed in Israel. Construction in some future of a SOFT system near to the Dead sea in Israelian desert would provide the country with needed power, chemicals and fresh water on account of solar energy. The system is protected by USPat 6,477,841 B1 of 12.11.2002 with priority in Israel of 22.03.1999.

In the paper is highlighted much more benefits to customer, than in the patent text, including fresh water by desalination. Some guesses of a desert surface for a massive scale use of ponds are given.

Introduction

Algae cultivation for electricity generation is discussed in some recent decades . All algae have been divided by microalgae (size of some microns) and macroalgae or seaweeds, which are much greater. The photosynthesis is similar in the both kinds and the early history we will start from microalgae. But the technical problems of cultivation and combustion are different, that is why we will focus on macroalgae only.

*Corresponding author: phone 49-241-9976669,
E-mail iksvotnay@aol.com

First published results of the use of open ponds with microalgae to convert carbon dioxide from power plants into methane fuel belong to Golueke and Oswald (cited in [1]). They demonstrated a small system, involving microalgae growth, digestion to methane and recycle of nutrients. They tried to catch CO2 injecting the flue gases into the pond regardless to a very small fraction of CO2 in flue gases, about 10%. Then especially active was Solar Energy Research Institute SERI (now NERL) in "Aquatic species program". After the testing of the three outdoor algae facilities in California, Hawaii and New Mexico it was concluded that it is possible to

produce microalgae in a large-scale pond at high productivity and relatively low cost.

Similar results published Alexejev et al.[2] from Moscow University, demonstrating a small microalgae system "Biosolar" with production of 40 g/sq.m dry biomass in a day. The mineralized elements from the tank of produced methane are reused by algae. CO2 is restored after burning. They stated " 1 mtce of methane might be produced from a surface of 70 sq. km annually."

Chemistry of algae pond was described by L.Brown [3,4] along with the outlook of a raceway-type pond and a paddle-wheel to move water. The overall reaction for photosynthesis by cianobacteria, micro- and macroalgae is as follows:

$$CO2 + H2O + light => CH2O + O2 \quad (1)$$

He also stated: "We estimate that microalgal biomass production can increase the productivity of desert land 160-fold (6 times that of a tropical rainforest). Microalgae require only 140-200 lb of water per pound of carbon fixed even in open ponds and this water can be low-quality, highly saline water".

If the pond water is rich with nutrients like a wasted municipal water or released from an animal farm the very high figures of dry biomass production have been published: 120 g/sq.m in a day[5]or 175 g/sq.m.day by Pulz (cited in[6]). These figures translate into 40-50 kg/sq.m annually.

In parallel to the ponds developments some schemes of relevant power plants to use produced biomass as a fuel have been proposed. Patent by Yamada [7] contains the use of dry algae as an addition to the regular fuel. A fraction of flue gases is released to atmosphere by a stack, the rest is directed to an absorption tower to be washed by water, which dissolves CO2 from the flue gases and returns it to the pond. The sore point of this scheme is rather small fraction of CO2 in flue gases, where the dominant gas is the inert nitrogen. The separation of CO2 from nitrogen turned out to be an insurmountable problem.

The radical solution, the separation of nitrogen not after, but before combustion has been described by Yantovski [8]as the cycle entitled as SOFT (Solar Oxygen Fuel Turbine). Further development of the SOFT cycle see in the subsequent sections.

Combustion of biomass in the "artificial air", the mixture of oxygen and steam or carbon dioxide, gives the flue gases without nitrogen and CO2 might be returned in the pond to feed algae.

Macroalgae cultivation in Israel

The crucial data for this paper are based on Israelian experience [9]. There are three raceway-type ponds, each surface of 1500 sq.m with the paddle-wheel sea water circulation. CO2 is supplied by a tank on a lorry and injected into water by perforated tubes. The depth of water 0.4 m, hydrogen factor pH=7. The firm figures were obtained for a seaweed *Gracilaria* only. The stable productivity of dry mass from a pond was 12 t/year or 8 kg/sq.m.year. By the use of seaweed *Ulva* the expected productivity is doubled. These ponds are located in Northern Israel, near to shore of the sea, from where the sea water is pumped into ponds. Still the produced biomass is used as raw material for chemicals and pharmaceutics. Recently some headway in seaweed cultivation had made Noritech-Seaweed Biotechnologies Ltd.

Energy flow concentration

The main obstacle of solar energy capture is its very low current density, especially annually averaged. In Israel it is about 220 W/sq.m, only 16% of the Solar constant 1368 W/sq.m. In central Europe it is a half. Thus the energy expenditure and cost of incidental energy absorber is of primary importance. In case of photovoltaics with rather high efficiency (in laboratory about 30%, in practice a half) the pure silicon absorber takes by manufacturing lots of energy and money. That is why solar cells up to now are rather expensive. As it will be shown later, efficiency of the solar energy conversion into electricity through algae pond is much less, about 3-5%. But the energy expenditure of absorber – pond is hundred times less than that of silicon.

Having been absorbed by algae the solar energy in chemical form is concentrated by water flow much better than by optical concentrator. The concentration factor of a

paraboloid concave mirror is about 500, it means the averaged focal spot energy current density is about 500x220= 110 kW/sq.m. Energy flow in the pipe from algae pond to processing is about

$\alpha \times \rho \times V \times H = 0.001 \times 1000 \times 1 \times 19.10^6 = 19\ 000$ kW/sq.m (2)

Here $\alpha = 0.001$ = mass fraction of biomass in water, ρ= 1000 kg/cub.m= water density, V = 1m/s = water velocity, H = 19 MJ/kg = dry biomass heating value.

It is evident that energy current density in the pipe is hundred times more than that in the focal point of optical concentrator. It means the equipment size for the subsequent energy conversion processes should be rather small. It is more important than large size of solar energy absorber.

Power unit outlook

Schematics is presented on Fig.1. Water with algae 6 from the pond 4 is going to the water separation unit 12, from where the pure water without algae is used as a circulating water to cool condenser 14 and absorb CO2 in 16. Wet organic matter is dried in 18 by heat of flue gases . Relatively dry fuel is directed to the fluidized bed combustor 8. After combustion in the artificial air, (the mixture of oxygen and carbon dioxide) flue gases go in the cyclon separator 20, the deflected ash is returned into the pond .CO2 with some steam go through heat exchanger 19 and fuel drier 18 to a separation point, from where a major part is mixed with oxygen, forming artificial air for fluidizer and a minor part is directed to absorber 16 to be dissolved in circulation water and returned to the pond. This minor fraction of CO2 flow is exactly equal to CO2 appeared in combustion. Oxygen is produced from air at the cryogenic or Ion Transport Membrane unit 10. Water from condenser 14 goes by a feed water pump through heat exchangers 18 and 19 into tubes of the fluidised bed combustor 8 (boiler). Produced steam expands in the turbine 22, driving generator. Low pressure steam is condensed in 14. Actually it is the ordinary Rankine cycle.

Some words on the chemicals production. It is unwise to combust the crude seaweed at power plant in the same sense as it is unwise such use of crude oil. A small mass fraction of seaweeds contains very useful organic chemicals which should be deflected along with water separation before the fuel combustion. There exist lots of methods of high organics separation, which is far from the scope of present paper. In any case the chemicals production could improve economics of the SOFT cycle.

Let us take for a numerical example the decentralized power supply by a small power plant of 100 kW [10]. In order to get the reliable figures we make rather modest assumptions :

- Fuel is wet (50% water content)
- ASU power consumption by 98% oxygen purity 0.22 kWh/kgO2
- Superheated steam before turbine 130 bar, 540 C,
- Isentropic coefficients of turbine 0.80, of feed pump 0.75.
- Seaweed productivity 16 kg/sq.m.year or 10 W(th)/sq.m
- Photosynthesis efficiency 4.6%.

Calculated results:

- Heat input 425.5 kW(th)
- Net output 107.3 kW (el)
- Cycle efficiency 25.2%
- Pond surface 4 hectar.

The graph of efficiency versus fuel moisture see in Fig.2. For quite possible figures of Rankine cycle with reheat and efficiency of 35% the needed surface of the pond is 3 ha. For an israelian kibbutz of some hundred people is enough only 4-5 such units and a pond of 15-20 ha. A local power plant of 10 MW by the cycle efficiency 40% and photosynthesis efficiency 6% the specific power per square meter is about 5 W (220x0.4x0.06=5.28) and pond size is about 2 square km. By order of magnitude it is comparable with Yatir –reservoir in the desert Negev near to Beer Sheva. The Keren Kayemeth LeIsrael[11]is planning to build 100 water reservoirs in the next fife years. One of these might be used for the SOFT demonstration.

Finally, for the national power demand of 10 GW (about 2 kW pro capita) in Israel a reasonable extrapolation is possible: expecting specific power of 10 W/sq.m due to increase

of the cycle efficiency and photosynthesis one. It means the needed pond surface is about 1000 sq.km. The surface of the Dead Sea is just the same (exactly 980 sq.km). If in some future a Life sea (with the normal, not deadly salt concentration for seaweed) would appear in the desert, not too far from the Dead one, it could give the country full electrical power along with lots of fresh water and organic chemicals. There would be no emission of combustion flue gases and no consumption of oxygen, which is consumed in combustion but released in photosynthesis. The only need is solar energy and a piece of desert. Neither terror attack could cause any serious damage.

An israelian representity at Johannesgurg Summit, Mr Jacob Keidar announced the Israel-Jordan project of a 300 km long pipeline just from Red to Dead Seas. The Life Sea might be a useful consumer of the transferred water at the middle of the pipeline.

Gasification

In the proper energy mix not only electricity , but also gaseous or liquid fuel is needed. In the SOFT cycle it is attainable by a small modification (Fig.3). The difference is the incomplete combustion (gasification) in the fluidised bed reactor, now it is a gasifier 24. Biomass gasification is well documented [12]. Fluidized bed gasification experiments with the sugarcane bagassa described by Gomez [13]. Produced gaseous fuel mixture consists of carbon monoxide, hydrogen and carbon dioxide. After cleaning in 20 it is used in a piston engine or turbine 26, producing mechanical power. The same fuel gas mixture might be converted into liquid fuel like methanol or even gasoline. After combustion in 26 the flue gases are absorbed by circulated water and returned to the pond 4 to feed seaweed 6.
The figures in brackets 0.06 and 10^3 reflect mass ratio water/CO2. Minus before the last number is a misprint.

Water desalination

For the state of Israel the problem of fresh water is not less severe as of electrical power supply. The annual demand is about 1.4 cub.km of fresh water. It rains only 50 days in a year and 60% of the land are deserts.

Let us consider what might the SOFT cycle do for a water desalination: is it possible to use low-grade heat after the turbine expansion to evaporate of a fraction of the circulating salty water (sea water) with the subsequent condensation of vapor for the fresh water production (desalination).
Assume an evaporator of a minor fraction of circulating water after turbine. Cooling and condensing this vapor by the major part of circulating water gives fresh water as condensat.
How large is its flowrate ? Assume the turbine as of back-pressure type, by exit steam pressure 1.2 bar. If in a modern high temperature steam turbine inlet is 1000 K by 200 bar, the enthalpy is 3874 kJ/kg. After expansion the steam is at 450 K and 2830 kJ/kg. For water evaporation by 1 bar the enthalpy drop of 2500 kJ/kg is enough.
In a small power unit of 100 kW the mass flowrate of cycle water of Rankine cycle is 100/0.25.1044 = 0.4 kg/s. The mass flowrate of desalinated water is the same 0.4 kg/s.
For a small demonstration plant the figures are:
Pond surface 4 ha (40 000 sq.m). Power 100 kW. Dry fuel flow 0.021 kg/s Chemicals (4%) 1 g/s . Fresh water 0.4 kg/s
Specific dry fuel consumption is 756 g/kWh. It is about twice in excess of a standard fuel consumption in microturbine power units due to lower heating value and low efficiency.

In a 1 GW power plant with cycle efficiency 40% and pond surface 10x20 km the flowrate of produced fresh water is 4 t/s or 14400t/h. Assuming 7000h/year operation the yield of water annually is about 0.1 cub km. It is evident, that if the SOFT cycle with water desalination would be used in full scale, it might meet all water demand. Contemporary practice of the use of18 power generating and desalinating plants at the West bank of Arabian Gulf[14] giving 15 GW of power and 1.9 cub.km of desalinated water annually, confirms above guesses.

Comparison with the first SOFT version of 1991.

The closed cycle power plant concept, based on algae photosynthesis in a pond, combustion of organic matter of dried algae in a zero-emission power plant and CO2 capture to return in the pond for feeding algae has been published in 1991[8] see Fig.4. Here was used air separation and expansion in a steam turbine. The difference was in the inert gas, replaced nitrogen in combustor. It was not carbon dioxide but steam. Also different was algae: not mAcro but mIcro, that is why not fluidised bed combustor but the gas-turbine one as for clean fuel was assumed. After the triple expansion in turbines together with steam the carbon dioxide was returned to the pond. Now this version is actively used by Clean Energy Systems (CES) creating a demonstration plant of 5 MW in California not for algae, but ordinary gas fuel. It might be the first Zero Emission power plant. Had it been successful, it might be added by an algae fuel system for a SOFT cycle demonstration.

Conclusion

The SOFT power cycle protected by U.S.Patent [15] is of practical interest to countries with deserts and intensive solar radiation. The concept is ready for Engineering and economical calculations. In any case, even by modest economics, it deserves of a demonstration in a small scale.

COWI a/s, DK-2800 Kgs. Lyngby, Denmark

ABSTRACT

A simple, dynamic, 1-dimensional model describing heating, drying and pyrolysis of thermally thick wood particles with a 1-dimensional geometry has been developed and implemented. The model output is the dynamic evolution of both the char yield and the amount of volatiles. The model is developed in such a simple and accessible way, that it easily can be implemented in a larger model for dimensioning and optimisation of applications where pyrolysis is a part of the overall process as for instance gasification.

Experiments using a Thermo Gravimetric Analyser (TGA), built so pieces of wood can be fed into a hot atmosphere instantaneously, have been used to observe the influence of various parameters like temperature and size and wood types on the pyrolysis process.

Results from the model have been compared with results from the experiments. The comparison showed good accordance when both wood particles with a well-defined geometry (a cylinder) and when beds of wood chips and wood pellets, respectively, were pyrolysed.

The model has proven that transport of heat to the wood; internal transport and accumulation of heat inside the wood and kinetics of pyrolysis are all important parameters.

Keywords: Biomass, drying, modelling, pyrolysis, thermally thick, wood, TGA.

NOMENCLATURE

A	Frequency factor	[s^{-1}]
c_p	Heat capacity for const. pressure	[J/kg·K]
c_v	Heat capacity for const. volume	[J/kg·K]
dm	Dry mass	[g]
E	Activation energy	[J/mole]
h	Mass specific enthalpy	[J/kg]
h_k	Convective heat transfer coef.	[W/m^2·K]
HHV	Higher heating value	[MJ/kg]
k	Conductivity	[W/m·K]
m	Mass	[kg]

INTRODUCTION

A well documented and simple model calculating drying and pyrolysis under various conditions is needed to perform a successful modelling of larger energy systems like combustion and gasification plants. Most identified work has been focused on kinetics of pyrolysis, only. These analyses are accessible, but only valid for pieces of thermally thin wood, where no significant internal temperature gradients at any time are present.

Many authors have done thorough experimental work on pyrolysis of wood chips. But accessible, consistent data on the pyrolysis of thermally thick wood (e.g. wood chips or wood pellets) and the influence of variations on single parameters like particle size and temperature are rare [1]. It is assessed that such data is valuable for future construction of, among others, gasification applications. The experimental work is done under slow pyrolysis conditions with a low heating rate corresponding to the common conditions during fixed bed pyrolysis and gasification.

Some effort has been done in the past to develop models describing the simultaneous drying and pyrolysis of thermally thick wood. [2], [3], [4], [5], [6], [7], [8] have all in different ways developed models which include kinetics of drying and pyrolysis and heat balance. In particular, different approaches have been used to describe the kinetics of pyrolysis and drying, whereas both conservation of energy and mass are included in all identified models. Due to the complexity attributed to biomass in general, most models are either simplified by the geometry or by the kinetics of pyrolysis (or both).

MODELLING SECTION

The objective of this work has been to develop a simple, accessible model for implementation in a larger model of a whole gasification unit. The model is 1-dimensional. Two other important simplifications have been to neglect diffusion of volatiles and vapour and to describe the kinetics of pyrolysis to one, single first order reaction expressed in Arrhenius form.

Drying of wood is a complex phenomenon. Due to this complexity, the descriptive equation of drying [4] in the model is valid for drying below the fibre saturation point only (moisture at app. 23-30% wet basis) [3],[8].

Drying [kg/s]:

$$\frac{dm_{evap}}{dt} = \phi \cdot \rho_{wood} \cdot A_{evap} \cdot \exp\left(-\frac{E_{evap}}{\hat{R} \cdot T}\right) \quad (1)$$

The way of describing the kinetics of pyrolysis in the model developed in this study is fairly simple compared to other ways of modelling wood pyrolysis. [4], [5], [7], [9] use a more complex description where the thermal degradation is divided into the degradation of the three main polymers in wood (cellulose, hemicellulose and lignin). It has been chosen to model these processes in a more accessible and simple way.

Pyrolysis [kg/s]:

$$\frac{d\Phi_{vol}}{dt} = A_{py} \cdot \exp\left(-\frac{E_{py}}{\hat{R} \cdot T}\right) \cdot \left(\Phi^{*}_{vol} - \Phi_{vol}\right) \quad (2)$$

An analysis of combined heating, drying and pyrolysis of thermally thick wood consists basically in a control volume analysis [10]. Equations describing drying and thermal degradation are used for a differentiated control volume.

Conservation of energy [W]:

$$\sum_i \frac{\partial\left(m_i \cdot u_i\right)}{\partial t} + \sum_i d\left(\dot{m}_i \cdot h_i\right) = d\dot{Q} \quad (3)$$

Conservation of mass [kg/s]:

$$\sum_i \frac{\partial m_i}{\partial t} = -\sum_i d\dot{m} \quad (4)$$

Heat conduction [W/m^3]:

$$d\dot{Q}''' = \frac{1}{r}\frac{\partial}{\partial r}\left(k \cdot r \cdot \frac{\partial T}{\partial r}\right) \quad (5)$$

Index i in equation (3) and (4) corresponds to the different matters: wood, volatiles, vapour and char. Φ^{*}_{vol} in equation (2) is the maximum amount of volatiles pyrolyzable from biomass at one certain temperature. In other words, Φ^{*}_{vol} is a temperature dependent figure that must be experimentally evaluated for the specific type of wood. This has been done for beech, which is used in this study. Five descriptive equations are hereby valid in the differentiated control volume.

To describe the geometry of wood chips using cylindrical coordinates a transformation of length, height and width into a length and a radius is necessary. Keeping the volume and length of a wood chip constant during the transformation from Cartesian to cylindrical coordinates does this.

A combination of the five equations above given results in a system of partial differential equations, which is solved numerically. It is assumed that the heat transported to the wood by convection and radiation is conducted into the wood. An energy balance (no accumulation) applied on the surface of a particle is expressed by the equation:

$$k \cdot \left.\frac{dT}{dx}\right|_{sur} = h_k \cdot \left(T_g - T_{sur}\right) + \sigma \cdot \varepsilon \cdot \left(T_w^4 - T_{sur}^4\right) \quad (6)$$

Two important parameters to be determined are the conductivity and the heat capacity of both wood and char. With the objective of keeping the model simple, no dependency of temperature is included and the heat capacity of wood and char is assumed to be equal. Thus, the values of c_p in table 1 are used throughout this study. The conductivity for char in table 1 is the value assumed for pure charcoal. During the pyrolysis the solid fraction is not assumed as pure charcoal. In the model the conductivity of the sample decrease gradually during the thermal degradation of the material, where high degradation (low density) causes low conductivity:

$$k_{sample} = \frac{\rho}{\rho_{wood}} \cdot k_{wood} + \frac{\rho_{wood} - \rho}{\rho_{wood}} \cdot k_{char} \quad (7)$$

The pyrolysis time (reaction time) is defined as the time from when the particles were fed into the balance pan until the weight reach 98 % of the total weight loss.

Parameters describing pyrolysis and drying are found in [3],[4], (table 1).

Parameter	Value	Unit
A_{py}	$2 \cdot 10^4$	s^{-1}
E_{py}	70.4	kJ/mole
A_{evap}	$5.13 \cdot 10^6$	s^{-1}
E_{evap}	87.9	kJ/mole
c_p	1900	J/kg·K
k_{wood}	0.15	W/(m·K)
k_{char}	0.05	W/(m·K)
ε	0.9	-
ρ_{wood}	545-1200	kg/m^3
h_k	10	$W/(m^2 \cdot K)$

Table 1. Important parameters used in the model

Model assumptions

The most important assumptions are: (1) The model is 1-dimensional; (2) operating with two components: gas and wood, where the gas consist of tars, steam and other gasses (CH_4, N_2, CO, CO_2, H_2) and wood covers both wood and char; (3) ideal gases; (4) no shrinkage of the wood; (5) constant specific heat capacity; (6) no potential or kinetic energy; (7) no gas radiation; (8) no mechanical work on the system; (9) constant atmospheric pressure; (10) no diffusion limitations; (11) accumulation of gasses are neglected; and (12) the reaction enthalpy of pyrolysis is assumed to be zero [11].

EXPERIMENTAL SECTION

Apparatus

A large scale Thermo Gravimetric Analyser (TGA) operating at atmospheric pressure has been constructed [12]; an airtight, well-insulated, cylindrical reactor with adjustable electric heating elements in the isolation materials is continuously purged with N_2. Inside the reactor, a scale connected to a lever and a weight is positioned. Thus, pieces of wood can be fed into an inert, hot atmosphere instantaneously and the weight loss due to thermal degradation at various conditions can be observed. Maximum sample size is approximately 30 g. Computers do simultaneous data logging of both temperatures (T_1 - T_7) in the reactor and the mass during pyrolysis. (Figure 1).

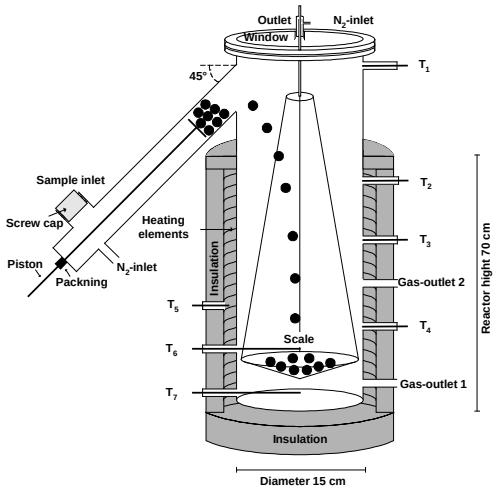

Figure 1: Thermo Gravimetric Analyser (based on [12])

In addition, a minor rearrangement on the TGA makes it possible to measure the composition of

the volatiles after water and tar components are removed. In this set up, the volatiles is removed instantly from the reactor and transported to cooling, cleaning and eventually an analyser (Servomex) detecting the gases: H_2, CO, CO_2, O_2 and CH_4.

Raw materials

A wide range of commercial wood materials for gasification and combustion was investigated: wood chips, small and large wood pellets made of sawdust (table 2).

Wood type	Species	Supplier	Diameter [mm]	Moisture (wet basis) [%]	Density [kg/m^3]
chips	beech	Danish Forest	3-100	0 - 32	545[a]
pellets, Ø6	birch	Norwegian Forest	6.25	6.9	1170
pellets, Ø10	pine	Shell	10.2	7.2	1200

Table 2: Characterisation of raw materials a: From [3]

The first type of wood pellets was made from Norwegian birch and had a diameter of 6 mm. The second type with a diameter of 10 mm was made of surplus pine from Danish furniture production.
The wood chips was produced on a commercial forestry chipper (Silvatec 478CH), sieved and tree fractions was selected together with a fraction of dried, unsieved wood chips (table 3):

Fraction	Size [mm]	Fraction of total [wt. %]	Moisture (wet basis) [%]
small	3 < x < 8	2	32
medium	8 < x < 16	19	32
large	16 < x < 45	76	32

RESULTS AND DISCUSSION

The pyrolysis experiments was separated into two sessions:

1. The first session quantified the weight loss and char yield during pyrolysis when parameters such as temperature, heating conditions and size of wood particles were changed. All variations were made from a reference experiment with a set of parameters at 600°C. Emphasis has been put on the fraction of large wood chips, which is the preferred selection for combustion and gasification in fixed beds. a
2. In the second session the gasses (CO, CO_2, CH_4 and H_2) in the volatiles from the pyrolysis at different temperatures were measured.

A combination of the results from these two series of experiments gives a well-documented picture of pyrolysis of wood chips and wood pellets.

Char yield from the pyrolysis depends on the temperature. Samples of 30 g of wood have been fed into the TGA when it was preheated to a constant temperature of 400°C, 600°C and 800°C, respectively. Initially, samples of large wood chips with a well-known, uniform (app. 5·25·25 mm) size both wet and dry were pyrolysed. Then, samples of unsieved wood chips and two types of wood pellets were pyrolysed under the same conditions. The results are shown in table 5. The char yield determine by the experiments with large particles is influenced by secondary reactions as tar cracking and is by its nature not a measure of the primary char yield as seen by using small particles but a mix of both primary and secondary reactions.

		Wood chips			Wood pellets	
		large	large	unsieved	Ø6	Ø10
Initial dry mass (dm)	[g]	19.8	28.5	25.6	26.3	28.8

		Wood chips			Wood pellets	
		large	large	unsieved	Ø6	Ø10
Initial dry mass (dm)	[g]	19.0	29.9	25.3	26.3	28.8
Moisture content	[%]	32	0	13	7	7
Time for pyrolysis	[s]	156	66	81	93	129
Char yield (% of dm)	[%]	**15**	**15**	**15**	**15**	**17**

Table 5C: Pyrolysis of samples of wood chips and wood pellets at 800 °C

The results (Table 5) show a clear trend of decreasing char yield with increasing temperature. The char yield from pyrolysis of wood chips and wood pellets showed the same magnitude of char yield independently of both size and type of wood and moisture content.
This trends correlates with results found from similar experiments with differently sized wood chips and findings identified in the literature [5],[13].

[5],[9] reports identical results for pyrolysis of pine wood cylinders and [14] on pyrolysis of beech wood cylinders

Pyrolysis of thermally thick biomass can be carried out using a preheated reactor or by heating biomass and reactor from ambient temperature.
Focusing on the heating conditions during the pyrolysis another series of experiments was conducted using the large fraction of wood chips:

- A Inserted in a hot reactor at final temperature.
- B Inserted in a 300°C warm reactor succeeded by heating to final temperature.
- C Inserted in a cold reactor (20°C) succeeded by heating to the final temperature.

Heating rate		**A**	**B**	**C**	**A**	**B**	**C**	**A**	**B**	**C**
Final temperature	**[°C]**	**400**	**400**	**400**	**600**	**600**	**600**	**800**	**800**	**800**
Initial dry mass (dm)	[g]	20.5	20.2	19.1	20.7	20.3	20.5	20.5	20.7	19.0
Char yield (% of dm)	**[%]**	**28**	**30**	**29**	**19**	**21**	**19**	**18**	**17**	**15**

Table 6: Pyrolysis of samples of large wood chips (ϕ = 32 %) using three different heating rates and three different temperatures – Determination of char yield

Results of these experiments are shown in table 6. While wood chips is thermally thick by nature the three different applied heating conditions where all limited to the conditions of slow pyrolysis, no difference in char yield were found in the tested heating conditions. A comparison to results from table 5 shows the same magnitude of char yield.

Composition of pyrolysis gas was measured after pyrolysis of samples of large wood chips in the reactor preheated to 400°C, 600°C and 800°C. The reactor was made airtight and a flow of N_2 was sucked through the reactor and sent through cooling equipment and filtering. Thus, the volatiles were removed on-line from the reactor, cleaned and sent to an analyser detecting for CO, CO_2, CH_4 and H_2. The amount of tar and water (condensed from the volatiles) was not measured but calculated by difference (Figure 2).

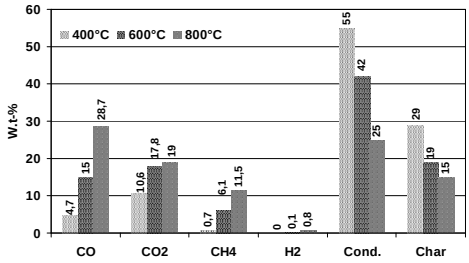

Figure 2: Composition of pyrolysis products at three different temperatures [15]

In figure 2 it is shown that the amount of tar mass decreases from 55% to 25% of the pyrolysis products.

Char

The char produced by pyrolysis of wood chips in a hot reactor at 600°C until no further mass loss, was succeeded by an ultimate analysis (table 7):

Element		
C	[wt. %]	88.9
O	[wt. %]	5.95
H	[wt. %]	2.7
S	[wt. %]	< 0.05
N	[wt. %]	0.2
water	[wt. %]	-
ash	[wt. %]	2.2

Table 7: Ultimate analysis: char of large wood chips pyrolyzed to 600 °C.

This shows clearly that a significant amount of both H and O are still present in the char even though the char has been kept in several minutes at 600°C without any further mass loss.

VERIFICATION AND USE OF MODEL

A dry, cylindrical piece of pinewood (diameter 16 mm and length 100 mm, ϕ = 0 %) with thermocouples (diameter: 0.5 mm) built into the centre and at a radius of 5.6 mm (Figure 3) was placed instantly in the TGA holding a constant temperature of 615°C. A similar cylinder was placed in the TGA to observe the mass loss under these conditions.

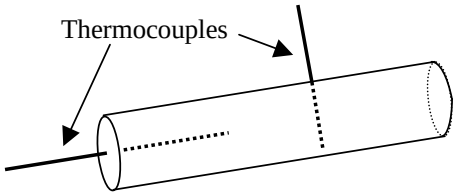

Figure 3: Wood cylinder equipped with thermocouples

Thus temperature profiles in two positions and the weight loss due to pyrolysis were measured. Due to the dimension of the cylinder, 1-dimensional geometry could easily be assumed (Figure 4).

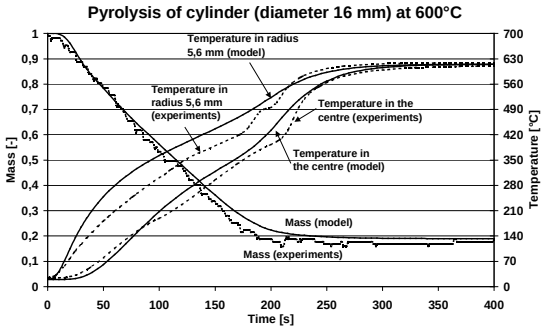

Figure 4: Pyrolysis of a cylindrical piece of pinewood. Model results and experiments. [15]

The mass decrease is well predicted by the model and the most noticeable trend, which is seen in figure 4, is the sudden rise in temperature measured in both the centre and closer to the surface in the cylinder after approximately 220 s. This can be attributed to the change from wood to char, which results in a lower heat capacity and a lower density. In the model the heat capacities for wood and char have been assumed equal and constant. Another

important finding is that the temperature profiles do not show a tendency to small exothermic reactions in the final part of the pyrolysis. This is reported in [13] with similar experiments where the maximum temperature is measured higher than the final temperature. In the model developed in this study, the enthalpy of reaction for pyrolysis is assumed to be zero [11].

Samples of 30 g large wood chips with different moisture contents (0% and 32 %) were placed in the TGA holding different, (table 5) constant temperatures, and the weight loss under thermal degradation was measured. It was hereby possible to test whether the developed, 1-dimensional model could be used for calculations on a bed of wood chips. A 1-dimensional geometry of a cylinder was found suitable (Figure 5).

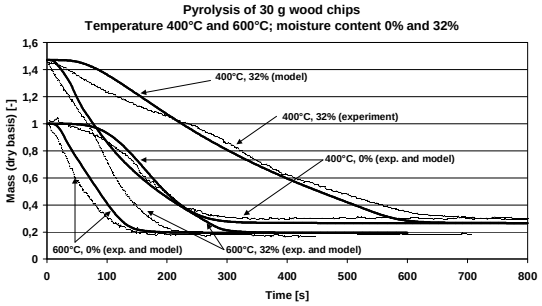

Figure 5: Pyrolysis of samples of wood chips with two different moisture contents at two different temperatures [15].

The good agreement suggests that it is enough to use a simple, 1-dimensional model to predict drying and pyrolysis of a bed of wood chips. It should be noted that a similar accordance at 800°C was not observed. This can be attributed to the constant heat capacity assumed in the model. In order to obtain a better accordance at 800°C, another value for the heat capacity should be used (see table 1).

By means of the developed and verified model, deeper investigations on the process of pyrolysis was carried out. It is investigated which of the three possible parameters: heat transfer to the particle from the surroundings, internal accumulation and transport of heat, or kinetics of pyrolysis one possibly may either neglect or see as the most important limiting part of the process.

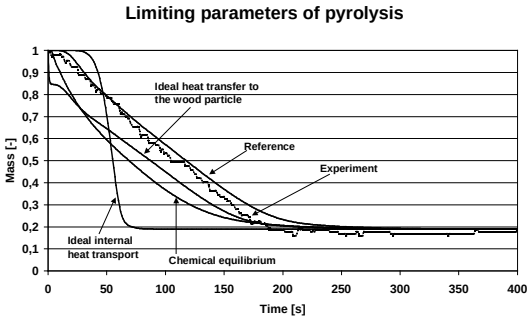

Figure 6: Investigations of the limiting parameter in pyrolysis at 615 °C [15].

The results can be found in figure 6, where these three parameters are excluded from the model one by one and the results can be compared with a reference case, where the parameters are set as normal (see table 1).

The reference line is in figure 6 also compared to the experiment, where a cylinder was pyrolysed. This experiment is the same as shown in figure 4. "Ideal heat transfer to the wood particle" in figure 6 corresponds to a simulation, where the surface temperature of the wood immediately after entering the TGA is set to the final temperature (615°C) - the limitation in external heat transfer is hereby removed. "Chemical equilibrium" corresponds to a simulation where the activation energy in the Arrhenius expression describing pyrolysis is set to 0 – Assuming chemical equilibrium. Finally, "ideal internal heat transfer" corresponds to a simulation, where the conductivity of wood and char is increased by a factor of 100, corresponding to approximated perfect internal heat transport. From figure 6 it is evident that when describing the pyrolysis of thermally thick particles none of the evaluated parameters can be assumed negligible. Therefore both internal- and external heat transfer and kinetics of pyrolysis should be included to obtain a good simulation of the pyrolysis.

CONCLUSION

Experimental investigation of slow pyrolysis of thermally thick wood was carried out on commercial wood chips and wood pellets. A decrease in char yield with increasing temperature was seen. This occurred independently of the moisture content, size and wood type.

A simple model describing drying, heating and pyrolysis of wood particles with a 1-dimensional cylinder geometry has been developed and verified.

Good agreement between calculation and experiment was obtained by comparing the 1-dimensional cylindrical model with pyrolysis experiments made on both cylinders of wood and commercial wood chips.
Model calculations showed that in order to obtain a good simulation of the pyrolysis for thermally thick particles in a pyrolysis reactor both internal and external heat transfer and kinetics of pyrolysis should be taken into account.
