The RThPSD models the calcination reaction based on a shrinking core model, where a CaCO₃ core leads to a shell of CaO. It also models the dynamics of the porous structure using a rate equation based on balances to the number of vacancies of various sizes. The original RThPSD considers that two phenomena can change the porous structure during the calcination reaction: the release of CO_2 from the reaction, which creates vacancies by leaving the lattice; and the sintering process, which occurs naturally in CaO due to the high temperatures necessary for calcination.

The model, as presented by Li et al. (2016), has its shortcomings addressed by the modified version, mRThPSD, developed in this work, with the lack of initial conditions for the vacancy distribution being one those drawbacks. Without these, the parameter values that result from model validation will not accurately represent the decomposition and sintering processes. The original model assumes that the particle is initially a solid with no porosity and that the porous structure present in the final PSD is formed solely from the release of CO_2 and from the sintering of those vacancies, which is not true, since the unreacted CaCO₃ is already porous, as seen in the work of Dennis and Pacciani (2009). The final PSD is thus inextricably linked to the PSD of the unreacted CaCO₃. The mRThPSD model addresses this problem by deriving initial conditions from the PSD of the initial unreacted CaCO₃, through the assumption that the measured total pore volume for a given pore diameter is equal to the total volume of vacancies of that respective size, assuming these vacancies to be spherical. It is also assumed that these vacancies are homogenously distributed throughout the particle. The initial conditions are calculated with Eq. (2), where $N_{i,k,Initial}$ is the initial number of vacancies of size i in the kth layer, V_{Pore_i} is the porous volume for pore diameter i of the unreacted CaCO₃ in m^3g^{-1}, Vol_{R_0} is the particle volume in m^3 and k_{Layers} is the number of layers. The remaining variables and respective units are found in the original paper by Li et al. (2016).

$$N_{i,k,Initial} = \frac{V_{Pore_i} M_{CaO} Vol_{R_0}}{V_{CaO}^M v_1 q^{i-1} k_{layers}}, \forall \, \kappa \in [1, k_{layers}] \tag{2}$$

Furthermore, in the original model, the area of the solid surface around the vacancies is calculated as the surface area of a sphere of the same diameter. However, sorbents for CaL are typically analyzed using N_2 adsorption-desorption experiments together with the BJH model, where the cylindrical pores assumption, among others, leads to Eq. (3).

Since for a sphere of volume V and radius r, the superficial area S is $3V/r$, assuming the vacancies as spherical when calculating their solid surface area generates values 1.5 larger than using Eq. (3). Since, as reported by Dennis and Pacciani (2009), the total pore surface area plays an important role in the carbonation reactivity of the sorbent, overestimating this property will skew future simulations towards unconservative conversion values. To address this, the mRThPSD assumes that the total surface area of pores of a given size is equal to the superficial area of a cylinder with the same total volume as the vacancies of the same size, calculated by Eq. (3) (SI units).

$$V_{Pore_i} = D_{Avg.} S_i / 4 \tag{3}$$

Also, on the proposed mRThPSD the vacancy balance was modified to make the effects of $CaCO_3$ decomposition and CaO sintering simultaneous. Also, an error was corrected in the vacancy balance where the total volume of vacancies would decrease, which does not occur during calcination, as stated in the work by Li et al. (2016), as no pore straightening mechanism is

Figure 2 – Total Pore Volume along time using the Original and the Modified Vacancy Balance in the RThPSD model;

present. Figure 2 highlights this error by showing the evolution of the total pore volume along the time during simulation with the original balance versus with the modified balance. The decrease in pore volume in the original balance is very apparent in Figure 2, caused by the artificial volume consumption brought on by this error being larger than the vacancy generation. As for the modified balance, it is possible to see that the volume created is conserved, as expected.
3. Results

Experimental data from fixed bed reactor experiments were used to validate both models. The OGM was validated for three different sorbents: commercial $CaCO_3$, dolomite, and waste marble powder, a residue from the Portuguese marble industry, shown to have economic potential as a CaL sorbent (Pinheiro et al., 2016). As for the mRThPSD, it is currently only validated for dolomite due to the extensive experimental work required, and its validation with other sorbents is underway. The OGM was able to replicate both reaction regimes for all sorbents with an excellent accuracy, as shown on Figure 3 and by an average error of approximately 2%, for all sorbents. The reaction regimes are highlighted for the dolomite series as line segments i and ii (Figure 3). As for the validation of the mRThPSD, in terms of the estimation of the post-calcination particle's total pore volume, Figure 4 shows a quite satisfactory fitting, considering the complexity of the system. Despite observing that part of the volume allocated to the peak of the mRThPSD post-calcination curve should be located in higher pore diameters, there is an excellent agreement between the estimated and the experimental total pore volume, with a deviation of approximately 3%. As for the calcination conversion profile the proposed

Figure 3 – Validation of the OGM for different sorbents (700 °C, 0.15 bar CO_2). Reaction domains for Dolomite: i – Kinetic Regime, ii – Diffusional Regime;

Figure 4 – Validation of the mRThPSD for Dolomite (800 °C, 0% CO_2);

mRThPSD can estimate it precisely, with an average deviation of approximately 1.2% to the experimental results. The fact that the solid's porous structure influences the reaction rate, highlights the necessity of an adequate fitting to the evolution of the particle's PSD, as seen in Figure 4. However, the inclusion of Eq. (3) limits the effect of an imperfect fit to the superficial area, whereas the overestimation of this

Figure 5 – Sorbent Deactivation (%) Vs. Surface Area Loss (%) for cycles 2, 5, 10 and 20 (from left to right);

property in the original model would result in lower diffusivity values and thus lower reactions rates, hindering the fitting to the conversion profile. As for the cyclic structure of the model, it was implemented using the relationship between the loss of superficial area and sorbent deactivation, shown on Figure 5. This was used to redefine the OGM's deactivated fraction V_d, thus connecting the sub-models. The mRThPSD estimates the total loss of area during calcination, which determines the extent of the following carbonation. Figure 5 shows the importance of using the mRThPSD to model these mechanisms to estimate sorbent deactivation in the case of incomplete reactions, different temperatures and CO_2 partial pressures.

4. Conclusions

A new model that combines carbonation and calcination was implemented in gPROMS ModelBuilder®. Both sub-models were successfully validated using data from fixed bed reactor experiments, for three different sorbents, commercial $CaCO_3$, dolomite, and waste marble powder, a Portuguese marble industry residue, recently shown to have economic potential as an industrial sorbent for CaL. The predicted values have errors below 3% for both sub-models, when compared to experimental results. Only dolomite was used for the validation of mRThPSD and further experimental work with other sorbents is underway. The proposed model contains a cyclic structure accounting for sorbent deactivation, based on the relationship between loss of superficial area of CaO sorbents and loss of reactivity. While only one cycle was simulated in this work, experimental work is underway to validate the cyclic structure for more reaction cycles.

Abstract

The problem of optimal distribution of two types of catalytic active sites for yield maximization is solved for a spherical porous catalyst pellet. The case where two consecutive chemical reactions with one reversible step following arbitrary kinetics occur under isothermal conditions is investigated numerically using the global searching technique. The constraints given by mass balances of the reactants within the pellet accounting both for internal and external mass transfer resistances are reduced by means of Proper Orthogonal Decomposition combined with Galërkin projection method. The applied computational procedure gives significant savings in calculation time as compared to classical discretization approach based on finite differences. Results demonstrate that particle microstructuring via optimal catalyst distribution within the pellet may constitute a powerful means of multistep process intensification.

Keywords: multifunctional catalyst pellet, numerical optimization, reduced order modeling, proper orthogonal decomposition

1. Introduction

Multifunctional catalyst pellets are a relatively new concept, therefore many issues concerning their performance, design, and feasibility of technological implementation as well as economic aspects remain open. Multifunctionality extended down to the particle level may consist both in the integration of sorptive mass storage and catalytic sites as well as coupling of two or more catalytic active sites in a single particle of the catalyst (Grünewald and Agar, 2004; Lugo and Wilhite, 2016). Due to the reduction of mass transfer resistances both applications may result in the enhancement of process performance, as compared to the processes carried out in reactors that integrate different functionalities solely on the apparatus level.

According to Grünewald and Agar (2004), the enhancement of yield through particle microstructuring depends on many factors including the reaction rate constant and composition of the gaseous phase. The authors demonstrated superiority of some selected non-uniform over the uniform distribution of active sites. However, the analysis was limited to a discrete set of a priori selected particle structures. Moreover, while the optimization of the distribution of a single active component within catalyst

particles was examined thoroughly in the past decades (Morbidelli et al., 2001), there are no reports dealing with optimization of the distribution of multiple active components.

In this work, the optimal distribution of two active centers in terms of the yield is determined for a single isothermal catalyst pellet by means of a global searching technique. In order to increase the efficiency of the numerical algorithm, differential equations describing concentration profiles of the reactants within catalyst pellet are reduced using Galërkin projection onto empirical modes determined via Proper Orthogonal Decomposition.

2. Mathematical model and algorithms

2.1. Model of a single isothermal catalyst pellet

Let us consider as a test case a general multistep chemical reaction:

$$A \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} B \overset{k_2}{\longrightarrow} C \tag{1}$$

developing in an isothermal spherical catalyst pellet. Under the assumption that all chemical reactions are first order, the steady-state mass balances in a catalyst written in terms of dimensionless variables are (Bizon, 2017):

$$\frac{d^2\beta_A}{d\zeta^2} + \frac{2}{\zeta}\frac{d\beta_A}{d\zeta} - f_1\Phi_1^2 \frac{k_1\beta_A - k_{-1}\beta_B}{k_1 + k_{-1}} \tag{2a}$$

$$\frac{d^2\beta_B}{d\zeta^2} + \frac{2}{\zeta}\frac{d\beta_B}{d\zeta} + f_1\Phi_1^2 \frac{k_1\beta_A - k_{-1}\beta_B}{k_1 + k_{-1}} - f_2\Phi_2^2\beta_B \tag{2b}$$

where $\zeta = r/R_p \in [0,1]$ is the dimensionless radial coordinate with R_p being the dimensional particle radius, $\beta_i = C_i/C_{ref}$ is the dimensionless concentration, whereas f_1 and $f_2 = 1 - f_1$ denote the volume fractions of two types of catalytic active sites which are function of the radial coordinate ζ. If the pore diffusion occur with the same effective diffusion coefficient D_{eff} for all reactants, then Thiele moduli Φ_1 and Φ_2 can be defined, respectively, as (Roberts and Lamb, 1996):

$$\Phi_1 = R_p\sqrt{\frac{k_1 + k_{-1}}{D_{eff}}}; \quad \Phi_2 = R_p\sqrt{\frac{k_2}{D_{eff}}} \tag{3}$$

The boundary conditions associated with Eq. (2) are:

$$\left.\frac{d\beta_A}{d\zeta}\right|_{\zeta=0} = 0; \quad \left.\frac{d\beta_A}{d\zeta}\right|_{\zeta=1} = \text{Bi}\left(\beta_{bulk,A} - \beta_A(1)\right) \tag{4a}$$

$$\left.\frac{d\beta_B}{d\zeta}\right|_{\zeta=0} = 0; \quad \left.\frac{d\beta_B}{d\zeta}\right|_{\zeta=1} = \text{Bi}\left(\beta_{bulk,B} - \beta_B(1)\right) \tag{4b}$$

where the mass Biot number is defined as $\text{Bi} = k_m R_p / D_{\text{eff}}$.

2.2. Formulation of the optimization problem

Several indices may quantify the performance of a single catalyst pellet when multiple chemical reactions occur, including effectiveness factor, selectivity or yield. Let us assume that C (Eq. (1)) is the desired product. Following Morbidelli et al. (2001), the yield of product C with respect to reactant A can be defined as the ratio between the actual production rate of C and the consumption rate of A in absence of internal and external transport resistances. Hence, for the yield, the objective function is given by:

$$Y_{CA} = \frac{3 \int_0^1 f_2 k_2 \beta_B \zeta^2 d\zeta}{k_1 - k_{-1}} \tag{5}$$

The optimization problem consists therefore in finding the distribution $f_2(\zeta)$, which maximizes the yield given by Eq. (5) under the constraint given by Eq. (2) and Eq. (4), and the constraints related to the volume fractions of each functionality and to the constant total amount of each catalyst:

$$0 \le f_2(\zeta) \le 1 \quad \text{and} \quad 3 \int_0^1 f_2(\zeta) \zeta^2 d\zeta = \upsilon \quad \text{where} \quad 0 \le \upsilon \le 1 \tag{6}$$

Since the cost function has local minima, the global search algorithm with a scatter-search mechanism for generating start points (Urgay et al., 2007) was applied to solve the optimization problem. The problem was solved directly using the Galërkin projection combined with Proper Orthogonal Decomposition (POD) to transform the boundary value problem given by Eq. (2) into a set of algebraic equations, along with the trapezoidal rule to evaluate the integrals given by Equations (5) and (6). Thus, the adjustable parameters of the problem are the values of the distribution f_2 at the discrete nodes ζ_i, $i = 1,...,N$ with $N = 51$.

2.3. Model reduction

Let us consider a steady-state boundary value problem:

$$L(y(x)) + F(y(x)) = 0, \quad x \in [a,b] \tag{7a}$$
$$B_a(y(a)) = A, \quad B_b(y(B)) = B \tag{7b}$$

where L is a linear operator containing spatial derivatives, F is a non-linear function of y whereas B_a, and B_b are boundary operators. The approximation of the spatial derivatives by finite differences leads to the transformation of Eq. (7) into the following system of N algebraic equations, where N is the number of discretization nodes:

$$\mathbf{Ay} + \mathbf{G(y)} = 0 \tag{8}$$

where $\mathbf{y}$ is a state variable vector, $\mathbf{A}$ is a coefficient matrix whereas $\mathbf{G(y)}$ is a vector accounting for the system nonlinearities and non-homogenous boundary conditions. By employing a POD basis (Bizon, 2017) the state variable vector can be represented in a truncated form as:

$$\mathbf{y} \approx \mathbf{\Phi}_K \mathbf{c}_K \tag{9}$$

where $\mathbf{c}_K$ are modal coefficients, and $\mathbf{\Phi}_K$ are K leading POD modes, $K \leq N$ determined by solving the eigenvalue problem:

$$\mathbf{C}\mathbf{\Phi} = \mathbf{\Lambda}\mathbf{\Phi} \quad \text{where} \quad \mathbf{C} = \frac{1}{M}\mathbf{Y}\mathbf{Y}^T \tag{10}$$

with the autocorrelation matrix $\mathbf{C}$ calculated from M solutions of the system given by Eq. (8) for various values of the selected model parameters. Introduction of the truncated state variable (9) into the system (8) and its projection onto the basis yield the following reduced order model consisting of K algebraic equations:

$$\mathbf{\Phi}_K^T \mathbf{A} \mathbf{\Phi}_K \mathbf{c}_K + \mathbf{\Phi}_K^T \mathbf{G}(\mathbf{\Phi}_K \mathbf{c}_K) = 0 \tag{11}$$

3. Results and discussion

Table 1 reports the values of the model parameters employed in the numerical simulations. The values of dimensionless concentration of reactant A and intermediate product B in the bulk gas were set respectively to $\beta_{bulk,A} = 1$ and $\beta_{bulk,B} = 0$. In terms of the entire tubular reactor, such boundary conditions can be interpreted by assuming that the considered particle is located in the vicinity of the reactor inlet.

Table 1. Main model parameters used in the numerical simulations

Parameter	Value	Unit	Parameter	Value	Unit
D_{eff}	10^{-6}	m²/s	k_2	10	1/s
k_1	10	1/s	k_m	0.01	m/s
k_{-1}	5	1/s	R_p	10^{-3}	m

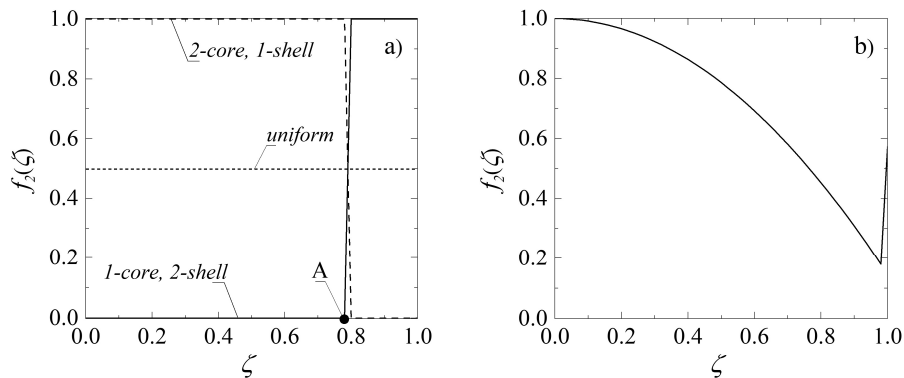
The POD basis functions used for order reduction of the constraint (2) were determined from the solutions of the mass balance equations determined with three arrangements of catalyst 1 and catalyst 2. Figure 2a shows the employed distributions of the volume fraction along the particle radius for the catalyst 2, $f_2(\zeta)$.


Figure 1. Distributions of the catalyst f_2 used for the determination of the POD basis (a) and optimal distribution of the catalyst f_2 determined via optimization method.

In each case the total volume fraction of each type of active centers was set to $\upsilon = 0.5$, therefore for both core-shell arrangements the point A (Fig. 2a) corresponds to $\zeta = 0.7937$. Since three leading POD modes resulted to contain more than 99% of the so-called cumulative correlation energy (Bizon, 2017), $2 \cdot N = 102$ algebraic equations obtained from the discretization of the Eq. (2) using finite differences were reduced using the Galërkin projection to $2 \cdot K = 6$ equations.

Figure 2b shows the optimal distribution $f_2(\zeta)$ obtained from the optimization procedure coupled with POD-Galërkin. It needs to be mentioned that the computations were also performed using non-reduced mass balance equations. The results obtained, that is both the optimal profile of the volume fraction and the corresponding value of the cost function Y_{CA} were almost identical to those achieved when applying POD-Galërkin. However, the computational time was about 20 times greater.

The determined optimal distribution $f_2(\zeta)$ provides a substantial yield Y_{CA} enhancement with respect to the values of Y_{CA} that may be obtained with a uniform and core-shell distribution of the catalyst (Table 2).

Table 2. Comparison of the selectivity of A towards C, Y_{CA}, achieved using the uniform, core-shell and optimal distribution of active centers within the catalyst pellet

Catalyst arrangement	Uniform	1-core 2-shell	2-core 1-shell	Optimal
Y_{CA}	0.1808	0.1148	0.1263	0.3093

The analysis of Figure 2 demonstrates that the type of catalyst arrangement within the particle strongly influences the concentration profiles of reactant A (Fig. 2a) and intermediate product B (Fig. 2b) within the particle and, as a consequence, the average process rate and the desired product concentration.

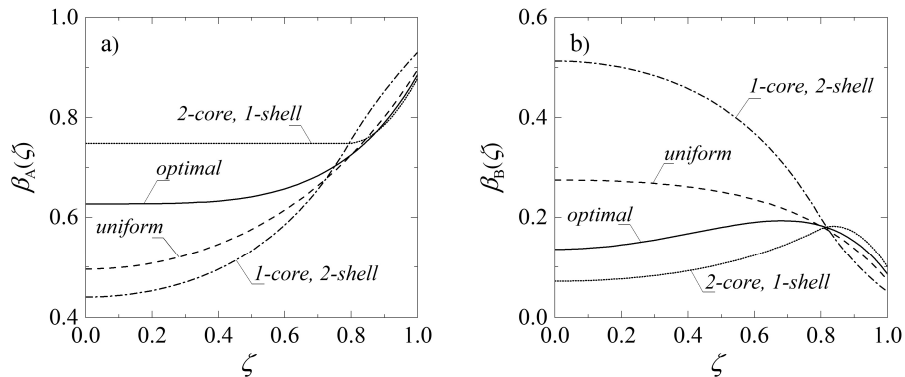

Figure 2. Concentration of reactant A (a) and intermediate product B (b) within particle calculated for different arrangement of the active centers.

Keeping in mind the spherical shape of the particle, it can be observed that in fact the optimal distribution of f_2 (Fig. 2a) provides the highest conversion of the intermediate product B (Fig. 2b) towards the desired product C. Although for the *1-core* and *2-shell* arrangement the average concentration of B is the highest, it should be remembered that in this case the second chemical reaction takes place only in the outer shell of the pellet.

4. Conclusions

Comparison of the catalyst performance indices that may be achieved when using a uniform or a core-shell arrangement of active sites, with the performance achieved for the optimal catalyst distribution within the pellet, confirms that particle microstructuring is a powerful tool for multistep process intensification. The methodology discussed can be easily adapted to more complex chemical kinetics and non-isothermal processes or even to multiscale optimization of the catalyst distribution both at particle and at reactor scale. In such case, computational expenses resulting from additional constraints in the form of a larger number of mass and/or energy equations can still be kept at a reasonable level, thanks to model order reduction based on POD-Galërkin. Moreover, the computed optimal distributions of active centers are non-uniform and can be non-smooth or even discontinuous functions, which is of great importance in view of the catalyst preparation.

Abstract

Monoclonal antibodies (mAbs) represent a significant class of biopharmaceutics with a wide range of diagnostic and therapeutic applications. Typically, mAbs are produced by cultivated mammalian cells, to meet the high quality product specifications. For new products and cell lines, an adaptation of cultivation conditions is required. This is usually performed experimentally. Model-based approaches can be a powerful tool to reduce experimental efforts and accelerate process development. We present optimizations using the process model in Kappatou et al. (2018), which is based on Quiroga et al. (2016). In particular, we perform fed-batch optimizations following a sequential and a simultaneous approach. In the sequential approach, we first find optimal initial conditions for the batch process using different objectives, and then we optimize the feeding for constant initial conditions. In the simultaneous approach, we directly optimize for initial conditions and appropriate feed rates. The optimizations lead to significant improvements compared to the base case presented in Quiroga et al. (2016). The results indicate that the sequential approach is sometimes able to outperform the simultaneous one by overcoming limitations of the local optimization used. This may be due to the flexibility of the sequential approach to use different objectives for the two steps (batch and fed-batch). Therefore, the results further highlight the importance of utilizing good initialization procedures in local optimization.

Keywords: monoclonal antibodies, bioprocess intensification, model-based optimization

1. Introduction

Within the biopharmaceutical industry, monoclonal antibodies (mAbs) are important products. Their increasing demand, together with the advent of biosimilar products and the necessity for incorporation of quality by design (QbD) principles, constitute current challenges (Shukla et al., 2017 & Collins, 2018). Therefore, a shift towards methods that can provide better mechanistic process understanding, and thus facilitate process intensification and control, is needed. To this end, model-based approaches outweigh considerable advantages.

Although recent advances in modelling have paved the way for model-based optimization strategies, there is so far only a limited amount of publications reporting on optimization of mAb production using mathematical models. In batch processes, optimization of the initial nutrient composition is a key feature. In fed-batch, optimal feeding compositions and rates are explored. Nevertheless, the great majority of existing studies considers only feeding of glucose and/or glutamate, which might not be the only growth limiting nutrients (Pörtner and Schäfer, 1996). In an industrial scale, fed-batch optimizations are often performed empirically, based on a long history of data usually obtained from batch experiments. Optimizing the fed-batch culture for both initial concentrations and feeding strategies is advantageous, as it reduces experimental costs (fewer experiments) and product time to market.

We focus on dynamic optimization of mAb producing processes in fed-batch mode of operation. We optimize using a reformulated version of the metabolic model proposed by Quiroga et al. (2016) that we presented in Kappatou et al. (2018). These models enable multiple component feeding. To describe cell's metabolism, metabolic shifts are also incorporated. More information about the modelling part can be found in Quiroga et al. (2016, 2018) and about the undertaken reformulations in Kappatou et al. (2018).

The remainder of the article is organized as follows: In Section 2 we present fed-batch optimizations following the two different methodologies, namely the sequential and the simultaneous approach. Section 3 discusses the formulation of the optimization problems. The optimization results are presented in Section 4. Section 5 summarizes this work and provides conclusions and future directions.

2. Fed-batch process optimization

We consider two different approaches for optimization of initial concentrations and feeding profiles of nutrients, as shown in Fig. 1. The ultimate goal in both cases is to maximize the final antibody concentration (mg/L), which corresponds to the high-value pharmaceutical product.

In the sequential approach, we first find optimal initial concentrations for the batch process (batch optimization), and then we optimize the feeding using the previously derived optimal initial concentrations (fed-batch optimization). Different objectives can be used in these steps. For the batch optimization, we consider to maximize final product concentration (mAb) and/or to maximize viable cell density (Xv), as these turned out to be the most promising objectives for our case study. The subsequent fed-batch optimization maximizes the final product concentration. In the simultaneous approach, we directly optimize for both initial concentrations and appropriate feed rates with the objective to maximize the final antibody concentration. Note that the terminology

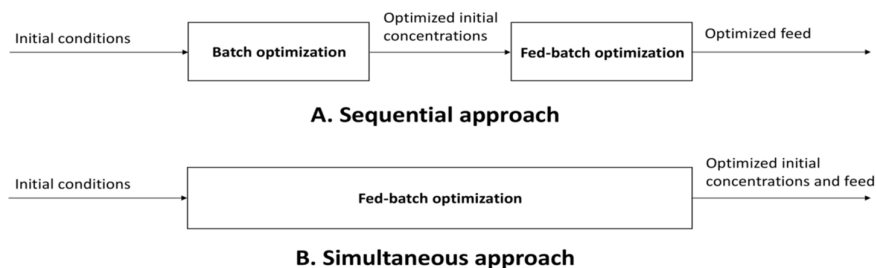

Figure 1- Solution approaches considered in the case studies

sequential and simultaneous should not be confused with that typically used in dynamic optimization theory to describe the indirect numerical solution methods single-shooting and orthogonal collocation, respectively.

3. Problem formulation

We investigate optimization problems with embedded process dynamics, using the reformulated metabolic model in Kappatou et al. (2018). The model consists of 31 differential, 81 algebraic equations and 41 parameters. The key components for the different optimization problems are summarized in Table 1. A brief description of the constraints and the control variables included into the optimization formulations is given.

Table 1- Optimization problem formulations

Optimization approach	Sequential		Simultaneous
Operation mode	Batch	Fed-batch	Fed-batch
Objective	max mAb or Xv	max mAb	max mAb
Constraints			
Viability		Viab ≤ 60 %	
Residual nutrients		$[NUT(t_f)] \leq 0.1\ [NUT]_0$	
Glutamate depletion	$t_{cr,GLU} \leq 92.5$ h	n/a	$t_{cr,GLU} \leq 92.5$ h
Volume limitation	n/a		$V \leq 1.1\ V_0$
Control variables			
Final time		$t_{batch} \leq t_f \leq 2\ t_{batch}$	
Feeding rate	n/a		$0 \leq F_{in} \leq F_{in,max}$
Initial nutrients	$[NUT]_{min} \leq [NUT]_0$ $\leq [NUT]_{max}$	n/a	$[NUT]_{min} \leq [NUT]_0$ $\leq [NUT]_{max}$

3.1. Control variables

In this study, six growth limiting nutrients (NUT) are considered, namely glucose (GLC), glutamate (GLU), arginine (ARG), asparagine (ASP), isoleucine (ILE) and leucine (LEU). Optimal initial concentrations for these nutrients are sought. As concentration ranges of the nutrients, we consider the bounds reported by Pörtner et al. (2014). Fed-batch optimization aims at deriving optimal feeding strategies (feeding -composition, -time and -rates). Note that the feeding composition is already optimized in a previous study (Quiroga et al., 2018), and thus is not examined here. The final time of the culture is also an optimization degree of freedom, and is allowed to vary between 144 h (batch time) and 288 h. From our current experience, the upper bound in the culture time is sufficiently large (Kappatou et al., 2018).

3.2. Constraints

Cell viability refers to the percentage of viable cells into the culture. In the considered optimization problems, it represents an indirect quality measure, and thus should be kept above a critical value. This way quality reducing effects are avoided. In this study, we impose a lower value for viability at 60 %. To reduce unnecessary residual nutrients, we impose an additional constraint on the residual concentrations to be lower than 10% of their initial concentrations. This is because, although on the one side nutrient exhaustion induces cell starvation, on the other side, excessive supply can cause inhibition of cell

growth and increased production of inhibitory by-products (Bibila and Robinson, 1995). One of the essential nutrients is glutamate. The cells can only survive for a limited duration, after glutamate depletion (Meister et al., 1980). Therefore, an additional constraint on the culture duration after exhaustion of glutamate (92.5 h) is incorporated to the model. This value corresponds to the value, at which culture was terminated after glutamate depletion at the real batch experiments used for model validation. Finally, in the fed-batch optimizations we impose an additional constraint that the volume is at most increased by 10% to account for dilution effects (Kiparissides et al., 2015).

4. Results and discussion

The optimization studies are performed using gPROMS v.5.0.1 (Process Systems Enterprise, 1997-2018) using a piecewise constant discretization of the controls. The simulation times vary from a few seconds for the batch cases to a few hours for the fed-batch cases with no significant differences with respect to the different approaches.

We show the optimal initial concentrations for all cases in Table 2 and the key indicators for the optimizations of the batch processes in Table 3. The max (mAb) case achieves a higher antibody concentration than maximizing the viable cell concentration, max (Xv). However, the max (Xv) case aiming at (and achieving) a higher viable cell concentration, does not reach the bound on the viability constraint and yields a lower accumulation of toxic lactate. All these are desired characteristics, and indicate the potential of utilizing these optimal concentrations for subsequent fed-batch optimization studies.

We give the optimization results for the fed-batch processes in Table 4. A comparison of the results between the simultaneous and the sequential approach reveals that the simultaneous max (mAb) performs slightly better than the sequential max (mAb, mAb) within identical process duration. This is expected due to the higher degree of freedom in the simultaneous approach. However, the latter is outperformed by the sequential max (Xv, mAb) approach that achieves 7 % higher product concentration with 12 % longer process duration. This approach yields a final mAb improvement of 244 % and an expansion of the culture spam around 1.5 days compared to the unoptimized batch case presented in Quiroga et al. (2016).

Table 2- Optimal initial nutrients concentrations in mM

Objectives	Approach	ARG	ASP	GLC	GLU	ILE	LEU
max(mAb)	Sequential batch	3.82	1.38	28.51	2.99	3.13	4.27
max (Xv)	Sequential batch	3.71	1.28	24.80	2.22	2.86	4.27
max (mAb)	Simultaneous fed-batch	4.27	1.43	35.31	3.03	3.33	4.27

Table 3- Batch optimization results

Objectives	mAb (mg/L)	Xv (cells/L)	Culture Duration (h)	LAC (mM)	Viability (%)
max (mAb)	487	3.87E9	166	10.9	60
max (Xv)	393	4.44E9	157	8.8	73

Table 4- Fed-batch optimization results

Optimization Approach	mAb (mg/L)	Culture Duration (h)	LAC (mM)	Viability (%)
Sequential max (mAb, mAb)	582	166	11.5	60
Sequential max (Xv, mAb)	635	186	10.5	60
Simultaneous max (mAb)	592	166	11.7	60

An illustrative representation of the optimization results for the different approaches is shown in Fig. 2. The sequential max (mAb, mAb) and the simultaneous max (mAb) case perform quite similarly. The feeding is introduced early in order to extend the exponential growth phase of the culture. The culture grows faster, but also the release of lactate is faster (results not shown here). In contrast, in the sequential max (Xv, mAb) approach the feeding is added a later time period, which initially slows down the growth, but leads to extended process duration and a higher final product concentration.

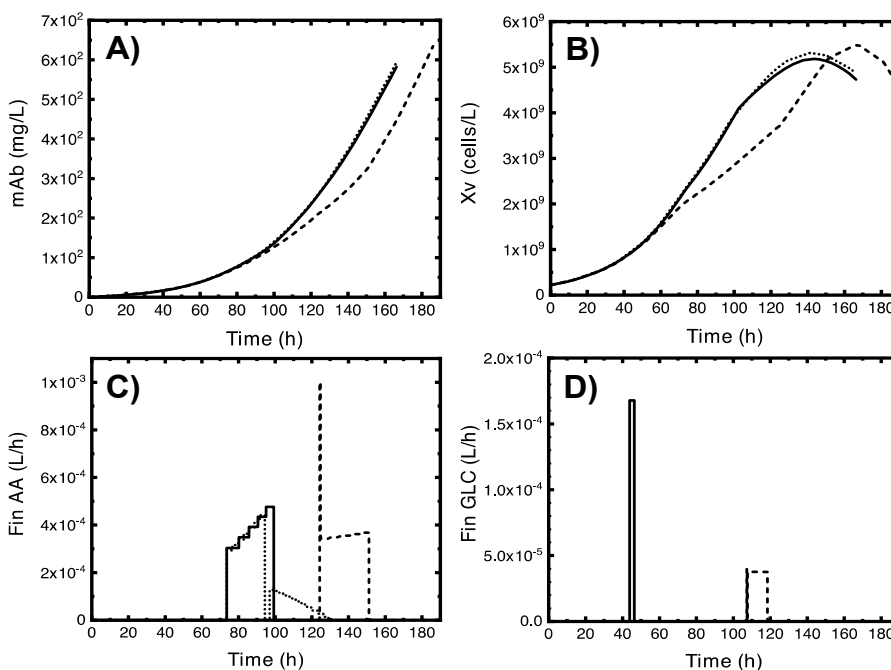

Figure 2- Key trajectories for the different optimization approaches
(A) Optimized mAb production [mg/L], (B) Viable cell concentration [cells/L], (C) Optimal feeding profiles of amino acids [L/h], (D) Optimal feeding profiles of glucose [L/ h]
—— Sequential max (mAb, mAb) ········· Sequential max (Xv, mAb) ·········· Simultaneous max (mAb)

If the dynamic optimization problem was solved globally, the simultaneous approach would give the best results in terms of maximizing process objective. The better performance of the sequential approach in case that different objectives are used in the two stages can be explained by the limitations of local optimization. More precisely, by solving the optimization problems locally, we end up with suboptimal solutions, the performance of which (as shown) can be strongly affected by good initial guesses.

5. Conclusions

This work applies dynamic optimization studies to a predictive mathematical model developed by Quiroga et al. (2016) and numerically improved by Kappatou et al. (2018). The main scope of the study is to develop computationally efficient and biologically meaningful optimization strategies for mAb process intensification. In practice, being able to optimize a fed-batch culture for both initial concentrations and feeding strategies at the same time provides a real commercial advantage due to its general cost- and time to market- reducing effect. Following a sequential and a simultaneous approach for fed-batch optimization, we exploit different suboptimal solutions to our problem. The higher flexibility of the sequential approach, in terms of being able to utilize different objectives for the two step batch and fed-batch optimization, seems to offer certain advantages. In order to overcome such limitations of local solutions, future research focus should be shifted towards global dynamic optimization techniques.

Abstract

In the design of a reactive distillation column, aspects such as column configuration, catalyst loading, tray temperature, and side extraction rates should be well considered. Though preferences in Fischer–Tropsch (FT) synthesis may vary, it is acknowledged that the final product contains a wide range of hydrocarbons including fuel gas, gasoline, diesel, and linear wax. We previously developed an equation-oriented framework for optimal synthesis of integrated reactive distillation systems for FT processes (Zhang et al., 2018).

Here, we extend the mass, equilibrium, summation, and heat equations to a mathematical programming with complementarity constraints model to deal with possible dry trays in the non-reactive sections. The purpose of describing disappearing phases is to avoid infeasibilities due to multiple bilinear terms in the model for complicated model structures. The model is implemented by solving initialization steps and a sequence of nonlinear programming problems to determine an optimal structure and operating conditions.

Design specifications for multiple products could be set as individual objectives to determine design limits. Moreover, a balance of multi-objectives could be reached by formulating the reactive distillation model as a multi-objective optimization problem. In this work, we employ the augmented ε-constraint method. The results show that significant design insights can be gained from the Pareto-optimal front regarding acceptable trade-offs amongst various objectives.

1. Introduction

The Fischer–Tropsch (FT) reaction is generally assumed to be kinetically determined (Lu et al., 2017) with an Anderson–Schulz–Flory product distribution that describe the product range with a single parameter α (Eze and Masuku, 2018). This presents a challenge in optimizing for a specific product range (Masuku et al., 2015). We recently presented an equation-oriented reactive distillation (RD) model for a typical low-temperature FT processes favoring wax production to overcome the selectivity challenges (Zhang et al.,

2018). In this study, we introduce a method to solve multi-objective optimization (MOO) in FT RD syntheses. The next section discusses relevant model formulation based on a previous study from Zhang et al. (2018). The third section focuses on the implementation procedure by solving a sequence of NLPs and initialization steps to determine optimal structure and operating conditions with multiple objectives. An example is given for a typical low-temperature FT process in the fourth section, along with results, discussions and model validations. The last section summarizes the key points and conclusions of the paper.

2. Model Reformulation

Figure 1 shows the superstructure of the FT RD synthesis problem along with the basic nonreactive stage model as the building block for the purple tray sections. Here, the mass and heat balance equations from Zhang et al. (2018) are extended with stream connection variables γ for each stream and bypass variables ζ for each stage. As bypass variables are used to deal with the optimization of stage numbers, the equilibrium equations for non-reactive stage model with bypass are reformulated as follows (Dowling and Biegler, 2015):

$$\zeta_k \gamma_{v,k+1} V_{k+1} y_{i,k+1} + \zeta_k \gamma_{l,k-1} L_{k-1} x_{i,k-1} - V_k^* y_{i,k}^* - L_k^* x_{i,k}^* = 0 \tag{1.1}$$

$$L_k x_{i,k} = L_k^* x_{i,k}^* + (1 - \zeta_k) L_{k-1} x_{i,k-1} \tag{1.2}$$

$$V_k y_{i,k} = V_k^* y_{i,k}^* + (1 - \zeta_k) V_{k+1} y_{i,k+1} \tag{1.3}$$

$$y_{i,k}^* = \beta_k K_{i,k} x_{i,k}^*, \quad \beta_k = 1 - S_k^L + S_k^V \tag{1.4}$$

$$0 \leq S_k^V \perp V_k^* \geq 0, \quad 0 \leq S_k^L \perp L_k^* \geq 0 \tag{1.5}$$

$$\sum_i y_{i,k} = \sum_i x_{i,k} = \sum_i y_{i,k}^* = \sum_i x_{i,k}^* = 1 \tag{1.6}$$

where S_k^L and S_k^V are non-negative slack variables for the liquid and vapor phases leaving stage k respectively. β_k is the slack variable to relax phase equilibrium. When both phases are present, $V, L \geq 0$ and $S_k^L = S_k^V = 0$, here $\beta = 1$ is not relaxed (Burgard et al., 2018). However, if the liquid phase disappears ($L = 0$), S_k^L moves away from zero and $\beta_k \leq 1$, thus relaxing (1.4). Also note that, γ_k are connecting variables to connect adjacent stages when modifying column structure, ζ_k are bypass variables indicating the existence of stage k. The purpose of describing disappearing phases is to avoid infeasibility issues of bilinear terms in the model when column structure becomes complicated.

For the multi-objective optimization We employ the augmented ε-constraint method proposed by Mavrotas (2009) to formulate the reactive distillation model into the following MOO problem:

$$\textbf{Problem}(\varepsilon_i) \min f_1(x) - \rho \left(\sum_{i=2}^{p} s_i / r_i \right), \text{ s.t. } f_i(x) + s_i \leq \varepsilon_i, \ i = 1, \ldots, p, \tag{2}$$

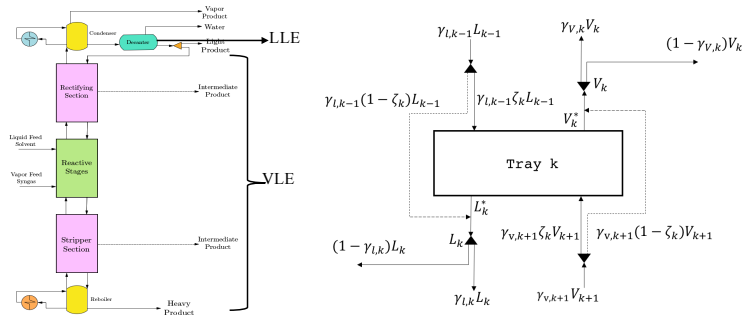
where $\rho > 0$ is a small penalty parameter, and $r_i > 0$ and $s_i \geq 0$ are the range constants and the slack variables for the ith objective function, respectively.


Figure 1: FT reactive distillation superstructure and nonreactive stage model

3. Implementation and Initialization Procedures

The **Algorithm** to find column structure and operating conditions for a multi-objective FT RD production is given below in the form of pseudo-code.

1. Set initial column structure with non-reactive and reactive trays. Set iteration $j = 1$.

2. **If** max. outer loop iteration times reached: **goto** 7; **else**: Implement **base case** run.

3. Implement **adiabatic case** run.

4. Determine $\{\underline{f_1^j}, \underline{f_2^j}, ..., \underline{f_p^j}\}$, $\{\overline{f_1^j}, \overline{f_2^j}, ..., \overline{f_p^j}\}$, q_i^j, δ_i^j, r_i^j for multiple objective functions;
   Pos$^j = \emptyset$; **Pof**$^j = \emptyset$; **I**$^j = \{\zeta^j | \text{Obj}_{\min} = f_i^j, \forall i = 1 \text{ to } p\}$.

5. Set $\varepsilon_{i,0}^j = \overline{f_i^j}, \forall i = 2 \text{ to } p$;
   while $\varepsilon_i^j - \delta_i^j \geq \underline{f_i^j}, \forall i = 2 \text{ to } p$ **do**:

        update ε_i^j by δ_i^j;

        solve $\{\mathbf{x}, \mathbf{f}(\mathbf{x})\} = \mathbf{Problem}(\varepsilon_i^j)$;

        If $(\{\mathbf{x}\} \not\subset \mathbf{Pos}^j \text{ or } \{\mathbf{f}(\mathbf{x})\} \not\subset \mathbf{Pof}^j)$:

            Pos^j = **Pos**$^j \cup \{\mathbf{x}\}$, **Pof**^{j} = **Pof**$^j \cup \{\mathbf{f}(\mathbf{x})\}$, **I**^{j} = **I**$^j \cup \{\zeta\}$;

        If $\{\mathbf{x}\} = $ *null*: skip; **else**: skip;

   end while

6. Visualization of **Pof**^{j} and analyze to get **Pof**^{j}.
   If (desired subset of **I**^{j}=**I**$^{j-1}$ **and/or max**$\{ \, |\frac{f_1^{j-1} - f_1^j}{f_1^{j-1}}|, |\frac{f_2^{j-1} - f_2^j}{f_2^{j-1}}|, ..., |\frac{f_p^{j-1} - f_p^j}{f_p^{j-1}}| \} \leq \varepsilon)$:
   goto 7; **else**: update column structure from **I**^{j}, $j = j + 1$, **goto** 2.

7. Fix column structure from desired subset of **I**^{j}.

The core of the algorithm lies in two nested loops. In each iteration of the outer loop (steps 2-6), denoted by iteration number j, a new column structure is explored; the inner loop (step 5) transforms the whole objective space as a rectangular axis-parallel domain with respect to objectives f_2 to f_p under a fixed and continuous column structure search space. The output of the outer loop gives information on bypass variables from single-objective and multi-objective optimizations. These results give us information to add or remove additional trays, which updates the outer loop with a new structure.

The **base case** and **adiabatic case** mentioned in steps 2 and 3 refer to the stage model formulations in Zhang et al. (2018) with the updated MPCC reformulation introduced in Section 2. The MPCC reformulation aims to deal with infeasibility issues caused by dry trays or trays with total bypass, which relaxes equilibrium constraints for disappearing phases. The **adiabatic case** reformulates the **base case** into an optimization problem by defining heat duty as an objective to minimize.

In step 4, $\underline{f_i^j}$, $\overline{f_i^j}$ denote the respective lower and upper bounds of the ith objective function in outer loop j; the results are obtained by setting f_i^j as a single objective. In step 5, by dividing the range of the ith objective function to q_i^j equal intervals using $\delta_i^j = (\overline{f_i^j} - \underline{f_i^j})/(q_i^j - 1)$, the original rectangular optimal search space, denoted by vertices $\{\underline{f_1^j}, \overline{f_1^j}\} \times ... \times \{\underline{f_p^j}, \overline{f_p^j}\}$, is gradually reduced, leading to poorer solutions. The detailed implementation of **update** could be found in the flowchart of the AUGMECON method in Mavrotas (2009). The **Pos**^{j} and **Pof**^{j} sets collect exclusive Pareto-optimal set and corresponding Pareto-optimal front values. $\mathbf{I}^j$ is the exclusive set of bypass variables obtained from single-objective (in step 4) and multi-objective optimizations (in step 5). These three sets provide information for visualization of Pareto-optimal front and column structure modification. If the given optimal search space is infeasible, i.e., no **Pos**^{j} and **Pof**^{j} are found, or if the same result is found with different optimal search spaces, the results are not recorded, ε_i^j is further updated, and the inner loop continues.

The entire optimal search space is visited through the equally-spaced gridding in step 5. Through visualization of MOO Pareto curve in step 6, we get a better sense of the tradeoffs among multiple objectives. By restricting attention to the subset of choices that are Pareto-efficient (where a gain in one objective leads to a significant loss of another objective), we extract values of corresponding ζ obtained and update the column structure to the next outer loop iteration. The determination of the desired subset is based on preference of the decision maker.

The termination conditions in step 6 could be interpreted as: if no change of bypass variables is observed between the last two outer loop iterations (no indications on column structure change) and/or no great improvements of single objectives from column structure modifications, the outer loop terminates. It should be mentioned, the outer loop also terminates when the "maximum outer loop iteration times" is reached in step 2. The value of "maximum outer loop iteration times" and threshold of improvement ε in step 6 are preferences of the decision maker. $\varepsilon > 0$ is normally set to around 1%, with which all absolute values of normalized improvements on single objectives are compared. With the improvement of column structure after each outer loop, values of $\underline{f_i^j}, \forall i$ are normally smaller under the convention of minimization problems.

4. Case Study Results and Discussions

In this section we consider reactive distillation with low temperature Fischer-Tropsch kinetics, where we minimize -(wax mass flow rate) as the main objective is f_1 and minimize -(naphtha purity) and -(diesel purity) are subsidiary objectives, f_2 and f_3, respectively. Catalyst loading of reactive stages are fixed during simulation and optimization; heat duty is freed on reactive trays and are minimized to zero for non-reactive trays during **adiabatic case** run; 1000 $[kmol/hr]$ syngas ($H_2 : CO = 2 : 1$) (Kapfunde et al., 2018) is fed to the last reactive tray; pressure of the column is fixed at 21 $[bar]$; temperature of condenser is fixed at 35 °C; temperature range of reactive stages is from 190 °C to 260 °C; liquid extraction fraction (γ_l) for naphtha and diesel streams are freed from [0,1] after step 3. Also, the following carbon number cut specifications from the previous work (Zhang et al., 2018), naphtha (C_5-C_7), fuel gas (C_1-C_4), gasoline (C_8-C_{12}), diesel (C_{13} to C_{18}), wax (C_{19}-C_{56}) are defined.

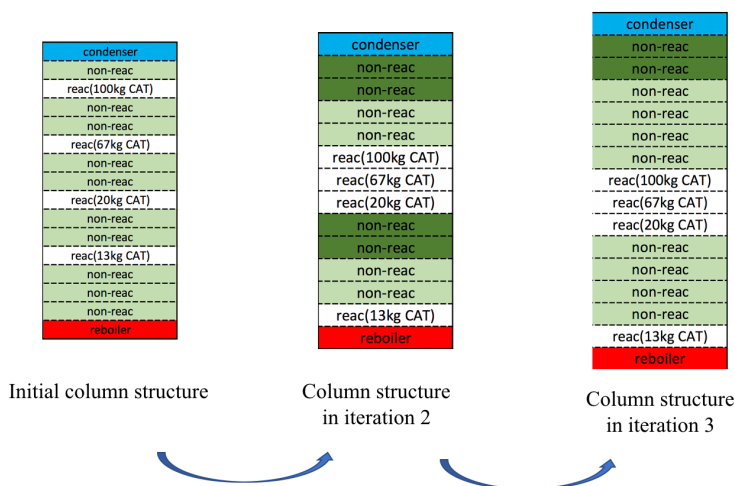

Figure 2: Typical evolution of RD column structure through MOO algorithm. Trays in green are non-reactive trays; those in dark green are from update, those in light green are results from the previous iteration.

The optimal column structure and operating conditions are found through the implementation of **Algorithm** introduced in the previous section over three major iterations. A typical evolution of the column structure (e.g., for $f_1^* \approx -822$) can be observed in Figure 2. From results of **base case** and **adiabatic case** runs, we found that the maximum diesel purity is found on the tray above the last reactive tray; this was set as location for diesel product side-draw all along. The Pareto-front for the three-objective optimization study is shown in Figure 3. The Pareto-front and utopia point (red star) is shown for the final iteration. The three-objective optimization case can then be studied by visiting a uniformed grid of ε_i of the defined **Problem**, and selecting the desired subset of the Pareto-front to provide bypass variable information. The iterations terminate because modification of column structure leads to improved single objectives by less than 1%. For instance, by

selecting one Pareto set of interest, we could get 821.73[kg/hr] bottom liquid wax mass flow rate, 0.934 naphtha purity in the top liquid and 0.706 diesel purity on stage 14. This corresponds to the rightmost column in Figure 2.

Figure 3: Pareto fronts for three-objective optimization

5. Conclusions

Since the FT reaction produces a range of products, we described a multi-objective optimization model that could be used to optimize the production of one product whilst restricting the negative impact on other valuable products. The model considers disappearing phases in the reactive distillation calculations and uses bypass variable information to avoid large computational efforts on the multi-objective case. The column structure is determined from the Pareto optimal set.

Abstract

Although the number of sensors in chemical production plants is increasing thanks to the IoT revolution, it is still a crucial problem what to measure and how to place the sensors as such the resulted sensor network be robust and cost-effectively provide the required information. This problem is especially relevant in flexible multi-purpose, multi-product production plants when there are significant differences among the operating regions. The present work aims the development of a sensor placement methodology that utilizes the advantages of local linear models. Realizing the often conflicting nature of the key objectives of sensor placement, the problem is formulated as a multi-objective optimization task taking into consideration the cost, estimation accuracy, observability and fault detection performance of the designed networks and simultaneously seeking for the optimal solutions under multiple operating regimes. The effectiveness of the Non-dominated Sorting Genetic Algorithm-II (NSGA-II)-based solution of the defined problem is demonstrated through benchmark examples.

Keywords: sensor placement, multi-objective optimization, data reconciliation

1. Introduction

Data reconciliation is a widely applied technique to increase the accuracy of the measured variables and calculate the unmeasured variables using the known uncertainty of the applied sensors and the structure and the balance equations as technological constraints. Data reconciliation-based optimal sensor placement can be considered as an optimization problem (Bagajewicz (1997)). As several objectives can be defined to measure the goodness of a sensor placement in a given technology, the visualization of the Pareto optimal solutions can facilitate the work of the decision makers (Bagajewicz and Cabrera (2003)). The problem is much more complex when the process is flexible and its structure changes in time. Xie et al. (2018) incorporated multiple operation modes to data reconciliation. However, in this work the optimal and robust placement of the sensors is not studied although the solution of this crucial problem significantly determines the applicability of data reconciliation in complex multi-mode technologies. To handle this problem we define a multi-objective optimization task that ensures the observability of the system, and generates the Pareto front of the best solutions in terms of estimation accuracy, fault detection performance and cost of the designed sensor networks in all of the operating modes of the technology. Formerly, Brown et al. (2005) incorporated multiple objectives

to process measurement system design.

The core concept of our methodology and the main contributions of the present paper is twofold: first, we describe how a multi-objective optimisation problem can be formulated taking into consideration the general aspects of observability, detectability, estimation accuracy and cost-effectiveness and highlight the conflicting nature of these objectives. Second, as many of the modern production technologies can be operated in multiple modes, the optimal sensor placement solution is sought globally for multiple operating modes. The main steps of the methodology are represented by the blue arrows in Figure 1. The boxes above and below the arrows show the required input and the obtained output information, respectively. Therefore, first the structure of the technology is analysed in order investigate the observability, estimation accuracy of the variables and the cost of the tested sensor network. Then data reconciliation is applied to reconcile and estimate the variables and determine the reconciliation accuracy. In the following, the detectability of faults is tested based on Type I and II errors using simulated gross errors on the measurement values. Finally, the optimisation algorithm evaluates the given performance measures and creates the next candidate sensor placement.

The roadmap of the present paper is as follows. Section 2 describes the proposed multi-objective and multi-operating mode sensor placement problem. Firstly, the reconciliation and estimation of measured and unmeasured variables are discussed, together with the fault detection basics. This will be followed by the presentation of the performance measures used in the objective function of the multi-objective optimisation problem. The applicability and effectiveness of the proposed solution is described in Section 3.

To stimulate further research, the resultant MATLAB codes of the optimisation algorithms are publicly available on the website of the authors (www.abonyilab.com).

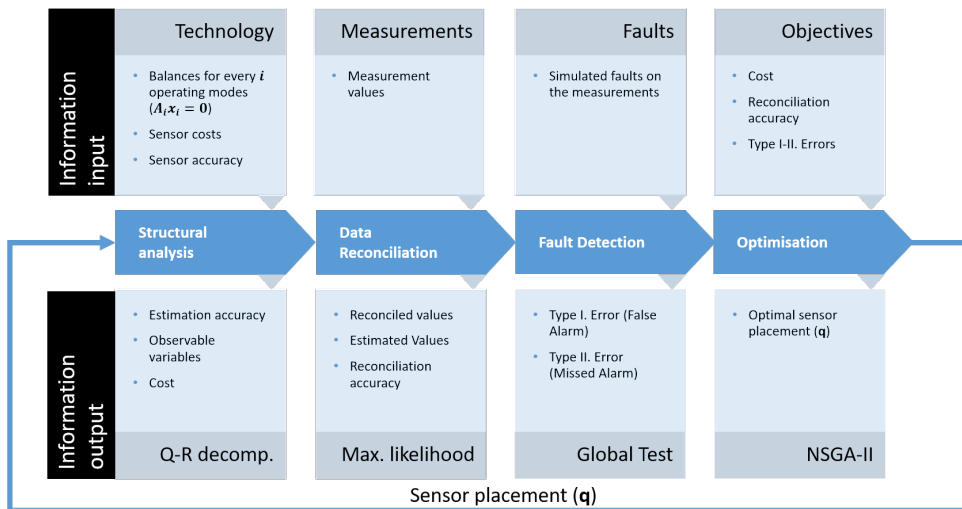

Figure 1: The workflow of the proposed optimisation-based sensor placement methodology. The optimisable variable is the **q** binary vector indicating whether the kth variable is measured ($q_k = 1$) or not ($q_k = 0$).

2. The multiobjective multi-mode sensor placement problem

The balance equations of chemical technologies can be compactly represented as the functions of the variables ($\mathbf{x}$) and the inputs ($\mathbf{u}$), $\dot{x} = f(\mathbf{x}, \mathbf{u})$, which is represented by a nonlinear algebraic equation system $\mathbf{0} = f(\mathbf{x}, \mathbf{u})$ in the case of steady state operations. Generally, the variables ($\mathbf{x}$) can be classified into three major groups: variables, whose values are exactly known ($\mathbf{w} = \begin{bmatrix} w_1 ... w_{N_w} \end{bmatrix}^T$), measured variables ($\mathbf{y} = \begin{bmatrix} y_1 ... y_{N_y} \end{bmatrix}^T$) and unmeasured variables ($\mathbf{z} = \begin{bmatrix} z_1 ... z_{N_z} \end{bmatrix}^T$). $\begin{bmatrix} \mathbf{w} \, \mathbf{y} \, \mathbf{z} \end{bmatrix}^T = \mathbf{Px}$ where $\mathbf{P}$ is a permutation matrix, which reorders the elements of vector $\mathbf{x}$ according to this classification system. The general $\mathbf{Ax} = \mathbf{0}$ form of the linearised balance equations can be written as $\mathbf{Ax} = \mathbf{AP}^T \mathbf{Px} = \mathbf{AP}^T \begin{bmatrix} \mathbf{w} \, \mathbf{y} \, \mathbf{z} \end{bmatrix}^T = \mathbf{0}$ where $\mathbf{AP}^T = \begin{bmatrix} \mathbf{A_w} & \mathbf{A_y} & \mathbf{A_z} \end{bmatrix}$ and the matrices $\mathbf{A_w}$, $\mathbf{A_y}$ and $\mathbf{A_z}$ are the columns of the original $\mathbf{A}$ matrix assigned to the variables $\mathbf{w}$, $\mathbf{y}$ and $\mathbf{z}$, respectively. Hence, the $\mathbf{Ax} = \mathbf{0}$ form of the balance equations can be expressed as $\mathbf{A_w w} + \mathbf{A_y y} + \mathbf{A_z z} = \mathbf{0}$. The aim of data reconciliation is to minimize the difference between the measured and the reconciled values taking into consideration the variance of the measurements and the constraints formed by the balance equations of the system. This can be expressed by the following constrained objective function:

$$\min_{\hat{\mathbf{y}}} (\mathbf{y} - \hat{\mathbf{y}})^T \mathbf{V}^{-1} (\mathbf{y} - \hat{\mathbf{y}}) \tag{1}$$

subject to $\mathbf{A_y} \hat{\mathbf{y}} + \mathbf{A_z} \hat{\mathbf{z}} = \mathbf{b}$ (2)

where the vectors $\hat{\mathbf{y}}$ and $\hat{\mathbf{z}}$ are the vectors of estimates (reconciled values) for the measured and the unmeasured variables, respectively. If $rank(\mathbf{A_z}) = r$ and N_u is the number of unmeasured variables then we know that at least $N_u - r$ variables are unobservable and the vector of unmeasured variables can be divided into observable and unobservable variables $\mathbf{z} = \begin{bmatrix} \mathbf{z_r} & \mathbf{z_{N_u-r}} \end{bmatrix}^T$. Since observability is a key aspect of industrial process control, in the following we investigate the observability of $\mathbf{z_r}$.

Most industrial processes can be operated under multiple operating modes and this can be indicated by the modified incidence matrix of the technology. Therefore, the general $\mathbf{Ax} = \mathbf{0}$ equation can be replaced by the $\mathbf{A}_i \mathbf{x}_i = \mathbf{0}$ equation, where $i = 1 ... N_m$ indicates the operating mode. However, in order to keep the representation simple, we only indicate the operating modes in situations where it needs to be highlighted. An example for different operating modes can be the optional deletion of Stream 3 in certain operating modes in Figure 2 (marked with red). Since the element $\mathbf{A_w w}$ is known, it is useful to replace it by $-\mathbf{b}$ and reformulate the equation as $\mathbf{A_y y} + \mathbf{A_z z} = \mathbf{b}$.

Figure 2: Definition of the operating modes and their objective functions

The core concept of optimal sensor placement design is to determine which process variables to measure in order to maintain an optimal trade-off between the cost (both in terms of capital and operational costs) and accuracy of measurements. However, primarily the cost and accuracy of measurements is mentioned, these goals call for further practical aspects: the control goals of the optimized industrial facility and the robustness of the control network. According to Bagajewicz (1997), the robustness of a network incorporates three properties: availability, error detectability, and resilience. Based on this, the following objectives are defined:

Cost of the network: For all the measured variables there is a measuring instrument with an associated cost c_k. Assuming a binary vector variable **q** with the following definition: $q_k = 1$ if x_k is measured, $q_k = 0$ if x_k otherwise. The cost of the sensor network can be expressed as $C(q) = \sum_k c_k q_k$.

Observability: The observability of the variables of the analysed or planned technology is a crucial industrial factor. Therefore, the placement of sensors aims to maximize the number of observable sensors through both measurements and the estimation of unmeasured variables, $N_{obs} = N_y + N_r$.

Reconciliation error: Assigning the reconciled and estimated observable variables as $\hat{\mathbf{o}} = \begin{bmatrix} \hat{\mathbf{y}} & \hat{\mathbf{z}}_\mathbf{r} \end{bmatrix}$ and **o** as the nominal value of these variables, the reconciliation error can be calculated. In the following this error term is marked as *RMSE*.

Gross error detection: In most of the cases during data reconciliation, only normally distributed random errors are assumed to be present on the measured data. However, due to different faults in the analysed process, gross errors can be present as well. In order to determine the presence of gross errors, one of the first test proposed by Ripps (1965) and Almasy and Sztano (1975), the global test was applied. However, the test does not indicate the place of the gross error, it provides a good preliminary analysis before the application of more advanced techniques. Therefore, the results of the hypothesis tests are applied as a performance measure to describe the detectability of the network using the *Type I* error (false alarm) and *Type II* error (missed alarm).

Our aim is to design sensor networks that simultaneously meet multiple requirements, so we intend to design sensor networks that optimal from the view of all m properties in every N_m operating modes $\mathbf{Z}(\mathbf{q}) = \begin{bmatrix} Z_{1,1}(\mathbf{q}), \ldots Z_{1,m}(\mathbf{q}) \ldots Z_{N_m,1}(\mathbf{q}), \ldots Z_{N_m,m}(\mathbf{q}) \end{bmatrix}$. In practice, we look for four properties to be optimal: $Z_{i,1}(\mathbf{q}) = min_q\ C(q)$, $Z_{i,2}(\mathbf{q}) = min_q\ RMSE$, $Z_{i,3}(\mathbf{q}) = min_q\ Type\ I$, $Z_{i,4}(\mathbf{q}) = min_q\ Type\ II$.

The huge search space is further complicated by the often competing objectives of the design process. A genetic algorithm is a promising method for the generation of multipurpose senor configurations. Multi-objective optimization algorithms generate a set of optimal solutions. The Pareto fronts of these solutions simultaneously consider several design aspects. Since when solving the problem multiple operating modes and objectives must be taken into consideration at the same time; the problem has been implemented in a well-established genetic algorithm-based multi-objective optimization environment, the Non-dominated Sorting Genetic Algorithm-II (NSGA-II) Deb et al. (2000). The search space is conveniently described by the binary **q** vector. The observability is tested by feasibility constraints.

3. Application example

The applicability of the proposed optimisation-based sensor placement methodology is demonstrated on two benchmark data reconciliation tasks, the mass flow network originally published by Rosenberg et al. (1987) and the steady state steam-metering example of the methanol synthesis unit of a large chemical technology Serth and Heenan (1986) as presented in part (a) and (b) of Figure 3. The multiple operating modes are defined by deletion of the streams marked by red in (a) and (b) of Figure 3 (Stream 9 in part (a) and Stream 2 and 14 in part (b)). The networks in part (c) and (d) show an exemplary optimal sensor placement solution for the networks presented in part (a) and (b), respectively.

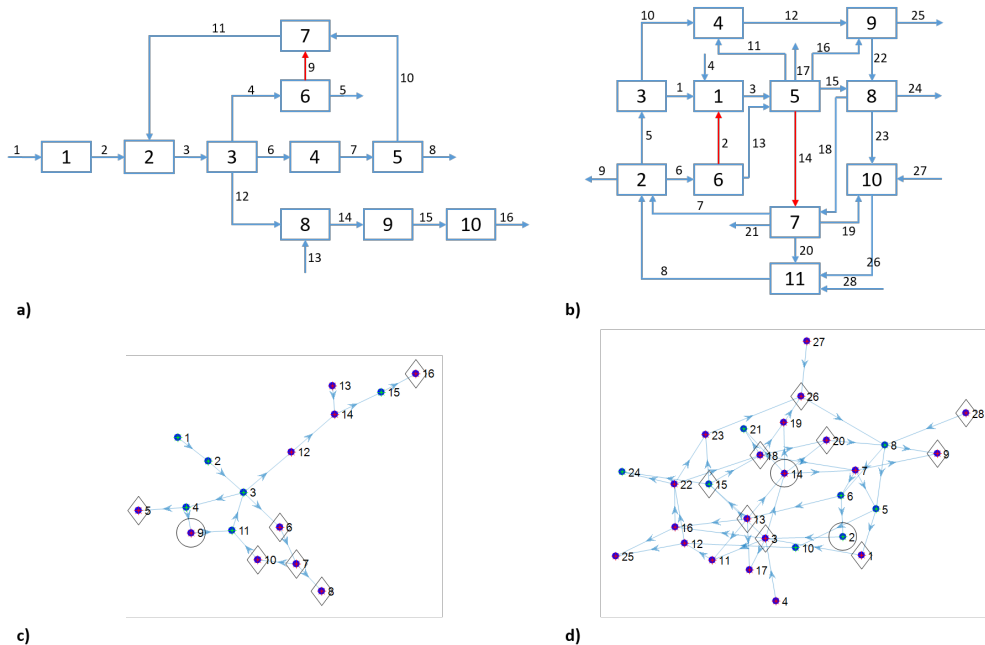

Figure 3: Network representation of the analysed technologies and an exemplary solution of their optimal sensor placement. The mass flow network of Rosenberg et al. (1987) and its solution (a, c) and the steam-metering system for methanol synthesis of Serth and Heenan (1986) and its solution (b, d). In the exemplary solution of networks (c, d) the streams are represented by the nodes, the nodes marked by red and green stars show the measured and estimated variables, respectively, while the nodes framed with a diamond shape are the nonredundant measurements. The circles show the streams that are neglected in certain operating modes (same as the red streams in part (a, b)).

As can be seen in the bottom part of Figure 3, every streams are observable in the network, although some of them are estimated instead of sensory measurements. The redundant measurements increase the accuracy of data reconciliation and increase the detectability of the network. Figure 4 shows the normalized values of the cost function of the obtained Pareto optimal solutions on a parallel coordinates-based visualisation for the problem published by Rosenberg et al. (1987).
Figure 4: Parallel coordinate representation of the conflicting objectives

4. Conclusions

According to our knowledge, this paper is the first (and yet only introductory) work that defines the problem of multi-mode sensor placement as a multi-pbjective optimization problem. The cost, accuracy, Type I and II errors of the gross error detection performance were defined as cost functions to evaluate each configurations of the technology, while the constrains were defined to ensure the observability of the system. To handle these conflicting objectives and the complexity of the search space, the NSGA-II evolutionary optimization algorithm has been utilized. The efficiency of the proposed approach is examined through two modified benchmark problems with multiple operating modes. The results prove the applicability of the proposed algorithm and motivate our work for the improvement of the algorithm for dynamic sensor placement with different sensor types.

Abstract

Islands are very special geographical areas with distinct and unique characteristics, often presenting slow infrastructure advancement, rendering the 'Water-Energy Nexus' (WEN) subject of increasing attention at all levels of policy making. This works aims to contribute in the optimisation of infrastructure development for the integrated solutions of water-energy systems by devising suitable optimisation models that capture technical and economic aspects. The developed framework is applied to a set of two Aegean Sea islands, assessing alternative scenarios for energy and water planning, with vast RES penetration, either if each island operates in stand-alone mode or the two of them interact as an energy community, via an undersea cable. The results of the work evidence that the solution of interconnection between remote islands could be economic viable, thus leading to downsized plants' installations and decreased capital investment costs, as greater exploitation of RES is achieved.

Keywords: Water-Energy Nexus, Islands, Frameworks, Desalination, Interconnection.

1. Introduction

Water and energy are two fundamental resources with the supply of one highly depended on the availability of the other. The recognition that their scarcity underpins socio-economic development, has resulted a growing interest of policy makers in the so-called 'Water-Energy Nexus', a policy priority which is also reflected in the rising interest of the research community: the water-energy (WE) supply problem affects all types and sizes of contemporary communities around world due to the spatial characteristics of the water availability, also challenged by the availability and the security of energy supply.

With our special focus on small-scale and isolated economies and societies, like the ones of the Aegean Archipelagos that are more likely to be affected by WE problems, the present work seeks to introduce an integrated evaluation framework for the optimal design and operation of water and energy supply chains (WESCs) with special focus on the community-based perspective. To that end, two scenarios are currently elaborated: a) optimisation of the WESCs of two typical Aegean islands operating independently (stand-alone mode), resulting for each one the most economic and environmental viable energy and water supply solution for the upcoming 25 years and b) the two islands operating as a community, being interconnected via undersea cable, revealing possible WE synergies (energy interactions) for the community to exploit. The proposed WESC optimisation framework, apart from achieving the optimal design of the energy and water supply systems (considering RES-based hybrid energy configurations) of the two islands, also

investigates the performance of their interconnection as a feasible and profitable / valuable solution.

2. Background of the work: The island communities' dimension in the WESC optimisation problem

Islands render a special field of study in the WESCs optimisation, focusing on the local specific characteristics of each community namely size, topography, population, energy and water demands. That is why, well-known island communities have been extensively studied by the researchers seeking to identify the optimum WESC, for now and for the future. Focusing on the Aegean Sea, aiming at establishing a sustainable electrification model, the "Green Island" model for (island) communities, Kaldellis et al. (2017) carried out a theoretical analysis estimating the contribution of wind energy curtailments (of both new and existing parks) on the island's energy supply. The results of the work, under the elaborated case study for the island of Kos strongly support the necessity of energy storage introduction, if one may compare the expected and the finally absorbed wind power of the installation: 9.74GWh (final absorbed wind power, according to the official data by the local operator), while the expected wind energy yield was 14.13GWh (on the basis of the available wind potential), thus almost curtailing 4GWh of clean electricity on an annual basis.

Acknowledging the necessity of sustainable energy supply at small-scale islands on the basis of RES, Bertsiou et al. (2018), investigated the implementation possibilities of a Hybrid Renewable Energy System (HRES) in Fournoi island, operating on the basis of hydropower for electricity generation aiming at meeting both drinking and agricultural water demands through desalination of sea water, with wind contribution used for supplying the local power network and for pumping and/or desalination operation depending on the scenario examined. The results of the work support the possibility of achievable high level of water and energy coverage and days of electricity autonomy, according to the water coverage consumption pattern.

Towards the same direction, Papapostolou et al. (2018), emphasising also on small-sized islands, thus energy and water vulnerable islands, studied the case of Irakleia, an island of 151 inhabitants during winter season. With the current energy supply both for the existing desalination plant and the electricity demands of the islanders being met by conventional fuels, which also demanding water imports via shipments to fulfil irrigation needs, the authors propose a RES-based desalination configuration (wind turbine, PV, energy storage battery) limiting the diesel operation to meet just the stability of the network. The results of the work also support high RES energy coverage minimising the CO_2 (diesel-based emissions by ~92%) balancing the calculated capex required for the specific solution (1.87MEUROS).

Tzanes et al. (2017), also dealing with the emerging issue of electrification of remote islandic Greek communities, developed an advanced software tool named Energy System Analysis (ESA), for evaluating different energy and water local scenarios, accounting also the available geographical information and the corresponding RES potential characteristics of the island examined. The study identified optimal solutions comprising HRES and desalination installations for the islands of Anafi and Agios Efstratios, with minimised LCA costs achieved for 85% annual coverage of electricity demand.

Consequently, one may conclude that using hybrid power systems results to better balances in energy supply while facilitates the matching of demand and production, with energy storage contributing also towards this direction. However, of great significance is also proven the consideration of larger spatial distribution of RES generation along with the aggregation of diversified load and water demands (community-based perspective), which, in the majority of the cases, leads to improved cost performances.

3. Case study characteristics

The proposed framework is implemented in two (medium-sized) remote islands of South Aegean Sea, namely Amorgos and Astypalaia. Both islands are characterised by a) high wind and solar potential, capable of achieving high RES capacity factors (Fig. 1a, 1b) and b) by significant water deficits, some of them met by ship transfers (Table 1). The load demand profile in these islands is characterised by high alteration, as tourism is the main economic activity. The most recent official available data (2013 for Amorgos and 2014 for Astypalaia, with no variations till today, as stated by the local authorities) are presented in Fig. 1c. In the case of water (in the absence of official recorded data) a typical (hourly-based) water demand profile is assumed, reflecting the islands' potable water and irrigation needs (~57,000 m^3 for Amorgos and ~37,500 m^3 for Astypalaia). The water and electricity needs have a similar pattern in time. However, in the case of water demand, the profiles present a quite low correlation. Therefore, the results of the work include an optimal WE solution for each island separately and in the second case as a community for a time-span of 25 years.

Table 1. Annual water deficits for Amorgos and Astypalaia (YPEKA, 2015)

| Island	Irrigation (m³)	Potable (m³)	Ship transfers (m³)	Total (m³)	Peak demand (m³/h)
Amorgos	~7,500	14,000	~35,500	57,000	27,2
Astypalaia	12,500	25,000	-	37,500	24,8

Figure 1. a) PV and b) wind power utilization factors, c) the load demand profiles and d) the islands hourly water demand correlation

4. Optimisation model

For the evaluation of the optimal power and water supply systems size in stand-alone mode, the optimisation model developed by Papapostolou et al. (2018) has been deployed. The key features of the model include two interlinked components, Eq.(1) and Eq.(2), the energy balance of the system (island or islands) and the island's water tank (WT) balance, for a time step of 1h, respectively:

$$\sum_{r=1}^{r=\max} Eg_r(t) + ESSg(t) - ESSs(t) - \sum_{l=1}^{l=\max} Ed_l(t) = 0 \tag{1}$$

$$WTank(t) = WTank(t\text{-}1) + \sum_{wr=1}^{wr=\max} F_{wr}(t) - Wd(t) \tag{2}$$

Where, in Eq.(1), 'Eg_r', represents the energy production of the resource, 'r' (wind, diesel and solar PV power installations), at time step, 't', '$ESSg$' and '$ESSs$', stands for energy storage either generated or stored accordingly, and finally the electricity needs are represented by 'Ed_l', with the index 'l' being equal to 1 for the present load demand and 2 for additional demand due to the desalination plant operation. Water balance described in Eq.(2), considers a typical water storage tank operation, whereas the level '$Wtank(t)$' at each time step 't' is a function of the water initially stored '$Wtank(t\text{-}1)$', as well as of the sum of the inflows '$Fwr(t)$' of water resources 'wr' minus the water demand '$Wd(t)$'.

In the case of integrated operation (two islands operating as a community in terms of exchanging energy), which becomes possible through an undersea cable installation, the main model modifications are applied in the system's electrical balance Eq.(3), the energy storage Eq.(4) and in the objective function Eq.(5):

$$\sum_{r=1}^{r=\max} Eg_r(t) + ESSg(t) - ESSs(t) - \sum_{l=1}^{l=\max} Ed_l(t) - \frac{Et_{load}^{isl}(t)}{\eta t} + Et_{load}^{isl+1}(t) * \eta t = 0 \tag{3}$$

$$ESSs(t) \leq dEres^+(t) - \frac{Et_{storage}^{isl}(t)}{\eta t} + Et_{storage}^{isl+1}(t) * \eta t \, , \tag{4}$$

$$f_{\to\min} = \frac{\sum_{r=1}^{r=\max} \left[N_r * IC_r * (1 + n * FC_r) \right]}{(1+i)^n} + \frac{n * \sum_{t=1}^{t=\max} Eg_{r=diesel} * OC_{diesel} + F_{ship}(t) * OC_{ship}}{(1+i)^n} \tag{5}$$

$$+IC_{cable}(D, N_{cable})$$

More precisely, the 'Et' stands for energy transfers. The index '$load$' refers to the case of energy generated directly addressing (sent) to meet electricity needs, and the index '$storage$' indicates the energy transfers for charging the energy storage systems. The upper index indicates whether the energy is provided, at island 'isl', or drawn, from every next island '$isl+1$'. The term '$dEres^+$' represents the renewable energy surplus, which occurs when the renewable energy production potential is larger than actual utilisation of the installations. The losses of trading energy are represented by the factor 'ηt'. Concerning the objective function to be minimised Eq.(5), it represents the installation 'IC_r', maintenance 'FC_r' and operation costs 'OC_r' for 25-year time-period, of resource

'r'. The last term 'cable' stands for the installation cost of the undersea cable, which is a function of the distance between the two islands and its power capacity (Fig. 2, Kokotsakis 2018). Both optimisation problems, were modelled as Linear Programming Problems (including 30 blocks of equations and 19 of respective variables) in GAMS (www.gams.coms) and solved with NEOS Server IBM ILOG CPLEX Optimizer (https://neos-server.org) with typical computational times starting from 5s. NEOS Server is hosted by the Wisconsin Institutes for Discovery at the University of Wisconsin in Madison with typical high-level hardware specs.

5. Results

5.1. Stand-alone, island operation

Model implementation resulted viable solutions (in terms of plant-sizes, see Table 2) for both examined scenarios. In stand-alone mode, the islands have a similar behavior, mostly utilising RES for the operation of the corresponding desalination plant (Fig. 2a), which is sized to 0.33 and 0.43 times peak hourly water demand, for Astypalaia and Amorgos island respectively (Fig. 2c). At the same time, the water tanks are mostly utilized until the electricity demand peaks (Fig. 2d).

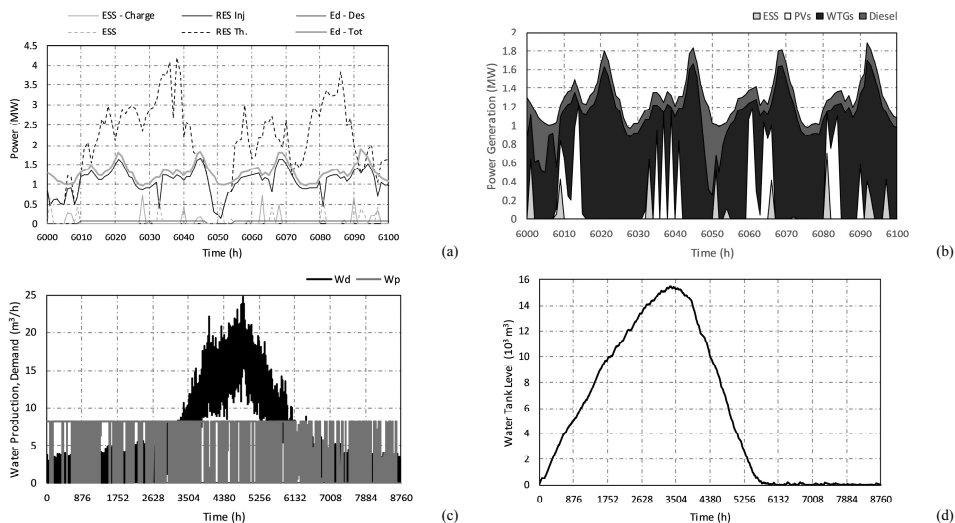

Figure 2. Optimal W-E solutions for Amorgos (a,b) and Astypalaia (c,d)

5.2. Community-based islands' operation

In the scenario of islands operating as a community, via an undersea cable of 1 MW capacity (40km in length), the flexibility in designing (allocation of resources) as well as exploiting individuals' RES surplus for covering the needs of the opposite island accordingly, results mainly to significant downsizing of thermal power and energy storage capacity as well as large increase in installed wind power (Table 2). In terms of cost, accordingly, the total expenditures get reduced from 50.2M€ (stand-alone scenario) to 41.36M€ (community-based scenario). The approx. 8.5M€ difference justifies a further research and application of the framework to islands with similar distance and features (different size, complementarity in energy demand), hence a large number of Aegean islands, heavily relying on diesel.

Table 2. Optimal Capacities- Modeling Results

Stand-alone, island-based operation optimal results				
Island	Diesel Plant (MW)	Wind Park (MW)	PV Park (MW)	ESS Cap. (MWh)	Desalination Plant (m³/d)
Amorgos	1.91	3.01	1.39	0.84	287
Astypalaia	2.04	1.74	0.73	0.23	199
Community-based (set of islands) operation optimal results				
Amorgos	1.83	2.88	1.26	0.46	235
Astypalaia	1.72	2.42	0.05	0.17	181

Conclusions

In this work an integrated WESCs optimisation framework has been introduced and tested comparing the single-island to the community-based (island) operation. The results evidenced that RES-based hybrid energy supply solutions including the desalination option are economically attractive for small-sized Aegean Sea islands while also serving at increasing the security of supply, especially under the community-based perspective and for reasonable cable sizes (length and capacity). The present framework will be further tested to other sets of islands (more than 2), with characteristics and complementarities regarding water and energy demand and RES potential (e.g. Santorini-Anafi (distanced ~24km)), for enabling strategic planning with regards to Aegean Sea islands water and energy future infrastructures.

Abstract

Lactic acid is one of the most important organic acids on the market due to its wide field of applications. The bio-production of lactic acid has acquired great attention due to the environmental and energy benefits; however, its production bottleneck by fermentation is the cost of the separation and purification stages, representing about 50% of total production cost. Therefore, reducing such costs through the development and design of purification technologies is mandatory. This work presents a techno-economic assessment for lactic acid bio-production process from the residues of the sugar industry, using different alternatives of separation and purification technologies, namely reactive distillation and reactive extraction. The design of the separation systems was performed in Aspen Plus and Matlab. The lactic acid production processes were evaluated to determine the economic feasibility of each separation strategy based on the total annual cost (TAC) and return of investment. It is shown that reactive extraction reduced the total annual cost and energy requirements with respect to reactive distillation by 44% and 37.5%, respectively. Additionally, the return on investment using reactive extraction is 1.2 years faster. Therefore, the reactive extraction process appears as a promising alternative to increase profitability of lactic acid bio-production within a biorefinery. Finally, it is important to highlight that this work discusses the design of a novel reactive extraction system for lactic acid recovery; and, to the best knowledge of the authors, this emerging technology is still under experimental development and has not been extensively investigated from a simulation perspective.

Keywords: Lactic acid production, Aspen plus, Reactive distillation, Reactive extraction

1. Introduction

In a bio-economy, the production of high value-added products from renewable resources, such as biomass, has been established as a strategy to reduce the environmental

impact generated by human activities. Biomass can be used to produce biofuels and other chemicals, thus, decreasing our dependency on fossil fuels as feedstocks. Particularly, one of the chemical products that can be obtained from biomass is lactic acid (LA). Great interest has been placed on this compound due to its diverse applications in the chemical, pharmaceutical, food and plastic industries. More recently, research has focused on LA due to the possibility of transforming it into polylactic acid (PLA), which is considered a biodegradable polymer with applications in the production of packaging, sutures and medical applications in drug delivery systems (Serna et al., 2005)**.** Lactic acid can be produced by chemical synthesis, but it has been estimated that ~90% of the total worldwide production is by bacterial fermentation, since this process uses cheap renewable raw materials, low processing temperatures and low energy consumption (Udachan et al., 2014). However, the bio-production of lactic acid is challenging, especially in the downstream stage, where several separation and purification steps are needed to recover the lactic acid from the fermentation broth. Specifically, it is difficult to obtain high purities of lactic acid mainly due to the high affinity with water and its decomposition at high temperatures. Therefore, separation and purification stages represent up to 50% of total production costs (Komesu et al., 2015).

Several separation techniques have been proposed for lactic acid recovery such as precipitation, distillation, solvent extraction, adsorption and membrane separation processes such as reverse osmosis, electrodialysis, ultrafiltration and ultrafiltration (Prado-Rubio et al., 2009). Despite the efforts, there are still some challenges to overcome, which could be solved at industrial scale, for instance, high equipment cost, solvent recovery and high energy consumption (Komesu et al, 2015). Therefore, the objective of this work is to use a systematic design methodology to perform a techno-economic assessment of the lactic acid bioproduction process, using residues of the sugar industry as main feedstock. Reactive distillation and reactive extraction processes have been investigated to determine their economic feasibility based on total annual cost (TAC) and recovery time. The obtained results showed both technologies potential and could be used as driving force for further technologies development for Lactic acid production.

2. Methodology

For this analysis a calculation base of 28,886.6 kg/h of sugar cane bagasse was considered. The composition of the sugarcane bagasse used was: cellulose (68.22 % w/w), lignin (29.19 % w/w) and xylene (2.59 % w/w). The design of the lactic acid bio-production process used in this paper has been previously proposed by Mendez-Alva et al. (2018). The bio-production stages including pre-treatment, enzymatic hydrolysis and fermentation stages were taken from Morales-Rodriguez et al. (2016). For the separation and purification stages, they have been based on the studies of Pérez-Cisneros et al. (2015), Su et al. (2013) and Pérez et al. (2016). The process was simulated in the software Aspen Plus V8.8 complemented by integrating a Matlab code where it was necessary. The phase equilibrium has been modeled using the NRTL and Hayden-O'Connell thermodynamic methods, according with a previous work (Méndez-Alva et al., 2018), which employed the NRTL parameters of the National Renewable Energy Laboratory (NREL) database (Wooley and Putsche, 1996).

2.1. Reactive distillation

The scheme shown in Figure 1 was used for the purification of LA by reactive distillation (Su et al., 2013). This separation scheme is composed by four sections: pre-concentrator,

esterification, hydrolysis and the alcohol recovery. The process begins feeding lactic acid aqueous solution (30% w/w) from a filtration and precipitation process to the pre-concentrator column. The pre-concentrator column is used to remove excess water from the feed stream. Lactic acid esterification is performed using methanol in a molar ratio of 2:1 alcohol to acid and using Amberlyst 15 as a catalyst at a concentration of 2.5% w/w. Subsequently, in the hydrolysis section, the lactic ester is hydrolyzed back into lactic acid and alcohol using Amberlyst 15 at the same concentration. Finally, at the recovery section the alcohol is separated from the water and other impurities. The alcohol is recirculated to the esterification section while the water can be recirculated to the hydrolysis section. The kinetic model of Sanz et al. (2004) was used to represent the esterification and hydrolysis reaction. The distillation columns presented in this paper have been modeled with the RADFRAC module in Aspen Plus.

Figure 1. Lactic acid purification process by reactive distillation (Su et al., 2013).

The design of reactive distillation columns was a combinatorial optimization problem with total annual cost (TAC) as objective function. A strategy based on sensitivity analysis was performed to design of the separation scheme considering as degrees of column freedom: number of stages (N), the number of reactive stages (N_{rxn}), feed stage of LA (N_{FLA}) and feed stage of alcohol (N_{FOH}). The design methodology for the reactive and non-reactive distillation columns is presented in Figure 2, where ND is the number of designs obtained in the combinatorial problem. The equilibrium stages, the reactive stages of the column as well as the purities of the required products must be specified, while the position of the feed stages to the column are automatically varied by Aspen Plus. Subsequently, considering the all possible designs obtained through sensitivity analysis, the design that minimizes the total annual cost is selected.

2.2. Reactive extraction

On the other hand, the purification of LA by reactive extraction has been proposed to separate the LA from the fermentation broth using trioctylamine (TOA) and 1-dodecanol as diluent (Pérez et al., 2016). The process has been simulated using the EXTRACT module in Aspen Plus. However, the simulator does not have the binary interaction parameters between amine and system components in its database for the NRTL model; therefore, these parameters could be estimated by the UNIFAC method or employ the NRTL parameters and a chemical equilibrium model with distribution coefficients for this system previously published by Pérez et al. (2016). In this simulation, the parameters

estimated by the UNIFAC method were used since the phase equilibrium could not being reproduced using the parameters reported by Pérez et al. (2016).

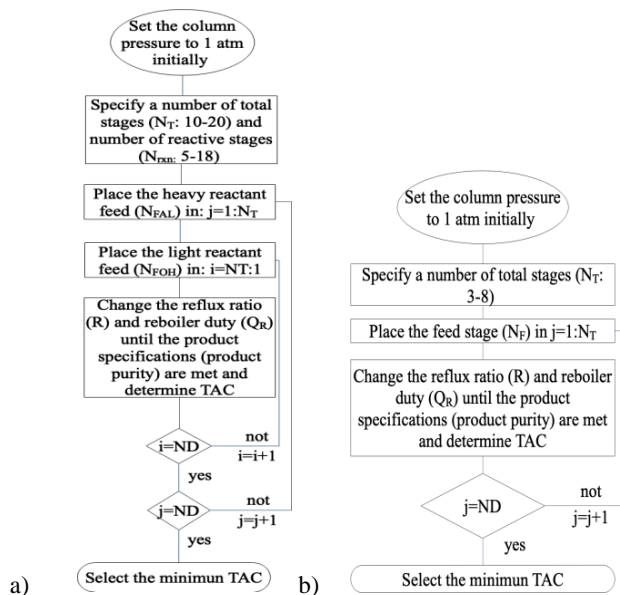

Figure 2. Methodology for the design of the: a) reactive and b) non-reactive distillation columns.

The reactive extraction separation scheme is presented in Figure 3. The extraction was carried out in a counter-current column feeding an aqueous solution of LA (30% w/w) using a molar ratio of 1:1 amine to acid and keeping a concentration of 0.8 mol/L (of TOA in 1-dodecanol). In this system, there is a chemical reaction between LA and TOA producing an amine-lactate complex. This complex promotes separation and provides a greater degree of separation. The extract stream is a mixture of LA-TOA and 1-dodecanol, while the refining stream contains water and a small part of 1-dodecanol. The extract is sent to a distillation column to separate the solvent and TOA from LA and reuse it in the extraction unit.

Figure 3. Lactic acid purification process by reactive extraction.

For the design of the extraction column the equilibrium stages have been determined through the equilibrium model reported by Pérez et al. (2016), which considers the

distribution coefficient, the equilibrium constant of the chemical reaction and the mass balances. It is important to mention that the equilibrium model considers that LA is the only compound transferred from the aqueous phase to the organic phase. The analysis of the best design for the extraction column in terms of TAC was limited because the chemical structure of the amine lactate complex changes according to the molar feed ratio. The calculations required the integration of Aspen Plus and Matlab through COM objects since the reactive extraction module was not available in Aspen Plus as a unit operation.

3. Results

Computer-assisted simulation enabled the design of both purification schemes and the economic evaluation of both technologies using Aspen Economic Analyzer.

The best design of the reactive distillation purification scheme consists of four distillation columns: The pre-concentrator column with 8 stages and the feed stream is introduced at the stage number 4. The esterification column has 17 stages and 5 reactive stages (12-16), feeding the stream leaving the concentrator column through stage number 7, while the methanol stream is fed through stage number 13. The hydrolysis column has 30 stages and 25 reactive stages (5-29), feeding the methyl lactate stream through stage number 10, while the water stream is fed through stage number 20. Finally, the column has 14 stages and the stream containing the methanol-water mixture is fed through stage number 6. The separation system operates at 1 atm pressure and the esterification and hydrolysis reactions are carried out at a temperature of 353.15 K.

The reactive extraction process consists of one extraction column and one distillation column. The extraction column has 5 stages, where La is fed at stage number 1, while TOA and diluent are fed at stage number 5, the extraction column operates at 1 atm and 316.1 K. The distillation column has 11 stages and is fed at stage number 7. Both LA purification designs achieved a purity of 88% w/w.

Table 1 presents a comparison of the economic evaluation for both technologies and Table 2 presents a comparison of the energy requirements of both purification schemes.

Table.1 Costs for the proposed purification processes.

Analysis	Reactive distillation	Reactive extraction
Total Capital Cost (USD)	93,107,800.00	93,107,800.00
Total Operating Cost (USD/y)	49,011,200.00	27,654,000.00
Desired Rate of Return (%/y)	20	20
Return of investment (Year)	2.7	1.48
Equipment Cost (USD)	672,500.00	536,500.00
Total Annual Cost (USD/y)	53,666,590.00	27,680,825.00

Table.2 Energy requirements for the proposed purification processes.

Purification process	Heat Duty (kW)
Reactive distillation	31,601.00
Reactive extraction	19,771.00

The economic evaluation of both technologies has shown that reactive extraction substantially reduces the total annual cost of LA purification by 44% compared to reactive distillation. Also, using reactive extraction for LA purification reduces the energy requirements of the purification stage with respect to the use of reactive distillation by 37.5%.

4. Conclusions

A techno-economic analysis of the LA reactive purification technologies has been carried out. Both processes have been designed and analyzed using CAPE tools. The use of reactive extraction in LA purification promises to substantially reduce total LA production costs and energy requirements. However, this technology according to Technology Readiness Level (TRL) is still under development (TRL 3 - TRL 7) because the exact nature of the chemistry involved in acid absorption is unknown and the chemical structure of the complex varies according to several factors, such as: the concentration of the LA in the aqueous phase, the type of diluent and the molar amine to acid feed ratio. Therefore, efforts should be made to provide more reactive extraction system understanding that allows to have more accurate prediction useful for detailed design. However, this work is the starting point for the development of a methodology for the design and simulation of reactive extraction systems for LA recovery in Aspen Plus. Finally, reactive distillation presents a total annual cost and much higher energy requirements, however, the results obtained are much more reliable because it is a mature technology (TRL 8 - TRL 9), which has already been tested industrially.

Abstract

Jet biodiesel derived from energy crop has been promoted by the Chinese government to decrease oil dependence of the aviation industry. This study carried out a life cycle assessment on jatropha-based jet biodiesel in China condition to evaluate the energy balances and GHG emissions. This life cycle process covered data from Southwest China with the help of CNPC. Detailed information with practical data in the production process and by-products recycling ways were provided. 18 cases were utilized to compare the influence of different planting output, oil extraction model and recycling pathway. Centralized extraction model and by-product re-used as fertilizer and biogas can be developed in the future. The formation of a multi-scene analysis results is useful for policy makers

Keywords: Life-cycle analysis, jet biodiesel, Jatropha, By-product, Scenario analysis

1. Introduction

China had become the world's largest oil consumer and GHGs emitter (EIA. 2014). The aviation industry, which had since long been pointed out as fastest growth contributors to global warming in the transportation sector, emited 2% of global GHGs emissions (Jong, S. D et al. 2017). A huge increasing demand of jet fuels not only led to an increase crude oil imports and price but also an potential risk for energy safety (Han J. et al. 2013).

Jet biodiesel derived from energy crop had been promoted by the Chinese government to decrease oil dependence of the aviation industry, according to the Medium and Long-term Development Plan for Renewable Energy issued by the National Development and Reform Commission, 2007. However, the controversy surrounding the social impacts such as food safety and environmental impacts promoted the government to impose a ban on expanding grain-based jet biofuel production(Hong, Yuan et al. 2009). In order to find a truly sustainable jet biodiesel, the feedstock should be an effective alternative to mitigate GHGs emissions, should be economically feasible to plant, and should not threat food security.

Jatropha curcas appeared to be an idealized feedstock to produce jet fuel in China conditions (Hou J et al. 2011). These inedible crop grows widely in the Southwest China due to its stable price, drought tolerance, and little agricultural inputs (Blanco-Marigorta et al.2013). While some environmental impact studies were carried out from India (Kumar S, 2012), Mexico (Fuentes A, 2018), US (Han J. et al. 2013; Stratton R W, 2011), Nigeria (Onabanjo T, 2017), a few studies had been carried out in China. Ou X et al. (2009) examined the jatropha curcas as one of six biofuel pathways in China, considering the fossil energy consumption and greenhouse gas emissions. Other impact categories

were taken into account to evaluate the sustainability of jatropha curcas comprehensively by Hou J (2011). Both of them considered LCA on the same scenario. Wei et al. (2018) carried out a LCA of corn-based jet fuel production using Fischer-Tropsch synthesis. Except this, there are few practical data regarding jatropha production process and few case about the use of the by-products from jatropha oil extraction. In addition, studies have little knowledge about whether distributed production or centralized production is better.

Besides, jet biodiesel are considered as a low-carbon alternative to fossil fuels. At a country level, the China National Petroleum Corporation (CNPC) had promoted Jatropha jet biodiesel production under the policies and financial supports from the government since 2011. The documents by government and companies both target mitigation of GHG emissions as central sustainability criteria. However, there are a few studies on the GHG balance of jet biodiesel from jatropha to give advice to policymaking.

This study carried out a life cycle assessment on jet biodiesel made from jatropha in China condition to evaluate the energy balances and GHG emissions in order to provide more detailed information and data in the production process and by-products recycling. Different allocation methods were combined to deal with various by-products. Scenario analysis were utilized to predict different plant output and oil extraction model. Three by-products from oil extraction recycling pathways were investigated. The formation of a multi-scene analysis results is useful for policy makers.

2. Methods

2.1. LCA framework

A cradle-to-gate LCA was performed with GaBi ts Education software. The analysis focuse on determine the energy consumption and GHGs emissions of jet biodiesel produced by jatropha in Southwest of China, to compare the results with different oil extraction model and to find an eco-friendly by-products recycling pathways.

2.2. System boundary and functional unit

The stages considered and the calculation logic of the energy consumption and the GHGs of the entire process is present in the Figure 1, including the plant cultivation, production and transport process. Effects of fertilizer emissions and land use change will not be considered for the moment due to the data given in the IPCC Guidelines have large deviations. The assessments were compared on the basis of their GHG emissions in g

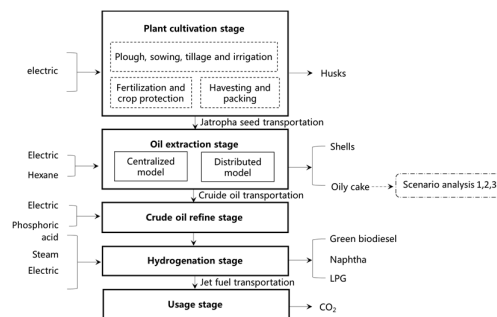

Figure 1. Product system boundary of this study.

Table 1 Allocation method for by-products

By-product	Method	By-product	Method
Husk	Energy method	Jatropah oily cake recycling as fertilizer	Displacement method

Naphtha	Energy method	Jatropah oily cake recycling as biogas	Displacement method
LPG	Energy method	Green biodiesel	Energy method

CO_2 per MJ and energy consumption in MJ per Kg of jet biodiesel produced from jatropha.

2.3. Product system description

In the plant stage, three planting output conditions were investigated: low output, basic output and high output which depends on the management level and effect of fertilizer. There were two kinds of oil extraction models: distributed extraction model where famers extracted jatropha on local plant transported oil to the refine factory, and centralized extraction model where here the jatropha was transported to the centralized extraction factory. The hydrogenation process was based on technology from the UOP company.

2.4. Method to deal with of by-products

In this case, there were various by-products in the production process. There are four allocation method: displacement method, and the mass, energy, market method. Different allocation methods showed in the Table 1 were combined for different by-product, considering the practical data and usage of the by-product.

2.5. Scenarios for reusing the by-products

For the further applications, the jatropha oily cake that can be used as forage, fertilizer or biogas will be comprehensive utilized. The data were gained from the factory and the farmers. The possible systems for recycle the jatropha oily cake are divided into 3 scenarios: Scenario 1: All the jatropha oily cake is used to fertilizer; Scenario 2: After detoxification, all the jatropha oily cake is used as forage to replace soybean; Scenario 3: All dried distiller produce biogas, where need extra coal.

2.6. Life cycle inventory

Based on the investigation with the technology developer and farmers, open LCI databases and references, the part of key LCA parameter is showed in the Table 2.

Table 2 Parameter about jet biodiesel production (To produce 1 kg jet biodiesel)

| Item Parameter	Value						Item Parameter	Value

Figure 2. Energy consumption of the basic case in each production process.

3. Result and discussion

3.1. Energy consumption in the basic condition

The contribution of different processes and different oil extraction model to the energy consumption are showed in the Figure 2. The total energy consumption is 61.04 MJ primary energy/kg jet biodiesel in the basic output of centralized extraction model, while the energy product occupy 78.24 MJ including all the by-product. The total energy efficiency is 0.78 MJ primary energy/MJ jet biodiesel. Because of a lot of fertilizer input, the planting unit exhibits high contribution to energy consumption. Besides, the centralized extraction model is benefit for mitigation energy consumptions, it may be because of its advanced technology and high rate of extraction, but it also need time to develop the famers' market. To reduce the GHGs and enhance energy efficiency, enhancing the separation efficiency or using by-product to supply energy can be considered.

3.2. Scenario between output, extraction model and recycling of by-products

To illustrate the impact of output, oily cake extraction model and recycling of by-products, Figure 3 shows that the emissions for the Jatropha range between -36.28 and 466.69 g CO_2 /MJ for 18 cases. Scenario 2 increased a lot of GHGs emissions and the detailed reason will be discussed in the next part. For different planting output, it's obvious that the harvest yield is the key factor. The high output cases even cause negative emissions in the scenario 1 and 3, this may be because the by-products replaced a high emission substitution and the professional plantation management increased the efficient of fertilizers. From the Figure 3 it can be concluded that scenario 1 and 3 have positive environment impact, comparing to the fossil fuel, whose baseline is 91.8 g CO_2 /MJ in the US renewable fuel standards (WTW).
Figure 3. 18 cases with different planting output, recycling scenarios and extraction models.

3.3. Influence of recycling by-product

To examine the high emission in the scenario 2, Figure 4 shows the GHGs emission in each process where the jatropha oily cake from the oily extraction process will be used as forage. The detoxification for recycling need huge fuel and chemical substances input such as methyl alcohol. But the high economic value of forage, such as soybean, is an considerable reason to recycle by-product. From the scenario analysis, the conclusion that comprehensive utilization about the by-product especially like jatropha oily cake will have huge influence to the environment impact can be drawn.

4. Conclusion

The life cycle analysis about the jatropha jet biodiesel in the southwest China was conducted in this study. 18 cases with different oil extraction model, planting output and recycling pathway for by-products was utilized to compare the influence to energy consumption and GHGs emissions in the production process. The result shows that centralized extraction model is better than distributed extraction model especially in the low planting output condition. Scenario 1 and 3 showed the systematic and suitable utilization of by-product will improve the environment impact, with the emission of 80.1-88.28 g CO_2 /MJ even in the low output case of centralized model. The practical data regarding plant process and cases about the use of the by-products is valuable to the researchers. Besides, the formation of a multi-scene analysis results is useful for producer and policy makers.

Abstract

The current work addresses the investigation of phase-change solvents behaviour during the design of post-combustion CO₂ capture processes. The use of phase-change solvents leads to energetic gains due to their lower regeneration energy demands. The latter are enhanced in this work by the consideration of systematic structural and operating modifications imposed on a reference absorption/desorption flowsheet. Such modifications are realized with the help of a rigorous and flexible model that can represent the phase-change behaviour and includes stream redistribution options that aim to enhance the main process driving forces. An aqueous N-methylcyclohexylamine (MCA) solution is employed in an effort to exploit the solvent's phase separation behaviour towards the reduction of the total process cost and energy requirements.

Keywords: CO₂ capture, optimal design, phase change solvents, MCA, N-methylcyclohexylamine.

1. Introduction

Solvent-based absorption/desorption processes represent a mature technology for post-combustion CO₂ capture. A major drawback is the high regeneration energy requirements which prohibit the wide industrial adoption of such systems. Phase-change solvent processes are emerging as a new and promising technology which enables up to 50% reduction in regeneration energy requirements (Pinto et al., 2014). This is achieved through the use of solvents which exhibit phase-change behavior due to the appearance of a second liquid phase upon reaction with CO₂ and possibly a subsequent increase of temperature. This enables the use of a physical process usually in the form of a decanter to separate the two liquid phases; one of them can be partially or totally recycled directly to the absorber, whereas the other is transferred to the desorber, resulting in significant energy reduction. Despite the obvious advantages, there is very limited research addressing modelling and design of such systems, leaving considerable space for performance improvements. The very few reported studies pertain to technoeconomic assessment of specific solvents using commercial software, with no systematic optimisation approaches reported to date (Raynal et al., 2011; Pinto et al., 2014).

In this work, a rigorous and flexible model that can represent the phase-change behaviour of absorption/desorption CO_2 capture processes is proposed. The column models are based on the orthogonal collocation on finite elements (OCFE) technique tailored to three phase systems that support a sufficiently accurate but also computationally tractable process representation. The main advantages include the transformation of discrete process characteristics into continuous decision variables, and the ability to represent and track sharp changes of important variables such as concentration and temperature profiles along the column domain. The model is also employed in the context of a superstructure representation which supports optimisation.

2. Methodology

2.1. Modelling framework

The use of phase-change solvents (PCS) systems in CO_2 capture processes provides the opportunity for enhanced performance as well as the reduction of process energetic demands and economic resources through the exploitation of their liquid-liquid phase separation capabilities. The optimum design of three-phase flowsheets is challenging because it requires (a) a systematic modelling approach able to capture transitions between vapour-liquid (VLE) and vapour-liquid-liquid (VLLE) equilibria regimes, and (b) an underlying framework, which is sufficiently flexible to account for the interactions of the large number of the desired structural and operating features.

The modeling framework employed in this work to meet requirement (a) is based on the OCFE approximating technique (Dalaouti and Seferlis, 2006; Damartzis and Seferlis, 2010) to model three-phase reactive separation systems. The separation column is divided into column sections, defined as the column segment between two successive feed or draw streams. A section is further subdivided into finite elements (FE) of variable size. Within each finite element a given number of collocation points (CP) are defined based on the degree of polynomial approximation. These points are selected as the roots of the discrete Hahn family orthogonal polynomials. A finite element is illustrated in Figure 1 (left) with the two liquid and vapour flows leaving and entering the collocation points.

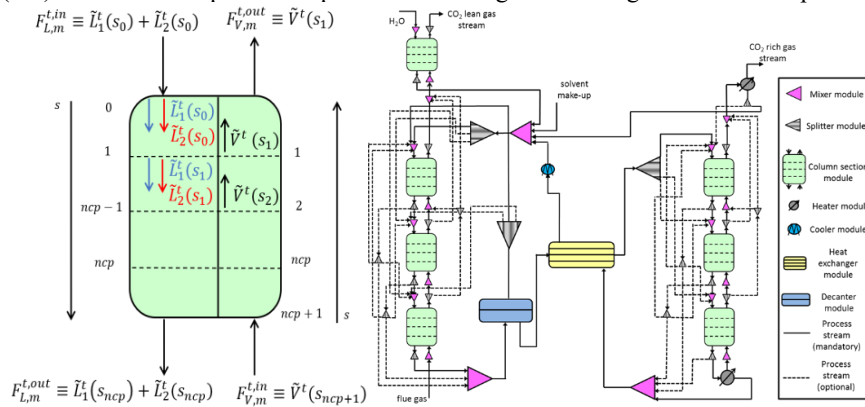

Figure 1: Three-phase OCFE presentation (left), superstructure with indicative placement of liquid-liquid phase separator (right)

Eq. (1) – (5) represent the main equations of a VLLE model with *NC* components and *n* collocation points under the assumption of a dispersed second liquid phase. Eq. (1) is the

Optimal design of post combustion CO$_2$ capture processes based on phase-change solvents

material balance and Eq. (3) the energy balance at collocation point j that corresponds to a location in the column s_j; x_i^{L1} and x_i^{L2} are the molar fractions of each component in the two liquid phases and y_i^V is the vapour molar fraction of each component. The reactive absorption is incorporated implicitly in the phase equilibrium model. In Eq. (3) symbol H represents the enthalpies of each phase and ΔH is the heat of reaction. The equilibrium between the vapour and the $L1$ phase is presented in Eq. (4) by K_i^V, whereas Eq. (5) is the equilibrium between the two liquid phases, represented by K_i^L. The dispersed liquid phase (2nd liquid phase) does not interact with the vapour phase and therefore only two interfaces are considered; vapour – liquid $L1$ and liquid $L1$ – liquid $L2$.

$$L1_i(s_j + 1) + L2_i(s_j + 1) - L1_i(s_j) - L2_i(s_j) + V_i(s_j - 1) - V_i(s_j) = 0 \qquad (1)$$

$$x_i^{L1}(s_j) = \frac{L1_i(s_j)}{\sum_{i=1}^{NC} L1_i(s_j)}, \; x_i^{L2}(s_j) = \frac{L2_i(s_j)}{\sum_{i=1}^{NC} L2_i(s_j)}, \; y_i^V(s_j) = \frac{V_i(s_j)}{\sum_{i=1}^{NC} V_i(s_j)} \qquad (2)$$

$$L_1^t(s_j + 1)H^{L1}(s_j + 1) + L_2^t(s_j + 1)H^{L2}(s_j + 1) + V^t(s_j - 1)H^V(s_j - 1) -$$
$$L_1^t(s_j)H^{L1}(s_j) - L_2^t(s_j)H^{L2}(s_j) - V^t(s_j)H^V(s_j) + \Delta H = 0 \qquad (3)$$

$$y_i^V(s_j) = K_i^V(s_j)x_i^{L1}(s_j) \qquad (4)$$

$$x_i^{L2}(s_j) = K_i^L(s_j)x_i^{L1}(s_j) \quad i = 1, \dots, NC, \; j = 1, \dots, n \qquad (5)$$

2.2. Design framework

The model shown for the column section is directly adapted on the superstructure proposed by Damartzis et al. (2014) for two-phase post-combustion CO$_2$ capture processes. The superstructure, shown in Figure 1 (right) consists of modules representing generic process tasks (e.g., reactive, separation, heat transfer) and interconnecting streams emulating material flows. Reactive separation and liquid-liquid phase change processes may be represented by different modules through the column section. Additional information is reported in Damartzis et al. (2014) pertaining to heat transfer tasks. Several different modules may be connected in the same flowsheet using a broad set of stream types (e.g., recycle, bypasses and so forth). The proposed generic tasks account for (a) reaction, mass and heat exchange between different phases within each module, and (b) stream mixing and splitting to enable distribution of materials among different modules. This representation enables the reproduction of any potentially desired representation of solvent-based CO$_2$ capture processes. For clarity, the liquid-liquid separator is illustrated before the heat exchanger in Figure 1 (right), but it can also be placed after the heat exchanger and connected in any desired way to the columns as in Figure 2.

The combination of the superstructure approach with the OCFE representation introduces important advantages in process optimization. The element length becomes a design variable that indicates the number of stages or equivalent packing height in the column. Accordingly, the size of the separation column can be deduced from the sum of element lengths comprising the column plus the discrete stages, if any, such as the distinct feed stages, reboilers and condensers. Hence, the integer variable denoting the number of stages becomes continuous. Further avoidance of integer variables is achieved by the continuous representation of the location of side feed or draw streams in the columns. Temperature and composition profiles in the column are approximated by continuous Lagrange polynomials of position inside the column. Finally, OCFE supports a significant reduction in terms of the total number of model equations without compromising the resolution of the model, by enabling the solution of the material and energy balances of the equilibrium model on a reduced number of collocation points.

3. Implementation

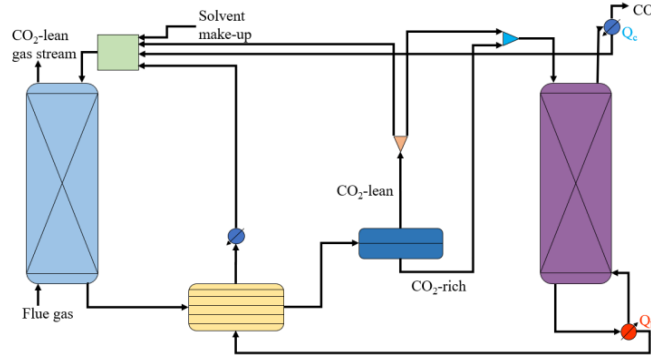
To investigate the effect of PCS on the optimal design of CO_2 capture processes a N-methylcyclohexylamine (MCA) 35 wt % aqueous solution is considered. MCA is a cyclic secondary aliphatic amine, which has been shown to demonstrate enhanced CO_2 capture capabilities (Jeon et al. 2014; Zhuang et al., 2016) is used. The flowsheet investigated in this work is shown in Figure 2. In addition to the absorption and desorption columns a liquid-liquid phase separator is employed to exploit the phase-split exhibited by MCA.


Figure 2: Flowsheet structure used in optimal design.

In the case of MCA, phase separation occurs at 90°C, so the liquid-liquid phase-separator (LLPS) is positioned after the intermediate heat exchanger. In principle, the superstructure may be used to investigate various structural flowsheet options. In this work, for the first time the performance of MCA through systematic process design is investigated and a new structural design option in phase-change flowsheets is explored. After the phase separation, the CO_2-rich phase is directed to the stripper column, whereas the CO_2-lean stream may be recycled entirely or partially to the absorber top through a splitter. The fraction of the CO_2 lean stream leaving the LLPS is a degree of freedom in optimisation. This design option is considered to investigate the trade-off between the regeneration energy requirements and the effects of absorber size on the total process cost. The only flowsheet proposed to date for PCS allows for complete recycle of the CO_2-lean stream to the absorber, leaving the interplay of regeneration energy-absorber size unexplored. A total of seven design decision variables is considered including the split fraction after the LLPS, the pressure in the columns, the reboiler temperature, the amine flowrate as well as the column sizes. The objective function is expressed as the sum of the total process capital and operating expenses as follows:

$$F = \underbrace{\sum_{i=1}^{N_{sep}} C_{sep,i} + \sum_{i=1}^{N_{HEX}} C_{HEX,i} + \sum_{i=1}^{N_{pump}} C_{pump,i}}_{CAPEX} + \underbrace{C_{steam} + C_{cool} + C_{amine}}_{OPEX} \qquad (6)$$

CAPEX terms reflect the annualized capital costs of the separation, the heat exchangers and the pumping equipment, whereas the OPEX terms stand for the costs of steam in the reboiler, water (both process and cooling) and the fresh amine used in the system. Employed initial conditions as well as process specifications are listed in Table 1.

The CO_2 vapour pressure (P_{CO_2} in kPa) with respect to loading (a mol CO_2 / mol amine) and temperature (T) is represented by Eq. (7) which is fitted from experimental VLLE

data (Tzirakis et al., 2018), with R^2 =0.96 for T=40 ℃, 60 ℃, and 90℃. For MCA and H_2O in the vapour phase ideal behavior is assumed. The heat of reaction (*ΔH* in J/mol) is calculated using Eq. (7) derived by a polynomial approximation (Oexmann, 2011):

Table 1: Initial conditions and process specifications.

Initial Conditions		Specifications	
Vapour flow in absorber (mol/s)	320	CO_2 Absorption (%)	≥90
CO_2 composition in flue fas (% v/v)	14.11	Cooler temperature (K)	≥313
Vapour inlet temperature (K)	298	Condenser temperature (K)	313

$$log10(P_{CO2}) = 21.65 - 19.81 \cdot a - \frac{7343}{T} - 75720 \cdot \frac{a^2}{T^2} + 721500 \cdot \frac{a}{T^2} + 5435 \cdot \frac{a}{T} \quad (7)$$

$$\Delta H = -R \cdot (-7343 - 2 \cdot 75720 \cdot \frac{a^2}{T} + 2 \cdot 721500 \cdot \frac{a}{T} + 5435 \cdot a) \quad (8)$$

4. Results and discussion

Table 2 presents the optimal solution for MCA (MCA[opt]) compared to an optimal solution obtained for monoethanolamine (MEA) 30 wt %. Two more cases are explored, namely MCA[1] and MCA[2], where the split fraction after the liquid-liquid phase separator is fixed at specific values, one lower and one higher than the optimal solution. This enables the investigation of the effect of the split fraction in the overall performance.

Table 2: Design optimization results

| Case	MCA[1]	MCA[opt]	MCA[2]	MEA
CO_2-lean phase split ratio (%) to stripper	20	28.63	50	-
Equivalent Stages:				
Absorber / Stripper	24 / 26	22 / 26	22 / 27	11 / 27
Reboiler Temperature (K)	376.58	376.87	377.35	393.15
Phase Split Ratio (%) (rich/lean)	30.63	30.63	30.63	-
Bottom Pressure (bar):				
Absorber / Stripper	1 / 1	1 / 1	1 / 1	1.9 / 1.8

Figure 3: Both reboiler duty and annual cost of MCA aqueous phase split ratio cases, all values scaled with respect to MEA case, values lower than 1 indicate better performance than MEA.

Optimization results reveal that all the cases using MCA exhibit lower operating pressures in both columns as well as reduced operating temperature in the reboiler than MEA. The

second liquid phase is formed above 363.15 K, so this is the target temperature in the decanter for the liquid-liquid phase separation that must be provided by the heat exchanger. Reduced reboiler duty (2.3 GJ/ton CO_2) by 42.5 % at a lower temperature level by 16.2ºC is required in the optimised MCA case compared to the conventional MEA case (4.0 GJ/ton CO_2). This is a significant advantage of the phase-change solvent capture system. When the recycle of the CO_2-lean stream to the absorber increases (i.e. in MCA[1]), a larger absorber column is needed in order to achieve the overall CO_2 capture specification. A large recycle of the aqueous liquid stream reduces the total amount of CO_2 captured per pass. Eventually, this results in lower regeneration energy, due to lower volume in the desorber, but at a higher investment cost, as shown in Figure 3. MCA performs better even at pressures of 1 bar (thermodynamic data were available only for this pressure). Potential increase of pressure in the desorber would further improve the capture performance.

5. Conclusions

The optimal design of an amine-based post-combustion CO_2 capture process using a phase-change solvent was presented. The process was modelled using a rigorous, equilibrium-based model, able to accurately represent the underlying physical and chemical phenomena, coupled with the OCFE technique for model size reduction. An aqueous MCA solution was used as a representative phase-change solvent, aiming to investigate the impact of phase-splitting behaviour. Stream redistribution possibilities and a flowsheet that takes advantage of the two liquid phases that are formed, were generated using a generalized process design superstructure. Design optimization results indicate a substantial energy reduction in the reboiler and subsequent reduction in the total annual cost compared with a reference plant operating with a MEA solvent, making phase-change solvents a promising alternative for further investigation.

Abstract

The economic evaluation of alternative process configurations is an important step in process development. It should be based on optimization to correctly investigate the potential of different process routes and process variants. In many companies, such design studies are performed using block-oriented flowsheet simulators such as Aspen Plus to utilize the extensive model libraries and the ease of model building. We developed an optimization framework that integrates a process simulator (specifically Aspen Plus) with a memetic algorithm (MA). This MA combines an evolution strategy (ES) with derivative-free (DFO) local search methods. The ES addresses the global optimization of all design variables, whereas the DFO method locally optimizes the continuous sub-problems that arise by fixing the discrete variables. In this work, the performance of the memetic algorithm is evaluated for different local methods, involving different DFO methods or the internal equation-oriented optimization engine of Aspen Plus. We discuss the results and the efficiency of the different local methods.

Keywords: Chemical process synthesis, Flowsheet simulation, Aspen Plus, Memetic algorithms, Flowsheet optimization

1. Introduction

Chemical process design in industrial practice is usually done by an interdisciplinary team in an iterative process of comparing the performances and costs of alternative process configurations. In many companies, such design studies are performed using block-oriented flowsheet simulators as e. g. Aspen Plus. The optimization of a chemical process is a challenging task as the models that represent the process units, e. g. a reactor, are in general nonlinear. Discrete decisions like the number of stages and the feed stage of a distillation column enlarge the complexity of the optimization problem. In this case, the optimization of a chemical process is a mixed integer nonlinear program (MINLP). In research usally equation-based models are used (see e. g. Urselmann et al. (2011)). From an industrial perspective this approach has the disadvantage that the extensibility and applicability of the models heavily rely on the experts who created them. Often, as in Waltermann and Skiborowski (2017), a tailor-made initialization procedure is needed to converge the model. In contrast, Aspen Plus offers a large model library and the models are initialized automatically. We therefore investigated the coupling of external process simulators, like Aspen Plus, to optimization methods. The biggest drawback from an optimization perspective is the lack of derivative information in commercial process simulators such that optimization of these flowsheets

is not as efficient as the optimization of equations-based models with mathematical programming. In this contribution we extend the approach of Urselmann and Engell (2015), to include features of Aspen Plus that can utilize derivative information. We demonstrate the performance of our approach for a case study that has been studied extensively in other work.

2. Optimization Method - Memetic Algorithm

The optimization of a chemical process can be mathematically formulated by:

$$\min f(\mathbf{x}, \mathbf{y}, \mathbf{z}) \text{ subject to } g_i(\mathbf{x}, \mathbf{y}, \mathbf{z}) \le 0$$

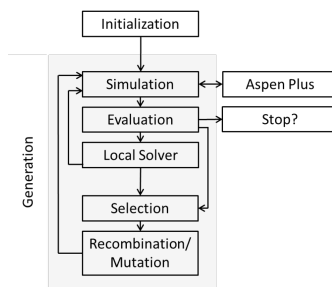
A cost function f will be minimized in respect to a set of constraints g_i. The variables are divided in three sets, where $\mathbf{x}$ denotes the discrete design variables, $\mathbf{y}$ the continuous design variables and $\mathbf{z}$ the state variables of the process. $\mathbf{x}$ and $\mathbf{y}$ represent degrees of freedom that are determined by an optimization method and $\mathbf{z}$ represents variables that are calculated by the process simulator and are also used by the cost function.


Figure 1: Memetic Algorithm

2.1. Memetic Algorithm

Urselmann et al. (2011) proposed a memetic algorithm to solve MINLPs that formulate an optimization problem for chemical processes. A memetic algorithm is the combination of an evolutionary algorithm, e. g. an evolution strategy (ES), with a local solver (meme). The ES is referred to as the 1st stage and fixes the discrete design variables and provides an initialization of the continuous optimization variables in the NLP problem. The meme solves the NLPs in a more effective manner than the ES and is referred to as the 2nd stage. Figure 1 shows the memetic algorithm. In an initialization step a generation of size μ, i. e. a set of solution candidates, is generated, where the design variables $\mathbf{x}$ and $\mathbf{y}$ are initialized within their bounds by a random uniform distribution. The individuals are simulated by Aspen Plus and then evaluated by the cost function. A meme then computes a local minimum of the continuous sub-problem using Aspen Plus evaluations. After solving the sub-problem for all members of the population the MA is initialized. Then the MA generates a set of λ offspring individuals and evaluates them to select the new μ individuals of the next population. These two steps are repeated until a stop criterion, e. g. the maximum number of function-evaluations, is fulfilled. To generate an offspring, two parents are randomly chosen from the population and act as an input for a recombination operator that generates a new offspring. This offspring is further modified by a mutation operator before it is evaluated.

2.2. Aspen Plus Equation-oriented Mode

Traditionally Aspen Plus uses a sequential modular approach to simulate the flowsheet. Meanwhile, an equation-oriented (EO) mode of Aspen Plus has been implemented which solves the underlying model equations simultaneously. The sequential modular mode is used as an initialization strategy. Aspen Plus supports simulation and optimization in the EO mode. The EO mode distinguishes between calculated and constant types of variables and every variable of the EO mode is initialized by a default type that can be changed. Constant variables are inputs from Aspen Plus, e. g. the reflux ratio. If a constant variable is changed to calculated the underlying equation system becomes over-determined and if a calculated variable is changed to constant it becomes under-determined. Fixing the value for a calculated product purity is permitted if a constant variable, e. g. reflux ratio, is changed to calculated accordingly, such that the equation system is not under-determined. In this way a specification is defined and is realized if the computations

are successful. The EO mode supports an internal local optimizer which has access to derivatives. Variables are marked as degrees of freedom and a cost function is defined in EO mode optimization. The drawback of the internal optimizer is that it does not support arbitrary cost functions, due to technical limitations. In this work we extend the MA by two local solvers, which exploit the EO mode of Aspen Plus. The first meme uses the EO mode simulation to realize specifications and the second meme applies the Aspen Plus internal optimizer to perform a local optimization of an approximated cost function.

3. Flowsheet Optimization of the Hydroformulation of 1-Dodecene

As a case study, the homogeneously catalyzed hydroformulation of 1-dodecene in a thermomorphic solvent system (TMS) is investigated. This case study has been investigated by various groups within the TR SFB Inprompt. Steimel and Engell (2016) optimized this case study based on a simpler model and cost function using an equation-oriented model. The process consists of a reaction step, a decanter and a distillation column, two recycles and includes complex kinetics (Kiedorf et al. (2014)) and uses liquid-liquid separation modelled according to (Merchan and Wozny (2016)) to recover the expensive homogeneous rhodium-based catalyst from the reaction mixture. Due to the coupling of the separation units with the reactor a simple objective function as e. g. the selectivity of the reaction is not sufficient (see Hentschel et al. (2014)). A data-based model describing the catalyst loss is employed, since this loss greatly influences the overall costs.

(a) Flowsheet Diagram   (b) Reaction Network
Figure 2: TMS model with DoFs and Specifications

3.1. The Aspen Plus Flowsheet

Figure 2a illustrates the Aspen Plus flowsheet that represents the process. The degrees of freedom are highlighted in bold. The feed flows of the reactant dodecene and the solvents decane and DMF flow are pre-heated and pressurized. The optimizer can change the solvent ratio by adapting F_{DMF} and F_{DECANE}, the residence time τ, the temperature T_R and the pressure P_R to alter the performance of the reaction, in which 1-dodecene reacts to tridecanal. The basic scheme of the reaction network is shown in Figure 2b and is implemented in Aspen Plus. The reacted mixture is cooled down by two heat-exchangers. The first heat exchanger is operated with cooling water and the second heat exchanger is either operated with ammonia or with cooling water depending on the decanter temperature T_E, which is varied by the optimizer. The decanter uses the miscibility gap of the mixture at lower temperature to separate it in a polar phase that contains the catalyst and an unpolar phase that contains the product containing both tridecanal isomers. The polar phase is recycled back to the reactor and the unpolar phase is further purified in a distillation column. The optimizer varies the stage count N_s, the feed position N_F, the distillate to feed ratio $D2F$ and the reflux ratio RR of the column.

Table 2: Variants of Memetic Algorithm

Name	Local Solver	Avg. Costs	Best Costs	Best Purity	Fails
ES-SPECS	EO Sim.	3443 ± 4.76 € / T	3439 € / T	99.00 %	37.6 ± 1.7 %
ES-CATOPT	EO Opt.	3449 ± 3.05 € / T	3445 € / T	99.18 %	26.6 ± 2.5 %
ES	None	3506 ± 5.23 € / T	3500 € / T	99.40 %	27.7 ± 4.0 %
ES-NOMAD	NOMAD	3594 ± 40.6 € / T	3549 € / T	99.49 %	6.1 ± 0.7 %
ES-CMAES	CMAES	3728 ± 217 € / T	3554 € / T	99.43 %	17.5 ± 1.6 %

3.2. Catalyst Loss and Cost Estimation

Our approach supports the definition of arbitrary cost functions. Here the cost function is an indicator of the costs per ton of product depending on the amount of catalyst loss:

$$f(\mathbf{x}, \mathbf{y}, \mathbf{z}) = \frac{C_{OU} + C_{Mat}}{8000 \cdot \dot{m}_{Product}} + Penalty$$

With $C_{Mat} = C_{Raw} + C_{Cat} + C_{Makeup}$ and C_{OU} equals the sum of the capital and utility costs of every operation unit, as proposed by Turton et al. (2008). The capital costs are pressure dependent, e. g. a reactor operated by a pressure of thirty bar instead of twenty raises the capital costs by approximately 45 %. We fitted a 2nd order polynomial model to describe the catalyst loss based on the temperature and solvent data measured by Brunsch and Behr (2013). The catalyst loss is represented by:

Table 1: Model Parameters

a	0.00112
b_1	−0.1743
c_1	6.9086
b_2	0.2033
c_2	1.7474

$$Loss = (a \cdot DMF_p^2 + b_1 \cdot DMF_p + c_1) \cdot (b_2 \cdot T + c_2)$$

where the parameters are defined in Table 1. T represents the temperature in the decanter and DMF_p represents the fraction of DMF of the solvent. With this loss term the costs for catalyst loss regarding the volume flow $\dot{V}_F$ of the decanter is calculated by $C_{Cat}(\dot{V}_F) = \dot{V}_F \cdot Loss \cdot C_{Rhodium}$. The penalty term of the form $Penalty = 4000 + v \cdot 10000$ is used to penalize the constraint violation. Here v represents the constraint violation in molar fraction of the tridecanal purity in the bottom flow of the distillation column.

4. Optimization Results

The optimization problem contains 10 design variables (see Table 3). The purity of the sum of iso- and n-tridecanal is specified as 99 mol % in the bottom stream of the distillation column. We compare the results of several variants of the MA, which are summarized in Table 2. The parameters for the ES are $\mu = 10$ (generation-size), $\lambda = 20$ (number of offsprings) and $\kappa = 5$ (maximum age of an individual) which have been determined in previous studies as a robust setting for a range of problems. We compare the performance of a traditional ES with four MA variants that differ in their meme, i. e.

Table 3: Boundaries of Design Variables

Variable	Unit	Lower	Upper	BFS
T_R	[C°]	80	120	111.34
P_R	[bar]	15	30	23.06
τ	[h]	0.1	5	4.49
T_E	[C°]	-5	25	-5
N_s	unitless	4	40	27
N_f	unitless	2	dynamic	6
$D2F$	unitless	0.6	0.95	0.61
RR	unitless	0.1	15	0.17
F_{dmf}	[kmol/h]	20	100	81.44
F_{dode}	[kmol/h]	20	100	20.76

we test four different local optimization

strategies. The Aspen Plus equation-oriented (EO) optimization and the EO simulation represent two memes. The former minimizes the catalyst loss and the latter fixes the tridecanal specification. The derivative free methods (DFO), covariance matrix evolution strategy (CMAES) and the solver NOMAD represent the other two memes. These peformed best from a set of DFO methods which have been compared by Urselmann et al. (2016) for water-ethanol-benzene separation case study.

4.1. Cost Distribution

The best found solution (BFS) is shown in Table 3 which has the cost distribution shown in Figure 4. The raw material costs have the biggest impact on the cost. The heat exchangers and the column cause the main equipment costs. The catalyst and solvent makeup costs are only a small fraction of the entire costs of the BFS. The HEX2-1 may use ammonia if the target temperature is below 5 C° and this increases the costs considerably. Nonetheless, the optimizer chooses a decanter temperature of −5 C° because the cost of using ammonia is compensated by the reduction of catalyst loss. The high fraction of DMF in the solvent is also chosen by the optimizer to reduce the loss of catalyst. The design parameters of the reactor are chosen such that there is a good trade-off between selectivity and conversion to reduce the size of the recycle. The high influence of the pressure on the capital costs of the reactor causes the pressure to be below the upper bound.

4.2. Convergence Behavior and Runtime

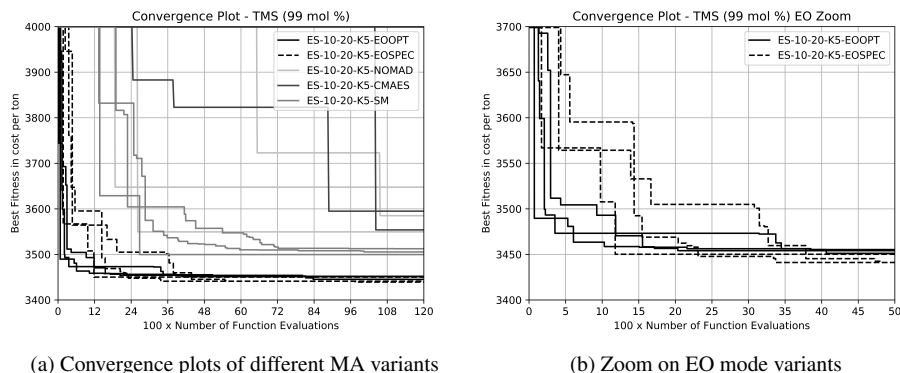
(a) Convergence plots of different MA variants   (b) Zoom on EO mode variants


Figure 3: Convergence Plots of three runs of different MA variants

Figure 3 shows the convergence of three runs for each MA variant, i. e. lines of the same type represent different runs of the MA variant that is identified in the legend. Table 2 shows the average and best costs, the best purity and the average percentage of failed simulations and is ordered ascending by costs.
Figure 4: Cost Distribution of Optimal Solution

The memes using Aspen Plus features perform best, as they can access derivatives. All the Aspen Plus meme variants found an optimum that is closer than one percent to the optimal solution after 40 % of the optimization time, i. e. after 4.800 function evaluations which are processed in ten hours on a i7-4790S CPU with 3.20 GHZ. Here 99 % of the time is spent in the Aspen Plus

simulation which is solved in 8.4 seconds on average. The best found solution was detected by the variant that fixes the specification, since a distillation column that operates at a high purity is more expensive. Nonetheless the optimization of the catalyst loss with Aspen Plus leads to a faster convergence in the early stage of the optimization. Although the variants that use DFO methods fail less, the ES variant that does not make use of a local optimization performs better than the DFO variants. This means that the function evaluations used by the DFO methods are not worth the effort. At least at the early stages of the optimization, i. e. using these function evaluations in the ES leads to a faster convergence. Both variants ES and ES-CATOPT fail approximately in 27 % of the simulations. However the ES-SPECS variant fails 10 % more often such that the fraction of failed simulation is traded for a solution that fulfills the specification accurately.

5. Conclusion

Based on the case study of the hydroformylation of 1-dodecene into tridecanal we showed that the new implemented memes that use the equation-oriented (EO) mode of Aspen Plus and therefore utilize derivative information speed up the convergence. As long as the derivative information is not accessible by external tools, the benefit of the ease of modeling larger processes using a process simulator is traded for significantly higher computation times of the optimization. For the example it turned out that in general a MA that uses a derivative-free method (DFO) as a local solver does not outperform a pure evolution strategy with respect to speed of convergence. We therefore propose that a DFO based local optimization should only be performed in the later stages of the optimization.

Abstract

In this study, Exergy Analysis (EA) and Energy Integration (EI) analyses are employed as decision factors to select the best heat exchanger network (HEN) configuration and applied to improve a bioethanol production process plant by evaluating its irreversibilities. The results of EI and EA reveal that the HEN configuration A6 allows to obtain a value of rational efficiency for the process of 87.88 % (an increasing of 12.33 % respect to base case scenario) by a diminution of the process irreversibilities of 28.85 MW. With this HEN configuration, the equipment cost increases by $158,432.57 with a decrease on services cost of 750,615.06 $/year, obtaining an energy saving of 21.37 MW.

Keywords: Exergy, Energy Integration, Bioethanol production

1. Introduction

The world is starting to face energy resources depletion and non-renewable resources are the most employed as a fuel in the auto transport sector. The use of non-renewable resources has also showed negative environmental consequences for some decades, which has been catalogued as one of the main global problems that the nations aim to solve, figuring in the list of Sustainable Development Goals that might be reached in 2030 (United Nations General Assembly, 2015). Thus, different alternatives to minimize the negative effects are being evaluated, among them it is the use of alternative fuels such as bioethanol. Bioethanol is an organic biofuel that is obtained from lignocellulosic biomass, a renewable substrate that through a process of numerous unit operations could be converted in an ethanol solution with high purity grade. The second-generation bioethanol production process has begun to be commercially feasible, however, improvements in the process performance are still necessary to reduce production cost.

EA is useful to evaluate thermodynamic efficiency of chemical processes by the calculation of its irreversibilities. EI is a tool that allows development and analysis of several HEN configurations that seeks energy benefits by exchanging the available energy between process streams that may contribute in the reduction of the total cost of the process. Usually, the cost of the process is considered a performance criterion for selection of the best HEN, leaving apart the thermodynamic criteria for the best HEN selection. Therefore, the objective of this works is employing these two tools to design and evaluate HEN configurations in a bioethanol production process, aiming to reduce energy consumption and determine thermodynamic efficiency by using a computer-aided based approach.

2. Exergy Analysis

Exergy is the maximum theoretical work obtainable from a given thermodynamic state when this reaches thermo-mechanical and chemical equilibrium with a reference state on environmental conditions entering in a state called "dead state" (Kotas, 1995). In open systems, exergy content can be classified by its origin: a) exergy accompanying energy flows and b) exergy accompanying material flows. In material flows, excluding kinetic, potential, nuclear and electromagnetics effects, exergy can be then divided into: thermo-mechanical or physical exergy and chemical exergy (Marmolejo-Correa and Gundersen, 2015).

Thermo-mechanical exergy in Eq. (1) is defined by differences in enthalpy ($h-h_0$) and entropy ($s-s_0$) from the current conditions of the system (T, P) to the ambient conditions (T_0, P_0), where T and P stand for temperature and pressure, respectively. Chemical exergy for a non-ideal mixture is shown in Eq. (2), where x_i are the mole fractions, ε_i are the standard chemical exergy and γ_i are the activity coefficient of each component. The irreversibility rate (I) in bioethanol production plant is calculated developing an exergy balance as shown in Eq. (3), where, E_i and E_o are the net exergy rates entering and leaving the system, respectively. ΣE^Q is the net exergy flow accompanying the energy entering in heat exchangers and leaving in coolers, and, ΣE^W is the net exergy flow accompanying the work applied to process. The rational efficiency is a measure of the process performance and is defined by Kotas (1995) as it is illustrated in Eq. (4), this is a relation between useful exergy in the products and exergy driven to the system.

$$e^{ph} = h - h_0 - T_0(s - s_0) \tag{1}$$

$$e^{ch} = \sum_{i=1}^{n} \varepsilon_i^0 x_i + \sum_{i=1}^{n} x_i ln x_i \gamma_i \tag{2}$$

$$I = E_i - E_o + \Sigma E^Q + \Sigma E^W \tag{3}$$

$$\psi = 1 - I / \Delta E_i \tag{4}$$

EA has been previously applied in bioethanol production processes, reporting overall analyses to the complete process configurations (Ojeda et al., 2011; Silva Ortiz and de Oliveira Jr, 2014, Zeineb et al., 2018). However, these studies simulate the process employing other feedstocks and in some cases the papers do not include an EI analysis.

Regarding to exergy calculation, the simulation software employed in this work provides the calculation of physical exergy, but it is necessary to calculate the chemical exergy, in order to obtain the net exergy that material flows contain. Therefore, the usage of computational tools linked to the simulator is a useful strategy. The methodology applied to link the computer-aided tools was already described in a previous work (García-García et al, 2018), thus, it was possible to obtain the exergy balances stage by stage and in overall plant in the bioethanol production process studied.

3. Energy Integration

The EI task relies on proposing several configurations of heat exchanger networks with the aim of minimizing the utility consumption, employing as a performance criterion to determine the best configuration the energy savings, total costs and heat exchangers areas. The EI could be achieved employing the pinch analysis, which provides a systematic methodology for energy saving in process and total sites heat integration (Goodarzvand-Chegini and GhasemiKafrudi, 2017). The exergy analysis has been successfully employed for the EI in previous studies, for example, Janka, A. et al (2018) employed this methodology to evaluate the energy integration in distillation technologies focusing on dividing-wall columns. Goodarzvand-Chegini and GhasemiKafrudi (2017) developed an exergy analysis to improve the heat integration efficiency in a hydrocracking process. On the other hand, Staine and Favrat (1996) proposed a pinch analysis method extended to include exergy factors in the process. The state of the art does not show this type of thermodynamic and process design approach for bio-based production processes, for example for bioethanol production, which is divided in diverse stages and includes several unit operations that need and release energy. Therefore, this work employs the exergy analysis as a performance criterion to select the best HEN obtained by a pinch analysis on a bioethanol production process, the selection also considers the lowest cost on services and equipment.

4. Bioethanol Production Process

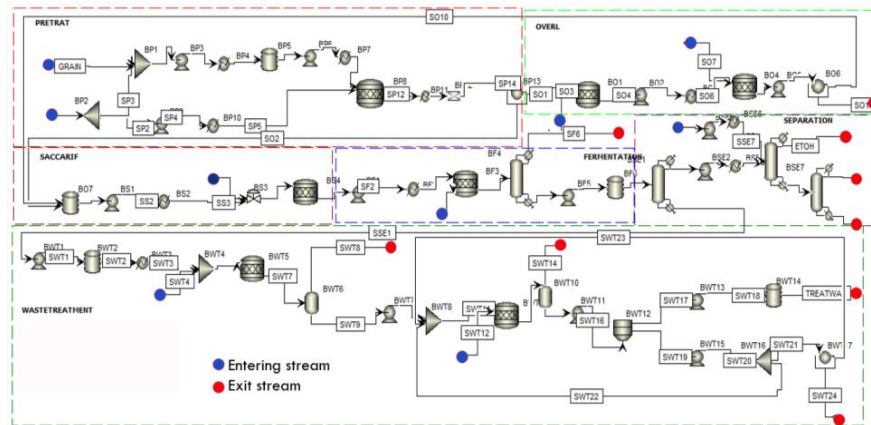
The second-generation bioethanol production plant was simulated employing the Aspen Plus v. 8.8 process simulator and divided into six stages: pretreatment, overliming, saccharification, fermentation, separation and waste treatment. The data for the equipment and initial conditions of the streams was taken from (Sánchez et al., 2013). The process simulation was carried out taking wheat straw as raw material with a mass flowrate of 7,752.13 kg/h with composition in mole fraction of 0.47 of water, 0.34 of cellulose, 0.15 of xylan, 0.05 of lignin and traces of ash. In the saccharification section, the cellulose that cannot be dehydrated during the pretreatment section is converted into glucose, with the help of enzymes that favour its reaction. During fermentation the fermentable sugars present in the stream are converted into ethanol by *Zymomonas mobilis*. The separation stage employs a system of sequential distillation columns that allows obtaining high-purity ethanol that can be used as biofuel. Finally, in the waste treatment stage, the residual streams are conducted to biological treatment where three streams are obtained: residual solids, biogas and treated water. The Figure 1 shows a bioethanol process diagram, the streams labelled with points indicate the entering and exit streams using blue and red points, respectively. It is important pointing out these streams are used in the exergy analysis lately.


Figure 1. Bioethanol production process diagram

5. Results

The methodology proposed by Garcia-García et al. (2018) was used in this study for calculating the irreversibility rate and rational efficiency, and the previous results were used as the base case scenario. The results of thermal exergy in streams are show in Table 1. The EI analysis was performed employing the computational tool HINT (Martin and Mato, 2008).

Six HEN configurations were designed and analysed (Table 2). The energy integration and exergy analysis considered the usage of direct flame, high, middle and low pressures steams as heating0 utilities, and cooling water and Freon as cooling utilities. In Table 2 could be observed that the equipment cost increased in all proposed configurations, due to the number of heat exchangers; in base case scenario the number of heat exchangers were 18 while in all the proposed configurations were 23. It can be also observed that the configurations allow a decrease in the utilities cost in all configurations with energy savings of 21.37 MW, that in fact it was equal in all configurations. Employing only this information obtained from EI analysis was difficult to select the best configurations, because the results are very similar. However, the use of exergy analysis results provided an important and additional information that allowed making a better selection of the best HEN option. Table 2 also shows that the rational efficiency was improved by the selection of any of the proposed HEN, but it was more effectively improved with the configurations A1 or A6 that represents the higher rational efficiency. Comparing the results of energy integration and exergy analyses was possible to select the configuration A6 as the best because improved in 12.10 % the rational efficiency and represents one of the minimum equipment cost in the configurations constructed (US$ 158,432.56).

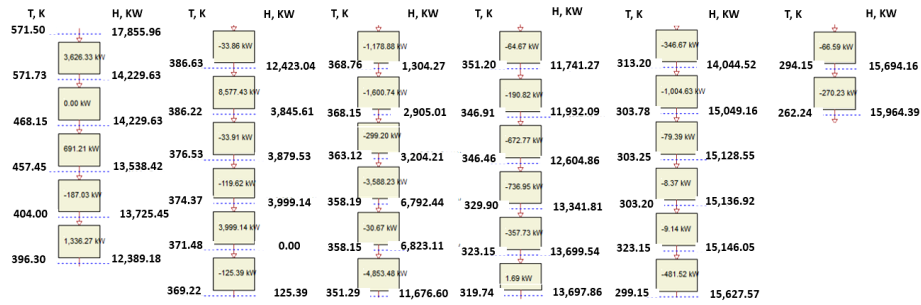
The minimum energy requirements for configuration A6 are shown in form of a heat cascade (see Figure 2).


Figure 2. Cascade diagram to determine the energy requirements in scenario A6

	SWT24	0.731	11,665.444	11,667.171

Table 2. Results of EI and Exergy analysis

Configuration	Equipment cost, US$	Utilities cost, US$/year	Rational efficiency, %	Irreversibility, MW	Energy Saving, MW
Base case	225,151.88	1,715,486.19	75.55	44.76	0
A1	457,430.13	964,871.13	87.88	15.91	21.37
A2	383,584.45	964,871.13	83.96	21.06	21.37
A3	385,959.90	964,870.46	83.76	21.33	21.37
A4	388,128.80	964,870.48	83.55	21.42	21.37
A5	387,922.24	964,871.13	83.88	21.15	21.37
A6	383,584.45	964,870.47	87.65	16.22	21.37

Conclusions

The results reveal that without EI and employing utilities to cover the total energy requirements the rational efficiency and total irreversibility of the process are 19.92% and 68,187.75 KW, respectively. Employing the energy integration and exergy analysis was found that the configuration A6 represent the better option to improve the process performance with a rational efficiency value of 87.65%, total irreversibility of 16.22 MW and savings energy of 21.37 MW. The implementation of both, EI and exergy analysis demonstrates to be a useful methodology to determine the best HEN configuration in accordance with the energy savings and thermodynamic feasibility.

Abstract

Process industry is always in quest for innovative designs which are both efficient, safe and sustainable. The feasible search space of all unit operations that can be combined to generate process flowsheet alternatives for a given synthesis problem can be large and difficult to manually navigate in order to determine the best processing route. Therefore, it is helpful to utilize computer-aided methods and tools to enumerate, analyze and determine within the design space, the more sustainable processes. In this paper, an integrated computer-aided method and corresponding software-tool that's capable of generating and searching the entire design space for more sustainable process options is presented. In this work a comprehensive analysis method consisting of economic, life cycle, sustainability and process safety indicators is used to identify process bottlenecks on the selected alternative which are translated to design targets. Matching of these design targets minimizes/eliminates the process hot-spots and, thereby generating non-trade-off innovative process designs.

Keywords: Process synthesis, ProCAFD, Process Optimization, Process Safety.

1. Introduction

Due to increased emphasis by governments concerning environment, public health and safety through regulatory enforcements and growing competitiveness through globalization, the process industry is moving towards the design of innovative, more sustainable processes. Since synthesis problems are by nature combinatorial and open ended, several approaches have been proposed, these approaches can be broadly classified into three main classes of methods. (1) Rule based heuristic methods, which rely on rules based on a combination of experience, insights and engineering knowledge (data) to solve the synthesis problem; (2) Mathematical programming-based methods, where the best flowsheet alternative is determined from network superstructure optimization. This approach requires one to define and represent the network of alternatives in a mathematical form and solve the resulting mathematical problem using suitable solvers. (3) Hybrid methods that combines different approaches to solve the synthesis problem. Simultaneous based process synthesis approaches require the generation of a superstructure which contains a finite number of processing units with their corresponding interconnections. The resulting superstructure is solved by, using equations that describe the equipment, connectivity together with the process constraints and specifications. Even though it is advantageous to perform simultaneous optimization of the flowsheet structure and operating conditions there are few limitations. The major limitations of this approach are that the solution of the synthesis

problem heavily depends on the superstructure of the alternatives considered. So, in order to find the optimal process topology, the original search space should constitute the optimal pathway. Also, since the process synthesis problem is by default nonlinear in nature, the solution to such optimization problem is difficult. Since applying only knowledge-based methods or optimization-based methods often over simplifies or complicates the process synthesis problem, a more logical way is to use hybrid methods where we can leverage the advantages of the two approaches while still keeping the complexity of the synthesis problem manageable. his work focuses on the development of hybrid method and computer aided software tool (ProCAFD) capable of enumerating all feasible alternatives within the entire search space and efficiently evaluate them. This work also focuses on introducing new analysis methods related to process safety along with economic, sustainability, and life cycle assessments during selection of process alternatives. This paper also shows successful application of ProCAFD on different case studies where different options are highlighted such as generation of integrated/hybrid/intensified configurations based on problem formulation.

2. ProCAFD architecture based on 3-stage Framework for Innovation

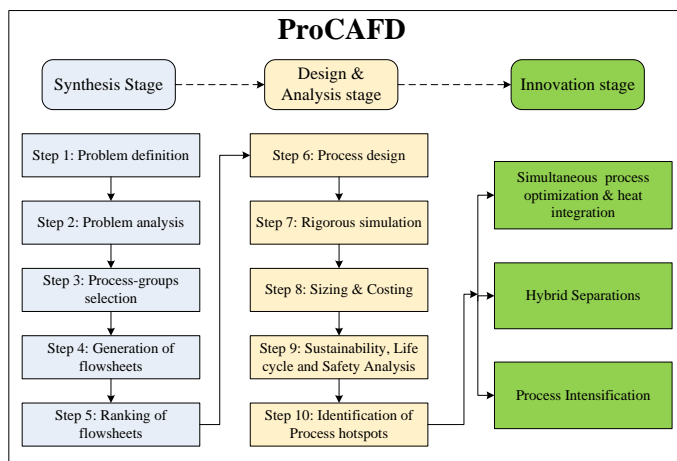
An overview of the 12-step method, which is an extension of the synthesis method proposed by Tula et al. (2015), is presented in Figure 1. The method is based on 3 stage approach for innovation proposed by Babi et al. (2015). Brief overview of the steps involved in the method are given below:


Figure 1: Sustainable process synthesis-design and analysis method (in ProCAFD)

<u>Problem Definition</u>: In this step the synthesis problem is defined along with process specifications, design constraints and performance criteria against which the generated alternatives are screened.

<u>Problem Analysis:</u> In this step, analysis is done to generate information through use of knowledge bases and physical insights methods to solve the synthesis. The outcome of this analysis includes, i) List of all chemical species in the synthesis problem, including

reaction intermediates and/or any mass transfer agents, ii) Reactions, if needed, to convert the given raw materials to desired products, iii) List of all the possible separation tasks along with feasible separation techniques.

Process-groups selection: The selection and initialization of the process groups is based on analysis carried in step 2. This is carried out in three tasks: i) selection and initialization of inlet and outlet process-groups, (based on step 1 information) ii) selection and initialization of reaction process-groups, and iii) selection and initialization of separation process-groups.

Generation of Flowsheets: In this step, the initialized process-groups are combined using connectivity and logical rules to generate structurally feasible process alternatives. These rules also safeguard against any combinatorial explosion that is generally associated with generate and test approaches.

Ranking of Flowsheets: In this step, different flowsheet property models are used to calculate flowsheet properties which are used to screen and rank the generated alternatives. The flowsheet property models are based on a group contribution *(GC)* approach, where the property of the entire flowsheet is estimated using contributions of individual process-groups present. Flowsheet models are available for carbon footprint, energy consumption, product recovery and, product purity

Process Design: Operational design parameters of the selected process alternative(s) are calculated in this step. This is achieved through the following two tasks: i) the resolution of the mass and energy balance, and ii) calculation of flowsheet design parameters of the process unit operations in the flowsheet structure through reverse simulation. The separation factors and temperature data required for performing mass and energy balance are obtained from the process-group definitions and driving force available. Design parameters for separation process-groups (such as distillation, extractive distillation, and flash), are estimated based on the driving force (DF), while attainable region theory is used to design reactor networks.

Rigorous Simulation: ProCAFD is integrated with commercial simulators like PROII, ASPEN where the design is automatically setup using rigorous models to verify performance of the selected alternatives.

Sizing & Costing: In this step, equipment sizing, and costing calculations are performed for all equipment in the process flowsheet. The sizing and costing values are estimated using ECON (Kalakul et al. 2014).

Analysis: The results of the rigorous simulation, sizing and costing (stream summary, equipment sizing, energy balance etc.) are used to perform economic, safety, sustainability and life cycle analyses.

- *Economic Analysis*: The mass and energy balance results from the rigorous simulation are used to calculate the capital and utility costs for each unit operation which are used to identify hotspots involving high operational and capital costs.
- *Sustainability Analysis*: This analysis is based on an indicator-based methodology (Carvalho et al., 2013), which identifies critical flow paths within the process. Here analysis is done on both open (where a chemical species enters and leaves the process) and closed paths (like recycle loops where mass and energy are recycled without going out of the process). The main indicators, which are estimated, include material value added (MVA), energy and waste cost (EWC), total value added (TVA).
- *Life Cycle Analysis*: This analysis is used for environmental assessment of the selected process alternative. This is carried out through LCSoft (Kalakul et al. 2014) that helps to quantify potential environmental impacts of chemical process. The main factors which are estimated in this analysis are Carbon Footprint (CF),

Human Toxicity Potential by Ingestion (HTPI), Human Toxicity Potential by Exposure (HTPE) and Global Warming Potential (GWP).

- *Process Safety Analysis*: This analysis is based on Dow's (1987) scoring system to estimate the inherent safety of the process alternative. This method considers different aspects like process conditions, chemicals involved, and equipment types etc. to identify different hazards in the plant. The total inherent safety index is a combined score of chemical inherent safety and process inherent safety. While the chemical inherent safety index considers reactions hazards and chemical hazards; process inherent safety index takes process and equipment conditions

<u>Identification of Hotspots:</u> The indicators from the analysis step are used to identify the process hotspots (Babi et al., 2015), which are in turn used to set design targets for overall process improvement

<u>Innovative Designs:</u> In this step, different strategies/methods are applied individually to the selected alternative to target the hot-spots for overall process improvement.

- *Simultaneous Process Optimization and Heat Integration:* Simultaneous process optimization and heat integration approach is applied to the analyzed base case design, to target process hot-spots involving high operational costs. In this approach, rigorous models from the process simulator are used to calculate the process inputs, which are sent to an integrated heat integration module to estimate the minimum utility requirements. Both module results are used in the optimizer to minimize the total utility of the process. In this method, the heat integration module is based on the condensed LP transshipment model for calculating the minimum utility consumption.

- *Hybrid Separations:* A generalized method based on Tula et al. (2016) for synthesis-design of hybrid distillation-membrane systems is applied to replace the distillation columns in the base case design with a hybrid system to reduce the operational cost substantially. Tula et al. (2016) showed that 30-50 % of energy savings can be achieved for any distillation column by replacing the less efficient region of the distillation operation with membrane based separation technique.

- *Process Intensification:* Phenomena based intensification method proposed by Babi et al. (2015) is applied in this step. This approach breaks tasks into phenomena within the unit operations involved. These phenomena are analyzed and re-combined using combination rules to generate new and/or existing unit operations that constitute the (more sustainable) flowsheet alternatives which satisfy the set design targets.

Case Study

2.1. Synthesis stage:

The synthesis problem definition is to develop an energy efficient process to produce cumene from propylene and benzene. This reaction is exothermic and typical operating conditions are 600 K at atmospheric pressure. In this problem definition, the propylene stream has propane as impurity. As a process specification, the minimum purity of cumene should be 99.5 wt%. A total of 10 binary pairs are formed from 5 compounds present in the synthesis problem. For this synthesis problem, a total 155 process-groups are selected and initialized, which include 148 separation tasks process groups, 6 inlet/outlet process groups and 1 reaction process group. A total of 240 process

alternatives are identified, and the best alternative with respect to energy consumption is shown in Figure 2. The objective from the problem definition step is to find an energy efficient process so, energy consumption property model is used in this case study. Different flowsheet models can be used to screen the alternatives based on the problem definition.

2.2. Design & Analysis stage:

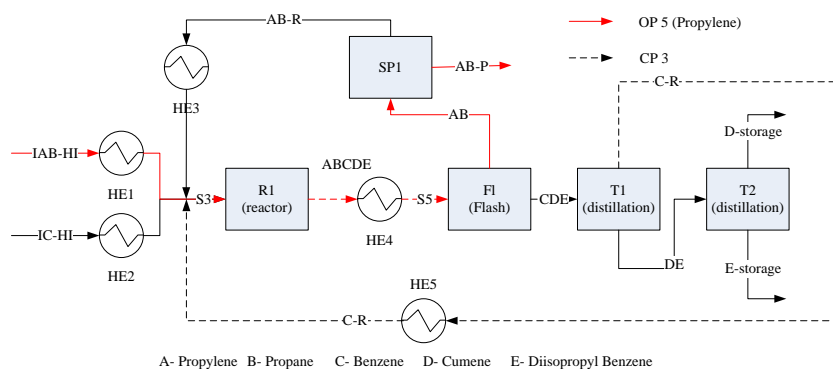
In this stage the selected process alternative (Figure 2) is designed and simulated using rigorous models. Based on the simulation results economic, safety, sustainability and life cycle analyses are performed on the base case. From economic analysis the heat exchangers on the recycles streams (HE3, HE5) along with HE4 share 57% of total equipment cost and 42% of the total utility cost. These results are also complemented by sustainability analysis, which showed a high energy and waste cost (EWC) associated with closed path 3 and loss of material (MVA) for propylene in open path 5. Life cycle analysis showed high carbon footprint associated with heat exchangers HE3 & HE5. LCA analysis also flagged environmental impact from the purge stream AB-P. Safety analysis on the process alternative gave a combined score (total inherent safety index) of 18. The identified hotspots are translated into design targets: Increase plant profit, reduce energy consumption, and improve LCA/sustainability indicators while maintaining the product purity and production rates (kept as the base case values).


Figure 2 : Selected base case design for further analysis. The open and closed paths (OP, CP).

2.3. Innovation stage:

In this case study, simultaneous optimization and heat integration strategy is used to satisfy the design targets set in stage 2. The process is optimized to maximize the operational profit (Fobj= Revenue – Cost) and the heat integration targeting heat exchangers (HE3, HE4, and HE5). The operational profit has increased by 28% in the optimized case mainly due to reduction of heating and cooling utilities. Since the purge stream ratio is optimized to maximize the profit, waste generation is also reduced which also reduced the environmental impact.

Table 1 shows the application of ProCAFD on various industrially important processes. In all the cases, ProCAFD was able to generate numerous alternatives quickly that are truly innovative and that have not been reported in the literature. This is because the work-flow and data-flow of ProCAFD is organized in such way that all the steps can be performed very fast, consistently and reliably to solve the complete synthesis-design and innovation problem. More details on the solutions can be obtained from the authors.

Table 1 : Solved case examples using ProCAFD. Where improvement is wrt utilities consumption

Case Study	Alternatives Generated	Innovation Strategy	Improvement
Production of Benzene	64	Simultaneous Opt, & Heat Integration	67.0%
Separation of Alkanes	184	Hybrid Separations	60.5%
Production of Cumene	240	Simultaneous Opt, & Heat Integration	27.6%
Production of Biodiesel	502	Process Intensification	24.3%
Production of DMC	53	Process Intensification	86.7%

3. Conclusions

In this work, the main achievement is the development of a computer-aided method and its software to systematically solve complex process synthesis and design problems, which facilitates more efficient and innovative solutions. This work also focuses on extension of previous method to include comprehensive analysis involving sustainability, life cycle, safety and economic in early states of process synthesis. The developed method and software differ significantly from conventional synthesis-design methods/tools as it is not iterative nor is it based solely on mathematical optimization techniques to synthesize an optimal solution. It is a hybrid method based on decomposition-based approach where in the complexity of the synthesis problem is decomposed into a set of sub-problems and solved sequentially.

Abstract

Computer-aided methods and tools are used at different stages of chemical process development. However new tools are needed to meet the current and future challenges through innovative and more sustainable solutions that the currently available tools may not be able to provide. This work focuses on component-based software architecture for development of tailor-made computer-aided tools for specific application objectives. The architecture is based on "components", which can be model-objects that are stored in a library; collection of property models; databases; numerical solvers; design-algorithms (work-flows) etc. The main idea of these components is to incorporate a plug & play framework, where for a specific purpose, after the work-flow and associated data-flow are established, a specific computer-aided tool can be configured through a library of software components. Also, through the use of software components that are based on predictive model-based solution techniques, the final software can be reliably used to provide innovative and more sustainable solutions over a wide range of problems.

Keywords: component-based, tailormade tools, software architecture.

1. Introduction

Chemical engineering is in constant evolution and access to computational resources are changing the way chemical engineering problems are addressed. Process simulation, which emerged in the 1960s, has become one of the great success stories in the use of computing in the chemical industry. Process simulators are used today in most of the chemical engineering disciplines ranging from process design, research and development, production planning, optimization to training and education making it one of the most sought-after software. Some well-known process flowsheet simulators are Aspen Plus, ChemCad and PRO/II. This success, however, has led to a negative trend, that is, replacement of the trial and error experiment-based solution approach to a trial and error simulator-based solution approach, which is a faster and less expensive option. However, does it lead to the innovative and significantly better solutions which are required to deal the grand challenges of health, food, water, energy and environment (Negro et al., 2018)? The current unit-operation based process simulators, although having great success and wide applications, are not able to satisfy the demands for the new technologies (multiscale, multipurpose, new concepts leading to new algorithms, visualization, etc.). For example, process simulators can only be used indirectly for synthesis, control, analysis, etc., purposes through iterative approach. In this approach, the simulator is in the inner loop generating the simulation data for each trail while the

outer loop has the techniques for synthesis, design and control. This is not the best way moving forward to solve where innovative and significantly better solutions are need of the hour. Clearly, a new class of methods and associated model-based computer aided tools are needed, and most importantly a structured approach in development of these software. This new software development approaches have to be modular, which can be described as component-based modeling that are flexible and easy to integrate with other components (pieces) of software. In this way one can easily design and develop smaller and flexible tailormade problem specific tools configured from a library of different software components (databases, models, design work-flows, analysis tools, solvers, etc.) according to the needs of the user. Modular based strategies have been proposed in different application areas ranging from modular modeling and simulation of chemical flowsheets to cellular systems however they failed to explain how a common interface can be used to develop software for different applications. This capability is important in industrial research and development where tools are developed for different applications. In this work a standard framework for software development based on components is proposed along with several illustrative examples of new tools that are able to achieve significant improvements through innovative, new and more sustainable solutions. This work also highlights the development of the component library and the common framework (standard interface) for the handling these components.

2. Overview for component-based software development

The main features of this new class of computer-aided tools are that they are based on software components that are taken from a database of components and are assembled through a standard interface (software framework) according to the needs of the user. This modular framework emphasizes separating the functionality of a software into independent, interchangeable components, such that each contains everything necessary to execute only one aspect of the desired functionality. Figure 1 shows the general framework for component-based software development, where it's possible to develop user specific tools by adding the necessary software components from the database. Figure 1 shows how 3 different problem specific software can be developed using components repository.
Figure 1: Framework for software component-based software development

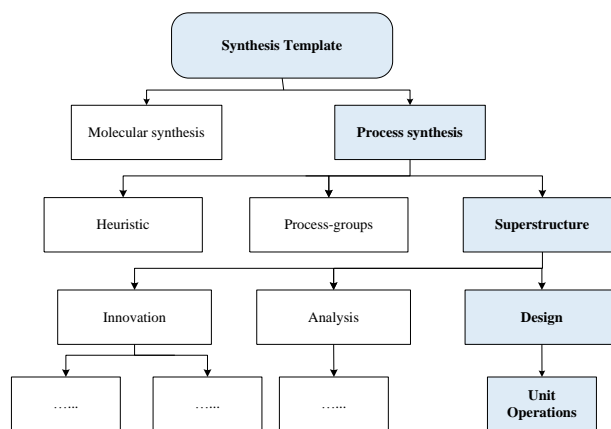
Here components C1-C7 represents application specific components while C8-C12 represents common components. Compared to the classic development of large and complex generic software, modular approaches break down the complexity into smaller building blocks, making it easier to modify, maintain and most importantly reuse. This type of modular framework will be beneficial to research centers to reduce the software development times considerably and reuse components effectively. Here the software components can be databases, property models, process models of different types, and method-templates (for example, synthesis, design, analysis, control) with their specific work-flows (for example, step by step algorithms), the associated data-flows and computer-aided tools. Figure 2 shows the example of data and workflow of an integrated system, where in a template for process synthesis-design using superstructure-based optimization is shown. A software component is obtained through a collection of basic-tools and associated methods. A collection of components leads to a computer-aided tool. For example, a simulator for wastewater treatment industry can be constructed through the following software components: databases, membrane library, solver library, chemical dosing models, scaling models, flowsheet representation system. These software components define the application range and predictive capability of the software, so it is very important to select appropriate components keeping in mind the needs of the final software. With regard to system-wide co-ordination, these software components communicate with each other via the main interface.


Figure 2 : Template example for Process Synthesis-Design

3. Application examples

3.1. Computer-aided tools for process-product synthesis, design, analysis

ProCAFD (Tula et al., 2017) is an integrated software component-based computer-aided tool that has been tailor-made for synthesis, design, analysis and optimization of chemical and related processes employing 12 hierarchical tasks based sustainable design methodology. It has only one design-template where the work-flow consists of 12 tasks organized into 3 stages. Each task has its associated list of software components, where the user has multiple options to carry out the task. For example, processing route generation may be performed based on well-known heuristics, group contribution based

generate and test or superstructure optimization. Figure 3 illustrates the workflow and software components of ProCAFD, consisting of 12 tasks are performed in 3 stages. First define the problem; then solve the synthesis problem in stage-1; then perform design-analysis after process simulation in stage-2; finally, in the 3rd stage, apply process intensification, hybrid separations etc., to generate alternative more sustainable process designs. In stage 1, once the all the process alternatives are generated, the superstructure can be solved using mathematical optimization method or generate and test approach based on user choice. SUPER-O which is integrated with ProCAFD, can be used to automate the mathematical formulation of the generated superstructure and solve mathematically or the user can choose ProCAFD's built-in ranking algorithm based on generate and test approach to solve. In stage 2, ProCAFD is also integrated external simulation tools like Aspen, PROII, where the generated designs are automatically transferred, and a rigorous simulation model of the alternative is setup. Tula et al. (2015, 2017) illustrates the application of ProCAFD for sustainable chemical process synthesis and design where new innovative solutions have been found. In all the examples ProCAFD was able to quickly generate and evaluate numerous process alternatives that are truly innovative and better than the designs published in literature.

ProCAFD : Computer-aided Flowsheet Design

Synthesis Stage
Step 1: Problem definition
Step 2: Problem analysis
Step 3: Process-groups selection
Step 4: Generation of flowsheets
Step 5: Ranking of flowsheets

Components :
Compounds database, Reaction database, Group contribution-based property model package, Azeotrope analyzer, Eutectic analyzer, Feasible separation identifier, Driving force analyzer, Process-groups database, Superstructure generator, Process synthesis, Molecular and/or mixture design, SFILE generator, Flowsheet property calculator

Design & Analysis Stage
Step 6: Process design
Step 7: Rigorous simulation
Step 8: Sizing & Costing
Step 9: Sustainability, Life cycle and Safety Analysis
Step 10: Identification of Process hotspots

Components :
Process-groups database, Design template, Economic analyzer, Sustainability analyzer, Life cycle analyzer, Hazop analyzer, Indicator-hotspot database

Innovation Stage
Step 11: Simultaneous process optimization & heat integration
Step 12:Process Intensification & Hybrid separations

Components :
Heat integration module, PI database, Process intensification template, Hybrid separations template, Duty database

Figure 3 : Architecture of ProCAFD (Computer-aided Flowsheet Design)

ProCAPD (Kalakul et al. 2017) is an integrated tool for computer aided product design. This is analogous to process simulator, that is, it helps make the product design and development easier and faster and provides for a unified and consistent product documentation. However, unlike process simulators, ProCAPD can also be used directly for design of chemicals-based products, such as, single molecule products, formulations, blends, emulsions and devices (using different in-house synthesis design templates). It also has property-process modelling options, a large collection of databases for different classes of chemicals and properties and an interactive design template developer for new products and/or design methods. Figure 4 highlights the architecture and workflow of ProCAPD, where the main interface is at the inner core, then the method-template, then the associated software components and finally, the basic-tools. To design this chemical product simulator (ProCAPD), the components that

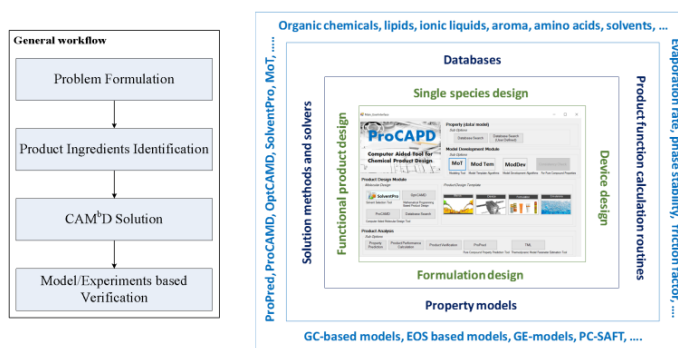
must be selected are databases (chemicals, solvents, active ingredients, aroma, color-agents etc.); model objects (properties, product performance, etc.); solvers (product attributes, blend compositions, environmental impact, etc.); design algorithms (single molecules, blends, formulations, emulsions, devices). ProCAPD has been applied to design solvents & refrigerants (Kalakul et al., 2018), surrogate fuel blends (Choudhury et al., 2017) and formulated liquid products (Conte et al., 2011). Note, however, the objective of ProCAPD is not to provide the final design of a chemical product but to quickly screen-out inappropriate alternatives so that focused experiments could be performed on a small set of promising candidates, thereby saving resources by reducing the product development time.


Figure 4 : Architecture of ProCAPD (Computer-aided Product Design)

3.2. ProCAPE: Computer aided property estimation

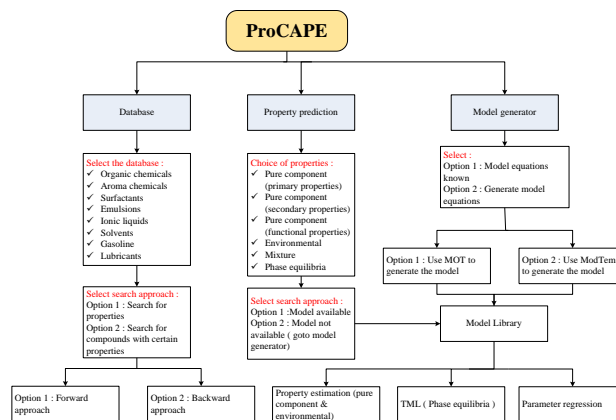
ProCAPE is a computer-aided property estimation tool consisting of chemicals database, pure component property models, mixture property models & phase equilibrium-based property calculation modules. It has the database for pure component, mixture properties of chemical species. To expand the capability and predictive nature of the software, software components related to property prediction models based on group contribution are also selected.


Figure 5 : Overview of ProCAPE (Computer-aided Property Estimation)

ProCAPE has different method templates like thermodynamic model selection guide, equilibrium analysis, parameter fitting for thermodynamic modes and simulation design calculations, etc. ProCAPE also has user model software component, where user can introduce his own models which can be used in performing different calculations. ProCAPE has models to predict 55 pure component properties (such as critical properties, acentric factor and solubility parameter) and 10 functional (temperature dependent) properties (such as vapor pressure, liquid viscosity, and surface tension) and collected measured data in database-tools covering 42,970 compounds. Also, ProCAPE has models (such as SRK, PR, UNIQUAC, UNIFAC, NRTL, PC-SAFT, etc.) for phase equilibrium calculations (vapor–liquid, liquid–liquid or solid–liquid) as well as mixture stability predictions.

4. Conclusions

Process systems engineering can play a leading role to address the current and future challenges of energy, water, food and health. Inorder to achieve innovative and sustainable solution we need to have access to next generation tools that can handle large datasets, models from different disciplines, establish solution strategies for multidisciplinary nature of problems. The key to these next generation tools would be software component-based computer-aided tools that has the flexibility to handle large and complex problems by breaking them down into smaller solvable problems (as in the case of 12 tasks based sustainable process design) while at the same time, designing different chemicals-based products through similar design templates but having different software components (for example, database and property models). The developed component-based software architecture has been successfully implemented in developing user specific tools ranging from property prediction to sustainable process-product design and analysis.

Fouling Modelling in Crude Oil Heat Exchanger Networks using Data Reconciliation and Estimation of Unmeasured Process Variables

José Loyola-Fuentes[a,*], Megan Jobson[a] and Robin Smith[a]

[a]*Centre for Process Integration, School of Chemical Engineering and Analytical Science, The University of Manchester, M13 9PL, UK*
jose.loyolafuentes@manchester.ac.uk

Abstract

In crude oil refineries, fouling has a significant impact on operating and maintenance costs. The growth of fouling layers on the surface of heat exchangers in a crude oil heat exchanger network (HEN) also increases both energy use and CO_2 emissions. Fouling models facilitate process design and integration while systematically accounting for the impact of fouling. The most common models use a series of parameters that are specific to the type of crude oil, as well as the operating conditions of the pre-heat train. These models are of great importance as they can indicate the set of operating conditions (stream velocities and temperatures) at which the occurrence of fouling might be avoided. A key challenge is to define an accurate method for determining fouling models for each side of a heat exchanger within a network. To achieve this goal, plant-measured data are used to monitor the thermal performance of a pre-heat train, and to obtain specific insights related to the impact of fouling. The main concern related to these data and their interpretation is the effect of measurement error and the limited number of measurements available in the process. This work presents a new methodology for calculating fouling model parameters for both sides of shell-and-tube heat exchangers using simulated plant-data along with data reconciliation and gross error detection. A heat exchanger network model coupled with fouling dynamics is used for simulating a crude oil pre-heat train and for the prediction of fouling behaviour. The effect of full and partial instrumentation in the estimation of reconciled measurements is accounted for in a case study, where the prediction of fouling deposition is assessed.

Keywords: Crude Oil Distillation, Heat Integration, Optimisation, Process Simulation

1. Introduction

The reduction of energy demand is a global concern. A considerable amount of research efforts has been centred in developing new technologies to continuously decrease the energy use, specifically in crude oil refining processes. In general, crude oil is initially pre-heated to approximately 380°C before entering the crude distillation unit (CDU). A heat exchanger network (commonly known as the pre-heat train) is used for this pre-heating, recovering around 60-70% of the heat needed in the CDU (Panchal and Huangfu, 2000). Unfortunately, fouling deposition in the Pre-heat Train decreases the thermal and hydraulic performance of the network. In order to avoid the growth of fouling layers on

the surface of heat exchangers, fouling models can be used for model-based predictions and design of mitigation strategies.

Fouling models can be grouped according to their physical basis. In particular, the concept of the so-called fouling threshold (Ebert and Panchal, 1995) provides a useful theoretical basis for establishing a relationship between the fouling phenomena and the pre-heat train operating conditions. Fouling threshold models are crude oil-dependent; the set of parameters in each model captures the characteristics of a particular crude oil or a crude oil blend. These parameters can be determined using experimental or field data by fitting these data to an appropriate fouling model. Both methods have their own advantages and disadvantages; however, the use of field data contributes to a more realistic representation of the process, when such data is appropriately processed.

Data Reconciliation is a widely used method for processing measured data. This method reduces the impact of measurement error in a data-set. In general, measurement error is defined as the sum of random and gross (or systematic) errors (Narasimhan and Jordache, 2000). To account for these two contributions, gross error detection should be included in the data reconciliation method; this simultaneous strategy is able to estimate the presence and value(s) of miscalibration(s) within the set of data. An equally important challenge is the presence of unmeasured process variables. When a set of process variables is unmeasured, the number of degrees of freedom and available linearly independent equations limit the estimation of this unmeasured variables (Romagnoli and Sánchez, 1999). Therefore, the selection of unmeasured variables should be (in principle) such that the available information is sufficient for the estimation of all unmeasured variables.

This work proposes a methodology to determine fouling threshold models for a crude oil pre-heat train subject to fouling in both the shell and tube sides. Data reconciliation and gross error detection techniques are integrated with an optimisation-based parameter fitting to calculate fouling model parameters associated with different mechanisms within the network. The effects of different gross error and unmeasured process variables is analysed in a case study, in which the set of missing measurements is classified according to whether each missing process variable in the set can be estimated or not.

2. Modelling and Formulation

This work uses a matrix-based HEN simulation strategy along with data reconciliation and gross error detection, together with a hybrid optimisation approach to calculate specific fouling models for a crude oil pre-heat train. The effect of missing process measurements are accounted for by exploiting the matrix formulation of the HEN and by classifying such missing measurements according to the concepts of observability and redundancy defined by Narasimhan and Jordache (2000), as described in Section 2.2.

2.1. HEN and Fouling Modelling and Simulation

The model used in this work calculates the internal flow rates and temperatures of the HEN using inlet information from the crude oil and the CDU side-products streams. The simulation strategy was proposed by de Oliveira Filho et al. (2007) and later modified by Ochoa-Estopier et al. (2015) to include the simulation of unit operations such as desalters and flash units. The proposed approach integrates the dynamic effects of fouling using an

explicit Euler integration, as it was previously shown in Loyola-Fuentes et al. (2017). The HEN is simulated in order to obtain a set of simulation-based data. Random and gross errors are systematically added to these simulated data in order to replicate the variability of an existing process. Following the reconciliation of these measured data, the HEN and fouling models are used for prediction of fouling depostion.

2.2. Data Reconciliation and Gross Error Detection

The data reconciliation algorithm minimises the value of the measurement error, which is defined as the difference between the measurements (y_m) and the reconciled process variables (y_r). These reconciled variables are estimated via nonlinear constrained optimisation, where each measured value is weighted by the corresponding accuracy of the measurement (usually approximated by the variance of such measurement) in matrix ψ. The whole set of constraints considers the presence of unmeasured process variables in the vector y_u. The set of equality constraints $f(y_r, y_u)$ represents mass and energy conservation equations, and the set of inequality constraints $g(y_r, y_u)$ represents specific lower and upper bounds for each measurement. The effect and presence of gross error is accounted for by including the gross error magnitude (measurement bias is assumed in this work) g_ξ in the measurement error vector. The simultaneous optimisation problem is solved by the combinatorial strategy proposed by Romagnoli and Sánchez (1999), which is updated in this work to take into account nonlinear systems. The data reconciliation and gross error detection problem is defined in Eq. (1).

$$
\begin{aligned}
\min_{y_r, y_u} \quad & (y_m - y_r - g_\xi)^T \psi^{-1} (y_m - y_r - g_\xi) \\
\text{subject to} \quad & f(y_r, y_u) = 0 \\
& g(y_r, y_u) \leq 0
\end{aligned}
\tag{1}
$$

The minimisation problem in Eq. (1) is solved via Sequential Quadratic Programming (SQP). The values of reconciled and unmeasured process variables are estimated simultaneously. The effect of missing measurements is analysed based on the concepts of observability and redundancy (Narasimhan and Jordache, 2000).

- Observability: An unmeasured variable is observable if it can be estimated using measurements and process constraints.

- Redundancy: A measured variable is redundant if it is observable even when its measurement is missing.

2.3. Fouling Model Parameter Estimation

A hybrid optimisation approach is implemented for determining fouling parameters. The value of fouling resistance is calculated using the overall heat transfer coefficient in clean and fouled conditions. The parameter estimation is formulated as a nonlinear constrained optimisation problem and solved using Genetic Algorithm. The solution of this problem is then fine-tuned using a deterministic nonlinear programming technique; in this work, the interior point method is implemented.

The objective function shown in Eq. (2) represents the minimisation of the root mean squared error between measured and fitted fouling resistances, defined by R_f^{msr} and R_f^{fit} respectively. The optimisation variables correspond to the specific fouling parameters (vector b) of a fouling model that is previously selected according to operating conditions. Each data-set and the total amount of data-sets are represented by the counter k and number n respectively.

$$\min_{b} \quad \sqrt{\frac{\sum_{k=1}^{n} \left(R_{f,k}^{msr} - R_{f,k}^{fit}(b) \right)}{n}} \tag{2}$$
$$\text{subject to} \quad b^L \leq b \leq b^U$$

3. Case Study

This new methodology is tested in a HEN case study, comprising of eight process-to-process heat exchangers, one desalter unit, three cold utilities and one hot utility. The pre-heat train is depicted in Figure 1. Fouling is assumed in the shell-side and the tube-side of all process-to-process heat exchangers. Deposition of waxes is considered in both sides of the heat exchangers at the cold end of the pre-heat train (exchangers E1 to E4) as well as in the shell-side of the heat exchangers at the hot end (exchangers E5 to E8). The fouling rate for this mechanism, α_1, is set to be 5.50×10^{-4} m^{2}K kW^{-1}h^{-1}. Chemical reaction fouling based on the model proposed by Polley et al. (2007) is assumed to occur in the tube-side of exchangers at the hot end of the pre-heat train. The fouling models are shown in Eq. (3) and Eq. (4) respectively, where Re, Pr, R_g and T_W are the relevant Reynolds number, Prandtl number, the ideal gas constant and the tube-wall temperature. The parameters of the chemical reaction model α_2, E_A and γ are given in Table 1. The simulation time is one year and the operational data are generated using the simulation strategy described in Section 2.1. Random and gross errors are systematically added in order to replicate the variability of a real operating process.

The cold stream outlet flow rate of exchanger E3 and the hot side outlet temperature of exchanger E7 are chosen as unmeasured variables. These variables are to be estimated using the available measurements, in order to check the observability of such missing data. Random errors are added to each measurement across the whole time-span. A constant single gross error of magnitude of 4°C is added to the furnace inlet temperature. After reconciliation and identification of gross errors, the fouling parameters for the shell and tube-sides of all heat exchangers are back-calculated via the parameter estimation method explained in Section 2.3.

$$\frac{dR_f}{dt} = \alpha_1 \tag{3}$$

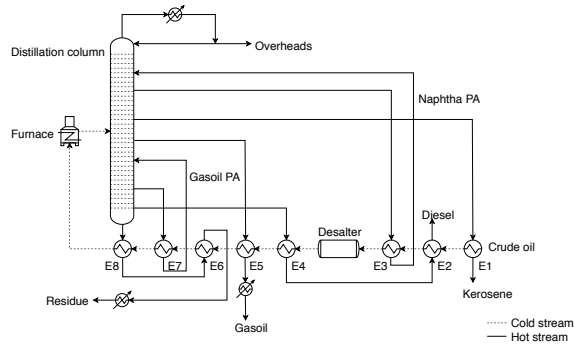
$$\frac{dR_f}{dt} = \alpha_2 Re^{-0.8} Pr^{-0.33} exp\left(\frac{-E_A}{R_g T_W}\right) - \gamma Re^{0.8} \tag{4}$$


Figure 1: Crude Oil Pre-Heat Train Process Flow Diagram

Table 1: Fouling model parameters for chemical reaction mechanism (Polley et al., 2007)

Parameter	Units	Value
α_2	$m^2K\ kW^{-1}h^{-1}$	1.00×10^6
E_A	$kJ\ mol^{-1}$	48.00
γ	$m^2K\ kW^{-1}h^{-1}$	1.50×10^{-9}

The results from the estimation of missing measurements are compared with a fully-instrumented scenario. The missing flow rate estimation results give a constant value of 194 kg s^{-1}, as no mass losses are considered. This value is in accordance with the full instrumentation scenario. The comparison for the missing temperature measurement is shown in Figure 2. The agreement between these two scenarios indicates that both of these unmeasured variables are observable, as their magnitudes are accurately estimated.

The average value of the estimated gross error is 3.98°C, which is in good agreement with the initially simulated value of 4°C. The performance of the data reconciliation can be assessed by analysing the values of the fitted fouling parameters for all heat exchangers. These values are shown in Table 2. The agreement of each parameter with respect to their corresponding base-value (see Table 1) shows how well these parameters can be used for the prediction of fouling behaviour in the network.

Table 2: Fitted fouling model parameters for all heat exchangers

	$\alpha_1\ (m^2K\ kW^{-1}h^{-1})$	$E_A\ (kJ\ mol^{-1})$	$\gamma\ (m^2K\ kW^{-1}h^{-1})$	$\alpha_2\ (m^2K\ kW^{-1}h^{-1})$
E1	5.42×10^{-4}	–	–	–
E2	5.42×10^{-4}	–	–	–
E3	5.42×10^{-4}	–	–	–
E4	5.42×10^{-4}	–	–	–
E5	9.36×10^{-4}	44.18	1.11×10^{-7}	3.85×10^5
E6	9.70×10^{-4}	51.54	9.89×10^{-8}	2.66×10^6
E7	8.43×10^{-4}	44.10	6.65×10^{-8}	4.16×10^5
E8	8.66×10^{-4}	48.28	5.05×10^{-8}	1.11×10^6
Figure 2: Comparison between full and partial instrumentation scenarios for the missing temperature measurement

4. Conclusions

This work proposes a new method for regressing fouling models for shell and tube-sides of a crude oil pre-heat train using data reconciliation and gross error detection. The Data Reconciliation method accounts for the effect of two different types of measurement errors and the presence of missing measurement(s). These missing measurements are classified according to their observability in order to identify their potential for accurate estimation. The proposed methodology is tested in a case study, where significant agreements were found when full and partial instrumentation scenarios were compared. Further study is needed for multiple combinations of missing measurements presenting different degrees of observability. For achieving this goal, a topological analysis of the network, together with a set of measured values are needed. The degree of observability for this case can be evaluated using matrix-based techniques such as Q-R decomposition.

Abstract

This study aims to develop a novel method to synthesise site-wide heat recovery, distribution, cogeneration systems with optimum operating conditions of the steam mains. Previous approaches have simplified the problem to the extent that many important practical issues have been neglected and restricted the scope of the options included. The proposed methodology uses a combination of total site analysis and mathematical programming for a holistic approach to the steam system, which accounts for interactions between site utility system and processes. The optimisation problem involves the selection of more realistic operating conditions of the steam mains (superheating and pressure). The model will also account for water preheating, and superheating and desuperheating for process steam generation and use. Deaerators and let-down stations are also included in the analysis. The application of this methodology to a case study yielded a 7.6 % reduction in total energy requirement, compared to conventional utility system design method. The proposed approach addresses severe shortcomings in previous research on this topic and provides a foundation for future work to explore the next generation of sustainable utility systems.

Keywords: Cogeneration targeting, heat and power integration, total site integration, steam level optimization, mathematical programming.

1. Introduction

Sustainable development, as one of the most significant challenges faced by society, is closely related to the rational generation and use of energy. For this reason, in the process industries it is important to place a focus on the synthesis of energy-efficient sustainable utility systems and how this can shape energy use patterns. The energy transition of existing systems to meet future demands needs to be directed to be on a sustainable basis (Broberg Viklund, 2015). In the future, process utility systems will need to incorporate a much greater contribution from renewable energy sources. This will create a paradigm shift in the way such utility systems are designed and operated.

One of the key performance indicators for the synthesis of utility systems is cogeneration potential, which establishes objectives on heat and power generation as well as steam distribution and boiler fuel requirement (Ghannadzadeh et al., 2012). Steam mains pressures and superheating play an essential role in the performance of both heat and power generation at the site. Research has analyzed the influence of the

steam levels on the energy targets in total site heat integration (Mavromatis and Kokossis, 1998; Shang and Kokossis, 2004; Beangstrom and Majozi, 2016). However, previous methods do not consider the degree of superheat and its effect on the potential shaft power generated by steam expansion.

In addition to these models, Kundra (2005) and Ghannadzadeh et al. (2012) presented targeting approaches, in which both sensible and latent heat of steam has been considered. However, previous methodologies have been based on the assumption of fixed steam mains pressure, usually based on heuristics. This neglects the close interrelation between the processes and the system and its subsequent implications. Moreover, the superheat for both the steam generation and use has been assumed to be the same. This premise might lead to thermodynamically infeasible solutions or further difficulties in practice, because of limitations associated with the materials used for construction, or due to the design complexity.

Sun et al. (2015) proposed a graphical approach to overcome the shortcomings in relation to assessing cogeneration potential and enhancing site-wide heat recovery methodically. Whilst the proposed methodology by Sun et al. (2015) allows for useful thermodynamic and physical insights for understanding some of the interactions within the system It does not provide a systematic decision-making approach to determine the optimum utility system performance since it does not allow the analysis of the trade-off between the cost of the additional steam and the profit from power generation.

Though there is extensive literature for cogeneration targeting in utility systems, the conventional concepts present a number of limitations and drawbacks for the selection of optimum site operating conditions. This study aims to offer the basis for a systematic approach to explore the next generation of sustainable utility systems. For the first time, a study in this area combines an extended transshipment method based on Shang and Kokossis (2004) with total site analysis and more realistic site conditions. In turn, this determines the total site heat and mass flow and ensures that the total operating cost is minimized.

The novelty of this work is derived from the requirement of increased practical and realistic conditions for both steam generation and usage. This is used in combination with an evaluation of the interactions between steam mains conditions (pressure and superheat) and system performance. The effect of process steam generation at a different temperature from the steam mains, as well as the efficiency and the exhaust temperature of the steam turbines based on steam conditions (superheating) and load, is also explored to provide a more realistic and accurate heat recovery. Ultimately, this methodology allows for power targeting of utility systems operating at optimum conditions. In essence, the study provides a framework for the analysis of sustainable steam systems.

2. Methodology

Cogeneration targeting with simultaneous steam mains selection requires making continues and discrete decisions, where non-linear energy terms are involved. Thus, to produce a linear model and avoid convergence and robustness issues, some properties are fixed during the optimization. Every optimization step is succeeded by a rigorous

simulation, as shown in Figure 1. The following subsections provide a summary of these steps.
Figure 1. Schematic representation of optimization approach

Step 1 Total site construction and potential steam levels generation

The extended Total Site Profile (TSP) concept of Varbanov et al. (2012) is adopted to obtain the potential steam levels required for the heat recovery and power generation via the utility system. Apart from the stream data specification - i.e. number of processes involved, number of stream of each process, parameters including supply and target temperatures, as well as the heat capacity- the specific minimum approach temperature (ΔT_{min}^{PU}) is used to avoid misleading energy targets that can result from the use of inaccurate global minimum temperature difference (ΔT_{min}) values between process streams.

Saturated temperature (pressure) denotes the potential steam levels. The temperatures are obtained by partitioning the site-wide temperature range into intervals. Since the sink profile defines the quantity and quality of heat required, steam intervals are based on its temperature range. Operational constraints are also taken into account, such as minimum/maximum temperature for process and utility steam generation. Additionally, minimum temperature and pressure difference between each potential level are set by the designer, to guarantee a representative number of options and avoid unnecessary levels. Once generated the potential steam levels, they are classified based on the number of steam main required and the pressure ranges for each header.

Step 2 Steam level optimization

The MILP formulation is based on Total Site Heat and Mass Cascades (TSHMC) employing a transshipment model. An extension of Shang and Kokossis (2004) model enables recording energy and mass balances among process source/sink streams and potential steam levels. The TSHMC are formulated by the temperature intervals (defined by the steam levels) and comprise three cascades: source, steam and sink, as illustrated in Figure 2(a) Process streams act as steam sources or sinks, where the (residual) heat that cannot be used in the interval for either steam generation or use is going to the next lower temperature level, at the respective cascade. Heat flows from the process sources to sinks through steam. Utility steam is raised at boiler house at VHP conditions and distributed to the different headers by either passing through steam turbines or let down stations.

In the source cascade, the heat from process sources is used to raise steam at the steam level pressure, from Boiler Feed Water (BFW) conditions to superheating. The latter is a designer variable and is restricted by the source profile and the heat exchanger equipment. Regarding sink cascade, heat flows from steam level to process sinks via steam desuperheated. Steam is desuperheated prior its use by BFW injection. For the development of the TSHMC, let m^H, m^{ST}, m^{LD}, m^{Cmain}, m^{BFW} be the steam mass flowrates of the process steam generation, steam turbines, let-down stations, process sinks and BFW injected, respectively.

(a) *Total site heat and mass cascade* (b) *Mass balance for i-th steam main*
Figure 2. Schematic representation of optimization approach

The MILP formulation is based on the minimum annualised utility cost as the objective function, where the steam flows, heat loads, fuel consumption, electricity generation and cooling water requirement are continuous variables. Binary variables are associated with whether a steam main (defined as *i*) exists at a given condition, denoted by the set of potential steam levels *j* or *jm*. Binary variables are also related to the steam turbines operation between steam mains (*i,j*) and (*i+1,jm*) and the operating status of boilers at VHP conditions.

Energy and mass balance, as well as the electricity balance are the main equality constraints. While equipment size constraints -- that avoid equipment operating at lower efficiency -- are inequality constraints. Power generation and fuel consumption are estimated employing the linear models of Sun and Smith (2015) and Shang (2000), respectively. Both models accounts for full and part-load operating performance.

Step 3 Calculation of steam mains' superheating
Once the optimum steam level placement (saturated temperature/pressure) has been obtained, the actual superheating temperature of the header is calculated. The superheating is defined through a material and energy balance in each steam main. This is determined by the enthalpy and flow rate of the process steam generation, turbine exhausts, steam passing through let-down valves, and any BFW injected in the steam main. The calculations require top-down iterations that start with the utility steam and work down through the cascade from high to low pressure until superheating constraint is satisfied by all the steam mains. Turbine exhaust properties are obtained using the Willan's linear model presented in the Sun and Smith (2015) research, based on the inlet steam conditions and the steam main pressures. The steam is expanded through letdown valves at isenthalpic conditions. Finally, Step 2 and 3 are repeated until achieving convergence (usually 3-4 iterations).

3. Case Study

Site data was adapted from an example available in the literature (Sun et al., 2015). The number of streams and ΔT_{min}^{PU} for each process are detailed in Table 1. Power site demand is 40 MWh. The site energy requirement is satisfied using a steam system comprising a natural gas boiler, three distribution steam mains, a deaerator, expansion

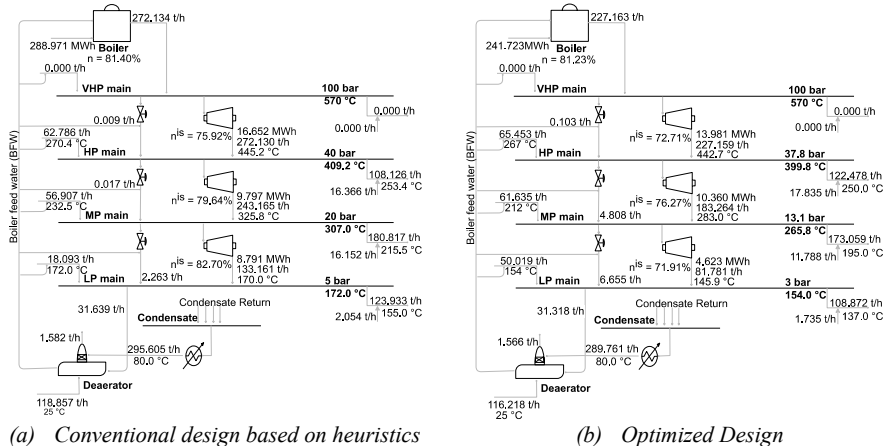
valves, steam turbines and a single cold utility (cooling water). The utility steam is generated in the boiler house at the very high pressure (VHP) main conditions (100 bar). The inlet temperature of the cooling water is 20 °C. Electricity is generated by single back-pressure steam turbines allocated between each level. The HP, MP and LP steam mains operating conditions are estimated to minimize the total operating cost.

Table 1. Summary of the stream data for case study

	Process A	*Process B*	*Process C*	*Process D*	*Process E*
No. of streams	4	8	9	6	9
ΔT_{min} (°C)	15	5	5	10	15

In order to assess the benefit of the methodology, the optimized system configuration is compared against a conventional design based on heuristics, where the HP, MP and LP mains pressure are 40, 20 and 5 bar, respectively. Figure 3 compares the two steam system configurations. Both systems were obtained based on the temperature specifications presented in Table 2. For the optimization, the present case study has considered 65 potential steam levels, based on the specifications and the sink profile temperature. The potential steam levels has been classified in 15 levels for HP ($\geq$ 30 bar), 42 levels for MP (6 – 30 bar) and 8 levels for LP (3 - 6 bar).

Table 2. Temperature specifications for the steam system

Constraints	Temperature [°C]
Maximum boiler steam temperature	570
Minimum process steam generation temperature (saturation)	134
Minimum steam main superheating	20
Degree of superheating for process steam generation	20
Degree of desuperheating for process heating	3


(a)   Conventional design based on heuristics   *(b)   Optimized Design*
Figure 3. Steam system configuration

The steam main pressures for the optimized system configuration are 37.8, 13.1 and 3 bar; respectively.The manipulation of steam main conditions affects site operational performance. Steam mains selection is affected by several factors i.e. process steam generation, turbine exhausts and let-down flows. Steam passing through let-downs is required to achieve steam balance and more important to maintain the minimum

superheat of 20 °C in each steam main. However, this may result in a reduction in the power generation as it is observed in Table 3. Compared with conventional design cost, the proposed design diminishes the fuel and CW consumption by 16.35 % and 10.61 %, respectively. Even though the power generation is less than the traditional design, the total utility cost decreases 7.61 %.

Table 3. Comparison of steam system designs

Parameter	Conventional	Optimization	Difference in units
Fuel consumption [MWh]	288.97	241.72	- 47.25
Power Generation [MWh]	35.20	28.96	+ 6.24
Cooling Utility [MWh]	237.54	212.33	- 25.21
Fuel Cost [M£ y^{-1}]	51.19	42.82	- 8.37
Power Cost [M£ y^{-1}]	3.62	8.38	+ 4.76
Cooling Cost [M£ y^{-1}]	10.21	9.13	- 1.08
Operating Cost [M£ y^{-1}]	**65.02**	**60.33**	**- 4.69**

4. Conclusions

A new methodology has been developed to provide increased realism and accuracy in utility systems synthesis, operating at optimum conditions for future utility systems. The study shows the close relation between steam level selection and heat recovery and power generation enhancement. In an illustrative example, the new model presents a significant reduction of the total energy requirement at the site compared to a conventional design method (7.61 %). This proves that the energy requirement can be further reduced by holistically optimizing the steam mains operating conditions and the site heat recovery and cogeneration.

Abstract

The direct link between climate change and anthropogenic industrial activity resulted in a need more prominent than ever to cut emissions. At the Paris climate conference (COP21), 195 countries adopted a legally binding global climate deal to put the world on track to avoid dangerous climate change effects. This sets a challenge for many countries to draft sustainable climate policies by 2030. Climate change has social, environmental and economic consequences. Therefore, it is important to understand the impact of these interconnected factors on climate strategies. Multi-period carbon integration allows carbon reduction over a certain time horizon. The multi-period planning approach identified allocation of carbon dioxide between sources and potential sinks in each period, compared cost elements simultaneously and resulted in a low cost network across all periods. In this work the approach was expanded to evaluate two conflicting objectives. An example was solved to assess climate policies under two objectives. Good carbon reductions were achieved.

Keywords: Optimization, carbon dioxide reduction, renewable energy, sustainability, climate policy

1. Introduction

Policy-making entities have proposed ambitious carbon dioxide emission reduction targets as a means of mitigating global warming effects. Many policies are drafted yearly, in an attempt to successfully reduce carbon dioxide emissions. Most of the policies are outlined for regulatory reasons, by prescribing a required target, over a specified time horizon. Different carbon dioxide emission reduction strategies that are often dictated by over time GHG emission targets, (Huisingh et al. 2015). While other policies define individual emission reduction targets across different industrial sectors, especially ones associated with carbon dioxide point sources that result in considerable emissions (Pinho and Madaleno, 2011). A number of conventional methods may be applied to reduce carbon dioxide emissions such as energy efficiency, carbon capture utilization and storage (CCUS) and the use of renewable energy. Energy management techniques have been implemented by works like Klemeš and Kravanja (2013) and Varbanov et al. (2004) among others. In CCUS, which minimizes emissions by allocating the CO_2 source to sinks for storage, sequestration and utilization. Works such as Boot-Handford et al. (2014) offer a review of possible CO_2 storage sinks, while work such as Al-Mohannadi and Linke (2016), optimized CO_2 networks converting CO_2 to value added products in sinks among others that can be found at Foo and Tan (2016). Moreover, emissions are reduced further

by the use of renewable energy. Carbon dioxide emission reduction policies may prescribe appropriate target emission goals or specific technologies to achieve their reduction goal such as the European Commission Climate Action Plan of 20-20-20, which specifies carbon reduction by 20% by the year 2020 using 20% renewable technology for energy production and 20% increase in energy efficiency.

Carbon dioxide emission targets are often proposed for a point in time in the future. Multi-period carbon integration methods allow carbon reduction schemes to be identified over certain a time horizon. The same target may be achieved in various ways, depending on how the carbon reduction policy is being implemented over time. Therefore, this work studies the effects that result from incorporating different objectives over a given time horizon onto carbon integration networks, using a multi-period approach (Al-Mohannadi et al, 2016). Economic or environmental objectives often have a trade-off that works such as Jing et al (2018) used in energy planning. This work expands the representation by Al-Mohannadi et al, (2016) to evaluates the impact of different time dependent policies onto CCUS–RE decisions, using a multi-period carbon integration approach and understanding the trade-offs between economic and the reduction targets through assessments of multiobjectives. The next sections include a brief description of the problem statement, and is followed by an illustrative example.

2. Description and problem statement

The overall goal is the identification of climate strategies under two conflicting constraitnts which are to achieve the maximum economic and maximum environmental preforamnce in terms of carbon reduction. The challenge is to identify the most promising network allocations from the possible reduction alternatives found for each objective.

The problem addressed requires setting a number of periods, knowing for each period the number of plants and their locations. Based on the existing plants, the total CO_2 emission from the cluster is known with defined CO_2 emission sources in terms of flowrates, compositions, condition (temperature and pressure). A given total power requirement of the cluster, a common utility system with known power demand and supply. In addition, to reduce emissions further renewable power generations options are available with known limits and prices. The model was solved for each objective using "What's Best 9.0" Lindo Global solver for MS-Excel 2010 via a desktop PC with Intel Core i7 Duo processor, 8 GB RAM and a 32-bit operating System (Lindo, 2006). Next, a Pareto curve is constructed to evaluate the performance of each objective. The next section illustrates the concept.

3. Case Study

The proposed concept is illustrated in the following case study, which is an industrial cluster that includes a set given plants. The plants are Oil refinery, Steel production, a fertilizer production facility producing both ammonia and urea in addition to a Natural Gas Fired Power Plant which main information is shown in Table 1. In the industrial clusters, plants and processes were included to reduce carbon dioxide footprint such as a Renewable solar power plant, Enhanced Oil Recovery (EOR), Saline Storage, and a Methanol plant, which is also shown in Table 1.

Table 1: Carbon Integration Data obtained from Al-Mohannadi et al, (2016)

Plants		CO₂ Composition. (wt%)	CO₂ Flow (t/d)	Sink fixation (t CO₂ emitted/ t CO₂ captured)	CO₂ Cost (USD/ t CO₂)
Sinks	Enhanced Oil Recovery (EOR)	0.94	6317	0	-30
	Methanol (MEOH)	0.99	1710	0.098	-21
	Fertilizer Complex - Urea	0.99	1126	0.39	-15
	Saline Storage	0.94	8317	0	8.6
Sources	Fertilizer Complex -CO₂ amine unit	1	977	0	0
	Steel-iron mill	0.44	3451	0	29
	Power Plant-gas turbine	0.07	9385	0	43
	Oil Refinery-boiler	0.27	1092	0	35

Carbon dioxide treatment efficiency parameters, treatment removal, power needed for the compression and transmission were taken from Al-Mohannadi and Linke, (2016). Transmission data including sizes and costs of pipeline and compression were obtained using the method proposed by Kwak, (2016). For a given time frame of five periods over 10 years, the network was first optimized to achieve the maximum economic benefit. The allocation of the network is shown in Table 2.

The network resulted in a total profit of 395 million USD. The most profitable sinks, EOR and methanol, were supplied from the sources that has the lowest treatment needed. Next, the network was optimized to achieve the maximum environmental benefit. The network allocation flows are provided in Table 3.

When the maximum capture target was imposed without any economic constraint, the network resulted in a cost of -600 million USD and 68 thousand CO_2 captured across all periods. The same structure, sources to sinks, connections were chosen. As EOR and Storage had the largest capacities to reduce CO_2 and the highest efficiency of fixating CO_2. The network also activated the maximum allowed renewable power.
Figure 1: Pareto Optimal Solution of the bi-objective problem

From Figure 1, it can be seen that none of the points within Pareto front were identical, in terms of both of the specified objectives. However, the optimum points for the cost objective, still reduced a good amount of CO_2.

4. Conclusions

The approach takes into account multiple time periods, multiple processes including renewable power generation, CCUS, treatment, compression and transmission options needed to develop carbon dioxide allocation networks. The network optimization problem has been formulated as a MILP and can robustly and quickly be solved for industrial clusters of typical size. Different scenarios for an industrial park were explored using the proposed approach and compared using Pareto curve. The approach gives the regulator or policy makers a tool to develop future mitigation strategies and compare plans.

hmackey@hbku.edu.qa

Abstract

The study carried out a life-cycle environmental impact assessment of two reverse osmosis plants located within the Arabian Gulf using three different electric submersible pump (ESP) designs for subsurface intake of seawater and compared these with an existing open intake design. The study used life cycle assessment to quantify impacts for construction and operation of the plant for the various intake options. All values were compared to a functional unit of $1.0 \, \text{m}^3$ of produced desalinated water based on individual well capacities of 15,000 m^3/d and a design life of 50 years. Results showed that the subsurface system performed better across the various impact categories than the open intake. Construction phase impacts of the beach well were insignificant in comparison to operational phase with the exception of abiotic depletion potential, which was still minor. Nevertheless, of the three subsurface beach wells evaluated the slickline ESP design was consistently better than the other two subsurface options, albeit very similar to coil tubing ESP.

1. Introduction

Global freshwater scarcity affects at least 2.8 billion people globally. Of this population, at least 43% (1.2 billion people) have no access to clean drinking water (United Nations, 2014; Mekonnen and Hoekstra, 2016). In response, use of desalination as a reliable alternative water source is increasing (Hoekstra and Mekonnen, 2012). Reverse osmosis (RO), which employs semipermeable membrane barriers, is the current desalination method of choice due to its energy efficiency compared to thermal techniques (Raluy et al., 2006).

Subsurface intakes, particularly if abstracting from brackish ground water, are a superior RO feed source to open seawater intakes due to better chemistry, microbiology and physical properties (Stein et al., 2016). In contrast to open seawater intakes which have high fouling potential requiring significant pre-treatment, subsurface intakes allow natural filtration of sediments, salt precipitates, and active biological treatment, which eliminates or reduces the need of pre-treatment (Missimer et al., 2015; Stein et al., 2016).

There are six types of subsurface seawater intakes, which are classified according to onshore location (vertical wells and beach infiltration gallery) and offshore location in

the seabed (slant wells, horizontal wells, radial collector wells, and seabed infiltration galleries). Vertical wells, also commonly called beach wells, are the simplest subsurface intake systems, constructed according to designs and processes that are similar to conventional groundwater production wells. They are typically located along the beach, where they are screened within unconsolidated beach sand and alluvial materials. They are fitted with pumps, installed vertically above the wells, which induce radial inflow of seawater and inland groundwater into the wells. The rate and sustainability of seawater recharge of the beach wells is limited by local hydrogeology, especially the transmissivity of the aquifers (Missimer et al., 2015). Thus, beach wells have a limited production capacity. A recent modeling study, demonstrated that a beach well in Qatar drilled to a depth of 100 m can produce a maximum of only 16,000 m^3 per km^2 in the coastal zone, which can be considered suitable for small-capacity seawater desalination plants (Baalousha, 2016).

The conventional beach well layout includes an electric submersible pump (ESP) design, which was utilized as early as 1928 (Takacs, 2017). Newer ESP designs, such as coil tubing and slickline, were developed to boost production capacity and efficiency in the oil industry and could find useful application for subsurface seawater RO intake (Dieuzeide et al., 2014). The proposed alternative beach well layout designs using coil tubing ESP and slickline ESP designs are shown in Figure 1. Both designs have been proven worldwide in the oil industry (Dieuzeide et al., 2014) and as summarized in Table 1, provide operational and installation advantages, with slickline ESP systems being optimal. Given these benefits this paper aims to evaluate the environmental impact of ESP systems for subsurface seawater RO intakes and assess their performance over conventional vertical wells and open intakes. This is conducted through the use of life cycle assessment (LCA) of environmental loads associated with the construction and operation of the RO plant and intake systems.
Figure 1: Proposed alternative beach well layouts; A. Current conventional well design; B. Proposed Coil tubing ESP subsurface intake and; C. Proposed Slickline ESP subsurface intake.

Table 1: Comparison between typical beach well design and ESP coil tubing and slickline subsurface intake designs

Design aspects	Typical beach well	Coil tubing beach well	Slickline beach well
Maximum Run Deviation	90°	90°	60°
Installation Mean	Specialized truck or rig	Coil tubing unit	Slickline unit
OPEX	Higher	Lower	Lowest
Production Downtime	3-6 months	1 month	10-15 days

2. Materials and Methods

2.1. Life Cycle Assessment Goal and Scope

LCA is a widely-used process to measure the environmental impacts of different life cycle stages of a system, or compare system alternatives. A cradle to gate boundary LCA was undertaken to investigate the environmental impacts associated with the construction of the various intake systems and the plantwide process operation. The assessment scenarios included an open intake system and three alternative subsurface intake systems (conventional, coil tubing and slickline ESP). The LCA covered materials and diesel associated with machinery for the intake construction, as well as power, material and chemical inputs for the operation phase of the entire plant. The pretreatment and RO unit construction were excluded due to lack of suitable data, but would be identical for all three subsurface systems. All values were compared to a functional unit of 1.0 m^3 produced desalinated water based on individual well capacities of 15,000 m^3/d and a design life of 50 years. LCA was carried out with GaBi software.

2.2. Life cycle impacts

The LCA considered the following impact categories: global warming potential (GWP), acidification potential (AP), eutrophication potential (EP), ozone layer depletion potential (ODP), abiotic depletion potential of elements (ADP-e), abiotic depletion potential of fossil reserves (ADP-f), freshwater aquatic ecotoxicity potential (FAETP inf.), photochemical ozone creation potential (POCP), human toxicity potential (HTP inf.), marine aquatic ecotoxicity (MAETP inf.), and terrestrial ecotoxicity potential (TETP inf.).

2.3. Life cycle inventory

Data from two existing RO plants located across the Arabian Gulf were utilized for this comparison, both using similar pre-treatment processes of DAF and UF, and operating currently with open intakes. Plant 1 had a capacity close to 175,000 m^3/d while Plant 2 had a capacity of close to 275,000 m^3/d. Plants with subsurface intakes were modelled with the DAF pre-treatment units removed based on previous literature that indicates even the UF could potentially be dropped (Shahabi et al., 2015). Construction requirements associated with subsurface wells and open intake were taken from an oil and gas company operating within Qatar. Pumping heads were calculated based on 40 m drawdown for

subsurface wells in the local hydrogeology (Baalousha et al., 2015). Distance from the different subsurface wells and RO plant were assumed to be similar.

3. Results and discussion

3.1. Intake construction impacts

Open intakes exhibited the highest overall environmental impacts related to construction in the areas of GWP, AP, EP, ODP, ADP-f, FAETP inf., MAETP inf. and POCP. The conventional ESP intake in contrast showed maximum impacts with respect to ADP-e, HTP inf., MAETP inf. and TETP inf. Coil tubing and slickline ESP intakes generally exhibited lower impacts than conventional ESP, with slickline ESP consistently exhibiting the lowest impact of the ESP systems with the exception of ADP-e, which was 100% for all three ESP systems (Figure 2).
Figure 2: Construction environmental impacts across various RO intake systems.

3.2. Operational impacts of ESP intakes versus conventional vertical wells

The impacts from plant-wide operation at Plant 1 and Plant 2 were significantly higher than construction impacts for all environmental impact categories assessed, as shown in Figure 3. The low construction impacts is due to the minimal excavations and due to the long lifetime of the two plants of 50 years. The most significant contribution was to ADP-e which accounted for around 6.5% of total ADP-e impacts due to the high use of metals in the intake system.
Figure 3: The percentage of total impacts associated with construction of the intake itself at Plant 1 and Plant 2 for the three different types of subsurface intakes.

3.3. Benefits of using subsurface intakes

Figure 4 demonstrates the relative environmental impacts at the two modelled plants using open and subsurface intakes for the operation phase only, given the minor impact from the intake construction phase. It is clear that subsurface intakes provide significant improvements across all selected environmental impact categories, although significant differences exist between the two plants based on chemical usage for the pretreatment.
Figure 4: The reduction in various impact categories associated with moving from open intake to subsurface intake (modelled as conventional vertical well) with natural gas as energy source.

4. Conclusions

SWRO has the potential to alleviate water scarcity in coastal regions. While subsurface intakes are suitable due to their low environmental impacts, vertical beach wells have bottle neck effects on their potential production capacity. The current study evaluated the environmental impacts of conventional ESP layout design for beach wells and optimized ESP beach well designs, slickline and coil tubing. The conclusions deduced from the LCA are as follows:

- Construction phase impacts of subsurface beach well intakes are minimal compared to the operational phase requirements.
- Operational phase reductions in impacts are significant for subsurface intakes compare to conventional open-water intakes, particularly for ADP and ODP.

- While only small differences exist between the impacts associated with various beach well designs, slickline ESP consistently had the lowest construction related environmental impacts and is therefore the most suitable candidate given its proven economical value also,.

Abstract

Biofuels are attractive energy renewable sources to satisfy the current growing energy demand, but large-scale production requires the installation of complex biorefinery systems that involve strategic decisions for design and operation such as to determine the location, feedstocks, production capacities, as well as the impact on the surrounding environment. This work proposes an optimization model for the design of a biorefinery system through an efficient supply chain considering economic (minimization of the total annual cost) and environmental objectives (minimization of the overall CO_2 emission and the water consumption along the nexus). This approach considers the inherent uncertainty on prices of feedstocks and products, biofuel demands, biomass requirements, weather conditions, agricultural production, etc. Finally, a case study located in Mexico is solved for several scenarios to illustrate the capacity of this approach. The solution shows the trade-off among the considered objectives affected by uncertainty in the biorefinery system.

Keywords: Biorefineries, Supply chain, Nexus, Uncertainty, Material flow analysis.

1. Introduction

Nowadays, the high energy demand has allowed the development of other energy sources such as of biofuels. This energy alternative represents an attractive and renewable option to partially reduce the consumption of fossil fuels. Nevertheless, large-scale production requires the installation of several biorefineries. A biorefinery is an industrial plant that from biomass produces high value-added chemicals and biofuels (bioethanol and biodiesel) [1]. Currently, the design of sustainable processes is essential [2]. Recent advances in processing technologies enable the conversion of non-food biomass resources for the controversy that exists against the food sector through second generation biofuels where the use of residues involves higher environmental benefits. With the variety of feedstocks, processing technologies, portfolio or products, geographic and market conditions, involves complex decisions to determine the optimal location, equipment, and operation of these industrial plants [3]. The objective is to synthetize a supply chain to

satisfy the market demand while the production of feedstock is determined, as well the capacity and location of the processing facilities to convert this biomass to biofuels. Also, to design a robust biorefining system and to have a close estimation of the environmental impact that this energy sector can produce, the uncertain effects should be considered as weather conditions, agriculture parameters, conversion factors, etc. We propose an MFA (Material Flow Analysis) [4] approach for the watershed segmentation in reaches, where in each of them exists the possibility to install a biorefinery. Within each reach, the flow and main characteristics are assumed constant, even considering that several tributaries can feed to each reach. In this regard, this approach accounts for water extractions and discharges associated with domestic, agricultural and industrial uses, in addition to the natural phenomena such as filtration, evaporation and precipitation. Thus, mass balances, property tracking, and physical, chemical, and biochemical phenomena are included for each reach. Also, it estimates the overall CO_2 emissions by the industrial activity related to the biofuels production, and the balance considers the CO_2 fixation by the cultivation lands where the feedstocks are cultivated. The optimization approach is driven by economic (maximization of the total annual costs for the whole supply chain) and environmental (Minimization of the overall greenhouse emission) goals considering simultaneously the effects on the watershed. Because water is the resource of interaction between the sectors that make up the nexus.

2. Model Formulation

The problem is focused on satisfying the biofuel demand in a specific region where several feedstocks are candidate to be processed with existing and new potential cultivation areas, processing technologies, potential location for installing biorefineries, and large portfolio of bioproducts. Given the installation and operation of a biorefinery system (set of biorefineries to supply great demands) the impact on the environment must be considered in a sustainable design, in this case according with numerous studies the water reservoir is the most affected by this industrial activity. Surrounding watershed provides water for different facilities, as well as pollutant effluents are discharged. Implementing a Material Flow Analysis technique, the watershed is analysed to determine the environmental impact through water balances accounting for the availability of resources and environmental constraints along the watershed to avoid affectations for existing tasks as agricultural, residential or industrial activities. The proposed complex industrial system studied as a water-energy-food nexus is design through synthetizing the supply chain obtaining the production and operation specification. Also, the uncertainty that affects several parameters is considered.

The optimization approach is described and proposed as follows:

Watershed at initial conditions before the implementation of the biorefining system

$$Q_{r,s}^{Initial-Out} = Q_r^{In} + P_{r,s} + D_{r,s} + H_{r,s} + \sum_{t=1}^{N_{(t)}} FT_{r,t,s} + \sum_m w_{m,r,s}^{Discharge-feedstocks\_Initial}$$
$$- \sum_m w_{m,r,s}^{Used-feedstocks\_Initial} - L_{r,s} - U_{r,s}, \qquad \forall r, \forall s \tag{1}$$

Watershed at final condition (once the biorefining system is establish)

$$Q_{r,s}^{Out} = Q_r^{In} + P_{r,s} + D_{r,s} + H_{r,s} + \sum_{t=1}^{N_{(t)}} FT_{r,t,s} + \sum_m w_{m,r,s}^{Discharge-feedstocks} + \sum_k w_{k,r',s}^{Discharge-biorefinery} -$$
$$\sum_m w_{m,r,s}^{Used-feedstocks} - \sum_k w_{k,r',s}^{Used-biorefinery} - L_{r,s} - U_{r,s}, \qquad \forall r, \forall s \tag{2}$$

Wastewater discharges from new biorefineries

$$w_{k,r',s}^{Discharge-biorefinery} = \sum_m \alpha_{k,m,s}^{ww-biorefinery} P_{k,m,r',s}^{Bio}, \quad \forall k, \forall r', \forall s \tag{3}$$

Production at the cultivating fields

$$f_{m,r,s}^{Prod-feedstock} = \alpha_{m,r,s}^{fedstock} \left[a_{m,r}^{exist} + a_{m,r}^{new} \right], \quad \forall m, \forall r, \forall s \tag{4}$$

Activation of binary variables for biorefineries

$$F_{m,r',s} \leq F_{m,r'}^{max} y_{r',s}^{Biorefinery}, \quad \forall r', \forall s \tag{5}$$

Production of biofuels

$$P_{k,m,r',s}^{Bio} = \alpha_{k,m,s}^{Bioref} F_{m,r',s}, \quad \forall k, \forall m, \forall r', \forall s \tag{6}$$

Distribution of products to the markets

$$P_{k,r',s} = \sum_j P_{k,r',j,s}^{Prod-market}, \quad \forall k, \forall r', \forall s \tag{7}$$

Economic equations

Capital cost for biorefineries

The capital cost for biorefineries has associated fixed and variable charges as follows:

$$CapCost_s^{Biorefineries} = k_F \left[\sum_m \sum_{r'} FC_{m,r'}^{Biorefinery} y_{r',s}^{Biorefinery} + \sum_m \sum_{r'} VC_{m,r'}^{Biorefinery} \left(F_{m,r',s} \right)^{\sigma_{m,r'}^{Biorefinery}} \right], \quad \forall s \tag{8}$$

Objective function

Total annual profit

The total annual profit accounts for all the sale gains, minus the cost of installation and operation of biorefineries, the agriculture cost to cultivate the biomass, water costs, and product and raw material transportation costs.

$$Profit_s = G_s^{Products} + G_s^{Grains} - CapCost_s^{Biorefineries} - OpCost_s^{Biorefineries} - OpCost_s^{Feedstocks} - $$
$$OpCost_s^{Water-biorefineries} - OpCost_s^{Water-feedstocks} - TCost_s^{Feedstocks} - TCost_s^{Grains} - TCost_s^{Products} \tag{9}$$

For this proposed system, the profit has a different value for each scenario, the involved uncertainty drastically impacts the economic target.

Expected profit

Considering the strong fluctuation that affect the profit, the model formulation defines the expected profit, which corresponds to the distribution profile for all the scenarios:

$$MProfit = \overline{Profit_s} = \frac{1}{scenario(s)} \sum_s Profit_s(s), \quad \forall s \tag{10}$$

Worst Profit

It is particularly important to maximize the worst scenario for the economic performance. Thus, the decision makers can decide among risky configurations for the uncertainty management in the project.

$$MProfit \geq WProfit \tag{11}$$

Total water requirements for the proposed biorefining system

$$Water_s^{required} = Q_{s\,final}^{Initial} - Q_{s\,final}, \quad \forall s \tag{12}$$

Expected fresh water consumption

The available sites to install industrial plants will define the requirements of water for this location, also it is important to include the expected value for the fresh water consumption:

$$MWater = \overline{Water_s} = \frac{1}{scenario(s)} \sum_s Water_s^{required}(s) \tag{13}$$

Worst fresh water consumption

In the same way, it is essential to know the worst scenarios for the performance of the fresh water consumption in the biorefining system:

$$WWater \geq Water_s^{required}, \qquad \forall s \tag{14}$$

CO₂ emissions

The overall CO_2 emissions are estimated by the industrial and transportation operation where the capture of emission by cultivating areas is considered:

$$CO2_s^{total} = CO2_s^{prod} P_s^{biototal} - CO2_s^{abs} A_s^{total}, \qquad \forall s \tag{15}$$

3. Results

The proposed optimization model corresponds to a mixed integer non-lineal programming (MINLP) model. The model was coded in GAMS (General Algebraic Modelling System), and the data of the case study were charged. The uncertainty was considered for several parameters, where N-scenarios are generated through the Latin Hypercube Sampling method under normal distributions. Monte Carlo simulation is implemented to evaluate the risk in quantitative analysis for the parameters analyzed.

A case study was solved to evaluate the capacities of the proposed model. This case study is located in the central part of Mexico that is considered as a high-potential region due to the availability of resources and the predominant agricultural activity. The balsas river is considered as the watershed of analysis to estimate the environmental impact for the water consumption and the effluent discharges using the MFA approach. The watershed was divided in 23 fixed reaches based on hydrologic and geographic studies considering some parameters of the watershed system such as precipitation, filtration, evaporation or discharges due to industrial or residential activities to estimate the biomass and biofuel production. The total demand of biofuels is required by 10 markets, where each one is represented by a city along the studied region. The feedstocks are second generation biomass, where residues of corn, wheat, sorghum, and sugar are used to produce bioethanol, and for biodiesel production are cultivated jatropha and palm oil. The biofuel demands for each market were estimated using projections by the Energy Council of Mexico (SENER), and SENER-BID-GTZ (2016) projected for the next decade that the 10 % of the total energy demand will be satisfied by biofuels. The model was solved using the solver CPLEX. The optimization model consists of 309,650 continuous variables, 84,947 constraints, and 23 binary variables. The CPU time and the average solution for the objectives in expected and the worst scenarios are presented in Table 1. The time horizon is a year with an investment time of ten years. 50 scenarios were generated using Monte Carlo simulations.

The optimization problem was solved for the economic targets. At first, it is obtaining the maximization of profit being the greatest value that represents the optimistic economic condition, and the lowest represents the worst condition. Figure 1 shows the profit and water demands, where 3 interested scenarios were chosen. The solution for each scenario represents a specific configuration for the supply chain, as well the composition and operation of the biorefining system. For example, in scenario 3 with 94 % probability of occurrence, the expected profit is $US 7.58×10^8/y and 3.24×10^7 m³/y of demand of fresh water. where 7 biorefineries are required to satisfy the biofuel demands in the considered markets. The total biofuel production is 6.71×10^7 L/y of bioethanol and 8.66×10^7 L/y of biodiesel, the distribution between the type of biomass used and produced biofuels are presented in the Figure 2. But for the greatest economic risk that we have the worst profit that can be obtained of US$ 7.32×10^8/y and 3.25×10^7 m³/y of fresh water consumption.

Also, the satisfied demand of feedstocks and products are estimated. The availability of land to cultivate crops in the region was considered but also the possibility of increment, in the presented solution 19, 377 ha of new area should be cultivated to satisfy the biomass demand. For scenario 2, with 70 % of occurrence, it is possible to obtain approximately at least a profit of US$ 673 million for the worst profit, when the profit can reach up US$ 720 million (achieving an increase of 6.98 %). For the optimistic environmental conditions, the system has the lowest consumption of water, where the system with the greatest probability of occurrence yields a profit of US$ 1.68×10^8/y and the demand of water is 2.07×10^7 m³/y with a biofuel production of 4.4859×10^7 L/y for bioethanol and 1.701459×10^8 L/y for biodiesel, for this scenario the area requires to be increased in 34,224 Ha to cultivate corn, 55 Ha for wheat, and 3,268 ha for oil palm.

Table 1. Case study solutions.

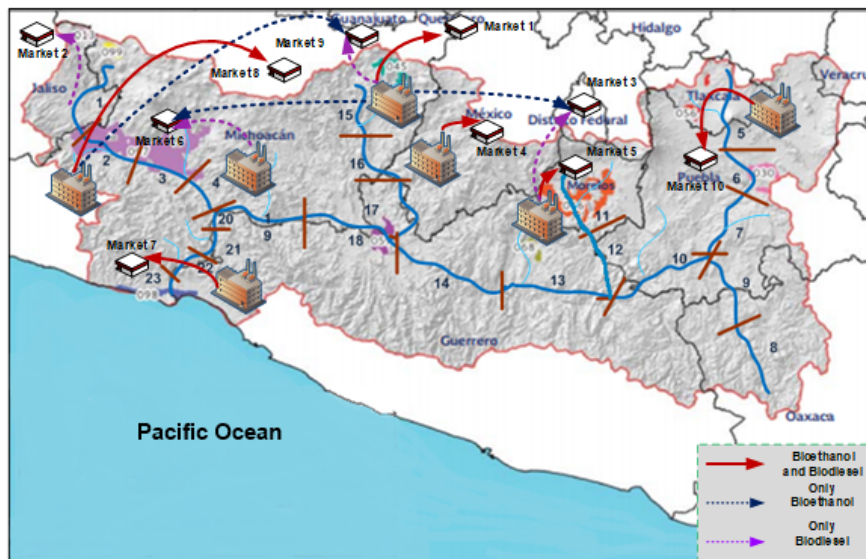
Case	CPU TIME (s)	AVERAGE SOLUTION
Maximizing Mprofit	2426	US$6.79 x10⁸/y
Maximizing Wprofit	90.4	US$6.44 x10⁸/y
Minimizing Mwater	244.7	2.01 x10⁷ m³/y
Minimizing Wwater	27.05	5.04 x10⁵ m³/y
Figure 1. Pareto curve for the profit vs water demand.


Figure 2. Optimal configuration for the biorefinery system in scenario 3 for expected profit.

4. Conclusions

The proposed mathematical approach incorporates the use of agricultural residues to reduce the environmental impact, as well as an analysis in the watershed to understand the interconnection between sector that works as a nexus, the sale of grains as economic retribution in the system, and the uncertainty to have a robust model.

The optimization approach is an efficient tool that determines the location and operation logistics of biorefineries, new cultivation areas and associated food profits and biomass wastes, fresh water demands, production of feedstock and biofuels, production and capture of greenhouse gas emission, routes of distribution considering environmental and economic objectives. The tradeoffs between these objectives were analyzed and discussed with focus on the strong impact of some environmental constraints on the selection of feedstock growth and location as well as production capacities and impact on the surrounding watershed.

Reduced model-based global optimisation of large-scale steady state nonlinear systems

Min Tao[a], Jie Li[a] and Constantinos Theodoropoulos[a*]

[a]*School of Chemical Engineering and Analytical Science, The University of Manchester, M13 9PL, UK*
*k.theodoropoulos@manchester.ac.uk

Abstract

Many engineering systems can be accurately simulated using partial differential equations (PDEs), resulting in large-scale distributed parameter systems. Deterministic global optimisation algorithms (GOP) can compute global optimal solutions offering theoretical guarantees on the global optimality. However, distributed parameter systems pose computational challenges for these optimisation methods. Model reduction techniques can produce low-order systems that are computationally amenable. In this work, a combined principal component analysis (PCA) and artificial neural networks (ANNs)-based model reduction methodology is employed for the global optimisation of large-scale distributed steady state systems. Still, the optimisation problem is hard to solve due to the high nonlinearity of activation functions in the reduced ANN structure. A novel piece-wise linear approximation reformulation is introduced to reduce the complexity of the original problem and to provide a good globally approximate solution. The performance of the proposed PCA-ANN-GOP framework is demonstrated through an illustrative example: a tubular reactor where an exothermic reaction takes place.

Keywords: Model reduction, Distributed parameter systems, Artificial neural networks, Global optimisation

1. Introduction

PDE-constrained black/grey box modelling and optimisation methodologies have wide applicability in industrial engineering areas where many finite approximation-based generic commercial simulators or input-output data from real complex systems are available (Boukouvala et al., 2017). However, many simulators solely provide input-output results of simulation process and can not perform optimisation tasks. Hence, the optimisation of real complex systems is problematic. Even if the high dimensional complex model codes are available, the cost of computing derivatives is often unacceptable. One of the most effective techniques to reduce computational costs for input/output systems is the use of *equation-free* methods (Theodoropoulos, 2011). Recently, equation-free based reduced SQP algorithms have been exploited for large-scale local optimisation with black-box steady-state simulators (Bonis and Theodoropoulos, 2012). With a small set of input-output data from the simulator, matrix-free reduced Jacobian and Hessian matrix techniques can be employed. The aim of this work is to construct deterministic global optimisation methods for large-scale input/output simulators. Such deterministic global optimisation methods are usually computationally intensive due to the repeated utilisation of branch-and-bound algorithms. Hence, in terms of computational cost, detailed models of large-scale problems are very hard or even impossible to deal with.

In this work, a data-driven methodology is employed first to create a good approximate surrogate model for large-scale steady-state systems. Principal component analysis (PCA) in combination with artificial neural networks (ANNs) is used to produce a reduced order model. The reduced model (ANN-constrained model) is then utilized by the global general-purpose optimisation solver BARON (Tawarmalani and Sahinidis, 2005). Furthermore, we present a novel piece-wise linear approximation reformulation for the nonlinear constraints in order to accelerate the computation of the global optimum for the reduced system.

2. Model Reduction

The focus of this work is on optimisation of spatially distributed processes, described by a set of steady-state dissipative PDEs with accompanying boundary and initial conditions:

$$\frac{\partial X}{\partial t} = D\{\frac{\partial X}{\partial y}, \frac{\partial^2 X}{\partial y^2}, ..., \frac{\partial^n X}{\partial y^n}\} + R(X, P_m) \tag{1}$$

where D is a dissipative spatial differential operator, $R(X, P_m)$ is a nonlinear function, P_m are the parameter variables and X the set of state variables. If we consider the steady state analysis of these equations, we assume that $X(t, y) \rightarrow X(y)$, and we can set $\frac{\partial X}{\partial t} = 0$, giving the equations:

$$0 = D\{\frac{\partial X}{\partial y}, \frac{\partial^2 X}{\partial y^2}, ..., \frac{\partial^n X}{\partial y^n}\} + R(X, P_m) \tag{2}$$

Due to the large number of variables in the corresponding discretised problems, the full model is usually too big for global optimisation (Houska and Chachuat, 2017). This barrier can be overcome by employing model reduction methodologies such as artificial neural networks and principal component analysis. Principal component analysis (PCA) is a powerful methodology for data compression. Common linear PCA is a transformation of the original data space spanned by the principal components (PCs). *PCs* are the basis vectors for the new space and are ranked by the magnitude of variance of the original data projected onto the corresponding PCs. PCs can be computed by matrix decomposition as in (Jackson, 2005):

$$Y = TP^T + E \tag{3}$$

where $Y \in R^{N \times m}$ is the high dimensional sample data from the large-scale steady state simulator given by Eq.(2), N and m, the number of sample data and data dimension, respectively. $T \in R^{N \times a}$, is the score matrix for the *PCs* and a $(a \leq m)$, the number of *PCs*. $P \in R^{m \times a}$ is the loading matrix and $E \in R^{N \times m}$ the residual matrix.

In order to compute a representation for the outputs produced by the the black-box simulator, the Latin hyper-cube (LHC) sampling method is applied to collect snapshots. LHC sample method can maximize the sample information content for a limited number of samples. After snapshots collecting and PCA reduction steps applied, the high dimensional input-output data is transformed into lower dimensional PC scores. Subsequently a reduced order model is built through the use of the reduced data obtained. Here, we adopt artificial neural networks (ANNs) because standard

feed-forward artificial neural network (ANN) with one hidden layer can be an universal approximator for any smooth function (Hornik et al., 1989). The structure of the feed-forward ANN is relatively simple and easy to be constructed. In this work, the training process for ANN is performed in MATLAB R2017a with Neural Networks toolbox. The activation function is chosen to be the hyperbolic tangent function. The neural network is trained with the Levenberg-Marquardt back-propagation algorithm, which can reduce the mean square error quickly. The input is the low-dimensional input parameter matrix from the black-box simulators. The output is the reduced principal component scores of the output data from black-box simulators. At this point, data-driven PCA-ANN based surrogate model has been built that can be employed for global optimisation.

3. Model reduced global optimisation

The general nonlinear optimisation problem with embedded neural networks (reduced model) is considered. The general problem can be formulated as follows:

$$
\begin{aligned}
\min_{x \in R^c, y \in R^d} \quad & f(x,y) \\
s.t. \quad & h(x,y) = 0, \\
& g(x,y) \le 0
\end{aligned}
\tag{4}
$$

where the objective function $f(x,y) : R^c \times R^d \to R$, $x \in R^c$ is an input vector of the black-box simulator, $y \in R^d$ is an output vector of the black-box simulator, $h(x,y): R^c \times R^d \to R$ is ANN constraint derived from the reduced model, and $g(x,y): R^c \times R^d \to R$ represents other constraints.

In the current work, $g(x,y)$ are the bound constraints for the state variables. The intrinsic nonlinearity of the optimisation problem lies on $h(x,y)$ due to the activation function of the ANN structure. The feed-forward ANN uses the hyperbolic tangent function $tanh(\cdot)$. The general global optimisation software BARON is employed to solve the above problem. General global solvers in GAMS such ANTIGONE and BARON can not identify $tanh(\cdot)$, so its explicit algebraic form ($tanh(x) = \frac{e^x - 1}{e^x + 1}$) is utilized. The basic formulation is transformed into $tanh(x) = \frac{-2}{e^x + 1} + 1$ in order to produce a tighter under-estimator for the global solver.

However, the computational cost of global solvers increases exponentially when reducing the high non-convexity of the activation function. We propose a novel piece-wise linear approximation (PWA) reformulation for the activation function. With an accurate PWA model, a good approximation to the true global solution can be obtained. It should be, however, noted that a PWA reformulation transforms the high non-convex NLP problem into a set of MILP problems. The global solvers for both NLP and MILP problems are based on the branch and bound framework. The biggest difference is that they turn the continuous variables into auxiliary binary variables on the branch step. The advantage of the PWA reformulation lies on the use proven MILP software such as CPLEX. Here, we present an iterative way to collect piece-wise points for PWA models. $tanh(x)$ is an odd function of central symmetry, which is concave on $[0, +\infty]$ and convex on $[-\infty, 0)$. So it is easy to compute the grid points for piece-wise approximation of $tanh(x)$ on $[-\infty, 0)$ when the grid points on $[0, +\infty]$ are available. On the range of $[0, +\infty]$, $tanh(x)$ experiences a short-time' increase and then tends to be "static" (very slow growth to its limit value). In the current work, we start from only two intervals and three grid points (original point and two static points) in this range. The linear model in a static interval can approximate the activation function accurately. For the 'initial short-time' increasing interval, we reduce the error between the multiple linear models and the nonlinear $tanh(x)$ by iteratively narrowing the interval sizes.

The iteration procedure is performed by adding more partitioning points where the largest error is calculated. In addition, a sub-interval is acceptable if the biggest error or the number of intervals satisfies a set requirement. This iteration process efficiently produces a set of collecting points, which contribute to a tight piece-wise linear representation of the highly nonlinear activation function. Assume that there are N linear models , $N+1$ generated grid points $x_1, x_2, ..., x_{N+1} \in R$ and approximate function $f = tanh(x_i)$ in the ith interval. By introducing auxiliary variables h_i and λ_i , we can generalize the formulation of a piece-wise linear approximation as follows (Floudas, 1995):

$$
\begin{aligned}
f(x) &= \sum_{i=1}^{N+1} \lambda_i f(x_i) \\
x &= \sum_{i=1}^{N+1} \lambda_i x_i \\
\sum_{i=1}^{N+1} \lambda_i &= 1 \\
\lambda_1 &\leq h_1 \\
\lambda_i &\leq h_i + h_{i-1}, \forall i \in \{2, 3, ..., N\} \\
\lambda_{N+1} &\leq h_N \\
\lambda_i &\geq 0, \forall i \in \{1, 2, ..., N+1\} \\
\sum_{i=1}^{N} h_i &= 1 \\
h_i &\in \{0, 1\}^N
\end{aligned}
\tag{5}
$$

In the next section, this algorithm is employed to a system of steady-state PDEs after collecting a "good" set of snapshots in order to illustrate its computational capabilities.

4. Application

We first apply our methodology to an example with known global optima for illustration purposes. Then we apply our PCA-ANN-GOP framework to a large-scale steady state nonlinear PDE-based system.

4.1. Illustrative example

In this illustrative example, a two-dimensional multimodal function is chosen, obtained by translating and scaling Gaussian distributions:

$$
\begin{aligned}
g_{peaks} = 3(1-x)^2 exp(-x^2 - (y+1)^2) - 10(\frac{x}{5} - x^3 - y^5)exp(-x^2 - y^2) \\
- \frac{1}{3}exp(-(x+1)^2 - y^2)
\end{aligned}
\tag{6}
$$

where variables $x, y \in [-3, 3]$. Multiple local solutions exist in this defined domain. The known unique global optimum lies on the point $(0.228, -1.626)$ where the function value is -6.551. We just use it to show the performance of our reduced global optimisation methodology.

Table 1: Comparative results of ANN-constrained model and PWA models

Model	Solver	Optimal value	CPU time (s)	Rel.gap
ANN-constrained model	BARON	-6.555	30294.26	0.002
PWA model1 (31 grid points)	CPLEX	-6.542	1004.71	0.002
PWA model2 (59 grid points)	CPLEX	-6.540	4190.16	0.002

After sampling and ANN learning , we obtain an ANN-constrained reduced model with 52 neurons. we do the global optimisation with reduced model and PWA models. ANN-constrained model is the surrogate model after ANN step. PWA model1 is the piece-wise approximation model for hyperbolic activation function with 31 grid points while PWA model2 is the piece-wise approximation model with 59 grid points. The number of grid points depends on the chosen error during the above iteration process. The NLP with ANN-constrained model is solved by the general global solver BARON 17.4.1/GAMS 24.8.5, and MILP with PWA model is dealt with CPLEX 12.7.1/GAMS 24.8.5 on a Desktop (Intel Core(TM) CPU 3.3 GHz, 8 GB memory, 64-bit operating system) running Windows 7. The results are given in Table 1. From Table 1, we can see that we obtain almost the same optimal solution, very close to the true global optimizer of the original problem. In addition, our proposed PWA formulation can reduce the computation time greatly with high accuracy.

4.2. Case study

The effectiveness of our PCA-ANN-GOP is illustrated using a chemical engineering application; a tubular reactor, where an exothermic reaction takes place. The mathematical formulation of the tubular reactor optimisation is given below:

$$\max_{T_{wi}} C_{exit}$$

$$s.t. 0 = \frac{1}{Pe_1}\frac{\partial^2 C}{\partial y^2} - \frac{\partial C}{\partial y} + Da(1-C)exp(T/(1+T/\gamma))$$

$$0 = \frac{1}{LePe_2}\frac{\partial^2 T}{\partial y^2} - \frac{1}{Le}\frac{\partial T}{\partial y} - \frac{\beta}{Le}T + BDa(1-C)exp(T/(1+T/\gamma)) + \frac{\beta}{Le}T_w$$

$$0 \leq Twi \leq 5$$

(7)

Here C and T are the dimensionless concentration and temperature respectively, while C_{exit} is dimensionless output concentration .The system parameters are $Pe1 = 5, Pe2 = 5, Le = 1, Da = 0.1, \beta = 1.5, \gamma = 10, B = 12$; T_w is the adiabatic wall temperature of the cooling problem with three cooling zones, expressed as following:

$$T_w(y) = \sum_{i=1}^{N} (H(y-y_{i-1}) - H(y) - y_i) T_{wi}$$

(8)

The resulting discretised 500 algebraic equations comprise our house-made simulator . After model reduction step (PCA and ANN steps), a small size ANN-constrained optimisation problem (3 input, 12 output, 20 neurons ANN) is generated, which is easy to be solved. In order to compare the computation efficiency of ANN-constrained model and PWA models, we compute the results with different numbers of neurons. All these computation cases converge to almost the same
Figure 1: Solution profiles at optimum for concentration
Figure 2: Computation time (sec) under different number of neurons

solution, whose objective values are extremely close to 0.999. Figure 1 gives the optimal solution profiles for concentration distribution under 30-neuron ANN structures. The three concentration distribution curves for different approximate models almost overlap. Hence, our PWA models show high computation accuracy. Figure 2 illustrates the comparison of the computation cost for the different models. The limit time (max time for computations to stop)is set to be 36000 seconds. As it can be seen, computation time increases rapidly as with increasing number of neurons. The computation cost reaches the limit time for the ANN-constrained model with only 40 neurons while the computation times are much smaller for both PWA models. This verifies the high computation efficiency of our PWA models.

5. Conclusion

We propose a reduced model-based global optimisation framework for large-scale steady state nonlinear systems. Data-driven PCA and ANN techniques are employed to produce a small or middle size surrogate model for the original system. To further reduce computation complexity, novel PWA models are utilized to replace the reduced ANN-constrained model. Illustrative examples are presented to verify the efficiency of our framework. Computation results reveal that our PCA-ANN-GOP framework can capture the global optimum with acceptable computational cost, especially when PWA approximations are used.

Abstract

The development of new technologies is essential to contrast the increasing global CO_2 emissions. Microalgae-based biorefineries present a promising tool to reduce the presence of CO_2 in our emissions (Bekirogullari et al 2018, Bekirogullari et al 2017). The development of processes for the simultaneous production of more than one product are essential to increase the possibility of making such biorefineries profitable (García Prieto, Ramos, Estrada, Villar, & Diaz, 2017). Microalgae eukaryotic cells are able to produce pigments and lipids. The production of lipids and pigments could vary depending on the environmental stress conditions such as light intensity, nutrients concentration, medium salinity, and temperature (D'Alessandro & Antoniosi Filho, 2016). *Haematococcus pluvialis* produces lutein, β-carotene, and lipids during growth, which makes it a potential candidate for the simultaneous production of high value products. *H.pluvialis' * division pattern ranges from the formation of two daughters up to 32 cells by multiple-fission (Shah, Liang, Cheng, & Daroch, 2016). New born cells achieve after a dimensional growth step a critical size point, where after that, they are able to keep growing and reproduce without any further input in the system, this point is called commitment point (CP). The achievement of an higher number of CP lead to a higher number of cells in the day/night cycle (Bišová & Zachleder, 2014). The above phenomena reaching one commitment point are described using a population balance model (PBM), in order to evaluate the influence of some environmental conditions on the cell growth. The model was fitted against synchronized experimental data, and then tested on a long duration experiment.
Keywords: microalgae; population balance models, synchronisation.

1. Introduction

The capability to produce high-value products such as neutral lipids, pigments, carbohydrates, proteins, and other products makes the development of the microalgal biorefinery processes interesting. The development of microalgae biotechnology is a

possible candidate to solve significant issues such as the depletion of fossil fuels through the production of biofuels, wastewater removal through the consumption of NH_4^+, NO_3^-, and $PO_4^{3-}$and land utilization reduction utilising less land per litre of products produced. Moreover, they have a variety of metabolites produced which can be useful in many fields (Mata, Martins, & Caetano, 2010). Furthermore, CO_2 emissions from fossil-fuel shows an increase during the last decades, especially in developing countries (Olivier, Schure, & Peters, 2017), and microalgae are considered within a biotechnology perspective for CO_2 sequestration (Singh & Ahluwalia, 2013).

Microalgae, during cultivation, cover a series of essential steps leading to multiplication. Starting from the new born cell, the first phase is represented by the cell volume growth up to reach the commitment point (CP) (Bišová & Zachleder, 2014). This first cycle phase could be observed through a synchronisation of the cell population, and then following the cell population volume growth through the light cycle (Hlavová, Vítová, & Bišová, 2016). The given procedure could be improved and applied to other cell constituents, such as lipids and/or pigment. In this work the basis for a volume-structured PBM model was constructed, and the parameters related with the volume growth rate were estimated from synchronous experiments, followed by a prediction of a long-term experiment. Such models can give accurate predictions of individual cell growth and can be subsequently efficiently coupled with kinetic expressions and/or metabolic-level models to predict the production of lipids pigments and of metabolites within.

2. Materials and Methods

Haematococcus pluvialis strain FLOTOW (1844) CCAP 34/6 was purchased from Culture Collection of Algae and Protozoa (CCAP) Scotland, United Kingdom. The medium is carbon-free NIES-C. Two experiments were carried out and the starting point for both experiments is a cell culture inoculated at 5.5×10^3 cell mL^{-1} in 215mL medium in a glass bottles (500mL) with a sponge cap. Both of them were incubated at 27°C, stirred at 130 rpm, and illuminated at 60 µmol $m^{-2}s^{-1}$ by using white fluorescent neon, and considering 16/8 light dark cycle. The first experiment examines microalgae synchronisation, following an adapted procedure suggested by (Hlavová *et al* 2016), and the second experiment is a long-term photoautotrophic growth. The synchronisation experiment reaches around 2.0×10^5 cells mL^{-1} after 16 days. Starting from this point cells were kept at this concentration for 72 hours diluting the culture with NIES-C medium at the beginning of every light cycle. Starting from the 72th hour regular sampling was performed until the end of the light cycle, in order to follow the dimension, and the number of the cell population by using Cellometer Auto T4 purchased from Nexcelom Bioscience LLC. In the second experiment samples were taken starting from time zero every seven days until the 3tth day, and the volume and number population properties weremeasured. All of the experimental results presented are the mean of duplicate experiments.

3. Model development

The proposed model is based on the PBM model equations firstly proposed by Fredrickson (1967). The model is represented by an integro-partial differential equation (Eq.1) including a vector of initial conditions (Eq.2), and boundary conditions (Eq.3). The particle state is assumed to depend only on the volume which is an internal coordinate. The choice of the volume is related to the considerations given in many works where the volume seems to be the variable related to the CP achievement in

microalgae (Bišová & Zachleder, 2014; Šetlík & Zachleder, 1984; Zachleder & Vítová, 2016), which aims to give a solid basis for future works in this direction. The term Ψ represents the number concentration density function, r_v and Γ^v are the rate of change for the particle state vector, and the transition rate for the birth term, respectively. They depend on the volume v, and on the attenuated light I_{att}.

$$\frac{\partial \Psi(v,t)}{\partial t} + \frac{\partial [r_v \Psi(v,t)]}{\partial v} = 2 \int_v^\infty \Psi(v',t)\Gamma^v(v',I_{att})p(v,v')dv' - \Psi(v,t)\,\Gamma^v(v,I_{att}) \tag{1}$$

$$\Psi(v,t) = \Psi^0(v) \text{ for } t = 0 \text{ and } \forall v \tag{2}$$

$$\Psi(v,t) = 0 \text{ for } t > 0 \text{ and } v = 0 \tag{3}$$

The model was reduced in order to perform an ideal fitting procedure. The birth term is set to zero, and only the part regarding the volume growth considered (Eq.4).

$$\frac{\partial \Psi}{\partial t} + \frac{\partial (r_v \Psi)}{\partial v} = 0 \tag{4}$$

$p(v,v')$ represents the partitioning distribution function, which considers how mother cells internal properties are redistributed in daughter cells. The one used here is able to get unequal partitioning (Hatzis, Srienc, & Fredrickson, 1995), q being a coefficient.

$$p(v,v') = \frac{1}{\beta(q,q)} \frac{1}{v'} \left(\frac{v}{v'}\right)^{q-1} \left(1 - \frac{v}{v'}\right)^{q-1} \tag{5}$$

Light attenuation functionalities related to volume-structured PBM models are not present in literature. In this model a functionality is given (Eq.6), which takes into account the ratio between the total cells volume V_{cell}^T, and the total volume of the culture V^T, α_{att} being a fitting parameter. The total volume of the cells is given by the first order moment of the distribution multiplied by the total cell volume (Eq.7).

$$I_{att} = I_0 \left[1 - \frac{V_{cell}^T}{V^T}\right]^{\alpha_{att}} \tag{6}$$

$$V_{cell}^T = V^T \int_0^\infty v\Psi(v)dv \tag{7}$$

The rate of change for the particle state vector considers the light attenuated by using a Monod functionality (Monod, 1949), where $K_{I_{att}}$ indicates the half saturation light term. Moreover, the volume is considered to influence the volume growth, in particular the raising volume is considered to make the volume growth rate lower, it is represented by an inhibition functionality with K_v inhibition constant. The latter right-hand term represents the decay rate, and μ_C is the decay rate constant (Eq.8).

$$r_v(v,I_{av}) = \mu_v \frac{I_{att}}{I_{att}+K_{I_{att}}} \frac{K_v}{v+K_v} - \mu_C v \tag{8}$$

The transition rate between mother cells and daughters is expressed as a function of the rate of change for the particle state vector multiplied by the gamma function γ^v (Eq.9). The functionality is like the one used in previous a previous work, considering the mass

as internal variable, for microalgae (Concas, Pisu, & Cao, 2016). The probability to undergo division increases when the cells are approaching the critical volume v_c. σ_c^2 is the variance of the Gaussian functionality considered in equation 11.

$$\Gamma^v(v, I_{av}) = r_v(v, I_{att})\gamma^v(v) \tag{9}$$

$$\gamma^v(v) = \frac{f(v)}{1-\int_0^v f(v')dv'} \tag{10}$$

$$f(v) = \frac{1}{\sqrt{2\pi\sigma_c^2}}\exp\frac{-(v-v_c)^2}{2\sigma_c^2} \tag{11}$$

4. Results and discussion

Parameter estimation has been carried out for the parameters involved in the cell volume growth description by using the data obtained from the synchronisation experiment, following a possible ideal procedure (Fadda, Cincotti, & Cao, 2012). The partial model showed in equation 4 was utilized. The initial volume distribution for the parameter estimation was obtained by fitting the initial number histogram percentage for the synchronisation experiment (Fig.1a) and converting it in terms of the number concentration density function. The parameters are obtained by fitting the mean volume during the synchronisation experiment (Fig.1b). The experimental volume increases in agreement with the model predictions. The normalized density function during the volume growth process (Fig.1c) in the light period agrees qualitatively with the experimental distributions (data not showed). The q parameter was specifically used for binary fission in microalgae (Concas et al., 2016).

The set of parameters obtained was used to predict the long-term experiment. The initial volume distribution showed in figure 1d was obtained by fitting the number histogram percentage of a duplicate experiment at time zero of the long-term experiment, and then it was converted to a number concentration density function. N_0, σ_0, and μ_0 were obtained by using this fitting. The critical volume was considered to be the double of the initial volume at time zero of the synchronisation, where the cells should be averagely at the minimum volume related to daughter cells (Bišová & Zachleder, 2014). The σ_c used was the same as the one of the initial distribution. The results of the complete model prediction are shown in figure 1e, where the total cell number shows a good agreement with the experimental data.

Table 1. Definition of model parameters and their respective values.

Parameter	Definition	Value	Units
N_0	Initial total cell number	9.11×10^5	Cells
σ_0	Initial distribution parameter	2.30×10^3	μm^3
μ_0	Mean initial volume	6.94×10^3	μm^3
α_{att}	Light attenuation shape parameter	8.84×10^3	-
q	Coefficient symmetric beta function	4.00×10^0	-
K_v	Volume inhibition constant	5.43×10^3	μm^3

5. Conclusions

A population balance model was proposed to describe the growth of microalgae cells. Biomass growth is limited by the light attenuation, and the model takes into account the observed phenomena affecting growth rate decreasing in correspondence of the mean volume growth. The model parameters were estimated observing the volume growth phase during the light cycle in a short duration experiment trying to exclude other phenomena. Model predictions for the long-term experiment show the potential ability of the model to predict cell populations in term of total cell numbers for long-term experiments from a fitting data from short-term experiments. The fitting procedure could be adopted extended to other variables, making the model able to work in a wide range of operative conditions, and including the production of individual metabolites in order to take into account added-value products.

Abstract

Enterprises comprise highly complex systems that need to be coordinated in order to maintain their productivity and competitiveness. During last years, companies have developed information systems to support end users to exploit data and models, with the final objective of improving the decision-making task. Main decisions concern key process characteristics, which are essential for the viability to achieve enterprise wide optimization (EWO) and industry 4.0 approaches. This work focuses on the automated creation of a semantically enriched problem statement of production processes based on system characterization and problem definition. First, features related to the system are defined and the characterized by making use of knowledge models. As a result the system is semantically defined and conceptual enriched. Next, the second step of the approach consists on an automated problem definition process. This process comprises eight main phases to obtain a systematic problem definition. Finally, this work presents a case study base on scheduling problem in order to show the performance of the tool. The case study comprises a system that has been treated with mathematical models for solving a multistage scheduling problem.

Keywords: Artificial Intelligence; Problem Modelling; Intelligent Systems

1. Introduction

Enterprises comprise highly complex systems that need to be correctly managed and coordinated in order to maintain their productivity and competitiveness. During last years, due to accessibility to technological advances, companies have been focused on developing information systems to support end users to exploit data and models, with the final objective of improving the decision-making task in an automated and semi-automated processes environment. Nevertheless, decision-making modeling lies in to human factor (human capacity and expertise). Thus, tools that support fast and reliable problem solve activities related to production process are crucial elements in those information systems.

What is more, nowadays industry is deep into in the fourth industrial revolution, so-called Industry 4.0, where computers and process devices aim for autonomous process by interacting together. In this context, sensors and actuators should be connected remotely to computer systems, equipped with sophisticated algorithms that can

understand, learn and decide with small intervention from human operators. The success on improving decision-making broadly depends on how analytical models and data are integrated. On the one hand, the correct modelling task, when a problem or certain reality is found, increases the success of the decision. On the other hand, the responsiveness and accuracy to get information quality and data complement how good the decision can be. Thus, a key task in the improvement of decision- making depends on having an appropriate and enhanced characterization of the system. This work focuses on the main decisions concerning key process characteristics, which are essential for the viability and competitiveness of the enterprise.

This work presents a methodology for an automated problem definition resulting in a semantically enriched problem statement. This problem statement comprises system characterization and problem definition process, which are based on formal knowledge models namely ontologies. First, features related to the system are defined and then characterizing by making use of knowledge models. System features comprises to general tactical and strategic process issues. Besides, knowledge models enable identifying and matching every process with their functions, objectives and relations regarding different levels of process abstraction within the enterprise structure. As a result of this first step system features are extracted and presented in a taxonomical structure manner conceptually enriched. Next, an automated problem definition comprising nine main phases, namely: a) automated process system definition, b) Problematic situation recognition; c) Solution goal statement; d) General system relations; e) Definition of variables; f) system assumptions; g) parameters and engineering metrics (time & space scales); h) definition of problem statement and solution objectives; and i) search for similar problematic or solutions.

Finally, this work presents a case study base on scheduling problem in order to show the performance of the approach. Scheduling problems are critical in the decision-making of process operations.. The case study comprises a system that has been treated with mathematical models for solving a multistage scheduling problem.

2. Proposal description

Decision Support Systems (DSS) are information technology solutions that can be used to support complex decision-making and problem solving. DSS are defined as aid computer systems at the management company level that combine data and sophisticated analytic models for support decision-making (Simon and Murray, 2007). Classic DSS design is comprised of components for (i) sophisticated database management capabilities with access to internal and external data, information, and knowledge; (ii) modeling functions accessed by a model management system, (iii) simple user interface designs that enable interactive queries, reporting, and graphing functions, and (iv) optimization by mathematic algorithms and or intuition/knowledge.

This work is based on formal knowledge technologies, which allow working in a semantical environment where machines can understand domain and human knowledge. Besides, the development of models and solution strategies to tackle the decision-making from a broad perspective has been the result of integration and collaboration from areas, such as, Process Systems Engineering (PSE), Information Technologies and Communications (ITC), and Operations Research (OR).

Thus, the proposed approach can be generally stated as follows. Given a formal domain knowledge model, the following information must be captured in order to obtain

semantically system features: i) Production system characterization comprising Physical, Procedural and Recipe (Site & General) models; ii) Products to be produced according to the processing order activity in the industry recipes defining the production requirements and production path for the products in the Physical, Process and Recipe (Master & Control) models, and; iii) Resource availability and plant status provided by the process management and production information management activities, as shown in Figure 1, Part I-A and Part I-AA.

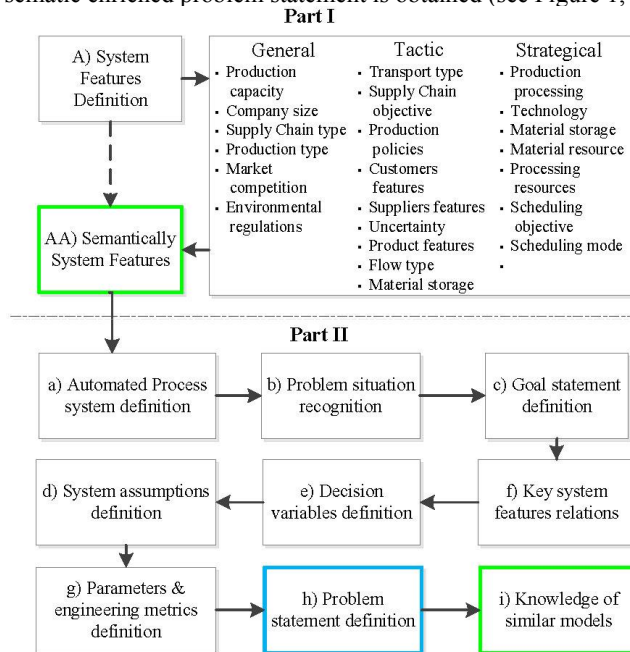
The main goal consists on create an enriched problem statement. Thus the following nine steps have been automated comprising: definition of the process system from tactical, strategic and operational views (see Figure 1, Part II - a); an algorithm for monitoring key process features (isolated or integrated) for detecting abnormal or problem situations (see Figure 1, Part II - b); an option for choosing among economical, time or other aim solution perspective (see Figure 1, Part II - c); important relations among problem and direct features in the system are stated (see Figure 1, Part II - d); decision variables, assumptions of the process and the engineering metrics are suggested by the proposal and chosen by the user (see Figure 1, Part II - c, d and e); finally a sematic enriched problem statement is obtained (see Figure 1, Part II – h and i)


Figure 1. Intelligent system characterization and problem definition procedure diagram.

3. Methodology

This work develops a software platform in Jython, which is integrated to the knowledge models described previously by using OWLAPI as an improved modeling and communication tool in the process domain. Then the proposed framework consists on two main processes, Enterprise Structure Definition and Problem Definition (Figure 1).

On the one hand, enterprise structure definition comprises conception of a real system, considering general, tactic and strategic features (Figure 1, part I). Then, a semantic enriched taxonomical model of the features is obtained. Likewise, this work tackles the conciliation, standardization and management of data and information existing in the process system. On the other hand, the different phases of the proposed framework (Figure 1, part II) define the phases to obtain the systematic problem definition.

4. Case Study

The case study comprises a system that has been treated with mathematical models for solving a multistage scheduling problem. Specifically, the scheduling problem presented in the paper by Capon-Garcia et al. 2011 and detailed in Muñoz et al. 2018, is considered, where acrylic fibers are produced along 14 stages in a batch production plant, structured in 8 recipe unit procedures and 6 recipe operations. As primary information, production process was defined in a master recipe involving 27 different resources, which are basically material and energy resources. Two alternative production processes are assessed in this work, namely acrylic fiber A uses acetone as solvent in the polymerization and acrylic fiber B uses benzene

Thus, system features definition requirements have been defined and fulfill, comprising information as shown in Table 1, based on Enterprise Ontology Project from Munoz et al. 2012.

Table 1. General, tactic and strategic features for system characterization.

General Feature	Value	Tactic features	Value	Strategic features	Value
Production capacity	Medium	Transport type	Land	Production processing	Sequencial
Company size	medium	Supply chain objective	Economic	Technology	Multi task
Supply chain type	Good availability	Production policies	Defined	Material storage	Limited
Production Type	Multi Stage	Customer features	-	Material resource	Not perishable
Market competition type	Low	Suppliers features	-	Processing resources	Limited
Environmental regulations	Defined	Process flow type	Forward	Scheduling objective	Timing
Demand feature	High volume	Material storage type	Limited	Scheduling mode	On-line

Next, in order to obtain a problem definition Part II from Figure 1 is explained and detailed.

a) *Automated Process system definition*. From previous system's instantiation within EOP knowledge model, a semantically enriched machine-readable system structure is obtained. The model comprises 934 instances concerning 295 classes, 257 Object properties, 33 data properties. As example of class instantiation made, the *RawMaterial* class ha*s Input1_1 (Acrylonitrile), Input1_2 (MethylMetaacrilate), Input1_3 (VinilChloride), Input1_4 (solvent-Acetone)* as instances.

b) *Problem situation recognition*. In this phase, indicators derived from an automated SWOT are defined. Each indicator is mapped into a semantic concept (class) from the EOP knowledge model. Then, upper and lower boundaries of control are set. One of the main advantages of the system is the fact that problem recognition is coming from the knowledge model. As a result data and information, usually hidden

for a human, can be easily manage by the system. Table 2 shows the different indicators and their corresponding upper and lower boundaries values.

Table 2. Indicators and control boundaries of the problem recognition.

SWOT	Indicator	Related feature	Metric	UBV	LBV
O	Energy comsumption	Electric comsuptiom	kWh	30000	50000
		Water comsumption	m^3/ton	6000	10000
		Natural gas comsumption	m^3/ton	39000	45000
W	Time delivered failure	Tardiness finish orders	u/month	15	45
W	Demand unacomplishment	Orders out of schedule	u/month	5	15
		Outsourcing orders	u/month	10	20
T	Changes in product order	Product demand changes	u/month	30	50
T	Cleaning overtimes	Cleaning task with overtime	u/month	0	5
T	New product order	Order pleced out of the shcedule	u/month	0	40

c) *Goal statement*. Once that a problem has been identified an optimization goal can be obtained by specifying the minimization or maximization of the indicator chose in the previous phase. *Time Delivered Failure* indicator has been defined as a problem by the system, due to a violation in the upper boundary. Besides, the goal is stated as a minimization problem.

d) *Key system features relations*. Based on the EOP knowledge model, the proposed framework is capable of finding the closer relations among the indicator (EOP class) chose in (b) and other process systems' concepts, potentially to be converted into decisions variables. Table 3 shows some examples of properties involved in the query in this phase.

Table 3. Domain and range of "Resource" class and subclasses.

Processing time	
hasID	ResourceID
hasUpperBound/hasLowerBound	float
hasResourceCost	ResourceCost
hasEnvironmentalPerformanceIndex	EnvironmentalPerformanceIndex

e) *Decision variables definition*. In his phase, a decision about which and which not concepts (EOP classes) are defined as decision variables provided in (d) must be done.

Table 4. Main classes and derived classes potentially become decision variables.

ProcessingTime	TimeInterval	ProcessingActivity
Information	Information	ProcessAction
Parameter	Parameter	ProcessStage
ProcessInformation	ProcessInformation	ProcessOperation
ProcesParameter	ProcessParameter	Thing
Thing	ClaeningTime	
TimeInterval	WaitingTime	
	ProcesssingTime	
	Thing	

f) *System assumptions definition*. From the system structure defined in (a), the most important and used assumptions based on the appropriate physical laws governing the process can be chosen to form part of the current problem definition. For this case study the process conditions are fixed according to the recipe definition.

g) *Parameters & engineering metrics definition*. In the same manner, parameters coming from the EOP's classes' data properties are chosen and defined. Then, engineering metrics are also specified automatically.

h) *Problem statement definition*. As the main goal of this approach, the proposed framework is capable of creating a problem statement in the form of natural language, which can be used to verify and validate the problem in an easy human readable way. The following paragraph has been obtained as a resulting problem statement from the current case study: "A problem regarding *tardiness finish orders* has been detected, resulting from violating upper bound of control, an optimization problem statement is proposed as follow: Taking into account variables *StartingTime, BatchSequencing*; parameters *ChangeOverTime, BatchProcessingTime*; Minimize *FinishTime*"

i) *Knowledge of similar models*. Finally, the framework executed a query that classifies similar optimization problems in order to suggest possible solutions to those similar problems, based on Capon-Garcia et al. (2017).

5. Conclusions

This work develops a semi-automatic process for semantically enriched problem statement based on formal knowledge models. Thus, features related to the system are easily defined and characterized, resulting in a virtualization of the system that comprises strategic, tactical and operational features. Next an automated problem definition process improves how information and data are considered lying in the potential of knowledge models and semantics technologies. In addition, knowledge models provide additional reasoning capabilities to support decision support system for the Wide Optimization and Industry 4.0 approaches. For illustrating purposes, a case study was presented using a scheduling of a multiproduct batch plant, where the systematic approach presented was used resulting in a semantic problem statement and presented in natural language.

Abstract

A general classification agent has been developed based on a semantic model for supporting the modelling of problems in the chemical modelling domain. Two case studies are used to illustrate the proposed approach, which stands for a routine that solves the modelling task easily and quicker and less error-prone approach in comparison to the traditional problem.

Keywords: first-principles, mathematical modelling, chemical processes, semantic modelling.

1. Introduction

Currently, chemical and other process industries, such as food, agriculture or pharmaceutical, evolve in a highly dynamic and changing environment. Indeed, the globalization of trade, product customization and stricter environmental and societal requirements, among others, seriously challenge the performance and operation of the process industry. Indeed, time response and solution quality for critical problems are critical issues that motivate the development of new solutions.

In such scenario, enterprises strive to remain competitive by improving their functional, technological and operational advantage. Although chemical processes are intrinsically complex, the underlying chemical and physical phenomenal can be explained by a self-contained set of mathematical expressions and models, which derive from physical laws and experimental. In this sense, the quick and flexible development of models that fundamentally support: (i) the understanding of the underlying phenomena and (ii) the implementation of advanced decision support systems, is a crucial issue in the process industry.

Mathematical models use equations and concepts in order to describe a systems and particular situations with the aim of explain, predict and simulate them. The advances in computers systems in recent years have allowed an exponential growth in scientific computation, enhancing the capacity for solving mathematical models with algorithms, easier to treat and solve. In this sense problem modelling has become a key activity where process activities exists as base for make more efficient the mathematical optimization task.

This objective of this work is to support the automatic generation of constraints design by using semantic modelling and mathematical programming, based on problem classification. An intelligent agent proposes a set of model equations which help to understand how those set of constraints can be built up. Besides, the proposed system makes use of semantic technologies enhancing the comprehension among decision variables and parameters. Thus, model constraints using semantic networks link relationship among different components of the system, concepts, physical laws and principles of the phenomenon based on standard conceptualizations.

2. Problem statement

The starting point when posing a model for solving a problem in the chemical process domain mainly consists of defining the problem features, namely the elements which represent the system and describe its behavior, as well as the system parameters and variables.

Hence, a multi-label classification problem can be associated with process modeling. Therefore, given (i) a set of process features (attributes) and (ii) a set of existing mathematical equations related to such problem features (labels); the objective is to match a given instance with a subset of the features in (i) with its corresponding equations in (ii). A goodness function for each label will be used to check the ability of the classification approach to select the appropriate labels (ii).

3. Methodology

On the one hand, an ontology has been created comprising the chemical engineering domain described in Section 3.2. Therefore, Section 3.1 presents the basis for the ontology development. Ultimately, this work develops a software platform in Jython, which is integrated with the semantic model derived as presented in Section 3.1 using OWLAPI, and stands as an improved modeling tool in the chemical process domain.

Different areas in the chemical engineering domain, including basic unit operation principles, transport phenomena, reaction kinetics and thermodynamics, have been revised in order to collect and examine the most relevant formulae (Cameron and Hangos, 2001). In this sense, it is essential to work out the expressions in a very precise and thorough way, since every imaginable system and process configuration has to be considered to account for all possible cases. As a result, a complete table of equations with their attributes has been built up. In summary, 102 distinct equations have been classified to enable a complete and most realistic description of a given system or chemical process. In order to select the appropriate equations, 39 system attributes have been specified. The full description of the knowledge base is provided in Section 3.2.

3.1. Semantic modelling

Ontologies stand for a formal specification of the domain, that is, a body of formally represented knowledge based on conceptualizations, which are abstract, simplified views of the physical or procedural elements. On the one hand, the ontology elements should be part of the model intended to represent a system for some purpose, managing the relationships that hold among the elements of the model, thus allowing the ontology to be usable. On the other hand, reusing ontologies requires not only consideration of

the ontologies, but also of the tasks for which they are intended. The base of this work lies down in the use of an ontology that deals with diversity in scheduling problem representation and allows effective data sharing and information flow. Ontologies are hierarchical domain structures that provide a domain theory, have a syntactically and semantically rich language, and a shared and consensual terminology (Klein et al. 2002). The body of knowledge for this ontology stems from the chemical engineering modelling domain, and a PDCA methodology (Munoz et al., 2012) has been used to create the ontology. The final ontology, called Chemical Engineering Ontology (ChEnOn), contains 154 classes, 33 object properties and 21 data properties.

3.2. Modelling domain and classification approach

The chemical engineering domain can be broadly classified in different knowledge areas. In this work, we have considered mass, energy and momentum balances, as well as mass and heat transfer equations, and thermodynamics and reaction kinetics. Besides, classification approaches are described for each knowledge area, presented next.

3.2.1. Mass balances

First of all, the conservation principle of mass was considered. In general, there are three distinct systems that have to be considered: the isolated system, the closed system and the open system in relation to the surrounding environment. All three systems have to be taken into account to fully study the conservation principles of mass, energy and momentum in every real case example. For mass, there is no difference between the isolated and closed system, since mass can only be exchanged in an open system. The first mass balances for a closed system were stated and the descriptor "State" was introduced to differentiate between a steady state system and a transient state system. These two characteristic, yet clearly opposite attributes of a system were the first guiding principle on how to distinguish and classify equations. In total there are three different situations possible in a closed system. The first two systems time-independent described with the attribute steady state, while the third system's components change their mass due to the reaction, which results in a transient state system. To differentiate between the first two systems, a new descriptor and its corresponding attributes were introduced, being "Components" and "Single Component" and "Multiple Components", respectively. Also the descriptor "Reaction" with an attribute "Generation" was proposed. All these parameters and equations are part of the ontological model, where each equation was inserted as a class with a descriptive name and a unique ID code, while the descriptors and its attributes were put into object properties of the ontology. If now a system possesses or an equation fulfils a certain attribute, the corresponding cell between them was marked with a 1 or else with 0. In this way 16 different mass balance equations could be identified and expressed with the help of additional system descriptors like "Mass Flow" (Attributes: Feed, Mass Outflow), "Evolution" (Accumulation/Depletion) and "I/O Structure" (Single Stream, Multiple Streams).

3.2.2. Energy balance

Next, the conservation law of energy and its energy balances for the three aforementioned systems: isolated, closed and open was considered. The approach was similar to the determination of the mass balances and 21 different energy balances could be formulated, covering all imaginable system configurations. To be able to differentiate between these energy balances, additional categories to the old ones of system descriptors and their attributes had to be proposed, namely "Heat", with the attributes consisting of "Heat Inflow", "Heat Outflow", "Conduction", "Convection"

and "Radiation", as well as "Work" with "Work Input" and "Work Output" as the corresponding attributes.

For the derivation of the energy balances, it was assumed that the kinetic and potential energy of the system are negligible.

3.2.3. Momentum balance

To conclude with the conservation principles, the conservation law of momentum was examined and similar to the energy balances, 21 momentum balances could be postulated. Since most of the momentum balances are simply correlated to the mass balances, only one additional attribute "Force" had to be added in order to account for the sum of gravitational, friction, pressure and shearing forces, which might act on the system. As a result of the conservation principles in chemical systems and processes, 58 different equations could be found to describe a potential real life system.

3.2.4. Mass transfer

For this purpose, the descriptor "Diffusion" and five more attributes being "Dilute Solution", "Concentrated Solution", "Membrane", "Diffusion", and "Convection" have been created. With these, nine more equations concerning diffusion in different systems could be classified and added to the list of classes of the ontology.

3.2.5. Heat transfer

Another examined aspect of transport phenomena includes the heat transfer to or from a given system. Heat transfer is a very common issue in chemical engineering. Again the focus was put on the most practical and applicable heat transfer equations and eight common heat transfer equations could be ascertained. For these equations, no further descriptors and attributes had to be assigned, since heat transfer had already been accounted for by the derivation of the energy balances. The transport phenomena encompasses a total of 17 equations.

3.2.6. Reaction kinetics

Alongside the classical and convenient reactor kinetics of batch, semibatch, CSTR and PFR, a numerous of typical reactions were investigated and postulated. A total of 19 reaction kinetic equations were amassed with 10 more attributes required to differentiate and classify them all.

3.2.7. Thermodynamics

Last but not least, thermodynamics and its equations of state were put into consideration and eight of the vast number of equations has been chosen according to their applicability and frequency of usage. The five specified attributes regarding the thermodynamic equations were "Ideal", "Non-Ideal", "Empirical", "Gas" and "Liquid". The last two attributes correspond to the phase of the considered fluid.

4. Case study

The applicability of the proposed equations has been tested in two different systems, namely a tank system and an equilibrium stage. The case studies allow to understand the usability of the proposed framework. This validation allows for the direct evaluation of the work and gives insights in the usefulness of having such a tool.

4.1. Tank system

The first example deals with a standard tank system, where both input and output streams are constant and all initial conditions like volume, temperature and concentration of the solution inside the tank are known. The feed stream has constant composition, concentration and temperature and identical properties of both solutions to water as well as perfect mixing are assumed. The goal is to determine the time evolution of the tank level, its concentration and its temperature.

As a first step, the system attributes were determined from the problem description: Open system, transient state, accumulation (since inflow was greater than outflow), single input/output stream, single component, no generation (reaction), no heat or work flows. The time evolution of the tank level is directly correlated to the mass inside the tank, hence a mass balance was required that is described by all the above-mentioned attributes. The overall set of equations proposed by the developed agent consist of M4, M16 and E12 (Figure 1). From the proposed set of equations to the problem solution, a few set of adjustments are required. M4 had to be slightly modified, since volume and not mass was targeted, and integrated to give an exact answer in the form of an analytical expression. M6, which relates mass and concentration, could be used to find an analytical expression for the time evolution of the concentration. In order to determine the temperature evolution of the system, E12 underwent some changes, namely the conversion of the equation from energy to temperature, and the equation could eventually be integrated and the temperature profile of the system with respect to the time was obtained. This methodical way of solving the problem by determining system attributes and supporting agent proved to be very successful and timesaving.

Problem Description	System Attributes	Set of Equations	Problem Solution
Tank (Area: A = 2 m^2, Height: H) filled with 0.8 m^3 (V) of 0.15 wt% (c$_0$) NaCl solution at 35°C (T$_0$). At constant feed (Q$_1$) of 0.20 wt% (c$_0$) NaCl solution at 25°C (T$_1$) and outflow (Q$_2$), determine time evolution of tank level, concentration and temperature. 4.2. Equilibrium stage

The following example covers the traditional equilibrium stage of a distillation column. In a distillation column, two streams with different compositions enter an arbitrary stage in counter-current mode, where some components inside the stage change from the liquid phase to the vapour phase or vice versa and the compositions of the two streams leaving the stage are assumed to be in thermodynamic equilibrium. The task is to determine all possible equations to fully describe and solve the system.

The task requires to find the appropriate mass and energy balances, as well as the thermodynamic equilibrium expression. For this purpose, the following system attributes were identified: Open system, steady state, neither accumulation nor depletion, no generation (reaction), multiple input/output streams, multiple components,

no heat or work flows (adiabatic), gas-liquid equilibrium, ideal system (assumption). The developed agent proposed equations M9, E15 and T7 (Figure 2), which had to be adequately adapted. With these three equations, the overall mass balance of the stage, the mass balances of each component, the energy balance of the stage and the equilibrium condition for each component between liquid and gas phase could be obtained. From there, the system was explicitly solvable, which underlined the usefulness of working with system attributes and having the effective classification matrix.

Problem Description	System Attributes	Set of Equations	Problem Solution
Modelling of a Single Stage in a Distillation Column.	Open System, Steady State, No Depletion or Accumulation, No Generation (Reaction), Multiple I/O-Streams, Multiple Components, No Heat or Work Flows, Gas-Liquid Equilibrium, Ideal	$0 = \sum_{s=1}^{S} F_i - \sum_{s=1}^{S} Out_i$ [M9] $0 = \sum_{s=1}^{S}\sum_{i=1}^{C} h_{F,i}(F_i)_s - h_{out,i}(Out_i)_s$ [E15] $p y_i = x_i p_i^S$ [T7]	Mass Balance: $0 = V_{i+1} + L_{i-1} - V_i - L_i$ Component Balance: $V_{i+1}y_{i+1} + L_{i-1}x_{i-1} = V_i y_i + L_i x_i$ Energy Balance: $0 = h_{V_{i+1}}V_{i+1} + h_{L_{i-1}}L_{i-1} - h_{V_i}V_i - h_{L_i}L_i$ Equilibrium Condition: $y_i = m_i x_i$ with $m_i = \frac{p_i^S}{p}$

5. Conclusions

This work presents an intelligent agent which is capable of recognizing the system attributes, and links them to specific equations from the areas of conservation principles, transport phenomena, reaction kinetics and thermodynamics. The agent is based on a semantic model and has been programmed in Java. It has proved to be very helpful in quickly finding the appropriate set of equations to determine or solve for certain properties of the system in a systematic and methodical way. Likewise, a general classification algorithm has been develop to assist in the assignment of the problem to the correct equations. What this all amounts to is that the overall definition of a chemical engineering problem can be monitored on a regular basis and mistakes or inaccuracies in the table are removed at an early stage. As a future work, the developed framework is a cornerstone for a larger enterprise wide framework, which processes the information and data required for the model fitting and problem optimization. The overall framework should be designed such that it is capable of managing, structuring and delivering information as required by the constraints, thus being able react to production system changes or modeling changes, based on flexible data and information structures.

Abstract

In this work, we study *in silico* photoautotrophic bioethanol production with *Synechocystis* sp. PCC6803 by a two-stage approach in two bioreactors in series. In the first stage the conditions are set for the maximization of growth rate, with optimal conditions of light intensity and carbon sources, while in the second a state of nitrogen limited conditions that tends to maximize ethanol production instead of growth rate is considered. Both stages are optimized by Flux Balance Analysis with different objective functions: Maximization of biomass for the first stage and Minimization of ATP production for the second. A previously developed genome scale metabolic network model is used for the optimizations. Results are promising into considering this strategy experimentally.

Keywords: Synechocystis, Bioethanol, FBA, Nitrogen limitation, phosphorus limitation.

1. Introduction

In recent years cyanobacteria have been considered as promising candidates to become cell factories in the context of systems biology research. This is due to the fact that these microorganisms are capable of growing only on ambient carbon dioxide and minimal inorganic nutrients. More specifically, photoautotrophic bioethanol production has been widely studied with mutant strains of *Synechocystis* sp. PCC6803 (*Synechocystis*) harboring the genes *pdc* and *adh* from the ethanol producing bacterium *Zymomonas mobilis*, achieving experimental production rates of 0.261 g L^{-1} day^{-1} (Dienst *et al.*, 2014).

Mathematical models of metabolism are useful into quantifying the metabolic capabilities of the microorganism and predicting experimental results through optimization problems. The most useful kind of models are genome scale metabolic networks (GEMs), that include information of all the enzymes, reactions and metabolites, with their corresponding stoichiometry, in the genome of the considered microorganism. GEMs allowed the development of *in silico* strategies to improve the production of high added value products. One of these strategies is coupling the production of the compound of interest to growth by the identification of a set of reactions to eliminate ("knock-outs"),based on a bi-level programming approach, where the knock-outs are represented by binary variables, resulting in MILP programming problems (Chowdhury et al., 2015). In previous work (Lasry Testa et al., 2017) we applied a modification of this strategy to a previously developed GEM of *Synechocystis*

to couple bioethanol production to growth with good results, but requiring a high number of genetic interventions.

In this work we propose a two-stage ethanol production approach in two bioreactors in series to improve ethanol production based on nutrient limiting conditions. In the first stage the conditions are set to maximize growth rate, while in the second stage the conditions are set to limit growth and allow for ethanol production. For the second stage, two different limiting nutrients are considered: Nitrogen and Phosphorus. A similar strategy has been used to produce bioethanol with yeast (Gowtham et al., 2014), but is has not been applied to cyanobacterial to our knowledge so far. We evaluate our model against fluxomic experimental data for a nitrogen limited state (Nakajima et al., 2017). Namakoshi et al. (2016) provide experimental evidence on ethanol production under nitrogen-limited conditions by a mutant strain of *Synechocystis* harbouring deletions for both glycogen and PHB synthesis pathways.

2.   Materials and Methods

2.1. Genome Scale Metabolic Network Model and Conditions

We consider a genome scale metabolic network model (GEM) of the cyanobacteria *Synechocystis* that contains 709 reversible and irreversible reactions, 80 exchange reactions and 535 metabolites. The ethanol production pathway is added by incorporating the heterologous gene *pdc* from Zymomonas mobilis, which encodes for the enzyme pyruvate decarboxylase (PDC) that catalyzes the non-oxidative decarboxylation of pyruvate (PYR) to produce acetaldehyde (ACAL) and CO_2. Carbon is considered to be taken up as carbon dioxide (CO_2) and bicarbonate (HCO_3^{3-}). HCO_3^{3-} uptake is active by a Na^+ dependent ATP consuming transporter, while CO_2 uptake is passive with the posterior conversion to HCO_3^{3-}. The CO_2 from intracellular decarboxylation is considered to be converted into HCO_3^{3-} by a reversible reaction (Nogales et al., 2012). For all the optimizations performed in this work, photoautotrophic growth is considered, and carbon uptake is restricted to 3.7 mmol gDW^{-1} h^{-1}, divided into CO_2 and HCO_3^{3-}, with all other possible carbon sources set to 0. For the light uptake an upper bound of 100 mmol gDW^{-1} h^{-1} is considered. Nitrogen is considered to be taken up as nitrate, while phosphorous is taken up as orthophosphate, both through active transport. For the TCA cycle, we take into account two possibilities, proven to be functional by experimental data: (a) The γ- aminobutyric acid shunt (GABA shunt) and (b) the enzymes 2-OGDC and SSDHA.

The model is built in SBML format with the tools provided in COBRA Toolbox and is then turned into the GAMS Data eXchange (GDX) format to be used in the GAMS environment (GAMS Development Corporation, Washington, DC).

2.2. Flux Balance Analysis and evaluation against experimental data

Flux Balance Analysis (FBA) is used to determine the flux distribution of a metabolic network under a specific steady state condition. It consists of a linear programming (LP) problem, which is defined with the steady state mass balances of the network (Eq. (2)), the lower and upper bound on fluxes (Eq. (3)) and an objective function. In this work we consider two different objectives functions (Eq. (1)): (a) Maximization of biomass production and (b) minimization of ATP production.

$$\max v_{biomass} \; (\min v_{ATP\,production})$$ (1)

$$\sum_j S_{i,j} v_j = 0$$ (2)

$$LB_j \leq v_j \leq UB_j$$ (3)

To evaluate the GEM against experimental fluxomic data, Flux Variability Analysis (FVA) is considered. FVA is a strategy derived from FBA, where the fluxes of all the reactions in the model are maximized and minimized subject to FBA constraints (Maranas and Zomorrodi, 2016). In the evaluation, the lower and upper confidence bounds of the experimental data are set as bounds for the corresponding reactions in the GEM and the bounds for all other reactions are obtained by FVA. The resulting flux distribution must be feasible and have the same growth rate as reported in the experimental data.

2.3. Two stage production approach

In this *in silico* bioethanol production strategy we consider a first stage were conditions of carbon and light uptake are set for the strain to be in exponential growth phase, where all the carbon flux is directed towards biomass production. This stage is simulated by FBA with biomass objective function (Maximization of Biomass). Then, the biomass produced in the first stage is transferred to a second stage where the conditions are set for the growth to be in stationary phase. For this, we consider two different cases of nutrient limitation that allow for the redirection of carbon flux to the production of biofuels. This stage can also be simulated by FBA with an objective function of ATP production minimization, characteristic of the stationary growth phase where growth rate tends to zero, as the growth and death rates are balanced. The limitations considered are nitrogen and phosphorus. Experimental evidence reveals ethanol production under nitrogen limited conditions in a mutant of *Synechocystis* incapable of glycogen and PHB storage (Namakoshi et al., 2016). With this approach we simulate a nitrogen limited scenario according to experimental values and study the case of phosphorus limitation with different scenarios as there is no experimental evidence to validate it.

3. Results

For both limitation cases we modify our GEM eliminating glycogen and PHB storage as this favours biofuel production (Namakoshi et al., 2016). The first stage of the approach presented in section 2.3 is the same for both cases as it is not limited by any other nutrient than carbon or light. The FBA optimization provides a maximal growth rate of $0.089 \; h^{-1}$ for the first bioreactor, which is consistent with experimental data for these conditions.

3.1. Nitrogen limited conditions

We evaluated our model against experimental fluxomic data from Nakajima et al. (2017) as described in section 2.2. The growth rate reported in this study is $0.015 \; h^{-1}$. We evaluate our model for this growth rate to obtain the nitrogen uptake that corresponds to the experimental flux distribution, which results in a flux of 0.135 mmol $gDW^{-1} \; h^{-1}$. With this uptake value we run FVA and obtain a very accurate correlation between the experimental values and the flux distribution obtained (Table 1), showing that our model is capable to reproduce nitrogen limitation. We only find significant difference for the reaction converting Fumarate to Malate (FUM -> MAL) which is

probably due to the different modelling of the TCA cycle. Nakajima et al. (2017) consider the Glyoxylate Shunt and the OGDH complex which are proven to not be present in cyanobacteria. Based on the evaluation against experimental data, we chose to consider a case of nitrogen uptake restricted with an upper bound of 0.135 mmol gDW^{-1} h^{-1} to assure that the uptake is feasible and limiting, experimentally. This value and the growth rate of 0.015 h^{-1} are fixed, and ATP production is minimized by FBA with a result of 6.285 mmol gDW^{-1} h-1. These conditions provide an ethanol production of 1.547 mmol gDW^{-1} h^{-1}.

3.2. Phosphorus limited conditions

As there is no experimental data available on cases of phosphorus limitation, we chose to simulate a set of cases for different phosphorus uptakes to study the possibilities for ethanol production in the second stage. The phosphorus uptakes considered are 6: 0.03, 0.025, 0.02, 0.015, 0.01 and 0.005 mmol gDW^{-1} h^{-1}, respectively. For each of the uptakes maximum growth rate, maximal ethanol production rate and minimal ATP production are obtained with FBA and reported in Figure (1) a, b and c respectively. We can see that as the upper bound on phosphorus uptake decreases the maximal biomass production also decreases, leaving more carbon flux available to be redirected towards ethanol production, which has the opposite tendency. The minimal ATP production required for each state decreases as growth rate, since the ethanol production pathway does not require the production of ATP, contrary to biomass production. We chose the case of 0.01 mmol gDW^{-1} h^{-1} of phosphorus uptake as the best one as the growth rate of 0.014 h^{-1} is very close to the case considered for nitrogen limitation. For this case the ethanol production is 1.57 mmol gDW^{-1} h^{-1} and the minimal ATP production is 6.269 mmol gDW^{-1} h^{-1}.

4. Discussion

To compare the results obtained for the two cases of limitation with data from bibliography, we assume experimental culture conditions to calculate ethanol production rates. The initial biomass concentration (X_0) considered is of 0.078 gDW L^{-1}. For the first stage we consider growth in exponential phase and calculate the final biomass concentration assuming a cultivation time of 2 days (t) and a growth rate (μ) of 0.089 h^{-1} (see section 3). According to Eq. (4), the final biomass concentration for the first stage is 5.589 gDW L^{-1}. This value is the same for both cases of nutrient limitation.

$$\ln X - \ln X_0 = \mu t \tag{4}$$

For the second stage the culture is considered to be in stationary phase, so the net growth rate is 0. With these assumptions the ethanol production is calculated based on the final biomass concentration of the first stage, considering a cultivation time of 1 day. For both stages, a light limitation function is considered to include shade effect of biomass (Laiglecia et al., 2013). The ethanol production for both limitation cases, compared with the case of the coupled mutant presented in Lasry Testa et al. (2017) are shown in Figure 2.
Figure 2: Ethanol and biomass productions for all the cases compared

Numerical results show a very similar ethanol production for the nitrogen and phosphorus cases, with an increase of only ~1.5% for the phosphorus case. In contrast, the results obtained for the two-stage approach are more promising than the ones obtained in previous work for a coupled mutant obtained by a set of genetic

interventions, and higher than the best result of 332 mg L^{-1} reported by Namakoshi et al. (2016). These results are obtained for constant illumination, so the cultivation needs to be carried out in a closed photobioreactor at industrial scale, where the main obstacle would be the cost of the system compared with open ponds. However, encouraging new photobioreactor designs are beginning to be available to address these difficulties (Johnson et al., 2018)

5.   Conclusions

In this work, we have addressed photoautotrophic ethanol production by the genetically modified cyanobacterium *Synechocystis* sp. PCC 6803 with a novel strategy trough mathematical modelling. The ethanol productions obtained for both limitation cases are promising as they are higher than the best experimental results from bibliography. The model could be successfully evaluated against experimental data for nitrogen limited conditions, but no experimental data is available for the phosphorus case. Mathematical models of metabolism become more reliable with the inclusion of experimental values. The results obtained are encouraging into testing this kind of approach in experimental studies.

Application of plate heat exchangers into heat exchanger networks retrofit with fixed structure

Kexin Xu[*], Robin Smith

Centre for Process Integration, School of Chemical Engineering and Analytical Science, The University of Manchester, M13 9PL, UK.
kexin.xu@ manchester.ac.uk

Abstract

Heat exchanger enhancement technologies have been widely used into heat exchanger networks (HENs) retrofit. However, the heat recovery is limited through the enhancement, which is restricted by the geometry of existing heat exchanger. Plate heat exchangers are widely used in energy-intensive process industries to increase heat recovery and reduce greenhouse gas emissions with the features of small minimum temperature approach and high effectiveness. Thus, plate heat exchangers are taken into consideration to replace conventional heat exchanger in crude oil preheat trains to enhance heat transfer coefficient and reduce energy consumption. A major limitation of applying plate heat exchanger is lack of reliable optimization method to quantity the energy saving effectively. Due to the high installation cost of plate heat exchangers, the optimization is based on the trade-off between energy reduction and capital cost. This work proposes a new methodology of application of plate heat exchanger in HENs retrofit with a fixed network structure. A change in one component in heat exchanger networks can have an effect on other downstream heat exchangers. Therefore, the proposed methodology also presents a way of eliminating the need for additional heat transfer area after replacement, while ensuring the stream target temperatures are met. Case studies highlight the benefits of the new approach.

Keywords: plate heat exchanger, heat exchanger network retrofit, energy saving

1. Introduction

With the growth of energy consumption and the increase of CO_2 emissions, it is more and more important to improve heat transfer efficiency. Heat exchanger network retrofit is a cost-effective way to increase heat recovery based on the existing heat exchanger network in process industries. Plate heat exchanger, including gasket plate heat exchanger and welded plate heat exchanger, is one of the most high-efficiency heat transfer equipment. Compared with conventional shell-and-tube heat exchangers, plate heat exchangers could significantly increase energy efficiency with minimum approach temperature as low as 2 °C, decrease the possibility of fouling and reduce the fuel consumption and CO_2 emissions. Thus, plate heat exchangers can be considered to improve the energy performance of an existing heat exchanger network.

Established techniques and methodologies for the retrofit of HENs focus on modifying the existing HENs to obtain energy savings and overcome network bottlenecks. Pinch analysis, mathematical programming and hybrid methods are the three main retrofit methods in existing heat exchanger networks. There are several reports in literature dedicated to the retrofit of HENs based on these methods. Sreepathi and Rangaiah

(2014) presented a detailed review of the different methods for HEN retrofit. The book by Smith (2005) has full chapters that introduce the fundamentals of energy targets, capital and total cost targets, and network design of HENs.

In the recent years, there has been an increasing number of research applying heat transfer enhancement techniques in HEN retrofit. Adding inserts and fins in the existing heat exchangers, which could increase the heat transfer coefficient, are the two main techniques in heat transfer enhancement. Heat transfer enhancement increases heat recovery and can also reduce the energy consumption. (Akpomiemie and Smith, 2015) However, for heat transfer enhancement to be effective, one of the film coefficients must be controlling. Besides, although heat transfer enhancement techniques can be performed during the normal shutdown time, the potential risk of damaging the heat exchangers when adding inserts or fins is not negligible. Thus, to overcome these drawbacks, this work presents a new retrofit method that provides insights into the application of plate heat exchangers into heat exchanger network in order to reduce the network energy consumption and increase heat recovery. However, there is no published literature shows the possibility of integrating plate heat exchanger into traditional shell-and-tube heat exchanger networks and quantity the potential effect on energy saving.

The main objective of this work is to develop cost effective retrofit methods for HENs with plate heat exchangers. The benefit of retrofit profit of the existing heat exchanger network is highlighted.

2. Methodology

This section presents a retrofit design methodology of application of plate heat exchanger into an existing fixed structure HEN. The methods, including identify the best candidate heat exchanger to replace, apply plate heat exchanger and set up non-linear model to rebalance network, are detailed in this section.

2.1. Identification of heat exchanger candidate to replace
Utility path is used to identify candidate heat exchanger and sensitivity analysis is used to determine the rank of identified exchangers.

2.1.1. Identification of utility paths
A utility path is a connection between two utilities through process heat exchangers. To develop a cost effective retrofit method of an existing HEN without structure modification and additional heat transfer area, the exchangers to be replaced must be on a utility path so that heat loads can be shifted along the path (Linnhoff and Hindmarsh, 1983). A change in a HEN can affect the performance of other components; thus, the utility path can also be used in the rebalance the HEN after replacement of shell-and-tube heat exchangers. For a simple network, utility paths can be specified by inspection. However, for a complex HEN, Incidence Matrix Approach is used to identify utility paths in the HEN (Akpomiemie and Smith, 2015).

2.1.2. Sensitivity analysis

Sensitivity analysis is used to identify the best heat exchangers, which can bring the most energy saving among others, to be replaced by plate heat exchangers. It also helps users to select the sequence of replacement. Kotjabasakis and Linnhoff ([1986a](#)) are the

first researchers that proposed sensitivity analysis. This method is based on the equation:

$$Q = UA\Delta T_{LM} F_T \tag{1}$$

In which Q is the total heat load, W; U is the overall heat transfer coefficient, W/(K·m^2); A is surface area of heat exchanger, m^2; ΔT_{LM} is the logarithmic mean temperature difference; F_T is the correction factor. The key point of sensitivity analysis is increasing the inlet temperature of key utility, which is identified as the one that have the most energy consumption, by adjusting the heat transfer coefficient, surface area and correction factor of candidate heat exchangers. Wang (2012) developed a mathematical model to identify the high sensitivity heat exchangers. He concluded that the amount of energy saving largely depended on the distance between the heat exchanger and the key utility. Easy implementation and short computation time are the main advantages of sensitivity analysis.

2.1 Application of plate heat exchangers

After the best heat exchangers for replacement are identified, plate heat exchangers need to be applied in the replacement of selected shell-and-tube heat exchangers. The plate heat exchanger model used in this paper is from Xu et al. (2017), where the effects of multi-pass flow arrangement, plate geometries and chevron angle on heat transfer behavior are considered in the model. The input process stream data are derived from candidate heat exchangers. The maximum heat transfer coefficient of the single plate heat exchanger can be derived from the optimization model in GAMS.

2.2 Optimization of HEN

Application of plate heat exchangers to replace the conventional heat exchanger in the existing HEN can affect the other heat exchangers performance. After replacement, the heat transfer coefficient of new plate heat exchanger significant increased, which leads an increase of the inlet temperature of the next heat exchanger in the hot stream and a decrease of the inlet temperature of the next heat exchanger in cold stream correspondingly. These changes could further affect the other components. To rebalance the HEN, the heat loads of heat exchangers need to be relocated. The heat loads can be shifted through the utility paths. Thus, an optimization method to retrofit an existing heat exchanger network without additional heat transfer area and topology modification is proposed. Plate heat exchangers may decrease energy consumption but the high installation cost of plate heat exchanger may be a significant negligible. Thus, there is a trade-off between energy saving and total retrofit cost. The objective of this optimization problem is to maximize retrofit profit. The total cost of retrofit includes the implementation cost of bypass, the capital cost of plate heat exchangers, the cost of adding heat transfer area only if the heat exchangers are not on the utility path. To achieve target temperatures of the process problem and maintain the existing heat exchanger areas (exclude the candidate heat exchangers to be replaced) are the two main constraints of the design.

Objective Function: *Maximize Retrofit Profit* = Profit from energy saving – Total cost of retrofit

Constraints: $A_{ex} = A_E$ $\forall_{\text{exchangers (excluded the candidate heat exchanges)}}$

$TT_s = TT_E$ $\forall_{\text{streams}}$
Figure 1. Simplified crude oil preheat train

Variables: heat load for all exchangers on a utility path

　　　　　　heat transfer coefficient for candidate heat exchanger

3. Case study

A simplified preheat train is used to illustrate the benefit of application of plate heat exchanger into retrofit design of HEN in a fixed network structure. The existing structure of the network is shown in Figure 1. There are in total 12 exchangers, and five hot streams and one cold stream. The objective of this study is to maximum the retrofit profit of applying plate heat exchangers into existing network without adding area and structure change. Table 1 summarized the cost parameters used in this study. The streams properties are assumed to be constant. To quantify the retrofit profit, the operating time is fixed as one year.

The first step is to identify the best heat exchanger to replacement. It can be inspected from the Figure 1 that only process heat exchanger 7 is not on the utility path. Thus, heat exchanger 1, 2, 3, 4, 5 and 6 are selected to further sensitivity analysis. According to the result of sensitivity analysis, heat exchanger 5 is the most sensitive exchanger which can bring the most benefit of energy saving. Thus, heat exchanger 5 is identified to be replaced by the plate heat exchanger. To maximum retrofit profit, the heat duties of heat exchanger 5 and corresponding cold utility exchanger 10 are set as variables. After inputting the process stream data of exchanger 5 into the optimization model of a single plate heat exchanger in GAMS, the maximum heat transfer coefficient can be derived with the number of 3.75 m^2, which is a significant increase compare with shell-and-tube heat exchangers.

The optimization procedure is conducted to rebalance the network by using global solver on LINDO Systems What's Best!. The heat duty of exchanger 5 is increased by 814.96kW and the utility consumption in exchanger 10 decreases to 0. Although the heat load of heat exchanger 5 increases, the area of exchanger 5 decreases from 183.85 m^2 to 23.83 m^2 by applying the plate heat exchanger. Three bypasses are implemented

Table 1. Cost data of case study

Utility cost data	Retrofit cost data
Hot Utility Cost: 400 ($/kW y)	Cost of Installation of plate heat exchangers: 2.5*2070*A0.85($)
Cold Utility Cost: 5.5 ($/kW y)	Implementing By-pass: 5000 ($)
	Cost of increasing heat exchanger area: 6000 + 200 * A ($)

Table 2. Results of replacement

	Parameter	Replace E5	Replace E5&E1	Replace E5&E1(allowing extra area on E2 & E3)
Retrofit Cost	Replacement	$76,630	$272,893	$324,287
	Increasing Area	$0	$0	$199,323
	Implementing By-pass	$15,000	$15,000	$15,000
	Total Cost	$91,631	$287,893	$539,110
Retrofit Profit	Utility Savings	$296,684	$296,604	$494,325
	Net Saving (Utility Savings – Total Cost)	$205,054 (~3.5% of initial utility cost)	$8,702 (~0.5% of initial utility cost)	-$44,785
	Payback	0.31 yr	0.97 yr	1.09 yr

to reduce the duty of heat exchangers. The results of retrofit cost and retrofit profit are detailed in Table 2 with the initial utility cost of $5,801,396.

The procedure is repeated until the net saving starts to decrease since the retrofit objective is to maximize retrofit profit. According to the sensitivity analysis, the next heat exchanger to be replaced is heat exchanger 1. The results after replacement of heat exchanger 5 and heat exchanger 1 are listed in Table 5. The net saving after replacing heat exchanger 1 is smaller than only replacing heat exchanger 5, which violates the objective function, thus the replacement is stopped after replacing heat exchanger 5. The main reason that limits the net saving is the limited utility saving which is restricted to the fixed area of heat exchanger 2 and heat exchanger 3. Thus, another trail allowing extra area on heat exchanger 2 and 3 is carried out.

The comparisons between application of plate heat exchanger and enhancement (Akpomiemie and Smith, 2015) are also highlighted in Table 3. The retrofit profit of replacement is $11,217.97 smaller than enhancement due to the high installation cost of

Table 3. Comparison of replacement and enhancement

	Parameter	Replacement	Enhancement
Retrofit Cost	Replacement	$76,630.58	$3,981.16
	Increasing Area	$0	$0
	Implementing By-pass	$15,000	$15,000
	Total Cost	$91,630.58	$18,981.16
Retrofit Profit	Utility Savings	$296,684.13	$237,252.68
	Net Saving	$205,053.55	$216,271.52

plate heat exchanger. However, the replacement is more environmental friendly since utility saving in replacement is $59,431.45 larger than enhancement. Thus, heat transfer enhancement is a cost effective retrofit method. However, when one of the film coefficients is not controlling, applying plate heat exchanger to replace shell-and-tube heat exchanger can be regarded as an alternative option for retrofit, which can bring more energy saving at the same time.

4. Conclusions

A new retrofit method for heat exchanger networks based on the application of plate heat exchangers has been proposed in this work. The case studies highlight the retrofit benefit of the new methods. Compared to the traditional heat transfer enhancement technologies, replacing the shell-and-tube heat exchangers with plate heat exchangers can significantly increase the heat recovery and decrease energy consumption with smaller heat transfer area. However, the installation cost of plate heat exchanger is relatively high. Thus, plate heat exchangers can be used as an alternative retrofit option when one of the heat transfer film is not controlling. The savings are constrained, as all of the existing matches, except the new plate heat exchangers, are being maintained at their original sizes.

Abstract

In this work, we propose a mathematical model within a dynamic optimization framework to address management and economic valuation of ecosystem services in a salt lake basin, located in a semiarid region in Argentina (Chasicó Lake). Ecosystem services are valuated by considering water, land and food provision, water flows and disturbance regulation, as well as cultural aspects. Numerical results provide useful insights on optimal management strategies effects and how they can improve services provided by the ecosystem under study.

Keywords: Dynamic Optimisation, Hydrological Mathematical Model, Ecosystem Services, Drought and Flood Mitigation

1. Introduction

The first step to develop useful tools for decision-making in the management of salt lakes is the identification of meteorological, hydrological and ecological components and driving forces of floods, drought and hypersalinisation. Additionally, ecosystem services valuation is essential to assess the relative contribution of the natural capital stock and to effectively manage sustainable human well-being (Costanza et al., 2014). In this work, we extend our previous ecohydrological models formulated as optimal control problems to plan management strategies in salt lakes (Siniscalchi et al., 2018). We formulate optimisation models for dampening extreme hydrological events and related lake salinity oscillations and to irrigate a drought-resistant crop in the grassland basin of a Pampean salt lake, also including equations for the calculation of crop water requirement dynamics. Further, we identify and valuate the ecosystem services offered by the studied endorheic basin and relate them to the management strategies proposed in this work. Numerical results provide control variables profiles to plan actions and their ecological and hydrologic effects.

2. 2. Mathematical Model

2.1 Hydrological Model

We formulate dynamic water mass balances for a salt lake and an artificial reservoir located nearby. Eqn. (1) and (2) show water and salt mass balances for the salt lake.

$$\frac{dm}{dt} = \left[Q_{pp}(t)\left(\frac{V}{h}\right) + Q_{river}(t) + Q_{gw} - Evap(t)\left(\frac{V}{h}\right) + Q_{res}(t) \right] \delta_w/1000 \qquad (1)$$

where **m** is total water mass in the lake (kg); δ_w, is water density (kg. m^{-3}), which is assumed constant; **V** corresponds to salt lake volume and **h** is average depth. Q_{pp} (L.day^{-1}.m^{-2}) corresponds to precipitations, Q_{river} (L.day^{-1}) is the tributary flowrate, Q_{gw} (L.day^{-1}) is groundwater flowrate, (Q_{res}) is the flowrate of a water stream that can be diverted from an artificial reservoir to the salt lake for salinity and volume control in drought periods. **Evap** (L.day^{-1}.m^{-2}) corresponds to evaporation per unit area in the lake. As salt concentration in both groundwater and the tributary is negligible, we assume that salt mass is constant within the lake (*d(CsV)/dt*=0) and salt concentration (Cs) is calculated as:

$$\frac{dCs}{dt} = -\frac{Cs}{V}\left[Q_{pp}(t)\left(\frac{V}{h}\right) + Q_{river}(t) + Q_{gw} - Evap(t)\left(\frac{V}{h}\right) + Q_{res}(t) \right] \delta_w/(\delta_w 1000) \quad (2)$$

Equation (3) is the water mass balance for the artificial reservoir of fixed area, located upstream of the tributary, assuming constant water density.

$$\frac{dVres}{dt} = Q_{pp}(t)A\,\delta H_2O - Evap(t)A\delta H_2O - Q_{res}(t) - Q_r(t) \qquad (3)$$

where $Q_r(t)$ is the flowrate of a water stream used for crop irrigation, calculated based on crop evapotranspiration (*ETc(t)*) as:

$$Q_r(t) = ETc(t) - Q_{pp}(t) \qquad (4)$$

ETc(t) is calculated for a hypothetic *Chenopodium quinoa* crop after Penman-Monteith, considering the evapotranspiration of a hypothetic crop (*ET0(t)*) and a cultivation coefficient for quinoa (*Kc*, Garcia et al., 2017) as follows:

$$ET0(t) = \frac{k*\Delta*Rn+\gamma*\frac{900}{Tair+273}*Fwind*(Prvap-Tvap)}{\Delta+\gamma*(1+0.34*Fwind)} \qquad (5)$$

$$ETc(t) = Kc(t) * ET0(t) \qquad (6)$$

Irrigation crop water requirement taken from the artificial lake and diverted flowrate for irrigation are calculated as:

$$CropWR(t) = ETc(t) - Q_{PP}(t) \qquad (7)$$

$$Q_r(t) = CropWR(t) * A_{cult} \qquad (8)$$

where A_{cult} corresponds to total cultivated area.

Evaporation is calculated taking into account energy and momentum balances (Penman 1948).

$$Evap = \frac{10}{\lambda v}[W\,Rn\,(t) + (1-W)F_{wind}\,(T_{vap0} - T_{vap})] \tag{9}$$

where W is a weighting factor of the radiation effects on evaporation; $Rn(t)$ is net radiation (ly.d^{-1}), F_{wind} expresses wind effects as available energy to evaporate water (km.d^{-1}) and (T_{vap0} - T_{vap}) is a vapour saturation deficit. Additional algebraic equations include latent heat of vaporization for water and forcing functions, represented by Fourier series, including tributary and groundwater flowrate, air temperature, relative humidity, solar radiation, mean wind rate and related meteorological variables.

The model has three differential and twenty five algebraic equations and has been implemented within a control vector parameterisation environment in gPROMS (2017).

2.3 Dynamic Optimisation Model

We formulate management problems for water bodies as optimal control problems subject to the differential algebraic equation (DAE) systems described in the preceding sections. The goal is to keep salt concentration in the lake (Cs) around a desired value of 23 kg.m^{-3} within a drought climate scenario, considering the flowrate of a diverted stream from the artificial reservoir (Q_{diver}) as the control variable. The objetive function is:

$$\min Z = \int_{0}^{tf} (Cs(t) - 23)^2 \; \mathrm{d}t$$

Qres

st

DAE system (1)-(9)

$Cs(0) = Cs^0$, $V(0) = V^0, V_{res} = V_{res}^0$, $Q_{diver}^L \le Q_{diver} \le Q_{diver}^U$ $Cs^L \le Cs \le Cs^U V^L \le V \le V^U$

2.4 Ecosystem Services Valuation

Ecosystem Services for the salt lake basin were identified in previous work (Siniscalchi et al., 2018) and global valuation for each service was carried out following de Groot et al. (2012), in USD.ha $^{-1}$.yr $^{-1}$. These values were multiplied by the corresponding areas (basin, lake and natural reserve).

3. Case Study

Chasicó Lake is located in a depression, 20 m below sea level in the southwest of the Chaco-Pampean plain (38°38″ S 63°03″W), Argentina. The maximum and average depths of this water body are 13.2 and 8 m, respectively. This salt lake (6,500 ha) is part of a natural Reserve (7,800 ha) situated in an endorheic basin (376,400 ha). The hydrologic regime of this basin is closely related to climatic conditions, with dry and wet cycles (D'ambrosio et al., 2013). During the last

century, there were flood events in 1918, 1923, 1924, 1976, 1978, 1983, 1993, 2001and 2002, alternating with dry periods during 1930–1970 and 2006–2014 (Lara, 2006). Salinity values in the lake during the last fifty years ranged between 100 g.L^{-1} (1963) and 16 g.L^{-1} (1993). A wide variation in lake extension and salinity is the result of natural periods of drought and flooding, and is reflected on changes in water quality and biota (Kopprio et al., 2014). It also affects the economy of the region through losses in cropland area and investment uncertainty in relation to tourism and sport fishing of silverside. The severe impact that droughts and floods cause to inland water resources and to the associated socioeconomic activities requires close monitoring of this lake.

4. Results and Discussion

4.1 Salinity and flood control in Chasicó Lake

In previous work, we proposed a hydrological model for Chasicó Lake calibrated and validated with collected salinity data throughout the last ten years (Siniscalchi et al., 2017, 2018). In this frame, we proposed the construction of an artificial reservoir for water storage during wet periods. In this work, we extend the model to drought scenarios, in which the reservoir is used to damp salinity oscillations in Chasicó Lake and to irrigate a drought-resistant crop. Dynamic optimization problems are formulated within a control vector parameterization framework in gPROMS (PSEnterprise, 2017). Annual rainfall and evaporation during the dry period were 400 and 1100 mm, respectively. Figure 1 shows rainfall and evaporation profiles during a 1.5-year dry period. The basis for hydric calculations for cultivation of *Chenopodium quinoa* in Chasicó basin is 300 ha, which corresponds to 23% of the entire area of the natural reserve that may be used for crop cultivation. Figure 2 shows rainfall and CropWR profiles for quinoa crops, from sowing to harvesting, throughout a drought period in which total CropWR is 1254.2 m^3.ha^{-1}. The maximum CropWR, 2.8 L.d^{-1}.m^{-2}, corresponds to the onset of grain maturation.
Figure 1. Rainfall and evaporation for 1.5-year drought period in Chasicó Lake
Figure 2. Rainfall and CropWR for *Chenopodium quinoa* crop in Chasicó basin (Oct.15th-Feb.15th)

Figure 3. Inflow profiles into Chasicó Lake from the river (Q_{river}), groundwater (Q_{GW}) and reservoir (Q_{res}), for a 555-day dry period
Figure 4. Volume (continuous lines) and salinity profiles (dotted lines) with and without optimal management

Figure 3 shows inflow profiles into Chasicó Lake from the river (Qriver), groundwater (QGW) and reservoir (Q_{res}), being the latter the control variable. Q_{res} peaks correspond to Qriver minima and evaporation maxima (see Fig.1). Chasicó Lake volume and salinity profiles with and without optimal management through water input from the artificial reservoir (Q_{res}) are shown in Fig. 4. It is important to remark that the water volume stored during four wet years in an artificial reservoir is enough for keeping salinity at an optimum (23 g.L^{-1}) and simultaneously irrigating a 300 ha-quinoa crop during ca. 1.5 years, thus increasing the socio-ecologic system resilience to extreme drought periods.

3.2. Ecosystem Services Valuation

In this work ecosystem services were valuated for the Chasicó region (Gomez, 2015), including regulating (climate, water flows, disturbance dampening), provision (water, land and food) and cultural services (tourism and recreation). Following de Groot et al. (2012), valuation was carried out by multiplying a reference value (MMUS$/(ha.y) for each service by the corresponding area, as follows. For water flows, disturbance dampening, water and land supply, a basin surface of 376,400 ha was taken. A lake surface of 6,500 ha was used in the case of food supply (silverside). To calculate cultural services, the nature reserve surface (7,800 ha) was taken. Ecosystem Services with the highest economic value (in MMUS$/y) were water flows (2100) and disturbance dampening (1120), further supporting the importance of optimal salinity and lake volume regulation, as well as the construction of a buffering reservoir. Provisioning services valuation include land (450), water (154) and food (4) supply. Additionally to lake food supply services, optimisation results show the possibility of irrigating a 300 ha-quinoa crop. This would produce an improvement of the basin economic value due to quinoa sales of 1.5 MMUS$/y, considering a 2 t/ha yield. Cultural services were valuated in 33 MMUS$/y.

4. Conclusions

In this work, we propose detailed mechanistic models of salt lakes as constraints for optimal control problems to provide tools for planning water body management and exploring the associated effects. Numerical results show the optimal profile for the water stream flowrate that should be diverted from an artificial reservoir to mitigate drought effects by keeping lake salt concentration at the physiological optimum for a high-commercial value fish and irrigation of 300 ha of drought resistant crops (quinoa). Water flows and disturbance regulation correspond to ecosystem services with highest economic value for the basin where Chasicó Lake is located. Dynamic models provide useful insights for water flow regulation and food provision.

Abstract

Agriculture has become one of the largest concerns in the field of sustainability science, while it is a major consumer of resources such as nitrogen, phosphorus, water, and land. Plant factories, indoor hydroponic farming systems, can be divided into two types according to the light source: plant factories with sunlight (PFSLs) and plant factories with artificial light (PFALs) also called as vertical farming. Through the previous studies, it was revealed that these plant factories reduced the use of irreplaceable resources for food production, i.e., phosphorus, water, and land area, at the expense of additional energy consumption compared with conventional Japanese horticulture systems. In this study, we are tackling with the sustainable agriculture mixing conventional and advanced farming technologies, especially plant factories. Based on the comprehensive assessment, an analysis was conducted on the current energy usage and applicability of technology options in plant factories. The results demonstrated that the regional characteristics should be taken into account in the design of plant factories, especially for the insulation and lighting sources in PFAL. The market fluctuation has also large impacts on the profitability of plant factories.

Keywords: vertical farming, power grid, variable renewable energy

1. Introduction

Agriculture has become one of the largest concerns in the field of sustainability science (Kajikawa et al., 2007), while it is a major consumer of resources such as nitrogen, phosphorus, water, and land (Schnoor, 2014). Although phosphorus is essential for food production (UNEP, 2011), it has not been effectively recycled (Matsubae et al., 2011) and there is a strong need to close the phosphorus loop (Christen, 2007). Many countries face food insecurity and starvation induced by a water deficit (Yang et al., 2003), and water resource management is crucial to food management. Land use is an important index of food environmental impacts (Heller et al., 2013).

Plant factories, indoor hydroponic farming systems, can be divided into two types according to the light source: plant factories with sunlight (PFSLs) and plant factories with artificial light (PFALs) (Kozai et al., 2015). Because PFSLs and PFALs feature semiclosed and closed cultivation rooms, respectively, plants cultivated in these factories can be protected from pathogens and harmful insects, leading to high stability of food production. As a proof of such concept of plant factories, a comprehensive analysis was conducted for the multiple aspects and technology options of plant factories: the use of nitrogen, phosphorus, and potassium (NPK) fertilizers, the consumption of water, the occupation or transformation of land, and greenhouse gas (GHG) emissions for the demonstration PFSL and PFAL located at Chiba University in Kashiwa, Japan (Kikuchi et al., 2018a). It was revealed that these plant factories reduced the use of irreplaceable resources for food production, i.e., phosphorus, water, and land area, at the expense of additional energy consumption compared with conventional Japanese horticulture systems.

Decentralized energy systems have been recognized as a solution to increase the resource utilization including locally available renewable resources (Kikuchi et al., 2018b; 2016). control systems for voltage and frequency should be equipped to accept the massive implementation of variable renewable energy (VRE) such as photovoltaic and wind turbine power generation, e.g., virtual power plant or demand response systems (Kikuchi, 2017) considering the future energy supply and demand structure (Kikuchi et al., 2014; 2016).

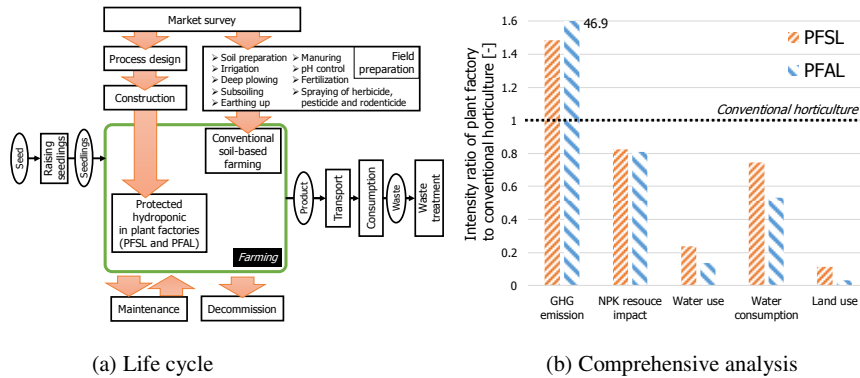
In this study, we are tackling with the sustainable agriculture mixing conventional and advanced farming technologies, especially plant factories. An analysis was conducted on the current energy usage and applicability of technology options in plant factories for designing the life cycles of plant factories considering their harmonization with future energy systems.

2. Materials and methods

2.1. Overview of plant factories in this study

Figure 1 shows the plant factories examined in this study (Kikuchi et al., 2018a). The PFSL and PFAL examined in this paper were demonstration factories located at Chiba University in Kashiwa, Japan, where long-stage, high-density cultivation and a 10-stage vertical horticulture system were adopted to produce fresh tomatoes and lettuce in hydroponic culture using rockwool and polyurethane, respectively, as the culture media. The life cycle of plant factories shown in Figure 1(a) includes the market survey and process design before farming of vegetables. As summarized in Figure 1 (b) which was obtained from the comprehensive analysis based on the same methods by Kikuchi et al., (2018), the use of irreplaceable resources for food production can be mitigated at the expense of additional fossil energy consumption indicated as the GHG emission.

2.2. Analysis on current energy utilization and technology options

The suppression of VRE has been conducted in Kyushu area in Japan shown in Figure 2. Especially in remote islands in the area, the capacity of suppression is increasing due to the depopulation within such area and additional installation of photovoltaic power generation.


(a) Life cycle

(b) Comprehensive analysis

Figure 1 Overview of plant factories examined in this study (Kikuchi et al., 2018a)

(a) Power mix and suppression needs

(b) Actual records in Tanegashima, Japan
Figure 2 Suppression of VRE in Japan (Kyushu Electric Power Company, 2018)

Considering the harmonization of plant factories with such decentralized energy systems implementing massive amount of VRE, the properties of power demands in plant factories are analysed by utilizing the automatically logged power consumption in the actual PFSL and PFAL in this study for every 1 minute from May 2011 to September 2014. The daily power consumption [Wh/day], maximum power demand [W], and peak demand time are selected as the properties of power demand. These properties can be changed by applying technology options in plant factories. The options to be considered for the plant factories in this study are the utilization of unused heat, a solid-oxide fuel cell, PV power, improved electric devices such as heat pumps and lighting, insulation, and the installation of all options. Their applicability and consequences are analysed and discussed in this paper.

3. Results and discussion

3.1. Current power consumption

Figure 3 shows the power demand properties in PFSL and PFAL in this study. The maximum daily power consumptions were 674 kWh/day and 3.32 MWh/day for PFSL and PFAL, respectively. The maximum power demand were 52.4 kW and 174 kW for PFSL and PFAL, respectively. The largest power demand in PFSL was air conditioning

(Kikuchi et al., 2018a), which gets higher in the morning, evening, and night during winter season. Due to the semiclosed environment of PFSL, the power demand is strongly affected by the seasonal changes, which means not easily controllable. The lighting in the PFAL, the largest power demand, is based on the production amount of vegetable (Kikuchi et al., 2018a). The peak demand time was fluctuated even though the power demand was at the maximum in 2014, which means that the lighting plans are controlled not by the time, but the operation considering the characteristics of plant growth.

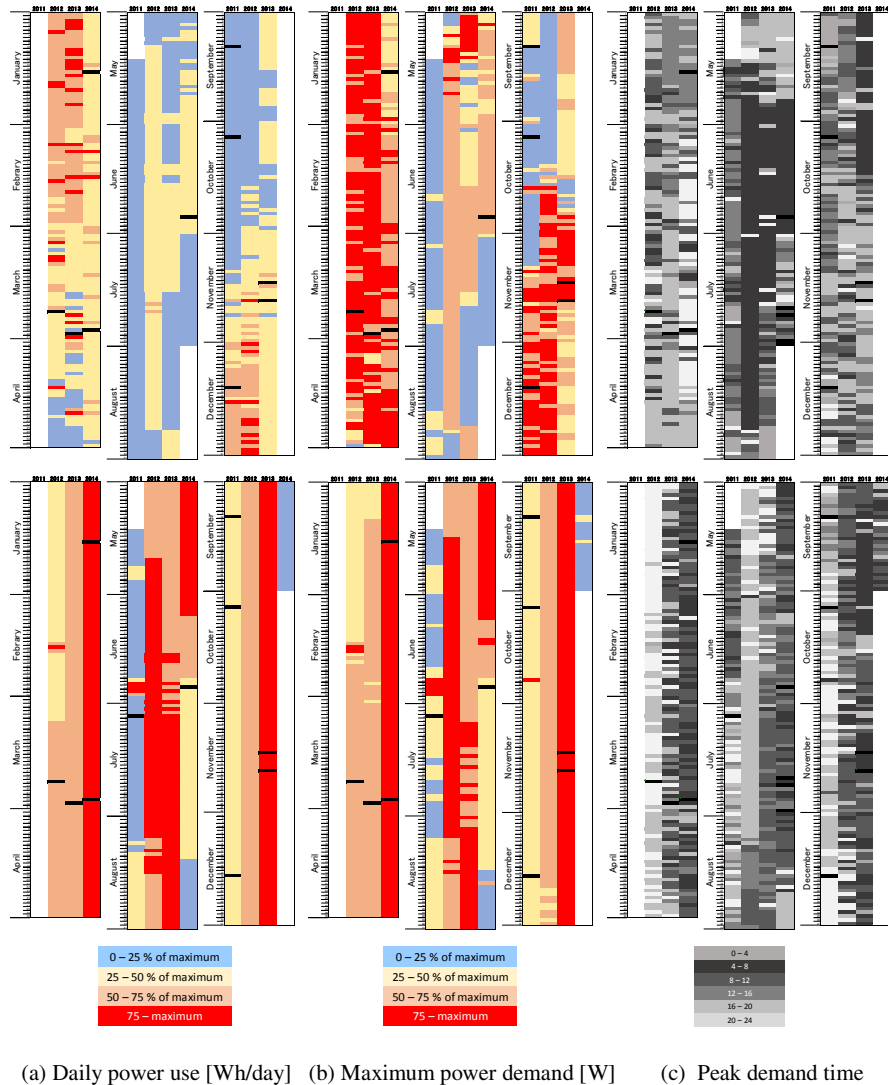

Figure 3 Power demand properties indicated as the ratio to the maximum during all periods (a,b) and ranges of time (c); upper and lower diagrams show the results of PFSL and PFAL, respectively
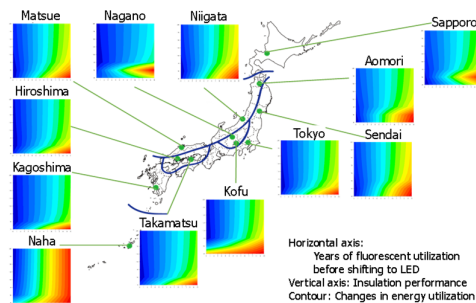

Figure 4 Regional differences of effects of LED implementation in PFALs considering their insulation

3.2. Applicability of technology options

The power demand properties shown in Figure 3 should be taken into account for the harmonization of plant factories with decentralized energy systems in the future. The application of technology options should also be addressed for such harmonization. For example, the implementation of fuel cell into PFSL can achieve the net-zero GHG emission (Kikuchi et al., 2018a), which means that the PFSL can supply power derived from fuel cell. This is partly because the power demand for air conditioning can be supplied by fuel cell as electricity and hot/cold heat with absorption chiller. As for the PFALs, their lighting needs electric power, which cannot be supplied by implementing small scale fuel cell and photovoltaic. At this time, the suppressed power due to the limitation of load following capacity in power grid shown in Figure 2 can be utilized in PFALs as a kind of virtual power plant or demand response, if the power demand can be controlled along with the condition of power grid.

The implementation of LED can also be considered for mitigating power demand in PFALs, where the relationship with insulation of PFALs should be carefully examined. Figure 4 shows the regional differences of effects of LED implementation in PFALs considering their insulation. Because the air conditioning in PFAL is always cooling mode, the lower insulation can reduce power demand in some cold area. However, if the fluorescent is applied at the design of PFALs, the LED implementation can disturb the design rationales and increase the power demand for air conditioning.

4. Conclusions

Food supply security can be also addressed by implementing plant factories (Kikuchi et al., 2018a). They can become a new energy demand to support the regional systems to supply foods. The radical changes in future energy systems should be taken into account for designing the life cycle of plant factories. For this purpose, computer-aided approaches are strongly needed for designing process and operation of plant factories.

A Data-Driven Robust Optimization Approach to Operational Optimization of Industrial Steam Systems under Uncertainty

Liang Zhao, Chao Ning, Fengqi You

Cornell University, Ithaca, New York 14853, USA

Abstract

This paper proposed a data-driven adaptive robust optimization approach to deal with operational optimization problem of industrial steam systems under uncertainty. Uncertain parameters of the proposed steam turbine model are derived from the semi-empirical model and historical process data. A robust kernel density estimation method is employed to construct the uncertainty sets for modeling these uncertain parameters. The data-driven uncertainty sets are incorporated into a two-stage adaptive robust mixed-integer linear programming (MILP) framework for operational optimization of steam systems. By applying the affine decision rule, the proposed multi-level optimization model is transformed into its robust counterpart, which is a single-level MILP problem. To demonstrate the applicability of the proposed method, the case study of an industrial steam system from a real-world ethylene plant is presented.

Keywords: data-driven, adaptive robust optimization, industrial steam system, operational optimization, uncertainty

1. Background

In recent years, system modelling and optimization methods are employed to improve the efficiency and economic benefits of industrial steam systems. In steam systems, it is an important issue to accurately model the steam turbines to improve the steam system efficiency (Petroulas and Reklaitis, 1984; Li et al. 2014). Turbine models based on thermodynamics were proposed to optimize the performance of steam system (Aguilar et al. 2007). Hybrid models were developed to improve the performances of steam turbine models (Luo et al. 2011). Building upon the developed steam turbine models, several optimization models for synthesis and design of steam systems were proposed (Tveit et al. 2006, Li et al. 2013, Beangstrom et al. 2016). A stochastic programming approach was employed to deal with uncertainties in the site utility system (Sun et al. 2017). However, the optimization results of stochastic programming are highly sensitive to the pre-defined probability distributions, which could deviate significantly from the "true" uncertainty information. The static robust optimization (SRO) approach might make the resulting solutions very conservative (Soyster, 1973; Bertsimas et al. 2011; Ben-Tal and Nemirovski, 1998). More recently, data-driven robust optimization has emerged as an effective tool for optimization under uncertainty (Ning et al. 2017, 2018, Shang et al. 2017). In industrial steam systems, large amounts of historical data are collected and stored in a database that records all operational information of the devices and their connected networks. A semi-empirical model of steam turbine is first developed based on process mechanism and operational data. Then, the uncertain parameters are collected from process historical data. A data-driven two-stage ARO method for operational optimization of steam systems under uncertainty is presented. The robust counterpart of

the proposed data-driven ARO model is derived as a single-level MILP model to facilitate the solution process. A case study of the steam system in a real-world ethylene plant is presented to demonstrate the effectiveness of the proposed method.

2. Deterministic MILP model of industrial steam system

Mixed-integer optimization models were developed for operational optimization of the steam systems, which rely on the linear or nonlinear model of the basic components (Varbanov et al. 2004; Chu and You, 2015). A decomposition method is employed to develop extraction steam turbine model (Aguilar et al. 2007). The semi-empirical model of steam turbine is presented as follows,

$$m_t^{in} = a_t \cdot m_t^{ext} + b_t, \ \forall t \tag{1}$$

where a_t and b_t, are parameters of the model and can be calculated by process data.

The deterministic MILP model optimization model of steam system (DOSS) is given by,

$$\min \quad c = c^{SS} \sum_{t \in TSS} m_t^{in} + c^e \sum_j y_j^e + c^{water} \sum_{lv} (l_{lv} - 1) m_{lv}^{in} \tag{2}$$

$$\text{s.t.} \quad \sum_t (a_{sh,t}^{in} m_t^{in} + a_{sh,t}^{ext} m_t^{ext}) + \sum_j a_{sh,j}^M (1 - y_j) F_j^S + \sum_{lv} (a_{sh,lv}^{in} m_{lv}^{in} + a_{sh,lv}^{out} m_{lv}^{out}) \geq md^{sh} \tag{3}$$

$$e_t + W_t \geq WD_t \tag{4}$$

$$m^{\min} \leq m \leq m^{\max} \tag{5}$$

Equations (2)-(4) are steam demand constraints, mechanical power demand constraints and variables range constraints, respectively.

3. Data-Driven ARO Model for Steam System

3.1 Deriving uncertain parameters of semi-empirical model for steam turbines

The parameters of the steam turbine models are derived from process operation parameters according to equation (1). The schematic diagram of uncertain parameter derivation process is given in Figure 1.
The procedure of deriving uncertainty parameters from historical operation data.

The process historical data of steam system can typically be collected conveniently. A couple of parameters, a_t and b_t, in the proposed semi-empirical model can be calculated by process data, including temperatures, pressures, and flow rates of inlet, extraction and exhausting steam of turbines. Then, the uncertain parameters are derived.

3.2 Data-driven uncertainty sets for ARO

RKDE is employed to construct data-driven uncertainty sets for the ARO framework (Kim et al. 2012). The correlation information is also considered in the construction of uncertainty sets (Ning et al. 2017). The data-driven uncertainty set is reformulated as follows,

$$U^{cor} = \left\{ \zeta \left| \begin{array}{l} \hat{F}_{RKDE}^{i-1}(\alpha) \leq \zeta_i \leq \hat{F}_{RKDE}^{i-1}(1-\alpha), \ \forall i \\ \sum_i \zeta_i^0 (1-r_i h) \leq \sum_i \zeta_i \leq \sum_i \zeta_i^0 (1+r_i h) \\ \left\| M(\zeta - \zeta^0) \right\|_1 \leq \beta \end{array} \right. \right\} \tag{6}$$

where α is a predefined parameter to denote the confidence level $(1-2\alpha)$, h is a predefined uncertainty budget to control the level of conservatism as the parameter α. re $M=\Sigma^{-1/2}$, Σ is the covariance matrix of the uncertain parameters, and β is a parameter used to adjust the size of l_1 norm ball in $\left\| M(\zeta - \zeta^0) \right\|_1 \leq \beta$.

3.3 Data-driven robust MILP model of steam system

A novel data-driven adaptive robust MILP model for operational optimization of steam systems is then developed based on the uncertainty sets (6). The multi-level data-driven adaptive robust steam system model based on RKDE incorporating correlation information (DDARSS-RKDECI) is developed as follows. Noted that the model is also subjected to constraint (4) in model DOSS.

$$\min_{m_t^{in}(\cdot), m_t^{ext}, m_{lv}^{in}, y_j} \max_{\zeta \in U^{cor}} c_e \sum_j y_j^e + c_{water} \sum_{lv} (l_{lv} - 1)m_{lv}^{in} + c_{ss} \sum_{t \in TSS} m_t^{in}(\zeta) \tag{7}$$

$$\text{s.t.} \quad \begin{array}{l} \sum_t (a_{sh,t}^{in} m_t^{in}(\zeta) + a_{sh,t}^{ext} m_t^{ext}) + \sum_j a_{sh,j}^M (1-y_j) F_j^S \\ + \sum_{lv} (a_{sh,lv}^{in} m_{lv}^{in} + a_{sh,lv}^{out} m_{lv}^{out}) \geq md^{sh}, \ \forall sh \in SH, \ \zeta \in U^{cor} \end{array} \tag{8}$$

$$m_t^{in,\min} \leq m_t^{in}(\zeta) \leq m_t^{in,\max}, \ \forall t \in T, \ \zeta \in U^{cor} \tag{9}$$

$$m_t^{exh,\min} \leq m_t^{in}(\zeta) - m_t^{ext} \leq m_t^{exh,\max}, \ \forall t \in T, \ \zeta \in U^{cor} \tag{10}$$

3.4 Robust counterpart reformulation of data-driven ARO model for steam system

Because there are uncertain parameters in the objective function, the epigraph reformulation of objective function (7) is presented by,

$$\min_{m_t^{in}(\cdot), m_t^{ext}, m_{lv}^{in}, y_j, z} z \tag{11}$$

$$\text{s.t.} \quad c_e \sum_j y_j^e + c_{water} \sum_{lv} (l_{lv} - 1)m_{lv}^{in} + c_{ss} \sum_{t \in SS} m_t^{in}(\zeta) \leq z, \ \forall \zeta \in U^{cor} \tag{12}$$

By applying the affine decision rule $m_t^{in}(\zeta) = P_t \zeta + q_t$, constraint (12) is reformulated as follows,

$$\max_{\zeta \in U^{cor}} c_{ss} \sum_t P_t \zeta \leq z - c_e \sum_j y_j^e - c_{water} \sum_{lv} (l_{lv} - 1)m_{lv}^{in} - c_{ss} \sum_t q_t \tag{13}$$

Because the left-hand side of constraint (13) is a linear program, dual variables λ_i, γ_i, π, Ω, $C1$, $C2_k$ and $C3_k$ are introduced. Constraint (13) is then reformulated as follows,

$$\sum_i \zeta_i^{\max} \lambda_i - \sum_i \zeta_i^{\min} \gamma_i + \zeta^{sum,\max} \pi - \zeta^{sum,\min} \Omega + \beta C1 + \zeta^{sum,cor} C2_k - \zeta^{sum,cor} C3_k$$
$$\leq z - c_e \sum_j y_j^e + c_w \sum_{lv} (l_{lv} - 1) m_{lv}^{in} - c_{ss} \sum_t q_t \tag{14}$$

$$\lambda_i - \gamma_i + \pi - \Omega + \sum_k M_{k,j} \cdot C2_k - \sum_k M_{k,j} \cdot C3_k = c_{ss} \sum_t P_t, \ \forall i \tag{15}$$

$$C1 + C2_k - C3_k = 0, \ \forall k \tag{16}$$

$$\lambda_i, \ \gamma_i, \ \pi, \ \Omega, \ C1, \ C2_k, \ C3_k \geq 0, \ \forall i, \ k \tag{17}$$

Similar to constraint (13), constraints (8)-(10) can be transformed to new constraints by dual variables. Then, the data-driven adaptive robust counterpart for steam system operational optimization (DDARCSS-RKDECI) is formulated as a single-level optimization problem, which can be solved by optimization solvers like CPLEX directly.

4. Applications

To demonstrate the applicability of the proposed approach, a case study on the steam system of an ethylene plant is presented. There are four steam grades (SS, HS, MS, and LS), four extractions turbines (T1, T2, T3, and T4), 29 backpressure turbines (T5 to T33), three let-down valves in the given steam system. The prices of SS, water and electricity are set to be 180 m.u./t, 15 m.u./h and 1.5 m.u./kwh, respectively (where m.u. stands for "monetary unit"). In RKDE, the parameter α is set as 0.02, and the parameter h is set as 0.8. The parameter β in uncertainty set U^{cor} is set as 3.2.

The proposed method is compared with the deterministic and RKDE-based method (DDARCSS-RKDE). All optimization problems are coded in GAMS 24.8.3. The CPLEX 12.7.0.0 with an optimality tolerance of 0% is used to solve the single-level MILP problems. The computational results of different methods are given in Table 1.

Table 1 Problem sizes and solution comparisons for different methods.

	DOSS	DDARCSS-RKDE	DDARCSS-RKDECI
Binary variables	29	29	29
Continuous variables	11	397	732
Constraints	13	196	369
Min. operating cost(m.u./h)	88,720	96,750	96,366

The optimal operating cost obtained by the deterministic method is 88,720 m.u./h, and it is obviously less than the values determined by the data-driven ARO methods, because the deterministic model uses fixed parameters during the optimization process. Due to the consideration of correlation information among uncertain parameters, the solution of DDARCSS-RKDECI method is less conservative than that of the DDARCSS-RKDE approach.

The effects of parameters α and h on the solution of the proposed method are investigated by changing their values. α is set as 0.02, 0.05, 0.1, 0.2 and 0.4, and h is set as 0.05, 0.1, 0.2, 0.4 and 0.8. The heat map of operational cost is shown in Figure 2. When the value of α decreases from 0.4 to 0.02 for any fixed h, the operational cost increases by 6.3% on

average; when h increases from 0.05 to 0.8 for any fixed α, the operational cost increases by 0.9% on average. For a fixed value of parameter h, the operational cost decreases obviously with the increase of α, because the confidence interval becomes smaller with a large value of α. Since h is used to control the effect of uncertainty deviations, the objective value increases slowly as the value of parameter h increases.
Heat map of solutions determined by DDARCSS-RKDECI.

The breakdown of the optimal operational costs determined by different methods in Table 1 are shown in Figure 3. The percentage of electricity obtained by the deterministic method is the largest among the three methods. The parameters of the semi-empirical model are fixed as nominal values, meaning the steam demands from processes can be satisfied easily. As a result, more electrical motors will be turned on, replacing the steam turbines as the method of power generation for the pumps. The data-driven two-stage ARO methods have similar breakdowns of operational costs, because the consumptions of electricity and water are determined at the first stage. The minor differences are caused by the difference of their uncertainty sets.
Comparison of operational cost breakdown for different methods.

5. Conclusion

A novel operational optimization model of steam system under uncertainty using data-driven two-stage ARO was proposed. The uncertain parameters of semi-empirical models for steam turbines were collected from historical process data of an industrial plant. The RKDE method was then employed to construct the uncertainty sets from the derived uncertain parameters. The correlation information was considered in the construction of uncertainty sets through the covariance matrix of uncertain parameters. The data-driven

two-stage ARO model of steam system was formulated based on the constructed uncertainty sets, and the corresponding robust counterpart was developed using affine decision rule. A real-world case study on the steam system of an ethylene plant was presented to demonstrate the effectiveness of the proposed methods.

Abstract

In this work we develop a Bayesian framework for building surrogate stochastic models of complex multi-step processes for which tractable mechanistic models are difficult to construct. The probabilistic process envelope defined by the design space provides an extra level of assurance of product quality over and above that provided by traditional process control. While the application we report is specific to drug products manufactured using traditional batch processing, the proposed framework is applicable in general to batch and continuous manufacturing of products that must meet a set of critical product quality specifications.
Keywords: stochastic process model; surrogate process model; batch process; continuous process; Bayesian statistics.

1. Introduction

The ICH guideline on pharmaceutical development (ICH, Q8(R2)) introduced the concept of design space, a construct that defines the operating region within which the resulting product can be assured to be at the required quality level. Recognizing the inherently stochastic nature of the design space, (Peterson, 2008) demonstrated the use of Bayesian statistics to facilitate its construction. More recently, (Bano, et al., 2018) proposed an approach based on partial least square regression to establishing a probabilistic design space, under the assumption that product quality is linearly related to process inputs. The key distinctions of the approach proposed in our work is, first, that the stochastic model utilizes historical process performance. Second, it is parametric with regards to product quality attributes as opposed to process performance and therefore aleatoric uncertainties (unknown unknowns) can be implicitly captured. In addition, the proposed framework is independent of linearity assumptions.

To find the design space of a process, quantification of the "assurance of quality" for the product under development or being manufactured is required. In this study, the experimental data for multiple pharmaceutical products manufactured by different manufacturers is used to determine the variation between and within product lots. Uncertainty quantification is obtained by employing multi-level hierarchical models at different levels of fidelity combined with Bayesian inference. This allows prediction of the TRUE between- and within-lot variability. In addition, several ways to predict the TRUE measurement uncertainty are identified.

2. Probabilistic design space

We identify the design space by constructing a process envelope which ensures that the manufactured product is of required quality. The ICH Q8(R2) Guideline (ICH, 2009) defines "Design Space" as: "The multidimensional combination and interaction of input variables (e.g. material attributes) and process parameters that have been demonstrated to provide assurance of quality." From a Bayesian perspective, one could define the ICH Q8 design space as:

$$DS = \left\{ x \in X \mid \Pr\left(Y \in A \mid x, data\right) \geq R \right\},$$

where x is a vector of process input variables, X is the experimental region, Y is a vector of product attributes defining quality (assay, % dissolved at Q time, tablet hardness, etc.), A is the acceptance region for the product, R is a reliability value which defines the desired level of "assurance" of quality, and DS is the design space. Q is the time point at which the dissolution performance specified in the corresponding pharmacopeial monograph must be satisfied.

The above probability measure is based upon the posterior predictive distribution for Y given the process inputs. The specifications are typically established based on human clinical trials to ensure absence of adverse events and efficacy of the product.

In this work we propose to define the design space in terms of the parameter space associated with the process responses, namely, the product quality attributes. Specifically, these consist of the product grand mean of these attributes as well as the intra and inter lot variability of these attributes. This allows the quality of a product to be determined by measuring the probability of meeting specifications established during pivotal clinical trials. The product quality is deemed sufficient if the probability is equal to, or greater than, an assigned threshold.

For a complex multi-step batch process, it is difficult and often infeasible to derive a rigorous and explicit model, therefore we propose to use a surrogate model expressed in terms of the product quality attributes, specifically, the attribute means and intra/inter lot variabilities. It should be noted that the traditional concept of lot may be extended to continuous processing by defining the lot in terms of an appropriate time interval of production during which product attributes and external intervention (human operator actions, raw material supply, etc.) are constant within some tolerance. Over that time period the process is said to be in the state of control.

In addition, the proposed stochastic model utilizes historical process performance which is incorporated as prior information via a Bayesian framework. It is parametric with regards to product quality attributes as opposed to process performance and therefore aleatoric uncertainty (unknown unknowns) is implicitly considered.

The proposed methodology is easily generalizable to batch and continuous processing industries (i.e., conformance to grade requirements in oil refinery). Significant change in between/within lot variability indicates that measures have to be taken to ensure adequate process control (i.e., quality of incoming materials).

By making the simplifying assumptions of normality, the surrogate process model may be expressed as follows:

$$
\begin{aligned}
Y_{ij} &= \mu_j + \eta_{ij} \\
\mu_j &\sim N\left(\mu, \sigma_B^2\right), \\
\eta_{ij} &\sim N\left(0, \sigma_W^2\right) \\
\theta &= \left(\mu, \sigma_B, \sigma_W\right)
\end{aligned}
\tag{1}
$$

where Y_{ij} is the true value of product attribute (for assays this is expressed as % of label content, while for dissolution this is expressed as % dissolved), μ_j is the true mean for lot j, and η_{ij} is a deviation of the true value of unit i from lot j from the true lot j mean. σ_B and σ_W are corresponding inter-lot and intra-lot variabilities. μ is the attribute mean. The prior $P(\theta)$ for $\theta=(\mu,\sigma_B,\sigma_W)$ encapsulates expert knowledge and could be derived from historical data.. Without loss of generality and to simplify further development, we assume that $P(\theta)\sim1$.

It should be noted that the simplifying normality assumptions may be relaxed by treating the intra and inter lot variations to be distributed according to a more robust Student t distribution or even more general distributions such as the four parameter Johnson SU (Johnson, 1949) or the skew-normal or skew-t distributions which can model the presence of skewness and/or kurtosis (Dagne, 2013; Sahu, et al., 2003; Azzalini & Capitanio, 2003). However, in this work we will focus on the simplest normal form since under that assumption the design space may be expressed in terms of an analytical expression. In more complicated cases the design space boundaries have to be estimated using numerical simulation.

The design space boundaries based on the normality assumption may be expressed as:

$$DS_b = pnorm\left(ub, \mu, \sqrt{\sigma_B^2 + \sigma_W^2}\right) - pnorm\left(lb, \mu, \sqrt{\sigma_B^2 + \sigma_W^2}\right), \qquad (2)$$

where pnorm is the quantile function for the normal distribution, ub is the upper bound of product attribute, lb is lover bound of product attribute (for assays the typically lower/upper bounds are 90/110%, for dissolution the lower/upper bounds are % dissolved at Q time.

In the multidimensional case (i.e. assay, % dissolved, and tablet hardness are bounded) the design space boundaries may be derived analytically using multivariate normal distribution. For purposes of the present discussion, we assume that inter and intra lot variabilities are independent.

3. Case study

We have experimentally tested 18 different immediate release drug products manufactured by different generic manufacturers and determined their product quality attribute means and inter/intra lot variabilities from the experimental data (Morris, 2018). We also assume that the reliability measure is R=0.95. The choice of R is based on acceptable quality level (typically 5%). This choice is very important: higher values may be chosen for narrow therapeutic range products as is the case with some oncology therapies.

The 50% highest probability density region of the estimated joint distribution for mean, intra and inter lot variability of dissolution attribute (% dissolved at Q time) are depicted in Figure 1. To simplify the presentation, we combine the inter and intra lot variabilities by using:

$$\sigma^2 = \sigma_B^2 + \sigma_W^2 , \qquad (3)$$

where σ is a lumped standard deviation.

The joint probability distribution estimates for mean μ, standard deviations σ_B and σ_W were obtained using Markov Chain Monte Carlo procedure (Morris, 2018) using a hierarchical model by also considering analytical variability.

We observe that for some products those regions are close to the design space boundary (black line). The number beside the product name indicates the probability of the tablet being within design space. Each oval corresponds to a different product and manufacturer combination. The names of the drug products that are below desired quality level are

shown next to their corresponding oval. The probability of a given product being within the design space is shown to the right of product name. For example, Product P12 manufactured by M11 has probability of 34% being within design space.
Figure 1. Probabilistic design space for dissolution. Ovals represent various products. The probability of a given product being within the design space is shown to the right of product name. The units of process mean and standard deviation are % dissolved.

The corresponding landscape for the product assay is depicted Figure 2. Since the assay is bounded from both sides of the design space, the boundary has a parabolic shape. Note that there are a number of products that fall outside of the design space boundary. One reason for this being that manufacturers overshoot to ensure that the content of active pharmaceutical ingredient (API) is not too low. Another artefact is that the assay is defined as the average content over several tablets, as specified by US Pharmacopeia. Averaging effectively masks intra-lot variability. While the average active content is below the upper bound the active content in individual tablets fluctuate. The proposed framework allows detecting "unobserved" behaviour.

It is of interest to note that the four large ovals lying outside of the design space on the top right corner of the Figure 2 represent the same product P11 manufactured by different manufacturers M1, M5, M2, and M10. It is very possible that overage is explicitly specified in the corresponding batch record.
Figure 2. Probabilistic design space for assay. Ovals represent various products. The probability of a given product being within the design space is shown to the right of product name. The units of process mean and standard deviation are % of label claim.

The distributions of the probability that the product is within assay specifications for well performing (within design space) and poorly performing (outside design space) processes are depicted in Figure 3. A well performing process (solid line) is characterized by probability mass concentrated around one which is indicated by a sharp peak close to one. A poorly performing process (dashed line) is characterized by a diffuse probability mass that is indicated by a low and very wide hump in the distribution profile.
Figure 3. The probability distributions of probability that product is within assay specifications.

4. Conclusion

In this work we develop a Bayesian framework for building surrogate stochastic models of complex multi-step processes for which tractable mechanistic models are not available. The proposed framework may be a valuable tool to detect the "unobserved" process shifts and serve as an additional measure to ensure product quality.

The proposed framework can be easily extended to batch and continuous processing manufacturing of products that must meet a set of critical product quality specifications (i.e., conformance to grade requirements in oil refinery).

In addition, we expect that this work could potentially support FDA's risk based approach and quality metrics initiative - the proposed framework explicitly identifies the sites that may require attention - as well as continuous process verification as delineated in (FDA, 2011).

Abstract

A life cycle assessment (LCA) of photovoltaic (PV) power is conducted. The PV LCA is used to estimate the emissions impact of a common PV practice that has not been comprehensively analyzed by LCA: solar tracking. Relative to stationary mounting, solar tracking is found to decrease the greenhouse gas emissions of power from multi-crystalline silicon PV in most regions analyzed (by 0 to ~12%, or 0 to ~4 gCO_2e/kWh), and to increase the emissions of power from cadmium telluride PV in most regions analyzed (by 0 to ~12%, or 0 to ~4 gCO_2e/kWh). This dependence on cell type is explained by the interaction of tracker production emissions, module production emissions, and tracking energy gain. For both PV cell types, if the ratio of module production emissions to tracker production emissions increases in future, independent of absolute emission values, tracking will more commonly decrease PV carbon intensity. Conversely, if the ratio decreases, tracking will more commonly increase PV carbon intensity. Equations are presented to explain this relationship between module production emissions and tracker production emissions. These equations apply to emissions of all pollutants, not only greenhouse gases.

Keywords: photovoltaic (PV) power, life cycle assessment (LCA), greenhouse gas (GHG) emission, solar tracking

1. Introduction

Since 2008, solar tracking has grown from rare to common in photovoltaic (PV) power production. In the US from 2008 to 2014, 19 % of new utility-scale projects with cadmium telluride (CdTe) modules employed tracking (16 of 86 projects); in 2015 and 2016, the number was 56 % (44 of 79 projects), including locations outside the exceptionally sunny US southwest, such as Colorado and Tennessee (EIA 2016). For all PV module types, tracking was used on 53 % of cumulative and 70 % of new capacity at utility-scale sites in 2016 in the US (EIA 2016). The impact of solar tracking on emissions from PV generation has not been comprehensively analyzed by life cycle assessment (LCA). This study fills that gap. It provides a general methodology for estimating the emissions impact of adding performance enhancing equipment to PV, and applies this methodology to model the impact of solar tracking on emissions of greenhouse gases (GHGs). This paper refers to life cycle GHG emissions from AC electricity generation as "carbon intensity", and the units of grams-CO_2-equivalent/kilowatthour as "g_C/kWh".

Several LCAs analyzed the impact of solar tracking on carbon intensity, but with limited geographic scope and tracking set-ups that do not (and do not claim to) represent industry practice. Desideri et al. (2013) analyzed 1-axis tracking systems with 30º tilt in southern europe. In contrast, the industry norm for PV tracking is horizontal 1-axis tracking; in the US in 2016, 97 % of utility-scale tracking PV projects used horizontal 1-axis tracking (Bolinger et al. 2017). Two PV LCAs did analyze industry-representative tracking. Leccisi et al. (2016) found that horizontal 1-axis tracking reduced carbon intensity by 11 % and 1 % for mc-Si and CdTe PV, respectively, given installation in the US southwest. Sinha et al. (2013) estimated that tracking reduced the carbon intensity of CdTe PV by 3 % in the US southwest. This paper aims to build on these studies by calculating and explaining tracking's impact on PV carbon intensity over a range of locations.

2. Methodology

We developed a solar life cycle assessment tool (SoLCAT) following ISO 14040 standards for LCA (ISO 14040 2006) and IEA PV LCA guidelines. To estimate GHG emissions from PV power, SoLCAT integrates four elements: published PV life cycle inventories (LCIs), background emission factors from Ecoinvent, known physical correlations, and capacity factors from PVWatts, a software tool from the US National Renewable Energy Laboratory.

The goal of our LCA is to estimate the impact of solar tracking on the carbon intensity of PV power. The system is electricity production by PV. The functional unit is a kilowatthour of AC electricity supplied to the grid. In addition to electricity, the other system output analyzed is GHG emissions. These two system outputs combine into our central metric: GHGs emitted per AC electricity generated (g_C/kWh), or carbon intensity. PV electricity production can be elaborated as shown in Figure 1.

Figure 2 gives an overview of SoLCAT's operation and utilization of data sources. Our primary sources for PV LCIs are the IEA Report "Life Cycle Inventories & Life Cycle Assessments of PV Systems" (Frischknecht et al. 2015) and the ESU Report "Life Cycle Inventories of Photovoltaics" (Jungbluth et al. 2012). Sinha et al. (2013) provides an LCI of a horizontal 1-axis tracking system. For emission factors of background processes, our primary source is the Ecoinvent V3 database. In the absence of data, our model does not account for emissions from PV EOL processes.

SoLCAT converts amounts (a) to GHG emissions (e_{total}) using three general equations:

$$e_{total} = \sum_i e_{stage\ i} \tag{1}$$

$$e_{stage\ i} = \sum_j e_{input\ j\ to\ stage\ i} - \sum_k^{stages\ before\ i} e_{stage\ k} \tag{2}$$

$$e_{input\ j\ to\ stage\ i} = a_{input\ j\ to\ stage\ i}\ EF_j \tag{3}$$

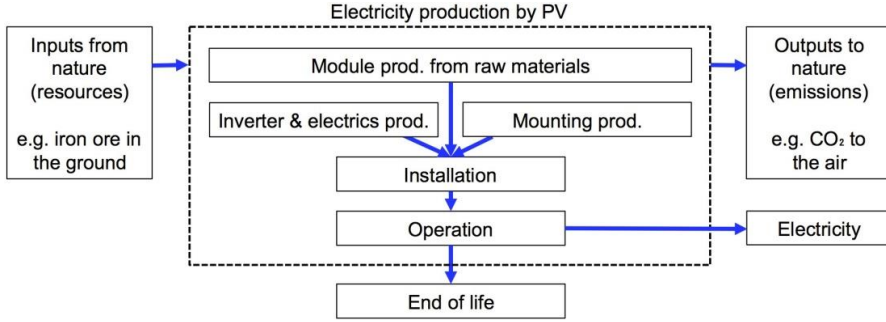
where e is emissions (g_C), a is amount (e.g., kg-iron), and EF is emission factor (e.g., g_C/kg-iron). Amounts ($a_{input\ j\ to\ stage\ i}$) are provided by the PV LCIs or determined by parameters input to SoLCAT. Emission factors (EF_j) are provided by Ecoinvent or SoLCAT inputs. Miller et al. (2018) describes how SoLCAT input variables impact amounts and emission factors.


Figure 1. Life cycle stages of PV electricity production.
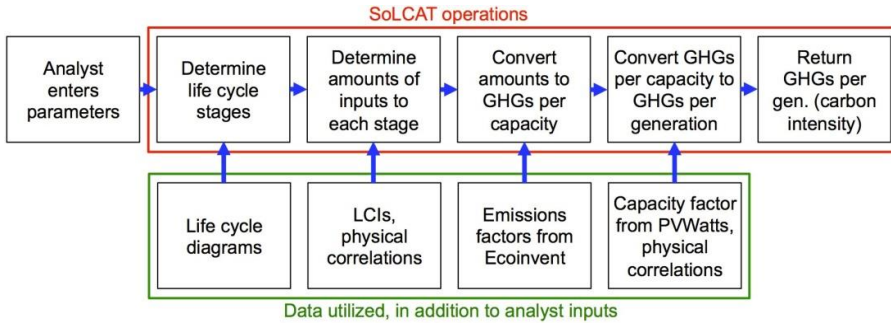

Figure 2. Flowchart of SoLCAT operations and utilization of data sources.

SoLCAT's last operation utilizes capacity factor estimates from PVWatts (Dobos 2014). As detailed in Miller et. al (2018), our model adjusts capacity factors from PVWatts to account for shading, snow, degradation, and tracker energy consumption, to calculate a lifetime average capacity factor (F). Carbon intensity is then calculated as:

$$I = e_{total} / (Fc_g t_{hr}) \qquad (4)$$

where I is carbon intensity (g_C/kWh), e_{total} is life cycle GHG emissions (g_C), c_g is rated power capacity, and t_{hr} is PV system lifetime (h).

Analysis of solar tracking's impact on carbon intensity requires calculation of tracking energy gain (TEG). TEG is the percent increase in PV power output that results from tracking the sun, relative to a fixed-position system, and can be estimated as

$$TEG = (\bar{P}_{AC, track} - \bar{P}_{AC, fixed}) / \bar{P}_{AC, fixed} \times 100 \, \% \qquad (5)$$

where $P_{AC, track}$ is the AC power output of a PV system with tracking, and $P_{AC, fixed}$ is the output of a PV system with fixed orientation and otherwise identical features (location, modules, etc.). The fixed base case orientation is assumed here to be irradiance-maximizing, with equator-facing azimuth and near-latitude tilt. The tracking system is horizontal 1-axis tracking with $\pm 45\,°$ rotation limits.

3. Results and discussion

Using SoLCAT, base case results are calculated and shown in Figure 3:
Figure 3. Carbon intensities of PV power installed in different locations circa 2015. Installation type is large-scale, open-ground, fixed-tilt. Lifetime is 30 years. Rated efficiencies are 17, 16, and 15.6 % for sc-Si, mc-Si, and CdTe. Degradation is 0.7 %/yr. GHG emissions of upstream electricity are 660 & 510 g_C/kWh for module and BOS production, assuming 2015 China & world averages.

We find that in the US southwest, for mc-Si PV, horizontal 1-axis tracking reduces carbon intensity by 12 % relative to the fixed-tilt base case (from 34 to 30 g_C/kWh), consistent with previous results (Leccisi, Raugei, and Fthenakis 2016). Tracking produces this reduction despite requiring ~50 % more structural metal and ~30 % more copper cable per module, compared to fixed mounting (Sinha et al. 2013). Emissions from producing tracker materials are offset by increased generation from tracking, such that overall emissions per generation decreases.

Analogous calculations are conducted for PV systems in 4 other locations and presented in Figure 4, which underlines several related findings. (1) location influences the emissions impact of tracking, via TEG; (2) tracking decreases the carbon intensity of mc-Si PV in most locations; (3) consistent with Sinha et al. (2013), tracking reduces the carbon intensity of CdTe PV in the US southwest by ~3 %; and (4) the US southwest is exceptional: for most locations analyzed, tracking increases the carbon intensity of CdTe PV power.

The dependence on location is driven by latitude and cloud cover. The greater the latitude, the greater the module incline that maximizes incident irradiance, and the more irradiance is lost by "reclining" to horizontal for 1-axis tracking. Greater latitude also means more atmosphere for sunlight to travel through. This increases light scattering, as does greater cloud cover. The greater the fraction of ambient light that is scattered (i.e., diffuse), the less energy there is to be gained from tracking the sun's non-diffuse direct beam irradiance. Lower tracking energy gain (TEG) means less extra electricity over which to amortize extra emissions from tracker-production. For both module types, this explains why, as TEG decreases left to right in Figure 4, tracking's emissions impact increases.
Figure 4. Relative impact of horizontal 1-axis tracking on PV carbon intensity in different locations, for mc-Si PV and CdTe PV.

The varying impact by module type can be explained with the following equations. Let:

$T \equiv$ factor by which tracking increases electricity generation.

$e_{f,i} \equiv$ emissions of fixed PV system (g_C). i = mc-Si or CdTe

$e_t \equiv$ emissions from adding tracking (g_C)

$E_f \equiv$ generation from fixed PV system (kWh)

$E_t \equiv$ generation from tracking PV system (kWh)

$I_f \equiv$ emissions per generation (carbon intensity) of fixed PV system (g_C/kWh)

$I_t \equiv$ emissions per generation (carbon intensity) of tracking PV system (g_C/kWh)

$M \equiv$ factor by which tracking changes carbon intensity

$$M = I_t / I_f$$
$$= [(e_{f,i} + e_t)/E_t]/[e_{f,i}/E_f] = [(e_{f,i} + e_t)/(TE_f)]/[e_{f,i}/E_f]$$
$$M = (e_{f,i} + e_t)/(Te_{f,i}) \tag{6}$$

Consider Eq. (6) when $e_{f,i} \gg e_t$, i.e., when emissions from module production are much larger than emissions from tracker production:

$$M_{f\ large} = 1/T \tag{7}$$

$M_{f\ large}$ will always be less than 1, because T always exceeds 1. In other words, for a module type with large production emissions, adding tracking always reduces carbon intensity. This explains why adding tracking reduces the carbon intensity of mc-Si PV in most locations (blue bars in Figure 4). Multi-Si module production is significantly more carbon intensive than CdTe module production, as seen in Figure 3 and previously reported (Frischknecht et al. 2015). $e_{f,multi-Si}$ is approximately 11 x e_t whereas $e_{f,CdTe}$ is approximately 5 x e_t. Eq. (6) thus also explains why adding tracking increases CdTe PV's carbon intensity in most locations (red bars in Figure 4):

$$M_{CdTe} \approx (e_{f,CdTe} + e_{f,CdTe}/5)/(Te_{f,CdTe}) = 1.2/T \tag{8}$$

For M_{CdTe} to be less than 1, T must exceed 1.2. In other words, CdTe PV requires TEG above 20 % for tracking to reduce its carbon intensity, a TEG only possible in exceptionally sunny regions like the US southwest.

4. Conclusion

A modeling tool (SoLCAT) is presented. SoLCAT estimates GHG emissions from solar PV generation under a broad range of conditions, partly by combining life cycle inventories and PV performance models. Using this tool, we find that solar tracking decreases the GHG emissions of power from multi-crystalline silicon PV in most regions analyzed (by 0 to ~12 %, or 0 to ~4 gCO$_2$e/kWh), and increases the emissions of power from cadmium telluride PV in most regions analyzed (by 0 to ~12 %, or 0 to ~4 gCO$_2$e/kWh). For any PV cell type and any emitted pollutant, if the ratio of module production emissions to tracker production emissions increases in future, independent of absolute emission values, tracking will more commonly decrease PV emissions intensity.

Abstract

In this work, the microscale (bio)process development based on scale-up/numbering-up concept in combination with model-based optimization is presented. The main features of microscale systems are reflected in fluid dynamics, therefore the understanding of fundamental mechanisms involved in fluid flow characteristics at the micro scale is essential since their behaviour affects the transport phenomena and microfluidic applications. Theoretical description of transport phenomena and the kinetics at the micro scale is discussed and illustrated on the cases of a lattice Boltzmann simulations for flow distribution in the packed bed microreactor "between two-plates" and the biocatalytic enzyme surface reaction.

Keywords: process intensification, miniaturization, model-based design

1. Introduction

Process intensification has been considered important for the future of (bio)chemical engineering for a while now. Stankiewicz and Moulijn (2000) defined process intensification as the development of novel and sustainable equipment that compared to the existing state-of-the-art, produces dramatic process improvements related to equipment sizes, waste production, and other factors. The application of microreactor technology in (bio)chemical processes meets these criteria, with the most obvious one being the equipment size reduction. However, besides spatial benefits, microreactors also provide enhanced heat and mass transfer, safety, environmental impact, and others (Pohar and Plazl, 2009). A key advantage that this technology brings is the precise process control that comes with it. This allows for repeatable conditions within the reactor system which leads to improved yields and product quality at a more consistent rate compared to the batch procedures. With the listed advantages there is no doubt that process intensification through the application of microreactor technology holds the potential to revolutionize (bio)chemical synthesis, but specific suggestions for possible replacement of established industrial processes are scarcely encountered. A number of highly innovative and systematic approaches, protocols, tools, and strategies are however currently being developed in both — industry and academia, all to minimize the gap between research and industry, and to enable a smooth transfer of lab-on-a-chip to the industrial scale. To deal with these challenges it is necessary to advance the field from (bio)catalyst discovery to (bio)catalytic microprocess design. Not only will this require a new level of understanding of the underlying reaction mechanisms and transport phenomena at the microscale, but also the

development of relevant computational tools. The quest for high-performance manufacturing technology places the combination of biocatalysis and microscale technology as a key green engineering method for process development and production (Wohlgemuth et al., 2015). The aim of this work is to present the microscale (bio)process development based on scale-up/numbering-up concept in combination with model-based optimization. As microscale systems are flow-based it is essential to understand the fundamental mechanisms involved in fluid flow characteristics at the micro scale, because they affect the transport phenomena and microfluidic applications. Theoretical description of transport phenomena and the kinetics at the micro scale is discussed and illustrated on the cases of lattice Boltzmann simulations for flow distribution in packed bed microreactors "between-two-plates" and the biocatalytic enzyme surface reaction.

2. Model-based design

2.1. Macrosopic models

A theoretical description of transport phenomena and kinetics for different chemical and biochemical processes in the microfluidic devices have to be developed using the bases of continuum theory. The following set of partial differential equations regarding momentum and mass conservation (Eqs. 1, 2), heat conservation (Eq. 3), and species conservation (Eq. 4) have to be solved to describe the convection-diffusion dynamics in all three spatial directions and to depict the governing transport characteristics of processes in microfluidics:

$$\frac{\partial \vec{v}}{\partial t} + \vec{v} \cdot \nabla \vec{v} + \nabla p_k - \nu \nabla^2 \vec{v} = 0 \tag{1}$$

$$\nabla \cdot \vec{v} = 0 \tag{2}$$

$$\frac{\partial}{\partial t}(\rho h) + \nabla \cdot (\rho h \vec{v}) - \nabla \cdot [\lambda \nabla T] - S_h = 0 \tag{3}$$

$$\frac{\partial c_i}{\partial t} + \vec{v} \cdot \nabla c_i - D_i \nabla^2 c_i = 0 \tag{4}$$

where $\vec{v}$ is the velocity vector (m s^{-1}), p_k is the kinematic pressure (m^2 s^{-1}) and ν is the kinematic viscosity (m^2 s^{-1}) — Eqs. 1, 2; ρh is the thermal energy (W m^{-3}), λ is the thermal conductivity (W m^{-2} K^{-1}), T is the temperature (K) and S_h is the volumetric heat source (W m^{-3}) — Eq. 3; c_i is the concentration of the solute i, D_i is the diffusion coefficient of the species i (W m^{-2}) and $\vec{v}$ is the velocity vector obtained from Eqs. 1 and 2 — Eq. 4.

2.2. Mesoscopic models

Lattice Boltzmann methods are computational methods, that were primarily developed to solve fluid-dynamic problems, but can also be used among other to simulate heat and mass transport (Succi, 2015). The core of the method is the lattice Boltzmann equation, which is a special form of the Boltzmann equation, discretized in both — space and time. This gives the methods a base in the statistical mechanics and therefore steers them away

from the "traditional" continuum-based methods, which are usually applied in chemical engineering process simulation. The lattice Boltzmann equation reads as follows:

$$f_a(\vec{x}+\vec{e}_a\Delta t, t+\Delta t) - f_a(\vec{x},t) = \Omega_a(\vec{u}, \rho, \tau) \tag{5}$$

f is a discrete distribution function, which represents a packet of particles with statistically the same momentum in direction a, which is represented by a set of basic lattice velocities $\vec{e}$. $\vec{x}$ is the positional vector and t is time. Ω is the collision operator, and it can take on different forms, but they essentially all depend on the local flow velocity and fluid density $\vec{u}$, and ρ respectively. τ is the relaxation time, which is directly related to species' physical properties such as kinematic viscosity or molecular diffusivity.

2.3. Model verification and validation

Microfluidic devices have justified the high expectations and successfully demonstrated their advantages for intensification of chemical and biochemical processes in many different research areas and fields. Schematic representation of some typical microfluidic devices, known as enzymatic microreactors is given in Figure 1 (a-g). On these schemes of different microfluidic systems, one can observe the most typical enzyme (or cell) immobilization techniques as well as the most typical flow patterns of two-phase flows: the parallel and droplet flow regime, which allow for efficient performance of various processes from chemical reaction, enzyme catalyzed reaction with immobilized enzyme or cells to separation, extraction, and purification. In order to transfer these systems, successfully developed and tested on the laboratory scale, to the industrial environment and to increase the productivity from microliter scale to bigger scales at the same process efficiency and minimized costs, the optimized scale-up/numbering-up concepts have to be implemented, where the model-based design plays a key role. For this purpose, only pre-verified and validated macroscopic and lower-lever mathematical models can be used. Only verified and especially validated models bring about the understanding of basic principles and mechanisms taking place in chemical and biochemical processes at the microscale.

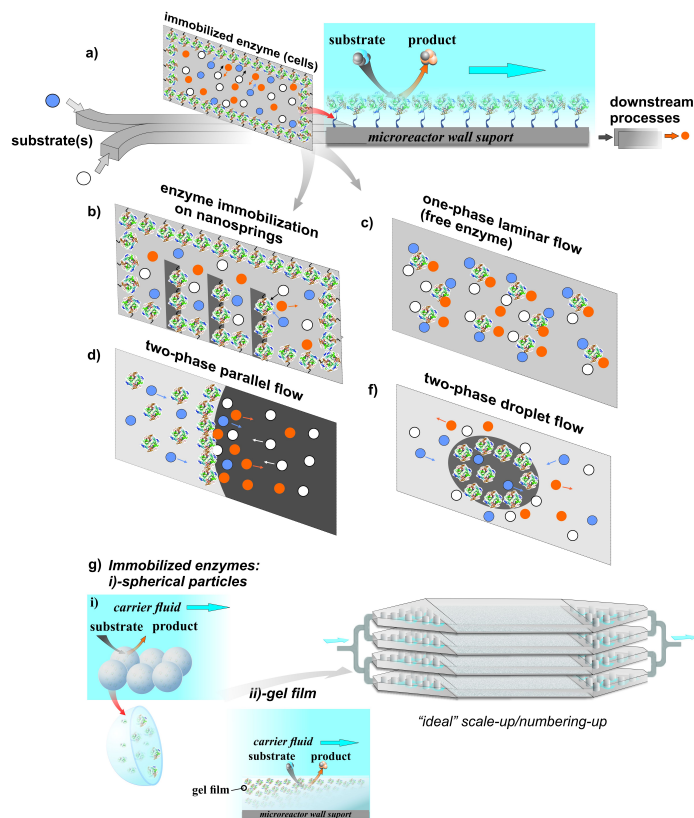
The model equations are usually solved numerically by writing them into computer code. Once the code is complete and error free, the model needs to be verified. In this process the model is tested whether it gives sensible results, which do not necessarily need to be correct (Plazl and Lakner, 2010). The correctness of the model's predictions is put to the test during model validation. Models can be validated either by comparing them to other already valid models or by testing them against experimental observations. Validating via experimental methods can be done in different ways, such as *e. g.* online validation, and inline validation. Common to all is that theoretical predictions and simulations matched to experimental measurements without any fitting procedures. In our previous work, we showed that macroscopic mathematical models can reliably describe various complex processes in microfluidic devices. In the case of non-homogeneous system with parallel flow pattern the steroid extraction in a microchannel system was studied theoretically and experimentally. In order to analyze experimental data and to forecast microreactor performance, a three-dimensional mathematical model with convection and diffusion terms was developed considering the velocity profile for laminar flow of two parallel phases in


Figure 1: Schematic representation of some typical homogeneous, non-homogeneous and heterogeneous microfluidics systems: a) immobilized biocatalyst on the inner walls of microreactor with integrated down-stream processes; b) immobilized biocatalyst on the inner surface and pillars to increase surface area and biocatalyst loading; c) free enzyme in a one-phase laminar flow; d) free enzyme in a two-phase parallel flow; f) free enzyme in a droplet flow; g) packed-bed microreactor with immobilized enzymes in a spherical particles (i) and gel film (ii) with scale-up in one dimension and numbering-up of microreactor systems "between two-plates".

a microchannel at steady-state conditions. Very good agreement between model calculations and experimental data was achieved without any fitting procedure (Žnidaršič Plazl and Plazl, 2007).

Online oxygen measurements inside a microreactor with modelling of transport phenomena and enzyme catalyzed oxidation reaction was performed for online model validation of the homogeneous system with biochemical reaction. Continuum based mathematical models, with a full 3D description of transport phenomena, incorporating convection, diffusion and enzymatic reaction terms along with the parabolic velocity profile in a microchannel was developed to simulate the concentration of dissolved oxygen inside

the microchannels, to assess the required model complexity for achieving precise results and to depict the governing transport characteristics at the microscale (Ungerböck et al., 2013). Droplet-based liquid-liquid extraction in a microchannel was studied, both theoretically and experimentally to online validate macroscopic models for complex two-phase droplet flow microfluidics. The finite elements method, as the most common macroscale simulation technique, was used to solve the set of partial differential equations regarding conservation of moment, mass and solute concentration in a two-domain system coupled by interfacial surface of droplet-based flow pattern (Eqs. 1, 2, 4). The model was numerically verified and validated online by following the concentrations of a solute in two phases within the microchannel by means of a thermal lens microscopic (TLM) technique coupled to a microfluidic system, which gave results of high spatial and temporal resolution. Very good agreement between model calculations and online experimental data was achieved without applying any fitting procedure to the model parameters (Lubej et al., 2015).
Figure 2: A snapshot of the pulse test simulation. Domain size = $2048 \times 256 \times 32$ lattice units^3, Reynolds number = 0.95, Schmidt number = 1000. The flow is from west to east.

(a) Narrower, empty inlet.   (b) Narrower, filled inlet.   (c) Narrower, pillars.

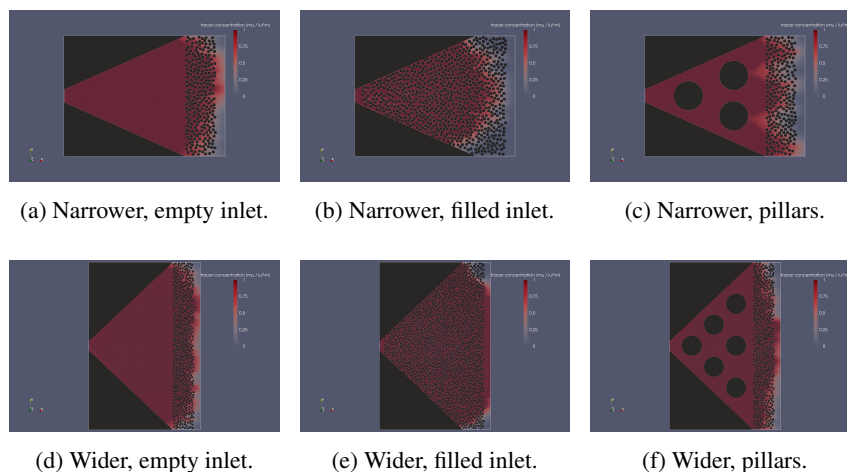
(d) Wider, empty inlet.   (e) Wider, filled inlet.   (f) Wider, pillars.


Figure 3: Different scenarios for inlet flow distribution in one-dimensional scale-up. "Empty" channels do not utilize any obstacles to distribute the flow, "filled" channels use the same particles in the flow distribution zone as they do throughout the rest of the channel, and "pillars" channels have pillars in the flow distribution zone. The tracer is colored red, and flows from west to east.

The lattice Boltzmann method was applied to obtain the velocity field in a packed bed

microbioreactor, and to simulate mass transport in a pulse test through it. First a computer program generated a randomly packed bed, then the flow field was calculated, and finally the mass transport of an inert tracer was simulated (Figure 2). The results were recorded and compared to experimentally collected data. In the experiments the channel was packed with enzyme-containing particles, and an inert tracer was injected through it via an HPLC-type 6-port valve. At the outlet an inline biosensor was recording the tracer concentration. The simulations and the experiments show a good agreement (Strniša et al., 2018).

A validated lattice Boltzmann model could then be further used to simulate mass transport in a "near-perfect" scaled-up microchannel, where only one dimension of the channel is increased — its width (Bajić et al., 2017). Similar simulations as above were constructed, where 3 scenarios were tested: empty space at inlet, inlet filled with biocatalytic particles, and pillars in the inlet. Unlike previously the inert tracer was supplied into the system continuously. The results (Figure 3) show that filling the inlet with particles does not create uniform flow conditions downstream, where as leaving the space empty or introducing pillars in it improves the downstream hydrodynamics. Similar simulations should be used further to determine the optimal inlet geometry, which will assure the optimal flow conditions in the microchannel.

3. Conclusions

Several studies have shown the advantages of microfluidic systems. Here it was shown how computer modelling and simulation can (or rather should) work within the research and development of such systems to optimize their performance. We now have the knowledge and technologies for building them, and the (bio)chemical industries need to recognize the potential of process intensification and miniaturization, with the consideration of new modelling approaches, such as multiscale modelling.

Abstract

This work proposes the use of graph partitioning tools to identify clusters in a possible large space of plausible product formulations, with each cluster representing a significantly different design alternative that deserve to be tested. The partitioning tools are used to find clusters in a large set of previously generated alternatives, and are also incorporated into a mixed-integer programming problem whose solution generates clustered alternatives (within a feasible space defined by available models and heuristics). An example of a cosmetic emulsion is provided.

Keywords: product design, formulated products, graph partitioning, cluster analysis

1. Introduction

Computer-aided design of formulated products, moreover of those having characteristic microstructural attributes, is hindered by the lack of quantitative reliable property models. It is then important to develop tools able to handle qualitative knowledge (Zhang *et al*., 2017), including lists of often used ingredients, databases of known successful formulations, and a variety of heuristic rules regarding typical combinations of ingredients, amounts used, known effects, synergies and antagonisms. We have recently proposed a method to generate alternative product formulations, based on mixed-integer programming and using propositional logic to model heuristic rules as algebraic restrictions (Arrieta-Escobar *et al*., 2017, 2018). The list of plausible alternatives thus generated may be long, due to acknowledged uncertainty in the assumed models and heuristics, and therefore it may not be clear what smaller subset of alternatives really deserves to be manufactured and tested.

Here, we propose the use of graph partitioning tools to identify clusters of formulations within a given space of feasible alternatives. Formulations belonging to a given cluster have a certain similarity between them and should be as dissimilar as possible to formulations belonging to other clusters. Therefore, an exploratory design of experiments should include at least one instance from each cluster. As a first contribution to this problem, the only clustering criterion here adopted is the qualitative composition of the formulation, such that similarity between formulations is defined by the number of shared components. Two subproblems are addressed: (i) to find clusters in a given, possibly large, set of alternative formulations (previously generated using e.g. integer programming and/or constructed from databases of product formulations); (ii) to simultaneously generate and cluster alternative formulations obeying to a given set of property models and heuristic constraints.

2. Matrix and graph representations of a set of product formulations

Given a set of available components, $C = \{c_1, \ldots, c_{NC}\}$, a product formulation is defined by a vector yV of binary variables, with dimension NC, indicating which components are present in the formulation, and a corresponding vector xV of mass fractions.

Solely in terms of qualitative composition (i.e., regardless of xV values), a set of NF alternative formulations, $F = \{f_1, \ldots, f_{NF}\}$, may be represented by a list of vectors yV organized in a matrix $Y = (y_{fc})_{NF \times NC}$, with $y_{fc} = 1$ if component c is present in formulation f, for all $c \in C, f \in F$. An equivalent representation is that of a bipartite graph $G = (C, F, E)$, with vertex sets C and F, and edge set E. Edge $f - c$ exists if and only if the corresponding matrix entry $y_{fc} = 1$. Figure 1 illustrates both matrix and graph representations.
Figure 1. Matrix and graph representations of 7 product formulations (f1 to f7), each one having a subset of 18 possible components (c1 to c18). A partition in three clusters is shown: in the matrix, clusters correspond to diagonal blocks; in the graph, clusters are delimited by dashed lines.

3. Clustering of alternative product formulations

Given a set of product formulations F represented by a 0-1 matrix Y as above defined, the problem of partitioning F in NP clusters may be stated as: "find row and column permutations of Y in order to obtain NP diagonal blocks and minimizing the number of external elements "1" outside the diagonal blocks". Figure 1 (left) represents a possible solution to this problem with 3 clusters corresponding to 3 diagonal blocks and 5 external elements. Cluster P1, for instance, has formulations f1, f2 and f3, and components c1 to c8. Each external element represents a component from one cluster that is used in a formulation belonging to a different cluster, and therefore the number of external elements is a measure of similarity between clusters that should be minimized.

The same clustering is shown on graph format (Figure 1, right). The external elements of matrix Y here correspond to external edges, which are those connecting vertices located in different clusters. External edges are also designated by cut edges, since their removal decomposes the graph into NP disconnected subgraphs. For this reason, the set of external edges is designated by edge separator.

Using graph language, our problem of partitioning F in NP clusters is thus a problem of graph partitioning by edge separator (known in the graph literature as GPES): "given a set of product formulations F and its graph representation $G = (C, F, E)$, divide the graph into NP subgraphs (also designated by partitions or clusters) minimizing the number of external edges".

Graph partitioning is a better studied problem than sparse matrix rearrangement. In addition, the latter is often solved first translating the matrix into an equivalent graph and then applying graph partitioning methods (Aykanat *et al.*, 2004). Graph partitioning is thus the basic clustering technique here used, although the representation in the matrix form is preferred for its simplicity.

The graph partitioning problem is an NP-complete combinatorial optimization problem, well studied in multiple contexts (e.g. parallel computing, sparse matrix computations, VLSI design, biological and social networks, data mining). Exact solutions using, for instance, integer programming are in practice limited to relatively small graphs with some hundreds of vertices. For larger graphs, several heuristic algorithms are available with different performances in terms of computational time/quality of solutions (Fjallstrom, 1998). Here, we use integer programming to generate and simultaneously cluster a small set F of alternative formulations (section 4), and a heuristic algorithm to find clusters in large given sets. In particular, we use the multilevel algorithm of the publicly available tool hMeTiS (Karypis and Kumar, 1998). In its simpler form, hMeTiS only requires two inputs: the number of partitions NP and the allowed difference in the cardinality of different partitions (in Karypis Lab, MeTiS is the standard tool for large graphs partitioning, but if the focus is on solution quality rather than on computational efficiency then hMeTiS in advised; hMeTiS is a tool to partition hypergraphs, which are generalization of graphs, and thus may also be applied to our relatively simple graphs G).

4. Simultaneous generation and clustering of alternative formulations

Here, we present a new optimization formulation that extends the one presented in Arrieta-Escobar *et al.* (2017, 2018), in order to solve the following problem: "find the NF most dissimilar formulations of NC components (dissimilarity in qualitative composition defined by yV), obeying to a set of product design constraints (e.g., composition, performance and cost)". Using a graph representation, what is here being equated is how to connect two given sets of vertices (components C and formulations F) in order to obtain well defined clusters of components c around each formulation f. In other words, this is a graph partitioning problem with edges $f - c$ still to be decided and with each cluster having one and only one formulation ($NP = NF$). Further, the decision about the edges is subject to the condition that the set of edges connected to each f must define a feasible product formulation (according to the available product models).

The standard 0-1 formulation for graph partitioning is adopted (Boulle, 2004), with two sets of binary variables: $y_{fc} = 1$ if component c is chosen to be in formulation f, and $v_{fc} = 1$ if component c is located in cluster f (but not necessarily belongs to formulation f). Then, edge $f - c$ exists if and only if $e_{fc} = y_{fc}. v_{fc} = 1$. The goal is to minimize the number of external edges (NEE) equal to the total number of edges (NE) minus the number of internal edges (NIE):

$$\min_{y_{fc}, x_{fc}, v_{fc}} NEE = \sum_{f,c} y_{fc} - \sum_{f,c} e_{fc} \tag{1.1}$$

$$s.t. \quad e_{fc} \leq a_{fc}, e_{fc} \leq v_{fc}, e_{fc} \geq a_{fc} + v_{fc} - 1, \forall f, c \tag{1.2}$$

$$\sum_f y_{fc} = 1, \forall f, c \tag{1.3}$$

$$v_{fc} = 0, \forall c, ord(f) = ord(c) + 1, \dots, NF \tag{1.4}$$

$$g(yV_f, xV_f, p_f) \leq 0, yV_f = \{y_{fc}, \forall c\}, xV_f = \{x_{fc}, \forall c\}, , \forall f \tag{1.5}$$

$$y_{fc}, v_{fc} \in \{0,1\}, 0 \le e_{fc} \le 1, 0 \le x_{fc} \le 1 \qquad (1.6)$$

Restrictions (1.2) are a linear formulation of $e_{fc} = y_{fc} \cdot v_{fc} = 1$; equations (1.3) impose that each component belongs to only one cluster; equations (1.4) are anti-degeneracy constraints (c_1 must belong to cluster f_1, c_2 must belong either to f_1 or to f_2, and in general c_k must belong to one of the first kth clusters); restrictions (1.5) represent the available product models, relating the composition of formulation f (vectors yV_f and xV_f) with performance metrics p_f (cost included) and imposing desired limits to these metrics. Although variables $e_{fc} \in \{0,1\}$, they may be treated as continuous due to restrictions (1.2). The decision variables are the composition of all NF formulations (y_{fc}, x_{fc}) plus the assignment of components to clusters (v_{fc}). The total number of binary variables (y_{fc} and v_{fc}) is $2NF.NC$.

For a graph with NE edges, NEE is an absolute measure of the partitioning quality. When comparing solutions for graphs of different dimensions, the fraction of external edges should be used instead: $FEE = NEE/NE$.
Figure 2. Set of 50 alternative formulations, before (left) and after (right) clustering. Order of components before clustering: {i3, i4, i5, i9, j2, j6, j7, j8, k3, k5, m1, m2, m3, r2, r3}. Order of components after clustering: {i4, k5, m3, j2, j7, j8, k3, m1, r2, r3, i3, i5, i9, j6, m2}. Clustering metrics: $NE = 375$, $NEE = 174$, $FEE = NE/NEE = 0.46$.

5. Example of a cosmetic emulsion

Here, the above proposed tools are applied to the example of Arrieta-Escobar *et al.* (2017, 2018). This is the formulation of a hair conditioner (which is an o/w emulsion), from an initial list of 32 possible ingredients organized in 6 subsets: emollients of type i ($i1$ to $i9$),

emollients of type j ($j1$ to $j8$), emollients of type k ($k1$ to $k7$), fatty alcohols ($m1, m2$), thickening polymers ($n1, n2, n3$) and cationic surfactants ($r1, r2, r3$). Known heuristic rules (regarding amounts and combinations of ingredients), together with models for product viscosity and greasiness index, define a space of feasible formulations of the type $g(yV, xV) \leq 0$. All optimization problems here formulated are MILP problems and were solved using GAMS/CPLEX.

Through successive solution of the problem "min $Cost, s.t. g(yV, xV) \leq 0$", and using binary cuts to prohibit previous solutions, a rank of 50 formulations with increasing cost (only of raw-materials) is generated. These formulations (Figure 2, left) use 15 different components and have a cost between 0.884 and 0.952 USD/kg. They are then clustered using hMeTiS and with the additional constraint of a minimum of 3 components by cluster. As shown in Figure 2 (right), the result for $NP=3$ is poor, with FEE being quite large (0.46). For larger values of NP, the partitioning quality is even worse. One then concludes that, within this set F of 50 formulations, significantly different subsets of alternatives cannot be identified, which means that F is not diverse enough to there identify a reduced number of exploratory experiments.

Next, the most dissimilar NF formulations obeying to $g(yV, xV) \leq 0$ and also subject to an upper limit on cost ($Cost_f \leq Cmax, \forall f$) are generated by solving the optimization problem (1.1)-(1.6). Figure 3 and Table 1 shows results for different input values of NF and $Cmax$. Set $F1$ contains the three most dissimilar formulations within the considered design space, with only 5 external edges (corresponding to shared components $m2$, $r2$ and $r3$) of a total of 19, and thus a value of $FEE=5/19=0.26$.
Figure 3. Sets of dissimilar formulations generated solving the optimization problem of section 4. The order of components (columns of the matrices) is shown on Table 1.

Table 1. Data regarding the sets of formulations represented in Figure 3 ($Cmax$ is in USD/kg).

Set	Em	$Cmax$	FEE	Components
$F1$	3	1.1	0.26	{i5, j2, k3, m1, i4, j6, j7, k2, m2, r2, i9, j8, k5, r3}
$F2$	5	1.1	0.47	{i9, k5, m2, i3, j6, k6, i5, j2, k3, i4, i7, j7, j8, k2, m1, r2, r3}
$F3$	5	1.3	0.36	{i2, j2, k5, i3, j1, j7, k6, i4, j5, j8, k4, m2, i9, j6, k2, m1, i5, j4, k3, r2, r3}

Table 2. Data regarding set $F3$. Cost is $Cmax$=1.3 USD/kg for all formulations.

Formulation	Emollients	Emollients mass percentage
f_1	i2, j2, k5	1.3, 2.8, 1.9; Total = 6.0%
f_2	i3, j1, j7, k6	2.0, 1.5, 1.5, 1.0; Total = 6.0%
f_3	i4, j5, j8, k4	1.1, 1.0, 2.9, 1.0; Total = 6.0%
f_4	i9, j6, k2	1.9, 2.7, 1.5; Total = 6.1%
f_5	i5, j4, k3	2.3, 1.7, 1.0; Total = 6.0%

Keeping $Cmax$ at the same level and increasing NF to 5, one obtains set $F2$ that uses more components but has less dissimilar formulations (FEE=0.47). Relaxing $Cmax$ to 1.3 USD/kg, the more diverse set $F3$ is obtained, with FEE decreasing to 0.36. Additional data regarding set $F3$ is given in Table 2. For other input values of NF and $Cmax$, the same tendency is observed: a more diverse set of alternatives (low value of FEE) come at the price of more expensive formulations.

6. Conclusions

The proposed graph representation and graph partitioning tools are able to identify significantly different alternatives within a space of plausible product formulations (possible large due to uncertain models and heuristics) and thus may be very useful to design an exploratory set of experiments or to build different product lines from a given set of ingredients. Several extensions and refinements of the proposed tools are still to be done, namely the use of additional clustering criteria apart from qualitative composition of the formulation, which was the only one here considered.

Abstract

Current graph-based approaches for modeling, simulation and optimization of complex cyber-physical systems have motivated the development of new graph-based abstractions. We propose an algebraic graph to represent physical connectivity in complex optimization models and a computing graph to capture computational aspects of cyber/control architectures. The algebraic graph facilitates the analysis and decomposition of optimization problems and the computing graph enables the simulation of optimization and control algorithms in virtual distributed environments. The proposed abstractions are implemented in a `Julia` software package called `Plasmo.jl`.

Keywords: cyber-physical, structured modeling, complex systems, decomposition

1. Introduction

Modeling and simulating cyber-physical systems is becoming increasingly important, but capturing interdependencies between cyber and physical systems in a coherent manner is technically challenging. Physical systems (such as chemical processes) can be driven by control systems, which in turn are cyber systems comprised of computing devices (e.g. sensors, controllers, actuators) that execute tasks (e.g., data processing, control action computation) and that exchange information (e.g., measurements and control actions) through a communication network. Physical systems are expressed mathematically in the form of *algebraic models* while cyber systems are expressed in the form of *algorithms* which are often executed under heterogeneous computing architectures that exhibit complex communication protocols.

This work discusses newly proposed *graph-based* abstractions that facilitate modeling and simulation of cyber-physical systems. Graph-based modeling approaches have appeared in various engineering applications. Preisig (2007) used graph-theoretic approaches to perform on-line mass and energy balancing in large-scale plants given incomplete sensor data. Couenne et al. (2007) presented bond-graph modeling for chemical engineering applications and highlighted the advantages of model encapsulation and re-use. Elve and Preisig (2018) recently applied graph-based concepts to develop a process simulator with automatic code generation capabilities.

In this work we analyze the concept of an *algebraic model graph* that facilitates the im-

plementation and solution of physical systems and the concept of a *computing graph* that facilitates simulation of cyber systems. The graph abstractions exploit *physical and communication topology* to facilitate model construction, data management, and analysis. Both abstractions are implemented in the `Julia` package `Plasmo.jl` (`https://github.com/zavalab/Plasmo.jl`).

2. Algebraic Graphs

Here we present a **model graph** abstraction to represent complex optimization models found in physical applications. A model graph $\mathscr{MG}(\mathscr{N}, \mathscr{E})$ is a *hypergraph* wherein each node $n \in \mathscr{N}(\mathscr{MG})$ has an associated component optimization model of the form:

$$\min_{x_n \in \mathscr{X}_n} \quad f_n(x_n). \tag{1}$$

where x_n are decision variables, $\mathscr{X}_n := \{x \mid c_n(x) \geq 0\}$ is the feasible set with associated constraint vector mapping $c_n(\cdot)$, and the mapping $f_n(\cdot)$ is a scalar objective function.

Coupling is captured between component models using *link constraints*. In particular, we consider linear linking constraints of the form:

$$\sum_{n \in \mathscr{N}(e)} \Pi_{e,n} x_n = 0 \quad e \in \mathscr{E}(\mathscr{MG}). \tag{2}$$

where $e \in \mathscr{E}(\mathscr{MG})$ are the hyperedges of the model graph and $n \in \mathscr{N}(e)$ is the set of nodes that support hyperedge e. The matrix $\Pi_{e,n}$ corresponds to the coefficients of the linking constraints between edge e and node n.

We can represent hierarchical optimization structures using subgraphs as shown in Figure 1. A model graph can contain an arbitrary number of subgraphs by defining $\mathscr{SG}(\mathscr{MG}_0)$ (with elements $\mathscr{SG}$) as the set of subgraphs defined on the parent model graph $\mathscr{MG}_0$. This allows us to express the model graph in the form of Equation 3.

$$\min_{x_{\mathscr{MG}_0}} \sum_{n \in \mathscr{N}(\mathscr{MG}_0)} f_n(x_n) \qquad \text{(Graph objective function)} \tag{3a}$$

$$\text{s.t.} \quad x_n \in \mathscr{X}_n, \quad n \in \mathscr{N}(\mathscr{MG}_0) \qquad \text{(Local node constraints)} \tag{3b}$$

$$\Pi_{\mathscr{MG}_0} x_{\mathscr{MG}_0} = 0 \qquad \text{(Graph link constraints)} \tag{3c}$$

$$\Pi_{\mathscr{SG}} x_{\mathscr{SG}} = 0 \quad \mathscr{SG} \in \mathscr{SG}(\mathscr{MG}_0) \qquad \text{(Subgraph link constraints)} \tag{3d}$$

Graph models provide structural information which facilitates decomposition and model management. For example, Formulation (3) has a partially separable structure because eliminating the linking constraints (3c and 3d) results in a fully separable problem. These problems can be solved using Schur decomposition schemes such as done in Chiang et al. (2014). It is also possible to aggregate the nodes in a model graph and into a traditional optimization form which can be solved with an off-the-shelf solver such as Ipopt (Wächter and Biegler (2006)). The graph structure also allows one to produce decompositions using graph analysis techniques such as partitioning and community detection (Tang et al. (2017)).
Figure 1: A model graph with two subgraphs. $\mathcal{MG}_1$ contains three nodes (n_1, n_2, n_3) and one linking constraint (e_1). $\mathcal{MG}_2$ contains three nodes (n_4, n_5, n_6) and two linking constraints $(e_2$ and $e_3)$. $\mathcal{MG}_0$ is the top layer of the graph containing all six nodes and connects the two subgraphs with a single linking constraint between nodes n_3 and n_4 (e_4).

3. Computing Graphs

Simulating a cyber system requires capturing real-time computing aspects such as as latency, failures, and asychronicity. To approach these challenges, we introduce the **computing graph** which is a directed multi-graph that we denote as $\mathscr{CG}(\mathcal{N}, \mathcal{E})$ and that contains a set of nodes $\mathcal{N}(\mathscr{CG})$ which execute tasks and edges $\mathcal{E}(\mathscr{CG})$ which communicate attributes to other nodes.

In a computing graph, A node $n \in \mathcal{N}(\mathscr{CG})$ contains a set of *attributes* $\mathscr{A}_n$ and tasks $\mathscr{T}_n$ and an edge $e \in \mathcal{E}(\mathscr{CG})$ contains a pair of attributes $\mathscr{A}_e$ which it communicates between supporting nodes $\mathcal{N}(e)$. The attributes $\mathscr{A}_n$ represent data and tasks $\mathscr{T}_n$ are computations that operate with and/or change attributes. Tasks require execution time $\Delta\theta_t$ and edges involve communication delay $\Delta\theta_e$. Under the proposed abstraction, computing and communication can be synchronous (a task is not executed until all attributes are received) or asynchronous (a task is executed with current values). This enables capturing a wide range of behaviors seen in cyber-system applications.

A simple computing graph is depicted in Figure 2. Each node contains a single task which operates on its attributes x, y, and z as input and updates one of their values. The nodes communicate attribute values with each other using six edges. For example, attribute y is communicated to both nodes n_2 and n_3 which updates the value of y on these respective nodes. The superscript $+$ means that attributes are updated after a given time which captures computing and communication delays.

The computing graph differs from the model graph abstraction in that it contains a dynamic component (a task) while a node in a model graph contains a static component (a model). Moreover, edges in a computing graph connect attributes while edges connect algebraic variables in a model graph. We highlight that the *solution* of a model graph is a computing task and we can thus use model graphs in individual nodes of the computing graph. This greatly facilitates simulating the behavior of cyber-physical systems.
Figure 2: Depiction of a computing graph with three nodes and six edges. Node n_1 computes $task_{n_1}$ using the data attributes ($x, y,$ and z) and updates the value of attribute y. Similarly, node n_2 computes $task_{n_2}$ and updates attribute x, and node n_3 computes $task_{n_3}$ and updates attribute z. Attribute values are communicated between nodes using edges.

4. Case Study: Evaluating Control Architectures

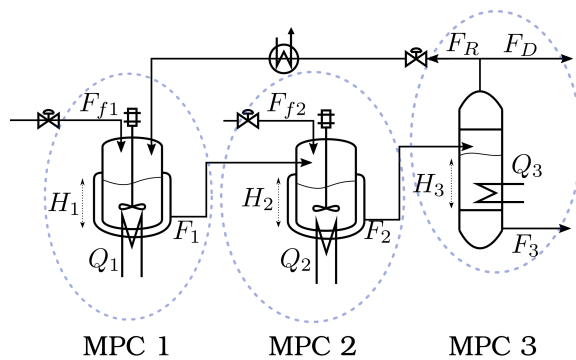
This case study demonstrates how a model graph can be used to formulate and solve an optimal control problem for a dynamic physical system and how solving the model graph can be embedded in a computing graph to evaluate various distributed control architectures subject to real-time latency (i.e., computation and communication times). We consider a reactor-separator system (see Figure 3) from Stewart et al. (2010) which is a standard for evaluating distributed model predictive control.


Figure 3: Reactor separator process. The control can be decomposed into 3 MPC controllers.

We first create a model graph using `Plasmo.jl` for the process in Figure 3 using three nodes. Two nodes contain optimization models to track reactor setpoints, and the other node contains a model to track the separator setpoints. The three nodes are linked together using algebraic *link constraints* which represent the flows that couple the systems together.

The process is simulated using the computing graph for three different control architec-

(a) Centralized   (b) Decentralized   (c) Cooperative
Figure 4: Simulated control architecture topologies. (Left): Centralized control. (Middle): Decentralized Control. (Right): Cooperative Control

tures. We simulate a *centralized* model predictive control (MPC) architecture wherein a central MPC controller calculates all inputs for the process. To do so, we solve the entire model graph as a single MPC node in the computing graph (Figure 4a) and use another computing node to simulate and advance the state of the plant.

We also decompose the process into three MPC controllers and simulate a *decentralized* control architecture wherein controllers do not communicate (Figure 4b) and a *c*ooperative architecture (Figure 4c) such that controllers share state and intended control trajectories. For these cases, the nodes in the computing graph (MPC1,MPC2, and MPC3) compute tasks which solve and update the individual model nodes we defined in the model graph. We highlight that the computing graph captures the *asynchronous* behavior of the decentralized and cooperative schemes. Because we account for real computation times, the controllers inject their inputs when they finish their computation as opposed to all at the same time.
Figure 5: Communication pattern for each simulated MPC architecture

Figure 5 presents communication and computation patterns for each MPC algorithm. The centralized MPC pattern shows the communication delays between the plant and the controller (grey arrows), the time required to compute the control action (the purple bar), and highlights how the plant state advances continuously while computation and communication tasks execute. Despite the delays enforced for the controller, centralized MPC is able to drive the state to the setpoint (as shown in Figure 6). Decentralized MPC does
Figure 6: Temperature evolution for each simulated MPC architecture

not require communication between controllers which decreases computing times, but we observe that the setpoint cannot be reached. Finally, cooperative MPC shows a more complex communication pattern but we observe that this mimics the performance of centralized MPC.

5. Conclusions

We have presented graph-based abstractions that facilitate modeling complex cyber-physical systems. We showed how a model graph abstraction facilitates modeling complex physical systems and how a computing graph enables simulating computational behaviors. We provided a case study using the package `Plasmo.jl` that demonstrates how these abstractions can be used to evaluate distributed computing architectures.

Abstract

The ever increasing complexity of processing systems and the requirements to be satisfied by the processes make process design and process operation more and more complex. Because of that, the reliability/availability is to be taken into account together with other requirements in process design/synthesis. Similarly, failure analysis is also an important part of process operation. In the current work, it has been shown that in addition to the widely used unit level redundancy, process level redundancy must also be considered in synthesizing a process for satisfying high level availability. Therefore, in case of failure, the determination of the best corrective action must be based on more general process networks than considered before. The proposed procedure determines the best or n-best corrective actions for the most general types of highly complex process networks, e.g., including process level redundancy. The P-graph based procedure is effective in generating corrective action suitable for industrial processes.

Keywords: process synthesis, process availability, failure analysis, corrective action.

1. Introduction

Availability, the rate of operability, is an important indicator of a process since it directly influences the profitability. A high level availability can usually be achieved if redundancy is built in the process. If this is the case, the failure of an equipment unit of the process does not necessarily mean that the process becomes non-operational. To keep the process operational in an event of failure of equipment units, a corrective action is to be done. Since a process may have a large number of alternative feasible operating modes with different operating costs, the determination of the corrective action should be systematic and based on optimization if possible.

Corrective actions are, especially, widely used in power distribution networks. Because of the need of an almost immediate action, decisions are usually based on heuristics and genetic algorithms with no guarantee of the optimality. Ela and Spea (2009) applied genetic algorithms to minimize the losses in transmission lines. Korad and Hedman, (2013) developed a hybrid method for taking into account uncertainties in determining the corrective switching action.

Distefano and Puliafito (2007) solved computer system failure problem by two different approaches, one is based on reliability block diagram and the other on fault tree analysis. Though the results were similar for them, the typical issue is that the mathematical model is not generated algorithmically for either method. Goel et al. (2002) simultaneously considered availability and profitability in synthesizing a

chemical process in a mixed integer programming model. The method considers only specific flowsheets, e.g., no redundancy is allowed in the flowsheet of the synthesized process.

Stated formally, if an equipment unit is capable of performing its designated job on a sufficient level, it is called as functional, otherwise, non-functional. Similarly, an operating unit is functional if there are functional equipment units assigned to this operating unit that can perform the transformation identified by the operating unit.

A process is operational if it is capable of generating all products in the required amounts and qualities. An operational process may have several different modes of operations, i.e., the operation can be performed under different process networks. The best of the operating modes is called as on-design operation, all the others are the off-design operations. The mode of operations that is currently working is called as active operating mode. Not necessarily all functional equipment units assigned to the operating units of an active operating mode are in service, consequently, the equipment units of this operating mode can be either active or non-active.

For practical reason, the procedure for determining the corrective action must systematically satisfy the following four criteria:

  (i)   Keep the system operational as far as it is possible;
  (ii) Keep the operating cost of the selected operating mode as low as possible, i.e., it is based on optimization;
  (iii) Robust, i.e., it determines the corrective action for any possible flowsheet;
  (iv) Generates the corrective action promptly.

To fulfil criterion (iii), the types of flowsheets (networks) that can appear in a real process must be determined first. For example, Goel et al (2002) considered redundancy free flowsheets. However, if redundancy is allowed, the most common redundancy is realized on operating unit level, i.e., more than one equipment unit is established for an operating unit. The basic question now is if this operating unit level redundancy covers all possible options or more general types of redundancies are to be considered.

The flowsheet or network of a process is determined during its synthesis. Thus, the types of networks to be considered in making a corrective action depend on the possible flowsheets (networks) that can be the result in synthesizing a process. An example, Example 1, will illustrate that unit level redundancy does not necessarily cover all important cases for optimal decision.

In practice, the network of the most preferred processes are usually complex, highly interconnected involving several loops. There are two types of optimization tools for process design in terms of structure representation, implicit, e.g., mathematical programming approaches and explicit, e.g., the P-graph framework. Methods with explicit structure-representation provide additional opportunities on structural properties of process networks including an appropriate interface to failure analysis and to develop systematic method for determining the optimal corrective action. The P-graph framework (see, e.g., Peters et al, 2003) is formulated by combinatorial mathematics, based on the five axioms of feasible process networks and includes combinatorial algorithms, e.g., for synthesizing processes. There is a close relation between the process feasibility in process synthesis and the process operability in failure analysis, since the axioms are valid for both. Therefore, these two types of requirements can be considered simultaneously without compromising any of them. A P-graph is a directed graph and it represents the process network by two types of vertices, i.e., dots for materials and horizontal bars for operating units. Software implementations of the main algorithms are available at www.p-graph.org.

2. Structural redundancy in a process

A processing system is termed as redundancy-free, if the failure of any of its equipment units makes the system non-operational. Because of the high level of requirements on the availability, in most cases, redundancy free systems are not acceptable, redundant systems are to be designed. The redundancies in the process are determined during its synthesis. The availability of a redundancy-free system is simply the product of the availability indicators of the equipment units. The determination of the availability for systems with redundancies is complex both in theory and applications. Since the availability of a processing system can be determined similarly to its reliability, an available method can be applied for that (Kovacs et al., 2018).

Frequently, designing a process with unit-level redundancy satisfies the system's availability requirement, and has been widely used in practice. However, this doesn't necessarily give rise to the optimal process for simple reasons. The off-design operations are performed only a short period of time compared to the on-design operations. It is quite possible that the flowsheet (network) of the off-design operation is different from that of the on-design operation. For example, in total site system, there can be other resources of the intermediate products with possibly higher cost against reduced investment requirements. Another type of process level redundancy is shown in the following example where the synthesis procedure is also given in determining the optimal process.

Example 1

Figure 1 shows the maximal structure (super-structure) of a synthesis problem for producing material A, it is also supposed that the availability of the process must be at least 0.999. Figure 2 shows the optimal process with 9,312 USD/y cost, it is a redundancy free solution. The availability of this process, 0.989, does not satisfy the requirement, and there is no other redundancy free solution with the required availability. Thus, redundancy must be considered during synthesis. On Figure 3, the maximal structure is shown with assigning double equipment units to each operating unit. Figure 4 shows the cost optimal process synthesized by simultaneously taking into account the availability constraint (Kovacs et al, 2018). Bold lines give the on-design operating mode and the thin lines represent the spare part of the system. Note that the optimal solution is based on process level redundancy. Consequently, optimality can only be guaranteed if process level redundancy is taken into account in process synthesis under availability constraint. Furthermore, methods for generating optimal corrective actions must consider flowsheets (networks) with no structural limitations.

3. Systematic procedure for corrective actions in case of failure

The procedure for determining the corrective action in an event of failure is based on P-graph synthesis tools, it is called as procedure CAF. It is supposed that the flowsheet of the process is given in the form of a P-graph. Let the mathematical model of each operating unit with its cost function, the unit cost of each raw material, and the demand of each product be given. If for a running process one or more equipment units become non-functional, their identifiers are assumed to be available immediately for the CAF procedure.
Figure1. Maximal structure of a process synthesis problem
Figure 2. Network of the optimal solution of process synthesis problem given on Figure 1, availability requirement is violated
Figure 3. Maximal structure of process synthesis problem given in Figure 1 with redundant equipment units
Figure 4. The network of optimal solution of process synthesis problem given on Figure 3 satisfying the availability requirement (bold lines indicate the on-design operating mode)

First, algorithm MSG (Friedler et al., 1993) determines if the remaining functional equipment units may compose a structurally feasible process. In case of negative answer, the procedure halts, there is no feasible operating mode on the basis of the functional equipment units. Otherwise, algorithm ABB (Friedler et al., 1996) is executed to determine the optimal operating mode, if there is one. Note that a structurally feasible process is usually feasible, but not necessarily. Algorithm ABB is a branch&bound type algorithm, the bounding part can be linear or nonlinear depending on the mathematical models of the operating units. The algorithm is also able to give the n-best solutions in addition to the optimal one. Note that algorithms MSG and ABB are available at www.p-graph.org.

Example 2

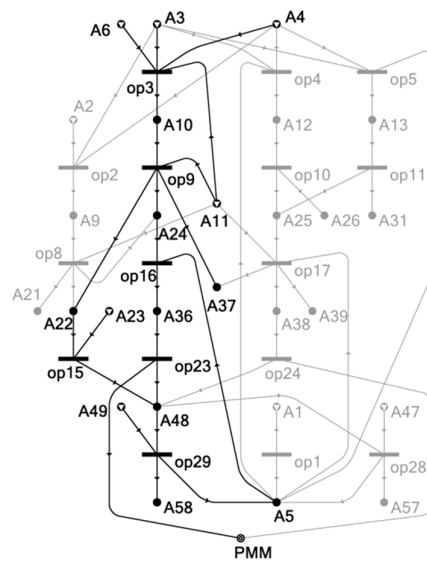
One product, PMM (Perchloromethyl mercaptan), is produced by a processing system of 16 available operating units from 9 available raw materials. Each operating unit is realized by one equipment unit. The network of a process that includes process level redundancy is shown on Figure 5. The mathematical models of the operating units in this example are linear, they are available at www.p-graph.org/case-study-pmm. There are 24 feasible operating modes producing the product. The best of them in terms of cost is shown on Figure 6, it is considered as the on-design operating mode with the cost of 3,144,010 USD/y.
Figure 5. A process with process level redundancy for producing material PMM


Figure 6. Bold lines indicate the on-design operating mode of production PMM (cost: 3,144,010 USD/y)

Suppose that equipment unit that realizes operating unit op29 fails, then, the number of feasible operating modes is reduced to 12. Figure 7 shows the optimal operating mode under this condition, the cost of operation is increased to 3,228,140 USD/y.

If equipment units op9 and op16 fail simultaneously as a possible consequence of cascading effect, there are 8 remaining feasible operating mode, the optimal of them is shown on Figure 8, its cost is 3,819,490 USD/y. If both equipment units op16 and op17 fail, the process becomes non-operational, as no feasible operating mode exists.

4. Conclusions

It has been shown that process level redundancy must also be considered in process synthesis for optimally satisfying high level availability. Because of that, the corrective action in an event of failure must be prepared for a more general network redundancy. The procedure developed here keeps the process operational as far as it is possible, determines the most cost effective corrective operating mode practically promptly for any possible process network.

Abstract

Better management of anthropogenic organic waste and other primary sources of nutrient pollution such as agricultural, municipal, and industrial waste, will reduce the human impact on the environment. Harmful algal blooms (HABs) are a major environmental impact from organic waste and nutrient pollution. HABs can pose severe threats to human health due to the release of dangerous toxins in fresh or marine water that can negatively affect public health, increase treatment costs for drinking water, and cause enormous economic loss in industries that depend on clean water. In this study, the effect of decisions made in the organic waste supply chain (SC) on reducing the potential for HABs is investigated by integrating three types of models: a SC optimization model, a nutrient transport model, and an algae growth model. This contribution presents a comprehensive spatio-temporal management strategy for short-term HAB reduction by adjusting components in the SC, including technologies, logistics, nutrient management plans (NMPs) or environmental costs, and seasonal waste storage planning. In addition, it is presented a case study of the Upper Yahara Watershed in the State of Wisconsin to illustrate the practicability of this modeling framework.

Keywords: supply chain, nutrient pollution, spatial-temporal control, harmful algal blooms

1. Introduction

The role of nutrient pollution (specifically nitrogen and phosphorous) is central to the underlying causes of HABs. Sources of nutrient pollution are classified as either non-point source or point source. Non-point sources include agricultural land, stormwater etc., and the point sources include permitted facilities, e.g. wastewater treatment plants (WWTPs). Complex point and non-point nutrient management strategies will be required to achieve a more comprehensive and permanent solution to controlling the nutrient pollutions. The increasing rate of HAB development is a complicated problem faced by human populations around the world. Algal species involved in a HAB can generate significant levels of toxins threatening public health. According to Heisler et al. (2008), HABs have economic impacts in the form of remediation costs for water treatment and reduction in property value of the impacted areas . Graham et al. (2009) estimated that 30% of lakes from 36 states in the US have reported toxic cyanobacterial bloom issues . The US Environmental Protection Agency (US EPA) reported the tourism losses of one billion dollars annually

and commercial fishing losses on the order of tens of millions of dollars annually [1].

By designing an appropriate transportation network for organic matter and incorporating technology placement for treatment and processing, the nutrients in organic waste can be more efficiently recycled for agricultural use in the growth of crops, feeding of grazing animals, and ultimately for human benefit. However, from Zandi Atashbar et al. (2018), current sustainable SC design studies typically incorporate metrics such as global warming potential and eutrophication potential which measure the chronic environmental impacts. Yet, the effects of seasonal variations in nutrient loading must be considered. Therefore, an extended modeling framework is needed to better describe the explicit environmental consequences caused by decisions made in the organic waste SC design.

In this work, we apply, adapt, and combine multiple types of modeling tools, including a SC design model, a nutrient transport model, and an algae growth model to create an optimization framework that analyzes the effect of nutrient controlling strategies in SCs on HABs. We present a case study in the Upper Yahara Watershed in the State of Wisconsin.

2. Modeling Framework

In this section, we introduce a modeling framework to connect the decision-making and control strategies in the SC with the environmental consequence of HABs. The modeling structure is shown in Figure 1.

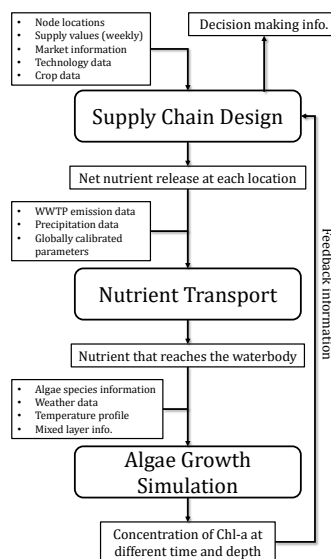
Algae growth shows seasonal dependence, and this is because its growth is affected by water temperature, sunlight, nutrient concentration, and other factors. Steady-state modeling will not adequately capture the impact of seasonality, nor will models with large time steps (e.g. annual based decision making). For example, nutrient leaching in cold months will raise the probability of HABs in the spring. Therefore, management and prevention actions must be taken in advance, but there is still ambiguity about the optimal lead time for actions to be effective. The models for algae growth, nutrient transport, and SC, all have an explicit time dependence.


Figure 1: Modeling structure

2.1. Supply Chain Model

We extend the supply chain framework from Sampat et al. (2017) and Hu et al. (2018). The SC model is a constrained dynamic optimization model, which takes the input of node locations (e.g., dairy farms), the weekly supply amount of organic waste, market information including demand amount and price for each product, technology data (yield factors, investment and operational costs), and crop data, such as the crop type, yield, growing season, and nutrient uptake rate.

---

[1]https://www.epa.gov/nutrientpollution/effects-economy

The SC structure is shown in Figure 2. The farms can send organic waste to transportation sites to process it, storage systems to store it temporarily, or directly apply it to agriculture lands. The value-added products from technologies can be purchased by external customers. The main decision variables in the model are transportation flows, inventory levels, installation of technologies and storage systems, and amount of commercial fertilizers applied. The SC model can also output the amount of applied organic waste, which can be fed into the nutrient transport model to support runoff calculation.

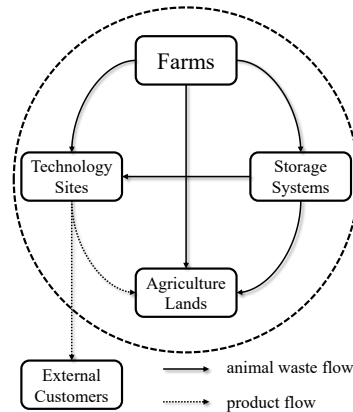
The constraints in the optimization model include: the flow conservation at each node (product balance), the product conversion at technology sites, capacity constraints for demand, inventory, and processed waste, the nutrient requirement for each crop at each node and time period, and the economic metrics. The objective function is to minimize the overall costs plus the excess nutrients in the system, where the weight can be interpreted as unit environmental costs or the strictness of environmental policies regarding nutrient management plan at each node.


Figure 2: Supply chain structure

2.2. Nutrient Transport Model

A nutrient transport model tracks the nutrient transport process from point and non-point sources to surface water. To reduce the computational burden, increase the compatibility of the framework, and generate results at preliminary development stages, instead of using advanced and data-intensive simulation tools such as SWAT (Neitsch et al. (2011)), we select a watershed-level model called NEWS2 (Nutrient Export from WaterSheds 2) proposed by Mayorga et al. (2010). The NEWS2 model is a more general model that takes input data of WWTP emission data, precipitation data at a watershed level, globally calibrated parameters, and the net nutrient release information from the organic waste SC management model.

The model calculates the phosphorus and nitrogen that reach the water body considering both the contributions from point and non-point sources. The point source part is calculated using the population data and nominal nutrient release per person. The contribution from non-point sources is calculated using some global parameters, precipitation data (which is used for surface runoff calculation), and the net nutrient release accounting for fertilizer, animal waste application, fixation and deposition, and crop need.

We note that in the application of the NEWS2 model, two main assumptions are made. First, the NEWS2 model is originally used for annual nutrient transport. We assume a biweekly nutrient transport amount can be assessed using the same approach with finer input data, and with a transport delay included. Second, we assume the model can be fit into the use of small watershed. The modeling framework is equipped with more powerful functions under these functions, which might lead to lower accuracy. We will continue to extend the scope in the nutrient transport modeling and simulation.

2.3. Algae Growth Model

An algae growth model is used to relate the nutrient concentration in a water body with the HAB level and the corresponding consequences. The algae growth model used in this framework is the PROTECH (Phytoplankton RespOnses To Environmental CHange) model, which is proposed by Reynolds et al. (2001), and takes the input of nutrient concentration data, algae species information, weather data, lake profile (e.g. temperature). The model uses the concentration of chlorophyll-a (chl-a) as a measurement of the abundance of algae.

The PROTECH model calculates the daily concentration of chl-a by considering the growth rate, the rate of decrease due to animal grazing, settling out (algae movement), and dilution. For each term, the rate is mainly related to temperature, nutrient level, and sunlight intensity. The model can output the concentration of chl-a at different times and at different depths of the lake.

3. Case Study

We apply this modeling framework to a case study considering the region of Upper Yahara Watershed within Dane County in the State of Wisconsin. This region has suffered from nutrient pollution for years. The NBI (nutrient balance index, defined as the ratio of nutrient applied to land over the amount of nutrient that is removed by crops) was 1.95 and 1.35 in the year of 2012 and 2013 respectively (Larson et al. (2016)) . For the year 2017, the NBI index was 1.46 based on our estimation. The Lake Mendota has been categorized as eutrophic since the 1980s.

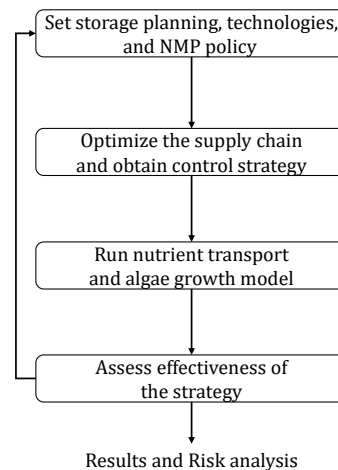
In the case study, we use the crop and weather data of the year 2017. The time period of interest is from April 1st to October 31st, where the HABs are more likely to happen. The data of nutrient recovery technologies are from previous studies (Sharara et al. (2018); Sampat et al. (2018)). The decision-making procedure in this case study is illustrated in Figure 3, and the control techniques in the SC are the strictness of NMPs, the availability of nutrient recovery technologies, and the seasonal storage planning. Although the SC framework has the capability of placing facilities, the facility sites in this case study are predetermined using real data. After solving the SC optimization problem, it can provide a spatio-temporal strategy containing different transportation flows and inventory levels in different times, which is able to control the net nutrient release in the system while balancing the economic objective. Based on this procedure, we start from the worst scenario (no technologies or NMPs, and poor storage planning), and compare the effectiveness of each technique individually. Finally, we study the overall influence of adopting three techniques simultaneously. We obtain economic information from the SC model. From the difference of scenarios, we


Figure 3: Decision-making scheme

can estimate the preventive cost for reducing HABs risk.

4. Results and Discussion

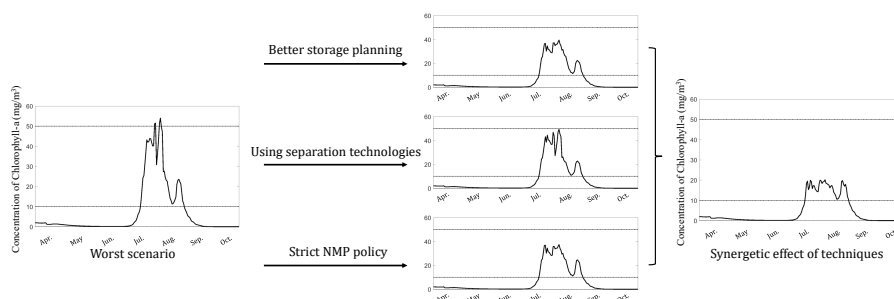
First, we compare the predicted TSI (trophic state index, proposed by Carlson (1977)) of the scenario closest to reality with observed data. A lake is defined as eutrophic when TSI is between 50-70. The predicted TSI is between 55 and 65; while the observed TSI fluctuates between 50 and 60, which indicates the practicability of the framework.


Figure 4: Model prediction

In Figure 4, we show the predicted concentration of chl-a under different control strategies. We observe that, in the worst scenario, the concentration exceeds the warning line of a high risk of acute health effect for humans suggested by the World Health Organization World Health Organization (2003) (50 mg chl-a/m^3), while the control techniques can reduce the HAB level under the warning line. From the comparison between the three control techniques, we find the incorporation of separation technologies is the less effective strategy, which may have attributed to the fact that the derived products are not valuable, and the economic driving force is not large enough. On the other hand, direct environmental policy changes (better storage planning or strict NMP policy) are more effective at controlling the nutrient runoff and thus the HAB level. Additionally, we observe that, by combining the three techniques, the HAB level can be reduced substantially, which means the strategies have an overall synergistic effect. However, even for the best scenario, the concentration of chl-a still exceeds the middle warning line (moderate risk of having acute health problems, 10 mg chl-a/m^3). This indicates that long-term effort (perennial SC optimization and nutrient management) is necessary to further eliminate the HABs risk.

From the economic results of the SC optimization problem, we can obtain the overall cost in the system (operational cost of technology, transportation cost, and fertilizer cost). For the worst scenario, the overall cost is 1.18 million USD while for the best scenario, the overall cost is increased by 32.2 % and reaches 1.56 million USD. This indicates the cost corresponding to the prevention of HABs in the same year can reach 0.38 million USD. We note that this estimation is conservative because the cost of implementing strict policies, the increased holding cost in inventory management, and the investment cost of technologies are not included.

5. Conclusions

In this work, we formulate a dynamic modeling framework by combining a SC optimization model, a nutrient transport model, and an algae growth model. The management elements in the SC network can be regarded as controlling techniques, and the output from the algae growth model can provide feedback information for the SC design. We provide a case study of Upper Yahara Watershed to illustrate the practicability of the model. We find by designing appropriate SCs, the nutrient loading in runoff can be decreased and the risk of HABs will be lower, but a corresponding cost of prevention will be incurred. In future work, we will conduct more scenario analyses and study the influence of logistics and the cost distribution at different times. We will extend our framework so that a perennial influence can be forecast.

Abstract

Recently, process industries have experienced a significant pressure to shift from centralized energy supplying systems to the in-situ exploitation of renewable resources. Special attention has been paid to multi resource-based energy systems, a particular case of distributed generation where processing nodes include energy generation and can operate either grid-connected or isolated. This work proposes a general model to determine the optimal retrofitting of a supply chain integrating renewable energy sources under uncertain conditions and to analyze the effect of different planning horizons in the solution. The proposed mixed integer linear programming (MILP) formulation allows determining the best combination of available technologies that satisfies the internal energy demand of a given set of scenarios while addressing total expected cost and expected environmental impact minimization. The potential of the approach is illustrated through a case study from the sugar cane industry proposed by Mele et al. (2011).

Keywords: Multi resource-based energy, Optimization under uncertainty, renewable energies, closed-loop energy integration

1 Introduction

Growing energy demand about 60% over the last 30 years and increased industrial electricity and gas prices more than double in comparison with 20 years ago ((Zukunft, 2014) force industries to plan their eventual transition to a new energy system that will be largely based on Renewable Energy Sources (RES). This is one of the greatest challenges of our time. Over the latest years, process integration involving different renewable resources for their more efficient use, managing and controlling their uncertain availability, has been considered. Therefore, several alternative approaches are available to satisfy process energy demand and exploit the availability of renewable sources. In this line, a number of studies have been focused on single renewable sources such as first and second generation bioethanol production processes, which were integrated to use the excess of energy when processing lignocellulosic biomass for ethanol dehydration (Čuček et al. 2011; Mele et al. 2011), and cogeneration exploitation (Morakabatchiankar, Hjaila, Mele, Graells, & Espuña, 2018). Different energy sources have also been integrated with biomass types (Martín & Grossmann, 2017; Prasad et al. 2017; Vidal & Martín, 2015). Recently, Martín et al. (2018) proposed an integrated renewable energy resource network to produce biofuels and generate power combining two supply chains that traditionally are developed as independent entities. However, the satisfaction of large scale demands of multiple resources, such the one that should be faced at regional or country level,

requires the integration of resources at a larger scale and needs more flexibility in terms of resources configuration. Hence, this work is focused on the development of a general optimization model for the retrofitting of sustainable process systems integrated with multi-energy generation system. The model is applicable to different ranges and scales while considering energy demand uncertainty to optimize the decisions of country-size SCs in the presence of conflicting objectives at different time spans.

2   Problem statement

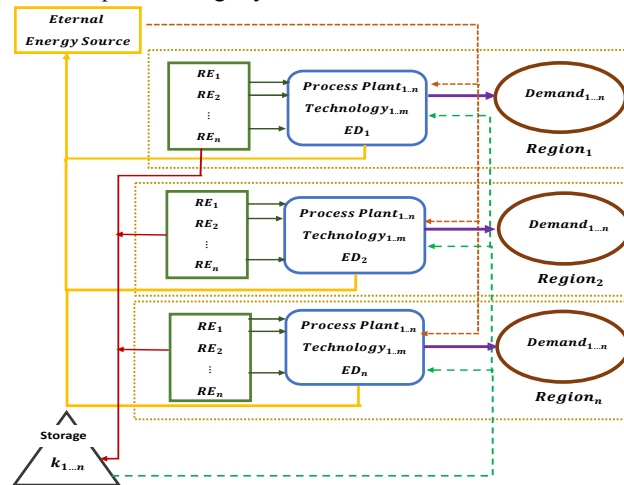
According to the objective previously outlined, the proposed model determines a generic multi resource-based integration supply chain network as illustrated in Fig. 1. It is aimed to propose configurations associated with structural decisions that can be considered more sustainable. These decisions include the type, number, location and capacity of the energy generation units and production process plants (including the technologies selected in each of them); their capacity expansion policy and the transportation links between the energy-material SCs entities. The operational decisions are the energy generation level, the production rate at the plants in each time period, the flows of materials and energy between plants, warehouses and product markets, and the sales of final products and excess energy. Then, the SC configurations obtained by means of stochastic mathematical programming at different planning horizons can be compared. Additionally, this generic model determines the power to be installed at each internal or external resource and also the capacity of the required storage systems.


Fig 1. Multi resource-based Energy Integration SC

3   Multi-Objective stochastic Model

In this work, a scenario-based stochastic MILP formulation, considering a given distribution probability along the whole time horizon, based on the models introduced by Mele et al., (2011) (production process part) and Alabert et al., (2016) (multi resource energy integrated part) is proposed. Sizing is constrained to accomplish all scenarios, and operation variables are calculated according to each scenario. The number of necessary scenarios will be set in accordance with the characteristics of the case study to deal with. The model equations are classified as i) production process mass balances and capacity constraints; ii) energy generation mass/energy balances and capacity constraints; iii) energy storage management iv) External resources management; and v) objective

function. The result of the model provides a set of Pareto solutions to be used by the decision maker in order to take the optimum tactical/strategical decision.

3.1 Energy generation

The balance representing the need to meet the (uncertain) energy demand during a certain period is shown in equation 1:

$$\sum_{ei} EnIJ_{ei,g,t,sc} + \sum_{ex} EnXJ_{ex,g,t,sc} \\ + \sum_{k} EnKJ_{k,g,t,sc} = ED_{g,t,sc} \qquad \forall\, g,t,sc \qquad (1)$$

where $EnIJ_{ei,g,t,sc}$ is the energy flux between source ei and region g at time period t for scenario sc; $EnXJ_{ex,g,t,sc}$ is the energy flux between the external source x and region g at time period t for scenario sc; $EnKJ_{k,g,t,sc}$ is the energy flux between storage k and region g and $ED_{g,t,sc}$ is total energy demand in region g at time period t.

For the management of the own energy sources, the energy balances in equations (2) and (6) consider that all the generated energy has to be consumed or sold. The variable $EnEx_{ei,t,sc}$ represents the eventual excess of energy, and SL represents the slot length.

$$EnIG_{ei,g,t,sc} = PwIG_{ei,g,t,sc} \times SL \qquad\qquad \forall\, ei,g,t,sc \qquad (2)$$

$$PwI_{ei} \le PwIMax_{ei} \qquad\qquad \forall\, ei,g \qquad (3)$$

$$TotalEnIG_{t,sc} \ge TotalED_{g,t,sc} \qquad\qquad \forall\, g,t,sc \qquad (4)$$

$$\sum_{g} EnIJ_{ei,g,t,sc} + \sum_{ex}\sum_{g} EnIX_{ei,g,ex,t,sc} + \\ \sum_{k}\sum_{g} EnIK_{ei,k,g,t,sc} + EnEx_{ei,t,sc} = \sum_{g} EnIG_{ei,g,t,sc} \qquad \forall\, ei,t,sc \qquad (5)$$

$$PwEx_{ei,t,sc} = EnEx_{ei,t,sc} / SL \qquad\qquad \forall\, ei,t,sc \qquad (6)$$

Equations (7-9) allow the management of external energy sources; they are similar to (4-5), but adding the possibility to sell energy. In these equations, $EnXP_{ex,t,sc}$ denotes energy purchase, whereas $EnXS_{ex,t,sc}$ represents the energy sales. Energy to be sold can only come from stand-alone generation, and it is considered that extra energy can be accumulated in storage elements.

$$PwX_{ex} \le PwXMax_{ex} \qquad\qquad \forall\, ex \qquad (7)$$

$$EnXP_{ex,t,sc} = \sum_{g} EnXJ_{ex,g,t,sc} + \sum_{k} EnXK_{ex,k,t,sc} \qquad \forall\, ex,t,sc \qquad (8)$$

$$EnXS_{ex,t,sc} = \sum_{ei}\sum_{g} EnIX_{ei,g,ex,t,sc} \qquad \forall\, ex,t,sc \qquad (9)$$

Storage units are modelled through equations (10) to (12), which introduce the charge and discharge limits.

$$EnK_{k} \le EnKMax_{k} \qquad\qquad \forall\, k \qquad\qquad (10)$$

$$EnKCh_{k,t,sc} = \left[\sum_{ei} \sum_{g} EnIK_{ei,g,k,t,sc} + \sum_{ex} EnXK_{ex,k,t,sc} \right] \times EfCh_k \qquad \forall\, k,t,sc \qquad (11)$$

$$EnKDh_{k,t,sc} = \sum_{g} EnKJ_{k,g,t,sc} \times 1/EfDh_k \qquad \forall\, k,t,sc \qquad (12)$$

3.2 Costs equations

The objective function considers the installation and operational costs of the facilities along with the planning horizon (eq. (13) and (14)), also considering the environmental impact costs for installation and operation Eq. (15) and (16).

$$CIns = \sum_{ei} \sum_{g} \Pr PwI_{ei} \times PwI_{ei,g} + \sum_{k} \Pr EnK_k \times EnK_k \qquad (13)$$

$$COP_{t,sc} = HL/PL(\sum_{ei} \sum_{g} \Pr EnI_{ei} \times EnIG_{ei,g,t,sc}) + \qquad \forall\, t,sc \qquad (14)$$

$$\sum_{ex} (\Pr EnP_{ex} \times EnXP_{ex,t,sc} - \Pr EnS_{ex} \times EnXS_{ex,t,sc}) +$$

$$\sum_{ex} (\Pr EnCh_k \times EnKCh_{k,t,sc} + \Pr EnDh_k \times EnKDh_{k,t,sc})$$

$$GHGIns = \sum_{ei} \sum_{g} GHGPwI_{ei} \times PwI_{ei,g} + \sum_{k} GHGEnK_k \times EnK_k \qquad (15)$$

$$GHCOP = \begin{array}{l} (HL/PL)\sum_{ei} \sum_{g} GHGEnI_{ei} \times EnIG_{ei,g,t,sc} \\ + \sum_{ex} GHGEnX_{ex} \times EnXP_{ex,t,sc} \\ + \sum_{k} GHGEnCh_k \times EnKCh_{k,t,sc} \\ + GHGEnDh_k \times EnKDh_{k,t,sc} \end{array} \qquad \forall\, t,sc \qquad \begin{array}{c} \\ \\ (16) \end{array}$$

3.3 Objective functions

The whole SC system must attain two targets: an economic objective, represented by the NPV, and an environmental objective quantified by the global warming potential (GWP). Different NPV values are obtained for each scenario under study, so an expected value ($E[NPV]$) of the resulting NPV distribution can be computed by considering the estimated probability for each scenario:

$$E[NPV] = \sum_{sc} Prob_{sc} \times NPV_{sc} \qquad (17)$$

The resulting objective functions are finally expressed as follows:

$$Min\{-E[NPV]; E[GWP]\} \qquad \text{S.t. constraints 1-17 and the constraints} \qquad (18)$$
$$\text{proposed by Alabert et al., 2016; Mele et al.,}$$
$$\text{2011}$$

The solution of this problem consists of a set of Pareto optimal SC configurations, which can be by applying the ε-constraint method.

4 Case Study

The first example introduced by Mele et al. (2011), which addresses the optimal retrofit of an existing sugar cane industry established in Argentina, is revisited herein: 5 different technologies are available to manufacture 2 main products: ethanol and sugars. Nominal capacity of the sugar mill and the distillery plants are 350 and 300 thousand tons per year. The time horizon is divided into a set of time periods, and the specific geographic area is divided into a set of regions where the facilities of the SC can be located. Each region has

an associated supply capacity (sugar cane crop) at every time interval. Waste (bagasse) is supposed to be sent to cogeneration units to produce electricity as added-value product. Energy demand uncertainty is represented by 3 scenarios. Following Illukpitiya et al. (2013) assumptions, the estimated total electricity requirement for internal use in the processing plants is 0.0441 kWh per kg of cane. It is also assumed that the nominal capacity of the power plant is 8.33 MW and the power generation is available on a continuous basis for at least 7800 h annually. The electricity market price and the operational cost of electricity generation are 0.15USD/kWh and 0.08USD/kWh respectively.

5 Results

Figure 2 shows the Pareto curve obtained using the stochastic approach under several CO_2 emission levels and depicts a compromise between Expected Net Present Value and Expected Global Warming Potential. Each solution represents a specific design configuration of whole energy/material supply chain system. The results show that by increasing planning horizon length NPV value increases so it is also interesting to point out that, for the same cogeneration capacities of renewable resources, NPV increases up to 50% in longer planning horizons but tends to be constant for horizons longer than 10 years (Fig. 3). It is observed that the solutions allow operating at most for satisfying energy demand so that it involves more resources for generating renewable energies. As it is also shown in Fig. 4, a significant part of the expected electricity demand should be supplied by wind turbines.
Fig. 2 Pareto set of solutions EGWP100 vs ENPV
Fig. 3 NPV variation in Planning Horizons
Fig. 4 Energy generation per Resource
Fig. 5 Satisfaction level of Products Demand

The results show the maximum satisfaction level of products demand with a maximum expected NPV and minimum expected GWP conditions (Fig. 5).

6   Conclusions

A MILP formulation to address the retrofitting problem of a multi-resource based energy integrated SC under uncertainty has been presented. The model produces a set of feasible energy/material networks addressing the optimization of conflictive objectives. The capabilities of the model are highlighted through its application to a case study. The proposed stochastic approach maximizes the expected profit while satisfying a minimum environmental impact for each scenario. The interaction between the objectives has been shown. This way of generating feasible configurations will help the decision-maker to determine the best design according to the selected objectives. In this particular case, the results show that 100% of internal energy demand and 94% of biofuel demand can be met by an entirely renewables-based process network, which majorly generates energy by cogeneration unit and wind power.

Abstract

Bio-refineries are promising production options of chemicals production, capable to produce a wide range of fuels and chemicals equivalent to the conventional fossil-based products. To establish bio-refineries as mature choices and achieve the commercialization of their technologies, the application of sustainable solutions during the design and development stages are crucial. The innovative character of bio-based production and therefore data availability and access on process modelling details, is a challenging point for decision makers to move towards this direction.

Considering the environmental dimension out of the three aspects of sustainability, Life Cycle Assessment (LCA) is a suitable methodology for the evaluation of environmental impacts of bio-based processes because it highlights the stages with the greatest impact along a production chain. LCA studies require large amount of information, usually extracted from detailed flowsheets or from already completed pilot plants, making this procedure, costly, time consuming and not practical to act as a decision- support tool for the development of a bio-refinery.

The aim of this study is to develop predictive models for the assessment of LCA metrics and use them to highlight sustainable design options for bio-refineries. Models require the least possible information, which can be obtained from chemistry - level data or early (conceptual) design stages.

The modelling techniques used in this study are decision trees and Artificial Neural Networks (ANN), due to their easily interpretable structure and high computational capabilities, respectively. Models are based on the extraction of knowledge from a wide dataset for bio-refineries (it refers to 32 products that is, platform chemicals (e.g., syngas, sugars and lignin) and biofuels (e.g., biodiesel, biogas, and alcohols), starting from diverse biomass sources (e.g., wood chips, wheat straw, vegetable oil)). Input parameters include descriptors of the molecular structure and process related data which describe the production path of a study product.

Models are able to predict LCA metrics which cover the most critical aspects of environmental sustainability such as cumulative energy demand (CED) and Climate Change (CC). The average classification errors for decision- tree models range between 17% ($\pm$10%) to 38% ($\pm$11%) whereas for ANN models the average R^2_{cv} values (coefficient of determination) range between 0.55 ($\pm$0.42%) to 0.87 ($\pm$0.07%).

Demonstration of models is provided using case studies found in literature. Models are used to rank options in various design problems and support decisions on the selection of the most profitable option. Examples of such cases are the selection of the appropriate technology or feedstock to produce a desired product or the preliminary design of a bio-refinery configuration.

The proposed approach provides a first generation of models that correlate available and easily accessed information to desirable output process parameters and assessment metrics and can be used as pre-screening tools in the development of innovative processes, ahead of detailed design, thus saving time and money.

Keywords: GWP, early stage process design

1. Introduction

Decision making in identifying and developing the most sustainable option among a range of alternatives from biorefinery configurations pre-supposes a great amount of knowledge that is hardly available at early stages of process development. On top of that bio-based processes, in their majority, are characterized by low technology readiness level. Furthermore, there is a strong need to configure sustainability criteria (energy and water consumption, toxicity) as early as possible and identify critical aspects and profitable solutions from the portfolio of possible options.

To give answers for the most profitable option, the commonly used methods such as LCA require data collection and analysis, a kind of information usually obtained from simulations or already existing infrastructures, e.g. pilot plants. In addition, detailed LCA as a standardized method is limited to the final judgment of design decisions, as it is placed at the end of process development steps (that is, conceptual design, mass and energy balances, process integration and optimization) (Fig. 1a). This procedure leads to the formation of economic and environmental data which feed inventory analysis and the assessment of environmental profiles.

This study aims at the development of a streamlined LCA methodology which predicts LCA metrics and it can be applied at early stages of process development of biorefineries using the minimum required information. The proposed method supports decisions towards sustainable design options, providing assessments which can be conducted "ahead of detailed design" and identifies critical parameters which affect LCA metrics, thus providing guidance for design choices (Figure 1b). The concept is based on the FineChem tool (Wernet et al. (2008), Wernet et al (2010)) which predicts LCA metrics for petrochemical industry using as input the molecular structure of the product and no prior knowledge of process flowsheets. The current method expands this concept for bio-based production and, although it adopts molecular descriptors proposed by FineChem, it is enriched with process related information, easily found from laboratory scale and early conceptual design stages.

The proposed method is data-driven and based on a range of biorefinery configurations including all the impacts generated along the production pathways. The predictive LCA models use machine learning techniques and adopt molecular descriptors of the products chemical structure and minimum process information, extracted from a large database of biorefinery case studies. These types of models can be a valuable tool in early design phases for screening alternative biorefinery layouts considering their environmental impact or to guide design considerations without detailed modelling requirements.

Sources, money, infrastructures, time…

(a)   The conventional approach

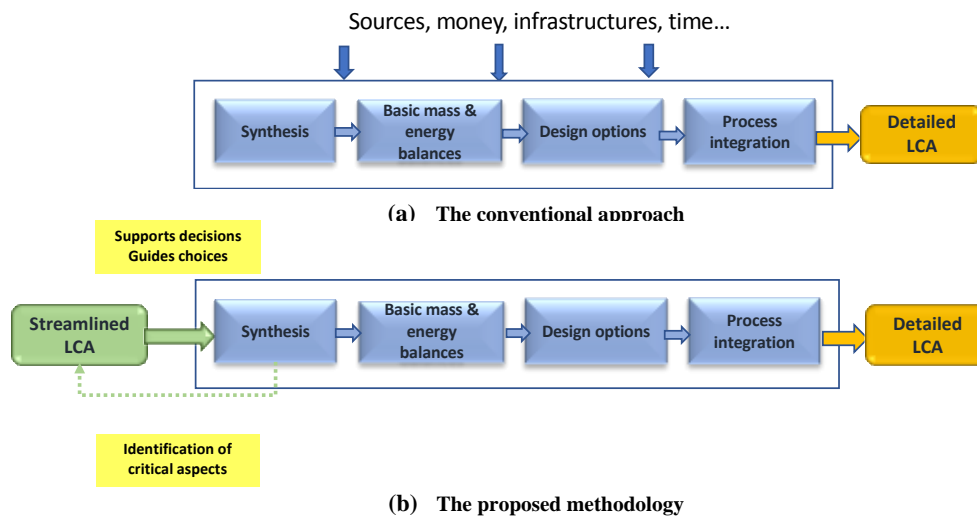
(b)   The proposed methodology


Fig. 1 (a, b) The research question

2. The methodological framework

The predictive models development procedure consists of 4 main steps that is:

- Step 1: Research question
- Step 2. Data collection and pre-processing
- Step 3. Use of data mining techniques to develop prediction models
- Step 4: Modelling performance-validation -demonstration in biorefinery cases

The research question addressed is the development of an amended version of LCA, able to predict LCA metrics for a wide range of environmental issues and guide design options at early design stages (Step 1).

The challenge to guide decisions "ahead of design" comes from the experience of machine learning to exploit data structures and identify patterns. The mathematical formulation aims at the development of functions $Y=f(X)$ which correlate Y, i.e. an LCA metric with a set of input variables $X=[X_1, X_2..X_n]$ easily available at early design stages. Thus, data for predictive model's training and development (Step 2) are collected from a wide range of biorefinery systems. The training dataset used in this study refers to thirty-two products produced from various synthesis paths which represent the most important groups found in literature (Karka et al. 2017). Training size refers to 91 study systems and data sources for the development of flowsheet models are pilot plant data, combined with literature sources and the knowledge acquired from industrial partners.

Two LCA metrics were selected as target attributes (one for each model), the Climate Change (CC) and the Cumulative Energy Demand (CED) which provide assessments for carbon dioxide emissions and the non-renewable fossil energy demand. Target attributes for the corresponding products were estimated using the LCA method according to the ISO 14040 for each study system as described in Karka et al. 2017. The functional unit is 1kg of product. Values of LCA metrics of each observation of the dataset are also provided for three allocation approaches (mass, market price, substitution).

Input (descriptor) variables refer to the molecular structure of the product of interest (e.g. molecular weight, number of oxygen atoms, number of hydrogen atoms etc.) and process-chain related variables corresponding to chemistry, complexity and generic process conditions (e.g. maximum temperature, efficiency factors, number of processing steps for the synthesis of the final product). Descriptor variables are arranged into two sets of 24 (reduced) and 30 (detailed) input variables depending on the level of access on early design stages, i.e. lab scale and conceptual design level, respectively. Thus, 12 datasets are developed which correspond to an equivalent number of models (2 metrics x 3 allocation approaches x 2 sets of predictor variables).

Data mining techniques used are decision trees which segregate the set of descriptor variables into classes of Low, Medium and High impacts in case of categorical prediction results, and RBF Artificial Neural Networks (ANN) in case of numerical result (Step 3). For the former technique all variables were discretized whereas for the latter they were normalized in the range [-1, 1] before entering the model.

Average modelling capabilities are obtained as a result of an iterative cross validation procedure in Step 4 using average classification error and coefficient of determination (R^2_{cv}). Classification error was defined as $\frac{\sum_{i=1}^{l} fp_i}{n}$, where fp is the number of wrong predicted class labels to the total number of observations, n, in the dataset and l is the number of class labels.

3. Results

Neural network models present a distinctive performance for both CC and CED metrics for the detailed set of predictor variables and especially for mass and economic allocation approaches. R^2_{cv} values result as an average of 500 cross-validation iterations, varying among 0.55 to 0.87 (Fig. 2).

Compared to the FineChem tool (Wernet et al., 2008) the respective performance ranges are about 0.3 for CC and 0.25-0.4 for CED depending on the number of predictor variables selected each time.
Fig. 2 Average and standard deviation values of R^2_{cv} for NN based models from 500 cross validation iterations (Values for substitution approach for the reduced sets are close to 0 and they are not shown)

The average prediction performance of the decision tree-based models results from a cross-validation procedure for 100 iterations (Table 1). The classification error values for CC and CED metrics (depending of the mass allocation approach and the set of predictor variables) range between 17% to 38%. These values can be acceptable for pre-screening models.

Table 1: Average classification error for CC and CED metrics and for all allocation scenarios and input variables dataset

Predictor variables	Allocation approach	CC		CED	
		Avg.	St. Dev.	Avg.	St. Dev.
Detailed	Mass Allocation	22.2%	8.6%	21.6%	9.0%
	Economic Allocation	28.5%	9.1%	23.4%	9.1%
	Substitution	26.1%	10.2%	33.9%	10.8%
Reduced	Mass Allocation	19.6%	9.0%	17.3%	10.1%
	Economic Allocation	22.5%	8.7%	25.5%	10.7%
	Substitution	32.4%	12.2%	37.8%	11.0%

3.1 Models use in biorefinery processes

For demonstration purposes the graphical representation of the CC model (Fig. 3) for the mass allocation approach and the reduced set of predictor variables is used. Three paths of glucose production are tested, glucose through steam explosion (Option A), concentrated acid hydrolysis (Option B) and through biomass decomposition with organic acids, organosolv (Option C). Table 2, shows the minimum amount of information which is required to obtain an estimation whereas Table 3 summarizes the validation of prediction results using reported data for the options A, B and C.

Table 2: Input data for the assessment of CC metric of glucose following the rules of the tree

	(A)	(B)	(Γ)
Feedstock	WChips	WChips	WStraw
Reacts	0	0	0
Steps	2	2	2
RME	Medium (0.211)	High (1)	
WAirReacts	100%	100%	
MaxT			Moder (100C)
Oxygen			=1

Table 3: Predictions using the CC metric tree, and respective reported values

Production path	Estimation	Real class	Value	Source
Glucose (steam explosion) (A)	Low	Low	0.7	(Morales et al., 2017)
Glucose (acid hydrolysis) (B)	Low	Low	0.3	(Morales et al., 2017)
Glucose (organosolv) (C)	Medium	Medium	1.46	BIOCORE, 2010-2014, Karka et al. (2017)

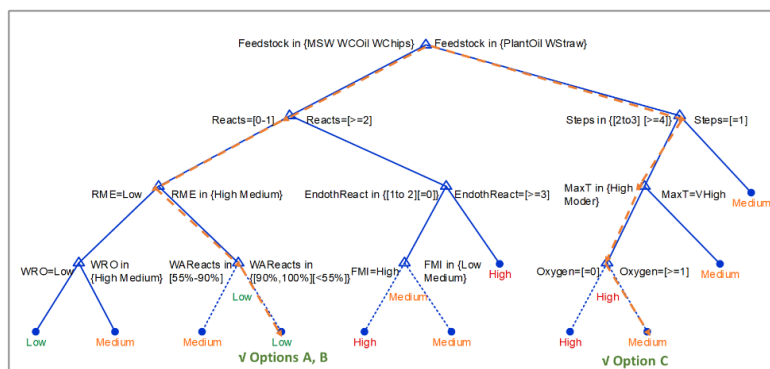
✓   Correct ranking
✓   Correct class estimations


Fig 3. Decision tree for CC metric

Despite the practical use of decision trees, because of their interpretable format, we highlight below an example of using neural networks as a supportive tool to the categorical form of decision trees predictions.

Dihydroxyacetone-DHA (Morales et al., 2015; Lari et al., 2016), produced from biocatalytic processing of glycerine can be derived from plant oil based or waste cooking

oil glycerine. The reported CC values per 1kg of DHA is 9.4 CO_2-eq and 6.4 CO_2-eq, respectively, which have been assessed following the steps of the ISO norm of LCA, both belong to the class of high impacts according to the categorization and classification of decision trees. A prediction like that would not support the designers towards the most profitable selection. Thus, the contribution of a numerical technique would enhance the capability of a classification model to rank the alternative options. In this case, neural networks can give a useful trend on the ranking of solutions even when their predicted values present high deviations from the reported values as shown in Table 4.

Table 4: Neural metrics predictions for CC, and respective reported values

	Production path	Reported value	30 predictor variables Estimation of NN	24 predictor variables Estimation of NN
1	*DHA crude (biocatalytic), plant oil*	9.4	6.28	4.84
2	*DHA crude (biocatalytic), waste cooking oil*	6.40	3.44	3.02

4. Conclusions

This study is a contribution towards estimating the environmental impacts of biorefinery products in early stages of process design, based on molecular descriptors of the bio-product and minimum process information. The resulting models for CED and CC show satisfactory accuracy in validation terms (e.g., coefficient of determination values around 0.6-0.85 and average relative errors of 17%-38%), similar to short-cut models previously developed for fossil-based production. The same modeling methodology (both classification trees and NN) was applied in LCA metrics provided by the ReCiPe method giving satisfactory results for other midpoint and endpoint LCA metrics such as Human Health, Ecosystems Quality, Marine Eutrophication etc. It is expected that an enrichment of the database and the appropriate selection of predictor variables will allow the development of a robust tool for predicting/benchmarking the cradle-to-gate environmental performance of the bio-based production.

Abstract

The stochastic and non-controllable nature of most of renewable energy sources makes it necessary to include extensive use of energy storage in national grids to overcome periods with low availability. Hence, effective energy storage technologies will be requiredfor achieving a 100% renewable energy system.

Currently used technologies are only partly suitable for this task. Batteries are efficient but expensive, and mostly suitable for daily storage. Hydrogen has a significant potential, but suffers from a low energy density and difficulties in handling and transportation. Among different potential solutions, ammonia was often pointed out as a high-density and low-cost hydrogen carrier.

In this paper, we analyze the efficiency of an ammonia-based pathway for the storage of excess energy from renewable energy sources, its transportation, and its final use. As a case study, we consider the use on board of a urban car transport vessel as the user of the stored energy. The energy efficiency and cost of the whole chain, from the production at the wind farm until its use on board of the ferry, is evaluated and compared with competitive alternatives, namely batteries and hydrogen storage.

The results show that, while not being a game-changer, the use of ammonia as mean for storing and transporting excess energy from renewable power plants is viable and, in combination with other storage systems, contributes to a relevant part of the share of total installed storage capacity in the most cost-effective solution.

Keywords: energy storage, renewable energy, ammonia, fuel cells

1. Introduction

The challenge of making human activities environmentally sustainable is one of the most important that humanity will have to face in the coming years. While the solution will be provided by a combination of different technological developments, it is widely recognized that renewable energy sources will take a major share of the task.

Given the stochastic and non-controllable nature of most of renewable energy sources, improving the performance of energy storage represents one of the most important challenges to face for achieving a 100% renewable energy system. Batteries, while being the most efficient storage technology, suffer from limitations in energy density and high cost. Hydrogen generated by electrolysis, while still providing a reasonably high round-trip

efficiency, has limitations in energy density and in handling.

As a solution for long-term storage and for transportation, various authors have proposed the conversion of hydrogen to conventional fuels, such as syngas, methane, methanol, and Diesel, but none of these solutions would prove to be carbon neutral, unless the carbon is originated by biomass, or by carbon capture and storage.

The use of ammonia as fuel can provide a valid alternative to carbon-based fuels. Ammonia has a relatively energy density in its liquid phase, that can be achieved at conditions relatively close to ambient conditions. For this reason, we believe that there is an interest in proposing ammonia as an energy vector, and as a mean for energy storage.

In this paper, we aim at investigating the potential role of ammonia as a way to store renewable energy that is produced in excess during low-demand periods. We address this by looking at a specific case study, based on the hypothesis to use the extra energy to propel ferries. The study aims at comparing existing storage technologies (batteries and hydrogen) with the potential case of ammonia.

2. Method

In order to investigate the potential role of ammonia as means for storing renewable energy during periods of excessive availability, in this paper we refer to the case of an offshore wind farm of a rated power of 200 MW. The excess energy can either be curtailed, and hence lost, or stored and then transferred to a harbor, where it is assumed that a car ferry will be the final user.

The process of storage and transportation of the excess energy is allowed to take different ways, as shown in Figure 1:

Electric way : Excess energy is stored in batteries, and then sent to shore via existing power lines. The power transmission is allowed whenever there is no excess energy generation.

Hydrogen way : Excess energy is used in an electrolyser to generate hydrogen, that is stored in either compressed or liquid form. It is here assumed that the hydrogen is stored in container-sized tanks, that can then be loaded on supply vessels that regularly serve the wind farm. A bi-weekly frequency is assumed for the purpose of this study, as reported by CIT.

Ammonia way : Excess energy is used to generate hydrogen from water in an electrolyser, and nitrogen from air in a cryogenic air separation unit. Hydrogen and nitrogen are then used in an ammonia synthesis plant (here assumed based on the Haber-Bosch technology) that converts them to ammonia, that is then stored in liquid form at low temperature. The transportation is assumed to happen in the same way as assumed for the hydrogen way.

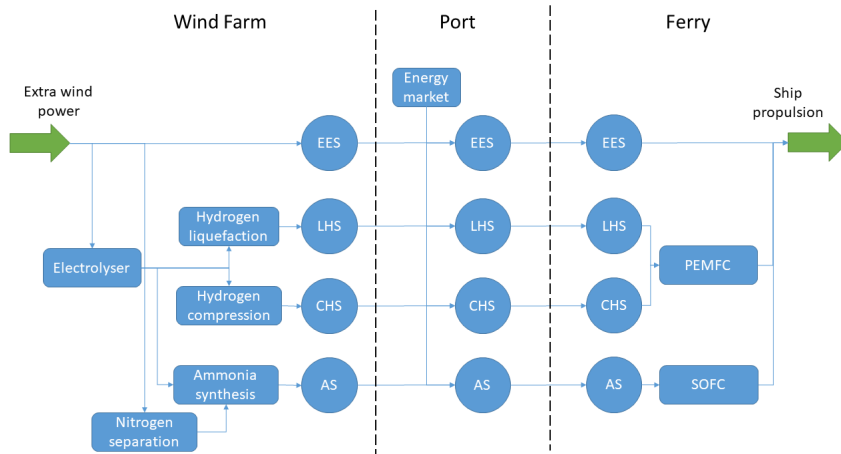
Once delivered to the port, the different fuels can be loaded on board of the ferry that operates on daily round trips. Electrical energy can be stored onboard in batteries, and directly used to power electric motor. Hydrogen is assumed to be used in a proton exchange membrane fuel cell (PEMFC), a well-developed technology extensively tested for


Figure 1: Representation of the superstructure for the optimization model

Table 1: Numerical assumptions employed in the study

use with hydrogen as fuel, also in maritime applications CIT. Ammonia is assumed to be used in a solid oxide fuel cell (SOFC); while the technology of SOFCs is less mature when compared to PEMFCs, particularly when powered by ammonia, recent tests have shown that there is no conceptual, or practical obstacle to a wider adoption of this technology CIT. The assumptions related to unit cost and efficiency are summarized in Table XXX. We assume that the maintenance cost does not significantly vary between different options and technologies and that, hence, can be excluded from the analysis.

The evolution of the excessive power generation over the year is represented using to the processed data provided by Zerrahn et al. (2018), originally retrieved in raw format from ?, and refer to the German electrical grid for the year 2014. This dataset provides hourly values for the curtailed energy from the combination of all renewable power plants. The implicit assumption of using this data in this paper is that the excess power is redistributed among different plants based on the installed power capacity. While this can be considered as a strong assumption, this approach provides a relatively accurate representation of the size and frequency of power curtailment in a European electrical grid. A representation
Figure 2: Wind curtailment power, probability of occurrence

of the resulting frequency of different curtailment powers is provided in Figure XXX.

Both the excess power and the power demand of the ferry are represented with a two-hour definition. As this would require a total of 4320 time steps for one year of operation, we assume that yearly operations can be summarized with a total number of four "reference periods" of the duration of two weeks, where the choice of the period length is based on the frequency available for transporting fuel from the wind farm to shore. The four reference periods where defined as follows:

- Maximum cumulated excess energy (for dimensioning the storage), occurring once per year

- Maximum peak excess power (for dimensioning the conversion units), occurring once per year

- Reference period at low cumulated excess energy, occurring 15 times per year

- Reference period at high cumulated excess energy, occurring 9 times per year

3. Results and discussion

The results for the optimal annualized costs in the different cases are provided in Figure 3. The option of using only electric energy storage in the form of batteries is clearly the least convenient case: as a consequence of the high specific investment cost, the optimizer chooses to reduce the total storage installed capacity, hence increasing the operational costs related to energy curtailment. The results also show that, for the selected case study, liquid hydrogen storage is more competitive in comparison to compressed hydrogen storage. Both the increased energy cost for liquefaction and the relatively high investment
Figure 3: Comparison of operational, investment, and total costs for the different investigated cases

cost of the hydrogen liquefaction plant are offset by the lower investment cost for hydrogen storage.

When ammonia comes into play, a combination of effects can be observed. The use of ammonia alone as storage option is less profitable compared to the case of liquid hydrogen storage. This is mostly due to the high specific investment cost of the ammonia synthesis plant, which in this case is the largest contributor to the investment cost (32%), while the cost of the storage is only marginal (less than 1%). On the other hand, when other storage possibilities are included, the ammonia production plant is downsized (the installed capacity is reduced by 38%), and liquid hydrogen is used for intermediate storage. The detailed cost share in this case is shown in Figure 4: the electrolyser, the SOFC and the ammonia synthesis plant all contribute with 20-25% of the investment costs, while the use of a battery for part of the onboard power generation is favored because of the lower operational costs, particularly when energy is bought from the energy market.

4. Conclusion

Abstract

Daily industrial operations consume large quantities of energy and water but are often considered marginal to their processes. Energy is used to heat or cool water; water is frequently used in production or utility systems as steam or cooling water. This emphasizes the interconnectivity of water and energy, stipulating their simultaneous consideration to address resource use in industrial processes which requires systematic methodologies. Two main complications have been observed within methodologies proposed in literature. As discussed in this work, these difficulties affect the overall mathematical formulation in mixed-integer nonlinear programming models; thus, resulting in a complex formulation. These difficulties have been addressed in this work by proposing a novel hyperstructure and a sequential solution strategy for the design of heat-integrated water allocation networks. Emphasis is placed on generating a set of promising solutions by addressing different performance indicators which is achieved via implementation of integer cut constraints to support decision-making for potential configurations. Applying the proposed methodology on several test cases from literature illustrated that the methodology is not only able to reach minimum total cost of the system, but also generates a set of alternative solutions exhibiting various performances with respect to other indicators.

Keywords: mathematical programming, superstructure optimization, heat-integrated mass allocation network, non-linear programming, non-isothermal mixing.

1. Introduction

Savulescu and Smith (1998) published the first work on heat-integrated water allocation network (HIWAN)s. They emphasized the importance of simultaneous consideration of heat and water and provided a graphical approach. Since then, many authors have proposed methodologies to better capture the trade-offs among the two resources which can be categorized into either conceptual or mathematical. The latter is based on developing mathematical models, incorporating all potential alternatives, and optimizing the system with respect to a well-chosen objective function. Several comprehensive reviews have been published on the subject (Ahmetović et al., 2015; Kermani et al., 2018). Two main complications have been observed within the mathematical methodologies proposed in literature, namely, the choice of the thermal state of a water stream (being hot or cold) and

its thermal matches. The formulation of the latter requires the knowledge of the thermal state of the water stream *a priori*. Both complexities have been addressed in the literature via considering binary variables. This results in a mixed-integer nonlinear programming (MINLP) model. Comprehensively addressing the two requires a complex formulation which may fail to provide promising solutions in a reasonable time-horizon. This has prompted researchers to propose several solution strategies to facilitate the solving process (Kermani et al., 2018). This work proposes a novel sequential solution strategy and a novel nonlinear programming (NLP) hyperstructure, addressing the aforementioned difficulties in a systematic manner.

2. Problem definition

Given are two sets of water unit operations (source, sink) with their specific operating temperatures. Maximum allowed inlet (outlet) contamination levels are defined for each sink (source). Mass load removal rates are also defined in case a water unit operation is a mass-transfer unit. Furthermore, non-water process and utility (steam, cooling water) streams are also present. Freshwater sources and wastewater sinks at different temperature and contamination levels are also provided. The objective is to design the total heat-integrated water allocation network exhibiting the lowest total annualized cost. This cost consists of operating costs (consumption of freshwater, wastewater treatment, and thermal utilities) and investment costs (heat exchanger network (HEN) cost, equipment cost, etc.).

3. Methodology

The overall HIWAN problem is generally formulated as an MINLP. In this work the problem is reformulated into three subproblems, namely: targeting, heat load distribution (HLD), and design. The focus of this work is on formulation of the design stage together with the overall solution strategy.

Problem P1 - Targeting: Problem **P1** is formulated as mixed-integer linear programming (MILP) model (Kermani et al., 2017). This problem considers water network constraints, heat network constraints (Maréchal and Kalitventzeff, 1998), and connections between the two. The linearized formulation of non-isothermal mixing (NIM) allows for modeling sets of potential water thermal streams for each water unit operation (assignment of binary variables to each water thermal stream). This formulation solves the first difficulty in design of HIWANs, i.e., the thermal state of water streams. In addition, the solution of problem **P1** provides utility targets and a feasible water allocation network. The problem is solved by minimizing the total annualized cost of the system.

Problem P2 - HLD: Problem **P2** is the well-known HLD model (Papoulias and Grossmann, 1983; Marechal et al., 1989; Cerda and Westerburg, 1983) formulated as MILP with the objective of minimizing the number of thermal matches in each pinch interval, i.e., minimizing the number of heat exchangers. HLD solves the second difficulty in the design of HIWANs, i.e., the potential thermal matches. Furthermore, the solution of problem **P2** provides the heat loads of each thermal match which is used as a good initialization point for the subsequent design stage.

Problem P3 - Design: Knowing the set of thermal streams from problem **P1** and the potential thermal matches from problem **P2**, problem **P3** is formulated as an NLP hyper-

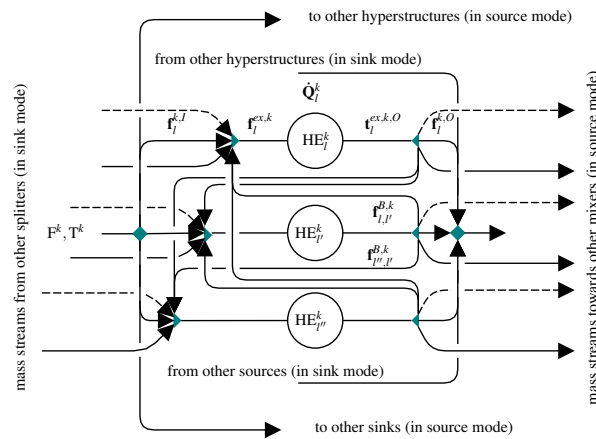
structure. It is adapted from HEN hyperstructure of Floudas and Ciric (1989) for thermal streams. More specifically, in the classical approach by Floudas and Ciric (1989), no interconnection is allowed among different superstructures of thermal streams; however, considering the fact that these thermal streams are water streams, these connections bring potential mixing and splitting opportunities which can further reduce the HEN cost. Several structural changes are implemented in the HEN hyperstructure to consider the new possibilities (Figure 1) including removing the final mixer (initial splitter) from a super-structure if the stream is associated to a source (sink) unit. It should be highlighted that the non-water thermal streams keep the original formulation. Problem **P3** minimizes the HEN cost subject to mass, contamination, and energy balance constraints.


Figure 1: Schematic of the proposed hyperstructure (dashed arrows indicate flows among hyperstructures of the same source (sink) similar to the definition of $\mathbf{f}_{l,l'}^{B,k}$ and $\mathbf{f}_{l'',l'}^{B,k}$)

3.1. solution strategy

Problems **P1**, **P2**, and **P3** are solved in sequence. The original HEN model of Floudas and Ciric (1989) can be solved before problem **P3** to provide an initialization point. The solution of this model is also considered a feasible solution to the overall HIWAN problem. Several drawbacks can be observed in this sequential solution strategy, namely that it fails to: address the trade-off between operating and investment costs, guarantee the global optimality due to non-convexity of the problem, and guarantee a solution with overall minimum HEN cost (Floudas and Ciric, 1989). To address these drawbacks, an iterative sequential solution strategy is proposed, more specifically, by applying integer cut constraints on problems **P1** and **P2** and solving the overall problem for different values of heat recovery approach temperature (HRAT). This approach can be regarded as iteratively optimizing the overall MINLP model within different regions of the global search space (as imposed by the formulations of problems **P1** and **P2** at each iteration).

4. Results and discussion

Two test cases from the literature were selected to validate the proposed approach. The maximum allowed number of integer cuts was limited to 50. The value of HRAT was var-

ied between 1–10°C. These values are passed to problem **P3** as heat exchanger minimum approach temperature (ΔT_{min}). Test case I is a threshold problem and hence the value of HRAT does not affect the utility consumptions. This, however, becomes a decisive factor for test case II where both hot and cold utilities are required. Several key performance indicator (KPI)s are considered:

- Resource indicators: freshwater ($\dot{\mathbf{m}}_{fw}$) and thermal utility consumptions ($\dot{\mathbf{Q}}_u^H$, $\dot{\mathbf{Q}}_u^C$);
- Network indicators: number of thermal streams (N_s^{th}), number of heat exchangers (N_{HE}), total area of heat exchangers (A_{HEN}^{total}), number of mixing points (N_{mixer}), number of non-isothermal mixing points (N_{mixer}^{NIM}), number of mass streams (N_s^m), and total heat load of all heat exchangers (Q_{HEN}^{total});
- Economic indicators: HEN cost (C^{HEN}) and total annualized cost (TAC) (C^{TAC}).

4.1. Test case I: single-contaminant problem

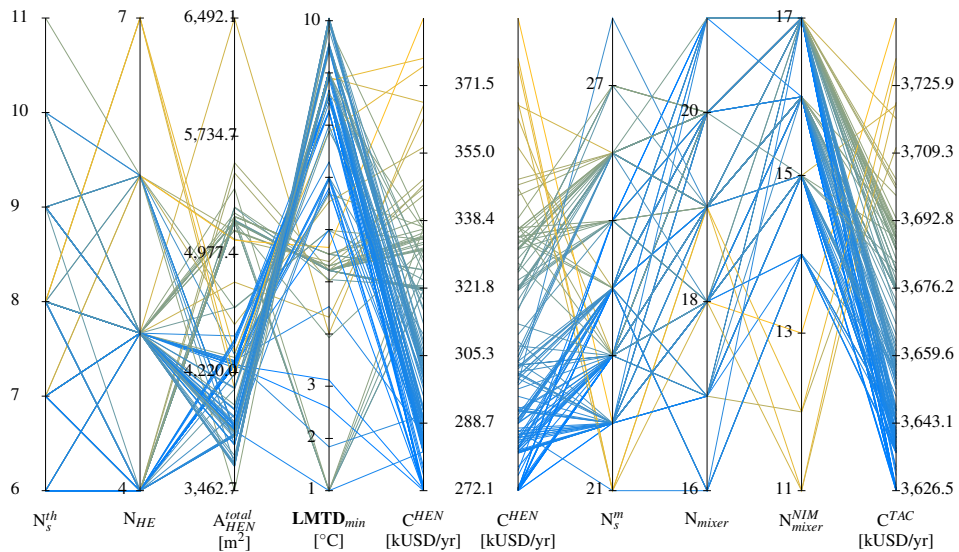
Test case I is a single-contaminant problem proposed by Bagajewicz et al. (2002) that consists of eight water unit operations. The solution with minimum operating cost exhibits 125.94 kg/s of freshwater consumption and 5,289.6 kW of hot utility consumption. Out of 26,010 possible solutions, 5,260 solutions exist to problem **P2**. The objective value of problem **P2** varies between 6–15. From this set of solutions, 565 solutions converged for problem **P3**, among which, HEN cost varies between 272.1–529.3 kUSD/yr for 554 solutions. The minimum HEN cost reported by the literature is 257.2 kUSD/yr (Ibrić et al., 2014), however, the freshwater and utility consumptions were reported to be 126.71 kg/s and 5,322.1 kW, respectively. Several filters were applied to further reduce the number of solutions to aid in visualization based on their corresponding maximum values reported in literature: $N_s^m \leq 32$, $N_{mixer} \leq 21$, $N_{mixer}^{NIM} \leq 17$.


Figure 2: Visualization of selected KPIs for test case I (155 solutions)

Figure 2 presents the remaining 155 solutions. Considering total annualized cost as the

main objective in this case study, the proposed set of solutions encompass the design
with the lowest cost of 3,626.5 kUSD/yr. Comparing this with the minimum reported
in the literature (3,628 kUSD/yr), one can observe that the proposed sequential solution
strategy can reach the minimum while also proposing a set of alternatives which show
varying performance for the defined objective and other KPIs. The advantage of such an
approach is providing many potential solutions which may yield more desirable solutions
in non-objective KPIs which would not be discovered by conventional approaches. For
instance, among all solutions with the lowest HEN cost, the solution with the lowest
number of mixers and mass streams exhibits a simpler network design while its HEN cost
is penalized by less than 0.1%.

4.2. Test case II: multi-contaminant problem

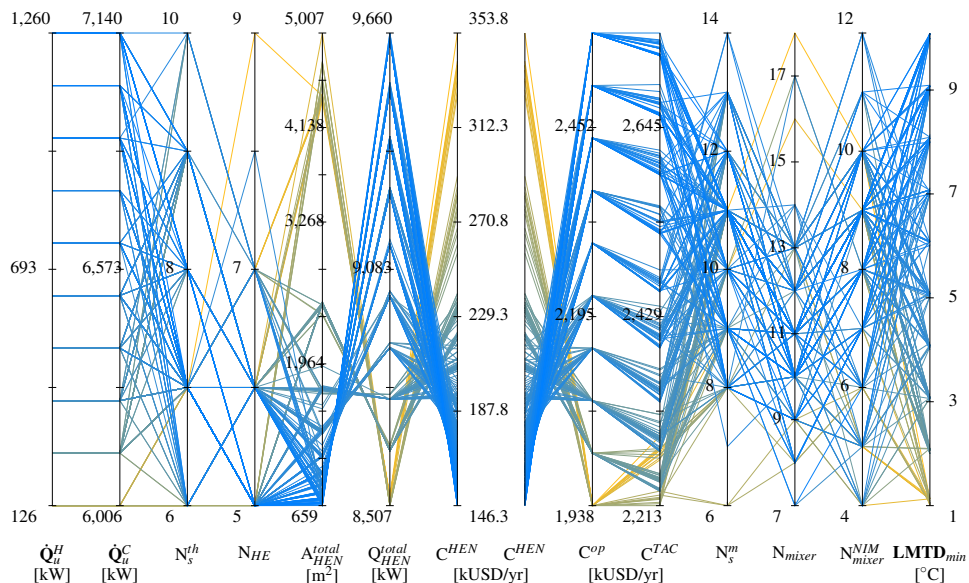
Test case II is a pinch, multi-contaminant problem proposed by Dong et al. (2008) with
the minimum freshwater consumption of 70 kg/s. The value of HRAT affects the thermal
utility consumptions. Jagannath and Almansoori (2016) proposed a solution in which
they constrained the number of heat exchangers and mass exchanges to four and seven,
respectively, and reached 74.3 kg/s of freshwater consumption, 8,760 kW of hot utility
and 2,520 kW of cold utility ($\Delta T_{min} = 20°C$). Although they reported the lowest HEN cost
(117.2 kSUD/yr), their solution exhibits the highest total cost and the highest thermal
utility consumption among the reported values in the literature. Out of 26,010 possible
solutions, 982 solutions exist to problem **P2**. The objective value of problem **P2** varies
between six and nine thermal matches. Among these solutions, 299 converged for prob-
lem **P3** with minimum and maximum HEN costs of 146.3 kUSD/yr and 353.8 kUSD/yr,
respectively. Figure 3 illustrates the KPIs of these 299 solutions.


Figure 3: Visualization of selected KPIs for test case II (299 solutions)

5. Conclusions

Two main complexities are observed within literature methodologies for HIWANs. The first difficulty is selecting the thermal state of water streams, leading to the second difficulty of selecting thermal matches with undefined thermal states. Accounting for these complexities results in a complex MINLP formulation which is difficult to solve optimally with current solutions strategies; therefore, this work proposes a novel hyperstructure and solution strategy to treat this complex problem. An initial MILP model provides minimum utility consumptions with a list of potential thermal streams for achieving them. In the second step, thermal matches are identified by solving the HLD model minimizing the number of thermal matches. A novel NLP hyperstructure was developed in the last step for a complete design of the network combining the water allocation the HEN hyperstructures. Results indicate that the approach reaches optimal designs efficiently, and additionally generates a set of near-optimal solutions; thus, providing a practical approach to selecting the final implementation and contrasts the single-solution approach in literature. This approach allows experts to provide additional insights into the performance of all solutions with respect to additional indicators before selecting the solution for implementation. Finally, all possible interconnections are incorporated; therefore, providing a comprehensive approach that allows any type of heating and cooling for any water stream, bringing novel improvements to the state of the art.

Abstract

In the first years of the 2000's the late professor Peter Bongers introduced together with his co-workers at Unilever a design methodology that could be applied in the development of new products and processes for structured food products; the product-driven process synthesis method (PDPS). The method was successfully employed in the following years, designing new products from different bio based sources. Although researchers used the method and even made improvements; the structural incorporation of mathematical programming tools has been lacking and this seems to be a crucial component for decision-making processes. In this contribution we will discuss the possibilities to extend the PDPS framework with several of these optimization tools.

Keywords: Product-driven process synthesis, mathematical programming, agro-food products.

1. Introduction

We can agree that the procedures and methods for the development of (petro) chemical processes and products have matured significantly over the last 50 years. However, in new areas such as the bio-based-, food-, pharmaceutical- and water sectors, where feedstock, processing and product are dynamic and complex these developments lag and right now such methods are not at hand. A more structured approach for the synthesis of process and product was developed in the last decade by the late professor Peter Bongers, the so called product-driven process synthesis (PDPS) approach. This method makes use of the synergy of combining product and process work streams. The PDPS delivers a hierarchy of design levels of increasing details, where complex and level-interacting decisions are made from one level to another.

The application of the PDPS approach has resulted in a significant financial benefits in the fast-moving consumer goods industry and lead to novel and differentiating alternatives to current manufacture practices. Although the PDPS is a systematic approach, many of the decisions made at the different levels of the PDPS are based on expertise and knowledge brought in via experienced engineers and scientists (so called heuristics). It is clear that model-based optimization and mathematical programming

could further enhance this decision process. In this work we will outline our vision for the integration of systematic optimization methods into the PDPS.

2. Product driven process synthesis (PDPS)

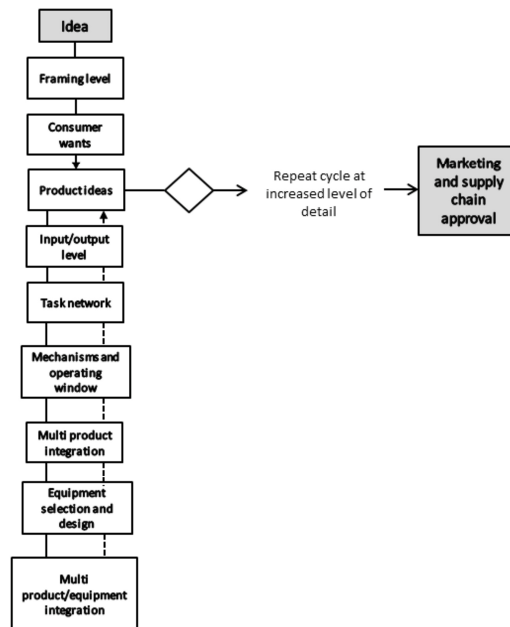
The product driven process synthesis methodology has been described in detail in (Almeida Rivera et al., 2016) and consists of nine levels of increasing detail, where complex and emerging decisions are made. These levels include the: framing level, consumer wants, product function, input–output level, task network, mechanism and operational window, multiproduct integration, equipment selection and design, and multiproduct equipment integration. Each level follows the general design paradigm cycle (Siirola, 1996): scope and knowledge, generate alternatives, analyse performance of alternatives, evaluate and select, report.


Figure 1: The product-driven process synthesis framework of 9-levels.

At all levels estimates of economic potential, turndown ratio, changeover time, sustainability, process complexity, scalability, hygiene design, among others, and all of them at various degrees of detail are made. The aim is also to include a multi criteria decision-making approach to assist in the "evaluate and select" activity (De Ridder et al. 2008). This approach, termed BROC (benefits, risks, opportunities, and costs), is used in industrial R&D settings and combines quality function deployment (QFD) and analytic network process (ANP). QFD is a method for structured product planning and development that enables a development team to specify clearly the customer wants and needs, and then to evaluate each proposed product or service capability systematically in terms of its impact on meeting those needs (Cohen, 1995).

The backbone of QFD is the so-called "house of quality", which displays the customer wants and needs, and the development team technical response to meeting those wants and needs. ANP is a commonly used benchmarking technique to compare alternatives. QFD has been applied to several PDPS cases but only in a qualitative fashion.

3. Examples of successful application of the PDPS to agro-food products

In the last years the PDPS has been successfully employed in several projects in the agro-food industry. These projects focused on the mild disclosure of added value chemicals from biological raw materials. In (Zondervan et al, 2015) a new process is designed for recovering vitality ingredients such as antioxidants from liquid tea-streams via solvent swing adsorption. In (Zderic et al, 2016) the scope was extended and novel methods for disclosing the antioxidants directly from fresh tealeaves using pulsed electric fields and ultrasound techniques were developed. In both studies the PDPS plays an important role for decision-making. (Zderic et al, 2017) also used the PDPS to extract oilbodies from soy.

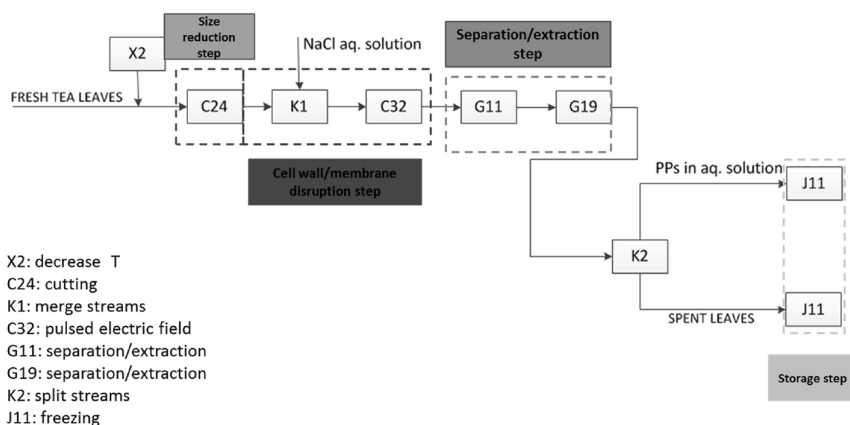
G19: separation/extraction
K2: split streams
J11: freezing


Figure 2: Example of a task-network for the isolation of antioxidants from fresh tealeaves.

In (Jankowiak et al, 2013) the PDPS was used as tool to find new pathways for isolating isoflavones from Okara and in work by (Kiskini et al., 2016) an extensive portfolio of different products that can be obtained from sugar beet leaves was set out, including proteins, carbohydrates, lipids and phenolics.

Although all studies delivered valuable insights and pointed to a strategy for an advanced product portfolio; the main strategy in decision-making was based on brainstorm sessions, experimental work and expert knowledge available in the project teams. The use of mathematical optimization techniques to facilitate decision-making would have certainly been of value, knowing the combinatorial complexity resulting from many different choices that can be made at each of the levels of the PDPS.

4. The use of mathematical optimization in the PDPS framework

4.1. The House of Quality in the PDPS
In the "framing" and the "consumer wants" levels of the PDPS one important question that needs answering is how to link the (qualitative) properties that a consumer wants in

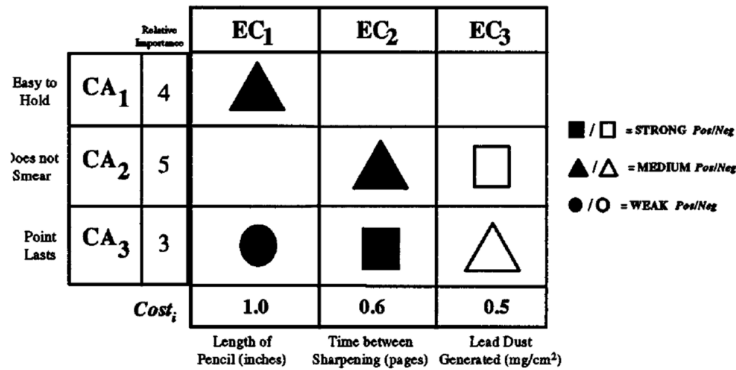
a product to measurable indicators (such as physical properties or product formulations). For example: there might be a clear link between the "mouth feel" and the viscosity of a mayonnaise. The House of Quality (HoQ) is a graphic tool that establishes such links. The HoQ comes in different appearances, but an example is given in figure 3 below, which was taken from (Dawson et al., 1999). The figure shows the interactions between the physical properties of a pencil and how a user experiences the use of the pencil.


Figure 3: The Pencil design HoQ without roof.

The HoQ has been widely proposed as a method for capturing the voice of the customer when developing requirements for new products. But the methodology lacked a formal mechanism for trading off customer preferences with technical feasibility and economic reality. However, in the work of (Dawson et al., 1999) a non-linear mathematical program for determining the optimal engineering specifications during new product development as a function of elicited customer value functions, engineering development and production costs and development time constraints is proposed. Such models are shown to be computationally feasible for realistic-size problems and to outperform heuristic approaches.

4.2. Superstructure optimization of task networks in de PDPS

In the "Task network" level of the PDPS different definitions of the fundamental tasks that are needed to convert a raw material into product are taken from a cluster of tasks and its subgroup. Then, a network is made from the selected tasks and clusters. This work flow is often done on the basis of knowledge available within the project team. This leads to sound proposals for the task networks, but there are no guarantees that all possible network configurations have been evaluated. This is where superstructure optimization can be brought into the PDPS.

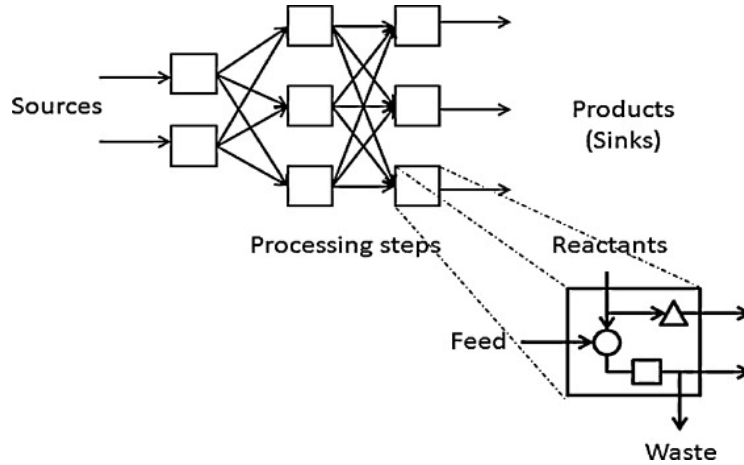
Figure 4 shows the general format of a superstructure, which consists of sources (raw materials), sinks (products), arcs (possible flows of mass/energy) and blocks (contained unit operation- or task models). In superstructure optimization the main question is, which route to take through the network in such way that a criterion is optimized (for example, costs, environmental impact, product yield).


Figure 4: General format of a superstructure (Nawaz et al., 2011)

Of course, there are many possible routes to be evaluated. The number of alternatives increases factorial with the number of components that flow through the network, the number of technology options available and the number of processing stages allowed. The arcs and the blocks in the super structure can be translated into a mathematical program that can be used to evaluate many hundreds or thousands of possible pathways. The general structure of such model is:

$$\min f(x, y)$$
$$\text{s.t.}$$
$$g(x, y) = 0$$
$$h(x, y) > 0$$
$$x_L \leq x \leq x_U$$
$$x \in X; y \in Y$$

$$(1)$$

With f being the objective function (economic- or environmental criterion), x and y the decision variables, g the equality constraints (often mass- and energy balances), h the inequality constraints (often operating limits). There are also logical constraints (could be equalities as well as inequalities). The decision variables x and y are bounded and defined over the domains X and Y, respectively (this determines the nature of the problem; continuous or discrete). Often these models are captured as mixed integer linear (or nonlinear) programming problems, which can be handled well with appropriate software.

4.3. The use of propositional logic in the PDPS
As a complement to the use of superstructure models to generate and evaluate task networks a more intensive use of propositional logic is foreseen. Propositional logic is a tool that can be used to translate heuristics into mathematical constraints to reduce network complexity. The development of propositional logic in process design finds its roots in the work by (Raman & Grossmann, 1991). Propositional logic can be used to convert logical expressions into inequalities. As an example: "If the dryer or the hydro-cyclone is selected, then do not use a crystallization step". This heuristic can be written as a logic expression:

$$P_D \vee P_H \Rightarrow \neg P_C \tag{2}$$

Removing the implication yields:

$$\neg(P_D \lor P_H) \lor \neg P_C \qquad (3)$$

After applying de Morgan's theorem:

$$(\neg P_D \land \neg P_H) \lor \neg P_C \qquad (4)$$

Distributing the OR over the AND:

$$(\neg P_D \lor P_C) \land (\neg P_H \lor \neg P_C) \qquad (5)$$

After assigning the corresponding binary variables in the above conjunction two inequalities are obtained:

$$y_D + y_C \leq 1 \qquad (6)$$
$$y_H + y_C \leq 1 \qquad (7)$$

Which can be added to the superstructure model. The house of Quality, superstructure optimization and propositional logic are three examples of applying quantitative methods to the PDPS.

5. Conclusions

Product driven process synthesis has over the years proven to be an effective tool for process- and product design for novel agro-food based products. The method deservers further improvements by the inclusión of mathematical programming tolos that can be used to link sensory attributes with product properties (House of quality), the application of superstructure optimization for the evaluation of different task networks and the use of propositional logic in the development of constraints for the superstructure optimization.

Abstract

The Dutch ISPT (Institute for Sustainable Process Technology) executes an innovation program that focusses on system integration and circularity. This program explores amongst others pathways for the re-use of CO contained in waste gases produced by steel making processes so to enable the circular use of carbon. ISPT commissioned an Energy System Modelling (ESM) project to demonstrate how ESM can be used to explore options for the upgrading of these CO-rich waste gas streams and to show which upgrade investments over time could meet CO_2 emission targets in the most cost-effective manner.

Keywords: Multi-Period Mixed Integer Linear Programming, monetisation waste gases from steel manufacturing, CO_2 abatement pathways, impact CO_2 taxation on CCS.

1. Introduction

Deep decarbonization of the energy system is required to mitigate climate change. ISPT executes an innovation program in the Netherlands that focusses on system integration and circularity to enable such a radical transformation. An example is the study on the re-use of CO from waste gases by steel making processes to enable circular use of carbon. Against this backdrop, ISPT commissioned a project to demonstrate how Energy System Modelling (ESM) could be used to explore a set of options for the most effective upgrading of CO-rich waste gas streams produced by a steel manufacturing complex.

2. Energy System Modelling

Energy System Modelling (ESM) is a dedicated application of the more generic network simulation and optimisation algorithm. It is based on a detailed techno-economic description of the conversion of energy flows. ESM systematically explores how to use over a given time horizon optionality in energy resource availability and conversion capacity in order to meet demand for heat, power, mobility and petrochemical products in the most cost-effective manner. An appropriately defined objective function that maximizes the net present value of the energy system whilst obeying CO_2 emission targets supports the evaluation of options how to be best structure the energy system. Scope and granularity for energy system modelling can vary widely: ESM can be applied at country level (Kejun and van der Made, 2014), but also at industrial cluster levels as shown by the example below for a steel manufacturing complex.

3. Mathematics

Energy System Modelling (ESM) is based on a mathematical optimization framework that uses a combination of the mathematical modelling system AIMMS and the mixed-integer solver CPLEX (Lasschuit and Thijssen, 2004). At the heart of ESM lies a Multi-Period Mixed Integer Linear Programming Model designed for strategic value chain studies and supply chain optimization purposes. ESM is a dedicated application of this generic framework with a focus on determining an economically optimal configuration of energy conversion systems such that it meets CO_2 emission targets and energy demand levels given available energy resources.

Mixed-integer Linear Programming (MILP) models have been successful in a vast range of applications. These algorithms evaluate the impact of integer decisions (on-off or 0-1) on the objective simultaneously with continuous variables subject to various constraints. ESM supports the selection and timing of conversion technology investments to meet CO_2 emission targets in the most cost-effective manner. The true value of the implemented mixed-integer linear programming model lies in its multi-period character. In particular, this means that multi-period mixed integer linear programming ensures that from a given set of potential technology investment options, those are selected and timed such that they minimize the total costs over the entire time horizon. This holistic approach avoids "technology lock-in situations" whereby technology options are selected with regrets later on leading to sub-optimal solutions over the time period considered. ESM adopts a complete end-to-end view both on a time-scale as on an infrastructure scale allowing for a fully integrated system optimisation from raw materials, to intermediates, to finished products that serve demand. ESM also allows to model non-linear 'economy of scale' features as multiple capacity choices aligned with relevant line-ups.

Figure 1 outlines the Energy System Modelling framework. Inputs define the structure of the energy system model and include data on various constraints and costs. The structure of the energy system may consist of various feedstock sourcing options, yields for conversion technology options and a distribution network to bring product to markets. Additional data are to be provided to define the optimisation space, such as product demand, CAPEX & OPEX for the conversion options and product distribution costs. Furthermore, the scope of the optimization space is defined by strategic input such as the time horizon considered and a set of scenarios to be evaluated. Simulation and Optimisation return a set of attractive energy system options for further analysis.

The model considers an annual planning horizon where t is the time period index, l the location index, p the conversion technology index, m the mode of operation index, s the stream index, i the investment index and r the investment effect time range index. The integer variable $\iota_{t,r,i}$ specifies the number of investments per investment option i, how many times it is active in period t and r periods after the start period of the investment. With r (relative to start) the aging of a conversion unit is tracked. The continuous variables $\sigma_{t,l,s}$, $\delta_{t,l,s}$, and $\pi_{t,l,p,m}$ denote supply, demand & processing variables for the infrastructure of the system. Processing optimizes the production yields per conversion technology per mode of operation per stream. Input and output yields for the production process are parameters denoted by $IY_{t,l,p,m,s}$ and $OY_{t,l,p,m,s}$. Mass balance constraints ensure that the total inflow equals the total outflow at each node.

$$\sigma_{t,l,s} + \sum_{(p,m)} \left(\pi_{t,l,p,m} * OY_{t,l,p,m,s} \right) = \sum_{(p,m)} \left(\pi_{t,l,p,m} * IY_{t,l,p,m,s} \right) + \delta_{t,l,s}$$
$$\forall t \in T, l \in L, s \in S$$

$PC_{i,r,l,p,m}$ denotes the processing capacity of a conversion unit with an age of r time periods. Cost minimization steers the investment in processing capacity for conversion technologies and determines the optimal set of conversion technologies.

$$\pi_{t,l,p,m} \leq \sum_{(i,r)} PC_{i,r,l,p,m} * \iota_{t,r,i} \quad \forall t \in T, l \in L, p \in P, m \in M$$

The yield structure in the ESM denotes the amount of end products and by-products such as CO_2 generated at each production process in the energy system. A CO_2 abatement pathway can be modelled by assigning a cost per ton CO_2 leaving the energy system. Alternatively, direct emission targets can be defined to limit CO_2 emissions and set additional constraints that guide the model towards selection of the optimal energy system layout for the desired CO_2 abatement pathway. Let $MD_{t,l,s}$ be the maximum flow leaving the energy system, then the CO_2 emission limit is defined as follows.

$$\delta_{t,l,s} \leq MD_{t,l,s} \quad \forall t \in T, l \in L, s \in S$$

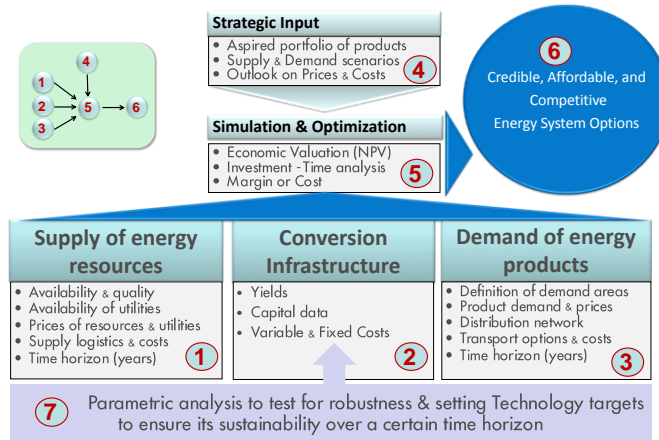
From Figure 1 it can be inferred that the results of the optimised energy system depend on various input factors such as the layout of the system, conversion technology options, capital intensities & operating expenditures, feedstock availabilities & demand figures, which are deterministically modelled. In practice these input factors are of stochastic nature. This demands for sensitivity analyses to cope with the various types of uncertainties that affect the optimal results. Uncertainties emerge in different ways such as multiple scenarios for the outlook on energy supply and demand, technological developments affecting the capital intensities of conversion technologies or policy changes with regard to imposed CO_2 emission penalties. Therefore, the success of the decision-making process not only relies on the availability of a global optimal solution but also on sensitivity checks on the input data to address and confirm the robustness of the proposed optimal configuration of the energy system.


Figure 1: Generic framework for Energy System Modelling

4. Example

Europe produces some 170 million tonnes of steel per year. Significant volumes of waste gas are co-produced, like blast furnace gas (BF) and basic oxygen steel off-gas (BOS). Typically 1,7 tonnes of waste gases are produced per tonne of steel for a world scale plant

producing 7 mln tonnes of steel per year. Apart from a high CO_2 content (40 wt%), waste gases contain high concentrations of valuable components, e.g. 23 wt% of carbon monoxide (CO). The remainder is predominantly N_2. Waste gases are burned to preheat enriched air for the blast furnaces. Waste gases are also used for steam and power generation. The resulting CO_2 footprint is some 1,3 tonnes CO_2 per ton of steel.

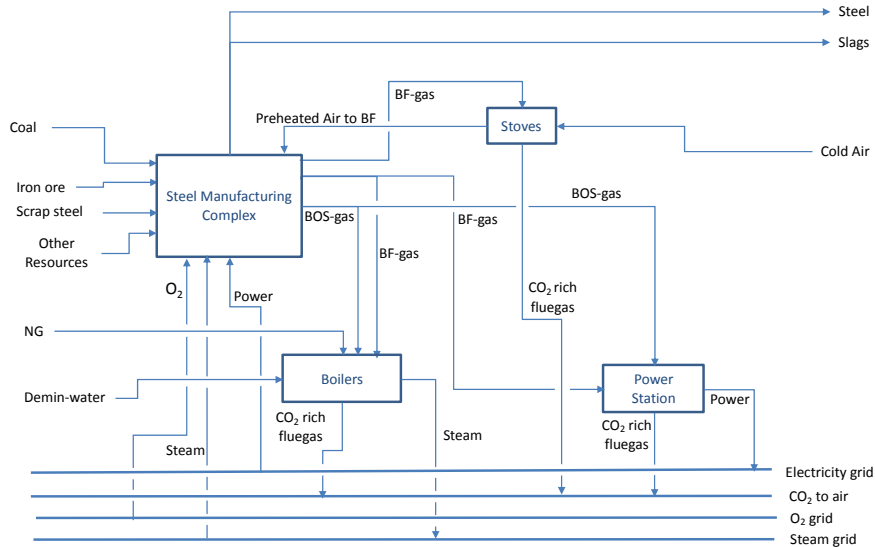
The combustion of CO contained in BF and BOS gas (see Figure 2) results in a major loss of potential value from a circular economy perspective. The recovery and conversion of CO into chemicals is therefore an alternative worthwhile pursuing. This has been studied by the CORESYM project (ISPT, 2017). This example builds on this project.


Figure 2: Base case upgrading waste gases from a steel manufacturing complex

Figure 3 below shows a superstructure of options for the upgrading of CO contained in BF and BOS waste gas into valuable products like Fisher-Tropsch (FT)-naphtha and methanol. The deficit in the amount of hydrogen to achieve this is by water electrolysis, steam methane reforming (SMR) and/or by shifting the H_2/CO content of the BOS gas in a dedicated water-gas shift reactor (WGS) or by buying H_2 from the grid. Furthermore, the superstructure shows a number of CO_2 capture units to ensure that remaining CO_2 volumes are captured and can be fed into a CO_2 grid for (deep-sea) storage. The purpose of this EMS pilot project is to analyse the attractiveness of recovery and conversion of CO into chemicals whilst simultaneously addressing the impact of CO_2-to-Air taxation in combination with a feed-in tariff of 50 $ per ton of CO_2 for a CCS system assumed to be in place. Another task set for the pilot is the development of a CO_2 abatement pathway to meet the 'Paris' goals set for 2030 and 2050 in the most cost-effective manner.

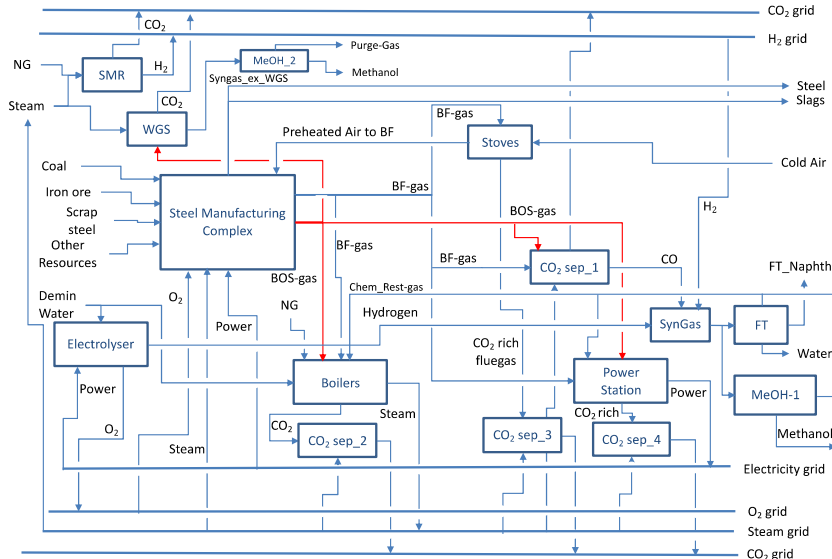
Figure 4 shows the relative attractiveness of the options studied. With CO_2-to-Air priced in accordance with a low ETS (Emission Trading System) price level of 4 $ per ton of CO_2, ESM identifies the recovery and conversion of CO into methanol (1350 ktpa methanol) with H_2 to be supplied through Steam Methane Reforming as most profitable (bar at the right).


Figure 3: Options for the upgrading of waste gases steel manufacturing complex

Apart from a higher NPV, this option also lowers the CO_2 emission level of the reference case by some 12,5% from 9250 ktpa CO_2 to 8080 ktpa CO_2. This is due to the rerouting of the BOS and BF streams for methanol and hydrogen production and the elimination of NG imports to the boilers. This results in steam and power imports to meet all process requirements. Adjacent steam and power units allow for these imports. The resulting shift of CO_2 emissions to air to outside the complex is not accounted for.
Figure 4: Relative attractiveness of CO monetisation options

Would CO_2 emissions to air be taxed at 100 \$/ton, the most attractive CO-conversion option remains the methanol option. At this 100 \$/ton CO_2 penalty, ESM concludes that it would be more cost-effective to invest in CCS facilities (and capture 50\$ benefit per ton of CO_2) rather than enlarging methanol or FT-naphtha production (the amount of CO contained in the waste gases allows for the production of either 2500 ktpa methanol or 900 ktpa FT-naphtha). FT-naphtha and methanol are feedstocks for Base-Chemicals.

Figure 5 shows the CO_2 abatement profile with the CO_2-to-Air penalty set at 0 \$/ton. In order to meet the 50% CO_2 reduction target in 2030 (50% relative to 2017, taken as Reference Year) investments are needed for the separation of CO_2 and CO from the BF and BOS waste gases, the production of Blue H_2 (e.g. through steam-methane-reforming

while capturing and sequestering CO_2), the synthesis of methanol and treatment of flue gas ex boilers for CO_2 capture. Apart from the latter investment (taken in 2030), all other investments are advised to be taken in 2020. To meet the 95% reduction target in 2050 (again relative to 2017, taken as Reference Year), CCS investments are needed in 2050 for Power unit and Stoves. Timing of investments is optimal from an NPV perspective.
Figure 5: CO_2 abatement curve for steel manufacturing complex

5. Conclusions

ESM is a powerful decision support tool to assess the cost effectiveness of options for the upgrading of CO contained in waste gases from a steel manufacturing complex whilst simultaneously reducing its CO_2 emission footprint. Upgrading of CO into methanol is both economically attractive and it lowers CO_2 production by some 12,5%. This scenario assumes that CO_2-to-Air emissions are not subjected to any tax. In case 100 $/ton tax would be levied on CO_2-to-Air emissions, methanol remains the preferred upgrading option. Assuming a CO_2 sequestration grid in place with a feed-in tariff of 50 $/ton of CO_2, ESM shows that capturing and sequestering all CO_2 is economically preferred over increasing methanol production.

ESM supports the development of CO_2 abatement profiles defining which investments over time are needed to meet CO_2-to-Air emissions targets as set by the Paris agreement in the most cost-effective manner.

Are renewables really that expensive? The impact of uncertainty on the cost of the energy transition

Abstract

The dramatic evidence of climate change is making the transition to more renewable energy systems an urgent global priority. As energy planners normally look 20-50 years ahead, it is crucial to consider the key uncertainties stemming from inaccurate forecasts (e.g. of fuel prices, investment costs, etc.) in energy models to ensure making robust investment decisions. Nonetheless, uncertainty is to date seldom accounted for in energy planning models.

In this paper, we challenge the general perception that the transition to a more renewable energy system always comes at a higher price; to do this, we analyze the impact of uncertainty on the cost of this transition for a real-world national energy system. Concretely, we first generate a set of energy planning scenarios with increasing renewable energy penetration (REP); in a second stage, we perform an uncertainty analysis to compare the cost of these scenarios and thus to determine the significance of the difference in their total cost in presence of uncertainty. Our results show that increasing the amount of renewable energy in a national energy system is not necessarily associated to a higher cost, and can even lead to a cost reduction for some specific realizations of the uncertain parameters.

Keywords: Energy planning, Uncertainty, Energy transition, Mixed-integer linear programming

1. Introduction

The Earth is warming up at an alarming pace. Most countries have agreed on ambitious goals for reducing the human impact on the climate (Rogelj et al., 2016) and have started to make plans for a transition towards more sustainable systems (Kern and Rogge, 2016). A major part of this *energy transition* is related to an increased use of renewable energy sources (RESs). Many authors have thus used energy models to evaluate the impact of an increased share of RESs in energy systems planning. Jacobson et al. (2015) investigated the feasibility and cost of a fully renewable-powered system for the United States and concluded that, when externalities are accounted for, such system would be less expensive than a traditional energy system; Schill (2014) performed a similar analysis for the German energy system with the objective of achieving 86% REP by 2050, showing that this can be done with a relatively limited investment in energy storage capacity as long as a higher flexibility in the operation of fossil power plants is allowed.

Despite these results, and despite the fact that today there are several technological options for a cost-competitive generation of renewable energy, the public opinion often still perceives RESs as being far more expensive than fossil fuels. As an example, Ntanos et al. (2018) report the results of a recent survey in Greece, in which the respondents identified in the "high installation costs" the main reason for not using RESs. In this paper, we challenge this general perception. The main
Figure 1: Modeling flowchart

contribution of our work compared to the literature is the consideration of multiple sources of uncertainty in the analysis. In fact, the main shortcoming of most works proposed in the literature lies in the use of "deterministic" models, which do not consider uncertainty and assume that long-term forecasts for the key parameters (e.g. fuel prices) are correct. However, long-term forecasts are inevitably inaccurate (Moret et al., 2017), and thus it is crucial to consider uncertainties in long-term energy modeling (DeCarolis et al., 2017; Mavromatidis et al., 2018).

In this paper, we propose an analysis of the cost and investment decisions for different degrees of REP in an energy system, with a particular focus on the impact of uncertainty in the process, taking the national energy system of Switzerland as a real-world case study. The methodological approach is shown in Figure 1. First, we model the Swiss energy system using the Swiss EnergyScope (SES) framework (Moret et al., 2014; Codina Gironès et al., 2015). SES, which we describe in Section 2, is a mixed-integer linear programming (MILP) model, which identifies the optimal investment and operation strategy to minimize the total annual cost of the energy system. In a second phase, the model is used deterministically (i.e. with all parameters at nominal values) to determine the optimal energy planning scenarios under increasing shares (ε_i) of RESs (Section 3). Third, the impact of uncertainty is evaluated: for each of the previously obtained scenarios, the investment strategy is fixed and the total cost of the system is evaluated with a Monte-Carlo based approach, considering as uncertain parameters all the costs, the discount rates and the lifetime of technologies. This allows to perform an uncertainty analysis of the solution (Section 4).

2. The energy model

The paper is based on the SES model, a framework for the strategic energy planning of the Swiss energy system. In particular, in this paper we use the open-source MILP version of the model by Moret (2017)[1]. It is a representative model of an energy system, including electricity, heating and mobility: given the end-use energy demand, the efficiency and cost of energy conversion technologies, the availability and cost of energy resources, the model identifies the optimal investment ($\mathbf{F}$) and operation ($\mathbf{F_t}$) strategies to meet the demand and minimize the total annual cost of the energy system. In comparison to other energy models, which often consider hourly timesteps and multi-stage investment plans, it has a lower level of detail, but it offers a reasonable trade-off between CPU time and accuracy; in particular, its multiperiod monthly formulation allows accounting for the main dynamics of concern in energy systems planning, such as seasonal variations, long-term energy storage management, and uncertainties in loads and renewable production.

The objective of the SES model is to minimize the annual total cost $\mathbf{C_{tot}}$ expressed by the sum of the annualized investment cost ($\mathbf{C_{inv}}$), of the annual operational costs ($\mathbf{C_{op}}$) and of the annual maintenance cost ($\mathbf{C_{maint}}$) (1).

$$\min \mathbf{C_{tot}} = \min \left(\sum_{j \in \mathscr{E}} \mathbf{C_{inv}}(j) + \sum_{j \in \mathscr{E}} \mathbf{C_{maint}}(j) + \sum_{r \in \mathscr{R}} \sum_{t \in \mathscr{T}} \mathbf{C_{op}}(r,t) t_{op}(t) \right) \tag{1}$$

[1]Model available at `https://github.com/stefanomoret/SES_MILP` and fully documented in (Moret, 2017)

where the sets $\mathcal{E}$, $\mathcal{R}$ and $\mathcal{T}$ represent the technologies, the resources (renewables and non-renewables as well as electricity import) and the time periods (months) respectively. $t_{op}(t)$ denotes the duration of the period t. The main constraints are the energy and resource balance in each period; the limited availability of resources; the capacity factor of different energy conversion technologies; the limits to the maximum installed capacity of different technologies; and the limits to grid capacity (accounting for the additional investments linked to a higher penetration of stochastic renewables).

In this paper, we modify the model presented by Moret (2017) as follows: *i*) we allow individual technologies to cover the full share of the demand in their sector, e.g. electric vehicles can satisfy all the private mobility demand ($f_{min,\%}(j) = 0$, $f_{max,\%}(j) = 1 \; \forall j \in \mathcal{E}$); *ii*) we allow freight transport to be fully satisfied by trains; *iii*) we impose the phase out of nuclear energy, in agreement with the Swiss energy strategy.

3. Deterministic energy planning

In addition, in order to quantify and to constrain the impact of RESs, Eq. (2) is added to the model formulation.

$$\sum_{r \in \mathcal{R}_{RES}} \sum_{t \in \mathcal{T}} \mathbf{F_t}(r,t) t_{op}(t) \geqslant \varepsilon \sum_{r \in \mathcal{R}} \sum_{t \in \mathcal{T}} \mathbf{F_t}(r,t) t_{op}(t) \tag{2}$$

where the parameter ε represents the minimal renewable penetration ratio in the energy system and the set $\mathcal{R}_{RES}$ is a subset of $\mathcal{R}$ composed of all renewable resources (solar, wind, wood, hydro, geothermal, synthetic natural gas, bioethanol and biodiesel). In Eq. (2), $\mathbf{F_t}(r,t)$ stands for the utilization of resource r at period t. In this paper we analyze 11 scenarios with different values of the ε parameter, ranging from 0 % to 90 % with 10 % steps, plus the "maximum REP" scenario with $\varepsilon = 95 \%$.

The energy mixes of the resulting 11 scenarios are shown in Figure 2. It should be noted that scenarios 1, 2 and 3 are equivalent, due to the fact that the REP in the unconstrained (i.e. with 0 % minimum REP) case is approximately 20 %. Among the RESs, wind and (new) hydro-power are the most competitive from a cost perspective and reach their maximum potential at a REP level of
Figure 2: Renewable energy production and storage capacity in different REPs
Figure 3: Sankey diagram for energy flows in 95 % REP scenario [TWh]

60 %. The use of solar energy emerges in the optimal solution only starting from a REP of 50 %, and it is only used extensively for REP ≥ 70 %. Wood is only used in very high REP scenarios, due to its high assumed cost in the model. The results of the deterministic optimization also show that the required storage capacity is relatively limited: hydro-electric storage reaches its peak in the 40 % REP scenario, at a value approximately 35 % higher than the base case, while power-to-gas is only activated in the 95 % REP scenario, allowing to reach a total seasonal storage capacity of approximately 4,000 GWh. Note that, due to the monthly resolution of the model, here dynamic storage technologies for balancing in-time supply-demand at a daily or more fine time resolution (such as batteries) are not considered. This choice is motivated by computational reasons.

How does an almost completely renewable-based energy system look like? This is shown in Figure 3, where the energy flows in Scenario 11 are represented. As expected, the demand is dominated by the use of electricity, with the exception of part of the high-temperature heat demand (provided by biomass boilers) and of the low-temperature heat demand (provided by thermal solar and by geothermal heat). The use of boilers and gas-driven heat pumps for low-temperature heat is completely discontinued, substituted by electric heat pumps.

4. Uncertainty analysis

As highlighted in the Introduction, the problem of strategic energy planning is subject to a high degree of uncertainty, which should not be neglected. In this article, we consider five main uncertainty categories: interest rate, investment cost, maintenance cost, resource prices, and technology lifetime. In the SES model, this translates to a total of 157 uncertain parameters. We assume that all these uncertain parameters are uniformly distributed between their lower and upper bounds, adopting the methodology and the uncertainty ranges defined by Moret et al. (2017).

In the uncertainty analysis, the decision variables related to the installed capacity of each technology, and the energy utilization for each mobility technology in each period are fixed to the optimal values calculated in the deterministic optimization for each scenario ($\mathbf{F}^*$ and $\mathbf{F_t}^*$, respectively). Then, for each of the 11 scenarios, the SES model is run for different realizations of the uncertain parameters with a Monte-Carlo approach. This corresponds to a situation where a decision for the strategic energy planning has been taken, and we aim to analyze the cost of the application of that specific strategy with different values for the uncertain parameters, corresponding to different
Figure 4: Nominal and uncertain mean total cost
Figure 5: Nomalized total cost distribution

possible future scenarios. A total of 3,000 Monte-Carlo simulations (based on an observed convergence after 2,600 simulations) is run for each scenario.

In the Swiss energy system, a large share of the total annual cost (equal to 6,654 MCHF/y) derives from fixed costs, i.e. costs which are equal for all the solutions (such as the investment cost of existing hydroelectric power plants, of the electricity grid and of energy efficiency measures). In the simulation runs, we fix these costs to zero; this means that we do not consider them as uncertain in the simulations, but we add them to the simulation results at their nominal values.

Figure 4 shows the results of the uncertainty analysis. It can be osberved that the mean total cost values obtained by Monte-Carlo simulations are consistent with the deterministic results for each scenario, as in both cases the total cost increases with ε. However, the results also show that there is a high uncertainty in the total cost of the system for all REP levels, leading to a relatively high overlap between the different distributions (Figure 5). This can lead to the conclusion that, while on average increasing the share of renewable energy beyond 20 % involves a higher cost for the system, this is not necessarily true once uncertainty is accounted for.

A higher REP has also an impact on the variance of the total cost (Figure 6): given the high uncertainty on the price of different fossil fuels, excluding them from the energy mix generates a clear reduction in the uncertainty of operational costs. In contrast, the uncertainty on the investment increases, partially balancing the previous effect, as a consequence of both the larger uncertainty of the investment cost of technologies activated with higher REP, and of the overall higher investment cost of the system, which amplifies the uncertainty related to the interest rate. Overall, it can be concluded that cost uncertainty decreases when the share of RES increases.
Figure 6: Total cost standard deviation breakdown

	Penetration of renewable energy

Cost increase wrt to base scenario

Figure 7: Probability of total cost increase for different REP scenarios

Figure 7 shows the percentage of Monte-Carlo simulations where a given REP scenario was more expensive than the base case by a certain amount. An energy system with 70 % REP was less than 20 % more expensive than the base case in 76 % of the simulations, and in 12 % of the simulations it was actually less expensive than the base case. Even the 95 % REP case was, in most (78 %) cases, no more than 50 % more expensive than the baseline case, while the less ambitious 50 % REP scenario is at most 10 % more expensive than the baseline. These results are in accordance with what previously published in the academic literature (e.g. Jacobson et al. (2015)), and the cost difference is expected to be even lower if the external costs were included in the analysis.

5. Conclusions

Are renewable really that expensive? Based on the work that we present in this paper, the answer is that yes, a renewable-based energy system will most likely be more expensive than one where we apply no constraint on the share of renewable energy, but not always, and not by much. Furthermore, a renewable-based energy system will be, overall, inherently more robust against unexpected developments, particularly with respect to fluctuations in fuel prices.

The results of our uncertainty analysis, in fact, reveal that the variance in the total cost of the system is high, and of the same order of magnitude of the average cost difference between different scenarios. This suggests that, when considering uncertainty, increasing the amount of renewable energy in a national energy system is not necessarily associated to a higher cost, and can even lead to a cost reduction in some specific realizations of the uncertain parameters. These results are of particular value to energy planners, as they challenge the common perception of a very high cost related to the energy transition towards a renewable energy-based system. While these conclusions are drawn based on a specific case study (the Swiss energy system), we consider that they are sufficiently general to be applicable to other countries.

Abstract

Technology and energy saving potentials in the industrial sector are key data that policy makers rely on to drive decision making. A literature review reveals a distinct discrepancy between *general potential estimation* and *detailed design* studies. The former relies principally on top-down conceptual approaches based on temperature levels of the processes' thermal requirements, while the latter aims at mathematically optimized solutions for specific technologies in specific processes under specific economic conditions.
This work attempts to close this gap by proposing a bottom-up method for potential estimation of energy saving measures. To this end, a generalized optimization framework was developed which aims at generating a database of optimal solutions which are independent from most economic and environmental input data. By fixing these data, the optimal solution for the same process type in different countries and under various criteria can be identified in the database. The method also increases accessibility of optimization techniques by providing the solution database which then requires limited input parameters and background knowledge to provide expert guidance toward optimal utility integration. The method was applied to the dairy industry, highlighting that energy saving potentials can be achieved through heat recovery and integration of heat pumps, mechanical vapor re-compression, and co-generation units economically favourable especially in Japan and Switzerland.

Keywords: dairy industry, heat pump, co-generation, MINLP, mathematical programming, generalized optimization

1. Introduction

Constant efforts are undertaken to estimate energy saving and technological potentials in the industrial sector. Such analyses are used to formulate policy recommendations, determine target markets, and advance technological development. A state-of-the-art analysis is introduced concerning both *general potential estimation* and *detailed design* studies, before highlighting the contribution of this work and the outline of the study.

General potential estimation: This section concerns studies which aim at estimating energy saving potentials in the industrial sector. Most such studies are based on top-down approaches relying mainly on the temperature levels of the thermal requirements in certain industries and with specific technologies. Concerning heat pump integration, Wolf et al. (2014) presented a study which focused on the German low temperature sectors, estimating the overall energetic potential of heat pumps used as hot utilities. Similarly, Brückner et al. (2015) performed such an analysis for the European industrial sector with compression and absorption heat pumps. For other technologies, analogous studies have

been conducted by Lauterbach et al. (2012) (solar thermal) and Campana et al. (2013) (organic Rankine cycles), as representative examples.

Though top-down approaches offer a clear and simple approach to estimate general potentials, conclusions drawn from such analysis may be misleading. Firstly, they account only for hot utility requirements neglecting the double impact of certain utilities (especially heat pumps) according to the 'more in, more out' principle of pinch analysis. Secondly, they do not consider possible process improvements and efficiency measures such as internal heat recovery.

Bottom-up approaches have also been presented by Wilk et al. (2017) who analyzed different process types and the heat pump integration potential for a set of energy price ratios, and Müller et al. (2014) who suggested an approach for solar thermal integration to the liquid food industry based on the available land surface area and process temperature levels. These approaches are often limited in their scope (in terms of economic and environmental boundary conditions) and lack rigorous methods.

Detailed design: Various detailed design studies are present in academic literature and typically focused on few technologies and processes. Studies by Kamalinejad et al. (2015), Yang et al. (2017), and Becker (2012) presented optimal integration approaches of heat pumps in different industrial processes relying on mathematical programming and superstructure-based design. Most recently Wallerand et al. (2018) presented a comprehensive heat pump integration method based on mathematical programming and expert insight. For organic Rankine cycles, superstructure-based approaches are also common, such as presented by Yu et al. (2017) and Kermani et al. (2018).

Though such approaches offer rigorous solutions to complex problems, the scope of treated problems is usually limited to specific processes, technologies, and economic and environmental boundary conditions.

Synthesis: The state-of-the art analysis can be summarized in two points.
1. Potential studies are either conducted coarsely by top-down approaches, or in a non-rigorous and limited in scope with bottom-up analyses.
2. Detailed design studies provide rigorous methods, however limited to specific conditions.

This work attempts to bridge this gap by suggesting a bottom-up method for potential estimation of energy saving measures through heat recovery and technology integration. The methodology is presented in section 2, followed by the results in section 3 presenting the solutions for various perspectives (from policy-makers to plant managers). The work is summarized and critically reviewed in section 4.

2. Methodology

The methodology presented in this work aims at reducing computational time while producing a large set of feasible and potentially 'good' solutions. The expensive optimization problem is therefore solved once, independent from most input parameters and its solutions are stored in a database from which a large number of scenarios with varying input conditions can be derived. An overview of this approach can be seen in Figure 1. The approach is clarified below in more detail.

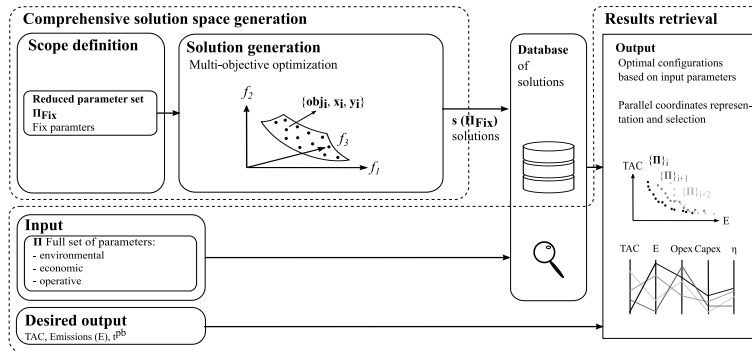
Comprehensive solution space generation: The goal of this part is to formulate an op-


Figure 1: Bottom-up method for potential estimation.

timization problem independent of most typical input parameters. Usually the objectives of main interest for such analyses are the *total annual system cost (TAC)* and/or the *total emissions*. Both of these objectives require a wide range of input parameters ranging from economic (energy prices, investment cost parameters, interest rate, CO_2 tax, maintenance cost), operative (operating time), process specific (product mass flow rates, specific requirements), equipment specific (lifetime, efficiency, fuel consumption) to emissions associated with electricity and natural gas consumption (environmental parameters). Even though the final objectives are *total system cost* and/or the *total emissions*, a different set of objectives is selected at this stage, which requires fewer input parameters with the goal of generating a large set of potentially optimal solutions. The choice of objective depends on the exact goal of the study. In this case, the focus was placed on national differences, which have a drastic effect on energy prices, interest rates, and environmental parameters.

Therefore, the new set of objectives was defined as *consumption* of all resources and *investment cost (capex)*, which requires less input parameters to be fixed. The choice of the new set of objectives requires engineering common sense and needs to be carefully adapted to each problem. The new objectives are fed to a multi-objective optimization framework, similar to the one described by Wallerand et al. (2018) and Weber et al. (2007) to generate a set of solutions. The solution space generation needs to be carried out only once and requires a few days of computational effort.

Database: Depending on the number of objectives, the previous step generates a multi-dimensional surface of solutions. In this study, the resource consumption was distinguished between electricity and natural gas consumption, which led to a total of three objectives. Upon successful completion of the optimization, all solutions and the corresponding values of their decision variables (solution properties) can be stored in a database for later access and evaluation.

Results retrieval: The results retrieval procedure works in two steps: Initially, a solution together with its entire set of properties is retrieved. Subsequently, knowing the optimal values of each decision variable, a user can evaluate the original objective function as well as any other indicators given a new set of parameters (e.g. energy prices, operating time, CO_2 tax). This leads to a new set of objective values among which the user can identify their preferred choice. In this case, the lowest cost and lowest emission solutions were selected. This step is accessible without knowledge of optimization algorithms thus encouraging utilization of such methods by a variety of audiences which is briefly demonstrated in section 3.3. The results retrieval has been implemented in a tool, which can be found online.

3. Results

3.1. Case study

The underlying case study of this section is a dairy plant as presented by Kantor et al. (2018) with a two-stage refrigeration cycle, free cooling water (from a nearby river) and an existing boiler. The heat pump superstructure suggested by Wallerand et al. (2018) with various fluids and a co-generation engine (Becker (2012)) were studied as potential new technology options. Decision variables were the heat pump fluids, temperature levels, and number of stages, as well as the T_{min} of the heat recovery in the process. The heat exchanger network cost was graphically approximated as proposed by Townsend and Linnhoff (1984).

3.2. Comprehensive solution space generation

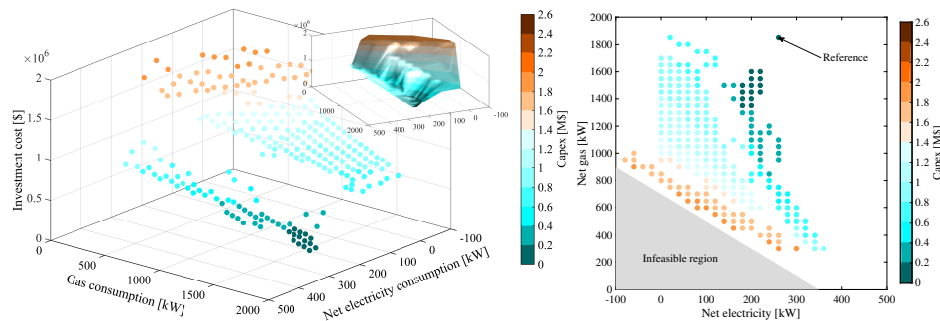
The three-dimensional surface of solutions resulting from the multi-objective optimization described in section 2 is shown in Figure 2. It can be seen that points closest to the reference case have lowest capital expenses (capex), while lower electricity and/or natural gas consumption necessitates an increase in capex.


Figure 2: Solutions from multi-objective optimization considering consumption of natural gas and electricity with the corresponding investment required.

3.3. Results retrieval

The retrieval of results is illustrated in Figure 3 for the three exemplary countries, namely Switzerland (CH), Germany (DE), and the United States of America (US). The countries were selected due to their different economic and environmental conditions, as illustrated in the figure, ranging from a high natural gas price and low electricity/natural gas ratio in CH to a low natural gas price and high electricity/natural gas price ratio in the US. The total emissions and TAC are calculated for each solution in the database, but only the minimum cost solutions are selected (indicated with grey circles).

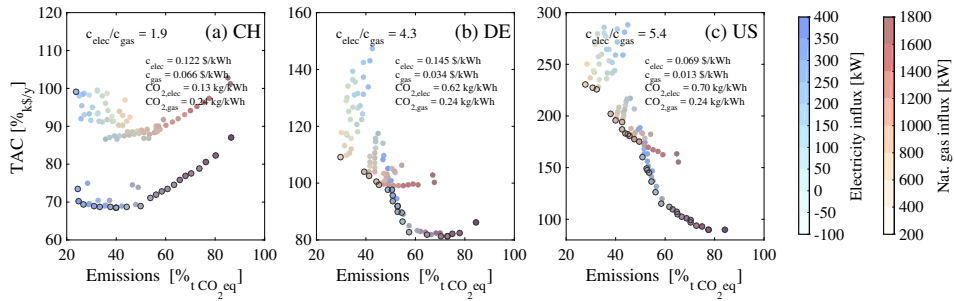
Plant operators: The minimum cost points from Figure 3 are depicted with more cost details in Figure 4, indicating the potential interest of a plant operator in reducing energy-related costs or emissions. CH is visibly the country with highest potential where up to 70% emission reductions could be achieved with heat recovery (firstly), with heat pumping providing options with payback times below 5y. This is in stark contrast to the US context where solutions are not economically attractive compared to the reference case. Here, and in DE, the highest emission reductions can only be achieved with heat pumps and co-generation units, due to the high emissions related to generation of electricity.


Figure 3: Results retrieval: minimum cost solutions, 8000 h/y operation, 0 $/t CO_2.
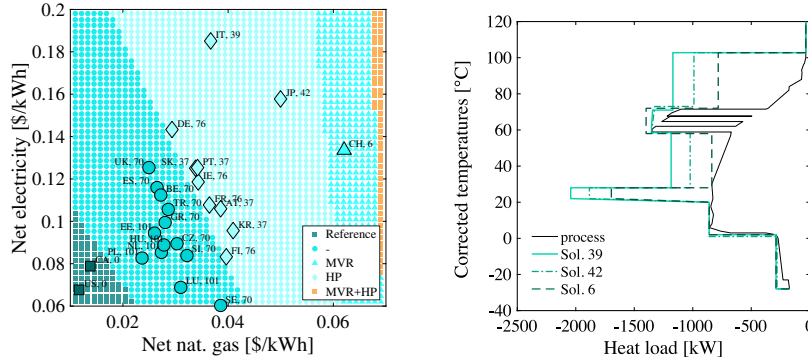
Figure 4: Minimum cost solutions for operating time 8000 h/y, 0 $/t CO_2.


Figure 5: Utility map for operating time 2500 h/y (left), 0 $/ton CO_2; composite curves of solutions for Italy, Japan and Switzerland (right).

Policy-makers: Another type of analysis can be conducted for policy-makers as shown in Figure 5. With this analysis, the lowest emitting solution for each country (resource price) is selected with a payback time below 3 years. The countries with highest resource prices (Italy (IT), Japan (JP) and Switzerland (CH)), have the highest heat pump potential. The other solutions are principally based on improving process heat recovery to achieve the potential reduction in consumption.

4. Conclusions

This work proposes a bottom-up method for potential estimation of energy saving measures. To this end, a generalized optimization framework was developed based on multi-objective optimization which aims at generating a database of optimal solutions which are

independent from most economic and environmental input data. By fixing this data, the optimal solution for the same process type in different geographical, economic and environmental contexts are retrieved from the database to address various objective criteria.

The method was applied to the dairy industry investigating energy saving and technological potentials through heat recovery and utility integration with heat pumps, mechanical vapor re-compression, and co-generation units. A set of countries was determined in which industrial heat pumping is particularly beneficial from environmental and economic perspectives, namely: Switzerland, Japan, and Sweden. Use cases for plant operators and policy-makers were briefly demonstrated and a variety of additional analyses could be conducted using the solution database; one such example was briefly presented.

Analysis of the Tri-Reforming of Methane in a Membrane Reactor

Samuel S. Q. Jardim, José E. A. Graciano and Rita M. B. Alves[*]

Universidade de São Paulo, Escola Politécnica, Department of Chemical Engineering, Avenida Prof. Luciano Gualberto, trav. 3, 380, São Paulo, 05508-010, Brazil
rmbalves@usp.br

Abstract

This paper analyses the tri-reforming of methane as a reactive way to use natural gas rich in carbon dioxide, without a previous separation. The tri-reforming of methane (TRM) produces syngas suitable for GTL processes and also avoids coke deposition, depending on specific process conditions. For this reason, a thermodynamic analysis was conducted to investigate the possible operating regions to avoid coke formation; then, an operating point was determined by maximizing the CO_2 conversion at a fixed H_2: CO ratio. The given results suggested that the use of large amounts of oxygen are necessary to overcome the coke formation and to increase the syngas yield. In those conditions, the reactor may present hot spots that damage the reactor catalyst. A porous membrane reactor that distributes oxygen along the reactor dropped the sharp thermal profile; the hot spot was mitigated, obtaining 94 % of methane and 30 % of carbon dioxide conversion.

Keywords: membrane reactor, tri-reforming of methane, carbon dioxide, syngas.

1. Introduction

Natural gas is one of the most available sources of energy and a feedstock to the chemical industry. However, in many exploitation sites, the high content of the associated carbon dioxide increases the production cost. For example, in the new Brazilian petroleum off-shore fields, the associated CO_2 is usually between 8 and 18 % and, in some cases, up to 79 % (Gaffney et al., 2010). The elevated CO_2 content in NG requires separation previously to its commercialization, increasing the energy requirement and the production cost. An alternative to mitigate this problem is to use the associated CO_2 as a constituent block to produce added-value products, by combining CO_2 and CH_4 to produce syngas.

Tri-reforming of methane (TRM) is a synergetic combination of Steam Methane Reforming (SMR: $CH_4 + H_2O \rightleftharpoons 3\,H_2 + 1\,CO$), Dry Reforming (DMR : $CH_4 + CO_2 \rightleftharpoons 2\,H_2 + 2\,CO$) and Partial Oxidation of Methane (POM: $CH_4 + 0.5\,O_2 \rightarrow 2\,H_2 + 1\,CO$), able to convert both methane and carbon dioxide into syngas. The POM is an exothermic reaction which provides energy for endothermic SMR and DMR. As a result, TRM can operate adiabatically, unlike conventional reformers, which demand external heat. Moreover, the coke formation is mitigated due to the introduction of oxygen when compared to DMR and SMR processes. Despite several thermodynamic studies in the literature, less attention has been paid to industrial pressures (> 20 bar) and none to adiabatic conditions. As a result, the benefits reported, such as CO_2 conversion over 90 % (Zhang et al., 2014), might not hold true at industrial conditions. The equilibrium analysis in these conditions

is a good alternative to determine the best operating point for the membrane reactor and to verify if the TRM is: (i) able to efficiently convert the carbon dioxide and (ii) suitable for the downstream process in a GTL plant.

Additionally, the presence of fast and exothermic reactions makes the reactor design challenging, creating hot spots that can damage the reactor materials and threaten the process viability. For example, Arab Aboosadi et al. (2011) optimized a TRM reactor for hydrogen production but obtained a hot spot near to the melting point of nickel (1455 °C), which can easily deteriorate the catalyst activity. The use of a membrane to distribute oxygen along the reactor can be a promising technology to better control the kinetics and the temperature profile of the TRM, as initially proposed by Rahimpour et al. (2012). However, the requirement of large permeation fluxes and severe operating conditions promote the use of porous membranes in detriment of the perm-selective ones. Indeed, α-alumina membranes may be an interesting choice for this application, since they are chemically stable and their permeability can be easily adjusted to a required value (Alibrando et al., 1997; Coronas and Santamaría, 1999; Godini et al., 2014).

In the present work, the TRM is investigated over a large range of feed composition, for an adiabatic operation at 25 bar, aiming to increase the syngas production from a CO_2-rich NG. The initial thermodynamic analysis is conducted using a simplified equilibrium reactor to determine the operating condition that maximizes the CO_2 conversion, syngas yield and prevent coke formation. After that, the obtained optimum operating point is applied to study the behaviour of a phenomenological membrane reactor, in which the ideal oxygen distribution over the membrane is determined by a sensitivity analysis.

2. Modelling

The thermodynamic analysis is performed to convert CO_2-rich natural gas (CO_2: CH_4 = 0.5) into syngas. This process was simulated by an equilibrium reactor model (*RGibbs* in Aspen Plus V8.8®), considering seven gaseous species (CH_4, CO_2, H_2O, O_2, CO, H_2, N_2) and solid carbon (C), subjected to the elemental balance at constant pressure (25 bar) and isenthalpic operation (adiabatic). The thermodynamic behaviour of the fluid was predicted by the Peng-Robson equation of state. A parametric analysis is conducted to evaluate the influence of water and oxygen ratio (H_2O: CH_4, O_2: CH_4) in four defined metrics, namely: coke yield (Y_{coke}), syngas yield (Y_{syngas}, eq. 1), CO_2 conversion (X_{CO_2}) and syngas quality (H_2: CO).

$$Y_{syngas} = \left[(F_{H_2}^{out} + F_{CO}^{out}) - (F_{H_2}^{in} + F_{CO}^{in}) \right] / (4 F_{CH_4}^{in}) \tag{1}$$

After that, the operating point for the membrane reactor was determined by maximizing the CO_2 conversion, subjected to: syngas ratio equal to 1.6; syngas yield greater than 70%; absence of solid carbon (coke); and inlet and outlet temperature limited to 900 and 1000 °C, respectively. The set of independent variables was defined as: the inlet composition of oxygen, water and feed stream temperature. The stated optimization problem was solved with the SQP method implemented in Aspen Plus V8.8®.

The first-principle membrane reactor was modelled as a packed bed tube with an inert porous membrane wall. Oxygen was fed through both feed stream and membrane, from an outer compartment (shell). On the proposed shell side, the oxygen was fed at 900

°C and 29.5 bar. The reactor had 6 m in length, 0.1 m in inner diameter and 0.43 in bed porosity. The nickel catalyst had 0.015 m in diameter and 2100 kg/m^3 in density. The TRM kinetics were the same used in Arab Aboosadi et al. (2011). The permeation through the α-alumina porous membrane was modeled by Darcy's equation (eq. 2a) for flow in porous media ($B_0 = 2 \times 10^{-16}$ m^2 and $\delta_{membrane} = 1.5$ mm) and the pressure drop was determined by Ergun's equation (Salehi et al., 2016).

$$J_{O_2} = \frac{B_0\, \rho_{gas}}{\mu\, \delta_{membrane}}(P_{shell} - P_{tube}) \tag{2a}$$

$$\frac{dF_i}{dz} = A_t \rho_{bed} \sum^q v_i r_q + J_{O_2}\, \pi D \tag{2b}$$

$$\frac{dH_{total}}{dz} = J_{O_2}\, \pi D h_{O_2} \tag{2c}$$

A plug-flow regime was assumed with uniform concentrations in the cross-section area. Additionally, no heat conduction is accounted trough the wall (membrane). The resulted 1D-pseudo-homogenous model (eq. 2) was implemented in Aspen Custom Modeler® (ACM). The system of differential algebraic equations was discretized by backward finite difference method with 300 internal nodes, resulting in a system with (75,156) algebraic equations, solved by a Newton-like method.

3. Results and Discussion

3.1. Thermodynamic analysis

Coke production is one of the major problems encountered in industrial reformers. It is responsible for catalyst deactivation, requiring a high proportion of steam to methane in the feed stream (between 2 to 3). Tri-reforming requires less water due to the presence of a stronger oxidant - O_2. As observed in Figure 1(a), the minimal oxygen amount to mitigate the coke formation is above 40 %. For oxygen feeds below this proportion, more water is required.

The syngas yield is positively affected by both water and oxygen (Figure 1(b)), due to the SMR and the raise of the adiabatic temperature. The yield is more sensitive to oxygen, growing up to a maximum of 0.73 for 55 % of oxygen (O_2:CH_4) and 100 % of water (H_2O:CH_4). The excess of oxygen is also responsible for a decrease in the syngas selectivity, as a result of the higher conversion of methane into carbon dioxide and water (total combustion). In conclusion, both coke and syngas yield profiles stress that a high proportion of oxygen is required for adiabatic operation at 25 bar. However, this imposes a challenge to the reactor design because this high content of oxygen might produce temperatures over the safe operating limits.

The syngas ratio (H_2: CO) grows with water (Figure 1 (c)), as a result of the higher syngas ratio provided by the SMR. On the other hand, it decreases with oxygen, due to the rise of the adiabatic temperature, favoring the DMR. Within the coke free region, the syngas ratio tends to be lower than 2.0. Consequently, more water is needed (> 100 %) to attain syngas ratios stoichiometrically suitable for methanol and Fischer-Tropsch plants (around 2). As observed in Figure1(d), the carbon dioxide conversion is more influenced by steam
Figure 1: TRM thermodynamic equilibrium analysis at 25 bar, 900°C and 50 % of CO_2: CH_4

than oxygen, due to the presence of the water-gas-shift reaction ($H_2O + CO \rightleftharpoons CO_2 + H_2$). By simultaneously comparing the syngas ratio and CO_2 graphs it is possible to observe a trade-off (Figure1 (c),(d)). If syngas ratios of 2 or higher are desired, the corresponding CO_2 conversion is low. Conversely, in order to convert the most of the CO_2, the syngas ratio should be the lowest possible. In other words, the maximum conversion of CO_2 is at an active constraint on the syngas quality, which is set at a minimum value of 1.6 (a useful value for some special schemes of Fischer-Tropsch synthesis (Graciano et al., 2018)).

The described optimization found an optimum operating point with the inlet composition of $CH_4 : CO_2 : H_2O : O_2 = 1 : 0.5 : 0.679 : 0.4522$, at 900 °C and 25 bar. This condition resulted in conversions of 31.2 % of CO_2 and 93 % of CH_4 with 71 % of syngas yield, as indicated by the asterisk shown in Figure 1.

3.2. Membrane Reactor

Since a large amount of oxygen is required for adiabatic operation, it is important to know how the oxygen distribution affects the reactor performance, especially the thermal behavior. Therefore, the effect of the oxygen partition (proportion of oxygen injected at the feed to the one permeated through the porous membrane, $O_{2,feed}|O_{2,membrane}$) is shown in Table 1 and Figure 2. As verified, the kinetic model deviates slightly from the equilibrium results, favoring more conversion of CO_2 and CH_4. The oxygen partition does not significantly shift the overall reactor performance. In contrast, the thermal behavior changes drastically (Figure 2). For example, at 0 % oxygen partition (no oxygen distribution through the membrane) the temperature goes up to 1650 °C, far away from

Table 1: Overall results of oxygen partition in the membrane reactor

$O_{2,feed}|O_{2,membrane}$	equilibrium	0%|100%	20%|80%	40%|60%	60%|40%	80%|20%	100%|0%
O_2/CH_4 at feed	45%	45%	36%	27%	18%	9%	0%
$J_{O_2} (mol/m^2 s)$	-	0.00	0.10	0.20	0.30	0.40	0.51
X_{CH_4}	0.93	0.94	0.94	0.94	0.94	0.94	0.93
X_{CO_2}	0.31	0.33	0.33	0.33	0.33	0.33	0.33
Y_{syngas}	0.71	0.71	0.71	0.71	0.71	0.71	0.71
H_2/CO	1.60	1.58	1.58	1.58	1.57	1.57	1.57
Figure 2: Temperature profile of the membrane reactor for different oxygen partitions, full (a) and zoomed (b) profile.

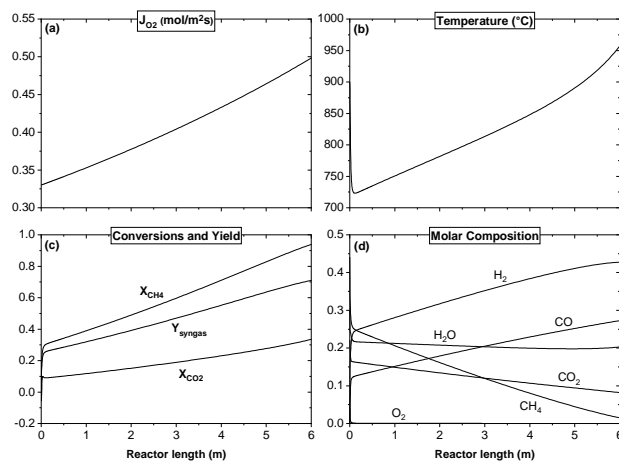
the melting point of nickel (1455 °C). Cold spots also occur, especially at low oxygen feed because the inlet oxygen is not enough to overcome the endothermic reactions. Despite different profiles for the oxygen distribution, their temperatures coincide at the reactor end (about 950°C). The partition results indicate that a sharp temperature profile is unavoidable. There will always be either a hot or a cold spot due to the extreme enthalpy and reaction velocities at the reactor inlet. Since a hotspot is undesirable for safety reasons, a partition of 80 % is chosen for the porous membrane study.


Figure 3: Profile of the membrane reactor using 80 % of oxygen partition. The shell pressure is fixed at 29.5 bar.

Figure 3 shows the reactor behaviour operating at the conditions determined in the thermodynamic analysis and oxygen partition study. As observed in Figure 3 (a), the permeation flux grows from 0.33 up to 0.50 mol/m^{2}s due to the pressure drop in the catalytic bed. Therefore, the transmembrane pressure, pressure drop and the permeability of the membrane should be well designed and controlled to prevent an undesired flux of oxygen. As expected, the temperature profile (Figure 3(b)) reveals no hot spot but rather a cold spot in the inlet region followed by a smooth growth up to the equilibrium temperature, from 725 to 953°C. The conversions and syngas yield profiles (Figure 3(c)) have similar behaviors, a sharp increase at the inlet due to the fast reforming reactions, followed by a smoother growth caused by the temperature increase. The methane and carbon dioxide conversions go up to 94 % and 33.5 % with syngas yield of 71 %. The molar composition shows the same trend with a very steep change at the inlet (Figure 3(d)). Oxygen is extremely low

since it reacts faster as soon as it is introduced in the reactive mixture.

4. Conclusions

The TRM thermodynamic analysis revealed that the adiabatic operation demands substantial oxygen feed to obtain high syngas yields and to avoid coke formation, around half of the methane feed. Moreover, there is a trade-off between the CO_2 conversion and the syngas ratio; CO_2 is converted at the expense of hydrogen production. The membrane reactor showed to be a good alternative to safely provide a high amount of oxygen. The reactor consumed 93 % of the methane and 32 % of the carbon dioxide feed, producing 71 % of the methane into syngas at a 1.6 ratio. As shown, different ratios of oxygen partition do not change the overall reactor performance. No matter how the oxygen is partitioned, drastic temperature behavior is found in the inlet region, either by hot spot or cold spot. However, the chosen oxygen partition of 80 % makes the operation possible by keeping the temperature profile within the limits imposed by the catalyst. The porous membrane imposes a non-uniform distribution of oxygen that grows with the reactor length. As a result, over-oxidation can occur due to the low methane pressure in the outlet region. In short, the proposed porous membrane reactor can perform TRM adiabatically, processing natural gas with high CO_2 content without previous separation.

Abstract

This study focusses on the design and simulation of sour water stripping (SWS) unit in the refinery setup for the reuse of sour water. In this study, process simulation has been performed to analyze the energy saving and cost reducing prospects in the sour water stripping unit. First, a base case design has been simulated using a reference sour water stripping unit data. The developed model is validated against the plant data in order to ensure the model validity. A novel design has been proposed in this study that can reduce the energy requirement by 53 % compared to the conventional designs. The results of this study provide a meaningful analysis in terms of energy and economic considerations to improve the performance of the sour water units in the refineries.

Keywords: Sour water stripping, energy efficiency, process simulation, economic analysis.

1. Introduction

Refineries around the world process thousands of barrels of crude oil every day for the production of various petroleum products. The oil refineries generate considerable amounts of sour water from various processes that should be treated before the water can be reused or disposed of. In a typical refinery setup, the stripped sour water can be reused in the crude de-salter section for the removal of chloride salts to inhibit the formation of HCl in the downstream distillation columns (Lieberman, 2013). The stripped water can also be used in the hydrotreater unit for the removal of ammonia sulfide which otherwise could lead to a serious plugging of the condensers in the presence of CO_2 (Gai et al., 2008). Many studies in the past have focused on how to reduce the energy requirement of the sour water stripping process while meeting the environmental regulatory requirements. Sour water strippers can be configured in a variety of ways including column configurations, condensing and reboiler system and stripping methods.

Weiland and Hatcher (Weiland and Hatcher, 2012) studied the sour water stripping process employing a rate based simulation model using ProTreat. Their results showed that depending on the stream rate and H_2S to NH_3 ratio, the overall tray efficiency can vary widely between 15 to 45 %. Bellen (Bellen, 2009) described a step-by-step guide to the design and operation of sour water stripper and showcased the process simulation using Aspen HYSYS and PRO/II simulators. Nabgan et al. (Nabgan et al., 2016) compared the operational performance of single column and double column SWS process using Aspen HYSYS. Their results showed that 100% of NH_3 was stripped in

the two columns model whereas only 24% was stripped using the single column model. Sharma and Nag (Sharma and Nag, 2009) analysed the design modifications in the sour water stripping unit installed at one of the refineries in the India to enhance the H_2S recovery from the sour water before it is fed to the stripper. The simulated the SWS process using Chemcad and showed that approximately 7.5 % more H_2S can be recovered compared to the base design by installing a hot flash drum upstream of the stripper column.

Although, SWS systems have been installed and operational in the industry since decades, however, not enough effort has been done to improve their design and performance. With growing concerns on the environmental issues and energy efficiency improvements in the industry, there is a need to look into SWS system which is an important unit in the refineries. Most of the above mentioned studies simulated the SWS systems and analyzed the process performance. However, very few studies considered the tray efficiencies in their simulation with no details on the model validation. In addition, most of the studies were focused on how to achieve the desired stripped water composition with little attention to the process improvement. Also, to authors knowledge, no previous studies in the open literature have quoted the cost information required for the sour water stripping. The goal of this study is to utilize the process simulation tool for analyzing the sour water stripper process and improve the process performance by design modifications. A novel vapor compression design has been proposed in this study which is compared with other conventional designs reported in the literature. The effect of the design modifications are then evaluated economically in order to check the feasibility of the design.

2. Process Design

The design of the sour water stripping unit considered in this study is based on the refinery data processing a mixture of light and heavy Arabian crude oil. The sour water stripping simulation has been performed using the Aspen HYSYS. The feed specifications along with the major components in the system are shown in table 1. As recommended by previous studies (Nabgan et al., 2016), NRTL has been selected as the thermodynamic property package because the activity coefficient models are suitable in the presence of polar components and non-ideal system.

Table 1: Feed specifications used in the simulation model

Feed flow rate	t/h	185
Temperature	^oC	40
Pressure	bar	4.9
Composition		
H_2S	mass fr.	0.0030
NH_3	mass fr.	0.0016
H_2O	mass fr.	0.9953
NaCl	mass fr.	0.0001

2.1. Base case design

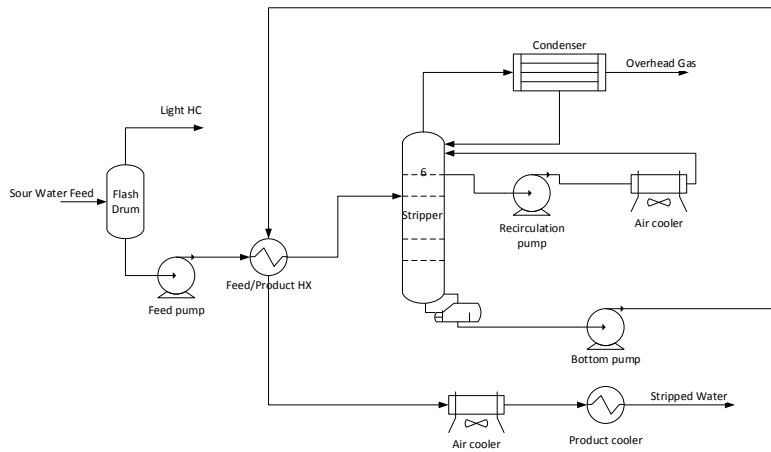
Most of the new industrial stripper installations are similar to this design scheme. Figure 1 shows the process flow scheme for the base case design. The sour water feed is pre-heated with the stripped water to 60 °C before entering the stripper. The purity requirement of the stripped water is maintained by providing heat through the reboiler. Liquid phase side draw is withdrawn from the stage 6 which is then cooled down to 65 °C using an air-cooler and returned back to the top of the column. The vapor stream leaves at the top of the column mainly comprising of H_2S, NH_3 and water. This design as referred by its name is simple without a condenser that can save the cooling utility along with some capital cost while meeting the purity requirements of the stripped water.


Figure 1: Process flow diagram of base case design

2.2. Bottom cycle vapor compression design

A new design is proposed in this study with the aim to reduce the energy requirements of the conventional sour water stripping process. The proposed design employs mechanical work using a compressor instead of hot and cold utilities. In this design, the stripped water stream leaving at the bottom of the column is flashed to a reduced pressure, whereby, some amount of vapours are generated. The produced vapours leave at the top of the flash drum and are fed to the two-stage compression train. A compression ratio of three is assumed in each compressor stage with an intercooler. The compressed vapor stream at 2.1 bar and 240.7 °C then heats up the incoming feed stream and is fed to the bottom of the column at 121.7 °C. The incoming feed stream is heated from 40 °C to 53.5 °C using the heat available from the compressed vapor. It is then heated to 60 °C using the hot utility before bring fed to the 7th stage in the stripper column. The advantage of this design is the elimination of stripper's condenser and reboiler which leads to a reduction in the utilities requirement. Since, the compression also increases the process stream temperature, the heat available from the compression work is supplied to the bottoms of the stripper. However, this design requires an additional compressor work to increase the stream pressure and subsequently the

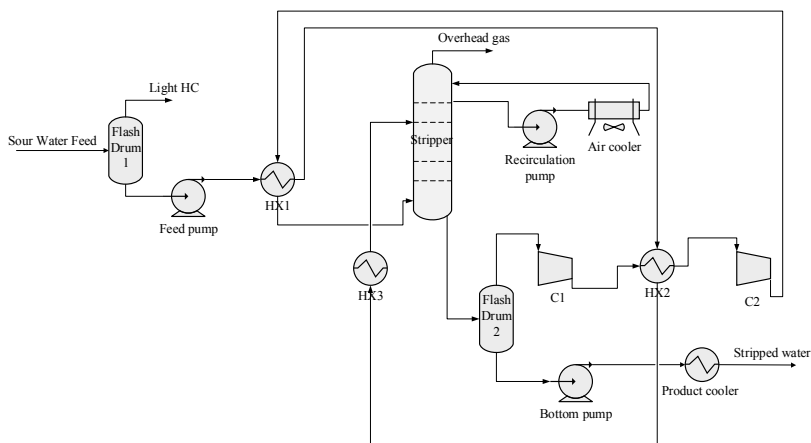
temperature. Figure 2 shows the process flow diagram for the vapor compression design. The reflux at the top of the column is provided in the same way as that of the simple stripper design by a circulation loop. A recirculation cooling loop withdraws some of the liquid from stage 6, cools it down to 60 °C and pump it back to the top of the column.


Figure 2: Process flow scheme for the bottom cycle vapor compression design

3. Results

3.1. Tray efficiency

The tray performance and its efficiency depends on the design, active area, weir length and height, down-comer area and so on. Since, no information regarding the tray efficiency was known from the plant data, the efficiency is estimated by fitting the simulation results with the plant data. The results show that the overall efficiency of the stripper trays is approximately 15 % which is a typical value for an industrial sour water strippers (Hatcher and Weiland, 2012; Nagpal, 2014).

3.2. Energy analysis

The stripped water stream is set to contain no more than 10 and 100 ppm of H_2S and NH_3 content respectively. The results show that the base case design consume more energy compared to the bottom cycle vapor compression design. Figure 3 shows the total energy and unit energy requirement per ton of water stripped. The novel design consumes approximately 53 % less energy compared to the base case design. This significant improvement has been made by cutting down the cold and hot utilities for the condenser and reboiler respectively. The largest energy consuming equipment in the base case is the reboiler which requires more than 70 % of the total energy. This hot utility requirement of the reboiler has been saved in the vapor compression design by using the mechanical energy instead of thermal energy. Cooling is the second highest energy consuming process in the base case which in most of the cases is provided by the cooling utility as shown in figure 4. In case of vapor compression design, cooling and

compression are the main energy consuming steps accounting to around 48 % and 36 % respectively.
Figure 3: Comparative energy analysis sour water stripper designs

Figure 4: Percent energy share for the sour water stripper designs

Figure 5 shows the vapor phase composition profile of NH_3 and H_2S in the stripper. The results show that the removal of H_2S is accomplished easily and require less number of stages to achieve the desired stripped water purity specification. However, the removal of NH_3 from the sour water is more difficult and require more number of trays to satisfy the stripped water composition standards.
Figure 5: Vapor phase composition of H_2S and NH_3 in the stripper

4. Conclusions

In this study, Aspen HYSYS has been used to simulate the sour water stripping unit of a refinery. The base case design has been compared with a novel vapor compression design. Both the process designs were compared in terms of energy requirement while maintaining the stripped water purity of 10 ppm H_2S and 100 ppm NH_3 content. This study presents a novel design that can reduce the energy requirement of the stripping process significantly compared to the conventional designs. The results show that the proposed vapor recompression design can reduce the hot and cold utilities requirement by 90 % and 22 % respectively compared to the base case design.

Techno-economic Assessment of Future Generation IGCC Processes with Control on Greenhouse Gas Emissions

Usama Ahmed [a*], Umer Zahid[a]

[a] *Chemical Engineering Department, King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia*

usama.ahmed@kfupm.edu.sa

Abstract

Integrated gasification and combined cycle (IGCC) is a pre-combustion carbon capture technology that can be used to generate electricity and hydrogen while reducing the green house gas emissions. In this study, three IGCC based process models are developed in Aspen Plus ® followed by their techno-economic evaluation. Case 1 is the conventional IGCC process which is considered as a reference model, whereas, case 2 and case 3 are the conceptual process models. In case 2, gasification unit in the conventional IGCC model is integrated with the reforming technology to utilize the steam produced in the gasification unit in the methane reforming process. This concept not only increased the overall yield of syngas but also the H_2 production capacity. On the other hand, the case 3 is modified to convert the conventional IGCC into oxy-fuel IGCC process keeping the reforming unit in place which nullifies the need of using standalone energy intensive water gas shift units and CO_2 capturing unit. The efficiencies calculated for case 1, case 2 and case 3 are 35.86%, 40.7% and 41.3%, respectively. The economic analysis showed that the cost required for each unit of energy generated is 2.93, 2.06 and 2.01 M€/MWe, respectively. The results also showed that the case 3 design not only offers highest process performance and economics but it offers least CO_2 specific emissions compared to the case 1 and case 2 designs.

Keywords: IGCC, SMR, Oxyfuel, CCS, LCOE.

1. Introduction

With the increase in population and industrialization during the last few decades have increased both the energy demand and pollution in the world. The power generation sectors mainly relies on the fossil fuels to compete the world energy demand and are held responsible for 35% of greenhouse gas (GHG) emissions where 75% of total emissions includes CO_2. Among various fossil fuels, coal and natural gas have been receiving a lot of attention for power generation due to their abundance in nature and already developed infrastructures. International Energy Agency (2014) statistics showed that almost 40.58% of electricity in 2010 was generated from only coal where its consumption is expected to increase by 33% in 2035 compared to 2009. Due to an ever increasing energy demand in future also, carbon capture and sequestration (CCS) technologies will play a vital role in controlling and abating GHG emissions. Natural gas combined cycle (NGCC), ultra-supercritical pulverized coal (USPC) and integrated gasification and combined cycle (IGCC) power plants are currently the main sources of electricity generation. However, the efficiency of power plants tremendously drops with the implementation of CCS

technology. For instance, NGCC, USPC and IGCC power plants shows an efficiency drop of 7.1%, 11.4% and 9%, respectively with the CCS technology. Moreover, currently operating post combustion carbon capture processes from coal would nearly double the cost of electricity (COE) while decreasing the net output by 7-10%. On the other hand, pre-combustion processes have higher capital investments but they are more energy efficient if CCS is implemented on large scale. Although, NGCC processes offers higher process performances with CCS, however, the higher and fluctuating cost of natural gas limits its extensive utilization over coal based power plants. Therefore, the state of art technologies for power and H_2 generation can be integrated to enhance the overall process performance while abating the GHG emissions.

Process optimization and intensification techniques along with the better heat integration methods provides an opportunity to increase the reliability and sustainability of processes. Recently, Ahmed et al. (2016) and Cormos et al. (2015) explored the various design routes for enhancing the IGCC performance with CCS techniques. On the other hand, Yi et al. (2014) performed the studies for integrating IGCC and natural gas reforming processes to enhance the H_2/CO content in the syngas followed by their consequent use in various poly generation processes. Recently, Ahmed et al. (2017) presented the model for integrating the gasification and reforming technology that utilizes the in-process generated steam during coal slurry gasification process to assist the reforming process and makes the process more self-sustainable. This study has been performed in continuation of the previous work performed by Ahmed et al. (2016, 2017) with more promising results. In this study, the idea of integrating the available technologies (IGCC, Reforming and Oxyfuel) is presented to enhance the overall process sustainability. The results for the conventional and proposed processes will be compared in terms of both the process performance and economics to assess the design reliability.

2. Simulation Methodology and Process Description:

Three simulation models are developed in Aspen Plus ® using Peng Robinson equation of state as a thermodynamic package. Coal is an un-conventional compound and has been modeled based on proximate and ultimate analysis. The gasification, water gas shift and reformer reactors are modelled on the basis of RGibbs reactor models which are operated on the Gibbs free energy minimization laws to generate syngas reaction products as shown in Table 1.

Table 1: Design Assumptions for Model Development

Unit/Component/System	Modelling Unit	Parameter
Gasification Reactor	RGibbs (Reactor)	Coal flow rate= 38.51kg/s Temp/Press: 1550°C/32 bar

Acid Gas Removal H_2S and CO_2	RadFrac (Selexol Solvent)	H_2S/CO_2 Removal Percentage: 99.9 / 90

2.1. Conventional IGCC process (Case 1):

Case 1 is a conventional IGCC process which is taken as a base case model that sequentially integrates the gasification unit (GU), air separation unit (ASU), water gas shift reactor (WGS), heat recovery steam generation (HRSG), acid gas removal section (AGR), and combined cycle (CC) as shown in Figure 1. Coal water slurry is fed to the entrained flow gasification unit to generate syngas which is a mixture of CO, H_2, CO_2 and H_2O. Syngas leaves the gasification unit at a very high temperature (~1600 °C) and contains high concentration of H_2 and CO. The temperature of the syngas is reduced to 250-500 °C in the radiant and convective heat exchangers to carry out WGS reactions as shown in equation in Eq.(1).

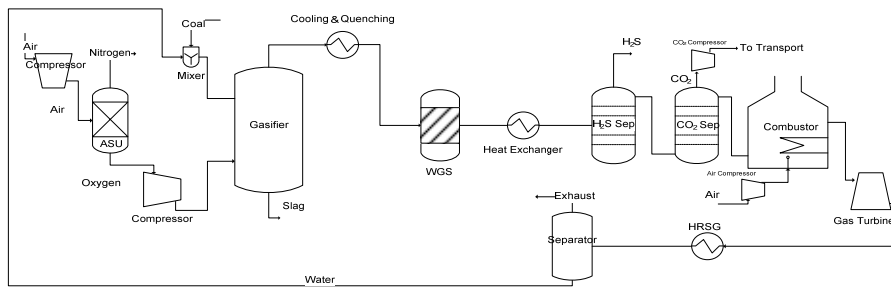
$$CO + H_2O \leftrightarrow H_2 + CO_2 \qquad \Delta H = -41 \text{ KJ/mole} \qquad (1)$$


Figure 1: Case 1 – Conventional IGCC design for power generation with CO_2 capture

The syngas from WGS reactors is then passed through AGR section where most of the CO_2 and H_2S is removed and recovered by Selexol solvent. The separated CO_2 is than further processed and compressed to an elevated pressure for its transport and storage, whereas, H_2S is further treated in a Claus plant to recover elemental sulfur. The syngas leaving from AGR section contains high concentration of H_2 which is directed towards CC section to generate electricity and the process heat.

2.2. Integration of IGCC and SMR Process (Case 2):

Steam methane reforming (SMR) technology is extensively used for the commercial production of H_2 gas. SMR is an endothermic process which is carried out by reacting high pressure steam with the methane gas at a temperature range of 627-827°C as shown in equation (2). Reforming process is usually carried out in two sequential steps i.e. pre-reforming and reforming. Firstly, the compressed methane is heated and mixed with a high enthalpy steam in a pre-reforming section. Ahmed et al. (2017) and Lucero et al. (2015) demonstrated the reforming process over the nickel-based catalyst to generate H_2.

$$CH_4 + H_2O \leftrightarrow CO + 3H_2 \qquad \Delta H = 242 \text{ kJ/kmol} \qquad (2)$$
Conventional SMR processes requires an additional heat source for preheating the gas stream to assist the reforming process. However, in this case, the syngas generated during gasification process is cooled and mixed with the compressed natural gas where the inlet temperature of the reformer is maintained at 1150 °C. As the mixture passes through the reforming unit, the temperature reduces to 1040 °C due to an endothermic reforming reactions. The conceptual process flow diagram of case 2 can be seen from Figure 2. The

syngas from the reforming section is then directed to the WGS reactors to generate additional H_2 and CO_2. The CO_2 and H_2S generated in the process is removed in the AGR section using Selexol process, whereas, the H_2 is sent to the CC section to generate electricity. As natural gas used in this case is an important utility, therefore, the corresponding net efficiency of NGCC power plants have been also incorporated for the fair evaluation of the analysis in the next section.
Figure 2: Case 2 – Integration of IGCC and methane reforming process with CO_2 capture

2.3. Integration of IGCC, SMR and Oxyfuel Processes (Case 3):

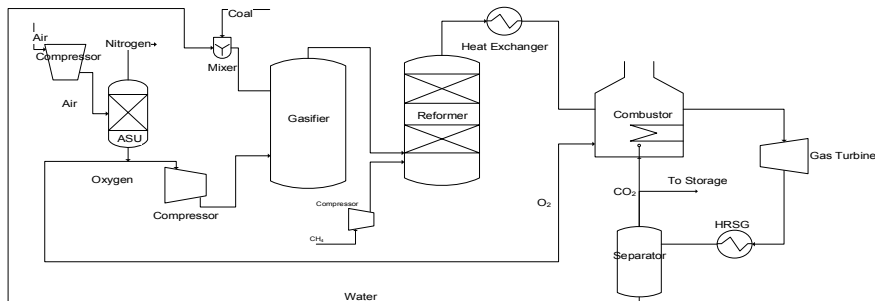
Oxyfuel combustion technology can be used for burning the fuel in the presence of high purity oxygen to generate more heat compared to air by avoiding its dilution with N_2. The flue gas generated from the oxyfuel combustion process contain high purity CO_2 and H_2O which do not requires any standalone chemical or physical sorbent process to capture CO_2. The temperature of the flue gas is reduced in multiple heat exchangers to condense the moisture and pure CO_2 is separated followed by its compressing in the multi-stage compression unit for further utilization. The case 3 design is an advanced version of case 2 in which we can integrate the oxyfuel combustion technology with the gasification and the reforming processes as shown in the Figure 3. The CO_2 generated in the combustion section is partially recycled to the combustion reactor to control both the combustion temperature and maintaining the inlet temperature of flue gas for gas turbine power generation unit. This integration will also nullify the need of installing additional WGS and CO_2 capture units compared to the case 1 and case 2 designs that will also improve both the process performance and economics of the overall process.


Figure 3: Case 3 - Integration of IGCC with the Reforming and Oxyfuel Technology

3. Results and Discussion

Case 1 is a conventional IGCC process design where the heating value of syngas typically depends on the operational conditions of the gasifier. The addition of reforming unit with the gasification unit in case 2 generates an additional syngas from SMR process. The SMR process utilizes high enthalpy steam from the syngas to convert CH_4 to H_2 while maintaining the reformer's temperature and pressure. Figure 4 provides the comparison of case 1 with the other two cases in terms of syngas composition and heating value at the outlet of the reforming unit. The case 2 and case 3 has the same configuration up to reforming unit so the syngas composition and heating value remained same at the reformer's outlet.
Figure 4: Syngas Composition & Heating Values at the Reformer's Outlet

The results showed that syngas production capacity for case 2 and case 3 has been increased compared to the case 1 design due to installation of the reforming unit. Due to the increase in H_2/CO ratio and heating value of the syngas in the case 2 and case 3 designs, the power generation capacity from both the steam cycle and the gas turbine section are also increased compared to the case 1 design. While comparing case 2 and case 3, it has been analyzed that case 3 generates more power in the steam cycle process due to an oxyfuel nature of the process and also due to an absence of WGS unit which requires steam to convert CO to H_2. However, the power generation from the gas turbine section for the case 3 is lower than the case 2 design as less flue gas passes through the gas turbine section due to syngas combustion with the high purity oxygen instead of excess air. The net power generated and process efficiency for case 1, case 2 and case 3 is calculated as (375.08, 472.92 and 495.01) MWe and (35.86, 40.7 and 41.3) % respectively. The breakup for power generation from the combined cycle processes is given in Figure 5.
Figure 5: Comparison of process performance of all cases

The key purpose of any power plant is to produce electricity at an economical price. Some of the process performance and economic indicators are used to evaluate the LCOE (cost of electricity) with CCS technology, CO_2 specific emissions and CO_2 capture cost in terms of

CO_2 removal and avoidance cost for all the cases which are summarized in Table 2. It has been seen from results that the case 3 design has a potential to reduce the LCOE by 11.6% and 6.2% compared to the case 1 and case 2 designs, respectively. Moreover, the case 3 design also offers a reduction in both the CO_2 specific emissions and CO_2 capture cost compared to the case 1 and case 2 designs.

Table 2: Comparison of some economic indicators for case 1, case 2 and case 3 designs

	Units	Case 1	Case 2	Case 3
LCOE	€/MW$_h$	70.57	66.47	62.35
CO_2 Specific emission	kg/MW$_h$	87.74	80.26	78.45
CO_2 avoidance/removal cost	€/t	36.23/26.99	27.97/20.45	25.66/18.35

4. Conclusions

In this study, three IGCC based process models have been developed and techno-economically compared. Case 1 is based on the conventional IGCC process, whereas, case 2 integrates the conventional IGCC with the reforming technology. Case 3 is a further modification of the case 2 design which converts the downstream process into oxyfuel technology which nullifies the utilization of standalone WGS and CO_2 capture units. It has been seen from results that the case 3 design offers higher process efficiency and economics compared to other cases which makes the overall process more reliable and sustainable.

Abstract

Analysis of radionuclides in radioactive waste is performed according to a number of operating protocols which are usually time-consuming and difficult to implement. The use of microdevices for liquid-liquid extraction of radionuclides is promising, since small amounts of materials are needed. In this work, a plug flow modelling approach for the liquid-liquid extraction in microdevices is presented. A multi-component chemical process based on the PUREX-TRUEX waste management treatment is analysed. We evaluate the performance of the coupled micro-units as a function of channel size, superficial mixture velocity, and initial loading. The results show that it is possible to use the model in an optimisation based design procedure for microfluidic devices.

Keywords: Microdevices, Radionuclides, Plug flow, Sensor design

1. Introduction

Liquid liquid extraction (LLE), also known as solvent extraction, is a method used to distribute one or more species (solutes) between two immiscible liquids in contact with each other due to a difference in solubility. It is among the most common separation techniques used in industrial processes. In this regard, computer simulations of LLE processes are very useful tools that can aid the design and testing of process flowsheets. They can form the basis for applications in optimisation, control, and system analysis.

The analysis of radionuclides present in high level radioactive waste (HLRW) is performed using operating protocols including several separation and purification steps which are difficult to implement in glove boxes and hot cells (Hellé, et al., 2015). Among those steps, LLE is essential to obtain a pure fraction containing the radionuclides of interest. However, one of the disadvantage of this separation method is that a large amount of organic solvent is need to dissolve the extractant and the radionuclides of interest. This entails both radiological and chemical risks. Therefore, in order to reduce the amounts of solvents used, as well as the radioactive material needed for the analysis, modifications of operating procedures are important. In the frame of studies aiming to overcome these limitations, microfluidic devices have attracted much attention, and micrototal analysis systems (μTAS) have been advocated (Ciceri, et al., 2014). Normally, in μTAS, solvent mixing, reaction, separation, and detection are integrated onto a microfluidic chip. These

microfluidic technologies are suited for the efficient implementation of LLE due to the intrinsic advantages of the small dimension, i.e., high surface-to-volume ratio and laminar flow conditions. Other attractive feactures of microfluidic devices are the ability to control the contact time of the liquids involved and the use of small manipulating volumes, which decrease both chemical and radiological risk.

Micro-chemical systems that implement two or more liquid streams flowing laminarly in a micro-channel have been development for some specific radiochemical applications. These studies include the extraction of uranium U(VI) by tributylphosphate (TBP) in n-dodecane (n-DD) (Hotokezaka, et al., 2005) and the extraction of Am(III) by n-octyl(phenyl)-N,N-diisobutylcarbamoylmethylphosphine oxide (CMPO) (Ban, et. al., 2011). For industrial application of these techniques, however, one of the challenges is to have continuous and multiple separations of individual metal elements occurring in the same microtool (Hellé, et al., 2015).

Despite the interest in the development of μTAS or lab-on-chip devices, researchers typically do not have large amounts of time and money to build and test several prototypes in order to optimise performance. To reduce the number of iterations of prototyping, it is imperative to develop the best computer-aided design-forecasting methods. With the aim to improve these prediction methods, we present and validate a mathematical modelling framework to simulate continuous separations of radionuclides in a single microdevice. The long term aim is to use the mathematical model with an optimisation based design procedure. This procedure will aim to generate and evaluate alternative channel layouts and identify those that have the best performance for the online determination of radionuclides following microchip extraction by using for example the so-called thermal lens microcopy system (Hotokezaka, et al., 2005).

In the following section, we present the radiochemical system under consideration. Then, we introduce the mathematical model and present the results. We finalize with the conclusions.

2. The chemical system

In this section, we describe the radiochemical process implemented in this work.

2.1. Motivation

Reprocessing of spent nuclear fuels (SNFs) from power reactors by PUREX process is aimed at recovery of uranium and plutonium (Bascone, et al., 2017). It consists of a LLE process using 1.1 M TBP as extractant present in n-DD as diluent. Since the trivalent actinides and lanthanides (i.e. Am(III) and Eu(III)), are inextractable by TBP, they are normally rejected to HLRW. However, the trivalents can be then extracted by the TRUEX process, which is a mixture of 0.2 M CMPO - 1.2 M TBP in n-DD. In this part of the waste treatment, TBP is added as a diluent modifier in order to minimize third phase formation. It has been also observed that the extraction of trivalent actinides by CMPO decreases with the presence of uranium in the feed as it tends to saturate CMPO in the organic phase (Mathur, et al., 1993). These LLE processes are mostly carried out in pulsed columns and mixer settlers. In the following subsection, we describe a simplified version of the PUREX-TRUEX waste treatment, which will be used in the subsequent sections to

validate our approach.
Figure 1: Conceptual diagram of a microchip involving two LLE steps, two different extractants, and three different radionuclides.

2.2. Process description

An HNO_3 aqueous phase, containing U(VI) (in the form of UO_2^{2+}) and Am(III) (in the form of Am^{+3}), is initially brought into contact with the organic phase containing 1.1 M TBP diluted in a hydrocarbon phase. This occurs in a hydrophilic small channel where dispersed plugs (elongated drops) of the organic phase are formed inside the continuous aqueous phase. It is assumed that, after the extraction of uranium, the organic stream will be separated in a side hydrophobic channel. The aqueous stream with the rest of uranium and all the americium will be mixed in a second micro-channel with another organic phase containing 0.2 M CMPO also diluted in a hydrocarbon phase for the extraction of remaining U(VI) and Am(III). We consider the plug flow pattern because it combines improved mixing with large interfacial areas. We will assume a constant HNO_3 concentration along the processes. We refer to Fig. 1 for a general schematic representation of a microchip containing two LLE steps and flow patterns as those described here. In both stages, the extraction proceeds according to the following reaction (Hellé, et al., 2015)

$$M^{n+} + nNO_3^- + nS_f \rightleftharpoons M(NO_3)_n \cdot nS, \qquad (1)$$

where for the reaction along the first channel, M=UO_2 and S=TBP. For the reaction along the second channel M=UO_2 or Am and S=CMPO. The symbol S_f represents the free or unbounded extractant along the channel. For uranium $n = 2$ and for americium $n = 3$.

3. Mathematical model

As previously mentioned, the organic phase consists of dispersed plugs moving in a continuous phase containing the aqueous solution which initially contains the two radionuclides. In this work, the $i \in \{1, 2\}$ channel will be modelled as an ideal plug flow reactor with the concentration of the $j \in \{U, Am\}$ radionuclide in the dispersed (organic) phase described by the so-called operational line given by

$$C_{i,j,d}(x) = C_{i,j,d}(0) - q^{-1}\left[C_{i,j,c}(x) - C_{i,j,c}(0)\right], \qquad (2)$$

with the concentration of the j radionuclide in the continuous (aqueous) phase, $C_{i,j,c}(x)$, calculated from

$$v_{mix}\frac{dC_{i,j,c}(x)}{dx} = -K_L a_i \left(C_{i,j,c}(x) - C^e_{i,j,c}(x) \right),\tag{3}$$

where the equilibrium concentration of the j radionuclide in the aqueous phase is obtained using the equilibrium line, $C^e_{i,j,c}(x) = C_{i,j,d}(x)/D_{i,j}$. The paremeter $q = 1$ is the ratio of the volumetric flow rates of the dispersed phase to the continuous phase. The parameter $D_{i,j}$ is the distribution coefficient defined as the ratio of the concentrations of each radionuclide in the organic and aqueous phases at equilibrium. From the complexation kinetics (see Eq. 1) we have that, $D_{1,U} = K'_{1,U}(C_{TBP_f}(x))^2$, $D_{2,U} = K'_{2,U}(C_{CMPO_f}(x))^2$, and $D_{2,Am} = K'_{2,Am}(C_{CMPO_f})^3$. We also assume that $C_{TBP_f}(x) = 1.1 - 2C_{1,U,d}(x)$ and $C_{CMPO_f}(x) = 0.2 - 2C_{2,U,d}(x) - 3C_{2,Am,d}(x)$ are the concentrations of the free extractants at position x along the channel. The parameters $K'_{1,U}$, $K'_{2,U}$, and $K'_{1,Am}$ are the conditional extraction constants. In Eqs. 2 and 3, $C_{i,j,d}(0)$ and $C_{i,j,c}(0)$ are the inlet concentrations, $K_L a_i$ is the volumetric overall mass transfer coefficient, and v_{mix} is the superficial mixture velocity. Following previous works using circular channels and plug flow conditions (Bascone, et al., 2017), we assume an average volumetric mass transfer coefficient given by

$$K_L a_i = 0.88\frac{v_{mix}}{L_i}Ca^{-0.09}_{mix}Re^{-0.09}_{mix}\left(\frac{ID_i}{L_i}\right)^{-0.1},\tag{4}$$

where L_i and ID_i are the length and diameter of the channels. The symbols Re_{mix} and Ca_{mix} are the Reynolds and capillary numbers of the mixture, which are functions of the properties of the phases, v_{mix}, ID_i, and q. Crucial for the coupling between the two channels is the assumption that the outlet concentration of radionuclides in the continuous phase of the first channel becomes the inlet concentration of the continuous phase in the second one.
Figure 2: Evolution of the concentration of Am(III) in a) dispersed/organic phase and b) continuous/aqueous phase, for two different values of $C_{1,U,c}(0)$, with $C_{1,Am,c}(0) = 0.01$ M. The fluids along the channels have the same properties. In this case, $K'_{1,U} = K'_{2,Am} = 10^3$ and $K'_{2,U} = 10^2$. For the dimensions, $L_1 = L_2 = 0.1$ m and $ID_1 = ID_2 = 0.002$ m. For the integration of Eq. 3, we use the fourth order Runge-Kutta method with $\Delta x = 5 \times 10^{-6}$ m. Note that $C_{2,U,c}(0) = 0.127$ M and 0.468 M, for $C_{1,U,c}(0) = 0.5$ M and 1 M, respectively.

4. Results and validation of the model

It has been recognised that the extraction of trivalent actinides, like for example Am(III) decreases in the presence of large amounts of uranium in the feed as it tends to saturate CMPO in the organic phase (Mathur, et al., 1993). In the following, we show that our model reproduces, at least in a qualitative manner, this interesting finding. To this end, in Fig. 2 we plot the concentration of americium along the second channel (i.g. $C_{2,Am,d}$ and $C_{2,Am,c}$), for two large enough values of $C_{1,U,c}(0)$ (note that the concentration of Am(III) along the first channel is constant, as TBP does not extract trivalent actinides). The figure clearly shows that the extraction of americium decreases with the initial uranium loading.

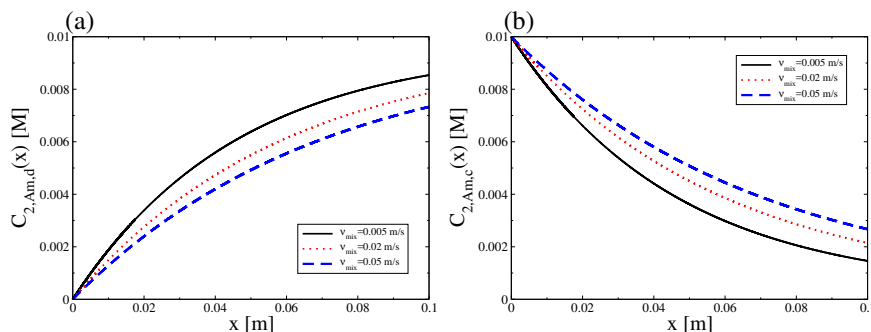
Our model also predicts some interesting features that can be tested against future experiments. For example, in Fig. 3 we plot the concentration of americium as a function of the superficial velocity of the mixture v_{mix}. The figure clearly show that the extraction of americium in the microchip device should decrease with v_{mix}. This is due to the fact that an increase of the mixture velocity decreases the residence time available for mass transfer. The model also allows us to analyse the extraction as a function of the geometric


Figure 3: Evolution of the concentration of Am(III) in a) dispersed phase and b) continuous phase, versus v_{mix}. In this case, $K'_{1,U} = K'_{2,U} = K'_{2,Am} = 10^3$. For the dimensions, $L_1 = L_2 = 0.1$ m, and $ID_1 = ID_2 = 0.002$ m. The inlet concentrations are $C_{1,U,c}(0) = 0.05$ M and $C_{1,Am,c}(0) = 0.01$ M. Note that $C_{2,U,c}(0) = 0.006$ M, 0.010 M, and 0.013 M for $v_{mix} = 0.005$ m/s, 0.02 m/s, and 0.05 m/s, respectively.

properties of the microchannel. Figure 4 shows the concentration of americium along the second channel as a function of the channel diameter. The figure shows that the extraction is always higher as the channel size decreases. The interfacial area available for mass transfer decreases with the channel size, because the length of the plugs in the larger channels are longer; thus small number of plugs and reduced interfacial area are available for mass transfer.

5. Summary and conclusions

A mathematical model for the coupling of different LLE micro-unit operations in a single microchip is introduced and validated with a continuous radiochemical process, inspired by the PUREX-TRUEX waste treatment. The model reproduces, in a qualitative manner, the experimental observation that the extraction efficiency of americium decreases with
Figure 4: Similar to Fig. 3 but as a function of $ID = ID_1 = ID_2$, with $L_1 = L_2 = 0.1$ m. Note that $C_{2,U,c}(0) = 0.006$ M and 0.002 M, for $ID = 0.002$ M and 0.0002 M, respectively.

the initial loading of uranium. Our results also indicated that for fixed parameter values (i.e. channels size and flow conditions) as the mixture velocity increases the extraction efficiency of Am(III) decreases. It also shows that, for the same mixture velocity, the extraction efficiency is always higher as the diameter of the channel decreases. Our modelling approach constitutes a proof of concept and a first step towards a general modelling of analytical processes with continuous flows in microchips. The next step is to use the mathematical model with an optimisation based design procedure. For example, it could be interesting to determine the optimal channel size and layout in a constrained space for each separation step of the analytical process.

Abstract

This study is focused on the production of syngas using gasification and dry methane reforming (DMR) technologies. The two processes are compared as a standalone design for a syngas production capacity of 10,000 kmol/h with H_2 to CO ratio of 0.88. The two processes are then integrated to develop a novel design that can reduce the CO_2 emissions to a near-zero level with reasonable amount of energy requirement. In this study, Aspen Plus® has been employed as a process simulation tool. The results reveal that the DMR process consumes 3.4 times less energy compared to a gasification plant of same capacity. The result also shows that the integration of gasification and DMR design off-sets the negative aspects of gasification technology enabling it to utilize conventional solid fossil fuel with low emission levels.

Keywords: Gasification, dry reforming, syngas, energy.

1. Introduction

The production of syngas is one of the important process in the petrochemical industries from which many downstream products like ammonia, methanol and fertilizers are produced. In order to have a sustainable hydrocarbon fuel usage, the amount of carbon dioxide in the atmosphere must be reduced. As in the Paris agreement at COP21 conference in 2015, there are 195 countries who signed a ratification to reduce carbon emissions. The Paris accord can be realized by supplying clean fuels and renewables for the energy production, improving efficiency of the current energy consuming processes, and utilization of fossil fuels by eliminating the pollutants and GHG emissions. Syngas production technologies can play a role in bridging the gap for the use of fossil fuels while keeping the emissions within the limits. Syngas can be produced using gaseous fuels, liquid hydrocarbons and solid feedstocks. The gaseous and liquid feedstocks utilize technologies such as steam reforming, partial oxidation, dry reforming, and auto-thermal reforming. With solid feedstocks such as coal and biomass, gasification is the main technology available for the syngas production.

Recently, dry methane reforming is gaining a lot of attention as an environmentally friendly process for syngas production because it consumes two major GHGs, carbon dioxide and methane. It requires 363.6 kg of methane to consume 1 ton of CO_2 for the production of 90.9 kg of H_2 and 1.27 tons of CO. The main reaction taking place in the dry reforming is shown below:

$$CH_4 + CO_2 \leftrightarrow 2H_2 + 2CO \qquad \Delta H_{298} = 247 \text{ kJ/mol} \qquad (1)$$
Reverse water gas shift reaction also takes place in the DMR reaction, which combines the CO_2 and H_2 to produce CO and water. The reverse water gas shift reaction is shown below:

$$H_2 + CO_2 \leftrightarrow H_2O + CO \tag{2}$$

The reaction is favoured by low pressure and high temperature which means high energy requirement and high production cost. Gasification is a proven and commercialized technology to convert solid feedstocks into syngas along with other impurities such as H_2S and CO_2. Gasifiers are operated with limited amount of oxygen to conduct the pyrolysis reactions for the formation of syngas. Although there are many simultaneous complex reactions taking place in the gasifier, some of the main reactions are shown below:

$$C + \tfrac{1}{2}\,O_2 \leftrightarrow CO \qquad \Delta H_{298} = -110.5 \text{ kJ/mol} \tag{3}$$
$$C + H_2O \leftrightarrow CO + H_2 \qquad \Delta H_{298} = -131.4 \text{ kJ/mol} \tag{4}$$
$$C + CO_2 \leftrightarrow 2CO \qquad \Delta H_{298} = -172.0 \text{ kJ/mol} \tag{5}$$
$$C + H_2O \leftrightarrow CO + H_2 \qquad \Delta H_{298} = -41.0 \text{ kJ/mol} \tag{6}$$
Gasification process is usually following by a gas cleaning process where acid gases are removed from the syngas. Depending on the downstream requirement, another reaction known as water gas shift reaction is usually followed to convert CO to CO_2 and increase the syngas ratio as shown below:

$$CO + H_2O \quad \leftrightarrow \quad H_2 + CO_2 \quad \Delta H_{298} = -891 \text{ kJ/mol} \tag{7}$$
Many studies in the past have focussed on the syngas production technologies in order to improve the process performance by developing new catalyst materials, optimizing the process conditions, and integration with other processes. Mallick et al. (Mallick et al., 2018) analysed the effects of co-gasification of coal and biomass experimentally on the process performance. They concluded that the co-gasification of coal and biomass has synergetic effects with merits compared to the individual feedstock gasification. Li et al. (Li et al., 2018) studied the design of dry methane reforming with CO_2 utilization using nickel based catalyst. Their results showed that the catalyst development can be an important factor in the commercialization of DMR technology. Wu et al. (Wu et al., 2005) combined the coal gasification with steam reforming to evaluate the feasibility of process integration. Lim et al. (Lim et al., 2012) studied the combination of steam reforming with dry reforming. Their results showed that the combined process can reduce the net CO_2 emission by 67 % compared to the standalone steam reforming process. Ahmed et al. (Ahmed et al., 2017) studied the integration of gasification with steam reforming for power generation application with CO_2 capture unit.

Although, standalone syngas production technologies have been widely investigated in the literature, however, there is no significant research available that compared the DMR process with that of gasification process and considered their integration. The goal of this study is to compare the process performance of DMR and gasification technologies in terms of energy efficiency and economics. Aspen Plus® V9 is used to simulate the two processes. In order to have a fair comparative analysis, syngas production rate and ratio (H_2/CO) have been fixed for the two processes at 10,000 kmol/h and 0.88 respectively.

2. Process Design

2.1. Dry methane reforming

Dry methane reforming process has been simulated using the design outlined in the literature (Luyben, 2014). Peng-Robinson property method has been used for the simulation of DMR section while Amines package has been employed in the CO_2 removal section. The feed stream containing methane and excess CO_2 is compressed to the required reactor pressure of 4 bar. The temperature of feed stream after compression increases to about 130.6 °C which is further heated using a counter current process heat exchanger. The syngas formation reaction takes place at 4 bar and 1000 °C. The reactor effluent stream is used to cool down the incoming feed stream. The reactor effluent stream contains H_2, CO_2, unreacted CO_2 and CH_4, and small amount of water. The CO_2 is removed from the gas stream using a typical absorber-stripper system by employing MEA as a solvent. The syngas free of CO_2, contains 44 mol % of H_2 and 50.5 mol% of CO is compressed in multi-stage compressor train with intercooling to a product pressure of 30 bar. The capture CO_2 from the absorber is stripped from the solvent in the stripper and is recycled back to the feed compressor.

2.2. Gasification

Feedstock for the syngas production using gasification technology in this study is coal. The composition and heating value for the coal has been adapted from the literature (Ahmed et al., 2016). Multiple property packages have been used to precisely predict the properties of gasification simulation. Solids property method has been used for the feed preparation block, while Peng-Robinson has been used for the gasification, cleaning units and WGS blocks. Figure 1 shows the simplified block diagram of the gasification process for syngas production.
Figure 1: Simplified block diagram of gasification process for syngas production

Coal slurry is first prepared by crushing the coal to a size of 0.2 mm particle diameter along with water addition. The coal slurry is the pumped to the gasifier where the reactions take place in the controlled amount of oxygen. The gasifier effluent contains a mixture of gaseous products including CO, H_2, CO_2, H_2O, Ar, H_2S and minor quantities of other gases. The reactions in the gasifier takes place at 33 bar and 1200 °C. The hot effluent gas is cooled down in a series of heat exchangers to generate high pressure steam. The cooled gases at 152 °C are then sent to the cleaning unit where H_2S and CO_2 is removed from the syngas in separate absorbers. Methanol is employed as a solvent in the cleaning unit for the removal of acid gases from the syngas. The syngas coming out of the cleaning unit has a H_2/CO ratio of approximately 0.80. In order to meet the required H_2/CO ratio of 0.88, approximately 4.3 % of the total syngas is sent to the water gas shift reactor where CO is converted H_2 by reaction with steam. The additional

CO_2 produced from the water gas shift reaction is removed using methanol absorption to get the syngas product of required purity.

2.3. Integrated design

Integrated design combines the gasification and DMR process in series to enhance the process performance as shown in figure 2. The raw syngas produced from the gasification process is sent to the cleaning unit, where only H_2S is removed and the remaining gas is fed to the DMR section. Methane is also fed to the DMR unit along with the gases entering from the cleaning unit. In this way, the CO2 generation from the gasification process can be utilized as a feed material for the DMR process. As in the standalone designs, the integrated design is also set to produce 10,000 kmol/h of syngas with the syngas ratio of 0.88. The desired production rate and product purity has been maintained by varying the coal flowrate to the gasifier and methane flowrate to the DMR reactor respectively.
Figure 2: Simplified block diagram of integrated design for syngas production

3. Results

Energy analysis has been performed for the two systems to estimate the power requirement of various units in the process. Table 1 shows the power consumption of various units in the DMR and gasification designs.

Table 1: Energy consumption of various sections in DMR and gasification units

Dry methane reforming (MW)		Gasification (MW)		Integrated design (MW)	
Compression	33	Gasification unit	341	Gasification unit	271
Reactor	183	Cleaning unit	75	Cleaning unit	53
Stripper	7	WGS reactor unit	485	DMR	93
Cooling	42				
Total	265		901		417

The results shows that the DMR process consumes 3.4 times less energy compared to the same size of gasification unit for syngas production. The results also show that since

the DMR process consumes CO_2 as a feed material, the amount of CO_2 consumed in DMR process is approximately 5 times compared to what the gasification process emits. This makes DMR process more environmentally sustainable for the syngas production. The gasification section in the integrated design produces around 500 kmol/h of CO_2 which is used a feed material in the DMR process. In order to maintain the required syngas ratio in the product, CH_4:CO_2 molar ratio in the DMR reactor is maintained at 2.3 in contrast to the standalone DMR design. Figure 3 shows the total energy consumption and CO_2 emissions for the three designs. The results show that the integrated design produce no CO_2 emissions and can reduce the energy requirement by approximately 53.6 % compared to the gasification process. Figure 4 shows the energy requirement per unit of syngas produced from the three processes. The results show that syngas can be produced with a lower energy requirement in case of an integrated design while mitigating the CO_2 emissions.
Figure 3: Energy consumption and CO_2 emissions comparison for the standalone and integrated designs
Figure 4: Specific energy requirement for the three designs

4. Conclusion

Dry reforming of methane is considered as an environmentally friendly process to produce syngas as it consumes two GHGs. The energy requirement for the DMR process is significantly lower than what is required in the gasification process. The O/C ratio is an important parameter which controls the syngas composition and its heating value. Adding WGS to gasification process can give a wide range of syngas ratios for downstream consideration. There is a need to further investigate the feasibility of the process by analyzing process economics.

Abstract

The rise in world population and industrialization in developing nations has tremendously increased the demand for water and has resulted in wastewater contaminated with several pollutants. Thus, wastewater treatment (WWT), reuse, and safe disposal have become crucial for sustainable existence. We believe that generation of a maximal structure (superstructure) comprising of all possible treatment methods and flow patterns using a systems approach, followed by optimization to decide the best treatment pathway, will enable efficient designing of WWT networks. In this work, the technologies/methods involved in WWT such as sedimentation, filtration, membranes, adsorption, activated sludge, etc. are modelled using material and energy balances, equipment design, costing and environmental impact. Utilizing systematic methods (*e.g.* mixed-integer non-linear programming, MINLP), we frame the WWT network selection as an optimization problem for cost and energy minimization along with sustainable goals. In our analysis, we demonstrate a case study of Municipal WWT and determine the best strategy in compliance with the 1972 US EPA's Clean Water Act to reuse the treated water for cropland irrigation. In the next step, we use the P-graph approach for solving the same problem and this tool provides a ranked list of candidate solutions.

Keywords: water, technology model, optimization, P-graph, sustainable process design

1. Introduction

Water is a necessary commodity, without its services in the industry, agriculture and domestic sectors the human species would cease to exist. The population rise has resulted in increased environmental pollution, majorly influencing urban water resources with issues such as low dissolved oxygen, bacterial contamination, and disruption in aquatic flora and fauna. Thus, strategies for judicious water consumption, pollution prevention, and efficient WWT are required for sustainable existence. Water pollution control boards and federal regulatory agencies (NIH, 2015; US EPA, 2013) have a well-defined list of pollutants and their safety limits, however, with advancements in industrial processing, new and unknown contaminants enter the waste streams ultimately leaching in groundwater sources. Hence, the need for improved

technologies and stage-wise WWT methods (Melo-Guimarães et al., 2013; Ponce-Ortega et al., 2009). Additionally, treatment plants need policies to minimize costs and energy requirements while maintaining the necessary regulations. Some factors that affect technology selection in WWT network are the wastewater characteristics, purity requirements, reliability, sludge handling, and costs.

2. Materials and Methods

2.1. Treatment Stages and Technologies

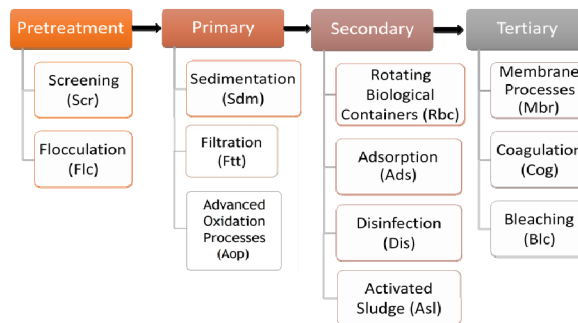
WWT is usually considered as a four-stage process: pretreatment, primary, secondary, and tertiary. An overview of the treatment stages and technologies involved are described in Figure 1 (Inc et al., 2002; Lipták and Liu, 2000; Liu et al., 2015). Depending on the purity standards and the number of contaminants in the waste stream, WWT plants may utilize one or more technologies from each stage, for example, a treatment path might follow screening, sedimentation, adsorption, and bleaching.


Figure 1 Traditional stage-wise wastewater treatment scheme

Pretreatment methods are used to enhance the operations in the following stages. Primary stage involves the removal of solid wastes. Sdm and Ftt are very successful at removing solid waste from wastewater. Aop can remove other harmful agents such as active pharmaceutical ingredients (API). Secondary stage methods may utilize microorganisms (Rbc, Asl) and disinfectants (Dis) to purify wastewater (Deng and Zhao, 2015; Shukla et al., 2006). Tertiary stage removes leftover contaminants and colour imparting impurities.

2.2. Heuristics, Technology Information and Engineering Judgement

Heuristics can guide in shortlisting the appropriate technology options. For example, characterizing the properties of contaminants present is a stream coming from a specific source of wastewater. Few identifiers for contaminant properties include physical state, size, and shape, density, relative amount, toxicity index, boiling point, biological affinity, chemical reactivity, etc. The second set of information should include the treatment technology options, the principle or driving force behind the purification and the process conditions or specifications that are essential while designing a treatment technology. Table 1 enlists a few technology options with their defining characteristics. However, heuristics can sometimes lead to the elimination of important non-intuitive solutions and thus a more systematic approach, which is more inclusive and unaffected by prior biases, is desired for efficient design.

Table 1. Wastewater treatment technologies and their important characteristics

Technology	Principle/driving force	Specifications/Process conditions
Sedimentation (Sdm)	Density gradient Particle settling velocity	Size, Particle density, Tank depth, Residence time
Filtration (Ftt)	Particle size	Average flux, Pressure gradient, Filtration rate
Advanced Oxidation Process (Aop)	Oxidation reactions for contaminant degradation	Ozone, peroxide, UV reactor
Disinfection (Dis)	Chemical, radiation	Chlorine dosage, Acid/Alkali treatment, UV radiation
Rotating Biological Contactors (Rbc)	Biological mechanism	Biological film on discs, speed of rotation, aeration rate
Membranes (Mbr)	Particle/molecular size Sorption/Diffusion Pressure	Pore size, Mol. wt. cut-off Flux, Pressure gradient, Type - MF, UF, NF and RO
Activated Sludge (Acs)	Microbial activity	Detention time, mixing efficiency, aeration rate

Sources: (Deng and Zhao, 2015; Ho and Sirkar, 1992; Lipták and Liu, 2000; Liu et al., 2015; Melo-Guimarães et al., 2013)

2.3. Wastewater Treatment Superstructure

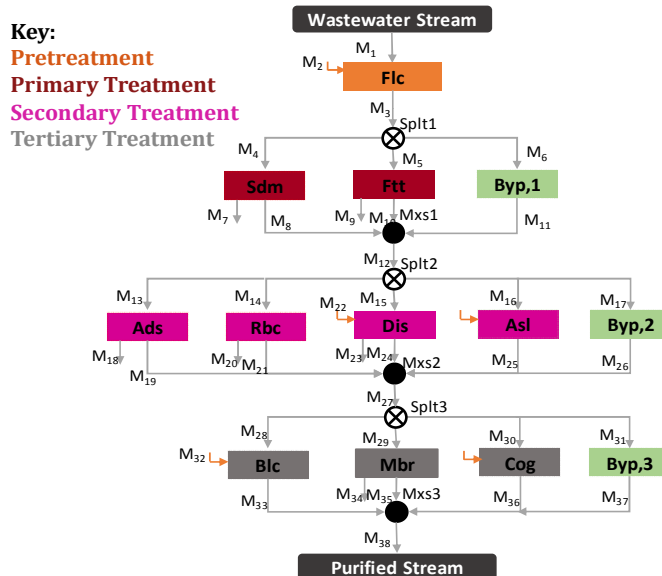
Superstructure is a systematic representation of all possible treatment technologies available in the four stages of wastewater treatment. It also shows the flow from the initial wastewater stream towards the final purified water stream. Figure 2 shows the current WWT superstructure for treatment of municipal wastewater. The bypass (Byp) option is inlcuded in stages 2, 3 and 4. The current superstructure consists of 4 treatment stages, 10 technologies, 38 streams, 3 splitters, and 3 mixers.


Figure 2 The stage-wise wastewater treatment superstructure for municipal wastewater treatment to reuse it for cropland irrigation

2.4. Framework for Evaluation

Step#1: Formulate the case study by defining the input stream composition and output stream purity specifications

Step#2: Construct an optimization model as a Mixed-Integer Non-Linear Programming (MINLP) problem that consists of:
  - Mass and energy balances
  - Design equations, cost calculations: capital (equipment) and operating (utility, materials, consumables, labor and overhead requirements) costs
  - Binary integer variables to select technology in use by holding a (0,1) value

Step#3: Minimize treatment costs while still reaching target values for safe reuse/ disposal of wastewater written as a mathematical objective function

Step#4: Develop the optimization model in GAMS (General Algebraic Modeling System) and solve by global MINLP solvers such as BARON (Branch-and-Reduce Optimization Navigator) (Kılınç and Sahinidis, 2018)

Step#5: Implement the same case study in P-graph studio (Friedler et al., 1992; Heckl et al., 2010) that utilizes concepts from graph theory to obtain the maximal structure, list alternative paths (solutions) in the superstructure and rank them

3. Results and Discussions

The case study details with the list of inlet contaminant concentrations and the purity requirements for cropland irrigation are presented in Table 2 (Page et. al., 1996). Inlet wastewater flowrate is assumed at 100 m^3/h and plant operates for 330 days annually.

Table 2. Municipal case study contaminant concentrations and purity levels

Contaminant	Inlet Concentration (g/L)	Outlet Specification (g/L)
Solids (Settleable)	200	≤ 0.5
Metals (Pb, Cu, Zn, Ni)	0.1	≤ 0.05
Chemicals (Acids, chlorides, organics, and inorganics)	1	≤ 0.5

3.1. Solution from the GAMS-MINLP problem

The model in GAMS had a total of 267 equations, 199 variables, and 12 binaries. The solution time was less than a minute with a relative gap of 0.00001. The cost of the wastewater treatment per hour was obtained as 6252.27 USD/h. The technologies selected (Flocculation, Flc, Sedimentation, Sdm and Adsorption, Ads) and active streams are highlighted in Figure 3 and the cost distribution chart shows that the materials cost (flocculent and adsorbent) is the highest contributor. Utility costs are negligible as the selected technologies do not require significant amounts of electricity, cooling or heating.

3.2. Solution from the P-graph framework

The same case study was implemented in P-graph; the maximal structure and the comparable structure to the GAMS-MINLP solution is presented in Figure 4. The cost of wastewater treatment from P-graph is 6219.14 USD/h, which is comparable to the GAMS solution (6252.27 USD/h). This cost discrepancy is due to the linearized cost (capital and operating) equations required in P-graph. However, the cost deviation in

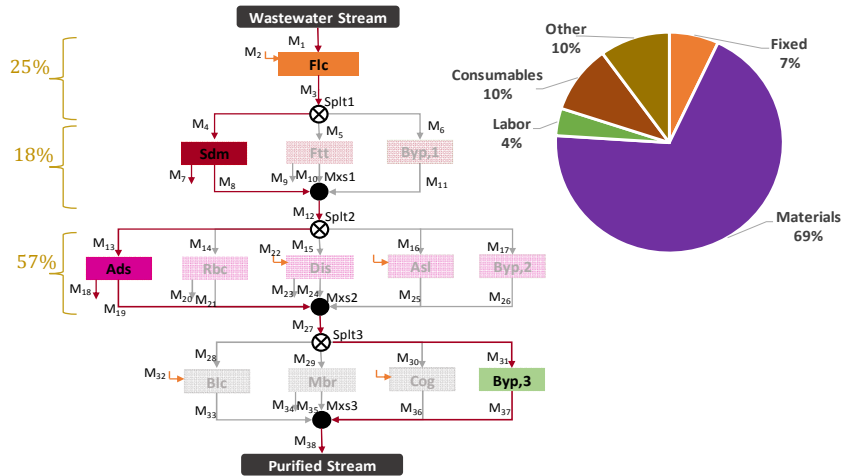
values predicted by GAMS and P-graph is less than 1% and we gain additional insights which were not possible in the GAMS-MINLP framework.


Figure 3. Solution for Municipal WWT case study from GAMS showing the active technologies and streams with cost distribution chart on the right

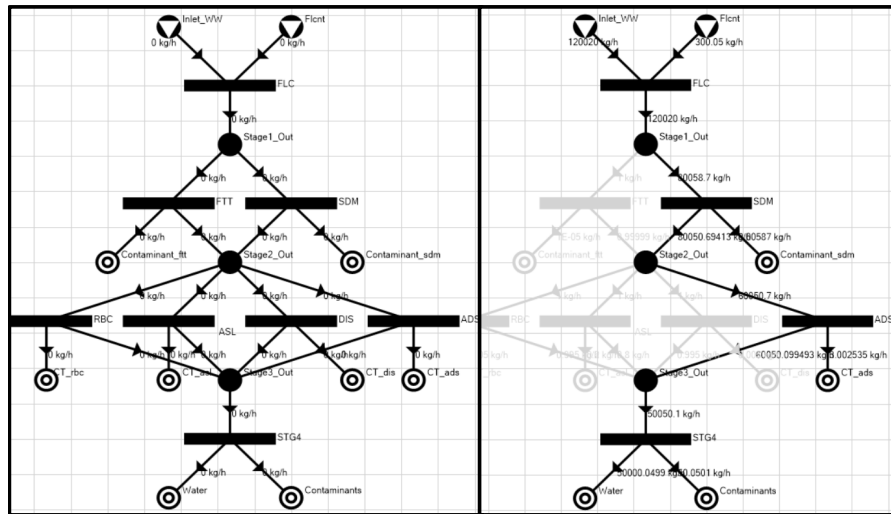
However, the structure (Flc-Sdm-Ads) is ranked#3 in the optimal feasible structure list. The rank#1 (2673.7 USD/h, consisting of Flc-Sdm-Rbc) and rank#2 (5033.33 USD/h, consisting of Flc-Ftt-Rbc) low-cost feasible structures (networks) are not predicted by the GAMS model. We tested these low-cost structures in GAMS and found that the purity levels of the outlet streams were lower than desired for cropland irrigation. We plan to investigate the differences in costing due to linearizations in the future analysis.


Figure 4. The Municipal WWT case study implemented in P-graph showing the maximal structure on the left and the feasible structure comprising of flocculation, sedimentation, and adsorption with the active streams on the right.

4. Conclusions

In this work, we have proposed a systematic framework for designing wastewater treatment networks. The heuristic-based superstructure is modelled as a MINLP problem in GAMS and the optimal network includes, Flc (stage-1) – Sdm (stage-2) – Ads (stage-3) – Byp (stage-4) with a cost of 6252.27 USD/h. The same case study is modelled in P-graph studio and the results show that the GAMS optimal network is ranked #3 with a comparable cost of 6219.14 USD/h. We believe that the comparative analysis provides a complete perspective into ranked solutions and identifies options, which may prove cost effective by comprising on certain purity constraints. In future, we plan to evaluate the networks with multiple outlet streams with different specifications. Furthermore, we will extend the analysis to include sustainability index for the ranked list of optimal networks predicted by both these approaches.

Abstract

Utility operators involved in energy, waste and water sectors are exploring technology options to generate energy in a sustainable way, while also dealing with waste streams including sewage and municipal solid waste from growing urban environments. The resilience.io platform was developed to study long term changes and development in an urban area of region under a range of policy, behaviour, economic and technological scenarios, to meet local resource demands in a cost-effective and sustainable way. A systems modelling approach studying waste-to-energy in New South Wales suggests initial findings are a suitable starting point for further exploration of the potential in the region using this approach as well as complementary tools and methodologies. Model results show 854 GWh renewable energy could be generated through waste-to-energy pathways in 2036.

Keywords: waste to energy, water, infrastructure modelling

1. Introduction

The Hunter region, in New South Wales, Australia, is undergoing an economic and sustainability transition. Hunter's Smart Specialisation Strategy (Regional Development Australia Hunter, 2016) is Australia's first policy aimed to identify the region's competitive strengths and formulate specific activities to make the most of the key growth areas. "In a post-mining boom economy", it encourages new ideas to "build on [the Hunter's] strong knowledge-base in mining, energy, agriculture and medical research" (ibid: p.14). It also highlights the wider context of climate related challenges, the call for a reduction in greenhouse gas emissions, an energy matrix with an increasing proportion of renewables, demographic shifts and urbanisation (Government of Australia, 2015).

The focus on energy security in a changing environment is reflected at the state level, where the government intends to ensure that NSW is well prepared for the current transformation of the energy markets. Therefore, key actions in the NSW State Infrastructure Policy 2018-2038 (NSW Government, 2018) ensure reliable and affordable energy, focus on supporting private investment in efficient energy generation and horizon-scanning for new approaches. Moreover, the NSW government has set an aspirational goal to achieve
Figure 1: The study area in the Hunter Region, focusing on the area supplied by Hunter Water (highlighted) as well as neighbouring regions in Upper Hunter and Central Coast.

net-zero emissions by 2050 which can be clearly seen as a driver for innovation and development of new climate-compatible growth, jobs and livelihoods in the region.

Utility operators in urban environments, particularly those involved in energy, waste and water sectors, are exploring technology options to generate energy in a sustainable way, while also dealing with waste streams (e.g. sewage and municipal solid waste). Policies at different levels and from different angles appear to provide a window of opportunity to consider waste-to-energy (WtE) as a catalyst for green growth in the region. This paper explores this potential using an optimisation model representing the region and its resources, networks and technologies.

2. Methodology

The resilience.io platform (Triantafyllidis et al., 2018) was developed to study long term changes and development in an urban area of region under a range of policy, behaviour, economic and technological scenarios, to meet local resource demands in a cost-effective and sustainable way. It provides modules to allow forecasting of socio-demographic scenarios, simulating spatio-temporal activities, and planning investment and operational strategies. Agent-based modelling to simulate the population (with their activities and resource demands) is combined with resource-technology-network optimisation to find a suitable combination of technologies, their location and size, to meet these demands. Scenarios can be set up to vary the population, their activities, new technologies and economics properties. To study the nexus between water, energy and waste, this platform can then be used to identify opportunities based on modelled material flows and conversion technologies. Resources available and waste generated can be simulated or included from published data and regional forecasts, with specific technologies (with their economic and environmental performance) selected as input for the optimisation model.

3. Case study

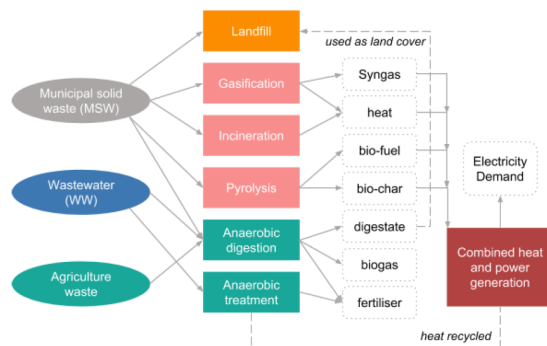
In close cooperation with a local utility operator a model has been set up to simulate the current water and energy demand, supply and networks for a region in New South Wales, Australia, to explore potential future designs and interventions to take advantage of synergies at the water-waste-energy nexus. Figure 1 shows the main case study area. Key resources incorporated in the model include potable water, non-drinking water (industrial use), source water, electricity, gas, domestic waste (municipal solid waste, sewage),


Figure 2: Possible pathways for processing and use of waste from households, waste water and the agriculture sector with technologies that can supply energy. Based on Wang et al. (2018)

Table 1: Data sources used as input for the optimisation model

agricultural waste, sludge, and carbon dioxide. Potential conversion technologies are compared to alternatives for waste handling such as landfill (see Figure 2). The spatially explicit optimisation model selects which options can be attractive from an economical and environmental perspective, where to locate them to take advantage of local feedstock, and sizing to meet local demands as well as the creation of distribution networks.

The year 2016 is taken as base year, simulating 5 year intervals until 2036 which is the target year for the regional plan (NSW Government, 2018). The population is characterised by Sex, Age, Employment status, Income status, and annual population growth rate for this period is assumed to be the same level as in 2016. Demand data from 2016 was used as baseline, with the growth related to the population growth in the different regions from Figure 1. For modelling the current infrastructure networks, existing technologies for energy, waste and water, and for waste produced (municipal solid waste, agricultural waste, and waste water) a rich selection of local sources was used, see Table 1.

The agricultural and other organic waste data is from MRA's report to Hunter Water, which identifies a total of 3.3 million tpa of organic feedstock in Lower Hunter and Central

Coast. It is understood that the spatial distribution and amounts of accessible organic waste is unclear at this time. However, since the model investigates the development of Hunter region until 2036, all feedstocks are assumed to be accessible and their spatial distribution is assumed to follow the sociodemographic growth trends in different regions.

4. Scenarios

This section describes the waste to energy scenarios explored in this project using the systems model for the Hunter region described above, leading to insights on the potential contribution of waste to energy pathways in the region. Three scenarios related to waste to energy are explored:

1. Business-as-usual; a baseline scenario using the current infrastructure in the region for water and energy (electricity and gas)

2. Waste to energy scenario (WtE), in which biosolids, municipal solid wastes, agricultural wastes and other organic wastes are considered as the (co-)feedstock of renewable energy generation using anaerobic digestion (with thermal hydrolysis), incineration, gasification and pyrolysis.

3. Economic/policy scenarios, including changes feed-in-tariffs and carbon credit to study the sensitivities of waste to energy. Each scenario is considered at the current situation (based on 2016 data as a baseline) as well as forecasts at 5 year intervals until 2036 following the timeline of the 20-year regional blueprint published by the NSW government.

The Business as usual (BAU) scenario serves as a basis to analyse the changes in other scenarios. In terms of waste management, biosolids is modelled by using BAU options provided by GHD Pty Ltd (2018)'s thermal hydrolysis option comparison. The input waste streams are assumed to leave the system through recycle/recovery and landfill at different prices. The biosolids disposal cost via land application program is included in the system based on cost data provided by Hunter Water. Other than biosolids, MSW will have a landfill levy assumed to be AUD 78.20 dollar per tonne.

5. Results

The model simulation and optimization starts from year 2016 where no WtE facility is installed. With five year intervals, the model progressively suggests optimal WtE strategies up to 2036 based on both economic incentives and spatial-temporal constraints. The results are generated for biosolids, municipal solid waste, agricultural waste and other organic waste. Note that agricultural waste and other organic waste (post-consumer food waste, etc) are shown together as same technology data are used. Figure 3 shows the transportation of biosolids between the different sites in 2036 as a result of optimal allocation of WtE installations, and similar graphs can be generated specifically for e.g. municipal solid waste.

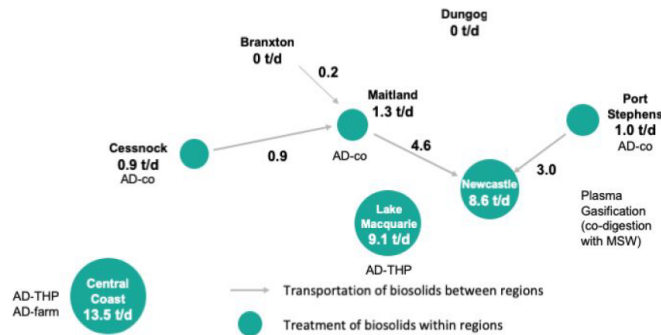
Four biosolids WtE options have been selected by the model at the timestamp of 2036. Plasma gasification with MSW as co-feedstocks (plasma), AD with thermal hydrolysis


Figure 3: Treatment and transportation of biosolids between and in district (tonnes per day) after the optimisation of WtE technologies and their locations for 2036

(AD-THP) and AD with MSW and wastewater as co-feedstocks (AD-co) are favoured by the model using the objective function and defined economic and environmental performance indicators

Pyrolysis and incineration of biosolids are eliminated by the model, as they are not allocated for waste to energy conversion. The reason is presumed to be their inefficient renewable energy generation under the assumptions of the model. 16.5 GWh of energy can be generated from biosolids mainly in the form of natural gas. If all natural gas is converted to electricity, the value is 5.1 GWh, which can be used to reduce wastewater treatment energy consumption by 16%. Two centralized AD-THP are suggested by the model in Central Coast and Lake Macquarie to treat biosolids only, accounting for 70% of total biosolids in the study area. They are selected for major biosolids WtE pathway due to their relatively low costs. Plasma gasification are proposed to treat 8.6 tonnes per day biosolids together with municipal waste generated in or transported to Newcastle. The plasma plant is mainly used for municipal waste treatment, but the remaining capacity of the facility is identified by the model to be further utilised for biosolids WtE processing. AD co-digestion of MSW with biosolids are also proposed in Port Stephens, Maitland and Cessnock. The plants treat most of the MSW in the corresponding region and also handle a smaller potion of local biosolids. The remaining biosolids will be transported to Newcastle for centralized plasma treatment. The selection of an AD-co plant can be explained by the increased wastewater generation in 2036. With no wastewater reclamation facilities installed over 20 years, AD-co plants can effectively reduce the load of wastewater treatment plant and recover energy from biosolids. A farm AD plant is also allocated in Central Coast to recover energy from the remaining biosolids that will not be treated by the centralized AD-THP. This shows that the model only select decentralized facilities when centralized plants cannot treat all the waste in a region in an efficient way.

A carbon pricing scheme was introduced to Australian industrial sector from 2012 with a cost of 23 AUSD per tonne of emitted carbon dioxide, which was abolished later in 2014. The previous WtE scenario thus assumes zero carbon price in the optimization. In a further scenario, the carbon credit prices are set as alternatively 25 AUSD, 75 AUSD or 125 AUSD per tonne of CO_2 to study its effects on the three key indicators: CAPEX, OPEX and GHG emission.

6. Conclusions and final remarks

A total of 854 GWh renewable energy can be generated through WtE pathway in 2036. 94% of the generation from waste is in the form of biogas or syngas. By upgrading to natural gas and injecting into gas grid, the gas-to-electricity conversion losses can be avoided, and less energy transmission losses will incur. Biogas generation is thus considered to render more economic benefits than electricity. Decentralised technologies are optimal due to the large amount of waste distributed in each region. Organic feedstocks identified in the study region possess vast potential for WtE pathway, as the WtE energy contributed by agricultural waste in 2036 will cover about 80% of total generation.

The systems approach presented in this report can be seen as a starting point for the exploration of different visions and futures for the region, with local stakeholders at the centre of the decision making process. The data as well as simulated scenarios will enable well-informed decisions and further detailed examination of options deemed attractive at the systems level. Following a systems approach, the interdependencies between infrastructure systems and sectors will continue to be at the core of planning integrated solutions at the national, regional and local level.

Abstract

Flexible operation of the switchable chlor-alkali process is a novel strategy for minimizing electricity costs in markets with volatile prices (Brée et al. (2018)). This strategy allows for adjusting the process to electricity price profiles, by varying the production rate and by switching the operation between two different modes: the H_2 mode and O_2 mode. The size of the electrolyzer is a crucial factor because oversizing on the one hand leads to higher operational flexibility but on the other hand to increased capital costs. Here, we combine the optimization of the operation and electrolyzer size in the switchable chlor-alkali process for given electricity price profiles. To arrive at the optimum in reasonable computation time, we use a piecewise linear approximation and decomposition method employing the golden-section search. We verify that electrolyzer oversizing in the switchable chlor-alkali process is a suitable strategy for reducing the total production cost when the specific capital costs of the oversizing are low enough and the electricity price strongly fluctuates.

Keywords: demand side management, bifunctional cathode, chlor-alkali electrolysis, decomposition method, MILP

1. Introduction

As intermittent renewable energy penetrates the power grid, electricity prices and availability fluctuate more. A need could arise for power-intensive processes like chlor-alkali (CA) electrolysis to employ smart operation strategies. One possible strategy is demand side management (DSM), which allows for flexible operation of the process to adjust the production rate to electricity price profiles (Daryanian et al. (1989); Ghobeity and Mitsos (2010)). The production rate can be varied when an electrolyzer is oversized; and intermediates are storable or the downstream processes are also operated flexibly. Another DSM strategy for CA electrolysis is to switch its operation mode by implementing a bifunctional cathode. This novel cathode (Bulan et al. (2017)) enables to switch the operation between hydrogen (H_2) and oxygen (O_2) modes. The O_2 mode demands less electricity than the H_2 mode at the expense of not producing H_2.

Brée et al. (2018) examined the optimal operation of an oversized CA electrolyzer with the bifunctional cathode implemented. The operation was optimized by solving a mixed-
Figure 1: Description of the electrolysis and operation of the switchable CA process.

integer linear program (MILP) that minimized operating costs on the basis of a discrete-time model. The results verified that oversizing the electrolyzer can reduce operating costs when electricity prices fluctuate sharply. Moreover, additional savings are achievable by adopting the switchable operation. When electricity is expensive and H_2 and O_2 are cheap, operation in the O_2 mode is economically preferred.

Oversizing the electrolyzer, however, affects the total production cost of the CA process. It requires extra capital cost, which reduces the profitability. Therefore, the electrolyzer oversizing and reduction of operating costs are at a trade-off (Williams et al. (2012)).

Herein, we examine how electrolyzer oversizing affects the optimal operation of the switchable CA process by modifying the optimization problem formulated by Brée et al. (2018). A sizing factor is introduced as a continuous variable. The modified optimization problem minimizes the total production cost that is the sum of the operating cost and annualized additional capital cost resulting from oversizing the electrolyzer. The modification results in a large-scale mixed-integer nonlinear program (MINLP). Its solution to global optimality is computationally demanding. To reduce the computation cost, we consider the sizing factor as a complicating variable and utilize a decomposition method. At the outer, the golden-section search (GSS) technique is applied to optimize the sizing factor while the subproblems are MILPs. This strategy gives the global optimum in tractable computational time.

2. Description of Operation Strategies

Two operation strategies are applied to the switchable CA process. One is designed to vary the production rate while the other aims to switch the operation between the H_2 and O_2 modes. Figure 1 illustrates the operation scheme.

2.1. Production Rate Variation

Conventional CA electrolyzers in Germany produce chlorine (Cl_2) typically at very high utilization capacity (>95 %), so there is only little potential for flexible operation (Ausfelder et al. (2018)). When a CA electrolyzer is oversized, i.e., its production capacity exceeds the demand in the downstream process, it is possible to adjust the production rate to electricity price fluctuations by changing the voltage applied. When electricity is expensive, the production rate is reduced so that less electricity is consumed. A Cl_2 storage tank is installed as a buffer to guarantee the constant Cl_2 supply to the downstream, that is assumed to operate as is. If necessary, the process can be shut down.

2.2. Switchable Operation

In the H_2 mode, the anode compartment is filled with saturated brine to produce Cl_2 gas and sodium ions (Na^+). Na^+ ions migrate through an ion-exchange membrane, and then sodium hydroxide (NaOH) is produced along with H_2 gas at the cathode compartment. In the O_2 mode, the reactions are the same as in the H_2 mode at the anode side. At the cathode side, gaseous O_2 contacts the cathodic liquid phase and is reduced without H_2 production. The O_2 mode demands less electricity than the H_2 mode by 33 % (Jung et al. (2014)) while still producing the same amount of Cl_2 and NaOH. However, operation in the O_2 mode no longer generates the H_2 by-product while it requires additional O_2. To avoid the presence of both gases simultaneously, a cleaning process that removes either H_2 or O_2 inside the cell is required when the operation is switched.

3. Problem Formulation and Algorithm for Optimization

3.1. Problem Formulation

In this optimization, the electrolyzer size and the operation of the switchable CA process (the active operation mode and production rate) are simultaneously optimized. A sizing factor (α) is considered as a continuous variable with given bounds as $1 \leq \alpha \leq \alpha^{up}$. For example, α of 1.3 indicates the production capacity is increased by 30 %.

Mass Balance and Mode Transition Constraints to calculate the consumption and production rates ($\dot{m}_{C,t}$) of each component C and control the mode transition and level of the Cl_2 storage tank are the same as Brée et al. (2018) except for the changes described in the following. The CA process can operate only at of three modes $m \in \{H_2, O_2, Shutdown\}$. Once the process is shut down, either the H_2 or O_2 mode can be active after a certain duration for cleaning. The production rate during the operation is limited by the equation

$$\alpha \underline{\dot{m}}_{Cl2} y_{m,t} \leq \dot{m}_{Cl2,m,t} \leq \alpha \overline{\dot{m}}_{Cl2} y_{m,t}, \quad \forall m \in M, t \in T, \tag{1}$$

where $\overline{\dot{m}}_{Cl2}$ and $\underline{\dot{m}}_{Cl2}$ denote the maximum and minimum active production rates, respectively. When mode m is active at time t, a binary variable $y_{m,t}$ is 1. The production rate is kept above 50 % of the production capacity to ensure the product quality, but it cannot exceed the production capacity. Both the lower and upper bounds are proportional to α.

Power Demand Function The power demand for the reactive modes, calculated as

$$P_t = \frac{a}{\alpha} \dot{m}_{Cl2,t}^2 + b \dot{m}_{Cl2,t}, \quad t \in T, \tag{2}$$

is a quadratic function of the Cl_2 production rate. The sizing factor influences the power demand function. Here, a and b are parameters. To formulate an MILP, we perform a piecewise linear approximation by dividing the Cl_2 production rate into four ranges:

$$P'_{t,e} = a'_e \dot{m}_{Cl2,t} + b'_e \alpha + c'_e, \quad e \in \{1,2,3,4\}, \quad t \in T, \tag{3}$$

where a'_e, b'_e, and c'_e are obtained by parameter estimation from the original power demand P_t calculated.

Ramping Constraints A ramping constraint is imposed on the production rate by

$$\Delta \dot{m}_{Cl2} = \alpha \left(\overline{\dot{m}}_{Cl2} - \underline{\dot{m}}_{Cl2} \right) / \theta_{ramp}, \tag{4}$$

where θ_{ramp} denotes the number of time steps necessary to ramp the production between $\overline{\dot{m}}_{Cl2}$ and $\underline{\dot{m}}_{Cl2}$. The maximum and minimum allowable production rate of the subsequent time step $(t + 1)$ depends via

$$\dot{m}_{Cl2,t+1} \leq \dot{m}_{Cl2,t} + \sum_m y_{m,t} \Delta \dot{m}_{Cl2} + \left(1 - \sum_m y_{m,t}\right) \alpha \underline{\dot{m}}_{Cl2}, \quad \forall m \in \{H_2, O_2\}, \quad t \in T, \tag{5}$$

$$\dot{m}_{Cl2,t+1} \geq \dot{m}_{Cl2,t} - \sum_m y_{m,t+1} \Delta \dot{m}_{Cl2} - \left(1 - \sum_m y_{m,t+1}\right) \alpha \underline{\dot{m}}_{Cl2}, \quad \forall m \in \{H_2, O_2\}, \quad t \in T. \tag{6}$$

Objective Function We minimize the total production cost (C^{TO}) calculated by

$$C^{TO} = C^{OP} + C^{CAP} = \sum_{t=0}^{t_n} (C_{C,t} + C_{El,t}) + (\alpha - 1) a^{CAP} f^{CAP}, \quad \forall C \in \{H_2O, O_2, H_2\}, \tag{7}$$

which is the sum of the operating cost (C^{OP}) and annualized capital cost (C^{CAP}). Inclusion of the H_2 cost indicates that H_2 should be supplemented when the O_2 mode is active. The annualized capital cost for the oversized portion of the electrolyzer is a function of α and a coefficient a^{CAP}. A 1-year depreciation factor f^{CAP} is calculated by

$$f^{CAP} = (i(1+i)^n)/((1+i)^n - 1), \tag{8}$$

where i and n denote an interest rate and electrolyzer lifetime, respectively.

3.2. Optimization Algorithm

The inclusion of the sizing factor results in an MINLP problem due to bilinear products (e.g., $\alpha y_{m,t}$) that demands heavy computation costs. Note that since the bilinear products all involve a binary variable, the MINLP can be exactly reformulated as an MILP, e.g., using the big-M method. Our computational experimentation, however, showed that these MILPs are still expensive to solve. To reduce the load, we apply a decomposition method, considering the sizing factor as a complicating variable. This leads to an MILP subproblem. The global solution is then found by the GSS on the complicating variable.

4. Simulation Results

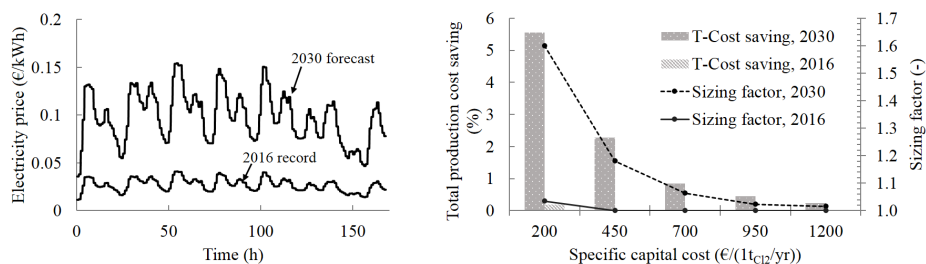
The nominal plant capacity ($\alpha = 1$) is 1 t_{Cl2}/h. The storage tank can store the nominal Cl_2 supply to the downstream for a maximum of 3 hours. The time horizon T for simulation


Figure 2: Electricity price profiles in 2016 and 2030 in Germany (left) and simulation results; savings in the total production cost and the optimal sizing factor (right).

is one week and discretized into 672 time steps (15 minutes for one time step). The maximum oversizing is up to 100 % ($\alpha^{up} = 2$). The specific capital cost for oversizing the electrolyzer highly depends on the individual settings of the pre-existing site. To calculate the annualized capital cost, a specific capital cost of €200 up to €1,200 per yearly production of 1 t_{Cl2} (Arnold et al. (2016)), 7 % of the interest rate, and 10 years of the electrolyzer lifetime are assumed. Two electricity price profiles recorded in first week of June in 2016 (Agora Energiewende (2018)) and assumed for 2030 by Brée et al. (2018) are considered (Figure 2, left). The latter one with the higher average price and more pronounced fluctuation reflects the prediction that employment of renewable energy sources in the German power sector will increase in 2030. H_2, O_2, and water (H_2O) prices are 2 €/kg_{H2}, 0.05 €/kg_{O2}, and 0.01 €/kg_{H2O}, respectively. The shutdown mode is active for at least 30 minutes. Once a reactive mode becomes active, such a mode lasts for at least 12 hours to prevent shortening the electrolyzer lifetime. The optimization problem implemented in GAMS 24.9.2 is solved by CPLEX 12.7.1.0 with a relative optimality tolerance of 10^{-5} and 12 threads for parallel processing.

Figure 2 (right) shows that, the specific capital cost for oversizing the electrolyzer highly influences the optimal size of the electrolyzer in the switchable CA process as well as the reduction of the total production cost compared to the reference case with no oversizing and operation switch. The lower specific capital cost leads to the larger electrolyzer and higher savings in the total production cost accordingly. The optimal size of the elec-
Figure 3: Optimal Cl_2 production rate profile and active mode for the specific capital cost of 200 (left, α=1.6) and 1,200 €/($1t_{Cl2}$/yr) (right, α=1.02) in the 2030 scenario. Blue indicates the H_2 mode, yellow the O_2 mode, and orange the Shutdown mode.

trolyzer in the 2030 scenario is far bigger than in the 2016 scenario. When the electricity price fluctuates sharply, varying the production rate becomes advantageous. Unless the specific capital cost is very low, the oversizing is not recommended in the 2016 scenario.

Figure 3 represents the optimal Cl_2 production rate profile and active mode of the switchable CA process in the case where the specific capital cost for oversizing the electrolyzer is 200 €/($1t_{Cl2}$/yr) and 1,200 €/($1t_{Cl2}$/yr) on the basis of the 2030 scenario. More frequent shutdown of the process is observed with the lower specific capital cost: 10 times in the 200 €/($1t_{Cl2}$/yr) case and only twice in the 1,200 €/($1t_{Cl2}$/yr) case in a week. The larger electrolyzer provides more flexibility for the operation switch.

5. Conclusions

We investigated the influence of the capital cost for oversizing the electrolyzer in the switchable CA process on its optimal operation for DSM concerning electricity price profiles. We formulated an MINLP problem to minimize the sum of the operating and annualized capital costs while optimizing the electrolyzer size and operations. To find the global solution within reasonable computation time, we applied a decomposition method employing the GSS. As a result, it is noted that the specific capital cost for oversizing the electrolyzer highly affects the optimal operation. The cheaper the specific capital cost, the more frequent the plant is shut down and the higher the savings in the total production cost are. Finally, we verify that oversizing is a suitable strategy for DSM when the electricity price fluctuates strongly and moderate storage of Cl_2 (order of three hours) is allowed.

Abstract

Argentina targets a 20% share of renewables in the energy mix by 2025 and a 15% emissions reduction by 2030, while at the same time removing subsidies for grid electricity. This paper aims to provide a feasible solution for small farm owners for sustainable and affordable energy: a grid-connected hybrid system able to fulfill the demand in a cheaper, reliable and sustainable way. The case study of an existing dairy farm in Carmen de Areco, Buenos Aires, is taken. A grid-connected hybrid system with solar photovoltaics, unheated anaerobic digestion (AD) coupled to an internal combustion engine and storage system, was selected. The size of the hybrid system was optimized via a mathematical model that compared different technologies. The interrelation between sources was economically optimized in order to match the demand on an hourly basis. The scenario comparison defined the optimal solution for this case study, which was the installation of an unheated AD plant with 2.4 kW capacity, and 16 solar panels with a capacity of 5.2 kW, added to a shift in the demand profile. The initial investment required is 17,042 USD, with a payback of 3.4 years and a GHG reduction of 275.9 tons of CO_2 eq per year.

Keywords: bioenergy, solar energy, dairy farm

1. Introduction

New targets defined by Argentina include an increase in the share of Renewable Energy (RE) to 20% in the energy mix by 2025 and a 15% emissions reduction by 2030 (Porcelli and Martínez, 2018). Together with this shift towards sustainability, the government implemented a subsidy scheme removal in 2016, generating a rise in electricity bills that affected end users in domestic and business segments, including rural sector (Observatorio Economico Social, 2017). The affordability and reliability concerns of the rural grid increased the problems for agricultural farmers. This project aims to provide a feasible solution for small farm owners: a grid-connected hybrid system able to fulfill the demand in a cheaper, reliable and sustainable way. The case study of an existing dairy farm in Carmen de Areco, Buenos Aires, is taken.

The power industry is facing new network challenges worldwide with the rise of the re-

newables. The supply/demand equilibrium can be compared to a RE curtailment in case of an excess of generation, or to a rapid power compensation from fossil fuel power plants in case of unavailability of renewable resources. RE intermittency introduced a new need to the grid operators: today's power plants need to be more flexible, operate within a large load range and minimize emissions in order to react and compensate for possible RE changes. The higher the RE share in the energy mix, the higher the flexibility needed from back up fossil fuel plants to ensure heat and power availability when demanded. Gas-fired power plants will support this balancing given that nuclear energy cannot offer a rapid answer. Available capacity and response times are the key factors for conventional plants, since RE are intermittent (Qadrdan et al., 2017; Welch and Pym, 2017).

In this case study, the combination of an intermittent renewable with a fast responding, flexible biogas plant can deliver secure, reliable, and low-carbon energy. The constant biomass input into an anaerobic digester can produce a secure amount of biogas, being able to balance the supply. The surplus RE generation, rather than being constrained, can be stored (in gas or electricity form) for future use ensuring maximum flexibility. Affordable and reliable electricity can be provided thanks to a fully integrated hybrid system as the one presented before, minimizing environmental impacts and providing dispatchability and flexibility.

2. Approach

The literature mention two approaches: sizing the system and resources needed regarding the demand (Pantaleo et al., 2013), or calculating the energy supply from the resources available (Vis et al., 2010; Elbersen et al., 2012). In this case study, both approaches are proposed, but the heat and power demand will be the decisive approach. First, biomass and solar energy potential are estimated (see Section 3.1) then a demand analysis will define the system sizing; finally, a cost minimization procedure will determine the hybrid system to be implemented, based on the heat and power demand (see Section 3.2). The interrelation between the different sources was economically optimized in order to match the demand on an hourly basis. A baseline scenario was run with available farm data, obtaining a benchmark grid-connected hybrid system configuration. An economic analysis evaluated the investment profitability. Afterwards, multiple scenarios are run, evaluating demand side response, possible regulations outcomes, and technological upgrades (mesophilic AD technologies).

2.1. Case study

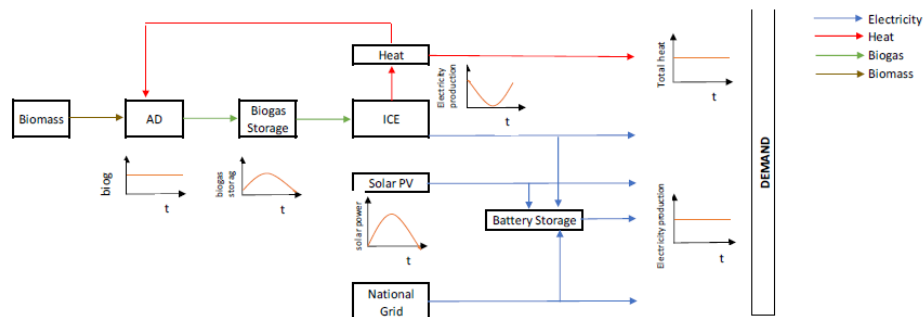
The case study is a family business in which the owner takes strategic investment decisions and operates the farm. The company has 7 workers, divided between stable and cattle operation, milk extraction operation, milk refrigeration and raw milk transfer. Having 304 cows, of which 256 in actual milk production, producing approximately 6,000 L of milk per day, it is a small-scale company. Cattle confinement is limited to twice a day for the milking. The mixture of manure, urine and water is held in an open lagoon. This is a normal structure for small and medium farms but lacks in design can potentially generate contamination problems. The decrease in water quality can affect the animal nutrition, minimizing milk production and productivity. In addition, bad water quality can potentially contaminate milk. Moreover, open tanks generate odors, favor insect proliferation


Figure 1: Hybrid System 2 (HS2) model (PV + AD).

(cow health and milk quality could be endangered), and CH4 emissions (Alessandretti, 2011). The farm's installations are common in small farming operations, including the milking room, the milk process and the waiting stable.

2.2. Hybrid PV + AD system

Eight different hybrid systems were compared, with a hybrid system based on biogas production from an AD digester, an ICE to generate electricity and heat and an array of PV and a storage system (see Figure 1) considered as most attractive option for this case study. The operation modes are the following:

- MODE 1: when the solar power is sufficient to meet the demand and charges the battery with the excess energy produced.

- MODE 2: when the solar power is sufficient to meet the demand, but not to charge the battery, the grid will charge it during off-peak hours if the grid price is lower than the bioenergy price.

- MODE 3: when solar power is insufficient to meet the demand and the ICE starts generating to meet the demand. Excess energy produced will charge the battery.

- MODE 4: when solar power is insufficient to meet the demand and the ICE starts generating to meet the demand, but not to charge the battery. The grid will charge it during off-peak hours.

- MODE 5: when solar power and ICE generation are insufficient to meet the demand and grid electricity is cheap (valley period), the grid starts providing the electricity needed.

- MODE 6: when solar power and ICE generation are insufficient to meet the demand and grid electricity is expensive (peak period), the battery starts providing the electricity needed.

- MODE 7: when solar power, ICE and battery are insufficient to meet the demand, the grid will provide the electricity needed, independent on its price.

The automatic selection of this modes by the energy management system (EMS) will define the instant operation of the system.

3. Methodology

3.1. Energy potential

Bioenergy production and potential depends on the number of cows in the farm, and on breeding and nutritional characteristics (Pantaleo et al., 2013). The total solid manure collected depends on the total number of cows producing milk (N^C), the number of hours in a closed stable (H^C) (manure collection is unfeasible in the fields) and a tabulated potential daily Manure Production per Cow (P^C). Total Manure Production per Day (P^d) becomes:

$$P^d = N^C * \frac{H^C}{24} * P^C \tag{1}$$

From (1) it is possible to obtain the volume of biogas generated per day.

The potential for solar energy varies depending on the power rating of the solar panels installed, the number of panels, the day of the year and the hour of the day. For these calculations, different literature was revised and used: McEvoy et al. (2003); Wenham et al. (2013); Mahachi (2016). Calculations take into account: Installation Relative Azimuth, Installation Tilt, Case Study's Latitude (φ) Sun radiation (P_{sun}), Day number (d), Solar Time max (ω), Temperature max avg, Sun radius (R_{sun}) and Relative distance Sun/Earth (r_o). Potential solar energy produced was calculated for winter and summer solstice, considering the available space for panels.

3.2. Optimisation model for the sizing of hybrid systems

An optimisation model was built in AIMMS with a modular structure. Demand and energy supply were divided into sections in order to organize and aggregate them in different ways. The different sections were demand per day, bioenergy per day, solar energy per day, storage per day, grid per day and finally the optimization and total emissions. The model represents the current Argentinian situation in which it is not possible to sell the energy surplus to the grid.

Demand parameters include hourly electricity demand, maximum electricity demand during peak, and minimum electricity demand during off-peak (in kW). Bio-energy parameters are those ones reported in eqn (1), together with investment and operational bioenergy plant costs. Solar energy parameters include peak power, area of panels, roof area, solar variation, capacity factor, CAPEX and OPEX. Further input parameters include storage investment and potential, grid connection operating costs (energy and power prices during peak and off-peak periods), and emissions.

The objective function for the model then is:

$$\text{minimise } Cost^{Tot} = Cost^{BG} + Cost^{SP} + Cost^{sto} + Cost^{NG} \tag{2}$$

where $Cost^{Tot}$ is the total cost, $Cost^{BG}$ is the cost for bioenergy, $Cost^{SP}$ is the cost for solar power, $Cost^{sto}$ storage costs and $Cost^{NG}$ the cost of supply from the national grid. This
Figure 2: Demand and supply per energy source with the optimised hybrid PV and AD solution.

is subject to constraints on meeting demand, maximum available supply from biogas, available supply from the solar installation, space constraints, battery constraints, and national grid constraints, as well as mass and energy balances.

The objective function in Eqn 2 represents yearly costs considering an annualized CAPEX, as well as fixed and variable OPEX of each technology, so both investment and operational costs of each technology are considered. This economic optimization aims to find the most cost-effective combination of technologies, sizing a hybrid system capable of supplying the electricity demand. However, according to the Argentinian energy market regulation limitations, the model does not take into account selling surplus renewable energy to the grid.

4. Results

For the baseline scenario, the optimal solution was a bioenergy installation of 2.3 kW, a solar energy installation of 5.2 kW (supplied by 16 solar panels) and a storage capacity of 29.9 kW. Figure 2 shows the demand and supply profile with this installation.

The baseline scenario optimization results are very specific of the techno-economic and regulative input conditions assumed for the dairy farm under investigation, and which could be, at some extent, extended to other rural farms in Argentina. However, changes in regulations, demand profile or in the hybrid technology are possible. In order to assess the influences of these key factors, different scenarios have been evaluated: 1) national grid prices before subsidies scheme removal; 2) shifting load demand (mid-night peak) and keeping milk refrigeration on during peak period; 3) regulations evolution, selling electricity to the grid; 4) Mesophilic AD tank with electricity retrofit; 5) mesophilic AD tank with CHP (heat retrofit). Results from these scenarios are shown in Figure 3.

For this small-scale dairy farm the recommended investment is scenario 2: installing a bioenergy plant with 2.4 kW capacity (and no CHP), and 16 solar panels (345 Wp) with a total capacity of 5.2 kW. To avoid the purchase of a battery, a modification in the demand profile is endorsed: a switch of the milking process to after midnight will be sufficient, being able to keep the milk refrigerated after 6 pm. This solution requires an initial investment of 17k USD with 317 USD monthly savings for the first year, and with a payback of 3.4 years. This leads to a GHG reduction of 275.9 tons of CO_2 eq per year.

Description		Scenario (-1)	Baseline-Scenario 1	Scenario 2	Scenario 3.1	Scenario 3.2	Scenario 4.1	Scenario 4.2	Scenario 5.1	Scenario 5.2
		Before subsidies scheme removal	Baseline	Shifting demand	FIT UK	FIT UK with demand shift	Mesophilic AD with ICE	Mesophilic AD with ICE and demand shift	Mesophilic AD with CHP	Mesophilic AD with CHP and demand shift

Figure 3: Comparison of the different scenarios results

5. Discussion and future work

The results show that the proposed model can generate cost-optimal solutions to meet the demand profile of a small dairy farm, and that additional scenarios can be explored to derive optimal solutions in different regulatory framework or technical hybrid solutions implemented. In order to generalize the model, the scheduling of different RE could lead to a complete and more integrated approach. For example, a solar section could have subsections with solar PV (panels, HCPV) and solar thermal (flat plates, PT, HCSP). The model could define which RE and technology or combination of RE and technologies would be the most appropriate from a cost-effective point of view for a particular case study, with results likely to depend on demand profile, location, space constraints etc. Another approach for further work would be a more detailed temporal analysis, considering seasonal variations of resources and energy demand. Various political and economic risks can be faced while developing this project, which is highly uncertain and depends on Argentina's policy stability, but latest trends demonstrate a promising future market.

Abstract

For the modelling of novel solvent systems for CO_2-capture in AspenPlus®, data fitting of physical-chemical properties is needed. In this work the challenges and results are presented for fitting such experimental data for aqueous solutions of 2-(diethylamino)ethanol (DEEA) and 3-(methylamino)propylamine (MAPA). Without CO_2 present, the default regression tool of AspenPlus® gave good data fits for the binary systems H_2O-MAPA and H_2O-DEEA. In the presence of CO_2, regression of parameters was not successful and an additional Particle Swarm Optimization (PSO) algorithm was needed to determine the many molecule-ion parameters for the ELECNRTL model. With this, for DEEA a good fit to experimental data has been obtained, whereas for MAPA, due to the high number of ionic species, the results were still not satisfactory. To resolve this, independent measurement of equilibrium constants for the ionic equilibria is recommended.

Keywords: CO_2 capture, novel solvents, thermodynamic modelling, regression

1. Introduction

Post-combustion CO_2 capture from coal and natural gas fired power plants is widely recognized as one of the most effective techniques to reduce CO_2 emissions. The conventional technology is chemical absorption using aqueous amine solutions, in which amines react with CO_2 and the solvent circulates between the absorption and desorption column. The benchmark solvent is monoethanolamine (MEA), which is a primary amine solvent. However, the energy requirements in the regeneration step of this process are significant, leading to a continuous search for novel solvent systems that require less energy for regeneration (Bernhardsen and Knuutila, 2017). Interesting solvents have higher CO_2 capacities often combined with a lower heat of absorption. Tertiary amines are potentially good candidates, having lower heat of absorption and higher CO_2 capacity compared to primary and secondary amines. Unfortunately, their kinetic absorption rates are much lower compared to primary and secondary amines, which means that larger absorption columns are needed. A promoter (primary/secondary amine) could increase the kinetic absorption rates, while keeping a relatively low heat of absorption and high capacity (Arshad et al., 2013). A blended amine solution consisting of the tertiary amine 2-(diethylamino)ethanol (DEEA) and the primary/secondary amine 3-(methylamino)propylamine (MAPA) is described by Pinto et al. (2014b) as a potential replacement for the conventional MEA solvent. A mixture of these solvents shows high CO_2 capacities, high kinetic absorption rates and relatively low heat of absorption in experiments. This work focused on the thermodynamic modeling of the DEEA+MAPA mixture in the AspenPlus® flowsheet program in order to determine the industrial viability of these novel solvents.

2. Chemistry

The molecular structures of DEEA and MAPA are shown in Figure 1 below. DEEA acts as a free base in the hydration reaction with CO_2 to form bicarbonate and MAPA reacts with the CO_2 to form primary and secondary MAPA carbamate and MAPA di-carbamate, as shown in Equation 1. Additional reactions that are present in both reaction schemes but not shown below are the dissociation reactions of water and bicarbonate (Monteiro et al., 2013).

$$2\,H_2O + CO_2 \rightleftharpoons H_3O^+ + HCO_3^- \tag{1a}$$

$$DEEA + H_3O^+ \rightleftharpoons DEEAH^+ + H_2O \tag{1b}$$

$$MAPAH^+ + H_2O \rightleftharpoons MAPA + H_3O^+ \tag{1c}$$

$$MAPAH^{2+} + H_2O \rightleftharpoons MAPAH^+ + H_3O^+ \tag{1d}$$

$$MAPA + H_2O + CO_2 \rightleftharpoons MAPACOO^-_{(p)} + H_3O^+ \tag{1e}$$

$$MAPA + H_2O + CO_2 \rightleftharpoons MAPACOO^-_{(s)} + H_3O^+ \tag{1f}$$

$$MAPAH^+COO^-_{(p)} + H_2O \rightleftharpoons MAPACOO^-_{(p)} + H_3O^+ \tag{1g}$$

$$MAPAH^+COO^-_{(s)} + H_2O \rightleftharpoons MAPACOO^-_{(s)} + H_3O^+ \tag{1h}$$

$$2\,HCO_3^- + MAPACOO^-_{(s)} + MAPACOO^-_{(p)} \rightleftharpoons 2\,H_2O + 2\,MAPA(COO^-)_2 \tag{1i}$$
Figure 1: The molecular structures of (a) DEEA and (b) MAPA.

3. Important properties for CO_2-absorbents

In this work, several properties for DEEA and MAPA were fitted to experimental data. These properties can be divided in three categories, namely: Pure properties, binary properties with water, and loaded properties upon CO_2 loading. The fitting was performed in steps: The pure component properties were fitted to form the boundaries of the binary properties at infinite dilution of either component, which again gave initial values for the loaded properties at a certain concentration of the solvent. Process simulations require detailed sub-models that can describe the absorption kinetics and physical properties like vapor-liquid equilibria and viscosity, describing the absorption capacity and solvent volatility as well as the equilibrium partial pressure of CO_2 at different solvent loadings. Furthermore, heat capacity and heat of absorption have an important role in correctly estimating the energy requirement of a process. Finally, equilibrium constants for the reactions have to be defined to determine the speciation of ions in the liquid phase. The equilibrium constants for the DEEA dissociation reaction were regressed against pKa data from Hamborg and Versteeg (2009) and the constants for the hydration reac-

tion of CO_2 were taken from Edwards et al. (1978). Unfortunately, no equilibrium constants are known for the (bi)carbamate formation reactions in the MAPA reaction scheme. AspenPlus® (Version 8.6) has built in (thermodynamic) models that can be used to represent all the properties described above. The thermodynamic model used in this work was the Electrolyte Non-Random Two Liquid (ELECNRTL) model (Chen et al., 1982). This extended NRTL model takes the activity coefficients of ions in the liquid phase into account. For the vapor phase, the Redlich-Kwong equation of state was used. Additional property models used in this work can be found in Table 1 below.

Table 1: Property models used in this work as defined in AspenPlus®.

	Pure	**Binary**	**Loaded**
VLE	PLXANT	NRTL	GMELCC/GMELCD
Density	DNLDIP	VLQKIJ	VLCLK
Viscosity	MULDIP	MUKIJ/MULIJ	IONMOB/IONMUB
Heat capacity	CPLDIP	No model available*	CPAQ0

*Calculated from the liquid enthalpy at constant pressure

4. Available experimental data

DEEA and MAPA have been researched extensively the past years, and data is widely available in literature. The pure vapor pressure data for DEEA and MAPA, the binary VLE data for DEEA-H_2O and the binary VLE data for DEEA-MAPA were taken from Hartono et al. (2013). The binary VLE data for MAPA-H_2O was taken from Kim et al. (2008). The loaded VLE data for the DEEA system was taken from Monteiro (2014) and Xu et al. (2014) and all viscosity and density data were taken from Pinto (2014a). Unfortunately only pure component heat capacities are available in literature and no binary or loaded heat capacities were found. The pure heat capacity for DEEA and MAPA was taken from Maham et al. (1997) and Lin et al. (2014) respectively. AspenPlus® has default values for all H_2O pure component parameters discussed in this work. Furthermore, the default CO_2 Henry coefficients were used.

5. Fitting procedure

The regressed parameters in this work regard the Antoine equation, NRTL, ELECNRTL, density, viscosity and heat capacity parameters. Experimental data is added to the model and the regression tool performs the iterative regression. For the models with typically three parameters to fit the regression tool performs well. However, when the number of parameters to fit increases, the use of the regression tool becomes more challenging. Using this tool is still possible, however it requires substantial amount of trial-and error and understanding of how the different parameters influence the fit. This is the case in fitting the ELECNRTL model which is based on the local composition of molecules and ions. For example in case of the DEEA system, 8 components can be distinguished resulting in 72 parameters whereas, in the MAPA system, 14 components can be distinguished resulting in 360 parameters. Additionally, for the MAPA system, the equilibrium constants of the reactions are regressed together with the molecule-ion parameters. To lower the amount of parameters to fit, the default ELECNRTL parameter values for the sub-system H_2O-CO_2 are typically fixed to the values estimated by the program. This lowered the

amount of parameters in the DEEA and MAPA system to 36 and 300 respectively. Still this is too high for the regression tool, resulting in many regression steps, where only few selected parameters would be regressed at once and manual trial and error is necessary. Therefore in this work, an external MATLAB® code is coupled with AspenPlus®, that provides an alternative solver. This solver is based on the Particle Swarm Optimization (PSO) algorithm (Kennedy and Eberhart, 1995). With this algorithm, more parameters can be regressed simultaneously to experimental data compared to the conventional solver. The MATLAB® code generates parameter sets according to the PSO algorithm as input for the AspenPlus® model, which uses the ELECNRTL model to calculate the chemical equilibrium and phase equilibrium. This is iteratively done, until a certain threshold is reached for the accuracy of the solution. A drawback of this algorithm is that the computation time for the regression is significantly increased. However, this regression is still much faster than manual fitting by changing a few parameters at a time using the conventional regression tool.

6. Results

The accuracy of the fitted model to the experimental data was assessed using the averaged absolute relative deviation (AARD) error definition, as defined by

$$AARD = \frac{1}{N} \sum_{i=k}^{N} 100 \frac{|\eta_k - \phi_k|}{|\phi_k|}, \tag{2}$$

where N is the amount of data points, η_k is the value of the fit at a certain point and Φ_k is the experimental value at the same point. The AARD values calculated in this work are listed in Table 2. It can be seen that all pure component properties have accurate fits to the experimental data. Also the considered properties for the binary systems were fitted with an acceptable low AARD. Further, a satisfactory fit of the DEEA model was found to the loaded VLE data, whereas the MAPA model gave no satisfactory fit. It is important to note that without the ELECNRTL parameters, no concentration/activity of ions is known and loaded density, viscosity and heat capacity parameters cannot be fitted, as these parameters are dependent on these concentrations or activities. The reason for the bad fit for the MAPA system is probably due to the high amount of parameters and missing equilibrium constants. The phase envelope diagram for the DEEA-H_2O and MAPA-H_2O mixture is shown in Figure 2. It can be seen that for both mixtures, with the regressed NRTL parameters, the model gives accurate bubble and dew point curves. The DEEA-MAPA mixture data is fitted with an AARD of 3.0 %. The loaded VLE results for the regression of the molecule-ion parameters of the DEEA-H_2O-CO_2 system can be found in Figure 3. As can be seen in this figure, for 2M and 3M DEEA solutions, a satisfactory fit is found and the AARD value is 16.7 %. This is a relatively high error compared to the other component parameters, however it is comparable to other modelled data found in literature for loaded VLE data (Monteiro et al., 2013). The valid range of operation for this model is between 2M and 3M DEEA solutions, and between 40 and 120 °C. The sufficient fit for the DEEA solution proves that the regression algorithm used in this work is an effective algorithm to fit VLE data upon CO_2 loading. The focus of future research should move towards the fitting of the ELECNRTL parameters for the MAPA solution. In order to obtain a satisfactory fit, more molecule-ion pairs should be assumed constant and the equilibrium constants of all reactions should be known. Furthermore, the model results for combining the two solvents should be validated against experimental data.

Table 2: The AARD (%) values obtained in this work.

	DEEA			MAPA		
	Pure	**Binary**	**Loaded**	**Pure**	**Binary**	**Loaded**
VLE	0.29	0.71	16.7*	0.85	1.44	No fit
Density	0.01	0.59	0.78	0.20	0.51	No fit
Viscosity	0.64	6.9	9.1	0.21	5.0	No fit
Heat capacity	0.15	No data	No data	0.04	No data	No data

*Regressed with the PSO algorithm

7. Conclusions

In this work, the basis for the thermodynamic model for the promising DEEA+MAPA solvent for post-combustion CO_2 capture was developed using AspenPlus®. Different pure, binary and loaded parameters for the DEEA and MAPA system were regressed with the conventional regression tool, while the PSO algorithm was coupled with AspenPlus® to regress the molecule-ion parameters of the ELECNRTL model for the DEEA solution. No good fit was obtained for MAPA, and research should focus on the regression of the ELECNRTL molecule-ion parameters of this MAPA system.

Abstract

This study presents an assessment of the main research problems addressed in the literature on New Product Development (NPD) and its methodologies, for the pharmaceutical industry. The work is particularly focused on the establishment of an evolutionary perspective of the relevant modelling approaches, and on identifying the main current research challenges, considering the fast-changing business context of the industry. Main findings suggest a generalized misalignment of recent studies with today's technological and market trends, highlighting the need for new modelling strategies.

Keywords: New product development, capacity planning, portfolio management, modelling, decision-making.

1. Introduction

The world is currently experiencing unprecedented fast changes, with major technological breakthroughs that are transforming the way companies operate and manage their systems. Pharmaceutical companies are constantly being challenged to become ever more cost efficient and responsive in the delivery of drugs. Consistently launching new drugs into the market is, therefore, critical to support the industry's economic sustainability. However, the traditional NPD process still imposes considerable challenges for practitioners and researchers. In this sector, the Operations Research (OR) and the Process Systems Engineering (PSE) communities have been developing reliable and effective model-based decision-making tools. Understanding how these developments have been impacting the industry is crucial for establishing new management directions that take into account the paradigm changes currently faced by the industry. The main goal of this work is, therefore, to present a research review with two perspectives: first, identifying the main problems on the pharmaceutical NPD process and the corresponding modelling approaches; and second, analyzing how research has evolved along the years, assessing the methodological main progresses and envision future directions.

2. Literature Review

In order to clearly define the scope of the present study the following research question was formulated: "*What have been the main research concerns and modelling approaches in the pharmaceutical NPD process?"* Based on this question, the following criteria were

used to perform the review: (i) studies specifically addressing decision-making problems in the pharmaceutical sector; (ii) works within OR, PSE, and related communities; and (iii) full research papers, written in English. The search was performed considering the boolean combination of keywords *(("planning" OR "scheduling" OR "decision-making" OR "supply chain") AND pharma*)*, complemented by the analysis of several review papers. After excluding duplicates, review papers, conference papers (with some limited exceptions), and works at a hospital/pharmacy level, a total of 113 research works was obtained covering the complete pharma industry management problems. A second round of analysis was then performed to keep only works related to the development of new products. Finally, a set of 53 papers was considered for a complete analysis.

3. Analysis

The 53 papers selected for full analysis cover the years from 1996 to early 2018 and are distributed in 16 scientific journals and 2 conference proceedings. "Computers and Chemical Engineering" appears as the most represented journal, with 18 published papers. Two broad research areas emerge from the selected papers, namely: (i) the portfolio management area; and (ii) the clinical trial supply chain management area. Portfolio management is the most developed area, being addressed in 31 papers and representing about 58% of the total selected works, while the clinical trial supply chain management area is tackled in the remaining 22 papers. Each one of these areas is described in the following sections.

3.1. Portfolio Management (PM)

The main goal of PM is to determine the portfolio of new products to be developed and the schedule of the associated testing tasks (clinical trials) under uncertainty in the outcomes of the tests. Therefore, two decision problems are usually found in the literature, namely: i) the portfolio selection (PS), and ii) the scheduling of the testing tasks (ST). In the first case, the main decisions include the determination of which targets should be selected for further clinical development. These decisions rely on two issues: i) the assessment of the value of the portfolio, based on its probability of success and on its potential returns; ii) and on the company market strategy.

The ST problem is closely related to the typical Resource-Constrained Project Scheduling (RCPS) problem, but with the possibility of task failing during the development process. The main decisions involved here are related to the determination of the tasks starting and completion times. Uncertainty in trials' outcomes is addressed in 28 of the 31 selected papers, thus highlighting its importance in these problems. In both cases (PS and ST) there are also resource-related decisions, in order to ensure the necessary resources availability. Moreover, most of the studies deal with the two problems simultaneously (17 papers). The modelling details and progresses on portfolio management in the pharmaceutical industry are presented in the next section.

3.1.1. Modelling approaches
Analysing the complete set of the selected papers, the prevailing modelling approaches can be broadly divided in optimization (18 papers), simulation-optimization (11 papers), and simulation (2 papers) approaches. In the optimization case, problems are formulated as deterministic MILP models or as stochastic versions of RCPS problems (two-/multi-stage stochastic programming MILP models). In the simulation-optimization case, there is a combination of combinatorial optimization models with a discrete-event simulation.

Simulation is used to capture uncertainty more realistically and to evaluate the optimization results, thus giving insights to the determination of the optimized solution, in an iterative way. In the simulation case, models are used to perform sensitivity analysis and capture the risk/reward of the portfolio value. Figure 1 depicts the evolutionary path of the most relevant contributions to the PM problem. The first work addressing this problem (Schmidt and Grossmann (1996)) was based on a MILP model and a two-stage stochastic programming (TSSP) approach, to account for uncertainties in task costs, durations, and trials outcomes. The goal was to determine the schedule of testing tasks that maximizes the expected net present value (eNPV), considering task precedence and timing constraints. This model, however, does not account for important features such as product interdependencies or resources limitations.

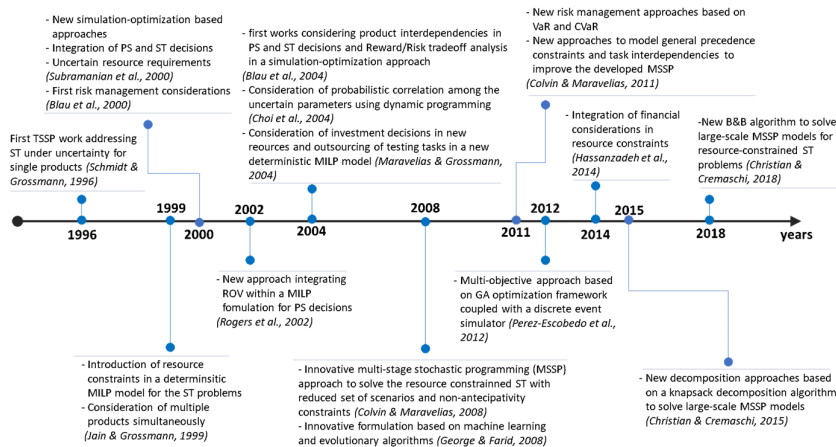
Later, an evolution has been observed (Figure 1), with works incorporating ever more sophisticated modelling features and broadening the problem scope. It is, therefore, possible to outline the basic structure of the MILP formulation that is common to most of the works addressing ST/PS decisions. This formulation can be generalized as follows. We are given: i) a set of time periods $t \in \mathbf{T}$; ii) a set of potential drugs $i \in \mathbf{I}$ to develop; iii) a set of clinical tests $j \in \mathbf{J}$; iv) a set of resource types $r \in \mathbf{R}$; and v) a set of scenarios $s \in \mathbf{S}$. The goal is to determine which tests should be selected and when (X_{ijts} binary variables) to maximize the eNPV, subject to the following general constraints: i) assignment constraints of clinical tests to starting times; ii) test precedence constraints; and iii) resource constraints. The main evolution here was on the resource constraints representation, by considering more industry-specific decisions, such as investment in new resources, outsourcing resources or out-licensing tests.


Figure 1. Timeline of the most relevant contributions in Portfolio Management.

3.2. Clinical Trials Supply Chain (CTSC) management

At CTSC management, two broader areas were identified. The first area *(CTSC operations)* is related to management of all the activities required to undertake the clinical trials, including: product manufacturing, packaging, storage, and distribution to clinical sites. In this type of supply chains (SC), special attention needs to be given to aspects such as: the limited time-horizon by trials duration; leftovers at the end of each trial that cannot be reused; delivery failures (seriously compromising time-to-market); and the significant uncertainty affecting the process. The main challenge is, therefore, to

efficiently manage this unique SC, guaranteeing the timely fulfilment of the clinical trials demand. Despite their relevance for the industry, only 8 papers explicitly addressed the CTSC operational problems, showing a very limited attention paid by researchers to this issue. These works span from SC/plant design to production/ inventory planning, with most of the papers integrating these two decision-levels at some extent.

In a second area, the Product Launch planning problem is related to the important link between product development and the capacity planning needed to accommodate both existing and new products. 14 works addressing this link were considered with decisions comprising portfolio selection, capacity and production planning.

3.2.1. Modelling approaches

CTSC operations

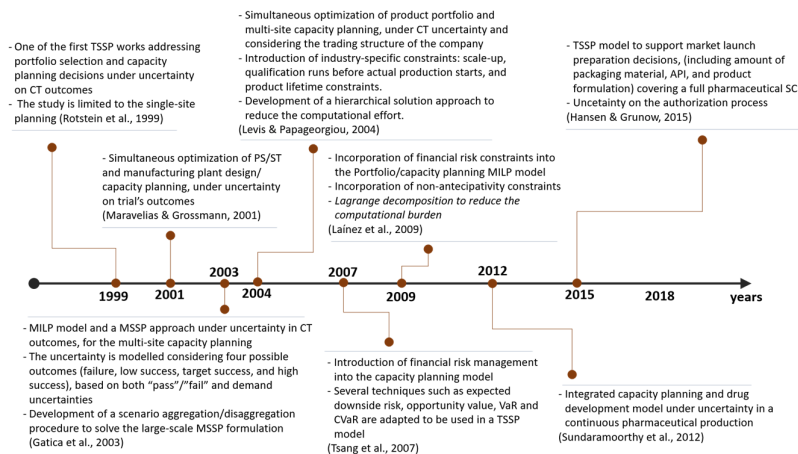
CTSC operations are clearly a new area in the OR and the PSE communities, being still at its infancy of development. Selected works can be divided into simulation (2 papers) or simulation-optimization (6 papers) approaches. The early works addressing this problem, particularly regarding inventory management, were based on simulation approaches for assessing different scenarios, and decisions were taken mainly based on sensitivity analysis. The introduction of optimization approaches starts to emerge only recently, and works are still very scarce. The most relevant contributions were by Chen et al. (2012) with an integrated approach to manage the multi-echelon CTSC under uncertainty on patient demand, and the work by Marques et al. (2017), integrating capacity planning and process design decisions under uncertainty with an on time supply of the clinical trials. Both approaches integrate simulation methods to tackle uncertainty with MILP optimization models.


Figure 2. Timeline of the most relevant contributions in Product Launch planning.

Product Launch planning (PL)

Regarding the product launch planning problem, all the selected papers developed optimization approaches based on MILP formulations, and only 3 presented deterministic models. The remaining 11 papers addressed the uncertainty on trials' outcomes through multi-stage stochastic programming (MSSP) approaches. Most of the works deal with the decisions such as portfolio selection and capacity/production planning, and constraints on

material balance, production/manufacturing, resource allocation/investments, or sales/demand.

Figure 2 depicts the evolutionary path of the most relevant contributions to the PL problem. One of the first works addressing this problem was by Rotstein et al. (1999), proposing a MILP model under uncertainty in trial's outcomes for the selection of the most profitable products, capacity planning, and investment strategy to accommodate the new products. Subsequent works tend to deal with ever more complex features by adding problem-specific constraints to the base model, such as: scale-ups; qualification runs; product lifetime, financial, and risk constraints. It is interesting to note that the increase on the models' size/complexity has also motivated a further development of new decomposition techniques, contrasting with the lack of exploitation of alternative modelling approaches.

4. Research directions and final remarks

This work shows that PM problems have been object of significant research activities, contrasting with the CTSC operations with still very modest developments. However, current technological trends (continuous manufacturing and digital capabilities) and market (personalization) trends are still absent or only discreetly considered in research works.

Future modelling approaches should take the following new aspects into account: i) assessment of the portfolio "value", including patient-related considerations (e.g. specific unmet needs); ii) patient-centric delivery models, linking "quantity" variables to new "outcome" variables reflecting benefits for patients; iii) market segmentation constraints; iv) integrated approaches and coordination between actors; v) exploitation of the benefits of continuous manufacturing settings and digital capabilities to leverage efficiency; vi) functional integration between marketing (patient perspective), product development, and manufacturing; vii) exploitation of new performance metrics and multi-objective approaches to capture the multi-dimensionality of the problems; and finally viii) exploitation of innovative modelling approaches to tackle large-scale problems.

In short, future work should extend the analysis throughout the entire drug life-cycle, and define future modelling components (constraints, variables, ...) that are more aligned with the current context of the pharmaceutical industry.

Abstract

Producers of pharmaceuticals have to guarantee the quality of their products. Therefore, substantial efforts are invested in process monitoring and control. However, crucial parameters, such as the nutrient and product precursor concentrations often require time-consuming analysis of a sample. Infrared (IR) spectroscopy is a promising measurement technique for the online quantification of multianalyte solutions, such as fermentation broths. Besides the high investment cost of devices, chemometric models often are not fully transferable and provide noisy estimates which need to be treated before further usage. To increase robustness and accuracy of these measurements they can be combined with kinetics models under the usage of a state observation algorithms, such as Kalman- or Particle filters.

In this work, we present a unique combination of a transferable mechanistic process description with the real-time information derived from near and mid IR spectroscopy leading to stable, smooth and accurate state estimates. IR spectra were collected in *Penicillium chrysogenum* fed-batch processes. PLS models were trained for the prediction of nitrogen, product and product precursor concentrations, which were used as inputs for the state observer. The resulting probabilistic estimates provide a good basis for automatic control.

Keywords: bioprocess monitoring, spectroscopic measurements, state observeration, non-invasive NIR spectroscopy, MIR spectroscopy, PLS-regression

1. Introduction

To control fermentation processes, real-time measurements of critical process parameters are required. Since fermentation broths are a complex mixture of different analytes, their single quantification is difficult. Over the last decades promising technologies emerged to provide real-time information on the reaction kinetics during such processes (Vojinović et al. (2006)).

Near and mid infrared (NIR; MIR) spectroscopy combined with multivariate analysis can be used to quantify multi-analyte solutions. For the penicillin producing organism *P.*

chrysogenum the product, the product precursor and the nitrogen concentration could be successfully determined via NIR and MIR spectroscopy (Luoma et al. (2017); Koch et al. (2014)). Besides advantages like the non-destructive and possible non-invasive measurement, the multivariate models are not fully transferable and provide noisy estimates which need to be treated before further usage (Krämer and King (2017)).

In chemical engineering state observers, which are computational algorithms to estimate unmeasured state variables, are widely applied (Ali et al. (2015)). Hereby, secondary measurements provide real-time information of the ongoing process and Bayesian filters estimate the most probable states. Besides the often used extended Kalman filter, particle filters, which approximate the distribution of the estimated states, gained importance with increasing computational capacities (Goffaux and Wouwer (2005)). In recent works a particle filter configuration was compared to an extended Kalman filter for the examined penicillin production process (Stelzer et al. (2017)), and the better suited particle filter was extended to use delayed offline measurements (Kager et al. (2018)).

Although estimations already show good results the combination of spectroscopy and Bayesian state estimation offers a possibility to further improve bioprocess monitoring. This potential was shown by Golabgir and Herwig (2016) under usage of Raman spectroscopy and by Krämer and King (2017) with NIR spectroscopy for a yeast process. In this work two different IR measurements were carried out. One using an immersion probe in the MIR spectral region and the other through a glass window of the reactor in the NIR spectral region. The acquired IR data was included in a particle filter in order to estimate important process parameters such as product, product precursor, nitrogen and biomass concentration. The possibility to include redundant measurements and to combine them, to get robust and complete state estimates is of high relevance to biochemical production industry.

2. Materials and Methods

2.1. Cultivation & Reference Measurements

Fed-batch experiments were performed in a 2.7 l parallel bioreactor system (Eppendorf AG, Germany) using a spore suspension of an industrial *P. chrysogenum* strain for penicillin production. Dissolved oxygen was controlled above 40% by stirrer speed (350 - 850 rpm) and subsequent oxygen addition to pressurized air, while the reactor was aerated with 1 vvm of gas mixture. The temperature was maintained at 25 °C and the pH value was maintained at 6.5 by addition of KOH and H_2SO_4. Glucose (500 g/l), the penicillin V precursor (POX) (80 g/l phenoxyacetate) and the nitrogen source (100 g/l $(NH_4)_2SO_4$) were supplied as feeds. As glucose should be the only limiting component, nitrogen and precursor were kept at non-limiting concentrations (1 g/l and 2 g/l), by manipulating the $(NH_4)_2SO_4$ and POX feeds.

For online analytics, CO_2 and O_2 content in the off-gas were measured by a gas analyzer (DASGIP GA4, Eppendorf AG, Germany). The conversion of O_2 to CO_2 was calculated according to Aehle et al. (2011), giving the carbon evolution rate (CER) and the oxygen uptake rate (OUR) in mol/h. Reference samples were taken every 8 hours. Analysis of penicillin V (PEN) and POX concentration in the culture media was performed by HPLC using a ZORBAX C-18 Agilent column and 28% acetonitrile, 6 mM H_3PO_4 and 5 mM

KH$_2$PO$_4$ as elution buffer. Glucose and ammonia concentration were quantified by an enzymatic analyzer (Cedex Bio HT, Roche GmbH, Switzerland). Biomass concentration was determined gravimetrically by separating the cells from 5 ml culture broth via centrifugation at 4800 rpm for 10 min at 4 °C. The cell pellet was dried at 105 °C after a washing step with 5 ml of deionized water in weighted glass tubes.

2.2. Infrared Spectroscopy and Partial Least Square (PLS) Regression

Mid IR absorption (650-3000 cm^{-1}) was captured by an optical fiber immersion probe (ReactIR 45m, Mettler Toledo, USA) and near IR (5000-7500 cm^{-1}) was captured, through the glass wall of the reactor (NIRONE, Spectral Engines, Finland).

After data preprocessing (standard normal variate (SNV) transformation and Savitzky-Golay smoothing (SG) and differentiation (1st; 2nd), partial least square regression models (SIMPLS) were build in MATLAB (R2018a, MathWorks, USA). Spectra preprocessing was done according to Koch et al. (2014) for mid and Luoma et al. (2017) for near IR. Suitable wavenumber ranges were selected individually by selecting ranges with high PLS weights in the whole band including 1st and 2nd order derivatives. By an randomly sampling cross-validation procedure the number of latent variables were determined. The selected procedures for different analytes are summarized in Table 1.

Table 1: Near and mid IR PLS regression procedures for penicillin V (PEN), product precursor (POX) and nitrogen (NH3).

Model	Preprocessing	Wavelength ranges [cm^{-1}]	Latent variables	Datasets
MIR-PEN	1st	1307-1352 ; 1747-1817	4	3
MIR-POX	none	1000-1150 ; 1400-1750 ; 1900-2600	3	3
MIR-NH3	1st	850-1150 ; 1400-1520 ; 1950-2300	4	3
NIR-PEN	SNV, 2nd	6050-7500 ; 5200 -5700	4	4
NIR-POX	SNV, 2nd	5100-5500 ; 6100-6400 ; 6500-7500	4	4
NIR-NH3	1st	6200-7500	4	4

2.3. Non-linear Kinetic Model and Bayesian State Estimation

A kinetic process model taken from Paul et al. (1998) describing the states x (hyphal tips, hyphal bodies, glucose, gluconate, nitrogen, product precursor and product concentration) by ordinary differential equations was adapted to the current process (Stelzer et al. (2017)). In order to use the model during the process a state estimation algorithm, a SIR particle filter derived from Simon (2006) was used. The model states are hereby described by x and linked to the measurements y. As initialization step, a sample of N particles is drawn by the known probability density function $p(x_0)$ of the initial states x_0. Iteratively, for time steps $k \geq 1$, N particles $\tilde{x}_k^i$ are propagated based on the process model. Importance weights fro every particle, $\tilde{w}_k^i = p(y_k \mid \tilde{x}_k^i), i = 1,\ldots,N$, are calculated at measurement arrival. All measurements are hereby weighted by their error. Applying multinominal resampling, N posteriori particles $x_k^i, i = 1,\ldots,N$ are resampled from $\tilde{x}_k^i$ according to their importance weights. The distribution of these particles is an approximation of the probability density function, i.e. $x_k^i \sim p(x_k \mid y_k)$, from which the actual state estimates can be derived.

3. Results and Discussion

3.1. Model Building and Calibration

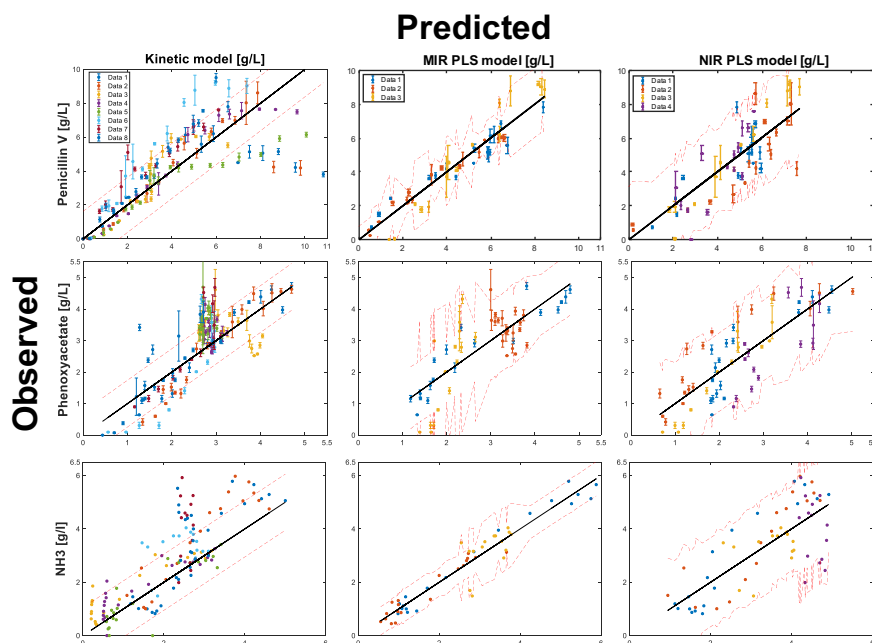
In Figure 1 observed vs. predicted plots show the calibrated models, with their confidence intervals and their Root Mean Square Errors (RMSE). PLS models were built according to Table 1 and parameters for the kinetic model were estimated according to the procedures described by Ulonska et al. (2018). For the product, the kinetic model is unable to predict the product degradation properly, which can be seen from the overestimation at high concentrations. Overall the submersed MIR shows the best calibration results, whereas the kinetic model predictions and the non-invasive NIR measurements are within the same error range.


Figure 1: Observed vs. predicted of kinetic model, MIR and NIR PLS model for Penicillin V (RMSE = 1.62; 0.69; 1.33 R^2 = 0.61; 0.93; 0.71), Phenoxyacetate (RMSE = 0.74; 0.76; 0.75 R^2 = 0.59; 0.62; 0.68) and NH_3 (RMSE = 1.05; 0.41; 1.01 R^2 = 0.55; 0.93; 0.58) under usage of historical experiments. Not in all 8 fermentations, IR spectra could be recorded

3.2. Monitoring Results

In Figure 2 prediction results for product and precursor concentrations of an selected process are displayed, wereas the errors are displayed in Table 2. The state observer is able to estimates of the biomass concentration, however it fails to estimate the product and precursor concentration correctly as no information of these states are included. By applying the PLS models on the incoming IR spectra good real-time estimates of product,

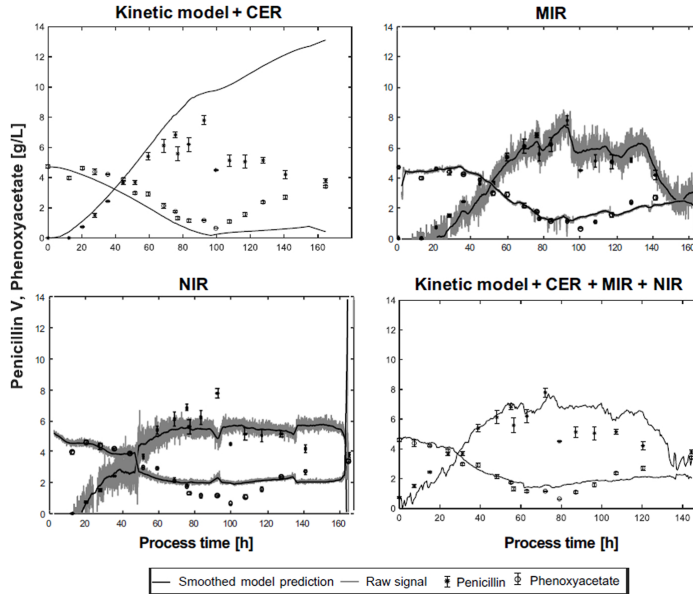
precursor and nitrogen can be obtained. However, results derived from spectral data are very noisy, outlier need to be removed and the signal needs to be smoothed to obtain meaningful results.


Figure 2: State estimation of validation dataset with kinetic model & CER and MIR & NIR PLS prediciton and their combination. Savitizky Golay with a window of 100 datapoints was used to smooth the raw signal.

In order to add needed real-time information to the state observer it can be extended by the IR predictions. This has the advantages that untreated results can be used and by including the measurement errors, redundant measurements derived by the submersed MIR probe and the external NIR sensor can be combined. This combination gives accurate and stable estimates for the entire process.

Table 2: Overall Root Mean Square Errors (RMSE) of different state estimation strategies

	Penicillin V [g/l]	Phenoxyacetate [g/l]	NH_3 [g/l]	Biomass [g/l]
state observer	3.97	1.14	0.90	4.01
MIR (immersion)	0.60	0.50	0.32	-
NIR (non- invasive)	1.11	0.65	0.88	-
state observer + IR	1.15	0.51	0.62	4.26

4. Conclusions

On the example of a *P. chrysogenum* fed batch process penicillin V, product precursor (Phenoxyacetate) and nitrogen (NH_3) concentration could be estimated by invasive MIR

and non-invasive NIR measurements. Through a kinetic model, describing growth, nutrient consumption, product formation and the measurement of the CO_2 production rate, biomass formation during the process can be estimated. The used state estimator, which in our case was a particle filter, is a useful tool for the combination of different and redundant measurements. By including the PLS prediction of the IR spectra, the state observer is able to predict all states accurately. The particle filter hereby filters the measured and partially redundant information and estimates the most probable system states through the kinetic model, giving a solid basis for feedback control.

Design of Multi Model Fractional Controllers for Nonlinear Systems: An Experimental Investigation

G Maruthi Prasad[a], A Adithya [a] and A Seshagiri Rao[a,*]

[a]*Department of Chemical Engineering, National Institute of Technology, Waranagal - 506 004, Telangana, India*
Email: seshagiri@nitw.ac.in

Abstract

Control of nonlinear processes is challenging when compared to those of linear processes. Conventional PID controllers can be used to control nonlinear processes based on a condition that these controllers must be tuned in such a way that they should provide a very stable behaviour over the entire range of operating conditions. Inspite of tuning the PID controllers, it still results in a degradation of the control system performance. In order to stabilise nonlinear systems, multi model control approaches are found suitable. Multi-Model Approaches (MMA) rely on the problem decomposition strategy where a nonlinear system is segregated into set of many linear models based on their operating points. These reduced models are used to tune model based PI/PID controllers. In the literature, different methods are proposed to design these controllers in MMA framework and they are all integer order controllers. In this work, fractional controllers based MMA framework is developed for enhanced control of nonlinear systems. Gap metric based weighting methods are used with proper weighting functions to obtain the global controller. The weighting functions are formed by using gap metric to combine local controllers. Three different nonlinear processes (CSTR, conical tank and spherical tank processes) are considered and implemented the proposed methodology. For the purpose of comparison, MMA framework with integer order controllers is considered and it is observed that MMA framework with fractional controllers provide improved closed loop performances. Experimental investigation is also carried out to verify the applicability of the proposed method for level control on conical tank process and it is observed that the proposed method provide enhanced closed loop responses.

Keywords: Multi-model approach, integer order controller, fractional order controller, gap metric, nonlinear system

1. Introduction

In process industries, behavior of most of the systems will be nonlinear and this type of systems mostly have performance degradation by using conventional PID controller. In order to overcome this degradation there are different types of techniques available and one of the most popular techniques which has been consider by several researches is the multi model approach (MMA) Adeniran and El Ferik (2017).This approach divides nonlinear systems into multi linear models sequentially based on the operating points. Controllers are designed by using this linear model and over decades most of the researchers considered integer order controllers only. When integer order controllers are

implemented practically overshoot and resonance are observed and in order to deal such effects fractional order controllers can be used which shows more promising results Podlubny (1999). In this paper an attempt has been made to apply fractional order controllers in order to design a new system called Multi model fractional order controller. This paper presents effectiveness of Multi model fractional order controller and Extensive numerical studies on nonlinear system demonstrate its performance.Section II of the paper describes multi-model approach, gap metric and fractional order controller design. In Section III nonlinear system are studied to demonstrate effectiveness of Multi model fractional order controller. Section IV numerical results and conclusions are presented.

2. Multi Model Fractional controller

2.1. Multi-model approach

The MMA deals with decomposition of nonlinear system into multi linear models based on sequentially steady states and mathematical model is developed for each of the operating range. These models now as a set, can be used as a valid representation of the nonlinear process. These models are further reduced into minimal set using gap metric.

2.2. Gap metric

Recent studies have showed that the most appropriate tool to quantify the difference between different linear systems using metrics based on norms is the gap metric Du et al. (2012); Du and Johansen (2014). The gap metric is calculated based on following formula

$$\delta_g(P_1, P_2) = max(\vec{\delta}_g(P_1, P_2), \vec{\delta}_g(P_1, P_2)) \tag{1}$$

Where as P_1 and P_2 are linear models and

$$\delta_g(P_1, P_2) = \inf_{Q \varepsilon H_\infty} \left\| \begin{bmatrix} N_1 \\ M_1 \end{bmatrix} - \begin{bmatrix} N_2 \\ M_2 \end{bmatrix} Q \right\|_\infty \tag{2}$$

From eq. (1), the gap metric range is considered as $0 \leq \delta_g(P_1, P_2) \leq 1$. If the value of gap metric is near to 0 a single controller is enough to control two operating regions effectively else it is difficult to use single controller to control the operating regions.

2.3. Fractional Order Controller

Implementation of Fractional calculus which is generalization of Integer order calculus is making a noteworthy advancement. Its significance lies in the fact that practical systems can be better identified as fractional order differential equations instead of integer order differential equations David et al. (2011). Fractional Order PID Controller which is usually described as $PI^\lambda D^\mu$ Controller was introduced by Podlubny (1999).

$$C(s) = K_p + \frac{K_i}{s^\lambda} + k_d s^\mu \tag{3}$$

where K_p is Proportional Gain, K_i is Integral Gain, K_d is Derivative Gain, λ and μ are integral and derivative orders and can be varied between 0 to 2. Non Integer Order Controllers offer more degrees of freedom and by using these controllers for Integer Order

plants, there is more flexibility in adjusting the gain and phase characteristics than using Integer Order controllers. Methods for design of fractional order controllers are discussed in Podlubny (1999); Monje et al. (2008). One such tuning method for Fractional Order PI controllers was proposed by Gude and Kahoraho (2009) in which a performance criteria (J_v) is minimized which is a measure of systems ability to handle low frequency load disturbances. Finally the normalized controller parameters are designed based on normalized dead time τ.

2.4. Multi model integer and fractional order controller

After multi model approach, minimized models are obtained using gap metric. Based on these models, PI values of integer and fractional order controllers are tuned, with the help of IMC technique and Gude method respectively. The global controller is formed by combination of local controllers. The combination is carried out using gap metric weighting function proposed by Du and Johansen (2014).

3. Nonlinear system

Spherical tank, conical tank and isothermal continuous stirred tank reactor(CSTR) are considered to study the behavior of nonlinear process.

3.1. Case study: Spherical Tank System

In a spherical tank process, level (h) is the controlled variable and input flow rate (q_i) is the manipulated variable. Applying mass balance equation, a mathematical model is obtained as

$$q_i - q_o = \pi[2rh - h^2]\frac{dh}{dt} \tag{4}$$

where r is the radius of the spherical tank, q_o is outlet flow rate and α is valve coefficient. Here, R is the resistance of outlet flow and is found experimentally. After linearizing the above Equation by using Taylor series, the transfer function model is obtained as

$$\frac{H(s)}{Q(s)} = \frac{(-K_1/K_2)}{(-K_2)s + 1} \tag{5}$$

where as $K_1 = (\frac{1}{\pi(2rh_s - h_s^2)})$ and $K_2 = (\frac{1}{\pi(2rh_s - h_s^2)^2})[-2q_{is}(r - h_s) - \frac{\alpha\sqrt{h_s}}{R}(1.5h_s - r)]$
Various steady state values for (h_s, q_{is}), in sequence are considered and the corresponding multi-model transfer functions are derived. Nine different multi linear transfer function models are found. Multi model control schemes states that, the number of linear models for design of controllers should be reduced. This is done by considering the gap metric value ≈ 0.1 and only 3 models are taken as shown in Table 1. Based on these three models, Integer and Fractional PI controllers are designed using the respective methods.

3.2. Case Study: Conical Tank Process

In a conical tank process, the level (h) is controlled by the input flow rate (q_i). It's mathematical model is obtained as

$$q_i - q_o = \frac{\pi D}{12H}\frac{d(h^3)}{dt} \tag{6}$$

Table 1: Reduced models by using gap metric for the nonlinear processes

Spherical Tank		Conical Tank		Isothermal CSTR	
Operating range	Min-imised Model	Operating range	Min-imised Model	Operating range	Min-imised Model
0-15 cm	$M_2 = \frac{0.26261}{330.132s+1}$	0-15 cm	$M_2 = \frac{0.6667}{12.253s+1}$	0-0.5 mole\ L	$M_2 = \frac{0.62834}{21.84s+1}$
15-40 cm	$M_6 = \frac{0.63323}{1194.09s+1}$	15-40 cm	$M_6 = \frac{1.466}{225.68s+1}$	0.5-0.77 mole\ L	$M_6 = \frac{0.32}{11.46s+1}$
40-50 cm	$M_9 = \frac{0.7972}{563.73s+1}$	40-62 cm	$M_9 = \frac{0.9579}{1160.9s+1}$	0.77-1 mole\ L	$M_9 = \frac{0.10417}{3.662s+1}$

Linearizing eq. (6) using Taylors expansion, the transfer function model is obtained as

$$\frac{H(s)}{Q_1(s)} = \frac{\frac{4H}{\pi D h_s{}^2}}{s + \frac{8q_{is}}{\pi D h_s{}^2} - \frac{C_D}{2h_s{}^{5/2}}} \tag{7}$$

where H is height of the tank, D is diameter and C_D outlet valve coefficient. Sequentially different steady state values for (h_s, q_{is}) are considered and derived the corresponding multi-model transfer functions and 12 different multi linear transfer function models as obtained. According to multi-model control schemes, multi models are reduce to the minimum number of local models using gap metric value of 0.1 is considered and only 3 models are retained as shown in Table 1. Based on these three models, the corresponding controller parameter values are tuned.

3.3. Case Study: Isothermal CSTR

An isothermal CSTR, consider a first-order irreversible reaction takes place. The mass balance is

$$\frac{dC_A}{dt} = -KC_A + (C_{Ai} - C_A)u \tag{8}$$

Where reactant concentration$(C_A(mol/L))$ is controlled variable, input$(u = q/V(min^{-1}))$ is the manipulated variable, q $(lmin^{-1})$ is the inlet flow rate and C_{Ai} is the inlet feed concentration(1.0 mol/L) and constant rate k is 0.028 (min^{-1}). Linearizing the above equation using Taylors expansion, the transfer function model is

$$\frac{C_A(s)}{u(s)} = \frac{1 - C_{AS}}{s + (0.028 + u_s)} \tag{9}$$

The CSTR model is divided into multi linear model based sequential steady states (u_s, C_{As}) of different operating ranges. Eighteen linear models are found and these are minimized into three model by using gap metric value of ≈ 0.1 are shown in table 1, based on these controller parameters are tuned.

4. Simulation and Experimental Results

Simulation results for spherical and conical tank processes and CSTR are carried out and are given below. Experimental implementation is also carried out for conical tank, the corresponding results are presented here.

4.1. Spherical Tank Process

Comparative results of Multi model integer and fractional order control are implemented in simulation for tracking of different set points of level and the corresponding responses are shown in Figure 1. Quantitative analysis of the spherical tank process has been done and integral absolute error (IAE) values for different set points 10, 30, 45, 35, 15 of integer order control are 32695, 14143, 8940.5, 5475.3, 16853 and fractional order control are 123.55, 2569.9, 2127.4, 579.44, 5512.7. It is observed that multimodel fractional order control approach is efficiently reducing the overshoot and the response is enhanced.
Figure 1: Compared closed loop response of spherical tank process
Figure 2: Compared closed loop response of conical tank process

4.2. Conical Tank Process

In the same way, for conical tank also the comparative results of Multi model integer and fractional order control is implemented in the simulation for tracking of different set points of level and the corresponding responses are shown in Figure 2. Quantitative analysis of the conical tank process has been done and IAE values for different set points 15, 35, 55, 41, 21 of integer order control are 1590.4, 91.70, 109.9, 231.64, 123.42 and fractional order control are 4.31, 13.29, 50.14, 37.61, 68.46. Experimental implementation is carried out for this process and response curves are plotted. The Figure 3 shows closed loop response of multi-model integer order controller and Figure 4 shows closed loop response of multi-model fractional order controller. The oscillations observed in Figure 3 (Integer order response) are very low in amplitude and in the case of fractional order controller, these oscillations become miniscule. Quantitative analysis of the conical tank process has been done and IAE values for different set points 15, 35, 55, 41, 21 of integer order control are 70995, 53654, 178050, 60935, 91032 and fractional order control are 862.05, 911.57, 4428.5, 680.81, 897.64.

4.3. Isothermal CSTR

Similarly, for CSTR also the comparative results of Multimodel integer and fractional order control is implemented in the simulation for tracking of different set points of concentration and the corresponding responses are shown in Figure 5. Quantitative analysis
Figure 3: Experimental closed loop response of conical tank process using multi-model integer order controller
Figure 4: Experimental closed loop response of conical tank process using multi-model fractional order controller

of the CSTR process has been done and IAE values for different set points 0.4, 0.55, 0.85, 0.6, 0.35 of integer order control are 2.71, 0.0872, 0.408, 2.865, 4.3766 and fractional order control are 0.096, 0.0464, 0.2337, 2.865, 4.3766.

5. Conclusion

Multi-model fractional order controller is evaluated for control of nonlinear processes and is compared with multi-model integer order controller. Both the methods are evaluated first by the simulation and then by performing experiments on conical tank process. It is observed that multi model fractional order controller provides better performance when compared to Multi model integer order controller.

Abstract

The aim of this work is to model the kinetics of the supercritical CO₂ extraction of oils from biomass, namely from industrial grape seeds and chia seeds. A model introduced by Sovova and Stateva (2015) is used and solved using gPROMS ModelBuider. The supercritical extraction experiments performed at different temperature, pressure and flow rate conditions, provide the data to the modelling studies and for model parameter estimation, using gPROMS parameter estimation.

The partition coefficient and the maximum oil content corresponding to monolayer adsorption was estimated and the absolute average relative deviation between the experimentally measured and simulated extraction curves for the cases examined is within the range (1-9) %, which may be considered as a good agreement taking into consideration the very complex nature of the systems under study.

Keywords: Grape seeds, chia seeds, supercritical CO₂ extraction, extraction kinetics, mathematical modelling.

1. Introduction

Increasing attention is being drawn to the effective use of waste biomass and vegetal material as renewable resources of high added value compounds with applications in food, cosmetics, pharmaceutical industries, biodiesel production, etc. Grape (*Vitis vinifera* L.) seed biomass contains typically (8-15) % (w/w) of oil rich in long chain polyunsaturated fatty acids (PUFAs) and antioxidants (Bail et al., 2008; Fernandes et al., 2013). Although representing about (20-25) % of the biomass generated by the wine industry, it is still considered a disposable material and rarely valorised. Chia (*Salvia*

hispanica L.) seeds are attracting great attention due to its health beneficial properties and are being studied as a source of protein and dietary fiber. Furthermore, they have a high oil content (20-35 % w/w), rich in PUFAs, mainly the omega-3 α-linolenic acid which represents (60-65) % of total fatty acids (Porras-Loaiza, 2014).

Supercritical CO_2 extraction (SCE) is known to prevent or minimize the degradation of bioactive compounds due to the comparatively low temperatures applied and oxygen free atmospheres. It also allows obtaining solvent-free products. Unsurprisingly, it is currently establishing itself as the viable and eco-friendly alternative to the use of organic solvents. Yet, kinetic data are not abundant, and, particularly for chia seeds oil extraction they are scarce and superficial.

In view of the above, the aim of our work is to model the kinetics of the SCE of oils from industrial grape seeds, obtained directly from a Portuguese wine industry (Coelho et al., 2018), and from two sets of chia seeds - high oil content (HOCS), and underutilized low oil content (LOCS) seeds, by applying an efficient solution method to a recently introduced kinetics model (Sovova and Stateva, 2015).

2. Methodology

The seeds were prepared prior to extraction. Grape seeds, which were supplied crushed, have been dried for 48 h at 343 K while the chia seeds were cleaned from straws and other extraneous material prior to being grounded and sieved. No other pretreatment was applied. The average particle diameter (d_p) was calculated to be 0.62 mm for the grape seeds and 0.37 mm for the chia seeds.

The SCE of the grape seeds was performed at temperatures of (313 and 333) K, pressures of (20, 30 and 40) MPa and flow rates of (1.8, 2.3 and 2.8) x 10^{-3} kg·min^{-1} of CO_2. Regarding the chia seeds, SCEs from LOCS were carried out at (25 and 45) MPa, (313 and 333) K and a CO_2 flow rate of 40 x 10^{-3} kg·min^{-1}. The extractions of HOCS were performed at 45 MPa, 313 K and several CO_2 flow rates, namely (27, 40 and 54) x 10^{-3} kg·min^{-1}. The amount of sample used for the experiments was 17 g (grape seeds) and 130 g (chia seeds). A detailed description of the units employed for the extraction of grape and chia seeds can be found, respectively, in the studies reported by Coelho et al. (2018) and Villanueva-Bermejo et al. (2017).

The grape and chia seed oils are very complex mixtures of mainly triacylglycerols (TAGs) with minor amounts of other compounds. Due to this complexity, and in order to reduce the size of the kinetics modelling task, the oils composition is usually being represented by model TAGs. Following the results of the composition analyses, the grape seed oil was represented by triolein (Coelho et al., 2018), while chia seed oil should be represented by trilinolenin. However, considering the lack of any experimental information on the VLE of trilinolenin+$scCO_2$ and the total lack of data (both experimental and estimated) on the thermophysical properties of trilinolenin, triolein was selected as the model TAG to exemplify the chia seed oil.

To calculate the solubility of the representative TAG in the $scCO_2$, the VLE of the two-component system (triolein+CO_2) was modelled applying the predictive Soave-Redlich-Kwong (PSRK) cubic EoS (Holderbaum and Gmehling, 1991).

To simulate the extraction curves in terms of yield and composition of the oil extracts for both the grape and chia seeds, the novel model of Sovova and Stateva (2015), which

reflects the complex relationship between kinetics and phase equilibria (solubility), was applied. Although the model was originally developed for multicomponent systems extraction, it remains valid for single component systems too.

This model considers homogeneous concentration in the extractor at both solid and fluid phases and assumes that the extracts are located on the surface of the solid particles. This assumption allows neglecting internal diffusion, which is compatible with finely ground substrates where the diffusion path in the particles is short and the extract is easily accessible, resulting in negligible internal mass transfer resistance. Further details on the model can be found elsewhere (Sovova and Stateva, 2015)

The model was deployed, validated and executed using gPROMS ModelBuilder (Process Systems Enterprise, Ltd.), an equation-oriented modelling and optimisation platform for steady-state and dynamic systems. gPROMS offers an integrated framework where all the tasks can be performed within the same environment, with embedded solvers that can usually complete the simulations without further user input provided that a complete and well formulated model, with the adequate initial conditions, is available.

gPROMS Modelbuilder parameter estimation was used to estimate the partition coefficient (K) for all the cases studied. The maximum oil content corresponding to monolayer adsorption (w_t) was also estimated for the chia seeds cases. gPROMS uses a maximum likelihood parameter estimation problem and attempts to determine values for the uncertain physical and variance model parameters that maximize the probability that the mathematical model will adequately predict the values obtained from the experiments.

In order to compare the fitting accuracy, a standard deviation measure, the absolute average relative deviation, *AARD*, was also calculated after the parameter estimation using Eq. (1), where N is the total number of experimental points, and e_i^{exp} and e_i^{est} - the *i*-th experimental and estimated point, respectively.

$$AARD = \frac{100}{N} \sum_{j=1}^{N} \frac{\left| e_i^{exp} - e_i^{est} \right|}{e_i^{exp}} \qquad (1)$$

3. Results and discussion

Figure 1 shows the experimental and simulated cumulative extraction curves and Figure 2 - the simulated composition profiles for the solid and fluid phases of the SCE of grape seeds oil. The positive effect of the pressure increase on the extraction rate is clearly demonstrated on the yield, while the effect of temperature is not so well-defined. The simulated profiles for solid and fluid phases depicted in Figure 2, where the increase in pressure results in higher extraction rates, are compatible with the behaviour depicted in Figure 1.

For LOCS (Figure 3) analogous effect of the pressure is observed, while the temperature effect on the rate of extraction and on the total amount of extracted oil is more significant. Figure 4 depicts the profiles for HOCS at different scCO₂ flows, with the yield increasing faster for higher flows.

From the analysis of Figure 1, 3 and 4, a steepest ascent in cumulative mass fraction may be observed for chia seeds, indicating that the oil is more readily available than in the in the grape seeds.

The parameter *K* was estimated for all systems studied, while w_t - only for the chia seeds cases. The values obtained are presented in Table 1. The AARD values obtained ranged approximately from (2 to 9) % for the grape seeds and LOCS, and from (1 to 7) % for HOCS, which should be considered as a good agreement taking into consideration the very complex nature of the systems under study.

The new modelling approach applied incorporates in a rigorous way the interplay between phase equilibria (solubility) and kinetics, and the results obtained demonstrate that albeit the simplifications introduced in representing the grape and chia seed oils, there is a good qualitative and quantitative agreement between the experimental and calculated extraction yields at the SCEs operating conditions examined. It should be emphasized that although the internal diffusion is neglected, the model can still deliver adequate results, providing that the particle size is small, as is the case for the matrix used in this work.
Figure 1. Experimental (symbols) and simulated (lines) extraction curves for grape seeds at different temperatures, p = 30 MPa (dashed lines) and p = 40 MPa (solid lines) and scCO$_2$ flow rate of 1.8 x 10^{-3} kg·min^{-1}.
Figure 2. Simulated profile of oil concentration in the grape seeds (w_s) and scCO$_2$ (w). T = 333 K and scCO$_2$ flow rate of 1.8 x 10^{-3} kg·min^{-1}.
Figure 3. Experimental (symbols) and simulated (lines) extraction curves for LOCS at different temperatures, p = 25 MPa (dashed lines) and p = 45 MPa (solid lines) and scCO$_2$ flow rate of 1.8 x 10^{-3} kg·min^{-1}
Figure 4. Experimental (symbols) and simulated (lines) extraction curves for HOCS at different at different flow rates. T = 333 K and p = 45 MPa.

The values of K are directly related with the extraction rate and the values presented in Table 1 follow generically the same trend observed in Figures 1, 3 and 4, namely K increases with the increase of pressure and temperature. Regarding the $scCO_2$ flow, the trend variation of K is not clear and shows to be system dependent. This behaviour is compatible with the results previously reported by other authors (Honarvar et al., 2013).

Table 1. Estimated values for parameters K and wt.

System	P (MPa)	T (K)	F (10^{-3} kg·min^{-1})	K (kg plant ·kg^{-1} CO₂)	w_t	AARD (%)
Grape	30	313	1.8	2.24E-1	-	4.51
Grape	30	333	1.8	2.22E-1	-	8.84
Grape	40	313	1.8	3.65E-1	-	6.73
Grape	40	333	1.8	4.33E-1	-	8.64
Grape	40	333	2.3	5.58E-1	-	6.68
Grape	40	333	2.8	3.46E-1	-	2.16
LOCS	25	313	40	3.22E-3	8.04E-2	4.82
LOCS	25	333	40	1.36E-2	8.04E-2	9.49
LOCS	45	313	40	4.27E-3	5.76E-2	5.64
LOCS	45	333	40	2.47E-2	5.20E-2	2.13

HOCS	45	313	40	1.69E-2	8.25E-2	2.47
HOCS	45	313	54	9.28E-3	8.07E-2	6.65

4. Conclusions

This work presents the results of the SCE of biomass from industrial grape seeds, obtained directly from a Portuguese industry without preliminary treatment, and from two sets of chia seeds. The influence of the operating conditions on the extraction yield were analysed in detail and reported.

To simulate the extraction process, a kinetic model assuming that the extracts are located on the surface of the solid particles, thus neglecting internal diffusion, was applied. The solubility in $scCO_2$ of the oil, represented as triolein, at the temperatures and pressures of interest to both experiments were obtained applying a rigorous thermodynamic framework, which allowed to interweave the respective solubility functions in the mass balance equations.

The model equations were then integrated using gPROMS ModelBuilder. The qualitative and quantitative agreement between the experimental and simulated extraction curves in terms of yields for both the grape and chia seeds oil was good taking into consideration the complex nature of the systems examined. We can also conclude that the model applied can be successfully used in finely ground matrix where the internal diffusion contribution to the extraction phenomena is very small and, thus, negligible.

Abstract

A dynamical pathophysiological model is presented in the case of septic shock. The proposed approach takes into account the environment and the different subsystems. The considered immune system is the blood, the subsystems are leukocyte cells and cytokines. The interactions between blood cells, plasma and the environment are described via mass balances. The transport phenomena between cells and blood and thermodynamic equilibrium are considered. The quantities of pro and anti-cytokines present in the body are combined to propose global information on the inflammatory state of the patient. The proposed model is strongly nonlinear. Simulations showed how the global information evolves after septic shock. In particular, the model has the ability to evolve to alternative homeostatic equilibrium in case of septic shock.

Keywords: septic shock, dynamic modelling, transport phenomena, thermodynamic equilibrium, simulation.

1. Introduction

Homeostasis refers to the ability of living organisms to maintain their internal state constant despite any change in the environment. Sepsis is the body's response to a very strong infectious attack by a pathogen. Septic shock is diagnosed when organ failure is observed with other various clinical symptoms, such as hypotension. The mortality of patients in France with sepsis was 27% in 2016. Worldwide, a person dies from sepsis complications every 4 seconds. Sepsis has been recognized as a major public health problem by World Health Organization in 2017 (WHA resolution, 2017). Alteration of immune homeostasis plays a central role in sepsis pathophysiology. Following the initial pro-inflammatory response leading to organ failure and shock, sepsis and septic shock are associated with the delayed development of immune dysfunctions (Hotchkiss et al., 2013) (Venet and Monneret, 2018). The intensity and duration of sepsis-induced immune alterations have been associated with increased risk of secondary infections and mortality.

However, a more exhaustive understanding of these alterations and of their evolution over time is mandatory and could lead to the elucidation of innovative therapeutic targets and associated companion biomarkers in a personalized medicine approach.

The immune system modelling is not new (Malek et al., 2015), but quickly limited by the number of species.

The system is closed, uniform and thermodynamic or transport phenomena between cells and blood are not considered. The objective of this paper is to improve the knowledge of the homeostasis evolution in the case of septic shock by establishment of dynamical pathophysiological model, to understand mechanisms involved in pro-inflammatory and anti-inflammatory responses and to predict the inflammation level (as shown in Figure 1). Our approach considers the environment and different subsystems. The immune system in this case is the blood, the subsystems are leukocyte cells and cytokine pairs (pro-inflammatory and anti-inflammatory). Cytokines are essential to mechanisms of inflammation and are widely described in the literature. They are released by various cells in the body, such leukocytes, and they induce responses through binding to specific receptors on the surface of target cells. The immune system is open and continuously in interaction with its surroundings. A model considering the previous assumptions has been developed for one cytokine pair, their corresponding receptors and leukocyte cells.
Figure 1: Different scenarios of the supposed evolution of inflammation state of patient

In section 2, assumptions of the model and different material balances are presented. In section 3 simulations of different scenarios of septic shocks are given. Finally, in section 4 we propose conclusion and future work.

2. Model

The objective is to describe the interactions between the cytokines, their receptors, and the leucocyte cells in the blood system. The interaction between the system and surrounding is introduced in the model by constant source terms: cells continually produced by the bone marrow, and cytokines continually produced by tissues and organs.

2.1. Assumptions

The blood system is described with two phases: a fluid phase, and leucocyte cells. The cells are uniformly dispersed in the fluid phase. The blood volume is assumed to be constant. The chosen pair of cytokines is IL10 and IL18 with their associated receptors. All the white blood cells are represented by average leucocyte cells. The receptors are described as being only on the surface of the cells and supposed uniformly distributed. The cytokines and receptors are produced in the cells.

Linear Driving Force model is used to represent the transfer of cytokines from the cell to the blood and the transfer of cytokines from the blood to receptors. The cytokines in the blood are adsorbed on receptors. This adsorption is already described in some existing pharmacokinetic models (Androulakis et al., 2015). Langmuir equilibrium is assumed for the adsorption. The inflammation comes from the variation of the cytokines, which can stimulate or inhibit the leucocytes production as schematically represented in Figure 3.

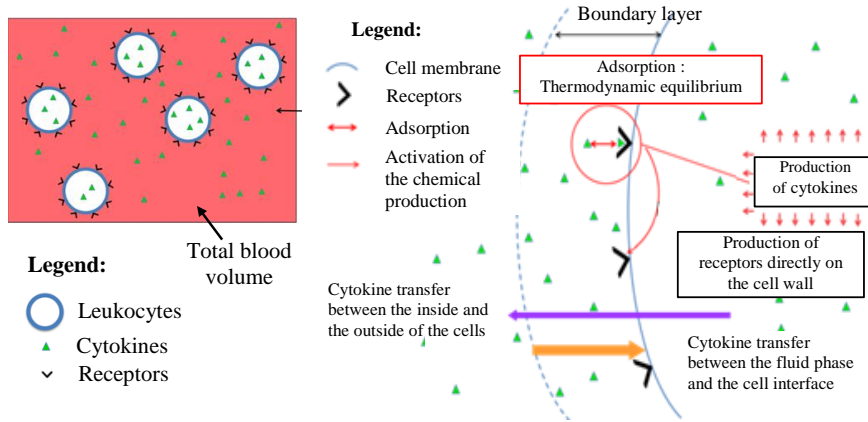
The adsorbed IL10 and IL18 cytokine on their receptors IL10R and IL18R respectively (see KEGG Pathway Database) can directly trigger the chemical production of the same cytokines and receptors by cells shown in Figure 4.


Figure 3: (left) Representation of the blood system and (right) representation of the cytokine adsorption
Figure 4 : Schematic representation of the mechanisms of the IL18/IL10 model

2.2. Notations

A and B notations have been chosen for IL18 and IL10 respectively. The adsorbed concentrations of A and B are denoted with index ads. The concentrations of A (mol/m^3) and B (mol/m^3) in the cell are denoted with index c and the ones at the interface with index int. The associated receptors will be denoted R_A (mol/m^3) and R_B (mol/m^3). The expressions of the adsorbed concentrations are given below:

$$A_{ads} = \frac{R_A \, K_A \, A_{int}}{1 + K_A \, A_{int}}, \quad B_{ads} = \frac{R_B \, K_B \, B_{int}}{1 + K_B \, B_{int}}$$

With K_A (m^3/mol) and K_B (m^3/mol) are the Langmuir coefficients.

2.3. Material balances of cytokines

The material balances of A and B in the fluid, at the interface of the cells and in the cells, are as follow:

$$\frac{dV_l \, A}{dt} = V_c(k_{la}^{intA}(A_{int} - A) + \; k_{la}^{cA}(A_c - A)) - k_d^A A \, V_l + S_A(t) \tag{1}$$

$$\frac{dV_c \, A_{ads}}{dt} = \; - k_{la}^{intA} \, (A_{int} - A) \, V_c \tag{2}$$

$$\frac{dV_c \, A_c}{dt} = V_c \, k_A \, A_{ads} - V_c \; k_{la}^{cA} \, (A_c - A) - V_c \, k_d^A \, A_c \tag{3}$$

$$\frac{dV_l \, B}{dt} = V_c \left(k_{la}^{intB}(B_{int} - B) + \; k_{la}^{cB}(B_c - B) \right) - k_d^B \, B \, V_l + S_B(t) \tag{4}$$

$$\frac{dV_c B_{ads}}{dt} = -V_c \, k_{la}^{intB}(B_{int} - B) \tag{5}$$

$$\frac{d \, V_c B_c}{dt} = \; V_c \, k_B B_{ads} + V_c k_{BA} A_{ads} - V_c \; k_{la}^{cB}(B_c - B) - V_c \, k_d^B B_c \tag{6}$$

Where $V_l \; (m^3), V_c \; (m^3)$ represent the volume of the blood system cells respectively. For cytokine A: $k_{la}^{intA} \; (m/s)$, $k_{la}^{cA} \; (m/s)$ represent the mass transfer coefficient between blood and interface and between blood and cell, respectively), $k_d^A \; (s^{-1})$ and $k_A \; (s^{-1})$ the death and production kinetic constants of cytokine A from A_{ads}, respectively. The same stands for B. $k_{BA} \; (s^{-1})$ represents the production kinetic constant of cytokine B from A_{ads}. $S_A \; (mol/s)$ and $S_B(mol/s)$ are source terms of cytokines from environment.

2.4. Material balances of the receptors at the interface of the cell

$$\frac{d \, V_c \, R_A}{dt} = V_c \, k_{RA} \; A_{ads} + k_1 \frac{d \, N_c}{dt} \, R_A \tag{7}$$

$$\frac{dV_c \, R_B}{dt} = \; V_c \; k_{RB}^A A_{ads} + \; V_c \, k_{RB} \, B_{ads} + k_2 \frac{d \, N_c}{dt} R_B \tag{8}$$

$k_{RA} \; (s^{-1})$, $k_{RB} \; (s^{-1})$ and $k_{RB}^A \; (s^{-1})$ represent the production kinetic constants of receptor A from A_{ads}, receptor B from B_{ads} and receptor B from A_{ads}, respectively. N_c is the number of cells in the blood. $k_1(m^3)$ and $k_2(m^3)$ represent the proportion of receptors A and B, respectively, produced or destroyed induced by the variation of cells numbers.

2.5. Material balances of the cell

Finally, the variation of the number of cells in the fluid is:

$$\frac{d \, V_l \, N_c}{dt} = f \, k_c \, N_c V_l - k_d^c \; N_c V_l + S_c(t) \tag{9}$$

With f (mol/m³) the inflammation level function defined as:

$$f(t) = A - \alpha * B \tag{10}$$

The parameter k_c ($m^3/mol/s$) is introduced to adjust the influence of the function f. k_d^c (s^{-1}) is a death kinetic constant for cells. $S_c(t)$ (mol/s) is a source term from the bone marrow.

3. Simulations

We perform three simulations with same parameters: $K_A = 1.5\ 10^{-7}$, $K_B = 9.08\ 10^{-7}$, $k_{la}^{intA} = k_{la}^{intB} = k_{la}^{cA} = k_{la}^{cB} = 10^4$, $k_d^A = k_d^B = 3.3\ 10^{-2}$, $k_d^c = 6.94\ 10^{-4}$, $k_A = 10^7$, $k_B = 0.12\ 10^7$, $k_C = 700$, $k_{BA} = 1.1\ 10^6$, $k_{RA} = k_{RB}^A = k_{RB} = 0.066$, $k_1 = 0.4$, $k_2 = 5\ 10^{-4}$, $V_l = 5\ 10^{-4}$, $V_c = 3\ 10^{-5}$, $A_{healthy} = 3.045$, $B_{healthy} = 3.18$, $\alpha_{healthy} = A_{healthy}/B_{healthy}$, $S_A = 7\ 10^{-3}$, $S_B = \alpha_{healthy}S_A$, $S_c = 7\ 10^{-4}$, $N_{healthy} = 33\ 10^9\ cells$, $R_{healthy} = 5.971$. The function f was defined to zero for the healthy patient: $f_{healthy} = 0$. Three different initial (non-stationary) states corresponding to an anti-inflammatory state ($f_0 = -10$) have been used:

IS1: ($A_0 = 3.045$, $A_{0ads} = A_0/10$, $A_{0c} = A_0/10$, $B_0 = 9.18$, $B_{0ads} = B_0/10$, $B_{0c} = B_0/10$, $R_{A0} = 5.971$, $R_{B0} = 7.401$, $N_{c0} = 88.5\ 10^9$),

IS2: ($A_0 = 3.045$, $A_{0ads} = A_0/10$, $A_{0c} = A_0/10$, $B_0 = 9.18$, $B_{0ads} = B_0/10$, $B_{0c} = B_0/10$, $R_{A0} = 5.971$, $R_{B0} = 9.401$, $N_{c0} = 35.5\ 10^9$),

IS3: ($A_0 = 3.045$, $A_{0ads} = A_0/10$, $A_{0c} = A_0/10$, $B_0 = 9.18$, $B_{0ads} = B_0/10$, $B_{0c} = B_0/10$, $R_{A0} = 5.971$, $R_{B0} = 9.401$, $N_{0c} = 82.5\ 10^9$).

A, B, R and N_c were made dimensionless by dividing by $A_{healthy}, B_{healthy}, R_{healthy}$ and $N_{healthy}$ respectively.

Figure 5 shows dynamic evolution in the case IS1. Figure 6 gives the inflammation function in the case of IS2 and IS3. With IS1 and IS3 the septic shock leads to death of the patient since the inflammation function does not tends to 0. With IS1 conditions the patient reaches a pro-inflammatory state. With IS3 conditions, the patient is initially in an anti-inflammatory state. In case of IS1 and IS2, the cell number is equivalent and high compared to the healthy patient and seems to lead to the early death and immunodepression for IS1 and IS2 respectively. The patient with IS2 initial state begins more initial receptor of anti-inflammatory cytokines that the patient with IS1 initial state. Even though its state (more anti-inflammatory cytokine receptors) seems to be first improved, it finally leads to the patient death. On the other hand, the patient with IS2 state but with a cell number corresponding to healthy state, returns to homeostasis state. It can be noticed that from three different initial conditions we obtain three different steady states. So the model is able to represent the change of homeostasis that appears after septic shock.

4. Conclusion

Very encouraging qualitative results were obtained by the model developed for homeostasis description on the basis of 2 types of cytokines indicating the interest of the proposed approach. However, many cytokines exist and have specific actions. So network modelling will be necessary and essential to better approach the behavior of the inflammation, because there is no species controlling all the others. Each molecule or cell

has its role in the immune system, and none is redundant. This approach will be further investigated. Finally, the simulations have to be confronted with experimental data.

More power to the individual modeller using ontologies

Heinz A Preisig[a*], Arne Tobias Elve[a] and Sigve Karolius[a]

[a]*Department of Chemical Engineering; NTNU; Trondheim, Norway*

Abstract

Ontology driven process simulation yields a significant improvement not only in terms of accelerating the modelling process itself, but also the quality. Time saving allows for exploring many more alternatives in a shorter time, thus the domain of design for a given process, is readily expanded and quality reduced debugging. To make the use of ontologies successful, one needs to step away from the common data-mining utilisation of ontology, but rather use them to control and guide the modelling process. The construction of the ontology itself is a stage-wise process, where the previously added knowledge is used to control the next stage. From the root definition to the structure of the multi-disciplinary domain, to adding the mathematical description, to designing the controls of the modelling-user graphical interface, the control of constructing the model interactively, to the instantiation an the numerical solution to the visualisation, the ontology is involved at every state improving the overall task equally on every stage.

Keywords: Process Modelling, Automatic Code Generation, Ontology, Graph-based Modelling

1. The Issues

1.1. The Multi-Disciplinary Challenge

Defining modelling as mapping a physical process into a digital twin, being a mathematical model that is realised on a digital device, the modelling activities of the typical chemical engineers would traditionally imply the modelling of unit operations and their combination into plants. Most of the modelling is centred around steady-state processes, with dynamic models mostly being used for control-related activities such as controller design, tuning and testing on a digital plant model. By also allowing for human-in-the-loop then this would also include the operating training with the human acting as a controller, mostly a supervisory controller.

Due to the fast development of computing, both on the hardware and the software side, the use of detailed models in the chemical engineering is rapidly increasing thereby enabling the handling of more and more complex digital twins of our physical plant object. The development affects all disciplines, and with the increasing capabilities, the demand for multi-disciplinary modelling activities is equally rapidly expanding.

Disciplines tend to live their own life generating and solving their problems. The call for interdisciplinary activities requires the integration of the respective software tools and

puts high demands on the users. Many companies have been or are in the process of establishing interdisciplinary modelling groups with the objective to increase the coverage of their modelling activities.

1.2. The Customer Challenge

The software users are primarily facing the need for broader knowledge. Disciplines tend to live their own life, for various reasons, but not at least because of the sheer volume of knowledge required for an individual to become functional in the discipline-specific domains. The users want to have the models to cover a broader range of scales and application domains. A prime example is the utilisation of material models, which has the simple objective to eliminate a large portion of the experimental work required to determine the properties of components but mainly of mixtures. The problem is easy to visualise: a mixture of 2 components covering the range of their concentration range will cover the whole feasible mixing range. Assuming it to cover the full range, thus from pure A to pure B, and performing an experiment in intervals of 10 % one needs 11 experiments to cover the range. With 3 components, this results in 66 experiments, thus naturally multiplying with the number of components and the reduction of the intervals.

The potential substitute is to model the mixture with molecular modelling tools. Programs such as COSMO-RS (Klamt, 2018), LAMMPS (Plimpton, 1995) and suits like MaterialStudio ™ are increasingly used to estimate physical properties. Despite having made significant progress on the user-friendliness, these programs typically have a steep learning curve as well as demanding a level of familiarity with the underlying theory to interpret the results. This applies equally to the next upper domain of granularity, the mesoscale, thus all those scales that lie between the molecular level and the macroscopic level whereby macroscopic refers to a scale that captures the dimensions of the product being modelled. The discipline-dependency is probably strongest on both ends of the scale, and weakest in the middle.

Even in the case where one succeeds to assemble a suitable team, the next barrier is the software. The programs, when not in-house developed, need to be evaluated and purchased or licenses must be obtained and maintained. This obviously requires money for the purchase or licence, but it also requires people who administrate and operate the software and the required hardware facilities.

1.3. The Provider Challenge

The customers are asking for integrated simulation environments that make it possible to predict a product based on the complete history being based on the computational integration of all scales. Whilst feasible to link essentially all the scales into a multi-scale modelling environment as was shown in the MoDeNa EC Framework 7 project, the demand on the people is enormous. Having a specialist in the consortium and intense communications are essential. Less of a problem was the construction of a software platform that allows simulating processes including the full range from quantum mechanics for kinetics to mechanical properties of a polymerised polyurethane foam. Having an experienced senior leader of the latter development proved to yield a solution within two years.

The customer is asking for a simple-to-use environment, preferably a graphical interface

that allows the definition of simulations[1] graphically. This implies that the provider is integrated into a platform, which knows about the different "programs" and which knows on how to combine the programs to generate the desired solution to a user-specified problem.

Technically, this implies that this platform knows about the different "programs" that provide solutions to specific problems, which for the time being we term *solvers*. The platform thus requires knowledge of the available solvers as well as the required data inflow and outflow. It also implies that these *solvers* can be connected by a piping mechanism, meaning that the data from one *solver* can be streamed as input to another. The mechanism is thereby not essential for the user. It may be realised as a data stream or may be passed through a file even with intermediate processing integrated. As long as the mechanism is not time limiting the specifics of the integration are of no concern to the customer. This also applies to the *solvers* being linked to the relevant databases. The dream, and thus the task, is to construct the platform such that it can provide this level of convenience and beyond – it should also advise on what to use and how to use all specific to the problem domain relevant to the customer.

2. Controlling the Modelling Processes using Ontologies

Ideally, the platform acts as an adviser and contracted builder of solutions to a domain of problems spanning over a specified set of disciplines. This can range from physics quantum mechanics to mechanical product properties to controlled unit operations, plant models, performance analysis, nearly anything that let itself capture in a mathematical model.

2.1. Simulation – the Core

Simulation is the core operation, whereby *simulation* is the task of computing the response of a mathematical representation of the plant, the mathematical model, to external excitations. For example, what is the effect of changing raw product quality on the product, what is the effect of changing the energy input into a device, the mass flow to be handled by a plant etc. Simulation is also the core of process design, where the design parameters are optimised based on the objective to meet defined production goals, like concentration and mass flow, whilst minimising waste and energy consumption.

A single-block simulation will capture the complete behaviour in a set of equations, which may be very large indeed and solve these equations using suitable methods. In contrast, a multi-scale, multi-block simulation will solve the problem by solving the blocks sequentially or more generically in a logic-controlled sequence. The MoDeNa project is an excellent example, where polyurethane foam was modelled over the full range from quantum to mechanical properties, which also lead to the definition of a standard for modelling processes (CEN workshop committee, 2018) .

Simulations are also the core of controller tuning and performance checking before implementing them on an actual plant. Operating training tests the operator as a human-in-the-loop, a concept which expands to reaction training in accidents. The latter is very much the same as the flight simulator training machinery for pilots.

---

[1]The term *simulation* is here used generically implying all operations that lead to the execution of a simulation.

2.2. Ontology – the Tool

The core of the platform provides the means to specify the problem. In accordance to the MODA (CEN workshop committee, 2018) a graphical interface could provide the means to define the problem interactively as a directed graph, where the nodes represent the computational tasks, some of which are solvers, some of which provide input convert and process output from the various solvers.

2.2.1. Base Ontology

The design philosophy has the main aspects of (i) **small is beautiful** constructing first of all the ontology from a minimal set of classes and a (ii) **context-free approach** constructing mathematical models named by the ontology in the (iii) **state space**.

The first lead to a high-level abstraction of a generic "process" or "system" , namely any process/system is represented as a directed graph in which discipline-specific tokens are "living". The nodes/vertices represent the capacities for the tokens, whilst the arcs/edges represent the transfer of tokens, thus model the interaction. The base ontology captures the multi-disciplinary domain into a tree of ontologies where each node in this tree inherits the parent nodes completely. The disciplines are thus split hierarchically into sub-disciplines. A simple example is given in Figure 1. This represents the first step in the construction of the ontology. It allows to control the definition of the *base component models* for each specified knowledge domain whilst providing the hierarchical structure of the different domains. The *base component models* are the mathematical models for the node/vertice and the arc/edge behaviour in the respective domain-specific graphs.

For example for process engineering, thus the continuous domain of physical systems, this may be a lumped system for a node giving equations for the conservation of mass, species mass and energy. For the arcs it may be the transfer of mass with the mechanism *convection* or the mechanism *diffusion*, to mention two.
Figure 1: A two-discipline ontology tree

2.2.2. The Multi-Network Framework

A different view is given in Figure 2, which indicates the multi-network for an unspecified example showing the nature of interactions: the intrafaces transfer tokens between subdomains, whilst interfaces transmute tokens from one type into another one. For example, a physical phase interface transfer tokens (energy, mass etc.) whilst the control system observes the state of the physical system and manipulates the physical valve position.

The approach gives an apparent meaning to both types of interaction, at the same time allowing for control of the node connections inside a domain and between domains. For the *interfaces* in the control case, it is the measurement on one side, whilst it is the simplified representation of a set of physical components that convert a control output signal into a valve position. For the *interface* to a material model, it is typically the canonical variables
Figure 2: Multi-network view with intra- and interfaces for token transfer & transmutation

of the energy representation whilst it is a physical property that is reported back. If the *interface* connects to a molecular simulation, the one side is typically a lifting whilst on the other side is a homogenisation.

2.2.3. Equations

The equations are appended to the ontology following the rule that they are inherited into all the branches. Thus the node representing the physical systems is populated with the basic conservation principles, whilst the frame variable, time, is in the root node for dynamic systems. The spatial coordinates, being also physical frame variables, are added to the node of the physical system. The population of the ontology with variables and equations is based on the **state-space approach**. The definition starts with the state and the constants as well as the incidence matrix capturing the model's network structure. The tokens in the nodes define the states, thus state variables are defined accordingly in the base ontology. They, together with the constants, define the physical units. Derived quantities can only be defined based on already defined quantities leading to a lower-diagonal definition space, which is also always closed and complete (Preisig, 2010). This provides control not only about the units, but also the indexing for nodes, arcs and tokens. This ensures complete control over the structure of the equation definition. When combined with the ontology it also enforces completeness of the model as an index-one simulation problem with a given sequence in which the equations must be evaluated.

The definition of the equations is done using a parser, the description of which lies outside of the scope of this paper. The parser generates an abstract syntax tree (Elve and Preisig, 2018). Compilation then only requires a set of target-specific templates that implement the syntax of the target language for the basic operations and functions. This can readily be extended to accommodate user-specified functions.

2.2.4. Model Construction

A graphical editor provides the interface for the modeller, the user that builds the process models based on a given ontology. The interface controls the user's input, ensuring that it is consistent with the context provided by the ontology. It makes it impossible to make mistakes that contradict the structures defined in the ontology. The editor allows for a hierarchical definition of the model, to allow for capturing complex models essentially without any limitations than basics of computing, such as the upper limit of an integer for the counter of model elements.

The user only specifies his view on the model topology by specifying the nodes, their dynamic and distribution nature and the arcs as token transfers including their nature, namely the transfer mechanism being modelled. The remaining part is automatically added to the model via a bipartite graph analysis operating on the equation/variable graphs of the respective domain specific equation set.

3. Achievements

- Tools to define a hierarchical multi-disciplinary ontology
- Equation inclusion tool that is controlled by the ontology and constructs lower-triagonal equation systems for the discipline-specific base components describing the capacity and transfer properties for all discipline-specific properties.
- Complete control over connecting discipline-specific domains.
- Proper handling of subdomains including the transition over scales and from particulate to continuous domains
- Result is index one differential algebraic or partial differential algebraic systems of equations conserving the model structure, which can be utilised in the solvers.
- Complete separation of model structure from behaviour description.
- Latter allows the implementation of model reduction algorithms that are based on order-of-magnitude assumptions.
- Time/length-scale motivated model reduction is facilitated as an operation on the structure, thus affects only the index sets, not the behaviour equations.
- Complete documentation of the model, structure, equations and all assumptions.
- For simulation, the initialisation is clearly defined.
- Explicit implementation of global boundary conditions.
- Highly efficient modelling tool – a reactor in 5 minutes...

Abstract

The present control solutions for power plants[1] have been developed to a level where it is difficult to make significant performance improvements using more advanced and systematic control policies, such as model predictive control, unless one has a clear definition of the overall control problem. Hence, the objective of this work is to make a first step in the direction of systematically defining the optimal operation and control problem for power plants. We use a systematic plantwide control framework to analyze a simple heat-to-power steam cycle with a single pressure level and a drum boiler. We evaluate two typical economic modes: I) given plant load, and II) given heat input. We determine that after fulfilling controlling the active constraints there are two unconstrained degrees of freedom left that can be used to achieve optimal operation.

Keywords: Plantwide control, power plant operation, power plant control, steam cycle

1. Introduction

The objective of this work is to provide a new perspective on optimal operation and control of heat-to-power cycles by viewing it from the more general setting of plantwide control. To the best of the authors knowledge, this procedure has so far mainly been applied to chemical plants, and it is yet to be applied to the steam side of heat-to-power cycles. Power plant control systems have been developed by industrial practices over many years, and it is not obvious what are the actual specifications and degrees of freedom. Moreover, power plants contribute to the electric grid stability, which may have priority over optimal operation of the plant itself.

In this paper we analyze this systematically, in the framework of plantwide control, and the goal is to find a control policy, preferably a simple one, which stabilizes the plant on a short time scale (regulatory control), and achieves near-optimal operation on a longer time scale (supervisory control).

The rest of the paper is organized as follows: in Section 2 we present the plantwide procedure; followed by applying it to the water side of a power plant in Section 3; presenting the resulted control structures and operation modes in Section 4 and making the final remarks in Section 5.

---

[1]In this work, the terms heat-to-power cycles and power plants are used interchangeably.

2. Plantwide control procedure

The typical control hierarchy in a process plant is illustrated in Figure 1. It is decomposed based on time scale separation into several simpler layers: scheduling (weeks), site-wide optimisation (days), local optimisation (hours), supervisory control (minutes) and regulatory control (seconds). The layers communicate by sending the process measurements upwards (i.e from the lower to the upper layers), while the setpoints for each layer are given by solving an optimisation problem in the upper layer (Skogestad, 2004). The procedure consists of a top-down analysis concerning optimal steady-state operation, and a bottom-up analysis targeting the lower regulatory control layer structure. In this work, we focus on the steady-state top-down analysis which involves the following steps (Skogestad, 2004):

Step 1 Define the optimal economic operation (cost function J and constraints).

Step 2 Identify the steady-state control degrees of freedom (DOF) (i.e. manipulated variables that are the setpoints for the lower layers). Use a steady-state model to find the optimal operation for the expected disturbances.

Step 3 Based on the previous step, select the control variables (CVs). Always control the active constraints, and decide to which process variables to allocate the remaining DOF.

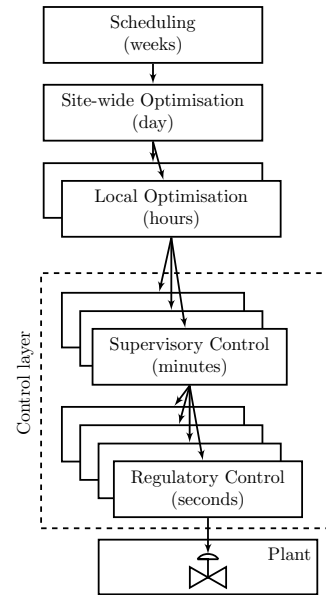
Step 4 Select the location of the throughput manipulator (TPM), i.e. choose where to set the production rate. This is a dynamic issue, but with economic implications.


Figure 1: Typical control hierarchy in a process plant.

3. Plantwide control applied to a simple heat to power cycle

3.1. Process Description

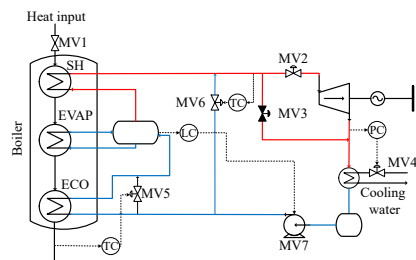
We consider the steam side of a heat-to-power cycle with a drum boiler and a single pressure level, as shown in the process flowsheet in Figure 2. In the boiler, there are three physically independent heat exchangers (e.g. economizer (ECO), evaporator (EVAP) and superheater (SH)) dedicated to well defined regimes such as heating of liquid water to or close to boiling point, evaporation and superheating. The superheated steam is expanded in a condensing type turbine, which drives a generator connected to the electric grid. We choose the drum configuration over a once-through boiler (with a single heat exchanger) because it is most common in operating power plants. Further, the drum has the advantage of energy storage which can provide additional operational flexibility.


Figure 2: Flowsheet of a power plant with a drum boiler and one pressure level. MV1 and MV2 are the two remaining degrees of freedom considered in this paper. Liquid water is in blue and vapor in red.

3.2. Top-down analysis

We proceed by applying the top-down analysis to the described process.

Step 1. The plant has two operational objectives. On a slow time scale (steady-state) it should achieve the economic optimum, while on a fast time scale it contributes to the grid stability. Due to the time scale separation, these objectives are decoupled. However, the grid stability requirement may impose a back-off from the maximum power production. We define the objective cost function to be minimize the negative profit, given by Eq.1.

$$J = -(p_W W + p_Q Q - p_F F - p_U U) \qquad [\$/s] \tag{1}$$

Here, W [J/s] is the produced power, Q [kg/s] is the produced steam (if any), F [J/s] is the heat input source, U [kg/s] are the utilities, and p [\$/kg] or [\$/J] is the price of each. As we consider an operating plant, capital costs, personal, and maintenance costs are not included. The cost function should be minimized subject to satisfying a set of constraints, related to products specifications, safe operation and environment. Typical constraints for a heat-to-power cycle include:

- C1 Superheated steam pressure and temperature (e.g. $T \leq 550$ °C, $P \leq 200$ bar to minimize thermal and mechanical stresses and extend the operating life).
- C2 Condenser pressure should be low to maximize the pressure ratio in the turbine, but also above a minimum threshold to minimize condensation on the last turbine blade and reduce erosion (e.g. $P \geq 0.01$ bar).
- C3 Exhaust gas temperature should be low to minimize heat losses, but above the dew point to prevent corrosion (e.g. $T \leq 100$ °C).
- C4 Drum level (stabilizaion and safety).
- C5 Requirement to participate in grid frequency regulation (some plants).
- C6 Fixed turbine speed (equal to the grid frequency, e.g. $n = 50$ Hz in Europe). For this reason, the turbine speed is not a degree of freedom for operation.

In addition, there are operation constraints on the combustion side (e.g. O_2, CO_2 or NO_x percentage in the flue gas or furnace pressure for combustion power-plants), but these are not relevant for the purpose of this study of the water side.

Step 2. Table 1 shows the degrees of freedom, main disturbances and control variables including the active constraints (a subset of the operational constraints from *Step1*). Here, the active constraints are determined based on engineering insight. The MVs are also shown in Figure 2.

Table 1: Manipulated, disturbances and controlled variables

Manipulated variable	Disturbance	Controlled variable
MV1: Heat (fuel) input	DV1: Quality of heat input	CV1: Power
MV2: Steam turbine valve	DV2: Grid frequency (Load)	CV2: (Live) Steam pressure
MV3: Turbine bypass[*]	DV3: Cooling water temperature	CV3: Drum level
MV4: Cooling water		CV4: Steam temperature[*]
MV5: Economizer bypass		CV5: Condenser pressure[*]
MV6: Feedwater bypass		CV6: Exhaust gas temperature[*]
MV7: Feedwater pump		

[*] Active constraint (at steady-state) controlled in Figure 2.

Step 3. We want to select control variables such that desired optimal operation is maintained even when disturbances occur. Firstly, all the active constrains need to be controlled, and one degree of freedom is used to control each of them. One possible pairing for the identified constraints is

shown in Figure 2, and is: control of steam temperature with MV6, gas temperature with MV5, condenser pressure with MV4, and the bypass MV3 should be closed. Further, the drum level can be controlled with MV7. The turbine speed is usually controlled by changing the steam mass flow using MV2. In this case, the setpoint given to the speed controller becomes a new degree of freedom instead of the valve position. In practice, this is often called *droop control*. In practice all turbines have droop control (Kurth and Welfonder, 2006). Note that the pairing of MVs and CVs (here, the active constraints) can be different, and that only the number of the remaining degrees of freedom is important for this step. We now have two degrees of freedom to use for optimal operation: the heat input MV1 and the and the speed controller setpoint MV2.

3.3. Droop Control

Droop control is commonly used to proportionally allocate the load between electrical generators running in parallel, to avoid a scenario where the load is taken by only one of them (Lipták and Bálint, 2003). This is a proportional controller, with a gain of typical 3 %/% to 10 %/%. In droop control, there is a fast MV (i.e. MV2, turbine valve), and a MV with a slow effect (i.e. MV1, heat). For exam-

Figure 3: Droop characteristics of 4 %/%.

ple, when the turbine speed decreases, the droop controller acts by opening MV2, which increasing the steam mass flow. This can be sustained on a long term only if the heat increases as well. Figure 3 shows an example of 4 %/% droop, i.e. a change of power of 100 %/% gives $50 \cdot 0.04 = 2$ Hz change in turbine frequency setpoint (Anderson and Fouad, 2003).

Step 4. The location of the throughput manipulator depends on the type of power plant, and we can identify two cases (i.e. economic modes) (Skogestad, 2004):

Case I The load is the throughput manipulator and optimal operation means maximizing the fuel usage (efficiency) (i.e. the plant is required to participate in the grid frequency regulation, or to supply utilities to a downstream process).

Case II The heat input is the throughput manipulator and optimal operation implies maximizing production (load). This case applies when the heat input is cheap, or "free" (e.g. solar or heat recovery from a gas turbine).

4. Control structures and operation modes

The standard industrial control structures are boiler driven, turbine driven, floating pressure and its variation, sliding pressure (Welfonder, 1999). However, if one disregards the common industrial practices for power plant control, alternative control structures can be proposed. For example, using valve position control (VPC), or both a P and a PI controller with a MID-selector. In the following, we only show the pairing options for the two remaining degrees of freedom (MV1 and MV2), and we assume that the inner turbine speed controller is active. We start with Case I.

4.1. Floating pressure operation

One degree of freedom is used to keep the throughput manipulator to its specification. The simplest options is to use MV1 to control the power output, and have MV2 fully open to minimize throttling losses. This structure is called floating pressure because the live steam pressure is left uncontrolled, as shown in Figure 4a. However, when a constraint on the maximum allowed pressure is reached, and the set of active constraints has changed, we have to give-up another constraint that is less important (Reyes-Lúa et al., 2018). In this case, we have to use the steam turbine bypass (MV3) as a degree of freedom. The disadvantage is a slow time response for load changes.

4.2. Boiler driven operation

To improve the response time of the system, one should control another intermediate variable. The only option is to keep the live steam pressure at a given set-point. The result is the boiler driven control structure, shown in Figure 4b. The output power is controlled with MV1, while the live steam pressure is controlled with MV2. This structure has the advantage that it dynamically responds faster to a change in load by utilizing the energy stored in the system, which comes at an expense of not utilizing the heat input at the maximum. Though it has a faster response compared to the floating pressure, the system still has a large time constant from MV1 to the power output, and the overall response is slow.

4.3. Turbine driven operation

The reverse pairing is turbine driven, as illustrated in Figure 4c. The live steam pressure is controlled with MV1, while the power output is controlled with MV2. It also has the advantage of utilizing the drum and the superheater energy storage, and the response time to load changes is faster. However, it also does not efficiently utilizes the heat input due to valve throttling losses.

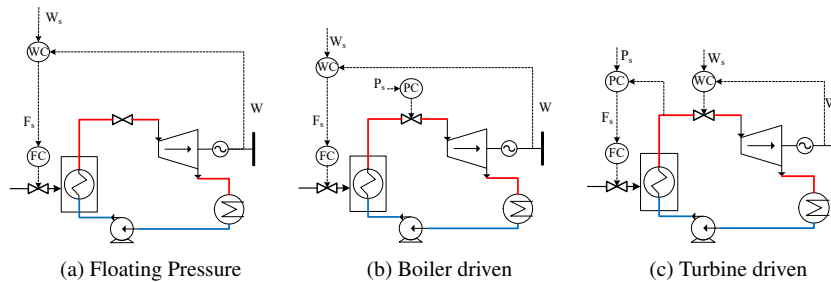
(a) Floating Pressure   (b) Boiler driven   (c) Turbine driven


Figure 4: Control structures for three operation modes for a simple heat-to-power cycle.

4.4. Sliding pressure operation

Sliding pressure is when the pressure setpoint is adjusted online, usually for the turbine driven operation mode. In this case, the power plant can participate in the primary frequency control, at the expense of having to back-off from optimal operation and have MV2 partially open (e.g. 90 %) (Weissbach et al., 2006). The cycle efficiency decreases due to throttling losses in the steam valve, but it allows the power plant to have a energy backup that can be dynamically used by fully opening the valve, and participate in the grid frequency control. However, assuming an isenthalpic expansion through the valve, the steady-state effect will be small. In practice, it is common to have a pressure controller with a varying setpoint given by a master controller in a cascade structure that receives the load as input, as shown in Figure 5a (Klefenz, 1986). Here, the pressure setpoint is changed based on a model that has the steam mass flowrate as input and the pressure setpoint as output.

Valve position controller. The conventional sliding pressure control structure can be improved by adding a valve position controller to bring back MV2 to its nominal opening (at steady-state) after it has dynamically contributed to grid frequency regulation, as shown in Figure 5b.

MID selector. We use both MV1 and MV2 to control the power, and the pressure is floating, as illustrated in Figure 5c. Here we use one P-controller, and one PI-controller because we can have only one integral action in a two-inputs one-output system. When pressure becomes an active constraint (i.e. at the minimum or maximum), we use a *MID* selector to control it using MV1.

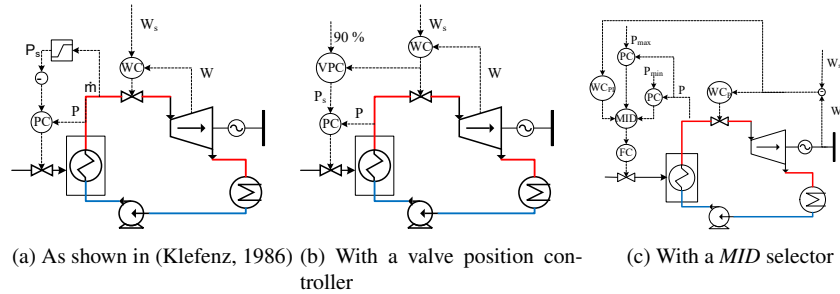
(a) As shown in (Klefenz, 1986)   (b) With a valve position controller   (c) With a *MID* selector


Figure 5: Control structures for sliding pressure operation mode

4.5. Case II - the heat input is the throughput manipulator

From a steady-state point of view, there are no degrees of freedom left to control the power. However, the turbine bypass can be used to reduce the power produced by decreasing the steam mass flow. However, the efficiency of the cycles will also decrease. Ideally, one should make use of energy storage solutions of superheated steam for the situations when more steam can be produced than is needed. This is an attractive idea for power plants using solar energy, especially since the maximum solar power is at midday, when the electricity market demand is lower.

5. Conclusions and final remarks

We have systematically identified the operational objectives, operational and environmental constraints for a heat to power cycle. The degrees of freedom left are MV1, the heat input, and MV2, the steam turbine valve. Now that we have systematically defined the optimal operation and control problem for power plants, it becomes easier to make improvements using more advanced and systematic control policies, such as model predictive control.

Abstract

This contribution introduces a new indicator called Relative Optimality Index (ROI) which measures the extent to which the expected objective value of a flexible process flow sheet obtained by an approximate sequential approach is similar to the optimal solution obtained by more rigorous methods. MINLP flexible process syntheses were performed using various approximate robust approaches and the results were compared to the reference value obtained with the Gaussian quadrature method: a) sequential one-scenario method over randomly selected vertices, b) sequential method in which a two-scenario problem was solved in each iteration simultaneously at the nominal point and randomly selected vertex point, c) a method similar to b) but the most violated point from the previous iteration was used in the subsequent iteration instead of a randomly selected vertex, and d) a novel method which identifies a few vertices critical for flexibility, and solves a few-scenario problem simultaneously in the nominal point and these critical vertices. In this way, better trade-offs between first- and second-stage variables are established. These estimated values are then used as target values during the fine tuning of process structure and design variables that should bring both the flexibility index and the ROI as close as possible to the desired value of 1.

Keywords: uncertainty, flexibility, Relative Optimality Index

1. Introduction

Synthesis of flexible process flow sheets with large numbers of uncertain input data suffers from the problem that the exact optimal results usually cannot be obtained, because rigorous methods, such as simultaneous multi-scenario Gaussian quadrature, cannot be carried out due to uncontrolled increase in the size of the mathematical model. Several approximate approaches have been developed that are based on a large reduction of scenarios, for example, a simultaneous few-scenario method at the nominal and critical points (Novak Pintarič et al., 2013), a method based on probability distances (Zeballos et al., 2014), or sequential procedures in which one-scenario problems are solved sequentially in numbers of randomly selected points (Zirngast et al., 2018). Decomposition approaches were also proposed to facilitate the solution of large-scale problems under uncertainty; for example, an improved L-shaped method based on Benders decomposition (Li and Grossmann, 2018).

The problem with approximate approaches is that the results deviate from optimality; moreover, when dealing with large numbers of uncertainty parameters, a compromise is

sought between flexibility, optimality and computational effort. It is therefore important to address challenges in the area of optimization under uncertainty, because industrial engineering problems, such as demand side management, supply chains and process planning, design and synthesis, require that the risk and uncertainties be taken into account (Grossmann et al., 2017).

In this paper, a robust approach is proposed for Mixed Integer NonLinear Programming (MINLP) process synthesis under uncertainty based on a new identification procedure of those points critical for flexibility. In addition, a new Relative Optimality Index (ROI) is proposed for evaluating the precision of the approximate methods. The developed ROI represents, on one hand, a tool to establish how close the expected value obtained by an approximate method is to the exact value. On the other hand, it provides an approach for targeting the expected values and the appropriate trade-offs between the first- and second-stage variables of those flow sheets generated by robust sequential approaches under large numbers of uncertain parameters for which exact results would be impossible to obtain.

2. Methods for synthesis of flexible processes under uncertainty

The presence of uncertain parameters during MINLP synthesis of chemical processes requires discretization of infinite mathematical models at several discrete points i.e. scenarios, and optimization of the expected objective function. The latter involves the solution of a multiple integral which is approximated in discrete scenarios weighted by the corresponding weights or probabilities as shown in Eq. (1).

$$EZ = \min\left(c^{\mathrm{T}} y + \sum_s p_s \cdot f(d, x_s, z_s, \theta_s) \right)$$

$$\text{s. t.} \quad h(d, x_s, z_s, \theta_s) = 0$$
$$\qquad g(d, x_s, z_s, \theta_s) + By \leq 0 \qquad\qquad s \in S \qquad\qquad (1)$$
$$\qquad d \geq g_{\mathrm{d}}(x_s, z_s, \theta_s)$$
$$\qquad Ay \leq a$$

$$d, x_s, z_s \geq 0, \quad y \in \{0,1\}, \quad \theta^{\mathrm{LO}} \leq \theta \leq \theta^{\mathrm{UP}}$$

Eq. (1) presents a two-stage stochastic model with recourse in which first-stage variables (topology and sizes of process units, y and d) should fit all scenarios, while second-stage variables (operating and control variables, x and z) are specific for each scenario. S is a set of selected scenarios denoted by subscript s, EZ an expected value of scalar objective variable Z, p probability of scenarios, c and f fixed and variable costs, h equality constraints, g inequality constraints, g_{d} design expressions, θ uncertain parameters, A, B and a are the matrices and vector of constants. The above problem can be solved using various methods which differ in selection of scenarios and in the way they treat the scenarios, either simultaneously or sequentially. The number of scenarios is a crucial factor, as the accuracy of the result and the computational effort increase with it.

2.1. Gaussian quadrature

The scenarios in this method correspond to the zeros of the Legendre polynomials, while their weight coefficients represent probabilities (see Acevedo and Pistikopoulos, 1998). The most accurate results would be obtained if the model would be solved simultaneously in all combinations of quadrature points of uncertain parameters; however, the problem size grows substantially as the number of constraints and second-stage variables are multiplied by $N_Q^{N_P}$, where N_Q is the number of quadrature points and N^U the number of uncertain parameters.

2.2. Sequential one- and two-scenario methods with randomly selected vertex

In order to avoid a tremendous increase in model size when using the Gaussian method, more robust sequential approaches were developed, based on the decomposition of the problem into a) determination of the first-stage variables, and b) adjustment of the second-stage variables (Zirngast et al., 2018). The procedure starts with the optimal process structure obtained by one-scenario MINLP synthesis at the nominal conditions. This structure is then solved at the randomly selected vertex so that the existing process units can enlarge, and new units can be added to achieve feasibility. The procedure continues with new vertices until the first-stage variables change. The flexibility index of the obtained process structure is then determined, and stochastic Monte Carlo optimization is performed in a finite number of randomly selected points for determining second-stage variables and the expected objective value at a specific level of confidence. The two-scenario approach differs from the one-scenario method in that MINLP synthesis problem for first-stage variables is solved simultaneously at the nominal point and random vertex in order to better target the trade-offs between first- and second-stage variables.

2.3. Sequential two-scenario method with most violated vertex

This approach is like the two-scenario method described in section 2.2, except that it does not use a randomly selected vertex next to the nominal point but the most violated vertex from the previous iteration. This vertex is identified by analyzing a flexibility index for the first-stage variables obtained in each iteration, as in (Bansal et al., 2002). The vertex with the lowest flexibility is then identified and added to the nominal point in the subsequent iteration.

2.4. Simultaneous multi-scenario method in critical and nominal points

The approaches described in sections 2.2 and 2.3 start with the initial process structure obtained at the nominal point whose flexibility index is usually close to 0. A new approach is therefore developed that starts with a partly flexible initial topology, and then derives a flexible structure by handling this initial topology through one of the previously described approaches. Identification of critical points starts with a two-scenario MINLP process synthesis at a nominal point and random vertex, followed by determination of the flexibility index of the first-stage variables obtained. After processing a specific set of vertices, those few vertices that produce the lowest flexibility indexes are selected as critical ones. MINLP synthesis is then performed as a few-scenario problem simultaneously at the nominal point and identified critical vertices yielding first-stage variables with flexibility index substantially higher than 0. This topology is then tuned to flexibility index 1 by using one of the approaches described in sections 2.2 and 2.3.

2.5. Relative optimality index

From the above described methods, the simultaneous multi-scenario Gaussian quadrature is regarded as the most precise one, so the results of the other methods are compared with the Gaussian result by defining a Relative Optimality Index (*ROI*) in Eq. (2):

$$ROI = 1 - \frac{\left| EZ_{\text{Gauss}} - EZ_{\text{appr}} \right|}{EZ_{\text{Gauss}}} \tag{2}$$

where EZ_{Gauss} and EZ_{appr} represent the expected values obtained by the Gaussian and approximate method, respectively. The closer the ROI value to one, the better the results obtained by an approximate method.

3. Case study

MINLP synthesis of a flexible Heat Exchanger Network (HEN) was selected as a case study. Data for process streams and utilities are given in Table 1, where T_s represents the supply temperatures, T_t target temperatures, *CF* heat capacity flow rates, and α individual heat transfer coefficients. Four uncertain parameters were supply temperatures of hot streams H1 and H2, supply temperature of cold stream C1, and heat capacity flow rate of hot stream H1. The number of uncertain parameters was intentionally kept low, so that the simultaneous Gaussian method could be performed as a reference. The objective function was minimum Total Annual Cost (TAC) composed of the utility costs plus annualized investment cost of heat transfer units. HEN synthesis was performed using MINLP model (Yee and Grossmann, 1990).

The numerical results obtained by different methods are presented in Table 2, and the optimal HEN structures in Figures 1, 2 and 3. MINLP synthesis at the nominal conditions produced an inflexible network with the lowest TAC. Simultaneous MINLP synthesis by Gaussian method was performed at three quadrature points for each parameter, yielding a flexible HEN with the reference expected TAC of 407,550 \$/y, and flexibility index equal to 1. The model size was 6,230 equations, 8,538 continuous variables and 36 discrete variables, while the required CPU time was 9 h using an SBB optimization solver within GAMS on an average personal computer.

Table 1: Data for case study of HEN synthesis

Stream	T_s (K)	T_t (K)	*CF* (kW)	α (kW/(m²·K))
H1	621 ± 5	350	28 ± 5	1.4
H2	583 ± 13	323	20	1.4
C1	388 ± 15	600	40	1.4
C2	313	393	60	1.4
Hot utility (HU)	620	619		3.5
Cold utility (CU)	298	315		1.4

Cost of heat exchangers and coolers (\$/y) = $1846 \cdot A^{0.65}$ (*A* in m²)
Cost of heaters (\$/y) = $2350 \cdot A^{0.65}$ (*A* in m²)
Price of hot utility = 230 \$/kWy, price of cold utility = 20 \$/kWy

Table 2: Results of flexible HEN synthesis by different methods

Method for MINLP synthesis	Expected TAC ($/y)	A (m²)	Flexibility index	*ROI*
Nominal point	358,524	663	0.00	0.880
Gaussian quadrature (2.1*)	407,550	742	1.07	1.000
One-scenario method with randomly selected vertex (2.2*)	446,981	956	1.12	0.902
Two-scenario method with randomly selected vertex (2.2*)	426,424	748	1.20	0.954
Two-scenario method with most violated vertex (2.3*)	426,237	748	1.11	0.954
Multi-scenario method in critical and nominal points (2.4*)	424,082	743	1.17	0.959

* Number of section where the method is described
Figure 1: Nominal inflexible HEN (358,524 $/y)
Figure 2: Flexible HEN obtained by Gaussian quadrature (407,550 $/y) and two-scenario method with most violated vertex (426,237)
Figure 3: Flexible HEN obtained by two-scenario method with randomly selected vertex (426,424 $/y), multi-scenario method at nominal and critical points (424,082 $/y), one-scenario method with randomly s elected vertex (446,981 $/y)

Computation times for the approximate sequential methods were significantly lower than for Gaussian integration, and amounted to around 15 s. Two-scenario approaches produced lower TACs than the one-scenario method, because the presence of the nominal point besides the vertex point during determination of the first-stage variables provides at least rough information about the trade-offs with the second-stage variables.

Those approaches initiating from the nominal inflexible structure (sections 2.2 and 2.3) gave higher costs than the approach that starts from a partially flexible initial structure with flexibility index 0.55 (section 2.4). This structure was then tuned to the required flexibility by using only around 30 vertices in a two-scenario method (section 2.2) while more than 100 vertices were needed when starting the same method from the nominal inflexible structure. All two-scenario approaches achieved a Relative Optimality Index around 95 % with regard to the reference Gaussian method.

4. Conclusions

This paper demonstrates several robust approximate methods for MINLP process synthesis under uncertainty, and compares their results with a more rigorous simultaneous Gaussian quadrature method. A novel indicator, called a Relative Optimality Index, was proposed for measuring how close the results of the approximate methods are to the Gaussian one. It was established that a novel sequential two-scenario approach starting from a partially flexible initial structure produced the closest result with a ROI value of 0.96. In the future work it is intended to upgrade these approaches for determining target ratios between the first- and second-stage variables, and to use them for the approximate synthesis of large processes with many uncertain parameters for which exact optimal results cannot normally be obtained.

Abstract

Process Systems Engineering (PSE) deals with decision-making, at all levels and scales, by understanding complex process systems using a holistic view. Computer Aided Process Engineering (CAPE) is a complementary field that focuses on developing methods and providing solution through systematic computer aided techniques for problems related to the design, control and operation of chemical systems. The 'PSE' term suffers from a branding issue to the point that PSE does not get the recognition it deserves. This work aims to provide an informative industrial and academic perspective on PSE, arguing that the 'systems thinking' and 'systems problem solving' have to be prioritized ahead of just applications of computational problem solving methods. A multi-level view of the PSE field is provided within the academic and industrial context, and enhancements for PSE are suggested at their industrial and academic interfaces.

Keywords: PSE, industry, education, research, interface, perspectives

1. Introduction

Process Systems Engineering (PSE) is a discipline concerned with methods and tools to support decision-making for the creation and operation of chemical supply chains, including the discovery, design, manufacturing, processing, and distribution of chemical products (Grossmann and Westerberg, 2000; Stephanopoulos and Reklaitis, 2011). In other words, PSE is all about rational decision-making, at all levels and length / time scales, by understanding complex systems using a holistic view (Kiss et al., 2015). PSE is the wider field embracing Computer Aided Process Engineering (CAPE) as an important sub-domain where computing and information technologies play an essential role in finding solutions for problems of design, control and operation of chemical systems (Cameron and Lewin, 2009; Dimian et al., 2014).

This paper has several contributions: it defines PSE and CAPE areas and their mutual relationship; it questions what makes PSE less effective in chemical engineering (ChE) than it could potentially be; it shows that industrial as well as academic PSE have stronger & weaker points with known causes and amplified by deficient interactions with each other; it offers a model for enhanced PSE interactions between industry and academia covering key topics (e.g. sharing of industrial PSE problems with academia;

knowledge generation by research & know-how transfer by moving PSE professionals between academia and industry; start-ups of companies with deep PSE expertise and tools for industrial services), and it concludes there is ample potential for improvement of effectiveness of PSE by working better across industrial and academic interfaces.

2. Problem statement

The international PSE research community has successfully established a vital science of engineering. Yet, its accomplishments are unevenly absorbed by the process industry and in educational programs. Application potential is lost and locally even branding issues arise. The analysis of this paper is based on authors' experiences in the Dutch process industry and academia, but carries over well to other countries. There is a known divergence between academia and industry due to different focus: research (funding and output) vs economic profit (Klatt and Marquardt, 2009). A key consequence is that industry considers most important the core ChE disciplines, while academia (mainly driven by research funding / input) focuses on biotechnology, nanotechnology, or science-centred topics – as shown in Figure 1 left (Varma and Grossmann, 2014). Some barriers to more daring and effective use of PSE concepts, methods, models and tools (shown in Figure 1, right) include the following:

• The opportunities in making advancements in PSE seem to have moved from its interior (e.g. better models, faster computing) to external interfaces with other chemical engineering disciplines, such as process intensification (PI), product innovation and engineering for multi-phase products (Harmsen et al., 2018).

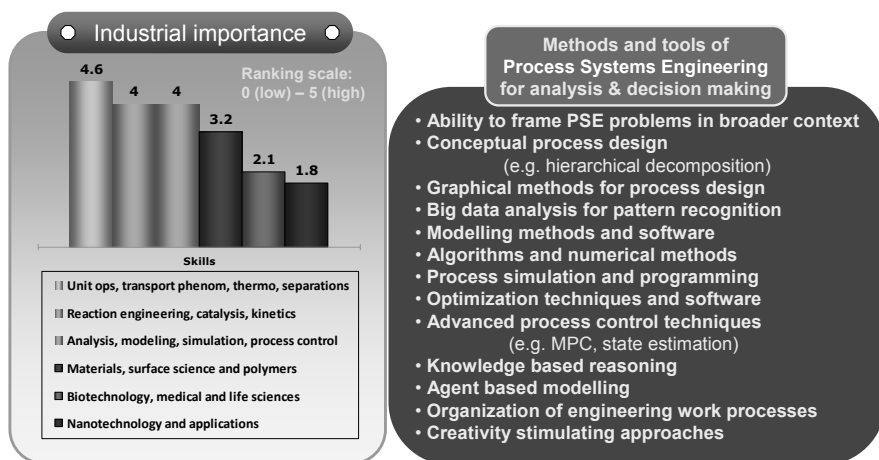
• The huge application success of CAPE tools has shifted barriers in process engineering projects. In the past doing process data handling and engineering computations fast and consistently was a key barrier. That kind of barrier has largely vanished, resulting in the emergence of other bottlenecks in: the human work processes; the knowledge levels of process engineers being incommensurate with the capabilities of the tools; at the interface of technology and society with societal acceptance of technology applications.


Figure 1. Industrial importance of PSE topics (left). Methods and tools for PSE (right).

3. PSE in industry

Research, development & innovation enable the introduction of new or improved products and processes, and reduce the uncertainty to acceptable levels. PSE supports such reductions: business risks, time, cost & profit, environment, safety, health, social. PSE is perceived as a service provider to "customers" in company applications, making it difficult to put a value (not a cost) on its activities or quantify their contribution.

Many industrial professionals have no idea about PSE, but they do know about process design, modelling, simulation, optimization, control, etc. This is likely due to the having these topics been taught at the university as separate topics without the interactions, but also due to the way in which the process design & engineering activities are compartmentalized in the engineering divisions of companies.

The industrial technology assessment models do take into account the probability of success when applying a new technology with a higher performance (or accounting for risk of failure), but it is rather unclear how does that tie in with PSE methods and tools for products and process innovations. Figure 2 shows a multi-level view of PSE positioning between the upper levels (determining the research directions) and the lower levels (tools and means to achieve the goals), with the "process" being seen as an optimized integrated production system, made up of one or more production plants.

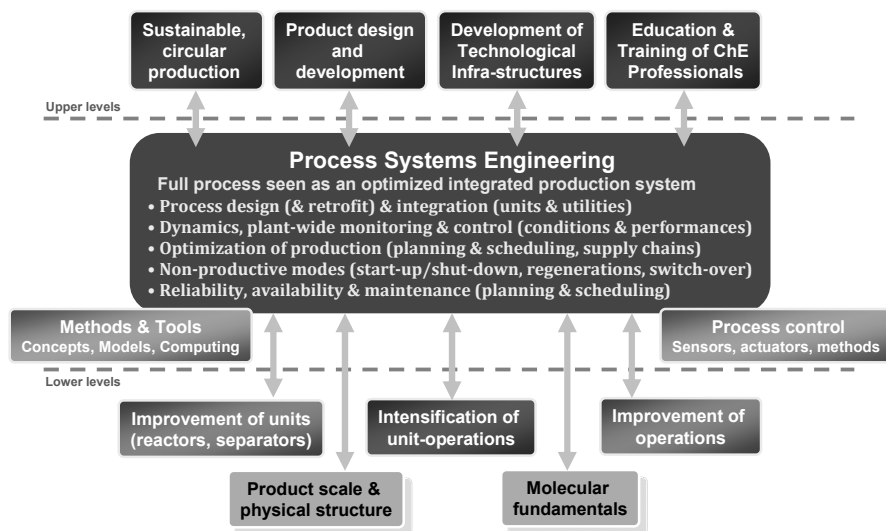
Figure 3 shows that PSE has a key role in delivering more profit in shorter time, along all phases (e.g. research & development, engineering, process optimization, operation) taking into account all sustainability pillars (ten Kate, 2016). Of course, there is a trade-off between multiple criteria in Pareto type of optimization. Moreover, PSE reduces uncertainty along the way from idea to implementation, with the addition that there is also a reverse flow of information from an operational plant to the collection of process models. Plant data periodically collected in operational plants offer a rich base for "big data analysis": e.g. finding patterns of behaviour that can be exploited to improve process performances and be captured in updated models.


Figure 2. Multi-level view of PSE positioning
Figure 3. Role of PSE along all phases of plant development and exploitation

In PSE activities, the purpose shapes the models and these models have the role of transferable knowledge carriers (if the physical principles underlying the model are kept transparent in the structure of the equations). Setting up a model provides structured approach to understanding the system. However, a combined approach of experiments supported by modelling is the most effective. PSE offers a structured approach in process and product development: guiding the lab-scale experiments, interpreting the experimental observations, and translating the results into the desired outcome.

4. PSE in academia

Figure 4 illustrates the career span and life-long learning for PSE professionals at the interface of industry and academia, with a required exchange of professionals between academia & industry. But in the academic world, one must make a distinction between the academic research agenda for PSE, and the teaching / education in PSE topics.

PSE research includes: spanning a wider ranges of physical scales in processes & supply chains; broader range of feedstocks; integration of process intensification and PSE; circular systems: integration in design & operation of product manufacturing, product application, recovery and recycling, medical process systems; multi-scale modelling and computing; uncertainty in design & engineering. Major achievements of PSE include the development of methodologies and tools to support process modelling, simulation and optimization (MSO). But MSO technologies have become a commodity; they are not a distinguishing feature of the PSE field any more (Klatt and Marquardt, 2009). Hence PSE has to play a supportive role to the other engineering sub-disciplines that focus on smaller scales with specific objects. The proper integration of such objects in products and/or processes is certainly part of PSE area. Also, a large-scale energy transition with electrified processes and inherent dynamic operations offers challenges.

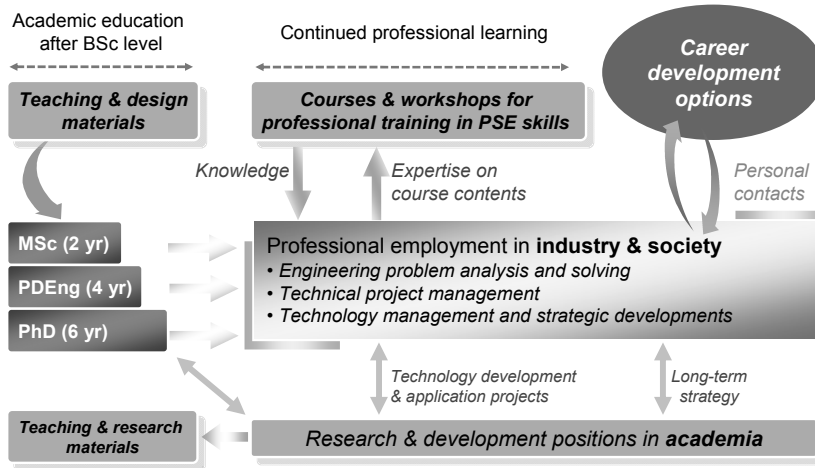
PSE education proved that one has to gradually build up the complexity, though the systems engineering aspects can be introduced from first year in BSc / BEng onwards. When teaching the PSE core elements in succession (e.g. process analysis, product & process synthesis and design, dynamics and control, optimization of process operations within supply chains, safety and reliability engineering) one could also emphasize the interdependencies between decisions made in these (PSE) activities.


Figure 4. Career span for PSE professionals in academia and industry

5. PSE perspectives

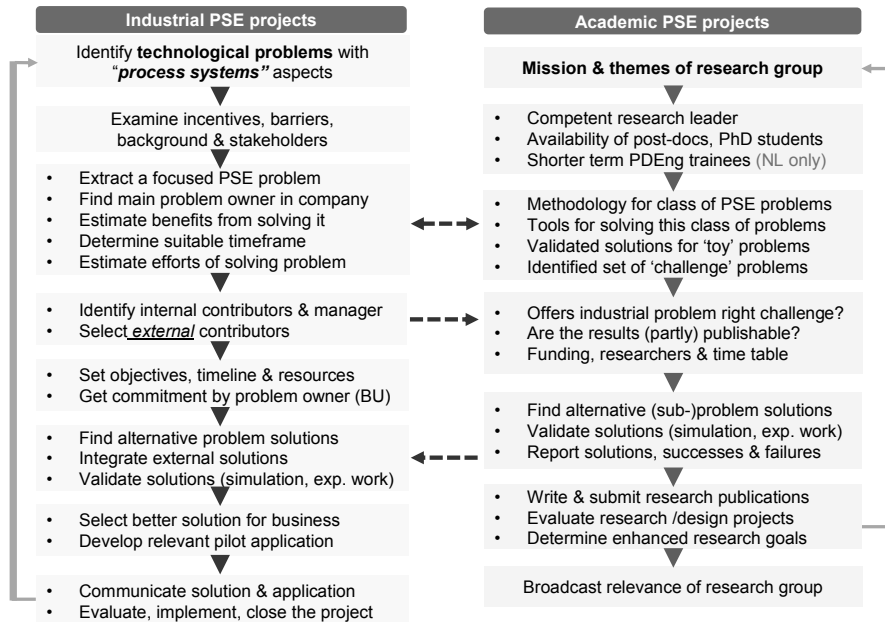
Enhanced PSE interactions between industry and academia needs to cover: sharing of abstracted, generic industrial PSE problems with academia (education and research); knowledge generation by academic research with selective transfer to supportive industrial partners (see framework in Figure 5); as well as knowledge and know-how transfer by moving PSE professionals between academia & industry; and start-ups of small companies (providers) with deep PSE expertise and tools for industrial services.


Figure 5. Industrial vs academic PSE projects

What needs to change for more enhanced interactions of both worlds includes:

• *Industry*: awareness from companies that the external development power is actually many times greater than internally in a company (although internally more focus on specific goals can be attained). Open innovation projects can accelerate the technology transfer of novel developments from the academic world into the industry.

• *Academia* needs to accept that the generation and use of engineering knowledge goes wider than writing good publications. The ultimate rationale for generating engineering knowledge is its application (potential) by joint projects & collaborations with industry.

6. Conclusions

PSE contributed significantly to chemical engineering, by providing MSO technology to address demanding and large-scale process problems in academia and industrial practice. Systems thinking and problem solving are indispensable in the academic education of chemical engineers and also in the industrial practice. Industry mainly focuses on profitability and sustainability, while academia aims at scientific progress, causing a potential gap between industrial practice and academic research. Sustainable success of PSE requires consistent co-operations between academia and industry. PSE is a key enabler for process and product innovation, and has a bright future with sustainable impact on the ChE sciences, and on industrial manufacturing processes.

Abstract

The analysis of issues within the 'water-energy nexus' has become a topic of increasing attention for the scientific and policy communities. Lately various water, energy and food nexus systems are developed to identify, analyse and better understand the interactions between water and energy systems with the purpose of managing these critical resources in the context of various conflicting requirements on top of the imperative need of their optimal use. The objectives of the present work are at first to identify the wide spectrum of problems being encountered under the term Water – Energy Nexus and to review the existing and recent advancements in the Process Systems Engineering (PSE) field that exploit optimisation models, methods and tools for the analysis and the operation of various integrated water energy systems. In addition, the work aims to provide a perspective to PSE and CAPE experts thus expanding their scope and interests and, at the same time, to provide the WEN with the knowledge, experience, tools and excellent quality researchers able to assist to the solution of these significant global problems.

Keywords: PSE and CAPE fields, Water-Energy Nexus, Optimisation models

1. Introduction – Objectives and Scope of the Work

Water – energy nexus (WEN) deals with the efficient integration of water and energy resources in order to tackle a wide range of design, operation and optimisation issues for systems including both of these two resources. Many problems such as the supply and the continuous availability of the resources, their quality and safety, the environmental and social impacts, along with the cost and/or profit emerged from their exploitation, are problems encountered in a very wide range of real situations. Food is in most cases involved due to its strong interaction with the other two utilities.

However, the present paper focuses mainly to the Water – Energy Nexus, mainly due to the types of problems that are analysed. The water and energy interactions are complex and they affect one another directly and indirectly. The dynamic behavior and the presence of multiple conflicting energy/water demands and the complex interactions between various sources and sinks of water and energy greatly impact decision-making within the water-energy nexus, taking also into account that related decisions depend strongly on the interests of the different stakeholders involved. Therefore, a systematic

and holistic analysis of the nexus is critical and there is a very wide scope for optimisation of the whole system, supporting unbiased decision-making.

2. Background of the Work - WEN representing a wide range of problems

By their definition PSE and CAPE fields investigate solutions for integrated systems and have made a tremendous progress all these years in the understanding, modeling and solving a wide range of problems met initially in process systems and now in a very wide spectrum of fields. Therefore, this integrated approach for problem-solving is very familiar to PSE and CAPE communities and many research works deal with this type of problems. The models, methods and tools of PSE may really be the most added value approaches for the WEN problems due to their integrated approach and their ability to address the complexity of these systems. PSE 2018 conference had a dedicated session in the WEN and in the last 2-3 ESCAPE events there are papers that explicitly deal with this issue. The basic parameters and dimensions of these problems are:

- The type of the problem under consideration.
- The geographic area, i.e. the spatial dimension of the problem
- The scope of the work, i.e. is it for households, for cities, for small isolated communities, for a whole country.
- The temporal dimension, i.e. for which time horizon is the problem being solved.
- The stakeholders and interested parties.
- The objective of the optimisation. For the same problem it will be different for a private investor that might seek for maximum profit, the entire society might seek for minimum environmental impacts, maximum security of water and energy supply, a local authority that might seek for the optimal policy / pricing / management of the resources, for the government that might seek for the best water and energy infrastructure investments.
- The importance for the optimal solution or for a set of feasible solutions.

There are very interesting and very recent review papers that deal with various aspects of the research work relevant to Water Energy (and possibly Food) Nexus. Garcia and You (2016) analyse relevant research works concerning Water – Energy and Food Nexus (WEFN) highlighting challenges and areas where PSE may find interesting research opportunities.

Dai et al. (2018) made an extensive survey of recent scientific literature on the water-energy nexus. The authors identified 70 studies and 35 were selected as comprehensive case studies for review. In their work the reviewed studies have been classified and assessed according to groupings based on both geographic scale and their 'nexus scope'. The review has also concluded that, while many studies aim to develop new methods and frameworks to comprehensively assess interactions between water, energy and other elements, none can or do provide a singular framework for performing a "nexus study".

In the context of these excellent review works the current study mainly aims to highlight different types of problems encountered within the WEN scope as well as some modern methods and tools employed to optimise the nexus. It should be stressed that the list of problem types is indicative and various other very significant works have been carried out. The selection has been based on the innovative character of the problem and/or the method being developed for the purposes of the specific work.

3. Types of problems tackled with the Water Energy Nexus

3.1. Water Supply

Although many papers have dealt with the production and the use of energy, much less attention has been paid to the water side of the problems.

Sea Water Desalination

The production of clean water through membrane processes requires large amounts of energy. On the other hand, in remote and isolated from central networks communities, there are is a significant technical potential for the simultaneous production of water and energy. A methodology to design desalinated water supply systems including solar energy as an energy source option is proposed by Herrera – Leon et al. (2018). The methodology consists of two stages and uses a MINLP model. The objective of the first stage is to minimize the total cost of the whole system, while the objective of the second stage is to minimize the greenhouse gases (GHG) emissions related to desalinated water transport by considering the opportunity of installing photovoltaic panels. The MINLP model considers the installation and operation costs of the desalination plants, pumping stations, pipes, and photovoltaic panels.

Optimisation of Water Supply systems

A very interesting review has also been carried out by Vakilifard et al. (2018), acknowledging that the utilization of WEN in optimising water supply systems not only ensures the sustainability of the water supply for increasing water demand but also diminishes water-related energy and environmental concerns. The work also presents a review highlighting knowledge gaps in optimisation models related to the water energy nexus in water supply systems or "water supply side of the nexus". Several major gaps are identified, including the lack of optimisation models capturing spatial aspects as well as environmental impacts of the nexus problems. The main gap is the absence of models for optimising long-term planning of water supply system considering renewable energy within an urban context.

3.2. Water Energy Nexus Optimisation in Remote Communities

Remote communities render a very special issue of investigation within the WEN research umbrella: WE supply problems in these communities are quite intense and require immediate solutions that can only be provided by optimisation approaches. Following that, various research works have been carried out by pioneering in the field teams, indicatively focused in the Greek, Aegean islands and/or in the Mediterranean Region and/or in Maldives islands.

Aiming at providing water and energy sustainable supply solutions for the isolated Aegean islands, Bertsiou et al. (2018), investigated the development of a Hybrid Renewable Energy System (HRES) in Fournoi, a small island in northern Aegean. The proposed methodological framework is designed to produce hydropower for the coverage of electricity needs and for the desalination of the amount of water that is needed for domestic and agricultural use. Data about the island's population and data of water and electricity consumption are collected, as well as, meteorological data from the nearby station. The authors make a Scenario Analysis with three different scenarios.

In the same field Papapostolou et al. (2017, 2018) implemented an optimisation framework for the optimal design and operation of water and energy supply chains (WESCs) accounting both economic and environment considerations. The framework

consisting of a representation following the Resource-Task-Network approach along with a developed MINLP model and its variations, was implemented and tested in different island topographies (a medium-size and a very small island in Cyclades Complex), so as to prove the most profitable WESC accounting: on the side of energy supply the options of diesel, PV, wind and battery storage, whilst on the side of water supply, the options of the desalination plant vs the traditional water transfer via ships, both acting operating complementary to the island's existing water tank. The results of the work provide a water supply strategy allowing in the case of RES excess the desalination plant to operate "free of charge" so as to allow the water intake to the water tank, a water to be supplied at the island network at a time whereas both peaks loads in energy and water demand occur (thus more expensive). Additionally, results evidence that energy autonomy and water demand fulfilment is possible for small-scale islands as well in a cost-effective way, that being achieved through RES, allowing a reduction of CO_2 emissions more than 90%.

3.3. Water Energy Nexus Optimisation in Urban – Residential Sector

Cities are concentrations of demand to water and energy systems that rely on resources under increasing pressure from scarcity and climate change mitigation targets. However, the effect of the end-use water and energy interdependence on urban dynamics had not been studied. In the work of De Stercke et al. (2018), a novel system dynamics model is developed with an explicit representation of the water-energy interactions at the residential end use and their influence on the demand for resources. The model includes an endogenous carbon tax based climate change mitigation policy which aims to meet carbon targets by reducing consumer demand through price. It also encompasses water resources planning with respect to system capacity and supply augmentation. Using London as a case study, the authors show that the inclusion of end-use interactions has a major impact on the projections of water sector requirements.

4. Modern Methods and Tools in the Optimisation of WEN

Certainly the well-known optimisation methods and tools (Mathematical Programming as MILP, MINLP, global optimisation, etc.) have extensively been used for the solution of the WEN problems. However, in the latest advancements the authors have used modern approaches concerning optimisation modelling and solution of the corresponding problems. Game Theory and Graph theory are two of the modern methods that have been identified in WEN optimisation works.

4.1. Game theory

Land use optimization can have a profound influence on the provisions of interconnected elements that strongly rely on the same land resources, such as food, energy, and water. Avraamidou et al., (2018b) have developed a hierarchical FEW-N approach to tackle the problem of land use optimization and facilitate decision making to decrease the competition for resources. The authors have formulated the problem as a Stackelberg duopoly game, a sequential game with two players – a leader and a follower. The government agents are treated as the leader (with the objective to minimize the competition between the FEW-N), and the agricultural producers and land developers as the followers (with the objective to maximize their profit).

Nie at al (2018) in the context of their work for land use optimisation analyse the FEW-N for crop-livestock systems with the development and implementation of a global

optimisation land allocation framework, providing an adaptive data-driven modeling method based on limited realistic data to predict yields for production components.

For the development of a feasibility model, Namany et al. (2018) developed a bottom-up approach in which the self-interested stakeholders, i.e. the players, are represented based on their own decision variables and objective functions at various levels, i.e. resources and environment systems, engineering systems, and their integration and operations. For this purpose, a combination of optimization models based on linear programming, stochastic programming, and game theoretic approach, represented by a Stackelberg competition, were developed. A case study is set in the State of Qatar with the objective of enhancing food security using hypothetical scenarios. The results obtained demonstrates that interesting interactions between systems can potentially result in the achievement of desired objectives under properly regulated markets.

4.2. Graph theory

Some very interesting modern tools seem to emerge that are exploited in the optimisation of WEN. For example, Tsolas et al. (2018) present a scalable and systematic method for the design and optimization of complex water-energy nexus using graph theory-based network representation and a novel (WEN) diagram. The authors show that for specified external grid demands, the optimal nexus configuration with minimum water and energy generation is the one without any redundant subgraphs. They then propose a systematic method to identify and eliminate redundant cycles, flows and entities within a nexus leading to (i) minimum generation/extraction of water and energy resources from the environment, or (ii) maximum yield of water and energy to meet external demands. Their approach results in optimal nexus configurations that also satisfy operational constraints, restrictions and water quality specifications. The approach is demonstrated using case studies on water-energy nexus systems focusing on power generation, seawater desalination, groundwater and surface water at regional and national scales.

5. Conclusions and Future Prospects

The interest and research challenge in the modelling and optimisation of WEN in various scales, expressions, communities is continuously increasing. There is a very important optimisation scope in these problems since there are a lot of conflicting demands in the resources involved. The present work made an effort to highlight the wide spectrum of real problems that may be encountered under the term Water – Energy Network. For so different problems it is clear that there is no unique modelling framework that could describe all of them. On the other hand it is obvious that there is a serious optimisation scope in these problems due to the different stakeholders, objectives and characteristics. Advanced model development that will describe the details and characteristics of the problems is still required since the interactions between the energy and water resources are complex and not yet clarified. The other important issue in this discussion is the implementation of the above in real problems and how the developed knowledge and knowhow will be useful and exploitable in real operating water – energy systems. Furthermore, it is certain that many investors (on a local or global perspective) will emerge finding business opportunities. Legislation, regulations and infrastructure expansion will definitely be needed in order to make this knowledge exploitable for the social and investor's benefit.

Abstract

Biological systems can be described by ordinary differential equations of the main components with non-linear and interacting reaction kinetics. This models are helpful tools for process development and optimization. The difficulty in building a model is not to find a mathematical expression for the different kinetics but to select the ones with identifiable parameters. Besides that also the right sampling time points are important to capture the needed information for model calibration.

Within this contribution, we show how time resolved sensitivity helps to tackle this question by using the example of an *Escherichia coli* (*E. coli*) growth model. We show how the time resolved parameter sensitivities of the dynamic batch and fed-batch can be used to determine identifiable parameter sets and to schedule samples for off-line and at-line measurements.

For validation of our framework, we compared our approach with equally distributed sampling over time. The results show that our sampling approach is able to determine the best identifiable parameter sets and helps to define sample time points to finally obtain the needed parameter accuracy. Besides that with less effort (number of samples) comparable parameter accuracies could be reached.

Keywords: Sensitivity; Identifibility; Model Parametrization; Sample Timepoint Optimization

1. Introduction

Having accurate process models is of great value for all production industries, offering them to do in-silico process scheduling and optimization and to use them to monitor and control their production processes (Mears et al. (2017)). In order to obtain reliable models that can be successfully used, the model calibration stage requires carefully designed experiments with high informative content (Muñoz-Tamayo et al. (2014)).

Hereby the sampling time points are of central importance to capture the information. Especially in fermentation processes, were sampling bears a contamination risk and off-line analytics are cost and labour intense, a proper sampling strategy is important. Often

equally distributed sampling or only end-points of process phases are sampled, which leads to the loss of important information.

Based on a simple *E. coli* fed-batch model, consisting of three state variables and four parameters (De Pauw and Vanrolleghem (2006)) a workflow is presented, to select identifiable parameter sets and to determine sampling time points and frequencies to obtain the aimed parameter estimation accuracy. The parameter identifiability, which considers the uniqueness of model parameters, is a prerequisite for reliable parameter estimation (Chiş et al. (2011)). Often biological models are over-parameterized, whereas only a subset of parameters are identifiable in practice. By ranking the parameters according to their influence on the model outputs, the so called parameter sensitivity, Brun et al. (2002) showed a procedure how best identifiable parameter sets can be selected for an over-parameterized model. The proposed procedure combines the collinearity, a measure of parameter uniqueness and sensitivity, a measure of parameter importance of all possible combinations.

In this contribution we extended this approach from continuous processes, were steady state conditions are reached to dynamic batch and fed-batch conditions by taking an *E. coli* growth model. The presented subset selection was based on the time resolved collinearity to determine process phases with different identifiable parameter subsets. In contrast to De Pauw and Vanrolleghem (2006) and Kutalik et al. (2004) which determined time points with highest information content, we optimized the sampling time points towards the selected parameter subset, guaranteeing reliable model parameter with preselected accuracies.

2. Materials and Methods

2.1. E. coli Fed-batch Model

For illustrating the algorithm an unstructured, unsegregated model describing an *E. coli* fed-batch process was taken from De Pauw and Vanrolleghem (2006). The model was extended by the concentration of dead cells. The model consist of three material balances: the living biomass C_X,

$$\frac{dC_X}{dt} = (\mu - k_d) \cdot C_X - \cdot C_X \frac{F_\alpha}{V}, \quad \mu = \mu_{max} \frac{C_{Glc}}{C_{Glc} + K_{Glc}} \tag{1}$$

the dead biomass C_{Xd},

$$\frac{dC_{Xd}}{dt} = k_d \cdot C_X - C_{Xd} \cdot \frac{F_\alpha}{V} \tag{2}$$

and the glucose concentration C_{Glc},

$$\frac{dC_{Glc}}{dt} = \frac{Y_{X,Glc}}{\mu} \cdot C_X + (C_{Glc,\alpha} - C_{Glc}) \cdot \frac{F_\alpha}{V} \tag{3}$$

where μ is the specific growth rate, k_d the constant death rate, $Y_{X,S}$ the yield coefficient for biomass on glucose, F_α the flow rate of the glucose feed and $C_{Glc,\alpha}$ the glucose concentration of the feed. A single substrate dependent Monod kinetic was assumed to fully

describe the growth behaviour of *E. coli* in which μ_{max} is the maximum specific growth rate and K_{Glc} the saturation constant.

Normal distributed white noise, ε_{ij} was added to the model states C_j to obtain realistic data $\tilde{C}_j(t_i)$. From this noisy, data samples were taken every 5, 10, 30 and 60 min and model parameters were estimated by minimizing the profile likelihood between simulated and sampled data.

2.2. Sensitivity and Identifiability Analysis

The local sensitivity s_{jk} of the state variable C_j to parameter p_k quantifies the deflection of the state variable C_j due to small changes in p_k (DiStefano III (2015)). To identify the parameters, which influences the outputs of the described *E. coli* model most, the first-order, local sensitivity functions were simultaneously solved with the specified state equations. This local sensitivity information provides a basis for calculation of two parameter selection measures proposed by Brun et al. (2002).

$$s_{jk} = \frac{\partial C_j}{\partial p_k} * p_k \qquad \delta_k^{msqr} = \sqrt{\frac{1}{n}\sum_{j=1}^{n} s_{jk}^2} \qquad \gamma_K(t_i) = \frac{1}{\sqrt{\lambda_k(t_i)}} \qquad (4)$$

The importance index δ_k^{msqr}, which ranks the parameter according to their influence on the model states and serves as a global importance measurement. Whereas the collinearity index γ_K for a chosen parameter subset k gives the linear dependency between the selected parameters. In contrast to Brun et al. (2002) the collinearity index $\gamma_K(t_i)$ was calculated for every time point t_i. To determine the best set of parameters, the smallest eigenvalue $\lambda_k(t_i)$ of the Fisher Information Matrix $FIM(t_i)$ was used. The FIM is a measure for the information content that is stored in a measurement. It is connected to the covariance matrix of the parameters by it's inverse and is defined as follows:

$$FIM = \frac{1}{\sigma^2}\sum_{i=1}^{N}\sum_{j=1}^{n} \nabla_p C_j(t_i,p)\nabla_p C_j(t_i,p)^T \qquad (5)$$

where σ^2 is the variance of the measurements, p the parameter vector, i the number of measurements and j the number of states (Kutalik et al. (2004)).

2.3. Optimal Sampling Schedule

To determine the best sampling times a D-optimal design was chosen, maximizing the determinant of the FIM (Berger and Wong (2005)). This scalar objective function is optimized by Powell's Method analogous to the publication of Kutalik et al. (2004). This simple algorithm allows to find a suboptimal sampling time vector.

2.4. Description of General Workflow

After stating the model (step 1) the sensitivtiy analysis (step 2) the importance ranking and collinearity index are calculated (step 3). These two criterions are essential for the parameter subset selection (step 4) including only parameter subsets fulfilling both conditions (high sensitive and uncorrelated). Time optimization (step 5 and 6). Thereafter the optimization algorithm maximizes the determinant of the Fisher information and selects

the most informative measurement points related to the parameter subset. Afterwards the parameter of the subset are estimated (step 7) showing acceptable errors (step 8).

3. Results and Discussion

Figure 2 shows the time series data of the simulated state variables and their corresponding in-silico samples, which were taken with a measurement frequency of 60 min. The fermentation starts in the batch mode with an initial working volume V_0 of 5 L, an initial glucose concentration $C_{Glc,0}$ of 6 g/L and an initial biomass concentration $C_{X,0}$ of 0.5 g/L. After a 6 h lasting batch phase a 4 h fed-batch followed. The fed-batch mode is characterized by a constant inflow of medium $F_\alpha = 5 * 10^{-3}$ L/h with a glucose concentration of 600 g/L.

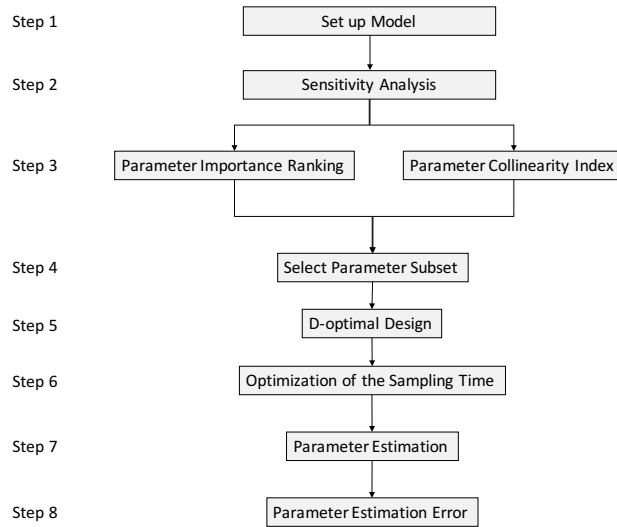
Step 1	Set up Model
Step 2	Sensitivity Analysis
Step 3	Parameter Importance Ranking / Parameter Collinearity Index
Step 4	Select Parameter Subset
Step 5	D-optimal Design
Step 6	Optimization of the Sampling Time
Step 7	Parameter Estimation
Step 8	Parameter Estimation Error


Figure 1: Overview of the workflow for improving the paramater estimation accuracy
Figure 2: Overview of the optimal sampling times (n_{sample} = 11), the mesasured (n_{sample} = 11) and estimated concentration profiles of living biomass, dead biomass and glucose during an *E. coli* fed-batch process with a total process time of 10 h. Shaded areas are the 95 % confidence intervals of the biomass concentration (light grey: before subset selection, grey: after subset selection, dark grey: after sampling time optimization).

In Figure 3 the importance index of the parameters for the *E. coli* model and the time resolved collinearity index of some feasible subsets are illustrated. In total there exist 11 parameter combinations consisting of 2,3 and 4 parameters. All 4 parameters together reached high collinearities. The same goes for combinations with K_{Glc} and μ_{max}, which are not displayed in Figure 3. The parameter ranking revealed that μ_{max} is the most sensitive parameter. A change in μ_{max} leads to the largest change in the state variables. K_{Glc} is characterized by a low importance index, because it is only active in a small time window around 6 h when the glucose is nearly depleted. The subset of μ_{max}, Y_{XS} and k_d is the most linear independent and important triple combination. Within Figure 3 a time window is indicated in gray, were the selected subset shows almost no linear dependency.
Figure 3: Selection of best identifiable Parameter set. a) Overall parameter importance, b) Time resolved identifiability of feasible parameter sets

In Table 1 the parameter estimation errors of all four parameters and the selected subset are compared for different measurement frequencies. These parameter estimation errors are based on the Cramer Rao lower bound. After parameter subset selection and exclusion

Table 1: Parameter estimation error (%) of the full parameter set with the selected parameter subset, excluding K_{Glc} at different measurement frequencies.

Data Frequency	$\Delta\mu_{max}$	ΔY_{XS}	Δk_d	ΔK_{Glc}	n Samples
(min)	(%)	(%)	(%)	(%)	
5	6.99 | 2.41	3.82 | 3.74	18.33 | 18.33	90.83 | -	121
10	9.81 | 3.41	5.47 | 5.35	23.13 | 23.13	148.10 | -	61
30	26.61|5.81	9.33 | 9.03	47.25 | 43.99	139.50 | -	21
60	29.21|7.96	12.58 | 12.27	56.62 | 56.59	1145.5 | -	11

of K_{Glc}, the parameter estimation error of μ_{max} decreases dramatically from 29 % to 8 % at a low sampling frequency. The other parameters are only slightly affected, which indicates a strong correlation between μ_{max} and K_{Glc}. The sample frequency has also an significant influence on the estimation error, showing a 3-fold increase comparing a 5 min to a hourly sampling rate. The estimation errors of the selected parameter subset with optimized sample time points are summarized in Table 2. It can be seen that by optimizing

the sampling time point the estimation error can be significantly reduced. The errors are in the range of a sampling rate lower than 30 min, with only half of the samples. Compared to the same amount of equally distributed samples (60 min) the estimation error decreased by approx. 35% for μ_{max} and k_d and by 25% for Y_{XS}. The 95 % confidence interval of the biomass is shown in figure 2 before/after the subset selection and at the end of the sampling time optimization .

Table 2: Parameter estimation error (%) of the selected parmeter subsset consisting of μ_{max}, Y_{XS} and k_d after optimization of the sampling time

Measurement Frequency	$\Delta\mu_{max}$	ΔY_{XS}	Δk_d	n Samples
(min)	(%)	(%)	(%)	
60	7.96	12.27	56.59	11
optim	5.20	9.20	35.70	11

4. Conclusions and Outlook

It is shown that a combination of parameter subset selection and optimization of the sampling time points reduces the parameter estimation error drastically. The presented approach ensures that important samples are taken while at the same time overall sampling effort can be decreased. By evaluating the collinearity and parameter importance, the subsequent parameter estimation leads to more reliable models.

Although the D-optimality criterion proved to be a suitable optimization criterion for the examined fed-batch process, a further improvement might be reached when a combination of different optimality criterions for example D-optimal und E-optimal is implemented.

Abstract

Industrial integration of solar for process heat applications with periodic heat storage and backup utility system ensures reliability and efficiency of renewable heat utilization, thus minimizing the dependence on fossil fuel and energy related emissions. Furthermore, by minimizing heat duty from backup utility, opportunities for matching solar thermal and solar heat storage could be fully explored. This study models the industrial application of solar thermal considering direct and indirect integration, periodic heat storage and backup utility. For the synthesis of the integrated design, a flowsheet superstructure is presented for multi-period heat supply network of industrial processes. The design and optimization of the integrated system is implemented and solved in GAMS with the objective of maximizing total heat output to the heat network. To demonstrate the performance of the model, the proposed solar heat network design for industrial utility retrofit is applied to an illustrative case study of preheating a cold industrial stream.

Keywords: Solar thermal, Solar heat, Thermal storage, Solar heat integration, Industrial solar integration.

1. Introduction

Over the past few decades, the global energy consumption has been on steady increase due to the rising of population and expanding economic activities. According to a recent report, heat consumption accounts for over 50 % of the annual global energy use (WEC, 2016) and analysis has revealed that as at 2014 about 75 % of this share of energy consumption (around 130 EJ) is currently sourced from fossil fuels (OECD/IEA, 2015) which negatively impacts the environment.

Solar thermal is a form of renewable energy with great potentials to substitute/ supplement the use of fossil fuels for various heating purposes because it is a low-carbon source of heat and power (electricity). Studies have shown that out of the total global industrial heat consumption of 85 EJ, 30 % is used for low temperature (<150 °C) heat operations (IEA, 2017). Due to the wide range of industrial processes with low temperature heat operations, industrial solar utilization is believed to have great potentials.

Solar industrial utility retrofit in combination with periodic heat storage (Abikoye et al. 2018) is a demonstration of how a renewable source of heat can be effectively planned for and harnessed with industrial heat networks. Due to supply variability and low thermal

value of solar over some time periods, an important feature which could further improve thermal performance in such designs is the inclusion of an effective backup utility system in the design framework.

While a significant number of research works has been carried out on solar thermal utilization, not much has been done on the application and optimization of solar technologies for industrial processes (Kong et al. 2018). Even in some existing solar designs with thermal storage, managing the intermittent fluctuations of heat supply is still quite challenging due to the technical difficulties and large number of decision variables involved, especially when considering backup alternatives to circumvent the supply gaps in solar systems. In this study, an integrated design of a solar heat network is proposed for stream preheating in industrial processes in order to study attainable quantities of solar heat that can be harvested regardless of economics considerations which can vary significantly both temporarily and spatially. The design includes strategies that account for the multi-period variability in solar energy supply on hourly basis according to meteorological data obtained from EC-JRC PVGIS (2017) for the specific location considered. The synthesis method involves a balanced close-loop circuit of direct and indirect solar thermal system with periodic heat storage and backup utility.

2. Methodology

2.1. *Solar heat network design for industrial utility retrofit*

The framework for solar industrial preheating is outlined to demonstrate the flow of harvested solar thermal for direct and indirect (via heat storage tank) plant integration. Figure 1 consists of a closed-loop superstructure of industrial solar thermal utilization incorporated with a periodic heat storage and a backup boiler to form an integrated heat supply network. In the resulting structure, harvested solar thermal flows through the splitter which gives opportunities for both direct and indirect industrial integration of the captured solar heat where indirect integration through storage tank enables solar heat use in time periods when there is no solar irradiation.

Figure 1: Integration of solar heat network for industrial stream preheating (modified from Abikoye et al. 2018)

The total solar heat available for integration is targeted for stream preheating across a specific heater for as much heat demand that could be satisfied while alternative heat source is provided to the network by the backup utility. The alternative heat source heats the cold stream to its final target temperature in cases where the captured solar heat is not sufficient. To ensure optimal and efficient solar heat use in the integrated system, another

splitter is placed at the outlet from the process plant such that the heat transfer fluid can return to the solar collector or to the storage tank depending on whether the temperature level of return could be useful to buffer the heat in the storage tank.

2.2 Model development

The developed model comprises material and energy balances across the solar collector, splitters, mixers, heat storage tank, backup boiler and the plant (two heat exchangers) that is targeted for solar heat integration. It should also be noted that the operational features of a typical solar heating system are transient, therefore to account for the time dependencies, the model is formulated as a mixed-integer non-linear programming (MINLP) problem. Also, the synthesis is implemented simultaneously with the objective of maximizing the average solar heat output to the network ($Q_{mp,dp,hp}^{solar}$) shown in Eq. (1).

$$\max \sum_{mp \in MP} \sum_{dp \in DP} \sum_{hp \in HP} \big|_{(dp,mp) \in DPM} Q_{mp,dp,hp}^{solar} \tag{1}$$

where *hp*, *dp* and *mp* represent the hourly, daily and monthly periods and *DPM* stands for set of pairs of days and months.

The model takes into account variable flowrates, temperatures and energy flows across each unit within the entire system. Additionally, area of a solar thermal collector and its efficiency and storage tank volume are optimization variables. The data required to achieve this were retrieved as actual measured values of hourly global horizontal irradiation and ambient temperatures. Thermal energy provided by solar collector (in kWh/period) and the data for its calculation are based on the work by Isafiade et al. (2016), however in this work equality constraint is used and is multiplied by the number of hours for specific period.

The MINLP model consists of linear and nonlinear equality and inequality constraints and additionally it includes discrete or binary decisions. The binary variables ($y_{mp,dp,hp}$) are associated with the temperature of heat storage tank and the heat energy provided by heat transfer fluid from the solar collector. Eq. (2) shows such a constraint which states that the temperature in storage tank ($T_{mp,dp,hp}^{\text{storage tank}}$) should be lower than the difference between outlet temperature of the heat transfer fluid returning to solar collector ($T_{mp,dp,hp}^{\text{out-2, storage tank}}$) and the minimum temperature difference ($\Delta T_{\min}$), in a case the flow is non-zero. On the other hand, when there is no flow, there is no specific constraint on the temperature in storage tank.

$$T_{mp,dp,hp}^{\text{storage tank}} \leq T_{mp,dp,hp}^{\text{out-2, storage tank}} - \Delta T_{\min} + M \cdot (1 - y_{mp,dp,hp}),$$
$$\forall (mp \in MP, dp \in DP, hp \in HP) \tag{2}$$

Eq. (2) represents big M constraint, *M* being big enough scalar, and binary variable $y_{mp,dp,hp}$ is connected to the flow from solar collector to the tank and back to the collector ($F_{mp,dp,hp}^{\text{in-1,storage tank}}$). If binary variable is 1, the flow should be between a minimum ($F^{\min}$) and a maximum value ($F^{\max}$), and 0 otherwise. Such constraints are shown in Eq. (3).

$$F^{\min} \cdot y_{mp,dp,hp} \leq F_{mp,dp,hp}^{\text{in-1,storage tank}} \leq F^{\max} \cdot y_{mp,dp,hp}, \quad \forall (mp \in MP, dp \in DP, hp \in HP) \tag{3}$$

3. Case Study

The developed model is implemented and demonstrated on a specific location near Maribor, Slovenia as a case study, partly because low temperature industrial operations represent approximately 37 % of the total industrial heat demand in Slovenia (RSSO, 2017). This location was a reference point to obtain required meteorological data, such as hourly solar irradiation and ambient temperature. The data, which are based on the year 2016, were extracted from the EC JRC PVGIS (2017) using coordinates 46.552 N: 15.676 E Latitude and Longitude, and an elevation of 267 m above sea level.

In the case study, solar thermal is integrated with an industrial heat network for process stream preheating as shown in Figure 1. As a heat transfer fluid, 50/50 water-ethylene glycol is considered. For simplicity, only 1 cold process stream is considered in this demonstrative example while opportunities for using backup utility are accommodated within the framework of the model (see Figure 1).

To reduce computational time, mathematical model reduction techniques based on an earlier procedure presented by Egieya et al. (2018), which is a modification from presentation of Lam et al. (2011), is adopted. The 24 hours of each day are discretized into 4 periods of different durations: H1: 9 pm – 7 am, H2: 8 am – 10 am, H3: 11 am – 4 pm, H4: 5 pm – 8 pm. The 29 – 31 days of a month are discretized into just one period, while 12 months are considered in total. The input data on an hourly basis were averaged as previously done by Egieya et al. (2018). The model consists of 4,504 single equations, 4,755 single variables, and 48 binary variables. It was solved using SBB solver in GAMS with 1 % optimality gap in up to few hours on a personal computer with an Intel® Core™ i7-8750 H CPU @ 2.20 GHz processor with 8 GB RAM.

The results from the model show that the allowable volume of heat transfer fluid (V^{fluid}) in the storage tank and solar collector area (A_{panel}) have strong influence on the solution. Thus, the model has been solved considering different upper bounds for V^{fluid} and A_{panel}. Additionally, upper bound on flowrates of 100 t/h has been set. In almost all the solutions obtained (except for A_{panel} = 100 m^2, where V^{fluid} was 56.6 m^3), both V^{fluid} and A_{panel} were set at their upper bounds. The graphs in Figure 2 show the relationship between the average heat load of solar thermal (Average DH^{solar}) exchanged with the cold process stream and the temperature of the stream achieved with solar (Average T^{solar}) for different values of A_{panel} between 100 and 10,000 m^2.
Figure 2: a) Average DH^{solar} and b) average T^{solar} with different sizes of solar collectors

From Figure 2, it could be seen that both DH^{solar} and T^{solar} significantly increase up to a A_{panel} value of 6,500 m^3, DH^{solar} for 80.9 W/m^2 and T^{solar} for 0.008 ºC/m^2 in average.

Beyond this A_{panel} value, the increase is lower, DH^{solar} is increased to about 16.7 W per additional m² of area and T^{solar} for 0.001 °C/m².

Figures 3 and 4 show the flow sheet values obtained for cases where the upper bound of the solar collector size is set to 1000 m³ and to 10,000 m³. Comparing these two figures, parameters such as the amount of heat captured by the solar collector, the amount of heat stored, and the quantity of heat that is ultimately exchanged between the solar heat transfer fluid and the cold process stream, are higher for the case where A_{panel}^{UP} is set as 10,000 m². It can also be noted that solar thermal achieves a higher preheating temperature of 69.2 °C for the 10,000 m³ case compared to the 1000 m³ case which only achieves a preheating temperature of 29.65 °C in average.

Figure 3: Average values of variables for the case $A_{panel}^{UP} = 1000$ m²

Figure 4: Average values of variables for the case $A_{panel}^{UP} = 10,000$ m²

4. Conclusions and Future Work

In this work, a simultaneous design and optimization procedure for integrating solar thermal with the heat network of an industrial plant has been developed. The new method which is based on an MINLP model, takes into consideration the time dependent variability in solar energy supply. It enables optimizing solar thermal utilization for industrial process pre-heating on hourly, daily and monthly time periods while also accommodating features that allow periodic storage of solar thermal and backup utility. Obtained results show the attainable quantities of solar heat that can be harvested for preheating of industrial process stream. The model demonstrates prospects of a good

decision support tool for industrial utility planning. For the demonstrative case considered, the solution obtained shows the non-linear relationships between the area of solar collector (and volumes of thermal heat storage fluid) and the quantity of heat captured by the solar panel and thus temperatures achieved in the process. Both variables, A_{panel} and V^{fluid} were mostly set at their upper bounds. Future work will entail investigation of opportunities for inclusion of heat pump to increase thermal efficiency of both the direct and indirect integration. Processes involving a larger number of hot and cold streams, with multiple options of backup utilities, and economics-based objective function, will also be considered.

Abstract

Processes including particles, like fermentation, flocculation, precipitation, crystallization etc. are some of the most frequently used operations in the bio-based industries. These processes are today typically monitored using sensors that measure on liquid and gas phase properties. The lack of knowledge of the particles itself has made it difficult to monitor and control these processes. Recent advances in continuous in-situ sensors, that can measure a range of particle properties using advanced image analysis, have now however opened up for implementing novel monitoring and modeling strategies, providing more process insights at a relatively low cost. In this work, an automated platform for particle microscopy imaging is proposed. Furthermore, a model based deep learning framework for predictive monitoring of particles in various bioprocesses using images is suggested, and demonstrated on a case study for crystallization of lactose.

Keywords: Bioprocess Monitoring, Advanced Image Analysis, Modeling Framework

1. Introduction

During the past two decades, bioprocesses have become an increasingly important part of many food, chemical, agrochemical and pharmaceutical industries. This has had an impact on both upstream and downstream processing. Here, fermentation, flocculation, precipitation and crystallization are frequently used processes for formation, separation and purification of products, respectively (Santos et al. (2017)). A common denominator for these processes is that they all contain particles in some form, whether it is cells, aggregates or crystals.

Despite the broad applications of these processes in industry, there is typically a problem of monitoring and controlling them to a satisfactory degree. This is evident in the common use of heuristics based control and the difficulties in obtaining consistent product qualities. Today, most of these bioprocesses are monitored and controlled using traditional sensors that measure gas and liquid phase properties. Only recently, there has been a focus on measuring particle properties continously (Biechele et al. (2015)).

Historically, particle characterization has been been either very time-consuming or associated with relatively high capital costs of the sensors needed. To accommodate this, in the past decade, there

has been a move towards developing soft-sensors, that utilize the measured gas and liquid phase properties, to estimate different process variables that relates to the particles. These have shown great potential (Damour et al. (2009); Mears et al. (2017)). However, these soft-sensors typically require a large amount of infrastructure, in terms of on-line sensors, and significant modeling efforts, as they are only indirect measures of the real process variables.

Meanwhile, there have been significant developments within the application of advanced image analysis in recent years, which has enabled reliable particle analysis in real time, providing an easy way of measuring a range of particle properties. Furthermore, with the current trends towards lab-on-a-chip solutions for industrial sensors, the use of advanced image analysis in bioprocesses can now be implemented at a relatively low cost, and add valuable insights to various bioprocesses.

In this work, a novel platform for automated particle microscopy is presented, where on-line microscopy images are taken from a flow cell. A model-based, predictive monitoring framework is proposed for a generic particle process, utilizing both quantifiable particle properties obtained from advanced image analysis and the captured raw-images themselves. Here, a deep neural network is used for estimating rates of phenomena, that can be used for prediction of process variable trajectories like particle count and size distribution. This model-based framework is subsequently demonstrated on a case study of lactose crystallization, showing the potential of this method, and finally compared to results of conventional white-box modeling.

2. Flow cell microscopy

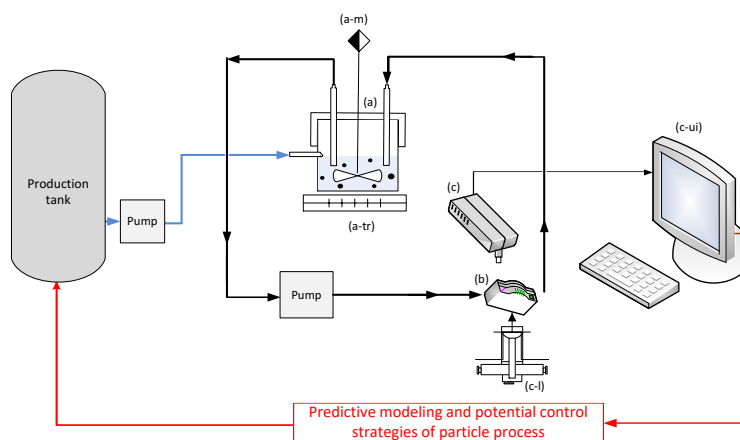
To measure a whole range of particle properties in a continuous fashion, a robust platform is introduced to automatically transfer samples from the production tank to the flow cell under the microscope for image acquisition and on-line monitoring of the process. The automated platform,


Figure 1: Illustration of proposed platform: (a) Sample unit with automated flowpath (blue and black lines) consists of mixer (a-m), temperature regulator (a-tr) and two pumps; (b) a modular flow cell; (c) Automated microscope with light adjustment (c-l) from bottom side; and a user interface (c-ui)

shown in Figure 1, consists of four core elements:

- Sample unit with automated flowpath consists of a mixer, temperature regulator and two pumps to transfer the sample from the production tank to the flow cell under controlled

conditions. The sample can be diluted inside the sample unit to a convenient volume for on-line microscopy.

- A modular flow cell consist of a monolayer channel, adjustable for a wide range of particle sizes and carrier fluid properties to hold the samples under the microscope for image acquisition

- An automated microscope to capture high quality images

- A user interface to extract meaningful information from an image through several steps such as image processing, segmentation, and characterization of the identified object. The segmented 2D- image will provide valuable information such as particle size, particle shape, and particle size distribution.

The proposed configuration allows rapid and nondestructive visual monitoring of samples with various compositions and enables the extraction of valuable chemical and physical information.

3. Model-Based Framework

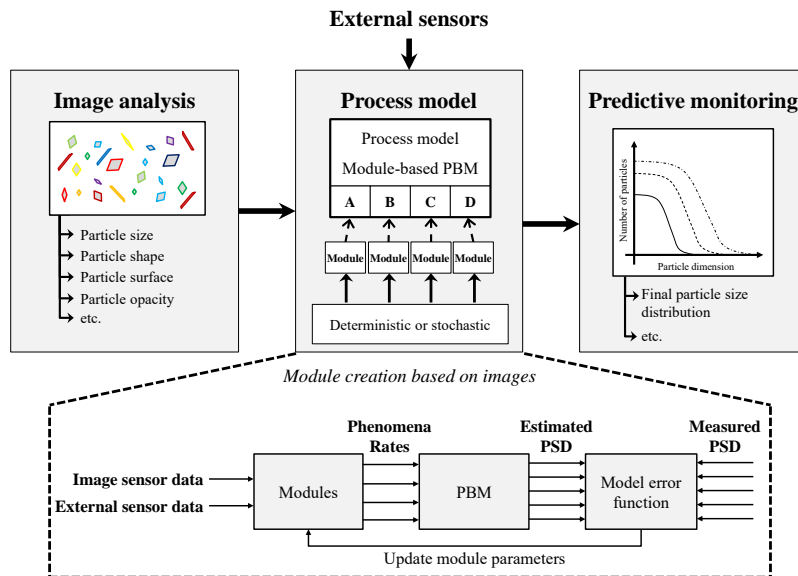
To benefit the most from these new real-time measurements, a predictive monitoring framework is proposed, utilizing the large amount of information that is generated from the captured images. The phenomena observed in a generic particle process include particle birth, particle growth (both positive and negative), particle agglomeration and particle breakage. To describe the overall par-


Figure 2: Proposed framework for monitoring of particles in bioprocesses

ticle processes, population balance modeling (PBM) has become a very popular and generic tool (Ramkrishna and Singh (2014)). For each type of process, a range of kinetic expressions are typically derived from experiments, describing the rate of a given phenomenon, as a function of a range of process variables like temperature, pH and composition. To determine these expressions, one has historically tried to study one phenomenon at a time, where a large fraction of these studies have only been looking at the development of a single particle as a function of time.

In this framework, we instead aim towards describing these phenomena, by analyzing sample populations during the process operation, containing several hundreds of particles. For each phenomenon that needs to be explained, a corresponding module will be included in the model. These modules can either be traditional white-box models like power-law expressions, utilizing a limited range of very specific measurements, or black box models like neural networks, random forests etc. that can take into account a much larger range of measured process variables. An overview of the framework can be seen in Figure 2.

By using this framework, with the latter black-box approach, which is combined with the white-box generic PBM, one can potentially save much time in process modeling. One will however still get an accurate description of the system dynamics, and at the same time take into account a lot more possible process disturbances and variables than in the conventional approach. Finally, this framework allows for implementing a robust model predictive control (MPC) in various particle processes.

4. Case study: Lactose crystallization

The presented framework is now demonstrated for a case study of lactose. For this study, a single crystallization experiment was carried out for the model generation and one for process model validation. A scanned 2D plane of 2288.5 μm x 1408 μm was used in both experiments.

A lactose solution was prepared by dissolving 35.0 g lactose per 100.0 g water, by heating the solution to 70 °C. Afterwards, the solution was cooled down by natural heat loss to the surroundings, which results in crystallization of lactose. Samples were taken regularly (every 3-4 minutes) using the presented flow cell microscopy, obtaining a range of particle properties, including the Feret diameters, projected area and sphericity of each particle detected on each image. Furthermore, the temperature of the crystallization process was measured continuously. Three examples of segmented images, showing the crystallization progress, can be seen in Figure 3. Note how the number of crystals is increasing and the crystals are increasing in size as a function of time.

(a) 25.0 °C (t=8979 s)   (b) 24.3 °C (t=10864 s)   (c) 23.9 °C (t=12632 s)
Figure 3: Images after segmentation of crystals.

In this case study, the crystals were binned according to their mean Feret diameter, starting from 20 μm moving up to 80 μm, with a total of 40 bins. Using the presented predictive monitoring modeling framework, a rolling prediction model was generated, using a deep neural network for estimating the nucleation and growth rates, and then compared to a conventional full simulation modeling approach, using white-box power-law expressions. Both approaches utilizes a generic 1D PBM, relying on the method of classes, where the effects coming from agglomeration, breakage and dissolution have been neglected in both.

The deep neural network used here consists of 4 dense layers in total, with a total of 296,000 weights. The inputs provided to the network are: a grey-scale and down-sampled version of the raw image (64 x 64 pixels) taken at the estimation time, the current temperature, the current temperature gradient and the time-horizon Δt to predict. This results in one growth rate per bin and a single nucleation rate. By transferring these rates to the generic white-box PBM, one can

obtain a grey-box running prediction of the size distribution at time $t + \Delta t$, where the initial size-distribution of the PBM is set to the measured distribution at the current time t.

In the conventional full simulation modeling approach, the solubility of lactose in water as a function of temperature was approximated by a second order polynomial fit of the datapoints measured by Hudson (1908). Furthermore, the density of lactose was set to 1.52 g/cm^3 as reported by Lewis (2007). The following three white-box rate expressions, similar to the ones presented by Szilagyi and Nagy (2016), where used in this work:

$$P = k_p \cdot \sigma^p \quad , \quad S = k_s \cdot \sigma^s \cdot V_c \quad , \quad G = k_g \cdot \sigma^g \cdot (1 + \gamma \cdot L) \tag{1}$$

where V_c is the volume of crystals per volume solute and L is the characteristic particle dimension. Thus, in the white-box model, there are seven kinetic parameters that have to be determined by experiments and a single parameter relating to the particle shape, the volumetric shape factor k_v.

The two models were fitted to the experimentally obtained data from a single batch crystallization, by minimizing the absolute error of the relative size distribution. The two fitted models can be seen in Figure 4a + 4b, showing the time-evolution of the relative size distribution. Note that only a selection of size-bins have been included in the figures for improved readability.

(a) White box model fitting

(b) Grey box model fitting

(c) White box model validation

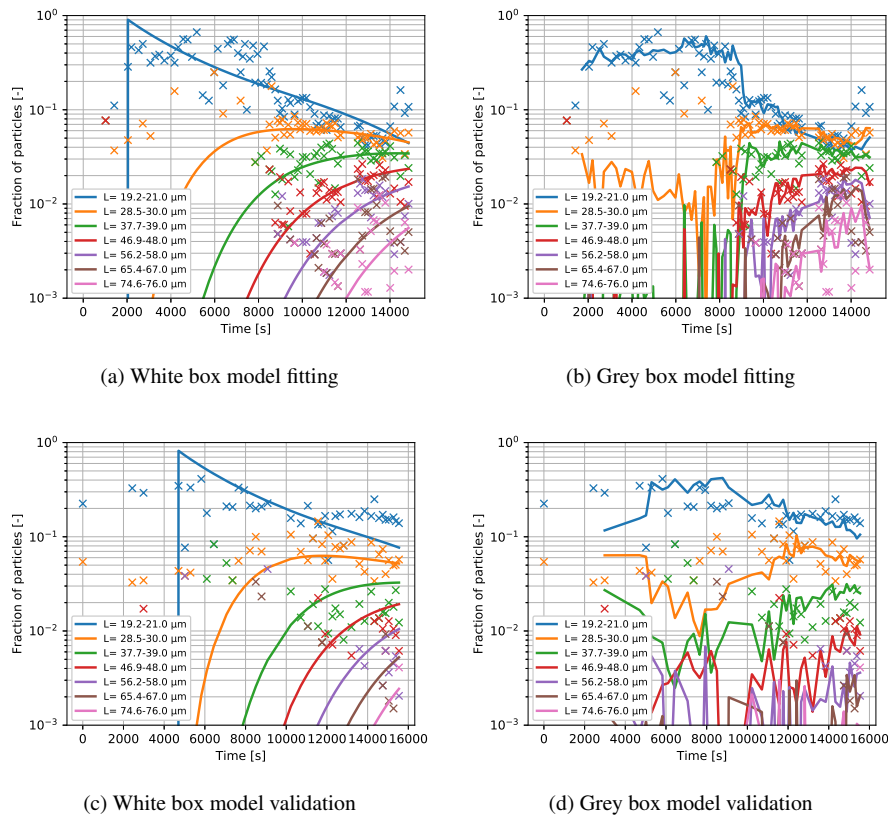
(d) Grey box model validation


Figure 4: Model fitting and validation for the two modeling approaches.

The two modeling approaches have subsequently been used to predict the evolution of the size distribution as function of time in the validation experiment. These results can be seen in Figure

4c + 4d, where the predicted time-horizon for the rolling prediction is set to 10 minutes. I.e. the deep neural network estimates the appropriate nucleation and growth rates for the next 10 minutes of crystallization operation.

It can be seen that both modeling approaches predicts the trends in the size distribution evolution well. However, the rolling prediction can be seen to produce more accurate predictions. In this, the adaptive nature of the rolling prediction does play a big role, as it is utilizing size distribution data as they become available. However, even for larger predicted time-horizons Δt, the grey-box model approach performs very well, indicating that the deep neural network does estimate the actual phenomena rates to a satisfactory degree.

With the presented grey-box model approach, it is shown possible to capture some effects in the crystallization, that would not be taken into account in a conventional modeling approach. However, the grey-box modeling is also relatively prone to measurement noise in he size-distribution sampling, which can be seen in as fluctuations in Figure 4b + 4d. These sources are especially critical, as they are both used as input and output variables while training the neural network, and would therefore be beneficial to minimize these uncertainties, possibly by using MCMC methods or input noise during training, as previously reported for neural networks (Wright et al. (2000)).

5. Conclusions

In this work, a novel continuous microscopy platform has been presented, showing a simple and cheap way of taking images of particles in suspension. A model-based predictive monitoring framework has been presented, utilizing particle parameters obtained from the images and the raw images themselves. This is used for modeling a generic particle process, and predicting the future particle population, utilizing deep learning neural networks for estimating birth and growth rates. The framework has been tested on a case study of lactose crystallization, where it has been shown that the framework can provide accurate predictions, even for small amounts of training data.

Abstract

The development of hybrid simulation-optimization methods has allowed to explore the complexities of planning and scheduling problems. In this work, a simulation-optimization approach is developed to provide decision-support to industrial processes, combining a mathematical formulation with a detailed discrete-event simulation model. To solve industrial planning and scheduling problems, the methodology iteratively estimates the modelling parameters to maximize the output in a multistage production facility, while guaranteeing allocation constraints and main process uncertainties to satisfy the demand. The production plan is evaluated at the MILP model and the capacity-feasible schedule is generated by the dispatching rules in the simulation model. Results highlight the advantages of the hybrid approach to guarantee optimized process performance metrics in a simulated operational planning.

 Keywords: simulation-optimization; production planning and scheduling; hybrid methodology

1. Introduction

Current industries are facing competitive environments that demand enhanced performance indicators, such as customer satisfaction, manufacturing/inventory holding costs, and delivery times. These challenging production environments have enabled the development of advanced planning and scheduling support tools, following the increasing digital transformation with process automation. Despite the significant developments in exact/non-exact modelling techniques in recent years, it is acknowledged that generalized mathematical formulations are limited by the inherent computational hindrance of system modelling with combinatorial complexity. As well, the development of novel simulation platforms has empowered the evaluation of scenarios that mimics real operations and explore the complexity of nonlinear and stochastic systems. Therefore, the potential hybridization of simulation with optimization approaches, as noted by Figueira and Almada-Lobo (2014), combines the advantages of the process detail representation with the ability to optimize solutions. With different abstraction levels in each model, the simulation includes features not addressed in the optimization to decrease complexity, while considering iterative parameters adjustment to allow solution convergence. This

methodology is categorized as a Recursive Optimization-Simulation Approach (ROSA), which recursively evaluates performance metrics until a stopping criterion is met.

In this work, we explore this ROSA methodology to address the planning and scheduling optimization problem in multistage production process. Based in Kim and Kim (2001) approach, the proposed hybrid approach combines a mathematical model with a detailed discrete-event simulation model to provide decision-support on the production planning and the required number of allocated shared resources. As follows, we present an overview of methodology of the proposed approach and discuss the results in a case example in order to formulate a planning/scheduling solution for the industrial operational management.

2. Background

The general problem of planning/scheduling operations has become one of the most challenging problems in process industry. Due to arbitrary network configurations of resources that accounts multiple materials recipes, the inherent complexity endures researchers on finding the key modelling solution on how to optimize the sizing, sequencing and allocation while matching the expected performance of an industrial process. Since operational decisions are strongly interconnected, it is difficult to develop competent decomposition approaches to solve real-size applications with good schedules and modest computational hindrance (Castro et al., 2011). And, as note by Harjunkoski et al. (2014), novel optimization methods are required to address the pressure toward further cost-savings, efficient use of resources, regulatory aspects and new technologies.

Among the diverse solution approaches, from mathematical programming to heuristic algorithms, the combination of the best assets of different methods has been gathering significant relevance. Hybrid formulations have been consistently addressing the reduction of the solution search-space to limit the number of operational and strategic decisions to a manageable level (Vieira et al. 2018). Noteworthy, simulation and optimization approaches are widely applied as sole methodologies to address operational problems. But with modern discrete-event simulation platforms, several authors have addressed the drawbacks by exploring the iterative combination of both in the evaluation of parameters, optimization of solution variables, and sampling of scenarios (Martins et al. 2017). For example, Kim and Kim (2001) developed an extended hybrid model for the multiperiod multiproduct production planning problem, based on an iterative process where the release plan determined by a linear programming model is evaluated by the simulation model. One of planning challenges relies in the real estimate of the lead time of production, since the release of the production order to its output dispatch to satisfy the demand, accounting to the uncertainty in resources' workload capacities. When the results are not feasible (e.g. the number of orders released by the optimization exceeds the workload capacity under simulated conditions), the simulation model adjusts a specific set of parameters of the optimization model and repeats the process under more restrict conditions. When the results from the analytical method are feasible and met the stopping criteria (e.g. number of iterations, production demand met or solution convergence), a near-optimal production schedule can be generated. The iteration considers factors that correlate the capacity and workload of the resources, namely loading ratios and unit utilization. The authors verified that the method consistently converges in few iterations, even in real problems of industrial complexity (Kim and Lee, 2016). However, it is acknowledged that the right level of abstraction in each model is

critical to avoid runtime becoming impracticable, since the simulation model is left to include the hard-to-model parameters, with particular significance on solution quality and convergence parameters of the method.

3. Methodology

The hybrid approach proposed in this work consists in the iterative use of optimization and simulation models to address the optimal planning and scheduling of an industrial production process. The problem defines the optimal allocation of shared resources to perform a production mix per demand period in a multistage facility considering the cost-efficient use of resources. This decomposition approach enables to generate a solution at the planning capacity level with a MILP model that is, iteratively, evaluated at the scheduling level with the visualization of the dynamic behavior of the production process. While the optimization model is formulated using GAMS/CPLEX, the detailed simulation model is implemented in SIMIO which systematically reproduces the real production facility. Besides the production mix, the capacities and workload of workstations in the manufacturing system are affected by various factors such as buffer capacity, task sequencing, operational uncertainty, input policy or dispatching rules. The main components and tools available at the SIMIO platform are used to achieve the most accurate representation of the manufacturing system, which requires advanced programming for modelling specific process features.

Based on the approach by Kim and Kim (2001), the proposed algorithm structure considers an iterative procedure to reach solution convergence at stopping criteria, i.e. if the solution objective is identical to the previous iteration. The original mathematical formulation considers four types of continuous variables expressed by product i at time period t: X_{ip} as the orders amount released at time period p, Y_{it} auxiliary variable that defines the effective proportion quantity following the release period ($t \geq p$), I_{it} as the inventory amount, and B_{it} as the backorder amount. That formulation is now extended to consider a binary variable O_{ijr} which defines the set of resources r allocation to perform the sequential operation stage j of a product i, while determining the number of shared resources R_t required to fulfil a demand plan μ_{it}.

$$Min \sum_i \sum_t (Y_{it}\alpha_{it} + I_{it}\sigma_{it} + B_{it}\pi_{it}) + \sum_t R_t\theta_t \tag{1}$$

$$\sum_i \sum_j \sum_r \sum_{p \leq t} \varepsilon_{ipt} X_{ip} O_{ijr} \tau_{ijkr} \leq \lambda_{kt}\delta_{kt} \qquad \forall k,t \tag{2}$$

$$I_{it} - B_{it} = Y_{it} - \mu_{it} + I_{it-1} - B_{it-1} \qquad \forall i,t \tag{3}$$

$$Y_{it} = \sum_{p \leq t} \varepsilon_{ipt} X_{ip} \qquad \forall i,t \tag{4}$$

$$\sum_i \sum_j \sum_k \sum_{r \in SR_A} \sum_{p \leq t} \varepsilon_{ipt} X_{ip} O_{ijr} \tau_{ijkr(A)} \leq \phi_t D_t R_t - S_t.TimeS \quad \forall t \tag{5}$$

$$\sum_r O_{ijr} = 1 \qquad \forall i,j \tag{6}$$

$$X_{ip}, Y_{it}, I_{it}, B_{it}, R_t \geq 0 \qquad X_{ip}, R_t \in \mathbb{Z} \tag{7}$$

The objective function Eq. (1) considers the minimization of total costs related to production α_{it}, inventory σ_{it}, backlog π_{it} and number of shared resources θ_t. The capacity constraint of each unit stage k in Eq. (2), with the average operation time given by τ_{ijkr}, is adjusted by the recursive simulated parameters, the average utilization of stage k, λ_{kt}, of the available time per period t, δ_{kt}, and by the effective loading ratio ε_{ipt} per

periods t of the amount released in p. The linearization of $X_{ip}O_{ijr} \equiv \Omega_{ijpr}$ as the released quantity to be performed by resources r was performed, considering the standard auxiliary restrictions to linearize the product of a binary and continuous variables. Eq. (4) considers the inventory balance of material flow and demand per period, and Eq. (3) enables the calculation of auxiliary variable Y_{it}. Eq. (5) considers the capacity constraint related to the operations that make use of shared resources SR_A per time period D_t, accounting the time spent ($TimeS$) with the number of changeovers S_t and the traveling between stages (ϕ_t as average operating rate). Finally, Eq. (6) enforces that all operations of product i are performed by one set of resources and Eq. (7) the non-negativity of variables (details in Kim and Kim (2001)). The first step of the algorithm consists in running the model in GAMS to determine the amount of production released X_{ip}, allocation of resources O_{ijr}, and number of shared resources required per period R_t. In the second step, the feasibility of the sequential release plan (one by one order) is evaluated in the SIMIO model and the statistics on effective loading ratios, unit stages utilization and number of changeovers/utilization of shared resources are collected. In the third step, these iteration statistics in the model updates the capacities constraints by using the recursive parameters from the simulation. The iterations procedure stops when the plan met the stopping criteria and the simulation generates the schedule based on a given dispatching rule.

4. Case study

4.1. Problem description

The example case is based on a multistage industrial process in a production plant composed by seven single-unit stages k (k1-k7) to produce five products i (i1-i5) in a U layout. The different processing stages for each 5 products follow a predefined sequence operation set j given by Table 1, where at each corresponding stage a series of tasks are executed, as displayed in Figure 1. Currently, all tasks are performed by one dedicated operator per stage (Op). Since some of the tasks at each stage can be performed in parallel, the decision-support at the operational level relies on the allocation of a mobile shared resource (Aut) able to perform one of these tasks, therefore existing the option for two sets of resources r per operation i,j. This can enable the decrease of the total processing time per stage, as shown in Table 1 (for this example, only one shared resource is allowed per stage to perform one of the simultaneous tasks.).

Table 1 – Sequence of process stages per product and corresponding processing time

Product i	Unit stage k							Resources r	Average operation time stage j (min/ton)				
	1	2	3	4	5	6	7		1	2	3	4	5
P1	●	●			●	●	●	1 Op	61,2	60,0	116,4	61,2	78,0
								1 Op+1 Aut	61,2	60,0	104,4	60,0	48,0
P2			●	●	●	●		1 Op	93,6	61,2	116,4	61,2	-
								1 Op+1 Aut	74,4	49,2	104,4	60,0	-
P3		●	●	●			●	1 Op	60,0	93,6	61,2	78,0	-
								1 Op+1 Aut	60,0	74,4	49,2	48,0	-
P4	●		●		●		●	1 Op	61,2	93,6	116,4	78,0	-
								1 Op+1 Aut	61,2	74,4	104,4	48,0	-
P5	●	●			●		●	1 Op	61,2	60,0	61,2	61,2	-
								1 Op+1 Aut	61,2	60,0	49,2	60,0	-
Figure 1 – Sequence of tasks per unit stage

The production follows a pull strategy, which means that the products are manufactured to assess a given demand for a time horizon of seven continuous 24 h production days. While the optimization model considers the Eqs. (1-6), the simulation model is able to accommodate the manufacturing system characteristics as close at the real facility, accounting for the routing distances, queuing, system layout and the detailed tasks sequence at each stage. The simulation inputs the determined release plan, allocation sequence and number of resources, which replicates the process operation during the planning horizon. The uncertainty in the process data is also considered, namely at the processing times of tasks performed by the operator and the changeover time of the shared resource, by assessing the corresponding variability distribution. A FIFO dispatching rule in the simulation is assumed throughout. For the minimization of operational costs, the request cost of one shared resource, θ_t, is assumed of 100 monetary units (mu), while the production α_{it}, inventory σ_{it}, backlog π_{it} costs are, respectively, 100, 25 and 400 mu.

4.2. Computational results

The results of the given example show that the methods quickly converge to a solution where the total output of the production plan is similar between models. The final results were obtained at the third iteration and the results are generated in a few seconds (optimality gap <1%), running on an Intel Core i7-7700HQ with 16GB of RAM. Whenever the optimization results were too optimistic (non-feasible), resources capacity constraints parameters were tightened to generate a more realistic production plan, given the simulation statistics (20 replications for a confidence level of 95%). For example, in the first run of the optimization model, since it considers nonrestrictive capacities of resources, the results match the total demand with only one shared resource allocation (Table 2). But when evaluated in the simulation, the output is a far different solution, due to lower effective loading ratio, percentage utilization of resources and number of setups. Iteratively the solution space is reduced, with a production release on the initial periods to reach a scheduling solution given by the simulation software. In the following iterations, the number of available shared resources per time period is increased to be able to accommodate the production, as well as the increase in inventory backorder and costs since the total demand is not satisfied on this planning horizon. The simulation model also enables to analyze the scenario results on the bottlenecks of the process, where it can be verified that stages 3 and 5 have utilization ratios between 98 to 99%, therefore restraining the fulfillment of demand (assumed to be satisfied in the following plan horizon). The reduction in the number of setups of the shared resources is verified since, with the increase of their availability with almost a full utilization, they were modelled in the simulation to preferably choose same product operations. This number is also influenced by the different allocation of resources to shared tasks performed in each iteration, which increased with the availability of the resources.

Table 2 – Iterations results of order release amount X_{ip}

Time period	Iteration 1						>>>	Iteration 3					
	P1	P2	P3	P4	P5	Shared resources		P1	P2	P3	P4	P5	Shared resources

5. Conclusions

This work presented a hybrid methodology to provide decision-support for the planning and scheduling of multistage industrial systems, combining simulation and optimization approaches. The methodology solution potentiates the advantages of an iterative procedure, combining an upper level optimization plan, which feasibility is tested in a detailed simulation of the real production process, while considering the production mix and allocation of a number of shared resources in order to generate a scheduling solution. The iterative procedure considers recursive parameters obtained from the simulations so that the solution between the two model converges, such as the effective loading ratio, utilization capacities and number of changeovers of the shared resources.

Simulation-optimization methods have been gathering significant relevance to overcome the challenges of dealing with the computational complexity and cost of implementation in industrial planning and scheduling problems. The ability to integrate the stochastic and non-linear constraints, such as allocation of resources and variable processing times or setups, in a solution search with mathematical foundation becomes of key importance. Although further experiments are required to evaluate the quality of convergence solution and the impact of simulation dispatching rules, along with additional decisional variables as the ones proposed in this formulation. The advantages of the simulator should also be explored to provide enhanced information to the decision-maker on the efficiency of resources utilization, while being reactive to changes in the production capacity, operational ergonomic or layout. Future work will aim to explore these issues by evaluating different optimization objectives to assess operational sustainability.

On Robustness of Mixed-Integer reformulations of Generalized Disjunctive Programs

Miloš Bogataj[*], Zdravko Kravanja

Faculty of Chemistry and Chemical Engineering, University of Maribor, Smetanova ulica 17, SI-2000 Maribor, Slovenija

milos.bogataj@um.si

Abstract

In this work, we compare the performance of the Alternative Mixed-Integer (AMI) reformulation of GDPs against those of the Big-M and Hull Reformulation (HR) in a framework of nonconvex mixed-integer nonlinear models. The robustness and efficiency of the reformulations are tested on a synthetic example using commercially available solvers, namely SBB, DICOPT++, SCIP, and Alpha-ECP. The comparison is carried out on the following key criteria: efficiency (CPU usage, number of iterations), robustness (number of successfully solved problems), quality of the obtained solutions (comparison of the objective function values). Results obtained in this study indicate that the AMI reformulation represents a competitive alternative to Big-M and HR.

Keywords: Disjunctive Programming, Mixed-Integer Programming, Nonconvex problems, Robustness, and Efficiency.

1. Introduction

The Generalized disjunctive Programs (GDPs), be it linear or nonlinear, can be formulated as mixed-integer (non)linear problems (MI(N)LPs) in several ways (Nemhauser and Wolsey (1988), Lee and Grossmann (2003), Trespalacios and Grossmann (2015)). This, however, leads to models of different sizes (i.e. in a number of variables and constraints) and tightness – tightness being the relation of the feasible region of a problem to the feasible region of its continuous relaxation. Furthermore, when GDPs are nonlinear and nonconvex, the robustness of nonlinear subproblems becomes an important aspect. We can infer that the ability of the solvers to solve these problems strongly depends on the type of reformulation.

The AMI reformulation was originally proposed by Bogataj and Kravanja (2018). The reformulation of a GDP to a MINLP is analogous to the HR presented by Lee and Grossman (2003), as shown below. The Boolean variables are transformed into 0-1 variables y_{ik}, the continuous variables x into disaggregated variables x_{ik}^{D} and the logical propositions reformulated into a set of linear constraints . There is, however, an important difference between the reformulations. That is, the disaggregated variables x_{ik}^{D} are not required to be forced to 0 when $y_{ik} = 0$. Instead, due to mixed-integer translation of variables they are forced to arbitrary fixed values x_{ik}^{F} , which are usually chosen between nonzero lower and upper bounds of the disaggregated variables.

$$\min Z = \sum_{ik} c_{ik} + f(x)$$

$$\text{s.t.} \qquad h^g(x) \le 0$$

$$\bigvee_{i \in D_k} \begin{bmatrix} Y_{ik} \\ g_{ik}(x) \le 0 \\ c_{ik} = \gamma_{ik} \end{bmatrix} \quad k \in K$$

$$\underset{i \in D_k}{\veebar} Y_{ik} \qquad k \in K$$

$$\Omega(Y) = True$$

$$x \in \mathbb{R}^n, c_{ik} \in \mathbb{R}, Y_{ik} \in \{True, False\}$$

(GDP)

$$\min Z = \sum_{ik} y_{ik} \gamma_{ik} + f(x)$$

$$\text{s.t.} \qquad h^g(x) \le 0$$

$$x = \sum_{i \in D_k} x_{ik}^D - (1 - y_{ik}) x_{ik}^F \qquad k \in K$$

$$g_{ik}(x_{ik}^D) - (1 - y_{ik}) g_{ik}(x_{ik}^F) \le 0 \qquad i \in D_k, k \in K$$

$$x_{ik}^D \ge x_{ik}^{D,LO} y_{ik} + (1 - y_{ik}) x_{ik}^F \qquad i \in D_k, k \in K$$

$$x_{ik}^D \le x_{ik}^{D,UP} y_{ik} + (1 - y_{ik}) x_{ik}^F \qquad i \in D_k, k \in K$$

$$\sum_{i \in D_k} y_{ik} = 1 \qquad k \in K$$

$$x^{LO} \le x \le x^{UP}, y_{ik} \in \{0,1\}$$

(AMI)

2. Optimization Problem

The problem used in the study represents a nonconvex variation of the Circles Example by Lee and Grossmann (2000). The GDP formulation of the problem is given by (GDP-NC).

$$\min Z = (x_1 - 3)^2 - (x_2 - 2)^2 + \sum_{k \in K} c_k$$

$$s.t.$$

$$g_j(x_1, x_2) \le 0 \qquad j \in J$$

$$\bigvee_{i \in D_k} \begin{bmatrix} Y_{ik} \\ \breve{h}_{ik}(x_1, x_2) \le 0 \\ \widehat{h}_{ik}(x_1, x_2) \ge 0 \\ c_k = \gamma_{ik} \end{bmatrix} \quad k \in K \qquad \text{(GDP-NC)}$$

$$\underset{i \in D_k}{\veebar} Y_{ik} \qquad k \in K$$

$$\Omega(Y) = True$$

$$x_1^{LO} \le x_1 \le x_1^{UP}, \quad x_2^{LO} \le x_2 \le x_2^{UP}$$

$$c_k \in R^1, Y_{ik} \in \{True, False\}, i \in D_k, k \in K, j \in J$$

It represents a minimization of a nonconvex objective function over disjoint nonconvex feasible regions. These are obtained by intersecting the feasible regions described by convex constraints $\breve{h}_{ik}(x_1, x_2) \equiv (x_1 - \breve{a}_{ik})^2 + (x_2 - \breve{b}_{ik})^2 - \breve{r}_{ik}^2 \le 0$ and their nonconvex counterparts $\widehat{h}_{ik}(x_1, x_2) \equiv (x_1 - \widehat{a}_{ik})^2 + (x_2 - \widehat{b}_{ik})^2 - \widehat{r}_{ik}^2 \ge 0$. Feasible regions of $\breve{h}_{ik}(x_1, x_2)$ correspond to the interior of circles with centers at ($x_1 = \breve{a}_{ik}, x_2 = \breve{b}_{ik}$) and radii $\breve{r}_{ik}$, whereas the feasible regions of $\widehat{h}_{ik}(x_1, x_2)$ are to the exteriors of the corresponding circles.

The coefficients $\hat{a}_{ik}, \hat{b}_{ik}$ and $\hat{r}_{ik}$ are determined in such a way that the graphical representation of each of the disjoint feasible regions corresponds to either crescent or annulus. The constraints $g_j(x_1, x_2)$ are hyperbolae (i.e. $x_1^2 - x_2^2 + d \leq 0$, $x_1^2 + x_2^2 - e \geq 0$) globally constraining the disjoint feasible regions.

2.1. Numerical Studies

To provide insights into the studied properties of the reformulations, two numerical examples of different sizes with respect to the number of equations, continuous and discrete variables were considered. The GDP representation of the optimization problem was reformulated into a MINLP problem using Big-M, Hull Reformulation and AMI reformulation. The examples were solved using Branch and Bound, Outer Approximation / Equality Relaxation and Extended Cutting Plane algorithms implemented in SBB, SCIP, DICOPT++ and Alpha-ECP solvers. The models were coded in GAMS 25.1.3 and solved on a PC equipped with Intel® Core™ i7-4770 3.40 GHz processor and 16 GB RAM.

The first example is a small instance of (GDP-NC). It is comprised of 6 disjunctions, each having 6 terms. The feasible region is constrained by 2 global constraints. The second example is a larger instance of (GDP-NC), comprised of 2 disjunctions, each having 500 terms. The global constraints were omitted in the latter example. In both, only one term per disjunction can be selected as *True*. The model statistics regarding the MINLPs for the three reformulations is given in Table 1.

Table 1: Model Statistics.

Example 1	Big - M	HR /AMI
Continuous Variables	49	121
Discrete Variables	36	36
Equations	91	247
Example 2	**Big - M**	**HR /AMI**
Continuous Variables	1,005	3,005
Discrete Variables	1,000	1,000
Equations	2,003	6,007

3. Results

3.1. Example 1

The example was solved with the four solvers from 100 randomly selected starting points - identical in each run for the different solves. The globally optimal objective value for the given example is –95.98, which was determined by Baron.

By comparing the mean values of the objective functions, as shown in Fig 1, we observe that AMI reformulation produces the most compliant results. The weighted average of objective values obtained by the AMI reformulation is –79.91, the weighted average of objective values obtained by the HR –70.57, and –63.67 by the Big-M reformulation.

In terms of robustness (i.e. number of feasible solutions), Big-M reformulation dominates the three formulations, producing 100% feasible solutions. AMI reformulation averaged at 92% and HR at 51%. A more detailed statistics regarding the robustness of the reformulations are presented in Fig. 2.

In terms of efficiency, the HR is computationally the least demanding (see Fig 3). The weighted average CPU time for HR is 1.7 s, which is, however, comparable to the

weighted average CPU time for AMI reformulation. The Big-M reformulation averages at slightly longer CPU time of 8.6 s.

Finally, there are a few additional results worth mentioning. In the case of the AMI reformulation, the largest standard deviations in objective function values and CPU time are observed when using AlphaECP solver. SCIP failed in each of the HR instances, however, it provided globally optimal solutions in all the instances of the Big-M formulation.
Figure 1: Mean values of objective functions.
Figure 2: Number of feasible solutions per 100 runs.
Figure 3: Average computational times.

3.2. Example 2

The example was solved from a starting point that is feasible with respect to the relaxed MINLP of a given reformulation. The CPU time limit was set to 3,000 s. The results are given in Table 2.

Table 2: Statistical results.

Reformulation	Metrics	SBB	DICOPT++	SCIP	AlphaECP
AMI	Z	−128,734	−128,734	−128,734	−95,870
AMI	t_{CPU}/s	96	62	1,632	299
AMI	Nds/Iter	517	14	1,969	274
HR	Z	/	/	−114,809	−41,577
HR	t_{CPU}/s	/	/	3,000	81.5
HR	Nds/Iter	/	/	919,662	114
Big-M	Z	−15,299	141.5	−15,296	−6,872
Big-M	t_{CPU}/s	3,000	35	499	3,000
Big-M	Nds/Iter	40,475	20	9,426	2,700

From the results presented in Table 2 we can conclude that the AMI reformulation outperformed both HR and Big-M reformulation in terms of solution quality and computational efficiency. Note that the CPU time limit was hit in 1 instance of HR (SCIP) and 2 instances of Big-M reformulation (SBB and AlphaECP).

All the solvers utilized in this study provided solutions to the AMI and Big-M reformulation, while two solvers (SBB and DICOPT++) failed to provide solution to the HR because of solver failure.

4. Conclusions

We have presented a study on the performance of the alternative mixed-integer (AMI) reformulation of GDPs against the Big-M and hull reformulation (HR) in a framework nonconvex MINLPs. The result obtained thus far indicate that AMI reformulation exhibits desirable properties that make it favorable for larger nonconvex MINLPs models. Although these results should not be generalized nor considered as conclusive, there are some theoretical indications as to why the AMI reformulation may outperform the other two. First, it tends to reduce the search space of nonlinear subproblems by bounding it to the true lower and upper bounds of continuous variables. Second, the reformulation avoids the usage of the perspective function and thus reduces the number of nonlinearities. Finally, due to the translation of continuous variables, the reformulation does not require the functions being defined at 0.

Future studies will focus on research dedicated to providing theoretical answers regarding the AMI reformulation, and testing it on different optimization/synthesis problems.

Abstract

Data Reconciliation is an important step in extracting data from an existing plant. It is especially important for Heat Integration Analysis. In this work, the Iterative PNS Method is introduced as a new method for Heat Exchanger Network Data Reconciliation. This method uses Linear Programming to reduce the computational cost of the complex non-linear data reconciliation problem. The results from the illustrative case study indicate that it performs almost as well as the other state-of-the-art method found in the literature.

Keywords: Heat Exchanger Network, Data Reconciliation, Iterative PNS Method.

1. Introduction

Data extraction is a key activity in performing retrofit of Heat Exchanger Networks (HENs) (Klemeš et al., 2018). It is used to obtain a credible set of data from measurements for the Heat Integration. The topic was briefly mentioned in the HEN synthesis book by Shenoy (1995), providing a non-linear optimisation example. In a previous work (Yong et al., 2016a), an Iterative Method for solving the HEN data reconciliation problem has been proposed. That reduced the model complexity and computational cost required during data reconciliation. VBA tools for energy systems data reconciliation have also been presented (Mayo, 2015). There have been further works – considering rigorous and simplified HEN models (Ijaz et al., 2013), as well as parameter tuning using process-network synthesis (PNS) algorithms (Bartos and Bertok, 2018). Sufficient accuracy of the model with user-friendly data input and acceptable computational time can be key in providing process engineers with a tool for efficient and accurate data extraction.

In this work, a new Iterative PNS Method is derived from the Iterative Method. It uses linear objective functions in the sub-models to reduce the required computational effort. The performance of this method is compared with standard NLP (simultaneous method in this work) and MILP using a linear reformulation.

2. Problem Statement

Consider an existing HEN with total m number of heat exchangers (including heaters and coolers) with m ∈ M. Each hot (H) or cold (C) stream has its own inlet (I) and outlet (O).

These generate a set of streams, s ∈ {HI, HO, CI, CO}. For each stream, *n* measurements are taken (n ∈ N). For the purpose of heat integration analysis, temperature (T) and heat capacity flowrate (CP) are required. It is desired to obtained the reconciled value (R).
Figure 1: An example of a HEN

3. Models and Equations

3.1. Simultaneous Method

Simultaneous Solving Method

$$Min \sum_{m}^{M} \sum_{s}^{S} \sum_{n}^{N} \left(\left(RCP_{m,s} - CP_{m,s,n}\right)^2 + \left(RT_{m,s} - T_{m,s,n}\right)^2 \right) \tag{1}$$

subject to:

Mass balance constraints around each heat exchanger, for all heat exchanger

$$RCP_{m,HI} = RCP_{m,HO} \tag{2}$$
$$RCP_{m,CI} = RCP_{m,CO} \tag{3}$$

Energy balance constraints around each heat exchanger, for all heat exchanger

$$RCP_{m,HI}\left(RT_{m,HI} - RT_{m,HO}\right) = RCP_{m,CI}\left(RT_{m,CO} - RT_{m,CI}\right) \tag{4}$$

Constraints from network arising from the connections between heat exchangers

$$RCP_{m1,HO} = RCP_{m2,HI} \tag{5}$$
$$RCP_{m1,CO} = RCP_{m3,CI} \tag{6}$$
$$RT_{m1,HO} = RT_{m2,HI} \tag{7}$$
$$RT_{m1,CO} = RT_{m3,CI} \tag{8}$$

Figure 2: Data reconciliation model for solving two types of parameters simultaneously

Eq. (1) contains the objective function, combining CP and T values. Since this is only a numerical abstraction without a direct physical meaning, the mixture of the measurement units is not a problem. While in general, the difference in magnitude may cause the model to be biased on either one of the parameters, in the current model such issues have not arisen. In the future work, appropriate weighting and normalization should be introduced for obtaining more robust models. In the simultaneous method, the model shows high non-linearity from the parameters, constraints and objective function. In the case of parameters, CP is a function of T. To reduce this complexity, it is assumed that CP is independent of T. The energy balance constraints, as in Eq. (4), contain bi-linear terms of the reconciliation variables. These non-linear constraints can be reduced to linear by applying the Iterative Method (Yong et al., 2016a)

3.2. Iterative Method

CP Model	T Model
$$Min \sum_{m}^{M} \sum_{s}^{S} \sum_{n}^{N} \left(RCP_{m,s} - CP_{m,s,n}\right)^2 \quad (9)$$ subject to: Mass balance constraints in Eq. (2) and Eq. (3) Energy balance constraints in Eq. (4) where RT is set to be constant	$$Min \sum_{m}^{M} \sum_{s}^{S} \sum_{n}^{N} \left(RT_{m,s} - T_{m,s,n}\right)^2 \quad (10)$$ subject to: Energy balance constraints in Eq. (4) where RCP is set to be constant
Constraints from network in Eq. (5) to Eq. (8)	Constraints from network in Eq. (5) to Eq. (8)

Figure 3: Equations used in the CP model and T model

The Iterative Method divides the model from the simultaneous method into two sub-models. In each sub-model, the instances of one parameter type are reconciled while the instances of the other type are kept constant. By only considering one type of parameter at a time, the energy balance constraints are reduced to linear. This also solves the problems arising from different magnitudes and dimensions in the Iterative Method. The method first chooses one of the sub-models are the starting model. After obtaining the reconciled parameters, they are used as constants in the other sub-model. This process iterates until the convergences or satisfactory level is met. This method is explained in details in the work of Yong et al. (2016b). However, the models used in the Iterative Method are still non-linear, due to the square operation in the objective function.

3.3. Iterative PNS Method

It should be noted that the purpose of the square operation in the objective function is to remove any negative values arising from large measured values, e.g. when $RCP_{m,s} < CP_{m,s,n}$. This is so that the negative values do not reduce any differences for other $RCP_{m,s} > CP_{m,s,n}$. To reduce this non-linearity, the absolute value is proposed i.e.

CP Model	T Model
$$Min \sum_{m}^{M} \sum_{s}^{S} \sum_{n}^{N} \left|RCP_{m,s} - CP_{m,s,n}\right| \quad (11)$$	$$Min \sum_{m}^{M} \sum_{s}^{S} \sum_{n}^{N} \left|RT_{m,s} - T_{m,s,n}\right| \quad (12)$$

Figure 4: Objective functions that use absolute value in sub-models.

Using these models following Iterative Method changes to mixed integer linear programming (MILP). As the models call for minimisation, $RCP_{m,s}$ are desired to be as close as to $CP_{m,s,n}$. By applying Process Network Synthesis (PNS) algorithm, these models can be further reduced to just linear programming (LP). Consider the following,

$$Y_{m,s,n} = \left|RCP_{m,s} - CP_{m,s,n}\right| \tag{13}$$

It can be interpreted as

$$Y_{m,s,n} = RCP_{m,s} - CP_{m,s,n} \qquad \text{for } RCP_{m,s} > CP_{m,s,n} \tag{14}$$

$$Y_{m,s,n} = CP_{m,s,n} - RCP_{m,s} \qquad \text{for } RCP_{m,s} \leq CP_{m,s,n} \tag{15}$$

To apply the PNS algorithm in the models, let

$$RCP_{m,s} = RCP1_{m,s,n} + RCP2_{m,s,n} \tag{16}$$

$RCP_{m,s}$ is the desired product that has a unit cost of 1. Let there be existing ($Y1_{m,s,n}$) and new ($Y2_{m,s,n}$) pre-treatment units. $Y1_{m,s,n}$ is to be fed with streams $RCP1_{m,s,n}$ and vice versa for $Y2_{m,s,n}$. It is assumed that $Y1_{m,s,n}$ has fixed operating cost at $CP_{m,s,n}$ but its capacity is limited at $CP_{m,s,n}$. The $Y2_{m,s,n}$ has only the operating cost of $2 \times RCP2_{m,s,n}$. The net profit is to be

$$ZCP_{m,s,n} = RCP1_{m,s,n} - CP_{m,s,n} + RCP2_{m,s,n} - 2 \times RCP2_{m,s,n}$$
$$= RCP1_{m,s,n} - RCP2_{m,s,n} - CP_{m,s,n} \tag{17}$$

With the following additional constraint

$$e \tag{18}$$

The objective is to maximise the net profit and the objective function for the CP model is

$$Max \sum_{m}^{M} \sum_{s}^{S} \sum_{n}^{N} ZCP_{m,s,n} \tag{18}$$

Eq. (18) has the same purpose as Eq. (9) in the CP model used in the original Iterative Method. It is to have $RCP_{m,s}$ to be as close as to $CP_{m,s,n}$. The same process is applied for the T model where all CP terms are replaced with T terms. All the equations are linear.

Table 1: Mean values for all the parameters in the illustrative case study.

m	$T_{m,HI}$ (°C)	$T_{m,HO}$ (°C)	$CP_{m,HI}$ (kW/°C)	$CP_{m,HO}$ (kW/°C)	$T_{m,CI}$ (°C)	$T_{m,CO}$ (°C)	$CP_{m,CI}$ (kW/°C)	$CP_{m,CO}$ (kW/°C)

4. An illustrative Case Study

An illustrative case study is used to demonstrate the use of Iterative PNS Method. The HEN is shown in Figure 5. All the measurements are taken at every inlets and outlets of every heat exchangers, heaters and coolers. After sets of measurements are taken repeatedly for a fixed period of time, the outliers are discarded using statistics. Out of these sets of measurements, 10 are chosen to be used as the input data. Table 1 shows the mean value for all the parameters.
Figure 5: HEN for an illustrative case study

5. Result and Discussion

In this case study, the CP path is chosen and the CP model is to be used first for data reconciliation. Three iterations were done as the work used for comparison in Yong et al. (2016) stopped at third iterations. It should be noted that further iteration can be done to obtain a more accurate result. The percentage difference at this iteration of all the parameters is less than 2 % when compared with the result obtained in the first iteration. Table 2 shows the reconciled values obtained using Iterative PNS Method. The result is compared against mean values, as shown in the percentage difference in Table 3.

Table 2: Reconciled values for all parameters using Iterative PNS Method.

m	$T_{m,HI}$ (°C)	$T_{m,HO}$ (°C)	$CP_{m,HI}$ (kW/°C)	$CP_{m,HO}$ (kW/°C)	$T_{m,CI}$ (°C)	$T_{m,CO}$ (°C)	$CP_{m,CI}$ (kW/°C)	$CP_{m,CO}$ (kW/°C)
1	185.0	62.0	407.3	407.3	28.9	130.0	495.5	495.5
2	250.0	170.8	506.8	506.8	130.0	211.0	495.5	495.5
3	568.1	370.0	297.9	297.9	211.0	330.1	495.5	495.5
4	411.0	339.0	192.0	192.0	330.1	358.0	495.5	495.5
5	469.0	368.3	295.2	295.2	358.0	418.0	495.5	495.5
6	560.9	525.0	967.5	967.5	418.0	488.1	495.5	495.5
H1	801.0	700.0	293.9	293.9	488.1	548.0	495.5	495.5
C1	62.0	18.0	407.3	407.3	4.0	9.6	3,200.0	3,200.0
C2	370.0	319.0	297.9	297.9	5.0	9.9	3,100.6	3,100.6

Table 3: Residual differences (in %) of all reconciled parameters when compared to mean values.

m	$\Delta_{Tm,HI}$	$\Delta_{Tm,HO}$	$\Delta_{CPm,HI}$	$\Delta_{CPm,HO}$	$\Delta_{Tm,CI}$	$\Delta_{Tm,CO}$	$\Delta_{CPm,CI}$	$\Delta_{CPm,CO}$
1	0.05	0.00	1.59	1.86	1.09	0.31	-0.50	-0.56
2	0.16	0.18	1.05	1.18	0.23	0.19	-0.92	-0.92
3	-0.22	0.11	-1.06	-1.10	0.48	0.00	-0.84	-0.95
4	0.17	-0.09	-4.05	-4.09	-0.24	-0.11	-1.18	-0.99
5	0.24	0.16	-1.36	-1.61	-0.17	-0.07	-0.80	-1.02
6	0.13	0.08	-3.32	-3.30	0.05	0.18	-0.90	-1.11
H1	0.10	-0.01	-1.88	-2.01	-0.17	-0.05	-0.80	-0.83
C1	2.82	-5.26	2.00	1.79	-13.04	-2.56	0.08	0.03
C2	-0.24	-0.16	-1.62	-1.10	0.00	-0.38	3.33	3.33

From the result, most of the reconciled parameters have values of less than 5 %. Although the reconciled inlet cold stream temperature for C1 only differs by 0.6 °C from 4.6 °C, it has a difference of 13 %. Most of the parameters with high percentage differences are having low value. Another parameter, although has 3 % difference, the reconciled cold stream CP for C2 differs by 100 kW/°C from 3,000 kW/°C. This is a good level of residual errors, comparable with typical values (Romagnoli and Sánchez, 2000) and a recent refinery study (Mayo, 2015). An error level of up to 5 % is very good for the purpose of Heat Integration, where energy savings of 10 % or more would warrant credible investments, while for performing operation optimisation this level may be too high, as the expected cost improvements are of the order 2-5 %.

The results obtained are also compared with results from the simultaneous method and Iterative Method, as shown in Figure 6. From this case study, it can be seen that the Iterative PNS Method performs almost as well as the Iterative Method with less than 10 parameters having higher percentage difference. It is speculated that having a square operation in Iterative Method poses a heavier penalty on outliers. As expected, the simultaneous method performs the best out of these three methods at the cost of high computational cost.
Figure 6: Comparison of three different methods.

6. Conclusions

An Iterative PNS Method is introduced in this work for HEN data reconciliation. It applies the Process Network Synthesis (PNS) Algorithm to augment the previous Iterative Method. In both of the sub-models, the objective functions are reduced from non-linear to linear, thus, it is completely solvable with Linear Programming (LP). Demonstration from an illustrative case study showed that the Iterative PNS Method is performing almost as well as the Iterative Method in terms of precision, at a reduced computational cost.

Abstract

Bio-based companies must keep up with the needs of the consumers and the developments from their competitors. This needs to be done while managing the inherent risk of launching new products from new technologies to the market. To thrive it is essential to speed up research and development programs, to make the right choices for investment and to evaluate opportunities for reduction of production costs. Today's business ambitions incorporate not only economic growth but also sustainability targets. In this context, mathematical models are crucial to face these challenges. They are key to guarantee economy of scale whilst delivering on the commitments for sustainable development. In this work, the contribution of mathematical models in the process innovation funnel not only for process design but also for sustainability assessment within Corbion is presented. The methodology is illustrated with two case studies, in which it is shown how models help to find the optimal process in terms of economy and sustainability.

Keywords: process design, sustainability assessment, process modelling, bio-based economy

1. Introduction

Bio-based products are totally or partly derived from materials of biological origin, such as crops, plants or other renewable agricultural, marine or forestry materials. These products provide alternative material options to conventional petroleum-based materials by using renewable carbon as feedstock [1]. The use of renewable carbon feedstocks for chemical production has a clear link to reducing the risk of climate change and reduced dependency on fossil resources [2]. However, this is not sufficient to ensure the launching of these products. The newly introduced bio-based chemicals must compete with the well-established petro-based counterparts, in terms of cost and functionality, while outperforming in sustainability performance.

Corbion thrives to turn science into sustainable solutions based on renewable materials for applications in food, bio-chemicals and bio-based innovation products. This needs to be done while managing the inherent risk of launching new products from new technologies to the market. To thrive in this dynamic and challenging market it is essential to speed up research and development programs, to make the right choices for investment and to evaluate opportunities for reduction of production costs, at early stages of innovation.

A key success enabler is the use of mathematical models throughout the different stages of process design, from research to implementation/optimization of commercial processes. It guarantees the speed and the economy of scale whilst delivering on the commitments for sustainable development.

In this paper the applications of mathematical models within the innovation funnel of Corbion for process design and sustainability assessment is shown. Our methodology and achievements are illustrated with two case studies.

2. Process design and sustainability assessment in the innovation funnel of Corbion

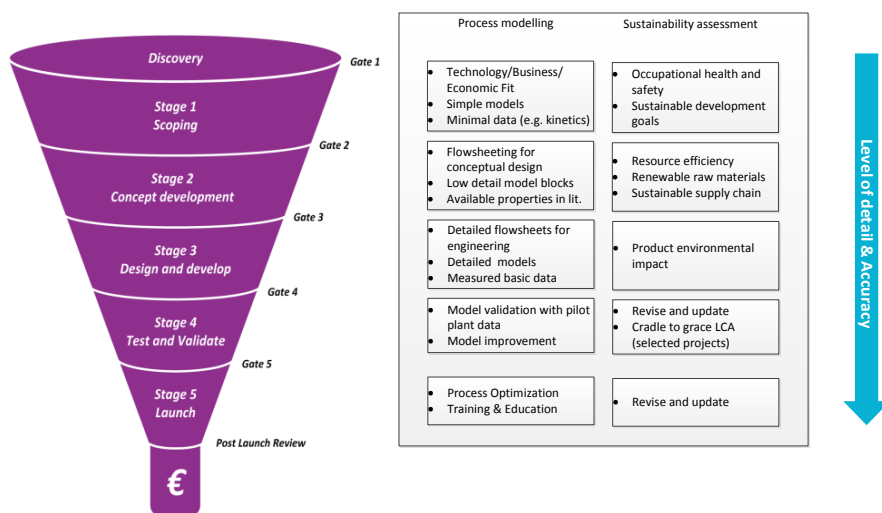
To guide, direct and accelerate innovation efforts from idea to launch, Corbion uses the "stage gate pass" model [3]. Projects must pass through a gate to enter a new stage. Figure 1 shows a typical scheme of the development of the process from the feasibility phase to implementation in commercial scale. In each gate, decisions are taken about the continuity of the projects. This decision is based on the marketing perspective of the new product, technical aspects, economy of the process and a sustainability assessment. During all this path, models of different complexity levels are used to evaluate the health of the process.


Figure 1. Stage gate pass model used by Corbion to evaluate new process and products.

In the early phase, screening of promising ideas is done. At this stage, typically few basic data are available, e.g. physical properties, and measuring them would be too expensive. Therefore, simple models are used to perform the techno-economical evaluation. Sustainability assessment in this stage consists in checking the safety of the chemicals (solvents, catalyst, etc.) used in the process and the impact of the project on the

Sustainable development goals (SDGs). This is a simple check but assesses safety risks. In case chemicals are found to be unsafe, they are replaced.

During Conceptual Design, different process alternatives are evaluated and the most promising is selected to move forward to the next stage. For this, models with a higher level of detail are developed. In this stage, physical properties available in literature or predicted by group contribution methods are used. Models based on short-cut methods are normally sufficient to achieve the goals of this stage. The aim of the sustainability assessment in this stage is to identify how the new process/product contribute to Corbion KPI's. Typical sustainability activities include comparing water and energy consumptions, waste and emissions to Corbion global average to create awareness of positive/negative impacts. The impact of the project on the SDGs is accessed at this stage.

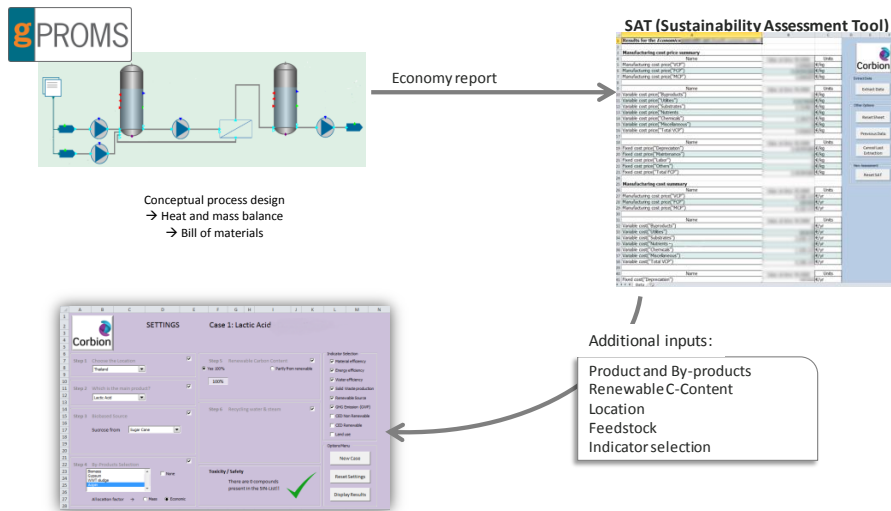
Once that the project moves to the Design and Develop phase, detailed models of unit operations are used for flowsheeting. In this stage, missing basic data are measured, i.e. phase equilibrium diagrams, reaction kinetics, etc. Mass and energy balance are generated for engineering activities, such as equipment design, piping and pump sizing, etc. Also a more thorough sustainability assessment is made to quantify the environmental impact of the new process/product over its life cycle. This is done by comparing it with commercial benchmark in terms of biobased C-content and life cycle assessment (LCA). To evaluate LCA, an in-house excel based tool has been implemented, which is integrated with our process design software. As one of the inputs to the LCA tool, the mass and energy balance of the process is required [4]. Figure 2, shows a generic workflow followed by Corbion for sustainable process design


Figure 2. Workflow to reach sustainable process design.

In the next stage of the funnel, the new process/product is tested and validated by e.g. piloting, and experimental data are used to validate the model. Raw experimental data must first be processed before they are used. Methods, such as data reconciliation can be applied to force these data to fulfil the mass and energy balance. In case, important differences between the model and the experimental data are found, the assumptions and basic data are reviewed to improve the quality of the model. LCA is also revised and updated.

Finally, after successful validation of the process/product in pilot scale, the next stage is Launch.

3. Case studies

3.1 Conceptual design

Part of the mission of Corbion is to offer choices to customers to reduce their impact on environment. Bioplastics, such as polylactic acid (PLA) and polyethylene furanoate (PEF), can replace fossil based plastics, such as PET and offer the same or even better properties. Monomer for PEF is 2,5-furan dicarboxylic acid (FDCA). Since 2013, when Corbion acquired BIRD Engineering BV, Corbion has been working on a biotechnological route for production of FDCA, aiming to the lowest possible costs and lowest impact for environment. Like all projects at Corbion, the FDCA project is following the stage gate approach, which involves that economy and LCA are evaluated frequently and used to steer process development and optimization.

The role of process modelling started in 2013 when principles of key unit operations had already been proven on lab scale. A typical start for the *scoping phase* involves brainstorms for process concepts that fit within the boundaries of the project, like no use of toxic chemicals, low energy consumption and low waste production. Subsequently, in the *concept development stage*, process schemes are drafted for the highest ranking options. To generate the mass and energy balance, a flowsheet model of the complete processes from feedstock to FDCA was implemented in the commercial software gPROMS [5]. For this, we have developed an *inhouse model library and inhouse physical property databank*. Where needed new unit operation models were added to the model library, e.g. detailed fermentation models, and the physical property databases were extended with relevant lab data for FDCA and derivatives. Input parameters for the unit operation models were aligned with unit operation experts and are an educated guess representing the expectation of what research can bring to improve the current performance. The gPROMS flowsheet model will automatically produce the mass and energy balance and estimations for Bill of Materials, input for sizing of equipment and estimation of carbon footprint.

The results of the modelling activities were used to select the best feasible process concept. In the *design and develop phase*, sensitivity analysis was carried out to determine the areas that have the largest impact and/or uncertainty on costs and sustainability of the selected process. This is then used to determine further research and the possible need to make changes to the process concept.

In the *test and validate phase*, an iterative process where the model is being extended and validated with new experimental data, proposed changes are evaluated, lacks in our knowledge were identified and results of the model were used to steer further research.

At the stage gates a detailed LCA and economic evaluation is done, which can also lead to process changes, for example when a feedstock was found to have a higher than accepted impact on sustainability or when a solvent choice was not accepted a being sufficiently safe. The LCA and economy of FDCA is benchmarked against the LCA of terephthalic acid to ensure the bio-based alternative represents a large improvement towards to the fossil based alternative.

This process of combining and iterating process modelling, sustainability calculations and lab and pilot research ensured Corbion the process that was being developed for production of FDCA will meet Corbion's targets on sustainability and cost effectiveness, while using resources in the most time-effective way.

3.2 Revamping

To fulfil the higher demand of one of our products, revamping studies were done in one of our facilities. The aim was not only to increase capacity but also to decrease energy consumption and thus, CO_2 emissions. One way to achieve this was to increase the temperature of the feed to the unit using an available hot water stream in the plant. Therefore, the following three concepts were evaluated with help of models.

- Scenario 1: use of a network of heat exchangers to heat up the feed to the unit.
- Scenario 2: application of heat pumps
- Scenario 3: flashing the hot water stream and upgrading the flash vapour with an steam ejector.
Figure 3. OPEX savings and reduction of CO2 emissions.

Figure 3 shows the reduction in OPEX for each concept with respect to the base case, and the reduction of CO_2 emissions are also presented. It can be noticed that scenario 2 is the case with both the largest OPEX savings and CO_2 emissions reductions. It is, however, the case with the highest investment, yet, the payback time is less than 3 years. The results of this study were presented during the stage gate assessment and allowed passing the Design and Develop phase.

4. Conclusions

In this paper, the contribution of mathematical models to steer research and development programs within Corbion was presented. By performing a techno-economical evaluation, sustainability assessment and lab/pilot research in each stage of the innovation funnel, Corbion ensures that the new process/product will meet sustainability and economic targets. Moreover, this approach also allows to identify changes needed in the processes and/or chemicals in the early stages of the process development, when this changes involves relatively low cost.

The methodology was illustrated with two different projects running at Corbion. One of them include the production of FDCA. For this case, the stage gate process starting from the scoping to the test and validate phase has been discussed. By process simulations, the most promising process, in terms of economy and sustainability has been determined. A second case study showed how models contributed to find the optimal solution in revamping studies.

Abstract

Establishing the steady state in hydrotreating process requires several days, leading to long experimentation times in order to obtain sufficient steady-state data for kinetic modelling. However, during the evolution towards this steady state, effluent analyses are already carried out at regular time intervals to determine whether the steady state has been reached and to ensure that the reaction is under control. In this paper, the stabilization time was assessed by using experimental data during these transient conditions. The stabilization evolution is supposed to follow a first-order response. A characteristic time for stabilization τ was defined. A linear model with interaction for τ prediction was developed. It was found that a higher LHSV leads to a quicker stabilization. The extent of the impact of LHSV on τ depends on the feed resin content, i.e., the polar components with high molecule weight. A direct relationship between reactor pressure and stabilization time was found. Temperature is not a dominant factor. Stabilization of spent catalyst depends on the previous operating conditions.

Moreover, online transient data can be used in order to predict, from the first two experimental points and τ calculated by the model, the future steady-state value. By testing against new data with other feedstocks, the model has been found to provide a good prediction of the stabilization evolution and the steady-state hydrotreating performance. If this value is far from the target, operators can change the operating condition without waiting for stabilization.

Keywords: hydrocarbon, hydrotreating, kinetic modelling, reactor, stabilization, transient data.

1. Introduction

Hydrotreating is a catalytic conversion process in petroleum refining, among others for removing impurities such as nitrogen and sulphur compounds from hydrocarbon streams. A kinetic model is a significant asset in, not to say essential for the adequate design and simulation of such a process (Becker et al., 2015). It is usually developed based on experimental data acquired at steady-state conditions. One of the main challenges of hydrotreating process is that establishing this steady state typically

requires several days, leading to long experimentation times in order to obtain sufficient data for kinetic modelling. However, during the transient phase towards the steady state, effluent analyses are already carried out at regular time intervals to detect the steady state and to ensure that the reaction is under control. These available transient data are currently not used for kinetic modelling because the stabilization behaviour is not well understood.

The aim of this work is, first, to get a better understanding of the stabilization behaviour during these transient conditions and secondly, to use these transient data to predict the steady-state reaction performance. If this value is far from a target, the operators can change the operating condition without waiting for stabilization and without the use of a complex model.

2. Materials & Methods

The experimental data are acquired using the IFPEN Hydrotreatment (HDT) pilot plant operating in a continuous manner. The total catalyst volume in the reactor amounts to 50 cm^3. Operating conditions are adjusted after having reached the steady state corresponding with the previous operating conditions. The acquired data cover 11 Vacuum Gas Oil (VGO) feeds over two catalysts. Operating conditions were chosen to cover a wide range for the VGO HDT process: Liquid Hourly Space Velocities (LHSV) from 0.5 to 4 h^{-1}, temperature from 350 to 410 °C and total pressure between 50 and 140 bar. The provided data are the 'liquid product nitrogen content' (N) with time on stream (TOS), totalling 920 measurements, see Figure 1. A series of points corresponding to one experimental run is called one 'episode'. Figure 1 shows 7 episodes corresponding to 42 data points during around 45 days.
Figure 1. Data representation (P = 140 bar, point: experimental data, solid line: model fitting Equation (1))

A hydrodynamics study on the pilot plant has been carried out using a tracer technique to estimate the stabilization time purely due to hydrodynamic. The objective is to identify whether the stabilization time is determined by hydrodynamic or kinetic phenomena.

Exploratory data analysis (Tukey, 1977) is applied to our available data to assess the stabilization evolution. It resulted in a first-order transfer function as shown in Equation (1).

$$N = N_{init} + \left(N_{final} - N_{init}\right)\left(1 - \exp\left(\frac{-\left(TOS - TOS_{init}\right)}{\tau}\right)\right) \tag{1}$$

Where N is the liquid product nitrogen at a specific time on stream (ppm); N_{init} is the liquid product nitrogen corresponding to the first experimental point of episode (ppm); N_{final} is the last experimental point of episode (ppm); TOS is the time on stream (h); TOS_{init} is the time on stream corresponding to the first experimental point of episode (h) and τ is the characteristic time of the episode (h).

The characteristic time τ of each episode presented in the equation is estimated via nonlinear least-squares (solid line in Figure 1).

A multiple linear regression with interaction technique is then used for τ prediction to evaluate the phenomena underlying the transient data. The general linear model with interaction is illustrated in Equation (2):

$$\tau = a_1 x_1 + a_2 x_2 + a_{12} x_1 x_2 + \ldots + b \tag{2}$$

Where x_1, x_2 are the input variables, which can be LHSV, temperature, pressure or feed properties such as organic nitrogen content, organic sulphur content, resin content in feed, etc.; $x_1 x_2$ is the interaction term between x_1 and x_2; a_1, a_2, a_{12},… and b are the coefficients.

The most influential input variables of the model are determined via variable selection technique called 'leaps' (Furnival and Wilson, 1974). Fitting linear model and nonlinear model was done by using respectively 'lm' and 'nls' function in 'stats' package in R software. Variable selection was carried out in R by using 'leaps' package obtained from CRAN repository (Lumley, 2017).

The model is then tested against new data with other feedstocks. For each episode, τ is predicted by the model. Knowing τ and the first two points of the episode, it is possible to predict the evolution of the episode as well as the Nitrogen content at steady state calculated via Equation (3) which is developed from Equation (1). The leftover data of the episode are used to validate the model. If the predicted steady-state value is far from the target, the operating condition can be adjusted without waiting for stabilization.

$$N_{final} = \frac{N - N_{init}}{1 - \exp\left(\frac{-\left(TOS - TOS_{init}\right)}{\tau}\right)} + N_{init} \tag{3}$$

3. Results

The hydrodynamic response to a tracer step reached steady state significantly faster than the stabilization of the HydroDeNitrogenation (HDN) behaviour. Hence, chemical phenomena are involved in the latter.

Stabilization was found to follow a first-order model, which is similar to the observation of Sau et al. (2005) in the study of effect of organic nitrogen compounds on hydroprocessing reaction. The characteristic time τ reflects the time required to reach this steady state. First episodes take more time to stabilize than other episodes. The model was applied on two similar HDT catalysts (Catalyst A and B). Two linear models for τ were built; one for first episodes (model M1) and another for other episodes (model M2).

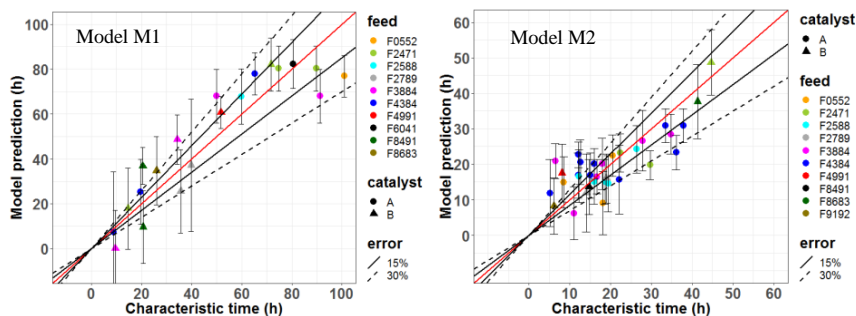
Model M1 was obtained with a R^2 of 0.83, as shown in the left side of Figure 2. It consists of three variables (LHSV, pressure, resin of feed) and one interaction term LHSV*resin, which are selected by the leaps algorithm. An inverse relationship between LHSV and τ was found. Temperature is not a dominant factor. These two results are coherent with Elizalde et al. (2016) who studied the dynamic behaviour of hydrocracking using the continuous kinetic lumping approach. A direct relationship between pressure and τ was observed. The interaction term shows that the impact of LHSV on τ depends on the value of feed resin, i.e., the polar components with high molecular weight. The resin in VGO can contain nitrogen.


Figure 2. Parity plot with 95% confidence interval for M1 (left, $R^2 = 0.83$) and M2 (right, $R^2 = 0.66$)

However, the stabilization of other episodes seems more complex. The parity plot for model M2 is shown in the right side of Figure 2. The latter includes seven input variables (LHSV$_{exp}$, LHSV$_{pre}$, T$_{pre}$, $\dfrac{LHSV_{exp}}{LHSV_{pre}}$, $\dfrac{LHSV_{pre}}{LHSV_{exp}}$, LHSV$_{exp}$*resin, S$_{feed}$);

where LHSV$_{exp}$ is the experimental LHSV of the episode; LHSV$_{pre}$ and T$_{pre}$ are respectively LHSV and temperature of the previous episode; resin and S$_{feed}$ are respectively resin content and organic sulphur content in the feed. As can be seen, the model relies by not only on the feed and operating conditions but also on the operating conditions of the previous episode. It shows that the transient behaviour of spent catalyst is more difficult to predict than for the fresh catalyst.

Model was tested by using new data with other feedstocks. τ is predicted by the model and the steady-state value is estimated via Equation (3). Figure 3 shows two examples of such prediction for first episodes (model M1). The two first points of episode which are used to estimate the steady-state value are shown in circle shape. The remaining data in the episode are represented by triangles. The Nitrogen predicted values are very close to the experimental values. The model can predict quite well the transient behaviour and the steady-state value. This algorithm may be linked to an Advanced Process Control method to reach as fast as possible some Nitrogen targets.
Figure 3. Two examples of the prediction of model M1 (points: experimental data, solid line: model prediction; TOS: time on stream)
Figure 4. Prediction of model M2 (points: experimental data, solid line: model prediction; TOS: time on stream)
Figure 5. Prediction of model M2 for episode 4 and episode 6 while discarding the first three experimental points of both episodes

Model M2 (for other episodes) is evaluated and is shown in Figure 4. Model predicts well the evolution of episode 2, 3, 5, 7 and 8. Regarding episode 4 and 6, it seems that the transient behaviour did not follow a first-order model, which could be explained by the measurement error/experiment problem or the complex behaviour of spent catalyst. The experimentation duration is longer for these both episodes than for the others. It is possible that there was an experiment problem. If the first three points of episode 4 and 6 are discarded, the prediction is more reliable, see Figure 5. This might be investigated in another study.

4. Conclusions

Stabilization behaviour is a critical point for hydroprocessing experiments. In this work, transient data of hydrotreating process were used to assess this stabilization. It is shown that the stabilization follows the first-order model. A characteristic time for stabilization τ was defined. Two models (one for the first episodes, another for the others) were built to calculate the stabilization time and identify the most influential parameters (LHSV, resin of feed, pressure). Good prediction results were obtained, particularly for the first episodes. The stabilization of other episodes is more complicated to predict.

The model can predict the stabilization time and steady-state value from two initial measures. If the predicted steady-state value would be far from the intended target, operators can change the operating condition without waiting for stabilization. This model will be linked with an Advanced Process Control Algorithm.

This model will be also linked to design of experiment algorithm in order to be used to fit kinetic parameters (Celse et al., 2016).

New MINLP Formulations for Flexibility Analysis for Measured and Unmeasured Uncertain Parameters

Maria Paz Ochoa, Ignacio E. Grossmann[*]

Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh, PA 15213, U.S.A.

grossmann@cmu.edu

Abstract

In this paper, we formulate the flexibility analysis with measured and unmeasured parameters as a rigorous multilevel optimization problem. First, we propose to recursively reformulate the inner optimization problems by the Karush-Kuhn-Tucker conditions and with a mixed-integer representation of the complementarity conditions to solve the resulting multilevel optimization problem. Three types of problems are addressed and solved with the proposed strategy: 1) linear programming problem, 2) nonlinear programming problem with monotonic variation of unmeasured uncertain, and finally 3) nonlinear programming problem. We illustrate the new formulation with a heat exchanger network problem with uncertain heat capacity flowrates.

Keywords: extended flexibility analysis, optimization under uncertainty, MINLP formulation.

1. Introduction

Traditionally, the approach to handle uncertainty in the parameters of a model is to consider nominal conditions in plant operation, and use overdesign to compensate for the potential impact of the uncertainty. In contrast, flexibility analysis addresses the guaranteed feasibility of operation of a plant over a range of conditions, with the ultimate goal being on how to design a process for guaranteed flexible operation (Grossmann *et al*., 2014). The flexibility test problem only determines whether a design does or does not meet the flexibility target. To determine how much flexibility can be achieved in a given design, the flexibility index is defined as the largest value of δ such that the model inequalities hold over the uncertain parameter range (Swaney and Grossmann, 1985).

However, these formulations are based on the assumption that manipulated variables can compensate for any variation in the uncertain parameter set and that during operation stage uncertain parameters can be measured with precision to take the corrective action. Ostrovsky *et al*. (2003) and Rooney and Biegler (2003) extended the analysis by taking into account the level of parametric uncertainty in the mathematical models at the operation stage, by grouping the uncertain parameters, $\theta \in \Theta$, into two types, measured and unmeasured parameters. The flexibility constraint was then extended to account for model parameters, θ_u, that cannot be measured or estimated during the operation stage.

In this paper, we propose a new reformulation of the extended flexibility analysis where the innermost problems are recursively replaced by their optimality conditions and the complementarity conditions are expressed with a discrete representation.

2. Mathematical Model

The basic model for the flexibility analysis involves design variables, d, control variables, z, and uncertain parameters, θ. One of the main problems addressed in the flexibility analysis is the flexibility test problem. It consists in determining whether by proper adjustment of the control variables the process constraints $g_j(d,z,\theta) \leq 0$, $j \in J$, hold for any realization of uncertain parameters for a given design (Halemane and Grossmann, 1983). This statement can be expressed with the logic expression (1), and is reformulated by the use of min and max operators as shown in Eq. (2).

$$\forall \theta \in \Theta \{\exists z \ (\forall j \in J \ [g_j(d,z,\theta) \leq 0])\} \tag{1}$$

$$\leftrightarrow \chi(d) = \max_{\theta \in \Theta} \ \min_{z} \ \max_{j \in J} g_j(d,z,\theta) \tag{2}$$

The main difference between the design and control variables is that the design variables are fixed during the operation stage, while the control variables can be adjusted in order to satisfy process constraints. In fact, to solve the flexibility constraint it is required to have accurate estimation of the uncertain parameters. This can only be achieved if there is enough process data for precise determination of all uncertain parameter values. However, this assumption is restrictive, and is often not met in practice.

To address these limitations, two groups of uncertain parameters are identified. The first group of uncertain parameters contains parameters whose values can be determined to within any desired accuracy at the operation stage, namely the measured uncertain parameters, θ_m. Meaning that appropriate sensors are available to determine accurate values of all the uncertain parameters by direct measurement or by solving parameter estimation problems. Therefore, recourse action can be taken in order to compensate for their variation. Examples of this type of parameters include process conditions such as feed flowrates, pressures, temperatures, concentrations, and input variables such as product demands. The second group includes the unmeasured uncertain parameters, θ_u, whose estimation cannot be performed during the operation stage, consequently no control actions can be applied to them.

This distinction has been taken into account and the flexibility constraint was then extended to Eq. (3) and reformulated as the multilevel optimization problem described by Eq. (4) by Ostrovsky *et al.* (2003) and Rooney and Biegler (2003).

$$\forall \theta_m \in \Theta_m \{\exists z \ (\forall \theta_u \in \Theta_u, \forall j \in J \ [g_j(d,z,\theta_m,\theta_u) \leq 0])\} \tag{3}$$

$$\leftrightarrow \chi(d) = \max_{\theta_m \in \Theta_m} \ \min_{z} \ \max_{\theta_u \in \Theta_u} \ \max_{j \in J} g_j(d,z,\theta_m,\theta_u) \tag{4}$$

To solve the extended flexibility analysis, Ostrosvky *et al.* (2003) suggested an algorithm for the calculation of the flexibility function based on the branch and bound strategy, while partitioning the uncertain set into subregions. On the other hand, Rooney and Biegler (2003) proposed an extension to the approach presented by Raspanti *et al.*

(2000), which involved the use of the KS smooth function (Krelsselmeler and Steinhauser, 1983) that aggregated all of the model inequality constraints, and the KKT derivation together with a smooth approximation of the complementarity conditions for the inner optimization problems. Therefore, the extended flexibility constraint resulted in a nonlinear program.

In this work, we reformulate the extended flexibility constraint by developing the optimality conditions for each nested problems. In addition, in order to make the formulation tighter, the bounds of the nonnegative Lagrange multipliers related to the inequality constraints and the bounds on the slack variables are treated as constraints of the following level optimization problem. Finally, we express the complementarity conditions with a mixed-integer representation and assume that the Haar condition holds, which states that the number of active constraints is equal to the dimension of the control variables plus one. This condition holds true provided the Jacobian is full rank (Grossmann and Floudas, 1987).

In the following subsections, we derivate the formulation of three different cases, linear problem, nonlinear problem with monotonic variation of unmeasured parameters with respect to model constraints, and nonlinear problems.

2.1. Special Case 1: Linear Programming problem

The order of the inner max operators in Eq. (4), are interchangeable and can be equivalently expressed as follows.

$$
\chi(d) = \max_{\theta_m \in \Theta_m} \psi(d, \theta_m)
$$
$$
s.t \;\; \psi(d, \theta_m) = \min_z \zeta(d, z, \theta_m) \tag{5}
$$
$$
s.t: \;\; \zeta(d, z, \theta_m) = \max_{j \in J} \max_{\theta_u \in \Theta_u} g_j(d, z, \theta_m, \theta_u)
$$

We consider that the inner problem is described by the linear inequality constraints:

$$
g_j(d, z, \theta_m, \theta_u) = a_j \cdot d + b_j \cdot z + c_j \cdot \theta_u + d_j \cdot \theta_m \leq 0, \forall j \in J \tag{6}
$$

Constraints g_j in Eq. (6) vary monotonically with respect to θ_u. Hence, the solution of the innermost problem must lie in one of the extreme points of its range of variation, depending on the sign of the derivative, $dg_j/d\theta_{j,u}$.

$$
\max_{\theta_u \in \Theta_u} g_j(\theta_{j,u}) \rightarrow \theta^*_{j,u} \tag{7}
$$

The bilevel problem M1 described by Eq. (8) is obtained by replacing Eq. (7) in Eq. (5). To obtain a single level optimization problem, the innermost problem of Eq. (8) is replaced by its optimality conditions with a mixed-integer representation of the complementarity condition following the active constraint set strategy (Grossmann and Floudas, 1987). This yields the MILP problem:

$$
M1: \chi(d) = \max_{\theta_m \in \Theta_m} \psi(d, \theta_m)
$$
$$
s.t: \psi(d, \theta_m) = \min_{z,u}(u \mid g_j(d, z, \theta_m, \theta_u) = a_j \cdot d + b_j \cdot z + c_j \cdot \theta^*_{j,u} + d_j \cdot \theta_m \leq u, \forall j \in J) \tag{8}
$$

Where u is a scalar variable that represents the worst constraint violation.

2.2. Special Case 2: Non-Linear Programming problem with monotonic variation of unmeasured uncertain parameters

If the set of functions $g_j(d,z,\theta_m,\theta_u)$ varies monotonically with respect to the unmeasured uncertain parameters, then the relationship expressed by Eq. (7) holds true. Therefore, the solution of the innermost problem lies at an extreme point of the range of variation of θ_u. Analogously, the following bilevel programming problem M2 is obtained and then reformulated in the same way as the previous case, but leading to the MINLP problem.

$$M2 : \chi(d) = \max_{\theta_m \in \Theta_m} \psi(d,\theta_m)$$

$$s.t: \psi(d,\theta_m) = \min_{z,u}(u \mid g_j(d,z,\theta_m,\theta^*_{j,u}) \leq u, \forall j \in J) \tag{9}$$

2.3. General Case: Non-Linear Programming problem

The extended flexibility constraint can be equivalently expressed as the following multilevel optimization problem M3.

$$M3 : \chi(d) = \max_{\theta_m \in \Theta_m} \psi(d,\theta_m)$$

$$s.t \ \psi(d,\theta_m) = \min_{z} \zeta(d,z,\theta_m)$$

$$s.t: \zeta(d,z,\theta_m) = \max_{\theta_u \in \Theta_u} \varphi(d,z,\theta_m,\theta_u) \tag{10}$$

$$s.t: \ \varphi(d,z,\theta_m,\theta_u) = \min_{u}(u \mid g_j(d,z,\theta_m,\theta_u) \leq u, \forall j \in J)$$

In order to solve Eq. (10), we propose to replace the inner problems by their optimality conditions in a recursive fashion. Due to space limitations, we cannot report the complete reformulation. To illustrate the solution strategy, we will replace the innermost problem of Eq. (10) by its KKT conditions (Eqns. (11) and (12)) and complementarity conditions (Eq. (13)). Bounds of the Lagrange multipliers, λ_j^0, and slack variables, s_j^0, are added as model constraints of the next level optimization problem, described by Eqns. (14) and (15), in order to tighten the formulation.

$$1 - \sum_j \lambda_j^0 = 0 \tag{11}$$

$$g_j(d,z,\theta_m,\theta^*_{j,u}) - u + s_j^0 = 0 \qquad\qquad \forall j \in J \tag{12}$$

$$\lambda_j^0 \cdot s_j^0 = 0 \qquad\qquad \forall j \in J \tag{13}$$

$$-\lambda_j^0 \leq 0 \qquad\qquad \forall j \in J \tag{14}$$

$$-s_j^0 \leq 0 \qquad\qquad \forall j \in J \tag{15}$$

Following this procedure, we obtain a single level optimization problem. The complementarity conditions are then expressed with a mixed-integer representation, the Haar conditions is assumed, leading to an MINLP problem.

3. Numerical Example

A well-known example in the flexibility analysis literature is the heat exchanger network shown in Figure 1. Grossmann and Floudas (1987) used this NLP example to introduce the active set strategy, which is able to find non-vertex solutions. After the elimination of the state variables, the reduced model consists of four constraints, and

three variables: the cooling load (Q_c) is the control variable and the heat capacity flowrate of streams 1 and 2 (F_{H1} and F_{H2}) are the uncertain parameters. We solve a modified version the problem for three cases. First, considering both uncertain parameters as unmeasured, so no recourse actions can be taken, corresponding to one of the special cases of the traditional flexibility analysis. Second, considering θ_1 as a measured uncertain parameter and θ_2 as an unmeasured uncertain parameter, where control actions can only be adjusted to compensate for variations in θ_1, solved with the formulation proposed in Section 2.3. Finally, we consider both as measured uncertain parameters like in the traditional flexibility analysis following the active set strategy (Grossmann and Floudas, 1987).
Figure 1. (*a*) Heat exchanger network scheme. (*b*) Feasibility diagram for fixed value of F_{H2}=2

Numerical results are summarized in Table 1Table 1. As we can see, we obtain positive values of u for all the cases, indicating an infeasible design. The worst constraint violation (u=138.5) is obtained for the case of no recourse actions. This value can be reduced up to certain degree (u=20) when control variables can compensate for the variations in θ_1. Furthermore, this can be reduced (u=7.08) when recourse actions can compensate for variation in both uncertain parameters. It is also important to note, that non-vertex critical points are obtained for the second and third cases. The different problems are implemented in GAMS 25.1.2 (GAMS Development Corporation, 2018) and solved with BARON 18.5.8 (Kilinc and Sahinidis, 2018) in an Intel i7 machine with 16 Gb of RAM. The tolerance of the solver is set to 0.01 and the big M value is 600.

Table 1. Worst constraint violation, critical parameters values for three examples and model size.

	Both unmeasured uncertain parameters[*] $\theta_u=\theta_1, \theta_2$	Combined type of uncertain Parameters $\theta_m=\theta_1, \theta_u=\theta_2$	Both measured uncertain Parameters $\theta_m=\theta_1, \theta_2$
u	138.5	20	7.08
θ_1= F_{H1}	1	1.333	1.398
θ_2= F_{H2}	1.95	2.041	2.034
#bin var	4	36	6
#cont. var	12	161	22
#constraints	13	163	21
CPU time	0.01	1.67	0.09

[*]For a fixed value of z.

4. Conclusion

In order to obtain more realistic results when dealing with operation under uncertainty, a distinction of the uncertain parameters can made between the measured and unmeasured uncertain parameters. Thus, the traditional flexibility constraint has been extended. In this work, we have proposed new reformulations of the resulting multilevel optimization problem, which involves the replacement the innermost problem by its optimality conditions in a recursive fashion and the introduction of a mixed-integer representation of the complementarity conditions, resulting in an MINLP problem.

We have developed the formulation of three different cases, linear problem, nonlinear problem with monotonic variation of unmeasured parameters with respect to model constraints, and nonlinear problems. A particular feature of the first two cases is that the worst constraint violation lies at a vertex of the unmeasured uncertain parameter set; where the formulation can be simplified, leading to a similar formulation as the one obtained by applying the active set constraint strategy, namely the traditional flexibility analysis (Grossmann and Floudas, 1987). An example of a heat exchanger network has been presented to illustrate the proposed reformulation of the general case and compared to cases with different degree of recourse actions.

Mathematical process modelling past, present and future – a personal perspective

J.P. Schmal

Process Systems Enterprise Inc., 4 Century Drive, Ste 130, Parsippany, NJ, 07054, USA[1]

p.schmal@psenterprise.com

Abstract

Progress in mathematical process modelling has been tied primarily to hardware developments and secondarily to better software, advanced algorithms and improved data availability. In this paper we review modelling history to extract some trends for the future. Modelling will play an increasingly important role in process industries. Historically separate techniques such as flowsheeting, custom modelling and CFD will likely merge as computational power increases. Initially parallel computing will give the needed additional computation power. Neural nets are expected to play a role in empirical models and analysis. We need to move from storing data to storing useful information.

Keywords: modelling, digitalization, big data, history.

1. Introduction

Mathematical process modelling has been around for many decades, but has evolved significantly with the advent of more powerful computers, better algorithms and the availability of more data. To help understand where mathematical process modelling may go in the future, we need to understand the past and the present. This paper represents a personal view and is based on historic events and personal experiences and beliefs. In a short paper, it is impossible to do justice to all people that contributed to these areas and to cover the history in the detail it deserves. The goal is to abstract general trends in the field and use them to look ahead.

Modelling technology encompasses four main elements: 1) modelling approaches, 2) software & algorithms, 3) hardware and 4) data. We will cover the status of each of these elements. For modelling approaches, we will cover custom modelling, flowsheeting, CFD and neural networks.

2. Past

2.1. Pre-1950

Process modelling has been around for a very long time. Initially the models needed to be solved analytically due to a lack of computers. The art of modelling was therefore to try and find a problem that was as close as possible to reality, yet could be solved analytically. As a consequence many simplifying assumptions were needed to make the

---

[1] Per May 1st 2019: ExxonMobil, 1545 US-22, Annandale, NJ 08801, USA

problem solvable. Several techniques were employed to get general solutions that could be used for different cases. For example, dimensionless numbers were extensively used to reduce the number of variables and allow for plotting solutions in 2-D. Dynamic behaviour was studied with the help of bifurcation studies, using the steady-state as a demarcation between regions of different dynamic behaviour (Aris, 1994). These general solutions or solutions to certain equations would often be published in books.

Process control was all manual and measurements were virtually non-existent. Chemical processes were run based on experience and by trial and error.

2.2. 1950-2018

With the advent of digital computers and the introduction of software, many areas such as modelling, control and neural networks evolved rapidly. Process modelling could relax some of the simplifying assumptions. One of the earliest industrial applications was by Sargent (1958) using a punch card computer to design a distillation column and a multi-stream heat-exchanger. Steady-state models were difficult to solve and dynamic models were used to find the steady-state as they were easier to initialise.

Initial computations could only use limited memory on what were slow computers, but memory, CPU clock speed and hard drive space grew rapidly. This allowed for ever more complex and realistic problems to be solved as demonstrated in Figure 1.
Figure 1: Historic size of RAM and hard drive (created with data from http://organdi.net/article.php3?id_article=82, https://en.wikipedia.org/wiki/History_of_supercomputing and personal experience)

Besides hardware improvements, advancements in several other areas were equally important to progress in modelling. New simulation-specific software, advanced algorithms and improved data availability all contributed to the development of more detailed and accurate models.

In 1957, Fortran (FORmula TRANslation) was developed and it allowed for easy implementation of equations. It is worth mentioning Matlab, whose first commercial version became available in 1985, Python, whose first version became available in 1980 and excel (1985; first spreadsheet was developed in 1969). Matlab, Python and excel have found wide spread use in the engineering community.

With regards to algorithms for sets of equations, broadly speaking two types of solutions were considered: sequential modular and simultaneous or equation-oriented. Sequential modular solvers were prominent in flowsheeting tools while simultaneous solvers were

more often used in custom modelling tools. In the sequential modular approach the structure of the problem is exploited and each process unit is solved in turn. This requires the inputs to the units to be known or given. Back to front calculations or including recycles and/or heat-integration is difficult or requires intermediate steps and/or iterations through the loop. Equation-oriented solvers, solve all equations simultaneously, allowing for back to front calculations, easier solution of recycles and heat-integration. Because equation-oriented solvers are Newton-based solvers, good initial guesses are required. Process Systems Enterprise developed automated initialization procedures to get these good initial guesses. As all equations are solved simultaneously, debugging a problem is usually less straightforward than in sequential modular approaches.

Gear was one of the key pioneers in solving sets of Differential-Algebraic equations (DAEs). In 1971 he introduced a multi-step, backward difference formula (BDF) method. Petzold (1982) developed DASSL, which is at the basis of many of today's BDF solvers. In 1989 the semi-implicit Runge-Kutta method, a one-step method, was introduced and the rivalry between BDF and Runge-Kutta caused significant improvements in both solvers. The interest in partial differential equations bloomed in 1996. Although many algorithmic improvements have been made in linear algebra (e.g. MA28 in 1977 & MA48 in 1996), non-linear solvers and integration solvers, the next logical avenue for speed an capability improvements was the exploitation of parallelization.

With regards to software we will briefly consider Computational Fluid Dynamic (CFD), Flowsheeting, custom modelling and neural networks. 2-D CFD solutions were available as early as 1930 and the first CFD calculations using finite differences were done on ENIAC in 1940, one of the world's first computers. In 1957 Los Alamos solved the first 3D CFD calculations with first publications by Douglas aircraft and Boeing in 1967 and 1968 respectively. Unsteady aerodynamic flows were first successfully solved in the 1970's. Two-phase flow and reacting media were developed in the early 1990's until today.

The first flowsheeting tool was developed in 1959 by Monsanto and was called Flowtran. They later participated in the Aspen project with MIT and DOE, which led to first version of Aspen in 1981. Two other notable developments for flowsheeting tools are the development of PRO/II by SimSci which was established in 1967 and later became part of AVEVA and CHESS developed in 1968 at the University of Houston and the US Navy, which became Chemcad in 1985. In 1996 Hyprotech, a company spun out of the University of Calgary, developed HYSYS, which was sold to Aspen and then divested due to the fact it was anticompetitive and bought by Honeywell. Some of the developers of HYSYS also developed Unisim in 2005. Most flowsheeting tools are sequential modular, but Aspen EO, ROMeo, gPROMS ProcessBuilder and gPROMS FormulatedProducts are examples of equation-oriented flowsheeting tools.

Hundreds of tools were developed for custom modelling (able to solve general integral-partial-differential-algebraic equations, IPDAE), but two key developments were SPEEDUP in 1964 developed by Sargent and Westerberg. SPEEDUP was sold to Aspen and later became Aspen Custom Modeller. Pantelides and Barton developed gPROMS in 1993 and Process Systems Enterprise was set-up to commercialize gPROMS in 1997.

Neural networks (NN) were first developed in 1943 where electrical networks were used to represent the neural network. In 1950 IBM had its first successful neural network and in 1957 Cornell university developed percepton for pattern recognition. In 1959 Stanford used NN to remove echoes in telephone calls, but in 1969 a critical paper proved that

percepton could not solve the "exclusive or" problem. As a consequence the interest in NN dissipated until 1982 when multi-layer NN were introduced. In 1989 feedforward was introduced, allowing for any function to be implemented in an NN. In 1995 another dead period started since people were unable to teach NN how to play chess. In 2006 the interest in NN rebounded by a rebranding to deep learning. Research led to a couple of key innovations with regards to initialization of the weights used to indicate the influence of each node in the previous layer on a node in the current layer. The weights traditionally were set randomly, requiring huge data sets to "train" the NN. The advent of big data and the use of GPUs (Graphical Processing Units) which sped up calculations drastically, allowed NN to become powerful (e.g. Watson, Google, Amazon etc.).

With the advent of computers and software to simulate complex models, the techniques of optimisation, parameter estimation and design of experiments became readily available. This in turn led to a need for data to estimate unknown or uncertain parameters and optimize the design or operation. In the early days measurements were analogue, often making use of pneumatic measurements, typically a pen moving up and down while a piece of paper was moving underneath it. This meant data had to be transcribed from the scrolls into usable forms. For example, the first electrical signal pressure measurements became available in the 1930's, but the first digital pressure sensor was developed by Honeywell in 1967 (http://www.sensorland.com/HowPage059.html). With the digitalization of operations more sensors were introduced in plants and the sensors were digital, meaning the data was easily accessible. The OPC, OLE (Microsoft Object Linking and Embedding) for Process Control) standard was introduced in 1995 and in 2001 the Historical Data Access (HDA) was introduced. As an example of this change, in 1994 during my internship at Hoechst, the unit I was modelling only had a few measurements (~25), while during my Ph.D. from 1999-2003, I modelled a large petro-chemical plant from Shell and 2300 sensors were available, (350 used in the modelling).

3. Present

Present capabilities include among many others: Flowsheets of connected gas processing plants (Aluma et al., 2016), combined product and process design (Martin and Martinez, 2013), coupled DEM (discrete element models), custom multi-scale models of wet granulation (Barrasso et al. 2015), three-phase CFD simulations of units and neural nets that control more and more parts of our daily life.

Tsay et al. (2018) give an overview of optimal process design capabilities and practices. They interviewed 110 industrial people and found that there is limited adoption of optimization and modelling tools.

With regards to hardware there is a clear trend towards parallelization and cloud computing as the improvements of a single core seem to be flattening off. As an example we ran the same large model using the same software version on a high end i7 machine in 2012 taking 156 s CPU time, while on a high end Xeon machine in 2017 it took 105 s CPU time (~32% improvement). During this same time period we have achieved speed improvements of a factor of 3 for large models due to algorithmic improvements. With parallelization we have managed to achieve speed increases of close to a factor of 1000. The latter, is case dependent and not generally applicable however.

Data standards, integration and increased hard disc space have led to much wider availability of data for analysis and training of neural nets. The fact that chemical plants

typically operate in a narrow operating window makes using neural nets both easier and harder: easier because it only needs to cover a limited number of possibilities and harder because it also means the information content in the data is limited and there is a danger of training the neural net how to predict noise.

On-line applications of models both linear and non-linear are common and models are used as soft sensors for unmeasurable quantities and phenomena such as coking and fouling. Advanced model-based control and optimization is applied in many different industries and on hundreds of plants world-wide.

4. Future

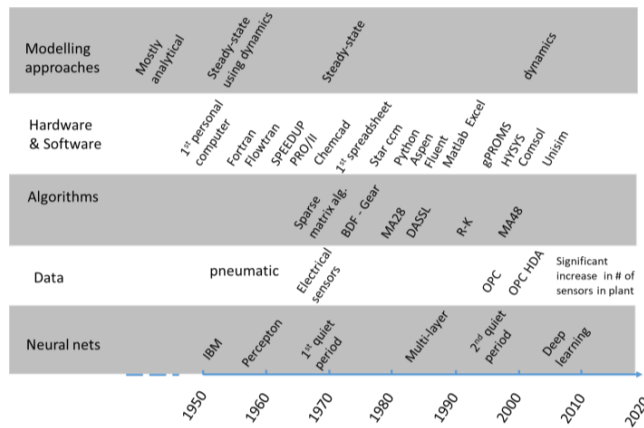
All we can do is consider different alternative scenarios and discuss their likelihood. It is clear from history (see Figure 2) that we have always tried to get the most out of the hardware and software. We always have been able to add complexity faster than hardware has been able to grow. The current digitalization trend is expected to increase the use of models both off-line and on-line. As such model-based engineering is expected to be a standard practice (e.g. see INCOSE vision 2025). In on-line models the use of more detailed models is now possible due to robust and fast solvers.


Figure 2: Summary of history

With regards to hardware, the trend we see towards cloud computing and parallelization most likely will continue and it seems it is the most secure way to get more computation power. There are still new developments in miniaturization allowing for more power. The development of the quantum computer is still progressing and has been for a long time (since 1982), chances of a major breakthrough in the next decade seem unlikely. Although progress is steady, the algorithms that can benefit from quantum computing are still limited. A breakthrough in quantum computing would be a disruptive event.

With the availability of more computational power, two trends most likely will continue: bigger envelops/systems and more detailed models. At the moment these bigger problems are solved using relatively simple models. Using more detailed models will require more computational power and bring additional benefits. The level of detail will also increase due to software like CFD, flowsheeting and custom modelling merging into a single tool.

Algorithms will keep on improving and there is still a lot of room for improvement in areas such as global mixed-integer non-linear programming. The application of neural nets will increase, but research interest (measured by hits in Google scholar) shows a decline in papers in this area. Neural nets can play an important role in cases where first-principles are not well-known or in areas such as data analytics.

Compared to nuclear physics, data analytics in chemical engineering can be improved upon. Also, techniques that combine information from signals to get a better overall picture (similar to PAT, Process Analytical Technology) can be improved. Finally, data is simply stored for a certain time and later simply deleted. With the increased availability of data it most likely will be necessary to extract useful information from the data to keep data storage requirements under control and the use of this data manageable.

5. Conclusions

Progress in hardware and software has driven mathematical process modelling and will continue to do so in the future. Single core hardware capabilities are flattening out, but parallelization and cloud-based solutions will allow us to keep expanding. A potentially disruptive technology of quantum computing is not expected to be available to engineers any time soon. Algorithm development has continued steadily and there is still room for improvements. With the availability of more data the application of neural nets will likely grow, but research interest seems to slow down. Neural nets will likely play a role in more traditional roles of pattern recognition for empirical elements of models, raw data analysis and generated data analysis. With the additional availability of data there is room for better analysis techniques such as PAT and a need for smarter storage, e.g. extracting the useful information before storing.

Abstract

Hydrogen losses in industrial waste gas streams, estimated as 10 billion Nm^3 per year in Europe, constitute potential sources for hydrogen recovery. Further use of this waste hydrogen in fuelled devices promotes a world powered by hydrogen while reinforcing the paradigm of the Circular Economy. This will require the availability of effective technologies for hydrogen recovery and purification as well as the techno-economic assessment of integrating the upcycled gas into a sustainable supply chain using decision-making tools. This work using a mixed-integer programming model (MILP), and scenario analyses, develops the techno-economic modelling over the 2020-2050 period, at a regional scale comprising the north of Spain. Two main industrial waste streams are considered; one produced at integrated steel mills and coke making industries and, the second one, at chlor-alkali plants. The proposed optimization model integrates the following items: i) technology selection and operation, ii) hydrogen demand forecast, iii) geographical information, iv) capital investment models, and v) economic models. The optimal solutions that arise from the combination of all the infrastructure elements into the mathematical formulation, define the gradual infrastructure investments over time that are required for the transition towards a sustainable future energy mix, including surplus hydrogen. The results confirm that the critical factor in the configuration of the proposed energy system is the availability of industrial surplus hydrogen, contrary to conventional hydrogen energy systems that are mainly controlled by hydrogen demand. Additionally, this study confirms that the optimal levelized cost of upcycled hydrogen is in the range of 0.35 to 1.09 €/kg H_2, which is 1.5 to 2 times lower than the price of hydrogen obtained by steam conversion of natural gas.

Keywords: Hydrogen recovery, surplus hydrogen, MILP optimization model, hydrogen infrastructure

1. Introduction

Hydrogen-based energy storage systems could play in the future a key role as a bridge between intermittent electricity provided by alternative sources and the common fossil fuel-based energy system. The versatility and unique properties of hydrogen open the way to accomplish this goal. Although in recent years, the prospects of a shift to a hydrogen economy have created great interest in the scientific community and social stakeholders, the success relies on the availability of the necessary infrastructures. A number of works focused on the use of decision-support tools for the design and operation of hydrogen

supply chains (HSC), have been reported addressing questions such as the design of the hydrogen fuel infrastructure applied at country, region and city levels [1–3].

Likewise, industrial waste streams with a hydrogen content higher than 50% are considered potential and promising sources for hydrogen recovery using cost-effective separation techniques [4]. Meanwhile, among the list of hydrogen-containing waste streams, some studies concentrated on the management, optimization, and utilization of steel-work off gases in integrated iron and steel plants [5,6]. However, little is focused on the optimization of various by-product gases to embed sustainability into HSC. To the best of our knowledge, reported optimization models for HSCs do not consider the competitiveness of upcycling hydrogen-rich waste gas sources for its reuse in both transportation and residential sectors. Hence, the originality of this study is to report the techno-economic feasibility of a HSC with contribution of upcycled hydrogen-rich waste gas sources to fuel both stationary and road transport applications [7].

2. Methodology

The methodology framework of this work is proposed in Figure 1. For that purpose, a mathematical formulation with the objective of maximizing the net present value (NPV) is proposed. The corresponding problem is stated as follows. Given:

- the potential sources for hydrogen recovery composition and their quality;
- a set of suppliers with their corresponding time-dependent maximum supply;
- locations of the key stakeholders in the target region: suppliers, merchants, and customers;
- a set of allowed routes between the three stakeholders, the transportation mode between them, the delivery distance between both routes; supplier-to-merchant and merchant-to-customer;
- hydrogen demand forecast by customer for both transport and residential sectors;
- raw material and product prices;
- a set of production, purification and conditioning technologies, and their yields to upgrade raw materials to hydrogen product, as well as their capacity at different scales;
- investment and operating costs of each intermediate technology, transportation mode, depreciation, and the residual values at the end of the time horizon;
- financial data (such as discount and tax rates).

The goal of the proposed model is to provide the optimum answer to the following questions: how much, where and when stakeholders shall make their investments. The outputs provided by the model are:

- optimal investment plan for all the merchants considered and related logistics;
- location (single- or multiplant), type, scale, and number of installed technologies.
- sourcing and supply routes for the raw materials and product considered;
- connections between the stakeholders, and hydrogen flows through the network.

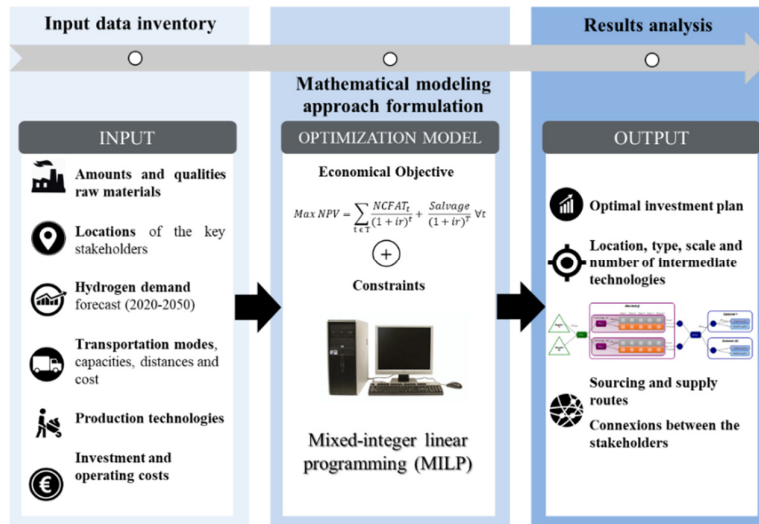
Within the network presented, the optimization model was developed by integrating the technology selection and operation, the hydrogen demand forecast, geographical information, capital investment models, and economic models.


Figure 1. Methodology to optimize a sustainable hydrogen supply chain

3. Optimization model

An optimization modelling approach based on multi-scenario MILP has been developed. The mathematical model was implemented in JuMP (Julia for Mathematical Optimization) and the optimization solver used was Gurobi 7.0.2. The objective of the model is to maximize the NPV over 30 years (2020-2050). Furthermore, the operational planning model regarding plant capacity, production transportation, and mass balance relationships, is considered together with the constraints of these activities.

Because of the complexity of the proposed model, a two-stage hierarchical approach has been used in order to solve the MILP model in reasonable computational time, achieving near-optimal solutions (5% optimality gap) in less than 2 h. The first step consists of the solution of a relaxed single-period problem to determine the location of production plants at the end of the horizon. From this initial assessment, merchant companies that are not selected in the first step are eliminated. Next, in the second step, the 30-year horizon problem is solved with a reduced set of merchants. The optimality gaps have been set to 2% and 5% for the first and second step, respectively.

4. Case study: Upcycled waste gas-based HSC for the North of Spain

This work is focused on the techno-economic feasibility of the upcycling of hydrogen-containing multicomponent gas mixtures to feed stationary and portable fuel cells using optimization tools, geographically located in the north of Spain. The proposed model is focused on two main industrial waste streams.

The first hydrogen source corresponds to high purity hydrogen off gases of the chlor-alkali industry denoted as raw material R99. The second most valuable by-product considered in the optimization model, is coke oven gas (COG) which is produced at integrated steel mills and coke making industries. Hereafter, this raw material has been denoted as R50 because the average hydrogen composition is between 36-62% vol.

Moreover, the geographic distribution of the future hydrogen market comprises a number of stakeholders that correspond to the three nodes of the hydrogen network, as illustrated in Figure 2. Suppliers, which are industrial companies that produce the surplus hydrogen. Merchants, which are the major industrial gases producers and responsible of the raw material transformation into the final product. However, surplus hydrogen transformation onsite was also considered at supplier's plant sites. Finally, the potential customers that are urban areas with more than a hundred thousand inhabitants.

4.1. Data collection

In this study, two scenarios concerning two levels of demand for road vehicle transportation and residential/commercial sectors have been considered (see Table 1) [8]. Regarding the intermediate technologies, steam methane, CH_4, reforming (SMR) with carbon capture and storage (CCS) has been considered as benchmark technology in order to satisfy the expected demand for hydrogen [9]. With regard to the upcycling of surplus hydrogen, we have selected a combination of two of the most mature technologies for hydrogen purification: membrane technology (MEM) followed by pressure swing adsorption (PSA) [10]. The final product P99, pure liquefied hydrogen, requires a liquefaction stage (LIQ.). Each plant type incurs in fixed capital and unit production costs, as function of its capacity. Furthermore, the transportation costs depend on the selected mode and distance [11]. We considered that raw materials are transported as compressed gas hydrogen (CH2) by tube trailer or pipeline (already installed), and the final hydrogen products are shipped as liquid hydrogen (LH2) by truck. We have considered the corresponding unit transportation cost for each type of hydrogen delivery mode.

Table 1. Demand scenarios of hydrogen market penetration by end users and timeframe

	Scenario (S)	End-use (e)	2020	2030	2040	2050
Hydrogen market penetration (%)	S1	e1: Transport sector	0.7	8.4	16.6	25.3
		e2: Residential/Service sector	0.0	0.7	3.0	6.7
	S2	e1: Transport sector	1.4	16.8	33.2	50.6
		e2: Residential/Service sector	1.0	6.0	10.0	13.5
Hydrogen demand	Total S1 (tons H$_2$ per year)		8.9E+03	1.2E+05	2.7E+05	4.6E+05
	Total S2 (tons H$_2$ per year)		4.0E+04	3.4E+05	6.3E+05	9.2E+05

4.2. Results and Discussion

This section shows the main results obtained by application of the proposed multiperiod mixed-integer programming model to the optimization of the network infrastructure for the fulfilment of low hydrogen demand (S1). The solution of the model determines: i) the amount of hydrogen-rich waste streams (R50 and R99) converted into liquefied hydrogen at the supplier's plants, and ii) the optimum SMR-CCS plant site locations.

Investment Network: Case S1 leads to a solution with a NPV of 941 MM , where the revenue derived from hydrogen sales (3370 MM€) is able to absorb the costs (2030 MM). No single hydrogen production method will be profitable to produce enough hydrogen to fulfil the expected demand on its own. The optimal solution of the integrated surplus HSC leads to the installation of ten units of different technologies until 2050 in northern Spain: W1 (7 units), W2 (2 units) and W3 (1 unit), as shown Table 2.

Table 2. Investment plan obtained for scenario S1

$j \in J$	Location	Period	Technology	Size (ton H2/year)	Investment (MM)
12	Asturias	2020	W3	50000	116.3
14	Huesca	2020	W2	1000	8
16	Cantabria	2020	W2	1000	8
6	Salamanca	2022	W1	200000	605.2
4	BCN (Rubí)	2028	W1	200000	605.2
7	Santander	2033	W1	200000	605.2
6	Salamanca	2037	W1	200000	605.2
5	Huesca	2041	W1	200000	605.2
6	Salamanca	2045	W1	200000	605.2
3	BCN (Parets del Vallés)	2048	W1	200000	605.2

Thus, decentralized on-site hydrogen production by the upcycling of industrial surplus hydrogen is the best choice for market uptake and for avoiding costly distribution infrastructure until the demand increases.

Surplus hydrogen flowrates: As summarized in Figure 3, in Case S1, the full amount of R99 is utilized with an inflow of 293.400 tons over the next 30 years, and R99 can meet 0.5% of the total hydrogen demand in the north of Spain for the whole time period. Whereas the amount of liquefied hydrogen produced from R50, which is 1.497.000 tons of R50, is able to cover a much larger hydrogen demand accounting for 10.1% of the total hydrogen demand. Consequently, the rest of the hydrogen produced to fulfil the total demand is obtained from CH_4 using SMR with CCS as benchmark technology while producing the least CO_2 emissions compared to the rest of the commercially available technologies.
Figure 3. Share of pure H_2 produced per raw material $r \in R$; ■ CH_4; ■ R99; ■ R50

However, the use of inexpensive surplus hydrogen sources may have a central role in the early phase of hydrogen infrastructure build up in the north of Spain. Therefore, industrialized hydrogen will also play an important role in initiating the transition to a hydrogen economy with localized plants of SMR with CCS; this will support the demand before expanding to less populous areas forming a more decentralized green hydrogen production. Analysing the surplus hydrogen flowrates by customer, it can be observed that though R50 is partially marketed to all final end-users, it has a pivotal contribution when the production of the final product is closer to the customers.

5. Conclusions

This research provides the methodology to assess the techno-economic feasibility of upgrading and reusing surplus hydrogen gases promoting the shift to the Circular Economy. The analysis has been performed over two scenarios of hydrogen demand (S1 and S2) and the results show that as long as both scenarios of hydrogen demand (S1 and S2) apply, all generated case studies lead to a solution with positive NPVs. The results confirm that the use of inexpensive surplus hydrogen sources such as R50 and R99 offers an economic solution to cover hydrogen demand in the very early stage of transition to the future global hydrogen-incorporated economy, especially when the industrialized hydrogen generation is closer to the demand markets.
