Figure 4. Dynamic change of the particle number on the middle actuator. (A) Open-loop control for relocating 15 particles. (B) Open-loop control for relocating 22 particles.

5. Conclusions and outlook

An automated open-loop control method for directed self-assembly using multiple actuators has been developed and experimentally validated in a microfluidic device. The method is illustrated with the control objective of transferring a specific number of particles from one control area to an adjacent control. The control approach has two main elements. First, a four-step framework can be utilized by engineering the different interactions between the particles and the electric fields. Second, an empirical model is used to describe the dynamics of the most critical step in that framework. The dynamic model is used to estimate the optimal actuation time for a given number of particles that need to be transferred to a different control area. The performance of two open-loop control experiments shows that the actually number of transferred particles is close to the targeted value. Since the involved interactions are generic, the approach can be applied to other small-scale objects such as nanoparticles or biological cells. Therefore, future work may focus on specific applications. The current framework may also provide a foundation for more comprehensive approaches to shape the particle density distributions over multiple control areas, which is needed for assembling complicated structures at the micro/nano-scale (Lakerveld et al., 2012; Solis et al., 2010). Finally, future work will involve using first principles for the development of the process model to improve the predictive capability of the model.

Divison of Sustainable Development, College of Science and Engineering, Hamad Bin Khalifa University, Qatar Foundation, Doha, Qatar

*talansari@hbku.edu.qa

Abstract

A continuous increase of anthropogenic greenhouse gas (GHG) concentrations in the atmosphere since the industrial revolution has been attributed to global climate change. Mitigation technologies, such as CO_2 Capture and Utilisation (CCU) is promising where by it can reduce the global environmental footprint of CO_2. In addition, CCU adds value to the producers by enabling the increase of exports of economically valuable products to the global markets. The objective of this study is to assess the integration of CO_2 utilisation in the existing processes and technologies to create economic opportunities within the State of Qatar. The study considers CO_2 capture and subsequent utilisation as chemical feedstock for several industrial applications. The methodology includes the development of a geospatial (network) optimisation model that comprehensively models the CCU infrastructure, from the CO_2 sources to sinks considering pipeline transportation routes in order to maximise the economic benefits of CO_2 utilisation. The methodology is primarily based on a techno-economic assessment and single-objective linear programming of the proposed CO_2 utilisation network which includes Methanol, Urea and Gas-to-Liquid industries. It considers the economic life cycle of the network at the plant-level and modelling the economic objective in terms of the net present value (NPV) and internal rate of return (IRR), implemented within a multi-period optimisation formulation. The results demonstrate that by applying back-testing using the market prices of value-added products, mainly for the urea, methanol, gasoline, diesel and wax for the period of 2005 - 2018, the optimal solution of the distribution and utilisation of CO_2 within the industrial network changes reach to 5.99 Mt/y, whilst considering the revenue functions as the network objectives vary from 1.17 to 3.99 Billion US dollar per year.

Key words: CO_2 Utilisation, Linear Programming, Methanol, Urea, GTL, NPV, IRR

1. Introduction

It is widely accepted that emissions of greenhouse gases (GHGs) have contributed towards global warming. Carbon Capture and Storage (CCS) and Carbon Capture and Utilisation (CCU) are considered promising technologies to control CO_2 emissions. CCU programs avoid the need to store CO_2 in underground storage sites which in many cases remain under research and development. Incidentally, CCU enables the creation of an ecosystem which encourages the recycling of CO_2 and conversion into value-added products, such as urea, methanol, cement, and other well-known applications in addition to its possible utilisation for enhanced oil recovery (EOR). Pérez-Fortes et al. (2016)

evaluated through a techno-economic analysis the potential to combine hydrogen with captured CO_2 from a coal power plant to produce Methanol product. Although, the system demonstrated a reduction in CO_2 emissions, the project was deemed financially unattractive due to the high price of hydrogen in relation to the market price of Methanol. Anantharaman et al. (2013) pointed out that most of the studies consider average steady-state flow of CO_2 from the source into the capture unit, as opposed to variable amounts of CO_2, which impacts the operations as well as the cost at the sink. The study concluded that to optimize the cost of capturing system, the trade-off between the CO_2 capture cost and the payment of the emissions cost or tax should be established. This will lead to the deployment of an optimal investment of the capturing system and assure steady state of the CO_2 mitigation profile. However, considering multiple sinks may overcome the cost of the CO_2 capture system and ensure the steady state of the CO_2 flow, according to King et al. (2013). They indicated that the CO_2 utilisation network comprising EOR sinks could be economically attractive taking into consideration low energy prices associated with the overall operations. The objective of this study is to evaluate the optimum pathways for network integration of CCU options, considering existing processes and technologies within the State of Qatar in order to create new economic opportunities. It considers a single CO_2 capture system located at the source with the highest CO_2 emissions, thereby reducing the CAPEX and OPEX of the required compression system and pipeline network. The methodology developed considers an optimisation framework utilising Linear Programming (LP) in order to determine the sinks that maximizes revenues/profits based on CO_2 allocations and market prices of value-added products. This approach was applied to the fertilizer, methanol and GTL plants located in Mesaieed and Ras Laffan industrial zones in Qatar.

2. Source and Sink Data for CCU system

The system considered comprises of a single CO_2 source, namely Qatar Gas (QG), and five potential sinks that have been identified for the economic utilisation of CO_2, namely: Qatar Fertilizer Company (QAFCO); two plants in Qatar Fuel Additives Company (QAFAC), one utilising natural gas, whilst the other utilising hydrogen; Oryx GTL; and Pearl GTL, all located in the Mesaieed and Ras Laffan industrial zones. The optimisation model was developed where the objective is to develop a profitable allocation plan for up to 25 years (assumed as the operating lifetime of the project) to maximize the total CO_2 captured and utilised, thereby achieving maximum economic benefits from all the sinks. The related costs for these include the capital cost of capture system and plants, including the equipments at the sinks, CO_2 compression and transportation, and other operating costs.

2.1. CO_2 Source Data

The CO_2 emissions from Qatar Gas is approximately 35.8 Mt/year (Sayeed, 2016). The capture of CO_2 is presumed to be via chemical absorption using amine solvents operating at 90% efficiency in which the assumed cost of the capture system is $40/t of CO_2 (Hildebrand, 2009). The estimated capital cost of the capture system is $169 million.

2.2. CO_2 Compression and Transport Data

Compression is needed to overcome the pressure drop in pipelines and to meet sinks pressure requirements. The unit cost of compression and transportation per 100 km of the pipeline is approximately $1.5/tCO_2$ (Herzog et al., 2004). In this study, the total cost of compression and transport to both QAFAC and QAFCO is approximately $0.5 million,

which is also the same for both Pearl GTL and Oryx GTL plants located in Ras Laffan. Considering that the distance between Messaid and Ras Laffan industrial zones is 100km, the capital cost was estimated according to the API 5L X60 and diameter 20".

2.3. CO_2 Sinks Data

Utilisation in GTL Plant (Pearl GTL and Oryx GTL)
In addition to the sinks considered by the authors in the previous study (Al-Yaeeshi, *et al.*, 2018), CO_2 can also be utilised within the GTL plants through the integration with the Fischer-Tropsch process (Rafiee et al., 2017), where the captured CO_2 is supplied into an auto-thermal reformer (ATR). For the case of Qatar, a CO_2 network consisting of both the Pearl GTL and Oryx GTL can be developed with an uninterrupted supply of pure CO_2 at the required flow rate and pressure. Furthermore, recycling some unreacted syngas to the reforming and F−T synthesis units can increase process efficiency and significantly reduce CO_2 emissions. In addition, the process can increase the output of products of gasoline, diesel, and wax therefore increasing plant revenue.

3. Methodology

The methodology developed in this work study is an extension of the previous models by Al-Yaeeshi, et al. (2018), where the optimised allocation was based on average prices of products in the CO_2 utilisation network. For this study, the LP formulation considers CO_2 allocation from QG to QAFCO, QAFAC with NG, QAFAC with H_2, Oryx GTL and Pearl GTL constrained by their utilisation capacities. The aim is to optimise the allocation in response to price variabilities of value-added products at the sinks, thereby maximising the overall revenue of the CO_2 utilisation network.

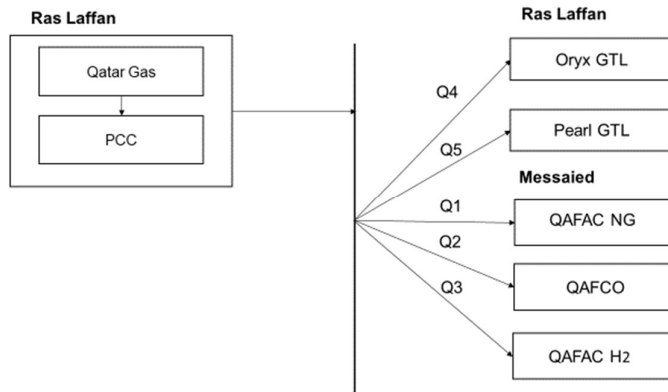

Figure 1 Proposed CO_2 utilisation network in Qatar

The decision variables used in the LP formulation are indicated in Figure 1. A detailed nomenclature of model parameters considered per industry within the CO_2 utilisation network are listed below:

Parameters related to Qatar Gas
- η: efficiency of CO_2 capture system = 0.9.
- e: CO_2 emissions rate = 15 Mt/year.
- C_1: cost factor incurred through CO_2 capture = $\eta \times e \times \$40/t\ CO_2$.

Parameters related to QAFAC (natural gas), QAFCO and QAFAC (Hydrogen), are available in (Al-Yaeeshi *et al.*, 2018). In this study, Revenue period formulation is added:
- R: Revenue factor from methanol = $\sum_{k=0}^{n} \left(\eta \times e \times q \times \frac{\$m}{t} \right)$, where n is the number of years, m is the price of the product and q is Amount of CO_2 required (kt/year) for each sink hence. In this work q is 0.6, 1.01, and 1.82 for R_2 (QAFAC NG), R_3 (QAFACO) and R_4 (QAFAC H_2) respectively

Parameters related to Oryx GTL
- D_5: pipeline distance from Qatar Gas = 5km.
- C_{51}: CAPEX of Reactors and utilities = \$2000 million.
- C_{52}: cost factor incurred through CO_2 transportation = $\eta \times e \times (d_5/100) \times \$1.5/t\ CO_2$
- R_5: revenue factor from Oryx GTL = $\sum_{k=0}^{n} \Big(\eta \times e \times ((0.0006c^2 - 0.2945c + 7662.5) * \frac{\$w}{t} + (-0.0006c^2 + 1.1319c + 1431.1) * \frac{\$d}{t} + (-0.0003c^2 + 0.2786c + 1237.1) * \frac{\$g}{t})) \Big)$
- Where n is the number of years and w, d, and g are the price of wax, diesel and gasoline respectively. In each formula, c is the desired production rate for product

Parameters related to Pearl GTL
- D_6: pipeline distance from Qatar Gas = 5km.
- C_{61}: CAPEX of Reactors and utilities plant = \$6000 million.
- C_{62}: cost factor incurred through CO_2 transportation = $\eta \times e \times (d_3/100) \times \$1.5/t\ CO_2$
- R_6: revenue factor from Pearl GTL = $\sum_{k=0}^{n} \Big(\eta \times e \times ((0.0006c^2 - 0.2945c + 7662.5) * \frac{\$w}{t} + (-0.0006c^2 + 1.1319c + 1431.1) * \frac{\$d}{t} + (-0.0003c^2 + 0.2786c + 1237.1) * \frac{\$g}{t})) \Big)^n$

Where n, c, w, d, and g are the years, desired production rate of products, prices of wax, diesel and gasoline respectively.

In addition to the reduction in CO_2 emissions, the main purpose is to optimize CO_2 allocations in order to maximize the economic returns within the utilisation network. Hence, the economic objective is given by:

Maximize {$Q_1 \times (R_2 - C_{11} - C_{21} - C_{22} - C_{23}) + Q_2 \times (R_3 - C_{11} - C_{31} - C_{32}) + Q_3 \times (R_2 - C_{11} - C_{41} - C_{42}) + Q_4 \times (R_4 - C_{11} - C_{51} - C_{52}) + Q_6 \times (R_5 - C_{11} - C_{61} - C_{62})$ }
subject to,
$Q_1 + Q_2 + Q_3 + Q_4 + Q_5 \leq 1$,
$Q_1 \times \eta \times e \leq 0.60 \times 10^6$,
$Q_2 \times \eta \times e \leq 1.01 \times 10^6$,
$Q_3 \times \eta \times e \leq 1.83 \times 10^6$,
$Q_4 \times \eta \times e \leq 0.36 \times 10^6$,

$Q_5 \times \eta \times e \leq 2.19 \times 10^6$,
$Q_1 \times (R_2 - C_{11} - C_{21} - C_{22} - C_{23}) \geq 0$ *(profit constraint QAFAC using natural gas)*
$Q_2 \times (R_3 - C_{11} - C_{31} - C_{32}) \geq 0$ *(profit constraints - QAFCO)*
$Q_3 \times (R_2 - C_{11} - C_{41} - C_{42}) \geq 0$ *(profit constraint - QAFAC using hydrogen).*
$Q_4 \times (R_4 - C_{11} - C_{51} - C_{52}) \geq 0$ *(profit constraints for Oryx GTL) and*
$Q_6 \times (R_5 - C_{11} - C_{61} - C_{62}) \geq 0$ *(profit constraints for Pearl GTL).*

In addition, the economic feasibility of the optimised network was evaluated using the Net Present Value (NPV) concept. The construction period and capital investment were assumed to occur in the first year, and the project life 15 years and the interest rate is 10%. The Internal rate of Return (IRR) is defined as the discount rate i at which the NPV equals to zero, and Profit to investment ratio (PIR) are part of the economic evaluation, hence;

$$NPV(t,n) = \sum_{t=0}^{n} (CF_t/(1+i)^t)$$

where CF is the cash flow, t is the year of the cash flow, i is the discount rate, and n is the total number of years.

$NPV \geq 0$ before year 15th ; IRR $\leq 20\%$; PIR≥ 0

4. Results

Table 1 indicates the optimum values for CO_2 allocations when the profit constraint is relaxed, i.e. the net revenue is maximised in the CCU network. Consequently, this also increases the annual rate of CO_2 utilisation by the sinks in the network.

Table 1. The profit constraints are relaxed.

Decision Variables (fractional amount of CO_2 from Qatar Gas)	% CO_2 Allocation
Q_1	0.045
Q_2	0.075
Q_3	0.14
Q_4	0.027
Q_5	0.16

The modelling results illustrate that when the CCU network optimisation is applied, a clear benefit is achieved in terms of generating revenues at the sinks, whilst reducing CO_2 emissions. The total CO_2 captured and transported to the sinks is 6.71 Mt/y, out of the annual emissions rate of 15 Mt/y, which corresponds to a 44.7%emissions reduction. As such, the model indicates that the CCU network is considered economically attractive when the prices of products, namely urea, methanol, wax, diesel and gasoline increases. Although it was expected that the main driver of the allocations are the product prices at the sinks, the allocation results in Table 1 were found to be constant for the period between 2005 – 2018. Furthermore, the economic evaluation yielded positive returns, as given below:
NPV = 4.43 Billion USD as the positive pay back starting between 2012 and 2013 (after 8 years)
PIR = 0.385
IRR = 16%

5. Conclusion

The modelling and analysis presented in this paper considers CCU technology to enhance the production of value-added products at the sinks such as methanol, urea, wax, diesel and gasoline, whilst reducing CO_2 emissions at the sources. The approach demonstrates the potential economic benefit of a proposed CCU network in Qatar whilst considering the market prices of value-added products. The price fluctuations of these products, however, does not significantly change the allocations in the CCU network, and as such the revenue maximisation by the network was directly linked to crude oil and commodities pricesIn addition, the economic feasibility of the network was also demonstrated by evaluating NPV, PIR and IRR which demonstrated a positive indication based on the optimal allocation for each sink although 40 % of CO_2 captured utilised. Future work will consider detailed environmental assessment in order to quantify CO_2 emissions in the network at the plant-level.

Abstract

The energy sector is undergoing a major transformation that is characterized by greater convergence of power, transportation, and industrial sectors and inter-sectoral integration. The existing techniques and tools are unable to accurately estimate the environmental impact of this paradigm shift. To develop a realistic understanding of these dynamics, we have developed a modeling framework that is designed to explore the emissions impacts of all relevant technological, operational, temporal, and geospatial characteristics of the evolving energy system. The tool is built as a MATLAB app that encapsulates MATLAB models, databases, and integrated process simulations. A modular framework constitutes the underlying analytical engine that covers all the life stages of major energy conversion pathways. The current version of the tool contains more than 900 individual pathways, which are responsible for ~80% of US greenhouse gas (GHG) emissions. Here wepresent an overview of the tool, the modeling approach and example results of case studies investigating electric power system.

Keywords: Life cycle analysis, multi-level analysis, energy systems modeling, computational tool, process simulation

1. Introduction

The global energy sector faces the grand challenge of meeting the increasing demand while profoundly reducing greenhouse gas emissions. Today's energy sector is responsible for approximately 80% of the world's total GHG emissions, and the electricity sector is the largest single emitting sector with 33% share. Industrial processes constitute 22% of emissions, while the transportation sector is responsible for 16% (Annual Energy Outlook 2018, 2018). Moving forward, the evolution of energy systems is characterized by greater convergence of power, transportation, and industrial sectors and inter-sectoral integration. Existing techniques and tools are unable to accurately estimate the environmental consequences of this paradigm shift. Understanding the implications of these dynamics requires novel tools that provide deep systems-level insights (Majumdar and Deutch, 2018). To address this pressing need, we have developed a modeling framework that is specifically designed to explore the emissions impacts of all relevant technological, operational, temporal, and geospatial characteristics of the evolving energy system.

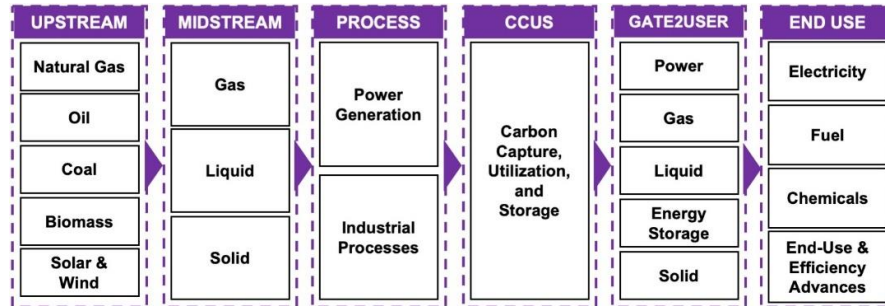
The tool is built as a MATLAB app that encapsulates MATLAB models, databases, and integrated process simulations. A modular framework constitutes the underlying analytical engine that covers all the life stages of major energy conversion pathways. The


Figure 1 Summary of the contents of the tool. All major conventional and renewable energy pathways with their associated end-uses covering more than 85% of GHG emission sources in the US are represented.

first version of the tool contains more than 900 individual pathways (Figure 1), which are responsible for ~80% of US greenhouse gas (GHG) emissions. For the GHG emission hot spots, such as power plants and some chemical conversion pathways, detailed process simulation capabilities have been incorporated for in-depth analysis. In addition to performing pathway-level life cycle analysis (LCA), a central aspect of this analytical framework is the ability to assess key systems interactions and couplings. The system-level analysis is enabled by the embedded power systems and vehicle fleet models that captures market dynamics and explore dynamics of technology adoption and usage.

This paper focuses on the overview of the tool, the modeling approach as well as the results of case studies investigating electric power system. We demonstrate how the changes in the operational variability of natural-gas fired power plants impacts the system-wide emissions. Specifically, the operation of NG power plants in the evolving power system that significantly reduces plant performance and increases the emissions footprint of NG power generation. Example results of analysis of power plant dispatch profiles and detailed life cycle analysis of the US power grid using high resolution plant level simulation models and incorporation of publicly available US-wide generation and emissions data are presented (U.S. EPA, 2018a, 2018b).

2. Methodology
A crucial aspect of this analytical framework is the ability to assess key systems interactions and couplings. This allows transition options to be comprehensively assessed on the same basis. To allow performing such comprehensive analyses, we have built a flexible and modular programming architecture specifically designed to evolve as the complex energy system restructures.

The modular approach composed of four main compartments at the very high-level: User input, Control panel, Life stage modules, and Model output. To initiate the computation the necessary input parameters such as selection of complete value chain, specifications of power grid mix, geographical location, and temporal resolution should be provided by user. Control panel module constitutes the core of the tool that takes user inputs and communicates with relevant life stage modules to send and receive information as shown in Figure 2(a). The results from each life stage module are adjusted and combined in accord with the user selections given by Eq. (1). The energy consumption by fuel type is used as the basis for calculations. The efficiency of each stage is accounted for in the

overall calculation denoted by ℓ. EF_i represents the emission factor from each stage given in the stage specific unit and χ is the conversion factor to adjust to the final unit. The results calculated as the sum of contribution from each stage is returned as output in desired unit and format.

$$EF = \sum_{i=1}^{6}(EF_i \times \chi_i)\prod_{j=1}^{i}1_j \qquad (1)$$

Each life stage module consists of sub-modules. Depending on options selected, different sets of submodules are activated in parallel with the real-world operation. For example, the bituminous coal upstream operation includes all steps of extraction described by the processes involved coupled with fuels and electricity consumed. The midstream and gate2user stages are characterized by the phase of the flow. Process step is represented with high resolution to include all feedstocks and energy flows. The detailed information and data are collected from published LCA literature, reports, publicly available tools and life cyle inventory databases such as technology baselines reports (DOE NETL, 2015), GREET model (Wang, 2011), ecoinvent database.

2.1. Modeling Approach

The described programming architecture and linked modules are implemented in MATLAB. We have augmented MATLAB's capabilities by integrating with Aspen Plus process simulation software (Gençer and Agrawal, 2017a). This approach allows complementing life cycle analysis with process simulation capabilities to capture the performance and emission changes arising from technological and operational variations. It is computationally very expensive and unnecessary to simulate every process for all potential conditions. However, the developed architecture provides a platform to implement simulations of process units with high emission rates, critical for the system design, or sensitive to externalities.

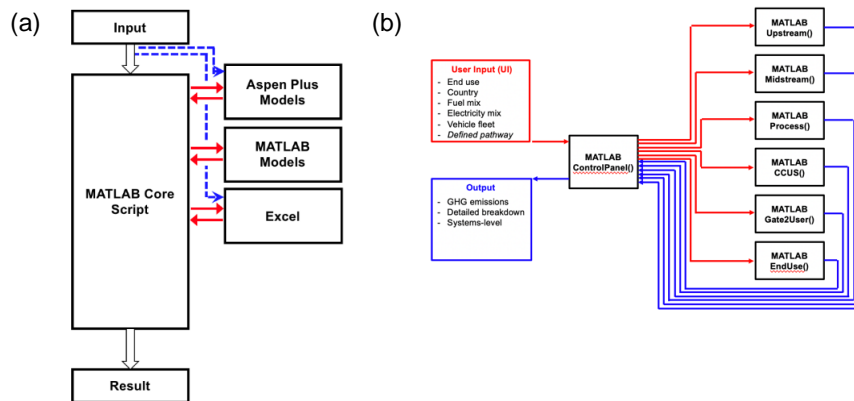

Figure 2 (a) The tool is developed in MATLAB with the added capabilities of communicating with various modeling programs such as Aspen Plus. (b) The modular structure: control panel connecting to primary life stage modules.

Figure 2(a) depicts the communication between MATLAB Core Script and auxiliary components: MATLAB Models, Aspen Plus Models, and Excel models and databases.

As needed, the tool can be equipped with more programming platforms. MATLAB is used to develop life stage modules, each one of which has its unique structure. Each module is composed of numerous custom developed MATLAB functions. Functions are designed to minimize the repetition of same scripts and framed clearly separate different tasks.

Natural gas fired power plants play a critical role in the evolving electric power system

Figure 3 Process flow diagram of natural gas combined cycle unit simulated in Aspen Plus to match the performance of GE's 7FA model.

both as a lower carbon intensity alternative to coal power plants, and as balancing capacity for variable renewable energy sources. Power plant performance is sensitive to parameters such as percent loading, ambient temperature and relative humidity. To have a representative characterization of power generation units, we have developed Aspen Plus simulations for the most widely used combined cycle and gas turbine units. The performance of models is validated using the manufacturer's catalogs (Chase and Kehoe, 2013). Simulations represents steady-state operation at various conditions including percent loading (Gençer and Agrawal, 2017b).

3. System Boundaries

Pathway level analysis constitutes the backbone of the computation engine. The platform is capable of calculating all the combinations of modules, presented in Figure 1, that form a meaningful pathway. The individual pathways can be further expanded with the addition of new modules. Cradle-to-grave system boundary for every complete pathway is set and the selections are limited to allowed components. System boundary for coal-to-electricity pathway is shown

Figure 4 Coal-to-electricity pathway system boundary.

Figure 5 (a) GHG emissions from the flue gas of NGCC for varying loadings. (b) Cradle-to-grave life cycle emissions of shale gas-to-power pathway for 100 % and 40 % of the nameplate capacity of NGCC unit.

in Figure 4. For every life stage, there are multiple options that can be selected such as the coal type (bituminous or subbituminous), the transportation method of coal (truck, rail, or ship). Combination of these alternatives can also be specified.

3.1. Representation of Systems
Pathway-level analysis provides valuable insights however, understanding system wide emissions impact is critical. The presented modular framework is designed to perform systems-level calculations. A system is defined as a collection of individual pathways. This approach allows performing high resolution LCA based upon detailed individual pathways embedded. System can be as small as two pathways and as large as a city or a region. To determine the minimum emission option, the problem can be optimized using genetic algorithm (Gençer et al., 2015; Liu and Bakshi, 2018).

4. Results

The model can be run in pathway level or systems-level modes. The pathway level calculations are performed to estimate the life cycle GHG emissions in a given system boundary. The impact of cycling for NGCC plants is explored. Simulation results for 40 % to 100 % loading relative to nameplate capacity for a NGCC unit is shown in Figure 5(a). The emission rate increases from 362 kgCO$_2$/MWh to 419 kgCO$_2$/MWh when the power output is reduced to 40 %. The emission impact of this variation is propagated to

Figure 6 Hourly LCA based on observed load profile of a NGCC unit in California.

all life cycle stages of the supply chain. Cradle-to-grave life cycle analysis for the two extreme cases are performed and results are summarized in Figure 5(b). The emission intensity increases by 15.3 % relative to operation at peak efficiency. Using the embedded hourly generation profiles of thermal generation units a life cycle emissions of generators in the US has been calculated. Results for a combined cycle unit in California (Dynegy Moss Landing Power Plant Unit 1A) is shown in Figure 6, the area graph shows the hourly electricity generation and dots are the calculated full life cycle emissions in tCO_2e. For this particular unit, we observe more than 40% fluctuations in total emissions. While one reason for this change is the lower net generation, the other reason is higher emission intensity operation due to operation at off peak mode.

5. Conclusions

The adoption of a holistic approach is increasingly important to accurately characterize the energy system. Here, we have demonstrated a novel tool to integrate the systems aspect for the conventional life cycle analysis. The underlying analytic engine constitutes of numerous individual energy pathways. The developed tool provides a consistent platform to estimate LCA of all components of the energy sector. Furthermore, the system representation is embedded into the tool for power and transportation sectors. LCA of power generation at hourly generator level resolution is estimated by integrating calculated performances from process simulations.

Contract Settlements for Exchanging Utilities through Automated Negotiations between Prosumers in Eco-Industrial Parks using Reinforcement Learning

Dan E. Kröhling, Ernesto C. Martínez[*]

INGAR (CONICET-UTN), Avellaneda 3657, Santa Fe, S3002 GJC, Argentina

Abstract

Peer-to-peer trading of utilities (heating, cooling and electric power) in an eco-industrial park (EIP) is key to realize significant economic and environmental benefits by exploiting synergistic co-generation and surplus trading. A crucial aspect of this symbiotic scheme is that each selfish company (prosumer) will participate in exchanging utilities to increase its own profits depending on its internal load. In this paper, an automated negotiation approach based on utility tokens is proposed to incentivize participation in a market of prosumer peers for trading surpluses in an EIP. During each negotiation episode, a pair of prosumers engage in a bilateral negotiation and resort to a learned policy to bid, concede and accept/reject using both private information and environmental variables. Contract negotiation revolves around agreeing (or not) on the price expressed in tokens of a utility profile. The time-varying value of the utility token accounts for contextual variables beyond the control of each prosumer. Simulation results demonstrate that reinforcement learning allows finding Nash equilibrium policies for smart contract negotiation in a blockchain environment.

Keywords: automated negotiation, blockchain, reinforcement learning, smart contracts.

1. Introduction

An EIP mainly consists of distributed co-generation (e.g. heating, cooling and electric power), shared storage systems and flexible/distributed demand/supply of intermediate products and waste materials (Chertow, 2007; Nair et al., 2016). A key aspect of this symbiotic scheme is that each potential partner company will only participate in exchanging utilities through loans or credits with the motivation of increasing its own profits. The selfish nature of each prosumer thus results in a conflict of interest which, if not resolved, may give rise to the failure of the EIP (Chew et al, 2009; Tan, et al., 2016). It is argued here that the Blockchain approach based on a distributed ledger (Sikorski et al., 2017) and smart contracts (Kristides and Devetsikiotis, 2016) can be used to foster decentralized, peer-to-peer automated negotiations between prosumer companies that want to trade their utility surplus with other peers in the park. Considering heterogeneous prosumer preferences, which are private information, each peer company (represented by a software agent) should learn to negotiate how to bid and what to accept in utility contract settlements by properly accounting for its context including weather, scheduled utility loads, season, oil prices, mood of the economy, etc. The strategic behavior of a prosumer (proactive consumer actively managing its consumption and production of different types of utilities) in EIPs depends significantly

on the influence of these environmental conditions or contextual variables on its negotiation policy, since they affect not only a given agent preferences and decision-making policies, but also those of other agents. A novel context-driven approach for policy learning in automated peer-to-peer negotiations between prosumers of an EIP is proposed. Reinforcement learning (Sutton and Barto, 2018) is key to learn negotiate utility contracts via simulation by properly accounting for most relevant environmental variables, other peer negotiation policies, their models and contextual information, which provides each prosumer agent a competitive edge while incentivizing its participation in an EIP near to Nash equilibrium conditions with other prosumers.

2. Peer-to-peer negotiations of utility contracts

Utility prosumers are agents that both consume and may produce different types (heating, cooling and electric power) of utilities in an EIP. Each prosumer company is assumed to be equipped with one or more utility generation means (e.g. a boiler, solar panel, freezer, heating/quenching streams, etc), has a scheduled profile load and, possibly, a temporary surplus for some of its internal generated utilities and extra needs for other utilities. Peer-to-peer local trading of such surpluses by taking advantage of material and energy integration in an EIP gives rise to unique opportunities to lower emissions and reduce energy costs.

Each company in the EIP is modeled as a software agent, $i \in N$, where N is the set of engaged prosumer agents in the peer-to-peer utility market of the EIP at time t. It is assumed that, depending on the utility needs for their scheduled load and surplus, if any, each agent negotiates buying/selling utility profiles and their prices in tokens (τ_t). For example, in Fig. 1 agent A, at time t, seeks and agreement with agent O_3 to sell part of its heating power. Concurrently, agent A aims to buy renewable electric power from agent O_1 and some cooling from agent O_2. The context for these negotiations is private information (X_i) and environmental variables (Y_j). The specific type for an agent i is summed up in state variable v^i, known as "necessity", whereas its external context is given by a "risk" ρ^i. Each agent necessity accounts for the needs and surplus derived from capacity slacks and scheduled usage loads. In turn, risk accounts for the different factors that may influence the current and future values of the token $\tau_t, \tau_{t+1}, \dots, \tau_{t+H}$.

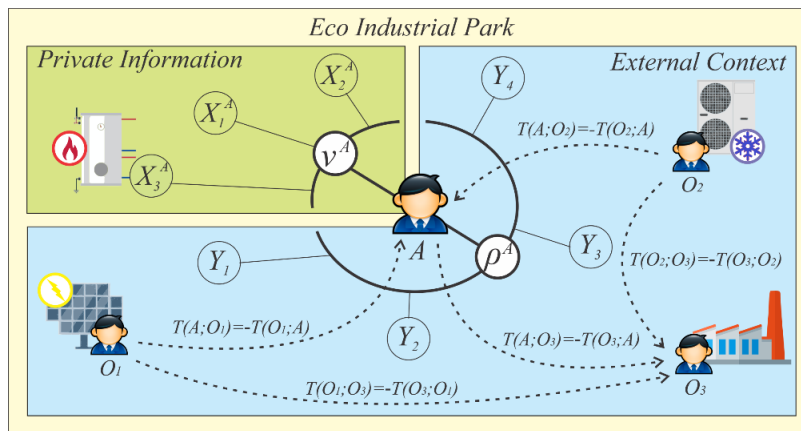

Fig. 1. Peer-to-peer negotiation setting at time *t* for utility surpluses in an EIP.

From the point of view of a central EIP authority, the exchange utility problem requires maximizing the overall value of surplus traded assuming perfect information about both public variables and private prosumer types, that is, their necessities and risks as follows

$$Max \sum_u \sum_t \sum_i T_t^u(i; -i) \tag{1}$$

subject to:

$$T_t^u(i) + T_t^u(-i; i) - T_t^u(i; -i) \geq NCT_t^u(i) \quad \forall i, u, t \tag{2}$$

$$T_t^u(i) + T_t^u(-i; i) - T_t^u(i; -i) - NCT_t^u(i) = MCT_t^u(i) - SCT_t^u(i) \quad \forall i, u, t \tag{3}$$

$$T_t^u(i; -i) \leq SCT_t^u(i) \quad \forall i, u, t \tag{4}$$

$$T_t^u(i), T_t^u(i; -i), NCT_t^u(i), MCT_t^u(i), SCT_t^u(i) \geq 0 \quad \forall i, u, t \tag{5}$$

where each variable represents:

- $T_t^u(i)$, the total amount of utility u in tokens traded by agent i at time t.
- $T_t^u(-i; i)$, the amount of u in tokens bought by i to all other agents $-i$ at time t.
- $T_t^u(i; -i)$, the amount of u in tokens sold by i to all other agents $-i$ at time t.
- $NCT_t^u(i)$, the overall power of u in tokens required by i in t to fulfil its necessity.
- $MCT_t^u(i)$, the max power of utility u in tokens that i could produce at time t.
- $SCT_t^u(i)$, the surplus capacity of u in tokens that i is ready to sell at time t.

The problem aims to maximize the number of tokens (utilities) traded between agents. This gives rise to a maximization of the EIP's social welfare while minimizing the surplus capacity loss over time, considering the maximum power per agent, its internal generation and scheduled usage. The assumption of a perfectly informed central authority is unrealistic in the selfish, competitive environment of any EIP. Prosumers are reluctant to provide their private information when behaving strategically.

3. Learning to negotiate

Bilateral negotiations between two agents using a discrete timeline will be used. The alternating offers protocol is used throughout. We will use a technique widely known, namely Reinforcement Learning (or RL) (Sutton and Barto, 2018). Prosumers in an EIP will learn to negotiate better by simulating negotiation episodes against each other using the Q-Learning algorithm and accumulate their experience rewards in a decision policy. A prior work on prosumers' negotiation can be found in (S. Chakraborty et. al., 2018).

The Q-Learning algorithm consists of a function that estimates the expected cumulative rewards for future time steps in negotiation episodes given the actual state s_t each agent is in, if it chooses for a certain action a. Which action to take is determined by the negotiation policy π derived from the Q-values. At the end of each episode, an agent receives the reward r which allows updating Q-values. To this aim, the learning rule is:

$$Q(s_t; a_t) = Q(s_t; a_t) + \alpha * [r_{t+1} + \gamma * max_a Q(s_{t+1}; a_t) - Q(s_t; a_t)] \tag{6}$$

Each state for the ith prosumer agents is defined by the tuple:

$$s = (v, \rho) \tag{7}$$

where v and ρ, as defined before, are the necessity and risk associated with the perceived state by an agent, including the token value and its utility needs/surplus.

Each action during the negotiation episode, on the other hand, will be defined by:

$$a = (RV, \beta) \tag{8}$$

where RV is the reserve value of the negotiation, that is, the worst agreement an agent is willing to accept, and β is the concession rate, or the way it concedes in negotiations.

The Q-learning algorithm hyper-parameters, as defined commonly in the literature, are set to $\alpha = 0{,}1$ and $\gamma = 0{,}9$. ε, that measures how much our agent will take random actions to explore different options, starts at 1 and slowly decreased towards 0. Next, we define the way our agents compute necessities and risks out of their context, considering time t as one entire trading day. Necessities will be given by:

$$v_t^b = 0.5 * g_t(e_t + p_t) + 0.3 * g_{t+1}(e_{t+1} + p_{t+1}) + 0.2 * g_{t+2}(e_{t+2} + p_{t+2}) \tag{9}$$

$$v_t^s = su_t \tag{10}$$

For the buyer, g_t is the probability of rescheduling production tasks at time t; e is the amount of energy needed for the period and p is the maximum utility power required. For the seller, su_t is the surplus utility capacity or power it has available to trade. The risk may be similar for both agents, but, as defined, when the risk is low, the buyer is in a stronger position, whereas when the risk is high, the seller is in a stronger position.

$$\rho_t = season_t * \tau_t \tag{11}$$

where $season_t$ represents the variability of demand and τ_t, the price of the token.

4. Simulation results

4.1. The nature of the negotiation learning process

In Fig. 2 is presented the learning experienced by prosumer agents via simulating negotiation episodes against each other. It is worth noting the random nature of the learning process in negotiation episodes as it is shown in the 10000 simulated outcomes and the rewards obtained by the agents. This is mainly due to a rather unknown context and private information our agents must deal with. Simulations with diverse environmental contexts were conducted, varying utility or maxim power needed, possibility of rescheduling tasks, seasonality influence and the token price. The average trend highlights how negotiating agents increasingly obtain better deals as simulations makes room for learning to concede and accept. From the sparsity of rewards obtained it seems contextual information influence less to the seller than to the buyer. In the latter, greater risks are at stake when a contract is not settled in due course.

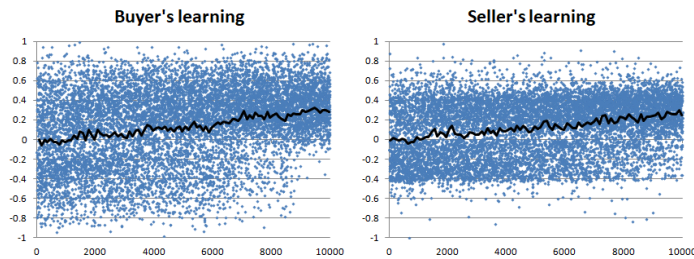

Fig. 2. Agents learning via simulation of negotiation episodes.

4.2. Reward functions

In Fig. 3, the functions used for rewarding negotiation outcomes of prosumer agents are shown. In the graph of the buyer's rewards when agreements are reached, it can be clearly perceived the importance of considering the risk ρ involved in the negotiation (the price τ of the token and the seasonality), given its reward function. On the other hand, it is very important for this agent to consider its necessity ν when it decides not to agree, as rewards strongly depend on such private information and the possibility of rescheduling tasks and changing the utility load by levelling power peaks.

Similarly, for an agent in the role of a seller, its necessity and risk should be taken almost equally into account when deciding to agree the terms of an offer, but the agent deems better considering mainly its perceived risk when not agreeing. Such a reasoning helps illustrate the importance of correctly designing a reward function for guiding negotiation agents about what to bid, when to concede, what to accept or reject in contract settlements by considering what is at stakes in different scenarios.

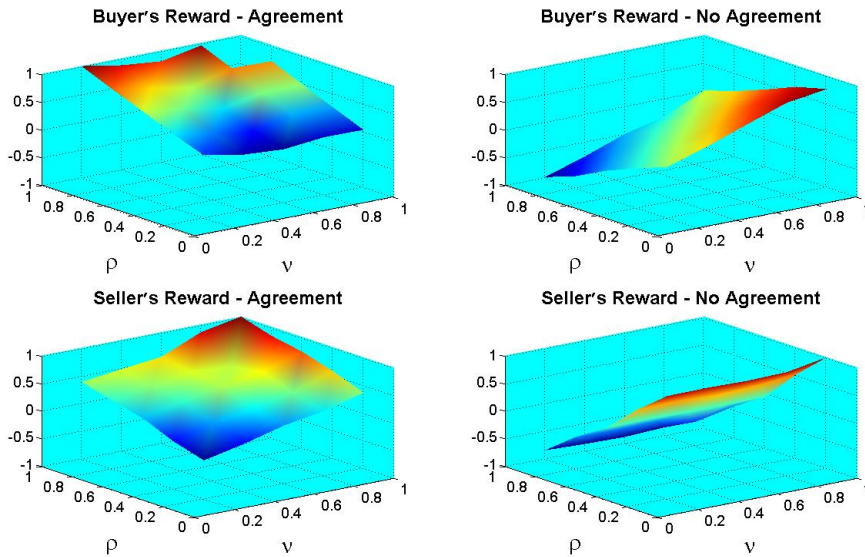

Fig. 3. Rewards for prosumer agents in different environmental contexts.

4.3. Agents' policies

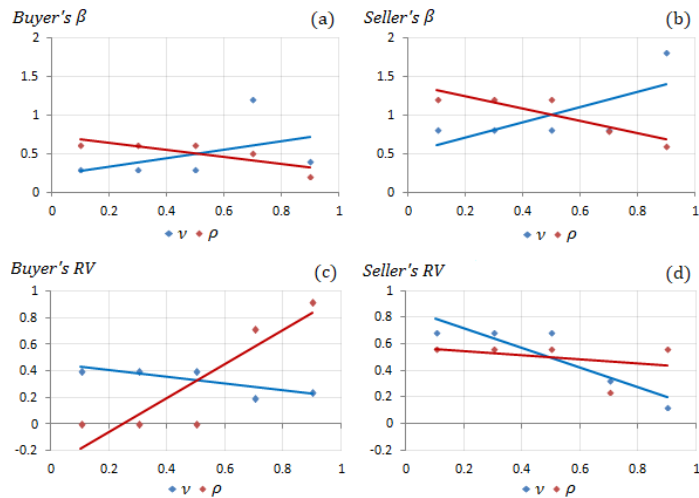
In Fig. 4, the policies learned by prosumer agents are shown. Given ν and ρ, agents behave differently depending on their role (buyer or seller). From a buyer's point of view, it will concede more slowly (β) and less (RV) as its perceived risk is higher, but it will concede faster and more as its necessity increases. From a seller's point of view, it will concede more slowly and to a lesser extent as its perceived risk is higher. Conversely, it will concede more quickly and to a lesser extent as its (internal) necessity increases. Having a near optimal policy for negotiating smart contracts is key for automating utility exchanges and incentivizing prosumer to participate in a peer-to-peer market. Social welfare in industrial parks is heavily dependent on negotiation policies that generate win-win deals that lower capital costs and carbon emissions.


Fig. 4. Behavior of negotiation agents in different scenarios.

5. Conclusions

The importance of learning to negotiate utility surpluses in eco-industrial parks where prosumers do have private information has been addressed. Simulation results highlight that reinforcement learning is key to learn negotiation policies based on each agent internal necessity and the perceived risk in its environment. The proposed approach can be readily implemented using the Blockchain technology, industrial internet of things and smart contracts to enforce the agreed upon terms automatically.

Abstract

In this paper, we investigate the Max-Plus-Linear (MPL) representation for the integration of scheduling and control problem. This is an attractive approach because the MPL representation can result in a convex scheduling problem. Using this representation, we have formulated the integration of scheduling and control problem considering the corresponding transitions time for each processing time. Furthermore, the MPL representation is combined with the sequential decomposition method (SDM) (Chu and You (2012)) in order to solve the integrated problem. The final result is a formulation that preserves the convexity of the original scheduling problem. Finally, the performance of the new formulation is tested on a simple case study and compared with the traditional method.

Keywords: Integration, Scheduling, Control, Max-Plus-Linear Systems

1. Introduction

Scheduling and control are complementary tasks for optimizing chemical process operations. Traditionally, these tasks have been implemented separately in a sequential way. Scheduling problems, whose solutions provide the optimal production sequence and production times, do not in general consider the dynamic behavior of the processes. The inclusion of such dynamics in the scheduling problem is called the integration of scheduling and control, and it has shown important economic benefits for the overall performance of the process. Despite the advantages of the integration, several challenges have been also reported. Nevertheless, the most critical issues are the modeling approach used in the scheduling problem and the computational aspects. Both topics are strongly related.

There are several approaches to model the scheduling problem i.e. the state-task network (STN) or resource-task network (RTN). These modeling options lead to transforming the integration of scheduling and control into an MINLP problem which is relatively computationally expensive (Chu and You (2012), Subramanian et al. (2012)). An attractive approach to avoid the MINLP formulation is modeling the scheduling problem using the MPL representation (Schutter and van den Boom (2001), van den Boom et al. (2018)). There are a lot of advantages of the MPL representation. The most remarkable one is that the scheduling problem can be transformed into a convex optimization problem. In addition, the MPL representation has not been investigated for the integration of scheduling and control problem.

In this paper, we assume a perishable goods scheduling problem and no disturbances affecting the completions of the tasks. Based on these assumptions, we propose an approach to formulate an integrated problem of MPL scheduling and control, and methods to solve the problem.

This paper is organized as follows. In Section 2, preliminaries related to the control problem and the MPL system are presented. Section 3 presents the formulation of the integration of scheduling and control using the MPL representation. The details on the new proposed methods to solve the integrated problem are presented in Section 4. The proposed formulation and solutions are demonstrated on a simple case study and compared in Section 5. Finally, the conclusion is given in Section 6.

2. Preliminaries

2.1. Max-Plus Linear (MPL) system

The MPL utilizes timed-discrete event system (timed-DES) in the modeling of time (Schutter and van den Boom (2001)). A max-plus-algebraic (MPA) model, called MPL system, can represent timed-DES with no concurrency, where we assume no capacity constraint and each unit starts working as soon as all parts or conditions are available. The general form of MPL scheduling model is as follows:

$$\breve{x}_i(k) = \breve{A}_i \otimes \breve{x}_i(k-1) \oplus \breve{B}_i \otimes \breve{u}_i(k); \quad \breve{y}_i(k) = \breve{C}_i \otimes \breve{x}_i(k) \tag{1}$$

where $\breve{A}_i \in \mathbb{R}_\varepsilon^{n_{x_i} \times n_{x_i}}, \breve{B}_i \in \mathbb{R}_\varepsilon^{n_{x_i} \times n_{u_i}}$, and $\breve{C}_i \in \mathbb{R}_\varepsilon^{n_{y_i} \times n_{x_i}}$ are system matrices configured by all units contributing in production line i. $\otimes$ is equal to operator "+" and $\oplus$ is equal to operator "max". In Eq.(1), the components of the input, the output, and the state are event times, and the counter k is an event cycle counter. For a process system, $\breve{u}_i(k)$ would typically represent the time instants at which raw material is fed to the system for the $(k+1)^{th}$ time, $\breve{x}_i(k)$ represent the time instants at which the unit start processing the kth batch of intermediate products, and $\breve{y}_i(k)$ represent the time instants at which the kth batch of finished products leaves the system (completion time).

2.2. Control Problem

We consider a batch reactor as a plant model equipped with controllers to reach an optimum set point. The controller(s) of each unit, i.e. MPC or PID can be expressed in general as: $u = K(x, t_s)$, where u, x and t_s are the input, states and the transition time of a processing unit, respectively. For example, a PI controller can be expressed as: $u = K_P(Cx - y^{sp}) + K_I \int (Cx - y^{sp})$, where y^{sp} is the optimal set point of a processing unit given by the Real-Time Optimization (RTO). The parametrization of the controller(s) in terms of the transition time can be done because the tuning parameters are a function of t_s. In the planning layer, where the planning decisions are taken, a set of transitions times has been determined based on the historical data. This set is expressed as: $\widetilde{t_s}^{(\mathbf{l})} = \{t_s^{(1)}, \ldots, t_s^{(n_l)}\}$, where l is the index of the reachable transition time.

The presence of transition time influences the accuracy of the scheduling policy. Thus, the controller is also responsible for reaching and tracking the given transition time that is regulated by controller parameters $\Omega_{i,ii}^{(l)}$ (e.g. $\Omega_{i,ii}^{(l)} = \{K_P, K_{I_{i,ii}}^{(l)}\}$ for PI controller), where

i is the production line and ii is the index of the unit contributing in line i. The controller parameters can minimize the difference between given transition time and the transition time obtained by an off-line simulation $\bar{t}^l_{s_{i,ii}}$. This simulation is only executed once at the beginning and it requires the dynamic behavior of the closed-loop control system that depends on three parameters: the initial condition value $y_{0i,ii}$, the set point $y^{sp}_{i,ii}$, and the controller parameters $\Omega^{(l)}_{i,ii}$ (Chu and You (2012)). Moreover, it also depends on three numerical parameters: the tolerable bound width of steady output condition $b_{i,ii}$ [in %], sampling time T_s, and the prediction horizon $N_{MPC,ii}$ for MPC controller. Thus, $\bar{t}^{(l)}_{s_{i,ii}} = f(\Omega^{(l)}_{i,ii}, y^{sp}_{i,ii}, y_{0i,ii}, b_{i,ii}, T_s, N_{MPC i,ii})$. After minimizing this difference, we assign the optimal controller parameters $\Omega^{(l)\star}_{i,ii} \to \Omega^{(l)}_{i,ii}$. Thus, we have the following set of controller parameters $\widetilde{\Omega}^{(1)}_{i,ii} = \{\Omega^{(1)}_{i,ii}, \ldots, \Omega^{(n_l)}_{i,ii}\}$. From the same calculation, we can also estimate the set of transition cost $\widetilde{\delta}^{(1)}_{i,ii} = \{\delta^{(1)}_{i,ii}, \ldots, \delta^{(n_l)}_{i,ii}\}$. This computation is part of Algorithm (1).

Data: Historical data, Closed-loop system dynamic model
Result: $u^\star_{i,ii}(t)$
Get transition set: $\{\widetilde{t}^{(1)}_{s_{i,ii}}, \widetilde{\Omega}^{(1)}_{i,ii}, \widetilde{\delta}^{(1)}_{i,ii}\} \leftarrow$ Execute simulation (Off-line computation) ;
$k = 1$;
while $k \leq$ *the total amount of production cycles* **do**

    procedure: Execute selection algorithm for all units ii (see Tab. (1));
        Identify the relation of $\{\widetilde{t}^{(1)}_{s_{i,ii}}, \widetilde{\delta}^{(1)}_{i,ii}\}$;
        Get $\{t^{(l)\star}_{s_{i,ii}}(k), \Omega^{(l)\star}_{i,ii}(k)\}$;
    Update (Integrated) MPL scheduling model (Eq. (3)): $t^{(l)}_{s_{i,ii}}(k) \leftarrow t^{(l)\star}_{s_{i,ii}}(k)$;
    Get $\breve{u}^\star_i(k) \leftarrow$ Solve Eq. (5);
    Controller $\leftarrow \{\breve{u}^\star_i(k), \Omega^{(l)\star}_{i,ii}(k)\}$;
    Get $u^\star_{i,ii}(t) \leftarrow$ Solve control problem from $t = \breve{u}^\star_i(k)$ to $t = \breve{y}^\star_i(k) - t_{e_{i,n_s}}$;
    (i, n_s indicates the last unit in the production line i);
    $k = k + 1$;
end

Algorithm 1: Sequential Decomposition Method

3. Integration of Scheduling and Control using MPL Systems

3.1. Batch scheduling problem

Batch scheduling problems typically have decision variables i.e. starting time. Currently, many scheduling problems are represented in the conventional algebra. This study focuses on the MPL scheduling problem called due date perishable goods which is a convex optimization problem (Schutter and van den Boom (2001)). If the due dates for the finished products are known, every difference between the due dates and the actual output time instants has to be penalized. Hence, the suitable cost criterion takes the following form: $J(k) = \bigotimes^{N_p}_{j=1} \bigotimes^{n_p}_{i=1} |\breve{y}_i(k+j|k) - \breve{r}_i(k+j|k)|$; where $\bigotimes^Q_{q=1}$ is equal to $\sum^Q_{q=1}$, N_p is the length of prediction horizon and $\breve{r}$ is the expected completion time. The standard

MPC for the MPL systems scheduling problem is introduced as follows:

$$\min_{\mathring{\mathbf{u}}_i(k)} J(k) \tag{2}$$

where $\mathring{\mathbf{u}}_i(k) = \begin{bmatrix} \breve{u}_i(k|k) & \dots & \breve{u}_i(k+N_p|k) \end{bmatrix}^\top$ and Eq. (2) is subject to: MPL scheduling model shown in Eq. (1) and scheduling linear constraint for N_p horizon, time as a non-decreasing input, and starting time constraint regulation. A well-developed MPC theory for MPL system has also been introduced (Schutter and van den Boom (2001)). Moreover, the study of MPL convexity has been conducted.

3.2. Integrated scheduling model

In a stand-alone scheduling problem, the transition time is assumed to be '0'. The presence of transition time cannot be ignored; therefore, the decision variables of scheduling problem should cope with the existence of the transition time. The scheduling problem requires information of the reachable transition time from all control problems, while a control problem in each cycle needs the optimal transition time and the set-points. As an additional information, the control layer interacting with scheduling layer can be a local, a supervisory control or the combination of both.

For simplicity reasons, this study considers a single product that is manufactured cyclically in a processing unit for a certain processing time $t_{p_{i,ii}}$ so that the completion time of product satisfies the due date at every cycle given by the planning layer.

In MPL model, we can modify Eq.(1) to facilitate the existence of transition, filling time $t_{f_{i,ii}}$ and emptying time $t_{e_{i,ii}}$ and represent the integrated MPL scheduling model as follows, where the filling and emptying times are usually constant:

$$\breve{x}_i(k) = \breve{A}_i(t_{s_{i,\mathbf{ii}}}^{(l)}) \otimes \breve{x}_i(k-1) \oplus \breve{B}_i(t_{s_{i,\mathbf{ii}}}^{(l)}) \otimes \breve{u}_i(k); \qquad \breve{y}_i(k) = \breve{C}_i(t_{s_{i,\mathbf{ii}}}^{(l)}) \otimes \breve{x}_i(k) \tag{3}$$

To accommodate an economic objective, we introduce a total cost ω consisting of due date deviation penalty cost ω_1, total production costs ω_2, and total transition costs ω_3 related to $\delta_{i,ii}^l$. The relationship between $\widetilde{t}_{s_{i,ii}}^{(\mathbf{l})}$ and $\widetilde{\delta}_{i,ii}^{(\mathbf{l})}$ will define the approach to minimize ω.

$$\omega = \omega_1 \otimes \omega_2 \otimes \omega_3 \tag{4}$$

4. Proposed algorithms

By means of off-line computation explained in Section 2.2, we obtain a set containing achievable transition times, their associated controller parameters, and transition costs: $\{\widetilde{t}_{s_{i,ii}}^{(\mathbf{l})}, \widetilde{\Omega}_{i,ii}^{(\mathbf{l})}, \widetilde{\delta}_{i,ii}^{(\mathbf{l})}\}$. In general, the integrated problem can be solved either sequentially or simultaneously. In this study, we utilize SDM, illustrated in Fig. (1) and described in Algorithm (1).

SDM consists of two steps in order to solve two main problems. The first problem is determining the element inside $\widetilde{t}_{s_{i,ii}}^{(\mathbf{l})}$ leading to the most (economically) optimal result (see Eq. (4)) by selecting the associated controller parameters. The idea of selection algorithm which is described in Tab. (1) consist of three cases. The solution for case (#1) is Conventional Sequential Method (CSM) and (#2) is Integration Method (IM) proposed

$\widetilde{\delta}_{i,ii}^{(\mathbf{l})}$ vs $\widetilde{t}_{s_{i,ii}}^{(\mathbf{l})}$	(#1) **Monotonically non-decreasing**	(#2) **Random**	(#3) **Monotonically non-increasing**

Table 1: The key approach of selection algorithms: to determine the most economically optimal transition set based on the relation of $\widetilde{\delta}_{i,ii}^{(\mathbf{l})}$ vs $\widetilde{t}_{s_{i,ii}}^{(\mathbf{l})}$.

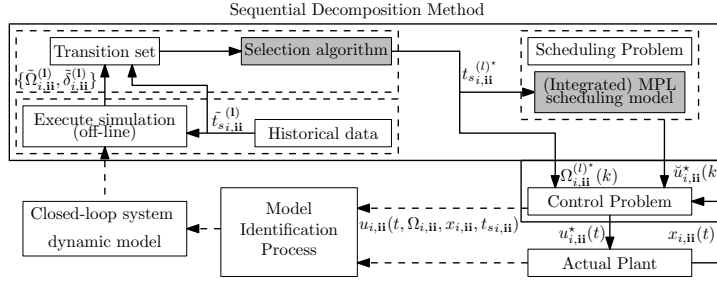

Figure 1: Illustration of SDM

in Chu and You (2012). Meanwhile, the solution for case (#3) is Constrained Deterministic Min-Max Method (CDM) inspired by Necoara et al. (2009) with some modifications incorporating threshold time to avoid penalty cost. Once we obtain the optimal transition time $t_{s_{i,ii}}^{(l)^\star}$ and its index $(l)^\star$, we can determine the associated control parameters $\Omega_{i,ii}^{(l)^\star}$ required for the controllers.

The second problem is determining the scheduling policy that considers the information provided by the solutions of the first step. By utilizing the SDM, where we incorporate $t_{s_{i,ii}}^{(l)^\star}$ in the integrated MPL scheduling model (3), we preserve the convexity of the problem (see problem (2) as the integrated MPL scheduling problem (5)). Once we solve the integrated MPL scheduling problem, the (integrated) scheduling policy is determined.

$$\min_{\hat{\mathbf{u}}_{\mathbf{i}}(k)} J(k) = \min_{\hat{\mathbf{u}}_{\mathbf{i}}(k)} \bigotimes_{j=1}^{N_p} \bigotimes_{i=1}^{n_p} |\check{y}_i(k+j|k) - \check{r}_i(k+j|k)| \tag{5}$$

subject to (for details of notations, please see Schutter and van den Boom (2001)):
- Scheduling dynamic for N_p horizon: $\hat{\check{\mathbf{y}}}_i(k) = \mathcal{H}(\hat{t}_{s_{i,\mathbf{ii}}}^{(l)^\star}) \otimes \hat{\mathbf{u}}_i(k) \oplus \mathcal{G}(\hat{t}_{s_{i,\mathbf{ii}}}^{(l)^\star}) \otimes \check{x}_i(k)$
- Scheduling linear constraint for N_p horizon: $\mathcal{D}_i\hat{\mathbf{u}}_i(k) + \mathcal{F}_i\hat{\check{\mathbf{y}}}_i(k) \leq \hat{\mathbf{h}}_i(k)$
- Time as non-decreasing input: $\Delta\check{u}_i(k+j) \geq 0$ for $j = 0,...,N_p-1$
- Starting time constraint regulation: $\Delta\check{u}_{i_-} \leq \Delta\check{u}_i(k+j) \leq \Delta\check{u}_{i_+}$

5. Case Study

We consider a simple case study, comprising a single processing unit of an input refinement problem for temperature control of a nonlinear chemical batch reactor. It is assumed that the reactor has a cooling jacket whose temperature is directly manipulated (Lee et al. (2000)). The control objective of this case study is to reach and control the reactor temperature at certain fixed set-point ($y^{sp} = 30^oC$) for a certain period ($t_p = 40$ sec) by means of

inlet coolant temperature. Moreover, the scheduling objective is that the heating process should be completed cyclically.

Fig. (2) shows the monotonically non-increasing relation between $\widetilde{\delta}_{i,ii}^{(\mathbf{l})}$ and $\widetilde{t}_{si,ii}^{(\mathbf{l})}$. In Fig. (3), the simulation result shows that the (integrated) MPL model requires less computation time than the traditional one in more accurate (frequent) sampling time, indicating similar result for longer processing time, $t_p \gg 40$ sec (even for less frequent sampling). Moreover, the MPL can be computationally efficient for a large-scale interconnected system. In terms of the performance, both MPL model and the traditional one yield the same trajectory. Unlike stand-alone model, Fig. (4) shows that the integrated MPL scheduling model is able to eliminate delay because it considers the transition time in the model.

Figure 4: Trajectories performance;
Due dates → [76 146 216]

6. Conclusion

In this paper, a new formulation for an integrated scehduling and control problem using MPL representation is proposed. Based on this formulation, the SDM sets the optimal (integrated) scheduling policy. Finally, the proposed formulation and solution are tested in simulation on a temperature control and scheduling of a nonlinear chemical batch reactor. Future work could include incorporating uncertainties and capacity constraint, investigating simultaneous solution method and the extension to other type of scheduling problems.

Nonlinear dynamic analysis of chemical engineering processes described by differential-algebraic equations systems

Ataíde S. Andrade Neto[a,*], Argimiro R. Secchi[a] and Príamo A. Melo[a]

[a]*Chemical Engineering Program, COPPE, Universidade Federal do Rio de Janeiro, Brazil*
ataide@peq.coppe.ufrj.br

Abstract

Chemical processes are subject to parametric variation due to, among others things, desired changes in process conditions, instrumentation malfunction or unpredicted disturbances. The outcome of these adversities is plural, the entire system may collapse or the output variables might not be affected at all. Thus, the theoretical analysis of processes prone to nonlinear responses plays a key role in design and operation of chemical plants either for safety or economic purposes. Because of the widespread use in the last couple decades of the differential-algebraic equations (DAE) approach in chemical processes modeling, the development of computational algorithms and tools specifically designed for the analysis of DAE systems becomes necessary, specially for high-index cases. In this work, we present a novel and index-free approach for the nonlinear dynamic analysis of mathematical models based on DAEs. A methodology for the direct detection of Hopf bifurcation points based on an optimization procedure, in which we rewrite the necessary condition for the Hopf bifurcation point occurrence as a constrained optimization problem was developed. In this approach, we do not compute the generalized eigenvalues of the system, but their Hurtwitz determinants using a new algorithm for the computation of characteristic polynomials of matrix pencils based on the La Budde's method. The resulting optimization problem was solved with a hybrid global optimization technique, coupling particle swarm (PSA) and active-set (ASA) algorithms. The parametric continuation of steady-state branches was conducted with the pseudo arc-length method and the stability analysis based on the spectral theory for linear matrix pencils. As an illustrative example we evaluate the dynamic behavior of a reactive flash drum formulated as an index-2 DAE system. The results show that the proposed methodology can handle DAE systems of high index in a fast and accurate way.

Keywords: Hopf bifurcation, differential-algebraic equations, stability analysis.

1. Introduction

Since the advent of calculus, the mathematical modeling of dynamic physicochemical processes has been based on ordinary and partial differential equations, with a very few exceptions (notably, the works of Lagrange on constrained mechanics dated from 1788 and Kirchhoff on electric circuits from 1847). However, with the growing studies on the differential-algebraic equations systems, started in the early 1970s, and also because their vast applicability this paradigm has been changing. Several authors have already pointed out numerous advantages of working directly with DAE; but we reinforce that formulating differential-algebraic models in many practical applications occurs naturally, specially in chemical engineering, as thermodynamic and equilibrium constraints, which are all imposed by algebraic equations, may be directly incorporated in

the process modeling. Because of this feature, the DAE approach is largely exploited by the majority of dynamic simulation software used in the context of Computer Aided Process Engineering (CAPE).

Regarding the dynamic analysis of chemical processes, we can safely say that it is a well-developed field for systems governed by ordinary differential equations (ODE) or discrete maps, specially the bifurcation theory which contemplates the study of dynamic systems under variation in their evolution laws. From a historical point of view, it is possible to recognize the importance of the bifurcation theory developed for ODE as a fundamental tool for nonlinear analysis. Unfortunately, for systems described by DAE, the same is not true. Because it is a rather new topic compared to ODE systems, computational algorithms and tools specifically designed for DAE have not evolved so steadily yet. It is noticed, nevertheless, that some works in the literature have already addressed the bifurcation analysis for DAE systems using either classical algorithms for differential equations or extensions of them for index-1 systems (Clausbruch et al., 2006), which are far much simpler than high-index DAE.

Although it is possible to reduce some high-index DAE to index-1 systems, this can be a tedious error-prone procedure and, in many cases, the solution of the reduced system may significantly differ from that of the original problem due to the well-known drift-off effect. Additionally, Harney et al. (2013) showed that the stability analysis of the reduced system may not represent the stability of the higher-index system from which it is derived, often being necessary to apply some stabilization methodologies, which has been developed for DAEs in Hessenberg form of size 2.

Knowing beforehand the precise location where nonlinear phenomena, such as bifurcation points, occur is of great importance in real-life applications, as not only safety but also economic issues may be avoided. Also, because the DAE approach is the current paradigm in the theoretical analysis of chemical processes, computational methods that efficiently handle DAE systems becomes necessary. Driven by this, we present, in this work, a novel and index-free approach for the direct computation of Hopf bifurcation points (HBPs), without the necessity of applying index reduction algorithms or stabilization procedures.

2. Theoretical framework

2.1. Linearization of differential-algebraic equations systems

The core of bifurcation theory of nonlinear system inevitably falls back to the dynamic analysis of linear ones. Because of that, the fundamental question one may ask is if there exist a linearized DAE system with the same qualitative behavior around fixed points of its nonlinear counterpart. Reich (1995) proved that the existence of such systems depends on some conditions which will be presented in the sequence.

Consider the nonlinear index-ν DAE system in the fully implicit form

$$f(x(t), \dot{x}(t); p) = 0 \tag{1}$$

with $f : \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}^m \mapsto \mathbb{R}^n$ and $p \in \mathbb{R}^m$ a vector of time-invariant parameters. A linearization of f around a fixed point x_e in the form

$$B(p)\dot{y}(t) = A(p)y(t) \tag{2}$$

where $A = \nabla_x f^T(x_e, 0; p)$, $B = \nabla_{\dot{x}} f^T(x_e, 0; p)$ and $y = x - x_e$, will exist only if the original DAE in Eq. (1) is regular (or solvable) and fulfill the following conditions:

$$\text{rank}\left[\nabla_{\dot{x}} f^T(x, \dot{x}; p)\right] = \text{constant for all } t \tag{3a}$$

$$\text{rank}\left[\nabla_x f^T(x_e, 0; p)\right] = n \tag{3b}$$

$$\text{rank}\left[\nabla_x g_\nu^T(x_e, 0; p)\right] = n \tag{3c}$$

in which $g_v(x,\dot{x};p)$ is a derivative-array obtained by stacking the vector f with all the equations that arise in an index reduction procedure. According to Campbell (1995), those conditions are simple to evaluate and often observed in physical systems.

2.2. Stability in DAE systems

Several authors have shown that the stability of a linear DAE is closely related to the spectrum, $\sigma(A,B)$, of the matrix pair (A,B) as defined in Eq. (2) (see Reich (1995) for a detailed overview on this subject). The spectrum of a DAE have exactly n_d finite values; the other $n - n_d$ values is said to be at the infinity. Here, n_d represent the number of Dynamics Degree of Freedom (DDoF) and n the dimension of the system. If all the finite values in $\sigma(A,B)$ lie in the left complex half-plane, then, the fixed point is stable.

2.3. Detection of Hopf bifurcation points

Hopf bifurcation points can be detected by an indirect method by tracing a branch of steady state solutions of an ODE system, usually done by homotopy continuation methods, while monitoring the eigenvalues of Jacobian matrix at the fixed points. When a single pair of eigenvalues crosses the imaginary axis a trapping method, such as the bisection or the secant method, can be used to refine the HBP. This procedure, despite being effective and easily extended to handle DAE systems, has a high computational cost. Alternatively, HBPs can be calculated directly. The first successful algorithm for the direct computation of Hopf bifurcation points in ODE systems was presented by Griewank and Reddien (1983) by formulating a set of $3n+2$ equations that algebraically determines these points. Later, Reich (1995) extended this algorithm to the DAE systems.

We present a different approach in which instead of an augmented algebraic system, we solve a constrained nonlinear optimization problem. The main advantage of this method is that we do not restrict the Hopf bifurcation points search to a single parameter of the model. In fact, our algorithm works for any number of parameters. Also, we do not compute the spectrum of the DAE system, but its $n_d - 1$ Hurwitz determinants, D_k.

The Hurwitz determinants can be calculated from the normalized characteristic polynomial:

$$P(\lambda;p) = \det(\lambda B - A)/\bar{a}_{n_d}(p) = a_0(p) + a_1(p)\lambda + a_2(p)\lambda^2 + \cdots + \lambda^{n_d} \tag{4}$$

by building the Hurwitz matrix:

$$L(p) = \begin{bmatrix} a_1(p) & a_0(p) & 0 & \cdots & 0 \\ a_3(p) & a_2(p) & a_1(p) & \cdots & 0 \\ a_5(p) & a_4(p) & a_3(p) & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{bmatrix} \tag{5}$$

then, evaluating its first $n_d - 1$ principal subdeterminants:

$$D_k(p) = \det(L_k) = \det\begin{bmatrix} l_{1,1} & \cdots & l_{1,k} \\ \vdots & \ddots & \vdots \\ l_{k,1} & \cdots & l_{k,k} \end{bmatrix} \tag{6}$$

where $a_i = \bar{a}_i/\bar{a}_{n_d}$ and $\bar{a}_i(p)$ are the coefficients of $\bar{P}(\lambda;p) = \det(\lambda B - A)$; $L \in \mathbb{R}^{n_d \times n_d}$, $L_k \in \mathbb{R}^{k \times k}$, $D_k \in \mathbb{R}$ and $k = 1,2,3,\ldots,n_d - 1$.

Extending the theorem of Liu (1994) for DAE systems, a Hopf bifurcation point arises when:

$$a_0 > 0,\ D_1 > 0,\ D_2 > 0,\ldots,\ D_{n_d-2} > 0,\ D_{n_d-1} = 0 \tag{7}$$

This allows us to formulate the following constrained optimization problem:

$$\min_{p\in\mathbb{P}^m,\ x\in\mathbb{R}^n} S(p) = D^2_{n_d-1} \quad \text{subject to:}$$

$$a_0 > 0,\ D_1 > 0,\ldots,\ D_{n_d-2} > 0 \tag{8}$$

$$f(x,\dot{x};p) = 0$$

where $\mathbb{P}^m \subseteq \mathbb{R}^m$ is a selected parametric space and $S : \mathbb{P}^m \mapsto \mathbb{R}$. The global minimum of this problem $(S(p) = 0)$ is always a Hopf bifurcation point.

2.4. Characteristic polynomials of matrix pencils

A general matrix pair (A, B) can be decomposed by Householder reflections into the form $A = QHZ$ and $B = QTZ$ where Q and Z are orthogonal, H upper Hessenberg and T upper triangular $n \times n$ matrices. Then,

$$\lambda B - A = \lambda QTZ - QHZ \Rightarrow \lambda Q^T QTZZ^T - Q^T QHZZ^T = \lambda T - H \tag{9}$$

Solving $\det(\lambda T - H)$ is numerically more efficient than solving $\det(\lambda B - A)$, because it can be rapidly evaluated by the following recursion formula derived from the La Budde method (Rehman and Ipsen, 2011):

$$\bar{P}_i(\lambda;p) = (\gamma_i\lambda - \alpha_i)\bar{P}_{i-1}(\lambda;p) + \sum_{k=1}^{i-1}\left[(t_{i-k,i}\lambda - h_{i-k,i})\bar{P}_{i-k-1}(\lambda;p)\prod_{m=i-k}^{i-1}\beta_m\right] \tag{10}$$

with $\bar{P}_0(\lambda;p) = 1$ and $\bar{P}_1(\lambda;p) = \gamma_1\lambda - \alpha_1$; $i = 2,\ 3,\ \ldots,\ n$. The coefficients α_i and β_i are, respectively, the diagonal and the subdiagonal of H; γ_i the diagonal of T; $t_{i,j}$ and $h_{i,j}$ are the (i,j)-elements of T and H; $\bar{P}_n(\lambda;p) = \bar{P}(\lambda;p) = \det(\lambda T - H) = \det(\lambda B - A)$.

3. Results

In order to evaluate the proposed methodology, it was applied to a benchmark model in chemical engineering. Consider the index-2 system describing the chemical reaction $A \to B \to C$ conducted in reactive flash drum:

$$f(x,\dot{x};p) = \begin{bmatrix} \dot{x}_A - x_{Af} + x_A\left[\ell + K_A\phi + D_{a1}\exp\left(\dfrac{-g_1}{u+1}\right)\right] \\[2mm] \dot{x}_B - x_{Bf} + x_B\left[\ell + K_B\phi + D_{a2}\exp\left(\dfrac{-g_2}{u+1}\right)\right] - x_A D_{a1}\exp\left(\dfrac{-g_1}{u+1}\right) \\[2mm] \dot{u} - 1 + u + \phi\delta - Q - H_1 D_{a1} x_A\exp\left(\dfrac{-g_1}{u+1}\right) - H_2 D_{a2} x_B\exp\left(\dfrac{-g_2}{u+1}\right) \\[2mm] K_A x_A + K_B x_B + K_C x_C - 1 \\[2mm] x_A + x_B + x_C - 1 \\[2mm] \ell + \phi - 1 \end{bmatrix} = 0 \tag{11}$$

where x_A, x_B and x_C are molar fractions, u the dimensionless temperature and ϕ and ℓ the vapor and liquid fractions; the vector of search parameters is $p^T = [D_{a1},\ D_{a2},\ g_1,\ g_2,\ \delta,\ Q,\ H_1,\ H_2]$. The feeding compositions x_{Af} and x_{Bf} were set to 0.8 and 0.2, respectively, and the equilibrium constants $K_i = P_i^{\text{sat}}/P_{\text{ref}}$. The saturation pressure was modeled by the Antoine equation

$$P_i^{\text{sat}} = \exp\left[\alpha_i + \frac{\beta_i}{(u+1)T_{\text{ref}} - \gamma_i}\right] \tag{12}$$

for some reference chemical species with the following parameters: $\alpha^T : [21.3,\ 23.2,\ 25.1]$; $\beta^T : [-2428.2,\ -3835.2,\ -6022.2]$; $\gamma^T = [35.4,\ 45.3,\ 25.3]$. The reference temperature and pressure were set to 298 K and 101,325 Pa.

The optimization problem in Eq. (8) for the model described by Eq. (11) was solved using a hybrid approach by coupling the particle swarm (PSA) and active-set (ASA) algorithms. The PSA was applied at the start of the optimization procedure until a predetermined value of the objective function was reached, $S(p_m) = \varepsilon_m$. Then, the ASA was called to refine the solution to $S(p_f) = \varepsilon_f$, where ε_f is a predefined tolerance. This technique can be more efficient and effective for non convex problems with high number of optimization variables. In Table 1, we present a comparison between the hybrid approach and the standalone algorithms in terms of number of successful attempts and spent computational time that support this assertion. All simulations were done with Matlab on a 8GB RAM, Intel CORE-i7 laptop running Linux. With the exception of the standalone ASA, the PSA and the hybrid approaches were able to attain the global minimum in every scenario.

Table 1: Average performance of optimization algorithms[†].

Parameters	PSA[††]	ASA[††]	Hybrid[††]
all	129.0/4	$-$/10	12.1/0
D_{a1}, Q	53.1/0	1.9/0	13.6/0
D_{a1}, δ	56.6/0	1.9/0	12.9/0
Q	51.1/0	1.8/0	11.5/0

[†] $\varepsilon_m = 0.099$; $\varepsilon_f = 10^{-8}$; random initial guess;
[††] Time (s) / Number of failures in 10 attempts.

An appropriated selection of $\mathbb{P}^m$ is necessary for the success of the optimization. The vectors $L^T = [0,0,0,0,0,0,0,0]$ and $U^T = [10,10,10,10,100,10,100,100]$ represent feasible values for all the parameters, as they are dimensionless groupings resulting from the combination of physical properties and operating conditions, therefore, they were chosen to bound the set $\mathbb{P}^m$. As a result of the optimization problem, we found that a Hopf bifurcation point occurs at:

$$x^T = [0.2920, \ 0.3469, \ 0.0681, \ 0.7466, \ 0.3611, \ 0.2534]$$
$$p^T = [8.6807, \ 9.9707, \ 6.7821, \ 3.8784, \ 15.5261, \ 1.3430, \ 35.9778, \ 99.8517]$$

The periodic solutions arising at this HBP are stable, as can be seen in the phase diagram and the time series in Fig. 1. Another HBP was found at $Q = 2.1741$, using Q as the single search parameter while fixing all other parameters. In this case, the arising periodic solutions were found to be unstable.

(a) Phase portrait x_B vs. x_A.

(b) Composition time profile.

Figure 1: Simulation in the neighborhood of Hopf bifurcation point at $Q = 1.3430$, the stable case. Total simulation time $t = 1000$.

The pseudo arc-length method was applied in order to make the one-parameter steady-state continuation of the model in Eq. (11). The resulting bifurcation diagram of this procedure is presented in Fig. 2.
Figure 2: Bifurcation digram for the model in Eq. (11) using Q as the continuation parameter. Solid line: stable branch; dotted line: unstable branch; ■: HBP around stable periodic solutions; □: HBP around unstable periodic solutions; ●: bifurcation point.

4. Conclusion

A novel methodology for the direct computation of Hopf bifurcation points in differential-algebraic equations systems was presented. This strategy is based on the formulation of the constrained optimization problem in Eq. (8) with multiple search parameters. With the proposed methodology, we were able to find the occurrence of HBPs in a benchmark model with up to eight search parameters in a fast and accurate manner.

Life Cycle Assessment of Petroleum Coke Gasification to Fischer-Tropsch Diesel

Ikenna J. Okeke, Thomas A. Adams II*

Department of Chemical Engineering, McMaster University, 1280 Main St. W, Hamilton, ON, Canada, L8S 4L8.
tadams@mcmaster.ca

Abstract

This work presents a novel study on the life cycle assessment of Fischer-Tropsch diesel (FTD) production via petroleum coke (petcoke) gasification with and without carbon capture and sequestration (CCS). A detailed analysis which focuses on evaluating and quantifying the well-to-wheel (WTW) environmental impacts of converting petcoke to FTD and its subsequent combustion is discussed. The overall process inventory includes mass and energy balances data from our Aspen Plus model, the US Life Cycle Inventory Database, and the GREET model. Life cycle impact assessment (LCIA) categories of the petcoke-derived diesel (PDD) were calculated using TRACI 2.1 v1.04 in SimaPro 8.5.0.0 which is compared against both conventional petroleum and oil-sands derived diesel. In addition, two different plant locations in Canada (Alberta and Ontario) which respectively have very high and low electricity grid emissions were considered as they are representative of grid emissions across the world. Results of the analysis showed an overall reduction in fossil fuel depletion of up to 80% and 83% for Alberta and Ontario respectively when compared to the fossil derived diesel. When operated with CCS, the WTW GHG emissions were 7% lower than conventional petroleum diesel and 18% lower than oil-sands diesel for the plant located in Ontario. However, when located in Alberta, the WTW GHG emissions were 49% higher than conventional petroleum diesel and 30% higher than oil-sands diesel. This is due to the significant electricity requirement for the PDD process and the vast differences in carbon intensities of the Ontario and Alberta grids. Overall, the other impact categories for the PDD process showed to be significantly lower than the petroleum and oil-sand derived diesel.

Keywords: Petroleum coke, Fischer-Tropsch, Life cycle assessment, CO_2 Capture.

1. Introduction

Petroleum coke ("petcoke") is regularly produced as a by-product of crude oil refining, especially from heavy crudes commonly produced in Canada. While some forms of petcoke are useful for steel making or other speciality purposes, it is often stockpiled in large quantities as a waste product. Although the stockpiled petcoke can be combusted for heat or electricity generation, it is more carbon intensive than coal, and this along with other environmental concerns makes combustion undesirable or even prohibited by government regulation. Hence, instead of the traditional stockpiling practice, petcoke can also be converted to liquid fuels both as a means of disposal and to help meet increasing fuels demand.

Recent studies have shown the technical and economic feasibility and the high fuel, energy, and carbon efficiencies of converting petcoke to chemicals and fuels (Salkuyeh et al. 2015, Okeke et al. 2018). Although several studies have presented the life cycle assessment (LCA) of other synthetic fuels processes such as gas-to-liquids (Forman et al. 2011), coal-to-liquids (Jaramillo et al. 2009), and biomass-to-liquids (Xie et al. 2011) processes, to the knowledge of the authors, no work has reported the LCA study of petcoke conversion to liquid fuels. Therefore, this study presents the first-of-a-kind detailed cradle-to-grave LCA of petcoke gasification to FTD so as to ascertain the environmental feasibility of this petcoke disposal approach.

2. Life cycle methodology and process description

2.1. Goal, scope, and boundaries

The goal of the LCA study is to evaluate the environmental impacts associated with the production of FTD from petcoke gasification operating with or without CCS. The scope covered in this analysis includes all the direct and indirect material and energy inputs with its associated output and emissions in the entire life cycle of the PDD process. The energy allocation method was employed for the distribution of emissions between diesel and gasoline fuels produced. Overall, the WTW system boundaries comprise of the cradle to plant exit gate emissions, the diesel fuel transportation and distribution (T&D), and the diesel combustion in a compression ignition direct injection (CIDI) vehicle as shown in Figure 1. The WTW inventory was normalized to 1 MJ_{PDD} combusted which is compared against conventional petroleum and oil-sands derived diesel (GREET, 2017). The impact categories considered were: ozone depletion potential (ODP), global warming potential (GWP), smog formation (SF), acidification potential (AP), eutrophication potential (EP), carcinogenic potential (CP), non-carcinogenic potential (NCP), respiratory effects (RE), ecotoxicity potential (ETP), and fossil fuel depletion (FFD).

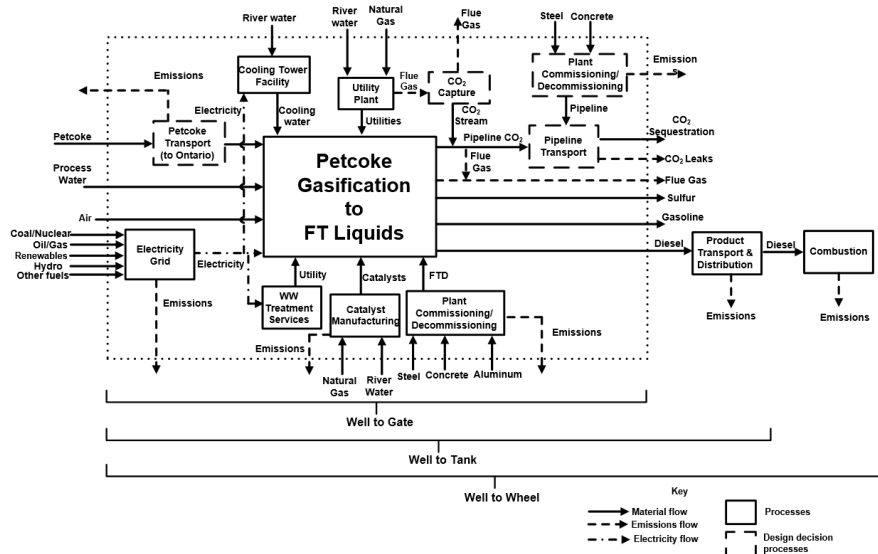

Figure 1: Complete WTW system boundary of the PSG designs studied

2.2. Process description

Figure 1 shows the system boundary for the WTW LCA of the PDD process which is based on our prior design (Okeke et al. 2018). Depending on the case, stockpiled petcoke at the refinery yard in Fort McMurry, Alberta is either directly sent to a petcoke standalone gasification (PSG) plant nearby, or, transported by train 3114 km to Sarnia, Ontario. The petcoke undergoes pre-processing prior to being fed to the petcoke E-gas gasifier operated with 99.5% pure oxygen from an air separation unit. Syngas is produced at 1426°C and 56 bar with the syngas cooling provided by boiler feed water sent through the radiant tubes, thereby, producing high-pressure steam (HPS).

The gasifier is designed for a carbon conversion of 99% (Amick 2000) while slag is collected which consists of unconverted carbon and trace metals such as nickel and vanadium (Basu 2006). An adiabatic water-quench saturation temperature of 200°C is employed to remove the entrained slag in the syngas while ammonia is removed from the syngas based on its high solubility in water to tolerable limits in order to avoid downstream catalyst deactivation (Pendyala et al. 2017). Water-gas shift and COS hydrolysis are employed to raise the H_2/CO ratio and convert COS to H_2S respectively.

Acid gases such as H_2S and CO_2 are removed from the syngas using the pre-combustion based MDEA solvent. The two-stage removal process is employed: H_2S removal in an H_2S absorber and CO_2 capture (for the CCS design) in a CO_2 absorber enhanced with piperazine. The absorbed H_2S is sent to the Claus unit for sulfur production while the captured CO_2 is compressed to 153 bar and sent via CO_2 pipeline to sequestration site. The minimum energy requirements for the overall system was determined by performing a heat exchanger network design (Okeke et al. 2018) of which all the required utilities and its associated emissions were considered.

FTD is produced by converting the syngas in a cobalt aluminium-based catalyst filled slurry reactor operating at 240°C and 30 bar. The slurry reactor design configuration consists of a once-through conversion of 80% CO and a chain growth probability, α, of 0.92. Up to 90% of the unconverted syngas was recycled to the FT reactor while the other portion is combusted primarily to produce HPS needed in the plant and the remaining HPS is sold. The boiler flue gas is emitted to the atmosphere which accounts for the direct process emission. The mass and energy balance results for the petcoke-to-liquids portion of the life cycle were determined and described in the prior work (Okeke et al. 2018) and incorporated within the present work. The system electricity demand is supplied from the local electricity grid, with the environmental impacts of the Alberta and Ontario grids considered (Environment and Climate Change Canada 2018).

Transportation of the PDD from the plant location to a bulk terminal for subsequent distribution to refueling stations was carried out using a combination of barge, pipeline, and rail for the transportation and truck for distribution based on the GREET model data (GREET, 2017). The subsequent combustion emissions of 1 MJ of PDD is evaluated in a CIDI vehicle with an assumed fuel consumption of 27.5 miles per gallon. In this analysis, we considered four cases, which were PSG plants with and without CCS, located either in Alberta or Ontario.

3. Results and discussion

Table 1 shows the plant gate-to-gate (GTG) process life cycle inventory of the PSG design with and without CCS. Both PSG processes were designed to consume the same amount of petcoke per FTD produced. However, a 27% increase in electrical consumption for the plant with CCS is observed due to the parasitic energy load of the CCS technology compared to the design without CCS.

Table 1. The total GTG life cycle inventory for the petcoke to diesel process.

Inventory	PSG-CCS	PSG
Input flows (kg)		
Petcoke	0.091	0.091
Petcoke transport, by train (t-km)	0.283	0.283
Catalyst, aluminium-based	6.11×10^{-5}	6.11×10^{-5}
Air	0.483	0.483
Process water	0.148	0.143
Cooling water, cooling tower	35.677	28.518
Waste water treatment (m^3)	1.81×10^{-4}	1.77×10^{-4}
LP steam generation (GJ)	5.67×10^{-4}	2.86×10^{-4}
MP steam generation (GJ)	-2.83×10^{-6}	-2.83×10^{-6}
HP steam generation (GJ)	-3.65×10^{-4}	-3.65×10^{-4}
Fired heat (GJ)	9.55×10^{-6}	9.55×10^{-6}
Electricity consumed (MW)	9.98×10^{-4}	7.88×10^{-5}
Output flows (kg)		
Products flow (MJ)		
Diesel	1	1
Gasoline	0.371	0.371
Sulfur (kg)	5.19×10^{-3}	5.2×10^{-3}
Sequestered CO_2 (kg)	0.177	0
Emissions flow (kg)		
Carbon monoxide	0	8.06×10^{-5}
Carbon dioxide	7.09×10^{-3}	0.186
Water (g)	1.57×10^{-2}	1.65×10^{-2}
Argon	1.51×10^{-3}	1.52×10^{-3}
Nitrogen	6.32×10^{-2}	6.33×10^{-2}
Nitrogen oxides	8.92×10^{-6}	8.92×10^{-6}

Similarly, there is an approximately 50% and 20% reduction in heating and cooling water requirements when the plant is operated with no CCS. Comparing the direct emissions of both plants, the GHG emissions for the design with CCS were 71 tCO$_2$eq/MJ$_{PPD}$ while the design without CCS emits up to 186 tCO$_2$eq/MJ$_{PPD}$. This amounts to a 162% increase in GWP and defeats the overall goal of alternative sources of fuel with reduced environmental impacts. Therefore, it can be concluded that it is not environmentally desirable to dispose petcoke by converting it to diesel without using CCS. The complete WTW environmental impacts of the PDD plants operating with or without CCS for the 2

locations studied compared against the conventional petroleum and oil-sands derived diesel with the oil-sands diesel as the reference process is shown in Figure 2.

Figure 2: WTW life cycle impact categories relative to oil-sands derived diesel. The "Alberta" cases are cases where the PSG plant is located at the source of the petcoke stockpile. The "Ontario" cases indicate that the stockpiled petcoke is transported to Ontario for conversion. "Conv. Petroleum" is for diesel fuel from conventional oil.

Analyzing the performance of the plants when located in Alberta, it can be observed from Figure 2 that the GWP for the PSG plant with CCS is 49% and 30% higher than the petroleum and oil-sands derived diesel processes respectively. Such a huge GHG emission above the reference processes is due to the high carbon-intensive electricity grid in Alberta. Without CCS, the GHG emissions rises as high as 167% and 135% above the petroleum and oil-sands derived diesel respectively. Comparing the GWP of the plants when located in Alberta and Ontario, there is a significant 37% and 16% reduction in GHG emissions for the Ontario plants with and without CCS respectively. Furthermore, this Ontario plant showed up to 7% and 18% reductions in GHG emissions when operated with CCS compared to the conventional and oil-sands derived diesel plants respectively. When the economics (Okeke et al. 2018) and GHG emissions reductions of the PSG design operated with CCS are considered, there is an incentive in constructing the plant. Although the GWP is higher in Alberta, its SF, AP, EP, RE, and ETP are 66%, 48%, 63%, 32%, and 20% lower than that of the Ontario plant respectively. These increased impacts are linked to the train transit emissions during petcoke transportation to Ontario. It is noteworthy to mention that the impacts of ODP, CP, and NCP are not significant but were presented for completeness purposes and thus, not discussed. Finally, FFD at Alberta is 19% higher than in Ontario because of Alberta's grid high dependence on fossil energy. However, its FFD is still 70% and 80% lower than that of the conventional petroleum and oil-sands derived diesel processes respectively.

4. Conclusions

A novel WTW study on the LCA of PDD operating with or without carbon capture at different locations in Canada was presented and compared against conventional petroleum and oil-sands derived diesel. It was found that the GHG emissions of the PSG with CCS plant at Alberta and Ontario were 137 and 86 tCO$_2$eq/MJ$_{PPD}$ respectively. This implies that the plant can compete favorably with the status quo refinery GHG emission if its sited in locations with grid emissions like that of Ontario. Similarly, it is generally preferable to transport petcoke from Alberta to Ontario to take advantage of its lower grid carbon intensity than to gasify petcoke at the source in Alberta. Also, the extent of FFD for the design at Alberta and Ontario are between 70-80% and 75-83% lower compared to the conventional and oil-sands derived diesel respectively. Overall, it can be concluded that disposing petcoke via diesel production is an avenue to be considered when GHG emissions and FFD are a concern.

Although this work focused on the WTW LCA of petcoke only gasification operated with or without CCS, in our future work, we will explore the WTW environmental impacts of other designs such as combining petcoke gasification and natural gas reforming to FTD so as to ascertain the technology which has the most reduced impact on the eco-system.

Khalifa University, Qatar Foundation, Doha, Qatar

Abstract

The production of renewable fuels and decreasing the dependency on fossil fuels is an integral component of sustainable development.

As the production and utilization of petrochemicals represent an extremely important economic pillar of modern society, there exists an impetus to identify alternative routes of production in order to conserve finite resources. Furthermore, there is an additional necessity to utilize waste to produce value-added products in order to reduce greenhouse gas (GHG) emissions. Biomass, a CO_2 neutral energy source, serves as a potential basis for the production of fuels, which would have otherwise been produced from natural gas. The gasification of biomass produces a hydrogen-rich syngas, which can be utilized in the petrochemical industry to produce ammonia and methanol or processed through the Fischer-Tropsch synthesis to produce liquid fuels. In this study, the utilization strategy of biomass gasification feedstock for the poly-generation of different products is environmentally and economically evaluated. The potential production volumes of fuels and green chemicals are increased by the addition of multiple biomass sources, and thereby gaining potential positive scale effects, and by the optimization of the gasification process, in terms of operating conditions and feed blending to yield high-quality syngas. This form a superstructure network of multiple biomass feedstocks (sources) and multiple potential applications (sinks) that can be optimized to yield the most economical and environmental-friendly production configuration. The base model developed is an oxygen-steam gasification process of different feedstocks available in the State of Qatar to generate H_2-rich syngas that is utilized in the production of value-added products: methanol, urea, power through integrated biomass gasication combined cycle (IBGCC) and Fischer-Trospch liquids (FTL). The results of the optimization problem demonstrated the domination of urea generation with an overall net cost objective function of $ 0.096 per kg of biomass input and an overall net emissions objective function of 0.83 kg of CO_2-e emitted per kg of biomass input. The manure based biomass is more suitable than sludge and date pits in the resulting optimum blending option for this utilization technique.

1. Introduction

Converting carbon-based wastes to valuable chemicals and energy through thermochemical conversion ranging from biomass and forestry residues to pet coke, have various advantages over conventional processes. Some of these advantages are the reduction of environment harmful emissions and the ability to produce electricity independently of an external power source (Mahinpey and Gomez, 2016). Biomass, waste or otherwise is a resource which can be processed into various chemicals and fuels. Biomass gasification (BG) is one process by which biomass can be converted into value added products, therefore mitigating polluting waste disposal strategies whilst simultaneously generating useful products such as bio-fuels, bio-char, syngas, power, heat, and fertilizer. Through the production of syngas, it creates flexible pathways by which advanced biofuels can be produced, e.g., methanol, di-methyl ether or Fischer-Tropsch diesel (Andersson, 2013). The high energy source feedstock into the BG process can include, wood waste, agricultural waste, municipal solid waste (MSW), sewage treatment waste, and food waste (Kumar and Shukla, 2016). BG technology can reduce the generated carbon to hydrogen (C/H) ratio resulting in a higher calorific value content and a favourable H_2 fraction. Syngas, the main product from BG consists of carbon monoxide (CO), hydrogen (H_2), methane (CH_4) and carbon dioxide (CO_2). It is an important element in the production of environment-friendly fuels and chemicals and in the generation of power. However, various types of contaminants are associated with syngas production such as tars, sulphur inorganic compounds, particulates and nitrogenous compounds. The properties and quality of the gasification product and its associated contaminants depend on the gasifying agent, feedstock material and dimensions, reactor conditions and design, presence of sorbent and catalyst (Sikarwar et al., 2016).

Anderson et al. evaluated a techno-economic analysis of methanol and ammonia production from BG and the co-gasification of pyrolysis oil and black liquor. The results demonstrated that the recovery of a bark boiler can be replaced by a biomass gasifier. This will improve the overall energy system efficiency and economic performance of green chemical production compared to the traditional mill operation (Andersson, 2013). Sara et al. carried out a techno-economic analysis on small scale biomass gasification and purification system for the production of hydrogen and power. A sensitivity analysis was conducted in order to study the effect of hydrogen production cost on capital cost, operating cost and process efficiency. The results indicated that costs cannot be reduced to a favourable level by only increasing the efficiency of the process unless the portable purification unit cost goes down (Sara et al., 2016). AlNouss et al. studied the utilization of multiple biomass sources to find the optimal blends for the generation of different value-added products. The objective was to maximize the production of syngas while constraining the H_2 to CO ratio with a specific application value. The results demonstrated a variation in the biomass blends for the different applications with a domination for date pits biomass in most cases (AlNouss et al., 2018). The literature is rich with other studies, which used similar pathways in identifying the top value added products generated from biomass. In this study, the utilisation strategy of biomass gasification for the poly-generation of different products is evaluated from economic and environmental perspectives to identify optimal poly-generation routes. An Aspen Plus model simulating oxygen-steam gasification technology is utilised to generate the optimal characteristics for each utilisation technique.

2. Model development

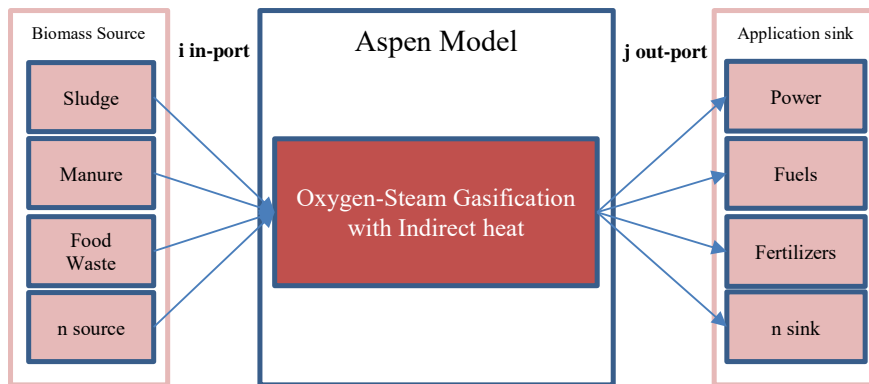
In order to efficiently utilize the biomass feedstock in a poly-generation system which produces value-added products, it is essential to use advanced system models. Hence, Aspen Plus software is utilized in this study to simulate the different generation technologies. An oxygen-steam gasification process is simulated in order to generate the optimal characteristics for each utilization technique. The optimization problem is built on the basis of superstructure representation with multiple biomass sources and multiple application sinks. The ultimate goal is to utilize the optimal blends of biomass feedstock in achieving optimal polygeneration routes of different utilization techniques as illustrated in Figure 1. The main focus of this study is the production of methanol, urea, power and Fischer-Trospch liquids (FTL) from biomass.


Figure 1: Superstructure representation of the biomass gasification to value added products

The first objective of the optimization problem is to maximize the production of syngas from the different biomass feedstocks, whilst constraining the specific H_2 to CO ratio of each generation technique. This was conducted partially by (AlNouss et al., 2018) and it is expanded here to capture the other optimization objectives. The H_2 to CO ratios considered the products are $H_2:CO = 2$ for Fischer-Tropsch liquids, $H_2:CO = 3$ for ammonia/urea, and $(H_2 - CO_2):(CO+CO_2) = 2$ for methanol. There is no specific ratio used for the generation of power through IBGCC. The formulation of the first objective function is presented in equations 1 and 2.

$$\text{Maximize} \qquad \sum_{i=1}^{n} x_i * Syngas \qquad \forall\, i \in Biomass\ Sources \qquad \text{eq. (1)}$$

$$\text{Subject to} \qquad \sum_{i=1}^{n} x_i = 1 \qquad \& \quad \frac{y_{H_2} * Syngas}{y_{CO} * Syngas} = Application\ unique \qquad \text{eq. (2)}$$

Where, Syngas is the molar flowrate of the generated H_2-rich synthesis gas, yH_2 & yCO are molar fractions of hydrogen and carbon monoxide and x is the blending fraction of each biomass feedstock.

The optimal biomass feedstock blends are then utilized in Aspen Plus to estimate the economic and environmental indicators of each utilization technique. The estimation is executed by means of the economic and energy activated analyses of Aspen Plus. These analyses are interfaces to the full software; Aspen Process Economic Analyser (APEA)

and Aspen Energy Analyser (AEA). The economic and environmental outputs are used in a multi-objective optimization problem with the aim of maximizing the economic benefit and minimizing the environmental impact for the poly-generation routes. Therefore, the second and third objective functions are formulated based on the net profit and net emissions of each utilization technique multiplied by the fraction of H_2-rich syngas produced, as illustrated in equations 3 through 5.

$$\text{Maximize} \qquad \sum_{i=1}^{4} x_i * Net\ Profit_i \qquad\qquad \text{eq. (3)}$$

$$\text{Minimize} \qquad \sum_{i=1}^{4} x_i * Net\ Emissions_i \qquad\qquad \text{eq. (4)}$$

$$\text{Subject to} \qquad \sum_{i=1}^{4} x_i = 1 \qquad\qquad \text{eq. (5)}$$

Where x is the specific faction of syngas and i is the index notation for each process from 1 to 4 according to table 1. The breakdown of the profit and emission equations are illustrated in Eq. 6 through 8.

$$Net\ Profit_i = \frac{Revenue_i - TAC_i}{(Annual\ Biomass\ input)_i} \qquad\qquad \text{eq. (6)}$$

$$TAC_i = CC_i \frac{i(1+i)^n}{(1+i)^n - 1} + OC_i \qquad\qquad \text{eq. (7)}$$

$$Net\ Emission_i = \frac{(Stream\ Emissions)_i + (Utility\ Emissions)_i}{(Hourly\ Biomass\ input)_i} \qquad\qquad \text{eq. (8)}$$

Where, TAC is the total annualized cost, CC is the capital cost, OC is the operating cost, i is the interest rate evaluated as 20% and n is the project life evaluated as 20 years.

As the capacity of the biomass-based value added products is below the established infrastructure worldwide, therefore the upper limit was set to 1. For the minimum limit, the production capacity of each technique based on natural gas (NG) were collected and a fraction of each based on the total NG utilized in Qatar is generated as demonstrated in Table 1 (Alfadala and El-Halwagi, 2017). The results of the optimization problem is a Pareto front demonstrating the most attractive poly-generation route for the generation of value-added products.

Table 1: Fraction of maximum limit of each utilization technique

	MMTPY	Fraction
(1) Ammonia	3.8	0.032
(2) Methanol	1	0.0085
(3) FTL	0.04	0.00032
(4) Power	4.93	0.042
Total Fractions		0.083
Total NG	117.6	

Therefore, the limits of the specific fraction are summarized in equations 6 through 9.

$0.032000 \leq x_1 \leq 1$ for Ammonia production technique
$0.008520 \leq x_2 \leq 1$ for Methanol production technique
$0.000032 \leq x_3 \leq 1$ for Fischer-Tropsch liquids production technique
$0.042000 \leq x_4 \leq 1$ for power generation technique

3. Results and discussion

Considering that the biomass feedstock is optimized in order to determine the optimum blended feedstock. The results of the biomass feedstock blends optimization are illustrated in Figure 2. An economic and environmental evaluation is done to quantify capital cost, operating cost and revenue along with the environmental emissions from streams and utilities for the optimal feedstock blends, determined. Table 2 summarizes the main results from the evaluation.

Figure 2: Biomass feedstock blending options for the different utilization techniques

The resulting optimized blends demonstrated a domination of date pits biomass for the methanol and liquid fuels options. Whereas, a domination of manure biomass is determined for the IBGCC alternative and 62:37 ratio of manure to date pits is accomplished for the ammonia/urea option. The economic and environmental results are used in a multi-objective optimization problem with the aim of maximizing the economic benefit and minimizing the environmental impact. The results of the optimization problem revealed the domination of ammonia/urea generation technique with around 95 % of the generation. The overall net cost objective function for the ammonia/urea production technique is $ 0.096 per kg of biomass input and the overall net emissions objective function is 0.83 kg of CO_2-e emitted per kg of biomass input. The rest of the distribution indicated around 4% for the IBGCC power generation and around 1% for methanol production technique.

Table 2: Results of economic and environmental evaluation

	Ammonia/ Urea	Methanol	FTL	IBGCC
Total Capital Cost [$]	2.4×10^7	2.5×10^7	1.9×10^7	1.5×10^8
Total Operating Cost [$/y]	9.7×10^6	9.7×10^6	6.0×10^6	3.7×10^7
Revenue [$/y]	5.2×10^6	6.0×10^6	3.0×10^6	1.1×10^7
Total Annualized [$/y]	1.5×10^7	1.5×10^7	9.8×10^6	6.6×10^7
Net Cost per Input [$/kg]	9.6×10^{-2}	2.4×10^{-1}	4.5×10^{-1}	9.6×10^{-2}
CO_2 Emissions (Streams) [kgCO$_2$-e/h]	9.2×10^3	6.8×10^3	3.1×10^3	6.8×10^4
CO_2 Emissions (Utilities) [kgCO$_2$-e /h]	8.3×10^1	9.8×10^2	4.1×10^2	4.6×10^3
Total CO_2 Emissions [kgCO$_2$-e/h] per input	8.3×10^{-1}	1.9×10^0	2.0×10^0	1.1×10^0

The results can be plotted in a Pareto front curve in order to inform decision making regarding the optimum biomass utilization technique. The Pareto curve resulting from the optimization of the different utilization techniques is illustrated in Figure 3.
Figure 3: Pareto Curve of the optimization problem

4. Conclusions

The growing demand for global energy has motivated the utilization of renewable sources such as biomass in the generation of green fuels and chemicals. This study considers the development of a superstructure representation to capture the various biomass feedstocks and utilization techniques for the generated H_2-rich syngas through gasification. The results demonstrated the enhanced urea production as the most attractive technique in the poly-generation route.

Parameter Estimation for Thermal Runaway of Li-ion cells: a Gaussian Process approach

Robert Milton[a], Peter Bugryniec [a] and Solomon Brown[a,*]

[a]*Department of Chemical and Biological Engineering, University of Sheffield, Sheffield, S1 3JD, United Kingdom*
s.f.brown@sheffield.ac.uk

Abstract

Lithium ion (Li-ion) cells are the most prominent electrochemical energy storage device in todays world as they are utilised in many applications across many scales. However, Li-ion cells can suffer from a severe safety issue known as thermal runaway (TR). This process is due to exothermic chemical decomposition of a cells components. Being able to understand and model this process is essential for the development of safer batteries. Lithium iron phosphate (LFP) cells are known to have the safest chemistry of Li-ion cells. However, TR models developed for LFP cells have not been validated and when compared to new experimental work are shown to be inaccurate. Hence, the development of an accurate and validated LFP TR model is the focus of present research.

Classical TR modelling of Li-ion cells utilises four Arrhenius equations to predict the reaction rate of these reactions and in turn the heat generated. However, the development of a TR model (via parameter estimation) is difficult due to 1) the large range some of the parameters of the Arrhenius equation can take i.e. several 10s order of magnitude between literature values for a given reaction, 2) the complex interaction between different parameters within an Arrhenius equation, and 3) the effect of the heat generated by each reaction on the others. Given this, direct minimisation of the root mean squared error (RMSE) between simulated and experimental results has proven to be difficult, with optimized parameters unable to represent important experimental features.

As such, an approach is developed in which the viable parameter space is defined and sampled using a pseudo-random sampling. The error of the heuristic fit (RMSE) is then emulated by a Gaussian Process, further refined by Global Sensitivity Analysis. The result is an emulator providing predictions (with attached uncertainties a part of the process) as a function of a reduced number of combined parameters. This is a reduction in model order achieved by a novel, optimal rotation of input basis.

Keywords: Li-ion, thermal runaway, Gaussian Processes, parameter estimation

1. Introduction

Lithium ion (Li-ion) cells are a prominent electrochemical energy storage device, being utilised in many applications across many scales from mobile phones, to electric vehicles and grid scale energy storage (Placke et al., 2017). However, Li-ion cells can suffer from a severe safety issue known as thermal runaway (TR) (Wang et al., 2012). The hazard of TR is one of an uncontrollable temperature rise of a cell, due to heat generation from the exothermic chemical decomposition of a cell's components (Melcher et al., 2016), that can lead to catastrophic failure and result in fire and explosion. Hence, understanding the TR process is essential for the development of safer batteries.

Significant research has gone into studying the safety of Li-ion cells of various chemistries under various abuse methods, which has shown that the Lithium iron phosphate (LFP) cathode is the safest (Liu et al., 2016; MacNeil et al., 2002). Additionally, much research has gone into modelling the TR of cells (e.g. Hatchard et al., 2001; Coman et al., 2017), as this is more cost effective and safer than iterating cell and battery design experimentally. Previous work utilises Accelerating Rate Calorimetry (ARC) to determine the initial reaction kinetics of the SEI and cathode reactions (Richard and Dahn, 1999a) and inverse modelling techniques for parameter estimation of reaction kinetics for cell components (Richard and Dahn, 1999b) and full cells (Ren et al., 2018; Liu et al., 2018). Ren et al. (2018) determine parameters values through Kissinger and nonlinear fitting methods of DSC data. Fundamental thermal abuse experiments of ARC, DSC and oven exposure are used to validate such models. However, TR models developed for LFP cells (Peng and Jiang, 2016) have not been validated and when compared to new experimental work (Bugryniec et al., 2018) are shown to be inaccurate. Hence, the development of an accurate and validated LFP TR model is the focus of present research.

The classical theory of TR attributes the heat generation to four chemical reactions, the solid electrolyte interphase, negative electrode, positive electrode and electrolyte reactions (Richard and Dahn, 1999a). The heat generation of these reactions is commonly modelled utilising Arrhenius equations (Hatchard et al., 2001), characterized by the activation energy, frequency factor and heat of reaction, which we refer to here as the "reaction parameters" (12 parameters in total, 3 for each of the 4 individual reactions). However, preliminary work has shown that direct minimisation of the root mean squared error (RMSE) between simulated and experimental results is difficult, with optimized parameters unable to represent important experimental features.

In order to address this, in this paper we develop an approach for estimating the parameters through the development of a Gaussian Process (GP) emulator. To increase the efficiency of the optimization the dimensionality reduction method is applied, which utilises both an appropriate kernel and a Global Sensitivity Analysis (GSA).

This work is organised as follows: Section 2 presents a description of the full model that is applied to simulate TR. Section 3 describes the approach to model order reduction using GPs and GSA, while Section 4 presents the application of this approach to estimating the parameters of TR in fully charged 18650 LFP cells. Section 5 presents the conclusions drawn.

2. Full Order Model

The full order model is constructed in *COMSOL Muiltiphysics 5.2a* (https://uk.comsol.com/) and simulates the thermal runaway behaviour of an 18650 LFP cell under an ARC heat-wait-seek (HWS) test. ARC is considered as it operates in such a manner that the cell experiences near adiabatic conditions. Hence, with no heat exchange to or from the ARC, the temperature rise of a cell is entirely due to self-heating and can be entirely attributed to the decomposition reactions, while the model can be simplified to a zero heat loss simulation, reducing the amount of uncertainty by eliminating the variable for heat transfer between the cell and its surroundings.

The cell is modelled by a 1 dimensional asymmetric line along the radius of the cell comprised of 102 finite elements. The geometry is simplified by considering the multilayer jelly roll (i.e the electrodes, separators and current collectors) as a single homogeneous material with averaged thermo-physical properties. Heat transfer in the model assumes a solid body throughout and considers conduction within the cell and convection at the cell's surface. Convection is only considered during the HWS part of the ARC simulation, upon self-heating detection the heat transfer coefficient is set to zero to simulate adiabatic conditions.

The governing equations for the heat generated by the decomposition reactions follows that outlined by Kim et al. (2007). Wherein the rate of each reaction follows an Arrhenius relation, while

the power generated by each reaction is the product of the specific heat of reaction, specific weight and reaction rate. In this work, the model geometry simulates a single domain for the jelly roll, with each decomposition reaction applied over the entire jelly roll domain, there would result in an over-estimate of heat generated. As such, to take account of this fact, the heat generated by each decomposition equation is scaled by a factor equal to the proportion of jelly roll that the reaction actually occurs in.

3. Model Order Reduction

To describe the dependence of RMSE on the reaction parameters we adopt the notation

$$
\begin{aligned}
&y \propto \text{RMSE} \\
&\mathbf{x} \propto (A_{ne}, A_{pe}, E_{a,ne}, E_{a,pe}, H_{ne}, H_{pe})
\end{aligned}
\tag{1}
$$

where each variable is offset and scaled to have zero mean and unit variance. Without loss of generality RMSE is represented as the scalar response f to input vector $\mathbf{x}$ plus independent noise e of zero mean

$$
y(\mathbf{x}) = f(\mathbf{x}) + e
\tag{2}
$$

Our first assumption is that y and e are normally distributed at any fixed $\mathbf{x}$, rendering this model as a GP, which is a cheap and versatile emulator.

The significance of each input dimension to the GP is readily discerned by an Automated Relevance Determination (ARD) kernel. However, this restricts the orientation of relevant dimensions to the fixed axes of $\mathbf{x}$. As an alternative, we develop an approach employing the GP simply as an emulator facilitating global sensitivity analysis (GSA) via the Sobol' indices (Sobol', 2001). Using an arbitrary basis to calculate the Sobol' indices furnishes a very practical method for optimizing the rotation of input dimensions.

Essentially, optimization is then a two-stage process: 1) a GP emulator is optimized, then GSA using the emulator rotates the input basis; 2) this rotated basis is then used in a new emulator. Ultimately this yields an emulator that only significantly depends on a dimensionally reduced basis.

3.1. Gaussian Process Emulator

The emulator takes a $(1 \times M)$ row vector $\mathbf{x}$ and returns a Gaussian random variable

$$
y(\mathbf{x}) \sim \mathsf{N}\left[\bar{f}(\mathbf{x}), \Sigma_y\right] \quad \text{where} \quad \bar{f}(\mathbf{x}) = k(\mathbf{x}, \mathbf{X})(k(\mathbf{X}, \mathbf{X}) + \sigma_e^2 \mathbf{I})^{-1} \mathbf{y} =: \sigma_f^{-2} k(\mathbf{x}, \mathbf{X}) \tilde{\mathbf{y}}
\tag{3}
$$

whose mean $\bar{f}(\mathbf{x})$ is learned from training data $\mathbf{y} = f(\mathbf{X}) + \mathbf{e}$. Standard Bayesian inference has been used to express the mean prediction in terms of the $(N \times 1)$ observed responses $\mathbf{y}$ to $(N \times M)$ training inputs $\mathbf{X}$. At the heart of this lies the kernel function $k \colon \mathbb{R}^{I+M} \times \mathbb{R}^{J+M} \to \mathbb{R}^I \times \mathbb{R}^J$, expressing the correlation between responses to input samples of sizes $(I \times M)$ and $(J \times M)$. In this paper, of course, the number of input dimensions is $M = 6$ throughout. This work exclusively uses the ARD kernel (Wipf and Nagarajan, 2007):

$$
k(\mathbf{x}', \mathbf{x}) := \sigma_f^2 \exp\left(-\frac{(\mathbf{x} - \mathbf{x}')\Lambda^{-2}(\mathbf{x} - \mathbf{x}')^\mathsf{T}}{2}\right)
\tag{4}
$$

where Λ is an $(M \times M)$ *diagonal* positive definite lengthscale matrix. The work which follows would be vastly complicated by any other kernel. However, this choice can be entirely justified from the assumption that the similarity function $k(\mathbf{x}', \mathbf{x})$ is differentiable at $\mathbf{x} = \mathbf{x}'$, together with original assumption that RMSE is normal (see Rasmussen and Williams, 2005, for further standard details).

3.2. Global Sensitivity Analysis

In this section an $(M \times 1)$ sample datum $\mathbf{u}$ is drawn from a standardized normal test distribution

$$\mathbf{u} \sim \mathsf{N}[(\mathbf{0})_{\mathbf{M}}, (\mathbf{I})_{\mathbf{M} \times \mathbf{M}}] \quad \text{where} \quad (\mathbf{I})_{\mathbf{M} \times \mathbf{M}} \text{ is the } (M \times M) \text{ identity matrix.} \tag{5}$$

This provides input to the emulator upon rotation by row orthogonal matrix Θ

$$\mathbf{x} =: \mathbf{u}^\mathsf{T} \Theta \quad \text{eliciting response} \quad \bar{f}(\mathbf{x}) = \bar{f}(\mathbf{u}^\mathsf{T} \Theta) \tag{6}$$

GSA proceeds by conditioning on several fixed components of rotated input $\mathbf{u}$. The variance of $\bar{f}(\mathbf{u}^\mathsf{T} \Theta)$ due to the first m components of $\mathbf{u}$ is

$$D_{\mathbf{m}} := \mathsf{E}\left[\mathsf{E}\left[\bar{f}(\mathbf{u}^\mathsf{T} \Theta)|(\mathbf{u})_{\mathbf{m}}\right]^2\right] - \mathsf{E}\left[\bar{f}(\mathbf{u}^\mathsf{T} \Theta)\right]^2 \tag{7}$$

The ARD kernel affords analytic expressions for these quantities, after some algebra. Firstly

$$\mathsf{E}\left[\bar{f}(\mathbf{u}^\mathsf{T} \Theta)\right] = \mathbf{g}\,(\mathbf{1})_{\mathbf{N}} \tag{8}$$

where $\mathbf{1}$ is a vector of ones, and $\mathbf{g}$ is the $(1 \times N)$ $(\Theta\text{-independent})$ row vector

$$\mathbf{g} := \left|\Lambda^{-2} + \mathbf{I}\right|^{-1/2} \sum_{n=1}^{N} (\tilde{\mathbf{y}})_n\,(\mathbf{I})_{n \times \mathbf{N}} \exp\left(-\frac{(\mathbf{X})_{n \times \mathbf{M}}\left(\Lambda^2 + \mathbf{I}\right)^{-1}(\mathbf{X})_{n \times \mathbf{M}}^\mathsf{T}}{2}\right) \tag{9}$$

the modulus of a matrix signifying, as usual, its determinant. Then

$$D_{\mathbf{m}} = \frac{\mathbf{g}\,\mathbf{W}_{\mathbf{m}}\,\mathbf{g}^\mathsf{T}}{\left|2(\Sigma)_{\mathbf{m} \times \mathbf{m}} - (\Sigma)_{\mathbf{m} \times \mathbf{m}}^2\right|^{1/2}} - \mathbf{g}\,(\mathbf{1})_{\mathbf{N} \times \mathbf{N}}\,\mathbf{g}^\mathsf{T} \tag{10}$$

where $\mathbf{W}_{\mathbf{m}}$ is the $(N \times N)$ symmetric matrix with components

$$(\mathbf{W}_{\mathbf{m}})_{n \times o} := \exp\left(\frac{-(\mathbf{T})_{n \times \mathbf{m}}(\Sigma)_{\mathbf{m} \times \mathbf{m}}^{-1}(\mathbf{T})_{n \times \mathbf{m}}^\mathsf{T} - (\mathbf{T})_{o \times \mathbf{m}}(\Sigma)_{\mathbf{m} \times \mathbf{m}}^{-1}(\mathbf{T})_{o \times \mathbf{m}}^\mathsf{T}}{2}\right)$$
$$\exp\left(\frac{+((\mathbf{T})_{n \times \mathbf{m}} + (\mathbf{T})_{o \times \mathbf{m}})(\Phi)_{\mathbf{m} \times \mathbf{m}}^{-1}(\Sigma)_{\mathbf{m} \times \mathbf{m}}^{-1}((\mathbf{T})_{n \times \mathbf{m}}^\mathsf{T} + (\mathbf{T})_{o \times \mathbf{m}}^\mathsf{T})}{2}\right) \tag{11}$$

and

$$\mathbf{T} := \mathbf{X}\left(\Lambda^2 + \mathbf{I}\right)^{-1} \Theta^\mathsf{T}$$
$$\Sigma := \Theta\left(\Lambda^{-2} + \mathbf{I}\right)^{-1} \Theta^\mathsf{T} \tag{12}$$
$$\Phi := \Theta\left(\Lambda^{-2} + \mathbf{I}\right)^{-1} \left(2\Lambda^{-2} + \mathbf{I}\right) \Theta^\mathsf{T}$$

These $D_{\mathbf{m}}$ are then maximized using gradient descent, for $m = 1, 2, \ldots$ in turn.

4. Results

In this section, the methodology developed above is applied to the estimation of the reaction parameters described in Section 2 for experimental ARC data of fully charged 18650 LFP cells during HWS testing. In order to provide the input data for applying the GP approach the parameter space is sampled using a standard Latin hypercube method. These inputs are then filtered for simulations in which physically incorrect reaction initiation temperatures are obtained.

Optimization of the Sobol' indices via GPs reveals that two directions account for less than 0.15% of RMSE variance in total. There is also a clear principal direction, composed mainly of H_{pe}, which accounts for at least 35% of RMSE variance on its own. The variance is therefore (almost) entirely captured in four dimensions, which could potentially be reduced to just two dimensions by accepting some loss of fidelity.

The optimal two-dimensional parameter subspace is shown as a contour plot in Fig. 1, alongside the least relevant two-dimensional parameter subspace. Fragmentation or noise in these plots indicates uncaptured variance in RMSE. Ideally, the optimal subspace exhibits a smooth contour plot. By the Bayesian measure of fit (log likelihood), the Sobol' optimized GP model improves 19% over an unrotated ARD kernel, and 37% over the optimal isotropic one.

(a) RMSE over the plane $(\mathbf{u}_1, \mathbf{u}_2)$.   (b) RMSE over the plane $(\mathbf{u}_5, \mathbf{u}_6)$.
Figure 1: Contour plots of normalized RMSE over (a) the two most significant directions and (b) the two least significant directions.

A GP has been fit to the two most relevant directions $(\mathbf{u}_1, \mathbf{u}_2)$ alone, selecting a somewhat regularized local optimum with noise variance of 0.36. This GP was searched for minimum predicted RMSE, and combined with mean values for the irrelevant coordinates to produce a set of optimal reaction parameters (ROM).
Figure 2: Comparison of predictions obtained with reaction parameters selected by reduced model (ROM) optimization, heuristic full model optimization, and experimental data.

Fig. 2 presents the variation of the temperature rate with temperature according to simulation and experiment. The reaction parameters used for simulation have been optimized by ROM, and independently by a costly heuristic full model optimization. Clearly the ROM optimized model is no substitute for full optimization at this stage, but it does lie within experimental range over most of the domain, and reflects the gross features of the experimental plots reasonably well.

5. Conclusions

In this work a GP approach for the estimation of reaction parameters for the simulation of thermal runaway in Li-ion batteries was presented. The method uses a GSA-based dimensionality reduction to increase the efficiency of the optimization process.

When applied to data obtained from the experimental testing of 18650 LFP cells, comparison of the reduced-dimension GP emulators showed that the difference in predictions between the four- and six-dimensional emulators was negligible. For optimization purposes nearly all the useful information resides in just two-dimensions. Future work will investigate less robust, but potentially more precise, high variance (low noise) GP solutions, and analyze the robustness of the reduced approach.

Techno-Economic-Environmental Study for Recovery of Novel Water Source within a Power Plant - Desalination Complex

Ahmed AlNouss, Fadwa Eljack [*]

Department of Chemical Engineering, College of Engineering, Qatar University,

Doha, Qatar

fadwa.eljack@qu.edu.qa

Abstract

The global water supply is at an already critical level; around 3.9 billion people (47% of the world population) will be subject to water stress in 2050, according to the Organization for Economic Co-operation and Development (OECD). Unless advanced and alternative technology solutions are applied, construction of desalination facilities will continue to rise, leading to higher CO_2 emissions. While desalination allows for the production of water from highly saline sources, it is considered an energy intensive process that is largely powered by fossil fuel sources. The natural interconnections between water and energy known as water-energy nexus has been widely recognized for desalination facilities; yet, there are tremendous amounts of cooling water that are still needed for condensing steam in the thermoelectric Rankine cycle to produce electricity; and large amounts of energy are typically required to transport and treat the water. For example, over 45 thousand cubic meter per hour of water are required to run a 500 MW power plant, for cooling and other process requirements. Moreover, large amounts of water vapour exit in the effluent flue gas from the combustion process. The amount of water that can be recovered from the flue gas is sufficient to substantially reduce the need for freshwater make-up. This represents a promising opportunity to exploit synergies among water and energy systems specifically for arid regions.

In this paper, the aim is to identify suitable water recovery (dehydration hybrid) technologies that are capable of maximizing the recovery of water from flue gas in gas fired power plant-desalination plant coupled system. Specifically, compression and cooling, quenching, membrane separation and absorption alternatives are studied. The capacity of the power plant, the capacity of the desalination plant, fuel consumption of the power plant and energy requirement of the desalination facility are known. This work studies the technical, environmental and economic competing objectives when integrating the dehydration hybrid technology within the desalination-power plant complex. In this paper, the results for all the considered alternatives will be presented in terms of water recovery, energy savings, emissions reduction and economic indicators. The integrated low pressure quenching water recovery alternative has shown promising results, with up to 42% water recovery, while the integrated low pressure absorption alternative has demonstrated the highest figure in energy savings and emissions reduction with around 37%. These results can aid the decision on the suitable water recovery alternative to be used in the integrated energy-water complex.

Keywords: Energy-Water Nexus, Desalination, Flue gas, Gas-fired power plant, Techno-Environmental-Economic Analysis.

1. Introduction

Fossil-based power plants consume vast quantities of water for heat rejection, fuel preparation, power augmentation, emissions control, and cycle makeup purposes. At the same time, global water resources are becoming scarcer especially in the arid areas which necessitates more efficient and inexpensive water production processes. Although dehydration is done extensively in natural gas processing, water recovery from power plant flue gas is a new concept. Liquid desiccant dehumidification can be used to remove 64-68% water from the flue of a coal fired power plant (Martin et al., 2016). Condensing boilers can be used in the coal fired power plant to recover water and almost 15% of energy (Chen et al., 2012). Thermal membrane condensers can be used to recover heat and water from flue gasses from coal fired power plant (Wang et al., 2012). Although water recovery from coal fired power plants have been studied, gas fired combined cycle power plants are yet to get significant attention. To offset these observed escalating consumption rates, a new system must be developed to meet partial water demand of power plants. Recovering substantial portion of the water vapour present in the flue gas can act as potential source of water. The recovered water is of a quality similar to the desalinated water from reverse osmosis (RO) systems. This water can be used for various plant needs as recovered or can receive minimal treatment so that it can be used as direct-cycle makeup (Copen et al., 2005). Recently, a simultaneous heat and water recovery from flue gas was experimentally studied using membrane condensation. Different operating parameters such as fluid flowrates and temperatures were tested against process performance (Zhao et al., 2017). The results from the study can potentially guide through optimising the operational performance of membrane condensation technology for water and heat recovery. Until the moment, all the power plants in Qatar use natural gas (NG) as source of fuel and all the power plants, except one, are coupled with desalination plants to reduce the heating requirement of the desalination plant. This set up gives an opportunity to integrate the available heat in flue gas to desalination plant. Apart from desalination plants, Qatar does not have an alternative source of fresh water. With a booming economy, the need for fresh water is increasing every day in Qatar. In 2013, 70.6 Million m^3 of fresh water was consumed for industrial and domestic use in Qatar. Power plants in Qatar exhausts 30 Million m^3 of water vapour every year. With proper design, this water can be captured and integrated with desalination plants to supplement fresh water production. In addition, the heat recovered from flue gas would be integrated with the desalination plant to reduce their economic implications and environmental impacts (TokyYasir, 2018).

The aforementioned preliminary studies have shown the feasibility of a technology to recover water from industrial gases as novel sources of water. Water from flue gas, if cost-effectively separated as fresh water, is expected to have major impact on overall fresh water generation and usage capacitates in Qatar and the world. It can be reused for industrial and agricultural purposes. The water management strategies will enable encapsulating water sources from flue gas and desalination for integration. In an earlier study, (TokyYasir, 2018) examined a case of combined cycle power plant that uses both gas turbine and steam turbine to produce electricity to show the applicability of recovering water from flue gas. Specifically, compression and cooling, quenching, membrane separation and absorption alternatives are studied as potential technologies for flue gas dehydration. Detailed modelling and simulation using Aspen HYSYS V9 was done for the potential flue gas dehydration technologies. Each simulated process has multiple processing steps. For example, pressurized feed absorption has 3 steps:

compression, cooling, and absorption. Process simulation results were validated by comparison with published actual plant data in terms of energy demand. From this recent research project, a feasible source of fresh water was identified and a suitable technology was synthesized. Simulations showed that, by quenching almost 75% of the available water in the flue gas of a natural gas fired combined cycle power plant can be captured. By energy integration with a desalination plant, the energy demand for quenching was reduced by more than 50%. For further reduction in capital cost, the flow can be divided into multiple streams and other technologies like membrane filtration and adsorption can be tested in order to check for enhanced water capture to cost intensity ratio. The primary aim of this study is to valorise novel suitable water recovery technologies that are capable of maximizing the recovery of water from flue gas in gas fired power plant-desalination plant coupled system. The capacity of the power plant, the capacity of the desalination plant, fuel consumption of the power plant and energy requirement of the desalination plant are known. The study looks over the technical, environmental and economic competing objectives when integrating the dehydration hybrid technology within the desalination-power plant complex.

2. Model Development

Given the capacity of the desalination facility, its water and energy needs, the product specification or water properties, and the amount of available recovered water from hybrid dehydration technology, the aim is to develop a multi-objective optimization approach to assess the process performance targets and economic indicators. The developed optimization method and simulation track and assess the environmental impact due to the addition of the proposed hybrid water recovery technology/system. The developed tool provides flexibility in the design of water networks considering varying water quality feed, and varying objectives of utilizing the recovered water. The outcome of the presented tool is a two objectives diagram to help the decision maker in understanding the competing trade-offs in the integrated gas fired power plant/desalination plant/ and the studied water recovery technology.

The detailed simulations of the flue gas dehydration technologies using Aspen HYSYS V9 are integrated with gas fired power plant-desalination plant coupled system. Desalination process simulation models for multi-flash separation (MSF) and reverse osmosis (RO) membrane separation are considered for this study and are also developed using Aspen HYSYS along with the gas fired power plant. Figure 1 illustrates the overall configuration of the system. Each simulated process has multiple processing steps. For absorption, glycol package is used to dehydrate the flue gas stream from the power plant. The cooling alternative is a series of chiller coolers, expanders and two phase separators to recover the water from flue gas. Combining the cooling and absorption gives another alternative to be studied where the flue gas is first cooled, expanded and purified before entering the glycol absorption. Compression and cooling option adds a compression unit to the cooling system. Whereas the quenching alternative looks at recycling part of the water to the two phase separation unit to increase the separation. Finally, the membrane system utilizes the membrane unit extension modelled in Aspen HYSYS to purify the flue gas stream and recover its water content. The systems are tested under high and low operating pressures (LP and HP) to evaluate the impact on the performance of the dehydration alternative.
Figure 1: Overall configuration of the flue gas dehydration coupled with CHP-desalination plant

The main characteristics for the simulation models of the flue gas dehydration technologies and desalination plants are summarized in Tables 1.

Table 1: Main characteristics of the flue gas dehydration technologies and desalination plants

System	Water Recovery (%)	Water Purity (%)
LP absorption (1)	2.9	99.55
HP quenching (2)	37.9	99.95
LP quenching (3)	41.2	99.99
Compression and cooling (4)	29.9	99.99
HP cooling and absorption (5)	40.8	99.56
LP cooling and absorption (6)	38.8	99.95
Membrane separation (7)	29.4	99.91
RO desalination	15.8	99.88
MSF desalination	24.6	99.88

In addition, the characteristics of the combined heat and power (CHP) gas fired plant are highlighted in table 2.

Table 2: Main characteristics of combined heat and power (CHP) gas fired plant

CHP plant property	Value	Unit
NG feed (mainly methane)	8.3	kmol/s
Air feed (21% O2, 79% N2)	79.4	kmol/s
Exhaust temperature	100	ºC
Power generated	4.5	GW

After the simulation of the different flue gas dehydration configurations in Aspen HYSYS, the built-in activated economic analysis is utilized to quantify the capital and operating costs. In addition, the activated energy analysis capabilities of Aspen HYSYS are utilized to estimate the potential heat integration between the different units in the

integrated water-energy system along with the emissions of carbon dioxide equivalent. The different performance indicators are then optimized to generate a two objectives diagram of the different flue gas dehydration configurations emphasizing the environmental and economic performance. The objective of the optimization approach is to minimize the economic parameter estimated as the levelized cost of water (LCOW) expressed in Eq. (1), in addition to the environmental parameter estimated as the emissions of carbon dioxide equivalent expressed in Eq. (3).

$$LCOW\left(\frac{\$}{m^3}\right) = \frac{(Capital\ Cost \cdot CRF) + Operating\ Cost}{rate\ of\ water\ recovery \cdot operating\ hours}$$ Equation (1)

Taking the discount rate (r) equal to 20% and plant useful life (n) equal to 25 years,

$$CO_2\ emission\ rate\ in\ [CO_2 - e] = Q\ EF\ \eta\ GWP$$ Equation (2)

Where, CRF is the capital recovery factor calculated in Eq. (3), Q is the energy calculated for each utility type (energy per time), EF is the emission factor associated with each utility type (kg CO_2 per energy), η is the CO_2 energy source efficiency factor associated with each utility type, and GWP is the global warming potential of CO_2 considered to be 1 on this study. The annual operating hours considered for this study are 8760.

$$CRF = \frac{r(1+r)^n}{[(1+r)^n]-1}$$ Equation (3)

3. Results

The results for all the considered alternatives are presented in terms of energy savings, emissions reduction and economic indicators. Figure 2 illustrates the energy savings across the heat integration for each of the integrated flue gas dehydration system. The figure indicates a higher saving for the alternatives containing the MSF desalination plant compared to the RO ones. Nevertheless, the overall costs associated with MSF is double that of RO. The low pressure absorption option coupled with CHP and MSF units demonstrates the highest percentage of saving among the different alternatives with around 37%.
Figure 2: Energy savings among the different flue gas dehydration systems coupled with CHP for a) RO and b) MSF options

The ultimate outcome of the developed tool is a two objectives diagram to help the decision maker in understanding the competing trade-offs in the integrated gas fired power plant/desalination plant/ and the studied water recovery technology. Figure 3 illustrates the resulting economic-environmental diagram for the different integrated

flue gas dehydration systems. It can be concluded from the figure that the alternatives with RO units have lower emissions compared to the ones using MSF units. In particular, the low pressure absorption and cooling alternative demonstrated the lowest LCOW with around 0.27 $/m^3 and 5.45x10^5 kg/h in terms of CO_2-e. Whereas, the compression and cooling alternative demonstrated the lowest emissions in terms of CO_2-e with around 5.19x10^5 kg/h and 0.38 $/m^3 in terms of LCOW.

Figure 3: Economic-environmental results for the different flue gas dehydration systems coupled with CHP and RO or MSF

4. Conclusions

Water recovery from flue gas can have a major impact on overall fresh water generation and usage capacities in Qatar and the world. This study examined the techno-economic-environmental evaluation of different flue gas dehydration alternatives when integrated with gas fired power plant-desalination plant coupled system. The generated economic-environmental diagram demonstrated a much lower environmental impact for the options utilizing RO unit.

Abstract

This paper proposes a new systematic methodology to design a distillation column with middle products (side-draw) for ideal ternary mixtures, where the middle boiling component is present at trace concentrations. The method uses a molecular tracking concept, which uses a probability function based on the thermodynamic properties of the system. The probability function expresses the possibility of upward/downward movement of a single molecule on a tray inside a column. The advantage of this method compared to other existing methods is in its capability to quickly and efficiently provide a feasible solution without relying on rigorous optimization or trial/error approaches. In addition, the inherently graphical nature of the methodology allows engineers to get an intuitive understanding of the movement of the often-complicated middle product. The methodology is demonstrated on an ideal ternary mixture of benzene and p-xylene with toluene as the trace middle boiler, where the results obtained through the molecular tracking were validated against a rigorous process simulation.

Keywords: molecular tracking, side-draw distillation, design, multi-component distillation

1. Introduction

Separation of mixtures through distillation is an established practice in many industries from petrochemicals to bio-manufacturing processes. Despite being the standard-choice for many separations, distillation typically consumes about 60 % of total required energy of chemical industries (Ma et al. 2018). Nonetheless, distillation contributes to about 3% of the total U.S national energy consumption (Seader et al., 1999). As a result, both industrial and academic practitioners have invested considerable efforts in reducing the amount of energy required to operate these units (Kraller et al., 2016), one avenue of which has been the process intensification route. One simple forms of distillation intensification at the unit operation level and in presence of trace component in the system is the replacement of sequential distillation columns by using a single side-draw distillation column. The parametric study in industrial distillation carried out by (Tedder et al., 1978) asserts that for all ternary mixtures where a low middle product purity is acceptable, a side-draw distillation should be considered as one of the possible

configurations. Early stage design of distillation columns with side-draw is challenging due to lack of a simple and reliable method to efficiently obtain the (near) optimal feed and side draw locations. Today, side draw distillation columns are designed by either a trial/error or rigorous mathematical formulation, both of which are time consuming and resource intensive endeavors. This work attempts to address this through a systematic design methodology with integration of several concepts and tools including molecular tracking at its core.

2. Molecular tracking

Molecular tracking is a probability-based concept, based on the thermodynamic properties of the system. The concept evaluates the probability of a single molecule to move upwards into the vapor phase or downward into the liquid phase at a given stage of a column. The mixture existing on each stage of a distillation unit splits into vapor and liquid flows with specific vapor and liquid concentrations. The liquid moves downward to the lower tray and the vapor moves upward to the upper tray. Hence, in order to evaluate the molecules probability of moving upward or downward, the function has to be defined over the flowrates of every component on each stage., The probability function as shown in Eq. (1) can be derived (Maat, 2017). The function is defined as the ratio between the existing vapor flowrate of a component over the total outlet flowrate of the same component as expressed below:

$$\beta_i^n = \frac{y_i^n V_i^n}{y_i^n V_i^n + x_i^n L_i^n} \tag{1}$$

Here, β is the probability function, x and y are liquid and vapor compositions respectively. The variables L and V are liquid and vapor internal molar flows and i denotes the component and n is the stage number inside the column.

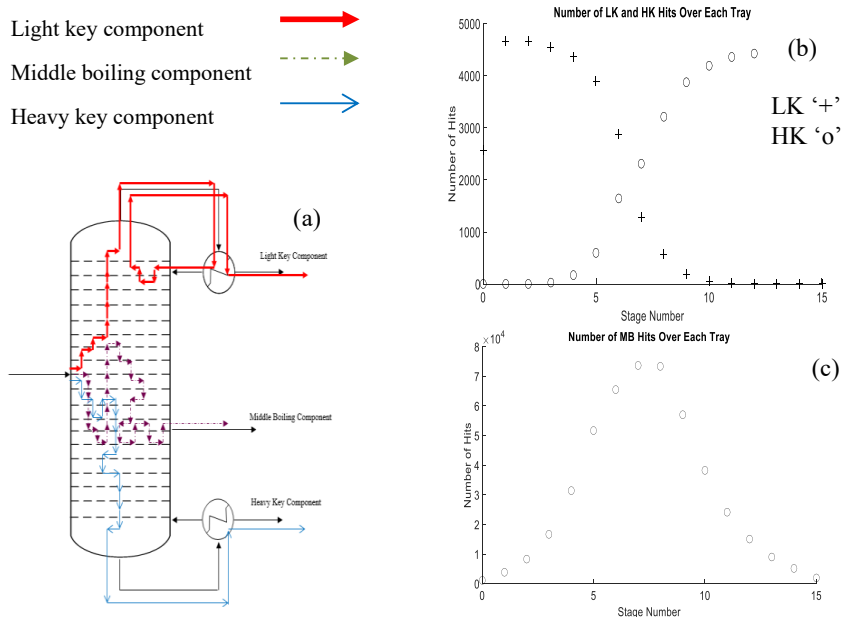
In molecular tracking concept, a single molecule (typically of the middle key) is tracked from the moment it enters the feed tray by comparing the output of a random number generator function with the calculated system probability value from Eq. (1). If the random number lies within the range $(0, \beta_i^n)$ the molecule is considered to have moved to the vapor phase and hence up to the stage above. This operation is repeated until the molecule leaves the column from one of the outlet streams. Figure (1) illustrates the concept of molecular tracking applied to the heavy key, light key as well as the middle boiling components. As shown in the figure, the light key component has a tendency to move directly towards the top of the column while the heavy key component has a tendency to move directly towards the bottom of the column. However, the middle boiling trace component tends to spend several steps in the middle of the column before eventually exiting the column. From a thermodynamic point of view, the tray with maximum number of hits for the middle boiling component identifies the most probable location for the side-draw as this is the location where the probability of the middle boiling molecules travelling with the vapor or liquid phases is the same (i.e. β of middle boiling component is 50%)


Figure 1: (a) Schematic of a side-draw distillation column with representative molecular pathways, (b) Number of hits of light key and heavy key components, (c) Number of hits of trace component versus stage number

3. Systematic design methodology based on molecular tracking

Here, a systematic hierarchical framework for designing a side-draw distillation column for a ternary mixture, with a middle boiling component at infinite dilution is proposed. In this methodology, the information of a distillation process for the hypothetical binary mixture of key components is used to design the side-draw column for the real mixture. In this work, the design methodology is presented systematically in Figure (2), and the corresponding case study is illustrated in the next section.

Methodology This methodology determines the number of stages, feed and side-draw location based on the specifications of the system. Specifications required to design the column are light key component purity in distillate and heavy key component purity in bottom stream. The reflux ratio of the final configuration of the column is implicitly calculated when the column model is solved.

Step 1. Design a binary column for separation of key components in the mixture

Step 2. Find composition and temperature profile of the system

Step3. Determine the vapor pressure profile of middle boiling component

Step 4. Calculate K-value profile of MB based on Eq. (2)

$$K_{MB} = \frac{y_{MB}}{x_{MB}} = \frac{p_{MB}^{sat} \gamma_{MB}^{\infty}}{P \varphi_{MB}^{\infty}} \qquad (2)$$

Step 5. Calculate the probability profile of the MB based on Eq. (3)

$$\beta_i^n = \frac{K_{MB}^n V_{MB}^n}{K_{MB}^n V_{MB}^n + L_{MB}^n} \qquad (3)$$

Step 6. Find the tray(s), in which probability equals 50 %

Step 7: trays (step 6) > 1

N → The tray found in step 6 is side-draw location

Y

Step 8. Simulate the column in a simulation software based on the distillate and bottom product specifications. Put side-draw on the trays found assuming the flowrate is fixed. Choose the one with minimum reboiler duty.

Figure 2: Workflow of methodology

4. Case study

The application of the design methodology is highlighted through a benzene and p-xylene mixture with trace amounts of toluene as an impurity. The separation process is considered isobaric at 1 atm. A comparison is carried out between this method and driving force based method for designing a side-draw column at the end of this section. The results of each step of design methodology are listed in Table (1). The outcome configuration of this algorithm shows that feed has to be located at tray 6 and side-draw has to be located at tray 7.

Table 1: Data sheet of benzene, p-xylene case study

Action	Feed: (B 58 %, T 1,000 ppm p-X 41.9 %)
Steps 1, 2	
1. Design the column, using driving force approach. $N=14,\ N_F=6$	McCabe-Thiele Diagram for B and p-X at 1 atm
2. Determine composition profile and temperature profile.	T-XY Diagram benzene, p-xylene
Steps 3-7 1. Calculate p_{MB}^{sat} profile. 2. Calculate K_{MB} profile. 3. Determine probability profile. 4. Find trays in which probability is 50 %.	Probability profile of middle component versus stages
Steps 7, 8 1. Simulate the column. Optimum Side-draw location is tray 7. $Q_{reboiler}^{MT}=7.77MW$ $Q_{condenser}^{MT}=12.01MW$	Reboiler duty v.s side-draw location

This information has been validated against a rigorous process simulation in step 7 and 8. Comparing the rigorous process simulation results for the molecular tracking is able to

narrow down the possible most energy efficient tray location for a column with a side draw purely based on thermodynamic properties (in this case to three options) and with the aid of process simulation narrow down the answer to the most energy efficient one that is illustrated in Table (1) at steps 7 and 8.

When comparing these results with driving force method proposed by Erik Bek-Pedersen and Gani (2004), the maximum driving force occurs at $D_x = 0.4$ (D_x is the liquid composition of light key component at maximum driving force) between benzene and toluene. The joint driving force diagram shows $D_s = 0.35$ (D_s is the liquid composition of light key component when two binary driving force diagrams intersect). Algorithm D2 on that paper shows that feed should be introduced at tray 5 while, side-draw should be introduced at tray 9. The simulation of this configuration in HYSYS. It can be clearly seen that molecular tracking proposes much more efficient configuration compared to driving force based method.

Conclusions

A systematic methodology to design side-draw columns for ideal ternary mixtures, where the middle component is at trace concentration level is proposed. The methodology is based on a probability function expressed in terms of thermodynamic properties of the system. The column is first designed for the key components in the mixture, and then the side-draw location is deterministically found. The side-draw is located at the stage, which the middle component (trace component) is indifferent to move either upward or downward. A case study of benzene, p-xylene and trace amount of toluene has been examined in this work. The design configuration of molecular tracking has shown less energy demand compared to the corresponding configuration of driving force. Considering that it is possible to find the side-draw location analytically by using trial/error approach, the real scope of molecular tracking is to design a dividing wall column by finding the location of dividing wall.

Improved Design of Experiments for Identification of MIMO Systems

Kurt E. Häggblom

Åbo Akademi University, Faculty of Science and Engineering, Biskopsgatan 8, Turku FI–20500, Finland

khaggblom@abo.fi

Abstract

A problem in the identification of MIMO systems is that the system outputs in an identification experiment may be strongly correlated if the inputs are perturbed by uncorrelated signals, as is standard practice. Such a correlation reduces identifiability.

A set of methods to design input perturbations that minimize the sample correlation between the outputs has previously been proposed. These methods require an initial model for the design. In this paper, a data-based design method is proposed. Data are obtained from preliminary experiments with the system to be identified. Besides being preferable from a practical point of view, the data-based approach makes it easier to handle some numerical issues that gave problems in the model-based approach.

A design method that minimizes the input or output peak value subject to desired output variances with no output correlation is presented. A model of an ill-conditioned distillation column is used to illustrate the method.

Keywords: System identification, Multivariable systems, Ill-conditioned systems, Experiment design, Data-based design.

1. Introduction

The quality of the data is of utmost importance in the identification of multiple-input multiple-output (MIMO) systems. The standard approach of perturbing all inputs simultaneously by uncorrelated signals tends to produce correlated outputs. For ill-conditioned systems this correlation is very strong. Such data may jeopardize identi-fiability (Koung and MacGregor, 1992).

A design method that addresses the output distribution was proposed by Häggblom (2017a, 2018b). The method can produce uncorrelated outputs, which is considered good for identifiability. A drawback of the method is that it requires an initial model of the system. A short overview of related design methods is given in Häggblom (2017a).

In this paper, a completely data-based method is introduced for the same purpose of obtaining uncorrelated outputs. Data are obtained from one or more preliminary experiments with the system to be identified. It is possible, for example, to use the data from a standard identification experiment with uncorrelated inputs to design a better experiment. Additional properties such as input and output peak values can be minimized in addition to correlation handling.

An ill-conditioned distillation column model is used for illustration of the methods.

2. Problem formulation

Experiment design for identification of MIMO systems is considered. The system has n inputs $u(k)$ and n outputs $y(k)$, sampled at time instants $k = 1,\ldots,n_s$, where n_s is the total number of sample points. The variables are related by a dynamic relationship

$$y(k) = G(\mathrm{q})u(k) , \tag{1}$$

where $G(\mathrm{q})$ is a matrix of pulse transfer operators defined through the shift operator q. This relationship is assumed to be initially unknown. It is not implied that a model of this form is to be identified.

The input design for the identification experiment is facilitated by the use of an n-dimensional perturbation signal $\xi(k)$. This signal is typically a random binary signal (RBS), a pseudo random signal (PRBS), or a multi-sinusoidal signal (MSS). The correlation between the individual signals $\xi_i(k)$, $i = 1,\ldots,n$, should preferably be small (ideally non-existent). In practice, this is achieved by constructing each ξ_i from a base sequence ξ_0, of length N, by shifting it (approximately) $(i-1)N/n$ positions in a circular way. As suggested by Ljung (1999), more than one period of the sequences may be used to give a total sequence length $n_s = n_p N$, where n_p is the number of periods.

The input $u(k)$ to be applied in the identification experiment is given by a linear transformation

$$u(k) = T\xi(k) , \tag{2}$$

where T is a constant matrix determined in the input design with the aim of making the output samples $y_i(k)$, $k = 1,\ldots,n_s$, $i = 1,\ldots,n$, uncorrelated with $y_j(k)$, $j \neq i$.

The output correlation depends on the output covariance matrix, which for an $n \times n$ system is defined by $n(n+1)/2$ parameters. This suggests that the same number of adjustable elements of T is sufficient to produce uncorrelated outputs. Thus, T can be a triangular or symmetric matrix, for example. If more elements are used, it is possible to optimize some quantity besides output correlation. In this paper, minimization of the peak values $\max_{i,k} |y_i(k)|$ and $\max_{i,k} |u_i(k)|$ is considered.

3. Input design

Applying the input $u(k)$, $k = 1,\ldots,n_s$, to a system yields an $n_s \times n$ matrix of sampled outputs Y, where the kth row and ith column of Y holds the sample $y_i(k)$. Given the perturbation sequence $\xi(k)$, $k = 1,\ldots,n_s$, it is desired to choose T in Eq. (2) to give Y specified properties. In particular, the covariance matrix $P = \mathrm{cov}(Y)$ is desired to be diagonal, which means no correlation between the outputs. Assuming the variances $\mathrm{var}\, y_i = 1$ are desired, the objective is to obtain $P = I$.

Assume it is known that the single input $u_i(k) = \xi_j(k)$ produces an output matrix Y_ℓ, $\ell = i + (j-1)n$. If the system is linear, applying an input $u_i(k) = T_{ij}\xi_j(k)$ would then

produce the output matrix $T_{ij}Y_\ell$. If Y_ℓ is known for every combination of $u_i(k)$ and $\xi_j(k)$, applying the input $u(k)$ given by Eq. (2) would then produce the output

$$Y = \sum_{i=1}^{n}\sum_{j=1}^{n}T_{ij}Y_\ell, \quad \ell = i+(j-1)n,\tag{3}$$

where T_{ij} is the element of T in row i and column j.

To streamline the notation needed further below, the vector

$$x = \text{vec}(T)\tag{4}$$

is introduced. The vectorization results in $x_\ell = T_{ij}$, where $\ell = i+(j-1)n$. Equation (3) is then replaced by

$$Y = \sum_{\ell=1}^{n^2}x_\ell Y_\ell.\tag{5}$$

The output covariance matrix becomes

$$P = \sum_{\ell_1=1}^{n^2}\sum_{\ell_2=1}^{n^2}x_{\ell_1}x_{\ell_2}P_{\ell_1\ell_2},\tag{6}$$

where $P_{\ell_1\ell_2} = \text{cov}(Y_{\ell_1},Y_{\ell_2})$ is the matrix of covariances between Y_{ℓ_1} and Y_{ℓ_2}. Thus, $P_{\ell_1\ell_2}$ can be calculated when Y_{ℓ_1} and Y_{ℓ_2} are known.

The task of the input design is now to determine the vector x to obtain $P = I$. The nonlinearity of Eq. (6) is a difficulty, however. To overcome this, Eq. (6) can be linearized and solved iteratively. The linearization is

$$P = \sum_{\ell_1=1}^{n^2}\sum_{\ell_2=1}^{n^2}\left(\tilde{x}_{\ell_1}x_{\ell_2} + x_{\ell_1}\tilde{x}_{\ell_2} - \tilde{x}_{\ell_1}\tilde{x}_{\ell_2}\right)P_{\ell_1\ell_2},\tag{7}$$

where $\tilde{x}$ is the previous value of x in the iteration procedure.

4. Obtaining data

Data for the design is generated by one or more experiments with the system to be identified. The most reliable method is to make an experiment with every combination $u_i(k) = \xi_j(k)$, $i = 1,\ldots,n$, $j = 1,\ldots,n$, one at a time. This results in n^2 experiments, each one yielding a matrix of sampled outputs Y_ℓ, $\ell = i+(j-1)n$, needed in the input design.

For $n > 2$, this is a lot of experiments, and even for $n = 2$, four experiments might be undesirable. An alternative is to make just n experiments with $u_i = \xi_j$, $i = 1,\ldots,n$ and j arbitrary (e.g., $j = i$ or $j = 1$). For each experiment, a pulse-response model $G(q)$ satisfying Eq. (1) can be determined in a simple way. This makes it possible to simulate all combinations $u_i = \xi_j$ to obtain the required output data matrices.

It is possible to take this one step further, and make only one experiment with $u(k) = \xi(k)$. Here, all inputs are perturbed simultaneously. If the components $\xi_i(k)$, $i = 1, \ldots, n$, are essentially uncorrelated with one another, it is possible to determine the n pulse-response models above and proceed in the same way. This kind of experiment is the standard identification experiment recommended in textbooks (e.g., Ljung 1999; Isermann and Münchhof, 2011), but here the data is used to design a better experiment.

5. Solution procedures

In the case of a structurally constrained T (which is a user choice) with $n(n+1)/2$ free elements such that T is not structurally singular, Eq. (6) can be solved directly to obtain a solution that yields $P = I$. However, there are multiple solutions because of the quadratic nature of Eq. (6). Moreover, various column and row permutations of T can be applied. For a triangular structure, there are $(n!)^2$ permutations; for a symmetric or skew-symmetric structure, there are $n!$ permutations of each.

To avoid the nonlinearity of Eq. (6), an iterative application of Eq. (7) can be used. It is then convenient to use an optimization framework to obtain a solution. Using the YALMIP toolbox (Löfberg, 2004) in conjunction with MATLAB makes it easy to formulate the problem as

$$\max_{x \in X} \lambda, \text{ s.t. (7) and } \lambda I \leq P \leq I, \tag{8}$$

where X denotes the allowed structures of x (and T). This procedure does not eliminate multiple solutions. Generally, the solution depends on the starting value $\tilde{x}$ in Eq. (7).

If T is constrained to a lesser degree, an unconstrained T being the typical case, Eq. (6) and (7), with $P = I$, are underdetermined with respect to x. This makes it possible to optimize some other property besides correlation. Minimization of the peak values $\max_{i,k} |y_i(k)|$ and $\max_{i,k} |u_i(k)|$ are very relevant choices.

Minimization of $\max_{i,k} |y_i(k)|$, later referred to as $\min Y_{\max}$, can be formulated as

$$\min_{x \in X} r, \text{ s.t. (5), (7), } P = I, \text{ and } -r \leq Y \leq r. \tag{9}$$

In the case of perturbation signals that switch between two levels, as e.g. PRBS inputs, minimization of $\max_{i,k} |u_i(k)|$ can be accomplished by minimization of T_∞ (Häggblom, 2018a, 2018b). This minimization can be formulated as

$$\min_{x \in X} r, \text{ s.t. (7), } P = I, \text{ and } \sum_{j=1}^{n} |T_{ij}| \leq r, \ i = 1, \ldots, n. \tag{10}$$

Because these optimizations are completely data based, they are also non-convex. This means that there is no guarantee that the obtained solution is a global optimum. Hence, many starting values $\tilde{x}$ should be tried. Fortunately, the differences between the best local optima tend to be small.

6. Case study

An ill-conditioned distillation column model introduced by Skogestad and Morari (1988) is used to illustrate the input design methods. This model was also used for input design in Häggblom (2017b, 2018b). The model is a state-space model

$$\dot{x}(t) = Ax(t) + Bu(t) \atop y(t) = Cx(t), \quad A = \begin{bmatrix} -\frac{1}{194} & 0 \\ 0 & -\frac{1}{15} \end{bmatrix}, \quad B = \begin{bmatrix} 1 & -1 \\ 0 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} \frac{87.8}{194} & \frac{1.4}{15} \\ \frac{108.2}{194} & -\frac{1.4}{15} \end{bmatrix}. \tag{11}$$

In this case study, the sampling time is $T_s = 1$ and a PRBS with minimum switching time $T_{sw} = 4$ and sequence length $N = 255$ is used as perturbation.

For a triangular T structure, including all permutations of columns and rows, eight solutions were found (two for each permutation) by the optimization in Eq. (8). The ones with the smallest peak values $\max|y| \equiv \max_{i,k}|y_i(k)|$ and $\max|u| \equiv \max_{i,k}|u_i(k)|$ are

$$\min Y_{\max}: \quad T = \begin{bmatrix} 1.4863 & 0 \\ 1.4652 & 0.0866 \end{bmatrix} \Rightarrow \max|y| = 2.5940, \ \max|u| = 1.5567 \tag{12}$$

$$\min T_\infty: \quad T = \begin{bmatrix} 0 & 1.5012 \\ -0.0820 & 1.4646 \end{bmatrix} \Rightarrow \max|y| = 2.9594, \ \max|u| = 1.5466 \tag{13}$$

For a symmetric or skew-symmetric T, including all permutations, eight solutions were found (two for each permutation). The ones with the smallest peak values are

$$\min Y_{\max}: \quad T = \begin{bmatrix} 1.0439 & 1.0875 \\ 1.0875 & 1.0179 \end{bmatrix} \Rightarrow \max|y| = 2.7250, \ \max|u| = 2.1315 \tag{14}$$

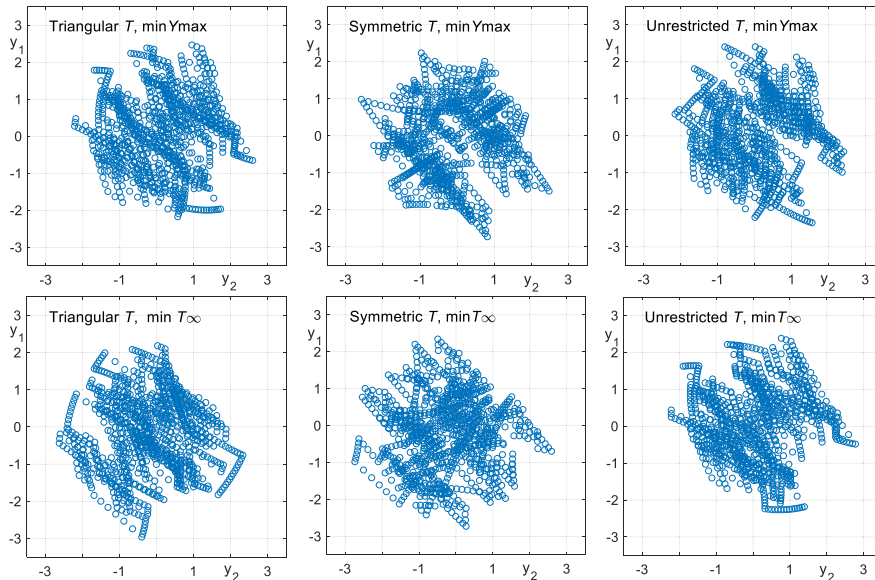
$$\min T_\infty: \quad T = \begin{bmatrix} 1.0628 & -0.9897 \\ 0.9897 & -1.0542 \end{bmatrix} \Rightarrow \max|y| = 2.7367, \ \max|u| = 2.0525 \tag{15}$$


Figure 1. Scatter plots of output distributions.

Minimization of the peak values with an unrestricted T matrix using the formulations in Eqs (9) and (10) gave the following results:

$$\min Y_{\max} : \quad T = \begin{bmatrix} 1.4568 & 0.3367 \\ 1.4189 & 0.4116 \end{bmatrix} \quad \Rightarrow \quad \max|y| = 2.4079 \, , \ \max|u| = 1.8305 \tag{16}$$

$$\min T_{\infty} : \quad T = \begin{bmatrix} -0.0363 & 1.4769 \\ 0.0432 & 1.4700 \end{bmatrix} \quad \Rightarrow \quad \max|y| = 2.7726 \, , \ \max|u| = 1.5132 \tag{17}$$

As can be seen, a triangular type of T matrix is a good choice for obtaining a small input peak value, whereas a symmetric type of T matrix is not good. A small output peak value requires minimization of $Y_{\max}$ with an unrestricted T matrix.

Figure 1 shows scatter plots of the output distributions of the various designs.

7. Conclusions

A data-based method for design of experiments for identification of MIMO systems was described. The required data can be obtained from some preliminary experiment(s) with the system. The input design, which is easy to carry out with standard optimization software, yields uncorrelated outputs. This is considered good for identifiability. In addition, input and output peak values can be minimized subject to desired output variances with no output correlation. It is an advantage in process operation to obtain desired output variances with input and output peaks as small as possible. The method works with any kind of standard perturbation signals used in system identification.

Abstract

Haemodialysis is a blood treatment technique used for patients whose kidneys are not working normally. A number of Linear Model Predictive Control (LMPC) formulations for controlling haemodialysis have been proposed in the literature. In this paper, a Nonlinear Model Predictive Control (NMPC) formulation is proposed that instead of using an approximated linear model takes into account the nonlinear model for haemodialysis. One of the key advantages of the NMPC formulation is that it gives more comprehensive control of the haemodialysis process. Four manipulated variables are considered: the blood flow out of the body, the blood flow returned from the dialysis machine to the body, the dialysate rate and the sodium concentration of the inlet blood flow. By manipulating these variables, the fluid volumes and the toxin clearance are monitored and controlled. The results show that a better control performance for the blood volumes and toxin clearance is obtained while the blood and dialysate flow rates are held at a relatively low level, which is expected to reduce the risk of adverse reactions for the patients.

Keywords: Haemodialysis, Model Predictive Control, Optimisation

1. Introduction

Human kidney functions as a crucial organ which balances electrolytes and volumes of body fluid, and filters toxin content out of the blood before the blood returns to heart. Approximately 20% of the blood is processed by kidneys which amounts to 1800 litres per day (Lote 2013). Haemodialysis refers to a blood treatment process that removes toxins and waste for patients with severe renal failure. In order to achieve normal functions of the kidney, the haemodialysis treatment typically takes 3 to 5 hours per week for one patient (Pierce, Tubing, and Cassettes 2008).

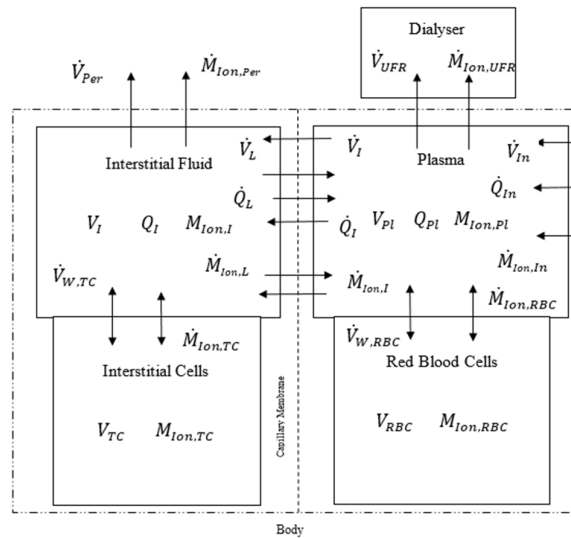
The blood and dialysate flowrates are normally considered as two key variables during the treatment process. A trade-off arises when determining the two variables: increasing the two flowrates will generally shorten the required treatment time period, but will result in higher risk of adverse reactions for the patients including headache and muscle cramps. Therefore, finding the optimum operating conditions for haemodialysis becomes a complex optimisation problem. Currently the haemodialysis treatment is usually performed by nurses under empirical operating conditions.


Figure 1.1: Mathematical model describing the haemodialysis process where four compartments are separated.

Eck and Dua (Eck and Dua 2016) performed simulation of the haemodialysis process based on the relevant mathematical model describing the dynamic behaviours of haemodialysis proposed by Gyenge et al.(1999) and Canete and Huang (2010). In the LMPC formulations proposed in the literature, the controlled variables include the relative blood volume (RBV), heart rate (HR) and systolic blood pressure (SBP). These variables are controlled by manipulating the ultrafiltration rate (UFR), the rate at which the fluid is being removed from the patient's body but the objectives regarding toxin clearance and excess water were not considered. In this work an NMPC approach taking into account the nonlinear model of the haemodialysis process, incorporating toxin clearance and excess water, is proposed.

2. Methodology

2.1. Mathematical model

A mathematical model describing the dynamic behaviour of the haemodialysis has been developed in order to achieve the desired optimisation. The model used in this paper is derived based on studies by Gyenge et al. (1999) and Canete and Huang (2010), as well as the modifications by Eck and Dua (2016). The proposed model divides the human body into four individual compartments and one dialyser compartment, as presented in Figure 1.1. The four compartments consist of two extracellular compartments: the red blood cells and the interstitial cells, as well as two intracellular compartments including the blood plasma and interstitial fluid, which are separated by the capillary walls. From Figure 1.1 it can be observed that the interstitial cells are connected to the interstitial fluid while the red blood cells are connected to the plasma compartment. The dialyser only connects to the plasma compartment, which indicates that the plasma compartment is the only compartment that is directly affected by external elements. V refers to the

volumes of the compartments (L), M represents the ion contents (kg), $\dot{M}$ is the ion flux (kg/h) and Q denotes the protein content (kg). The subscripts denote the different compartments and components including ions and toxins.

The development of the mathematical model takes the assumptions into consideration that the four compartments are perfectly mixed and homogeneous, and all proteins have the similar physical and chemical properties as albumin. The model contains theoretical and empirical correlations from literatures such as mass balances, ion distribution and concentration gradients. The state variables of the haemodialysis treatment process are described by simultaneous ordinary differential equations (ODEs) representing the interconnected compartments as shown in Figure 1.1. The values of the parameters are taken from literature (Chapple et al. 1993).

2.2. Orthogonal collocation on finite elements (OCFE)
When solving the mathematical model symbolic and numerical methods are considered. The symbolic method is not suitable due to the complexity of the model. Orthogonal collocation on finite elements (OCFE) is a numerical method for solving ODEs and is widely applied to chemical and biomedical engineering systems. The method minimises the difference between the Lagrange interpolation and the actual solution on predetermined collocation points. The OCFE method is used to both simulate the haemodialysis process and solve the control problem based on the proposed mathematical model.

2.3. Nonlinear model predictive controller setup
The objective function of the NMPC formulation is defined as follows:

$$\min_{u,z} E_{MPC} = \sum_{t=0}^{H_p} Q_z (z_c^{pred}(t_i) - z_c^{sp}(t_i))^2 + \sum_{t=0}^{H_c} Q_u (u(t_i) - u^{ref}(t_i))^2 \tag{1}$$

The objective function minimises the differences between the controlled predictive state variables $z_c^{pred}(t)$ and the set point $z_c^{sp}(t)$ over the prediction horizon H_p. In the objective function the volumes of plasma and interstitial cells compartments, the total body fluid volume and the urea contents are selected as controlled predictive state variables. The objective function also minimises the deviation of the input variables $u(t)$ from a reference value $u^{ref}(t)$ over the control horizon H_c. As mentioned above, four input (manipulated) variables are proposed: the blood flow out of the body, the blood flow returned from dialysis machine to the body, the dialysate rate and the sodium concentration of the inlet blood flow. Q denotes the penalty ratios which can be modified to adjust the controller performance. The total simulation time is set to 210 minutes since normal haemodialysis treatment time is 3 to 5 hours. In order to apply the OCFE method, the simulation time period is divided into 210 elements with 2 internal collocation points in each element. The prediction horizon is set to 5 timesteps while each timestep represents 1 minute. The values of the parameters and the initial conditions of the variables are taken from the literature assuming a 70-kg patient (Xie et al. 1995). The bounds and set points for the variables are given in Table 2.1.

Table 2.1: Values of variables in the NMPC set up

Variable		Units	Lower Bound	Upper Bound	Maximum Change	Set Point
Manipulated Variables	$J_{B,Out}$	ml/min	0.0	800.0	25.0	0.0
	$J_{B,In}$	ml/min	0.0	800.0	25.0	0.0
	J_D	ml/min	0.0	800.0	25.0	0.0
	$[Na]_{J_{B,In}}$	mmol/l	96.6	179.4	-	139.7
Controlled Variables	V_{Total}	L	-	-	-10; +5	40.74
	V_{Pl}	ml	320	32000	-	3200
	V_I	ml	840	84000	-	8400
	$Urea_{Ex}$	mmol	-	-	-	0.0

3. Results and discussion

3.1. Model validation

The mathematical model has to be firstly validated before implementation of the NMPC. The results of infusion simulation are compared with the experimental results obtained by Manning and Guyton (1980) who performed experiments in which dogs were infused with RS in an amount equivalent to 5%, 10, and 20% of the actual body weight. The results of dialysis simulation regarding the toxin concentrations were in good comparison with the experimental data obtained by Ziofcko (2000). The experimental data consists of the urea, uric and creatinine blood concentrations, which were obtained by measuring the dialysate and blood toxin concentrations 11 times in a 210-minute interval. The data was taken from a 58-kg bodyweight patient who experienced a dialyzing treatment lasting 3 hours and 30 minutes, 3 times a week. Two examples of comparison between the simulation results and experimental data, the blood volume change for infusion and the urea concentration change for dialysis simulation, are given in the top two plots in Figure 3.1. The comparisons show a good agreement which indicates that the model can be considered as a valid representation of the haemodialysis process.

3.2. NMPC

Figure 3.1 presents the change of the values of the objective function E_{MPC}. It can be observed that the initial value of 2.82 rapidly declines towards 0 in 18 minutes and is kept around the desired value of zero. Concerning the fluid volume change for the total body, it falls from 41.72 L to the set point of 40.73 L in 25 minutes. Afterwards, the total fluid volume is controlled around the desired level until the completion of simulation.

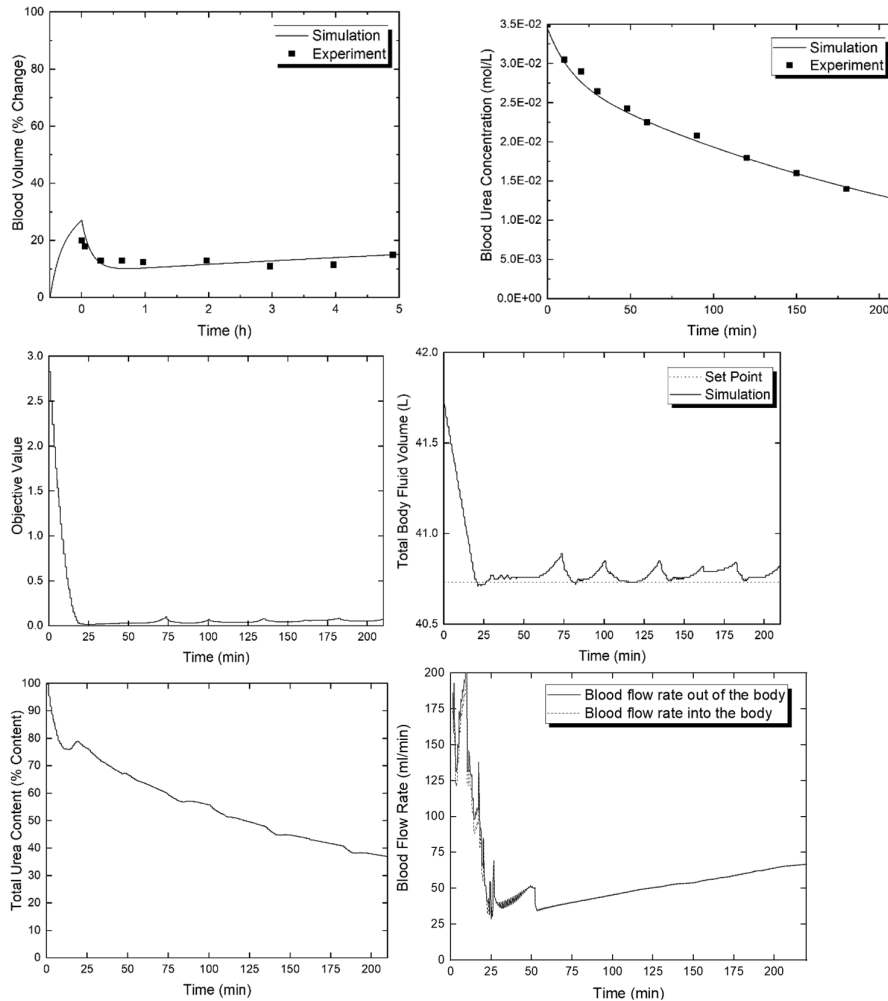
The graph shown in Figure 3.1 shows the change of total urea content in both the extracellular and intracellular compartments. It can be observed that the NMPC controller is able to achieve approximately 60% urea clearance, which satisfies one of the purposes of the haemodialysis process.


Figure 3.1: Results for NMPC of haemodialysis.

The dynamic behaviours of the blood flow rate out of the body and returned to the body are also plotted in Figure 3.1. From the graph the values of the two manipulated variables follows each other very closely during the entire horizon. This is due to the inequality constraint embedded in the NMPC: $0 \leq J_{B,Out} - J_{B,In} \leq 10$. The difference between the two blood flow rates also represent the ultrafiltration rate. The blood flow rates rapidly fall to their set points of zero in 25 minutes and from minute 50 on, the blood flowrates gradually increases and become stable eventually. In the previously developed Linear Model Predictive Controller (LMPC) by Javed et al. (2009, 2010), the systolic blood pressure (SBP) was controlled by manipulating the relative blood volume (RBV) and heart rate (HR) and the haemodialysis objectives regarding the toxin clearance and excess water content were not considered. In this paper, the NMPC controller successfully demonstrated that the desired toxin clearance can be achieved

while the flowrates are maintained at a relative low level to ensure the side effects will not occur. The NMPC controller also controls the sodium concentration to avoid hypotension.

4. Conclusions

A non-linear model predictive controller (NMPC) for haemodialysis treatment is proposed in this work. The developed mathematical model which describes the dynamic behaviours of haemodialysis is validated by comparing the simulation results with previously reported experimental data. The implementation of NMPC on haemodialysis gives promising results. The total body fluid volume is maintained around its set point and the blood flowrates are kept at a low level. As mentioned above, increasing the blood and dialysate flowrates will generally enhance the efficiency of haemodialysis and shorten the treatment time period, but may result in adverse reactions. The proposed NMPC controller is able to reduce the risk of side effects by controlling the flowrates. At the same time, it achieves desired goals of haemodialysis: clearance of toxins and filtration of excess water. Comparing to the Linear Model Predictive Control (LMPC) proposed in literatures (Javed et al. 2009, 2010), the NMPC gives more comprehensive control and could be considered as a more reliable controller due to the good control performance. Future work could include personalised therapy and clinical validation of the controller.

Abstract

In this paper, a machine learning method is proposed to extract molecular features as floating-point numbers in a high dimensional space from the language-like description Simplified Molecular Input Line Entry Specification (SMILES). Principle component analysis showed that this method can successfully classify alkanes and alcohols and also the chain lengths of the molecular by their location in a three-dimensional feature space. A neural network model is build using the location of a compound in this high dimensional space as input to predict the "sigma-profile", the charge distribution of the molecule near a perfect infinite conductor, which is calculated by quantum mechanics. The sigma-profile can be used in the COSMOSAC model for predicting thermodynamic properties such as activity coefficient. Preliminary results showed that an accurate neural work model with generalization ability can be developed.
Keywords: Machine Learning, Word embedding, COSMO-SAC, Sigma profile..

1. Introduction

One of the popular ways of generalized correlations of thermodynamic properties, developed over four decades ago, is the use of group contribution methods (Joback and Reid 1987, Fredenslund et al. 1975). Such methods required expert suggestions of the functional dependence of the predicted properties and regression of binary interaction parameters using large amount of data. In the last two decades, a priori, or first principle approach that used quantum mechanical calculations to predict thermodynamic properties has been developed (Klamt 1995, Lin and Sandler 2002). In the COSMO method, quantum mechanical calculations is used to predict the charge distribution of a molecule near an infinite conductor, known as the sigma σ-profile, which can be used to predict thermodynamic properties of mixtures (e.g. COSMO-SAC). Substantial effort needs to be expended in producing the σ-profile. Database of σ-profiles of a limited number of compounds was provided 0. Yet it is desirable that a fast surrogate generation method be developed to alleviate the load of first principle calculations.

Machine learning (ML) is the use of computer and statistics to learn from data with minimum human intervention. In other words, ML tries to identify the functional relation between an input and an output from a set of data, given that such afunctional relation exists. Sigma profile can be considered as a function of molecular structure since it is uniquely defined. Yet there are many ways to represent molecular structure ranging from aforementioned group contribution method to text-based description such as Simplified Molecular Input Line Entry Specification (SMILES, Weininger, 1998) or .mol file 0) or even three dimensional representation (Humphrey et al. 1996). Recent development in machine learning has been able to convert word-based content into vector space (Mikolov et al 2013). In this paper, a machine learning method is proposed to convert word-based molecular features from SMILES into a floating-point vector space representation, and used it to develop a neural network to generate σ-profiles.

2. Method

2.1. Molecular recognition using SMILES and word embedding

The SMILES format encoded molecular structure clearly with a short ASCII string. It is able to read the structures like chain length, double bond (=), triple bond (#) and aromatic ring (c1ccccc1) easily. With this link between molecules and nature language, we can use machine learning language model to extract molecular features.

The SMILES format is presented as word, which is not readable by machine. To translate the word to inputs of network, i.e. vectors, we build a "dictionary". In this dictionary, every elements and symbols can be transformed to a specific number. Then we can translate the SMILES format data to sequences of numbers. However, these number sequences are just encoding, and do not represent "characteristic" or feature of the molecules. Word embedding solve this problem by projecting translated sequence into a high-dimensional vector using a neural network.

In order to that the transformation is able to truly recognize molecule features, the high dimensional output of the embedding layer is collapsed by a dense-layer with 1 output. About 1372 true compounds are used and tagged 0, or "true-compound". Another 1372 compounds with randomly created SMILES file are tagged 1 as "false" or "fake-compound". Supervised learning are used until the recognizer network can accurately distinguish between the two classes. 274 true compounds and the same amount of fake-compound are used as test set.

2.2. Sigma profile predictor

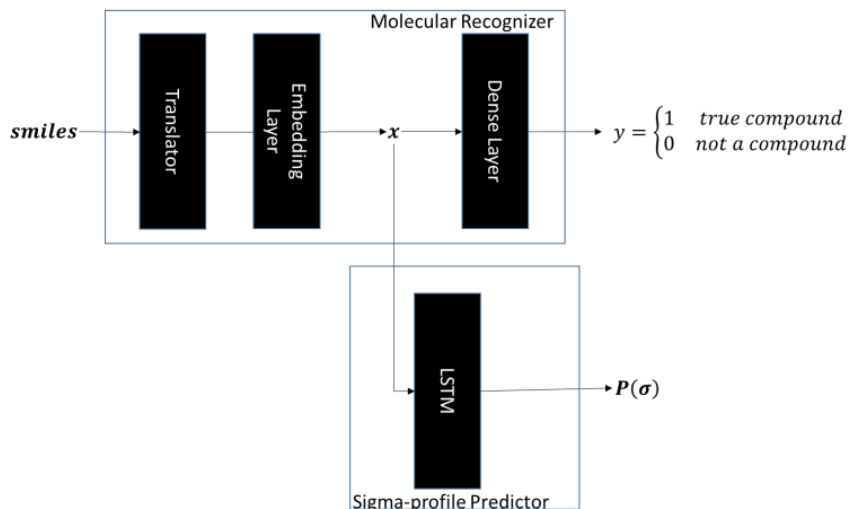
The high dimensional output of are then used as input into a Long short-term memory (LSTM), which is commonly used in nature language recognition is used (), with hyperbolic tangent activation function and 4-layer back-propagation network with rectified linear unit (RELU) activation function. It is trained with 1096 compounds while 279 were used as test data. The overall network structure is shown in Figure 1.


Figure 1：Overall network structure

3. Results

3.1. Recognizer and Molecular Classification

Table 1 showed the training performance of our recognizer. There is a limited number of false positive, i.e. fake compound recognized as true, are found because we may have 2 accidentally generated a true compound. There is no "false negative", i.e. true compound recognized as fake.

Table 1: Performance of the Recognizer

	True Compound	Fake Compound
Training Data		
Output 0	1372	1
Output 1	0	1371
Test Data		
Output 0	274	1
Output 1	0	273

Hence principle component analysis (PCA) (Joliffe 2011) was performed to help visualize how molecules are distributed in the high dimensional space. Figure 2(a) showed that the first 3 PCs account for about 80% of the variation. Furthermore Figure 2 (b) to 2(d) if we locate homologues of normal paraffins, straight chain alcohols and acids, they are arranged in an orderly manner, indicating that the embedment is able to transform the text-based SMILES input into a distance-relevant high dimensional space that can be used for molecular recognition and classification.

(a)

(b)

(c)

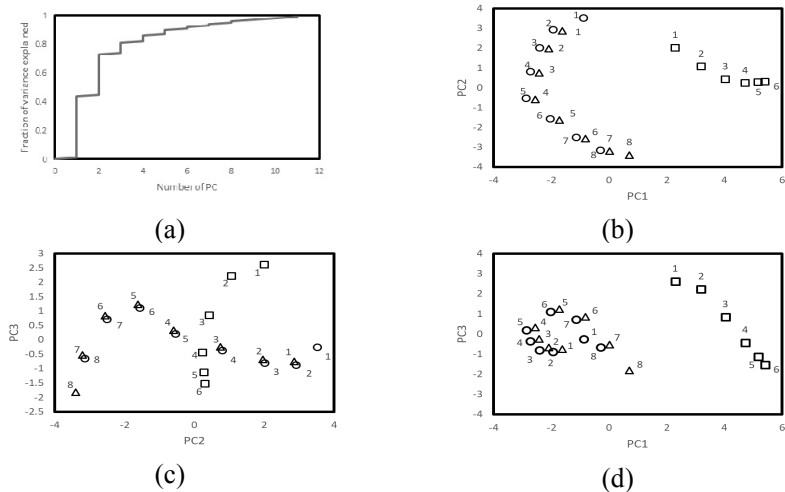
(d)


Figure 2: PCA projection of the high dimensional feature space

3.2. Sigma-profile prediction

Figure 3 showed the best model we obtained with different training set. Out of 274 test data, the average R^2 is 0.96, 179 has a R^2 of over 0.95, the worst R^2 is 0.79. Figure 4a and 4b showed ML predictions sigma profile for two compounds with R^2=0.99 0.79 respectively. Even when the actual agreement is inferior, the trend of the sigma-profile is consistent.
Figure 3 Distribution of prediction accuracy

(a)R^2=0.99   (b)R^2=0.79
Figure 4: Sigma profile correlations of (a) OC(=O)CCCCCCCCC(=O)O, R2=0.99

3.3. Prediction of infinite dilution coefficients

Figure 5a and 5b compare the infinite dilution coefficients obtained using sigma profiles predicted by ML and sigma profiles using quantum mechanical calculations in water and n-hexane respectively. Fair agreements were obtained between two types of sigma profiles. However, it was found that the ML model over-predicts the infinite dilution activity coefficient in water when they are much less than 1; and under-predicts the infinite dilution activity coefficient in n-hexane when is much greater than 1. This indicates that ML correlation is biased towards non-polar compounds. Improvement of model can be achieved by refined sampling of training data.

(a) water   (b) n-hexane
Figure 5: Prediction of infinite dilution coefficients

4. Conclusion

The above results serve as a preliminary demonstration that molecular classification and prediction of sigma-profile, results of quantum calculations, using text-based molecular description is possible. A recognizer was trained using word-embedment network, and a LSTM transformation network. The network gave no false negative and very few false positive. PCA analysis showed that the transformed space can be used as for molecular feature representation and classification. Use this space as input, we showed that fairly accurate prediction of sigma-profile can be developed. Optimization of network structure have not yet been considered. The promising results suggest that extension of this approach to a more extensive data base should be a valuable for a

priori property prediction and molecular design.   Refinement of neural network structure, better sampling of data and the use of other molecular representation should also be investigated.

Abstract

Photovoltaic/thermal systems are a novel renewable energy approach to transform incident radiation into electricity and simultaneously store the excess thermal energy produced. Both sensible and latent heat storage materials have been investigated in the past for thermal storage; with desert sand having been recently considered as an efficient and inexpensive alternative. In this work, we use a transient Computational Fluid Dynamics simulation to compare the performance of desert sand to that of well-established phase-change materials used in photovoltaic/thermal systems. The simulation gives as a result the temperature profiles within the device as well as the time evolution of the charge/discharge cycles when using PCMs. The results show the suitability of desert sand as a thermal storage material to be used in photovoltaic/thermal systems.

Keywords: photovoltaic/thermal system, phase change material, thermal energy storage, CFD, charge/discharge cycle.

1. Introduction

Amongst the different renewable energy technologies available, photovoltaic systems are currently one of the best positioned to be fully implemented in order to tackle the global carbon mitigation challenge. An important drawback however is their low efficiency, which results in only a fraction of the incident energy being converted into electricity, while the rest of the incident energy is lost to the surroundings in the form of heat (Preet, 2018). Nonetheless, this energy loss may lead to a temperature rise which can jeopardy the structure of the photovoltaic (PV) cell, ultimately causing a decrease in its lifetime. With the cooling of the PV panel being crucial, an alternative technology called photovoltaic thermal (PV/T) systems has emerged to allow for co-generation of both electricity and thermal energy. In PV/T systems, the heat loss can be stored by increasing the temperature of a material layer, i.e. a thermal energy storage (TES) medium, placed underneath the absorber. The thermal energy stored in this manner can subsequently be passed on to a liquid or gas stream. PV/T systems give way thus to increased general efficiency relative to photovoltaic cells cooled by natural convection (Preet, 2018). It is necessary then to determine the best material for the TES module to maximise the performance of the PV/T configuration. Sensible heat TES media and phase change materials (PCM) are the options available.

Sensible TES media store sensible heat as a function of their specific heat capacity, whereas PCMs allow for extra energy storage by undergoing phase change. PCMs can therefore pave the way to increased efficiencies and overnight use thanks to slow energy release after the external source of heat ceases to be applied. Moreover, the use of PCMs in conjunction with PV cells allows for effective control of the working temperature of the cell by damping any fluctuations (Alva et al., 2017; Sardarabadi et al., 2017; Ma et al., 2017). Regarding sensible heat storage, silicon carbide (SiC) and natural desert sand have also received attention recently because their particulate material gives way to enhanced heat transfer. Desert sand has also the advantage of presenting high availability and extraordinary resistance to agglomeration, being capable of withstanding temperatures of up to 1000℃.

Research on the use of desert sand as a TES medium began in the 1980s (Flamant, 1982), and has been taken up recently because the use of costless local materials is considered a key factor to reduce the levellised energy cost of CSP systems (Schlipf et al., 2015). A comprehensive assessment of the thermal and morphological properties of different types of desert sand from the United Arab Emirates was reported in the literature (Diago et al., 2018; Iniesta et al., 2015). They used these data to further develop a combined solar receiver/storage system (similar to that proposed by Flamant et al., 2013) using desert sand as TES medium.

The scope of the work presented here is to further develop the use of desert sand by presenting a transient CFD approach to compare the performance of sand and some well-established PCMs (including capric/palmitic acid, salt hydrate, and n-octacosane) in a PV/T configuration. A similar configuration has been reported by Mousavi et al. (2018), who run a steady-state 2-D CFD model to carry out a parametric study and exergy analysis of the system including different PCMs. The objective of this work, in contrast, is to assess the performance of desert sand in the same PV/T configuration by using a transient 3-D approach, and establish a comparison with various PCMs. The thermal efficiency of the system, temperature distributions within both the water channel and the surrounding thermal storage matrix, and the heating-cooling cycles of both n-octacosane and sand-based systems are simulated to quantify the suitability of desert sand as an effective material to be used in PV/T systems. As of today, to the best of our knowledge the use of desert sand in PV/T systems remains unexplored, and thus this article presents the first steps in that direction. The article begins with the description of the computational methodology employed (Section 2), and follows with a systematic grid convergence assessment for the main output variables from the simulation, i.e. temperature and density of the phase change material, before discussing the results in section 3 and presenting the concluding remarks in section 4.

2. Modelling methodology and grid convergence study

The computational domain is depicted in Figure 1, and consists of a copper pipe containing a water stream embedded in a rectangular PCM block exposed to the radiation from the sun. An additional layer, placed on top of the PCM, is included in the model in order to represent the absorber layer. The computational domain mimics, then, the configuration presented by Browne et al. (Browne et al., 2015; 2016), but only one of the copper pipes has been considered here for computational economy reasons. The schematic illustration showcases the dimensions and the different layers of the three-dimensional computational domain used in this work. The top wall of the absorber layer (the one which is not in contact with the PCM layer) is modelled as a constant heat

source wall in order to mimic the incident sunrays. A PCM matrix is placed directly underneath. A granular material is defined in the PCM matrix in those cases where desert sand was considered. Water enters the copper pipe with a specific mass flow rate and temperature (mass flow inlet boundary condition with 0.002 kg/s) and abandons the domain through a pressure outlet boundary. Adiabatic walls are specified as boundary conditions on the rest of the boundaries. The simulations were performed using the commercial software ANSYS Fluent v19.1. The options Solidification/Melting and Energy were switched on along with the laminar option for turbulence. The steady state solver was implemented to obtain the results in Figures 2, 3 and 4. Under-relaxation factors were kept at default values. Further simulations were run by using the transient solver, in order to monitor the time evolution of temperature difference between the water inlet and outlet. To do so, the heat flux wall boundary condition was switched on and off each other 4,000 s flow time in order to mimic the charge/discharge cycles of the PCM matrix.
Figure 1: Schematic illustration of the computational domain including boundary conditions, dimensions and a detail of the numerical grid.
Figure 2: Results of the grid convergence test.

A systematic grid convergence assessment has been performed by applying the Richardson extrapolation method (Roache, 1994), which allows to quantify the numerical error caused by the space discretization relative to the estimated solution of the conservation equations at zero grid spacing. A coarse (67,488 nodes), medium (186,951), and a fine mesh (496,824) were used to perform the grid convergence study. The results are reported in Figure 2, where the extrapolated value at zero grid spacing is

also represented in those cases that showed convergence (outlet water temperature and the density of the PCM zone). Oscillatory behaviour is observed for the average absorber plate temperature; this possibility is also covered in the literature (Ali et al., 2009). The order of magnitude of the maximum value observed for the grid convergence index (see its definition in Roache, 1994) using the fine and the medium mesh was 10^{-4}. This means a deviation obtained with the different grids of up to 0.01%.

3. Results and discussion

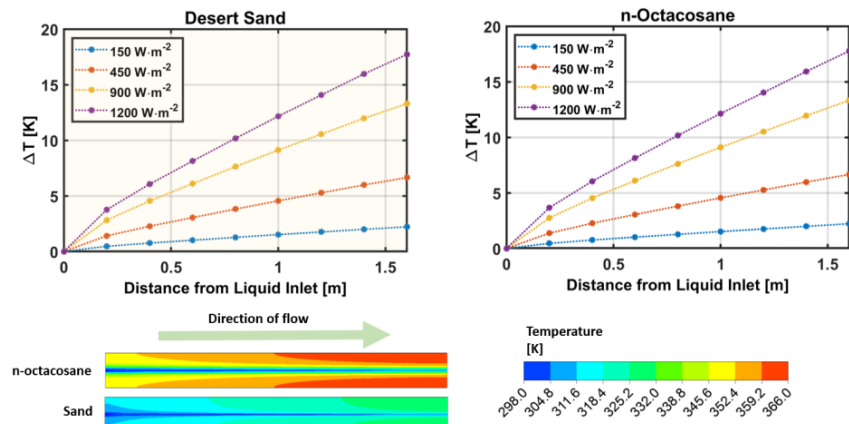
The steady state solver was initially used to check the temperature fields across the device upon a range of solar irradiance values (from 150 to 1,200 W/m^2) and using different options as PCM. The two plots on the top part of Figure 3 depict the temperature difference between the average temperature at successive cross-sections along the pipe and the temperature at inlet conditions (25°C). Similar values are obtained for n-octacosane and desert sand, proving the latter as a valid material in order to harvest the excess energy produced in the PV/T panel and transfer it to a working fluid. The colour maps on the bottom part of Figure 3 shows the temperature distribution in a plane parallel to the absorber and containing the symmetry axis of the pipe upon a solar irradiance of 1,200 W/m^2. The results show that the temperature attained by the liquid at the outlet boundary and the maximum temperature of the TES matrix do not match (~315 K against ~366 K) when using n-octacosane (a PCM). A longer domain would therefore be needed in order to fully avail the energy stored by the PCM. Conversely, they are close when using sand as TES medium (~315 K against ~319 K). This suggests that there is an advantage in using desert sand instead of n-octacosane because a smaller quantity of TES medium is required to fully avail the incident solar irradiance.


Figure 3: Temperature profiles in the symmetry axis of the copper pipe (top two graphs) and colour maps of the temperature distribution within the PCM matrix (bottom part of the figure) for n-octacosane and sand.

Figure 4 on the other hand shows the effect of the solar irradiance on the PCM solid fraction (left-hand side graph) for several materials. A visualization of the boundary delimiting the liquid and the solid fraction is included (right-hand side plot) for the case of n-octacosane. The graph on the left-hand side allows the reader to establish which PCM is more advantageous depending on the solar irradiance. Among the materials

used in our simulations, n-octacosane needed a solar irradiance of 600 W/m^2 to begin melting (subsequently storing latent heat), whereas capric-palmitic acid underwent full phase change for the entire range of solar irradiances tested in the present study. The results contained in Figure 4 allow the user of the present model to calculate the amount of latent heat that a given PCM can store for solar irradiances between 150 and 1,200 W/m^2 and different materials.
Figure 4: Relationship between the PCM solid fraction and the solar irradiance (left-hand side graph). Visualization of the PCM n-octacosane melted volume at steady state as a function of the solar irradiance (right-hand side). In the latter, the water outlet is visible, whereas the inlet is hidden by the solid portion of the PCM.

Finally, Figure 5 shows the transient charge/discharge cycle of the PCM material n-octacosane relative to the behavior of desert sand, which does not undergo phase change. This transient solution was obtained by using the results at steady-state as the initial values. In the beginning the heat flux was switched off, mimicking the conditions that the panel would have at night. In the case of desert sand, one can observe that heat has been retained during approximately 4,500 s (1.25 hours), after which there is no water temperature difference between inlet and outlet. The PCM, however, retains heat during more time by virtue of the phase change process. The results in Figure 5, however, prove as expected that the use of a PCM is more convenient than granular desert sand in those applications where heat needs to be released overnight.

4. Final remarks

A 3-D CFD model has been developed in order to compare the suitability of different materials to be used as thermal energy storage (TES) media in photovoltaic/thermal panels, including desert sand and different phase change materials (PCM).

Better heat transfer to the water stream occurs at steady state with desert sand than with n-octacosane (one of the PCMs studied), leading to a reduction on the volume of TES needed to fully avail the thermal energy excess. Moreover, since the 3-D model presented here calculates the solid volume fraction of PCM upon given conditions, the user can determine which PCM is best to be used for a particular value of the solar irradiance and to estimate the latent heat stored. The transient configuration proves as a useful tool to study the charge/discharge cycles of the thermal energy storage materials, and thus provides a value of the energy a particular TES medium can release and for how long.
Figure 5: Time evolution of the inlet-outlet water temperature difference.

Abstract

The work proposes a combination of model-free and model-based quality-by-control (mfQbC and mbQbC) paradigms as a general framework for the optimal crystallization design with the aim of minimization of fines and agglomerates in the product. This framework provides an improved alternative to the current industrial practice, by the combined use of feedback control and mathematical models for rapid design of robust crystallization processes. The implementation of the proposed mbQbC framework enhanced the prediction of crystallization events and was able to achieve better control of the crystallization processes by providing controlled heating/cooling cycles, for de-agglomeration and fines destruction. The information for parameter estimation and optimization calculations was collected from the experiments in mfQbC part, which additionally also provided a rapid design of robust operating conditions, which subsequently in the mbQbC approach were improved to achieve optimal operation.

Keywords: Optimization, modelling, control, crystallization, design.

1. Introduction

Batch crystallization is used substantially in purification of the active pharmaceutical ingredients (APIs) in the pharmaceutical industries. Particle size has a significant effect on the quality of drugs and on the efficiency of downstream processes such as filtration, milling, centrifugation, drying, granulation, and tableting (Rawlings et al., 1993). A narrow crystal size distribution (CSD) at the desired mean crystal size is crucial for efficient downstream processes and desired critical quality attributes (CQAs) of the final product, therefore crystallization control strategies such as model-based control approaches, automated direct nucleation control (ADNC), supersaturation control (SSC) or temperature control (T-control) have been developed to achieve desired CSD (Simon et al., 2018). Current industrial practice for the design of operating conditions generally uses a quality-by-design (QbD) framework, based on exploring the design space by experimentation, which can be time consuming even with a well thought experimental design. More recently, a novel and faster alternative, the quality-by-control (QbC) framework has been introduced as a new paradigm that uses feedback control (model-free or model-based) to automatically find the optimum operating profiles that lead to the manufacturing of final product with desired CQAs, rather than applying open-loop experimentation.

The new sequential QbC approach proposed consists of the combination of the mfQbC approach where first closed loop feedback control is used to automatically identify the design space and feasible region of operation, while also providing a robust, although probably suboptimal, operating procedure. This is followed by the implementation of a mathematical model that uses the information from experimental part for parameter estimation and model-based optimization to provide an optimal refined operating procedure. The experimental control strategy provides the first important step of improving the product quality and phase diagram information of the system. MbQbC provides the ability to predict crystallization phenomena or to enhance the control of crystallization processes. Worlitschek (2004) showed that a developed deterministic model for solution thermodynamics, crystal growth, and nucleation enhanced the control of the crystallization of paracetamol from ethanol. After optimization, the determined cooling profile was good enough to obtain the desired monomodal particle size distribution and supersaturation. Hermanto, Braatz et al. (2010) showed that an integrated batch-to- batch and nonlinear model predictive control (B2B-NMPC) strategy based on a hybrid model can be used to control the polymorphic transformation of L-glutamic acid. Nagy (2009) showed that a lower model-free approach can be used to operate the system in the phase diagram in combination with a higher-level model-based approach to maintain product uniformity. Acevedo et al. (2017) showed that model-based design can also be used for the design of model-free direct nucleation control (DNC) for the optimal operation in the case of continuous crystallization.

A critical step of model-based approaches is the parameter estimation of the crystallization kinetics, which requires the solution of the population balance equations (PBE) of the crystallization model. For efficient parameter estimation, model-based optimization, and real-time model predictive control, it is imperative to have fast and accurate solution. Various techniques have been proposed for the solution of PBMs, including analytical solution-based approaches, such as method of moments, quadrature method of moments, or method of characteristics, or direct numerical solutions such as finite volume method (FVM) or Monte-Carlo simulations, which have also been applied along with the solution of the optimization problem (Omar and Rohani, 2017). In this work, the model-free and model-based QbC approaches were combined for the optimal design of crystallization systems with the aim of minimization of fine formation and agglomeration of paracetamol (PCM) crystals, as the model compound. Although PCM is well-studied, only the parameters for the nucleation and growth kinetics have been determined so far. This work will be the first study that estimates all kinetic parameters for the primary and secondary nucleation, growth, dissolution, agglomeration and de-agglomeration mechanisms for the crystallization of PCM by developing a novel QbC framework combining model-free and model-based techniques.

2. Experimental Methods, Model Development, Parameter Estimation, and Process Optimization

Four types of batch experiments were performed to understand the system dynamics, seed production and for crystallization kinetics parameter estimation of the crystallization of paracetamol (PCM) from isopropyl alcohol (IPA). Seeded linear cooling and heating experiments were used for determination of the crystal count during secondary nucleation. These were followed by several direct nucleation control (DNC) experiments with different cooling/heating rates to keep the crystal count within certain thresholds.

DNC experiments provided the information about the primary and secondary nucleation curves in the phase diagram. After determining the metastable zone width (MSZW) according to these curves, a seeding point and set point were selected for the SSC experiments. The temperature data generated from SSC experiment gave the cooling profile required to operate below the secondary nucleation curve (e.g. growth zone) in the phase diagram. The cooling curve provided was approximated by a sequence of three linear cooling ramps and was used in an open-loop temperature control experiment to show that the simplified profile can produce similar product. Data from all experiments were used to estimate nucleation, growth, agglomeration, dissolution and de-agglomeration kinetic parameters. UV/Vis spectrophotometer, focused beam reflectance measurement (FBRM), and Particle Vision Measurement (PVM) were used as PAT tools to measure concentration, particle count, morphology and size. In addition, Malvern Mastersizer 3000 and Nikon SMZ1500 microscope were used for offline characterization of size distribution and crystal morphology.

A mathematical model is required for mbQbC that describes the crystal birth, growth, and death due to nucleation, growth, agglomeration, dissolution, and de-agglomeration. A 1D Population Balance Model (PBM) with size-independent growth and dissolution, including size-dependent agglomeration and de-agglomeration kernels (1) was used to model the system for the supersaturated and desaturated regions along with corresponding mass balances equations (2).

$$\frac{\partial n(L,t)}{\partial t} + G\frac{\partial n(L,t)}{\partial L} = B\delta(L - L_m) - \int_0^\infty \beta(t,L,\lambda)n(L,t)n(\lambda,t)d\lambda$$

$$+ \frac{1}{2}\int_0^L \frac{\beta(t,(L^3 - \lambda^3)^{1/3},\lambda)}{(L^3 - \lambda^3)^{2/3}} \times n(t,(L^3 - \lambda^3)^{\frac{1}{3}})n(t,\lambda)d\lambda, \text{if } \sigma > 0 \quad (1)$$

$$\frac{\partial n(L,t)}{\partial t} - D\frac{\partial n(L,t)}{\partial L} = \int_L^\infty b(L|\lambda)S(\lambda)n(t,\lambda)d\lambda - S(L)n(t,L), \text{if } \sigma < 0$$

$$\frac{dC}{dt} = \begin{cases} -k_V\rho_C\left(3G\int_0^\infty L^2 n(L,t)dL\right), \text{if } \sigma > 0 \\ k_V\rho_C\left(3D\int_0^\infty L^2 n(L,t)dL\right), \text{otherwise} \end{cases} \quad (2)$$

$$B = B_p + B_b, B_p = k_p\sigma^p, B_b = k_b\sigma^b A_c, G = k_g\sigma^g exp\left(-\frac{E_A}{RT}\right), \beta(\lambda,L) = k_{ag}F(\lambda^3 + L^3),$$
$$D = k_d(-\sigma)^d, S(\lambda) = k_{br}F(\lambda^3) \quad (3)$$

The model was solved by using the high-resolution FVM (HR-FVM) during parameter estimation and optimization calculations. Parameter estimation calculations were done to estimate 10 parameters in the crystallization events (3) which are also used in PBEs. The equations are given for primary and secondary nucleation, growth, agglomeration, dissolution, and de-agglomeration, respectively. Size dependent de-agglomeration and agglomeration selection functions F are described by hyperbolic tangent functions using the crystal crystals sizes for both cases. Optimizations were carried out for the temperature profile (T-profile), in three steps: a) first a preliminary stochastic global optimization of a crude T-profile defined by 10 discrete temperature points was performed to provide a good starting point for the b) gradient-based optimization (sequential quadratic programming-SQP) for refinement of the solution and c) SQP-based

optimization of a smoother T-profile (defined by 20 discrete temperatures), using as starting point the outcome of b). For global optimization, a custom implementation of Covariance Matrix Adaptation Evolution Strategy (CMA-ES) was applied. The objective function (4) was defined to minimize each term: the product fine index, product agglomeration index, sharpness of T-profile and agglomerates index during the crystallization, respectively. The weight factors (w_i) were set by preliminary optimizations so to ensure that the sub-objective values are in the same order of magnitude around the optimum. Note that changing the values of weight factors also changes the optimal solution. This is a subjective decision, which is taken based on detailed process understanding. In Eq. (4) N_A is the number of agglomerates, L is the length of the crystals, n is the population density. The product fine index is the ratio of the number of fine crystals to the total number of crystals in the product CSD; the product agglomeration index is the ratio of the agglomerates in the same product CSD. Sharpness of the T-profile was defined as the gradient of the profile to be minimized for smoother operation and the last term is defined as the total number of agglomerated crystal fraction during the crystallization rather than only in the product CSD.

$$OF = 100 \left[\frac{\int_0^{L_f} L^3 n(L, t = t_f) dL}{\int_0^{L_{max}} L^3 n(L, t = t_f) dL} \right]^2 + w_1 100 \left[\frac{N_A(t = t_f)}{\int_0^{L_{max}} n(L, t = t_f) dL} \right]^2$$
$$+ w_2 \sum_{i=2}^{N} (t_i - t_{i-1}) \left(\frac{T_i - T_{i-1}}{t_i - t_{i-1}} \right)^2 + w_3 100 \int_0^{t_f} \left[\frac{N_A(t)}{\int_0^{L_{max}} n(L, t) dL} \right]^2 dt \tag{4}$$

3. Results and Discussion

The experiments performed in the mfQbC framework were seeded cooling crystallization, DNC, followed by SSC, and a T-control experiments. The benefits of this procedure are to obtain detailed information about the system's phase diagram/operating zone, as well as to produce the product obtained from the close-loop SSC experiment by a more practical, simplified cooling crystallization (T-control). Volume-based crystal size distribution and microscopy images showed that similar products were achieved. Data from each controlled experiment was used as input for the parameter estimation calculations in the model-based approach.

The combined framework is designed so that the two parts to be complementary to each other. Collected data from mfQbC was used in parameter estimation and optimization calculations in mbQbC. Estimated parameters (Fig. 1) were used in the model for optimization calculations. The optimum temperature profile (T-opt) was obtained by the three step optimization calculations as described. The resulting profile exhibited two heating cycles including a small heating ramp at the end. T-opt was tested by an unseeded cooling crystallization experiment. Results show that the model predicts the nucleation accurately, and the system is heated before detectable nucleation by FBRM counts. Although the system was in the heating region the primary nucleation still occurred, but the first heating cycle was able to slow down the nucleation event. In addition, the 4 °C heating at the end was efficient to destroy fine crystals and to induce de-agglomeration. During the experiment, two samples were taken at the minimum temperature point and at the end to understand the effect of the last heating cycle. Microscopy images and the size distributions of the samples before and after this heating cycle showed that this small heating ramp (4 °C) was enough for de-agglomeration and elimination of fine crystals (Fig. 2), which could be observed by the corresponding FBRM peak before the decrease in the counts (2,500 counts/sec), respectively. The strength of fine elimination and de-agglomeration of the T-opt by predicting nucleation correctly can be emphasized by the comparison of the products from SSC, T-control and T-opt experiments. The size distribution (Fig.3) shows that, T-opt product contains more larger crystals and less fines. The model-free direct design approach provided automatically a T-profile from SSC

experiment that was implemented easily using a simple T-control experiment. While this is easy to develop and implement, this may not be the optimum operating profile especially for systems that tend to agglomerate or produce significant number of fines due to attrition, breakage or some secondary nucleation. The model-based optimization provided a T-profile that reinforces fine dissolution and de-agglomeration (Fig. 3). The shift in the distribution of the end-sample from the T-opt experiment shows that fines elimination is significant when compared to samples from other experiments or different time moment of the same experiment.

4. Conclusions

A new hybrid (model-based and model-free) QbC framework for crystallization design was developed that can predict the crystallization process and keep the measured CQAs at their desired values, while using feedback control approaches efficiently. This framework was developed to provide the optimum operating procedure for crystallization systems. The model could even predict the primary nucleation time and apply heating cycle before detectable nucleation. The experimental validation of the approach demonstrated that the desired fine dissolution was achieved, agglomerated index was significantly decreased and the mean crystal size of the CSD could be increased accordingly, indicating the potential benefits of the new approach as a novel and efficient design of crystallization systems governed by complex phenomena.

Abstract

A core is a special, preformed part of a casting which is essential for complex and delicate shapes in the casting process. Around 95% of sand and 5% of binder are mixed as the raw material for manufacturing the core. Organic binders exhibit a high performance but generate contaminants and toxic gases since they are composed of toxic chemicals, and therefore, the trend in popular types of binder is evolving from organic to inorganic. In this context, we focus on the development of a discrete element model (DEM) model for the mixer in the core manufacturing process using an inorganic binder. We validate the developed model by comparing it with an actual horizontal mixer system. The actual mixer has dimensions of 1.36 m in length and 0.17 m in diameter. When the process is simulated once under the same operating conditions, the actual process run time is the same as the simulation run time. Based on this model, we carry out case studies by varying conditions such as the length of the mixer, and location of injection nozzle. As per our DEM study, the mixer length can be reduced by more than 20% relative to the existing design. We also suggest alternative mixer designs by optimizing the location of the injection nozzle.

Keywords: Core, Inorganic Binder, DEM, Mixer.

1. Introduction

Casting is a manufacturing process in which molten metal is poured into a mould of desired shape and allowed to solidify. The core is the part of the mould which fills the empty space of the mould forming internal cavities in the casting process. Most moulds are made of sand. To fix the mould, a binder is added to the sand. In this regard, although organic binders are currently prevalent worldwide, they generate harmful gases such as benzene and formaldehyde. Further, air bubbles form when the molten metal solidifies, thereby deteriorating the quality of the product. In addition, since an organic binder is for single use only, a considerable amount of waste is discharged. However inorganic binders are eco-friendly because they can be reused and they do not emit harmful substances.

Despite industrial research on inorganic binders, very few manufactures have attempted to address the issue of core manufacturing based on inorganic binders. For core manufacture, it is important to mix a minimum amount of inorganic binder evenly with sand mould and simultaneously ensure excellent fluidity in the mixed state. Existing core manufacturing has relied on empirical manipulation. In order to produce a high

quality core, it is necessary to optimize the core manufacture process and analyse whether the process has led to appropriate mixing. Against this backdrop, in this study, we developed a computational fluid dynamics (CFD) mixing model and carried out simulations using the discrete element method (DEM) for core manufacturing. The DEM computes the flow of segmented fluid based on molecular dynamics. It is a numerical analysis method suitable for micro-mechanical behaviour calculations of particles or granular materials. Further, based on an intuitive representation of how individual particles collide with each other, contact stiffness can be used to express the interaction between the grid and the particles. Our simulation results were validated through experiment and the results can be applied directly to improve the actual process.

2. Experiments

The experimental horizontal mixer system used for our investigations consisted of a hopper with a pile of sand and a steel cylindrical vessel with a length of 1.36 m, and diameter of 0.17 m. Paddle impellers were positioned along a rotating shaft which was aligned along the centre of the stationary vessel. This shaft-impeller was connected to a motor. The paddle impellers on the shaft were arranged in various angled patterns as shown in Figure 1. Figure 2 illustrates the dimensions of the mixer considered in the study. In all our experiments, spherical sand particles with an average particle size of 0.15 mm and density of 550 kg/m^3 were used. This mixer operated at a rotational speed of 50 RPM. The inorganic binder used in the experiments comprised a mixture of silica calcium and sodium oxide.

Table 1. Binder content of corresponding to each curve in Figure 4

Data name	Binder content
A	0%
B	1%
C	2%
D	3%
E	4%

In order to determine the optimal binder ratio for the mixing process, we examined the fluidity of the mixture as a function of the binder content.

In Figure 4, curves A, B and C lying curves between the cohesive curve and the easy flowing ranges satisfy the appropriate fluidity condition. Among the three corresponding binder content values, we chose the binder with the lowest content (Curve C, 2%) in our experiments.

3. Simulations

Next, we constructed the simulation model using the experimental data. All the DEM and CFD simulations were performed with the use of STAR CCM+ (SIEMENS).

3.1. Numerical approach

In general, CFD simulations are based on continuum models. However, DEM is a discrete approach which accurately models the micromechanics of granular material. Further, the continuum model considers the entire material as one mass, whereas each particle is a unique quantity in DEM. The governing equations of the particle translational and rotational motions can be expressed as the following Newton's equations.

$$m\frac{dv}{dt} = \sum F_g + F_c + F_{fluid} \tag{1}$$

$$I\frac{d\omega}{dt} = \sum (M^T + M^r) \tag{2}$$

Here, m, v, I, ω represent the mass, velocity, moment and angular velocity of a particle, respectively. Further, $F_g, F_c, F_{fluid}, M^T, M^r$ denote the force due to gravity, contact force between particles, fluid force, torque produced at the point of contact, and rolling friction force corresponding to particle-particle and particle-wall contacts, respectively. Here, we note that the choice of the time step is critical in DEM simulations. The time step has to be set to sufficiently small value to ensure numerical stability and accuracy, and it is limited by the time taken for a Rayleigh wave to propagate across the surface of the sphere from one pole to the opposite pole.

$$\tau = \pi \frac{R_{\min}}{v_{Rayleigh}} \tag{3}$$

In the above equation, $\tau, R_{\min}, v_{Rayleigh}$ represent the time-step, minimum particle radius and surface wave speed, respectively. The τ value is set to 30%. The Rayleigh velocity is solved internally, however, it depends on the material properties, particularly the Poisson's ratio and Young's modulus. Thus, we have

$$\tau_2 = 2.94 \left(\frac{5\sqrt{2}\pi\rho}{4} \frac{1-u^2}{E} \right)^{0.4} \frac{R_{Particle}}{\sqrt[5]{v_{impact}}} \tag{4}$$

Here, $\rho, u, E, V_{impact}, R_{particle}$ denote the particle density, Poisson's ratio, Young's modulus, impact velocity and particle radius, respectively. Upon assumption of the Hertzian contact theory, the duration of impact of two perfectly elastic spheres needs to be equal to a minimum of 10time-steps to estimate the collision accurately.

3.2. Model setup

Our simulation geometry was the same as that shown in Figure 2. The material properties of the particle were set as follows; Poisson's ratio = 0.35 and Young's modulus =5MPa. The simulation consisted of more than 2 million polyhedral meshes. The
Figure 5. Simulation using The field function

Lagrangian multiphase interaction was used in this model. To simulate the mixing of the binder with the sand, we set the field function assuming that the binder is coated on the particle surface. The field function was declared such that the particle size after coating was 5% larger than that before coating. The field function was applied to the particles which existed in the area lying in the angular range of 0.3˚ below the injector, as depicted in Figure 5.

3.3. Simulation Results

We analysed the mixing results in 20 internal regions in the mixer. Figure 6 shows the model wherein the injector position is changed from 0 to 0.5 along the x-axis. Figure 7, shows the analysed regions of the mixer. In order for the blue region in Figure 7 to be distinguished in the grayscale mode, the blue area corresponding to coating degree = 0 was indicated by X.
Figure 6. Model representing position of binder injector (a) Sand inlet (b) Initial injector position (c) Final injector position

Figure 7. A model division coloured regions as per coating degree for mixing analysis
Figure 8. Coating degree as function of injector position
Figure 9. Coating degree as per location along mixer length

Figure 8 depicts the coating degree at the outlet as a function of the injector position Figure 6. When the injector is located at the zero point, the particle velocity tends to become low, thus leading to poor coating. Otherwise, the coating degree is satisfactory when the injector is close to the zero. The curve indicates that the overall coating difference is not large with change in the injector position. Therefore, the location of the injector is not a main consideration in the mixing process. Figure 9 shows the degree of coating obtained at each of the 20 segments shown in Figure 7. The coating degree increase up to location # 5, which is directly under the binder injection nozzle. However, the slope of curve is nearly zero beyond location #15, which indicates that the coating is well mixed and exhibits uniform distribution, and thus, further mixing is not necessary.

The coating degree was determined as the average particle data along the vertical cross section of the mixer Figure 11. The data were calculated as per Figure 8 at and each position shown in Figure 9.
Figure 10. Number particles in mixer as function of time
Figure 11. Particle coating degree along vertical cross section of mixer

The residence time in the mixer was defined as the start time at which the particle number began decreasing due to particles exiting the outlet. The residence time in this simulation was 12 seconds Figure 10. This value is the same as the corresponding experimental values, which result validates the reliability of the simulation.

4. Conclusions

We investigated the mixing performance of a horizontal mixer via experiments and DEM simulations. The results of the simulations and experiments were found to be in good agreement. The performance of the mixer was subsequently evaluated as a function of the mixer length and injection nozzle position. In addition, the flow pattern of particles was examined based on the particle size, and coating degree.

Our findings indicate that, the total length of the cylindrical vessel can be reduced to 70% of the original length; the particles were already uniformly distributed inside the mixer at a position 1.09 m away from the particle inlet along the x axis of Figure 2. When the injector of the binder nozzle was located close to the inlet along the x-axis, the mixing quality tended to improve, but the difference in the mixing quality as a function of the subsequent nozzle position was not large. When the particles were mixed with the binder close to the inlet, there was increased stacking and adhering of particles to the impeller. Further, we determined that minimized cleaning load improves the process operating conditions, while ensuring high mixing quality. Therefore, the injector should be located in the midpoint of the mixer along the x-axis.

We plan to focus on varying the vessel fill level, increasing the impeller rotational speed, and the DEM solving time in our follow up studies. We believe that our findings will significantly contribute to industrial manufacturing processes.

Abstract

The synthesis of distillation processes for azeotropic systems is a complex task for which commercial simulation software mainly offers a graphical analysis of residue curve maps for ternary (sub)systems or an iterative evaluation based on tedious simulation studies. The current work presents a novel algorithmic approach that aims at an automatic synthesis of distillation-based separation processes for azeotropic systems. Building only on a thermodynamic model of the multi-component mixture, split feasibility at both limiting operating conditions of total reflux and reversible distillation are considered. Possible process variants including the integration of suitable recycle streams are automatically generated and stored in a tree structure and the incorporation of an efficient pinch-based shortcut method provides initial estimates of the required energy demand of the generated process variants. The application of the proposed method is illustrated for the separation of a four and five component azeotropic mixture, which allow comparison with previous publications.

Keywords: conceptual design, flowsheet optimization, azeotropic distillation

1. Introduction

Conceptual process design is of imminent importance in process development, since the choices made in this early stage account for about 80% of the final cost of the entire process (Biegler et al., 1997). Due to the reliability and robustness, distillation still represents the default choice in fluid separation processes. However, the evaluation of split feasibility and the synthesis of alternative separation processes presents a significant challenge for the separation of azeotropic multi-component mixtures. While finding the optimal process configuration for the separation of a zeotropic mixture is a combinatorial problem, for which all alternative sequences can be generated automatically and only the computational demand increases with an increasing number of components (Agrawal, 2003), the feasibility of certain splits for azeotropic mixtures is governed by the location of the azeotropes and the emanating distillation boundaries. Only few methods for the generation of a distillation-based separation of azeotropic mixtures have been proposed. None of them was designed to be fully automatic and none is available in a commercial software tool. Wahnschafft et al. (1993) have developed a synthesis tool called *Split*, which is based on a blackboard architectural model for developing separation processes. Although their work provides significant insight into the use of recycles for separation processes, its application for automatic sequencing is limited. A major simplification is the initial grouping of binary *separation tasks*, before selecting applicable separation methods. Rooks et al. (1998) have devised a generalized algorithm to synthesize separation sequences based on the creation of adjacency and reachability matrices, similar to the proximity and reachability matrix proposed by Poellmann and Blass

(1994). Feasible splits are further identified based on the so called *common saddle test*, which checks if the residue curves (RC) for the top and bottom products approach a common saddle. This feasibility check is fully algorithmic, very efficient and allows for the identification of feasible splits considering total reflux operation. However, as pointed out by Thong and Jobson (2001a), it excludes a lot of feasible splits especially for azeotropic mixtures. In a series of articles, Thong and Jobson (2001a,b,c) and Thong et al. (2004) developed an alternative approach, which builds on the evaluation of a linear approximation of the operating leaves/manifolds for rectifying and stripping section to determine split feasibility. Furthermore, the generation of sequences with the possibility of internal recycles is developed on the basis of the split feasibility test in combination with the topological analysis of distillation regions on the basis of the adjacency and reachability matrices. While the developed method is very sophisticated, the considered linear approximation of the operating manifolds is equivalent to the rectification bodies at total reflux (Bausa et al., 1998), such that feasibility is also determined primarily for total reflux operation. Another algorithmic approach was presented by Wasylkiewicz (2006) and was even available for some time in ASPEN *Distil*, which is however no longer part of the software. The tool was also based on the identification of the topological distillation regions in order to identify feasible products and propose potential recycle streams. The latest effort on an algorithmic feasibility test was proposed by Brüggemann and Marquardt (2011). Opposite to all previous approaches this test is based on the concept of pitchfork distillation boundaries (PDB), which represent the distillation boundaries for reversible, rather than total reflux distillation. It was not applied in the synthesis of alternative variants, but rather for the optimization of fixed process flowsheets with shortcut models (Brüggemann and Marquardt, 2011). While the test implements a sophisticated homotopy continuation algorithm and bifurcation analysis, the identification of valid solutions in case of intersecting branches presents a significant challenge.

While currently no tools exist that consider both limiting operating modes, reversible distillation and total reflux operation, several studies showed that a simultaneous consideration can extend the range of feasible splits for distillation (Wahnschafft et al., 1992; Krolikowski, 2006; Kraemer et al., 2009). The current article fills this gap by proposing such a feasibility test and illustrates how an automatic generation of process variants for the separation of azeotropic multi-component systems can be accomplished. Feasible splits are determined based on the highest purity products w.r.t. the different modes of operation and validated through application of the rectification body method (RBM) (Bausa et al., 1998), which does not only indicate the intersection of rectifying and stripping profiles, but also provides an estimate of the energy requirements for the single splits. The developed methodology is introduced in Section 2 and illustrated for two representative case studies in Section 3, before some conclusions and an outlook are presented in Section 4.

2. Methodology

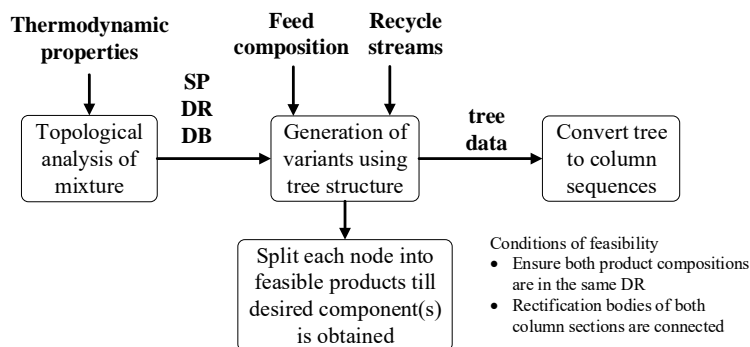
The general concept of the developed methodology is illustrated in Figure 1 and is composed of three consecutive steps. First, a topological analysis of the given mixture is performed based on the thermodynamic property models. The computation of all azeotropes allows for a characterization of all singular points (SP) (Skiborowski et al., 2016), which present the basis for further computation of pinch lines (PL) as well as the adjacency and reachability matrices (Rooks et al., 1998). The latter is used for the computation of the topological distillation region (DR) and distillation boundaries (DB), as well as the compartments for each DR (Thong and Jobson, 2001a), which are stored as ordered subsets of the SP. The second step computes feasible splits based on the generated topological information in combination with the computation of RC and PL, as well as the RBM, and stores the resulting information in a tree structure. Different branches of the tree, which are generated sequentially, can finally be converted to respective column sequences. After specifying the initial feed stream, possible sequences are generated based on a recursive algorithm, which evaluates the products of each split as new feed streams on a subsequent layer, until the desired products are obtained or no further splits are feasible. The results are stored


Figure 1: Schematic overview of the methodology for distillation process synthesis

in a tree-like structure, which links the feed and products via a number of nodes. These nodes represent the single splits that are located on different branches, which can subsequently be translated into corresponding column sequences. Figure 2 presents an exemplary illustration, which also indicates the consideration of a recycle stream and the translation of a branch (shaded) into the corresponding column sequence. Each layer of the tree is composed of alternative splits, for which distillate and bottom product result that each are potentially processed as feed streams on individual sub layers. For each feed stream that is to be separated, the topological DR is determined, by evaluating the terminals of the RC and PL passing through the feed composition. The RC is computed using the Runge-Kutta method and the PL is computed using continuation and bifurcation methods as described in more detail in the article of Skiborowski et al. (2016).

Subsequently all SP of the feed DR are considered as possible products and a split feasibility test is performed in order to evaluate if a sharp split is feasible, or if a DB is limiting the separation. For the latter, the highest possible purity (HPP) of the opposing product on the DB is determined, based on a bisection along the mass balance line, monitoring the terminals of the RC and PL. As long as the terminals are equivalent for both products, they are located within the same DR, while the change of any terminal indicates the transition to another DR. The transition point for the PL marks a point on the PDB, while the transition of the RC marks the corresponding location of the simple distillation boundary (SDB). This test can be performed efficiently for any number of components, and directly provides information on differences between the feasibility at total reflux and reversible distillation thus circumventing the complexities of the pitchfork bifurcation analysis proposed by Brüggemann and Marquardt (2011). Starting the bisection based on the potential sharp separation, product compositions located in a different DR than the feed composition, so-called curved boundary processes, are automatically identified as feasible splits in case the terminals of the RC and PL through the products are equivalent.

The determination of HPP products is essential for the final step of the split evaluation, which is the computation of the minimum energy duty (MED) based on the RBM (Bausa et al., 1998). The general idea of the RBM is to check for the intersection of the tray-to-tray profiles of the stripping and the rectifying section, which is also considered as the sufficient criteria for split feasibility. In order to do this efficiently, the RBM uses linear approximations of the manifolds of possible tray-to-tray profiles based on respective pinch points for specific reflux and reboil ratios. The underlying assumption of an infinite number of equilibrium trays per section mandates the specification of HPP products. Therefore, the initial split feasibility test provides the necessary product specifications for a reliable application of the RBM that furthermore determines an MED estimate, which indicates if the column profiles of both sections intersect. The MED can further be used to rank the different sequences, which are generated by the algorithm.

In case the desired products are located outside the feed distillation region and curved boundary

Figure 2: Exemplary illustration of the tree structure and a derived column sequence for the separation of an (A)cetone-(C)hloroform-(B)enzene mixture

splits are not feasible, recycle options can be included in the evaluation on demand. Hereby, the different SP are considered as internal recycle in order to reach the preferred DR, i.e. the DR with the desired product (Wasylkiewicz, 2006). In order to limit the number of options, potential recycle streams can be defined upfront. Necessary recycle ratios to shift the mixed feed to the preferred DR are again determined based on a bisection that aims at the maximization of the recovery of the desired product. After the variant generation, it needs to be checked if the necessary amount of the recycled stream is generated in the corresponding sequence. In the exemplary illustration of Figure 2, the possible recycle of benzene enables a full separation of acetone, as also demonstrated in the manual analysis of Wahnschafft et al. (1992). If only a fraction of a stream that is not a desired product is recycled, a post-processing step evaluates the feasibility of a full recycle, as will be illustrated in the subsequent case study. The methodology is implemented in a computer-based tool, which is primarily coded in Matlab and C-coded subroutines for thermodynamic property calculations and computation of all SP, RC and PL, which are available as open source code[1].

3. Case Studies

The application of the developed methodology is illustrated for the separation of a quaternary and a quinary mixture. The first case study considers the separation of an equimolar mixture of acetone, chloroform, benzene and toluene (ACBT). The mixture exhibits a maximum boiling azeotrope between acetone and chloroform and a respective DB, for which SDB and PDB deviate considerably, as illustrated in Figure 3. This mixture and possible separation sequences have been analysed in multiple studies (Thong and Jobson, 2001c; Kraemer et al., 2009) and the results of the proposed algorithm are further compared with the MED computations of Kraemer et al. (2009), who build up on the results of the process synthesis performed by Thong and Jobson (2001c). Figure 4 illustrates a combination of the four configurations (a-d) that were considered by Kraemer et al. (2009) and the highest ranked three configurations (b,d,e) of the

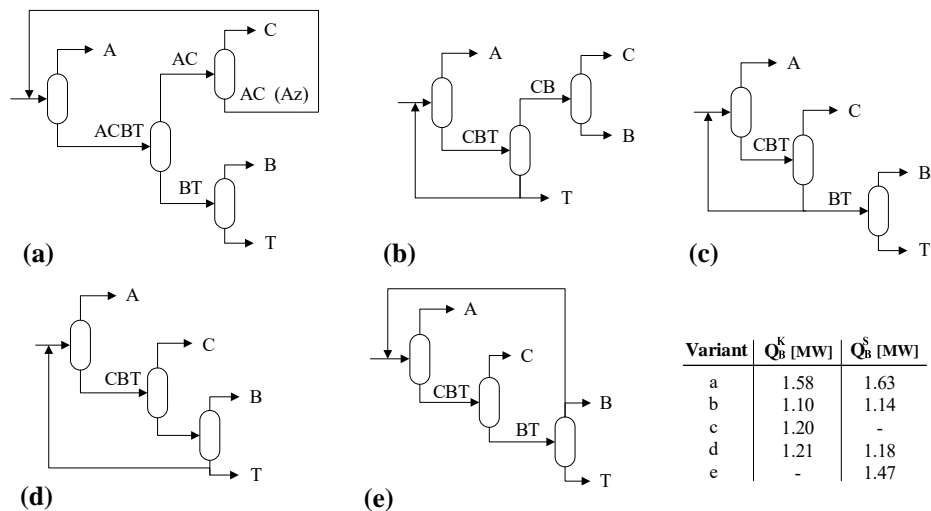

Figure 4: Alternative flowsheets for the separation of an equimolar mixture of acetone-chloroform-benzene-toluene (ACBT) alongwith their corresponding minimum reboiler duties

total 18 configurations, which are generated by the proposed synthesis method for the same feed and thermodynamic model as used by Kraemer et al. (2009). From the four variants considered by Kraemer et al. (2009), only variant (c) is not generated by the proposed method, since at current state only SP are considered as valid recycle streams. However, comparing the results in the embedded table it becomes apparent that the remaining three variants are evaluated with comparable MED by the current method (Q_B^S) and the approach by Kraemer et al. (2009) (Q_B^K) and that variant (b) is considered as lowest MED variant in both evaluations. The differences can be explained by different recycle rates, as Kraemer et al. (2009) perform a minimization of the MED for each process, applying the PDB criteria of Brüggermann and Marquardt (2011). While they report computational times of ~ 1000 s for each variant, the synthesis and ranking of the 18 variants in the current method is performed in less than 60 s.

To further illustrate the applicability of the method, the separation of a 25 mol-% acetone, 40 mol-% chloroform, 25 mol-% methanol, 5 mol-% ethanol and 5 mol-% benzene (ACMEB) mixture, as analysed in the article of Wasylkiewicz (2006), is studied. The quinary mixture exhibits six binary, two ternary and a quaternary azeotrope. The topological analysis identifies four distillation regions, with each of them containing four to six compartments. As in the study of Wasylkiewicz (2006), purified ethanol and benzene are to be separated from the feed. While overall nine process variants are generated by the proposed synthesis method, only the variant illustrated in Figure 5 allows for a full recovery of both products in only three columns. Herein, methanol is used as internal recycle, which enables a full separation of ethanol in the second column. However, the post-processing step shows that the

Figure 5: Process variant for ACMEB case study.

introduced methanol stream cannot be fully recovered from the third column. In fact, the generated process variant is equivalent to the one proposed by Wasylkiewicz (2006). However, Wasylkiewicz (2006) proposed operation of the third column at lower pressure, which then enables a
closed methanol recycle. Thus, the case study illustrates the capability of the proposed method to automatically generate feasible process configuration for this complex multi-component system, but also illustrates that further extensions, e.g. for the consideration of pressure variations, are required to further extend the search space.

4. Conclusion and outlook

The current article introduces a fully automated method for the synthesis of distillation processes for the separation of homogeneous azeotropic mixtures. The method is not restricted to any number of components and incorporates a general feasibility test, which examines both limiting operational modes for distillation, total reflux as well as reversible distillation. The integration of the rectification body method further checks for an intersection of the rectifying and stripping profiles and provides an estimate of the minimum energy duty that is used for a direct ranking of the generated variants. The only requirements for the application of the method is a reliable thermodynamic model of the multi-component mixture. The current implementation further allows for an automatic consideration of the singular points as internal recycle streams. Future work will focus on the extension of the method towards alternative and more complex recycle options, pressure variations, as well as other process options, like extractive and heteroazeotropic distillation for heterogeneous mixtures. Furthermore, an automatic evaluation of different options for energy-integration, as proposed by Skiborowski (2018), is considered as future post-processing step.

Abstract

Guidelines for optimal operation strategy of cooling water temperature are presented to find the maximum net electrical energy of a cogeneration system for turbine generators (TGs) and cooling towers (CTs). In this study, a real cogeneration plant in Taiwan, consisting of variable-frequency drive fan-based CTs and a generator, was chosen as a case study. Statistical linear models were used to build TGs and CTs. A multi-linear model was established to approach a nonlinear system in the cooling tower using a physically meaningful index, the cooling capability index, as an indicator of data clustering. The results showed that the cooling capability index was a good clustering index for the CTs. The cooling tower multi-linear model regressed by the clustering data performed well in predicting the cooling water outlet temperature. The simulated case verified that the online operating guidelines were consistent with real plant data and that it has the ability to find the optimal cooling water temperature. Two cases of plant test prove that the online operating guidelines can assist operators in operating cooling water temperature to the maximum net electrical energy.

Keywords: cooling capability index, multi-linear model, online operating guide, net electrical energy

1. Introduction

Steam turbine generators (TGs) are widely used in the chemical and energy industries, and optimization of the energy efficiency of a generator is an important issue in industrial energy conservation. In general, low-pressure vapor at the outlet of the generator is introduced into the condenser in order to increase the vacuum, thus increasing power generation. On the other hand, the supplied cooling water requires additional fan power in the cooling towers (CTs) to maintain a low water temperature.(Pan et al., 2011) Due

to the fact of the complexities in TG-CT systems, the optimization of these power generation processes is still an active area among the researchers (Hajabdollahi et al., 2012; Bornman et al., 2016; Li et al., 2018).

Cooling tower and generator modeling are essential to finding the optimal operating conditions. Models of CTs can be divided into theoretical models and data-driven models. The modeling of CTs and TGs using theoretical models to investigate the potential optimization of operating conditions have been reported in many papers(Zhao et al., 2008; Zhao and Cao, 2009; Ganjehkaviri et al., 2015; Hafdhi et al., 2015). However, the construction of theoretical models requires sufficient knowledge and is time consuming. Thus, constructions of such models cannot provide optimal conditions in a short period. Data-driven models were adopted in a few studies to shorten the modeling time and to investigate the interaction between steam TGs and the CW temperature of CTs to find the optimal operating conditions. Furthermore, the optimal operating condition between steam TGs and the CW temperature of CTs was rarely discussed and verified. Pan et al.(Pan et al., 2011; Pan et al., 2013) used the LMN method to establish a multi-linear model for cogeneration systems with two-speed fans. The model results suggested adjusting the CW temperature to achieve the optimization. The multi-linear model obtained by LMN via clustering had high prediction performance for the cooling water temperature, but the physical meaning of each cluster is unknown, such that operators cannot trust the model to implement on plants. Therefore, it is desirable to use a physically meaningful method to cluster the data to guide the operator in adjusting the cooling water temperature. On the other hand, the optimum operation strategy of fans was determined by the arrangement of fan speed modes for two-speed fans but it is not the ideal optimization method for variable-frequency fans. Furthermore, with an automatic clustering approach in LMN, the model may become rather unstable and need retune frequently. According to the above previous works, we found the following problems remained unsolved. (1) there exist many disturbances in the TG-CT systems, such as steam unstable steam flow, changing humidity as well as environmental temperature. Empirical models are basically not making sense to these changes. (2) First principle models are difficult to obtain due to the lack of trustworthy physical parameters. (3) The optimal conditions are changing from time to time due to the change of the system parameters mentioned above.

The purpose of this study was to tackle the above difficulties by constructing models of TGs with variable-frequency fans using a physical clustering index. Multi-linear model for variable-frequency fans was built. Online operating guidelines based on the models of TGs and CTs were presented to find the optimal cooling water temperature and maximum net electrical energy of the cogeneration system with some physically meaningful plant tests. The rest paper is organized as follows. Section 2 presents details of the modeling and optimal approach, including the TG model, the multi-linear model of CTs, and an optimal strategy named online operating guidelines. Results of a simulated case and plant tests are discussed in Section 3 to demonstrate the feasibility of the online operating guidelines, and a summary of findings is given in the concluding section.

2. Methodology

2.1 Cooling Tower Modeling with Multi-linear Model

Wang et al. (2013) presented a cooling capability index, γ, which can describe the cooling capability of a CT in terms of effective power utilization. The definition of γ is

$$\gamma = \frac{F_{CW} C_p \Delta T_{CW}}{W_{fan}} \tag{1}$$

In this study, the cooling capability index was adopted as a clustering index for regressing the CT multi-linear model. The format of the multi-linear model is a set of the following equations:

$$T_{CW,out} = a_0 + a_1 T_{CW,in} + a_2 H_{R,in} + a_3 T_{air,in} - a_4 W_{fan} \tag{2}$$

In the multi-linear model, the reciprocal of a_4 ($1/a_4$, kW/°C) is physically representative of the required fan power consumption per unit CW outlet temperature change, $\Delta \widehat{W}_{\text{fan}}$.

2.2 Last Stage Turbine Generator Modeling

The enthalpy of the steam at the last stage of the TG can be simplified and regressed as follows:

$$H_{\text{steam@the last stage of TG}} = b_0 + b_1 T_{CW,out} + b_2 F_{steam} \tag{3}$$

2.3 Online Operating Guidelines

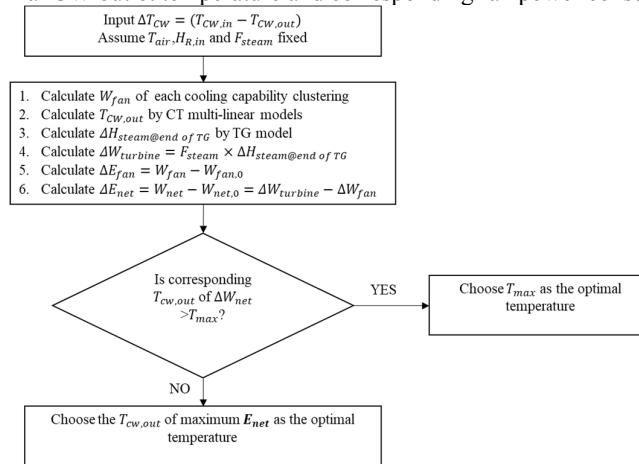
The procedure is shown in Figure 1. The optimal CW outlet temperature cannot be over maximum temperature, T_{max} because that will cause the vacuum in the condenser is not enough, leading the TG tripped. The procedure will give two online operating guidelines of the ΔE_{net} and W_{fan}. According to these two online operating guidelines, operators can find the optimal CW outlet temperature and corresponding fan power consumption.


Figure 1 Procedure of operating guidelines for CW temperature

3. Results and Discussion

3.1 Plant Description

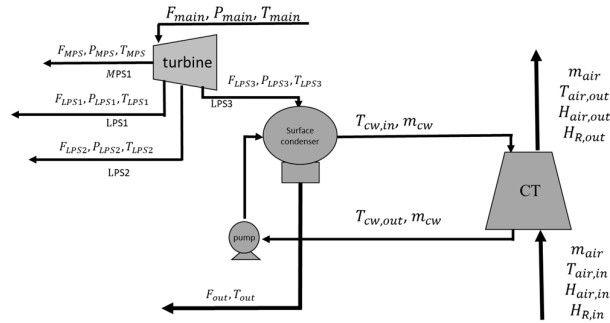
In this study, real cogeneration plant in Taiwan, consisting of a variable-frequency drive fan-based cooling tower and a generator, was chosen as a case study to demonstrate model establishment and the online operating guidelines according to the last stage TG and CT models. As Figure 2 shows, the cogeneration plant consists of a TG, a three-cell CT in which every cell has a fan, and a condenser. The range of the fan power is approximately 0–200 kW. The total supplied cooling water of the cooling towers is 5400 T/H. High-pressure steam is introduced into a TG, which in turn drives a power generator to produce electric power.


Figure 2 Schematic of a typical cogeneration plant.

3.2 Cooling Tower Model

The CT data presented in this study were divided into nine clusters (α = 1 to 9) according to the range of the γ. Every eight intervals of γ starting from the smallest value of γ served as a cluster. The range of the minimum γ_α was from 67 to 75; the range of the maximum γ_α was from 133 to 141. These nine clusters were used to regress the multi-linear model. The R^2 of each linear model is above 0.97.

3.3 Last Stage Turbine Generator Model

The enthalpy of the steam at the last stage of the TG correlation is regressed as the following:

$$H_{\text{steam@the last stage of TG}} = 2506 + 1.78T_{CW,out} + 0.2F_{steam} \tag{4}$$

The R^2 of the correlation is 0.99.

3.4 Demonstration with a Simulated Case

Figure 3 shows the online operating guidelines of the relative net electrical energy, ΔE_{net}. The values are 29.70 °C and 30.25 °C for the two cases of ΔT_{CW}, respectively. The trends of the ΔE_{net} calculated by historical data were consistent with the trend of the online operating guideline of the ΔE_{net}. As Figure 3(a) shows, the optimal CW outlet temperature is approximately 32.7 °C for the CT. However, the CW outlet temperature can only be increased to 34 °C if the optimal temperature cannot be found during the increase in the cooling water outlet temperature, as Figure 3(b) shows, because the T_{max} of the CW outlet temperature is 34 °C in this case study.

3.5 Plant Test

Figure 5 shows the plant test results and online operating guidelines of the case 2. The online operating guidelines were given based on 24.9 °C of T_{air} and 59.9 % of H_{air}. The initial CW outlet temperature was 29.1 °C. However, because the cooling capability index was 155 at this condition, which beyond the range of the CT multi-linear model, the online operating guidelines at this condition were obtained by extrapolation. According to the online operating guidelines, the CW outlet temperature must be raised to increase the net electrical energy. Thus, the CW outlet temperature was raised to 31.4 °C. The finial ΔE_{net} increased by 21.75 kW. Compared with Case 1, Case 2 had greater ΔE_{net} because the

CW outlet temperature was operated at the lower temperature, which required the larger fan power consumption. As the CW outlet temperature increased, the fan power consumption dropped dramatically, leading to the energy saving benefit appear. The results of cases 1 and 2 showed that the net electrical energy can be increased by the online operating guidelines and the finial ΔE_{net} of the plant tests are close to the finial ΔE_{net} of the online operating guidelines. These results prove that the online operating guidelines using the TG model and the CT multi-linear model are feasible.

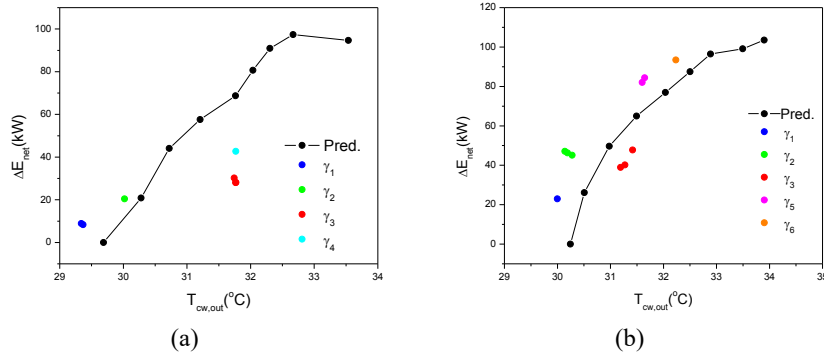

Figure 3 The agreement of the relative net electrical energy between multi-linear model and measurement using the conditions of (a) $T_{air,in}$: 28.5~29 °C, $H_{R,in}$: 78~79.5%, and F_{steam}: 30~32 (T/H), and (b) $T_{air,in}$: 30~32 °C, $H_{R,in}$: 70~73%, and F_{steam}: 35~36 (T/H)
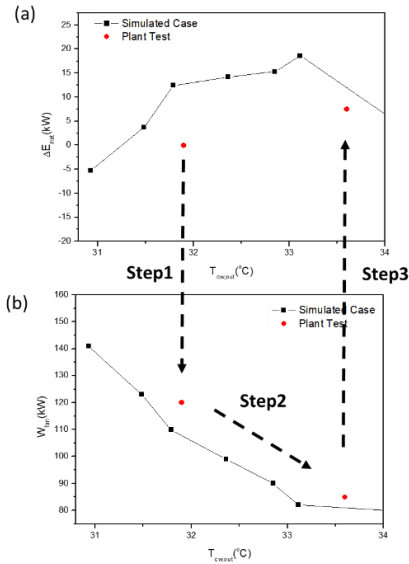

Figure 4 Measured data of (a) cooling water outlet temperature, and (b) fan power consumption for Case 1.
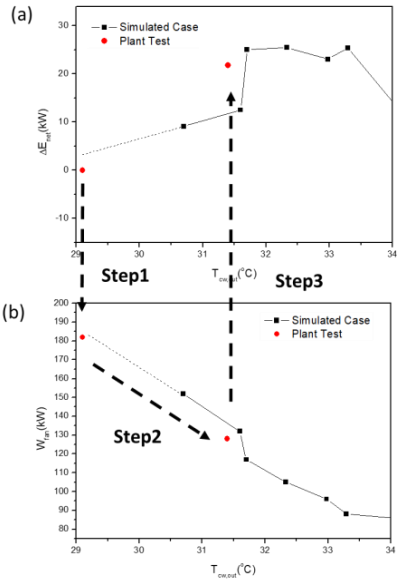

Figure 5 Measured data of (a) cooling water outlet temperature, and (b) fan power consumption for Case 2

4. Conclusions

In this study, we presented an optimal operation method for finding the maximum power generation for cogeneration systems by using a CT multi-linear model and a TG model. An online operating guidelines were used to determine the optimal CW outlet temperature to achieve maximum net electrical energy. In the demonstration, the online operating guidelines were consistent with historical data and that it had the ability to find the optimal CW temperature. Two cases of the plant test based on the online operating guidelines showed that the final ΔE_{net} increased by 7.5 and 21.75 kW, respectively. The difference of ΔE_{net} between Case 1 and Case 2 is mainly caused by the different initial CW outlet temperatures. The ΔE_{net} of plant test and ΔE_{net} of the online operating guidelines were close to prove that the online operating guidelines can be practically applied.

Abstract

This work presents the development and application of an efficient solution strategy for the optimal production scheduling of a real-life food industry. In particular, the case of a canned fish production facility for a large-scale Spanish industry is considered. Main goal is to develop an optimized weekly schedule, in order to minimize the total production makespan. The proposed solution strategy constitutes the basis to develop an efficient and robust approach for this complex scheduling problem. A general precedence Mixed-Integer Linear Programming (MILP) model is utilized for all scheduling-related decisions (unit allocation, timing and sequencing). To solve the scheduling problem in a computational time accepted by the industry, a two-step decomposition algorithm is employed. Salient characteristics of the canned fish industry are aptly modelled, while valid industry-specific heuristics are incorporated. The suggested solution strategy is successfully applied to a real study case, corresponding to the most demanding week of the plant under study.

Keywords: production scheduling, food industry, MILP, decomposition

1. Introduction

Market trends and competitiveness has steered food industry towards large production volumes, complex alternative recipes and an increasing product portfolio, making production scheduling a challenge. The current industrial practice imposes scheduling-related decisions to be mainly derived by managers and operators, hence the overall plant performance is subject to their experience. Computer-aided scheduling tools can significantly improve these decisions by proper consideration of all involved parameters and therefore significantly enhance production scheduling (Harjunkoski, 2016). As a result, productivity is improved, while customers remain satisfied and profits increase. Acknowledging the importance of optimized production scheduling, the scientific community has widely studied the topic over the last 30 years, introducing numerous scheduling models (Méndez et al., 2006). However, most of these works consider small-

scale study cases. This is mainly attributed to the fact that production scheduling is an NP-hard problem, therefore large complex instances can become intractable. The scientific community has widely recognised the lack of applications to real industrial cases (Harjunkoski et al., 2014). Recently some attempts have been made to close the existing gap between theory and industrial practice. In (Kopanos et al., 2010), the authors studied a real-life yoghurt production facility using a novel mixed discrete and continuous MILP model. Furthermore, Baumann and Trautmann, (2014) proposed a hybrid MILP method for make-and-pack processes using a decomposition strategy and a critical-path improvement algorithm. Moreover, Aguirre et al., (2017) combined a novel MILP model that incorporates TSP (Travelling Salesman Problem) constraints, with a rolling horizon algorithm. In this work a solution strategy is proposed that deals with scheduling problems of large-scale industrial food production facilities. In particular, an MILP model is proposed to optimize the production schedule, while a two-step decomposition algorithm is utilized to solve the problem in an acceptable computational time.

2. Problem statement

In this work, the canned fish production in a real-life industrial facility is examined. Specifically, the production process of Frinsa del Noroeste S.A., located in Ribeira, Spain, is investigated using real process data. The plant is capable of producing more than 400 codes, and it is one of the largest canned fish industries in Europe. The facility comprises of multiple stages, including both batch and continuous processes (Fig. 1). The raw materials arrive in the facility in the form of frozen fish blocks, and as such they need to be unfrozen in the thawing chambers. Then, the blocks are chopped in the appropriate size and filled in the cans alongside with all other ingredients (brine, olive oil etc.) required by the recipe. In the next stage, the sealed cans are sterilized in order to ensure the microbiological quality of the final products. Finally, the cans are packaged in their final form (6-pack, 12-pack, boxes etc.) and are stored in the warehouse, to be later distributed in the market.

Figure 1: Facility layout

The plant under consideration can be identified as a multiproduct, multistage facility with both batch (thawing, sterilizing) and continuous (sealing and filling, packaging) processes each utilizing multiple parallel units. Additionally, the large production demand and high production flexibility increases significantly the plant's complexity. The thawing stage is overdesigned compared to the processing capacity of all other stages, therefore it is a valid assumption to omit it from this study. Unfortunately, no clear bottlenecks exist, and as such all other processing stages need to be modelled. The short-term scheduling horizon of interest is 5 days, whereas all units are available 24 hours per day. Sequence-dependent changeovers are considered. All design and operating constraints of the facility, such as a limited waiting time between stages to ensure microbiological integrity, are taken into account. The objective is to minimize the total production makespan, while ensuring demand satisfaction.

3. Mathematical framework

The key scheduling decisions to be made are related to: a) the number of product batches required to satisfy the incoming orders, b) the allocation of product batches to units in every processing stage, c) when will the process of each batch in every stage start and finish and d) in what relative sequence. A typical industrial practice in most food industries, imposes the operation of the intermediate batch processes in their maximum capacity. Utilizing the batch stage to its fullest, leads to reduction of changeovers between products and a general increase in the plant's productivity. Thus, the number of batches of each product required to satisfy the demand is calculated a priori, based on the given demand, the inventory levels and the capacity of the sterilization chambers.

3.1. MILP model

The suggested MILP model is based on the general precedence framework. Due to lack of space, only a brief description of the model is presented:

$$\sum_{j \in (SJ_{s,j} \cap PJ_{p,j})} \overline{Y}_{p,b,s,j,n} = 1 \qquad \forall p \in I_p^{in}, b \in PB_{p,b,n}, n \in I_n^{in} \tag{1}$$

$$L_{p,b,s,n} + \sum_{j \in (SJ_{s,j} \cap PJ_{p,j})} (fs_{p,b,j,n}^{time} \cdot \overline{Y}_{p,b,s,j,n}) = C_{p,b,s,n} \qquad \forall p \in I_p^{in}, b \in PB_{p,b,n}, n \in I_n^{in} : s = 1 \tag{2}$$

$$C_{p,b,s,n} + W_{p,b,s,n} = L_{p,b,s+1,n} \qquad \forall p \in I_p^{in}, b \in PB_{p,b,n}, n \in I_n^{in} : s < 3 \tag{3}$$

$$L_{p',b',s,n} \geq C_{p,b,s,n} + ch_{p,p',j}^{time} - M \cdot (1 - X_{p,p',n}) - M \cdot (2 - \overline{Y}_{p,b,s,j,n} - \overline{Y}_{p',b',s,j,n})$$
$$\forall p \in I_p^{in}, p' \in I_{p'}^{in}, b \in PB_{p,b,n}, b' \in PB_{p',b',n}, j \in (PPJ_{p,p',j} \cap SJ_{s,j}), n \in I_n^{in} : p < p', s \neq 2 \tag{4}$$

$$L_{p',b',s,n} > C_{p,b,s,n} - M * (1 - \overline{X}_{p,b,p',b',n}) - M * (2 - \overline{Y}_{p,b,s,j,n} - \overline{Y}_{p',b',s,j,n}),$$
$$\forall p \in I_p^{in}, b \in PB_{p,b,n}, p' \in I_{p'}^{in}, b' \in PB_{p',b',n}, j \in (PPJ_{p,p',j} \cap S_{s,j}), n \in I_n^{in} : p < p', s = 2 \tag{5}$$

$$C_{p,b,s+1,n} - L_{p,b,s,n} \leq Q_p \qquad \forall p \in I_p^{in}, b \in PB_{p,b,n}, n \in I_n^{in} : s = 1 \tag{6}$$

$$C_{p,b,s,n} \leq 24 \qquad\qquad \forall p \in I_p^{in}, b \in PB_{p,b,n}, n \in I_n^{in} : s = 3 \tag{7}$$

$$C^{max} \geq C_{p,b,s,n} \qquad\qquad \forall p \in I_p^{in}, b \in PB_{p,b,n}, n \in I_n^{in} : s = 3 \tag{8}$$

Constraints (1) guarantee that all product batches p,b to be scheduled on day n will be processed by exactly one unit j in every stage s, using the binary allocation variable $\overline{Y}_{p,b,j,n}$. Constraints (2) impose the timing constraints in the sealing and filling stage. More specifically, they state that the completion of the sealing and filling task for every product batch to be scheduled in every day $C_{p,b,s,n}$ is equal to the starting time of the task $L_{p,b,s,n}$ plus the required processing time $fs_{p,b,j,n}^{time}$. Similar constraints are used for the sterilization and packing stages. To synchronize the stages, constraints (3) are employed. The continuous variable $W_{p,b,s,n}$ defines the waiting time between each stage. The sequencing

constraints between product batches in every stage are portrayed in constraints (4) and (5). Two general precedence variables are introduced, $X_{p,p',n}$ and $\overline{X}_{p,b,p',b',n}$, alongside a big-M parameter. The first precedence variable defines the sequencing of product batches in the continuous stages (sealing and filling and packing), while the latter in the batch stage (sterilization). Notice, that the batch sets b,b' are not used in the first precedence variable, since a single campaign policy is followed in the continuous stages. This way the binary variables are significantly decreased, thus the computational complexity of the problem is reduced. In particular, constraints (4) state that if a product p is processed prior to p' on day n ($X_{p,p',n} = 1$) and both product batches are processed in the same unit j ($\overline{Y}_{p,b,j,n} = \overline{Y}_{p',b',j,n} = 1$), then the starting time of p',b' must be greater than the completion time of p,b plus any required changeover $ch^{time}_{p,p',j}$. Similarly, constraints (5) impose the sequencing constraints in the sterilization stage. Constraints (6) enforce the waiting time between the sealing and filling stage and the sterilization stage to be less than a specific limit Q_p. This limit ensures the microbiological integrity of the final product. To ensure that the daily scheduling horizon is not violated, constraints (7) are used. The objective of the model is the minimization of the total production makespan C_{max} and is expressed by constraints (8).

3.2. Decomposition algorithm

The complexity of the examined plant is such that an exact method cannot solve the scheduling problem in reasonable time. Therefore, a two-step decomposition algorithm is employed to split the initial problem into several tractable subproblems. First, the weekly scheduling problem is decomposed in a temporal manner into 5 daily scheduling subproblems. Then, an order-based decomposition is utilized to solve the daily scheduling problem for a specific number of products in each iteration. Fig. 2. illustrates the flowchart of the proposed solution strategy. At first the batching subproblem is solved to translate the product orders into batches. Afterwards, the number of orders to be scheduled in each iteration are set. Then, the MILP is solved for the specified subproblem area (day and number of products) and only the binary variables (unit allocation, sequencing) are fixed. When all orders are scheduled for a given day, all variables are fixed, and the algorithm continues to the next day. Finally, when all days are considered, the complete schedule is generated.

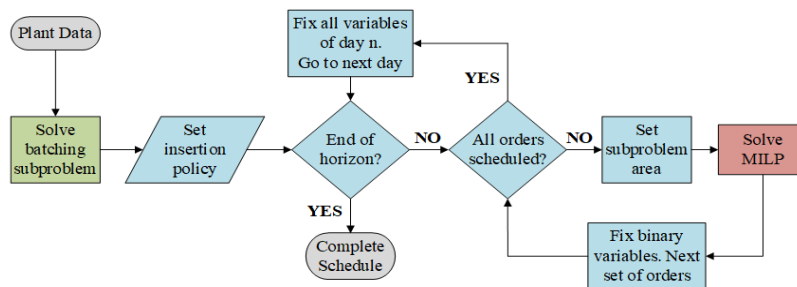

Figure 2: Solution strategy

4. Results

An industrial study case using real data from the Frinsa production plant is presented. In total 136 final products are to be scheduled, corresponding to a real weekly demand from a period with the most intensive production. To solve this complex case, the proposed solution strategy is utilized. In each iteration the daily schedule for half of the product-orders was chosen to be optimized. The MILP model was implemented in GAMS 25.1 and solved in an Intel Core i7 @3.4Gz with 16GB RAM, using CPLEX 12.0. Optimality is reached for all iterations of the suggested solution strategy. Figure 3 illustrates the complete schedule generated for all units of every processing stage. Each color corresponds to a batch or lot of a product-code.
Figure 3: Gantt chart of units of all processing stages

Compared to the real weekly schedule proposed by Frinsa, the optimized schedule of the proposed strategy illustrates interesting results. To satisfy the given demand, the manually derived schedule by Frinsa, requires the addition of a shift on Sunday evening, while the optimized schedule satisfy all orders within 5 days. Moreover, the total CPU time for the solution of the problem is approximately 1 hour and it is acceptable by the company.

5. Conclusions

This work presents the optimization-based production scheduling of a large-scale real-life food industry. More specifically, all major processing stages of a canned fish production facility have been optimally scheduled. The industrial problem under consideration illustrates significant complexity, due to the mixed batch and continuous stages, each having numerous shared resources, the large number of final products and the various operational, design and quality constraints. This make-and-pack structure (one or multiple batch or continuous processes followed by a packing stage) is typically met in most food and consumer packaged goods industries, hence, the presented solution strategy can be easily implemented in other industrial problems. It has been shown that the suggested solution strategy can optimally schedule even the most demanding weeks of the examined industry in acceptable time, leading to reduction of overtime production. The proposed strategy can be the core for a computer-aided scheduling tool that can facilitate the decision-making process for the production scheduling of food industries. Current work focuses on the introduction of cost related objectives, as well as, the incorporation of uncertainty in product demands.

A Systematic Parameter Study on Film Freeze Concentration

Jan-Eise Vuist[a], Maarten Schutyser[a,*] and Remko Boom[a]

maarten.schutyser@wur.nl

Abstract

Film freeze concentration is an alternative method to concentrate aqueous streams compared to suspension freeze concentration. Major advantage is that the equipment is less complex and thus capital costs are in principle lower. In our research we investigated especially how hydrodynamics, applied freezing temperatures and solution properties influence inclusion of solutes in ice and ice yield during film freeze concentration. For this we carried out both lab-scale experiments and CFD simulations. Model solutions of sucrose and maltodextrin were concentrated in a stirred vessel by growth of an ice layer at the bottom freezing plate. For varying stirring speeds, feed concentrations and freezing plate temperature profiles we determined the solute inclusion in the grown ice and the ice yield. When increasing stirrer speeds a decreasing amount of solute included in ice was found at constant freezing plate temperature. This can be explained because the transport of the solute molecules in the boundary layer is diffusion limited. An increase in shear above the surface reduces the thickness of this layer and therefore less solute is included in ice at high shear rates. CFD simulations were carried out to describe the hydrodynamics near the surface and to relate the shear rate to the impeller Reynolds number. Moreover, the CFD simulations could explain the increased solute inclusions for higher concentrations of sucrose as higher viscosities lead to significant reduction of shear rates close to the ice layer. The CFD simulations will facilitate easier translation of the obtained results for a differently designed film freeze concentration system. Sucrose and maltodextrin appeared to behave very similar with respect to inclusion behaviour, which may be explained from their similar diffusivities. Ice growth rate is found another important factor and is very much influence by applied freezing temperatures. Our experiments showed that there is a critical ice growth rate. If this ice growth rate is exceeded more solutes will be included in the ice layer. In this case the solute molecules will not have the chance to move away from the ice boundary. The next step in our research is modelling of the ice growth rate as function of the freezing plate temperature to optimise both ice yield and solute inclusion.

Keywords: freeze concentration, solute inclusion, modelling

1. Introduction

Concentration of aqueous food streams is a routine operation in food industry to increase their shelf-life and to reduce their transportation volume. To concentrate these streams multiple techniques are available based on evaporation, physical separation or freeze concentration. While thermal evaporation is the most common industrial technique and is readily applicable to many streams, such as dairy or sugar, it has drawbacks for streams containing heat-sensitive components as reviewed by Sánchez et al. (2009).

Heat-sensitive components such as proteins and flavours either become damaged by the heat-treatment or may be stripped away with the water from the product stream. Both phenomena result in a loss of product quality. During freeze concentration, these components are exposed only to low temperature and therefore minimally damaged. Because freeze concentration produces minimal thermal damage, it is considered a mild concentration technique.

Freeze concentration can be performed in two main modes: suspension freeze concentration and film freeze concentration. During suspension freeze concentration the ice is formed in suspension. The ice growth and the degree of supercooling are maintained by continuously seeding the suspension with fresh crystals. The ice crystals are then washed and melted in a continuous washing filter. This technique is commercially available and has applications in the fruit juice and beer industry. During film freeze concentration the ice crystal(s) are grown on the wall of a heat exchanger. Growing the ice crystals on the wall eliminates the need for a washing filter and reduces the complexity of the unit operation. This article will focus on the film freeze concentration process.

The objective of this study is to study the relationship between inclusion behaviour of solutes and the hydrodynamic conditions near the growing ice layer during film freeze concentration. Sucrose and maltodextrin are selected as the model solute components. To study their inclusion behaviour, a custom build freeze cell is used. Previous studies by Miyawaki et al. (1998) have often used progressive freeze concentration set-ups, which are optimized for studying solute partitioning behaviour at the ice water interface. In this study we chose for a different set-up that provides more realistic hydrodynamic conditions. This is especially relevant for scaling-up the film freeze concentration process. Previous studies by Jusoh et al. (2009) already indicated that hydrodynamic conditions in the liquid are relevant to inclusion behaviour. To gain more insight into this, we used a computational fluid dynamics (CFD) model to describe the hydrodynamic conditions near the ice-liquid boundary. The outcomes of this model are linked to the observed inclusion behaviour during the freeze concentration experiments.

2. Material and Methods

2.1. Experimental

The film freeze concentration experiments were conducted in a small-scale test apparatus designed after Genceli et al. (2007). The test apparatus was constructed from an acrylic cylinder with 90 mm internal diameter. The bottom of the cylinder was constructed out of a stainless steel chamber, which was cooled using a cooling fluid. The vessel was equipped with a pitched two-bladed stirrer. To monitor the temperature during the experiments, we placed thermocouples in the vessel at 1, 2, and 5 mm from the bottom surface, one thermocouple at 10 mm below the liquid surface and two thermocouples were placed in the in- and outgoing liquid flow. All thermocouples (type T) were connected to 24-bit data logger (National Instruments, cDAQ-9214, ±0.01 °C relative accuracy, USA).

Sucrose and maltodextrin solutions with various concentrations were used as feed solutions. The sucrose (342.30 g mol^{-1}) was obtained from Sigma-Aldrich (BioXtra, >99.5 %) and the maltodextrin DE12 ($\approx$ 3423.0 g mol^{-1}) from Roquette Freres (Glucidex 12). The feed solutions were pre-cooled to 4 °C before use. To determine the sucrose concentration in the sample, we used a refractometer (Anton Paar, Abbemat 500, Austria). To determine

the maltodextrin concentration, we heated the pre-weighed solutions overnight in an oven at 105 °C and weighed the samples afterwards. The solutions were reused for a maximum of 5 days and separate solutions were used for experiments on the same day.

At the start of the freeze concentration experiments, a droplet (100 μL) of pure water was deposited on the freeze plate. This ice droplet prevented the initial super cooling. Initial supercooling will cause fast initial freezing and very strong inclusion of solutes at the beginning of the freezing process and can even lead to ice crystals forming in suspension rather than on the freeze plate. When the droplet was completely frozen, the feed solution was introduced through a filling port at the top of the cylinder. Only when the liquid submerged the stirrer blades, the stirring was started to prevent major inclusions of air in the solution. The experiments were stopped after a half hour. At the end of the experiment the liquid was removed from the cylinder and the ice was melted. Both fractions were weighted and their contents analysed. All experiments were carried out in duplicate.

2.2. Modelling

A COMSOL Multiphysics 5.3a model was used to estimate the fluid flow induced by the stirrer near the bottom of the cylinder. The fluid flow is described by the Navier-Stokes equation (Batchelor (2000)). The model used a geometry similar to the experimental set-up. For the outer walls and the bottom walls of the cylinder a no-slip boundary condition was applied. A symmetry boundary condition was applied to the fluid surface. The behaviour at the fluid surface is assumed to have no influence on the ice formation. To simulate the stirring a rotating material coordinate system was used. The wall condition for the stirrer is equal to the rotational speed of the material coordinate system and the wall condition for the outside and bottom wall the rotational speed is equal to 0.

The system was simulated for stirring rates of 50 and 150 rpm (Re = 703 to 9845) with laminar flow model and a turbulent $\kappa - \varepsilon$ model was used for the simulation of 500 rpm (Re = 7030, 20674, 32818 respectively for 36, 18, 6 wt% solutions). For the wall treatment the built-in wall functions of COMSOL Multiphysics 5.3a were used. The mesh is based on the physics induced sequence with the fine settings.

Three sugar solutions were simulated at their freezing points. The density of the sucrose solutions was estimated by calculating mass fraction average. The viscosity of the solution was measured with a rheometer (Anton Paar MCR-301, geometry: DG26.7/200/AL, Austria) using a shear rate sweep in the range of 1-100 s^{-1}. The freezing point of the solutions was determined using the melting curve from differential scanning calorimetry (TA Instruments DSC-250, USA). The variables are summarised in table 1. These values are similar to the ones observed by Bubnick and Werner (1995).

3. Results

3.1. Ice formation

Table 1: Used constants for CFD simulations

Solution [wt% Sucrose]	ρ [kg m^{-3}]	η [mPa s]	T_{fp} [°C]
6	1021	2.1	-0.3
18	1072	3.6	-1.9
36	1156	11.1	-4.5

The ice yield of film freeze concentration was compared for different stirrer rates and cold wall temperatures. The ice yield showed little dependence on the stirrer rate. A clear dependence was found on the cold wall temperature. The lower temperatures yielded more ice because the driving force for heat transfer is higher. There was a slight dependence on the solution concentration due to the freezing point depression at higher sucrose concentrations (figure 1).

3.2. Sucrose and Maltodextrin inclusion

The effective solute inclusion (equation 1) versus the Reynolds numbers were compared for the same conditions as in figure 1 (figure 2). The solute inclusion decreased at increasing Reynolds numbers for all different solutions and cold wall temperatures. No major differences between the solutions could be found at Reynolds number below 10,000, the laminar regime. At Reynolds numbers above 10,000, differences were clear between the different solutions and the different cold wall temperatures. The 18 wt% sucrose solutions showed more inclusion than the 6 wt% sucrose solutions. The 6 wt% maltodextrin solution showed a similar behaviour to the 6 wt% sucrose solution. A lower cold wall temperature increased the amount of inclusions due to an increased freezing rate.

Figure 1: Effect of applied freeze plate temperature and solute concentration on the ice formation after freezing for a half hour. Ice yield for sucrose and maltodextrin DE12 solution averaged over the stirrer speeds.

$$K[-] = \frac{C_S[wt\%]}{C_L[wt\%]} \tag{1}$$

An increase of the stirrer speed increases the shear above the ice surface which improves the transport of the solute away from the ice-liquid boundary and therefore reduces the diffusion limitation of the freeze concentration. The solute inclusion will increase at lower cold wall temperatures. For a constant cold wall temperature, the freezing initially proceeds much faster than later. This implies that the inclusion rate in the initial stages is larger than later. Thus, by adjusting the cold wall temperature such, that it starts not too cold and gradually cools further, we may avoid the initial large amount of inclusions.

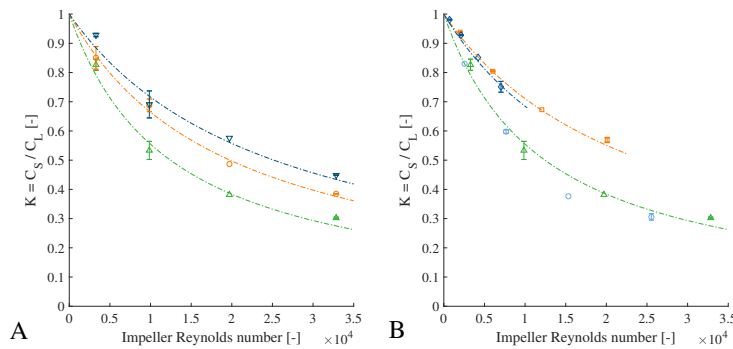
If one compares the freezing of solutions with different solutes, one observes that solutions with maltodextrin show less inclusion. We expect that this is because of the larger


Figure 2: Effect of impeller Reynolds number on the effective solute inclusion.
A.) 6 wt% sucrose at △ -5.0 °C; ◯ -7.5°C; ▽ -10.0°C below the freezing point of the solution.
B.) △, 6 wt% sucrose; □, 18 wt% sucrose; ◇, 36 wt% sucrose;

The error bars indicate standard deviation. The lines fitted to guide the eye.

molecular weight, giving rise to less melting point depression, hence a larger equilibrium concentration at a given freezing temperature, a stronger concentration gradient towards the solution and therefore faster diffusion from the freezing surface.

3.3. Fluid flow modelling

The shear rates present at the bottom of the cylindrical device was derived from the CFD simulations. The bottom surface, was taken from the result (figure 3). From this the average shear rate was calculated and compared to the Reynolds number (Re = $\frac{\rho ND^2}{\mu}$), with ρ in $kg \cdot m^{-3}$, N in s^{-1}, D in m, and μ in $Pa \cdot s$. The shear rate increased with increasing Reynolds number. Higher shear rates near the surface leads to a reduction of the thickness of the boundary layer. A thinner boundary layer will aid the transport from the solute away from the ice-water boundary and thus will lead to a solute inclusion close to the equilibrium between the ice and the solution. The diffusion through the boundary layer is the rate-limiting step in the freeze concentration process. The simulations show that there is a correlation between the surface shear rate and the impeller Reynolds number found for the vessel. This correlation is specific for our geometry. This correlation is a useful tool for translation of the found results to a pilot scale set up.
Figure 3: Shear rate magnitude in the freeze cell, from simulation. The arrows indicate the direction of the shear.

Higher viscosities of the sucrose solutions will diminish the intensity of the fluid flow

near the ice surface. The lower fluid flow will lead to higher rate of inclusions due to the aforementioned effects. To reach similar inclusion rates the stirrer speed needs to be increased proportionally. The increase in viscosity during a longer and larger freeze concentration process leads to a decrease in performance of the process.

4. Conclusion

In this study the inclusion behaviour of sucrose and maltodextrin during film freeze concentration was found to be closely linked with the stirrer speed and the ice growth rate. Fluid flow simulations showed that there is a direct link to the hydrodynamic conditions above the ice surface. The transport of the solute molecules in the boundary layer is diffusion limited and therefore an increase in shear above the surface reduces the thickness of this layer. The ice growth rate is the other important factor. Our experiments showed that there is a critical ice growth rate. Lewis et al. (2015) showed if the ice growth rate is exceeded more solute will be included in the ice layer . In this case the solute molecules will not have the chance to move away from the ice boundary. At a high enough stirrer speed and a sub critical ice growth rate the inclusions will reach a minimum dictated by a phase partitioning equilibrium as found by Jusoh et al. (2009). To improve the process and decrease the inclusions, experiments with a decreasing cold wall temperature will be carried out.

A Stacked Auto-Encoder Based Fault Diagnosis Model for Chemical Process

Yi Qiu, Yiyang Dai[*]

College of Chemistry and Chemical Engineering, Southwest Petroleum University, Chengdu 610500, China

daiyiyang1984@163.com

Abstract

Fault detection and diagnosis (FDD) is one of the key technologies to ensure the safe operation of chemical processes. With the widespread application of automation technology in chemical plants and the era of big data, data-based methods have become a hot research topic in the field of fault diagnosis. How to effectively extract the fault characteristics from the data and determine the cause of the fault is the key to help the operator deal with the abnormal conditions. Stack auto-encoder is a deep learning model with strong feature extraction and generalization capabilities. This paper proposes a SAE-based chemical process fault diagnosis model and applies it to Tennessee Eastman process. The performance of the SAE-based model is illustrated by comparison with the results of other methods.

Keywords: fault diagnosis, chemical engineering, stacked auto-encoder, neural network.

1. Introduction

With the development of science and technology, the chemical production process has become increasingly large-scale and complicated. When an abnormal situation occurs in the system, if it cannot be discovered and dealt with in time, it will cause huge economic losses and even casualties. Therefore, fault detection and diagnosis (FDD) have important application significance for chemical process.

Since Beard (1971) proposed the concept of fault diagnosis, many scholars have conducted related research in the field of fault diagnosis. Venkatasubramanian et al. (2003) classify fault diagnosis methods into three general categories according to models: quantitative model-based methods, qualitative model-based methods, and process history data based (data-driven) methods. With the widespread use of automation technology in the process industry, researchers can easily obtain a large amount of process history data. Therefore, the data-based FDD method has become a hot research topic in the field of fault diagnosis.

There are two types of FDD methods based on historical data. One type is statistical methods, such as principal component analysis (PCA), independent component analysis (ICA), kernel principal component analysis (KPCA), partial least squares (PLS) and their derivatives. The other type is pattern recognition methods, such as artificial neural networks (ANN), support vector machines (SVM), and so on. However, with the large-scale and complicated development of chemical units, the application of statistical methods and traditional pattern recognition methods will be limited by high-

dimensional data and high-correlation data. Since Hinton & Salakhutdinov (2006) proposed deep learning, the development and application of artificial intelligence technology has achieved great success in the past decade. Today, artificial intelligence is widely used in computer science, finance, and natural language processing. Zhang & Zhao (2017) proposed a chemical process fault diagnosis model based on deep belief network (DBN). Wu & Zhao (2018) proposed a chemical process fault diagnosis model based on convolutional neural network (CNN). The application of artificial intelligence technology in the field of chemical process fault diagnosis has also shown excellent performance.

In this paper, we propose a chemical process fault diagnosis model based on stack auto-encoder (SAE) and apply it to the fault diagnosis of Tennessee Eastman Process (TEP). The remainder of this paper is organized as follows: A brief introduction to SAE is given in Section 2. Section 3 shows a SAE-based fault diagnosis model. In section 4, The SAE-based model is applied in the TE process. Finally, we conclude the paper and describe some work in the future.

2. Stacked Auto-Encoder

The auto-encoder (AE) is proposed by Rumelhart et al. (1986), which is a typical single hidden layer neural network. The stack auto-encoder (SAE) is a modified model proposed by Hinton & Salakhutdinov (2006) based on the auto-encoder. SAE is an important deep learning model and it is a deep neural network essentially.

2.1. Structure of SAE

A SAE with 5 hidden layers is shown in Fig. 1. Structurally, the SAE consists of a coder layer (Layer-1 to Layer-4) and a decoder layer (Layer-4 to Layer-7), which assume a symmetrical structure. Each two adjacent layers from left to right is an AE, the weighted connections of neurons exist between each two adjacent layers.

Fig. 1 Structure of a SAE with 5 hidden layers

Because the network structure of SAE has multiple hidden layers, it can well represent complex high-dimensional functions and has powerful feature extraction capabilities.

2.2. Training of SAE

The SAE training process consists of the following two stages: Pre-training stage and fine-tuning stage. The first stage is to initialize the weight of the deep neural network by means of layer-by-layer unsupervised learning (unsupervised greedy algorithm). The layer-by-layer greedy algorithm can effectively avoid the network falling into local optimum. The second stage is to fine-tune the model produced in the previous step by supervised learning (such as backpropagation algorithm).

For a training set x containing m samples, each of the data passes through the encoder to obtain a characteristic expression of the hidden layer, as shown in Eq. (1).

$$y^{(i)} = f_\theta(x^{(i)}) = s(Wx^{(i)} + b) \tag{1}$$

Where $\theta = (Wx, b)$ is the network parameter, W is the weight, b is the bias term, and s is the activation function.

The reconstructed vector is obtained by the $y^{(i)}$ input decoder, as shown in Eq. (2).

$$z^{(i)} = g_{\theta'}(y^{(i)}) = s(W'y^{(i)} + b') \tag{2}$$

Where $\theta' = (W', b')$, $W' = W^T$.

In order to prevent the model from over-fitting, a penalty term (regularization) needs to be added. The cost function is shown in Eq. (3).

$$J = \frac{1}{m} \sum_{i=1}^{m} (\frac{1}{2} \|z^{(i)} - x^{(i)}\|) + \frac{\lambda}{2} \|W\|^2 \tag{3}$$

Where λ is the regularization parameter.

Iterative calculation is performed by the gradient descent method, and the optimal weight is obtained when the cost function is the minimum. In each iteration, the update process of the weight W and the bias term b as shown in Eq. (4) and Eq. (5).

$$W \leftarrow W - \alpha \frac{\partial J}{\partial W} \tag{4}$$

$$b \leftarrow b - \eta \frac{\partial J}{\partial b} \tag{5}$$

Where η is the learning rate.

After the pre-training stage, the weight of the pre-training model is iterated and updated again using the backpropagation algorithm until the error between the predicted label and the input label is lower than the expected value. Finally, the best weights and bias terms for each layer of AE are obtained.

3. Fault diagnosis model

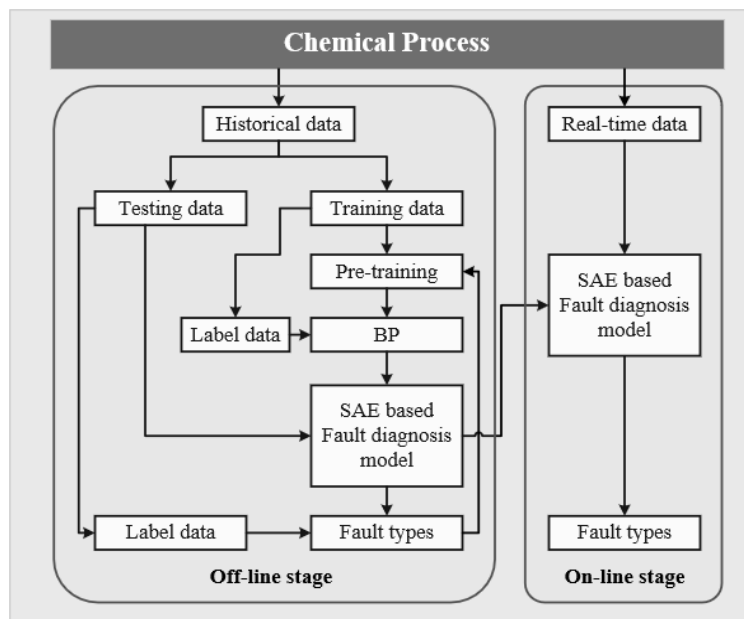
According to the training process of SAE, we constructed a SAE-based chemical process fault diagnosis model. The fault diagnosis model is shown in Fig. 2, which includes the offline stage and the online stage. 80% of the historical data is used as training data, and its corresponding label is generated. The model is trained using the training set and its corresponding labels, and the remaining data is entered into the model for testing. Compare the test results to the label, and apply the model to online-stage if it performs well. If the model has a low correct rate on the test set, the parameters should be changed for retraining.


Fig 2. The framework of the SAE based fault diagnosis model

4. Application to Tennessee Eastman process

In order to verify the performance of the model which is proposed in this paper. The dataset of Tennessee Eastman (TE) process is applied to the SAE-based fault diagnosis model. The results are compared to some other FDD methods.

4.1. TE process

TE process is a simulation based on the actual chemical industry process, which was proposed by Downs & Vogel (1993). TE process includes 12 manipulated variables and 41 measured variables. Since the 12th manipulated variable is a constant, the diagnosis model involves a total of 52 variables. There are 20 faults in TE process.

All simulation data come from http://web.mit.edu/braatzgroup/links.html. There are 2 sets in this data set. Each set contains 21 sets of data, which are normal state data and 21 types of fault state data. The first dataset was first simulated in the normal state for 1

hour, and simulation was continued for 24 hours after adding the disturbance. The second dataset was first simulated in the normal state for 8 hours, and simulation was continued for 40 hours after the disturbance was added. The sampling period for both sets of data is 3 minutes, so the dataset includes 30,260 samples.

4.2. Diagnosis results and comparison

We conducted comparative experiments by setting different hyperparameters. A multivariate hyperparameter set was obtained through experiments. The SAE model includes 6 layers of neurons, and the number of neurons in each layer is 52, 100, 50, 50, 100, 21. The number of pre-trainings is 200, the size of each batch in pre-training stage and fine-tuning stage is 89, the learning rate is 1, and the regularization parameter is 0.0000005.

The performance of the model is usually evaluated by the fault diagnosis rate (FDR). p_i is the count of type i samples that are classified to type i.

$$FDR_i = \frac{p_i}{total\ count\ of\ type\ i\ samples} \tag{6}$$

The comparison of diagnosis performance with several statistical methods and traditional pattern recognition methods is shown in Table 1.

Table 1 Diagnosis performance comparison of different methods. (a) based partitioning PCA (Wang et al., 2016); (b) based dynamic ICA (Hsu et al., 2010); (c) based designing a hierarchical neural network (Eslamloueyan, 2011); (d) based support vector machines(Yélamos et al., 2009); (e) based SAE (proposed in this paper).

FDR (%)	(a)	(b)	(c)	(d)	(e)
Fault01	99.8	100.0	97.0	95.0	98.2
Fault02	98.8	99.0	98.0	100.0	99.6

Fault17	96.3	90.0	72.0	68.0	92.4
Fault18	91.3	90.0	94.0	82.0	90.0
Fault19	39.4	81.0	52.0	16.0	86.3
Fault20	54.0	88.0	67.0	100.0	86.4
Average	74.6	78.1	67.8	56.4	86.5

5. Conclusions and prospects

With the widespread use of automation technology in chemical processes, it has become increasingly convenient for researchers to access historical data. Many new data-based methods have been applied to the study of chemical process fault diagnosis. In the increasingly complex chemical process, SAE has strong feature extraction and generalization capabilities. This paper proposes a SAE-based chemical process fault diagnosis model, and uses the data generated by the TE process for model construction and training, the average fault diagnosis rate reaches 86.5%. Compared to traditional shallow neural networks, deep learning requires a larger training sample to present its advantages. Therefore, our next work is to simulate the TE process to get more data. Then, the key variables are divided according to the relevance of the variables.

Simulation-based reinforcement learning for delivery fleet optimisation in CO_2 fertilisation networks to enhance food production systems

Rajesh Govindan, Tareq Al-Ansari[*]

Division of Sustainable Devlopment, College of Science and Engineering, Hamad Bin Khalifa University, Qatar Foundation, Doha, Qatar

*talansari@hbku.edu.qa

Abstract

As part of the drive for global food security, all nations will need to intensify food production, including those situated in hyper arid climates. The State of Qatar is one such example of a national system that whilst it is presented with environmental challenges, seeks to enhance food security. There is a consensus that CO_2 fertilisation of agricultural systems has the potential to enhance their productivity. In this paper, the authors present a novel study that involves the development of a simulation model of a GIS-based CO_2 fertilisation network comprising of power plants equipped with CO_2 capture systems, transportation network, including pipeline and roadways, and agricultural sinks, such as greenhouses. The simulation model is used to specifically train the CO_2 distribution agent in order to optimise the logistical performance objectives of the network, namely delivery fulfilment and network utilisation rates. The Pareto non-dominating solutions correspond to an optimal CO_2 delivery fleet size of around 1-2 trucks for an average year in the simulation example considered.

Keywords: CO_2 fertilisation, Simulation, Logistics, Reinforcement Learning

1. Introduction

With the changing climate and growing population, there exists a global drive towards the intensification of food production. Those countries particularly situated in hyper arid regions that seek to boost their agricultural productivity are faced with the challenges pertaining to the sustainable usage of their land, energy and water resources. As such, the importance of understanding the relationship between food security and the natural environment is recognised, as agricultural productivity essentially depends on the condition of the latter. This introduces the notion of 'sustainable intensification', which is related to the need to meet the nutritional demands of a growing population without furthering the depletion of resources and degradation of the environment (Godfray and Garnett, 2014). To this effect, there has been much discussion on the effect of elevated levels of CO_2 in the atmosphere on agricultural productivity. The consensus is that it is possible to obtain higher crop yields because CO_2 is an essential compound in the photosynthesis process where its carbon content is utilised to form carbohydrates. Furthermore, increasing the concentrations of CO_2 inhibits the loss of water, also known as transpiration, due to increased resistance from leaf stomata. The natural fertilisation of crops using CO_2 offsets the effects of increasing temperature and decreasing soil moisture (Lawlor and Mitchell, 1991). Moreover, CO_2 fertilisation of plants not only

results in increases in dry matter production but is also accompanied by improvements of water utilisation efficiency (WUE) (Kimball and Idso, 1983).

Previously, the authors developed a GIS-based EWF nexus model to explore the potential of enhancing agricultural productivity through CO_2 fertilisation at the farm level (Al-Ansari *et al*., 2018). It was noted that, the approach is promising from an environmental perspective, as the emission reduction that can be potentially achieved by the CO_2 fertilization network is between 0.5 - 1 Mt/year considering the integration of capture technology for both CCGT and BIGCC, with the potential benefit of saving precious water resource at the agricultural fields. However, the overall viability must also depend on the economic feasibility of the transport network. As such, there is a requirement of using a combination of pipelines and roadways (using trucks) for the transportation of CO_2 from the source to the sink. It is likely that a dedicated CO_2 fertilisation network for enhancing agricultural productivity could either remain underutilised or sometimes unable to meet the demands of new greenhouses that are expected to be built, and hence, extended studies are necessary to address such logistical issues. Furthermore, increasing utilisation reduces the amount of net traffic (in vehicle kilometres) needed to transport a given quantity of freight (in tonne-kilometres), which in turn corresponds to decreased energy consumption and reduced CO_2 emissions from transportation itself (McKinnon, 2010).

The objective of the research presented in this paper is to develop a network simulation model comprising of spatially-distributed and autonomous learning agents representing sub-systems participating in a national-scale CO_2 supply chain logistics problem. For the purposes of illustration in this study, the business logic to enable agent simulation representing CO_2 distribution centres and greenhouses, was implemented. The authors posed the logistics problem as non-linear and multi-objective optimisation model using Markov Decision Processes (MDP) framework. This allows to determine the optimal solution representing the size and routing behaviour of a fleet of delivery trucks that transport CO_2 from the distribution centres in order to simultaneously fulfil the demand at various greenhouse locations (dependent on seasonal weather conditions) and improve the network utilisation rate.

2. Available data and assumptions

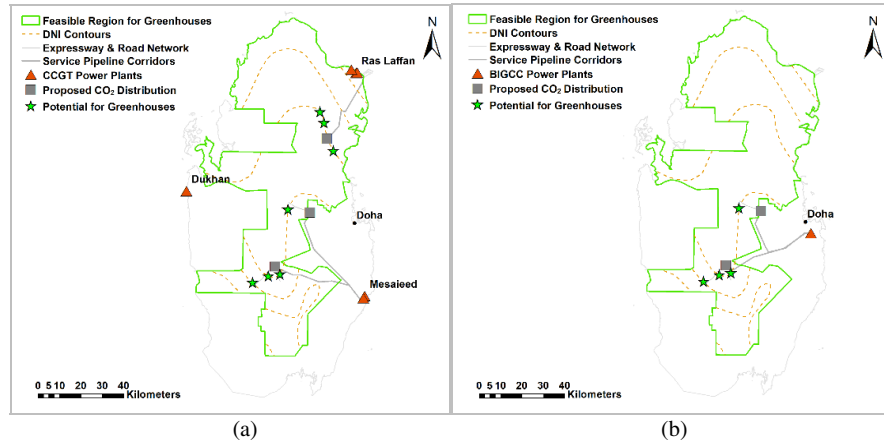
The information was derived from multimodal datasets for Qatar, each of which provides spatial information for: (a) distribution of land use for farming activities; (b) distribution of solar irradiance; (c) the locations of the major sources of CO_2 emissions; and (d) possible modes of CO_2 transport, namely pipelines and road transport. A meta-heuristic formalism was previously introduced by the authors which helped in determining the promising locations for new greenhouse developments as illustrated in Fig 1 (Al-Ansari *et al*., 2018). This served as the basis for setting up the CO_2 fertilisation network simulation model in the current study. It should, however, be noted that the locations of CO_2 distribution centres were assumed to be at the intersections of pipelines and roadways for simplification purposes and are not necessarily optimised.


Fig 1. Optimised locations of greenhouses in the State of Qatar for the case of CO_2 captured from: (a) CCGT plants; and (b) BIGCC plants (After Al-Ansari *et al*. (2018)).

3. Methodology

3.1. CO₂ fertilisation network simulation

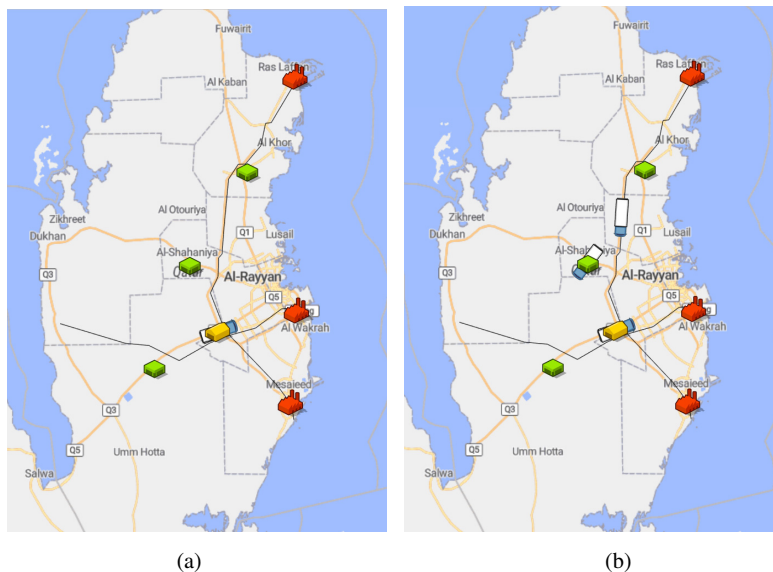
The network simulation model was setup using the Java-based AnyLogic® platform. The necessary spatial information was used in order to accurately capture the road networks in Qatar, which is used by the fleet in the model to transport CO_2 between the distribution centre and greenhouses, as illustrated in Fig 2.


Fig 2. Spatial simulation of the CO_2 fertilisation network indicating power plants; CO_2 distribution centre; and greenhouses for: (a) initial state of the fleet; (b) moving state of the fleet during simulation.

The simulation period corresponds to one year capturing the essential variability in the average seasonal temperatures, *i.e.* minimum, maximum and mean temperatures, at different locations in Qatar. The business logic for the agents representing greenhouses was implemented using the modified form of Hargreaves original equation for evapotranspiration (ET), which uses local weather data, such as the temperatures and solar irradiance distribution data, given by (Hargreaves and Samani, 1985):

$$ET = k \times 2.3 \times 10^{-4} \times (T_{max} - T_{min})^{0.5} \times (T_{avg} + 17.8) \times R_a \qquad (1)$$

Where, k is a factor which varies from 0.79 – 1.02. Increasing ET values (in mm) is an indicator of increasing CO_2 demand, and thus a maximum allowable water loss was assumed as the trigger condition for greenhouses to place an 'order' for more CO_2 from the distribution centre. Currently, this amount of CO_2 is assumed to be fixed, and the stock is fully utilised before a new order can be placed; no monetary transaction is associated with the placement of an order.

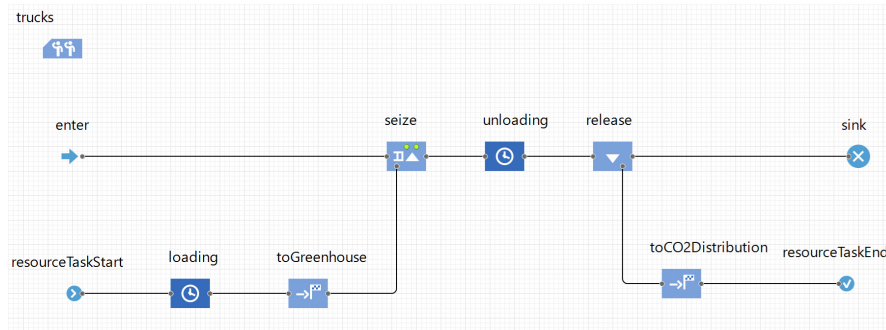
Meanwhile, at the distribution centre, the business logic for fleet management is illustrated by the process diagram in Fig 3. The 'seizing' of a truck from the fleet resource pool occurs whenever a demand trigger (order) is received. On the other hand, the 'loading' and 'unloading' times are assumed to be stochastic.


Fig 3. The process model setup in AnyLogic® representing the business logic for fleet resource pool management at the CO_2 distribution centre.

3.2. Fleet optimisation using Reinforcement Learning

The classical formalism of Markov Decision Process (MDP) was implemented to aid the learning feature in the agent representing the CO_2 distribution centre. More specifically, a temporal difference learning approach called Q-learning was used to maximise the expected cumulative value of an action (a) taken under a given state (s) of the agent during the simulation period of one year. More formally, the network objectives, namely order fulfilment time and utilisation rate, are modelled as Bellman Eq 2 and 3 (Sutton and Barto, 1998) to give the optimal policy for all states and actions in Eq 4 (Sutton and Barto, 1998):

$$Q(S_t = s, A_t = a) = E\left[r + \gamma V(S_{t+1} = s') \mid S_t = s, A_t = a\right] \tag{2}$$

$$V(S_t = s) = E\left[r + \gamma V(S_{t+1} = s') \mid S_t = s\right] \tag{3}$$

$$Q_*(S_t = s, A_t = a) = \max\left\{Q_\pi(S_t = s, A_t = a)\right\}, \forall s \in S, a \in A \tag{4}$$

Where 'r' is the immediate reward signal for an action 'a' in state 's'; γ is the discount factor whose value lies between 0 (short-term minded or greedy agent) and 1 (long-term minded agent), which indicates the importance the optimisation gives towards future rewards. Finally, the update of the action value function (Q) from a given time step to the next is given by (Sutton and Barto, 1998):

$$Q(S_{t+1} = s, A_{t+1} = a) \leftarrow Q(S_t = s, A_t = a) + \ldots$$
$$\alpha\left[r + \gamma \max_{a'}\left\{Q(S_{t+1} = s', A_{t+1} = a')\right\} - Q(S_t = s, A_t = a)\right] \tag{5}$$

4. Results and discussion

One of the performance metrics used by the agent (and receiving the corresponding reward signal) is the time it takes for the distribution centre to fulfil an order depends on both the speed of the truck (assumed constant) and the route it takes (assumed initially stochastic). The other performance metric used by the agent is the fleet utilisation rate. Q-learning was performed with respect to these performance metrics over the simulation period of one year.

The results obtained from the multi-objective optimisation using the Q-learning approach listed in Table 1 demonstrates that there exist Pareto non-dominating solutions for the optimal fleet size for the CO_2 distribution centre. It is therefore expected that the optimal fleet size is around 1-2 trucks for the simulation example considered. However, it is important to note that the study carried out thus far is a small network for the purposes of illustrating the technique, and does not consider the entire CO_2 fertilisation network, such as the power stations (see Fig 2).

Table 1. Objective function values using the Q-learning approach for various fleet sizes.

Size of the fleet	Order fulfilment time of the network (orders per day)	Utilisation rate in the network (%)
1	2.1	65
2	2.34	36
3	2.33	23
4	2.47	19
5	2.39	15

5. Conclusions

The study discussed in this paper provides an illustrative example of how simulation-based optimisation can aid in making large-scale logistical decisions for network-based applications having economic implications. With the recent advent of artificial intelligence, non-linear, multi-objective and sequential decision-making techniques such as reinforcement learning is useful in solving hard problems whose objective functions do not have closed form analytical representations, such as the CO_2 fertilisation network for the enhancement of agricultural productivity.

It is envisaged that the results obtained have important implications for planning the expansion of greenhouse networks, particularly for the State of Qatar, where self-sustenance and food security has become a priority. In this regard, it has been considered that both the environmental and economic dimensions are equally important. As such, the utilisation of waste streams such as CO_2 emissions for growing crops not only provides for food security, but also enhances the efficiencies of energy and water utilisation as highlighted in the research carried out by the authors.

With regards to the limitations of the current work, only a single agent has been considered thus far and hence there is scope to extend the work to develop multiple learning agents in large-scale network optimisation. The business logic considered are also likely to be simplified for the current illustration, and hence the simulator requires incorporating agent functions for real world scenarios, *e.g.* in multi-echelon supply chains where dynamic distribution of resources, inventory and supply risk management and long-term supply chain planning and development are some of the core problems to be generally solved.

Abstract

Dry reforming of methane is an innovative alternative method for the production of hydrogen that uses CO_2 for the reforming process, thus lowering the carbon emissions of the plant. With the rise of renewable energy sources (solar, wind), the difference between the power supply and demand within the grid increased heavily, making flexibility of power plants more important for costs and emissions reduction. This paper presents the exergoeconomic analysis performed on the dry reforming technology designed for flexible power and hydrogen co-generation with carbon capture. The examined power plants' output is 450 MW net power with the possibility of hydrogen production of 200 MW_{th} (based on lower heating value). The CO_2 capture rate is 90 % (a part being used in the reforming process). The energy efficiency of the plant is 50 %, the exergy destruction rate is 370 MW and the specific capital cost of the plant is 1,295 M€/MW. The goal of this work is to offer an alternative to conventional steam reforming, improve the process of dry reforming by finding and improving the components of the system that contribute the most to the destruction of exergy and present a new flexible power plant that can produce both power and hydrogen. The evaluated design concepts were simulated using process flow modeling software and the mass & energy balances were used for the exergoeconomic analysis to improve the overall performance of the plant.

Keywords: dry methane reforming, flexible power plant, exergy analysis, exergoeconomic analysis,

1. Introduction

As atmospheric CO_2 concentrations are on the rise, a shift can be expected in global energy sources from conventional power sources to renewable ones, like solar and wind. This transition generates a stress on the electric grid as renewable energy sources power output depend heavily on the weather. The flexibility of a power system describes the ability of the system to balance out predictable and unpredictable changes on the supply or on the demand side. Cruz et al., (2018a) presents an extensive review on this issue and discusses potential options to ease the integration of renewable sources. Alemany et al., (2018) proposes the storing of electric energy during high production intervals. Several storing possibilities were proposed in the literature, the use of chemicals being heavily discussed (Chiuta et al., 2016).

With the rise of carbon capture technologies, the amount of available CO_2 is expected to increase in the future and as storage can be geographically limiting, the use of captured

CO_2 can be an alternative. Dry methane reforming uses CO_2 for the reforming of methane in the process of obtaining syngas. Several studies have been published in the past year on the subject (Salkuyeh et al., 2017). Aramouni et al. (2018) did a comprehensive review on catalysts and identified carbon deposition as the major issue in deploying the technology. As the carbon ratio is high in the reactor, carbon deposition on the catalyst is a barrier that needs solving. Developing new highly active catalysts is one of the approaches in resolving this issue.

In the current global context, as energy consumption is constantly on the rise while carbon mitigation is becoming more important a stalemate situation will be reached. In order to comply with the strict emissions reductions, set either large-scale carbon capture deployment is needed or a shift will be necessary towards energy carriers with a lower carbon footprint. Hydrogen is one promising alternative to fossil fuels, however this is conditioned to an adequate supply-chain. Hydrogen is obtained from natural gas reforming (48 %), petroleum refining (30 %) and coal gasification (18 %) (Cruz et al., 2018b). In order for hydrogen to be a viable option, either these technologies have to be redesigned with lower CO_2 emissions or a new, carbon-free way has to be implemented for its production. One option is water hydrolysis, however this technology is too expensive. Flexible power plants with carbon capture producing hydrogen can be an alternative to supply the necessary hydrogen.

This paper investigates the thermodynamic performance of dry methane reforming for the co-production of power and hydrogen through exergy analysis and offers a glance into the economics of the process. The plant is divided into four subunits, gas reforming, syngas processing, CO_2 capture and purification and the power island. A model of the plant is implemented in Aspen Plus process simulator to obtain the mass and energy balance of the process. Each division is evaluated separately in the analysis to better understand and identify the least efficient units.

2. Evaluation methodology

The plant was designed based on the general structure of a steam-methane reforming system, as presented in Figure 1. The gas reforming unit consists mainly of the reforming reactor, the syngas processing unit contains the water-gas shift reactors and the steam generator. The carbon capture unit is a gas-liquid absorption system using MDEA solution. Part of the captured CO_2 is recycled to the reforming unit, while the rest is sent to a storage site. The power island is designed using a Mitsubishi Hitachi Power Systems M701G2 series gas turbine combined cycle with the following specifications: 334 MW net power output, 39.5 % net power efficiency. The heat and energy balances from the process flow simulator are at the basis of the economic calculations of the plant.

Figure 1. Simplified process flow diagram

The reactions describing the process of dry reforming are presented in Table 1. The reforming reaction is highly endothermic; hence 153 MW_{th} energy is necessary for the reforming reactor (this is provided by the burning of additional natural gas). The reverse-WGS reaction has a great impact on the final equilibrium and being endothermic, it is highly favored. Coke formation, the major issue in the case of dry reforming can be described by the last four reactions in the table, one of them being highly favored also because of its endothermic nature. In the process simulator, equilibrium reactors were considered, as equilibrium conditions can be easily achieved in these conditions.

Table 1. Governing reaction for dry reforming of methane

Reaction number	Name	Equation	ΔH_{298K} (kJ*mol^{-1})
Main reaction			
1	Dry methane reforming	$CH_4 + CO_2 \leftrightarrow 2CO + 2H_2$	+ 247
Side reaction			
2	Reverse water-gas-shift	$CO_2 + H_2 \leftrightarrow CO + H_2O$	+ 41.0
Coke formation			
3	Decomposition of methane	$CH_4 \leftrightarrow C + 2H_2$	+ 74.9
4	Disproportionation of CO	$2CO \leftrightarrow C + CO_2$	- 172.4
5	Hydrogenation of CO_2	$CO_2 + 2H_2 \leftrightarrow C + 2H_2O$	- 90.0
6	Hydrogenation of CO	$H_2 + CO \leftrightarrow H_2O + C$	- 131.3

Exergy analysis is a powerful tool for energy analysis of a system. By its definition, exergy is the maximum theoretical useful work obtained if a system S is brought into thermodynamic equilibrium with the environment by means of processes in which the S interacts only with this environment (Cruz et al., 2018b). In contrast to mass and energy laws, exergy is destroyed in a system due to irreversibility. A system is in equilibrium with its surroundings when there is no difference in temperature, pressure or chemical composition. In the present work, thermodynamic and chemical exergy was calculated with respect to the reference conditions (Table 2).

Table 2. Reference environment for exergy calculations

Thermo-mechanical exergy		Chemical exergy	
Parameter	Value	Component	Molar fraction
Temperature	18°C	N_2	0.7651
Pressure	1 atm	O_2	0.2062
		H_2O	0.0190
		Ar	0.0094
		CO_2	0.0003

The temperature and pressure data were used for the calculation of the thermodynamic exergy and the chemical composition for the chemical exergy. In both cases, atmospheric parameters were considered as a reference. For the calculation of the exergy flow and the exergy efficiency in the system, equations (1) and (2) were used.

Parameters were obtained from the exergy balance of the system. Simulation was performed using Aspen Plus process simulator.

$$E_f = E_p + E_d + E_l \tag{1}$$

$$\varepsilon = E_p / E_f \tag{1}$$

E_f - exergy flow; E_p - exergy of product; E_d - exergy destruction; E_l - exergy lost

The estimation of the capital costs for each unit were performed using capital cost correlations found in the literature (Cormos et al., 2017) based on the simulation results. On-site utility costs, owners' cost and land purchasing costs were estimated as 20 %, 15 % and 5 % of the total installed cost of the plant. Specific capital requirements were also calculated to ease comparison between technologies.

3. Results and discussion

Table 3. Exergy analysis results

	Exergy flow in (MW)	Exergy flow out (MW)	Exergy destruction (MW)	Exergy efficiency
Gas reforming unit	933.88	888.70	63.32	91.37 %
Syngas processing	888.70	863.20	33.47	93.72 %
CO_2 separation and purification	863.20	819.75	12.34	95.70 %
Power island	819.75	476.30	260.04	57.99 %

69 t/h of natural gas is required (900 MW_{th}) for the plant. The reforming, the water gas shift and the CO_2 capturing unit, all operate at 32 bar, whereas the gas turbine inlet pressure is at 19 bar. An expander is introduced to facilitate this pressure drop. The recovered energy is 2.3 MW. Combined with the gas turbine and the steam turbine the gross electric output is 476 MW_e. The ancillary energy for the system totals to 26 MW_e. This equals a net power output of 450 MW_e with a net electric efficiency of 50 %.
Figure 2. Exergy flow diagram for the process

The stream leaving the carbon capture unit is rich in hydrogen. With the addition of a pressure swing adsorption unit, the plant can produce high purity H_2 during low power demand offering a higher degree of flexibility to the system.

The results of the exergy analysis are presented in Figure 2 and Table 3. 934 MW exergy is introduced into the system with the natural gas stream. In the gas reforming unit with the compression of CO_2 another 38 MW of exergy is added. As a significant amount of heat is required for the endothermic reforming reaction, more than 60 MW of exergy is destroyed; the rest is fed into the Syngas processing unit (20 MW of exergy is transferred from the gas reforming unit to the syngas processing unit in the flue gasses stream leaving the heater). The syngas processing unit is significantly more efficient with an exergy efficiency of 93 %. The carbon capture unit is the most efficient, that is in part because 60 % of the captured CO_2 is recycled to the reforming unit. As expected, most of the exergy is destroyed in the power island; this is the subsystem with the highest grade of irreversibility, because of combustion. Energy and exergy analysis show similar results, the exergy analysis resulting lower efficiencies for the plant.

16% 17% 5% 45% 17%

= Gas Reforming Unit

⌁ SynGas Processing Unit

⌗ CO2 Separation and Purification

⬊ Power Island

⬈ Utilities and Offsite Units
Figure 3. Share of each subsystem in the total capital cost

Figure 3 presents the obtained costs share in the total capital cost requirement for each subsystem. The most expensive unit, the power islands' cost was estimated at 219 M€, the gas reforming unit at 83 M€, the CO_2 separation and purification unit at 80 M€. The syngas processing unit had the lowest cost, this was estimated at 24 M€. To obtain the total installed cost of the plant, utilities and offsite units capital costs were also added, these were estimated as 20 % of each units' cost resulting in 80 M€. The obtained costs for the proposed power plant are higher than in the case of a NGCC plant without carbon capture, however its comparable to the costs of a NGCC power plant with post-combustion capture.

Table 4. Capital cost data for the plant

Total Installed Cost	MM Euros	486.18
Total Investment Cost	MM Euros	583.41
Gross Power production	MWe	476.30
Net Power Production	MWe	450.30
Total Investment Cost per kWe (gross)	MM Euro / MWe	1,224.88
Total Invest ment Cost per kWe (equiv.)	MM Euro / MWe	1,295.60

Both exergy and economic analyses point to the power island as the unit that's improvement can have the highest positive impact on the plant. Exergy analysis shows, that the burning and boiling processes are responsible for this, however these are intrinsically low efficiency units. This calls for improvements to be made in other parts of the plant.

4. Conclusions

This paper presents the dry methane reforming technology as an alternative reforming process incorporated into a power plant for flexible operation. During low electricity demand, this can produce hydrogen for better efficiency. The system underwent a rigorous exergy analysis to better understand and to locate the least efficient units. Overall efficiencies for the two reforming systems are comparable, meaning dry reforming is a viable alternative for steam reforming if the issue of carbon deposition is addressed. The analysis also presented the effect of individual unit on the overall efficiency of the system simplifying the process of improvement. The highest grade of irreversibility was observed in the case of the power generation and reforming unit. Exergy analysis shows that most of the exergy is destroyed in the burner and in the boiler. The paper also presents an insight into the economics of the proposed flexible power plant, the power generation unit having the highest cost, the gas reforming and the CO_2 capturing unit having similar costs and the syngas processing unit having the lowest cost.

Structured millichannel multiphase reactors

J. Ruud van Ommen[*], John Nijenhuis, Johan T. Padding

Delft University of Technology, TU Delft Process Technology Institute & e-Refinery, Delft, the Netherlands

j.r.vanOmmen@tudelft.nl

Abstract

This paper examines the use of millichannels in designing multiphase reactors. We give a general analysis based on dimensionless numbers, followed by an illustration of this approach to catalytic packed-bed reactors. Finally, we discuss how such reactors can play an important role of increasing the number of electrocatalytic processes in the chemical industry. The increased degrees of freedom gives these reactors clear advantages over thermocatalytic non-structured reactors, as well as over electrocatalytic processes.

Keywords: electrocatalysis, fixed beds, degrees of freedom, reactor engineering

1. Introduction

The classical approach of randomly organized catalyst beds (either fixed or fluidized) is often outperformed by carefully designed channels or structures in which the reactions take place (Gascon et al., 2015). In recent years, microreactors have received enormous attention in academic research because they offer excellent mass and heat transfer performance, and provide a powerful tool for process intensification (Yao et al., 2015). However, their sub-mm channel diameters typically imply laminar flow, which is for many applications not optimal. Other drawbacks are high pressure drop and tendency to fouling. Moreover, a huge number of parallel channels or devices is needed to reach reasonable production volumes. Millireactors – reactors with structures and features in the mm range rather than the sub-mm range – have the potential to combine the best of both worlds: imposing a structure that enhances heat and mass transfer, while their somewhat larger feature size reduces capital and operating costs.

In this study, we explore the benefits and limitations of applying millichannel-based systems for multiphase reactions. We give a brief literature overview, and present a few cases. The interaction between reactor and catalyst will be discussed, as well as the interplay between chemistry and flow behavior. For example, we will show how filling millichannels with small particles leads to partially structured fixed beds, with attractive performance concerning mass transfer, heat transfer, and pressure drop. We will also discuss how millichannel reactors can contribute to the transition to electrochemical processes, in which the presence of sufficient electrode surface together with the ability to removed produced gases will be key. We conclude that millireactors can provide an attractive option for a range of applications in the chemical and pharmaceutical industry, giving a good compromise between physiochemical performance and cost-effectiveness.

2. Advantages of millistructured reactors

The reason why millistructured reactors offer advantages over microstructured reactors can be appreciated by estimating magnitudes of key dimensionless numbers for two

Table 1. Important dimensionless numbers for flow reactors. We use the hydraulic diameter d_h as characteristic length scale. For channels filled with particles, replace d_h by d_p.

Dimensionless number
$Re = \rho U d_h / \mu$
$Nu = \alpha d_h / \lambda = Nu(Re, Pr)$
$Sh = h d_h / D = Sh(Re, Sc)$
$Pr = c_p \mu / \lambda$
$Sc = \mu / (\rho D)$

archetypical systems: (1) An empty flow reactor of hydraulic diameter d_h and length L. (2) A flow reactor of the same dimensions, but filled with catalytic particles of diameter d_p, leading to an average porosity ε. We will consider flow of two types of fluids through these reactors, one gas-like and one liquid-like, for which we will use the physical properties of air and water at 20 ^{0}C temperature and 1 atm pressure.

A significant enhancement of mixing by convective flow is commonly experienced for sufficiently high Reynolds number Re (dimensionless numbers are defined in Table 1). Similarly, convective flows enhance the heat transfer coefficient h. A significant enhancement of heat transfer is possible for Re > 100. Similar conclusions may be drawn for mass transfer, with the roles of Nu and Pr replaced by the Sherwood and Schmidt numbers Sh and Sc (Hayhurst, 2000).

The differential pressure drop necessary to reach significant convective improvement of mixing and heat and mass transfer becomes prohibitive for small channels. For example, for an empty structured channel of hydraulic diameter d_h, the pressure drop associated with wall friction can be described by the Darcy-Weisbach equation (Romeo et al., 2002):

$$\frac{\Delta p}{L} = f \frac{\rho}{2} \frac{U^2}{d_h} \qquad (1)$$

where f is the dimensionless friction factor. For a smooth straight channel and Re < 10^3, $f = 64/Re$. For other channels and higher Re, f is larger and depends on the roughness characteristics of the channel. Fig. 1 shows $\Delta p/L$ as a function of d_h for liquid-like (black solid line) and gas-like (black dashed line) fluids at Re = 100, assuming $f = 64/Re$. At this *fixed* Re, U decreases like $1/d_h$, leading to $1/d_h^3$ scaling of the required pressure drop: for $d_h = 0.1$ mm, the pressure drop to reach Re=100 is already substantial, approximately 10 bar/m, while for $d_h = 1$ mm the necessary pressure drop is a more manageable: 0.01 bar/m.

For a channel filled with catalytic particles of diameter d_p, the differential pressure drop can be described by the Ergun equation (Ergun, 1952):

$$\frac{\Delta p}{L} = 150 \frac{(1 - \varepsilon)^2}{\varepsilon^3} \frac{\mu U}{d_p^2} + 1.75 \frac{1 - \varepsilon}{\varepsilon^3} \frac{\rho U^2}{d_p} \qquad (2)$$

The first part is dominant in the laminar regime Re < 1, the second part in the turbulent regime Re > 10^3. Figure 1 shows $\Delta p/L$ as a function of d_p for liquid-like (red solid line) and gas-like (red dashed line) fluids at Re = 100 and ε=0.5. At *fixed* Re, *both* laminar and turbulent terms scale like $1/d_p^3$. Under these conditions, for $d_p = 0.1$ mm, the pressure drop necessary to reach Re=100 is enormous, approximately 1000 bar/m, while for $d_p = 1$ mm, the necessary pressure drop is much more reasonable, approximately 1 bar/m.
Figure 1. Pressure drop necessary to reach Re=100 as a function of hydraulic or particle diameter. Red: packed bed (ε = 0.5), black: empty channel. Solid lines: liquid-like fluid, dashed lines: gas-like fluid. Blue: microchannel regime, yellow: millichannel regime.

Pressure drop is not the only important consideration. Smaller reactors are also more prone to contaminants and agglomerates getting stuck in corners of the channel or pore space. Moreover, it is important to tune the residence time in the channel to optimize reaction yield or selectivity. The average residence time is $\tau = \varepsilon L/U$. At fixed Re, this leads to $\tau/L = \rho d_h/(\mu Re)$ or $\tau/L = \rho \varepsilon d_p/(\mu Re)$, for the two respective systems. In the regime where inertial flow enhancement becomes relevant (Re>100), reaching sufficiently *long* residence times requires sufficiently wide channels or sufficiently large particles.

3. Filling channels with particles

Although we have highlighted a number of clear advantages in the previous paragraph, a concern with applying structured reactors for catalytic applications is often that the catalyst holdup (i.e., the volumetric fraction of catalyst) is typically much lower than in randomly packed beds (Vervloet et al., 2013). Even if one takes into account that the catalyst effectiveness in packed beds is often below 1, still the productivity per reactor volume will be typically lower. A hybrid form of the two approaches can yield us the best of both worlds: using a system of structured channels, that are filled with particles (Calis et al., 2001, Dautzenberg and Angevine, 2004). The advantage of filling channels with particles that are of the same order of magnitude as the channel diameter is that the particle packing also becomes regular; see Fig. 2. In this way, we obtain a porosity that is importantly lower than the one for a randomly packed bed, which is 0.36 (Torquato et al., 2000). This has the advantage of a much lower pressure drop at a given particle size and fluid velocity. Alternatively, one can use higher fluid velocities and/or smaller particles to increase catalyst effectiveness and productivity of the system.
Figure 2. Packings obtained by filling small channels with particles. The aspect ratio (*N*) and porosity (ε) are given. Please note that for certain values of *N*, such as 2.05, multiple arrangements are possible (From: (Romkes et al., 2003), © Elsevier).

When the ratio of tube diameter over particle diameter becomes around 3 or larger, then the chance of getting a regular packing like in Fig. 1 strongly reduces (Calis et al., 2001). However, even in this case that are still advantages compared to regular packed beds with N typically about 104. At the wall of a packed bed, the porosity is higher than in the centre of a bed. For a channel with N around 10, the wall region covers a large part of the bed, leading to an overall porosity that is importantly lower than 0.36. Again, this has the advantage of lower pressure drop.

Vervloet et al. (2013) showed that for channels with a triangular cross-section of 7.7 mm, filled with particles of 2 mm (N=3.8), no regular packing was obtained. Still, the porosity was 0.50 (as opposed to 0.38 which was experimentally obtained for a randomly packed bed in the same study). Moreover, the heat transfer coefficient for transfer from fluid to wall (especially important for strongly exothermal reactions) was double that of a packed bed, and comparable to that of structured packings with empty channels. This shows that filling structures with particles can lead to large advantages in terms of pressure drop and heat transfer, and by analogy also mass transfer. An additional practical advantage is that one can still use the same catalyst particles as in conventional packed beds, i.e., no novel catalyst preparation procedure is required. particles.

4. Use in electrochemical processes

There is a broad consensus that the chemical industry will have to make a transition to renewable feedstocks. An important route will be to use electrochemical processes, driven by electricity from sustainable sources, to produce hydrogen from water, hydrocarbons from CO_2 and water, and ammonia from nitrogen and water. This will require novel reactor designs, with special attention to the structured design of electrodes. Although there is progress in electrochemical flow reactors, scalable macro- and micro-reaction environments need to be developed involving e.g. gas-liquid electrolyte flow (Walsh and Ponce de León, 2018).

In gas producing electrochemical cells a gas-liquid mixture is produced which impacts on energy consumption in terms of increased Ohmic resistance in the electrolyte. This is largely due to bubbles which hinder the mass transport of ionic species or block the electrode surface, and thereby reduce the e ective electrode reaction sites i.e. by sticking to the electrode and/or forming a bubble curtain (Scott, 2018).

Traditionally, parallel plate structures are used in a wide range of electrochemical synthesis applications, where gas diffusion electrodes (GDEs) and Membrane Electrode Assemblies (MEAs) are used to reduce mass transfer limitations (Merino-Garcia et al.,

2016). Gas evolution and bubble formation at electrodes plus the coalescence of these bubbles leads to the formation of a heterogeneous electrolyte system with low conductivity, higher resistance and higher cell voltage, with corresponding electrical energy losses. The temporary or permanent occupancy of the electrode surface or the electrolyte volume by gas bubbles leads to a reduced performance (Ziogas et al., 2009). Bubble disengagement is therefore key.

In electrochemical rotating cylinder reactors, a high flow rate is induced such that the electrochemical process is enhanced by convective transport. In order to obtain the mass and charge transfer from the solution to the surface of the electrodes, an optimum flow field is essential (Tomasoni et al., 2007). Nonetheless, enhancement in mass transfer to a rotating cylinder electrode depends to a large extent upon micro turbulence at the electrode surface and is at the expense of high shear losses (Scott, 2018). Other forms of flow or turbulence promotors are also used to improve gas bubble disengagement. In general, it is observed that Ohmic voltage losses and overpotentials can only be reduced to a limited extent due to practical limitations of e.g. a higher pressure drop. Gas evolution reactions occur in the three-phase (gas–liquid–solid) interface formed at the electrode when a potential is applied with a magnitude greater than the equilibrium potential. The nucleation, growth and detachment of bubbles are affected by surface tensions of gas–liquid, gas–solid and liquid–solid (Scott, 2018).

The use of fluid flow to promote greater electrochemical reaction rates by increased mass transfer to surfaces is well known and commonly practiced in flow electrolysers. However, the approach has limited success since the scalability of these microflow systems is an issue, and has not led to a compact scalable cell design, as in flat plate electrode stacks. Since bubbles are transported more easily through millichannels than through microchannels, Taylor flow in millichannel electrochemical cells would be beneficial since; a) the bubbles naturally drive the flow, b) a still narrow channel inhibits coalescence of bubbles, c) it leads to more homogeneous behaviour of the electrolyte, and d) the flow induces transportation of products away from the reaction surface. Furthermore, millichannel Taylor flow systems could lead to better scalability and a compact cell design.

The electrodes in electrochemical reactors automatically introduce a certain degree of structuring; this can be combined with other functions of the structure. Moreover, introducing structure gives more degrees freedom, and thus the possibility to solve potentially conflicting design criteria.

5. Conclusions

Millichannels have clear advantages over traditional, non-structured reactors, both in thermocatalytic and electrocatalytic processes. Analysis based on dimensionless numbers shows that the use of millichannels has important advantages over microchannels. The potential drawback of too low catalyst holdup can be overcome by filling the channels with particles. Also in electrocatalytic processes millichannels reactors can play an important role: the walls can act as electrode, while the channel configuration prevents problems with gas bubbles encountered in other types of electrocatalytic reactors.

Abstract

This work presents a systematic computer-aided decision-support framework to tackle challenges faced when attempting to identify and develop resource recovery projects. The framework is hierarchical and has been developed to facilitate the industries' transition towards more sustainable production, providing users with the opportunity to evaluate and support decisions on not only a financial basis, but also from a comprehensive techno-economic and sustainability angle. To this end, the framework collects relevant aspects within the sustainability field and addresses concepts such as circular economy, waste management and 'legacy' compounds to name some of the more pertinent topics. The proposed methodology is generic and can be applied to a wide variety of potential resource recovery projects. The application of the framework is highlighted through two case studies, phosphorus recovery from a phosphate-based wastewater stream; and monosaccharide recovery from wheat straw liquor.

Keywords: Sustainability, Decision-support framework, Technology readiness level (TRL), Resource recovery, Circular Economy

1. Introduction

For over 200 years, the world economy has been built upon a linear economic model, leading for never before seen economic and societal transformation (Hayward et al., 2013). However, this human induced change has led to unprecedent global environmental degradation and rapid resource depletion, together with an unprecedented climate impact. The proposed countermeasure to this impending catastrophe is the circular economy model. In this model, resources are no longer extracted and discarded but instead products and revenues are generated from what in a linear economy would be considered waste. In this context, resource recovery, being the facilitating process to enhance attainable resource value and avoid resource deployment, perfectly fits the proposed paradigm shift. Today, the use of resource recovery is widely expressed in various industrial processes, including applications related to the dairy industry (Udugama et al., 2017) and biodiesel refining (Mansouri et al., 2019). In petrochemical operations, waste reintegration is also practiced widely (Mansouri et al., 2017). Consequently, resource recovery can be observed as a key missing element required to close an imperfect production cycle. Resource recovery project implementation enables companies to achieve several sustainable development

goals, such as responsible production and consumption, whilst improving their product portfolio and reducing dependency on external players in the supply chain.. Historically, little importance has been placed upon resource recovery, namely due to resource abundance, absence of reliable opportunity identification methods, and ease of waste treatment regulation compliance. In the domain of process systems engineering, this multi-dimensional and multi-scale problem has been an area of active interest with works on techno-economic sustainability analysis looking to address parts of these requirements (Gargalo et al., 2014, Gargalo et al., 2016, Hoseinzade et al., 2019). However, while these frameworks and methodologies can be adopted to perform a somewhat detailed analysis they do not consider the overall role of techno-economics and customer readiness feasibility in the pursuit of resource recovery technology deployment in an industrial context.

 Based on the above considerations, the authors have identified the need to develop a methodology to manage the multi-faceted and multi-disciplinary intricacies of deploying resource recovery concepts, with focus placed on employing separation technology for recovering resources. The proposed methodology not only explicitly takes into consideration the techno-economics aspects but also implications of technology development and customer readiness in implementing resource recovery projects as well as taking implicitly taking into account the environmental impact of recovering a resources in both early and late stage of the decision making process. The proposed a decision-support methodology is intended to employed in introducing the resource recovery paradigm within traditional organisations and provide them the necessary tools to transition to a circular economy.

2. Methodology

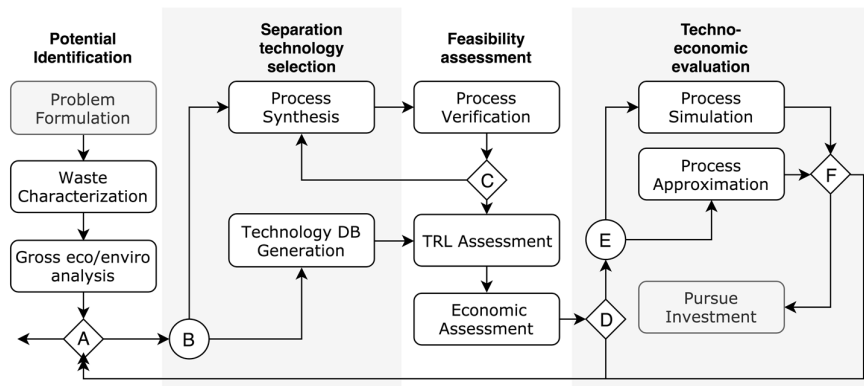
The framework is decomposed into five segments, each defined by a characteristic question. Figure 1. illustrates the overall work flow of the methodology.


Figure 1. Schematic representation of the workflow of the methodology. Grey framework steps indicate input/output.

2. 1 Step 1: Problem formulation. The first and most instrumental task of framework construction is the problem definition. It is here that the aim, objectives, and scope of the design problem are outlined mathematically. The objective function is formulated to fit the user's agenda, and demonstrates the desired outcome of the design problem. The subsequent algorithms are structured in a broad to narrow manner intended to thin the field of candidates that do not satisfy the objective function early on. This approach facilitates swift progression through the framework, especially in instances that manual input is required.

2.2 Step 2: Potential identification. The first screening phase, potential identification, preliminarily assesses whether resource recovery is relevant in the context of the stream studied and objective function set by the user. To account for all intentions, the gross sustainability potential is applied, providing a quantitative assessment of financial, environmental, and societal aspects. The information required in this section is easily attainable via the waste characterization algorithm, facilitating the rapid and efficient evaluation of many cases. The objective of this section is to identify valuable resources that can potentially justify the economic, environmental and societal aspects that are vital in implementing a resource recovery project and acts as a preliminary screening mechanism. Note: The gross sustainability potential in this step implicitly takes into account the overall environmental impact of recovering given resource, as such in a situation a pollutant or a "legacy" compound is captured, this will be reflected in the gross sustainability potential calculation. If a full circular economy model is desired, the potential identification step can be bypassed as all raw-materials are utilized irrespective of their value, generating no waste.

2.3 Step 3: Separation technology selection. In the next step of the framework, viable separation technologies for the recovery of the stream constituents are identified. Such technologies can then be sequenced to provide a physical feasible process synthesis for the recovery of the afore-determined target components. Separation task flowsheets should be furnished by process synthesis techniques where applicable, with the remainder subjected to technology database generation and manual pairing. A feedback loop is integrated with the feasibility assessment step to facilitate revisions of tasks that are not technically viable.

2.4 Step 4: Feasibility assessment. In the case of process synthesis, physically feasible flowsheets are automatically generated. This can be problematic as some tasks may be unsuitable or impractical, thus a feasibility assessment is carried out in the next step. This ensures that only technologically feasible flowsheets progress through the framework, each task is verified against openly available industrial implantations as well as academic literature where the concept of technology Readiness Level is applied. Preliminary financial viability is also assessed at this stage, by comparing the streams process revenue (Gross sustainability potential) to its estimated capital cost (Tsagkari et al., 2016). The payback period is then calculated and must surpass the user specified threshold to progress through the framework.

2.5 Step 5: Techno-economic evaluation. Now that basic technological and financial feasibility is proven, further granularity must be obtained to form a foundation for investment. If the user intends only on an order of magnitude estimate of the Net

Present Value, process approximation methods should also be applied to determine the associated operating costs. For more detailed assessments, process simulation is suggested. Once simulated, the model can be applied to determine recoveries, equipment costs, and operational expenses, ultimately resulting in improved NPV accuracy. If financially satisfactory, the framework is concluded with application of the WAR algorithm application to ensure environmental compliance. At this point the user should have a clear picture as to whether or not to pursue investment.

Note: the application of WAR algorithm as a part of this step implicitly takes into account the environmental impacts of a given resource recovery solution. The detailed economic analysis conducted will also account for the economic impact (marginal cost of abatement) which takes into account the environmental impact of reducing/eliminating a polluting compound.

3. Case studies

The application of the above framework is demonstrated through two case studies: phosphorus recovery from a phosphate-based wastewater stream; and monosaccharide recovery from wheat straw liquor. Besides the Biofuel and waste water treatment operations, the framework applicability is far reaching, providing potential in various other industries, such as petrochemicals and pharmaceuticals,

3.1 Monosaccharide recovery

In the case study the intention is to recover economically viable components from a wheat straw process stream (30,000 ton/yr), thereby improving economic potential and reducing waste, this was identified by applying step 1. Applying the potential identification, it was found that xylose ($241/m^3$) and arabinose ($236/m^3$) are the two most lucrative components in the waste stream. Applying step 2, a feasible process was synthesized for the case study where thermodynamic insights for process synthesis were used (Jaksland et al., 1995). The feasibility assessment step required five passes for an adequate flowsheet to be produced, as depicted in figure 2.
Figure 2. Output of step 2, final separation task flowsheet for monosaccharide extraction case study, generated by TaskGen software

Separation technologies were then paired to the successful separation tasks, resulting in a flowsheet consisting of detoxification via evaporation, glucose removal with nanofiltration, and monosaccharide purification with an ion exchange resin. Applying step 4 it was confirmed that the process sequence is a feasible one. In step 5, the recovery rates of the target components were then determined via process simulation, as seen in Table 1. Finally, the financial feasibility of the case was evaluated subject to uncertainty analysis, providing the results seen in Table 2.

Table 1: Results from process simulation in the techno-economic evaluation step

Target	Flow	Recovery
Xylose	16.36 kg/hr	56.5%
Arabinose	86.79 kg/hr	43.6%

Table 1: Results in million USD from the techno-economic evaluation step (10% DR).

Case	Present value	Capital cost	Development cost	Net Present value
Mono	39.1	-8.2	-11.0	19.6

Based on the results of the demonstration of the proposed methodology, the conventional bio-ethanol production process could be feasibly diversified with the recovery of supplemental products, prior to the fermentation process.

3.2 Phosphorus recovery

In this case, the framework was applied to a wastewater stream containing phosphate. Applying step 1, the problem is formulated as follows: "Given a pre-treated waste water stream of 14 mg/l of phosphate in water, 550000 m^3/day, return a feasible separation technique to recover the desired resource, maximizing the resource recovery net present value meanwhile minimising the environmental impact".

For step 2, potential identification, the user obtains an overview of the compound details to evaluate the most valuable resource on which the analysis can be carried forward. In this step, the gross sustainability potential and environmental impact was computed for both phosphorus and water. For phosphorous, the environmental influence and geopolitical considerations were significant factors behind the decision to target the resource for recovery. In this case, the geopolitical influence draws from the location of the case study, New Zealand, where Phosphorous-shortage has been increasing problem over the years (Cordell et al., 2014). Based on this consideration and on the higher phosphorus environmental impact value, phosphorus has been selected as the resource to be further analysed in the framework. The subsequent application of step 3, via technology database generation, illustrated that there are many potential phosphorus recovery pathways, but the application of step 4 illustrated that Crystallisation of phosphorus to struvite, using magnesium hydroxide was the only technologically mature and hence feasible pathway. The pathway was subjected to preliminary financial feasibility assessment by applying the capital cost estimation technique (Tsagkari et al., 2016). This yielded an estimated capital cost of USD 576 Million and a yearly process revenue of USD 0.62 Million. Based on this finding the financial infeasibility of the project is evident, and that the recovery of phosphorus in the form of struvite crystal is not a process to consider for implementation. Resultantly, the framework iterates back to step 2, to pick the next most feasible separation pathway. However, as no other technology meets the maturity requirement, the case exits the framework unsuccessfully.

5. Conclusions

In this work, a systematic computer aided framework has been developed to systematically evaluate the techno-economic and environmental potential of a resource

recovery initiative. The merit of the developed framework was then demonstrated on two practical case studies where the framework was able to systematically identify resource recovery potential, and synthesize first pass separation process designs. The diverse nature of the case study waste stream composition illustrates the generic structure, thus versatility of the framework. Analysis of the first case study demonstrated the framework's ability to identify and develop solutions in the presences of multiple target resources, and facilitate generation of lucrative technically feasible separation pathways. This established the frameworks applicability in the context of handling realistic waste streams, often containing numerous significant constituents. In the second case study, the framework facilitated the "weeding out" of numerous process technologies that illustrated phosphorus recovery potential, but were not currently at a sufficient technology readiness for industrial implementation. This illustrated the value of the multi-faceted approach undertaken by the framework, as feasible yet technologically underdeveloped solutions are quickly discarded in favour of the development of solutions that are of a sufficient technology development streamlining the long and resource intensive development phase.

Abstract

The hydrate-based carbon dioxide (CO_2) capture (HBCC) process has been widely studied for CO_2 separation and sequestration. This paper aims to conduct a model-based investigation of the kinetics of the HBCC process. A variation of the shrinking core model (SCM) was developed for the analysis of this heterogeneous system under varying boundary conditions. The results revealed that while CO_2 diffusion through the hydrate layer is the dominant controlling mechanism, for a realistic scenario in which a time-dependent bulk gas concentration exists, the model results would better match the experimental data if the effects of the reaction rate were incorporated into the diffusion-based model. Sensitivity analysis showed that increasing the diffusivity through the hydrate layer significantly decreases the full conversion time of the water. Moreover, the effect of temperature change was investigated, and it was found that lower temperatures slow the hydrate growth rate. The model was demonstrated to be a computationally effective and time-efficient predictive tool that does not require high-speed computers for large-scale (reactor) applications.

Keywords: gas hydrate, CO_2 capture, shrinking core model

1. Introduction

Gas hydrates are solid clathrates comprising gas molecules (guests) such as CO_2, nitrogen (N_2), hydrogen (H_2), methane (CH_4) encased in a cage of water molecules (H_2O) connected to each other by hydrogen bonds. Hydrates form under specific thermodynamic conditions, including low temperature and high pressure. The small and nonpolar CO_2 gas forms hydrate structure I at temperatures lower than 283 K and pressures lower than 4.5 MPa (Sloan and Koh, 2008). CO_2 hydration under 203 K and 0.08 MPa has also been reported (Falabella, 1975). The potential of gas hydrate technology to capture CO_2 from flue gases has sparked research interest in investigating different aspects of this novel technology (Dashti and Lou, 2018; Dashti et al., 2015). Early research mostly focused on the experimental investigation of CO_2 hydrate formation and methods to improve the hydration kinetics and separation efficiency. In recent years, studies focused on understanding gas hydrate formation kinetics have increased (Yin et al., 2018). Many of these studies have been based on the methane hydrate formation process, and the kinetic model reported by Englezos et al. (1987) has been frequently used (Englezos et al., 1987).

This model follows the modeling approach for crystal growth from solution (Karpiński, 1980) and divides hydrate particle growth into two steps: 1) diffusion of the dissolved gas from the bulk solution to the hydrate-liquid interface and 2) the hydrate formation reaction at the interface. According to Lederols et al. (1996), gas hydrate formation is similar to the crystallization process, which is governed by nucleation followed by the rapid growth of hydrates; both are controlled by kinetics and mass and heat transfer phenomena (Lederhos et al., 1996).

The unreacted shrinking core model (SCM) has been widely used for solid reactions in which the intrinsic reaction rate is much higher than the mass transfer rate (Amiri et al., 2013; Amiri et al., 2015). This paper applies a modified SCM to model the CO_2 hydrate formation process assuming a single mechanism for a better understanding of gas hydrate formation kinetics.

2. Modeling methodology

2.1. Base model with a constant boundary condition

A variation of SCM with the steady boundary condition was applied to the CO_2 hydrate formation case study. In a batch reactor, however, the composition of the bulk gas surrounding the reactive particle is significantly dynamic, which conflicts with the boundary condition assumption in a mechanistic model.

In the typical SCM paradigm, the gas-solid reaction initiates at the outer surface of a solid particle and then moves towards the particle core, leaving a product layer behind. The unreacted core radius shrinks with time until full conversion of the solid particles to products, as shown in Figure 1. The model can be adopted to describe the CO_2 hydrate formation process, which includes three steps. Assuming effective agitation leading to the formation of water droplets that interact with CO_2 to form gas hydrates, the whole process involves (i) CO_2 diffusion through the gas film surrounding the hydrate particle to reach the particle's surface; (ii) CO_2 diffusion through the hydrate shell to reach the unreacted core (water) surface; and (iii) reaction of CO_2 with water (Eq. (1)) at the hydrate–liquid interface or unreacted core surface. The overall reaction can be expressed using Eq. (1):

$$CO_2 + nH_2O \leftrightarrow CO_2 \cdot nH_2O \qquad\qquad r_h = kC_{CO_2} \qquad\qquad (1)$$

where n is the hydrate number, 5.75 (Sun and Kang, 2016); r_h represents the overall hydrate formation rate; C_{CO_2} is the CO_2 concentration at the water-hydrate interface; and k is the reaction rate constant for reaction (1).
Figure 1: Schematic diagram of the CO_2 hydrate formation in a well-mixed batch reactor (Left) and a shrinking core hydrate particle (Right)

To build a comprehensive model, the system is first analyzed step by step, assuming that the analyzed step is rate limiting. The results are then compared with the experimental data. According to Eq. (1) and Figure 1 (right), for a liquid droplet with a spherical geometry, water conversion (X_{H_2O}) and the unreacted water core radius (r_c) can be correlated as follows:

$$X_{H_2O} = 1 - \left(\frac{r_c}{R_p}\right)^3 \tag{2}$$

where R_p is the particle radius. Assuming a rigid hydrate shell and constant R_p, step (ii) and step (iii) occur instantaneously. There is a linear relationship between the conversion rate and time (Eq. (3)).

$$t = \frac{\rho_{H_2O} R_p}{3 n k_g C_{CO_2}^b} X_{H_2O} \tag{3}$$

where ρ_{H_2O} is the molar density of water and k_g and $C_{CO_2}^b$ are the mass transfer coefficient of CO₂ through the gas layer surrounding the hydrate particle and the molar concentration of CO₂ in the gas bulk, respectively. Similarly, the conversion rate and rate relationship for step (ii) rate limiting and step (iii) rate limiting can be expressed by Eqs. (4) and (5), respectively.

$$t = \frac{\rho_{H_2O} R_p^2}{6 n D_e C_{CO_2}^b} [1 - 3(1 - X_{H_2O})^{\frac{2}{3}} + 2(1 - X_{H_2O})] \tag{4}$$

$$t = \frac{\rho_{H_2O} R_p}{n k C_{CO_2}^b} [1 - (1 - X_{H_2O})^{\frac{1}{3}}] \tag{5}$$

where D_e is the CO₂ diffusion coefficient in the hydrate layer.

2.2. Base model with a varying boundary condition

The base model presented earlier is based on the constant partial pressure of CO₂ in the bulk gas, $p_{CO_2}^b$. However in a closed system, when CO₂ capture in the hydrate cages is exceedingly fast, $p_{CO_2}^b$ declines with time. Given that the partial pressure of CO₂ in the bulk gas is the boundary condition in solving the mass transfer differential equations, the CO₂ concentration profile inside the particle, C_{CO_2}, might be influenced by the transient CO₂ partial pressure in the batch reactor. The base model for the hydrate layer diffusion-dominated case, step (ii), is extended. Eq. (6) defines the rate of CO₂ capture:

$$\frac{dN_{CO_2}}{dt} = -4\pi r^2 D_e \frac{dC_{CO_2}}{dr} \tag{6}$$

in which N_{CO_2} is the number of moles of CO₂. The steady-state assumption and integration yield Eq. (7) and Eq. (8):

$$\frac{dN_{CO_2}}{dt} \int_{r_c}^{R_p} \frac{dr}{r^2} = -4\pi D_e \int_0^{C_{CO_2}^b} dC_{CO_2} \tag{7}$$

$$\frac{dN_{CO_2}}{dt} \left(\frac{1}{r_c} - \frac{1}{r_p}\right) = -4\pi D_e C_{CO_2}^b(t) \tag{8}$$

Instant N_{CO_2} can be presented as a function of $r(t)$ according to Eq. (9):

$$\frac{1}{n} dN_{CO_2} = 4\pi \rho_{H_2O} r_c^2 dr_c \tag{9}$$

CO_2 concentration in bulk gas is the boundary condition for Eq. (6) and is related to the CO_2 partial pressure in the reactor by Eq. (10):

$$C_{CO_2}^b(t) = \frac{p_{CO_2}^b(t)}{RT} \tag{10}$$

Eq. (9) and (10) are substituted in Eq. (8) and integrated across the hydrate layer, resulting in Eq. (11):

$$\frac{R_p^2 \rho_{H_2O} RT}{6nD_e}\left[1 - 3\left(1 - X_{H_2O}\right)^{\frac{2}{3}} + 2\left(1 - X_{H_2O}\right)\right] = \int_0^t p_{CO_2}(t)\,dt \tag{11}$$

which describes the correlation between water conversion and CO_2 partial pressure changes and allows monitoring of the time-dependent mass diffusion resistance based on the reactor pressure readings. Similarly, the governing equations for the reaction control case with a varying boundary condition have been derived and are given below:

$$\frac{R_p \rho_{H_2O} RT}{nk}\left(1 - \left(1 - X_{H_2O}\right)^{\frac{1}{3}}\right) = \int_0^t p_{CO_2}(t)\,dt \tag{12}$$

Combining Eq. (11) with Eq. (12), a model considering both the diffusion step (ii) and the reaction step (iii) is produced according to Eq. (13):

$$\frac{R_p \rho_{H_2O} RT}{n}\left[\frac{R_p}{6D_e}\left[1 - 3\left(1 - X_{H_2O}\right)^{\frac{2}{3}} + 2\left(1 - X_{H_2O}\right)\right] + \frac{1 - \left(1 - X_{H_2O}\right)^{\frac{1}{3}}}{k}\right] = \int_0^t p(t)\,dt \tag{13}$$

The right-hand side of Eq. (13) presents the measured time-dependent CO_2 partial pressure inside the reactor. This must be provided practically, making the presented model a semi-empirical model.

3. Results and Discussion

3.1. Controlling mechanism identification

The models derived based on the individual mechanisms (Eqs. 3, 4, 5) were compared against a set of experimental data obtained from batch reaction vessel experiments at 203 K and 0.08 MPa (Falabella, 1975). As shown in Figure 2(A), for the model based on step (ii), diffusion through the hydrate layer best fits the data. The model developed based on gas film control (step (i)) predicts a linear relationship between conversion and time that departs greatly from the experimental data. This is not surprising and is consistent with the assumptions of Englezos et al. (1987) (Englezos et al., 1987). Judgments about the dominant mechanism become critically challenging when comparing the modeling results based on the intrinsic reaction with those based on the diffusion controlling model. While both models follow the practically observed non-linear clathrate conversion trend, the diffusion-dominated model seems more appropriate. This is more obvious at the early stages of the process, from zero to 55% conversion, because the reaction on the water-hydrate interface occurs after gas diffusion through the hydrate layer. At higher conversion ranges, above 55%, both models reasonably predict the experimental data. It can be concluded that while diffusion through the formed hydrate predominantly controls the hydration progress rate, the inherent reaction kinetic role is not negligible. The former becomes more significant when considering the depleting CO_2 partial pressure in the bulk gas surrounding the particle that occurs in a batch reactor.
Figure 2: Comparisons of (A) the single-mechanism model prediction with the experimental data for constant bulk concentration and (B) the single- and combined-mechanism model predictions against the experimental data for constant ($C_{CO_2}^b$ = constant) and varying bulk concentration ($C_{CO_2}^b$ ≠ constant)

The assumptions, including the single mechanism control and constant CO_2 partial pressure in bulk gas, used in the base model derivation may be responsible for the observed deviation between the modeled and experimental results in Figure 2(A). The model was improved by accounting for combined mass transfer and reaction kinetics rates, both of which are influenced by the depleting CO_2 fraction in the surrounding gas. Figure 2(B) presents the prediction results for (i) the hydrate diffusion control model with varying CO_2 concentration in the bulk gas (Eq. (11)), (ii) the intrinsic reaction control model with varying CO_2 concentration in the bulk gas (Eq. (12)), and (iii) the combined model under a transient CO_2 concentration (Eq. (13)) and compares these results with the experimental data (Falabella, 1975). The results of the combined model fall between the hydrate layer diffusivity and reaction control results, thus improving the prediction results compared with the experimental data.

3.2. Model analysis

Due to the role of the diffusion rate demonstrated earlier, the accuracy of the diffusion coefficient estimation is of critical importance for model fidelity. The diffusivity of CO_2 in hydrates has been reported to be in the range of $1×10^{-16}$ m²/s to $2×10^{-14}$ m²/s (Liang et al., 2016). The effect of CO_2 diffusivity on the CO_2 hydrate conversion time was investigated as shown in Figure 3(A). The total conversion time increases dramatically with decreasing diffusivity because at lower diffusivity values, the diffusion of the gas into the inner layer of the gas hydrate shell is slower. As a result, it takes longer to form the gas hydrate particle and consequently reach the end of the conversion time.

In further analysis of the model, the effects of the gas hydrate formation temperature on the completion time were investigated. As shown in Figure 3(B), the effect of the temperature changes on the completion time is not as significant as the effects of the diffusivity on the completion time. At lower temperatures, CO_2 hydrate formation is faster. For example, at 250 K and 298 K, the completion times are approximately 107 min and 130 min, respectively.
Figure 3: Effects of (A) CO_2 diffusivity and (B) hydrate formation temperature change on the conversion time

4. Conclusions

The purpose of the present study was to determine the dominant controlling mechanism during gas hydrate formation using a novel variation of SCM. The primary model was proposed based on a constant concentration of CO_2 in the bulk gas. The model was further improved by considering the transient CO_2 concentration in the bulk gas, which is a more realistic case. While the diffusion-based model reasonably predicts the CO_2 hydration rate under a constant bulk gas concentration condition, for the realistic scenario in which the bulk gas varies with time, the model must consider the reaction control role as well. The proposed model was successfully used to quantify the effects of the CO_2 diffusivity and the operating temperature on conversion.

Abstract

The progress of the current energy infrastructure to a new pattern, where hydrogen plays an important role has been increasing the interest of industrial communities, as well as, academics. This is mainly associated with sustainability goals where reducing environmental impacts is a target while guaranteeing economic benefits. In this context, the development of hydrogen optimized global supply chains (SC) that can support industrial processes through renewable energy sources is to be pursued. In this paper, we explore this challenge and a multi-objective, multi-period, stochastic Mixed Integer Linear Programming (MILP) problem for design and planning a hydrogen SC is developed. Uncertainty over the availability of primary energy sources (PES) is considered through the definition of set scenarios. A Portuguese case is explored, from where it as concluded that the reduction in global warming potential is very small when compared to the increase in cost.

Keywords: Hydrogen supply chain, Renewable energy source, Multi-objective optimization, Uncertainty in primary energy sources.

1. Introduction

The use of fuels with low emissions has been recently highlighted as one of the trends to mitigate environmental impacts. In this set, the use of hydrogen as a fuel has been considered an alternative with significant potential to integrate a more sustainable energy matrix, especially in the transportation sector (Almansoori et al., 2011). Hydrogen has become a key element for governments under pressure of emission constraints and environmental laws. Despite this, there is still no appropriate infrastructure available and uncertainties are one of the main drawbacks to the development of the hydrogen economy as the case of primary energy sources (PES) availability.

Different approaches to formulating a hydrogen SC have been appearing in the literature, as an attempt to determine if hydrogen is a competitive option, as an energetic vector, while mitigating the high capital investment, this is the case of the study of Ogumerem et al. (2017), in which the oxygen co-produced form the electrolysis is further processed and sold to generate revenue. In the process of designing a hydrogen SC, forecasts associated with demand, price, and type of energy sources are the main uncertainty sources. But the existent literature studies have mainly focused on demand uncertainty and a few addressed cost uncertainty. To the author's knowledge, none explored uncertainty associated with the availability of PES, which are required for the hydrogen production technology.

Considering the aforementioned, a model to determine strategic and planning decisions taking into account uncertainty on the PES availability is here explored. A MILP is developed, considering a multi-period model and two objective functions: minimization of cost and minimization of global warming potential (GWP) in the SC network. A scenario-based tree approach is defined where scenarios describe the possible PES availability. The ε-constraint method with lexicography optimization is implemented and the results of several non-dominated solutions from the Pareto curve are characterized.

2. Problem definition

The hydrogen SC can include diverse echelons, depending on the specifications and needs of each application. The problem in this paper considers three mains echelons: primary energy sources, production plants, and storage facilities. The links between the different echelons are guaranteed through a multimodal transportation network to satisfy the hydrogen demand. Hydrogen production can use a wide diversity of energy sources, from this, were considered only renewables energies, and based on the hydrogen production technologies selection. The hydrogen produced is stored in storage facilities according to its physical form (gaseous or liquid). In order to satisfy the demand, importation is also allowed. In sum the problem in the study can be described as follows:

Given:
- A set of potential locations to install hydrogen production units as well as storage facilities;
- type of production and storage facilities;
- the maximum and minimum capacities for flows, production, and storage;
- primary energy source availability;
- global warming potential for each transportation mode;
- regional delivery distances;
- operating and capital costs;
- the initial existent number of production plants and storage facilities;
- customer's demand.

Determine:
- the number, location, size, capacity, and technologies of hydrogen production plants and storage facilities;
- the network planning with all flows, rates of hydrogen and primary energy sources consumption, production rates and average inventory of materials.

So as to:
- minimize the cost of the supply chain and the GWP.

GWP, stands for the global warming potential and is taken as an environmental indicator of the overall effect related to emissions of greenhouse gases (CO_2-equiv).

3. Model main characteristics

As mentioned above the model developed is a multi-objective, multi-period, stochastic Mixed Integer Linear Programming (MILP) where two main objectives are considered: minimization of cost and minimization of global warming potential (GWP). A set of constraints are defined considering: network expansion; PES availability, demand requirements, production, storage capacities, and transportation capacities; mass balances and importation needs. The demand is assumed to have a profile over the long-term planning horizon, and it follows an s-shape pattern, according to a hydrogen market penetration factor (Almansoori et al., 2009). Uncertainty in the PES availability is

characterized using a dynamic scenario tree approach as detailed in the following section. A ε-constraint method with lexicography optimization is implemented to avoid weak (dominated) solutions.

3.1 The scenario tree approach

To model PES uncertainty a dynamic scenario tree is considered formed by nodes and arcs. Every node represents a state of the random parameter, in our case the PES availability, at a given time point, which evolves over the planning horizon. A scenario comprises a sequence of nodes, and arcs, from the first time point to the last one. The probability of a scenario is given by the product of the probability of each arc between the root and leaf nodes (Lima et al, 2018). Fig. 1 depicts a scenario tree example with 8 scenarios, in which two branches leave, from the root node until the last node.
Figure 1 - Scenario tree example.

4. Case study

The design and planning of a hydrogen supply chain in Portugal is taken as case-study. An administrative segmentation of Portugal has been used to obtain a realistic path between districts with the existing main roads and truck lines and to estimate the potential demand from local population statistics (De-León Almaraz e al., 2014).

Four renewable energy sources are considered: wind power, solar power, hydroelectric and biomass. In production terms, two types of production technologies are assumed: electrolyzes and biomass gasification. Hydrogen is produced in liquefied form. Two transportation modes are used, a tanker truck and a railway tanker. Cryogenic storage is assumed.

To estimate the hydrogen demand was assumed the current number of private and light vehicles in Portugal, the average distance travelled, and fuel economy hydrogen (kg H_2/km) to calculate the total equivalent hydrogen demand. Furthermore, the demand equivalent was treated based on the penetration factor in each time period, in this case, 5 years per stage, in a horizon of 15 years of network planning. The hydrogen penetration factor starts at 5% in the first period, growing to 25% in the second period, and it reaches 50% in the third period.

To generate the scenarios considering the PES uncertainty availability an S-shape PES trajectory is considered, then a scenario tree of the form shown in Fig. 2 was obtained. Three time periods and nine distinctive scenarios are considered. The scenarios were structured from current energy data and considering variability over time, reaching a maximum growth of 11% in a scenario in the last time period compared to the initial information. The probabilities of occurrence of each scenario are given in Table 1, assuming a pessimist, a neutral and an optimistic scenario in each time period after the first one. The first time period has a deterministic PES profile. The model was solved through GAMS 25.1.1, using CPLEX 12.0, in a two Intel Xeon X5680, 3.33 GHz computer with 24 GB RAM. The time presented in table 3 is the sum of the execution times of the 10 points of the Pareto border.

Table 1 - Probabilities of occurrence.

Scenarios"w"	Probabilities
w1	6,25 %
w2	12,5 %
w3	6,25 %
w4	12,5 %
w5	25,0 %
w6	12,5 %
w7	6,25 %
w8	12,5 %
w9	6,25 %
Figure 2 - S-shape scenario tree of PES.

5. Results and Discussion

The results are summarised in the Pareto frontier represented in Figure 3. In order to detail its analysis, three points of the curve are selected as identified in Figure 3. The extreme points 1 and 10 corresponds respectively to the maximum values of GWP and total daily cost. The solution from the middle, point 7, was selected to evaluate the differences with the other selected solutions.

Table 2 depicts the topology, total costs and GWP of the three solutions. Comparing the point 1 and the point 10 solutions it can be seen an increase of 17 times in cost, and a reduction of 0.94, about 6%, in the GWP impact. Moreover, by comparing the lowest cost solution, point 1, and the middle solution, point 7, there is an 8-fold increase in the total daily cost of the network, while the reduction of the GWP is about a ratio 0,96, which indicates a reduction approximately 4%. This shows that the reduction in total GWP is very small when compared to the necessary increment in costs.

Thus, despite the high variability in the supply chain cost, a small impact in the GWP value was obtained, which is justified by the type of PES selected and its respective production technology. In point 10 biomass was selected as the primary energy source, while point 1 presents the selection of two types of production technologies, electrolyzes and biomass gasification, therefore having as energy sources not only biomass but integrating the other ones, such as solar power, wind power and hydroelectric.

These choices are justified by the fact that biomass has the lowest price compared to other energy sources, but biomass gasification is a less environmental friendly production technology when compared to electrolysis.

Related to the network decisions it is possible to observe that the number of production plants increases from 8 to 17 from point 1 to 10. These results are justified by the incremental use of biomass as the energy source that has associated lower technologies capacities. Since the demand variability is unchanged, the number of storage facilities remains the same for all solutions.

In sum the obtained results suggest decentralized SC topologies for lower values of GWP (point 10), with smaller capacities, and where the demand for hydrogen is supplied locally by production plants. On the contrary, when the objective is the minimization of costs a centralized topology is obtained (point 1), where higher capacities are installed.
Figure 3 - Optimal solutions in the Pareto curve.

Table 2 – Comparison of multiperiod solutions topologies

Point in Pareto Frontier	1	7	10
Total number of production plants	8	13	17
Total number of storage facilities	54	54	54
Total number of transportation units	1283	200	405
Average Total Daily Network Cost (M\$ per day)	4.19	33.67	74.11
Average GWP Production plants (10^3 t CO2 - equiv per day)	18.09	16.44	15.40
Average GWP Storage facilities (10^3 t CO2 - equiv per day)	35.85	35.85	35.85
Average GWP Transportation modes (10^3 t CO2 - equiv per day)	0.075	0.014	0.034
Average Total GWP (10^3 t CO2 - equiv per day)	54.02	52.31	51.28

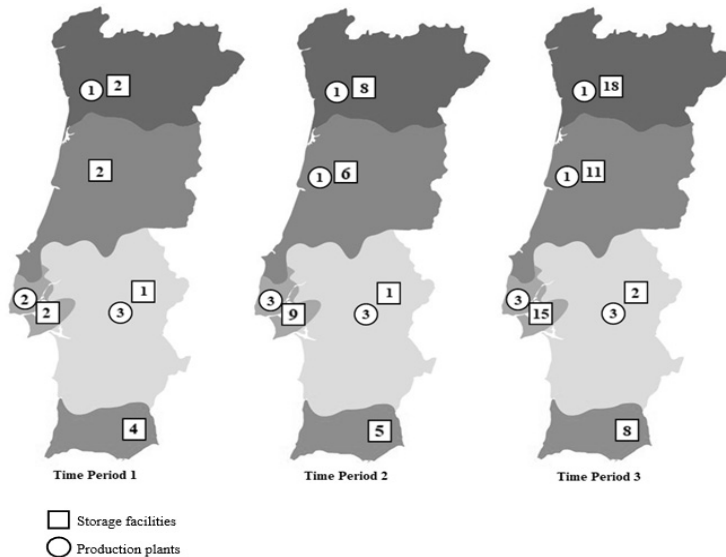
Considering point 1 it can be analyzed through Figure 4 the topology evolution over time. As demand increases, the number of production plants and storages facilities increases accordingly, in the same regions, to satisfy the increment of local demand. Production plants are strategically centralized disseminated along Portugal territory.


Figure 4 – SC topology evolution over the multi-period solution (point 1)

Table 3 – Computational results for the multi-objective optimization

Continuous variables	Binary variables	Constraints	CPU (s)	GAP (%)
8252	1621	10457	122	0

6. Conclusion

In this work, a MILP model to support the decision maker in the design and planning of hydrogen supply chains is developed. The model considers variability in renewable energy sources and integrates a set of constraints describing the supply chain characteristics. Economic and environmental objectives are considered.

The model is applied to the design and plan of a hydrogen supply chain in Portugal. When a cost objective is at stake a centralized network is obtained when compared to a decentralized supply chain when an environmental objective is considered.

It was also concluded that the reduction in total GWP is very small compared to the necessary increment in costs.

As future work is intended to explore other sources of uncertainty in the model and thus analyze their impact in the SC network. It is also expected to integrate the risk component as an objective function into the model.

*gsi@kt.dtu.dk

Abstract

In this contribution, we present and evaluate a systematic framework for comprehensive uncertainty and sensitivity analysis of a model used for design of Rotary Kiln processes. We consider two sources of uncertainties, namely operational (such as measurement errors, feedstock composition, etc.) and model (key assumptions in the model used for design equations) parameter uncertainty. As model outputs for evaluation we considered the impacts of these uncertainties on key process design metrics, specifically the minimum required rotary kiln length and the conversion degree of limestone. The results revealed that the operational sources of uncertainty lead to a higher uncertainty in process design metric (e.g. standard deviation of the computed length is 6.1 m) compared to the model parameter uncertainty (standard deviation of the computed length is 4.5 m). In order to achieve a robust process design, one needs to dimension the length of the reactor with 187 m so that all particles will be converted with 100 % efficiency with 95 % confidence. Ignoring these sources of uncertainty will lead to suboptimal process performance with the degree of conversion of limestone reduced to 97 %. Among input uncertainty considered, the global sensitivity analysis revealed measurement errors of temperature sensors as the most influential parameters. Overall the results encourage application of comprehensive sensitivity and uncertainty analysis methods for robust design of rotary kiln processes.

Keywords: Uncertainty, Sensitivity, Rotary Kiln, Monte Carlo simulation, Morris Screening, Sobol's method.

1. Introduction

A rotary kiln is a physically large process unit used in cement production where limestone is decomposed into calcium oxide which forms the basis of cement clinker particles under high temperatures. The modelling of rotary kilns are well documented in literature. Mujumdar et al. 2007 developed an iteration based rotary kiln simulator (RoCKS), which integrates models for a pre-heater, calciner, kiln and clinker cooling that agreed well with observations in industry. The model takes complexities in reactions and heat transfers with different sections into account by coupling multiple models with common boundaries regarding heat and mass communications. Other work (Ngadi and Lahlaouti, 2017) neatly demonstrates an experimentally proven kiln model being applied for screening of combustion fuel used for kilns, and how it may impact the production. This contribution coupled modelling of reactions and heat transfer in the bed region and another model for combustion and heat transfer in the freeboard region.

While modelling of these processes with varying degree of complexity has been performed, proper uncertainty and sensitivity analysis of these models have not been given due importance/consideration. As the use of computer aided process engineering tools increases, the need for robust uncertainty and sensitivity analysis frameworks becomes more important. There are several frameworks of uncertainty and sensitivity analysis applied for different problems, from good modelling practice (Sin et al, 2009) to process design and product design (Frutiger et al 2016). These frameworks typically include the following steps (0) problem statement, (i) identification of input sources of uncertainties, (ii) sampling (iii) Monte Carlo simulations and (vi) sensitivity analysis. The purpose of this work is to perform a systematic uncertainty and sensitivity analysis of rotary kiln process design in order to address the following: (1) Given a certain base case design, what is the impact of uncertainties in the model and measurements on the key process design metrics (minimum required reactor length and degree of conversion), and, (2) given a certain source of uncertainties, what is the robust design to ensure process performance with 95 % confidence.

2. Modelling of the Physical System

The overall goal of the rotary kiln model evaluated here is to determine the minimum required rotary kiln length to process 115,000 tons of limestone annually. The design model is built on a number of mechanisms and processes (Mujumdar et al., 2007), including a spherical particle model, a shrinking core model with three resistances (gas film, ash layer, and reaction at core), a steady state energy balance, and a counter-current gas-particle flow in kiln. The model accounts for changes in flue gas compositions, which affects the heat transfer coefficient and the particle core temperature.

Table 1: Summary of equations used in rotary kiln. Parameters marked up red are used in uncertainty analysis.

Equation	Description
$\dfrac{dX_i}{dt} = -\dfrac{3h_p}{\Delta H \rho R_i}$ $\left(\dfrac{\lambda(1-X_i)^{1/3}(T_g - T_c)}{h_p R_i(1-(1-X_i)^{1/3}) + \lambda(1-X_i)^{1/3}} \right)$	Conversion rate (X) of particle size i. h_p is the energy transfer coefficient, R is the particle radius, λ is the heat diffusion coefficient, and T_c is the particle core temperature. This is used to find the conversion for the drying and calcination, which uses enthalpies (ΔH), densities (ρ) and heat diffusion coefficients. Heat of reaction is used for calcination and the heat of vaporization is used for drying.
$h_p = 23.7G^{0.67}\left(\dfrac{A_{KW}}{A_P}\right)$	The heat transfer coefficient is dependent on the gas mass velocity (G) and the fraction of particles consuming heat.
$\log_{10}(P_i) = A - \dfrac{B}{C+T_c}$	Antoine's equation is used to find the temperature at the unreacted core of the particle.
$\left(\dfrac{A_{KW}}{A_P}\right) = \begin{cases} 0.0686 & for \quad t < \tau_1 \\ 0.1744 & for \quad \tau_1 < t < \tau_2 \\ 0.5194 & for \quad \tau_2 < t \end{cases}$	Increased effective area when particles are fully reacted. τ_i is the time required to fully convert a particle size i. A represents the area of the kiln wall (denoted KW) and particles (denoted P).
$G_1(X) = G_0 + m_K[(1-X_1) + (1-X_2) + (1-X_3)]$	A measure of the gas mass velocity. Throughout the kiln, the amount of gas changes accordingly to the calcination and drying.
$L = \dfrac{NDSt}{0.19}$	Used to find total kiln length, L. t is the residence time of the particles, D is kiln diameter, S is the inclination, and N is the rotational speed.

The model also accounts for discrete particle distributions, where fully reacted particles are assumed to no longer consume heat (Dam-Johansen K, 2018). The conceptual model is shown in Figure 1 and the equations are shown in Table 1 (Levenspiel, O., 1999). The model and the framework for the sensitivity and uncertainty analysis have been implemented in Matlab ® (Mathworks) while additional sensitivity analysis has been performed using Polynomial Chaos Expansion (PCE) with UQlab (ETH Zurich).

Figure 1: Defined rotary kiln system that have been modelled (stippled lines). Heat is produced through combustion of coal, which flows counter-current of the limestone. The wet limestone is first dried, where water vapor is added to the flue gas composition. Thereafter, the calcination reaction forms calcium oxide particles and carbon dioxide gas. The gas is added to the flue gas composition.

3. Methodology for Uncertainty and Sensitivity Analysis

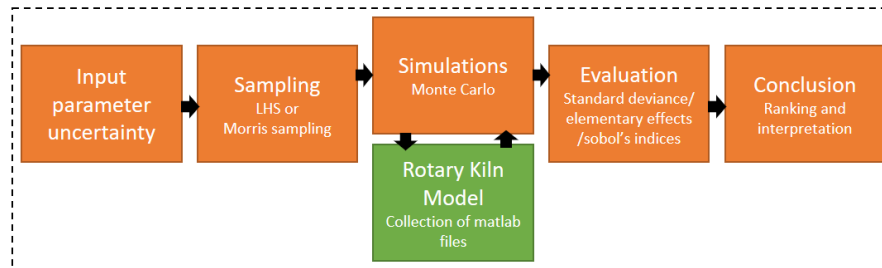
The framework for uncertainty and sensitivity analysis (Sin et al, 2009) used here is illustrated in Figure 2. Input uncertainty is first determined (Table 2), which is used to make a sample based on the input data (Figure 3a). Each parameter set in this sample is then used in the model to create a set of output data (Figure 3b). The output data can be evaluated accordingly to ambitions (uncertainty/sensitivity metrics etc.), which can be visualized and/or ranked to draw conclusions. In this work, input uncertainty in operational (Table 2) and model (highlighted in bold and red in Table 1) parameters are evaluated.


Figure 2: Overview of framework for uncertainty/sensitivity analysis according to Sin et al., 2009.

Table 2: Input uncertainty for operational parameters used in uncertainty and sensitivity analysis.

Parameter	Description	(Mean) μ	Unit	(Std.dev) σ
$T_{g,d}$	Temperature in drying section	573	K	12.76
$T_{g,c}$	Temperature in calcination section	1,373	K	12.76
m_{CaCO3}	Mass feed of limestone	115,000	t/yr	293.37
m_{Coal}	Mass feed of coal	9,547	t/yr	24.35
N	Rotational speed of kiln	1/3	1/min	1.70E-4
S	Inclination of rotary kiln	52.6	mm/m	8.06E-4

4. Results and Discussion

4.1. Uncertainty Analysis

The model output uncertainty is based on input uncertainty of parameters relevant for controlling the kiln operation, as shown in Table 2. Input space was sampled using Latin Hypercube Sampling (LHS) to generate 4,000 samples shown in Figure 3a. These samples are simulated using the model through Monte Carlo simulations (Figure 3b). Thereafter, the uncertainty related to the model output data were evaluated. Figure 3c and 3d present the model output results in cumulative distribution functions (CDF) of the kiln length and conversion rate for a fixed length. The figure shows that the operational uncertainty gives the highest output uncertainty. Therefore, taking the input uncertainties into account, to ensure a robust design, one needs to dimension the length of the reactor with 187 meters so that in 95 % of uncertainty realization (hence confidence) that all particles will be converted with 100 % efficiency.

(a) Sampling input data   **(b) Model output data**

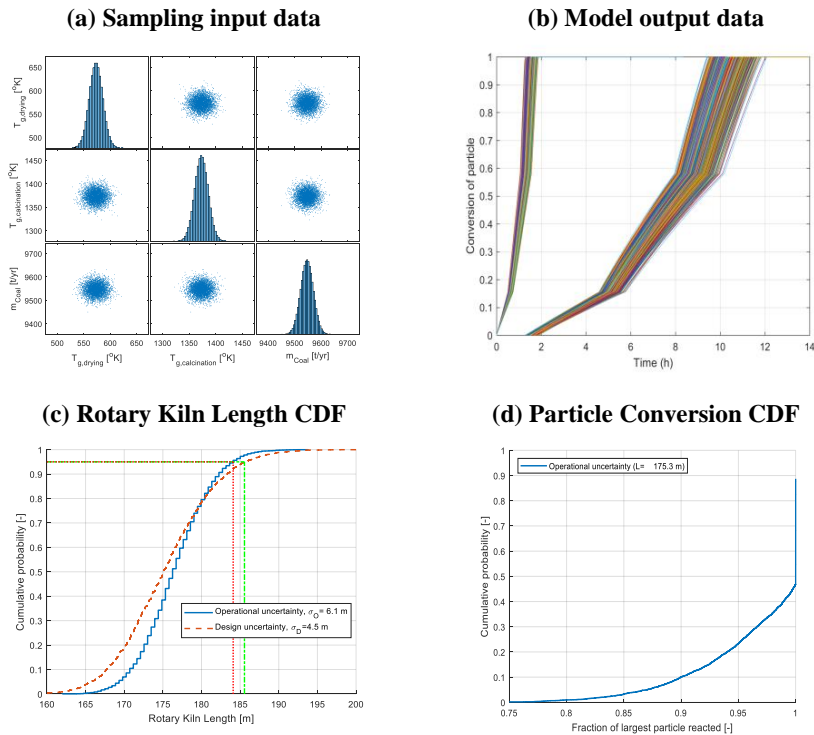
(c) Rotary Kiln Length CDF   **(d) Particle Conversion CDF**


Figure 3: Input (a) and output (b) data using operational input uncertainty accordingly to Table 2. Cumulative distribution function (CDF) of length (c) and average conversion with a fixed length (d) from uncertainty analysis. For the length, both operational and design uncertainty is included.

If the length is kept at 175 meters (base case design obtained by assuming no uncertainty), all but the largest particle in the particle distribution would be 100 % converted. However, it was found that the largest particle would on average be 97.15 %

(Figure 3d) converted. The latter particle consists of 35 w% of the limestone fed to the kiln, which amounts to roughly 1,147 tons of unreacted limestone annually wasted.

4.2. Sensitivity Analysis

Given that the output uncertainty is highest with operational sources of uncertainty, a global sensitivity analysis is performed on 6 operational parameters. To this end, two global sensitivity analysis techniques are used: Morris screening (Sin et al. 2009) and Sobol's method through Monte Carlo sampling and PCE-based method (Al et al. 2018).

4.3. Morris Screening

Morris Screening is a global sensitivity method that systematically varies one parameter at a time at randomly selected points in the input space. The input parameter change is then evaluated based on how much is changes the output, and stored as Elementary Effects (EE). By doing a sufficient amount of these local sensitivity measures, the mean value and standard deviance of the elementary effects provides a global context to the sensitivity analysis (Sin et al, 2009). Figure 4 show EE of the operational parameters, where high frequency at low values represents a non-influential parameter (low mean and standard deviance). Conclusions from this Morris screening is that N and S are insignificant, and the temperature is the most influential parameter.

4.4. Sobol's Method

Sobol's method determines the sensitivity of parameters on model output based on the decomposition of variance. Sobol's method produces two sensitivity measures, main effect (S_i) and total effect (S_{Ti}) respectively. Thus, S_i describes how much, on average, the model output variance could be reduced by if parameter i could be fixed. S_{Ti} is the expected variance when all parameters except i are fixed. While S_i is used to prioritize parameters relative to each other, S_{Ti} is used as a measure to

Figure 4: Morris screening result. High frequency of EE near 0 corresponds to low sensitivity.

determine non-important parameters. Table 3 show the results from Sobol's method. The table show which of the parameters are most influential for this model, where the parameter with rank 1 is the most sensitive. Notably, the results are well in accordance with the Morris screening results. All values should to be positive, where negative numbers can be described as a consequence of numerical approximation.

Table 3: Sobol indices for sensitivity analysis of operational parameters on the model output.

Parameter	S_i	S_{Ti}	$S_{i,PCE}$	$S_{Ti,PCE}$	Rank
Temperature in drying section	0.0463	0.0487	0.0490	0.0491	2
Temperature in calcination section	0.9470	0.9447	0.9467	0.9468	1
Mass feed of limestone	0.0001	0.0018	0.0011	0.0012	4
Mass feed of coal	0.0030	0.0040	0.0030	0.0031	3
Rotational speed of kiln	-0.0027	0.0005	0.0000	0.0000	5
Inclination of rotary kiln	-0.0014	0.0002	0.0000	0.0000	6
SUM	0.9924	0.9998	0.9999	1.0001	N.A.

5. Conclusions

This work demonstrates successful application of uncertainty and sensitivity analysis in the model-based design and analysis of a rotary kiln process. The results showed that there are significant uncertainties, and that the uncertainty attached to operational uncertainty (standard deviation equal to 6.1 m) gives higher model length output uncertainty compared to the design uncertainty (standard deviation equal to 4.5 m). This means that in order to counter the effect of the operational uncertainty, one needs to dimension the length of the reactor with 187 m so that in 95 % of confidence one can ensure that all particles will be converted with 100 % efficiency. If the length is kept at 175 m which corresponds to the base case design, the largest particle would on average be 97.15 % converted. Taking the annual capacity into account (115,000 t limestone/y), this amounts to 1,147 t of unreacted limestone wasted annually.

Moreover, global sensitivity analysis indicated the following as the most influential parameters from the operational uncertainty (in descending order): temperature in calcination zone (1) and drying zone (2), the mass flow of limestone (3) and coal (4), the kiln rotational speed (5), and inclination of the kiln (6). Based on the input uncertainty, the four latter parameters can be seen as non-influential for the model output variance. Overall, the results show a high model output based on the input uncertainty, which highlights the importance of including detailed uncertainty and sensitivity analysis in model development. The results encourage application of comprehensive sensitivity and uncertainty analysis to improve robustness of rotary kiln process design.

Abstract

Development of fast, robust and reliable computational tools capable of addressing the process management under uncertain conditions, is an active topic in the current process systems engineering literature. In fact, scenario reduction strategies (for example SCENRED and OSCAR) have acquired a lot of attention to overcome the traditional issues associated to large-scale scenario-based problems. Thus, this work proposes a novel scenario-reduction alternative (henceforth known as SCANCODE approach) by combining Graph Theory to construct a network and community detection methods to identify the clusters within the network. The capabilities and limitations of the proposed approach were tested through the two-stage MILP optimisation of a bio-based energy network under raw material availability and energy demand uncertainties. For comparison purposes, the same problem was solved using the sets of scenarios obtained with SCENRED and OSCAR. This comparison demonstrates the quality of SCANCODE approach while states the potential benefits of the proposed approach over the current alternatives.

Keywords: Scenario aggregation, Graph Theory, Community detection.

1. Introduction

The explicit consideration of the inherent uncertainty in a process system is becoming a key aspect for improving system performance and guaranteeing feasible operation. Two-stage programming and robust optimisation are the most used mathematical formulations/techniques to solve problems affected by uncertain conditions in which the conditions are modelled through a sufficiently large set of scenarios with their associated probability. Even though these formulations aid to effectively represent the whole uncertainty space, they are highly demanding in terms of computational effort. In order to address this critical challenge, scenario reduction strategies such as SCENRED and OSCAR have been successfully and extensively used during the recent past (Feng and Ryan, 2013; Li and Floudas, 2016). Essentially, both approaches identify a small amount of scenarios that minimise the total distance between them and the original uncertainty space; however, in the case of OSCAR, the effect of the input disturbances over the output performance is also considered. Despite being very effective, proximity might not be the best criterion to define clusters and more importantly, cluster centroids, since a lot of information associated to the pairwise relations is lost. Such information could be used as a metric to define and evaluate the quality of the clusters centroids.

Consequently, in this work an integrated framework of Graph Theory and network community detection methods is proposed. On one hand, Graph Theory is used to construct a network out of a large set of data using the pairwise information to determine connections. Disregarding the high-dimensionality or different distribution of the raw data set, the obtained network is composed essentially by a set of vertices (representing the scenarios) connected by edges if and only if the correlation of those vertices is equal to or higher than a desired value (threshold). On the other hand, any suitable algorithm can be used to extract a set of communities out of the network using a modularity function as quality metric (Xu et al., 2007). Several community detection methods are available in the literature including Girvan-Newman, Tyler-Wilkinson and Louvain algorithms among others (Javed et al, 2018). Individually, Graph Theory and community detection methods have been applied to different data management applications such as the worldwide web, collaboration networks and biological systems (Newman and Girvan, 2004). However, to the best authors' knowledge, they have never been used together in a scenario reduction framework.

The capabilities of the proposed approach were tested by comparing its performance against the ones obtained by the traditional SCENRED and OSCAR approaches, while using the two-stage MILP bio-based energy management problem described in Medina-González et al., (2017) as a comparison test bed.

2. Solution strategy

The proposed approach consists of four parts: Parameter initialisation/declaration, network construction, cluster generation and centroid identification. A detailed explanation of these elements is presented.

2.1. Parameter initialisation.

In this step, a sufficiently large set of scenarios is defined to represent the process's uncertainties. In order to create an interconnected structure out of this data set (i.e. a network), the pairwise relationship between vertices are modelled and collected in an adjacency matrix ($A_{i,j}$) using any suitable correlation metric. Finally, in order to reduce the network complexity, the connections quality might be assess using a tolerance value (threshold that lies between 0 and 1).

2.2. Network construction.

Using the above defined parameters, the quality of the network connectivity ($A_{i,j}$) is adjusted, by replacing any connectivity values that do not satisfy the minimum threshold condition by zero (non-connection state), hence obtaining a strongly connected network. Notice that even though the threshold definition is independent of the correlation value, it affects the network density, which might lead to an impractical solution. For example, low threshold values lead to "perfectly connected" networks and therefore the whole system is considered as a unique cluster, while large threshold values produce nodes that are considered as isolated clusters. Thus, a systematic threshold definition rule is vital.

2.3. Cluster/community generation.

This part of the algorithm aims to identify the communities that lead to the most efficient network division. Essentially, a community is a local area/group of vertices

densely connected between them and loosely (or not at all) connected with other groups. In order to assess the quality of these communities, the modularity metric (Q) can be used which represents the number of edges that fall within communities/modules minus the expected number of edges that should fall into communities in an equivalent network configuration with edges being placed randomly (Newman and Girvan, 2004). The general formulation of the community detection problem is presented in Eq. (1), where the partition that yields the maximum modularity for a target network is sought.

$$Q = \sum_{m} \left[\frac{L_m}{L} - \left(\frac{D_m}{2L} \right)^2 \right] \tag{1}$$

From Eq. (1), the first term $\frac{L_m}{L}$ represents the ratio of edges that fall into module m in relation with the total number of links in the network (L), while the second one represents the expected fraction of links that would fall in module m if they were randomly generated. Particularly, D_m is the total random degree in each module m and the difference in these terms indicate how "non-random" cluster m is.

2.4. Centroid identification.

For each one of the obtained communities/clusters, their centroids are identified by selecting the vertex with the highest centrality criteria value. For simplicity, three different criteria are suggested, however more options might be found in the literature:

- *Degree*. Represents the number of connections of each vertex.
- *Betweeness*. Accounts for the paths passing through a vertex.
- *Closeness*. Distance of a vertex against all the others within a cluster.

The general SCANCODE algorithm is presented next:

0. Initialise a defined amount of scenarios that represent the process uncertainties as well as a threshold value ($Th = [0, 1]$) in order to establish the connections between vertices.
   a. Generate the adjacency matrix (A_{ij}) by calculating the correlation between each pair of vertices.
1. Let the value in A_{ij} be zero if the correlation value is below the defined threshold ($A_{ij} < Th$) and create the network by using the new data in the adjacency matrix.
2. Identify the community arrangement that maximises the modularity metric using any available algorithm/method.
3. For each cluster, identify the scenario with the highest value in the desired centrality metric.

3. Illustrative example

Due to space limitations and since the scope of the paper is to describe and test the proposed approach, the mathematical formulation of the case study is omitted and the interested readers are referred to Medina-González et al., (2017). However, for

continuity purposes a brief description of the case study is included. The problem was formulated as a MILP problem that maximises the economic benefit of a biomass-based energy SC system through the management of its design and operations. The model considers nine districts (*fc*), and all of them can be simultaneously biomass suppliers, energy generation and market sites. 40 different biomass states (*s*), six available technologies (*tec*) and 79 activities (*act*) were considered across a monthly discretization (*t*) of a year horizon. Cassava Rhizome (CR) was used as a raw material for energy production, while its availability and the total energy demand (*As(s,fc,t)* and *dem(s,fc,t)* respectively) were considered as uncertainty sources. A total of 153 uncertain parameters are considered since *As* and *dem* are defined only for the first and last raw material state respectively while for *As*, only five time periods are considered (length of the CR production season). Without loss of generality, 100 equiprobable scenarios were randomly generated for each uncertain parameter using a normal distribution with the average values presented in Table 1 and a 30% standard deviation.

Table.1. Mean values for uncertainty conditions at each district.

District	fc_1	fc_2	fc_3	fc_4	fc_5	fc_6	fc_7	fc_8	fc_9
Demand (MJ)	1942	4055	15250	19363	2684	3198	913	3884	4169
Availability (kg)	12.75	24.38	81.1	122.18	16.22	22.07	5.27	21.08	28.15

4. Results and discussion

Using the Pearson correlation and three thresholds values (*0.91; 0.92 and 0.93*) the adjacency matrices and the associated networks were constructed as described in section 2. Then, the Louvain algorithm was used to detect the communities within each network. Essentially, Louvain is a two-step algorithm that maximises the modularity metric, in which for a given network, the first step assigns nodes into clusters only if that increases the modularity value, whereas the second step creates a new network where each node represents a cluster from the previous step. These two steps are iterated until no further modularity improvement is possible (Blondel et al., 2008). After applying the Louvain algorithm for this problem, a total of 9, 13 and 31 communities were identified for each threshold respectively. Analysing the obtained networks (Figure 1), it is evident that the density is inversely proportional to the threshold value. Particularly, the larger the threshold values, the more isolated scenario clusters are produced, whereas for small values a very densely connected network is obtained which compromises the definition of cluster centroids. Such a behaviour confirms the undesirable properties in the reduced set of scenarios for the extreme threshold points and stresses the need for a metric that represents a balanced rate between number of clusters and network density.

For the three generated networks, their centroids were identified using *degree* as centrality metric. The probability of each cluster centroid is represented by the aggregation of the original probabilities of all the elements within their respective cluster, while the original uncertainty parameters information was kept. Finally, the MILP problem was implemented in GAMS 24.7 and solved for each one of the reduced sets of scenarios using CEPLEX 12.6.3 to a relative optimality gap of 5%.
Figure 1. Networks and clusters for different thresholds values.

In order to illustrate the effectiveness of the proposed approach, SCENRED and OSCAR (the two most used scenario reduction approaches) were used as a comparison reference. The resulting set of scenarios from the three methods represent the input data to solve the MILP problem. Table 2 shows the optimal results for each case.

Table.2. Results for the optimisation of MILP problem.

	Size/modules(m)	ExpProfit (€)	PostProcess Profit (€)	Gap (%)	CPUtime (s)
FULL-SPACE	100	345,198	---	--	131,607
Th= 0.91			*Modularity (Q=0.205214)*		
OSCAR	9	346,642	345,231	0.4085	1,101
SCENRED	9	348,304	342,374	1.7322	1,193
SCANCODE	9	357,655	345,500	3.5183	1,137
Th= 0.92			*Modularity (Q=0.32264)*		
OSCAR	13	343,475	345,115	0.4752	1,459
SCENRED	13	349,373	345,500	1.1211	1,512
SCANCODE	13	348,142	345,115	0.8771	1,495
Th= 0.93			*Modularity (Q=0.43473)*		
OSCAR	31	346,051	345,115	0.2711	7,765
SCENRED	31	348,562	345,115	0.9987	7,812
SCANCODE	31	344,156	343,545	0.1779	7,818

Table 2, displays a significant dispersion between the expected performances (*ExpProfit*) for the reduced set of scenarios and the full-space (no reduction), since the scenarios in the reduced set may be different for each cluster and strategy. Therefore, a post-process analysis was performed in order to promote a fair comparison (*PostProcessProfit*). To derive those values, the first stage decisions obtained after optimising the MILP problem using the reduced set, were fixed for the full-space problem. The gap between the expected value and its associated post-process outcome was also calculated, confirming that the three approaches approximate the profit (variation <4%) and

proving that SCANCODE is a feasible alternative to the current scenario reduction approaches. Despite this small gap, the approximation error for SCENRED and SCANCODE increases as a function of the reduction degree while in the case of OSCAR, a relatively steady gap was obtained despite the level of reduction. Such a behaviour is due to the consideration of both, the original uncertain parameters and their effect over the expected performance. Nonetheless, obtaining such information implies a pre-processing task, which hinders its application to large-scale problems. In any case, further research seeking the reduction of the approximation gap in SCANCODE is crucial for its further application in real-life problems with large sized scenario sets.

5. Conclusions

This paper proposes a novel scenario reduction/aggregation framework that integrates Graph Theory and community detection methods. Numerical results demonstrate that the proposed strategy is as efficient as other well-studied techniques for identifying a reduced and representative set of scenarios. Additionally, the well-structured cluster definition used in the proposed approach justifies its potential applications to large-scale networks considering many uncertainty scenarios (of several orders of magnitude). Despite the efficiency of SCANCODE, some opportunity areas have been identified that will improve its performance. Particularly, further work is focused on combining this strategy with other data-management techniques to identify the most efficient relation between the number of clusters and the quality of the uncertainty space.

Abstract

Available treatment technologies for wastewater are diversifying as the industry is undergoing a paradigm shift from considering wastewater as a waste to treat to an increasingly valuable source for energy production and resource recovery. With the purpose of addressing the problem of determining optimal plant network for wastewater treatment plants, we develop a new decision support tool (SPDLab) relying on a novel simulation optimization based process synthesis framework and a library of rigorous process models. The capabilities of SPDLab are demonstrated with a case study for designing an energy surplus WWTP. The Benchmark Simulation Model No. 2 (BSM2) (Gernaey et al., 2014) plant layout is populated with additional options for primary treatment technologies, such as a rotating belt filter with or without polymer addition, and mainline treatment options including also fixed film activated sludge (IFAS) technology. A side stream treatment with partial nitrification-Anammox process is also included in the superstructure. Results obtained show that the combination of efficient carbon recovery with main stream Anammox and anaerobic digester produces the most net energy among the investigated alternatives.

Keywords: Process synthesis and design, wastewater treatment plant design, simulation-based optimization, Monte Carlo simulation.

1. Introduction

The design of domestic wastewater treatment plants (WWTPs) has seen an unprecedented shift since the inception of the widely used activated sludge process. The priority for a design engineer was mainly to ensure effective removal of organic pollutants from wastewater. However, with the ever growing demands on the WWTP, such as population growth leading to increased pollutant loads, stringent environmental laws, demand for energy neutrality and contributing to circular economy, the layout of WWTP looks more gigantic than ever. The WWTP design intricacy has been further exacerbated by the remarkable innovation and availability of novel treatment technology (both matured and emerging) in the market. Therefore, given the steadily growing number of competing treatment technologies and ever-ambitious performance goals, the need for the use of simulation, optimization, and systematic process synthesis methodologies for engineering design of WWTPs is becoming more pronounced among design professionals.

Accurate modelling of highly complex biological processes in WWTPs require use of rigorous (non-linear) bio-process models such as ASM1 (Henze et al., 2006), ADM1 (Batstone et al., 2002), etc. Such models remain too complex for use in traditional process synthesis approaches such as superstructure optimization using mathematical programming due to the highly nonlinear process equations (Chen et al., 2018). The main

contribution of this paper is the development and application of a new simulation optimization-based process synthesis approach to explore more rigorously alternative WWTP networks using a model library of high-fidelity mechanistic bio-process models. For this purpose, a decision support tool for sustainable process synthesis and design, SPDLab, has been developed to assist design professionals with the implemented methodology. SPDLab provides computational tools for interfacing with complex bio-process models implemented in a Simulink environment and searches for an optimal plant layout configuration for the given design objective. The process synthesis methodology consists of three major steps. First, a superstructure containing all different design configurations is created using combinatorial synthesis and expert knowledge approach (Bozkurt et al., 2015). Second, design degrees of freedoms of each configuration are investigated with Monte Carlo simulations and promising configurations are selected for the third step, which imposes user-defined effluent quality constraints to rank and select optimal plant layouts with preliminary design.

2. Methodology

Simulation is an established tool for evaluating and predicting the performance of complex engineering systems. Stochastic simulation optimization, also referred to as simulation optimization, uses simulation to find values of decision variables that will optimize the system's key performance indicators (KPI) of interest, which are obtained by performing stochastic simulations like Monte Carlo simulations. Promoted by recent advancements in computing power, simulation optimization allows one to work with arbitrarily complex simulation models, eliminating the need to keep model complexity to mathematically tractable forms as required by deterministic optimization frameworks (Pasupathy et al., 2011). A step-by-step overview of the proposed simulation optimization based process synthesis and design methodology is shown in Table 1.

Table 1: Overview of proposed methodology for early stage design of WWTPs.

Step 1	Generation of a superstructure containing all the different plant layouts using combinatorial synthesis and expert knowledge
Step 2	Design space exploration of each alternative plant layout with Monte Carlo simulations
Step 3	Ranking and selection of optimal plant layouts

2.1. Step 1: Superstructure generation

A superstructure is postulated to represent all practical plant layouts, which can be selected as an alternative plant design by the decision support tool, using combinatorial synthesis together with expert knowledge. Combinatorial synthesis allows exhaustive exploration of all different combinations of technologies whereas expert knowledge is used to exclude layouts with an infeasible sequence of treatment units from further investigation.

2.2. Step 2: Design space exploration

For each treatment technology, there exist several design degrees of freedom, such as the volume ratio of aerobic and anaerobic tanks in an activated sludge system, which needs to be selected by the designer and significantly affects the plant performance. Therefore, to achieve desired effluent quality levels, one often needs to explore these design degrees of freedom for every different technology. For this purpose, design-related parameters of each technology included in a given layout are gathered in a global parameter space, i.e. the design space, which is then sampled using a uniform space filling sampling design such as Latin hypercube sampling (LHS). The resulting design space is explored with Monte Carlo simulations to identify promising plant layouts which will provide optimized performance results by also satisfying imposed effluent constraints.

2.3. Step 3: Ranking and selection (R&S)

Among the methods developed for solving simulation-based optimization problems are ranking and selection (R&S), black-box search methods, surrogate model based methods, and sample path approximation, etc. For a detailed review of these methods, the work of Xu et al. (2015) can be consulted. For problems with a finite number of solutions in the search space, such as optimal plant layout among the alternatives contained in the superstructure, R&S procedures can be directly applied to find the most promising plant layout for the given design objective. To further assist the decision-maker in identifying promising layouts, results of Monte Carlo simulations are exposed to the performance constraints to filter out infeasible solutions and then ranked according to the design objective.

3. A decision support tool for process design of WWTPs: SPDLab

3.1. The model library and the user interface

The SPDLab model library (shown in Figure 1) encompasses models representing both conventional and emerging treatment technologies. The primary clarifier works based on gravity settling and is modelled as presented in Gernaey et al. (2014), whereas the rotating belt filter, which is an emerging technology, works based on cake filtration and sieving and is modelled as presented in Boiocchi et al. (2018), and Behera et al. (2018).
Figure 1: The model library of SPDLab is shown for different treatment steps in WWTPs.

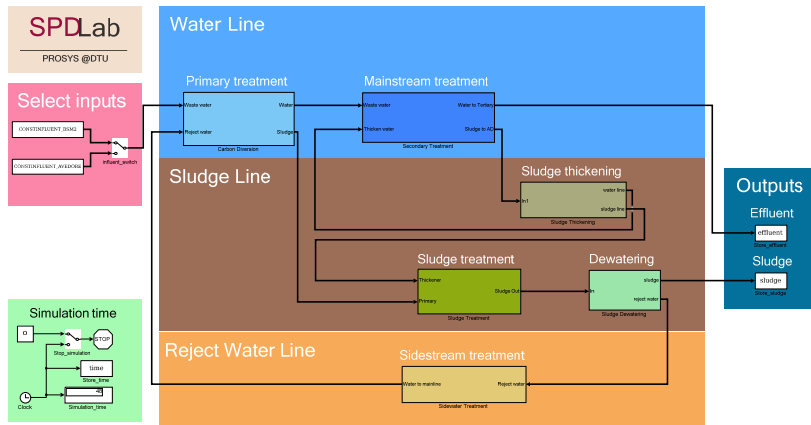
For mainstream nutrient removal the Modified Ludzack-Ettinger (MLE) system is used based on the ASM1 principle (Gernaey et al., 2014). Anammox based nutrient removal for both mainstream and side stream is modelled using a one-dimensional biofilm concept. The integrated fixed-film activated sludge (IFAS) system is a retrofitted version of the MLE system, where the aerobic tanks are filled with carrier in order to enhance the nitrogen loading rate. For sludge treatment, the anaerobic digestion (AD) system is modeled using the ADM1 (Batstone et al., 2002). The sludge thickening and dewatering are modeled using the approach of Gernaey et al., (2014). To design each unit, several widely used design parameters such as sludge retention time (SRT), hydraulic retention time (HRT), surface over flow rate (SOR), nitrogen removal rate (NRR), recycle ratio (RR), carrier filling etc. are used while sampling the design space using LHS. Figure 2 shows the SPDLab's user interface, which was developed in the Simulink modelling environment.


Figure 2: The main user interface of the decision support tool

3.2. A case study: Designing an energy surplus WWTP

The main objective of this case study is to illustrate the proposed methodology outlined in Table 1. To this end, a scenario is considered where the primary objective is to build an energy surplus WWTP for a benchmark municipal wastewater stream (Gernaey et al., 2014) with a plant capacity of 100,000 PE. Figure 3 depicts the synthesis problem along with the design flows and the effluent quality limits imposed in the case study.
Figure 3: Design flows and performance goals considered in the case study.

4. Results and discussion

Following the proposed methodology, a total of 80 different plant layouts were generated in step 1 with a combinatorial synthesis approach, and step 2 explored automatically the generated design space of each layout with Monte Carlo simulations using a LHS of size 100. Results are shown for net energy production of feasible designs in Figure 4. Furthermore, the solutions are screened and ranked (see Figure 5) by enforcing the effluent quality limits (COD < 100 mg/L, TN < 10 mg/L and NH_4^+ < 1 mg/L) and the plant KPIs such as methane gas production, aeration energy demand and sludge production, etc., are calculated for each design. Besides, the net energy is calculated by subtracting the aeration energy consumption from the energy produced via the methane gas. The energy modelling at this stage is kept intentionally simple as the primary objective of this work is to assess the methodology.
Figure 4: Comparing net-energy production of all potential plant layouts.

The top five feasible designs selected by the tool for building an energy surplus WWTP are shown in Table 2, which picks main stream Anammox as an efficient carbon recovery technology together with an AD unit. This combination also agrees well with the available process knowledge, i.e., increasing biogas production by diverting more carbon to the AD unit and then treating the low COD/TN load wastewater with Anammox technology. In this way the aeration energy demand can be reduced significantly as the Anammox process needs significantly less oxygen compared to the conventional activated sludge process (Morales et al., 2015).

Table 2: Top 5 promising plant layouts selected by SPDLab for energy surplus WWTP design.

Selected Configuration	Aeration Energy (kWh/d)	Methane Production (kWh/d)	Net Energy (kWh/d)
PC – Anx_carrier – Thickener – AD – Dewater	3662	19452	15790
RBF w/ polymer – Anx_carrier – Thickener – AD – Dewater	3795	18987	15192
PC – Anx_granule – Thickener – AD – Dewater	3721	18109	14388
PC – Anx_carrier – Thickener – AD – Dewater – Anx_granule_side	3546	17777	14231
PC – Anx_granule – Thickener – AD – Dewater – Anx_granule_side	3880	18018	14138

5. Conclusions

This paper presented a new methodology and a tool for process synthesis and preliminary design of WWTP networks using simulation optimization. The tool is targeted at exploring alternative WWTP designs for a given wastewater stream and design objective/constraints. The case study results demonstrate that SPDLab can provide decision makers with valuable insights during the early-stage design of WWTP networks with its rigorous search and advanced visualization capabilities for identifying promising

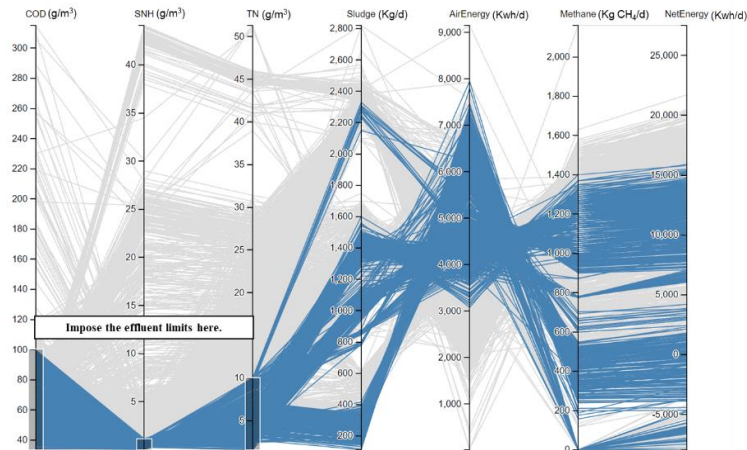
plant layout configurations. Furthermore, development of a fully-fledged commercial decision support tool allowing also for multi-objective design optimization, extension of the model library to newly arising treatment technologies, and integration of other early stage design tools, such as sustainability analysis, are planned as future work.


Figure 5: Comparison of all feasible designs after imposing effluent quality constraints.

Abstract

This work focuses on the optimization of a biogas upgrading process consisting of three CO_2-permeable membranes. A 1-D membrane model, capable of handling multi-component gas mixtures, is formulated as a set of differential algebraic equations and validated against experimental data. The model is used within a sequential algorithm to solve the simulation of the three-stage system. The key design variables (i.e., areas of each membrane module, stream pressures and recycle mass flow rates) are optimized using the recently developed MO-MCS algorithm, a derivative-free optimizer suitable for multi-objective problems. Results show that the Pareto-optimal solutions have a total plant cost in the range 720-770 €/(Nm^3/h of feed) and an energy efficiency of 87.7-89.2%.

Keywords: Biogas upgrading, membrane separation, black-box optimization, multi-objective optimization

1. Introduction

Biomethane is produced through the purification of biogas, a mixture of CH_4, CO_2 and other contaminants (e.g., H_2S, NH_3 and siloxanes) which is originated by the anaerobic digestion of biomass. Such biogas purification process is typically called "biogas upgrading". Among the available upgrading technologies (e.g. water scrubbing, amines, PSA), CO_2-permeable membranes appear as a promising option, especially for medium-low size plants (250-500 Nm^3_{CH4}/h), owing to their good separation efficiency, modularity, straightforward operation and maintenance, and low installation costs. However, since a single membrane stage cannot achieve high purity and recovery of the desired product (CH_4), it is advantageous to adopt integrated configurations which combine multiple modules placed in series and/or parallel, entailing recycle streams. Due to the presence of multiple design variables, optimization-based design approaches have been adopted by several authors. For example, Scholz et al. (2015) proposed a structural-optimization approach employing a flexible superstructure of possible process layouts. The modelling and optimization problems are solved together as a single MINLP, according to the equation oriented process optimization approach. Also, the choice of the optimal membrane material according to an economic criterion is tackled with the same approach. Gabrielli et al. (2017) adopt the black-box approach, combining a genetic algorithm with a 1-D model of the membrane modules, to minimize the compression energy and the required membrane area by selecting the optimal process layout.

This work investigates the numerical optimization of the most promising integrated membrane-based configuration found by Scholz et al. (2015) for biogas upgrading. First, the 1-D model proposed by Gabrielli et al. (2017) for co-current hollow-fiber membranes is extended to handle multi-component gas mixtures. Then, the model is validated with the experimental data available in Pan et al. (1986) and integrated into a modular Matlab algorithm to solve the overall process simulation. Finally, the key design variables (i.e., areas of each membrane module, stream pressures and recycle mass flow rates) are optimized using the recently developed MO-MCS algorithm (Capra et al., 2018), a model-based derivative-free optimizer for multi-objective problems.

2. Process description

The process configuration considered in this work is shown in Figure 1. A gas dryer and a bed of activated carbon, not shown in the figure, are placed upstream of the membrane system to remove H_2O and H_2S (and other contaminants) respectively. Then, sulphur-free dried biogas (stream 0) is mixed at atmospheric pressure with the recycle stream (stream 6), pressurized by the first compressor, and fed to the first membrane unit (stage A). The retentate flow (stream 2) can be further compressed (compressor 2, included in case Pressure$_{stage B}$> Pressure$_{stage A}$) and sent to the second membrane unit (stage B). Since the permeate flow of the first stage (flow 1P) may include a certain amount of CH_4, it is advantageous to perform a selective recycle including a third membrane unit (stage C) downstream of it. The permeate of stage C is expected to be nearly pure CO_2 with a very low content of CH_4, while the retentate stream (stream 5) can be mixed with stream 2P and recycled back to the process inlet (stream 6). According to Scholz et al. (2015), with the proper selection of the membrane material, this configuration combines high purity of the produced biomethane (96%$_{mol}$), high recovery of CH_4 (> 95%) and a good balance between energy consumption and investment cost.
Figure 1. Scheme of the integrated membrane configuration considered in this study.

As far as the membrane material is concerned, we selected a dense polymer, specifically polyaramid (PA), on the basis of the results found by Scholz et al. (2015) and Havas in (2017). According to Scholz et al. (2015), this commercially available material can be assembled in hollow-fibers modules featuring a CO_2 permeance of 200 gpu and a CO_2/CH_4 selectivity of 20.

The main process data (dry biogas composition and pressure) and specifications (grid injection requirements and membrane material properties) are reported in Table 1 and can be considered representative of an anaerobic digestion plant fed with chicken-manure.

Table 1. Assumptions and specifications for the process.

Biogas flow rate	11.75	mol/s
Dry biogas CH_4 content	56%	$\%_{mol}$
Dry biogas CO_2 content	44%	$\%_{mol}$
Biogas feed pressure	1	bar
Grid injection pressure	13	bar
Max biomethane oxygen content	< 0.6%	$\%_{mol}$
Max biomethane CO_2 content	< 3%	$\%_{mol}$
Biomethane HHV range	34.95 ÷ 45.28	MJ/Sm^3
Wobbe index range	47.31 ÷ 52.33	MJ/Sm^3
Relative density range	0.5548 ÷ 0.8	-
Membrane CO_2 permeance (polyaramide, Havas and Lin, 2017)	$6.8 \cdot 10^{-8}$	$mol/(s \cdot Pa \cdot m^2)$
Membrane CO_2/CH_4 selectivity (polyaramide, Havas and Lin, 2017)	20	-

3. Problem statement

The objective of this work is to identify the set of Pareto-optimal solutions which exhibit the minimum total plant cost and maximum process efficiency. More in detail, the optimization problem can be stated as follows: "Given the biogas specifications and the membrane material properties, determine the set of Pareto-optimal design solutions which minimize the total upgrading plant cost (TPC) while maximizing the primary energy efficiency η_{PE} (chemical power of biomethane/total primary energy consumed by the process) and meet the specifications on the produced biomethane (minimum CH₄ fraction, allowed ranges of HHV, Wobbe index, etc)". The primary energy efficiency is computed as the ratio between the primary energy contained in biomethane (given by the product between mass flow rate of biomethane and its LHV) and the primary energy input of the process (i.e. the primary energy contained in biogas plus the equivalent primary energy consumed by the upgrading process to operate compressors and other auxiliaries, etc).

The independent optimization variables of the selected process configuration are the areas of the three modules and the pressure ratios of the two compressors and the pressure of the permeate side of stage A membrane. Given the limited amount of independent optimization variables, the black-box approach has been selected to tackle the multi-objective optimization problem. MO-MCS, a recently developed multi-objective model-based derivative-free algorithm (Capra et al., 2018), optimizes the independent design variables and, for each sampled solution, the process simulation is executed and the total plant cost is assessed.

4. Membrane module model

We propose an extension for multi-component gas mixtures of the 1-D model originally formulated by Gabrielli et al. (2017) for the membrane separation of binary gas mixtures. The peculiarity of such model is the use of dimensionless parameters and variables which attenuate the numerical problems arising in the solution of the set of differential equations.

$$\frac{d\Psi}{d\zeta} = \frac{m_1}{y_1'}(x_1 - \beta y_1') \tag{1}$$

$$\frac{dx_i}{d\zeta} = \frac{m_i}{\Psi y_i'}(x_i - y_i')(x_i - \beta y_i') \qquad \forall i = 1, \dots, C-1 \tag{2}$$

$$0 = y_1'(x_j - \beta y_j') - \alpha_{1j} y_j'(x_1 - \beta y_1') \qquad \forall j = 2, \dots, C \tag{3}$$

$$0 = \sum_{i=1}^{C} y_i' - 1 \tag{4}$$

$$\Psi|_{\zeta=0} = 1 \tag{5}$$

$$x_i|_{\zeta=0} = x_i^{FEED} \qquad \forall i = 1, \dots, C \tag{6}$$

As described in Gabrielli et al. (2016), ζ is the non-dimensional variable representing the axial coordinate, $\Psi(\zeta)$ is the non-dimensional total molar flow rate on the retentate side (the ratio between the flow rate at point ζ and the one in the feed), $x_i(\zeta)$ is the molar fraction of the permeate bulk flow, and y_i' is the molar fraction at the membrane interface. The parameter β is the ratio between the permeate and retentate pressure, α_{1j} is the membrane selectivity of the j-th component with respect to the most permeable component (CO_2 in this application). The parameter m_i is defined as:

$$m_i = \frac{Q_i p^F A}{\delta U^F} \tag{8}$$

Where Q_i denotes the permeability of the i-th gas species, p^F is the feed pressure, A is the membrane area, δ is the membrane thickness and U^F is the total feed molar flow rate. Eq. (1) is the balance of total gas moles on the retentate side and it relates the variation of the total dimensionless flow on the retentate side Ψ with the total molar flux across the membrane. Eq. (2) relates the axial variation of concentration of species on the permeate side with the molar flux across the membrane. Eq. (3) expresses the membrane fluxes of the different gas species with respect with that of CO_2 ($i = 1$). Eq. (4) imposes that the sum of the molar fractions on the membrane interface is equal to one, while Eq. (5) and (6) are boundary conditions. Eq. (1-6) define a set of Differential Algebraic Equations (DAE) which is solved in Matlab® v. 2018-a with the *ode15s* algorithm.
Figure 2. Validation of the module model with the experimental data of Pan et al. (1986).

The permeability of the various species have been validated against the experimental data provided by Pan et al. (1986) for stage cuts of the membrane comprised between 0.4 and 0.6. Figure 2 shows that the model fits well the experimental data, with maximum discrepancies in the permeate molar fractions limited to 1%.

5. Process simulation and optimization

The process flowsheet is solved using a sequential-modular approach with tearing. The optimal precedence ordering consists in calculating the units in this sequence: inlet gas mixer (0+6), first compressor, membrane stage A, second compressor, membrane stage B and stage C, valve and the mixer (5+2P). It is important to note that the system of DAE described in Section 4 is solved for each membrane module. The recycle stream 6 has been selected for tearing and the tear stream properties (i.e., molar flow rates of the gas species) is updated with the direct substitution. All the membrane stages operate at a constant temperature of 40 °C and any enthalpy change related to the Joule-Thomson effect or non-ideal mixing has been neglected with limited loss of accuracy, as suggested by the literature. Test cases have shown that convergence of the tear stream is reached in a few iterations (10-30, corresponding to 15-40 s of computational time) not justifying the adoption of more sophisticated algorithms (because the maximum eigenvalue of the Jacobian of the overall simulation function is in the range 0.2-0.3). After the process simulation has reached convergence, the total plant cost (overall capital expenditure) and the primary energy efficiency are computed considering literature data for the cost of the units (for the membranes we considered a lumped-cost of the equipment of 50 €/m^2) and the performance of small size reciprocating compressors.

It is worth noting that the output of the process simulation (i.e., TPC and η_{PE}) are in general noisy and non-smooth due to the round-off errors and convergence tolerances of the algorithms which are called to solve the DAE and the process simulation. Moreover, the problem may feature multiple minima. For these reasons, gradient-based optimization algorithms are not suitable and it is necessary to adopt global-search, black-box algorithms. Recently, Capra et al. (2018) have proposed a model-based, derivative-free, algorithm which uses a local model of the black-box function so as to save computationally expensive evaluations. The algorithm is an extension of the MCS algorithm (Huyer & Neumaier 1999) to the multi-objective case. It allows for well-spaced Pareto fronts thanks to the integration of the Normalized Normal Constraint method (Messac et al. 2003). In MO-MCS the search for the Pareto optimal points is assigned to the available workers (cores) so as to reach the maximum possible parallelization of computations.

6. Results

The process optimization has been performed considering three different limits on the CH$_4$ slip (fraction of CH$_4$ which is lost to the process and goes together with the vented CO$_2$): no slip limit, 2% and 1%. The three Pareto fronts returned by MO-MCS are shown in Figure 3. The required computational time to obtain a Pareto front is 3 hours on a workstation with Intel® Core™ i7-3770 CPU @ 3.40 GHz and 4 cores. Their optimality have been double-checked repeating the optimization with different setup of MO-MCS and performing sensitivity analyses. The biomethane specification constraints are active for all Pareto-optimal points. Figure 3 indicates that setting a limit of 2% on the CH$_4$ slip does not penalize the achievable efficiency and it does not lead to a considerable increase of TPC. Instead, 1% CH$_4$ slip calls for 40% higher recycle flow rates causing an

appreciable increase of compressors costs and power consumption. For the case with slip < 2%, the total membrane area is approximately 1500 m^2 for the maximum efficiency design and 950 m^2 for the minimum total plant cost. Another interesting result is that no Pareto-optimal solution employs the intermediate compressor (compressor 2).
Figure 3. Pareto fronts returned by MO-MCS for three different limits of CH$_4$ slip.

7. Conclusions

The proposed 1-D model is suitable for multi-component gas mixtures and it can be efficiently adopted in sequential process simulation codes as well as derivative-free optimization algorithms, such as MO-MCS. The application to a biogas upgrading process with increasingly tight specifications has shown that the proposed approach is able to return very good approximations of the Pareto-front within a reasonable computational time. Optimization results indicate that the considered membrane process can achieve primary energy efficiency figures in the range 87.7%-89.2% with specific total plant costs ranging from 720-770 €/(Nm^3/h of feed).

A Fuzzy Analytic Hierarchy Process (FAHP) Approach to Multi-Objective Optimisation of Oil Palm Value Chains

John Frederick Tapia, Sheila Samsatli[*]

Department of Chemical Engineering, University of Bath, Claverton Down, Bath, United Kingdom, BA2 7AY

[*]*S.M.C.Samsatli@bath.ac.uk*

Abstract

The economic potential of palm oil and palm-based biomass can be realised through oil palm's very high vegetable oil yield and the wide variety of high-value products that can be derived from it. This potential can be maximised through streamlined oil palm value chains (OPVCs) which involve considering different environmental impacts alongside the economic benefits. Multi-objective optimisation aids in the development of a strong value chain by generating valuable planning insights based on the most appropriate set of impact weights. However, a typical approach in assigning impact weights is arbitrary or based on rough estimates. This study develops a decision framework to support planning and designing OPVCs. The decision framework is a novel approach of integrating a fuzzy analytic hierarchy process (FAHP) to the multi-objective optimisation of OPVCs. This enables descriptive judgments to be converted into numerical weights. An optimal design is then generated based on these weights. A case study based on Malaysian palm oil biomass scenario is presented to illustrate the decision tool. This could help develop better policies in the future through a systematic approach in dealing with sustainability issues in the palm oil industry.

Keywords: Value chain modelling, fuzzy analytic hierarchy process, palm oil biomass, environment-food-energy-water (EFEW) nexus.

1. Introduction

Palm oil is regarded as the world's main source of vegetable oil due to its excellent yield and low land requirement (Corley, 2003). The current status of vegetable oil industry is such that the replacement of palm oil is economically infeasible as alternative crops would likely require more land to produce the same yield as oil palm. However, several issues arise with palm oil plantations such as negative impacts of land use change, biodiversity losses and waste generation. In a typical palm oil mill, around four tons of waste materials are generated for every ton of palm oil produced. Bio-conversion technologies can transform these wastes into high-value products such as energy, fuels and other valuable products. To maximize the benefits from these transformations, a strong value chain is required. It is formed by a network of conversion technologies, logistical infrastructures and associated activities to convert low-value waste materials into high-value products (Jarvis and Samsatli, 2018). The development of a strong value chain requires rigorous planning and design considering the presence of multiple sustainability factors and the guidance of expert

recommendations. In this study, a systematic decision framework based on multi-objective optimisation and multi-criteria decision analysis (MCDA) approaches are developed to address these barriers in planning and design of oil palm value chains (OPVCs).

Recent PSE works on palm oil and palm-based systems presented methods to aid planning and designing systems such as integrated biorefineries and supply chains (Ng and Ng, 2013). Optimisation models on large-scale palm oil systems have been developed considering plantation management (Foong et al., 2019) and EFB valorisation (Abdulrazik et al., 2017). These models addressed specific problems focusing on maximising economic gains. None of the recent and relevant studies focused on large-scale palm oil systems addressed multi-objective and multi-criteria decision making simultaneously. Thus, in this paper a fuzzy analytic hierarchy process (FAHP) approach is integrated with a multi-objective mixed integer linear program (MOMILP) for OPVCs considering environmental and economic impacts weighted through expert judgement. Using FAHP to quantify verbal judgements as numerical weights has been demonstrated in a wide range of applications in sustainable technologies (Promentilla et al., 2018) and in multi-objective molecular design (Ooi et al., 2017). The rest of this paper is organised as follows. Section 2 gives a brief description of the decision framework and the models used are described in Section 3. Then, the framework is illustrated using the Malaysian palm oil industry case with results given in Section 4. Finally, conclusions and future works are given in Section 5.

2. Decision Framework

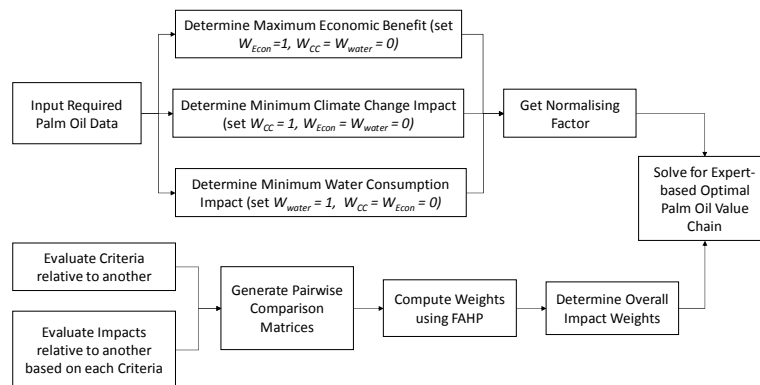
The FAHP approach to multi-objective optimisation of OPVCs is summarised in Figure 1. First, the optimal solution of the value chain based on the best economic potential, the minimum climate change impact and the minimum water impact are determined. This is to identify the factor to normalise the objectives when aggregated into a single objective. Then, the weights of each impact are obtained using FAHP approach based on four criteria, namely, short-term benefit, long-term benefit, policy development and social acceptance. Finally, an optimal solution based on the weights generated by FAHP is obtained.


Figure 1: Decision framework for multi-objective optimization of OPVCs with FAHP. The weights of each impact objective are determined based on a decision structure with four criteria.

3. Optimisation Models

3.1. Multi-Objective Oil Palm Value Chains

The MOMILP model is summarized below with an aggregated objective function subject to the following key constraints:

$$\min \sum_{i,p} W_i (NF_i)(IU_{i,p} + FIP_{i,p}^{OM} + VIP_{i,p}^{OM} + IP_{i,p}^{Cap} + IT_{i,p}^{OM} + II_{i,p}^{OM}) \tag{1}$$

$$RU_{r,z,s,y,p} + RP_{r,z,s,y,p} + RT_{r,z,s,y,p} + RI_{r,z,s,y,p} \geq D_{r,z,s,y,p}(D_r^{\min}) \tag{2}$$

$$RU_{b,z,s,y,p} \leq AE_{b,z}YFE_p Y_{b,z,s,y} + Y_{b,z,s,y} \sum_{p'} YF_{p,p'}AI_{b,z,p'} \tag{3}$$

$$RP_{r,z,s,y,p} = \sum_c (PROD_{c,z,s,y,p})(CONV_{r,c,p}) \tag{4}$$

$$RT_{r,z,s,y,p} = \sum_{t,z'} TR_{t,r,z,z',s,y,p} - \sum_{t,z'} TR_{t,r,z',z,s,y,p} \tag{5}$$

Eq. (1) defines the weighted objective function, including impacts from utilization, production, transportation and import of resources. Eq. (2) ensures the satisfaction of demands by balancing net resource utilisation, production, transportation and import. The constraint on the available oil palm biomass (Eq. (3)) is based on the area available for plantation, the biomass yield and the expansion of land at each time period. Resources are produced through conversion technologies with rates and conversion factors given in Eq. (4). Finally, the net rate of transportation of resources is denoted by Eq. (5). For brevity, only these main constraints in the model are shown. More details on how the impacts are defined and the other constraints in the model can be found in related works (Samsatli and Samsatli, 2018; Samsatli et al., 2015).

3.2. Fuzzy Analytic Hierarchy Process (FAHP)

The outline of the procedure to determine the impact weights to be used for the multi-objective optimization model is as follows:

1. The decision structure is developed based on a hierarchical structure in which three impacts are evaluated using four criteria. For each criterion, the relative importance of each impact is determined by qualitative expert judgment. Qualitative judgements are given as either "equally", "slightly more", "moderately more", "strongly more" or "very strongly more" important than the other with equivalent triangular fuzzy number (TFN) of <1, **1**, 1>, <1.2, **2**, 3.2>, <1.5, **3**, 5.6>, <3.0, **5**, 7.9> and <6.0, **8**, 9.5>, respectively. These judgments are based on a calibrated fuzzy scale derived from a survey with large number of respondents and applied in prioritisation of green technologies (Promentilla et al., 2018). Note that if an impact is less preferred than another, the reciprocal values are used.
2. The criteria set for the decision structure are then evaluated by pairwise comparison to obtain the relative importance of one criterion with respect to the others. The same fuzzy scales are used in this step.

3. The priority weights, w_i are calculated based on the nonlinear fuzzy preference programming model described by Promentilla et al. (2018). The model maximizes the degree of satisfaction λ with the given fuzzy triangular number $<l_{ij}, m_{ij}, u_{ij}>$:

$$\max \lambda \tag{6}$$

$$a_{ij} - l_{ij} \geq \lambda(m_{ij} - l_{ij}) \quad a_{ji} - l_{ji} \geq \lambda(m_{ji} - l_{ji}) \quad \forall(i,j)\,|\,i < j \tag{7}$$

$$u_{ij} - a_{ij} \geq \lambda(u_{ij} - m_{ij}) \quad u_{ji} - a_{ji} \geq \lambda(u_{ji} - m_{ji}) \quad \forall(i,j)\,|\,i < j \tag{8}$$

$$a_{ij} = w_i / w_j \quad a_{ji} = w_j / w_i \quad \forall(i,j)\,|\,i < j \tag{9}$$

$$\sum_i w_i = 1 \tag{10}$$

4. The final impact weights, W_i to be used for multi-objective optimization of oil palm value chains is given using the weighted sum of the priority weights of each impact i for each criterion k, w_{ik}. The criteria are also assigned with weights denoted by s_k using step 2:

$$W_i = \sum_k s_k w_{ik} \quad \forall i \tag{6}$$

4. Malaysian Oil Palm Value Chain Case Study

A case study based on the Malaysian palm oil industry is used to illustrate the decision framework. It is supposed that it is necessary to convert palm-based biomass materials such as palm oil mill effluent (POME), palm kernel shell (PKS) and empty fruit bunch (EFB) and to develop the value chain for the Peninsular Malaysia for the next 32 years.

To illustrate the generation of impact weights, supposed that an expert provides judgement based on future directions needed for the industry. The weights generated from FAHP are summarised in Table 1. The importance given to environmental impacts (i.e. climate change and water impacts) is higher than the economic benefits that can be generated from the value chain. Using these weights, the optimal value chain is presented in Figure 2. In this case, pathways to consider for the conversion of EFB lead to the production of energy products such as gasoline, jet fuel and diesel. On the other hand, POME is treated to produce usable water and undergoes anaerobic digestion to produce biogas. Pathways for PKS lead to generation of electricity used both internally and externally.

Table 1: Impact Weights Generated from FAHP

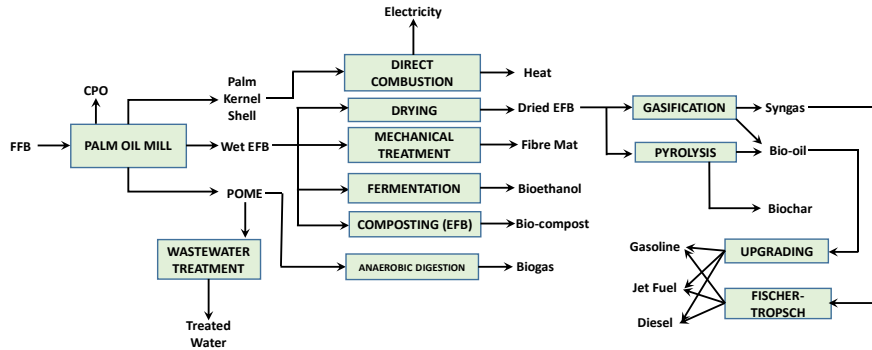
	Short-Term Benefits (0.038)	Long-Term Benefits (0.361)	Policy Development (0.361)	Social Acceptance (0.241)	Total
Economic Benefits	0.500	0.059	0.333	0.450	**0.269**
Climate Change Impact	0.250	0.471	0.333	0.300	**0.372**
Water Impact	0.250	0.471	0.333	0.250	**0.360**


Figure 2: Optimal Value Web Pathways for Malaysian Palm Oil Industry

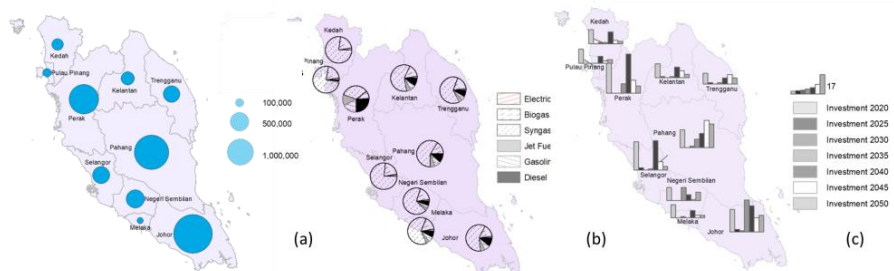
The resulting rate of production of palm oil per region, shares of energy distribution of palm-based biomass after conversion and the number of investments in units are shown in Figure 3. Three regions, namely Perak, Pahang and Johor contribute to the majority of the production having a total production of more than 3 MT of palm oil. Then, palm-based biomass materials are converted to different energy products, the majority of which is syngas. Biogas is also produced in the value chain to add value to palm oil mill effluent produced. The optimal solution also suggests investment in the beginning of the planning period and at the time period where most palm oil mills will retire. A summary of the results is shown in Table 2. The trade-offs between economic gains, climate change impact and water impact is balanced through expert judgment. Profit reduction of 8.93% is needed in order to achieve 31% less water impact and 11% less climate change impact if the expert judgment is to be incorporated as weights in the OPVC model. The contribution of FAHP in multi-objective planning of OPVC is that qualitative objectives are considered in the model. The decision framework can also provide scenarios for minimum climate change impact in which the highest attainable reduction up to 17% of the carbon footprint and 60% of the total water impact.


Figure 3: Results of the Malaysian case study: (a) palm oil production (t/y), (b) energy products from palm-based biomass and (c) conversion unit investment at each time period.

Table 2: Summary of scenarios for Malaysian oil palm value chain

Scenarios	Profit (billion MYR)	Climate Change Impact (Mt CO_2 equivalent)	Water Impact (million m^3 utilised H_2O)
Maximum Profit	414	426	12,923
Minimum Climate Change Impact	369	353	12,086
Minimum Water Impact	324	422	5,337
Expert-based Solution	377	375	8,932

5. Conclusions

A fuzzy analytic hierarchy process (FAHP) approach has been applied to multi-objective optimisation to generate an expert-based optimal plan of oil palm value chains. These weights, converted from verbal judgment by using FAHP, are used to generate an expert-based oil palm value chain design. A balance between economic gains, climate change impact and water pollution impact is obtained. Future work includes extending the case to incorporate biodiversity losses due to land use change.

Abstract

This study aims at exploring the thermo-hydraulic performance of 3D printed micro heat exchangers. We performed CFD simulations of single-phase laminar fluid flow and heat transfer in a microchannel with rough surface and compared the results with those obtained in a smooth channel. The model was based on the Navier-Stokes and energy equation. These equations were implemented and solved in the STAR-CCM+ commercial software. The Reynolds number was varied in the range 100-500, while two values of Pr number, 0.71 and 6.0, were chosen. The height of the channel varied between 0.2 and 0.5 mm. The micro-geometry of the surface roughness representing a completely random configuration was reproduced by a 3D scanner. Our results demonstrate that decreasing channel height leads to rising heat transfer rate and pressure drop. At the height of 0.2 mm, a significant rise in pressure drop is evidenced, which indicates a critical height limit for designing such microchannels.

Keywords: 3D printing, Heat transfer, stochastic roughness, 3D scanner, microchannel

1. Introduction

The demand for enhancement of heat exchanger performance is ever increasing (Haarlemmer and Pigourier, 2016). Such enhancement is challenging when manufacturing constrains become a significant factor, especially for micro and mini heat exchangers. Additive manufacturing (3D printing), an innovative type of fabrication, offers enormous design freedom and great potential to outperform conventional methods of manufacturing. Consequently, this technology has been exploited by various industries, such as aerospace, automotive, medical and fluid process engineering, in particular regarding microfluidic devices (Femmer et al., 2016). Moreover, 3D printed objects are characterized by a certain surface roughness resulting from the fabrication process; such rough surface can be used as a passive method to increase the efficiency of heat exchangers. This beneficial combination of both variability and inherent roughness justifies a new study route toward improving heat exchangers performance.

It is worth noting that at the moment, 3D printed micro heat exchangers are still in an early development stage. This is the reason why just a limited number of publications on this topic can be found in the open literature. Few recent works are focused on the

Nomenclature

$Re = \dfrac{\rho V_m D_h}{\mu}$	Reynolds number	V_m (m/s)	Mean velocity	μ (Pa/s)	Dynamic viscosity
$Nu_{ave} = \dfrac{h_m D_h}{k}$	Average Nusselt number	D_h (m)	Hydraulic diameter	T_b (K)	Bulk temperature

design flexibility aspect of 3D printing allowing manufacturing of uniquely formed micro heat exchangers. For example, Arie et al. (2017) conducted an experimental and a numerical study which mainly aimed to compare the performance of a manifold microchannel with heat exchangers with conventional surfaces. Air-water manifold finned microchannels (with a manifold as a flow distributor positioned above the microchannels) were fabricated using one of the additive manufacturing methods, namely, direct metal laser sintering (DMLS). Thanks to the ability to build objects layer-by-layer, the authors could fabricate manifold and microchannel segments together as one united construction and eliminated the bonding process.

Ferster et al. (2017) performed an experimental study on the microchannel pin fin arrays fabricated by DMLS. Various geometries of pin fins, such as star-formed, triangular and dimpled sphere, with different spacing and number of pin fins, were built and their influence on the friction factor and heat transfer was analysed. One work, which considered the effect of the inherent surface roughness due to 3D printing on the performance of a heat exchanger has been recently published by Saltzman et al. (2018). They replicated a crossflow heat exchanger with 20×9.25×11.5 cm dimensions using laser-based powder bed fusion process. The additively manufactured heat exchanger was characterised by a lower weight and significantly rougher surfaces. The authors reported that the additively manufactured heat exchanger showed around 10% improvement in the overall heat transfer, whereas the pressure drop was doubled.

The necessity of surface roughness modelling in microchannels originates from its great potential to improve the micro heat exchanger efficiency, which is still an open problem. Moreover, experimental studies on such a small scale are characterized by measurement uncertainties which represent an interfering factor for the experiments beside surface roughness. Numerous studies contributed to the modelling of surface roughness in microchannels by setting different geometries, e.g. regular configurations, such as wavy sinusoidal one (Wang and Chen, 2002), triangular, square and irregular or random geometries (Guo et al., 2015). In the latter work, the authors used random functions like the Gauss function and the Fractal model to create random roughness.

In this study, we created the roughness geometry of a printed surface by a 3D scanner. This geometry is very close to the reality and thus it can be called realistic roughness. For this realistic roughness, we performed a fundamental numerical investigation of forced convection laminar flow in a microchannel. The results are presented for a variety of channel heights and Reynolds numbers, thus yielding valuable data on pressure drop and heat transfer characteristics in a 3D printed micro heat exchanger.

2. Physical model

The initially studied geometry was a 3D printed flat plate (Figure 1a). The scanning results yield the mean roughness depth equal to 85 μm. This geometry was then

a   b   c
Figure 1. The steps of creating the geometry of stochastic roughness of 3D printed flat plate for CFD simulation: examined sample from 3D printing (a); scanning result of the selected area (b); prepared geometry for CFD study (c)

exported in CAD format (Figure 1b) which is readable by a corresponding software tool (Autodesk Inventor). The obtained surface geometry is represented by very small surfaces, which form the detailed roughness structure. To reduce computational effort, a small part of the surface was selected to perform the simulations (Figure 1c). The next step was to form the geometry of the CFD computational domain. This was done by adding side walls and an upper cover to the element. This configuration shown in Figure 1c was used for the CFD simulations.

3. CFD-based modelling

Three-dimensional fully developed steady-state laminar flow with constant physical properties in a microchannel with rough surface was studied. Finite volume approach implemented in STAR-CCM+ was applied in order to simulate the fluid flow and heat transfer in the duct. Periodic boundary condition was set at the inlet and outlet boundaries of the channel. In this way, the velocity profile is repeated after the channel length, so that after reaching convergence the whole periodic domain represents a hydraulically developed region. Thermally fully developed flow is characterized by a constant heat transfer coefficient. In STAR-CCM+, the temperature profile at the outlet is scaled and then used as the inlet profile, in such a way that the heat transfer coefficient remains constant for the whole domain. The bottom (rough) wall was maintained at a constant temperature, and the other walls were assumed to be adiabatic. No-slip boundary condition was assumed at all the walls. Figure 2 shows the geometry of the investigated microchannel element.
Figure 2. Periodic computational domain of microchannel and boundary conditions
Figure 3. Local Nusselt number along the length of wavy channel
Figure 4. Wall temperature along the channel length obtained from our simulations and empirical data from Qu and Mudawar (2002)

A direct validation of the simulation results was not possible because of missing data on such geometry. Therefore, we selected and modelled two other configurations from the literature sufficiently close to the studied original geometry. The numerical simulation of fluid flow in a wavy duct reported by Wang and Chen (2002) at Re=300 and Pr=6.93 was replicated. In their work, the geometry of wavy wall was considered as a kind of roughness. Further model validation was carried out using the heat transfer experiment in a microchannel conducted by Qu and Mudawar (2002). The wall temperature was estimated along the channel length and compared with that obtained from Qu and Mudawar (2002) at Re = 442 and Re = 864. The validation results are shown in Figures 3 and 4. In both cases, a good agreement between the numerical and experimental data was achieved.

The primary mesh independency test was performed with respect to the heat transfer parameter (average Nusselt number). As can be seen from Table 1, the relative difference between the two finest grids are less than 1%. Additionally, a study of the velocity profile (Figure 5) along the channel height revealed that the grid setting with 3,322,691 cells is sufficient for the whole simulation studies, yielding a reasonable compromise between computational time and accuracy.

Table 1. Mesh independency results for Nu_{ave}

Number of cells	Nuave
1,502,520	5.051
3,322,691	5.040
7,877,453	5.037
Figure 5. Velocity profile along the height of the channel

The effect of channel height on the pressure drop and average Nusselt number for various Re values between 100 to 500 and Pr = 6 are presented in Figures 6 and 7. As the channel height decreases, both Nusselt number and pressure drop increase. However, pressure drop change between 0.3 and 0.2 mm is much more intensive than the corresponding Nusselt number change, while this is true for all studied flow rates.
Figure 6. Pressure drop in rough channel versus channel height for Pr=6
Figure 7. Average Nusselt number in rough channel versus channel height for Pr=6

Figure 7 demonstrates that the effect of the channel height on pressure drop is much more significant than the effect of surface roughness. For instance, for Re=300 and H=0.3mm, the roughness results in just 10% increase, whereas the channel height variation causes substantially larger changes.

a

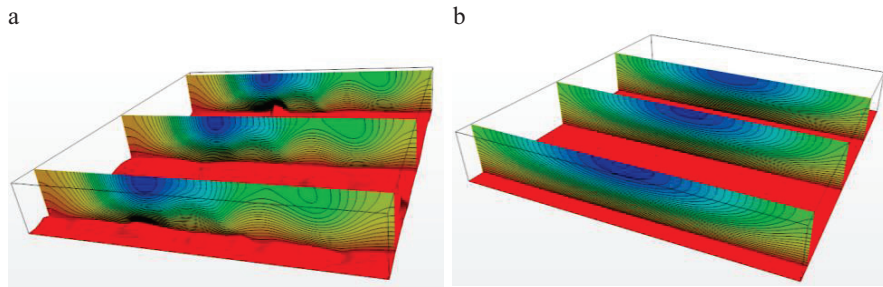
b


Figure 8. Isothermal line distribution in a rough (a) and a smooth (b) channel at Re=200 and H=0.3 mm
Figure 9. Nusselt number in a rough and a smooth channel as function of Reynolds number at H=0.3 mm

Figure 8 depicts the effect of stochastic surface roughness on the isothermal lines in a smooth and rough channel for Pr=6. They are shown in three different cross-sections normal to the flow direction. The isothermal lines in a smooth channel (Figure 8b) reveal regular structure throughout the whole channel. By contrast, in the channel with rough surface (Figure 8a), the stochastic geometry of the roughness perturbs the regular fluid behaviour leading to irregular configuration of isothermal lines. As the result, the interactions between hotter and colder layers become more intensive, which facilitates heat transfer. Another impact of the random roughness on the fluid flow can be seen in a shift of the cold fluid core position away from the top wall centreline visible in Figure 8a,

unlike in the smooth channel, in which it is placed in the centreline of top wall with a symmetric configuration.

The influence of surface roughness on the average Nusselt number is illustrated in Figure 9 for two Prandtl numbers. As expected, for smooth channels, the average Nusselt number remains nearly constant for both Prandtl numbers. For a rough channel at Pr =6, the average Nusselt number increases with increasing Reynolds number. For the fluid with Prandtl number below one, the Nusselt number dependence on Reynolds number is less pronounced, especially for small Reynolds numbers. However, starting from a certain Reynolds number value, the effect of surface roughness on the heat transfer rate becomes significant.

4. Conclusions

The CFD-based study of fluid flow and heat transfer in a microchannel with realistic roughness of 3D printed surface was carried out. The 3D scanner was used to create the geometry of the roughness on microscale. The simulations of a fully developed laminar flow were performed for smooth and rough channels with a height varying between 0.2 and 0.5 mm. Random roughness results in an increase of both the average Nusselt number and pressure drop, while for the smallest studied channel height, the largest pressure drop and the highest average Nusselt number are found. This helps to estimate the critical channel height value, 0.2 mm, for the heat exchanger design. The use of 3D printing in manufacturing of micro heat exchangers offers design flexibility along with the possibility to reach a high thermal performance due to the surface roughness.

Abstract

FMECA is commonly used as a tool for assessing the consequences of different failure modes of a component and the criticality of the consequences. Traditionally failure modes are generated using a one-factor-at-a-time method. In this study, we propose extensions to the FMECA procedure in which failure modes are sampled using statistical sampling techniques, and their effects are evaluated under a wide range of operating conditions. Morris's efficient sampling technique is used for generating failure mode effect analysis scenarios. The scenarios are evaluated in a K-Spice simulator with a model of an offshore gas reinjection system in the Danish North Sea. The impact of the failure modes on the process performance and process safety is evaluated under varying process conditions. The extended methodology enables fast screening of the effects of the failure mode under different realistic process conditions. This provides a more comprehensive and global assessment of the consequences for process safety and reliability in the chemical industry.

Keywords: Failure Mode Effect and Criticality Analysis, Morris screening, Gas reinjection

1. Introduction

For safety-critical systems, tools like Failure Mode, Effects and Criticality Analysis (FMECA), and Hazard and Operability Study (HAZOP) are important in reliability analysis as well as Quantitative Risk Assessment (QRA) studies to ensure an inherently safe design and safe operation of the system. For modern chemical process plants, a model is a requirement in the design phase. This model should be exploited, not just to ensure mass, energy and momentum balances of the system, and to optimize productivity, but also to ensure the safety of the system. In a previous study Enemark-Rasmussen et al. (2012), simulations are performed according to a single defined operational setpoint to evaluate failure modes . However as the economical experimental designs proposed by Morris (1991) are available and computational power increases, such evaluations should be carried out by rigorously investigating the influence of failure modes under a range of potential variation of the process conditions.

In this work we propose a quantitative approach to analyse the effects of failure modes of a control valve under a range of process conditions. Four failure modes of control valves on offshore oil and gas platforms have been identified, which will be simulated under varying process conditions. The method is more time consuming and computationally expensive than conventional approaches, especially as the number of process conditions, components and failure modes increases with system complexity. To avoid an excessively time consuming method, the process conditions, and

the failure modes are sampled by using a random and economically efficient sampling method: Morris screening. Morris screening is a discrete sampling method, and allows for evaluation of different and completely unrelated failure modes in one study.

2. Process system

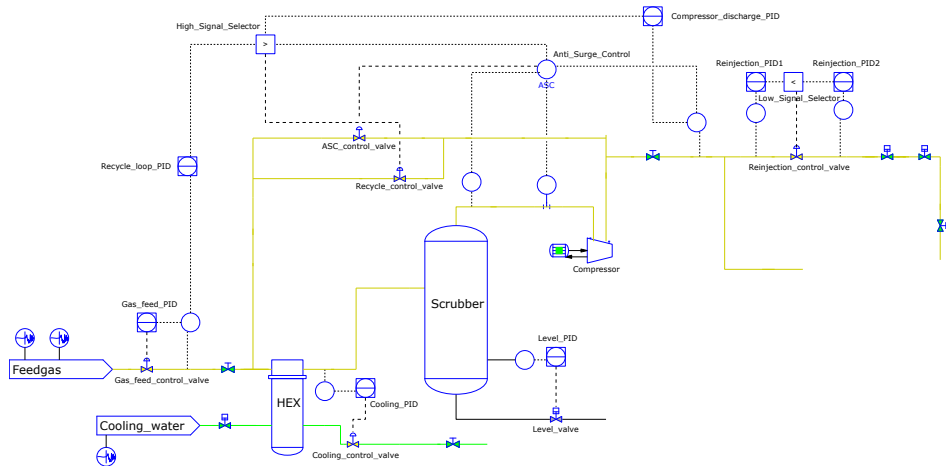
The approach is applied to an offshore gas reinjection system of Mærsk, that has been modelled in K-Spice based on design and operation data in Enemark-Rasmussen et al. (2012). The purpose of the gas reinjection system is to maintain the well pressure for enhanced oil recovery. The feed of gas from upstream is controlled by a control valve. In the reinjection system the gas is first cooled by a heat exchanger, supplied with sea water. The cooling rate is controlled by a control valve, at the outlet of the heat exchanger. Next, the gas enters the scrubber to avoid vapour in the gas being reinjected to the well. Production of liquids from the scrubber is undesired, however a control valve releases the liquid to a flare, if the level becomes too high. A compressor sucks the gas from the scrubber, after which the gas is either reinjected to the wells or recycled. The gas is recycled to avoid the compressor from surging. Surging is undesirable, however so is recycling the gas as it limits the productivity. An anti-surge controller controls the setpoint of four control valves, one for the gas feed, two for the gas recycling and one for the gas reinjection, to ensure a steady flow through the compressor. The system is modelled in K-Spice as shown in Figure 1. K-Spice, a dynamic process simulator for the oil and gas industry, is used for process design and engineering verification. It features parameterised process models for oil and gas processing.


Figure 1: Offshore gas reinjection system.

Various different failure modes have previously been simulated in K-spice for this system by Enemark-Rasmussen et al. (2012). However common for all simulations was the use of only a single set of process conditions according to the design specifications. The process conditions before and after introducing the failure mode was used to calculate the sensitivity of the process to assess the criticality of each failure mode using a one-factor-at-a-time approach. In this study, we use a global sampling based approach to assess the criticality of the consequences, and focus the study on four failure modes of one control valve evaluated under a range of process conditions.

The effort to document the occurrence of failure modes for valves, pumps etc. is extensive in the oil and gas industry, however the level of detail on reported failure modes is very sparse (Management, 2002; Peters and Sharma, 2003). In this study, the valve opening *P*, and the valve opening and

closing time t_{open} and t_{close} are used for implementing four different failure modes for the gas feed control valve. When implementing the failure mode, the manipulated parameter is fixed for the remaining simulation from t_{fm} to t_{end}. Apart from the failure modes, the sampled initial process conditions are the temperature T_{gas} and the pressure P_{gas} of the feed gas, and additionally the feed temperature T_{cool} of the sea water used for cooling.

The values of the sampled initial conditions is determined by a discrete cumulative distribution function (CDF). The variation in percentage for the conditions are as follows: $T_{gas} = 5\%$, $P_{gas} = 4\%$ and $T_{cool} = 4\%$. As described by Sin et al. (2009), it can be used to determine the minimum and maximum values of a uniform distribution discretized into $p = 4$ levels, around a mean or nominal value of operation. The nominal operation is defined here as: $T_{gas} = 44.5\,°C$, $P_{gas} = 121\,bar$ and $T_{cool} = 30\,°C$. Gaussian noise is added to the process conditions as measurement noise and varies during the simulation. The standard deviation σ_{noise} in Table 3 defines the normal distribution of the noise, around the values sampled by Morris screening for θ_{1i}, θ_{2i} and θ_{3i} as mean. The noise is randomly sampled and added by K-Spice as part of the simulation.

3. Procedure

First a set of k process conditions including the failure mode is sampled as the input $\theta_i = [\theta_{1i}, \theta_{2i}...\theta_{ki}]$ for the simulation for $i = 1, 2 ... n$ simulations. The n number of sampled sets are then simulated in K-Spice. All simulations start with a sampled set of initial process conditions θ_{1i}, θ_{2i} and θ_{3i} at time $t_{start} = 0\,s$. These conditions are used throughout the entire simulation. To allow the system to stabilize under the set of process conditions specified by the sampling, the simulation is run for 1200 seconds. At time $t_{fm} = 1200\,s$ the failure mode (FM) θ_4 is introduced. Next, the simulation is run for 7200 seconds until $t_{end} = 8400\,s$ after which the simulation is stopped, and the simulation output for every simulation $Y_{ij} = [y_{1ij}, y_{2ij} ... y_{mij}]$ for $j = [10, 20 ... t_{end}]$ is recorded by sampling every ten seconds. Here, j denotes a point in the time series of the mth output signal from the ith simulation. The steps, inputs and outputs of the procedure is shown in Table 3.

#	Step	Input	Output
1	Morris screening	r=40, k=4, p=4, $\Delta = 2/3$, CDF	θ_i
2	Load initial conditions in simulation i	$\theta_{1i}, \theta_{2i}, \theta_{3i}$	
3	Run simulation i untill $t_{fm} = 1200\,s$	$\sigma_{Noise} = [5, 2.5, 2.5]$	
4	Introduce failure mode	θ_4	
5	Run simulation i untill $t_{end} = 8400\,s$		Y_{ij}
6	Sensitivity analysis	θ_i, Y_{ij}	EE_i

Table 1: Procedure for sampling, simulating and analysing.

4. Experiment and sample design

Morris screening is a global sensitivity analysis method that employs a one-factor-at-a-time (OAT) approach for producing experimental designs. OAT analysis is performed for a number of randomly sampled nominal values in the design space. The analysis is based on the mean and standard deviation of the elementary effects, EE_i for the input i to determine how sensitive the outputs are to changes in the inputs $i = 1, 2, ...$ For these experiments $k = 4$ input parameters are sampled at $p = 4$ levels. Typically, the number of repetitions needed for Morris screening is in the range of $r = [10, 50]$ (Sin et al., 2009), and based on the required number of elementary effects F_i to be calculated. For this study $r = 40$ is used, however only five elementary effects are shown. Based on this, the number of samples are $n = r(k+1) = 40(4+1) = 200$ Sin et al. (2009). The elementary effects are calculated based on changes to the inputs, defined by the step size $\Delta = p/[2(p-1)] = 4/[2(4-1)] = 2/3$ for a uniform distribution of the sampling space. These

steps are used for performing local sensitivity analysis, however when averaging the mean of the elementary effects, the method can be used in a global context. The sampled probabilities in unit hyperspace [0 1] have been converted to real values by using their inverse discrete and cumulative probability distribution function. The values of the resulting four levels are shown in table 4.

Level	T_{gas} (θ_1)	P_{gas} (θ_2)	T_{cool} (θ_3)	Failure mode (FM) (θ_4)
1	28.6 °C	116.2 bar	17.9 °C	Valve seized at current position P
2	39.2 °C	119.4 bar	26.0 °C	Valve fail open at $P = 1\%$
3	49.8 °C	122.6 bar	34.0 °C	Valve fail close at $P = 99\%$
4	60.4 °C	125.8 bar	42.1 °C	Stiction $3t_{close}$ & $3t_{open}$

Table 2: Design space.

5. Results

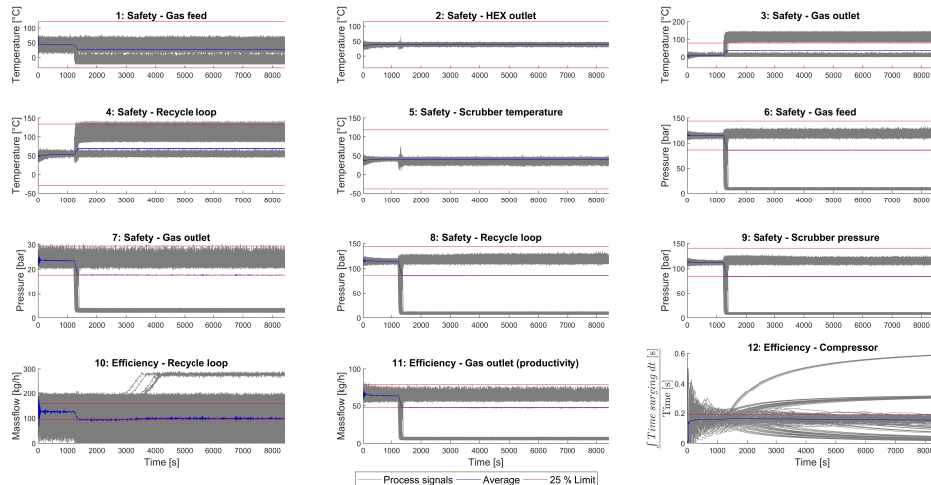
For each simulation i, the output Y_{ij} is a time series with j samples in time, corresponding to the sampled input θ_i. A selection of the process signals from the simulations are shown in Figure 2. The average of all 200 samples for each time step j is plotted for each output, along with a lower and upper safety limit. The limits are an average of the 200 process signals for each output from time t_{start} to t_{fm}, multiplied by $\pm 25\%$. In general the control system is capable of maintaining the temperature close to nominal operating conditions as can be seen on plot 1-5 in Figure 2. However, under some conditions, the temperature exceeds the upper limit at the gas outlet, and in the recycle loop. The plots 6-9 shows a stable pressure under the majority of process conditions, although it drops below the lower limit to nearly 0 bar under some conditions. This does however not pose a safety risk. Plot 10 shows that the amount of recycled gas varies a lot between 0 and 200 kg/h, and under some specific conditions the recyled amount approaches 300 kg/h. In general the productivity is stable, but it drops close to 0 kg/h under some conditions. The surge rate, defined as $\frac{\int \text{Time surging } dt \ [s]}{\text{Time } [s]}$, varies a lot initially, as expected, and in time splits up into four dinstinct bands, for which two of them increases over time, one remains constant and one decreases over time.


Figure 2: A selection of process signals for output Y_{ij} from the $n = 200$ samples.

The plots in Figure 3 of each output as a function of each input shows that failure mode two is the sole cause of the high temperatures for the gas outlet and recycle loop, independent of the process conditions. The plot also shows, that failure mode two is the sole reason for the pressure drop in the gas reinjection system, as only very little new gas is supplied. On the contrary, failure mode four consistently produces high pressure with almost no variation. The amount of recycled gas drops close to 0 kg/h for failure mode two as only a small amount of gas is supplied to the system. Failure mode three causes the high amount of recycled gas for a gas feed pressure of 125.8 bar. As previously mentioned, the productivity is stable, which is true for all process conditions, except those including failure mode two. Failure mode two results in three bands of surging, resulting in both the lowest and highest amount of time surged in total. The plots do however not show any unique set of conditions producing these bands. The variation in the amount of time surged is very low for both failure mode one and four as opposed to two and three.
Figure 3: Matrix plot of model output Y_i as a function of model input θ_i.

The most significant elementary effect has the highest average, and a high standard deviation is an indication of interactions or non-linearity (Morris, 1991). The elementary effects for some of the critical outputs are shown in Figure 4. The wedge in the figure can be used as an indication of significance, and is calculated as the mean of samples of the elementary effects: $\hat{d}_i = \pm 2SEM_i$. The standard error of mean, SEM_i is calculated as the variance S_i of the elementary effects of input sample i divided by the square root of repetitions r: $SEM_i = \frac{S_i}{\sqrt{r}}$. If an elementary effect is outside of the wedge it is considered significant, and insignificant if inside (Morris, 1991).

A change in failure mode can be considered as the most influential input parameter on the gas outlet temperature, recycle loop temperature, amount of gas recycled and the gas productivity, but shows no significance on the amount of time surged. This result for the total surge rate contradicts the observations from Figure 3. The values in Figure 4 are averaged elementary effects based on all changes to the respective input parameter. This can lead to ambiguous results and for this reason these results cannot be interpreted alone. The gas feed pressure change should also be considered significant for the increase in gas outlet temperature, and a change in temperature of the cooling feed is significant for an increase in temperature in the recycle loop. The mean of the total surge rate shown in Fig. 4 indicates no significant inputs, as the standard error of the mean SEM_i is quite large due to the high variance S_i of elementary effects. The estimated mean μ^* of the distribution of absolute values of the elementary effects is however useful for Type II errors when the variance
Figure 4: Elementary effects of outputs.

is both negative and positive (Campolongo et al., 2007). It reveals that the failure mode is the most significant parameter for the variation of the surge rate as $\mu^* = 5.70$ for FM, $\mu^* = 5.51$ for T_{cool}, $\mu^* = 4.02$ for T_{gas} and $\mu^* = 3.98$ for P_{gas}.

In general, the standard deviation of the elementary effects of the failure mode is quite large for all outputs except for the surge rate. However as this input parameter is not continuous, but merely four completely different parameters in itself, a high standard deviation is expected and should thus be either interpreted with caution or disregarded.

6. Conclusion

Morris screening has been used for analysing failure modes of a valve under varying process conditions in simulations of an offshore gas reinjection system. The analysis showed that only the temperature at the gas outlet and in the recycle loop could compromise the safety, caused by the gas feed valve closing. In general the results showed that within the studied range of variation the process conditions are insignificant, and that the effect of the failure modes is independent of the process conditions. The efficiency of the plant was also examined, and in general the productivity was stable, except for when the valve closes, and the gas feed is shut off. Additionally, the closed valve impacts the amount of time which the compressor surged both negatively and positively. In case of an open valve, the recycling rates increased, but only under high pressure.

Optimization of a large-scale biorefinery problem by decomposition

Varun Punnathanam[a] and Yogendra Shastri[a,*]

[a]*Indian Institute of Technology Bombay, India*
yshastri@che.iitb.ac.in

Abstract

The biorefinery system based on agricultural residue primarily consists of feedstock procurement and processing which need to be taken into consideration together in order to obtain a globally optimal design. This generally results in large-scale mixed integer linear programming (MILP) models that scale rapidly based on the number of technology and location options, resulting in highly complex and challenging optimization problems. This work considers a case study based on setting up a biorefinery system for the state of Maharashtra (India), and employs the Dantzig-Wolfe decomposition based approach to solve this problem. An approximation strategy is proposed to handle the binary variables of the problem. Our approach results in up to 92% reduction in computational time, and leads to a near linear increase in computational time as a function of the problem size. The proposed approach may be used to solve other large-scale optimization problems with a similar structure of various fields.

Keywords: Large-scale optimization, biorefinery, Dantzig-Wolfe decomposition

1. Introduction

A biorefinery is a plant which converts biomass into biofuels as well as other products. In the Indian context, biorefineries must largely rely on a variety of agricultural residues which can have varying compositions. Additionally, their availability is distributed and seasonal, due to which it may be required to collect them from large distances. The biorefinery problem primarily involves two aspects. Process synthesis is a large part of the problem, where the designer develops pathways to interconnect specific raw materials to products of interest. While there might be a myriad of possible pathways (Gong et al., 2016), the designer is required to identify a pathway which would optimize a specific objective, such as maximizing the profit generated by the industry. The selection of a process synthesis pathway is coupled with the design of an optimal supply chain network (Sun et al., 2018), which forms another significant part of the problem. As the raw materials can be procured from multiple sources, the selection of the raw material source as well as the quantity of raw material to be procured from individual sources can greatly impact the economics of the plant. In addition, there can be multiple potential locations for setting up one or more biorefineries. The biorefinery problem is generally formulated as a mixed integer linear programming (MILP) problem, and can potentially be very large in size, consisting of well over a hundred thousand variables and constraints.

In this work, we considered a biorefinery model described in literature (Vikash and Shastri, 2017) which incorporates a single fixed biorefinery and accounts for both feedstock procurement as well as processing. We have extended this model to consider the possibility of setting up multiple biorefineries, and to also optimize the locations of the biorefineries among several potential lo-
Figure 1: Increase in problem size with increase in potential number of biorefinery locations

cations. Figure 1 shows how the size of this MILP problem varies based on number of potential biorefinery locations. Depending on the specifics, we can expect the size of such a problem to increase rapidly with increase in model details. The full sized problem has more than 3 million constraints and 1.3 million variables including over 6500 binary variables, leading to enormous computational requirements. A popular method for solving large problems is to decompose them into smaller sub-problems which are easier to solve. These sub-problems are iteratively solved by employing certain strategies (Conforti et al., 2014) to ultimately obtain the optimal or near optimal solution to the original monolith problem. The constraint matrix for our biorefinery problem has a block diagonal structure except for a few constraints, which is a very favourable structure for employing Dantzig-Wolfe decomposition (DWD) (Dantzig and Wolfe, 1960).

We therefore propose a DWD based methodology to solve our large-scale biorefinery problem. The following section outlines the formulation of the optimization model. Section 3 presents the proposed solution methodology. The simulation results in terms of reduction in computational time requirement are discussed in Section 4. We conclude this report in Section 5 by mentioning some of the future directions for this work.

2. Problem formulation

The biorefinery problem from literature (Vikash and Shastri, 2017) integrated the biomass procurement and processing aspects into a single model, but considered the location of the biorefinery to be fixed. We expanded this model to consider multiple potential biorefinery locations, thereby drastically increasing the size of the model as shown in Figure 1. The revised model considers a second generation biorefinery which produces ethanol. The superstructure of the problem is conceptually shown in Figure 2 with the number of choices corresponding to each block mentioned in parenthesis.

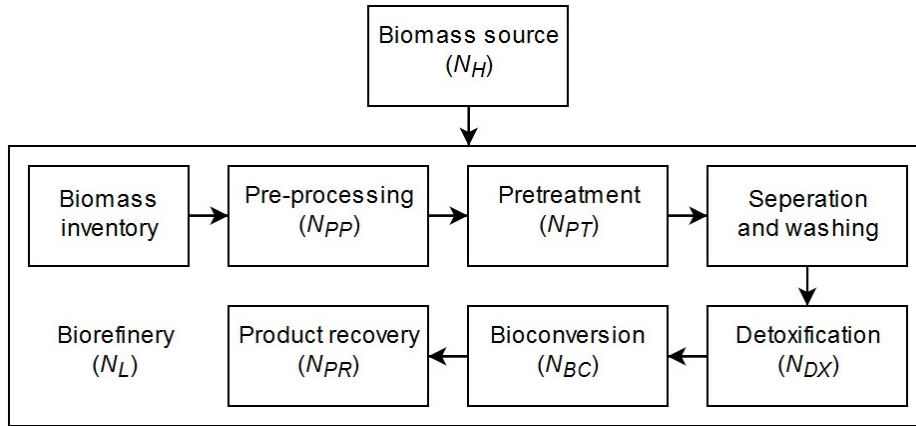
A specific case study for the production of ethanol for the state of Maharashtra, India (Vikash and Shastri, 2017) is considered. The time horizon is taken to be one year, which is divided into 12 time periods. There are 14 varieties of biomass (N_B) which can be sourced from 33 biomass availability sites (N_H) corresponding to 33 district centroids within Maharashtra. There are potentially 33 locations (corresponding to the 33 district centroids) (N_L) where one or more biorefineries can be located. The biomass is transported via trucks, and can be stored at inventories located at the biorefinery facilities. Regarding the selections involving technological stages within each biore-


Figure 2: Biorefinery problem structure

finery, $N_{PP} = 1$, $N_{PT} = 8$, $N_{DX} = 4$, $N_{BC} = 4$ and $N_{PR} = 3$. All the necessary data for the problem is reported in literature (Vikash and Shastri, 2017). The objective of the optimization problem is to minimize the total annualized cost (TAC) while meeting a specific monthly demand of ethanol. The problem variables and constraints include:

- Binary variables corresponding to selection of biorefinery location(s), biomass type to be processed at each time period at each biorefinery and the various technological selections within each biorefinery.

- Continuous variables corresponding to the flow of biomass to biorefineries, the size of biomass storage facility at each biorefinery, the amount of biomass stored at each time period for each biorefinery and the flow of intermediate products within the biorefinery.

- Constraints corresponding to the overall biomass availability and demand for ethanol at each time period, economic cost calculations and limiting the selections of processing technologies within each biorefinery, and mass balance constraints within each biorefinery at each time period.

The biorefinery optimization problem can be concisely represented as follows:

$$\min \sum_{l}^{L} \left(C_{\text{Total CAPEX},l} + C_{\text{Variable OPEX},l} + C_{\text{Fixed OPEX},l} \right)$$

subject to [individual biorefinery specific constraints]

$$\sum_{l}^{L} f_{b,h,l,t} \leq F_{b,h,t} \qquad\qquad \forall b,h,t \in B,H,T$$

$$\sum_{l}^{L} e_{l,t} \geq D_t \qquad\qquad \forall t \in T$$

where, C, f, F, e and D are the annualized cost, flow of biomass, availability of biomass, ethanol production and demand for ethanol, respectively. B, H, T and L corresponds to the set of biomass types, biomass sources, time periods and potential biorefinery locations, respectively. The constraints mentioned as "*individual biorefinery specific constraints*" correspond to the distribution of

biomass and intermediate products between processing stages, limiting the selections of processing technologies and maintaining the biomass inventory balance within a biorefinery. Thus, these are the process synthesis constraints focusing on process selection. We don't individually specify them for the sake of brevity. The problem in this form is referred to as the integrated problem.

3. Decomposition based solution approach

The Dantzig-Wolfe decomposition (DWD) (Dantzig and Wolfe, 1960) is a well known technique for solving problems in which the constraints have a block diagonal structure consisting of disjoint sets of variables linked by connecting or complicating constraints. In this section, we discuss the decomposition of the biorefinery problem such that DWD may be employed. Subsequently, we provide a detailed description on the proposed solution methodology for solving the biorefinery problem. In order to employ DWD, the biorefinery problem described in the previous section is decomposed in the following manner. Each individual biorefinery is modelled as a sub-problem, while the biomass supply and ethanol demand constraints connect the sub-problems and hence are part of the master problem. At iteration $i \in I$, the master problem is given as

$$\min_{\lambda} \ \sum_l^L \sum_1^i \left(\bar{C}^i_{\text{Total CAPEX},l} + \bar{C}^i_{\text{Variable OPEX},l} + \bar{C}^i_{\text{Fixed OPEX},l} \right) \lambda^i_l$$

$$\text{subject to} \ \sum_l^L \sum_1^I \bar{f}^i_{b,h,l,t} \lambda^i_l \leq F_{b,h,t} \qquad \forall b,h,t \in B,H,T$$

$$\sum_l^L \sum_1^I \bar{e}^i_{l,t} \lambda^i_l \geq D_t \qquad \forall t \in T$$

$$\sum_1^i \lambda^i_l = 1, \qquad \forall l \in L$$

$$\lambda^i_l \geq 0 \qquad \forall i \in I, \forall l \in L$$

where, $\bar{C}, \bar{f}$ and $\bar{e}$ denotes corresponding vertices obtained by solving sub-problems.

At iteration $i \in I$, sub-problem $l \in L$ has the following structure

$$\min_{\hat{X}_l} \ \left(C_{\text{Total CAPEX},l} + C_{\text{Variable OPEX},l} + C_{\text{Fixed OPEX},l} \right) -$$

$$\left(\sum_{b,h,t}^{B,H,T} \mu^i_{1,b,h,t} f_{b,h,l,t} + \sum_t^T \mu^i_{1,t} e_{l,t} \right) - \mu^{l,i}_2$$

$$\text{subject to} \ [\textit{individual biorefinery specific constraints}]$$

$$\hat{X}_l \geq 0$$

where, $\hat{X}_l$ denotes all the variables specific to sub-problem l, μ^i_1 is the dual variables corresponding to the master constraints and $\mu^{l,i}_2$ is the dual variable corresponding the the lth convexity constraint in the master problem.

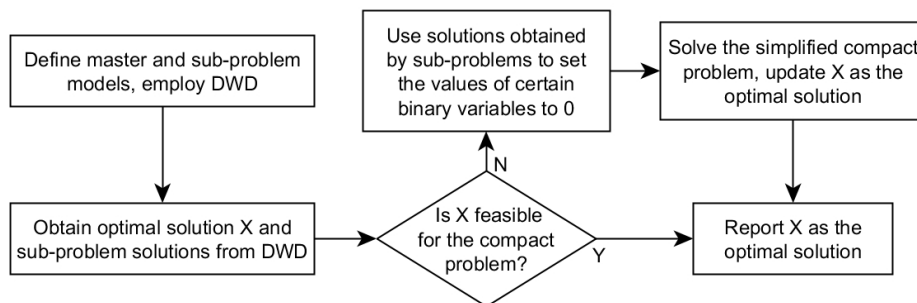
Figure 3 describes our approach for solving the decomposed problem. The first step is to define the master problem and sub-problem models, following which DWD is employed. Iterations corresponding to DWD terminates when (i) none of the sub-problem solutions correspond to a negative reduced cost, (ii) DWD exceeds the maximum number of iterations or (iii) change in objective function value over past few iterations is lower than a specified tolerance. In our implementation, we considered that the objective function value should change by at least 1% over 5 iterations. For the sake of brevity, we do not describe the implementation DWD as it is well documented in literature (Kalvelagen, 2003). For problems involving integer variables, the decomposition method


Figure 3: Flowsheet of the solution methodology

which we employ generates the lower bound for the problem, as the integrality of these variables are not guaranteed. Hence, if the solution obtained by DWD is feasible, this is reported as the final solution. On the other hand, if this is not feasible, we utilize the solutions obtained by the sub-problems over DWD iterations to simplify the integrated problem. This is done by filtering out certain selections (setting corresponding binary variable to 0) in the following manner. We identify the sub-problem solutions corresponding largest two λ for each sub-problem l. Subsequently, we filter out the processing technology selections (such as preprocessing, pretreatment, detoxification, bioconversion, fermentation strains and product recovery technologies) which do not appear in the solutions identified earlier. For instance, if the solutions corresponding to the largest and second largest λ for a particular biorefinery location selects pretreatment technologies Dilute Acid Hydrolysis and Lime Pretreatment, respectively, then all other pretreatment technologies are not considered in the simplified problem. The last step is to solve this simplified integrated problem using the standard CPLEX® solver in order to obtain the final optimal solution. Note that this method does not guarantee optimality, although we expect it to produce solutions reasonably close to optimality. In short, our approach is effectively to solve a decomposed problem in order to filter out options for various processing selections which seem to be sub-optimal, thus greatly reducing the complexity of the integrated problem. Subsequently, this simplified MILP problem is solved by standard procedures.

4. Results and discussion

This section presents the improvement in performance obtained by employing the decomposition based method as opposed to solving the integrated problem using the standard CPLEX® solver. The integrated and decomposed biorefinery problem models and the solution methodology were coded in GAMS® . The sub-problems and master problem at each iteration was solved using the standard CPLEX® solver. We do not describe the optimal solution in detail as the focus of our work is the solution methodology and the resulting reduction in computational time.

Figure 4 compares the performance of our approach with that of solving the integrated problem. Although solving the integrated problem requires lesser time for smallest three problem sizes ($N_L = 1$ to $N_L = 3$), the decomposition based approach is significantly faster for all the remaining cases ($N_L = 4$ to $N_L = 33$). For the $N_L = 18$ case, we observe a 92% reduction in computational time. Furthermore, this reduction in computational time is associated with no compromise in the optimal objective function value. It was observed that on employing the decomposition based approach, almost all of the computational time was utilized for solving the sub-problems, with the simplified integrated problem requiring comparatively negligible time. This is reflected in the fact that the computational time requirement for the decomposition based approach appears to be
Figure 4: Comparison of computational time requirement of the proposed approach and solving the integrated problem

a linear function of the number of biorefinery options. In comparison, the time taken to solve the integrated problem seems to increase exponentially with increase in the number of biorefinery location options. For the largest problem size ($N_L = 33$), the optimal solution determined by implementing the decomposition based approach corresponded to setting up a single biorefinery located at the Beed district centroid. Ethanol was largely produced by using sugarcane bagasse and wheat based biomass at a price of INR 52.72 per litre.

5. Conclusion

We solve a large-scale biorefinery problem which considers both biomass procurement and process synthesis within each biorefinery. Although this results in a very large optimization problem, its inherent structure allowed us to employ DWD. We developed a DWD based approach and employed it to solve the biorefinery problem. As a result, we obtained up to 92% reduction in computational time while obtaining the same optimal objective function value. This allows us expand the biorefinery model such that it describes the real-world scenario more accurately. In addition, this approach may be tested on similarly structured problems in various fields.

Abstract

Chemical supply chains are a crucial component in the ongoing supply of large population centres. Unfortunately, episodes of extreme weather have, in recent years, revealed vulnerabilities in global supply networks to high-impact events. With a possible increase in both frequency and intensity of these events due to climate change, supply chains are at risk of disruption now more than ever, with potentially dire economic, societal, and environmental consequences. Acknowledging that the direct application of stochastic programming can quickly lead to very large CPU times, we propose an algorithm that combines the sample average approximation method with a selection heuristic for extreme event scenarios. Our method allows to analyse the tradeoff between economic performance and disruption risk, identifying supply chain configurations which are more resilient against extreme events. We demonstrate the effectiveness of this methodology in multiple case studies, showing how it identifies near optimal solutions in short CPU times.

Keywords: supply chains, optimization, stochastic programming, climate change, extreme events

1. Introduction

Supply chains today have evolved to become an integral and indispensable part of the global economy. What started out centuries ago as small scale, local trade networks, has evolved into an interconnected system spanning all inhabited continents. Along with unprecedented scale and reach, todays supply chains involve more stakeholders than ever: Owners and operators with direct financial stakes, customers depending on an ongoing supply of essential goods such as food and medicine, and local and national governments tasked to supply their populace with water, gas, and other utilities.

As the value and importance of supply chains has increased, so has the academic interest in making them more efficient, with the fields of chemical engineering and operations research at the forefront. Much work done on the optimisation of supply chains has been deterministic, meaning that full information on the state of current and future parameter values is presupposed. In recent years however, optimisation of supply chains under uncertainty has become an active and important field of research, illustrating the importance of reflecting the uncertainty of everyday real-world processes in an accurate manner. In this context, the main focus in the literate has been to hedge against what we call "operational uncertainties", e.g. fluctuations in price, demand, or raw material availability. Significantly less attention has been given to uncertain events of higher

impact, but lower probability of occurrence. Extreme weather events, device failures, and blackouts (just to name a few) can all have potentially dire consequences for supply chains and the people that rely on them. This has been evidenced by periods of extreme weather affecting supply chains in recent years, like the 2011 Thailand floods, or the 2017 Atlantic hurricane season. And with recent findings projecting an increase in either frequency and/or intensity of such events due to climate change, the need for adequate methods to contribute to the resilience of such crucial systems is clear.

2. Problem statement

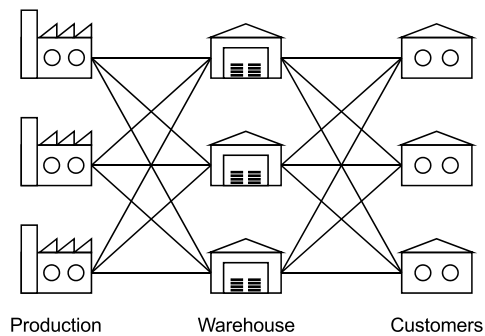
In this work, we will consider a multi-echelon supply chain similar to the one shown in Figure 1. We start with a number of potential and existing locations for production, storage, and sale of multiple products. Additionally, prices of materials and final products, costs of production, storage, and transport, as well as the cost of establishing new infrastructure are given. All production and storage locations may be disrupted by an extreme event with a certain probability of occurrence. The goal of this analysis is to determine the optimal supply chain configuration in terms of economic performance and risk, while considering said disruptions.

Figure 1: Example of a three-echelon supply chain (production, warehouse, customers), with transport connections linking adjacent echelons.

When applying a scenario-based, stochastic programming approach to such a task, the issue of problem size quickly becomes apparent. For example, a supply chain comprised of 10 disruptable units, along with 5 customer zones which can vary in demand between low, medium, and high, results in a set of $2^{10} \cdot 3^5 = 2.5 \cdot 10^5$ scenarios. While numerous methods exist to reduce the size of the problem to solve, these approaches often perform poorly when faced with disruption uncertainties, which are based on more heavy-tailed distributions than conventional operational uncertainties. The following section introduces a method to solve this problem efficiently.

3. Methodology

3.1. Two-stage stochastic programming

The method we propose to solve the issues mentioned above is based on two-stage stochastic programming (Birge and Louveaux, 1997), as well as the sample average approximation (SAA) method (Kleywegt et al., 2001). Two-stage stochastic programming, along with robust optimisation (Ben-Tal and Nemirovski, 2001), is one of the most common methods used to handle parameter uncertainty in mathematical programming, and usually relies on the partitioning of the underlying uncertainty into discrete realisations, or scenarios. Variables are partitioned into "first stage" and "second stage" variables. First stage variables are calculated before the realisation of any uncertainties and correspond to "here-and-now" decisions, such as initial capital investments. Second stage variables on the other hand are calculated after the uncertainties are revealed ("wait-and-see" decisions), and allow the model to take recourse, or corrective action. These second stage variables correspond to operational decisions, such as production rates and inventory levels.


3.2. Modeling disruptions

Applying stochastic programming, we can now introduce extreme event disruption into the supply chain model. These models typically contain constraints on the maximum available capacity for production or storage, of the form

$$prod_s \leq cap^{max} \tag{1}$$

where $prod_s$ is the current production level, and cap^{max} is the maximum production capacity. By introducing a disruption parameter φ_s, which can take a value between 0 and 1 for every scenario, we can vary the amount of capacity available for production, depending on the disruption scenario:

$$prod_s \leq \varphi_s \cdot cap^{max} \tag{2}$$

Assuming independence between disruption events, as well as binary disruption (disrupted, or not) with probability p, we can now construct a scenario set encompassing all units. For instance, let us consider a supply chain made up of two units, A and B. Four combinations of scenarios are possible here: 1. No disruption, 2. A disrupted, 3. B disrupted, 4. A & B disrupted. Assuming the disruption probability to be p and independent, the probability for each scenariowill be: 1. $(1-p)^2$, 2. $(1-p)p$, 3. $p(1-p)$, 4. p^2.

3.3. Sample average approximation

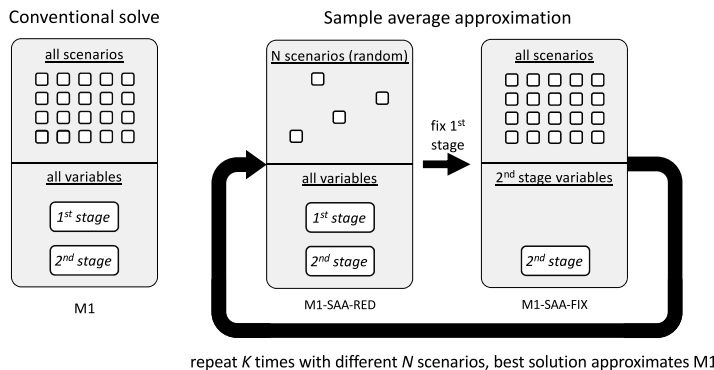
Our approach to improve the tractability of large supply chain problems is further based on the sample average approximation method, which is a Monte Carlo approach to reduce the problem size of large stochastic programs. When solving a conventional two-stage stochastic program, all first and second stage variables, as well as the full scenario space, are taken into account. The sample average approximation method on the other hand partitions the problem into two sub-problems, each of which is simpler to solve than the parent problem: First, the problem is solved using a random subset of N scenarios instead of the full scenario space. Next, the value of all first stage variables is fixed, and the problem is solved again using the full scenario space, ensuring feasibility of the solution in all scenarios. These two steps are now repeated K times, with a new independent sample of N scenarios chosen in each iteration. Finally, the best of the K candidate solutions is selected to approximate the true optimal solution. Figure 2 compares the SAA method to a two-stage stochastic programming model, in terms of scenarios and variables taken into account.


Figure 2: Illustration of the sample average approximation method (right), compared to a conventional two-stage stochastic programming solve.

3.4. Two-stage problem reduction

Based on these methods, we introduce the two-stage problem reduction (TSPR) algorithm, in which we follow the SAA, but apply a heuristic to formulate the sub-problems in a novel way. This heuristic capitalises on our knowledge of the structure of the disruption scenarios, as shown above. Specifically, instead of selecting *N* scenarios at random, we select scenarios with disruption of zero, one, and all units.

Exploiting our aprioristic knowledge of the scenario set allows the TSPR algorithm to approximate the true solution of the stochastic program after a single iteration, as opposed to *K* iterations in the SAA method. Furthermore, the TSPR method avoids the need to set parameter values (*N* and *K*), thereby simplifying implementation. Figure 3 illustrates this process.

Figure 3: Illustration of the TSPR method. Compared to the sample average approximation, predetermined scenarios are selected for the first solve, and no iterations are performed.

3.5. Risk management and multiobjective optimisation

When assessing the risk posed by extreme event disruption to supply chains, it is of importance to analyse the results beyond the expected economic performance, and to obtain information on the variability of the objective function in the uncertain parameter space. This can be achieved by implementing risk metrics in the optimisation model, which allow for the assessment of the performance of the supply chain in different scenarios. We employ the downside risk (DR) and worst case (WC) metrics (Sabio et al., 2014), though in principle others like the conditional value-at-risk can be implemented. The DR is calculated by comparing the performance of the supply chain in each scenario to a predefined cut-off Ω. Each scenario that falls under the cut-off is penalised by the product of this shortfall and the respective probability of occurrence. The WC metric on the other hand is obtained simply by taking the performance of the worst scenario. Once a metric is implemented in the optimisation model, multiobjective optimisation, for instance by way of the epsilon-constraint method (Ehrgott, 2005), can be employed to investigate the trade-offs between economic performance and risk of the supply chain, yielding a set of Pareto-optimal solutions. Figure 4 illustrates the process of combining the TSPR method with multiobjective optimisation from start to finish.

Figure 4: Combining the TSPR method with risk metrics and multiobjective optimisation.

Table 1: Comparing multiobjective optimisation of the petrochemical supply chain in terms of TSPR time reduction, difference in economic performance, and hypervolume measure.

Objectives	Time reduction	max E[profit] diff.	HV diff.
E[profit] vs. WC	93 %	0.0 %	3.2%
E[profit] vs. DR	99 %	0.0 %	0.0%

4. Case studies

4.1. Petrochemical supply chain

We demonstrate the capabilities of this methodology through its application to two case studies. The first is based on earlier work by Ruiz-Femenia et al. (Ruiz-Femenia et al., 2013), who investigated the trade-offs between environmental impact and economic performance in the design of a petrochemical supply chain in Europe.

In our case, the supply chain is made up of three echelons, with four potential locations for production plants, seven for warehouses, and four markets. The potential disruption of all plants and warehouses results in 2048 scenarios. The model seeks to optimise the supply chain's profit, and one of the risk metrics outlined above, while making decisions on production and storage capacities, transportation volumes, and inventory levels. We generated ten Pareto-optimal solutions using the epsilon-constraint method, both using the full scenario space, and the TSPR method. In order to adequately compare the two sets of solutions in each case, the hypervolume (HV) (Zitzler and Thiele, 1998) indicator was employed. This measure quantifies the area enclosed by the obtained solutions, and a reference point, as illustrated in Figure 5. The solutions obtained using the full scenario set are compared to the TSPR solutions in Table 1.

Figure 5: Illustration of the hypervolume (grey) enclosed by points p and the reference point r.

A significant reduction in solution time is evident, while at the same time the Pareto solutions of the TSPR run are close (WC) or near identical (DR) to their optimal counterparts.

4.2. Hydrogen supply chain

The TSPR method was further applied to the optimisation of a hydrogen supply chain for vehicle use in the UK, based on work by Almansoori and Shah (Almansoori and Shah, 2006). The model in our case has 9 regions, in each of which production and storage facilities can be established, along with a set customer demand. 512 disruption scenarios are considered, and the full-space solution is again compared to the TSPR solution for both the profit-WC and the profit-DR trade-off. A summary of the results can be found in Table 2, again showing that the TSPR method is able to achieve results close to the optimal case, while reducing the solution time significantly.

5. Conclusion

We addressed the problem of the design and risk management of optimal multi-echelon supply chains threatened by rare event disruptions, which to our knowledge had not been adequately

Table 2: Comparing multiobjective optimisation of the hydrogen supply chain in terms of TSPR time reduction, difference in economic performance, and hypervolume measure.

Objectives	Time reduction	max E[profit] diff.	HV diff.
E[profit] vs. WC	96 %	0.0 %	0.2%
E[profit] vs. DR	98 %	0.0 %	6.6%

addressed in the current literature. Combining the SAA algorithm with a selection heuristic, the TSPR methodology was developed to reduce the computational effort required to solve these types of problems. The effectiveness of the TSPR method was demonstrated through application to two supply chain case studies from the literature, achieving close to optimal results in significantly reduced time.

Abstract

The need for simultaneously decreasing carbon emissions and increasing operational profit motivates gas turbine and gas compressor operators to understand, minimize and control performance deterioration. Fouling is one of the most prevalent deterioration problems. This work addresses the causes and effects of fouling and investigates an approach to give decision-support on the questions if, how often and when compressor washing should be conducted. Integration with other maintenance actions is also considered. In this work, a discrete time-scheduling approach that follows the Resource Task Network framework is developed and formulated as a Mixed Integer Linear Program. A novel enumerator formulation makes this method simpler and easier to extend for different maintenance types than existing methods. Degradation is included in a linearized way for a case study from the Oil and Gas industry. Results indicate that washing scheduling is beneficial for the profit. This study gives the foundation for decision-support regarding additional investments in existing production systems, amortization, and supplies optimal maintenance schedules for various applied maintenance types.

Keywords: Maintenance scheduling, asset degradation, energy efficiency

1. Introduction and Background

Degradation of assets is an omnipresent phenomenon in the process industries where the lifetime of a plant easily reaches 30-50 years. Deterioriation of assets is inevitable. Over the lifecycle of an equipment its efficiency will decrease and it will degrade up to a level where it cannot be operated any longer or the operating company decides to take countermeasures. According to Diakunchak (1992) compressor fouling constitutes 70-85% of the performance loss caused by deterioration in gas turbines. With the latest IPCC report on achieving the maximum 1.5°C average temperature increase goal it is important to avoid any unnecessary waste of energy.

While the literature identifies performance degradation and declares washing as an appropriate countermeasure (Stalder, 2001), there is not much work done on the decision when to perform the washing procedure. The contribution of this work is to include the efficiency degradation of assets into the decision on when to perform maintenance tasks.
Figure 1: Example of the different types of degradation in a compressor and different types of maintenance to restore efficiency.

Kurz and Brun (2001) describe the degradation of gas turbine systems. Different mechanisms affect the degradation process: Increased tip clearance (Khalid et al., 1999) and changes in the airfoil geometry (Singh et al., 1996) are interlinked with the effect of non-recoverable degradation. Recoverable degradation, which can be (partially) reversed by specific methods (e.g. washing) is described as changes in the airfoil surface quality (Elrod et al., 1990). Kurz and Brun (2012) reported significant deterioration of different gas turbines, ranging between 2 and 12 % after one year of operation.

Hovland and Antoine (2006) optimise the power generation by applying parameter estimation via Kalman filtering combined with a hybrid dynamic model. Model predictive control is used with this hybrid dynamic model and compared to fixed washing schedules.

Xenos et al. (2016) investigate an air separation plant. Optimal operation and the maintenance of compressor networks are part of the developed MILP model. Online and offline washing are considered as part of the condition-based maintenance approach. The degradation is considered in three different cases: low, medium and high degradation. They are based on a study of industrial data. Offline-washing is not considered to be done during non-performance-related maintenance actions or regular shutdowns of the equipment. The degradation in the case study causes an increase in electrical power consumption of 2 % per month, which leads to high saving potential.

This paper addresses optimal scheduling of maintenance actions to increase operational efficiency. Section 2 presents the problem statement of this work. Even though this problem is common in many kinds of process industries, we will focus on a case study of an offshore compressor fleet of an oil and gas company, which is introduced in Section 3. A short overview of the mathematical formulation of the scheduling approach is given in Section 4. The results of the maintenance scheduling are illustrated and discussed within

the different subcases in Section 5. The conclusion gives an overview of the findings of this work and shows possible directions for future work.

2. Problem Statement and Case Study

The problem considered in this paper investigates how often online and offline washing in the context of other maintenance types should be conducted to optimally countermeasure deterioration effects and efficiency loss in compressors due to fouling. Furthermore, the actual benefit of washing can not always be determined beforehand. This information is important for the decision-making process; if a washing system should be installed on existing assets or not.

The case study that is used is inspired by a real fleet of compressors. In order to assess the performance of the formulation, the case study is analyzed with varying grid coarseness and time horizon length. For the length of the scheduling horizon a duration of 1-3 months was chosen, as this resembles the need for ahead-scheduling of maintenance workers and the ordering of specific resources such as spare parts or other supplies in most companies.

Table 1: Notation of the scheduling formulation

Index/Set	Description	Continuous Variable	Description
i	Task	$C_{r_c,t}$	Enumerator
j	Unit	$G_{r_c,t}$	Goodness of unit
t	Time Interval	K	Profit/Cost term
R	Resource	$\mu_{i,t}$	Discrete interaction
R_c	Resource (asset)	**Binary Variable**	**Description**
T_S	Time (Scheduling)	$N_{i,t}$	Maintenance task i starts at t
I	Maintenance tasks	**Parameters**	**Description**
		D_{r_c}	Degradation factor
Superscript	**Description**	**Superscript**	**Description**
NonRecov	Non-recoverable degradation	*ROnW*	Recoverable degradation (Online Washing)
RInsp	Recoverable degradation (Inspection)	*ROffW*	Recoverable degradation (Offline Washing)
Min	Minimum	*Max*	Maximum

3. Mathematical Modeling

The scheduling model is designed as a discrete-time model. While the exact starting times of maintenance actions depend on other external factors such as weather conditions or the changeover between two shifts, it is not important to work with a continuous-time model. A generic approach based on the Resource-Task Network (RTN) framework (Pantelides, 1994) is applied. The notation of the model is shown in Table 1.

The central element of the scheduling approach is the inherent goodness of every asset. This goodness is affected by degradation and therefore the efficiency decreases over time.

As depicted in Figure 1 the efficiency of the compressor is decreasing over time. There are different terms for the various types of degradation and there are 5 distinctive maintenance modes that have particular effects. Different counters for each type of degradation are used to calculate the time passed since the last maintenance has taken place. Every conducted maintenance resets one or multiple counters, which are used to model the degradation in a linear fashion. The goodness degradation is defined as follows:

$$
\begin{aligned}
G_{r_c,t} = & G_{r_c}^{initial} - D_{r_c}^{NonRecov}(C_{r_c,t}^{GN} - 1) - D_{r_c}^{RInsp}(C_{r_c,t}^{RInsp} - 1) \\
& - D_{r_c}^{ROffW}(C_{r_c,t}^{ROffW} - 1) - D_{r_c}^{ROnW}(C_{r_c,t}^{ROnW} - 1), \forall r_c \in R_c, \, t \in T_S
\end{aligned}
\tag{1}
$$

The enumerators are each formulated in a comparable way. As an example, the enumerator $C_{r_c,t}^{ROnW}$ for counting the time intervals since the last online washing is introduced:

$$
C_{r_c,t}^{ROnW} \geq C_{r_c,t-1}^{ROnW} + 1 - M \sum_{i_{r_c}}^{I_{OnW}} N_{i,t}, \forall r_c \in R_c, \, t \in T_S
\tag{2}
$$

$$
C_{r_c,t}^{ROnW} \leq C_{r_c,t-1}^{ROnW} + 1, \forall r_c \in R_c, \, t \in T_S
\tag{3}
$$

$$
C_{r_c,t}^{ROnW} \leq 1 + M(1 - \sum_{i_{r_c}}^{I_{OnW}} N_{i,t}), \forall r_c \in R_c, \, t \in T_S
\tag{4}
$$

$$
C_{r_c,t}^{ROnW} \geq 1, \forall r_c \in R_c, \, t \in T_S
\tag{5}
$$

The enumerator for the Remaining Useful Life of the assets works in a similar fashion. However, it is reset by a short-term maintenance I_{SM} that does not restore the goodness but fixes operational problems with the asset. The formulation is not shown in this paper. In a real-world application a continuous input from a Condition Monitoring System would be required.

The resource balance describes that every active maintenance task $N_{i,t}$ is consuming a specific amount of resources $\mu_{i,t}$ from the initial amount of resources R_0, including the compressors and the maintenance personnel. When a task is concluded, these resources are released again for the following time interval.

$$
R_{r,t} = R_{initial} - \sum_{i}^{I} N_{i,t}\mu_{i,t}, \forall r \in R, \, t \in T_P
\tag{6}
$$

The target of the optimization is to maximize the profit, calculated by the production profit from each compressor, multiplied by the goodness of the compressor in each time interval minus the cost for maintenance.

$$
\max z = K_{profit} \sum_{plat}^{r_c} G_{r_c,t} - K_i \sum_{i} \sum_{t}^{T_S} N_{i,t}
\tag{7}
$$

Table 2: Results of the washing scheduling for a fleet size of 10 compressors. (Legend: H - Time Horizon, G - Grid Size, Off - Offline Washing, On - Online Washing)

Case	H: 1 month, G: 4 hours			H: 2 month, G: 4 hours		
	On	Off	On+Off	On	Off	On+Off
Improvement[1]	0.97%	0.13%	1.07%	2.06%	1.50%	3.30%
MIP-Gap	0.72%	0.46%	0.61%	7.03%	4.45%	2.24%
CPU-s[2]	1800	1800	1800	1800	1800	1800

Case	H: 1 month, G: 8 hours			H: 2 months, G: 8 hours		
	On	Off	On+Off	On	Off	On+Off
Improvement[1]	1.29%	0.38%	1.28%	1.88%	0.84%	2.71%
MIP-Gap	0.26%	0.01%	0.28%	3.42%	2.91%	1.19%
CPU-s[2]	1800	1411	1800	1800	1800	1800

[1]Improvement is calculated as the ratio between the case with solely regular maintenance types, but without any washing.

[2]The computation was terminated after a maximum of 1800 s or when the MIP-Gap was below a threshold of 0.01%.

4. Results and Discussion

Four different cases with fixed fleet size, but varying time horizon and grid size were solved using GAMS 24.8.4/CPLEX 12.7.1.0. The calculations are carried out as follows: Each case has the information that two different maintenance actions (long overhaul and short maintenance, e.g. change of a broken seal) must be conducted within the time horizon. This information could come in a real-world implementation e.g. from a higher level planning system. Furthermore, a specific combination of washing actions (online, offline or combined) can be conducted. The optimization problem tries to optimize production profit by recovering degradation of the compressors at the right time.

The improvement is calculated by comparing the three different scenarios for each case against the base-scenario in which no washing is performed, just the basic maintenance such as long overhauls and short-term maintenance. The quotient of the objective function for a specific scenario and the base scenario indicate the improvement.

The results of four different cases with three scenarios each are shown in Table 2. While the specific values of the objective function represent the entire production profit within the time horizon (see Eq. 7), the actual values of the production profit are not insightful. As the size of the optimization problem is larger the longer the time horizon is and the finer the grid size is, the scheduling algorithm is terminated prematurely in all cases at 1800 seconds. Therefore, the result shows the minimum improvement, as further calculation might improve the objective function. More exhaustive calculations may be conducted in a follow-up study.

The results show that the algorithm is able to improve the operating profit. The improvement ranges between 0.4% and 3.3%. Several trends can be observed: The longer the time horizon is, the more improvement can be observed. As the overall degradation (non-recoverable plus all recoverable degradation) is set to 5% per year, this makes sense, as smaller decreases in the efficiency do not necessarily justify conduction of washing, while

on a longer time horizon washing is more economically viable. With fixed computational time, the gap between the best bound of the problem and the integer solution is dependent on the time horizon and the grid size and is thus scaling with the problem size.

5. Conclusion

A novel maintenance scheduling approach was presented in this work. The model differs from other work, as it combines the information about the asset degradation via an enumerator-approach into the decision-making for several types of maintenance actions, especially washing actions.

Degradation is considered to be a combination of recoverable degradation, non-recoverable degradation and the decreasing remaining useful lifetime of an asset. Results show that the scheduling of the proposed compressor washing in addition to other maintenance types is able to improve the production profit by up to 3.3% compared to operations without the compressor washing. Next to the fact that the scheduling model can give help to optimize the operation of process networks, it can be used as a decision-support tool. By comparing the possible saving introduced through new maintenance types, e.g. washing, a maximum capital investment for the amortization within a specific timeframe can be calculated.

Future work will investigate a multi-time-scale model that integrates both long-term planning and short-term scheduling of maintenance.

Turbulent flow modeling in continuous oscillatory flow baffled reactor using STAR CCM+

Nikola Kljajić, Branislav Todić, Danijela Slavnić, Nikola Nikačević[*]

Faculty of Technology and Metallurgy, University of Belgrade, Karnegijeva 4, Belgrade 11000, Serbia

nikacevic@tmf.bg.ac.rs

Abstract

A detailed transient tridimensional CFD model of the turbulent flow of liquid phase inside of 26 mm diameter continuous oscillatory baffled reactor (COBR) was developed using STAR CCM+ software. The model considered a large number of COBR cavities separated with single-orifice baffles. The CFD model was validated using residence time distribution experiments with several flowrates and frequencies. Different from previous studies, flow oscillations in our work were generated using a membrane pump, which enabled lower amounts of backflow. Simulations were used to analyse flow patterns and mixing for several values of inlet flowrate and oscillation frequencies.

Keywords: continuous oscillatory flow baffled reactors, process intensification, CFD modeling.

1. Introduction

Oscillatory flow baffled reactors are a successful example of process intensification in chemical engineering. They have been shown to provide improved performance in a number of process operations, including crystallization, polymerisation, adsorption, reaction etc. (Jolliffe et al., 2018). Typically, continuous oscillatory baffled reactors (COBRs) are made up of a number of equally spaced single-orifice baffles inside a tube. However, other designs (e.g. helical and double-helical ribbons) have been used as well. The main characteristic of COBRs is the enhancement of mixing by using flow oscillations, which periodically collide with baffles forming vortices. The intensity of mixing in COBRs is dependent on the oscillation amplitude and frequency, as well as reactor geometry. The application of these continuous reactors can lead to significant improvements in productivity, investment and operating cost savings, as well as better reaction control, for slow processes typically performed in batch systems. Initial studies with COBRs explained the mechanisms of oscillatory flow mixing by using a number of experimental approaches. Ni et al. (2002) presented the first 3-D CFD model which solved Navier–Stokes equations (i.e. without stream function) for oscillatory Reynolds numbers covering both symmetric and asymmetric flows. Due to computational complexity the model included only a few cavities (i.e. cells between baffles), and was validated with particle image velocimetry (PIV) experiments in oscillatory baffled column (OBC) with fixed baffles. Several other later CFD works also focused on a smaller number of cavities due to similar reasons (Hamzah et al., 2012).

In this study, the transient 3D CFD model of the turbulent flow of liquid inside of single-orifice baffled tube reactor was developed using K-Epsilon turbulence model and STAR CCM+ software. In order to provide a full picture of the flow inside the entire

reactor, the model included a large number of cavities (total of 29). This enabled direct experimental validation using residence time distribution studies, conducted for several sets of input oscillation frequency and amplitude. Backflow created during generation of flow oscillations was minimized by feeding the fluid to the reactor using a membrane pump with a non-return valve. Furthermore, by using a membrane pump, there is no need for an oscillator in addition to the regular pump (net flow), used in many previous studies (i.e. more cost effective). Detailed analysis of velocity streamlines, vorticity, turbulent viscosity, and kinetic energy is used to provide insights into fluid flow and mixing flow inside of COBR with this design.

2. Methodology

2.1 Experimental setup and procedures

Experiments were performed in a 2 m long reactor with an internal diameter of 26 mm. Single-orifice baffles were placed along the reactor tube, equally spaced at 1.5 times the internal diameter of the tube. The primary stream was generated by the dosing membrane pump and carried fluid oscillatory movement. The control unit of this pump allows the volume and frequency of strokes to be adjusted. The process fluid was water at atmospheric pressure and temperature. The tracer used in experiments was a solution of methylene blue in the concentration of 2.0 g/l. The pulse-response method was used to examine the liquid flow pattern in the COBR. The samples were taken from the 29th cavity, placed 1.03 m downstream of the injecting point. The absorbance of samples was determined using a UV-VIS spectrophotometer. Details of the experimental setup and procedures can be found in Slavnic et al. (2017).

2.2 3D COBR model development

The 3D COBR model was defined using Simcenter STAR-CCM+ 12.04 software. The reactor geometry was drawn using SolidWorks 2011 CAD software and imported into STAR CCM+. Reactor dimensions corresponded to our experimental setup. Due to the reactor symmetry, only one horizontal half of the full volume was modelled, in order to speed up the computing time. The reactor geometry was split up into regions, which define boundaries and regions of interest. Surface and volume mesh was generated using Polyhedral and Prism Layer Meshers, respectively. To ensure higher precision, denser mesh settings were used in boundaries around the baffles. A higher computational speed was achieved by decreasing the density of meshes around tube walls.

The reactor model includes balance equations for momentum, mass and energy, as well as continuity equations. The balance equations used can be presented as:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \left[\rho \left(\bar{v} - v_g \right) \right] = 0 \tag{1}$$

$$\frac{\partial (\rho \bar{v})}{\partial t} + \nabla \cdot \left[\rho \bar{v} \left(\bar{v} - v_g \right) \right] = -\nabla \cdot \bar{p} I + \nabla \cdot (T + T_t) + f_b \tag{2}$$

where ρ is fluid density, t time, $\bar{v}$ and $\bar{p}$ are mean velocity and pressure, v_g referent velocity, I identity tensor, T viscous stress tensor, T_t Reynolds stress tensor and f_b is resultant of the body forces. Unsteady state turbulent flow of multi-component non-reacting liquid was modelled using the K-Epsilon turbulence model:

$$\frac{\partial(\rho k)}{\partial t} + \nabla \cdot (\rho k \overline{v}) = \nabla \cdot \left[\left(\mu + \frac{\mu_t}{\sigma_t} \right) \nabla k \right] + P_k - \rho (\varepsilon - \varepsilon_0) + S_k \qquad (3)$$

$$\frac{\partial(\rho \varepsilon)}{\partial t} + \nabla \cdot (\rho \varepsilon \overline{v}) = \nabla \cdot \left[\left(\mu + \frac{\mu_t}{\sigma_\varepsilon} \right) \nabla \varepsilon \right] + \frac{1}{T_e} C_{\varepsilon 1} P_\varepsilon - C_{\varepsilon 2} f_2 \rho \left(\frac{\varepsilon}{T_e} - \frac{\varepsilon_0}{T_0} \right) + S_\varepsilon \qquad (4)$$

where μ is dynamic viscosity, μ_t is turbulent eddy viscosity, σ_t, σ_ε, $C_{\varepsilon 1}$, $C_{\varepsilon 2}$ model coefficients, P_k, P_ε terms which define generation of kinetic energy k and dissipation of turbulent energy ε, f_2 dampening function, S_k, S_ε source terms, T_e large-eddy time scale and T_0 specific time scale.

Inlet boundaries for base and tracer fluid were defined as oscillatory and impulse functions, respectively. The inlet of base fluid was defined using a data matrix generated in Matlab based on experimental measurements of the inlet flow. Schematic representation of base fluid oscillatory flow at the inlet is shown in Figure 1. The inlet of the tracer is defined as an impulse of flow with the volume of 2 ml in the 0.5 s interval, which replicates the syringe injection of tracer into the reactor.
Figure 1 - Schematic representation of base fluid oscillatory flow at the reactor inlet (A, B, C, D and E represent specific moments during each oscillation). Notes: f – pump frequency; Q_0 – base flowrate; Q_n – total flowrate;

3. Results and discussion

3.1 Model validation

Reliable design, scale-up and control of COBRs are conditioned by fluid flow accurate representation. One of the most effective experimental approaches for defining non-ideal flow is still the investigation of residence time distribution (RTD) of fluid elements, realized through tracer experiments and population-based analysis. In order to validate our CFD model, comparison with experimental RTD under a range of conditions was performed. Three tracer experiments covered a range of net flow Reynolds numbers (Re_n = 142, 453 and 678), oscillatory Reynolds numbers (Re_o = 670, 1644 and 2458) and frequencies (f = 0.5, 1 and 2 s^{-1}).

By solving the material balance for the tracer component in STAR CCM+, and integrating (spatially) molar fractions at the outlet plane, we are able to calculate the residence time probability distribution (i.e. E-curve). Comparison of E-curves for two of the experiments is shown in Figure 2 and depicts a very good agreement between the CFD model and experiments. E-curve from the third experiment (not shown in Figure

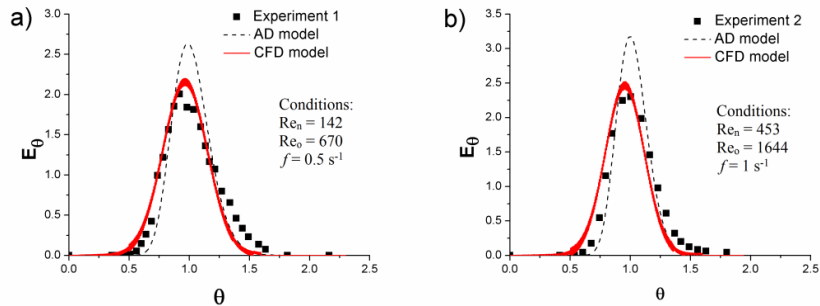
2) also matched well with the CFD model. We also compared the resulting E-curve obtained by using the axial-dispersion (AD) model, based on the empirical correlation for Peclet number (Slavnic et al., 2017). Figure 2 shows that in the range of high Re_n values, CFD model considerably outperforms the AD model. Albeit slower to solve and with a significantly higher computational cost, an additional benefit of the CFD model is it provides a more detailed picture of the fluid flow inside of COBRs. This is valuable for further process intensification considerations of such reactors.


Figure 2 – Comparison of RTD for CFD model with the experimental and AD model results: a) Experiment 1; b) Experiment 2.

Recently, Kimuli et al. (2017) performed a similar investigation, where a CFD model (using STAR CCM+ software) with a large number of cavities was developed and validated using RTD experiments. However, they focused on lower values of Re_n (i.e. laminar flows with $Re_n = 8.4$ and 21.2) and smaller meso-scale reactors (5 mm internal diameter). Mazubert et al. (2016) also used commercial CFD software to simulate laminar liquid flow through meso-scale COBRs with multiple designs of baffles. Several previous studies, which focused on turbulent flow, performed simulations for a small number of cavities (i.e one to three) (Nogueira et al., 2013).

Our results show that the developed CFD model can be used to predict turbulent liquid flow in larger-scale COBRs and that such model can provide more reliable information compared to the more traditional models, such as the AD model.

One of the critical parameters which can affect the solutions of CFD models in various simulations is mesh refinement and its convergence. To that end, we conducted simulations with several mesh densities (i.e. lower and higher densities) in order to choose optimal mesh density, which both do not extensively affect the final results and does not slow down the simulations. Results with the optimized mesh density were within 2% of those obtained with a very fine mesh.

3.2 Analysis of turbulent flow in COBR

The mechanism of oscillatory flow mixing in COBRs was examined in the literature. However, previous studies focused on experiments were flow oscillations were generated by either a piston which periodically moves the entire fluid volume inside the reactor or mechanical periodic movements of baffles inside the reactor tube or movements of the entire reactor (i.e. column). These approaches result in a significant amount of backflow, and are in addition costly in terms of additional equipment and devices. In our experiments, input flow oscillations are generated by a dosing membrane

pump which supplies the reactor with the fluid. In this type of design, fluids' forward flow rate is significantly higher than the backflow rate, due to the use of a non-return valve positioned after the pump. Thus, the mechanism of oscillatory flow mixing warrants a further evaluation for this case.

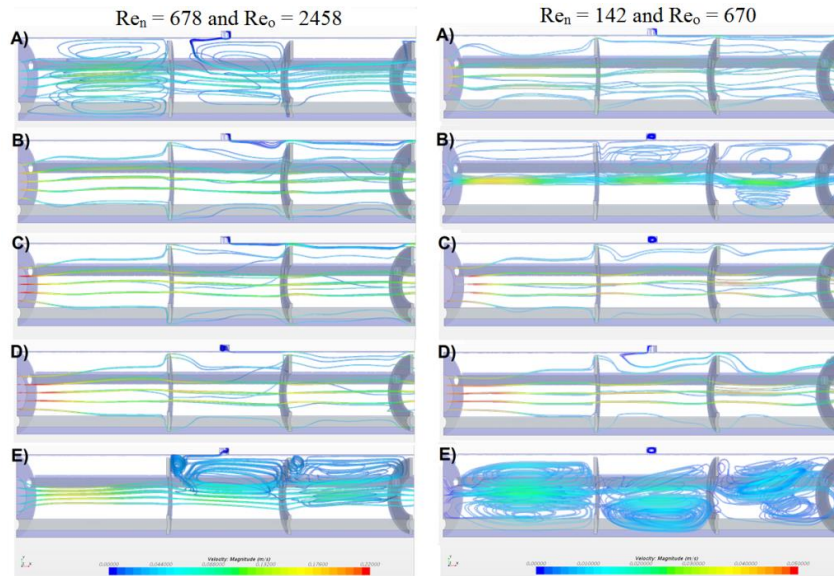
Simulation results were analysed in terms of velocity streamlines and intensity, vorticity, turbulent viscosity and kinetic energy for several key moments during each oscillation (marked A – E in Figure 1). Figure 3 shows the velocity streamlines for two sets of conditions. At higher inlet flowrates and oscillation frequency ($Re_n = 678$ and $Re_o = 2458$), velocity streamlines show that before the stoke of the oscillatory wave (period A), there is a recirculation of flow and mixing. Fluid energy is insufficient to be transported into the next or previous cavity, but is mixed inside of the current one. When the oscillatory component of flow is active (periods B, C and D), there is no considerable radial flow mixing and fluid energy is used for its transport through the reactor. At that time the flow core is formed by fluid moving through the baffle openings at higher velocities. However, a small fraction of fluid circumvents the baffles and moves along the tube walls at significantly lower velocities, due to loss of energy from the collision with the rings and wall friction (laminar flow). At the period after the stoke of the oscillatory flow wave (period E), inertial forces are decreased and there is intense (radial) fluid mixing. It is at this time turbulent eddies are formed, and their concentration is highest in the volume right behind the baffles. At lower flowrates and oscillation frequency ($Re_n = 142$ and $Re_o = 670$), the behaviour is quite different and fluid mixing is not pronounced in periods A-D. In this case, intense mixing only occurs in period E after the oscillatory flow wave impact.


Figure 3 – Velocity streamlines at higher inlet flowrates and oscillation frequency (left figure) and lower flowrates and oscillation frequency (right figure) for characteristic time periods (periods A – E shown in Figure 2).

In both cases (high and low flowrates and oscillation peak velocities), observed vorticity before the oscillatory flow wave (period A) is minimal. This is due to the low backflow

in our system. At the stroke start, during and right after the wave impact (B, C and D), vorticity increases in areas of fluid collision with the baffles. After the impact (period E), vortices spread within the same cavity, but decrease in intensity. The values of turbulent viscosity show the turbulent transport is dominant in both cases and the laminar layer only exists close to the walls. The laminar layer width for high and low inlet flowrates and oscillation frequency case is $0.5 - 2$ and $2 - 4$ mm, respectively.

4. Conclusions

3D CFD model of the oscillatory flow of liquid in turbulent regime inside of COBR was developed using STAR CCM+ software. The model included a large number of cavities and was validated by direct comparison to RTD experiments for several flowrates and oscillation frequencies. The developed CFD model was shown to outperform the classical AD model, based on literature correlation for Peclet number. The analysis of velocity streamlines, vorticity and turbulent viscosity, obtained with minimal backflow related to the generation of oscillations, revealed specific findings about fluid mixing inside of COBR with this particular design. Recirculation of fluid flow occurs when the oscillatory component of flow is not active, but its intensity can be affected by manipulating the magnitude and frequency of the flow. Turbulence is most intense in moments before and after the fluid wave collision. Higher frequencies and flowrates intensify the momentum transfer and cause for a higher fraction of reactor volume to be used in turbulent fluid mixing.

Abstract

Many studies focus on the performance of electrochemical reactors and very often result in presenting a polarization curve.

Modeling and simulation can simplify the examination of overpotentials, which reduce process performance, and thus help finding an improved electrolyzer for an envisaged application. Moreover, they are useful for optimization of the design and operation at process level.

Herein, we develop a mechanistic, dynamic model for electrochemical water splitting and compare two established cell setups, the PEM-cell and the GAP-cell, in order to assess the performance and optimization potentials of these processes. We model ohmic overpotentials and mass transport limitations in order to show their impact on energy losses, especially towards higher cell potentials. Further, we consider the formation of gas bubbles which have been identified as major source of undesired overpotentials at high current densities. We model this decrease of the effective electrode area via geometrical considerations using experimental investigations of bubble dynamics, including the formation, growth, and detachment of single hydrogen bubbles during electrolysis carried out by Yang et al. (2015).

A parameter estimation results in a good match of the experimental data and the simulation results. For the GAP-cell, the contribution of different overpotentials to the whole electrolyzer performance is determined with high accuracy.

We use the model to show reachable current densities, cell efficiencies and dominant loss terms of the reactor setups and thus indicate optimization possibilities and potentials.

Keywords: water electrolysis, rigorous modeling and simulation, overpotential distribution, performance comparison

1. Introduction

Electrolyzers face increasing overpotentials towards high cell potentials reducing the energy efficiency of the reactor. At elevated cell potentials, the reactors even tend to reach a limiting current density with high energy losses due to mass transport limitations or electrode coverage by evolving product gases. Therefore, an optimal operating point balances high product formation and high energy losses. Additionally, different concepts of electrolyzer setups exist with specific dominating overpotentials, such that depending on the type of application, one or the other setup must be selected. Therefore, the most beneficial combination of setup and cell potential should be found for an envisaged application.

To simplify this search, research activities in the field of electrochemical cell modeling is extensive and numerous models exist for various applications, setups or even individual components. These models vary in their level of detail, including 0D, 1D, 2D or even 3D models, the number

of assumptions taken into account, etc. For instance Wu (2016) presents a review on transport and performance modeling of PEM fuel cells.
Figure 1: Scheme of both reactor setups with overpotentials taken into account in the model.

A classic application of electrolysis is water splitting. Here, the oxygen evolution reaction (OER) occurs at the anode and the hydrogen evolution reaction (HER) at the cathode. There are (among others) two established cell setups for water electrolysis: The older and more common is the alkaline GAP-cell, where an aqueous ionic solution as liquid electrolyte is present. The newer setup is the Proton Exchange Membrane (PEM) electrolysis. Here a solid polymer like Nafion is used as a membrane and electrolyte at the same time (see Fig. 1).

In order to assess the performance and optimization potentials of these processes, we develop dynamic models for water electrolysis in an electrochemical membrane reactor (ecMR) with both cell setups. Dynamic models allow the analysis of control-strategies or demand side management, though, for the herein presented results the dynamics are not needed. The models take into account all important overpotentials mostly via state-of-the art equations found in literature. We introduce a new model for simulating the overpotential due to bubble formation.

The models are validated with experimental data from literature and unknown parameters are determined. Simulations are then executed to characterize the behaviour of each setup. Knowing the influence of relevant loss terms, individual optimization approaches can be developed for each setup.

2. Modeling

We develop dynamic models for potentiostatic electrochemical water splitting in a PEM-cell and a GAP-cell for unpressurised reactors at room temperature based on mass balances, transport equations and electrochemical kinetics. This results in models considering the overpotentials shown in Figure 1. Additionally, we assume ideal gases, 100 % Faradaic efficiency, fully hydrated membranes, no cross-over of gases and a uniformly distributed current across the cell.

In a PEM-cell the reactants need to pass through the porous gas diffusion layers (GDL) to reach the electrode-membrane interface, the products need to be removed from this site of the electrochemical reaction. We describe the transport through the GDL via mass balances with diffusion by Fick's law. In a GAP-cell, the electrodes are immersed in an ionic solution. Here, we model mass transport through the electrolyte via mass balances taking into account diffusion and migration, as

well as ionic equilibria with ph-calculation. Mass transport limitations causes the concentration of reactants to decrease and of products to increase leading to concentration overpotentials at the electrodes' surfaces.

We relate the molar consumption and production rates of the electrochemical reactions to the cell's current density by Faraday's law. The effect of changing concentrations on the concentration overpotential is then calculated via the Nernst equation (Newman and Thomas-Alyea, 2004).

The electrochemical reactions are induced by activation overpotentials. We calculate this activation loss via the Butler-Volmer equation (Newman and Thomas-Alyea, 2004) and use experimental results for nonlinear regression to estimate the reaction specific transfer coefficients α and exchange current densities j_0.

Ohmic overvoltages are caused by the resistance to the flow of electrons or ions by the electrolyte, the electrodes and their various interconnectors. According to Ohm's law, we correlate the ohmic overvoltage linearly proportional to the current by the conductivity factor.

In water electrolysis, a water flux through the membrane occurs, which is governed by: (i) electro-osmotic drag, (ii) diffusion driven by a concentration gradient and (iii) convection if a pressure gradient is present. In this study, no pressure gradient is considered.

The physical blocking of the electrodes in both setups by the gaseous reaction products is named as major source for undesired overpotentials according to Yang et al. (2015), though, no modeling approach could be found in literature. Therefore, we describe a first approach to model this effect:

Influence of electrode coverage by product gases The gas bubbles are formed at the surface of the electrode where they grow until the uplift force exceeds the surface forces binding the bubbles to the electrodes. During the time span τ from formation till detachment, the gas bubbles reduce the effective surface of the electrode that can be used for electrochemical reactions.

$$\eta_{ohm_{el}} = \frac{R_{0_{el}} I_{total}}{A_{rel}} \tag{1}$$

$$\left| \begin{array}{ll} \textbf{GAP} & \textbf{PEM} \\ A_{rel,GAP} = \frac{A_0 - A_{cov}}{A_0} & A_{rel,PEM} = \frac{V_0 - V_{gas}}{V_0} \\ A_{cov} = \frac{\pi d_{contact}^2}{4} number_{bub} & V_0 = x \cdot A_{PEM} \cdot \varepsilon \\ number_{bub} = \frac{V_{gas}}{\bar{V}_{bub}} \end{array} \right. \tag{2}$$

$$V_{gas} = \dot{V}_{gas} \tau \tag{3}$$

$$\dot{V}_{gas} = \frac{\dot{n}_{gas} R_{ig} T}{p} \tag{4}$$

For modeling the overpotential due to bubble formation, we introduce a dimensionless variable A_{rel} into the ohmic relationship of the electrode's overpotential as shown in Eq. (1). A_{rel} describes the fraction of the total electrode surface, which can still be used for electrochemical reactions, and is calculated according to Eq. (2) comparing the original electrode surface A_0 to the covered electrode surface A_{cov} for the GAP-cell and for the PEM-cell via comparing the product gas volume in the catalyst layer V_{gas} and the inner reactive pore volume of the GDL $V_{0,GDL}$. This allows to introduce a linear relationship between the resistance and the (un)covered area with an infinite resistance when the whole surface is covered by bubbles. $R_{0_{el}}$ is the electrode's electric resistance when fully surrounded by water. This resistance is the product of the specific electric resistance of the electrode's material and a geometric factor. For determining A_{cov}, we calculate the number of bubbles $number_{bub}$ using the total volume of produced gas V_{gas} and the mean volume of a single bubble $\bar{V}_{bub} = 0.45e^{-12}$ m^3 which was calculated by averaging time dependent bubble radii measured by Yang et al. (2015). The mean diameter of the contact area $d_{contact} = 80\,\mu$m is taken from the same data and probably a parameter dependent on $\bar{V}_{bub}$.

Using the ideal gas law (4), we calculate the volume flows of the evolving gases $\dot{V}_{gas}$ from the electrochemical consumption and production rates giving the total volume of gas bubbles bound to the electrode via Eq. (3). The simplified assumption of spherical bubbles is justified as the con-

tact angles between bubble and surface were small with values between $5°$ and $15°$ (Yang et al., 2015). V_0 for the PEM-cell is calculated using the GDL's porosity ε, its thickness x and the cross sectional area of the PEM-cell A_{PEM}.

3. Results

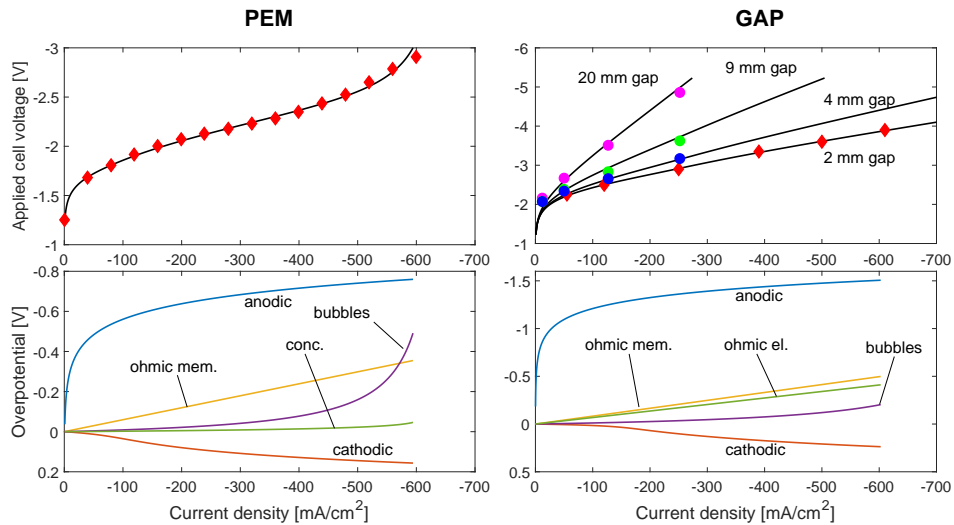
In Figure 2 we show the results of the parameter estimations comparing simulated and experimentally determined polarization curves for both reactor setups (upper row) as well as an analysis of the prevailing overpotentials (lower row). The estimated parameters are listed in Table 1. Note that τ for the PEM-cell is estimated as the value from literature holds for electrodes freely immersed in a liquid. The assumption of a constant membrane's proton conductivity is based on a well hydrated membrane due to the electro-osmotic drag. Especially for the GAP-cell it has to be noted, that the Butler-Volmer parameters correlate strongly and therefore, could not be identified.


Figure 2: Top row: Polarization curves (black line: simulation results; Red diamonds: experimental data by Dedigama et al. (2014) for PEM-cell and by Phillips et al. (2017) for GAP-cell used for parameter estimation; Blue/green/purple circles: experimental data by Phillips et al. (2017) used for model validation). Bottom row: Overpotentials depending on current density for PEM-cell and GAP-cell with $2\,mm$ gap. (shown: anodic activation; cathodic activation; ohmic overpot. of membrane; ohmic overpot. of electrolyte; concentration overpot.; overpot. caused by gas bubbles).

PEM-cell   With parameter estimation, we achieve a good match of the experimental and simulated data for the PEM-cell, even for high applied cell voltages (Figure 2, upper row, left). Close to the onset potential, the cell behaviour depends almost completely on the anodic activation overpotential (see Figure 2, lower row, left). This is caused by a high activation energy of the water splitting reaction which is a consequence of a non-optimized platinum electrode used in the experiments. A catalyst optimized for the OER reaction could lower this loss term significantly.

The current density shows the characteristic exponential rise governed by the reaction kinetics which turns into a linear section governed by ohmic overpotentials. The ohmic overpotential exhibits a fairly high influence compared to standard PEM-cells. Simulations with the same model with a typical value for fully hydrated Nafion membranes of $9.4\,\frac{S}{m}$ results in a significantly lower ohmic overvoltage of $0.12\,V$ at $600\,\frac{mA}{cm^2}$.

The concentration overpotential is low, indicating a sufficient transport of reactants through the

GDL. Towards higher current densities the gradient of the current density curve increases going over to an asymptotic course due to increased gas production and an exponential rise of the overvoltage caused by gas bubbles.

To reach higher current densities with the PEM-cell, the removal of gases through the GDL has to be improved. While the study by Dedigama employs a GDL with a porosity of 0.4, porosities over 0.5 are available on the market. Another possibility is the employment of water vapour instead of liquid water. Here, bubble formation can be avoided but this has to be contrasted with a much lower water concentration.

The efficiencies calculated with the PEM-model for the experimental setup by Dedigama are fairly low. At a typical current density for industrial applications of 500 $\frac{mA}{cm^2}$ the efficiency is only 46%. Simulating the same model with a membrane conductivity elevated to the literature value of 9.4 $\frac{S}{m}$ causes a small improvement to 50%. At a lower current density of 200 $\frac{mA}{cm^2}$ the cell efficiency reaches 61%, which is significantly lower than typical values shown by state of the art PEM-electrolyzers located around 76% (Bertuccioli et al. (2014)) at the same current density. To reach desired efficiency values in the range of 80% or higher, the utilization of an optimized catalyst material is mandatory.

Alkaline GAP-cell   We validate the GAP-cell model with experimental investigations by Phillips et al. (2017) who varied the inter-electrode gap (the distance between anode and cathode) between 2 mm and 20 mm. We use the experimental results of the 2 mm cell for parameter estimation and achieve a good match of the simulated and experimentally determined polarization curve as shown in Figure 2 (upper row, right).

The ecMR investigated by Phillips shows a relatively high onset potential of 1.75 V due to the non optimized stainless steel electrodes used for the experiments. The current density rises exponentially. Around 2.5 V the curve reaches a linear section as the ohmic overpotential gains increasing influence on the ecMR's performance. The overvoltage caused by evolving gas bubbles is negligible at low and medium current densities and rises with a fast growing gradient at elevated current densities. However, at 600 $\frac{mA}{cm^2}$ the overvoltage is still rather small with a value of 0.20 V.

Changing the inter-electrode gap-widths in the model, while keeping the estimated parameters constant we show that the simulations could be extrapolated to higher gap-widths (Figure 2, upper row, right, circles).

Comparison   The course of the anodic activation overpotentials of both reactor setups is similar, the absolute value, however, is about twice as high as for the GAP-cell. This indicates that the chosen stainless steel electrodes in the GAP-cell experiments have a significantly lower catalytic activity for the OER than the platinum electrode employed in the PEM-cell experiments. Even though different cathodes were also employed, this influence seems negligible, as the cathodic activation overpotentials reach similar values for PEM and GAP-cell. The ohmic overpotential of

the membrane used in the GAP-cell experiments shows a higher value than the Nafion membrane in the PEM-cell. The maximum total ohmic overvoltage of the GAP-cell at $600 \, \frac{\text{mA}}{\text{cm}^2}$ of $0.90 \, \text{V}$ is much higher than the ohmic overvoltage of the PEM-cell due to the additional ohmic resistance caused by proton movement in the electrolyte, only present in the GAP-cell.

For comparison purposes, we refer to a third study by Siracusano et al. (2017) which introduces an optimized PEM-cell. Instead of the typical Nafion membrane Aquivion was used as membrane material, which offers a higher proton conductivity along with a lower thickness. The second and most important improvement was the implementation of an $Ir_{0.7}Ru_{0.3}O_x$ catalyst for the OER. In simulations with these adjustments, the limiting current density remains the same, though high current densities are reached much faster with a competitive energy efficiency of $76\,\%$ at $200 \, \frac{\text{mA}}{\text{cm}^2}$.

4. Conclusion

In order to assess the performance and optimization potentials of different reactor setups for water electrolysis, we develop mechanistic, dynamic models for a PEM-cell and a GAP-cell. The models, based on mass balances, transport equations and electrochemical kinetics are mostly based on state-of-the art equations found in literature. We introduce a new model for simulating the influence of evolving gas bubbles on the reactor's performance.
The models are validated with chosen experiments from literature. We determine unknown parameters by estimation under consideration of reasonable upper and lower bounds. A good match of simulated and experimental data is achieved. We show that the GAP-cell model is able to be extrapolated to different gap widths.

We investigate the reactor setups with regard to reachable current densities, cell efficiency and dominant loss terms. For the chosen experimental setups we show that high anodic activation overpotentials due to poor catalytic activity of the anodic electrode for the OER limit the performance in both cases. Another major limitation for the PEM-cell is the formation of bubbles. A higher GDL porosity and the change from a liquid to a gaseous inlet stream could be possible solutions.

Study on the formation of chemical wave patterns for the *Belousov–Zhabotinsky* reaction system

Jiali Ai,[a] Wei Sun,[a] Chi Zhai[a]*

[a]*College of Chemical Engineering, Beijing University of Chemical Technology, North Third Ring Road 15, Chaoyang District, Beijing, 100029, China*

Abstract

The *Belousov–Zhabotinsky* (BZ) reaction system is famous because it can generate self-organized patterns, also known as "chemical waves". Pattern formation out of an initially homogeneous system is seemingly violating the 2nd-law of thermodynamics (order is produced out of disorder), while in fact, the BZ reaction is an open, far-from thermodynamic equilibrium system, where instability is the cause of morphogenesis and Hopf bifurcation of the reaction kinetics can generate self-oscillatory state trajectories. In this paper, the evolution of the BZ reaction in a two dimensional diffusion system is studied by the numerical computation methods, for the purpose of reconstructing the chemical wave patterns. The similarity of the chemical waves to many complex systems in biology, ecology and engineering makes current study potentially significant. With the study of the pattern formation, we hope provide some thoughts on complex system theory, thermodynamics of the self-oscillatory reaction system, and numerical computation methods on complex patterns, etc.

Keywords: far-from thermodynamic equilibrium, instabilities, reaction-diffusion system, Hopf bifurcation.

1. Introduction

As early as 1950s, Turing (1952) has studied the possibility of morphogenesis out of a diffusive-reactive system. While, Pattern formation out of an initially homogeneous system is seemingly violating the 2nd-law of thermodynamics (order is produced out of disorder), and is contradictory to the "equilibrium hypothesis" of the classic thermodynamics. Hence, instabilities may be the reason of morphogenesis, and since then, nonlinear dynamic theory has been introduced to study nonequilibrium systems. Prigogine (1978) expanded the domain of thermodynamics and developed the dissipative structure theory. By his theory, far from thermodynamic equilibrium may be the source of order (also means entropy decrease), and when the system is open and far from thermodynamic equilibrium, fluctuation could make the system unstable and self-organized patterns may form instead.

It is obvious that BZ reaction is a dissipative structure system because time-symmetric breaking bifurcation has taken place. In fact, various types of bifurcations may be the source of bio-complexity (Kitano, 2002). As for the BZ reaction kinetics, Hopf bifurcation causes the equilibrium point being unstable, changing stability via a pair of purely imaginary eigenvalues, and giving birth to a self-oscillator in the dynamic system, while the cooperative action of reaction and diffusion causes the (distributive) system to generate chemical-waves. As is shown in Fig. 1, when the 2-dimentional system is properly meshed, every "dot" on the picture can be viewed as a homogeneous subset,

and they are identical because they all follow relation of BZ reaction kinetics. One can view the dots as agents who behave self-oscillatory state trajectories (or, change color periodically), and each dot exchanges information with its neighbor by following the Fick's law of diffusion, then, mass transfer by diffusion causes time-delay, hence as a whole, all dots exhibit chemical wave patterns.

Fig. 1. Pattern of the diffusive *Belousov–Zhabotinsky* reaction.

Traditionally, one can adopt numerical simulation method to solve a mathematical model, ie, a reaction-diffusion system, established on a chemical wave physical background in a specific reaction system on a computer. Since a set of partial differential equations are obtained for this BZ reaction system, often a finite elements method is adopted, which meshes the 2-dimentioanl reaction region into subsets, each is assumed to be homogeneous at very short time interval; while each subset correlates to its neighbors by diffusion law. Therefore, one can summarize that, for the formation of a complex pattern as shown in Fig. 1, identical agents are distributed in 2-dimentional reaction field, and by diffusion law, these agents transfer information to one another, which is coherent to the idea of "cooperative information consensus" (Olfati-Saber,et al, 2007) in computer science terminology. Hence, the formation of chemical wave is studied by a decomposed procedure: the property of agent first, then, information exchange between agents.

The algorithm of cellular automata (CA) is introduced in this study; this method is a parallel, temporally and spatially discrete one proposed by Von Neumann (1966). The basic idea of CA computation is that the agent should follow specific dynamics which is comparatively independent to the environment, and each agent will exchange information with its nearest neighbors by a few rules. Different from the traditional way of thinking, the CA adopts a bottom-up computing strategy, which uses simple unit changes and unit interaction to show the changes of complex systems, reflecting a systematic and integrated way of thinking. As to the development of the CA algorithm, Conway developed a program called a life game using a cellular automaton. After that, Wolfram gave a more systematic explanation of the cellular automata, classifying the cellular automata according to the dynamic behavior (Tyson, et al, 1980), and further expanding the original one-dimensional system to two-dimensional one(Wang et al, 2018).

Since CA computation provides a framework of studying the complex system, namely, decomposing the system into time-dependent independent agents and locally information exchange in a special scale. Hence, for the study of chemical waves, the

following section is focused on the property of the BZ reaction kinetics, then, information exchange rules between agents, followed by the exhibition of CA simulation, at last, the conclusion remarks are provided.

2. The BZ reaction kinetics: a self-oscillator

Many models have been developed for BZ reaction kinetics, and the Oregonator is adopted here because it describes the self-oscillatory behavior properly, 5 species are identified and their reaction relations are provided as follows,

$$
\begin{aligned}
A + Y &\rightarrow X + P & r_1 &= k_1 AY \\
X + Y &\rightarrow 2P & r_2 &= k_2 XY \\
A + X &\rightarrow 2X + 2Z & r_3 &= k_3 AX \\
2X &\rightarrow A + P & r_4 &= k_4 X^2 \\
B + Z &\rightarrow 0.5f\,X & r_5 &= k_5 BZ
\end{aligned}
$$
Species identification with respect to the Field-Koros-Noyes (FKN) mechanism (Field, 1972) are X = HBrO2, Y = Br-, Z = Ce(IV), A = BrO3, B = Organic species, P = HOBr, and f is an adjustable stoichiometric factor. In fact, this is the reduction reaction of bromide iron, the overall reaction is A + B → P, while X, Y and Z are the intermediate species. The reactant species A and B are normally presented in much higher concentrations than the dynamic intermediate species X, Y and Z, and when A and B are viewed as constants, and a dynamic model is developed out of the Oregonator,

$$
\begin{cases}
X' = k_1 AY - k_2 XY + k_3 AX - 2k_4 X^2 \\
Y' = -k_1 AY - k_2 XY + 0.5 f k_5 BZ \\
Z' = 2k_3 AY - 0.5 f k_5 BZ
\end{cases}
\tag{1}
$$

From the viewpoint of dynamic system theory, nonlinearity of the intermediate terms (X, Y, Z) brings about a Hopf bifurcation where increasing one of the parameters beyond the critical point may cause a self-oscillatory structure to emerge. By properly normalizing of Eq. (1), bifurcation analysis can be implemented, and one can find that the working point ($f = 0.53$) is at the self-oscillatory region, as is shown in Fig.2.
Fig. 2. Numerical continuation and bifurcation of the Oregonator with varying f.

3. Cellular automation and the results

A complete cellular automaton consists of four parts: cells, cellular space, neighbors, and local rules, where the cell is the self-oscillator, the neighbors and the local rules are the interaction ones and their properties nearest to the considered cell, and space related to the mash space and cell numbers.

To determine the local rules, the property of the oscillator needs to be re-investigated. Here, the Tyson model is used, which is the normalization of the Oregonator,

$$\begin{cases} \varepsilon a' = (qc - ac + a - a^2) \\ b' = a - b = g(a,b) \\ \delta c' = (-qc - ac + 2fb) \end{cases} \tag{2}$$

Since $\varepsilon \ll \delta \ll 1$, one can get that $-qc-ac+afb \approx 0$. Substitute this relation to the 1st-formula of Eq. (2), and the right hand side of this formula becomes $f(a, b)$. To determine the local rules, the nullclines is drawn on the (a, b) plane, as is shown in Fig.3.
Fig. 3 The nullclines of the Tyson model.

The dashed line indicates the actual trajectory of the change of the state. At the intersection of the two zero lines is the only equilibrium point of the system, and is the equilibrium point of the local asymptotic stability. When the equilibrium is subjected to small disturbances, the medium can return fast; but once the disturbance exceeds a certain threshold, the change in the medium will pass through the excitation period, then, the drift period before it can finally return to the equilibrium state. In detail, the local rules are given in Fig. 4.

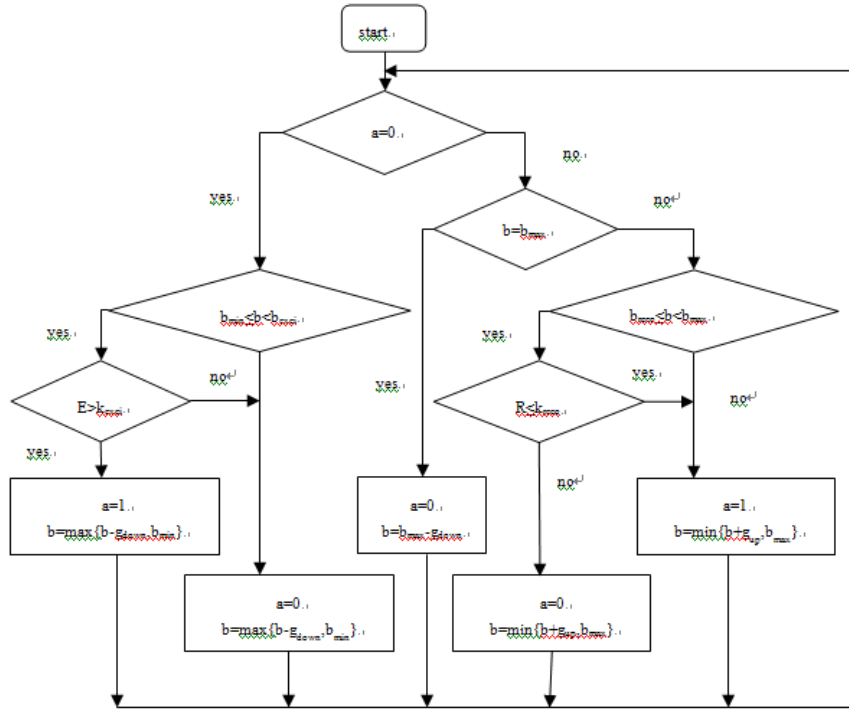
For the neighbors, the extended Moor type neighboring is selected. Since the diffusive character is decided by neighboring, one can select a weight *mask* to represent the effect of the distance on the cell. It can be seen from the simulation comparison that the *mask* has a good approximation to the diffusion coefficients, as is shown in Fig. 5.


Fig 4. CA block diagram
(a) actual diffusion coefficient effect   (b) *mask*
Fig 5. Comparison the musk and the diffusion coefficient.

With all the preceding work done, one can implement the CA computation. The result of the simulation on MATLAB is shown at Fig6.

4. Conclusions

By CA computation, the spiral wave is generated, as shown in Fig. 6, which simulates reasonable well the pattern of the diffusive BZ reaction shown in Fig. 1Therefore, the

formation of complex system (such as the chemical waves) usually undergoes two scales of evolution: on time scale, the agents exhibit unique dynamic behavior, i.e., in the case of chemical waves, the reaction kinetics exhibits self-oscillatory state trajectories; on the spacial scale, an agent exchanges information with its neighbors by some kind of local rules, i.e., in current case, identical agents behave mass transfer with their neighbors by diffusion law. As a whole, chemical waves propagate in time and space. Through the deconstructing procedure, one can conclude that the formation of complex chemical wave patterns is caused by agents obeying typical local rules, and this analyzing structure may aid the exploration of other complex systems in biology, ecology and engineering.

Abstract

Solvent-based separation processes, such as extractive distillation, show large potential for the separation of azeotropic mixtures. However, these processes are rather complex to design and optimize since the overall process performance depends strongly on the choice and amount of solvent and can only be evaluated for a process flowsheet with closed recycles. It is important to note that the potential for heat integration also depends strongly on the solvent choice. Consequently, a successive selection of a suitable solvent followed by process design and optimization and finally energy integration likely results in suboptimal choices. In order to allow for direct optimization of an extractive distillation process, including solvent selection and different means for energy integration, the current study proposes the use of a hybrid evolutionary-deterministic algorithm. The application is demonstrated for the separation of an azeotropic acetone-methanol mixture, considering six solvent candidates and up to four alternative means for energy integration. The results illustrate the existence of a multitude of suboptimal local solutions and demonstrate the capability of the proposed method to effectively overcome these limitations.

Keywords: hybrid optimization, evolutionary algorithm, solvent selection, energy integration

1. Introduction

The design of efficient separation processes is one of the key challenges for conceptual process design, as it accounts for almost 50 % of the overall process costs (Blahušiak et al., 2018). A considerable challenge, especially in the scope of a transition to bio-renewable feedstocks, is the separation of azeotropic mixtures (Skiborowski et al., 2013). Solvent-based separation processes, such as extractive distillation, are popular solutions for which process design is, however, a rather complex task. A key design decision is the choice of a suitable solvent that facilitates the desired separation and can be efficiently recovered. Since the choice of a suitable solvent is of major importance for the feasibility and performance of the separation process, a variety of computer-aided methods have been developed in order to support the solvent selection. Methods for computer-aided molecular design (CAMD), like the multi-level generate and test procedure by Harper and Gani (2000), screen solvents based on thermodynamic criteria, such as capacity and selectivity. The set of selected solvents can further be refined by a model-based evaluation of the process performance, for which shortcut methods and rigorous flowsheet optimization can be applied in a hierarchical fashion (Kossack et al., 2008, Kruber et al., 2018). Herein, the combination with a quantum mechanics-based property prediction

allows for the screening of thousands of solvent candidates based on computationally efficient shortcut methods (Scheffczyk et al., 2016).

While similar methods have been proposed for several solvent-based separation processes, the investigation of energy integration is generally considered as a potential post-processing step, similar to the classical hierarchical approach to process design (Douglas, 1985). In the case of distillation-based separation processes, there are various options for energy integration, which need to be considered (Kiss et al., 2012). Especially for solvent-based processes, such as extractive or heteroazeotropic distillation, energy integration can have a considerable effect on the screening of potential solvents, as e.g. indicated in the recent study by Waltermann et al. (2018). Thus, simultaneous evaluation of energy integration and solvent selection should be performed in order to identify the optimal process design and best solvent. While this task can in principle be formulated as a mathematical programming problem, the solution to this problem is specifically complex. In order to enable an automated evaluation that overcomes suboptimal solutions, the current work proposes of the combination of hybrid evolutionary-deterministic optimization approach (Skiborowski et al., 2015a) with a tailored polylithic modeling and solution approach, considering rigorous MESH models (Waltermann et al., 2018). To the best of the author's knowledge, this is the first approach that enables an optimization-based design of an extractive distillation process with simultaneous consideration of solvent selection and energy and mass integration. The methodology is described in Section 2, while the case study for acetone-methanol separation and the obtained results are discussed in Section 3. Finally, Section 4 provides a brief conclusion and outlook on future work.

2. Methodology

In order to solve the highly complex process design problem, it is formulated as a mixed integer nonlinear programming problem (MINLP), which is solved by a two-level hybrid evolutionary-deterministic optimization approach. The concept of this approach, which also qualifies as a so-called memetic optimization algorithm, was introduced by Skiborowski et al. (2015a). The specific difference to other memetic algorithms, like the sophisticated method of Urselmann and Engell (2010), is the distinct feature that a full MINLP is solved by the gradient-based solver on the lower level. Thereby the search-space of the evolutionary algorithm (EA) is reduced significantly. The subsequent subsections provide a brief description of the hybrid optimization approach and describe the performed extension for additional means for energy integration.

2.1. Hybrid optimization approach

As indicated in Figure 1, the hybrid approach is a nested combination of an EA and a local deterministic optimization. The local deterministic optimization is performed in order to evaluate the fitness of the individuals in each generation of the EA. However, the genome of each individual is not representing all design degrees of freedom (DDoF) of the process optimization problem. Only discrete decisions that significantly affect the size and complexity of the design problem and initial values for setting up the superstructure model for the local deterministic optimization are optimized by the EA. In the initial optimization of an extractive distillation process presented by Skiborowski et al. (2015a), the EA handled the choice of solvent, as this determines the structure and parameterization of the thermodynamic models, as well as the maximum number of equilibrium trays per column and the feed tray. In the current study, the conventional

process without energy integration (CONV) and additional four means for energy integration are considered, which are thermal coupling (TC), integration of both columns into a dividing wall column (DWC), direct heat integration (HI) and vapor recompression (VRC). As each of them requires modifications of the superstructure model, the type of energy integration is also introduced as DDoF optimized by the EA. This information extends the genome and is used for setting up the MINLP problem, which is to be solved by the local deterministic optimization.

2.2. Local deterministic optimization

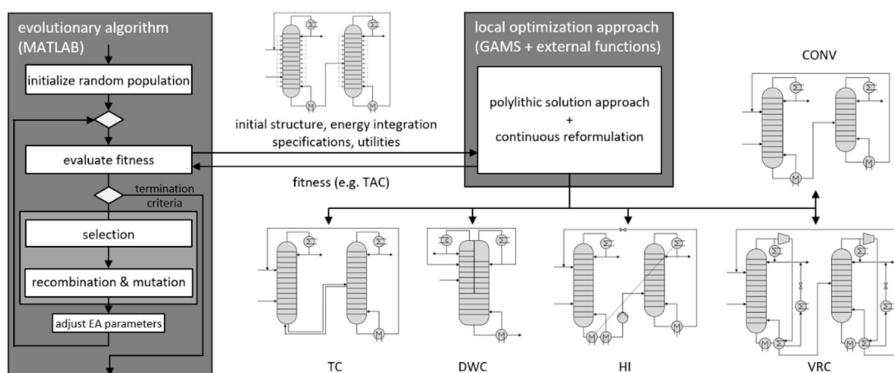
The local optimization builds on a superstructure formulation, derived from the information of the genome that is to be evaluated in the EA. The superstructure is based on a rigorous MESH model with up to 190 equilibrium trays in total and a number of binary decisions w.r.t. the allocation for the feed, boil-up and recycle streams. The solution of this highly nonlinear MINLP is achieved via a polylithic modeling approach that integrates implicit functions for VLE and enthalpy computations (Skiborowski et al., 2015b) and the solution of a series of successive relaxed NLP problems with additional NCP-functions. The necessary extensions for the optimization of the energy-integrated process variants are further described in the articles of Waltermann et al. (2016, 2018). Each of the variants builds on the initialization of the basic process variant, while specific modifications of the superstructure model are automatically introduced in a sequence of refinement steps and embedded optimization problems.


Figure 1: Scheme of hybrid optimization approach (based on Skiborowski et al. 2015)

3. Results

In order to illustrate the capabilities and the need for the developed optimization approach, the well-investigated separation of acetone and methanol is considered. Kossack et al. (2008) determined chlorobenzene, dimethyl sulfoxide (DMSO), ethanol, p-xylene, water and mesitylene as suitable solvent candidates based on an initial CAMD screening. Previous investigations showed that the hybrid optimization approach can reliably overcome local optima that might result in a sub-optimal solvent selection for the extractive distillation process (Skiborowski et al., 2015a), while the energy integration might again result in an alternative ranking of the different solvents (Waltermann et al., 2018). The objective of the current study is, therefore, to evaluate whether the extended hybrid optimization approach can reliably determine the optimal solvent choice for an

extractive distillation process with the considered options for energy integration. The optimal process design is determined w.r.t. the total annualized costs (TAC).

The same thermodynamic properties, as well as feed and product specifications that were used by Kossack et al. (2008) and Skiborowski et al. (2015a) are used in the current study. Only the economic process model was updated w.r.t. more recent cost indices and utility prices, which nevertheless has a recognizable effect on the results. Considering the previous investigation of the energy integrated process variants by Waltermann et al. (2018), the HI and VRC variant are not considered for the solvent DMSO, due to the significant pressure increase required for heat integration. Since the necessary pressure shift can be evaluated based on simple flash calculations for known product compositions, the complex optimization of the energy integrated variants should generally be avoided to save unnecessary computational load. For the current study, a (μ, λ, κ)-selection with 50 individuals and 15 parents with a maximum age of 6 generations is used, while an initial population size of 150 individuals is considered, covering all combinations of solvents and means of energy integration. The algorithm terminates in case the TAC of the best individual does not improve by more than 10 €/y, which is less than 0,005% of the best solution, in 3 consecutive generations. The optimization problem was solved on a HP Z820 workstation with two Intel Xeon E5-2660 CPUs and an evaluation of up to 24 individuals in parallel by means of a multi-threading approach. Four independent runs, with a mean computation time of 5.5 h, confirmed the best solution with a maximum deviation of less than 1% in TAC.

Figure 2 compares the lowest TAC of all process configurations, solvents and considered
Figure 2: TAC of the best individuals of four independent runs considering OPEX and CAPEX

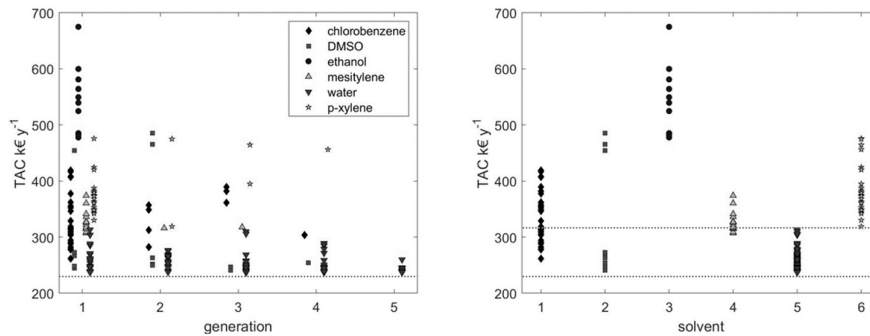
energy integration options. For each bar, the share of annual operating (OPEX) and capital expenditures (CAPEX) is illustrated. Interestingly, energy integration is only beneficial for ethanol and water. Depending on the product of the extractive distillation column, the potential decreases with increasing solvent boiling temperature. While ethanol results in the highest TAC, water becomes the favorable solvent in the HI variant and outperforms chlorobenzene and DMSO, which are superior in comparison to the basic sequence. Waltermann et al. (2018) obtained similar results in a local optimization study based on the embedded deterministic optimization approach. The results of the hybrid optimization approach further allow for an analysis of the sensitivity of the local optimization w.r.t. the initialization.


Figure 3: Evolution of the fitness over the generations (left) and variation for solvents (right)

Figure 3 summarizes the evolution of the fitness over the generations (left) and the distribution of the costs for all evaluations of each solvent (right) for a single run. The results indicate the capability of the hybrid optimization approach to quickly find a very good solution and confirm this in a few generations for which an increasing number of individuals focus on the preferred solvent and process variant. On the other side, the large variations in the TAC determined for the single solvents highlights the dependence of the results on the consideration of energy integration and the specifications of the initial superstructure, both of which are modified by the EA in the hybrid optimization approach. While the best individual for water outperforms all other solvents, a suboptimal solution may instead favor any of the remaining solvents (see dotted lines in Fig. 3 right), except ethanol, which can be discarded clearly.

Figure 4 further illustrates the distribution of the fitness of the evaluated individuals in the respective run in terms of OPEX and CAPEX (left) and a magnified illustration of the most effective water-based separation processes. Additional lines of constant TAC are introduced to highlight the existence of almost equivalent process designs with alternative DDoF. Thus, although a single objective optimization is performed, specific trade-offs of the different cost shares are automatically determined in the hybrid optimization approach. The illustration also highlights the concentration of solutions in close vicinity to the best performing process options (<5% higher TAC).
Figure 4: Cost distribution for all individuals (left) and for the best-performing processes utilizing water for a single run

4. Conclusion

The current work presents the purposeful extension of a previously introduced hybrid optimization approach and illustrates its capabilities for the optimal selection of solvents and the design of intensified separation processes. The investigated case study addresses the design of energy integrated extractive distillation columns and illustrates that superior solvent choices and process designs may easily be missed based on the limitation to a single locally optimal solution. The presented hybrid optimization approach effectively overcomes these limitations and increases the confidence in the determined optimization results. It furthermore provides information on possible trade-off solutions with similar TAC, but variations in CAPEX and OPEX, without the need for multi-objective process optimization. The fully algorithmic implementation should furthermore allow for an extension of the search space to an increased number of solvents and therefore enable integration with a CAMD approach that provides the necessary thermodynamic property predictions. However, as indicated for the case of DMSO, apparently infeasible or inferior process variants should be discarded directly to save unnecessary computational load. The transfer of the approach to other solvent-based separation processes requires the development of reliable deterministic optimization strategies, as well as the adaption of the EA and will be part of future work.

Flux Balance Analysis Incorporating a Coarse-grained Proteome Constraint for Predicting Overflow Metabolism in *Escherichia Coli*

Hong Zeng,[a] Aidong Yang [a,*]

[a]University of Oxford, Parks Road, Oxford OX1 3PJ, United Kingdom

aidong.yang@eng.ox.ac.uk

Abstract

Flux balance analysis (FBA) and its dynamic extension DFBA are typical constraint-based modelling tools in systems biology. They have been widely used for *in silico* analysis of intracellular metabolic flux distributions. The objective of this work is to use FBA and DFBA to predict quantitatively the extent of overflow metabolism in *E. coli* under a wide range of growth conditions. In light of the recently validated proteome allocation theory, we developed a coarse-grained constraint to represent the competition of the limited proteomic resource between energy biogenesis and biomass synthesis. Incorporating such constraint to FBA renders accurate predictions of the onset of overflow metabolism and the rates of acetate production at increased growth rates for various wild-type *E. coli* strains. On top of this, we further use DFBA to investigate how the production of a foreign protein affects the growth physiologies of recombinant *E. coli*. Simulation results show that the incorporation of proteomic burden and the tuning of cellular energy demand via strain-specific growth data are key to an accurate prediction. Although several limitations remain to overcome, this work provides a starting point of using FBA-based model as an efficient predictive tool to guide metabolic decisions to address issues such as reducing acetate production and enhancing protein productivity.

Keywords: *Escherichia coli*, overflow metabolism, resource allocation, recombinant protein production, genome-scale model

1. Introduction

Flux balance analysis (FBA) is a widely adopted modelling tool in metabolic engineering and systems biology for predicting intracellular metabolic fluxes (Orth et al., 2010). As a constraint-based modelling approach, the outcome of FBA depends on the constraints incorporated in the optimisation problem being solved. In addition to the built-in mass and energy balances, several constraints have been proposed to account for the previously proposed notion of constrained cellular resources (Molenaar et al., 2009) via quantifying the enzymatic cost of individual reactions (Nilsson et al., 2017). These constraints have been shown to improve efficiently the growth rate prediction by FBA. However, most of these models require extensive information of enzyme kinetics for thousands reactions involved in the metabolic network. In this work, we propose a coarse-grained constraint to represent the limit of cellular proteome resources and their allocation over (a small number of) energy pathways and the biomass synthesis flux, based on the recently-developed proteome allocation theory (PAT) for explaining the overflow metabolism in *E. coli* (Basan et al., 2015). We named this new constraint as the PAT constraint. Due to

its coarse-grained nature, the PAT constraint introduces only a small number of parameters (independent of the scale of the metabolic model), which can be estimated using experimentally determined growth data. In particular, we have focused on the prediction of acetate production at high growth rates, a phenomenon commonly referred to as the overflow metabolism, which represents not only a waste of substrate carbon but also leads to low cell density and low product yield (Eiteman and Altman, 2006) due to acid toxicity. In this paper, we describe the modelling approach and the results of simulation experiments that have been carried out to obtain the predicted growth phenotype of various wild-type and recombinant *E. coli* under a wide span of growth conditions. Comparisons are made with the experimental data in terms of (i) the steady state acetate-growth rate profile and steady state biomass yield-growth rate profile for wild-type *E. coli* and (ii) the biomass accumulation, substrate consumption, acetate accumulation and protein production of batch cultures of recombinant *E. coli*. Future perspective in terms of using the modelling framework developed in this work to guide metabolic decisions for efficient microbial protein production processes is illustrated in the end of the result section.

2. Methodology

Following the philosophy of multi-scale modelling, we propose to construct a FBA model that combines (i) detailed stoichiometry and topology of the cellular metabolic network and (ii) a concise global regulation rule to govern an accurate flux prediction. More specifically, a genome-scale metabolic model was adopted, and a coarse-grained PAT constraint was constructed at pathway level (on the contrary to reaction level constraints adopted in previous studies) to depict the constrained proteome to be allocated between energy biogenesis and biomass synthesis. The energy pathways discussed here are fermentation (involving glycolysis, acetate pathways and oxidative phosphorylation) and respiration (comprising glycolysis, tricarboxylic acid cycle and oxidative phosphorylation). Biomass synthesis flux includes primarily catabolic reactions, anabolic reactions and ribosomal reactions for the synthesis and assembly of biomass building blocks

2.1. PAT Constraint

Based on the recently published proteome allocation theory (Basan et al., 2015), we proposed the following coarse-grained proteomic constraint:

$$w_f^* v_f + w_r^* v_r + b^* \lambda + \phi_{recP}^* \leq 1 \qquad (1)$$

where v_f, v_r and λ are the fermentation, respiration and biomass synthesis flux, respectively; w_f^*, w_r^* and b^* are the proteomic cost parameters denoting the fractions of proteome required per unit fermentation, respiration and biomass synthesis flux, respectively; ϕ_{recP}^* represents the portion of proteome used for the synthesis of foreign proteins in recombinant strains, i.e. $\phi_{recP}^* = 0$ for wild-type strains. The equal sign of Eq. (1) is expected to hold in fast-growing conditions (e.g. overflow region) where the cell growth is limited predominantly by proteome resources; in other growth conditions this constraint is relaxed by the less-than sign. Eq. (1) is referred to as the PAT constraint.

2.2. Genome-scale modelling

The genome-scale metabolic model *i*AF1260 (Feist et al., 2007), integrated with the PAT constraint was used in FBA simulations to obtain the steady state growth rate and metabolic flux distribution for *E. coli* at different growth conditions. The generic optimization problem solved in FBA is formulated as:

Maximise growth rate λ, subject to

(i) $Sv = 0$

(ii) $v^L \leq v \leq v^U$

(iii) $w_f^* v_f + w_r^* v_r + b^* \lambda + \phi_{recP}^* \leq 1$

$$(2)$$

where S comprises the reaction stoichiometry defined by the *i*AF1260 model; v is a column vector containing intracellular metabolic fluxes with upper and lower bound set by v^L and v^U; the third constraint of Eq. (2) is the PAT constraint that depicts the global proteome allocation rule. The dynamic framework (DFBA) is achieved by coupling the standard FBA with a set of ordinary differential equations (ODEs) describing the dynamic extracellular environment:

$$\frac{dX}{dt} = \lambda X \tag{3}$$

$$\frac{dG}{dt} = -v_{glc} X \tag{4}$$

$$\frac{dA}{dt} = v_{ac} X \tag{5}$$

$$\frac{dP}{dt} = v_{recP} X \tag{6}$$

where X, G, A and P are the concentrations of biomass, glucose, acetate and recombinant protein in the bioreactor, respectively. The growth rate λ, glucose uptake flux v_{glc}, acetate production flux v_{ac} and protein synthesis flux v_{recP} are obtained from the solution of FBA. Dynamic simulation is carried out by exchanging information between FBA and ODEs at a number of time intervals: FBA is performed at the beginning of every time interval to give steady state flux distribution; the values of the fluxes of interest are then passed to the ODEs to update the outer environment state. This procedure is repeated until the entire time duration has been simulated.

3. Results

3.1. Predicting overflow metabolism for wild-type E. coli

Experimental data from the literature (Extended Data Figure 1, Basan et al., 2015) was used to estimate three PAT constraint parameters, namely w_f^*, w_r^* and b^*. FBA was then
Figure 1: Comparison between model predictions and experimental data

performed to obtain the steady state acetate production rate for wild-type *E. coli* MG1655 and NCM3722 under aerobic-glucose conditions. The predicted acetate production rate is in good agreement with the experimental results (Figure 1A), which validates the suitability of using the concise pathway-level proteome allocation constraint as the global regulatory rule to guide the prediction of the overflow metabolism in a FBA model.

Furthermore, we calculated the simulated biomass yield on glucose (g biomass produced per g glucose consumed). Interestingly, we found that the accuracy of the biomass yield prediction is closely related to the cellular energy demand (i.e. overall ATP production rate at steady state). When FBA was performed with the default energy demand given in the *i*AF1260 model, considerable inconsistency was observed between the simulation results and the experimental data for both MG and NCM strains. Such deviation indicates that the carbon utilization in the model is not consistent with the real case. In FBA models, carbon balance is dictated by three aspects: (i) the assumed biomass content of the cell; (ii) the endogenous structure of the metabolic network and (iii) the energy demand for supporting cell maintenance and growth. In *i*AF1260, the first aspect is determined by experimentally measured dry cell composition of *E. coli*; the metabolic network is obtained by well-developed *E. coli*-specific biochemical characterization. Only the last aspect is constructed with assumptions and is reported with ±50% uncertainty. Therefore, we decided to modify the default energy demand using experimentally determined strain-specific growth data. Subsequently, the prediction of biomass yield (Figure 1B) became highly coincided with the experimental values without compromising the accuracy in the prediction of the onset and extent of the overflow metabolism.

3.2. The effect of recombinant protein production

Having validated the efficiency of using the PAT constraint to guide the prediction of overflow metabolism in wild-type E. coli, we further investigated the impact of recombinant protein production on the overall growth physiologies. According to the proteome allocation theory, the production of a foreign protein should occupy a certain fraction of the proteome. Therefore, we added a recombinant protein sector (ϕ^*_{recP} in Eq. (1)) to the wild-type PAT constraint. We also added the synthesis reaction of the recombinant protein (in this case green fluorescent protein, GFP) to the model. DFBA was performed to simulate the dynamic cell growth in a batch culture. During the analysis, we found that the introduction of ϕ^*_{recP} alone is not sufficient to render satisfied predicted

results. Strong deviations were observed for both cell growth, glucose consumption, acetate accumulation and protein production when comparing with the experimental data. Based on the experience gained in the wild-type case, we considered that in this case it is likely that the energy demand again plays an important role. We thus co-estimated ϕ^*_{recP} and the maintenance energy (ATPM) simultaneously, and found that with $\phi^*_{recP} = 0.1333$ and ATPM = 32.6 mmol/gDW-h, the dynamic simulation results were in excellent agreement with the experimental data (Figure 2A). It is worth noting that the default ATPM of wild-type E. coli in iAF1260 is 8.39 mmol/gDW-h, which is significantly lower than the new ATPM determined for GFP-producing E. coli. The strong increase in maintenance energy for recombinant E. coli is consistent with previously proposed notion of "metabolic burden of recombinant protein production" (Wu et al., 2016). Our model suggests that the production of GFP provokes not only proteomic burdens to the allocation of cellular proteome resources, but also a significant increase in the overall energy demand, which is potentially used for plasmid maintenance, protein secretion and degradation of the misfolded protein. Building on the aforementioned findings on the impact of PAT constraint (with ϕ^*_{recP}) and energy demand on the growth predictions for GFP-producing E. coli, we further considered the potential of using the model to support the enhancement of protein productivity. According to the proteome allocation theory, the production of extra proteins, a desirable process from the engineering point of view, reduces the portion of proteome attainable to energy pathways and biomass synthesis, thus leads to more severe overflow phenomenon that gives rise to undesirable products such as acetate.

B. Impact of protein expression level on the overall protein productivity. Protein expression level is modelled as:

$$\phi_{GFP} = \frac{Mass\ of\ recombinant\ protein}{Total\ cellular\ protein} = \frac{v_{GFP} \times MW_{GFP}}{\lambda \times f_{protein}}$$

where ϕ_{GFP} denotes the mass fraction of GFP to the total mass of cellular proteins. v_{GFP} is the synthesis flux of GFP in mmol/gDW-h; λ is the growth rate in gDW/gDW-h; $MW_{GFP} = 27$ g/mmol is the molecular weight of GFP; $f_{protein} \approx 0.5$ is the mass fraction of total protein of the dry cell weight.

Figure 2: Modelling recombinant protein production and potential application

Investigating this trade-off, we performed further DFBA simulations with different protein production levels (while all the other conditions were kept identical between simulations), attempting to find an optimal expression level with highest GFP produced at the end of a batch culture (Figure 2B). Simulation results show the predicted existence of an optimal protein expression level ($\phi^*_{recP} \sim 0.5$), which offers a preliminary indication of the potential use of the proposed model for guiding metabolic engineering decisions. However, several limitations need to be resolved for the development of a fully predictive tool: (i) it is still unclear how the *in vivo* protein expression system is linked to the modelled proteomic burden ϕ^*_{recP}; (ii) a robust and reliable quantification of the protein expression level (currently quantified by mass fraction of the recombinant protein) remains unresolved; and (iii) how different protein expression levels affect the substrate uptake kinetics and the energy demand is still to be quantified.

4. Conclusions

This work shows that the incorporation of a coarse-grained proteome constraint into a genome-scale metabolic model can produce accurate prediction of the overflow metabolism in wild-type *E. coli* as well as predict key growth physiologies of a batch culture of recombinant *E. coli*. Although several limitations remain to overcome, the proposed modelling approach provides a basis of using FBA as an efficient predictive tool to guide metabolic engineering decisions to address issues such as reducing acetate production and enhancing the productivity of recombinant proteins.

Abstract

The pharmaceutical industry has been undergoing a paradigm shift towards continuous manufacturing, under which novel approaches to real-time product quality assurance have been investigated. A new perspective, entitled Quality-by-Control (QbC), has recently been proposed as an important extension and complementary approach to enable comprehensive Quality-by-Design (QbD) implementation. In this study, a QbC approach was demonstrated for a commercial scale tablet press in a continuous direct compaction process. First, the necessary understanding of the compressibility of a model formulation was obtained under QbD guidance using a pilot scale tablet press, Natoli BLP-16. Second, a data reconciliation strategy was used to reconcile the tablet weight measurement based on this understanding on a commercial scale tablet press, Natoli NP-400. Parameter estimation to monitor and update the material property variance was also considered. Third, a hierarchical three-level control strategy, which addressed the fast process dynamics of the commercial scale tablet press was designed. The strategy consisted of the Level 0 built-in machine control, Level 1 decoupled Proportional Integral Derivative (PID) control loops for tablet weight, pre-compression force, main compression force, and production rate control, and Level 2 data reconciliation of sensor measurements. The effective and reliable performance, which could be demonstrated on the rotary tablet press, confirmed that a QbC approach, based on product and process knowledge and advanced model-based techniques, can ensure robustness and efficiency in pharmaceutical continuous manufacturing.

Keywords: Quality-by-Design, Quality-by-Control, Continuous manufacturing, Process control, pharmaceutical

1. Introduction

The recent approval of four drug products using continuous manufacturing technologies, e.g., Orkambi (lumacaftor/ivacaftor) in 2015, Prezista (darunavir) in 2016, Verzenio (abemaciclib) and Symdeko (tezacaftor/ivacaftor) in 2018, by United States Food and Drug Administration (US FDA) is a strong evidence of the on-going paradigm shift from batch to continuous manufacturing in the pharmaceutical industry. The US FDA Quality-

by-Design guidance has also been widely acknowledged in providing directions with respect to product and process knowledge development, such as identifying critical process parameters (CPPs) in process design and linking critical material attributes (CMAs) to critical quality attributes (CQAs) (Yu et al., 2014). Control strategies that include specification of the drug substance, excipients, and drug products as well as controls for each step of the manufacturing process are also considered as important elements of the QbD concept. In addition to designing quality into the product during the early stages of drug development, the quality attributes must also be automatically and consistently controlled, in the presence of process uncertainties and disturbances, during drug manufacturing (Lee et al., 2015). This recognition has led to a call for Quality-by-Control, particularly in continuous manufacturing, consistent with the current Industry 4.0 or smart manufacturing approaches. The proposed QbC idea consists of the design and operation of a robust manufacturing system that is achieved through an active process control system designed in accordance with hierarchical process automation principles, based on a high-degree of quantitative and predictive understanding of product and process.

Our previous work has investigated the characterization of the compressibility of a model formulation, consisting of Acetaminophen (API, 10.0%), Avicel Microcrystalline Cellulose PH-200 (excipient, 89.8%), and SiO_2 (lubricant, 0.2%), using a Natoli BLP-16 tablet press (Su et al., 2018). System dynamics and hierarchical process control development for a direct compression line were also undertaken for this pilot scale tablet press. In this study, we demonstrate the use of the proposed QbC approach in transferring the product and process understanding generated with the Natoli BLP-16 to the commercial scale, Natoli NP-400, tablet press. The rest of the manuscript will first discuss the QbC concept, followed by a brief introduction of the features of the tablet press in a continuous direct compression process. The advantages of a QbC approach in continuous tablet manufacturing will be presented in the result and discussion section. Concluding remarks and considerations for future work are given at the end of the manuscript.

2. Quality-by-Control

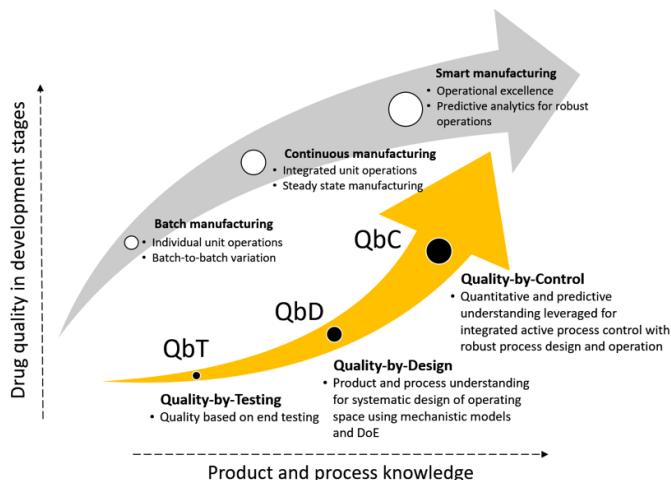
In traditional batch manufacturing quality attributes of products are tested at the end of each batch manufacturing step, following the so-called Quality-by-Testing (QbT) approach, as shown in Figure 1. Under the QbD guidance, systematic understanding of drug quality, including identification of CMAs and CPPs, is developed and monitoring is employed to assure that the quality attributes are met. The QbD approach is also very important to advancing the adoption of continuous manufacturing. However, assurance of quality in the continuous manufacturing mode in addition requires the use of QbC concepts to actively drive reduction in the variance of quality attributes, in the presence of process disturbances, raw material property variations, or uncertainties introduced as a result of scale up or technology transfer. The QbC approach builds on QbD by employing quantitative and predictive product and process knowledge in the form of models of appropriate fidelity, together with process analytical technology (PAT), to actively and robustly control the CQAs at the specified levels by adjusting CPPs, thus, achieving real-time quality assurance. The on-going trend towards Industry 4.0 or smart manufacturing also demands a high-level automation in process operation and quality control, which is fully consistent with the QbC approach.


Figure 1. The systematic progression in quality assurance via QbT, QbD, and QbC.

3. Continuous tablet manufacturing

3.1. Continuous direct compaction

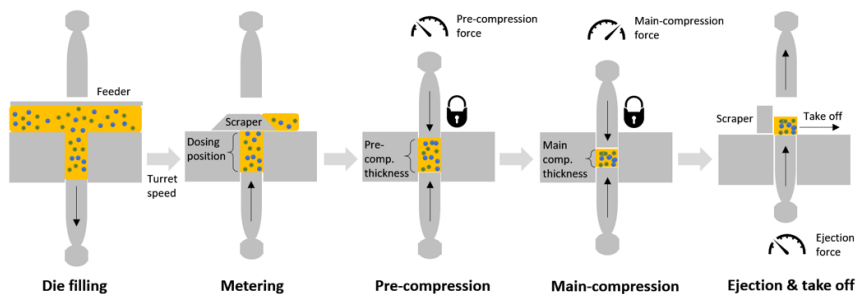
The continuous direct compression process under study consists of two Schenck AccuRate PureFeed® AP-300 loss-in-weight feeders which continuously feed the API and excipient ingredients into a Gericke GCM-250 continuous blender. A Schenck AccuRate DP4 micro feeder adds the lubricant into the powder blend exiting the continuous blender, which is then conveyed directly to a rotary tablet press (Su et al., 2017). The tablet press is a multi-stage process, in which each station undergoes the recurring major steps of die filling, metering, pre-compression, main-compression, tablet ejection and take-off, as shown in Figure 2. The tablet weight can be controlled by changing the dosing position subject to the variation of powder bulk density or filling time due to change in turret speed and/or feeder rotation speed. A Natoli BLP-16 tablet press (16 stations with flat-head punches) was employed in our previous work to characterize the formulation compressbility while a commerical scale Natoli NP-400 (22 stations with concave-head punches) was used in the present work for continuous tablet manufacturing. The two tablet presses are also different in size and design of hopper and feed frame, which may result in differences in powder bulk density at the die table.


Figure 2. Major steps in a Natoli rotary tablet press.

3.2. Formulation compressibility

The classical Kawakita model was employed to characterize the formulation compressibility in the Natoli BLP-16 tablet press (Su et al., 2018), as shown in Figure 3,

$$\frac{CF}{1 - \rho_c / \rho_r} = \frac{CF}{a} + \frac{\pi D^2 / 4}{ab} \tag{1}$$

$$\rho_r = \frac{4W_t}{\pi D^2 \rho_t T} \tag{2}$$

where CF is the main compression force, kN; ρ_c is the critical relative density, -, ρ_r the calculated in-die relative density from tablet weight W_t, and ρ_t the known a prior true density of the powder, g/cm^3; parameters a and b (MPa) are interpreted as the maximum degree of compression and the reciprocal of the pressure applied to attain the maximum degree of compression, respectively; D is the diameter of the die (mm) and T (mm) is the minimum in-die tablet thickness pre-set by the main compression thickness for B tooling punches with flat cylindrical punch surfaces.
Figure 3. Compressibility characterization by a classical Kawakita model.

3.3. Hierarchical control system

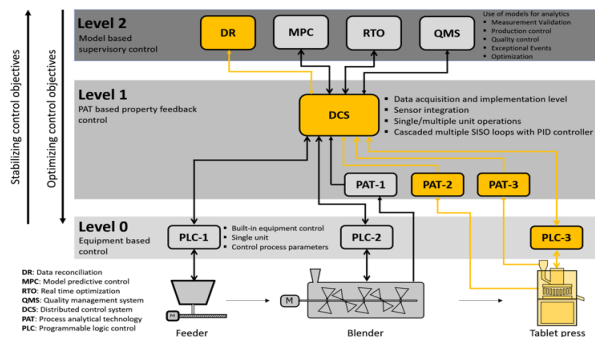
A three-level hierarchical control system, shown in Figure 4, was developed based on the product and process understanding developed using the Natoli BLP-16 tablet press (Su et al., 2018) and was transferred to the NP-400 tablet press. The CQA and CPP measurement data were collected using an Emerson DeltaV DCS system to support the process control system design following the ISA 95 standard (Su et al., 2017). Specifically, the vendor built-in machine control at Level 0 manipulates the dosing position, pre-compression thickness, main compression thickness, and turret speed. At Level 1, the DCS system employs four PID controllers, controlling the tablet weight, pre-compression force, main compression force, and production rate by manipulating the above four Level 0 variables, respectively. A Level 2 data reconciliation module was implemented which serves to reconcile the tablet weight measured by an in-house adapted load cell with the main compression force measurement using the constraints imposed by the Kawakita model, Eqs. (1) and (2) (see Su et al., 2018). Specifically, the model parameter ρ_c was continuously re-estimated and updated during data reconciliation to account for variation in the powder bulk density due to material property changes (particle size, water content) or differences in equipment scale (hopper and feed frame, etc.) that also results in changes in powder bulk density at die table.


Figure 4. A hierarchical three-level process control for direct compaction.

4. Results and discussion

With a QbC approach based on a quantitative model of compressibility, the Level 2 data reconciliation approach was able to reduce the uncertainty in real-time tablet weight measurement from the load cell for both tablet presses (see the reconciled measurement matched the at-line measurement of tablet weight), as shown in Figure 5. More importantly, the model parameter of critical density (which is related to powder bulk density) in the Kawakita equation (1), which was first estimated from BLP-16 runs, was readily updated from NP-400 tablet press real-time data. The shift in the critical density which was observed in the transfer from BLP-16 to NP-400 may be a result of changes in the bulk density at the die table due to different scale of hopper and different feed frame design. Assurance of model validity and parameter updating are the common concerns in most technology transfers and these results demonstrate that these concerns can be managed within a QbC approach. The high-level understanding of the process dynamics of the tablet press and resulting control structure design, such as the pairing of the control input and output variables, were readily transferable from the pilot to a larger scale press. Specifically, the control structure in which tablet weight was controlled by manipulating the dosing position and the production rate was controlled by adjusting turret speed (the feed frame stirrer speed also changes accordingly), resulted in effective control performance of both tablet presses. Both tablet presses could reach their tablet weight set points steadily. For instance, as shown in Figure 5, when the production rate was increased at 600 s from 3 kg/hr to 5 kg/hr after start-up of the NP-400 tablet press or reduced at 1000 s from 5 kg/hr to 4 kg/hr, the tablet weight was maintained at nearly constant levels.

5. Conclusions and future work

A Quality-by-Control approach was implemented in a continuous tablet manufacturing process based on the product and process understanding gained through the previous Quality-by-Design studies on a pilot unit. Compared to rigid process operation within a predefined design space, active process control response to common process variations, disturbances, or uncertainties can be automatically achieved under the QbC paradigm in a quantitative and predictive way to maintain consistent product quality. The systematic implementation of a hierarchical process control system in continuous direct compression process was highlighted, leveraging QbD understanding of the product and process to achieve robust and efficient process operations and real-time quality control of oral solid dosages. Future efforts in systematic sensor network maintenance, control performance

monitoring and continuous improvement should be pursued to further advance QbC implementation.

Abstract

In this paper we proposed a framework aimed to improve the sustainability of chemical processes based on the combination of data envelopment analysis and process system engineering tools. Given a set of chemical process alternatives, each characterised by techno-economic and environmental performance indicators, the framework discerns between efficient (optimal) and inefficient (suboptimal) processes in the sense of these indicators. We develop an approach to quantifying the closest targets for an inefficient process to become efficient, while avoiding unattainable targets by accounting for thermodynamic limitations in that process in terms of mass and energy flow constraints. We demonstrate the capabilities of the framework through a case study that involves the assessment of a methanol production process with CO_2 captured from power plants and H_2 derived from fossil fuels, in comparison to ten fuel alternatives. We find that this methanol fuel is presently suboptimal in comparison with other fuels. Making it competitive would require a significant reduction in hydrogen price, which is unrealistic in the short term. Alternatively, the methanol fuel could become competitive upon combining H_2 derived from fossil fuels with sustainably produced H_2 via wind-powered electrolysis.

Keywords: data envelopment analysis, chemical process targeting, sustainability, practical closest targets, process synthesis.

1. Introduction

The development of more sustainable chemical processes with good performance in the three sustainability pillars (i.e. economic, environmental and social) has recently attracted growing interest in the process systems engineering literature (Azapagic and Perdan, 2014). A wide range of methods for process design have been put forward, either based on heuristics or super-structure optimisation. These approaches often focus on optimising profit as unique criterion while disregarding other environmental and social indicators (Yuan and Eden, 2016). Furthermore, they are often based on a given chemical route and do not compare flowsheets based on alternative reaction pathways, which can be sometimes radically different. Last but not least, in the process of identifying the optimal solution to the problem, suboptimal alternatives are discarded without providing any analysis on why they underperform compared to others and on how they could be improved so as to become competitive. This piece of information, however, is highly

relevant and insightful for those developing new chemical routes that are at present suboptimal but could become competitive via targeted improvements. The sustainability assessment is further complicated by the existence of multiple indicators on the basis of which the process design alternatives need to be compared against each other.

Acknowledging these gaps in the literature, this work presents a framework that combines data envelopment analysis (DEA) (Cook and Seiford, 2009) with process systems engineering tools (Grossmann and Guillén-Gosálbez, 2010), with a view to improving the sustainability of chemical processes and products, and supporting decision-makers towards more sustainable design solutions. We demonstrate the capabilities of the framework on a real case study assessing eleven transportation liquid fuels: a new methanol process obtained from CO_2 captured from power plants and H_2 from fossil fuels, and ten existing alternatives.

2. Methodology

The proposed DEA framework comprises three steps, which are detailed next.

2.1. Step 1. Simplified input-output model representation

The first step consists of gathering information from a detailed process simulation of the candidate design in order to develop a simplified input-output model representation to be used in the DEA model in Step 2. In essence, this model relates a set of elementary mass and energy flows Z_f ($f = 1 \dots F$) to the key performance indicators (KPIs), treated either as inputs $x_{\ell,i}(Z_1, \dots, Z_F)$ or outputs $y_{\ell,j}(Z_1, \dots, Z_F)$ of the decision making unit (DMU). For instance, Z_f could comprise the flows of raw materials and utilities in connection to DMU inputs, or products and emissions in connection to DMU outputs. In turn, thermodynamic limits in the system can be enforced by restricting the flows, e.g. in the form of inequality constraints $g(Z_1, \dots, Z_F) \leq 0$, and these restrictions are then reflected on the KPIs. For instance, these constraints could represent the minimum amount of raw materials and energy that the process would consume under the assumption of a 100 % yield and a full heat integration of streams to meet the minimum utility requirements dictated by a composite curve.

2.2. Step 2. Enhanced closest-target DEA model

In this step the simplified input-output model from Step 1 is combined with a closest-target DEA model. Our enhanced DEA model projects inefficient DMUs onto the efficient frontier by minimising the distance to target (according to a given metric), while accounting for the thermodynamic limits of the process so as to prevent unrealistic targets. A certificate of infeasibility for this model is an indication that the candidate design may not be projected onto the efficient frontier within the design envelope dictated by the thermodynamic limits. The model takes the form of a mixed-integer program, either linear (MILP) or nonlinear (MINLP) depending on the nature of the simplified input-output model. This step is divided into three sub-steps.

2.2.1. Step 2.1 Definition of attributes

The attributes are classically labelled as inputs or outputs according to whether they are to be maximised (DMU outputs) or minimised (DMU inputs). A tailored approach to

sustainability assessment in process synthesis and design entails the selection of a single DMU output, corresponding to the functional unit in LCA; while all of the economic, environmental and social indicators are normalized in reference to the functional unit.

2.2.2. Step 2.2 Characterization of the efficient frontier

Given a set of n DMUs $k = 1 \dots K$, each consuming m inputs $x_{k,i}$ $(i = 1 \dots I)$ and generating n outputs $y_{k,j}$ $(j = 1 \dots J)$, the question about whether or not a DMU ℓ is efficient can be answered via the solution of the following LP model (Galán-Martín et al. 2016):

$$\max \theta_\ell^* = \sum_{j=1}^{J} v_j \, y_{\ell,j}^* \tag{1}$$

$$\text{s.t.} \sum_{i=1}^{I} u_i \, x_{\ell,j}^* \tag{2}$$

$$\sum_{j=1}^{J} v_j \, y_{k,j} - \sum_{i=1}^{I} u_i \, x_{k,i} \leq 0 \quad k = 1 \dots K, \ k \neq \ell \tag{3}$$

$$u_i, v_j \geq 0, \ i = 1 \dots I, \ j = 1 \dots J \tag{4}$$

where u_i and v_j denote the linear weights of outputs and inputs, which are treated as variables to be optimised; and the relative efficiency score θ_ℓ^* indicates whether the DMU ℓ is efficient ($\theta_\ell^* = 1$) or inefficient ($\theta_\ell^* < 1$) in comparison to the other DMUs. The best-practice or efficient frontier consists of the subset $E \subset \{1, \dots, K\}$ of all efficient DMUs and may be used as a benchmark to define improvement targets for the inefficient units.

2.2.3. Step 2.2 Target setting with thermodynamic limits

In the second step, the simplified input-output model from Step 1 is combined with a closest-target DEA model, based on the work by Aparicio et al. (2007). Our enhanced DEA model projects inefficient DMUs onto the efficient frontier by minimising the distance to target (according to a given metric), while accounting for the thermodynamic limits of the process so as to prevent unrealistic targets. A certificate of infeasibility for this model is an indication that the candidate design may not be projected onto the efficient frontier within the design envelope dictated by the thermodynamic limits. The model takes the form of a mixed-integer program, either linear (MILP) or nonlinear (MINLP) depending on the nature of the simplified input-output model. The targets for an inefficient DMU $\ell \notin E$ are computed by solving the model represented by Eqs. (5)-(15).

$$\min \ \sum_{f=1}^{F} \left| \frac{z_f - z_f^{\text{ref}}}{z_f^{\text{ref}}} \right| \tag{5}$$

$$\text{s.t.} \ \sum_{k \in E} \lambda_k x_{k,i} = x_{\ell,i}(Z_1, \dots, Z_F), \ i = 1 \dots I \tag{6}$$

$$\sum_{k \in E} \lambda_k y_{k,j} = y_{\ell,j}(Z_1, \dots, Z_F), \ j = 1 \dots J \tag{7}$$

$$g(Z_1, \dots, Z_F) \leq 0 \tag{8}$$

$$\sum_{j=1}^{J} v_j y_{k,j} - \sum_{i=1}^{I} u_i x_{k,i} + d_k = 0, \ \forall k \in E \tag{9}$$

$$d_k \leq M(1 - b_k), \ \forall k \in E \tag{10}$$

$$0 \leq \lambda_k \leq M b_k, \ \forall k \in E \tag{11}$$

$$b_k \in \{0,1\}, \ \forall k \in E \tag{12}$$

$$d_k \geq 0, \ \forall k \in E \tag{13}$$

$$u_i \geq 1, \ i = 1 \dots I \tag{14}$$

$$v_j \geq 1, \ j = 1 \dots J \tag{15}$$

The main degrees of freedom in this model are the modified mass and energy flows Z_f in order to make the DMU ℓ efficient. The objective function in Eq. (5) minimises relative deviations between Z_f and the original flows Z_f^{ref}. The improvement targets are enforced in Eqs. (6)-(7), where λ_k are the weights assigned to each efficient DMU (belonging to the reference set E). These targets are constrained by thermodynamic limits in the system via the generic inequality constraints in Eq. (8). The linear constraints in Eq. (9) combined with the big-M constraints in Eqs. (10) and (11) determine the peer group of the DMU ℓ. A binary variable b_k equal to 1 indicates that the DMU k belongs to the peer group, in which case $d_k = 0$ and $\sum_{j=1}^{J} v_j y_{k,j} = \sum_{i=1}^{I} u_i x_{k,i}$, and the corresponding weight λ_k can be adjusted freely (provided that the constant M is set to a large enough positive value). Otherwise, having b_k equal to 0 forces $\lambda_k = 0$ when the DMU k does not belong to the peer group of the DMU ℓ(Aparicio et al., 2007).

3. Case study in liquid fuels for transportation

We illustrate the capabilities of the enhanced DEA framework through the sustainability assessment of liquid fuels for transportation, which could be potentially employed in the automotive fleet powered by internal combustion engines. Our main objective is to assess methanol produced from H_2 derived from fossil fuels, and compare it with ten alternative transportation liquid fuels including gasoline, bio-gasoline, Fischer-Tropsch naphtha from natural gas, ethanol produced from three different sources (i.e. corn, sugarcane, switchgrass), liquid hydrogen produced from three sources (i.e. natural gas, coal, biomass), and methanol employing electrolysis powered by wind as a source of H_2. The methanol production process of interest is based on the work by Gonzalez-Garay and Guillen-Gosalbez (2018). If this process were found to be inefficient, a further objective is to quantify practical improvement targets that would make it competitive. The scope of our analysis follows a well-to-wheel (WTW) approach, which is further decomposed into well-to-pump (WTP) and pump-to-wheel (PTW) contributions (Greet, 2016). Two indicators are used to assess the performance of the liquid fuels: the total driving cost (DC) and the global warming potential (GWP) per driven mile. Both indicators are defined as inputs to be minimised, while the output is set to 1 driven-mile.

4. Results and discussion

The results in Figure 1 show that four fuels are efficient ($\theta_\ell^* = 1$), namely gasoline, EtOHsc-85, Bio-gasoline and 85-MeOH$_{\text{re}}$ and therefore, they constitute the efficient frontier which in turn may be used as a benchmark to define the improvement targets for

our fuel of interest 85-MeOH$_{re}$. Gasoline shows the lowest price, but the second highest GWP, being overcome only slightly by FT-naphtha. Ethanol from sugarcane has a very similar cost to gasoline, but a lower GWP. Bio-gasoline and methanol based on H$_2$ from renewable electrolysis are the cleaner fuels, showing the lowest GWP. On the other hand, ethanol from corn or switchgrass, hydrogen-based fuels, and our fuel of interest (85-MeOH$_f$) are all deemed inefficient. The comparison confirms that liquid H$_2$ from coal, natural gas and biomass perform significantly worse than the other fuels, both in terms of DC and GWP. This is principally due to the high cost and energy consumption associated to the transport and storage stages (IEA, 2013). Observe also that our fuel 85-MeOH$_f$ shows the second highest DC, just behind methanol employing renewable electrolysis as source of H$_2$ (85-MeOH$_{re}$). For the targets definition, we consider three cases: 1) H$_2$ flow defined as variable; 2) H$_2$ cost as variable (flows defined as constant); and 3) H$_2$ produced from two different sources, namely fossil fuels and wind-powered electrolysis. Case 1 is proved to be infeasible. Therefore, our fuel 85-MeOH$_f$ cannot be projected onto the efficient frontier by modifying the sole flow of H$_2$ subject to the stoichiometric limit defined by the reaction that governs the process (Gonzalez-Garay and Guillen-Gosalbez 2018). In Case 2 (see Figure 1), it is found that 85-MeOH$_f$ could reach the target defined by its peers, 85-EtOH$_{sc}$ and Bio-gasoline, on the efficient frontier, but this would call for a 60% reduction in H$_2$ price, down to 1.17 US\$/kg. In practice however, such a large drop is unlikely given the current state-of-the-art in H$_2$ production technology (Gonzalez-Garay and Guillen-Gosalbez, 2018). In case 3, 85-MeOH$_f$ could also reach the target defined by its peers, 85-MeOH$_{re}$ and Bio-gasoline, on the efficient frontier, by allowing for a mix of H$_2$ from fossil fuels and wind-powered electrolysis. This projection increases DC by 7.9 % and reduces GWP by 9.4 % with respect to their initial values, which is enabled by: (i) the reduction of the total H$_2$ flow to the stoichiometric lower bound which represents a decrease of 14.5 % compared with the initial H$_2$; and (ii) the use of a 26-74 % mix of H$_2$ from fossil fuels and wind-powered electrolysis, respectively, which suggests that our fuel 85-MeOH$_f$ may only become competitive upon substituting a majority of the H$_2$ feedstock from fossil fuels by a more sustainable production route, despite the resulting increase in fuel price.

5. Conclusions

This paper has presented a systematic framework for improving the sustainability of chemical processes, based on the synergistic combination between DEA and process synthesis tools. Our approaches improves the capabilities of standard DEA models and process targeting methodologies by providing realistic targets for suboptimal processes. Its main advantages are four-fold: (i) Applicability in the presence of multiple sustainability KPIs; (ii) Discernment between the efficient and inefficient options among a set of candidate designs, thereby defining an efficient frontier; (iii) Identification of quantitative targets for the inefficient process, which are at a minimum distance of the best-practise frontier in terms of mass and energy flow modifications; and (iv) Definition of realistic targets that account for the thermodynamic limits of the underlying process, by embedding a (simplified) model of the sustainability KPIs in terms of the process mass and energy flows into the enhanced closest-targets DEA model.

The application of the DEA framework to the case study reveals that for the methanol fuel 85-MeOH$_f$, the current price of H$_2$ is a major impediment to its competitiveness, the sole reduction of the H$_2$ flow from fossil fuels does not allow to reach the best-practise frontier when the stoichiometric limits are taken into account. However, if flexibility is introduced in the H$_2$ source by mixing H$_2$ from fossil fuels and wind-powered electrolysis,

it is found that 85-MeOH$_f$ could indeed become competitive due to a reduction in GWP despite an increase in its DC.

Abstract

This paper develops a mixed-integer linear programming (MILP) formulation to support the design and planning of agri-food supply chains (AFSC). The model focuses on the strategic-tactical decisions of capacity definition, selection of processing technologies, and the establishment of product flows to achieve expected net present value (ENPV) maximisation. Within the model, AFSC-specific characteristics are modelled as is the case of product perishability, flexible storage strategies, and reverse logistics operations. Supply and demand uncertainty is considered using a stochastic scenarios tree. The model is tested via the application of a case study from an existing sugar beet processing supply chain in The Netherlands.

Keywords: agri-food supply chain, perishability, reverse logistics, uncertainty

1. Introduction

With a growing world population and worldwide problems such as water scarcity and desertification, providing food on a global level will continue to be a challenge, one to which AFSC need to adapt to, cemented on solid drivers for change. Within the major drivers, sustainability concerns should be highlighted. Awareness for environmental impacts is currently on the rise, with a considerable portion of consumers beginning to adapt their consumption habits to reflect such concerns. Social concerns are also becoming generalised. These concerns, which span from supporting locally-grown products to investing in local job creation, lead customers to preferring a closer proximity to farms and markets, as well as paying more attention to the origin of their products. Naturally, this pushes supply chains (SC) towards a more local (decentralised) configuration and puts emphasis on product freshness and traceability. Finally, the access to ever-evolving technologies pushes changes and sector improvement at an increasing rate where uncertainty has to be dealt at both demand and supply sides.

This context creates a high level of complexity when designing and planning AFSC, that imply the development of decisions in tools, where AFSC characteristics are accounted for, so as to support the decisions makers in their decision making process.

In this paper we explore this need and a MILP modelling approach is proposed. This has a strategic-tactical breadth and focuses on defining technology and storage capacity for each AFSC facility, accounting for processing pathway selection, and definition of product flows between entities while considering the main ASFC characteristics as are product perishability, flexible storage strategies, reverse logistics operations, under a context where uncertainty on demand and supply exist.

The paper is structured as follows: Section 2 performs a literature review of papers addressing the design and planning of AFSC with quantitative methods. In Section 3, the major problem characteristics are introduced and briefly explained. In Section 4, the modelled objective is analysed, and novelties introduced explained. Section 5 highlights the details of the case study used to assess model performance. In Section 6, the results of the application of the case study are presented and discussed. Finally, Section 7 uses all previously gathered knowledge to arrive at conclusions and suggest future research directions.

2. Literature Review

The number of papers focusing on the design and planning of AFSC using quantitative models has been steadily increasing (Tsolakis et al., 2014), mostly due to the ever-increasing relevance of the topic on a worldwide scale. Sustainability is one of the most important current concerns. However, most authors still primarily address economic objectives, with just two publications addressing environmental sustainability without simultaneously pursuing economic goals (Banasik et al., 2017; Pipatprapa et al., 2016).

Among SC characteristics, a major focus is verified in centralised SC, against fewer which explicitly focus on decentralised configurations. This is particularly concerning, as decentralisation strategies may be a solution for current environmental and social challenges. In fact, decentralisation allows for the reduction of transportation costs and emissions, and supports local food production and job creation (Bosona and Gebresenbet, 2011; Accorsi et al., 2018). Apart from this, most studies have also addressed forward-oriented SC exclusively, in which reverse logistics are not considered. With current sustainability and waste reduction concerns on the rise, it is expected that the role of reverse and closed-loop SC will only increase (Barbosa-Póvoa et al., 2018). In light of this paradigm, the work of Banasik et al. (2017) must be highlighted, as it focuses on closing the loops in AFSC with the use of multi-objective optimisation.

In the literature is also clear that AFSC possess a series of characteristics which render them unlike any other, reason for which specific tools need to be devised for these SC. Among these, the high level of uncertainty verified in both supply and demand must be highlighted. Naturally, the inclusion of uncertainty modelling is an important trait when evaluating currently-proposed methodologies. Disregarding uncertainty drives models away from reality and, consequently, limits their applicability. When accounting for supply and demand uncertainty, it is clear that attention has been given to demand uncertainty. With fewer publications contributing with both demand and lead time uncertainty considerations (Galal and El-Kilany, 2016). Apart from recognising which authors address AFSC with uncertainty-encompassing approaches, the analysis of which methods have been used to model uncertainty is also interesting. Stochastic models are the more popular approach towards incorporating uncertainty in models.

To support solving some of the knowledge gaps identified throughout the literature review, this paper develops a generic model to assist decision makers on the design and planning of AFSC. The model achieves this goal by incorporating underexplored characteristics in the existing literature, such as reverse logistics, integration of both supply and demand uncertainty, as well as perishability and flexible storage strategies.

3. Problem Characteristics

A generic AFSC is here considered and it consists of five echelons: suppliers, which ensure the supply of raw materials; factories/processors, which use raw materials to manufacture products; warehouses/ distributors, which store products for posterior sale and distribute them to retailers; retailers, where products are sold to end consumers; and reprocessors, which receive wasted products from the remaining SC and produce other valuable products from them, which are then sold to end consumers. The different production processes are represented as technologies, which have associated production costs and bills of materials. To model supply and demand uncertainty, a stochastic scenario tree was established. Each tree node is associated to a randomised occurrence probability and has associated supply and demand variation rates. The problem can be described as follows:

Given: A set of products (raw materials, intermediate products, and final products); **a set of technologies**, which convert raw materials to intermediate and final products with associated operating costs, material inputs, and outputs; **a set of entities** (suppliers, processors, distributors, markets, and reprocessors) with associated locations and transportation costs, associated technology capacity, associated storage capacity, and associated demand.

Select the: Technology capacity to use in each entity in each time period; stored quantity in each entity in each time period; product flows between entities in each time period.

Subject to: Inventory/storage constraints; technology constraints; transportation constraints; demand constraints; supply constraints; reprocessing constraints; uncertainty-encompassing constraints.

4. Model Formulation

This section describes the modelled objective and puts emphasis on the differences operated from the modelling approach first proposed by Cardoso et al. (2013), which has been taken as basis for this work.

Equation 1 corresponds to the objective of ENPV maximisation, where the ENPV is expressed as a function of the cash flows ($CF_{s,t}$) of each time period (and scenario), corresponding interest rate (ir) and the probability of occurrence of each stochastic node.

$$maxENPV = \sum_{t \varepsilon T} prob_s \times \frac{CF_{s,t}}{(1+ir)^t} \tag{1}$$

Supply uncertainty has been pinpointed as one of the areas in which research is lacking. AFSC frequently show mismatches between supply and demand due to high lead times. To mimic this condition, the supply is a theoretical value (for instance, the total production from the arable land of a farm), which never truly corresponds to the effective supply that comes from it, due to inevitable loses. To mitigate such uncertainty, to the maximum expected production capabilities are then taken fractions corresponding to the various sources of loss and uncertainty that affect AFSC, Equation 2. This equation agglomerates all sources of waste in farms to obtain the total spoiled quantity in a given time period ($SQ_{p,v,t}$). The first element on the right hand side, takes into account what is produced ($W_{v,p,s,t}^{out1}$) and immediately spoiled ($imwf_{p,v}$) on each facility; the second element considers the mismatch between supply and demand and the spoilage created by

excessive supply ($p_{p,v,t}^{farm}$) ; finally the third element considers the spoilage ($lostsf_{p,v,t}$) in inventory ($INV_{v,p,s,t}$) along the supply chain.

$$\sum_{p\varepsilon raw(p)} SQ_{p,v,t} = \sum_{p\varepsilon raw(p)} (W_{v,p,s,t}^{out1} \times imwf_{p,v}) + \sum_{p} p_{p,v,t}^{farm} + \tag{2}$$

$$\sum_{p\varepsilon raw(p)} (INV_{v,p,s,t} \times lostsf_{p,v,t}) \quad \forall v\varepsilon v_{sup} \wedge p\varepsilon P_{raw} \wedge (s,t)\varepsilon S \tag{3}$$

The inclusion of reverse logistics is also of extreme relevance since it is able to generate value with otherwise disposable products. The production of the reprocessors ($W_{i,v,p,s,t}^{out}$) is considered in Equation 4, as a function of the waste input ($W_{i,v,p,s,t}^{in}$) taking into account both the raw material requirements necessary to produce the new product ($qrmat_{p,p'}$) and what can be used from reprocessed products ($reprof_{p,v}$).

$$W_{i,v,u,s,t}^{in} \times reprof_{v,u} = \sum_{p\varepsilon raw(p)} (W_{i,v,p,s,t}^{out} \times qrmat_{u,p}) \tag{4}$$

5. Case Study and results

The case study here described is based on the work by Jonkman et al. (2018), a schematic of the SC in presented in Figure 1. The case study was divided in three different scenarios, all with specific changes meant to be addressed comparatively to assess the applicability of the model to a realistic context. The different scenarios are structured as follows: **Case A**: the expansion of an existing AFSC is considered, in which storage is allowed solely in warehouses, and under supply and demand uncertainty; **Case B**: the expansion of the same AFSC is considered, but storage is allowed in every echelon, and under supply and demand uncertainty; **Case C**: the expansion of the same AFSC is considered, in which storage is allowed in every echelon, under supply and demand uncertainty, and including a reprocessing echelon where reverse logistics operations are allowed.

The SC includes two processing facilities (factories), and two potential processing facilities, one equipped with conventional technology, and one with a small scale bio-refinery technology. The processing echelon is served by 43 suppliers. The distribution echelon includes 4 facilities, and serves a total of 17 markets. For the third scenario, the reprocessing echelon corresponds to facilities in which reprocessing technologies are installed.

As final results, an ENPV of €3074961.95, 3080248.23, and 4053404.26 were obtained for Cases A, B, and C, respectively. The economic performance between Cases A and B is not remarkably different, as the added storage capacity throughout the SC can help prevent product wastage, but only up to a certain level, as product perishability prevents keeping high inventory levels. Still, as can be seen, this added storage capacity does impact the economic performance positively, even if not in a striking manner. However, the same does not hold true for Case C, in which a considerably higher economic performance is

Table 1: Economic and service level results

	Case A	Case B	Case C
ENPV (€)	3074961.95	3080248.23	4053404.26
Unmet demand (%)	9.8	7.6	6.5

achieved due to the additional sales unlocked by the existence of reverse logistics, Table1.

In fact, the addition of reverse logistics does provide a very meaningful increase in the maximum registered ENPV, a finding which goes well in line with what is seen in the literature review. The appropriate response to the subsequent additions of AFSC characteristics also translates the correct behaviour of the model when addressing the AFSC context, one of the desired goals of this work.

It can also be seen that the capital investments increase from one case to the next, as the addition of flexible storage capacity and one entire reprocessing echelon do come at a cost (aprox. 1M€ from Cases A and B to C). However, and as previously mentioned, the additional investment does bear significant economic compensation.

It is interesting to note that the model behaves similarly for all three cases in terms of storage capacity. As far as technology is concerned, it should be highlighted that the model chooses to operate processing capacity increases in already-existing factories rather than opening a new facility. Contrasting, the alternative biorefinery configuration is indeed installed,

Figure 1: Location of the facilities within the sugar beet SC. Suppliers are marked in blue, existing processors in red, the potential conventional processor in green, the potential bio-refinery processor in purple, warehouses/distributors in brown, and markets/retailers in orange.

in all cases, to satisfy demand for products not generated by the standard technology alternative.

It is important to recognise how the improved economic performance of the model impacts customer service, with unmet demand being a good performance indicator. Before further analysis, it should be noted that a minimum percentage of demand satisfaction of 90% is imposed to the model. It can be seen that in Case A the minimum percentage is barely achieved (90.20% demand satisfaction). An increase in demand satisfaction is registered between Cases A and B, as the additional scattered storage capacity in Case B reduces waste cost, by 26%, and improves demand fulfilment, by 2%. Finally, an additional small increase in demand satisfaction (1%) is seen between Cases B and C, as the reverse logistics activities provide further waste reduction and generate resources that can be applied to other productive activities, thus positively impacting the available quantities for sale. Case C is also where waste costs are reduced to the maximum with reductions of 68% and 57% if compared with Case A and Case B, respectively.

6. Conclusions

In the present work a quantitative model is proposed to support the design and planning of AFSC via an optimisation approach, focused on the strategic and tactical decision levels.

The satisfactory performance of the model in an AFSC context solves a set of clearly identified knowledge gaps. Firstly, the model is an important step towards encompassing both supply and demand uncertainty in the AFSC sector, traits deemed essential for the appropriate applicability of the model to real-world cases. Secondly, the model incorporates reverse logistics, which have been identified as powerful tools in the optimisation of both the economic and environmental performance of AFSCs and that, so far, had been understudied. Finally, the model includes specific under-explored AFSC characteristics such as product heterogeneity and a flexible storage strategy.

Despite providing several improvements when compared to non AFSC-specific models, the current model can still be subject to several improvements. At first, it should be noted that the model here developed incorporates one single economic objective, a trait which fails to meet current Triple Bottom Line (TBL) optimisation concerns. Secondly, more attention can also be given to the stochastic scenarios tree used to model uncertainty. The proposed scenarios tree seems appropriate to the modelled context, but the application of a larger set of possible scenarios could help improve on the model's realism.

Production scheduling of semi-continuous milk processing facility

Utkarsh Konge[a] and Sivakumar Subramanian[a,*]

[a]*TCS Research and Innovation, Tata Research Development and Design Centre, Tata Consultancy Services, Pune 411013, India*
sivakumar.subramanian1@tcs.com

Abstract

Production scheduling of a semi-continuous multi-product plant with multiple units working in series or parallel mode is a challenging problem. Furthermore, characteristics like limited inventory and single continuous packing campaigns add to its complexity. In this work, an MILP formulation with continuous time representation is implemented to maximize the production of a milk processing facility. Unlike the batch processes where the batch sizes in the time intervals are the key variables, in the semi-continuous process considered, the time duration for which the process is active in each time interval becomes the key variable. A schedule which maximizes the production is generated for each day so that a minimum market requirement is satisfied for each product. The results obtained can further be used to find the bottlenecks and help improve the productivity of the facility.

Keywords: MILP, Scheduling, Semi-continuous Process, Dairy Plant Scheduling

1. Introduction

High competition in process industries has led manufacturers to prioritize optimization of existing production operations. This is where optimal scheduling of the facility plays an important role. Harjunkoski et al. (2014) presented the impact of optimal scheduling for various industries. The case presented in Bongers and Bakker (2008) saw a significant increase in production due to optimal scheduling. This motivated a rich set of literature showcasing scheduling optimization in food industry. Most of the production plants in food processing industry work in semi-continuous mode as the production is flexible and production equipment can be utilized more efficiently. As discussed by van Elzakker et al. (2012) characteristics like multi-stage production, limited inventory, intermediate cleaning, and single continuous packing campaigns are representative of a typical FMCG industry. These characteristics were modelled for a semi-continuous ice-cream manufacturing process. Kopanos et al. (2010) discussed the scheduling of yoghurt production in detail. In both works, the stages of pasteurization, standardization, and homogenization were considered as a single stage. The schedule for downstream stages is thrown over the wall to this stage.

Most of the milk derivatives like ice-cream, yoghurt, milk powder and so on, have pasteurized and standardized milk as a precursor. This makes it imperative to schedule the process of pasteurization and standardization of milk. Bilgen and Dogan (2015) optimized the production planning of a milk pasteurization facility which comprised of raw milk tanks, pasteurization unit, intermediate storage tanks and so on. The work presented in this paper aims at developing optimal schedule for a similar semi-continuous process with characteristics like limited intermediate storage and single

continuous packing campaign. The model is expressed as an MILP formulation with continuous representation of time. A decomposition method is implemented to solve the problem in a reasonable time. Results obtained were used to find the bottlenecks of the process and improve the process further.

2. Problem Statement

Bylund (2003) discussed the pasteurization process in detail. It depicts the significance of various process components like milk silos, intermediate storage tanks, pasteurizer, standardization unit and so on. The semi continuous dairy plant, considered based on the discussion in Bylund (2003), is shown in Figure 1. This production facility converts raw milk into standardized milk, which is then converted into Stock Keeping Units (SKU). Raw milk is received in the silos at the beginning of each day. It is then processed in a pasteurization unit which operates in continuous mode. In a standardization unit, cream is separated from the raw milk in a continuous mode and collected in separate Cream Storage Tanks. The pasteurization unit and standardization unit work in continuous mode consecutively. Hence, these are considered as a single unit in the process. Apart from cream, the standardization unit produces standardized milk. This standardized milk is then stored in the intermediate storage tanks which is then converted into SKUs by the packaging lines. Changing the operation from one fat content to other on the pasteurizer stage can be done without any additional setup time or intermediate cleaning. As there are various types of intermediate products based on the fat content, multiple storage tanks are required to avoid mixing. The packaging lines operate in continuous mode with feed from the intermediate tanks. Typically, packaging lines can process multiple types of SKUs with different rates. Additional setup time or intermediate cleaning may be required while changing the mode from one SKU to other on the packaging lines. In Kopanos et al. (2010), typical daily production line shutdowns are modelled due to hygienic requirements. Similar shutdowns are modelled in the presented facility where the packaging lines are allowed to run only for 18 hours a day. At the end of the scheduling horizon (week) the levels of all the intermediate products are constrained to be zero. The objective of the scheduling problem is to maximize the total production subject to continuous single product packing campaign, limited intermediate storage and some minimum production of each SKU.
Figure 1: Schematic overview of a milk processing plant

3. Formulation

The key decision variables in this optimization problem are: (i) the start time of each stage in the production line, (ii) the amount of each SKU to be produced on each day of the week and on each packaging line, (iii) the order in which the SKUs and the intermediate products are processed. To keep track of the levels of intermediate products, a continuous time formulation is implemented. The start and completion times of products on the pasteurization stage and the packaging lines

are considered as events for the formulation. A slot is created between two events and since the processes are continuous, the time for which each stage is active in a slot is a key variable too. The binary variables denoting the start and end of a particular process for a specific product in the given slot are used to find the slots in which the process is active. The time of processing in each slot can be equated to this slot length. Let $\Delta t_{i,l,p,k}$ denote the time for which a process line p was active processing product i in slot l on day k. Let $s_{i,l,p,k}$ and $f_{i,l,p,k}$ be the binary variables denoting the start and end of this process in slot l respectively. The relation between these variables are captured in constraints (1)-(3). The variable $S_{l,k}$ denotes the starting time of slot l on day k. M is large value compared to $\Delta t_{i,l,p,k}$. $nslots$ is the total number of slots given.

$$\Delta t_{i,l,p,k} \geq S_{l+1,k} - S_{l,k} - M \times (1 - \sum_{lm \in \{1,2,3,...,l\}} (s_{j,lm,p,k} - f_{j,lm,p,k}))$$

(1)

$$\Delta t_{i,l,p,k} \leq S_{l+1,k} - S_{l,k} + M \times (1 - \sum_{lm \in \{1,2,3,...,l\}} (s_{j,lm,p,k} - f_{j,lm,p,k}))$$

(2)

$$\Delta t_{i,l,p,k} \leq M \times (\sum_{lm \in \{1,2,3,...,l\}} (s_{j,lm,p,k} - f_{j,lm,p,k}))$$

(3)

$$\forall i \in Products, p \in ProcessLines, l \in slots \setminus \{nslots\}, k \in Days$$

The levels of each intermediate product is updated at each event so that the input from the pasteurization stage adds to the level at previous event and the output to the packaging lines reduces it. The total capacity of intermediate storage is limited. To model this, the storage amount is divided into various bins. The parameters U^r_{cap} and L^r_{cap} are the upper and lower bounds of the bins respectively. Computation of these bounds is explained with an example here. Consider three tanks each with capacity of 1000 kg. The index r will run from 1 to 3 (total number of tanks). The set of parameters is as shown in constraints (4).

$$\{(L^1_{cap}, U^1_{cap}), (L^2_{cap}, U^2_{cap}), (L^3_{cap}, U^3_{cap})\} = \{(0, 1000), (1000 + \varepsilon, 2000), (2000 + \varepsilon, 3000)\} \quad (4)$$

Here ε is a small value compared to tank capacity. A binary variable keeps track of the bin in which the level of each intermediate product lie in each slot on each day. Now, to implement the maximum capacity constraint, the sum of U^r_{cap} for the bins in which the levels lie, is constrained to be less than or equal to the maximum capacity. Let the binary variable denoting whether the level of intermediate product j is in bin r in slot l for day k be $z_{j,r,l,k}$. The constraints capturing the relations are equations (5) and (6). The constraints (7) ensure that the levels are in exactly one bin for a given intermediate product, slot and day. The variable $R_{j,l,k}$ represents the amount of intermediate product j at the start of slot l on day k. $MPast$ is a large value as compared to $R_{j,l,k}$. I is the set of intermediate products.

$$R_{j,l,k} \geq L^r_{cap} - MPast \times (1 - z_{j,r,l,k}) \qquad \forall j \in I, r \in bins, l \in slots, k \in Days \qquad (5)$$

$$R_{j,l,k} \leq U^r_{cap} + MPast \times (1 - z_{j,r,l,k}) \qquad \forall j \in I, r \in bins, l \in slots, k \in Days \qquad (6)$$

$$\sum_{r \in bins} z_{j,r,l,k} = 1 \qquad \forall j \in I, l \in slots, k \in Days \qquad (7)$$

Since raw milk has a very short shelf-life, all the milk procured on a particular day must be pasteurised and stored in the intermediate storage. The input stream of the pasteurizer, which is converted into intermediate products with different fat content, has a constant flowrate. But the output flowrate depends on the type of intermediate product being produced. Cream is produced as a side product and stored in storage tanks of limited capacity. The pasteurized milk can be kept overnight in the tanks and used for production on the following day. For the first day of the

Intermediate Product	Output flowrate (kg/h)
Z1 (Low fat)	2199.5
Z2 (Medium fat)	2256.6
Z3 (High Fat)	2348.1

Table 1: Pasteurizer output flowrates of intermediate products

week, it is assumed that the tanks are empty at the beginning of the day. Packaging lines can start packing the products only when some buffer time has elapsed after the start of pasteurization of the corresponding intermediate product. Sequence dependent changeover is implemented on the packaging lines. When a product is assigned to a particular packaging line, some minimum amount of it has to be processed on the line. To maintain the hygiene of the plant, the fillers or the packaging lines are allowed to run only for 18 hours a day. Finally, the constraints ensuring meeting of the market demand and the mass balance between the intermediate products and the SKUs are enforced. Apart from these constraints, the regular scheduling constraints like non-preemptive assignment of units and sequencing of the products are enforced.

3.1. Decomposition

For the given case, the scheduling for the whole week turned out to be a difficult problem to solve due to the size of the problem. Hence, the problem was divided into smaller problems by de-composing the temporal dimension. In each of the smaller sub-problem, scheduling optimization was carried out for just one day with the objective of maximizing the production. Through the constraints of the model, it was ensured that the daily production of each product was more than the daily average requirement to satisfy the weekly target. The level of each intermediate product at the end of the day was recorded and was used to initialize the level of each intermediate product at the start of the following day. The sub-problems are solved for all the seven days of the week. A schematic of the decomposition method is given in Figure 2. The advantage of such a decom-position is that if in the optimal schedule for a day, the initial levels of the intermediate product are equal to the levels at the end of the day, then the problem need not be solved for the next day as it would have the same optimal schedule.
Figure 2: Decomposition strategy

4. Results and Discussion

The problem was formulated in Pyomo 5.5.1(Hart et al. (2017), Hart et al. (2011)) and solved using COIN-OR Cbc (Forrest et al. (2018)). For one day of scheduling, the MILP formulation consisted of 1281 variables and 2726 constraints and was solved within 120 seconds on a system with i5-2400 (3.10 GHz) processor and 10 GB RAM. The continuous time representation consisted of 20

| SKU | Rates (kg/h) | | Intermediate | Min Req.(kg) | Optimal production (kg) |
	S1	S2	Product		
A	600	540	Z3	30000	32899
B	900	600	Z2	20000	20000
C	-	600	Z1	15000	15000
D	540	540	Z1	7500	7500
E	720	780	Z3	15000	22399
F	600	-	Z2	2500	2500

Table 2: Packaging Rates, Minimum and Optimal production

events. The input flow rate of the pasteurization stage is 2400 kg/h. The output flow rates of various intermediate products are given in Table 1. The maximum capacity of the Raw Milk silos is 15000 kg. There are four intermediate storage tanks each with capacity of 5000 kg. The facility has two packaging lines namely S1 and S2. The packaging rates for the SKUs on each line are given in Table 2 along with the corresponding intermediate product. The sequence dependent changeover for the packaging lines ranges from 0.25 to 0.5 h. The minimum required quantity and the optimal production of the products are given in in the last column of Table 2. The products A and E are produced more than the minimum required value (9 % and 49 % more, respectively). Rest of the products met their demands exactly. The excess production of A and E can be explained by the fact that both A and E are produced with the intermediate product with the highest flow rate (Z3). This ensures high availability of intermediate product required for the production. The packaging rate of product E is high on both the packaging lines. Thus, more of this product can be processed in less time. Figure 3 depicts the optimal schedule for one day. Figure 4 depicts the time profile of quantities of intermediate products stored in the intermediate tanks. As the initial and final levels of all the intermediate products is same, the same schedule is optimal for all the days.
Figure 3: Gantt Chart of the schedule

As evident from the Figure 3, the packaging lines S1 and S2 are not being used to the fullest as there is some idle time apart from the sequence dependent changeover. This can be attributed to low capacity of the raw milk silos. This is explained even by Figure 4 in which the levels of all the intermediate products drop to zero at the end of the day. To improve the utilization of S1 and S2, the capacity of raw milk silo, in other words, the procurement of raw milk, should be increased. Additional optimization simulations can be performed to find the capacity of silos which enable
Figure 4: Levels of intermediate products

the packaging lines to be utilized to the fullest.

5. Conclusion

An MILP model was formulated for a semi-continuous milk processing facility. The process characteristics typical of an FMCG industry were successfully modelled. A decomposition algorithm was developed, implemented, and successfully tested. An optimal schedule was obtained using an open source solver. The results obtained were used to draw insights to further improve the performance of the plant. The framework developed here provides a good foundation to simulate additional scenarios and to further increase the throughput of the plant by varying the silo capacity. This naturally transitions into simultaneous synthesis and scheduling optimization problem.

Abstract

This paper provides a new and fast method to select bypass during the heat exchanger network (HEN) synthesis stage. An indicator, namely disturbance over utility (DoU), was introduced to measure the maximum simultaneous disturbance rejection ability over the utility consumption. Together with a physical distance study, they can select the bypass placement fast and efficiently. DoU can select preferable heat exchangers to place bypass, and compare different HENs. For a given HEN with specified bypass strategies, the higher the DoU is, the larger the disturbance rejection ability per unit utility consumption, which was solved by a non linear programming (NLP) model. The physical distance study utilizes the structural information to discard potential inverse response and compare response time of different bypasses. The method has been applied into two alternative HENs, illustrating the process to select better HEN and find preferable bypass placement strategies. The main goal of this work is to contribute to HENs synthesis, by proposing a fast and efficient bypass selection method to decide the control structure.

Keywords: heat exchanger network synthesis, bypass selection, simultaneous disturbance, inverse response, time response

1. Introduction

The operational performance of HEN is largely dependent on the control structure, which deserves to be set up at design stage (Escobar et al., 2013). The manipulation of HEN is usually achieved through the operation of bypass and utility when the system is facing disturbance. While the number of utility is often not adequate to meet the HEN control requirement, thus bypasses are required in the HEN, and they usually denoted as manipulated variables (MVs). A challenging work is how to find optimal bypass placement strategy considering the simultaneous disturbance rejection, utility consumption and dynamic performance fast and efficiently.

During the past decades, many approaches were put forward to select the bypass for HENs by studying the trade-off between disturbance rejection ability, investment cost and dynamic performance. For explicit disturbance, flexibility index is widely accepted as the criteria to iterate the synthesis stage, along with checking the disturbance range individually (Yan et al., 2001)(Escobar et al., 2013). Chen and Hung (2004) agreed that the individual disturbance cannot guarantee the feasibility of the network when simultaneous disturbance occurs. The simultaneous disturbance analysis is especially important when disturbances are not explicit, for example, the HEN integrated with renewable energy systems. For a given HEN, the disturbance rejection is actually the heat load redistribution process limited by the constraints in MVs and the utility cost.

The disturbance rejection ability is a static problem, while the dynamic part is mainly about the control problems and time response, and it largely depends on the control strategy and specific controller. The following discussion is based on decentralized control scenario with PID as controller, which is the most commonly selection for HENs. Escobar et al. (2013) applied PID controller in MATLAB to study the dynamic performance of different bypass selections without consideration of the potential inverse response. In decentralized control scenario, the presence of right half plane (RHP) zeros might evoke the inverse response, and lead to control difficulty which ought to be avoided(Skogestad and Postlethwaite, 2005). The presence of inverse response in HENs comes from different downstream pathways with contrary effect on the same controlled variable (CV). The time response is the time delay between two stable conditions when MV functions, and the faster the better. Lersbamrungsuk and Srinophakun(2009) introduced the structural time delay (physical distance from MV to CV) to represent time response. We employ the same idea to compare different bypass placement strategies.

In this context, we aim to propose a fast and efficient method to select control structure during the HEN design. The method employs disturbance-over-utility (DoU), coupling with RGA-number, inverse response and physical distance to find a preferable bypass selection. The calculation of DoU involves optimization, while the whole method is trying to locate a good result by integrating static and dynamic criteria.

2. Bypass selection process

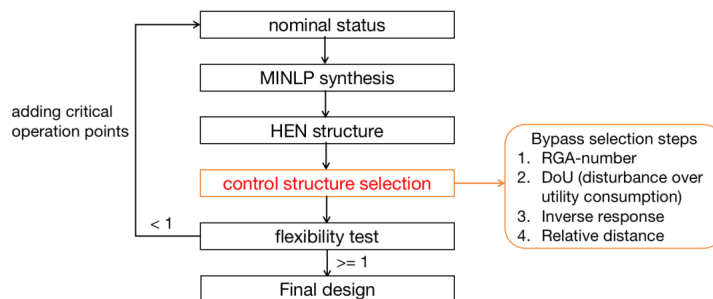
Figure 1 presents the integration of bypass selection in HEN sequential design process. In this paper we focus only on the control structure selection step. To reach the preferable bypass placement strategies, RGA-number and DoU will help to select preferable heat exchangers to place bypass, then potential inverse response and physical closeness will be employed to evacuate the most appealing bypass. RGA-number has been widely accepted as an efficient tool to quantify the interaction between different control loops and here it is also calculated with the same method as (Chen and Hung, 2004) (Escobar et al., 2013).


Figure 1: Bypass selection during the HEN synthesis

2.1 NLP model to calculate DoU
The HEN model regards the heat exchanger (HX) as the knot throughout each process stream, and for each stream there are '2*number of knots + 1' stages of temperature by assuming that bypass is on every side of all HXs. The simplified thermal effectiveness

method (Knut W. Mathisen, 1994) was selected to describe the energy balance of HX. The method is based on the simple relationship between the thermal effectiveness of the cold and the hot side (P^c and P^h) as in equation (4). With the constraint that P^c and P^h are within 0 and 1. For each heat transfer process, the heat transfer between two streams can be described as following:

$$P^h[i,j,k,l] = \frac{1 - \exp(-N_{tu}^h[i,j,k,l](1-R^h[i,j,k,l]))}{1 - R^h[i,j,k,l]\exp(-N_{tu}^h[i,j,k,l](1-R^h[i,j,k,l]))} \tag{1}$$

$$R^h[i,j,k,l] = CP_h[i,j,k,l]/CP_c[i,j,k,l] \tag{2}$$

$$N_{tu}^h[i,j,k,l] = UA[i,j,k,l]/CP_h[i,j,k,l] \tag{3}$$

$$P^c[i,j,k,l] = R^h[i,j,k,l]P^h[i,j,k,l] \tag{4}$$

$$P^h[i,j,k,l] = (T[i,2k-1]-T[i,2k])/(T[i,2k-1]-T[j,2l-1]) \tag{5}$$

$$P^c[i,j,k,l] = (T[j,2l]-T[j,2l-1])/(T[i,2k-1]-T[j,2l-1]) \tag{6}$$

Where i, j stand for the hot and cold stream of a HX; k, l stand for the order of knot that the HX lies in each stream; CP_h, CP_c are the heat capacity flow of hot and cold streams separately, U is the heat transfer coefficient, A is the transfer area; and T is the temperature. DoU is depicted as equation (7), d_i is the disturbance item, $d_{i,o}$ is the nominal value of that disturbance, and $W_{utility}$ is the utility consumption. The product can be interpreted as the volume by which the system can operate normally, the larger the DoU the better the disturbance rejection ability of HEN and utility consumption. It helps to select preferable HXs to place bypass and can also act as controllability indicator of HEN.

$$DoU = Max(\prod \left| \frac{d_i}{d_{i,o}} - 1 \right| / W_{utility}) \tag{7}$$

The constraint information to reach DoU is as following:

$$MV_y \in (0,1) \tag{8}$$

$$CV_x \in \left(CV_{x,o} - \alpha, CV_{x,o} + \alpha\right) \tag{9}$$

$$W_{utility} \leq load_{i,max} \tag{10}$$

$CV_{x,o}$ is the nominal value of CV_x, α represents the allowable range of CV.

2.2 Potential inverse response

Inverse response is a typical obstacle to achieve preferable control performance (Skogestad and Postlethwaite, 2005). It possibly occurs when there are different downstream pathways from a MV to a CV, and especially when those effects arrive at different velocity with contrary trend. Firstly, an algorithm will find the possible downstream pathway for a MV-CV pairing and the relationship between them. Then if the longest pathway dominates the integral effect and is contrary to the effect of other pathways, the inverse response will highly come out. By definition, the pathway length is the number of physical steps required from MV to CV. Refer to Figure 2 as example, when bypass at hot side of HX3 is changed, there are two downstream paths to affect y1 dotted curves illustrating.
Path 1: 3H->4H->4C->2C->y1, (4), +
Path 2: 3H->3C->1C->1H->2H->2C->y1, (6), -

where H and C stand for hot and cold side of HX; the number in the bracket stands for the pathway length. When the bypass increases, positive effect "+" means that the corresponding path will increase y1 while negative effect "-" means that it will decrease y1. In this example, path 1 is shorter physically, and if the effect of path 2 dominates the final variance of y1, the inverse response is expected to present. The integral effect can be read from bypass gain matrix directly.
Figure 2: Example of two downstream paths with opposite effect

2.3 Physical distance

The physical distance of certain control pairings can be represented by the longest downstream path among the selections. Taking Figure 2 as example again, compare two pairings P1 and P2 as shown in Table 1. For P1, path 2 is the longest one that requires 6 steps, which dominates the time response and requires 6 steps. For P2, path 2 dominates the time response and only requires 4 steps. Thus P2 is preferable in term of time response aspect. The above inverse response detection and physical distance study is carried out with a program in Python automatically.

Table 1: Result of physical distance of two pairings

P1, 3H-y1/4H-y2	P2, 2H-y1/4H-y2
Path 1: 3H->4H->4C->2C->y1, (4), +	Path 1: 2H->2C->y1, (2), -
Path 2: 3H->3C->1C->1H->2H->2C->y1,(6), -	Path 2: 4H->4C->2C->y1, (4), -
Path 4: 4H->4C->2C->y1, (3), -	Path 3: 4H->y2, (1), +
Path 3: 3H->4H->y2, (2), +	
Path 5: 4H->y2, (1), +	

3. Case study

The case study that involves two hot streams and two cold streams is a classical case discussed in many studies (Yan et al., 2001)(Escobar et al., 2013) (Masoud et al., 2016). The two alternative designs consist of three HXs and two coolers, as shown in Figure 3. The pinch method aims to reach the maximum energy recovery and leads to HEN1, while the superstructure approach aims to find the minimum total annualized cost leads to HEN2. The heat capacity flow of each stream is 10, 15, 20, 30 (kW/K) separately, heat transfer coefficient is 0.16 (kW/(m^2·K)) and their supply and target temperatures are also listed in the Figure 3. The four stream outlet temperatures are CVs with ± 1K allowable operational range. In addition to two utilities acting as MVs, two bypasses are required to help the system to reject disturbance, and inlet temperature variation of C1 and C2 are expected disturbance with unknown range.

RGA-number in Table 2 was calculated from the gain matrix result in Table 1. Pairings E1E3 and E2E3 are both perfect pairings in two structures according to the interpretation of RGA-number. The DoU results are presented in Table 3, the pairing

E1E3 in both structures get the largest DoU value which represents structure's maximum disturbance rejection region under the same utility cost. It can also be concluded that HEN1 is better than HEN2. Then physical distance result can help to select desirable bypass shown in Table 4 (pairing 1H3H means bypass at hot side of exchanger 1 and 3 will control y1and y2 separately). For all the pairings there exist three paths from MV to CV, while they all present the same change direction as bypass fluctuate, regardless of inverse response. Pairings 1C3H and 1C3C share the same longest path which is smaller than other choices, and 1C3C present smaller integral distance than 1C3H. Therefore, 1C3C in HEN1 is the best bypass selection both in static and dynamic aspects.
Figure 3: HENs in case study

Table 2: Gain matrix of HEN

	HEN1			HEN2		
	E1	E2	E3	E1	E2	E3
C1	-0.0376	-0.0511	0	-0.0259	-0.0501	0

Table 3: RGA result

HEN1, pairings	RGA-number	HEN2, pairings	RGA-number
E1E2	1.0488	E1E2	1.9362
E1E3	0	E1E3	0
E2E3	0	E2E3	0

Table 4: DoU result

HEN1, pairings	DoU*1,000	HEN2, pairings	DoU*1,000
E1E3	63.3	E1E3	62.6
E2E3	62.6	E2E3	62.3

Table 5: Physical distance analysis

Pairings	Pathway	Longest path	Integral distance
1H3H (1H-y1,3H-y2)	P1: 1H->1C->2C->y1, - P2: 3H->3C->y2, - P3: 1H->1C->2C->2H->3H->3C->y2,-	P3 (6)	11
1H3C	P1: 1H->1C->2C->y1, - P2: 3C->y2, - P3: 1H->1C->2C->2H->3H->3C->y2, -	P3 (6)	10
1C3H	P1: 1C->2C->y1, - P2: 3H->3C->y2, - P3: 1C->2C->2H->3H->3C->y2, -	P3(5)	9
1C3C	P1: 1C->2C->y1, - P2: 3C->y2, - P3: 1C->2C->2H->3H->3C->y2, -	P3(5)	8

4. Conclusion

The work provides a new method to select bypass during HENs synthesis, considering the simultaneous disturbance analysis and prediction of dynamic performance with pure static calculation. The method proposed an indicator DoU to represent the maximum disturbance rejection region over utility consumption, it can be used to compare the operability of different HENs, and select preferable exchangers to control HEN. A physical distance method is used to reject the potential inverse response and compare the response time of various bypass selections. The case study had shown the applicability of the method, they can reach optimal result quickly and efficient since only in static calculation is required. It deserves to be mentioned that the static result cannot guarantee the desirable dynamic performance, and a dynamic study is required to confirm the solution found by the method. Finally, it can be seen that implementing the method directly in the synthesis step is possible, and that allows designing HEN by considering simultaneously a main objective (energy consumption or cost) and disturbance rejection ability.

Integrating Oil Refineries and Bio-refineries: Upgrading Acetone, Butanol and Ethanol to High-Value Products

Elham Ketabchi, Laura Pastor-Perez, Tomas Ramirez Reina, Harvey Arellano-Garcia*

Department of Chemical and Process Engineering, University of Surrey, Guildford, GU27XH, United Kingdom

*h.arellano-garcia@surrey.ac.uk

Abstract

In this work, an integration systems approach connecting an oil refinery and a bio-refinery is proposed. These plants can be connected through various pathways such as on-site power generation, utility systems and syngas production with the feed of refinery residue, bio-oil and other streams. One important pathway that is the focus in this work represents the production of chemicals produced via biomass sources into the petrochemical and transportation industry as valuable products. Focusing on the latter route of integration, the upgrading of Acetone, Butanol and Ethanol produced by sugar fermentation via bacterial species, has been chosen as a pathway to produce valuable products that could be utilised in both the chemical sector and the transportation industry. There is little current literature regarding this upgrading process, making it a relatively novel option of producing valuable products.

The reaction systems studied consist of the self-condensation of the alcohols and cross condensation of alcohols and acetone using active metals supported on basic supports as catalysts at high temperatures and pressure in a batch reactor. Moreover, catalysts syntheses were conducted successfully to verify the proposed integration approach. The results have shown an outstanding performance for the catalysts in terms of conversion and selectivity, having conversions as high as 90%. The catalysts have also proven to yield valuable products with broad market options in the chemical Industry. In conclusion, this route has shown promising results in terms of providing valuable C_2-C_{15} products, useful for both the petrochemical industry and the transportation sector while using economically favourable catalysts in comparison with previous studies.

Keywords: Integration, oil refinery, bio-refinery, ABE, long-chain hydrocarbons.

1. Introduction

One of the main issues that many manufacturing sectors such as oil refineries are facing is that they are not performing as efficient as the past due to various factors. These factors could be environmental, economic, etc. A main factor that should be considered for oil refineries is their dependency on crude oil, the main feedstock of the process. Following this, the price fluctuation in crude oil has a direct impact on this industry. The price increase will force a rise in the search for fossil fuel substitutes from renewable and sustainable sources becoming a driving factor towards cheaper feedstocks, such as biomass. Another major factor impacting the oil refinery that should be taken into account

represents the strict environmental regulations that have raised the cost of producing clean fuels (Fahim, M. F., Alsahhaf, T. A., & Elkilan, 2010)(Leffler, 2008). As global energy consumption increases, as does the production of greenhouse gases like CO_2. The latter increase has caused the scientific community to look towards the "green" production of fuels and chemicals that were once dependant entirely on fossil fuels. The depletion of fossil fuels has also prompted interest in the production of fuels and chemicals that are compatible with petroleum liquids such as biomass-based products. Similar processes and approach to the refining industry that could be combined with the existing refining processes can be seen in bio-refineries. Using non-fossil fuel-based feedstocks, the bio-refinery produces low-value fuels and high-value materials and chemicals. Biomass conversion such as the production of ethanol and butanol through ABE (Acetone, Butanol and Ethanol) fermentation (Gupta and Demirbas, 2010) in which sugar is fermented using the bacteria genus Clostridium (Qureshi *et al.*, 2010)(Qureshi and Ejezi, 2008), is a well-recognized drop-in fuel option. Following upgrading and conversion, the products from the ABE mixture are compatible with fuel or chemicals, making the process an attractive option for the transportation and chemicals industry.

The focus of this work is to produce chemicals through the upgrading of ABE and to incorporate it in the proposed integration system aiming to decrease both dependency on fossil fuel and reduce greenhouse gas emissions. This process has been carried out previously in literature but with strong emphasis on the utilisation of noble metal-based catalysts. Amongst the noble metals, Pd has been proven to work better when compared to other noble metals such as Pt, Rh, Ru and Ir (Goulas *et al.*, 2017). Although they have performed efficiently towards converting ABE to valuable products, the economic aspect of these catalysts should also be considered as the process of ABE production is an expensive process in itself (Bîldea *et al.*, 2016). Therefore, one of the main aims of this work is to be able to achieve valuable products whilst using economically viable catalysts based on transition metals.

2. Methodology

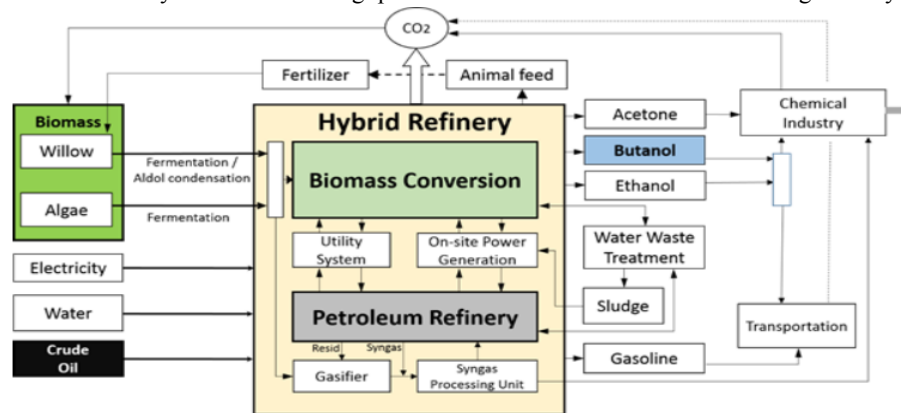
The integration system proposed, presented in Figure 1, depicts various routes to connect the oil refinery with bio-refining processes. These connections are through utility


Figure 1. Schematic of proposed integration routes between an oil refinery and bio-based processes.

systems, on-site power generation, production of ABE through biomass fermentation and further upgrading to chemicals and many more. Focusing on the latter route, the fermentation of sugar in this case, produces a mixture of acetone, butanol and ethanol. These products can either be transformed into pyrolysis oil through the pyrolysis unit or used to produce bio-fuels via self-condensation of the alcohols and cross condensation of the alcohols with acetone, known as upgrading, that can also blend with the gasoline produced from the oil refinery. This will form part of the whole picture that is provided through experimental work which can be directly applied to the integration system.

This process as can be seen in Figure 1 starts from using sugar as an input to the ABE fermentation unit while bacterial species such as Clostridium acetobutylicum ferment sugar producing the ABE mixture. This is then combined with extractive fermentation using a water-immiscible solvent of glyceryl tributate. Following this, a series of distillations occur separating the extractant phase from the ABE mixture (Sreekumar *et al.*, 2015). The ABE mixture obtained will then go through an upgrading process leading to the production of longer chained hydrocarbons.
Figure 2. Guerbet reaction pathway adapted from (Shimura *et al.*, 2013)

The upgrading reactions have been carried out in the laboratory using the mixture of reactants with the same molar ratio of 3:6:1 acetone:butanol:ethanol, as representative composition obtained from the sugar fermentation reactor. The reaction was then carried out in a pressure vessel at high temperature and pressures using an activated transition metal on basic support with the condition of purging air trapped in the reactor with N_2 to ensure an oxygen-free atmosphere. This upgrading reaction requires active catalysts which have been synthesised using the wet impregnation method that have also been proven successful through various characterisation methods such as XRD, BET, TPR, TGA, Raman, etc. The reaction route, also known as the Guerbet reaction, forms branched or unbranched products which is demonstrated in Figure 2. This reaction typically consists of three steps being the dehydrogenation of a primary alcohol, then a base catalysed aldol coupling reaction followed by the hydrogenation of an α,β -unsaturated aldehyde (Chakraborty *et al.*, 2015). Most industrial Guerbet reactions have been carried out over homogenous catalysts, usually corrosive bases using a soluble metal complex producing Guerbet alcohols. Throughout the process water is produced that must be removed by the addition of a desiccant such as CaO (Patel *et al.*, 2015). However, due to the disadvantages of these catalysts, mainly being their corrosive nature, hetergenous catalysts have been chosen in this reaction using a basic support and transition metal active phases.

Following the reaction, the products were analysed using a GC-MS for quantification and identification purposes. Using the results obtained from this, the conversion and selectivity were calculated using the following equations:

$$ABE\ Conversion\ (\%) = \frac{n_{Initial\ ABE} - n_{Unreacted\ ABE}}{n_{Initial\ ABE}} \times 100 \tag{1}$$

$$Selectivity\ (\%) = \frac{n_{Initial\ ABE}}{n_{Initial\ ABE} - n_{Unreacted\ ABE}} \times 100 \tag{2}$$

Where n is the number of total moles of reactants or product.

3. Results and Discussions

The catalysts have demonstrated exceptional results in terms of conversion and selectivity rates both having values up to 90%. They have also been successfully synthesised proven by the characterisation methods which due to space limitations are not presented in this paper. The BET analysis has shown the mesoporosity of the samples while also depicting the textural properties of the catalysts. The XRD has also clearly shown the presence of the metals and the support giving information about the crystal structure of the powder samples. The Raman spectroscopy carried out also proved the presence of the elements in each catalyst while providing information about the bonding structure of the sample. Due to the nature of the upgrade, which includes hydrogen transferring, the redox properties of the catalysts must be a relevant factor therefore TPR was carried out.

TGA conducted has demonstrated the weight loss and/gain occurring while heating the sample. This also demonstrates carbon loss associated with organic compounds attached to the samples after reaction which is a good indication that the reaction has proceeded successfully.

In terms of the products obtained, a range of hydrocarbons from C_2-C_{15} was identified using the GC-MS. The quantification of the products was carried out by establishing GC response factors of the main products identified, by the injection of samples with known concentrations prepared using standards. Following this, the conversion and selectivity was then calculated using Equations 1 and 2 which can be seen in table 1 and Figure 4.

Table 1. Selectivity of products in the range of C_2-C_{15} with the corresponding catalysts

Catalyst	Selectivity (%)	
	C_2-C_7	C_8-C_{15}
Active catalyst 1	60	5
Active catalyst 2	90	4
Active catalyst 3	43	14
Figure 3. Demonstrating conversion of reactants individually with the
corresponding catalyst

As demonstrated in Figure 3, all the catalysts are active in this upgrading reaction displaying very high conversion levels. As demonstrated in this figure, catalyst 1 is more selective towards ethanol conversion while catalyst 2 converts more butanol in comparison with the rest. This could be due to the fact that the catalysts are favorable towards the cross condensation of alcohols and acetone i.e. catalyst 1 is promoting the reaction between ethanol and acetone as well as ethanol dimerization (Zhu *et al.*, 2017) while the second catalyst is more favorable towards the reaction between butanol and acetone.

Using the data obtained and Equation 2, the selectivity was calculated considering all products in all concentrations presented in Table1. Catalyst 2 shows outstanding selectivity towards hydrocarbons in the range of C_2-C_7. However, catalyst 3 with the high conversion of 84.5% has demonstrated high selectivity in comparison with the others regarding the range of C_8-C_{15} which depending on the application of the products could also be the desired catalyst. Catalyst1 has also shown promising results with high conversions of 82.92% while favoring the products of C_2-C_7. However, the aforementioned catalyst demonstrated higher ability to push the reaction towards the production of higher carbon number chemicals, as high as C_{15}, when compared to the other catalysts.

Overall, among the catalysts, the second catalyst especially exhibits an excellent performance of 88.92% conversion and performing with the highest selectivity and yield amongst the selected products that were in significant concentrations.

Further details about the catalyst will be discussed in the presentation.

4. Conclusions

The successfully synthesized catalysts proven through various characterization techniques have performed effectively in terms of producing valuable range of chemicals from biomass-based sources. All catalysts have been able to convert the ABE reactants to the long chain hydrocarbons with significantly high conversion levels while also demonstrating reasonable selectivity towards the identified added value products.

Catalyst 2 has been chosen as the best performing catalyst in terms of conversion and selectivity. Nevertheless, the third catalyst has demonstrated notable performance to produce longer chain hydrocarbons and the first catalyst was able to push the reaction towards the production of the highest carbon number hydrocarbon in comparison to the rest.

Finally, taking all of this into account, it has been shown that this route delivers valuable chemicals that can facilitate the integration of a bio and a traditional refinery. One of the key parameters to be optimized is the catalytic reaction to obtain high value chemicals from ABE. This work showcases that transition metal-based catalysts are effective materials for this process and open new avenues for research in the catalysts design towards an optimized ABE upgrading pathway.

Abstract

The production of energy from solar cells is being considered as one key technology of the future. The remarkable growth in this market is primarily based upon solar cells made from polycrystalline silicon, which is typically produced via chemical vapor deposition of dichlorosilane or silane. Different technologies including reactive distillation have been considered for the production of polycrystalline silicon precursors. In the reactive distillation process, the trichlorosilane disproportionation reaction takes place producing monochlorosilane, dichlorosilane and silane. Steady state studies have reported that different silane products can be obtained by adjusting the operating condition of the reactive column. However, dynamic transitions from one product to another that can meet product quality specifications during operation still remains as a key challenge. This work investigates a feasible strategy for the dynamic transition and production of three silanes in a reactive distillation column. Results from this study show that there is a feasible dynamic transition from silane to monochlorosilane, then to dichlorosilane, and then back to monochlorosilane and silane. Temperature control and equipment sizing were identified as key design and operating variables to accomplish those transitions.

Keywords: reactive distillation; silane; solar cell; optimal transitions; dynamic transition; process control

1. Introduction

The need for additional renewable energy resources has led to the development of new green technologies that can aid to meet global energy demands in the coming decades. Solar energy technology has received special attention from industry and the scientific community mainly because of its positive impact on the environment. In this context, solar cells have emerged as one of the preferred technologies to produce clean energy; thus, the global market for this technology has been growing every year. Semiconductor industries use ultra-high purity polysilicon as the main raw material to produce solar cells. Polysilicon is synthetized using volatile silicon hydride. The most common silicon

hydride is silane; however, dichlorosilane or monochlorosilane can also be employed (Ceccaroli and Lohne, 2010). The first process used to produce polysilicon was the Siemens process, which is based on thermal decomposition of trichlorosilane; however, this process has been recently replaced by others because of the higher energy requirements of the Siemens process. Two industrial-scale alternative technologies used nowadays are the Union Carbide process and the Ethyl corporation process. In the latter, silane is used as the main precursor for polysilicon production (Ceccaroli and Lohne, 2010).

The trichlorosilane disproportionation process conveys three reversible reactions, which involve five components including dichlorosilane and monochlorosilane. The latter compounds are of particular interest because of their wide application in the semiconductor industry as well as the thin-film solar photovoltaic industry (Mochalov, 2016). The intensified reactive distillation process has been considered as an attractive process to produce silane, dichlorosilane and monochlorosilane with low energy consumption (Medina-Herrera et al., 2017). The pressure, distillate to feed ratio and reflux ratio in the reactive column have been reported as key variables that directly determine the desired silane product specifications. Optimal steady-state operation for the production of the three different silane products has also been reported (Medina-Herrera et al., 2017). Similarly, controllability studies showing that temperature control is a key feature for this process have also been reported (Medina-Herrera et al., 2017). On the other hand, studies on the dynamic transitions in the reactive column that can maintain dynamic feasibility and that comply with the product specifications are very limited (Ramírez-Márquez et al., 2016). Previous studies have shown that dynamic transitions impact process performance and the logistics of multi-product systems (Koller and Ricardez-Sandoval, 2017; Patil et al. 2015). The aim of this work is to present a systematic method that specifies the way in which the reactive distillation column needs to be operated in closed-loop to achieve dynamically feasible transitions for three trichlorosilane products, i.e. silane, monochlorosilane and dichlorosilane.

2. Steady-State: Reactive Distillation Column

The trichlorosilane decomposition process consists of three reversible reactions, i.e.

$$2SiHCl_3 \xleftarrow{\quad cat \quad} SiCl_4 + SiH_2Cl_2$$
$$2SiH_2Cl_2 \xleftarrow{\quad cat \quad} SiHCl_3 + SiH_3Cl \qquad\qquad (1)$$
$$2SiH_3Cl \xleftarrow{\quad cat \quad} SiH_2Cl_2 + SiH_4$$

This reaction mechanism, along with the kinetic parameters reported by Huang et al. (Huang et al., 2013), were used in this work to carry out both steady state and dynamic the simulations. The Radfrac rigorous distillation model of AspenPlus® process simulator was used for modelling the reactive distillation column.

In a previous study, a sensitivity analysis was performed to identify suitable conditions for the production of the silane products considered in this work (Medina-Herrera et al., 2017). That study suggested that the production of the different silane products could be achieved with appropriate pressure conditions and distillate to feed (D/F) ratio. Table 1 shows the parameters specified for the optimal steady-state operation of the reactive distillation unit reported in Medina-Herrera et al. (2017). The specifications obtained

from that analysis aimed to minimize the total annual cost by considering equal production of the three different products during the year.

Table 1. Optimal steady-state parameters, reactive distillation column (Medina-Herrera et al., 2017).

	Silane Production	Monochlorosilane Production	Dichlorosilane Production
Number of stages	89	89	89
Feed stage	42	42	42
Feed flowrate of SiHCl$_3$ (kmol/h)	10	10	10
Reactive Zone (Stage to Stage)	29-72	29-72	29-72
Purity of product in D1 (mol%)	99.5	99.5	99.5
Distillate to feed ratio	0.25	0.333	0.5
Reflux ratio	34.9	38.9	11.3
Operating pressure (atm)	4.9	2.3	1
Column diameter (m)	0.73	0.73	0.73
Holdup of Reactive Section (m^3)	0.068	0.068	0.068
Qc (kW)	292	712	375
Q$_R$ (kW)	333	739	387

3. Transient Analysis

In order to carry out the dynamic analysis, the reflux drum tank was sized taking into account the inventories for the different silane products. As shown in Table 1, the production of the monochlorosilane requires a higher vapor flow rate; therefore, the column's specifications for monochlorosilane were used to determine the size of the reflux drum. Once the steady state simulation converged, the simulation was exported to Aspen Dynamics. Rigorous hydraulics were considered for all simulations. Hold-up was evaluated at steady-state assuming a residence time of 2.5 second per stage (Huang et al., 2013). When dynamic transitions are considered, internal mass flows and therefore the residence time, will change accordingly, but under the assumption that hold-up on the reactive trays remains the same. The overall hold-up for the reactive zone is reported in Table 1. Ideal trays were assumed for the column.

Identification of the critical process variables in the transient domain was carried out by a degrees of freedom analysis. Due to their relevance for the dynamic operation, the pressure and D/F ratio were considered as part of the degrees of freedom in the analysis. Also, the liquid level in the reflux drum was controlled with the reflux flowrate. For this analysis, the heuristic rule of using reflux flowrate to control the level of the drum for reflux ratios higher that three was considered. Column hydraulics plays an important role on the dynamic simulations, since temperature and composition profiles inside the column are likely to change when disturbances enter into the process. Therefore, a key variable that should be taken into account for dynamic simulations is temperature. This variable needs to be controlled to promote production of the desired product. Furthermore, temperature control is required to avoid thermal degradation of the catalyst.

A sensitivity analysis was carried out to determine the most sensitive column trays for each silane product under changes in the reboiler duty (Luyben, 2006). For that purpose, changes of +/- 0.1% in the reboiler duty and in the reflux ratio were performed. The results from the temperature tray profiles allowed the identification of the trays with largest deviation in temperature. The trays that resulted with the largest temperature change were selected as controlled variables (Luyben, 2006). The results of the sensitivity analysis that show the tray selection for each individual silane product are presented in Table 2.

Table 2. Identification of the most sensitive stage for the production of silanes and PI tuning parameters for their controllers.

Production	Stage	PI tuning parameters	
Silane	79	P=4.7	I=9.2 min
Dichlorosilane	69	P=1.1	I=14.5 min
Monochlorosilane	63	P=0.9	I=11.8 min

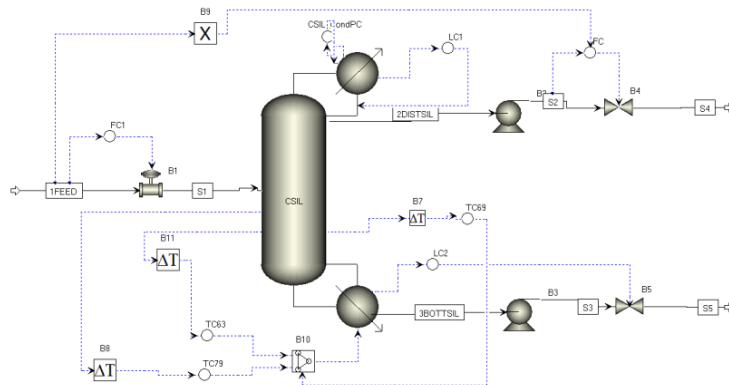
Temperature, pressure and D/F ratio control loops were taken into account to develop the following dynamic analysis procedure for the production of the silane products. In order to meet the desired operating conditions of each silane production, pressure, D/F and controlled tray temperature should be changed progressively. It was decided to implement setpoint ramps, as opposed to step ramps, to prevent abrupt changes that could lead to process instabilities. Therefore, setpoint ramps were imposed for distillate to feed ratio, pressure and the temperature controllers simultaneously while monitoring the reflux drum level. Figure 1 shows the control configuration of the reactive column as implemented in Aspen Dynamics to carry out the dynamic transitions, which was based upon an implementation for disturbance rejection strategies, with the tuning parameters for temperature controllers reported in Table 2. It is important to note that pressure changers where configured in order to develop pressure driven simulations.


Figure 1. Control configuration of the reactive column for the dynamic transitions.

As three different products can be produced independently for each design in the reactive distillation column, six possible routes can be followed to change from the production of a silane product to another. Those possible transitions are: silane to monochlorosilane, monochlorosilane to dichlorosilane, dichlorosilane to monochlorosilane, monochlorosilane to silane, silane to dichlorosilane and dichlorosilane to silane. In order to implement the procedure described above for all the different transitions, a selector

structure was implemented in the simulation. The selector model was configured so that the appropriate temperature stage in the loop was set as active for the desired transition.

4. Results

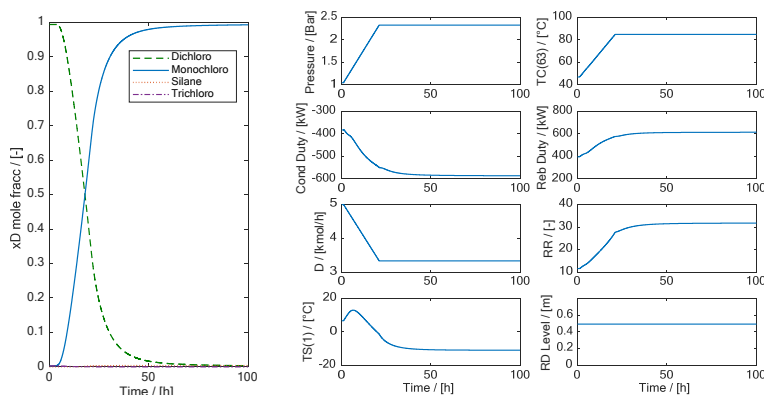
Dynamic transitions using the methodology described above were tested for all the different combinations. Figure 2 shows the liquid composition profiles for the production of monochlorosilane from dichlorosilane. Ramp set points of 20 h were configured in the column's pressure, D/F ratio and temperature controllers. As shown in Figure 2, it takes around 60 hours to obtain a high purity stream of monochlorosilane. This figure also shows that the dynamic setpoint changes imposed in pressure, and D/F ratio and temperature are tracked properly.


Figure 2. Column profiles for the transition of Dichlorosilane to Monochlorosilane in the distillate.

When the setpoint ramps in the controlled variables were applied for the other five transitions, it was observed that all of them were feasible in terms of reaching the desired new steady state for the corresponding silane products. Nevertheless, when the transitions silane to dichlorosilane and dichlorosilane to silane were tested, monochlorosilane was initially produced thus affecting the time to reach the final silane product (dichlorosilane). This behaviour is due to the nature of the reaction mechanism. Because of its impact on the process operating costs, another important result is that related to the column heat duty. Figure 2 also shows that higher energy requirements are needed for the dichlorosilane to monochlorosilane transition. This result agrees with the results reported in Table 1, which showed that higher energy requirements were needed for the production of monochlorosilane. Table 3 reports the overall transition times for the different silane products. Even when all transitions were successful to reach the desired set points for the products, an economic analysis should be used to assess the impact of the transition times observed for each case to quantify the impact of production losses during such time periods.

Table 3. Transition time for the different silane productions.

Transition	Time (h)	Transition	Time (h)
Dichlorosilane to monochlorosilane	62.6	Dichlorosilane to silane	94.5
Monochlorosilane to Silane	67.8	Silane to monochlorosilane	100
Silane to dichlorosilane	100	Monochlorosilane to dichlorosilane	61.2

5. Conclusions

This work explored the feasibility of implementing dynamic transitions for the production of three high-value silane products. Operating points obtained from steady-state calculations for the production of three silane products were used as target values for each transition. A control policy based on ramps for the controlled variables was implemented for the six possible transitions considered in this study. The results showed that such a control strategy was effective to yield feasible transitions from a silane product to another. The most critical transition was that from silane to dichlorosilane and viceversa. This was mostly due to the production of monochlorosilane as an intermediate product, which affected the length of the dynamic transition between these two products. An effective transition policy should avoid this condition; that is, given that the three products are desired to be produced, the production of either silane or dichlorosilane should be preceded by the production of monochlorosilane.

Abstract

In this paper a shape optimization approach based on the Hadamard geometric optimization method is developed. Four case studies representing typical fluid flow patterns in fluid dynamics, i.e. flow around an obstacle, flow in a 90 $^\circ$ or 180 $^\circ$ elbow pipe and flow in a dyadic tree, are considered. Low velocities are imposed at the inlet of each case study in order to operate in laminar flow regime. The objective is to determine the shape that minimizes the energy dissipated by viscous friction subjected to the Navier-Stokes equations and to iso-volumic constraint. The required gradients of the performance index and constraint with respect to the shape are computed by means of the adjoint system method. The momentum equations are implemented and solved using the OpenFOAM CFD software, and the solver ''adjointShapeOptimizationFoam'' is modified in order to compute the solution of the resulting optimization problems. The optimal shapes obtained in the four case studies are in very good agreement with the available literature works. Moreover, they allow a significant reduction of the dissipated energy ranging from 10.8 to 53.3 %.

Keywords: Shape optimization, Ajoint system, Energy dissipation, CFD, OpenFOAM

1. Introduction

Chemical industry is more than ever constrained to invest in research and innovation to remain competitive. This competitiveness necessarily requires the development of more flexible, intensified, efficient and compact processes. The shape of the units involved in these processes is very often critical to their efficiency and represents major scientific, technical and technological challenges. Shape optimization is a technology that is quite appropriate to meet these challenges. It consists of a set of techniques and methods allowing to find the best shape of an object that optimizes a cost function or a performance index while satisfying given constraints. Originally, shape optimization has been developed for aerodynamic industry and particularly for aircrafts. More recently, it has been used in chemical engineering to determine the optimal shape of a pipe (Henrot and Privat, 2010) or microchannels (Tonomura et al., 2010).

This paper presents the development of a shape optimization approach based on adjoint system method. The latter is used to derive the shape gradient needed in the optimal shape determination. OpenFOAM software is used as CFD solver for the flow model ,i.e. the Navier-Stokes equations, and adjoint system equations.

2. Case studies and modeling

The optimization approach developed in this paper is tested on four 2D case studies: flow around an obstacle, flow in a 90 ° or 180 ° elbow pipe and flow in a dyadic tree. Each initial domain, Ω_0, of the case studies is presented on Fig. 1. The boundary $\partial\Omega$ of the domain Ω is given by $\partial\Omega = \Gamma_{in} \cup \Gamma_{out} \cup \Gamma_{lat} \cup \Gamma$, where

- Γ_{in} is the inlet of the domain on which a quadratic velocity profile is imposed. Thus, the laminar flow is already developed at the inlet boundary (Eq (1c)).

- Γ_{out} is the outlet of the domain on which the normal component of the stress tensor is equal to zero (Eq (1e)).

- Γ_{lat} is the fixed edge of the domain on which a no-slip condition is applied (Eq (1d)).

- Γ is the free boundary of the domain, i.e. the unknown of the shape optimization problem. Moreover, it is the boundary that will evolve over the iterations of the optimization algorithm. A no-slip condition is applied on this boundary (Eq (1d)).

In each case, the velocity is set to a value leading to Reynolds numbers lower than 500, thus ensuring that the flow is laminar. The condition of zero absolute pressure is imposed at the outlet boundary. The system of Navier-Stokes equations describing the fluid flow is given as

$$\begin{cases} -\nu\Delta\boldsymbol{U} + (\boldsymbol{U}\cdot\nabla\boldsymbol{U}) + \nabla p = 0 & \text{in } \Omega & \text{(1a)} \\ \nabla\cdot\boldsymbol{U} = 0 & \text{in } \Omega & \text{(1b)} \\ \boldsymbol{U} = \boldsymbol{U}_{in} & \text{on } \Gamma_{in} & \text{(1c)} \\ \boldsymbol{U} = 0 & \text{on } \Gamma_{lat}\cup\Gamma & \text{(1d)} \\ \sigma(\boldsymbol{U},p).n = 0 & \text{on } \Gamma_{out} & \text{(1e)} \end{cases}$$

In the above system, $\sigma(\boldsymbol{U}, p)$ is the stress tensor, given by :

$$\sigma(\boldsymbol{U},p) = 2\nu\varepsilon(\boldsymbol{U}) - p\,\mathrm{I} \quad \text{with} \quad \varepsilon(\boldsymbol{U}) = \frac{1}{2}(\nabla\boldsymbol{U} + (\nabla\boldsymbol{U})^T). \tag{2}$$

where ν is the fluid kinematic viscosity, I the identity matrix, $\boldsymbol{U}$ and p respectively the velocity and the absolute pressure of the fluid and $\varepsilon(\boldsymbol{U})$ the strain tensor.

3. Shape optimization formulation

3.1. Optimization problem

In this work, the objective is to determine the shape of the four aforementioned case studies that minimizes the energy dissipated by the fluid due to the work of viscous forces. Such a criterion is relevant in practice since the energy dissipated is directly related to pressure losses. The performance index is therefore defined as

$$J(\Omega) = 2\nu \int_{\Omega} |\varepsilon(\boldsymbol{U})|^2 \, dx \tag{3}$$

This optimization problem is subjected to Navier-Stokes equations (1) and to the volume constraint given by Eq. (4). It is solved using the adjoint system method.

$$C(\Omega) = \mathcal{V}(\Omega) - \mathcal{V}(\Omega_0) = 0 \tag{4}$$
Figure 1: Initial shapes of the four case studies, (a) flow in a 180 ° elbow pipe, (b) flow in a diadyc tree, (c) flow around an obstacle, (d) flow in a 90 ° elbow pipe.

3.2. Adjoint system method

The shape optimization approach developed involves the differentiation with respect to the domain also called derivative in the sense of Hadamard (Allaire, 2007; Henrot and Pierre, 2005). It consists in moving all the meshpoints according to the following induction formula

$$\Omega_{i+1} = (\mathbf{X} + t\mathbf{V})(\Omega_i) \tag{5}$$

where $\mathbf{X}$ is the vector of meshpoints coordinates at iteration i, t the method's step and $\mathbf{V}$ is the vector field describing the mesh displacement. The objective of the method is to compute t and $\mathbf{V}$.

Let us introduce the lagrangian functional defined as

$$\mathcal{L}(\Omega) = J(\Omega) + \lambda C(\Omega) = 2\nu \int_{\Omega} |\varepsilon(\mathbf{U})|^2 \, dx + \lambda \left(\mathcal{V}(\Omega) - \mathcal{V}(\Omega_0) \right) \tag{6}$$

where λ is the Lagrange multiplier.

On the other hand, let $\mathbf{V} : \mathbb{R}^d \to \mathbb{R}^d$ be a regular vector field. The derivative of the Lagrangian $\mathcal{L}(\Omega)$ in the direction of $\mathbf{V}$ is defined by (Henrot and Privat, 2010)

$$\mathcal{L}'(\Omega)(\mathbf{V}) = <d\mathcal{L}(\Omega), \mathbf{V}> = \lim_{t \to 0} \frac{\mathcal{L}(\Omega_t) - \mathcal{L}(\Omega)}{t}, \qquad \text{with} \qquad \Omega_t = (\mathbf{X} + t\mathbf{V})(\Omega). \tag{7}$$

To implement the shape optimization algorithm, it is necessary to express the Lagrangian derivative in the following form

$$\mathcal{L}'(\Omega)(\mathbf{V}) = \int_{\partial\Omega} (G + \lambda)(\mathbf{V} \cdot \mathbf{n}) \tag{8}$$

where G is the shape gradient, i.e. a function defined on the boundary of the domain Ω depending on $\boldsymbol{U}$ but not on the vector field $\boldsymbol{V}$. Under this form, it will be easy to determine a new mesh choice leading to a decrease of the Lagrangian. The adjoint method is based on the introduction of an adjoint state $(\boldsymbol{U}_a, p_a)$. Straightforward computations (see (Henrot and Privat, 2010) for more details) lead to the following shape derivative of the Lagrangian functional expressed as

$$\mathscr{L}'(\Omega)(\boldsymbol{V}) = \int_{\partial\Omega} (2\nu(\varepsilon(\boldsymbol{U}):\varepsilon(\boldsymbol{U_a}) - \varepsilon(\boldsymbol{U}):\varepsilon(\boldsymbol{U})) + \lambda)(\boldsymbol{V}\cdot\boldsymbol{n})\,d\sigma \tag{9}$$

Thus, the shape gradient is given by

$$G = 2\nu(\varepsilon(\boldsymbol{U}):\varepsilon(\boldsymbol{U_a}) - \varepsilon(\boldsymbol{U}):\varepsilon(\boldsymbol{U})) \tag{10}$$

where $\boldsymbol{U_a}$ is the velocity of the adjoint state $(\boldsymbol{U_a}, p_a)$ defined as the solution of the following equations

$$\begin{cases} -\nu\Delta\boldsymbol{U}_a + (\nabla\boldsymbol{U})^T\boldsymbol{U_a} - \nabla\boldsymbol{U_a}\boldsymbol{U} + \nabla p_a = 2\nu\Delta\boldsymbol{U} & \text{dans } \Omega & \text{(11a)} \\ \nabla\cdot\boldsymbol{U_a} = 0 & \text{dans } \Omega & \text{(11b)} \\ \boldsymbol{U_a} = 0 & \text{sur } \Gamma_{in}\cup\Gamma_{lat}\cup\Gamma & \text{(11c)} \\ \sigma(\boldsymbol{U_a}, p_a)\boldsymbol{n} + (\boldsymbol{U}\cdot\boldsymbol{n})\boldsymbol{U_a} = 4\nu\varepsilon(\boldsymbol{U})\boldsymbol{n} & \text{sur } \Gamma_{out} & \text{(11d)} \end{cases}$$

known as adjoint system equations. Finally, the mesh displacement $\boldsymbol{V}$ is computed by solving the following system

$$\begin{cases} -\Delta\boldsymbol{V} + \boldsymbol{V} = 0 & \text{dans } \Omega & \text{(12a)} \\ \boldsymbol{V} = 0 & \text{sur } \Gamma_{in}\cup\Gamma_{out}\cup\Gamma_{Lat} & \text{(12b)} \\ \nabla\boldsymbol{V}\boldsymbol{n} = -(G+\lambda)\boldsymbol{n} & \text{sur } \Gamma & \text{(12c)} \end{cases}$$

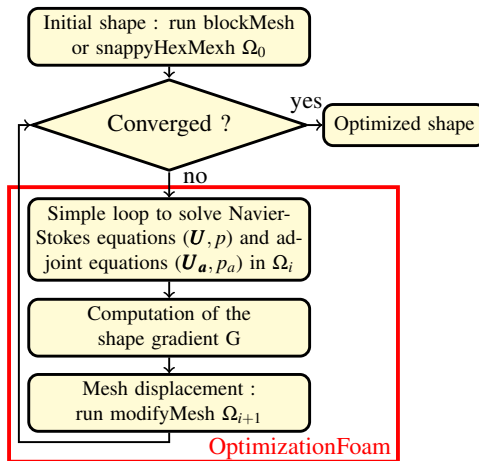
4. Implementation of the optimization algorithm


Figure 2: Shape optimization algorithm

The CFD equations are implemented using C++ language within OpenFOAM software (Weller et al., 1998). The latter is a free and open source software which allows to solve partial differential equations (Navier-Stokes and adjoint equations Eq. (1) and (11)) using finite volume method. OpenFOAM supplies a solver which solves the Navier-Stokes and an ajdoint system for topologic optimization. This solver is named ''adjointShapeOptimizationFoam''. The latter is modified and enriched in order to implement the optimization algorithm and determine the best shape in each of the four considered case studies. The algorithm is detailed in Fig.2. At each iteration, a test of the quality of the mesh is carried out through the aspect ratio. In 2D, the aspect ratio is defined as the ratio of its longer side to its shorter side. If the ratio is too large, i.e. higher than 5, the domain is remeshed.

Figure 7: Initial shape of the obstacle
Figure 8: Optimal shape of the obstacle

Figure 9: Initial shape of the 90 ° elbow
Figure 10: Optimal shape of the 90 ° elbow

5. Main results

Initial shapes and velocity distributions are presented in Figs. 3, 5, 7 and 9, and optimized shapes are shown in Figs. 4, 6, 8 and 10. In each case, moving the free boundary allows a reduction

Table 1: Performances of the optimization apprch

Case	Iterations	Simulation time	Reduction of dissipated energy	Reduction of pressure losses
180 ° elbow	300	40 min	30.7 %	33.3 %
Dyadic tree	550	1 h 01	53.3 %	40.4 %
Obstacle	200	9 mn 14	10.8 %	15.4 %
90 ° elbow	80	2 mn 30	27 %	24 %

of the velocity distribution due to an increase in the width of the channel (for the elbows and the dyadic tree) or to a decrease of the width of the obstacle. Thus, the reduction of the velocity and the increase of the section lead to a reduction of the velocity gradient and, consequently, to a reduction of the performance index. All the optimal shapes obtained in this study are in very good agreement with the literature works (Tonomura et al., 2010; Dapogny et al., 2017).

The performances of the optimization approach for each case study are presented in Table 1. Depending on the case, a significant reduction of the dissipated energy is observed, between 10.8 and 53.3 %. Since the energy dissipated by the fluid and the pressure drops are related, a decrease of pressure losses is also observed in similar proportions, i.e. between 15.4 and 40.4 %. The dyadic tree case is the most costly in terms of computation time. Indeed, the geometry in that case undergoes huge changes, and therefore, one has to finely remesh many times. In this case, the flow seems to privilege one of the two branches. The small one cannot be remove because the outlet is a fixed boundary and the geometric algorithm cannot modify the topology of the domain.

From a numerical point of view, the case "flow around an obstacle" is the most difficult to implement. Indeed, the initial Lagrange multiplier must be properly chosen in order to avoid the removal of the obstacle which would result in wrong simulations due to invalid meshes. To overcome this problem, the initial Lagrange multiplier λ_0 is set to a value higher than the absolute value of shape gradient G.

6. Conclusion

In this work, a shape optimization approach has been developed and implemented within Open-FOAM software. Four case studies representing typical fluid flow patterns in fluid dynamics were considered. The objective was to determine the shape that minimizes the energy dissipated by viscous friction while meeting the volume constraint and satisfying the momentum equations. A significant reduction of pressure losses was observed in each case study which will result in important energy savings. The coming works will focus on shape optimization of a mass or heat exchangers and the mixing in a stirred tank.

Abstract

Recently, the butanol purification from acetone-butanol-ethanol mixture was achieved in one azeotropic dividing-wall column requiring 2.7 MJ/kg butanol, which represents just 7.5% of the energy content of butanol. Compared to a conventional separation sequence, this design allows 60% energy savings due to heat integration and use of a heat pump. This work considers the dynamics and control of the process. The basic regulatory control can provide stability for small and short-time disturbances, but the process shuts down if the disturbances persist. By adding a reboiler and a condenser, better control becomes possible. As a result, the process can handle large and persistent disturbances in feed rate and composition, achieving good control of product purity.

Keywords: Dividing-wall column, optimal design, heat integration, process control.

1. Introduction

The biobutanol is considered a competitive fuel over ethanol, being characterized by low water miscibility, flammability and corrosiveness. In the upstream fermentation process, biobutanol is obtained with a concentration lower than 3%wt. Using gas stripping technology, the acetone-butanol-ethanol (ABE) mixture reaches 4.5 %wt. acetone, 18.6 %wt. butanol and 0.9 %wt. ethanol (Xue et al., 2013). In downstream processing, these components can be separated by distillation, reverse osmosis, adsorption, liquid-liquid extraction, pervaporation and others (Abdehagh et al., 2014).

For large scale plants, distillation remains the most promising technique. Significant energy savings can be achieved by employing novel configurations (such as dividing-wall column) and heat integration facilitated by heat pumps (Kiss, 2013; Luo et al., 2015; Kiss and Infante Ferreira, 2016). A novel heat pump assisted azeotropic dividing-wall column (A-DWC) was suggested for the ABE separation, allowing up to 60% energy savings compared to a conventional separation sequence (Patrascu et al., 2017, 2018). The present work considers the dynamics and controllability of this highly-integrated process. For this purpose, a rigorous pressure-driven simulation is developed in Aspen Plus Dynamics. After few design modifications, the process proves to be controllable by using only conventional control loops.

2. Problem statement

Fewer equipment units can drive the ABE separation by combining three distillation columns in a single A-DWC, while using heat integration and vapor recompression (VRC) technologies can further reduce the energy requirement. This highly integrated design delivers large energy savings of up to 60% but must be also operable. However, combining all these technologies in a single process can reduce the flexibility of the process due to fewer degrees of freedom, raising difficulties in the controllability of the process. In this paper the dynamics of the process is investigated by testing the stability and introducing minor design changes which offer two new variables to be manipulated.

3. Process design

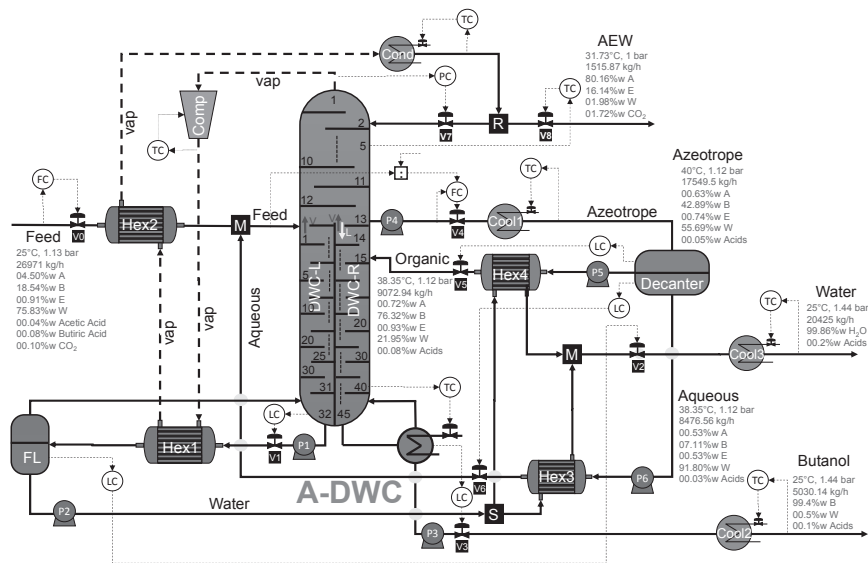
Patrascu et al. (2018) proposed a heat-integrated VRC-assisted A-DWC for ABE separation (Figure 1). The A-DWC contains two stripping and one fractionation sections. The feed-side stripping section (DWC-L) separates the most plentiful component (water) with high purity in bottom. In the fractionation section, the light components (acetone, ethanol and some water) are obtained as distillate, while the butanol-water azeotrope is routed to a side stream, and cooled for decantation. Here, the distillation boundary is crossed and breaking the butanol-water azeotrope is achieved. The aqueous phase is sent to DWC-L for water purification and the organic phase sent to the second stripping section (DWC-R) for butanol purification. The top vapor stream is compressed from 1 bar to 5.8 bar (60 °C to 150 °C) and used to drive the reboiler from DWC-L and to preheat the fresh feed, and the organic and aqueous phases, before being returned to the column. Performing this heat integration, the energy requirement is reduced by 69% compared to a simple A-DWC column. The purity of water product is 99.8 %wt. and the purity of butanol product is 99.4 %wt. (Figure 2). A small amount of water is present in distillate due to the ethanol – water azeotrope.


Figure 1. Heat-integrated VRC-assisted A-DWC for ABE separation
Figure 2. Temperature (left) and mass composition (right) profiles

4. Process dynamics

A dynamic simulation is built in Aspen Plus Dynamics. Two RADFRAC units are used to model the water removal section (DWC-L) and the combined fractionation (AEW) and butanol purification (DWC-R) sections. The reboiler on the water-removal side is represented as a HEATX (counter-current heat exchanger) followed by a FLASH. Several pumps and valves are provided, as required by the pressure-driven simulation. The basic control loops of flow rate, liquid level, pressure and temperature are shown in Figure 1. The column pressure is controlled with the reflux flow rate, which is subcooled at 31 ºC. Besides the inventory control loops, the temperature on stage 5 of the fractionation section is controlled by manipulating the valve position of the distillate stream; the temperature on stage 40 of the butanol-purification section (DWC-R), is controlled by manipulating the reboiler duty; the temperature of the compressed vapor (to not exceed 150 °C) is controlled by the compressor brake-power.

The dynamic of the process is tested by changing the feed flow rate (by ±5% for 10 minutes and by ±5% for one hour), as shown in Figure 3. The control structure can successfully reject small and non-persistent disturbances (top diagrams). However, when the disturbance persists (bottom diagrams), the stream entering the column cools down, and the pressure and the temperature in column drop. As a result, less vapours are sent to the fractionation section and to the compressor. In the meantime, the stage 40 temperature controller located on the butanol-purification section tries to compensate the disturbance by increasing the reboiler duty. This affects the temperature of stage 5, so the top temperature controller closes the distillate stream valve. Further, the pressure controller closes the valve from the reflux stream, trying to increase the column pressure. However, the vapours flow is too small. Although the compressor brake-power is available as a variable to be manipulated, this action would increase the temperature of the compressed vapours above 150 °C, which is not allowed for safety reasons. Therefore, another manipulated variable is needed.

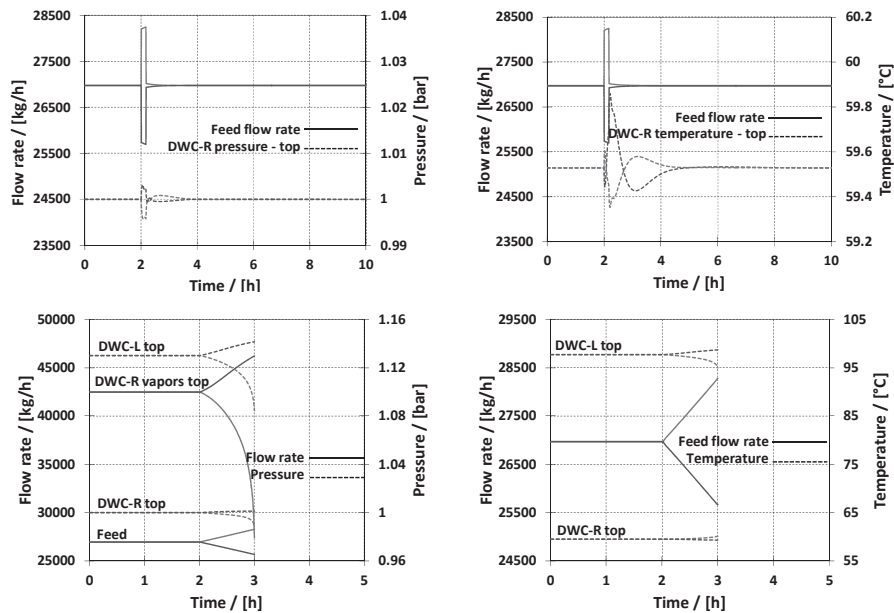
When the feed flow rate is decreased by 5% and the disturbance persists for a long time (Figure 3, bottom diagrams) the feed enters the column at higher temperature. In this case, more vapours are sent to fractionation section and more vapours are compressed, leading to a continually temperature increase in the water-removal section. As a result, more water is vaporized and eventually reaches the butanol product stream. Such disturbance could be rejected by controlling the temperature of the stream entering the column, but no manipulated variable is available.


Figure 3. Stability test of the basic control structure for 5% disturbance in feed flow rate (10 min. top, 1 hour bottom)

5. Process control

To overcome these control difficulties, two new variables to be manipulated were added (Figure 4). The first one is a small additional duty on the reboiler of the water-removal section, which represents 10% of the energy required. The second one is an additional cooler placed on the compressed vapor stream, between the reboiler and the feed preheating. These variables are used in new control loops, namely: a) temperature control of the preheated feed, by manipulating the duty of the additional cooler; and b) temperature on stage 25 in water-removal section (DWC-L), by manipulating the additional reboiler duty.

In addition, a valve-position controller has the task to keep the additional duty at its steady state value by changing the set point of the temperature controller of compressed vapor stream (a low-select block ensures that the setpoint does not exceed 150 °C). This controller is essential when the feed flow rate is decreased because if less energy is required, the additional duty will remain at steady state value by reducing the temperature of the compressed vapours. The additional duty will increase only when more energy is required. By introducing these controllers, the process can handle large feed flow rate disturbances for long time.

Other dynamic simulation results (not shown here) indicate that the transient regime takes about 5 hours. As the feed rate changes, the water purity and the mass fraction of water in the distillate are practically unaffected, while the butanol purity deviates by only 0.1 %wt. from the design value. When the fraction of butanol in the feed stream changes (from 18.6 %wt. to 17 %wt. or 20 %wt.) the behaviour is similar: water and

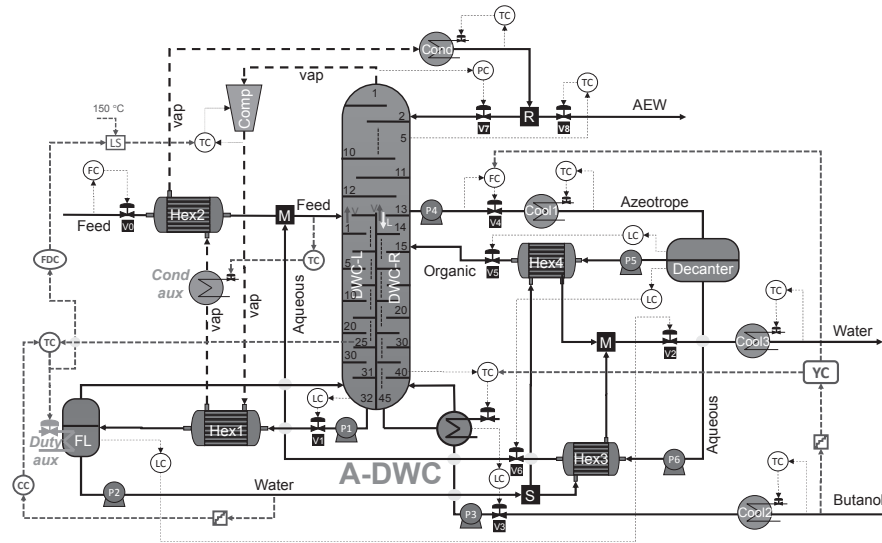
distillate composition is practically unchanged, while the concentration of the butanol product deviates by about 0.1 %wt. from the design value. The performance of the control system is excellent, considering that only temperature measurements were used.


Figure 4. Control structure of the heat-pump assisted A-DWC

Finally, the performance of the new control structure can be improved by introducing two concentration controllers for maintaining the products (water and butanol) quality (Figure 4). The slow dynamics of these measurement was taken into account by using the Aspen Plus Dynamics sensor model with 5 minutes sampling period and 5 minutes dead time. Figure 6 and Figure 6 show dynamic simulation results for the control structure employing the concentration controllers, for feed flow rate and concentration disturbances, respectively.

The deviation of butanol purity from the steady state value is quite small. Eventually, 4 hours after the disturbance, the butanol purity comes back to the design value (99.4 %wt.). Water purity is practically unchanged, while the mass fraction of water in the distillate is acceptable.
Figure 5. Performance of the control structure for 10% disturbance in feed flow rate
Figure 6. Performance of the control structure for feed concentration disturbances

6. Conclusions

The basic control structure of the A-DWC can reject small and short-time disturbance, but the process shuts down when the disturbance persists. Adding an additional reboiler and a condenser on the feed side stripping section provides two new variables to be manipulated. This change in the main design reduces the energy savings of 60% by only 4%. This is small penalty to pay, as the control structure performs successfully when disturbances of 10% in the flow rate and butanol concentration occur in the fresh feed.

Abstract

This work presents a novel combination of white-box models that describes heat transfer, mass transfer, and intracellular ice formation during freezing of human induced pluripotent stem (hiPS) cells. The models can be applied to the design of freezing processes for hiPS cells considering the diversity in cell quality within a container. In the case study, two design variables were defined, i.e., the cooling rate of a programmed freezer as an element of {1.0, 1.2, …, 3.8, 4.0 K/min} and the diameter of a vial as an element of {5, 50, 150 mm}. The objective functions were defined as the maxima of cell volume change and intracellular ice crystal volume as the proxy for the cell survival rate. The Pareto optimal solutions were obtained as 5 mm as the vial diameter with all considered cooling rates; given a threshold of the ice crystal volume, the feasible range of the cooling rate was strongly influenced by the diameter of the vial.

Keywords: Regenerative medicine, Cells, Cryopreservation, Numerical simulation, Multiobjective process design

1. Introduction

Regenerative medicine is the future technology that aims to heal or restore human tissues and organs damaged by age, disease, or trauma, back to the original condition (Mao and Mooney, 2015). Human induced pluripotent stem (hiPS) cells are considered as one of the promising sources of regenerative medicine products because of various advantages compared to the conventional sources. Towards industrialization of hiPS cells, freezing processes are essential in order to transport, distribute, and preserve the cells. However, hiPS cells are known to be sensitive to damages caused by freezing (Hunt, 2011), which could lead to undesired deviation of cell quality in the process. Several authors tackled the design of the freezing process by experiments using a programmed freezer (Li et al., 2018) or cryoprotective agents (Xu et al., 2014). However, it is yet to design reasonably the freezing process based on the fundamental understanding of physicochemical mechanisms.

In this work, we present a set of white-box models that describes heat transfer, mass transfer, and intracellular ice formation during freezing of hiPS cells. The novelty of this work is that the three models are integrated in such a way that the diversity in cell quality

inside a container can be evaluated, which would enable precise design of freezing processes.

2. Freezing process of hiPS cells

2.1. Manufacturing process of hiPS cells

Figure 1 shows the manufacturing process of hiPS cells. First, somatic cells are derived from a donor. Second, the somatic cells are converted to hiPS cells by introducing specific genes to the cells. Third, the number of hiPS cells is increased by cultivation. Finally, hiPS cells are differentiated to the target cells. It is estimated that a hiPS-based liver would require 10^{10} units of the cells, suggesting the importance of homogeneous cell quality. The freezing process is required to transport hiPS cells to the next process with protecting the cells from degeneration. In the freezing process, hiPS cells filled in a container named as vial with a cryoprotective agent are cooled in a programmed freezer as shown in Figure 2.

2.2. Damages to hiPS cells during freezing

As cooling progresses, extracellular water including a cryoprotective agent begins to freeze. At this point of time, the intracellular water is not yet frozen but remains in the supercooled state. Osmotic pressure difference between the inside and the outside of the cells occurs because the osmotic pressure of supercooled water is higher than that of frozen water. The pressure difference causes the dehydration of hiPS cells, decrease of the cell volume, and ultimately a damage to the cells (Mazur et al., 1972). Along with the further progress of cooling, intracellular water is eventually frozen, and ice crystals grow in the cell. The volume of intracellular ice crystals affects the degree of the additional damage to the cells (Mazur et al., 1972).

2.3. Formulation of the optimization problem

The optimization problem was defined as shown in Eq. (1):

$$\min \begin{cases} \Delta V_{\text{cell}}^{\max}(B, d_v) \\ V_{\text{ice}}^{\max}(B, d_v) \end{cases} \quad \text{s.t.} \quad \begin{array}{l} B \in \{1.0, 1.2, \ldots, 3.8, 4.0\} \\ d_v \in \{5, 50, 150\} \end{array} \quad (1)$$

where $\Delta V_{\text{cell}}^{\max}$ [m³] is the maximum cell volume change inside a vial, $V_{\text{ice}}^{\max}$ [m³] is the maximum intracellular ice crystal volume inside a vial, B [K min^{-1}] is the cooling rate of a programmed freezer, and d_v [mm] is the diameter of a vial. The final objective of the
Figure 1   Manufacturing process of hiPS cells

design is to determine the decision variables that could maximize the survival rate of cells after the entire freezing process. Based on the analysis presented in section 2.2, we considered the cell volume change due to the osmotic pressure difference and the formation of intercellular ice crystal as the key factors for the cell survival (Mazur et al., 1972).

3. Construction of the white-box models

3.1. Heat transfer model

Considering that the primary mode of heat transfer in a vial is conduction rather than convection, we adopted the following equations to calculate the temperature inside a vial (Hu and Argyropoulos, 1996):

$$\frac{\partial T}{\partial t} = \alpha_w \left(\frac{\partial^2 T}{\partial r^2} + \frac{1}{r} \frac{\partial T}{\partial r} \right) \tag{2}$$

$$\frac{\partial T}{\partial t} = \alpha_{ice} \left(\frac{\partial^2 T}{\partial r^2} + \frac{1}{r} \frac{\partial T}{\partial r} \right) \tag{3}$$

$$\frac{\partial T}{\partial t} = \alpha_v \left(\frac{\partial^2 T}{\partial r^2} + \frac{1}{r} \frac{\partial T}{\partial r} \right) \tag{4}$$

where T [K] is the temperature, t [s] is the time, α [m^2 s^{-1}] is the thermal diffusion coefficient, r [m] is the radial distance from the center of a vial, and the subscripts of w, ice, and v represent water, ice, and vial, respectively. According to Hu and Argyropoulos (1996), the position of the solid-liquid interface from the center of a vial δ [m] can be calculated as follows:

$$\frac{\rho_{ice} \Delta H_f}{M_{ice}} \frac{d\delta}{dt} = k_{ice} \left(\frac{\partial T}{\partial r} \right)_{r=\delta} - k_w \left(\frac{\partial T}{\partial r} \right)_{r=\delta+d\delta} \tag{5}$$

where ρ [kg m^{-3}] is the density, ΔH_f [J mol^{-1}] is the molar heat of fusion of ice, M [kg mol^{-1}] is the molar mass, and k [J s^{-1} m^{-1} K^{-1}] is the thermal conductivity.
Figure 2 Schematic representation of the freezing process (adapted from Fadda et al., 2010)

3.2. Mass transfer model

Transmembrane mass transport by the osmotic pressure difference was modelled using the following equations (Xu et al., 2014):

$$\frac{dV_{cell}}{dt} = -\frac{L_p A_{cell} RT}{v_w}\left[\frac{\Delta H_f}{R}\left(\frac{1}{T_0}-\frac{1}{T}\right)-\ln\left\{\frac{V_w}{V_w+v_w\left(\mu_s n_s+n_{cpa}\right)}\right\}\right] \tag{6}$$

$$\frac{dn_{cpa}}{dt}=\frac{\left(C_{ex}+C_{in}\right)\left(1-\sigma\right)}{2}\frac{dV_{cell}}{dt}+A_{cell}P_{cpa}\left(C_{ex}-C_{in}\right) \tag{7}$$

where V [m³] is the volume, L_p [m s⁻¹ Pa⁻¹] is the water permeability, A [m²] is the surface area, R [J mol⁻¹ K⁻¹] is the gas constant, v [m³ mol⁻¹] is the partial molar volume, μ [–] is the dissociation constant, n [mol] is the molar amount, C [mol m⁻³] is the cryoprotective agent concentration, σ [–] is the reflection coefficient, P_{cpa} [m s⁻¹] is the cryoprotective agent permeability. The subscripts of cell, 0, s, cpa, in, and ex represent cell, reference, salt, cryoprotective agent, intracellular, and extracellular, respectively. According to Xu et al. (2014), the cell membrane permeability coefficients of L_p and P_{cpa} are temperature-dependent and can be calculated using the following equations:

$$L_p=L_{p0}\exp\left[-\frac{E_w}{R}\left(\frac{1}{T}-\frac{1}{T_0}\right)\right] \tag{8}$$

$$P_{cpa}=P_{cpa0}\exp\left[-\frac{E_{cpa}}{R}\left(\frac{1}{T}-\frac{1}{T_0}\right)\right] \tag{9}$$

where E [J mol⁻¹] is activation energy.

3.3. Crystal growth model

Nucleation of ice in a cell occurs by two different mechanisms: homogeneous nucleation (HOM) and heterogeneous nucleation (HET). HET is further categorized into two types: surface-catalysed nucleation (SCN) that occurs at cell membrane and volume-catalysed nucleation (VCN) that occurs inside a cell. The nucleation rate of ice in a cell was modelled using the following equations (Zhao et al., 2014):

$$J_{ice}=\begin{cases}0 & \left(T_m<T\right)\\ I^{HOM}V_w+I^{SCN}A_{cell}+I^{VCN}V_w & \left(T\le T_m\right)\end{cases} \tag{10}$$

where J [s⁻¹] is the nucleation rate, I [s⁻¹ m⁻³ or s⁻¹ m⁻²] is the nucleation rate per unit, and the subscript of m represents melting point.

In order to estimate ice crystal growth under non-isothermal conditions, the radius of intracellular ice crystals was modelled using the following equations (Fadda et al., 2010; Karlsson et al., 1994):

$$r_{ice,i}=\begin{cases}0 & \left(0\le N_{ice}<1\right)\\ \sqrt{\int_{\tau_i}^{t}\gamma_{ice}^2 D_{av}\,dt} & \left(1\le N_{ice}\right)\end{cases} \tag{11}$$

where r_{ice} [m] is the radius of an ice crystal, N_{ice} [−] is the number of intracellular ice crystals, γ_{ice} [−] is the non-dimensional ice crystal growth parameter, τ [s] is the starting time of ice crystal formation, and D_{av} [m^2 s^{-1}] is the average water diffusion coefficient. According to Fadda et al. (2010), the total volume of intracellular ice crystals V_{ice} can be calculated using the following equation.

$$V_{ice}(r) = \sum_{i=1}^{N_{ice}} \frac{4}{3} \pi r_{ice,i}^3 \qquad (12)$$

4. Results and discussion

Figure 3 shows the relationship between the design variables, i.e., cooling rate B and the diameter d_v, and the objective functions, i.e., the maximum intracellular ice crystal volume V_{ice}^{max} and the maximum cell volume change ΔV_{cell}^{max}. The calculation results at $d_v = 5$ mm are the most favourable, and thus all values of B at $d_v = 5$ mm are the Pareto optimal solutions to the problem defined in Eq. (1). The graph shows that the change of ΔV_{cell}^{max} due to the difference in B and d_v is less significant than that of V_{ice}^{max}, and thus in practice, ΔV_{cell}^{max} could be ignored. Focusing on the results of V_{ice}^{max}, the values of B and d_v should be as small as possible. In case a threshold of V_{ice}^{max} is given, e.g., 8 μm^3, the volume of a human mitochondrion, Figure 3 indicates that the largest possible B would differ depending on d_v, i.e., dimensionality. In the literature, the ideal cell volume changes and ice crystal growth have been simulated for a type of mouse cells during the freezing process (Karlsson et al., 1994) by considering mass transfer and crystal growth. With a focus on hiPS cells, this study integrated heat transfer (see Eqs. (2-5)) in addition, so that the dependence of the cell quality on the intra-container dimensionality can be quantified, which is the novelty of this work.

A solver adopted solving partial differential equations was the Crank-Nicolson method and the algorithm was implemented in Python 3.6. The total CPU time that the results shown in Figure 3 was obtained was about 8 hours, using Intel(R) Core(TM) i5-6500 CPU@3.2 GHz with 8 GB RAM memory.
Figure 3　Relationship between cooling rate and volume change or ice crystal volume

5. Conclusions and outlook

We presented the white-box models that are applicable to dynamic and simultaneous simulation of heat transfer, mass transfer, and intracellular ice formation. The three models are integrated in such a way that the diversity in cell quality inside a container can be evaluated, which would enable precise design of freezing processes. We applied the models to calculate the change of the cell volume and the formation of the intracellular ice crystal that are considered to affect the survival rate of the hiPS cells. The Pareto optimal solutions were obtained as 5 mm as the vial diameter with all considered cooling rates; given a threshold of the ice crystal volume, the feasible range of the cooling rate was influenced by the diameter of the vial. The result implies the significance of the intra-container dimensionality in considering cell quality, which was made possible by the proposed models for the first time. In future, we will conduct dynamic optimization of the process parameters by quantifying the temperature distribution inside the freezer, and by evaluating the productivity of the entire process.

Abstract

This study provides optimally designed reactive distillation (RD) processes for the production of ethyl levulinate, taking into account costs, environmental impact and safety. The thermally coupled RD process is the most appealing with major energy savings in the range of 9.6-54.3% lower than other RD processes, reduced environmental impact in the range of 5.7-51% lower ECO 99 index value and similar process safety less than 2% difference compared to other RD processes considered. The lower energy requirement of the thermally coupled process was reflected in the lowest energy use to produce ethyl levulinate (1.667 GJ/ton.).

Keywords: Ethyl Levulinate, Reactive Distillation, Cost and Safety of chemical processes, Multi-objective optimization.

1. Introduction

Ethyl Levulinate (EL) is a valuable chemical whose utilization is extended in multiples industries, EL distinguishes as a product with the potential to be used as a replacement of the fuel additives such as Methyl Tert-Butyl Ether (MTBE) y el Tert-Amyl Methyl Ether (TAME), the industry related with the production of ethyl Levulinate can be considered in its infancy however the forecast for the ethyl Levulinate demand indicates that 49.1 tons will be demanded by the year 2022 with a worth value in the market of $11.8x10^6$ USD (Grand View Research, 2017). An appealing route to avoid the use of harmful solvents and larger amounts of energy is the reaction between the levulinic acid with ethanol to obtain ethyl Levulinate (Fernandes et al., 2012), however, this route is limited by the equilibrium of the reaction, in order to overcome the limitation, the implementation of Reactive Distillation is relevant, even more the heat integration and thermally coupling of these designs adds significant improvements to be consistent with the philosophy of seek for sustainable processes.

In this work, the evaluation of the TAC, the ECO 99 and the Individual Risk (IR) of proposals of processes based on heat integrated and thermally coupled reactive Distillation to produce Ethyl Levulinate is introduced, as these proposals involve the handling of organic compounds, which are the most common source of fires and explosions in industry, in addition to the traditional economic and sustainable evaluation, a quantitative risk analysis is highly desirable.

2. Methodology

Ethyl Levulinate is produced through the reaction of the Levulinic Acid with Ethanol, the reaction is showed in the Eq. (1).

$$C_5H_8O_3 + C_2H_5OH \underset{k_2}{\overset{k_1}{\rightleftharpoons}} C_7H_{12}O_3 + H_2O \tag{1}$$

$$A \qquad\quad B \qquad\qquad C \qquad D$$
From the Equation 1: A=Levulinic Acid; B= Ethanol; C=Ethyl Levulinate; D=Water.

The kinetics equation and the kinetic parameters were taken from a previous work by Tsai, 2014. In this work the Hayden-O'Connell model was selected as the thermodynamic model to properly estimate the vapor-liquid equilibrium. The binary interaction parameters of the components were taken from a previous work by Resk et al. (2014). Four different reactive distillation configurations are studied; the alternatives and the schemes of these configurations are shown in Figure 1 these consist in: Conventional Reactive Distillation Process (CRDP); Thermally Coupled Reactive Distillation (TCRD); Reactive Distillation With heat Integration (RDHI) and Reactive Distillation with Thermally Coupled and heat Integration (THRD). All of the sequences consist of a reactive distillation column (RDC) and two separation columns RC-1 and RC-2. The first separation column, RC-1, performs the separation of the by-product water from the main product, ethyl levulinate (EL) and the unreacted Levulinic Acid (LA), in the second separation column, RC-2, the separation of the Ethyl Levulinate and the Levulinic Acid is carried out, the Levulinic Acid is returned to the RDC column. In all cases, the feed flow of Ethanol and fresh Levulinic Acid were 100 kmol/h. The topology of these processes was taken from the previous work by Novita et al. (2017), however, in this work a rigorous multi-objective optimization algorithm is implemented, and three key factors are simultaneously evaluated, even more through the optimization strategy would help to contrast and eventually to carry out the selection of the optimal designs in terms of multiple objectives as the proposed in this work.

The total annual cost has been computed using the Guthrie methodology. Five years was assumed as a payback period, whereas carbon steel is considered as construction material for the process equipments. The operating costs included cooling utilities, heating utilities, and 8400 hours of yearly operation for each alternative have been considered.The ECO 99 is used to calculate the environmental impact. This approach is based on the evaluation of three impact categories: human health, ecosystem quality, and resources depletion. This method has been successfully implemented in the environmental evaluation of chemical processes (Quiroz-Ramirez et al 2017). According to the importance of three major impact categories the weighting for ECO 99 was realized as follows: damages to human health and damage to ecosystem quality are of equal importance, thus these were equally weighted while the damage to the resources was considered to be half of importance in weighting. The individual risk is an index used to quantify the safety of a process and it is calculated through a quantitative risk analysis where the damage caused by an accident is identified and quantified. For the cases of study seven possible incidents have been identified, these are divided in two categories. Instantaneous incidents are: Boiling liquid expanding vapour explosion (BLEVE), unconfined vapour cloud explosion (UVCE), flash fire and toxic release, whereas the continuous release incidents are: jet fire, flash fire and toxic release. The calculations of the individual risk were carried out for a reference distance

of 50 m, the complete set equations to calculate the IR is showed by Medina-Herrera et al. 2014.
Figure 1. Reactive distillation processes to produce Ethyl Levulinate.

The multi-objective optimization problem was solved using the mathematical technique called Differential Evolution with Tabu List (DETL) by Sharma, S., & Rangaiah, G. P. (2010). The values of the parameters required by DETL method are: Population size (NP): 200 individuals, Generations Number (GenMax): 500, Tabu List size (TLS): 100 individuals, Tabu Radius (TR): 0.01, Crossover fractions (Cr): 0.8, Mutation fractions (F): 0.3.The DETL method together with objective function were implemented in a hybrid platform involved, which linked Aspen Plus^{TM} and Microsoft Excel^{TM} through Visual Basic^{TM}. The design variables for the different processes are offered in the Table 1.

Table 1. Design variables for the processes separation of furfural.

Decision Variables	CRDP	TCRD	RDHI	THRD
Number of stages, RDC	X	X	X	X

Total number of variables	15	15	13	17

Finally, the overall optimization problem can be mathematically expresed as in Eq. (2) and Eq. (3):

$$\min \quad Z = \{TAC; ECO\,99; IR\} \qquad (2)$$

$$\text{Subject to:} \quad y_{i,F} \geq x_{i,F}$$
$$w_{i,F} \geq u_{i,F} \qquad (3)$$

The objective functions are restricted to satisfy the purity ($y_{i,F}$) and molar flowrate ($w_{i,F}$) especifications of Ethyl Levulinate and Water. The purity required for Ethyl Levulinate (EL) and Water was 99.5 mol%.

3. Results

The Pareto charts obtained for all of the reactive distillation processes at the end of the optimization process are offered in the Figure 2. Each point in the graphics represents a solution or design that meets the purity requirements with the best values of the three objective functions under evaluation.
Figure 2. Pareto charts of the RD processes.

The shape of the Pareto TAC vs ECO99, in the Figure 2, is explained relating the influence of total energy consumed by each process and the amount of steel required to build the equipments in the ECO 99 calculation. The Pareto front of IR vs TAC for all the processes exhibits a trend of opposite objectives for IR and TAC, this behaviour indicates that the selection of a design with the lowest TAC, it necessarily causes the value of IR to increase, therefore, the solutions that offer the best trade-offs between the two objectives are those located in the curve zone of the Pareto Chart for these sequences; the Pareto front of IR vs ECO 99, the shape of the Paretos of all the processes exhibits a similar trend as the IR vs TAC Pareto for these same sequences. In the optimal designs of all the sequences, the larger reflux ratios and reboiler duties the higher utilization of heating services and electricity for cooling services, these larger values have a direct contribution in the increment of the ECO 99 values. According to

the behaviour of the Paretos of the objective functions IR vs ECO 99 and IR vs TAC, which is the same behaviour for both combinations of indexes, it is possible to assert that the best optimal designs of the processes CRDP, THRD and TCRD are found in the zone of the Pareto that compensates both objectives, this is the curve zone as explained above. Therefore, the selection of a design that compensates the IR index with the TAC, this choice directly equilibrates the IR index with the ECO 99. The Table 2 provides the design variables of the selected designs of the Pareto charts of the processes.

Continue Table 2

Purity of EL product and by-product water (mol%)				
Ethyl Levulinate	0.9964	0.9998	0.9951	0.9999
Water	0.9957	0.9981	0.9950	0.9979
Performance indexes				
Energy per ton. of **EL** produced (**GJ**/ton. **EL**)	1.8712	1.6676	3.6539	2.2033
Utilities cost (million $/yr)	3.8125	3.7141	6.9426	5.0005
Equipment cost (million $)	0.2544	0.2305	0.2767	0.2218
TAC (million $/yr)	4.0670	3.9447	7.2193	5.2224
Eco99 (million Eco-points/yr)	1.7803	1.6592	3.3916	2.1465
IR (1/yr)*10^5	45.994	46.766	46.1502	46.962

4. Conclusions

The multi-objective optimization taking into account simultaneously the total annual cost, environmental impact and process safety, revealed that the thermally coupled reactive distillation (TCRD) process has the lowest energy use (1.667 MJ/kg EL) with major energy savings (9.6-54.3% lower than other RD processes), reduced environmental impact (5.7-51% lower ECO 99 index value) and similar process safety (less than 2% difference compared to other RD processes considered). Thus, the TCRD process is suggested as the best process alternative to produce ethyl levulinate, although there is room for further selection of other feasible RD processes where other tradeoffs among the indicators may be devised.

Abstract

Scheduling is a decision-making process that is often based on the assumption of nominal operating conditions. In reality, scheduling is a dynamic process and uncertainties often arise during the execution of a schedule. One way to handle uncertainty in schedule is via reactive scheduling, or rescheduling. Rescheduling accounts for uncertainty by revising the existing agenda in response to real-time events. The downside to frequent revisions of the schedule is that it often leads to scheduling nervousness. In this work, a novel set of constraints based on the Resource-Task Network (RTN), coupled with a region-based penalty approach is proposed to combat scheduling nervousness. Results show that the approach is able to produce more stable schedules, while still giving rescheduled agendas the flexibility needed to pursue the original scheduling objective.

Keywords: Resource-Task Network (RTN), Scheduling Nervousness, Rescheduling

1. Introduction

Scheduling is a decision-making process that plays a central role in almost any type of industrial production facility where tasks need to be processed on a set of resources. The production in these facilities needs to be appropriately planned in order to prioritize the tasks and to ensure that the equipment, material, utilities, personnel and other resources are available at the plant when they are needed (Harjunkoski et al., 2014). There exist several mathematical programming-based scheduling formulations that can be roughly divided into discrete- and continuous-time models, each of which have different strengths and weaknesses. One such mathematical programming-based scheduling formulation that has received significant attention is the the Resource-Task Network (RTN) model (Pantelides, 1994). The RTN model, particularly the discrete-time RTN model, is a generic scheduling framework that has been shown to be applicable to many different industries including stainless steelmaking (Castro et al., 2013), and petrochemical production (Wassick and Ferrio, 2011).

Most scheduling approaches are predictive techniques that deal with the generation of production plans while assuming a given set of tasks and resources. However, industrial environments are dynamic and unplanned events often disrupt the planned schedule. There are two main classes of approaches to accommodate these unplanned events, scheduling under uncertainty, and reactive/online scheduling. Scheduling under uncertainty aims at accounting for uncertain parameters *a priori* by building a production plan with some slack that is directly incorporated into the schedule (Gupta et al., 2016). Reactive or online scheduling on the other hand accounts for uncertainty by revising the existing agenda in response to real time events. Rescheduling approaches are the most common dynamic scheduling approaches in manufacturing (Ouelhadj and Petrovic, 2008).

The drawback to frequent revisions of the schedule is that they lead to what is known as scheduling

nervousness. Scheduling nervousness is an important aspect of online scheduling and is one of the reasons scheduling is not as widespread in industry as it could be (Henning, 2016). In this direction, Méndez and Cerdá (2004) proposed an iterative MILP framework to repair schedules by limited reallocation and reordering of operations defined by user-controlled sets. Other work in the area includes that of Novas and Henning (2010) who propose a domain knowledge-based rescheduling framework using constraint programming.

In this work, a novel method is proposed to avoid scheduling nervousness with minimal domain-specific knowledge. This is accomplished by using a set of general constraints to compare subsequent rescheduling iterations. Zones are defined in which subsets of these constraints are enforced more or less strictly than in other zones. Deviations from the existing schedules are penalized between iterations in a multi-objective optimization approach. The goal of this approach is to provide the subsequent scheduling iteration flexibility to respond to a disturbance, but in a way that minimizes the impact to the shop floor.

2. Methodology

The proposed approach is based on the discrete-time RTN framework to make it generic and easy to adapt to various applications. The RTN model represents the entire schedule as a set of resources (R) and tasks (I). In this formulation, tasks represent operations that need to be performed, which consume and produce sets of resources. Examples of resources in this case include raw materials, final products, and processing units. In the discrete-time RTN, the scheduling horizon (H) is divided into a set of δ sized intervals (T). The resource availability over the time grid is controlled by the variable $R_{r,t}$ which is modified by the execution of a task ($i \in I$) with a duration of τ_i time slots. These tasks are characterized by two sets of variables, the binary variable $N_{i,t}$ and the continuous variable $\xi_{i,t}$. The binary variables couple the execution of the task i with time point $t \in T$ and are associated with the discrete-interaction of a resource ($\mu_{i,r,\theta}$). For example, the execution of a reaction task always consumes a reactor regardless of the amount of product reacted. Conversely, the continuous variable $\xi_{i,t}$ indicates the amount handled by the task and is not considered in this work as batching functions are often handled by higher level planning functions (Harjunkoski et al., 2014) and are treated as inputs to the problem. External interactions with the scheduling system are modeled using the variable $\pi_{r,t}$. Examples of external interactions include raw material deliveries, product shipments, or equipment breakdowns. The modified resource balance that is considered in this work can then be seen in Eq. (1), while Eq. (2) limits the excess capacity of a resource.

$$R_{r,t} = R_{r,t-1}^{t \neq 0} + \pi_{r,t} + \sum_i \sum_{\theta=0}^{\tau_i} \mu_{i,r,\theta} N_{i,t-\theta} \qquad \forall r \in R, t \in T \qquad (1)$$

$$R_{r,t}^{min} \leq R_{r,t} \leq R_{r,t}^{max} \qquad \forall r \in T, t \in T \qquad (2)$$

When using the RTN, tasks are often aggregated together into a single binary variable in order to reduce the problem size. For example, if five orders of a product have been requested, it is possible to treat each order as an individual task which will execute once, or to treat the orders as a single task which must execute five times. This aggregation however creates problems when accounting for scheduling nervousness as it is uncertain which specific order an active binary is referring to. Therefore, in this work, non-aggregated tasks are considered. The same logic applies to aggregated resources, especially to equipment resources.

2.1. Additional Model Constraints

In order to define the constraints necessary to combat scheduling nervousness some additional notation and sets will be used. When a reschedule is performed at time $t^{resched} < H$ the set of all

tasks that have not yet been started is represented by $I^{resched}$. Additionally, tasks that have been assigned to a specific processing unit in the current iteration of the schedule will be denoted by I^u, where $u \in U$ represents a single unit in the set of all processing units. All units at a single production stage ($k \in K$) are referred to using U_k. The start time of a task ST_i^σ is given by Eq. (3), where the index σ is used to refer to a particular iteration of the schedule. Similarly, the end time of a task is given by Eq. (4). In the rescheduling problem, the new version of the agenda that is going to be calculated is given by σ while $\sigma - 1$ refers to the current in progress agenda. Lastly, each task that will be rescheduled ($i \in I^{resched}$) on a specific machine could potentially be directly preceded by a task ($i' \in I_i^{predecessor}$) and/or succeeded by a task ($i' \in I_i^{successor}$) both of which will have at most one member. Note that it is possible for the predecessor i' of a task to be already executed, or currently in progress, which implies it is not possible to reschedule this task ($i' \notin I^{resched}$). If a task has no direct predecessors or successors the corresponding sets will be empty. For example, tasks A, B and C are scheduled one after another on a specific machine. Task A has no predecessors but has task B as a successor. On the other hand, task B has task A as a predecessor and task C as a successor while task C has no successors but task B as a predecessor.

$$ST_i^\sigma = \sum_{t \in T} N_{i,t}^\sigma \cdot t \tag{3}$$

$$ET_i^\sigma = \sum_{t \in T} N_{i,t}^\sigma \cdot (t + \tau_i) \tag{4}$$

Scheduling nervousness is generally associated with three different components, the reallocation of tasks between units, the changing of task timings, and the reordering of tasks. Constraints (5) to (7) are proposed in order to account for these concerns:

$$1 - \sum_{t \in T} N_{i,t}^\sigma - S_i^{machine} = 0 \qquad \forall u \in U, i \in I^u \cap I^{resched} \tag{5}$$

$$ET_{i'}^{\sigma-1} - \sum_{u \in U_k} ST_i^\sigma + S_i^{backwards} \geq 0 \qquad \forall i \in I^{resched}, i' \in I_i^{predecessor} \tag{6}$$

$$\sum_{u \in U_k} ET_i^\sigma - ST_{i'}^{\sigma-1} + S_i^{forward} \geq 0 \qquad \forall i \in I^{resched}, i' \in I_i^{successors} \tag{7}$$

Eq. (5) penalizes the reallocation of tasks by summing up the binary variables corresponding to the execution of the task on the same machine as the previous scheduling iteration. If the task occurs on the same machine no value is assigned to the machine change slack variable ($S_i^{machine}$), else the slack takes a value of one. Constraints (6) and (7) together are then used to address the issues of task timing and sequencing. Each of these constraints penalizes changes in the timing of a task relative to the execution of either the tasks predecessor (Eq. (6)) or successor (Eq. (7)) in the previous iteration of the schedule. If a task should change places, large values of the slack variable will be needed to accommodate this. This also implicitly penalizes the deviations in the individual task timings within a certain range. This is because, if a task is planned to occur between two neighbouring tasks it can occur anytime in this range with the same total slack variable value. If a task is moved outside this range, a larger sum of slack variables will be incurred. It is worth mentioning at this point that these constraints will be penalized in the objective function according to the preferences of the scheduler. For example, if it is not a problem to move tasks forward from their planned time slot it may only be desirable to penalize backwards changes in the task timings. Some of these penalty function combinations may involve some additional constraints (for example, a penalty on the absolute value of a slack variable), however a detailed description of all these combinations is outside the scope of this paper. A general method to determine these penalties based on the timings of the tasks relative to the rescheduling point will be outlined below.

The objective function can be seen in in Eq. (8), where *OF* represents the original scheduling objective function, C_i^s represents the coefficient for the corresponding slack variable, and λ is a weight parameter to balance the two objectives. The set *Sl* refers to the set of the slack variables.

$$\min \quad \lambda OF + (1-\lambda) \sum_{s \in Sl} C_i^s \cdot S_i^s \tag{8}$$

2.2. Overall Framework to Address Scheduling Nervousness

The goal of rescheduling is to restore feasibility to the schedule and to reduce the effect that a disturbance has on the quality of the scheduling solution. In the near future of a rescheduling point it is undesirable to have large changes. Due to interactions with the longer-term planning systems it is also desirable to minimize the propagation of a disturbance to the long-term result. A three time region approach is therefore proposed; in the short-term after a reschedule ($t^{reschedule} < t^{ShT}$) any changes to the schedule are very undesirable due to operational concerns. Changes in the medium-term ($t^{ShT} < t^{MedT}$) have the most freedom and should be utilized to restore optimality to the schedule and to ensure that disturbances do not propagate to the long-term. In order to prevent tasks switching from the medium-term into the short-term Eq. (9) will be used with the slack variable ($S^{regionChange}$) as an additional penalty being appropriately added to the objective function. Note that pushing tasks backwards from the medium-term to the long-term is sometimes necessary if a large scheduling disturbance occurs and therefore is not penalized. In the long-term, changes to the schedule are undesirable due to the need to meet planning targets. If a scheduling disturbance occurs it should ideally be dealt with before it propagates enough to impact long-term planning targets.

$$\sum_{u \in U_k} ST_i^\sigma + S^{regionChange} \geq t^{ShT} \tag{9}$$

Tasks in the three regions will each have a set of constraints and corresponding penalties applied to them. The pseudocode for how these penalties are applied can be seen in Figure 1.

Data: Update $I^{resched}$ based on $ST_i^{\sigma-1}$ and $t^{resched}$
foreach $i \in I^{resched}$ **do**
    if $ST_i^{\sigma-1} \leq t^{ShT}$ **then**
        Apply constraints (5) to (7)
        Set C_i^s to a high value
    else if $t^{ShT} < ST_i^{\sigma-1} \leq t^{MedT}$ **then**
        Apply constraints (5) to (7), and (9)
        Set C_i^s to a low value
    else
        Apply constraints (6) and (7)
        Set C_i^s to a medium value
    end
end

Figure 1: Pseudocode outlining the definition of the different regions.

Based on the soft nature of all the constraints, there still is the potential to switch sequence and machines, however, due to the nature of the penalty terms, tasks in the near term are less likely to switch than tasks in the medium-term. Comparing this algorithm and constraint setup to earlier work (Novas and Henning, 2010) this roughly corresponds to tasks in the near-term being only allowed to shift timing on the same machine (*Shift-JumpAT*), while tasks in the medium- and long-term can be more easily reordered and shifted to other machines (*ReassignAT*). The added benefit of this algorithm is that it is possible for any task to be moved, both in respect to time or to the resources used if this a large enough change in the original scheduling objective function, and
Figure 2: Initial schedule for the problem (objective = 39030 min).
Figure 3: Pareto front illustrating the trade-off between scheduling stability and the original problem objective (sum of completion times).

that less expert knowledge is required as these regions need to be defined only on a time-basis, instead of a task-by-task basis.

3. Results

The aforementioned methodology is applied to the plant layout described in Harjunkoski and Bauer (2017). The first iteration of the schedule based on the minimization of the sum of completion times objective can be seen in Figure 2.

In this scenario, Reactor 2 needs to be maintained for two hours and rescheduling is performed at that point in time ($t^{resched} = 320min$). The length of the short- and medium-term regions are two and four hours respectively. The penalties (C_i^s) are 100 for the short-term region, 1 for the medium-term region, and 10 for the long-term region. There is a trade-off between the emphasis placed on scheduling stability versus the emphasis placed on the original scheduling objective. In order to analyze the effect of these parameters on the schedule a Pareto front is generated for a few scaling factors of these penalties. This can be viewed in Figure 3. Logically, the Pareto front shows that the more emphasis that is placed on scheduling stability, the larger the loss of optimality from the original scheduling objective. It is interesting that the lines seem to be very region-based, with nervousness dominating in one area and the original objective dominating in the other with little room in between. This indicates that several tasks need to be rearranged before a sufficiently large improvement in the original objective function is obtained.

Lastly a qualitative analysis of the results is performed. The Gantt charts for a complete reschedule ($\lambda = 1$) are compared with the values for a reschedule with large emphasis placed on nervousness ($\lambda = 0.1$), which can be seen in Figure 4. From the left Gantt chart it can be seen that the complete reschedule produces a vastly different result from the first iteration, with many changes being made in all three regions of the schedule. On the other hand, the reschedule with emphasis on stability produces a schedule with very similar sequence to the first iteration, but with a few modification
Figure 4: Gantt charts for the complete reschedule (left) compared to a reschedule with a large emphasis placed on nervousness (right).

being made in the medium-term region of the schedule. The more emphasis that is placed on the original scheduling objective, the more the resulting optimal solution reflects the solution obtained from the complete reschedule.

4. Conclusions and Future Work

In this work, a novel set of constraints and a corresponding region-based penalty method was proposed in order to combat scheduling nervousness. Results showed that the proposed method is able to produce the desired stability between scheduling iterations while still providing for sufficient flexibility to restore the quality of the resulting schedule. Additionally the trade-off between the original scheduling objective and the stability of the solution was explored. Results show that the stability of the solution is maintained for many different penalty values until the inertia to overcome these changes is surpassed by a sufficient improvement in the objective function. Future work will investigate the affect of the sizes of the regions on the optimal solution and stability as well as test the overall closed-loop performance of such an approach. Additionally, the constraints proposed focus on the stability between two subsequent iterations. It would be interesting to also investigate the effect of a bigger look-back period.

Abstract

Biorefineries is one of the main pathways towards energy transition. However, they are challenged by demand and supply variability. Moreover, the standalone and highly specialized biomass processing system has to face several internal and external constraints. To tackle this unstable ecosystem, it is necessary to provide agility in terms of both physical structure and organization. In this context, the ARBRE project proposes to redesign the biorefinery, at local scale, by introducing a collaborative network of stakeholders and the servitization of the biomass processing steps, and by integrating digital concepts from Industry 4.0. This paper proposes a framework to design agile biorefinery with a systemic approach by modelling the knowledge about the system and its environmental characteristics through a metamodel.

Keywords: Agility, Biorefinery, Collaboration, Industry 4.0, Virtual Organization, Meta-modelling

1. Introduction and motivations

Despite an increase of biomass processing projects these last years, the development of biorefineries is significantly slowed down because of several constraints.

First, the biorefinery concept is similar to the oil refinery principles [1] . Thus, the four major steps of the whole biomass processing are performed into a unique plant. Each step of the process requires specific devices, and specific operating conditions, according to the chosen biomass and the targeted bioproduct. In case of any changes regarding the biomass (type, quantity, quality, etc.) or the bioproduct, this physical, centralized, standalone and highly specialized plant cannot function at all. Adaptation to changes would require building a new plant, which is unrealistic considering investment and operational costs. Then biorefineries face high variability due to several constraints as: the external parameters influencing the availability of the biomass (seasonality, crop rotation), the natural biomass degradation or else the impurities inside the biomass feedstock (e.g. weeds, silica, minerals or soil). Therefore, this huge variability challenges the biomass supply leading to production irregularities. Additional challenging factors are the supply spreading and the geographic dispersion of both biomass feedstocks and biorefineries, increasing the nervousness of this supply chain.

All the aforementioned hurdles underline the need to design the biorefinery with its entire ecosystem to take into account uncertainties. This disruptive way to design biorefineries should be done on both the physical structure (equipment and apparatus) and the organisation (supply chain) to provide the required agility to face uncertainties.

Thus, our goal is to answer to the following research question: "How can biorefineries development be fostered with required agility to cope this unstable environment?" In the literature, biorefineries are analysed at different scales: molecular, equipment, process and supply chain scale [2] . Nevertheless, designing the biorefinery with a systemic approach, from the harvest to the final customer, as an agile collaborative network, is a new approach. This is the goal of our proposal.

2. State of art of agility in chemical process industry

Agility is used as well as a concept, a paradigm, a tool or else a method to qualify a professional sector or a means of production, in a context of changing, volatile and uncertain environment, characterized by the globalization and a production customization for customers. This concept was defined by several authors in the last years and leans on major development axis: responsiveness, flexibility, information and communications technology, and adaptability [3]. A relevant definition of agility that could be applied to the biorefinery system has been proposed by [4] as the ability of a system to "lead as quickly as possible, on the one hand, to the detection of its mismatch to a given context, on the other hand, to the set up of the required adaptation".

In the manufacturing industry literature, the expression "agile manufacturing" has been the subject of extensive researches for the last two decades. Whereas, in the process and the chemical industry areas, a few articles address about the agility issue. They often deal with subjects partially related to agility (as defined above) as flexible process, reconfigurable manufacturing, responsiveness system, modular production, with a technological or a chemical approach, at microscopic or mesoscopic scales. Considering, the whole biomass processing system, at the macroscopic scale, including both the chemical process and the environment, the entire biomass supply chain is then taken into account for the biorefinery design. Existing researches on this topic consider agility as the optimization criteria to design a standalone plant. but this standalone centralized plant cannot cope with the adaptation requirements to be considered as agile.

To switch from this centralized biomass processing paradigm, a few research works focus on decentralization by creating a collaborative network. [2] restrains its network to two stakeholders and assesses the decentralization based only on the cost of the transportation. Regarding [5], the concept of virtual biorefinery deals with a "loose coupling of decentralized stakeholders" where the biomass processing is dispatched according to the optimal biomass supply chain. In this work, the pre-treatment step is separated from the chemical process treatment. Within a service economy approach, the servitization aims to make the transition from material products (tangible) to global services (intangible). It enables to develop full services leaning on existing resources (equipment, devices, workforce…) and a know-how. A type of servitization, Product-Service System, has been studied by [6] in a manufacturing company in an organizational and a collaborative way. This type of work does not yet address the biomass processing. However, because of the high number of farmers involved in cooperatives, it could be economically attractive to enhance this collaborative behaviour with the share of the investment into apparatus and skilled workforce.

Plus, Information and Communication Technologies have a predominant position into agricultural and industrial sectors. They can provide a huge amount of data about weather forecast, crop state, device monitoring (e-farming) or market (economics) that are

relevant to support decision making about biomass processing. Among new technologies, Complex Event Processing could support data collection and analysis by detecting patterns over a stream of data [7]. It could be used to study the variability of the entire ecosystem: territory, weather, stakeholders and complex biomass chemical treatment.

3. ARBRE: A collaborative software platform to design and monitor agile biorefineries

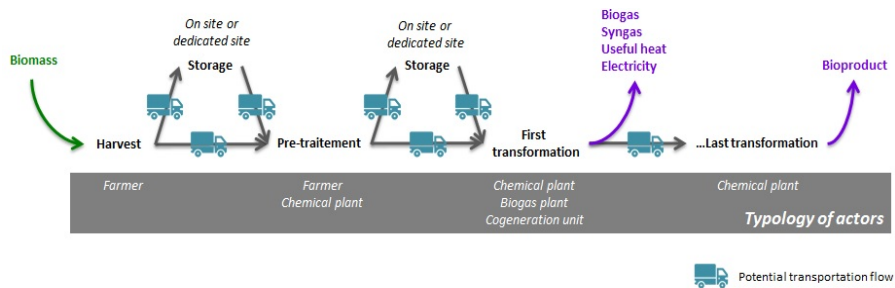
The part aims to present the methodological framework enabling to design and monitor agile biorefineries as a collaborative network, using stakeholders' services and reusing existing apparatus. Moreover, it can enhance the territorial anchorage of the biomass processing by choosing a local scale (biomass supply radius of fifty kilometres). This framework will be implemented as a decision support system (software platform) available for the biomass processing stakeholders, from farmers to customer.


Figure 1: Agile biorefinery concept

The agile biorefinery concept leans on two main axes. Within a systemic approach, the first axis considers that the chemical process could be performed not into a unique standalone plant but among a network of several existing plants and locations. Thus, the chemical process is decentralized. Each processing step is servitized. When a change occurs into the system (context, stakeholder, etc.), each actor of the biomass supply chain could propose a service matching the consequent need for adaptation. This service could address one or several steps of the biomass processing. The process is then easily reconfigured. Then, the collaboration between the stakeholders creates the biorefinery as a virtual enterprise, relevant to the biomass to process, the targeted bioproduct and the context. The role of each stakeholder and/or the choice of the process (steps, apparatus) can evolve according to the occurring changes: biomass, bioproducts (type, purity, quantity), context (weather, market, etc.). This agile biorefinery will use existing equipment, devices and workforce, which is highlighting the concept of "virtual biorefinery" as an agile collaborative process. The second axis focuses on the biomass processing itself. To design this process according to the available input, the targeted output and the system constraints, it is possible to combine knowledge management with a technological approach. The objective is to match a typology of services proposed by the stakeholders (farmers, chemical industry, cogeneration unit, local authority) with a typology of biomass processing steps, while taking into account constraints such as the location, the price, etc.

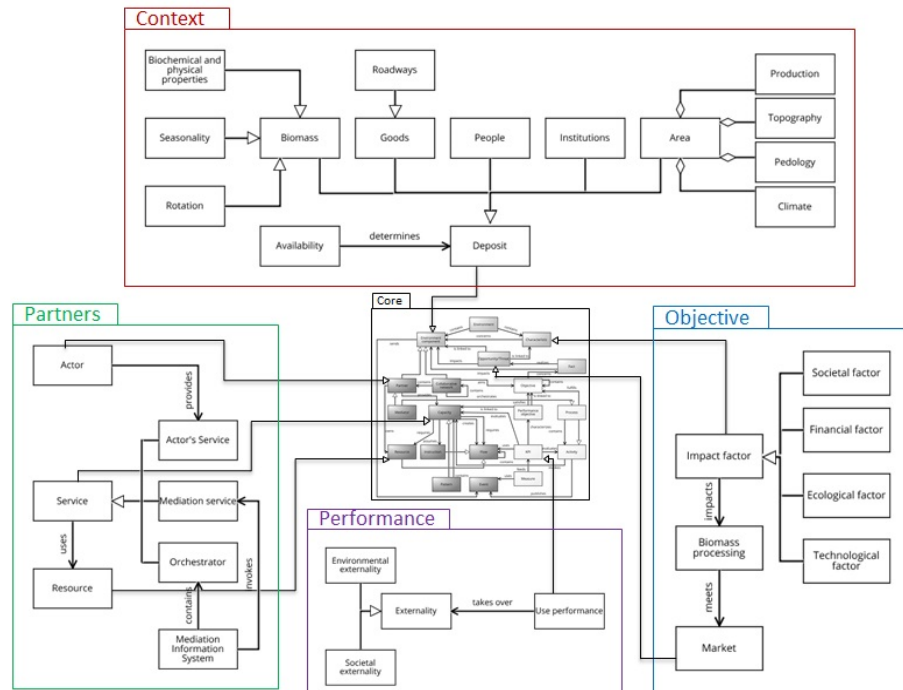
4. The agile biorefinery metamodel


Figure 2: Agile biorefinery metamodel

4.1. The CORE metamodel as support

The Model Driven Engineering (MDE) approach provides a better understanding of complex systems, as biorefineries, thanks to a high level of abstraction. This engineering practice is focused on the model, which is at the heart of the process. It defines the modelling language. In this way, it is adapted to define the required and relevant data about the agile biorefinery system. To this end, we used the CORE metamodel as defined into [8]. Organized in layers, the core of this metamodel represents any collaborative situations, by including general concepts categorized into four main packages: the context (what is the environment?), the partners (who are the actors and their services?), the collaboration objectives and the performance. Then, each successive layer defines a business domain, which inherits concepts from the core. Besides, in this way, it has been successfully used in various application domains as crisis or business organization. So, based on this CORE metamodel, a specific layer has been extended to model the agile biorefinery. Each concept and link have been defined in this application area. They are generic enough to be adapted to any type of agile biorefinery and specialized enough to be relevant to the biomass processing domain. This agile biorefinery metamodel has to be instantiated with real data, in order to ensure the validity of the obtained model and so the relevancy of the concepts.

4.2. The "Context" package

The context enables to determine the characteristics of the collaborative environment. The deposit concept is the entry point. It inherits from the environment component concept from the CORE package. Its availability (related to the quantity) is crucial to start a collaboration. Therefore, the deposit is about the organic deposit usable which does not include: the organic matter needing to return to the ground, the unusable organic matter and the organic matter already involved into a chemical transformation process. It contains biomass, which is specified by biochemical and physical properties (chemical composition, humidity, shape, size), a seasonality (biomass capacity to be productive and harvested over one or several seasons) and the crop rotation (crop diversification including intermediate crops). The deposit is set on an area owing topographic, soil and climate features, with a given kind of production (intensive, organic, reasoned). The good concept is related to the required equipment ensuring the proper management of the deposit. This one is specified with the roadways concept, enabling to determine the accessibility to the deposit (fields path, paved road). The deposit concept embodied the people concept, essential for the public acceptability issues. Institutions concept, as political and decision-making bodies, are key players to provide public aids and subsidies. The context is crucial to characterize the environment where the collaboration takes place.

4.3. The "Actor" package

Partners constitute the collaborative network. They participate actively in the biomass processing. In the servitization context, actors from the collaborative network bring information about their ability to provide a service, according to their existing resources (material, human, special skills) and their constraints. They inherit from the CORE partner package. The proposed services ensure one or several biomass processing and transformation steps. Moreover, Mediation Information System (MIS) coordinates the collaborative process, from the data collection until the conversion to information, as an orchestra conductor. It makes connections and shares information among all the actor services. The whole collaboration partners aim to reach a common goal.

4.4. The "Objective" package

The objective package defines a target for the agile biorefinery. This concept inherits from the objective concept from the CORE package. The main purpose is to process the biomass, by meeting the market. The market determines the supply, the demand and the competitive requirements between stakeholders. However, impact factor concept can foster or disadvantage the biomass processing. This concept highlights issues about the agile biorefinery operation. It encompasses criteria about sustainability (social, economic and environmental) and the system's evolution capabilities. It is specified into four types of impact factors: the societal factor concept relates to the impacts on the extended community organization (annoyances); the financial factor concept relates to process, equipment and maintenance work cost evolution (trend in price for biomass); the ecologic factor concept concerns changes about living beings and their environment which can affect the biomass processing (biodiversity trend); the technological factor concept gathers innovations and evolutions about devices, processes and methods that could affect also the biomass processing. Achievements enable to assess the performance.

4.5. The "Performance" package

Agile biorefinery performances are measured thanks to Key Performance Indicators (KPI) about the overall result of the collaboration and also each service used. To this end, the use performance concept inherits from KPI concept, in the CORE metamodel. KPIs ensure positive or negative impact of the agile biorefinery on a societal level as economic drive or job development (measurable with meetings and surveys) and on an environmental level as pollution (measurable with sampling program and measurement campaign in the environment).

5. Conclusion and future work

To increase the development of biorefineries, it is crucial to take into account its whole ecosystem, which is marked by a high variability. Agility represents an innovative way in the chemical and process engineering to reconfigure easily the biomass transformation process, according to the constraints and the stakeholders. Being aware of environmental, economic and human factors enables to keep the system functional (operational) and relevant. Thus, the ARBRE project proposes to transform and decentralize the biomass transformation process, leading to a collaboration-based biorefinery. In this paper, the metamodel supporting the characterization of the agile biorefinery has been presented. It defines the concepts and the links between them, enabling to model the environment of the collaboration according to: the context, the actors, the objectives and the performances. The next step of the ARBRE project will focus on the instantiation of the proposed biorefinery metamodel into a model, prior to its use for collaborative process deduction. This will be achieved with real data provided by local authorities from Southern France (interviews, feasibility study, etc.).

Abstract

In a recent work (Bousbia-Salah et al, 2018), dynamic real-time optimization (D-RTO) of a batch reactor where polymer grafting reactions take place is experimentally implemented within open-loop control. This paper constitutes the continuation of the work and presents the experimental implementation of closed-loop D-RTO in the same reactor. The objective is to determine and to apply the online reactor temperature profile that minimizes the batch period while meeting terminal constraints on the overall conversion rate and grafting efficiency. The computed and measured optimal profiles of temperature, overall conversion rate and grafting efficiency exhibit a good agreement and show also that the terminal constraints are satisfied.

Keywords: Dynamic real-time optimization, Closed-loop control, Polymer grafting batch reactor, Experimental implementation

1. Introduction

Dynamic real-time optimization (D-RTO) is the most suitable technology to successfully handle uncertainty and changing conditions in the operation of plants particularly those that are never in steady-state (Rawlings et al, 2011; Ellis et al, 2013 and 2014). It makes use of the online available measurements to maximize a process performance index while meeting environmental and operating constraints (e.g. terminal specifications, temperature limits…). The results from the optimization problem can be directly applied to the process or sent to a lower level where a (e.g. MPC) control law is designed to apply to the process the optimal profiles of decision variables.

In a recent study (Bousbia-Salah et al, 2018), we considered a batch reactor where polymer grafting reactions take place. The objective was to determine the reactor temperature profile that minimizes the batch period while meeting terminal constraints on the overall conversion rate and grafting efficiency. The resulting optimal temperature profile was then experimentally implemented within the reactor in open-loop control. Although the results showed a good agreement between the computed and the measured profiles, the implementation was not able to handle the possibly disturbances or model mismatch. Closed-loop control is therefore needed in order to overcome this problem.

In the present paper, the D-RTO approach developed in (Bousbia-Salah et al, 2018) is experimentally implemented within the same batch polymerization reactor, but in closed-loop control with the help of an efficient moving horizon observer designed to estimate unmeasured states of the system.

2. Grafting polymerization

When styrene is added to ground tire rubber (GTR) particles, it can be located inside and/or outside them, depending on the styrene/GTR ratio. The latter is kept below 2 so that styrene is completely located inside GTR particles where it polymerizes in two types of polymerization. The first type is the polymerization of styrene itself leading to polystyrene (PS) chains which are not linked to GTR particles. These PS chains are called free PS. The second type is the polymerization of styrene from the rubber chains and the resulting PS chains are attached (grafted) to the rubber ones. These PS chains are designated as GTR-g-PS. The resulting material is GTR particles inside which there are free PS and GTR-g-PS. The main objective is to minimize the amount of free PS in the PS/GTR-g-PS while maximizing the amount of GTR-g-PS in order to allow recycling a maximum of GTR with the best properties, especially the impact strength (Yu, 2015).

This objective is taken into account here through constraints on the grafting efficiency (GE) and the styrene conversion rate (X). GE is defined as the ratio between the amount of grafted PS and that of the total PS (grafted PS + free PS).

3. Formulation of the D-RTO problem

The dynamic optimization problem that is solved within the D-RTO approach may be formulated as

$$\min_{T(t),t_f} J = t_f \tag{1}$$

Subject to $\quad \dot{x} = f(x,T)$ with $x(t_k) = \hat{x}_k$ and $t \in [t_k, t_f]$ $\qquad$ (2)

$$GE(t_f) \geq GE_f \tag{3}$$

$$X(t_f) \geq X_f \tag{4}$$

$$T \leq T_{max} \tag{5}$$

where the reactor temperature $T(t)$ and the batch period t_f are the decision variables and x is the vector of state variables. GE and X are the measured process outputs and GE_f and X_f are their desired final values. T_{max} is the reactor temperature upper bound.
The model equations are derived after obtaining the moment rates of the polymer chains. Moreover, the model consists of a system of 20 non-linear ODEs involving 24 unknown kinetic parameters.
The process model equations (2) are derived after obtaining the moment rates of the polymer chains. Moreover, the model consists of a system of 20 non-linear ODEs involving 24 unknown kinetic parameters. (Yu, 2015).

The optimization problem is solved over a shrinking horizon using the control vector parametrization (CVP) method (Goh and Teo, 1988). The latter is based on the approximation of decision variables by means of piece-wise constant functions over the optimization horizon taken equal to 3. The vector of time-independent parameters is then given by $p^T = (T_1, T_2, T_3, t_f)$.
The resulting non-linear programming problem is solved by means of a gradient-based method where the gradients are computed through the integration of sensitivities at each iteration of the optimizer. The equations of sensitivities are defined as

$$\dot{s} = \frac{\partial f}{\partial x} s + \frac{\partial f}{\partial p} \text{ with } s(t_k) = 0 \tag{6}$$

where $s(t) = \frac{\partial x(t)}{\partial p}$ are the sensitivities of the vector of state variables with respect to the vector of parameters p. Note that Eqs.(6) are integrated from t_k to t_f at each iteration of the optimization solver.

The D-RTO approach proceeds then as follows. Starting from the real process to which the optimal decision variables are applied at a sampling time t_k, the outputs as well as inputs are used to estimate the state vector $\hat{x}_k$ that will be used as the initial condition for the next optimization at the sampling time t_{k+1}. The corresponding initial condition for the sensitivities is always taken equal to zero. The estimation $\hat{x}$ of x is carried out by means of a moving horizon estimator (MHE) in a closed-loop control (Michalska and Mayne, 1995; Robertson and Lee, 1995) using input and output variables.

4. Experimental rig and measurements

4.1. Experimental rig

The polymerization reactions take place in a stirred batch reactor equipped with a condenser, a temperature control device and a sample collection system. The substances involved in the reactions are GTR particles of 800 μm in diameter, styrene (monomer) and two initiators, i.e. benzoyl peroxide (BPO) and dicumyl peroxide (DCP). Hydroquinone (HQ) and chloroform are used for the measurements of the conversion rate and the grafting efficiency.

2.2. Conversion measurement

The conversion of monomer is measured by a gravimetric method. Samples are taken from the reactor and weighed. A known amount of hydroquinone is added in to stop the polymerization. Then they are put into a Halogen Moisture Analyzer and the temperature is raised to 170℃ and kept at this temperature for 10 min. The residual monomer could completely evaporate and the remaining material is composed of free PS, GTR-g-PS and HQ.

4.2. Grafting efficiency measurement

Samples taken from the reactor are put in chloroform to measure the grafting efficiency of the polymerization of styrene inside GTR particles. The free PS and HQ are soluble in chloroform, while GTR and/or GTR-g-PS are not. After at least 6 hours during which the samples are shaken many times, the solvent is removed using filter paper. The free PS and HQ are in the solvent, and the non-soluble portion in the filer paper is GTR or GTR-g-PS.

5. D-RTO implementation

The algorithm used to implement the closed-loop D-RTO is detailed below (Bousbia-Salah, 2018.

1. Initialize the iteration number and time: $k = 0$ and $t_k = 0$.
2. Solve the optimization problem (1-5) for T_1, T_2, T_3 and t_f.
3. Apply the first temperature T_1 during 60 minutes and set $t_k := t_k + 60$min and k := k+1.
4. Take a reaction mixture sample from the reactor for conversion rate measurement.
5. Apply the second temperature T_2 while the measurement is being performed, i.e. 30 minutes (time required for measurement). Set $t_k := t_k + 30$min and k := k+1.

6. Use the measured conversion rate to estimate the state $\hat{x}_k$.

7. Repeat the steps (2) to (6) until t_f is reached and stop the reaction.

It is noteworthy that since the dynamics of the polymerization reaction is relatively slow, manual temperature control is found to be sufficient to achieve reasonable accuracy. On the other hand, as mentioned above, the conversion rate is measured in 30 minutes, whereas the measurement of GE needs much more time and takes about 6 hours. The implementation is carried out for $GE_f = 60\%$ and $X_f = 85\%$.

Figures 1, 2 and 3 show the temperature, monomer conversion and grafting efficiency profiles, respectively. They compare the computed optimal profiles and the measured ones in the reactor. The temperature profile exhibits a regular increase in order to fulfill the required monomer conversion rate and grafting efficiency. This regular increase is meaningful since at constant temperature, the conversion rate increases with time whereas the grafting efficiency decreases. Therefore the temperature should increase with time in order to achieve the desired conversion rate but not too much in order to guarantee the specified terminal value of grafting efficiency.
Figure 1: Optimal profiles of reactor temperature for $GE_f = 60\%$ and $X_f = 85\%$.

Figures 2 and 3 show the time-varying process outputs, i.e. conversion rate and grafting efficiency, respectively, with two different profiles. The estimated profile using the moving horizon state observer, and the measured one. It can be seen that the computed terminal inequality constraints on both process outputs are satisfied and are almost the same as the measured ones. This very good agreement between the computed and measured profiles can be explained by the absence of disturbances and a very good quality of the process model.
Figure 2: Time-varying profiles of the conversion rate for $GE_f = 60\%$ and $X_f = 85\%$.
Figure 3: Time-varying profile of the grafting efficiency for $GE_f = 60\%$ and $X_f = 85\%$.

6. Conclusions

The closed-loop control results presented in this paper showed that dynamic real-time optimization is a suitable technology for online dynamic optimization of the grafting polymerization reactor considered here. It allowed to determine and implement online the temperature profile that minimizes the batch period under terminal constraints on monomer conversion and grafting efficiency using an optimization horizon of 3. The results show very good agreement between the computed and measured profiles of temperature, monomer conversion and grafting efficiency. Moreover, the computed and measured terminal constraints are fully satisfied. On the other hand, the stability of the computed optimal temperature is guaranteed since the process considered is of the batch type and the shrinking optimization horizon covers the whole operational time. The current works deal with the development of Raman spectroscopy to measure online the monomer conversion rate in order to improve the experimental implementation of the closed-loop control at the laboratory scale prior to its implementation within a reactor at industrial scale.

Optimizing Return on Investment in Biomass Conversion Networks under Uncertainty Using Data-Driven Adaptive Robust Optimization

Jack Nicoletti, Chao Ning, Fengqi You

Cornell University, Ithaca, New York 14853, USA

Abstract

Bioconversion networks provide a means of turning raw biomass feedstock into useful biochemicals and fuels. These networks can display not only how crops and plants can be converted into bioproducts, but also how organic waste and other unconventional feedstocks can be used to create useful products as well. In order to determine the economic feasibility of the conversion pathways in these networks, an economic measure of design profitability such as return on investment must be used. Given a bioconversion network containing 216 technologies and 172 materials/compounds, we propose a two-stage adaptive robust mixed integer fractional programming model capable of measuring the economic success of bioconversion technology pathways. The proposed approach yields the processing pathways with optimal return on investment subject to minimum demand and maximum capacity constraints.

Keywords: adaptive robust optimization, return on investment, biomass conversion

1. Introduction

One of the primary goals of any business is to maximize the profit of their operations. In the context of bioconversion, if a plant cannot produce biofuels or industrial chemicals at a price even to or lower than the market price for that product, then the plant will not operate at a profit (Dodds et al., 20017; Yue et al. 2014; Gallezot, 2012). One way to measure the profitability and economic sustainability of any process is to calculate its return on investment (ROI), which is calculated in this work as the net yearly earnings of the process over the total capital investment. While work has been done to consider the cost of a bioconversion network under budgeted demand and price uncertainty (Garcia et al., 2015), in practice these facilities will only be built if they are proven to be profitable. A network that ignores the selling prices of the products that it creates could risk being economically infeasible (Sahinidis, 2004). It is necessary to ensure that a model is constructed such that the selling prices of the products are taken into consideration when deciding whether a bioconversion pathway is optimal (Lipinsky, 1981). Furthermore, with the increasing prevalence of historical data used in forecasting and planning decisions, it is quite useful to consider the uncertainty in feedstock price to be dependent on the historical price.

In this work, the biomass conversion network is optimized using a two-stage adaptive robust optimization method (Ben-Tal et al., 2009), with the first stage representing decisions made during the construction and planning phase and the second stage representing decisions made continuous during the day-to-day operation of the processing network (Ning and You, 2017). In this formulation, both the demand for products and price of biomass feedstocks are taken as uncertain parameters. Latent uncertainty realizations in collected data are identified using principal component analysis, and a

kernel density estimator is used to form probability distributions of the projected uncertainty data given by principal component analysis like previous works (Ning and You, 2018). The resulting solution provided by this two-stage problem will be robust to worst-case instances of demand and price. Finally, the return on investment objective leads to an Adaptive Robust Mixed-Integer Fractional Program (ARMIFP) that can be solved using the Parametric Algorithm. This framework is then applied to an expanded bioconversion network, with the case study included in this work focusing on the upgrading and conversion of organic waste material to useful biomaterial.

2. Model Formulation

2.1. Return on Investment as an Objective

Return on Investment (ROI) is a key economic metric for measuring the payoffs of long-term investments (Gong et al., 2017). For the bioconversion network, return on investment was calculated as a ratio of the net revenue over the total capital cost of investment in the required processing and upgrading technologies. The net profit is expressed as the total revenue generated by selling units of bioproduct S_i, minus the cost of both the feedstock purchased P_i and the cost of operating the technology at a given operating level, W_j. The denominator is the total cost of building a plant of specified capacity Q_j. Overall, the objective function to be maximized is as follows:

$$\frac{\sum_{i \in I} c_{4,i} S_i - \sum_{i \in I} c_{3,i} P_i - \sum_{j \in J} c_{2,j} W_j}{\sum_{j \in J} c_{1,j} Q_j^{sf}} \tag{1}$$

where sf represents the scaling factor for technology j, $c_{4,i}$ represents the selling price of bioproduct i, and $c_{1,j}$, $c_{2,j}$, and $c_{3,i}$ represent parameters for economic evaluation as given in previous works (Gong et al., 2016). The first term of the numerator represents the profit from selling a specific quantity of bioproduct i at the market price. The second term represents the cost associated with buying a specific quantity of feedstock i. The last term in the numerator represents the cost associated with operating technology j. Upon inspection, it becomes clear that the decision variable for operating level W_j must be in the range of zero to the total capacity of the technology, Q_j. The denominator represents the cost associated with building technology j at a specific total capacity.

2.2. Two-Stage Adaptive Robust Optimization Formulation

Traditional robust optimization problems are static, meaning that all decisions are made at the same time and are final. However, in practice it is known that decision makers will make recourse decisions based on market conditions, risk tolerance, and many other factors. To ensure that the model accurately reflects the ability of a decision maker to act in real time, the model must allow for decisions to be made in multiple time frames. The solution is a two-stage adaptive robust optimization (ARO) formulation, which provides multiple advantages over static robust optimization (Shi et al., 2016). First, ARO leads to solutions that are less conservative that static robust solutions, as the solution can "adapt" to the uncertainty realizations. Additionally, ARO allows for "here and now" decisions to be made during the planning and construction of the bioconversion network as well as "wait and see" decisions to be made during the real-time operation of the facilities. In the bioconversion network, "here and now" decisions involve binary variables Y_j representing the decision to use technology j as well as continuous variables Q_j representing the

capacity of technology j. Meanwhile, the "wait and see" variables that can be chosen in the second stage are the operating level of each technology W_j, the amount of feedstock purchased P_i, and the amount of product sold S_i.

The resulting two stage adaptive-robust optimization model considers uncertainty in both feedstock price and demand. Furthermore, the model allows for selection and capacity decisions to be made before uncertainty realization while also allowing for operational, purchasing, and sale decisions to be made after uncertainty has been realized. The model also employs nonlinear functions to evaluate the technology capital costs associated with the first-stage decisions. Furthermore, the model allows for the building of backup technologies that can sit idle and guard against uncertain demand fluctuations.

The overall bioconversion optimization model is shown as follows:

$$\max_{Y,Q} \ \min_{c_3 \in U_2,\, d \in U_1} \ \max_{W,P,S} \ \frac{\sum_{i \in I} c_{4,i} S_i - \sum_{i \in I} c_{3,i} P_i - \sum_{j \in J} c_{2,j} W_j}{\sum_{j \in J} c_{1,j} Q_j^{sf}} \tag{2}$$

$$\text{s.t.} \quad a_{1,j} Y_j \leq Q_j \leq a_{2,j} Y_j, \quad \forall j \in J \tag{3}$$

$$W_j \leq Q_j, \quad \forall j \in J \tag{4}$$

$$P_i - S_i + \sum_{j \in J} a_{3,i,j} W_j = 0, \quad \forall i \in I \tag{5}$$

$$P_i \leq b_i, \quad \forall i \in I \tag{6}$$

$$S_i \geq d_i, \quad \forall i \in I \tag{7}$$

$$W_j, P_i, S_i \geq 0, \quad \forall i \in I,\, j \in J \tag{8}$$

$$Y_i \in \{0,1\}, \quad \forall i \in I \tag{9}$$

$$U_1 = \left\{ d_i \,\middle|\, \begin{array}{l} d_i = d_i^0 + \sum_k p_{ik}\left(\xi_k^L \cdot z_k^- + \xi_k^U \cdot z_k^+\right), \ \forall i \\ \sum_k \left(z_k^- + z_k^+\right) \leq \Phi^{dem},\ z_k^- + z_k^+ \leq 1,\ 0 \leq z_k^-,\ z_k^+ \leq 1 \end{array} \right\} \tag{10}$$

$$U_2 = \left\{ c_{3,i} \,\middle|\, \begin{array}{l} c_{3,i} = c_{3,i}^0 + \sum_l r_{il}\left(\beta_l^L \cdot \delta_l^- + \beta_l^U \cdot \delta_l^+\right), \ \forall i \\ \sum_l \left(\delta_l^- + \delta_l^+\right) \leq \Phi^{pri},\ \delta_l^- + \delta_l^+ \leq 1,\ 0 \leq \delta_l^-,\ \delta_l^+ \leq 1 \end{array} \right\} \tag{11}$$

where Eq. (2) represents the fractional objective, and Eq. (3) enforces first-stage capacity constraints. Eqs. (4), (5), and (7) enforce operational level, supply, and demand level constraints, respectively. Eq. (5) enforces a mass balance constraint, Eqs. (8) and (9) ensure non-negativity of continuous variable and range for binary variables, respectively. Eqs. (10) and (11) represent the data-driven uncertainty sets that are used in this work, with (10) representing the demand uncertainty set and (11) representing the feedstock price uncertainty set.

3. Solution Algorithm

The chosen approach for solving the computationally expensive ARMIFP is a combination of the parametric algorithm (Zhong et al. 2014) and a decomposition-based method. The parametric algorithm is first employed to handle the fractional term in the ARMIFP. We then break the MINLP into master problem and subproblem and solves these problems iteratively to obtain converging upper and lower bounds on the correct

solution (Takeda et al. 2008). The proposed solution algorithm works as follows. First, the decomposition algorithm solves the master problem with feasibility cuts. The optimal value is used to update the lower bound on the optimal solution. Next, the subproblem is solved to obtain the optimal solution. This optimal value is then used to update the upper bound. The subproblem also generates cuts for the master problem, which are then added to the feasibility cut set. The uncertain demand and uncertain feedstock price are then changed to reflect the addition of the cuts in the set as well. The inner loop will terminate when the upper and lower bounds converge. The inner loop returns the current numerator and denominator to the outer loop. The outer loop will terminate when the numerator of the objective minus the denominator times the current multiplier value equals zero. When the outer loop does converge, the resulting multiplier value will be the optimal return on investment of the bioconversion system. Pseudocode for the algorithm is given in Fig. 1.

Algorithm. Parametric algorithm and column-and-constraint algorithm

1:    Set $k \leftarrow 0, tol \leftarrow 10^{-3}, r \leftarrow 0$ and ζ;

2:    **while** $N^* - r \cdot D^* \geq tol$

        $iter \leftarrow iter + 1, LB \leftarrow -\infty, UB \leftarrow +\infty, m \leftarrow 0$

3:       **while** $|UB - LB| > \zeta$ **do**

4:           $m \leftarrow m + 1$

5:           Solve **(MAS)** to obtain mo^*, N^*, D^* and Q^*;

6:           Update $LB \leftarrow \max\{LB, mo^*\}$;

7:           Solve **(SUB)** to obtain so^*;

8:           Update $UB \leftarrow \min\left\{UB, -r \cdot \sum_j c_{1,j}(Q_j^*)^{sf} + so^*\right\}$;

9:           $M \leftarrow M \cup \{m\}$;

10:         $d_{i,m} = d_i^0 + \sum_k p_{ik}\left(\xi_k^L \cdot z_k^- + \xi_k^U \cdot z_k^+\right), \forall i$

11:         $c_{3,i,m} = c_{3,i}^0 + \sum_l r_{il}\left(\beta_l^L \cdot \delta_l^- + \beta_l^U \cdot \delta_l^+\right), \forall i$

12:         Create second-stage variables with respect to index m;

13:       **end**

14:       $r \leftarrow \dfrac{N^*}{D^*}$;

15:    **end**

16:    **return** UB;

Figure 1. Pseudocode for the proposed nested solution algorithm

4. Case Study

In the case study, the demands for bioproducts were chosen to showcase the capabilities of some of the new bioconversion pathways. As explained in the introduction, one novel contribution of this work was the expansion of the bioconversion network to include organic and inorganic waste material as alternative potential feedstocks. In this example, the demands and uncertainty set for raw biogas, methane, and pectin were given.

When the solution algorithm presented in previous sections was executed, the processing network displayed in Fig. 2 was constructed. To make pectin, orange peel waste was treated using microwave hydrodiffusion. This process yields pectin as well as small amounts of essential oils (EO) and phenolic compounds (TPC). Meanwhile, to satisfy demand for methane, landfill methane extraction techniques can be used on various types

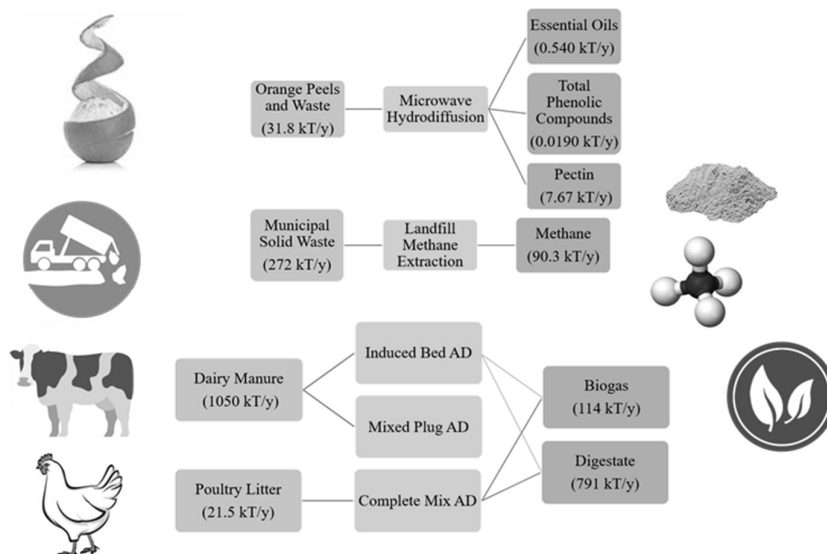
of municipal solid waste landfills. Finally, to satisfy the demand for biogas, multiple types of animal manure and anaerobic digestion (AD) methods were used.


Figure 2. Process diagram displaying the conversion of waste materials to useful biofuels and other bioproducts. The amounts produced by each process vary widely based on average demand for each product.

For dairy manure, the best way to product biogas was through induced bed and mixed plug anaerobic digestion. To process poultry litter, however, the most efficient was to produce biogas was using a complete mix anaerobic digestion system. The other main by-product of anaerobic digestion, digestate, was also produced in large quantities along with the biogas. We also find that one of the processing pathways was built to operate at maximum capacity, while the others were built to ensure demand satisfaction. The biogas and methane production pathways are producing at demand-satisfying levels, while the orange peel processing pathway to produce pectin is operating at maximum capacity. Maximum pectin production implies that for the current input price, making pectin using microwave hydrodiffusion is profitable. In the aggregate processing network, the total cost was $277.6 M/y, with the cost being split between capital cost ($170.5 M/y) and operating cost ($107.1 M/y). The purchase cost for this case was assumed to be zero because the feedstocks for each pathway are waste products, which are assumed to have negligible or zero cost associated with obtaining them. The overall return on investment of the alternative feedstock processing pathway was 6.2%.

5. Conclusions

In this work, we developed a two-stage adaptive robust optimization model to maximize return on investment of a bioconversion network. We focused on uncertainty in feedstock price and bioproduct demand. Feedstock price was derived from historical data, leading to a data-driven uncertainty set for feedstock price that was constructed using the machine learning techniques. Furthermore, we also investigated the economic feasibility of using organic waste and other waste material as feedstock. The two-stage adaptive robust

optimization problem with return on investment maximization is a MILFP which cannot be solved directly due to its multi-stage and fractional objective components. The case study focused on the production of useful chemicals from waste material. The result of the case study was a network that satisfied demand for all bioproducts and had a return on investment of 6.2%. Overall, the proposed solution method was able to quickly and efficiently identify optimal processing pathways for the bioconversion network.

Abstract

Direct compaction tabletting, a widely used secondary downstream processing operation, has recently received significant research attention. Experimental data can be used to fit model parameters for the prediction of single-component tablet thickness and hardness with good agreement, and this has been done for two components (Avicel® PH-101 and Pharmatose® 50M). These pure component parameters have then been used to predict multicomponent tablet properties, with the use of novel modified parameter averaging calculations improving predictions. Furthermore, a relation has been developed to estimate the required gap between tablet press punch faces for multicomponent tablets based on the gaps required for pure components; a quick and efficient way to estimate the necessary equipment settings to generate the desired compaction forces is a useful tool.

Keywords: direct compaction, tablet prediction, optimisation.

1. Introduction

Continuous Pharmaceutical Manufacturing (CPM) is a promising alternative to the current paradigm of batch production, and mathematical modelling and simulation is a useful tool within the methodology of CPM (Lee et al., 2015). The final step in many production process is final product formulation. In the case of solid dosage forms such as tablets the critical quality attributes include tablet tensile strength and thickness; appropriate dissolution rates are also crucial (Velasco et al., 1999). Currently, time-consuming design-of-experiment (DOE) approaches are commonly used to determine the necessary conditions to achieve the required tablet properties, and the need for cost-effective R&D methodologies brings process modelling and simulation to the forefront of initial stages of process option evaluation (Diab and Gerogiorgis, 2018).

In the present work, we predict the properties of multicomponent tablets using parameters determined from pure component compaction data; a model by Gavi and Reynolds (2014) has been used to fit the parameters for tablet compaction. The use of pure component parameters in the prediction of multicomponent tablet properties entails the use of some form of mixing or averaging rule, and the appropriateness of currently implemented rules are analysed, with novel modifications made where necessary.

2. Compaction experiments

Experiments (Papathanasiou, 2018) were performed for varying tablet weights (200, 250 or 300 mg) and components (microcrystalline cellulose: Avicel® PH-101; α-lactose monohydrate: Pharmatose® 50M). Tablet thickness and hardness were recorded for a range of compaction forces. Tablet masses were also measured after ejection (due to material flowability, there was always some variation from target tablet mass, approximately ± 2 %). For each compaction force, experiments were performed 10 times (*i.e.* 10 tablets were produced). In addition to the above experiments being done for pure components, a similar set of experiments were done for binary tablets of lactose and cellulose, to allow the assessment of binary tablet predictions.

The pure component experiments showed the expected trends, such as hardness increasing with increasing compaction force, and thickness decreasing with increasing compaction force (routine data not shown due to space constraints – available in the work of Papathanasiou, 2018). Cellulose achieves significantly higher hardness values (up to 450 N for 250 mg tablets) than lactose (up to approximately 50 N), which is unsurprising as Avicel® PH was introduced with direct compaction in mind. The hardness values achieved with the mixtures fall between those of pure cellulose and pure lactose, as one might expect.

3. Compaction model

The compaction model used here is one developed by Gavi and Reynolds (2014), and is also included in the FormulatedProducts module of the gPROMS software package (henceforth called gFormulate), produced by Process Systems Enterprise (PSE, 2018). The model has several key equations. The first computes the tablet relative density ρ^* (Equation 1). Here, ρ_0^* is the relative density at zero compaction pressure (taken to be the tapped density of the powder), P is compaction pressure (MPa) and K is the compressibility constant (a dimensionless fitting parameter). Tablet ρ^* values can be calculated from the compressed tablet densities and the true density of the material (ρ^{crys}, determined experimentally with a gas pycnometer). Equation 1 is used first in the calculations – the model is sequential. With relative density calculated, tablet thickness h is then calculated for known ρ^{crys}, mass M, and diameter d (Equation 2; assumes flat-faced cylinders) (Fell and Newton, 1970).

Another key equation is that governing tensile strength, σ (Equation 3). Here, σ_0 is the tensile strength at zero porosity (i.e. a fitting parameter corresponding to the theoretical maximum possible compaction, units of MPa), k_b is the bonding capacity (also a dimensionless fitting parameter), and ε is tablet porosity (Equation 4). The three key parameters, then, are the compressibility constant (K), the tensile strength at zero porosity (σ_0) and bonding capacity (k_b). Experimentally, tensile strength can be calculated from hardness via Equation 5, where F is the compaction force in kN.

$$\rho^* = \rho_0^* P^{1/K} \tag{1}$$

$$h = \frac{M}{\rho^* \rho^{crys}} \frac{4}{\pi d^2} \tag{2}$$

$$\sigma = \sigma_0 e^{-k_b \varepsilon} \tag{3}$$

$$\varepsilon = 1 - \rho^* \tag{4}$$

$$\sigma = \frac{2}{\pi} \frac{F}{hd} \tag{5}$$

4. Pure component parameter estimation

Comprehensive experimental data allows for parameters to be fitted for use in empirical and data-driven models. In this work, the parameters being fitted are compressibility constant (K), tensile strength at zero porosity (σ_0) and bonding capacity (k_b).

The pure component experimental data were imported into gFormulate, where a digital flowsheet of the process was created. The control variables are compaction pressure P and tablet weight M, while the key measured variables are tablet thickness h and hardness H (the diametrical load which causes tablet failure). With three fitted parameters and four variables (two control, two measured), the problem was straightforward, and computationally undemanding; the parameters themselves (for cellulose/Avicel® PH-101 and lactose/Pharmatose® 50M) are given in Table 1.

5. Multi-component tablet property prediction

Pure component parameters that reliably predict single-component tablets have been determined. The subsequent use of these for multi-component tablet property prediction has been investigated, which entails the use of some form of averaging or mixing rule for the model parameters K, σ_0 and k_b. Doing this by pre-compaction component volume fractions is one option (Equation 6) (Gavi and Reynolds, 2014). Results for mixtures of lactose-cellulose indicate that while predictions for hardness are good at lower compaction forces, there is a trend of over-prediction which becomes more evident at higher compaction forces (Fig. 1). However, this trend is not present for pure components, *i.e.* pure lactose and pure cellulose tablets are predicted reasonably well, with no significant hardness over-prediction at higher compaction forces (Fig. 1B). This implies the potential for prediction improvement from using alternative parameter averaging/mixing rules.

The volume fractions of the components after compaction (as opposed to prior) can be estimated by assuming they compact at similar rates as when they are a pure component (*i.e.* a 25 % volume reduction for pure material i when subjected to a given force implies a 25 % reduction for component i when a mixture is subjected to the same force), and can be computed via Equation 7 (Reynolds et al., 2017).

Table 1. Optimal pure component parameter values for Avicel® PH-101 and Pharmatose® 50M.

Component	Tensile strength at zero porosity		Bonding capacity		Compressibility constant	
	σ_0 (MPa)	99% CI	k_b (-)	99% CI	K (-)	99% CI
Avicel® PH-101	12.0067	±1.9080	7.5847	±0.6362	4.2008	±0.1372
Pharmatose® 50M	1.6789	±0.3212	11.6020	±0.8704	9.0901	±0.2130

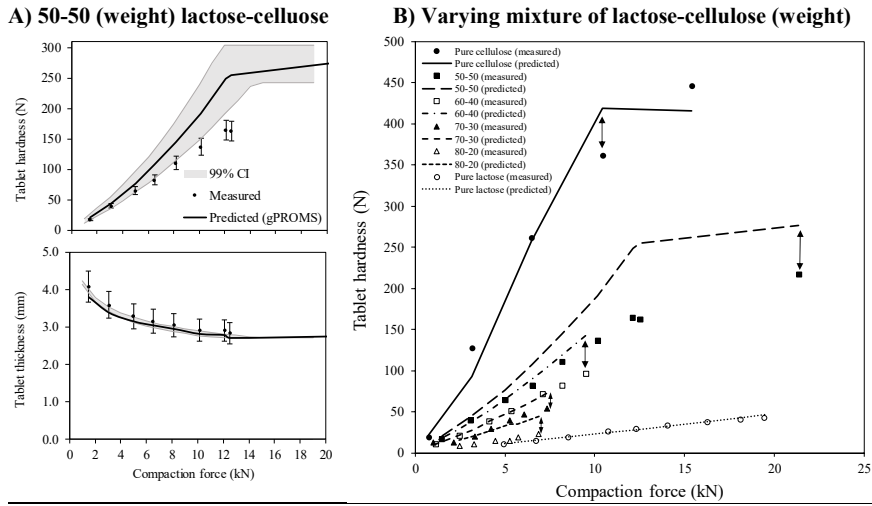
A) 50-50 (weight) lactose-celluose   **B) Varying mixture of lactose-cellulose (weight)**


Figure 1. Predicted (Gavi and Reynolds, 2014) vs measured 250 mg tablet hardness and thickness for varying mixtures of lactose-cellulose. For each substance, the predicted curves use the same respective set of parameters. The parameters can be found in Table 1. Arrows in B are a visual aid, to indicate which predicted curve corresponds with which experimental data set.

$$p_{mix} = \sum_{i \in C} \varphi_i p_i \quad , \qquad p = \{K, \sigma_0, k_b\} \tag{6}$$

$$\varphi'_i = \frac{m_i \big/ (1 - \varepsilon_i)\rho_i^{crys}}{\sum_{i \in C} m_i \big/ (1 - \varepsilon_i)\rho_i^{crys}} \tag{7}$$

$$\sigma_{Tab} = \prod_{i \in C} \sigma_i^{\varphi'_i} \tag{8}$$

The Reynolds et al. (2017) model then use Equation 8 to compute the tensile strength of multicomponent tablets. In essence, tensile strengths for each component are calculated on a pure basis, then averaged using Equation 8. However, this approach relies on the components being of similar particle size (Reynolds et al., 2017). For applications where the particle sizes are different, such as in this work (Avicel® PH-101 has an average particle size of 50 μm, Pharmatose® 50M has an average size of 360 μm), an alternative approach is required.

The approach used in this work is to use Equation 6 to average the compressibility constant *K* as before, then use Equation 7 to compute component volume fractions in the compact (φ'_i), and then use these volume fractions to average the post-compaction tensile strength (σ_0) and bonding capacity (k_b) parameters (Equation 9) for use with Equation 3.

$$\sigma_{0mix} = \sum_{i \in C} \varphi'_i \sigma_{0i} \quad , \qquad k_{bmix} = \sum_{i \in C} \varphi'_i k_{bi} \tag{9}$$
Figure 2. Predicted vs measured (experimental) 250 mg tablet hardness and thickness for 250mg lactose-cellulose tablets (50-50 by weight), illustrating prediction improvements from using post-compaction volume fractions to weight the pure component parameters.

This approach results in improved predictions (Fig. 2). Compared with the previous method (Fig. 1, Fig. 2 dashed lines) the improvements are evident, especially for tablet hardness. While predictions using the previous method agreed with measured data at lower compaction forces, the method outlined in here produces predictions which match the experimental data across the entire range of compaction forces.

The main variable in the compaction model used here is, as with many compaction models, the pressure applied (or the force in some cases) (Equation 1). However, in tablet presses there frequently is not a setting or dial for pressure, but a way to set the distance to which the punch faces compact the material (punch gap, PG); knowing what pressure or force is required might not be immediately useful to a user in the lab. We have taken the compaction force and PG data, and have been able to determine a relation between them, adjusted for tablet weight. An example of this for cellulose is given in Fig. 3A. This variable, which we have called the gap-mass factor γ, has units of mm/g. When plotted against compaction pressure as in Fig. 3A, a power law relation (Equation 10) can be determined for the curved portion corresponding to lower compaction pressures; the horizontal portion, corresponding to the limit of zero porosity, is less useful as there is no improvement in tablet properties at these compaction pressures. This fitting of the curved portion will result in two parameters a and b for a given pure component, and we have then used a mass fraction (m_i)-based mixing rule (Equation 11) to estimate what PG might be required for a binary tablet of given weight M. The predicted PG values are in good agreement with the experimentally required values for binary tablets, with the difference being of a similar order of magnitude as tablet thickness (Fig. 3B). Such a relation is envisaged to be useful to users wishing to apply a certain compaction force.

$$\gamma_i = a_i P^{b_i} \tag{10}$$

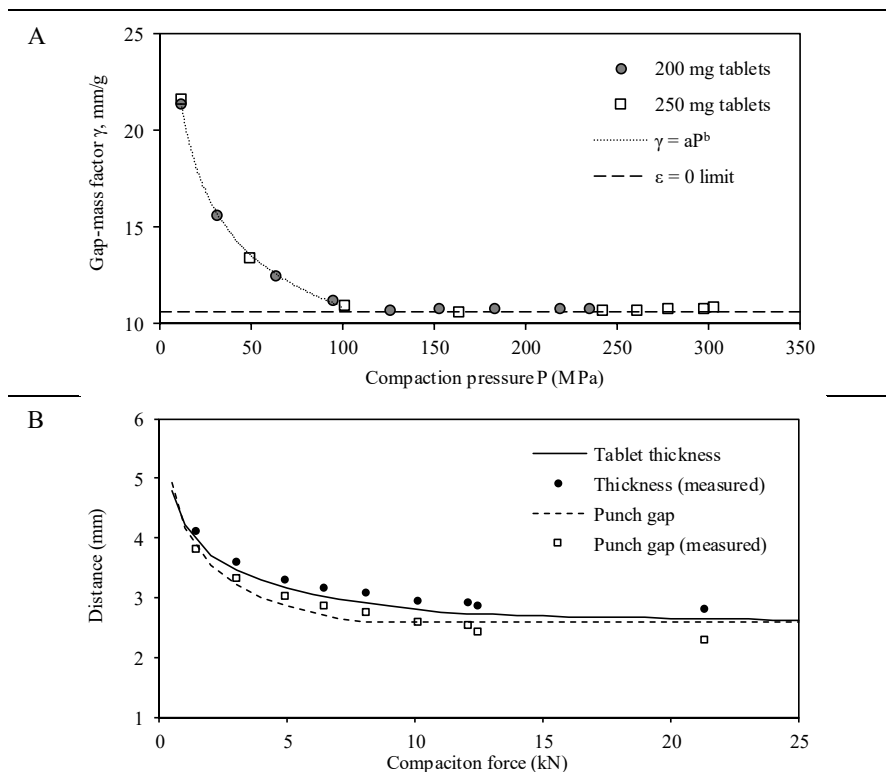
$$PG = M \sum_{i \in C} m_i \gamma_i \tag{11}$$


Figure 3. A) Punch gap-compaction pressure relation for Avicel® PH-101. Data points have been normalized by dividing punch gap values (mm) by tablet weights (g). B) Prediction from pure component data of required punch gap values of multicomponent tablets (Equations 10–11).

6. Conclusions

Pure component parameters can be fitted with good statistical results. The use of these pure parameters for the prediction of multicomponent tablet properties is possible, and predictions have been improved by a novel use of model equations. In addition, a relation between tablet press punch gap values and applied compaction pressures has been developed, which predicts necessary punch gaps with good accuracy.

Abstract

Industrial symbiosis plays an important role in the process industry, where an effective management of resources can bring both economic and environmental benefits. Traditionally, the design and extension of eco-industrial parks has been mainly based on intuition and experience; yet, the number of actors involved, the number of flows to manage and the different nature of the materials and energy exchanged lead to complex problems that can benefit from the use of systematic decision-making methods. The aim of this contribution is to produce useful tools to identify the most favourable synergies and transformations for a process network. The proposed model has been tested on a case study that consists of an ethylene and chlorine based eco-industrial park. Results confirm the capabilities of the proposed targeting methodology to match sources and sinks of resources.

Keywords: Industrial symbiosis, process networks, targeting, eco-industrial parks, optimization, sustainability.

1. Introduction

In the last years, there has been a growing awareness of the importance of applying circular economy approaches to close material, energy and water cycles (Merli et al., 2018). With their focus on closing loops in industrial processes, Industrial Symbiosis (IS) principles have been widely applied in many specific sectors (van Ewijk et al., 2018; Deschamps et al., 2018). A shared concern is engaging industries to join: the more participants are involved, the better environmental performance is achieved.

However, current eco-industrial parks (EIP) and resource exchange designs are mainly ad-hoc Industrial Symbiosis approaches, based on identifying opportunities through expert analysis. These strategies, even after a systematic local search, usually lead to sub-optimal solutions. In light of this, there is a need of systematic methods aimed at coping with the complexity of the problems by exploring only feasible and promising alternatives. Previous works have focused on the development of tools for transformation companies that might make profit of connecting sources and sinks of resources, and thus reducing the final waste involved (Somoza-Tornos et al., 2017 and 2018).

The aim of this work is to develop efficient targeting methods that identify the most promising synergies for industrial symbiosis while discarding infeasible links. A material network is designed to model the exchange of materials that become profitable

for the involved actors (sources, transformers and sinks). Conservation laws and thermodynamic constraints are used to discern between the resulting alternatives.

2. Problem statement

The system under study is illustrated in Figure 1.

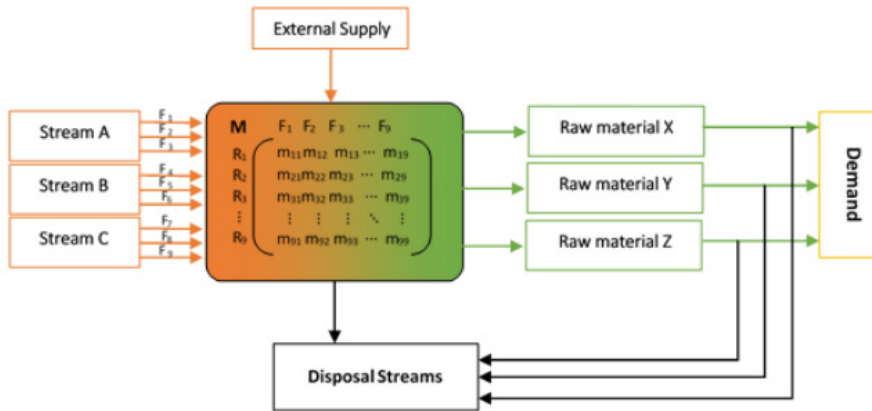
The targeting problem can be stated as follows: Given a set of waste streams j that could be potentially treated to satisfy the raw materials demand of streams k; a set of chemical reactions that may take place between the i products composing the mentioned streams: and other available data, including complete economic data, technical constraints and thermodynamic parameters. The decisions to be made comprise the amount of waste processed by the system, whether or not it is transformed, the requirements of external feeds or demands, how the products are distributed to satisfy the needs of customers and which side products have to be disposed.


Figure 1. Material network scheme.

3. Mathematical formulation

The problem is formulated as a MILP that finds the optimal synergies between waste producers and raw materials consumers.

The total inlet to the system includes waste streams W_{ji} and potential supply of products required to complete the transformation ES_i (Eq. (1)).

$$\sum_j W_{ji} + ES_i = F_i^{in} \quad \forall i \tag{1}$$

Eq. (2) defines the mass balance of the system considering the inlet, outlet and generation terms, the last one calculated through stoichiometric coefficients R_{mi} and the extent of the reaction F_m^{gen}.

$$F_i^{in} + \left(\sum_m R_{mi} \cdot F_m^{gen} \right) = F_i^{out} \quad \forall i \tag{2}$$

The result of the transformation F_i^{out} is then divided in two, the amount sent to customers F_{ki}^{rm} and the side products that are unassigned F_{li}^d (Eq. (3)). This balance is

completed with the introduction of the term F_i^{ed} to represent the external demand that new partners may have.

$$F_i^{out} = \sum_k F_{ki}^{rm} + \sum_l F_{li}^d + F_i^{ed} \quad \forall i \tag{3}$$

z_k is defined in Eqs. (4),(5) as a binary variable that takes a value of 1 if the amount sent to the customers, F_{ki}^{rm}, is greater than the demand.

$$D_{ki} \cdot z_k \leq F_{ki}^{rm} \quad \forall k, i \tag{4}$$

$$F_{ki}^{rm} - D_{ki} \leq M \cdot z_k \quad \forall k, i \tag{5}$$

Hence, when the demand is surpassed, the profit of selling C_k it is penalized with a cost for the excess of delivery C_k^d.

$$f_k^1 \leq M \cdot z_k \quad \forall k \tag{6}$$

$$f_k^1 \leq (\sum_i D_{ki} \cdot C_k) - C_k^d \cdot \sum_i (F_{ki}^{rm} - D_{ki}) \quad \forall k \tag{7}$$

On the contrary, when demand is not covered, only the amount sent to the customer must be taken into account for the profit calculation.

$$f_k^2 \leq M \cdot (1 - z_k) \quad \forall k \tag{8}$$

$$f_k^2 \leq (\sum_i F_{ki}^{rm} \cdot C_k) \quad \forall k \tag{9}$$

The energy balance of the system is calculated as in Eq. (10), where Q_m^{exc} denotes the amount of energy added or extracted from the system.

$$\left(\sum_i R_{m,i} \cdot F_m^{gen} \cdot H_i\right) = Q_m^{exc} \quad \forall m \tag{10}$$

Binary variable y_m is defined in Eqs. (11),(12) to differentiate processes that require heating or cooling and apply costs accordingly.

$$Q_m^{exc} \leq M \cdot y_m \quad \forall m \tag{11}$$

$$-Q_m^{exc} \leq M \cdot (1 - y_m) \quad \forall m \tag{12}$$

Eqs. (13),(14) apply when heat is extracted from the system, and cost parameter CQ_{out} is considered.

$$f_m^3 \leq M \cdot y_m \quad \forall m \tag{13}$$

$$-f_m^3 \leq Q_m^{exc} \cdot CQ_{out} \quad \forall m \tag{14}$$

Conversely, when heat is added to the system, the cost is calculated through Eqs. (15),(16).

$$f_m^4 \leq M \cdot (1 - y_m) \tag{15}$$

$$-f_m^4 \leq -Q_m^{exc} \cdot CQ_{in} \tag{16}$$

The objective function to be maximized is the economic balance shown in Eq. (17). It considers the profit obtained from satisfying the demand of current companies and potential new partners. Aggregated cost parameters associated with the different transformation routes are considered at this step. These aggregated costs, including capital and operational costs plus indirect costs like transportation and management, must be estimated according to the specific circumstances, and the sensibility of the results to these estimations must be adequately assessed.

$$OF = -\left(\sum_i \sum_l F_{li}^d \cdot C_l\right) - \left(\sum_i \sum_j W_{j,i} \cdot C_j\right) - \left(\sum_m F_m^{gen} \cdot C_m^R\right) - \left(\sum_i Es_i \cdot C_i^{es}\right) + \left(\sum_i F_i^{ed} \cdot C_i^{ed}\right) + \sum_k f_k^1 + \sum_k f_k^2 - \left(\sum_m f_m^3 + \sum_m f_m^4\right) \tag{17}$$

The resulting model for the targeting can be posed as follows:

TSym   min [OF]

      s.t.   Eqs. (1)-(17)

4. Case study

The capabilities of the model are illustrated in a case study consisting of an eco-industrial park based on ethylene and chlorine, with 10 available waste streams and 7 demands of raw material have been defined. The considered compounds include acetic acid, benzene, chlorine, vinyl chloride, ethanol, ethylbenzene, ethylene, ethylene dichloride, ethylene oxide, hydrochloric acid, oxygen, tetrachloroethylene, trichloroethylene, vinyl acetate and water. Eqs. (18)-(26) show the reactions that the park would consider can take place between the components by a transformation company.

$$C_2H_4 + Cl_2 \rightarrow C_2H_4Cl_2 \tag{18}$$

$$3Cl_2 + C_2H_4Cl_2 \rightarrow 4HCl + C_2Cl_4 \tag{19}$$

$$2C_2H_4 + 4HCl + O_2 \rightarrow 2C_2H_4Cl_2 + 2H_2O \tag{20}$$

$$C_2H_4Cl_2 \rightarrow C_2H_3Cl + HCl \tag{21}$$

$$C_2H_4Cl_2 + Cl_2 \rightarrow C_2HCl_3 + 3HCl \tag{22}$$

$$C_2H_4 + H_2O \rightarrow CH_3CH_2OH \tag{23}$$

$$C_2H_4 + \frac{1}{2}O_2 \rightarrow CH_2OCH_2 \tag{24}$$

$$C_2H_4 + CH_3COOH + \frac{1}{2}O_2 \rightarrow CH_3CO_2CHCH_2 + H_2O \tag{25}$$

$$C_6H_6 + C_2H_4 \rightarrow C_6H_5C_2H_5 + H_2O \tag{26}$$
5. Results

The resulting MILP problem, featuring 1209 equations, 1064 continuous variables and 159 binary variables, has been modeled in GAMS 23.8.2 and solved with CPLEX 12.4.

Four different scenarios have been defined to examine the chances of incorporating new participants in the symbiotic network. These new participants can either be a source of waste or raw materials consumers, all presenting their own capacity limitations.

a) Base case of the existing eco-industrial park (EIP)
b) New companies could join the EIP and offer new sources of waste
c) New partners could join the EIP and take advantage of generated waste
d) New companies could both as a source and sink of resources
Figure 2. Waste usage and raw materials satisfaction for scenarios a, b, c, d.

Figure 2.a depicts the waste usage and the raw materials demand satisfaction for the existing EIP. The first case, where no external supply is available, is constrained by the limit in the waste supply. Reactions (22) and (26) are active to produce ethylbenzene and trichloroethane. The lack of ethylene does not allow acidic acid to be used in reaction (25) and there are sources of an excess of HCl and water that is not reused. Figure 2.b shows the effect of finding new partners that may be a source of waste. By

adding new producers of chlorine, ethylene and ethylene dichloride to the park, more of the demands are internally covered and thus the external requirements of raw materials are reduced. Transformations (19), (24) and (25) would have to be activated to produce ethylene oxide, tetrachloroethylene and vinyl acetate, thus increasing the amount of waste processed and the profit of the entire complex. This would increase even more the excess of side products. In Figure 2.c the opposite case is represented, where new partners would only be interested in raw materials production. As the waste supply was limiting the base case, only the side products in excess can be used, resulting in a reduced grow of the EIP. When these limitations are overcome in Figure 2.d, the most promising ways of making the EIP grow are identified, and so are the transformations that the policy-makers should foster.

6. Conclusions

This work has addressed the development of a tool to identify the most promising routes to match sources and sinks of resources, even when a transformation step is required. This will help to reduce the complexity of the analysis required during the synthesis and design of industrial processing networks. Hence, the model offers policy-makers a method to systematically identify and assess opportunities for increasing the integration of process networks in industrial complexes. Thus, Administrations may use their resources to incentive partners that will ensure economically feasible synergies with the ultimate goal of reducing waste. An adequate reformulation of the objective function may also allow these companies to identify their opportunities, and even the different members of the industrial network the best cooperation opportunities (multi-objective approach). Future work will also focus on the application of combined targeting-synthesis methodologies to systematically analyse in detail the resulting proposals.

Abstract

This study used the Extreme Learning Machine (ELM), Kernel Extreme Learning Machine (KELM) and Artificial Neural Network (ANN) models with a feed-forward neural network structure and partial least squares (PLSR) methods to estimate total organic carbon. In order to develop models, on-line data measured at five-minute time intervals were collected through one year (2007-2008) from the online-monitoring stations which were built near the River Yeşilırmak in Amasya in North-Eastern Turkey. These stations were the first practice in Turkey. Twelve parameters as luminescent dissolved oxygen (LDO), pH, conductivity, nitrate nitrogen (NO_3-N), ammonium nitrogen (NH_4-N), total organic carbon (TOC), chloride, orthophosphate, temperature, turbidity, suspended solid and flow rate were measured at the on-line monitoring stations. To predict the total organic carbon, four input variables, pH, conductivity, dissolved oxygen and temperature were selected. Moreover, the data were also collected at the central office in Ankara via a General Packet Radio Service (GPRS) channel. The validity of models was tested by using statistical methods in MATLAB including correlation coefficients (R), mean absolute percentage error (MAPE%) and root mean square error (RMSE). The best result was obtained in the presence of KELM with a radial basis function (RBF) kernel. $R_{test}=0.984$, $MAPE_{test}=3.01$, $RMSE_{test}=0.9676$. Additionally, $R_{train}=0.995$, $MAPE_{train}=1.58$ and $RMSE_{train}=0.532$. Among the other two algorithms ANN provided better results than ELM and PLSR.

Keywords: Artificial Neural Network, Extreme Learning Machine, On-line monitoring, River water quality

1. Introduction

Rivers play a vital role not only as sources of drinking water but also basic elements in sustainable development especially in industrial and agricultural activities. Additionally, rivers and streams also serve as the lifelines of the population staying in the basins. Increased anthropogenic and other effects cause substantial increase in river pollution. Water quality in rivers has also been changed by environmental factors, but the main reason for water contamination is known to be caused by human activities. Especially in agricultural activities such as usage of chemical fertilizers, animal feeding and mining, combustion of fossil fuels affect the quality of all natural water bodies the most. Destruction of wetlands, point or diffuse pollution sources, large amounts of industrial

waste discharge and the exponential increase of population growth have also affected water quality within environmental factors. In the last decades, monitoring of water quality from several rivers by regular measurements has received increasing demand. In this context, a real-time monitoring station, as the first practice in Turkey, was built near the River Yeşilırmak in Turkey. The system involved two in-situ on-line analysis stations in River Yeşilırmak and a central monitoring office at Ankara University. Pollutant parameters of luminescent dissolved oxygen (LDO), pH, conductivity, nitrate nitrogen (NO_3-N), ammonium nitrogen (NH_4-N), TOC, o-phosphate, chloride, temperature, turbidity, suspended solid and flow rate were measured at five-minute intervals at the on-line monitoring stations. The data were collected at the central office in Ankara via General Packet Radio Service (GPRS). In these parameters, measurement of total organic carbon was the most expensive -about eight-fold of the total amount of LDO, conductivity, pH and temperature- parameter, therefore, various models for prediction of TOC was proposed in this study. Various types of river water quality models such as parametric, statistical and deterministic models were proposed in the literature. The use of water quality models is inevitable in explaining some problems like nonlinearity, subjectivity and cause-effect relationships between water quality variables and water status. However, deterministic modelling approaches for water quality parameters need a lot of information on various hydrological processes and several different units of input data to arrive the results, while these methods have been seen to be very effortful and time-consuming. Artificial intelligence methods have some advantages over semi empirical or deterministic models due to the fact that they contain a set of input data without assumption, and they are also able to map the nonlinear relationships that are characteristics of aquatic ecosystems. For these reasons ANNs, which are artificial intelligence methods, have widespread use in hydrological processes and modelling river water quality. Moreover, ANNs are used to forecast of water quality parameters, as well as determining the uncertainty of contaminant source and nonlinearity of water quality data. Csabragi et al. (2017) applied a neural network structure on dissolved oxygen levels in the River Danube. Within this context, four models were used. In order to estimate dissolved oxygen, multivariate linear regression, multilayer perceptron neural network, radial basis function network and general regression neural network models were developed. Another dissolved oxygen prediction study was carried out by Olyaie et al. (2017). In their study, they used two types of ANN structures, namely multi linear perceptron and radial basis functions. Moreover, linear genetic programming and support vector machine (SVM) were also proposed to estimate dissolved oxygen levels in the River Delaware. An extreme learning machine technique was used to predict dissolved oxygen concentration with and without water quality parameters by Heddam and Kisi (2017). Their study compared a standard extreme learning machine with a sigmoid activation function (S-ELM), an extreme learning machine with a radial basis function (R-ELM), an on-line sequential ELM (OS-ELM), and an optimally pruned extreme learning algorithm (OP-ELM). Temperature, specific conductance, turbidity and pH were used as the input variables. In the study without water quality parameters, year, month, day and month numbers were used as predictors. Using extreme learning machines for river water quality parameters is quite limited in literature.

We compared three data-driven approaches to predict TOC concentration from data collected from real-time monitoring stations. Extreme learning machine (ELM), kernel extreme learning machine (KELM) and artificial neural network (ANN) modelling methods were used to predict TOC. TOC is one of the most important pollution parameters in the topic of river water quality and measurement of this parameter is more

expensive than measuring other parameters. This state is important to reduce the costs of building stations. According to the results of our statistical analysis, KELM was better than the artificial neural network and ELM.

2. Data collection and modelling studies

A real-time central river monitoring system was built to monitor river pollution. The system involved two in-situ on-line monitoring stations. One of the stations was positioned in the Aynalı Cave region after the sewage system and Tersakan stream, while the other one was stationed at the Administration of Hydraulic Works' Durucasu station which had a 26.876 km distance from the first station and after the yeast factory. Furthermore, a central monitoring office was designated at Ankara University. The data were collected in a database at the station. The data were transferred from the stations to the central office in Ankara through a GPRS transmission channel as shown in Figure 1 and continuously monitored and displayed in different formats.
Figure 1. The locations of the on-line measurement stations and the data collection process

The study area has various pollution sources such as industrial, domestic, municipal and agricultural run-off. Real-time data were measured at five-minute time intervals for the parameters of luminescent dissolved oxygen (LDO), pH, conductivity, nitrate nitrogen (NO_3-N), ammonium nitrogen (NH_4-N), TOC, o-phosphate, chloride, temperature, turbidity, suspended solid and flow rate.

2.1 Modelling Studies

2.1.1 Artificial Neural Network

An artificial neural network is a type of artificial intelligence technique, and it was inspired by the learning algorithm of the human brain. An ANN is composed of a large number of processing elements with their connections, and it has three distinctive layers, namely input, hidden and output layers as shown in Figure 2.
Figure 2. Artificial neural network structure

These layers are called the basic elements of architecture and known as nodes/neurons. Connection of nodes is achieved with synapses, and each node has a weight factor. In an

artificial neural network design, signals are passed through the neurons, and simultaneously, the weights and transfer functions are modified, and this process is repeated until a broad output is reached. The numbers of neurons numbers in each layer is determined depending on the structure of the problem.

In this study, we used data for the one-year period of 2007-2008. Especially outlier detection, which was coded in MATLAB, was carried out to sort out the data that deviated from the normal value. The 70% and 30% of the remaining data were used for training and testing respectively. At the stage of artificial neural network modelling, a feed-forward neural network architecture was designed. Feed-forward neural networks have been shown to be an effective neural design for forecasting water quality parameters. The numbers of neurons in the input layer, hidden layer and output layer determined as 4, 25 and 1 respectively. In the training network, number of iterations, degree of training, number of neurons were determined by using a trial and error approach as in training of most network architectures. The transfer function was selected as tangent-sigmoid, and in the training of the network, a Bayesian Regularization Backpropagation (*'trainbr'*) algorithm was used. *trainbr* is a network training function that updates the weight and bias values based on the Levenberg-Marquardt optimization. It minimizes a combination of squared errors and weights, and then, determines the correct combination to produce a network which generalizes well. This process is known as Bayesian regularization.

2.1.2 Extreme Learning Machine

Extreme Learning Machine has become a new method developed in recent years (Huang et al. 2006). In the proposed method, learning algorithms, hidden node weights and biases randomly assigned and need not to be tuned, as well as output weights, are calculated by a simple inverse operation. Due to these properties and less human intervention, ELM provides an extremely fast learning speed and better generalization capability in comparison to traditional learning algorithms. However, ELM is not capable of managing large amounts of data with a high number of dimensions. The number of nodes of the ELM that was required was higher than those of traditional algorithms. So, in this study, we used five different activation functions and numbers of neurons in the ELM. These activations functions were triangular radial basis (*'tribas'*), radial basis (*'radbas'*), hard limited (*'hardlim'*), sigmoidal (*'sigmoid'*) and sinusoidal (*'sine'*) functions. In the KELM, the RBF kernel and linear kernel functions were used as activation functions in the presence of different numbers of neurons. The schematic representation of the extreme learning machine is given in Figure 3.
Figure 3. ELM architecture

The algorithm of ELM is given in the following steps (Ding et al. 2014)

Input: a training set $(x_i, t_i) \in R^n x R^m (i = 1, 2, ...N)$, activation function and number of neurons in the hidden layer (N); Output: the output weights, β (the output weights between the hidden and output layers which is calculated with Moore Penrose inversion as given in the last step)

Step 1: Randomly assign the parameters of the hidden layer

Step 2: Calculate the output matrix of the hidden layer

Step 3: Calculate the output weight β=H† T

According to these steps, we may say that ELM includes two phases: in the first phase, the hidden layer is initialized by ELM so that the input data can be mapped into a feature space. In the second phase, solution of β (linear parameters) is calculated by Moore Penrose inversion.

2.1.3 Kernel Extreme Learning Machine

In the kernel-based extreme learning approach, kernel functions are used as activation functions in the hidden nodes. In KELM, feature mapping is unknown, and the kernel matrix of ELM based on Mercer's condition can be defined. There are many types of Kernel functions that can be used. The most commonly used one of these are gaussian kernel, linear kernel, hyperbolic tangent kernel, radial basis function and polynomial kernel functions. In this study, RBF kernel and Linear Kernel functions were used.

2.1.4 Partial Least Square Regression (PLSR)

Partial least square regression is a generalization form of multiple linear regression. In this method, collinear, correlated, noisy and numerous X-variables can be analyzed according to this several response variables Y can also be simultaneously modelled.

3. Results and Discussion

In this study, three different artificial intelligence techniques were used to determine total organic carbon in the River Yeşilırmak. For this purpose, we used five different activation functions and numbers of neurons in ELM. These activation functions were triangular radial basis, radial basis, hard limit, sigmoidal and sinusoidal functions. The best result in ELM was obtained in the presence of the tribas activation function, and the number of neurons in the hidden layer was 350. In KELM, RBF kernel and linear kernel functions were used as activation functions in the presence of different numbers of neurons. In this study, 150 neurons were used, and a radial basis function was selected. The artificial neural network test was carried out with 4, 25 and 1 neurons in the input, hidden and output layers respectively.

The kernel-based extreme learning machine provided the best result. A kernel-based extreme learning machine is a powerful learning algorithm in comparison to an extreme learning machine and an artificial neural network. In fact, the ELM technique has many advantages, but ELM is not capable of managing data with high numbers of dimensions. In this case, ELM needs more nodes than traditional learning algorithms. In KELM, kernel functions were used instead of activation functions as shown in Table 1. Moreover, for KELM, it was not needed to choose the number of hidden neurons, and feature mapping was not needed to be known. KELM had the same generalization, but it was more stable than ELM. The performances of the models were tested by the results of statistical analysis as correlation coefficient (R), root mean square error (RMSE) and

mean absolute percentage error (MAPE%). The results of the statistical analyses are given in Table 1.

Table 1. Statistical performance indices of the modelling techniques

Modelling techniques	Activation Function	Number of Neurons	Training			Test		
			RMSE	MAPE (%)	R	RMSE	MAPE (%)	R
Kernel ELM	RBF Kernel	150	0.532	1.58	0.995	0.968	3.01	0.984
ELM	Triangular Basis	350	1.374	6.40	0.967	1.764	8.22	0.947
ANN	Tangent Sigmoid	25	1.430	6.09	0.966	1.430	6.48	0.965
PLSR	--	--	3.638	20.23	0.750	3.647	20.31	0.740

4. Conclusion

In this study, three different artificial intelligence techniques were used to predict the total organic carbon concentration in the River Yeşilırmak in Turkey. Actually, the River Yeşilırmak is the most important water resource considering its agricultural potential and other human activities. 12 river water quality parameters were monitored in two on-line measurement stations, but among these monitoring total organic carbon raised the cost considerably. For this reason, prediction of total organic carbon from the other parameters that are cheaper than directly measuring TOC significantly reduced the cost of building stations. The results showed that the kernel-based extreme learning machine is a good tool to predict TOC concentration. This may be explained by the reduction of the cost of measuring stations with the developed algorithm. The extreme learning machine worse than Kernel ELM due to data size, and this method required a higher number of neurons than the traditional ANN algorithm as shown in Table 1. Although the generalization ability of a kernel ELM is the same as ELM, a kernel ELM has good stability. Additionally, PLSR algorithm has the worst scenario. In the next time, other ELM and different kernel ELM structures will be used to predict river water quality parameters.

Abstract

A modelling framework focusing on the treatment of uncertainty is proposed. The framework is based on Julia, given that it is an open-source, modern, computationally efficient language (scripted but with just-in-time compilation) providing support for the design of domain specific languages via abstract types, multiple dispatch, operator overloading and full Unicode support. The framework provides a concise and natural syntax, allowing for a traditional mathematical notation. For instance, users can write $t = 700 \pm (3\delta)$ (uncertainty range), $X \sim \mathcal{N}\left(\mu, \sigma^2\right)$ (probability distribution) or $F_0 = V^3 + [21.3, 21.7]$ (interval arithmetic) without having to compromise between speed and code readability. A case study on the scale-up of an Aerosol-Assisted Chemical Vapour Deposition (AACVD) process is presented to exemplify the use of the framework.

Keywords: Modelling language, uncertainty, process modelling.

1. Introduction

The formulation of engineering processes has different stages. Importantly, uncertain parameters can be found from the synthesis and design through to the process operation. The ubiquity of uncertainty can be explained by its many sources, such as conceptual modelling errors (wrong or incomplete assumptions, simplifications, wrong equations); unknown consequences that depend on future events; imprecise decision-maker preferences; etc. Therefore, treating uncertainty is a key element in process modelling. Even though process simulation systems (e.g. Aspen, Hysys, gPROMS) and/or modelling systems (e.g. GAMS, AIMMS, AMPL) have made it easier for practitioners to apply process systems engineering methodologies to industrial applications, the treatment of uncertainty is not always straightforward. There is, therefore, a necessity of further research on the development of tools aimed at the modelling of uncertainty.

This paper proposes a framework characterised by methods and operators which allow users to easily write down models with intrinsic parameter uncertainty or distributed quantities and evaluate these models. Such a framework has the final goal of becoming a computational modelling language for incorporating uncertainty in mathematical modelling and also supporting communication with currently available modelling and simulation systems. The next sections present the background in uncertainty modelling; introduce the framework, and present examples to show the ease with which models can be developed. This includes a case study on the scale-up of an Aerosol-Assisted Chem-
Figure 1: Schematics of the AACVD process, including the atomisation of the solution containing the reactants, the aerosol transport, the chemical deposition and the film formation.

ical Vapour Deposition (AACVD) process. Such a process, schematically represented in Figure 1, can be summarised as a deposition method employed to produce high-quality, high-performance, solid materials. The process is often applied in the semiconductor industry to produce thin films, such as Transparent Conducting Oxides, used from personal digital devices through to solar panels.

2. Uncertainty in Computational Models

Uncertainty is ubiquitous in process design, given that there is always imperfect or unknown information where it is impossible to exactly describe all the parameters. Some of them may have a single exact value, which cannot always be known with precision, for example, transfer coefficients. Other parameters are themselves inherently distributed due to variability or heterogeneity, for example, the sizes of droplets generated by ultrasonic vibration. Both cases can be mathematically represented using the same approach, namely, probability theory. The strengths of this approach are exemplified by how straight forward it becomes to quantify and understand how likely different outcomes are and to visualise potential scenarios. There are a number of quantities which help decision makers to understand the impacts of uncertain variables, such as the mean, variance, skewness, upper and lower quantile values, confidence intervals, etc. Such information can also be represented graphically, using probability density functions or cumulative distribution functions. Once the uncertain parameters are modelled, all the pertinent information should be automatically provided by a computational tool focused on uncertainty representation.

The modelling of uncertainty is essential in process design and optimisation, evidenced by Grossmann et al. (2016), who also shared some challenges in the field. In particular, they showed how important it is to develop tailored solution strategies, which can be facilitated when there is a framework that allows easy prototyping, especially with specific tools dedicated to representing uncertainty. Additionally, when dealing with uncertainty, running simulations helps to rationalise and explain the results from models. That can be done, for example, incorporating Monte Carlo experiments and the associated statistical
Figure 2: Current type hierarchy of the Uncertainty.jl framework.

methods into the stochastic models. A modelling language focused on the treatment of uncertainty would, therefore, be helpful to facilitate writing, running, maintaining and sharing computational models.

3. Uncertainty.jl

This paper introduces the Uncertainty.jl framework, a high-level interface to represent uncertainty in process modelling, built to address some of the challenges previously mentioned. The framework is user-friendly and straight forward to be employed, aiming therefore at users who are not experts in computer programming. It was written in Julia[1] for a number of reasons. Firstly, Julia is a high-level, high-performance, dynamic language, which allows both large-scale computation and flexible prototyping without having to simultaneously use two or more languages; for example, many engineers use MATLAB (high-level, but slow) and C (fast, but low-level) at the same time. On the other hand, Julia is a high-level language and yet has been shown to at least approach the performance of C (Bezanson et al., 2017). Finally, the users of Uncertainty.jl can also join the large and active community of Julia and have access to a vast and growing number of packages focused on scientific computing, which they can employ and, when necessary, extend.

Chen and Grossmann (2017) outlined the current trend of allowing modellers direct access to model objects, which are easily created using Uncertainty.jl within Julia. This facilitates code sharing and the generation of models that are more readable and easier to validate. However, the main advantage is the use of Julia's multiple dispatch feature, allowing the overloading of generic functions using different type signatures (Zappa Nardelli et al., 2018). This gives a greater expressive power, since additional code can be written in a concise and clear style. Function calls will be dispatched to the relevant method, according to the type signature.

Another advantage of using multiple dispatch is how straight forward it becomes to extend any of the Julia packages already available. For example, Algorithm 1 shows how Uncertainty.jl extended the ODEProblem function, from the package DifferentialEquations.jl (Rackauckas and Nie, 2017). It now became possible to input uncertain parameters, which can be intervals or probability distributions, before solving the differential equations. Uncertainty.jl currently has the object hierarchy shown in Figure 2, which takes advantage of Julia's multiple dispatch. This allows, for example, that the appropriate ODEProblem method will be called according to the types of the input variables as follows: if the uncertain variables are all of the Interval type, Latin hypercube sampling will be used to generate samples. If there is a mix of intervals and probability distributions, a random

sampling will be performed. The differential equations are then solved using the generated samples from the uncertain variables, according to their distributions. The output will itself be a distribution built from the solutions of the ODEs. The relevant statistics are also automatically provided. The framework also includes methods to perform sensitivity and uncertainty analysis for the whole model or its parts.

```
1    δ = 20
2    x = 700 ± 3δ
3    y = x + [20, 50]
   y ∨ Interval
          min → 660
          max → 810
```

Figure 4: Example of consecutive operations using interval arithmetic. The final output is in grey, at the bottom. Screenshot from Atom editor.

Uncertainty.jl allows users to take advantage of the full expressiveness of the Julia programming language while writing their models, supporting all of the basic Julia arithmetic operators, Boolean operators, and comparison operators, which are similar to C. However, Uncertainty.jl also defined and/or extended some operators to perform specific tasks. For example, the $\sim$ operator was defined for declaring a random variable following a specific probability distribution, as exemplified in Figure 3. Uncertainty.jl also supports interval arithmetic, allowing the user to perform operations such as the ones shown in Figure 4. Additionally, the operator $\pm$ was also defined, acting on real numbers to produce an interval, which can then be used in any further interval arithmetic operations. Finally, independent model evaluations, including the solution of differential equations, are intrinsically compatible with parallel computing, easily done in Julia.

4. Case Study: Aerosol-Assisted Chemical Vapour Deposition

In the context of the AACVD process, the first step is to atomise a solution containing the reactants, generating the aerosol that will be transported to the reaction chamber. As seen in Figure 1, the aerosol is characterised by droplets of different sizes, which should be accounted for by the models, since the droplet sizes impact the loss of aerosol during transport and the solvent evaporation in the reactor. Details about the modelling and experimental validation of the aerosol transport system, accounting for the distributed nature of the droplet sizes, were previously presented by Filho et al. (2017). Subsequently, the uncertainty and sensitivity analysis of the overall AACVD system, including the aerosol generation, transport and delivery to the reaction chamber was performed by Filho et al. (2018). Finally, when the aerosol reaches the reaction chamber, the solvent evaporates and chemical reactions take place, resulting in the film formation. Equation 1 represents

---

Algorithm 1 Overloading the function ODEProblem from the DifferentialEquations.jl package. The function generateSamples identifies which parameters are exact and creates samples for the uncertain parameters.

Input: set of differential equations **f**; initial condition **u$_0$**; time interval **t$_{span}$**; set of exact and uncertain parameters **allParameters**.

Output: inferred probability distribution and its properties using the solutions of the ODEs system.

```
1        function ODEProblem(f, u₀, tspan, allParameters)
2            samples := generateSamples(allParameters);
3            sol := { };
4            for each exactParameters ∈ samples do
5                prob := ODEProblem(f, y₀, tspan, exactParameters);
6                sol := sol ∪ {solve(prob)};
7            end for
8            distribution := inferDistribution(sol);
9        return distribution;
```

---

general chemical reactions, where the film is formed mainly by the component D:

$$A_{(g)} \xrightarrow[k_1]{\text{gas}} B_{(g)} + C_{(g)}, \qquad B_{(s)} \xrightarrow[k_2]{\text{surface}} C_{(s)} + D_{(s)}, \qquad A_{(s)} \xrightarrow[k_3]{\text{surface}} 2C_{(s)} + D_{(s)} \tag{1}$$
Although these equations are general, Vallerio et al. (2016) used them specifically for the production of high-grade polysilicon, using monosilane as the reactant. Performing mass balances, the dynamic model equations for the CVD reactor is shown in Equation 2:

$$\frac{dC_i^g}{dt} = \frac{\dot{F}_{in}}{V} \cdot C_i^{in} - \frac{\dot{F}_{out}}{V} \cdot C_i^g - h_{m,i} \cdot \frac{A}{V} \cdot \left(C_i^g - C_i^s\right) - k_j \cdot C_i^g \tag{2}$$

where C_i^g $\left[\text{mol/m}^3\right]$ and C_i^{in} $\left[\text{mol/m}^3\right]$ are, respectively, the gas phase concentration and the inlet feed concentration of component i; C_i^s $\left[\text{mol/m}^3\right]$ is the volumetric concentration of component i on the surface of the glass, whose thickness grows with time, t $[s]$; $\dot{F}_{in}$ $\left[\text{m}^3/\text{s}\right]$ and $\dot{F}_{out}$ $\left[\text{m}^3/\text{s}\right]$ are, respectively, the inlet and outlet volumetric flow rates; k_j [units vary] is the kinetic constant of reaction j, in the gas phase or on the surface; $h_{m,i}$ [m/s] is the gas to solid phase mass transfer coefficient of component i; V $\left[m^3\right]$ is the volume in which the gas phase reactions take place; and A $\left[m^2\right]$ is the glass surface area in contact with the gas.

```
1    (k₁, μ, σ²) = (ProbabilityDistribution(), 25, 4)
2    (k₂, Range₂) = (ProbabilityDistribution(), [150, 250])
3    (k₃, Range₃) = (ProbabilityDistribution(), [0.03, 0.05])
4
5    k = [k₁ ~ 𝒩(μ,σ²), k₂ ~ 𝒰(Range₂), k₃ ~ 𝒰(Range₃)]
6    h = [Interval(100, 300), Interval(4, 20), Interval(20, 50)]
```

Figure 5: Defining the uncertain parameters, namely the three reaction kinetic constants and the three mass transfer coefficients, before solving the system of ODEs.
Figure 6: Plot showing the likelihood regions of the concentrations of components A and D, given the uncertainties in the model parameters. The darker the region, the more likely it is to represent reality.

The reaction rate constants and the mass transfer coefficients are usually quantified experimentally or using correlations from the literature. Such coefficients are known for their uncertainties and can be represented using probability distributions. Figure 5 shows how straight forward it is to define uncertain variables using Uncertainty.jl. Once k and h are defined, they can join any additional exact parameters to be the input for the ODEProblem function, which will return a distribution. Figure 6 shows a plot exemplifying how the information from the output can be visualised. Using similar visualisation tools and the statistics returned by Uncertainty.jl, users can understand what the most likely values of the variables are and make educated decisions.

5. Conclusions and Future Work

This paper introduced Uncertainty.jl, a user-friendly environment for the modelling of uncertainty. The examples provided, the case study on AACVD and the obtained solutions demonstrated the viability of this prototype language. Much more is required, especially in terms of incorporating existing methods for handling uncertainty. Future work will address, for example, the representation of model uncertainty. It will also facilitate and encourage the use of Machine Learning in the context of process modelling, from additional Monte Carlo algorithms through to defining and learning models using inference algorithms and probabilistic programming. Finally, Uncertainty.jl aims at supporting optimisation algorithms and the communication with the most established modelling platforms, such as GAMS, AMPL and gPROMS.

Abstract

One-third of the edible parts of food produced for human consumption is lost or wasted globally, amounting to 1.3 billion tonnes per year. Food waste contains many constituents, which makes it a promising source for fuels and chemicals production. Moreover, the State of Qatar, which is situated in a hyper arid region is characterized by a disproportionate distribution of resources. It is rich in natural energy resources, but suffers from water scarcity and its natural environment does not encourage food production. Qatar's economy continues to expand rapidly and faces a number of environmental challenges which include the management and disposal of wastes that are generated by industrial and domestic activities. As such, the pyrolysis of biomass waste and food waste specifically is a viable option to transform waste, which would have otherwise been disposed into the natural environment, into value-added products which can be utilized to enhance resource efficiency, especially water. In this work, the pyrolysis of different food waste has been simulated using Aspen Plus software to produce value-added biochar products. The pyrolysis of food waste in steady-state mode has been studied using a yield reactor, in the 300−600 °C temperature range, by feeding five types of food waste with different ultimate and proximate properties. In addition, the optimum feedstock is identified in which the objective is to optimize food waste blends for maximizing solids to syngas ratio. The optimization results indicated an increase in the yield of the solid biochar product from 36.56% to 41.81%, while both the ash and carbon content decreased slightly. These findings open the doors to the transformation of food waste into value-added biochar via pyrolysis. Furthermore, the produced chars can be utilized in carbon sequestration when applied as soil amendment and as precursors for higher value-added products such as adsorbents.

Keywords: Food Waste, Pyrolysis, Biochar, Simulation, Optimization

1. Introduction

With the predicted increase in population to 9.8 billion by 2050 according to UNO, the world is inevitably facing multiple dilemmas. Human and industrial activities are responsible for the creation of most types of waste. Urban and industrial wastes need to be managed sustainably if we are to avoid serious, lasting effects such as global warming. Furthermore, food waste is generated in abundance globally with estimated losses of 1.3

billion tonnes per year (Gustavsson et al., 2011) and hence it constitutes an attractive source for the recovery of energy and the production of value-added products (e.g. fuels and chemicals).

Pyrolysis is a promising thermochemical conversion method (Panwar et al., 2012; White et al., 2011) that transforms biomass into value-added products. In this process, biomass is heated to temperatures greater than 400 °C, under the partial presence of/or the complete absence of oxygen (Laird et al., 2009). The main products of the process are bio-oil, bio-gas, and biochar. There is a wide range of applications of the highly porous material and their composites that are produced by pyrolysis, which include their use as supercondensers, catalytic support materials, and adsorbents (Gordienko et al., 2017).

Many soils suffer from water deficiency and low soil fertility (Basso et al., 2013; Koide et al., 2015). Therefore, it is essential to improve soil fertility in order to achieve food security. Biochar, a product of the thermochemical conversion of biomass, can be implemented into soils as an enhancer that improves the fertility and quality of agricultural soils while enhancing the sustainability of biomass and crop production (Zhang et al., 2016).

The use of Aspen Plus in simulating the pyrolysis of waste streams, particularly municipal green waste, was previously demonstrated (Kabir et al., 2015). In their pyrolysis study, they investigated the production of bio-fuel from Australian municipal green waste (MGW) and then validated the simulation results against experimental results. The objective of this paper is to simulate the pyrolysis of different food wastes that are available in the State of Qatar using Aspen Plus software with the aim of producing a value-added biochar product. The pyrolysis of food waste in steady-state mode has been studied using a yield reactor, in the 300−600 °C temperature range, by feeding five types of food waste with different ultimate and proximate properties. The food waste includes banana peel, mango endocarp, orange peel, tea waste and cooked rice.

2. Methodology

2.1. Data: Proximate and Ultimate Analysis

The problem formulated in this study is based on experimental data obtained from the literature for food items that are available in the state of Qatar. Table 1 summarizes the proximate and ultimate analyses of the different food wastes considered here.

Table 1: Proximate and ultimate analyses of biomass (food waste) feedstocks

2.2. Modelling and Simulation

2.2.1. Model Development

The base model developed in this work and used in the generation of the carbon-rich biochar solid is based on the pyrolysis of different feedstocks. Moreover, the simulation software is composed of several unit operation blocks which are models of specific process operations (e.g. reactors). The blocks were placed on a flowsheet through the specification of material and energy streams. The pyrolysis of food waste in this study is modelled based on the assumptions of steady state, kinetic-free equilibrium model, isobaric process, neglected pressure drops, and neglected tar formation. Moreover, the RYield reactor type was used to convert the feed material into its constituent elements (i.e. pyrolysis part of the modelling) through using the calculator block formulation from (AlNouss et al., 2018), while the nonstoichiometric Gibbs free energy equilibrium-based splitter model was used for solid yield separation.

2.2.2. Simulation of the Results

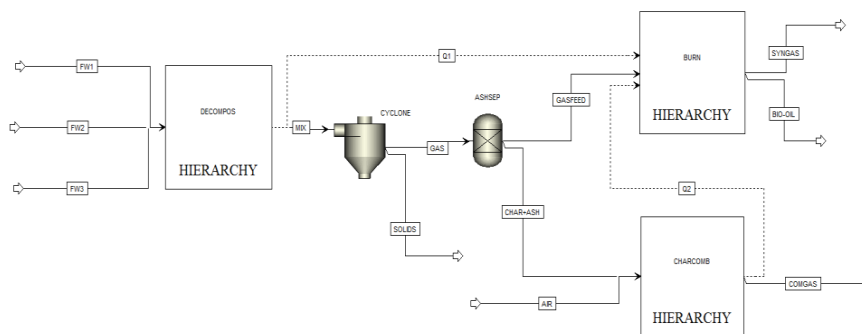
A computational model has been developed in this study to simulate this process using Aspen Plus software. Aspen Plus is a process-oriented software that facilitates calculation of physical, chemical and biological parameters (Puig-Arnavat et al., 2010). It can handle solid, liquid and vapour phases in the process. The process simulator does not have a built-in pyrolysis model; however it contains a number of built-in unit block models which enable the realistic specification of processes (Kabir et al., 2015). A pyrolysis process diagram is presented in Figure 1. An Aspen Plus model was developed based on this pyrolysis process flow diagram. The function of each block is summarized in Table 2.


Figure 2: Aspen plus flowsheet of the food waste pyrolysis

CYCLONE	Cyclone	Simulates the separation of bio-char using cyclone

Block ID	Aspen name	Description
ASHSEP	Sep	Separates gases from ash and small part of carbon by specifying split fraction
CHARCOMB	Stoic	Simulates combustion of carbon and ash to provide heat
BURN	RGibbs	Simulates the separation of syngas and bio-oil using flash separator and further syngas pyrolysis through Gibbs reactor restricting chemical equilibrium

2.2.3. Process Optimization

After the development of the pyrolysis model, the five food waste feedstocks were optimized to determine the optimum blended stream. The objective of the optimization problem is to maximize the solids to syngas ratio. The optimization equations are as below:

$$\text{Maximize} \quad \frac{Solid}{Syngas} \qquad \text{Eq. (1)}$$

$$\text{Subject to} \quad \sum_{i=1}^{n} x_i = 1 \forall i \in BiomassSources \qquad \text{Eq. (2)}$$

Where, Solid is the molar flowrate of the generated biochar, Syngas is the molar flowrate of the generated H_2-rich synthesis gas, and x is the blending fraction of each biomass feedstock.

3. Results and Discussion

The developed model has been tested against data provide in Table 1 in order to find the optimum blended feedstock. The results before and after the optimization are presented in Table 3 and Table 4 respectively.

Table 3: Results for Biomass Feedstock Blending without optimization at original moisture content

Total Biomass Input (kg/h)	5000 (1000 each biomass)		
LHV (MJ/kg) Input (dry basis)	12.94		
	Solids	**SYN**	**Oil**
Output (kg/h)	1828	3172	0.3700
N_2	0.0000	52.38	0.0000
O_2	0.0000	1871	0.0000
H_2O	0.0000	1015	0.0000
S	0.0000	0.9400	0.0000
H_2	0.0000	232.5	0.0000
C	1628	0.0000	0.3700
ASH	199.8	0.0000	0.0000
% Yield (kg/kg input)	36.56	63.43	0.0100
Energy Requirement (T=500 ºC)	DECOMP	CHARCOMB	BURN
Heat Flow (kJ/h)	31.08	2.900	-28.40

It could be noticed that the use of Cyclone has driven almost all the carbon and ash to the solid biochar flow. In addition, the reported composition of syngas is before utilizing it for further pyrolysis through Gibbs free energy.

Furthermore, a restriction on the modelling terms of the maximum amount of any of the feeds used has been identified. The results are highlighted in Table 4. The model results

demonstrated almost an equal amount of the 4 feed waste streams (2 through 5) as optimum blend. This reflect the amounts of carbon and ash per pure feed stream that these streams contain. Where, Banana peel contains around 41% (carbon+ ash), Mango endocarp (41%), Orange peel (40%), Tea Waste (45%) and cooked rice (16%). From this analysis it is clear that cooked rice has the lowest Carbon and Ash content and the highest moisture content and it is not of an interest.

Table 4: Results for Biomass Feedstock Blending with optimization at original moisture content

Total Biomass Input (kg/h)	3984.90				
Biomass Blends	FW1	FW2	FW3	FW4	FW5
	24.70%	25.10%	25.10%	25.10%	0.0000%
LHV (MJ/kg) Input (dry basis)	12.48				
	Solids	**SYN**	**Oil**		
Output (kg/h)	1666	2318	0.4400		
N_2	0.0000	46.66	0.0000		
O_2	0.0000	1699	0.0000		
H_2O	0.0000	369.3	0.0000		
S	0.0000	0.0200	0.0000		
H_2	0.0000	203.1	0.0000		
C	1469	0.0000	0.4400		
ASH	196.7	0.0000	0.0000		
% Yield (kg/kg input)	41.81	58.18	0.0100		
Energy Requirement (T=500 ºC)	DECOMP	CHARCOMB	BURN		
Heat Flow (kJ/h)	26.12	2.310	-24.79		

According to the results, prior to optimization, a percentage by weight of biochar obtained is 36.56 % w/w. The results of the optimization then improve to reach a yield of 41.81 % w/w biochar when a total food waste input of 3984.90 kg/h and a contribution of ~25 % w/w of each food waste except cooked rice is implemented. With respect to the ash and carbon contents of the produced biochars through the simulation, it can be observed that there is a slight reduction in their quantities (see Table 3 and Table 4).

With drying all the food waste streams to a maximum of 9.000 % moisture content and still restricting the flow of each food waste to 1000, the results showed equal distribution for all the feedstock. The drying energy requirement for the different food wastes were estimated at 0.1500, 0.0000, 0.0400, 0.0700 and 7.170 kJ/h, respectively. When releasing the restriction on the flow of each food waste to high number (~10^5), the optimization yields a feed of only Tea waste. This can be explained since it contains the highest Carbon and Ash content and with the releasing of the feed constraint, it has dominated the result.

4. Conclusion

In this work, the pyrolysis of different food waste feedstocks is simulated using Aspen Plus software in order to obtain biochar products at optimum conditions. While producing the value-added products, the objective is to optimize the food waste blends for maximizing solids to syngas ratio. The base model developed in this work used in the generation of the carbon rich biochar solid is based on the pyrolysis of different feedstocks with different ultimate and proximate properties and that are available in the State of Qatar. The results of the optimization indicated an increase in the yield of the solid biochar product from 36.56 % w/w (1000 kg/h of each of the food wastes as initial input) to 41.81 % w/w (food waste input of 3984 kg/h and ~25 % w/w of each food waste except cooked rice), while both the ash and carbon content decreased slightly. These findings are promising because they open doors to the transformation of the abundant amounts of food waste that are available globally into value-added biochar via pyrolysis.

Furthermore, the produced chars can be utilized in carbon sequestration when applied as soil amendment and as precursors for higher value-added products such as adsorbents.

Abstract

The pooling problem is a widely studied case study in global optimization. To date, it has largely been treated deterministically, neglecting the influence of parametric uncertainty. This work introduces a robust optimization formulation of the standard pooling problem with uncertain component concentrations. The quality constraints in which these uncertain parameters occur are non-linear and non-convex in the decision variables — something which has rarely been explored in the context of robust optimization. The resulting reformulation is a global optimization problem with the complexity determined by the selected uncertainty set. We compare the computational performance of three commonly used uncertainty sets on 14 pooling problem instances and demonstrate how accounting for uncertainty changes the optimal solution.

Keywords: robust optimization, global optimization, pooling problem

1. Introduction

The widely studied pooling problem has applications in oil and gas refining, water systems, supply chains, and more (Misener et al., 2011). It consists of optimizing material flow through a network of sources, pools, and terminals. Due to bilinear mixing terms at the pools it is non-linear and non-convex and is known to be NP-hard (Alfaki and Haugland, 2013). The pooling problem has frequently been used as a case study in global deterministic optimization (e.g. Floudas and Visweswaran, 1990; Meyer and Floudas, 2004; Quesada and Grossmann, 1995; Tawarmalani and Sahinidis, 2004; Wicaksono and Karimi, 2008; Gounaris et al., 2009; Misener and Floudas, 2010; Alfaki and Haugland, 2013; Baltean-Lugojan and Misener, 2018). Parameters of the pooling problem can be subject to uncertainty. In particular, the concentrations of components and pollutants entering the system can be subject to measurement errors and/or fluctuations over time. These concentrations will have a large effect on product quality at the terminals, which is often subject to constraints. Violating these constraints can have a negative impact on profit, health and safety, or the environment.

Nonetheless, to the best of our knowledge, only Li et al. (2011, 2012b) and Li et al. (2012a) have considered uncertainty in the pooling problem to date. Li et al. (2011) consider component concentration uncertainties for the extended pooling problem and pooling network synthesis. They utilize a two-stage stochastic programming approach: the first stage determines the number of sources, pools, and product terminals developed and the connections between them. The second stage assumes the uncertainty has been realized and optimizes the pooling network production. Li et al. (2012b) propose a decomposition strategy for solving the stochastic program. Li et al. (2012a) apply robust optimization to demand uncertainty in the standard pooling problem. An advantage of the robust approach is that the increase in problem complexity is moderate and no decomposition is required (Grossmann et al., 2016).

This work applies robust optimization to uncertain component concentrations in the quality constraints of the standard pooling problem. The process systems engineering community has recently been increasingly interested in applying robust optimization to chemical processes (e.g. Gounaris et al., 2013; Zhang et al., 2015; Janak and Floudas, 2005; Vujanic et al., 2016; Li and Ierapetritou, 2008; Ning and You, 2017; Shang and You, 2018). Most of these applications have been limited to linear models. The work by Li et al. (2012a) on the pooling problem is an early exception to this, even though the uncertain demand constraints considered are still linear. In fact, robust optimization in general is largely focused on problems which are convex in the decision variables and concave in the uncertain parameters (Ben-Tal et al., 2015). While concavity in the uncertain parameters is necessary for robust optimization reformulation, the restriction on convexity is largely due to a focus in the robust optimization literature on applications which are solvable in polynomial time. "Robust optimization" problems which are non-convex in the decision variables and non-concave in the uncertain parameters can generally only be addressed with semi-infinite programming.

In this work, we are interested in constraints which are non-convex in the decision variables but concave in the uncertain parameter, as is the case for the quality constraints in the standard pooling problem. Robust optimization reformulation can be applied to these constraints, but the result is a global optimization problem. In Section 2, a robust formulation for the standard pooling problem is derived. Section 3 demonstrates the computational complexity of the resulting problem for box, ellipsoidal, and polyhedral uncertainty sets and how the optimal flows in the network change when varying degrees of uncertainty are considered.

2. A robust pooling formulation

We consider the q-formulation of the standard pooling problem (Haverly, 1978) in which the uncertain component concentrations only occur in the quality constraints. This formulation is favorable for robust optimization because the uncertain parameters do not occur in any equality constraints. The robust counterpart of the uncertain quality constraint is

$$
\sum_{\substack{l:(l,j)\in T_Y \\ i:(i,l)\in T_X}} \tilde{C}_{i,k} \cdot q_{i,l} \cdot y_{l,j} + \sum_{i:(i,j)\in T_Z} \tilde{C}_{i,k} \cdot z_{i,j}
\begin{cases}
\geq P_{j,k}^L \left(\sum_{l:(l,j)\in T_Y} y_{l,j} + \sum_{i:(i,j)\in T_Z} z_{i,j} \right) \\
\leq P_{j,k}^U \left(\sum_{l:(l,j)\in T_Y} y_{l,j} + \sum_{i:(i,j)\in T_Z} z_{i,j} \right)
\end{cases}
, \forall j,k, \tilde{C}_{i,k} \in \mathcal{U}_p,
$$

(1)

where $\tilde{C}_{i,k}$ is the uncertain concentrations of component k in source i, $P_{j,k}^L$ and $P_{j,k}^U$ are their lower and upper limits at pool j respectively, and $\mathcal{U}_p$ is the uncertainty set. The decision variables are $q_{i,l}$, the fraction of flow to pool l from source i, $y_{l,j}$, the flow from pool l to terminal j, and $z_{i,j}$, the direct flow from source i to terminal j. The sets T_X, T_Y, T_Z describe the connections between sources, pools and terminals. By introducing the indicator function

$$
\mathbb{1}(s \in S) = \begin{cases} 1 & s \in S \\ 0 & s \notin S \end{cases}
$$

and rearranging, we can bring eqn. 1 into standard form

$$
\sum_i \tilde{C}_{i,k} a_{i,j} \begin{cases} \leq b_{j,k}^U \\ \geq b_{j,k}^L \end{cases} , \quad \forall j,k, \tilde{C}_{i,k} \in \mathcal{U}_p,
$$

where

$$a_{i,j} = \sum_{l:(l,j)\in T_Y} \left[\mathbb{1}\left((i,l)\in T_X\right) y_{l,j}q_{i,l} \right] + \mathbb{1}\left((i,j)\in T_Z\right) z_{i,j}, \text{ and} \tag{2}$$

$$b_{j,k}^{U/L} = P_{j,k}^{U/L} \left(\sum_{l:(l,j)\in T_Y} y_{l,j} + \sum_{i:(i,j)\in T_Z} z_{i,j} \right). \tag{3}$$

We define the uncertainty set $\mathcal{U}_p$ as

$$\mathcal{U}_p = \left\{ \tilde{C}_{i,k} = C_{i,k} + \hat{C}_{i,k}\xi_{i,k} \mid \|\xi_k\|_p \leq r \right\},$$

where $\xi_k = (\ldots, \xi_{i,k}, \ldots)^T$, $C_{i,k}$ is the nominal value of $\tilde{C}_{i,k}$, and $\hat{C}_{i,k}$ its maximum deviation. For $p = 1$ this corresponds to a polyhedral, for $p = 2$ to an ellipsoidal, and for $p = \infty$ to a box uncertainty set. For each set, standard robust optimization reformulation techniques can be used to obtain the deterministic equivalent of the robust counterpart:

$$\sum_i C_{i,k}a_{i,j} + r[\cdots] \leq b_{j,k}^u \qquad\qquad \forall j,k \tag{4a}$$

$$-\mu_{i,j} \leq a_{i,j} \leq \mu_{i,j} \qquad\qquad \forall i,j \tag{4b}$$

$$\left(\lambda_{j,k}^u \geq \hat{C}_{i,k}\mu_{i,j} \right) \qquad\qquad \forall i,j,k \tag{4c}$$

where $[\cdots]$ is $\sum_i \hat{C}_{i,k}\mu_{i,j}$ for $p = \infty$, $\sqrt{\sum_i \hat{C}_{i,k}^2\mu_{i,j}^2}$ for $p = 2$, and $\lambda_{j,k}^u$ for $p = 1$ and constraint 4c is only needed for $p = 1$. Substituting eqn. 2 for $a_{i,j}$ and simplifying gives

$$r[\cdots] \leq b_{j,k}^u - \sum_{\substack{l:(l,j)\in T_Y \\ i:(i,l)\in T_X}} C_{i,k}\cdot q_{i,l}\cdot y_{l,j} - \sum_{i:(i,j)\in T_Z} C_{i,k}\cdot z_{i,j} \qquad \forall j,k \tag{5a}$$

$$-\mu_{i,j} \leq \sum_{l:(l,j)\in T_Y} q_{i,l}y_{l,j} + z_{i,j} \leq \mu_{i,j} \qquad\qquad \forall(i,j)\in T_Z \tag{5b}$$

$$-\mu_{i,j} \leq \sum_{l:(l,j)\in T_Y} q_{i,l}y_{l,j} \leq \mu_{i,j} \qquad\qquad \forall(i,j)\notin T_Z \tag{5c}$$

$$\left(\lambda_{j,k}^u \geq \hat{C}_{i,k}\mu_{i,j} \right) \qquad\qquad \forall i,j,k \tag{5d}$$

where $[\cdots]$ is defined in the same way as above.

While the box and ellipsoidal uncertainty set both add $\mathcal{O}(|i|\cdot|j|)$ constraints, the polyhedral set adds $\mathcal{O}(|i|\cdot|j|\cdot|k|)$ constraints. An advantage of the polyhedral set, however, is that the problem remains bilinear, while the ellipsoidal set introduces a square root, which can be problematic numerically . Squaring each side of eqn. 5a avoids this, but the squared constraint is only equivalent if the nominal quality constraints (eqn. 1 with $\tilde{C}_{i,k}$ replaced by $C_{i,k}$) are added, increasing the total number of constraints once again.

3. Results

The robust formulation outlined above was applied to 14 instances from the literature (Adhya et al., 1999; Foulds et al., 1992; Ben-Tal et al., 1994; Haverly, 1978; Audet et al., 2004). The model was implemented in GAMS 25.1.2 and solved using ANTIGONE 1.1 (Misener and Floudas, 2014) on an i7-6700 CPU with 8×3.4GHz and 16GB RAM. Each instance was solved for 30 values of r using the box, ellipsoidal, and polyhedral uncertainty set with a time limit of 1 hr, a tolerance of 10^{-6}, and $\hat{C}_{i,k} = C_{i,k}$.

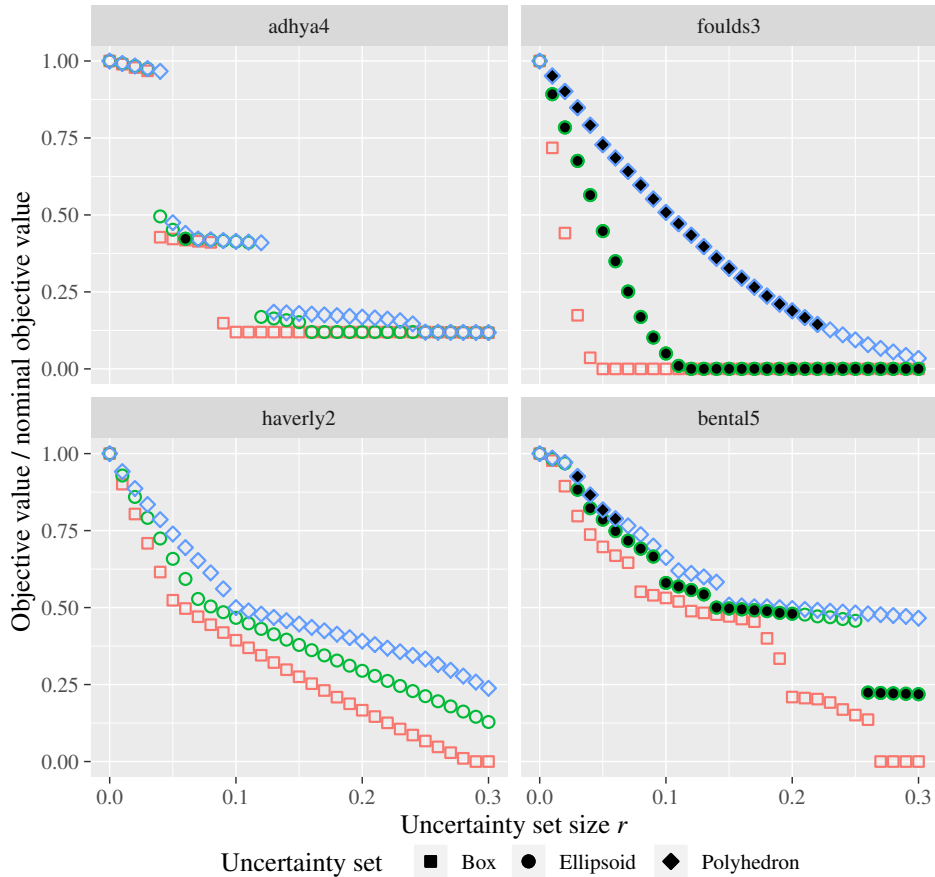
Fig. 1 shows the performance of each uncertainty set as a function of its size r for four representative instances. As expected, the fraction of the nominal objective value achieved decreases as


Figure 1: Objective value (relative to nominal case) for different uncertainty set types and sizes for four literature instances. Points filled black were not solved to global optimality within 1 hr.

the uncertainty set size r is increased. Since the polyhedral set is always smallest and the box set always largest, they consistently achieve the best and worst objective value respectively. For points filled in black the model could not be solved to optimality within 1 hr. Table 1 shows the fraction of instances solved for each uncertainty set. While the box uncertainty set could be solved for all instances, the polyhedral and especially the ellipsoidal cannot, due to the increased number of constraints for these formulations. The consistency between solutions which have and have not been solved globally indicates however, that in a lot of cases the global optimum (or a solution close to it) may have already been found though it has not been certified. For those instances which could be solved to optimality, Table 1 shows the median time taken across instances. While the box and polyhedral uncertainty set have very similar median times, the ellipsoidal set shows a moderate increase. The solution times for the box and polyhedral set are generally very close to the nominal case. As in linear robust optimization, the ellipsoidal set increases the complexity of the nominal problem, while the box and polyhedral set largely retain it.

Fig. 2 shows the obtained solutions for three different values of r for instance Adhya1 (Adhya et al., 1999) using a polyhedral set. The width of the arrows between nodes indicates the fraction of flow from/to each pool. Edges from a source to a pool are also labeled with this fraction, while edges from a pool to a terminal are labeled with the absolute flow. In the nominal case ($r = 0$),

Uncertainty set	% instances solved	median time [s]
Box	100	0.14
Ellipsoid	66	1.42
Polyhedron	83	0.15

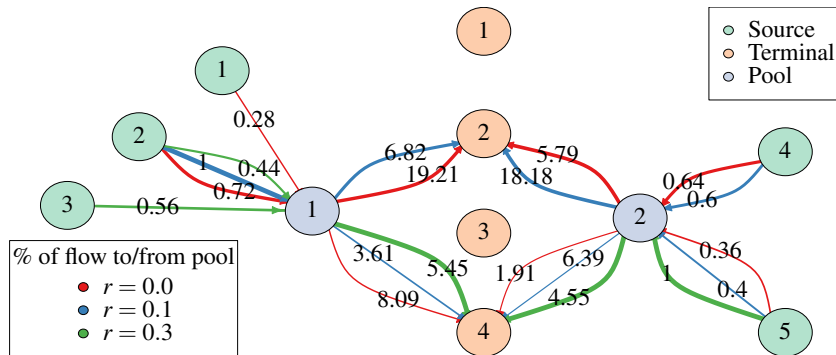
Table 1: Percentage of instances solved to global optimality within 1 hr time limit for different uncertainty set types.


Figure 2: Active source, pools, and terminals for three different uncertainy set sizes r using instance Adhya1 with the polyhedral uncertainty set. The width of the arrows shows the percentage of flow to/from each pool.

both product 2 and 4 are produced. As r is increased, hedging against more uncertainty, the total amount of products 2 and 4 produced remains constant, but the fraction coming from pool 1 increases drastically. The utilization of sources largely remains the same, with the exception of source 1. Once r is increased past 0.14, the quality of product 2 cannot be guaranteed anymore for all possible realizations of the uncertainty. This leads to a jump in the expected profit from 446.2 to 65.9. Similar jumps can be seen in Fig. 1 for instances Adhya4 and Bental5. In this regime, both sources 1 and 4 are replaced by source 3. All of this shows that optimal solution is clearly very dependent on how much uncertainty one wants to hedge against. In practice, the size of the uncertainty set therefore has to be determined based on the risk aversion of the decision maker.

4. Conclusion

Applying robust optimization to the non-convex pooling problem leads to a global optimization problem with increased complexity compared to the nominal case. The tractability of the resulting reformulation with global optimization solvers is highly dependent on the selected uncertainty set. While simple box uncertainty sets hardly increase computational time, more advanced ellipsoidal and polyhedral sets are more difficult to solve. The relevance of optimization under uncertainty is supported by the significant changes in the solution observed when different degrees of uncertainty are taken into account.

Abstract

Regulations and the public expectations on improving efficiency, reducing the carbon footprint and lowering the environmental impact drive the process industry towards improved operation and the development of new technologies. The efficiency of an existing production plant depends on a variety of factors like capacity utilisation, raw material quality, ambient temperature or operational performance. Identifying the influence of these factors on the performance of the plant helps to take suitable measures to drive it towards a more efficient operation. One approach to assess the resource efficiency potential of a plant is the comparison of the actual performance with the best possible operation under the given circumstances. This work presents a surrogate modelling approach for the identification of the best possible operation based on historical data. The surrogate model is compared to a more detailed rigorous model and advantages and possible shortcomings of the surrogate approach are discussed based on real production data at INEOS in Köln.

Keywords: Surrogate models, plant efficiency, energy management systems, model detail level, model identification

1. Introduction

The process industry is constantly developing methods for the evaluation of their resource consumption and the identification of possible improvement potentials. In cases where there are no structural changes of the process planned, on the one end this can be achieved by implementing Advanced Process Control (APC) solutions, which is time consuming and expensive. On the other end, there are well-trained operators who are often able to realize a significant fraction of the APC saving potential, if information on the magnitude of the performance gaps is accessible and the experience about how to improve the operational efficiency can be used. The international standard ISO50001:2011 demands the use of energy performance indicators (EnPI) which have to be compared with an energy baseline. The idea of the Best Demonstrated Practice (BDP), as shown

Figure 1: Illustrative example of the BDP concept

in Fig. 1, is similar and provides the operators with a performance reference model which represents the most resource efficient and stable production at a specific instance of non-influenceable

circumstances, as e.g. plant load. By comparing the real-time EnPI, which is defined as the specific steam consumption at a particular point in time in this example, with its BDP, the operational improvement potentials (OIP) can be identified (NAMUR WG 4.17, 2017).

2. BDP Model

The level of detail of the BDP models can vary from rigorous models to simple input-output models. The accuracy and the extrapolation capability of rigorous models are advantageous. However, the time and effort needed to develop these models is usually high. On the other end of the scale are input-output models based on linear regression which cannot always represent the complexities of the chemical processes properly.

An alternative to these two types of models are surrogate models (see e.g. Cozad et al. (2014)). In this modelling approach the process data is used to fit a model to the observations. The development of such models requires considerably less effort compared to the development of rigorous models and they are able to capture the plant behaviour better than linear regression models. Furthermore, the evaluation of the surrogate models is easier which makes them attractive for large scale optimisation (Søndergaard, 2003). On the downside, the validity of the surrogate models is limited to the range of the data that is used for their fitting and the results of the model for extrapolated data must be used with care.

2.1. Surrogate modelling procedure

This section briefly discusses the approach to surrogate modelling of the BDP curves that has been developed and implemented at INEOS in Köln. A detailed description of the procedure can be found in Beisheim et al. (2018). As depicted in Fig. 2, the method consists of five general steps. The first step is the acquisition of measurement data. The goal of this step is to collect representative and reliable measurements of the performance of the plant, where aspects as e.g. removal of gross errors, stationarity, selection of suitable sampling times and removal of abnormal operation windows have to be considered.

The second step is the preprocessing of the data. The goal of this step is to remove outliers, classify the data and to standardise. For the latter mean centring and unit variance scaling is used. Data standardisation is useful for the clustering of the data, which is explained in the next step.

The third step of the method is data clustering. The goal of this step is to reduce the large amount of the measurement data into a much smaller number of a few representatives of different operating regimes, which are then used for model fitting. In this work, the kmeans++ algorithm (Arthur and Vassilvitskii, 2007) is applied, which is an extension of the kmeans algorithm (MacQueen et al., 1967). The distance metric used for clustering is the Euclidean distance of the data from the cluster centres and therefore it is sensitive to the magnitude of the data and is prone to the assignment of a higher influence on a variable with a higher magnitude. As the important factor to consider in this work is the effect of the variation of the non-influenceable factors on the resource efficiency, the data is pre-processed by the subtraction of the mean of each variable and dividing the values by the

Figure 2: Steps of the BDP modelling procedure

standard deviation. The kmeans++ algorithm requires the number of the clusters as an input. The clustering algorithm assigns a centre to each cluster that represents the average of the points in that cluster. As the goal of the BDP model is to calculate the most efficient operational domain, the cluster centres are not used as representative values. Instead, a percentile analysis for each cluster

is performed:

$$\mathbf{r}_j = \frac{1}{|\mathscr{R}_j|} \sum_{\mathbf{x} \in \mathscr{R}_j} \mathbf{x} \tag{1}$$

$$\mathbf{x} \in \mathscr{R}_j \quad \forall \quad P_{j,n} \leq \text{EnPI}(\mathbf{x}) \leq P_{j,m} \tag{2}$$

$$\mathscr{R}_j \subseteq \mathscr{X} \tag{3}$$

$$\text{EnPI}_{\mathscr{R}_j} = \frac{1}{|\mathscr{R}_j|} \sum_{\mathbf{x} \in \mathscr{R}_j} \text{EnPI}(\mathbf{x}), \tag{4}$$

where $\mathscr{R}_j$ denotes the set of points which are assigned to the cluster j, $|\mathscr{R}_j|$ is its cardinality and $\mathbf{r}_j$ is the cluster centre. $P_{j,n}$, $P_{j,m}$ are the lower and and upper percentile bounds for cluster j. These bounds are used to select achievable good operation points as representatives, $\text{EnPI}_{\mathscr{R}_j}$, for each cluster. The chosen percentiles are tuning factors and can be modified for each case.

The surrogate model development is an adapted ALAMO approach (Cozad et al., 2014). It generates simple and accurate models from simulated or experimental data. In order to overcome the drawbacks of linear regression models, ALAMO selects a combination of transformed inputs using simple basis functions that fit the responses with an acceptable accuracy. The set of basis functions are defined by the user and ALAMO selects the most suitable ones and their respective parameters as a result of an optimisation. The details of the implemented adapted version of the ALAMO approach can be found in Beisheim et al. (2018). The model is fitted by solving an optimisation problem formulated as:

$$\min_{\beta, y} \quad \sum_{i=1}^{N} e_i \tag{5}$$

$$\text{s.t.} \quad e_i \geq z_i - \sum_{j \in \mathscr{B}} \beta_j X_{ij} \quad i = 1, \dots, N \tag{6}$$

$$e_i \geq \sum_{j \in \mathscr{B}} \beta_j X_{ij} - z_i \quad i = 1, \dots, N \tag{7}$$

$$\sum_{j \in \mathscr{B}} y_j = B \tag{8}$$

$$-U_j(1 - y_j) \leq \sum_{i=1}^{N} X_{ij} \left(z_i - \sum_{j \in \mathscr{B}} \beta_j X_{ij} \right) \leq U_j(1 - y_j) \qquad j \in \mathscr{B} \tag{9}$$

$$\beta^l y_j \leq \beta_j \leq \beta^u y_j \qquad j \in \mathscr{B} \tag{10}$$

$$y_j = \{0, 1\} \qquad j \in \mathscr{B}, \tag{11}$$

where z_i are the values of the responses, X is the matrix of the transformed inputs and β is the coefficient vector of X. $\mathscr{B}$ is the set of the basis functions and B is the number of the maximum allowed terms of the model. The binary variables y_j are equal to 1 if their respective basis function is selected. β^u, and β^l are the upper and lower bounds for the coefficient vector. N is the number of the samples and the indices i and j correspond to the samples and the basis functions respectively. The optimisation is done repeatedly for increasing values of B and the suitable level of complexity is decided based on the modified corrected Akaike Information Criterion (AIC_c). Eq. 9 is an additional constraint, which as described in Beisheim et al. (2018) uses the relaxed bounds U_j to convert the problem formulation into an MILP.

2.2. Application to production data at INEOS in Köln

In this section, the surrogate BDP modelling approach introduced in Sec. 2.1 is applied to two sections of the ethylene oxide production plant at INEOS in Köln and the results are compared to

the results of a rigorous model. All of the plots and information in this section are presented in the scaled space due to the confidentiality of the data.

2.2.1. Surrogate approach

The algorithm described in Sec. 2.1 is used with $[1, x^{\pm[1,2,3]}, \exp(x)]$ as basis functions. The first example is a section of the plant which processes the products from the ethylene oxide reactor. The upper and lower percentile limits, $P_{j,n}$ and $P_{j,m}$ are defined as 5 and 10 respectively.

As a result of discussions with plant personnel, the production load ($\dot{m}_p$) is defined as the only non-influenceable factor and is used to calculate the resource efficiency of the specific steam consumption ($\mathrm{EnPI}_{s,1}$). The number of the clusters is defined as 16. The algorithm results in a model with two basis functions:

$$\mathrm{EnPI}_{s,1} = -3.1902\,\dot{m}_p^2 + 1.4843\exp(\dot{m}_p) \qquad (12)$$

Fig. 3 depicts the results of the model fitting. Each data cloud (shown by coloured points) represents a cluster and the circles and the + signs represent the cluster centres and the percentile centres that are used for model fitting. As mentioned in Sec. 2, extrapolation of the model should be avoided. Therefore, the range of validity of the model is defined as the range between the minimum and maximum of the percentile centre values, and the data outside of this range are shown with dark diamonds.

Figure 3: Surrogate BDP model of the product processing section of the ethylene oxide plant

The second investigated section is the ethylene oxide reactor. Both the main and the side reactions are exothermic and the produced heat is used for steam generation. The heat of reaction of the side reaction is significantly higher than the heat produced by the main reaction. Therefore, the reduction of the catalyst selectivity increases the steam production. Considering this fact, the load of the reactor ($\dot{m}_{p,r}$) and the catalyst selectivity (S) which is available as a measurement, are used as non-influenceable factors for modelling the resource efficiency of the steam production ($\mathrm{EnPI}_{s,2}$). As the number of non-influenceable factors in this case is higher than the previous one, the number of the clusters is increased to 30. The other modification in this case is the choice of the percentile limits. Considering that this case is about the modelling of the production of steam, so higher values are preferable, the BDP is defined as the highest possible

Figure 4: Surrogate BDP model of the steam production of the ethylene oxide reactor

amount of steam production. Therefore the lower and upper percentile limits are defined as 90 and 95 respectively. The algorithm identifies a model, shown in Fig. 4, using three basis functions as:

$$\mathrm{EnPI}_{s,2} = -0.0669\,\dot{m}_{p,r}^3 - 5.7478\,S + 3.0651\exp(S). \qquad (13)$$

A conservative method for the definition of the domain of validity of regression models in higher dimensions is the "Convex Hull" of the input variables (Brooks et al., 1988). This method is used here to calculate the validity bounds of the model. The importance of the validity range is more obvious in this example compared to the previous model. It can be seen that outside of the convex hull, the model diverges from the data and should not be trusted.

2.2.2. Rigorous approach

In this section, a more detailed model of the ethylene oxide reactor is developed that is based on physico-chemical principles and measurement data. This model is then used to make a comparison between the detailed model and the proposed surrogate modelling approach and to identify the advantages and shortcomings of each. The model is based on the energy balance around the reactor as follows:

$$\frac{\partial Q}{\partial t} = \bar{C}_{p,in}\dot{n}_{in}T_{in} - \bar{C}_{p,out}\dot{n}_{out}T_{out} - \dot{Q}_{cool} + \sum_i(-\Delta H_{R,i}r_i) - \dot{Q}_{loss}, \tag{14}$$

where the left hand side of the equation is set to zero due to the assumed stationarity of the process. The first two terms on the right hand side of the equation represent the amount of the heat entering and leaving the reactor with the material streams. $\bar{C}_{p,j}$, $\dot{n}_j$, T_j denote average specific heat capacity of the gas mixture, mole flow and temperature at position j. $\sum_i(\Delta H_{R,i}r_i)$ represents the produced heat of reaction, $\dot{Q}_{cool}$ is the heat transferred from the reactor to the cooling fluid inside the jacket and $\dot{Q}_{loss}$ is the amount of heat that is transferred to the environment.

$\bar{C}_p$ is calculated as the weighted average of the values $C_{p,j}$ of the different components using the volumetric percentage values available in the plant, where the dependencies of the values of $C_{p,j}$ of the components on the temperature are determined based on the Shomate equation (Linstrom and Mallard, 2018). The molar flow $\dot{n}_{in}$ is not measured, but can be calculated based on the volumetric flow rate and the ideal gas law. The situation for $\dot{n}_{out}$ is more complex, as there is no direct flow measurements at the output of the reactor. However, using the composition measurements and the change of the volumetric percentage of an inert gas present in the mixture, this flow can be estimated.
The values of $\Delta H_{R,i}$ for each reaction are known and $\sum_i(-\Delta H_{R,i}r_i)$ is calculated using this information together with the selectivity measurement and the estimation of the ethylene conversion based on its volumetric percentage at the inlet and outlet flows. $\dot{Q}_{cool}$ is assumed to be equal to the amount of the heat required for the production of steam.

Considering the above mentioned assumptions, the value of $\dot{Q}_{loss}$ can be calculated from eq. 14. $\dot{Q}_{loss}$ can also be described as:

$$\dot{Q}_{loss} = k(T_{cf} - T_{amb}), \tag{15}$$

where T_{cf} and T_{amb} are equal to the cooling fluid and ambient temperature, and k is the heat transfer coefficient. Assuming that k remains constant for an unchanged setup (physical structure, cooling fluid etc.), its value can be estimated based on eq.15.

Eq. 14 is rearranged and $\dot{Q}_{cool}$, and thus the amount of steam produced is calculated based on the energy balance. Fig. 5 depicts the real steam production together with the values that are calculated based on the surrogate BDP model and the detailed model at two different time windows. The x-axis and the y-axis represents the time and the resource efficiency of steam production EnPI$_{s,2}$.
From Fig. 5a it can be seen that the surrogate model predicts a higher steam production rate compared to the real data and the detailed model. As the result of a deeper investigation it became clear that the conversion of ethylene in the reactor is lower in this period, which is not considered by the surrogate model and thereby deviates from reality. It is expected that the addition of conversion as a new non-influenceable factor to the surrogate model improves the accuracy of its prediction. Results from a second interesting time window are presented in Fig. 5b. Here it can be seen that the amount of produced steam predicted by the detailed model is significantly higher after a period of time. The reason is, that the heat exchanger that is used for steam production has a limit for the heat removal. Therefore, as a result of the decrease of the catalyst selectivity and the increase of the amount of heat produced by the reaction, the heat removal system is not able to convert all of the heat into steam, and this heat is lost in an extra heat exchanger against a large stream of cooling

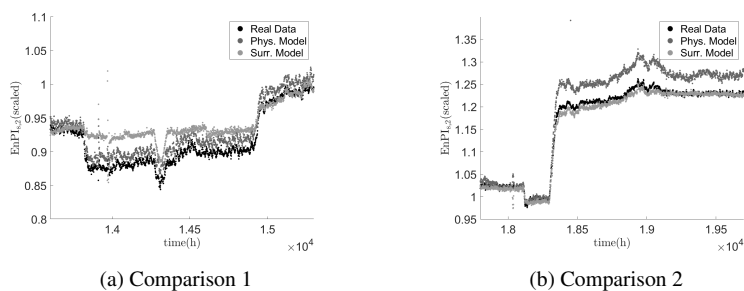
(a) Comparison 1   (b) Comparison 2


Figure 5: Comparison of the physical and the surrogate BDP models against production data

water. This limitation is identified with the help of the rigorous model, which is not possible with a surrogate BDP model.

3. Conclusions

In this work a surrogate and a more detailed modelling approach were used to calculate the BDP of production plants. It was observed that the surrogate modelling approach has a good performance in fitting the BDP data and requires a considerably lower modelling effort compared to more rigorous models. The proposed surrogate modelling approach is flexible and does not require a large effort. The time spent for the development of the surrogate model of the reactor was approximately 20 % of time that was needed for the development of the rigorous model. However, the range of trustworthiness of surrogate models is limited to the range of the observed data. Therefore, the performance of the models cannot be trusted beyond the data used for fitting them. Also, as discussed above for the situation depicted in Fig. 5b, deviations of the observed BDP from the possible best performance cannot be detected using a surrogate model and improvements of the plant that realize the potential cannot be deduced.

Abstract

Deciding price policies in order to attract new investments on renewable energy generation remains a challenge to many public policy-makers. This is particularly relevant to the Brazilian sugarcane industry, which has experienced a significant reduction in new bioenergy projects in recent years. Since investment costs thereof are expressive, a producer's willingness to increase energy generation is highly dependent on market conditions. Herein, we propose an optimization model based on portfolio theory to assess different price policies for attracting investment, where historical variations in sugar, ethanol and spot-market electricity prices are accounted for. Results obtained on a representative case study highlight the significant role played by regulated market prices in mitigating financial risks in the sugarcane business. The analysis enables a better understanding of investors' behavior according to their aversion to risk. It could support policy-makers with more effective pricing in the regulated market to keep promoting bioenergy generation.

Keywords: sugarcane, bioenergy, portfolio optimization, risk analysis, CVaR

1. Introduction

The Brazilian sugarcane industry is an example of a successful concerted public effort towards reducing a country's dependency on fossil fuels. In addition to its contribution to the energy sector with ethanol production, sugarcane mills now play an important role in the national electricity matrix. Cogeneration with bagasse—the fibrous residue after sugarcane stalks are crushed to extract their juice—currently holds a share of about 7% of the installed capacity in Brazil. Albeit significant, this share is still far from the industry's full potential, since less than half of all Brazilian mills are currently exporting electricity to the grid. All of Brazil's sugarcane mills are self-sufficient in energy through the use of bagasse for cogeneration of steam and power, but a majority still operates with low efficiency. Because the investment costs for new technologies to improve energy generation are high, a producer's willingness to invest is very sensitive to the market conditions and the prices practiced by the power sector.

Electricity in Brazil may be sold in either one of two ways: the free market and the regulated market. The former consists of a spot market, whereby prices are highly sensitive to the local weather conditions. The latter presents long-term contracts (e.g. over 20-25 years) with a determined rate (tariff) for the supplied power, in the form of power auctions organized by the Brazilian government. Since the free market is inherently high risk, new projects for renewable energy generation are usually enabled by the regulated market. However, the Brazilian government is yet to propose effective policies to incentivize the production of bioelectricity, withholding many producers from

wanting to bear the costs for modernizing their cogeneration systems and connect to the distribution network to sell electricity (Hofsetz and Silva, 2012). The absence of new installed capacity of bioelectricity into the Brazilian matrix in 2019 illustrates this trend perfectly.

Several studies have analyzed scenarios to increase power generation from the sugarcane bagasse. Grisi et al. (2012) applied an optimization model to decide the best economical combinations of sugar, bioethanol, biogas and electricity for production in a sugarcane mill. They highlighted the role of the regulated market in incentivizing sales of surplus power and showed that these sales could increase profits significantly. However, their assessment did not account for price risks, nor did it consider investments on new technologies to increase power production.

Accounting for risks in production and investment decisions is paramount in the sugarcane sector, especially since sugar, ethanol and spot electricity prices have been historically volatile. Hence, recent studies have applied Portfolio Theory to assess production decisions in the sugarcane sector (Carpio and Souza, 2017; Dutenkefer et al., 2018), but technological routes on bioenergy generation in the sugarcane sector have not been assessed yet in light of price risks, to the best of our knowledge.

This paper presents a risk-conscious assessment of investments on bioelectricity projects in sugarcane mills, through the application of a portfolio optimization strategy. Detrimental price scenarios are accounted for by means of the Conditional-Value-at-Risk (CVaR), a single tail risk-measure which is amenable to a fully linear optimization formulation using historical price data. The main objective of the analysis is to gain a better understanding of the role played by price policies on the increase of surplus power generation in the sugarcane sector, while accounting for the impact of bioelectricity sales on the sugar-ethanol business.

The proposed model is presented in Sec. 2. The case study of a generic sugarcane mill is introduced in Sec. 3, whereby investment decisions are assessed with regards to different scenarios of regulated market prices for electricity. The results of this case study are presented and discussed in Sec. 4, and final conclusions are drawn in Sec. 5.

2. Methodology

Our approach consists of modeling the production decisions related to the use of resources in the sugarcane mill and optimizing the trade-off between annual profit and risk in order to assess investments in new bioelectricity capacity.

2.1. Process Model

Production decisions in sugarcane processing plants generally relate to using available resources to produce a range of products that yield the largest economic profit. The resources comprise juice, bagasse, molasse and vinasse, denoted by the set $I = \{\text{ju}, \text{bag}, \text{mol}, \text{vin}\}$, whereas the products consist of sugar, ethanol, fertilizer, free electricity and regulated electricity denoted by $J = \{\text{su}, \text{et}, \text{fert}, \text{free}, \text{reg}\}$.

Assuming a predetermined amount of sugarcane to be crushed during the season, denoted here by the parameter Ca, and given a yield of juice extracted in the milling process, a producer needs to choose the amount that will be sent to both sugar and ethanol processes at the onset of the season:

$$r_{\text{ju,su}} + r_{\text{ju,et}} = \gamma_{\text{ju}} \text{Ca} \tag{1}$$

where the decision variable $r_{i,j}$ denotes the amount of each resource $i \in I$ used for the production of product $j \in J$; and γ_i is the yield of resource i. The product (sugar) and byproduct (molasse) in

the sugar production process are described by:

$$x_{su} = \theta_{ju,su} r_{ju,su} \tag{2}$$
$$r_{mol,et} = \gamma_{mol} x_{su} \tag{3}$$

where the decision variable x_j denotes the amount of product j; and $\theta_{i,j}$ are process conversion parameters describing the average yields from resource i to product j. Both juice and molasse can be used as inputs to the ethanol generation process, whereas vinasse, a residue of ethanol distillation, is widely used as a fertilizer in sugarcane plantation areas:

$$x_{et} = \theta_{ju,et} r_{ju,et} + \theta_{mol,et} r_{mol,et} \tag{4}$$
$$r_{vin,fert} = \gamma_{vin} x_{et} \tag{5}$$
$$x_{fert} = \theta_{vin,fert} r_{vin,fert} \tag{6}$$

Lastly, but not least importantly, the main residue from the milling process, bagasse, is used in all of Brazilian sugarcane mills as a fuel for thermal, mechanical and electrical energy through the use of power-steam cogeneration systems. Our main objective herein is to assess investments to upgrade bioelectricity from bagasse according to various free and regulated electricity price scenarios. Technological routes to increase energy recovery from bagasse are discussed by Dantas et al. (2013), who identify the use of condensation turbines within a Rankine cycle plant as the most competitive alternative for generating surplus electricity. Accordingly, we consider both a traditional Rankine cycle (base-scenario) and a Rankine cycle with a condensation turbine (improved scenario), so the surplus electricity available for commercialization in the sugarcane mill is such that:

$$x_{free} + x_{reg} \leq G_{base} z_{base} + G_{imp} z_{imp} \tag{7}$$
$$z_{base} + z_{imp} = 1 \tag{8}$$

where $z_k \in \{0,1\}$ is the investment decision variable; G_k is a parameter for the annual surplus electricity expected in each configuration $k \in K$ of the cogeneration process, with the set $K = \{base, imp\}$; and the surplus electricity production is separated into free and regulated market sales, which present different prices and risks.

2.2. Portfolio Optimization

The goal of the model is to enable risk-conscious decisions regarding product mix and investment in the sugarcane industry. We assume that product prices are the only source of uncertainty, so the optimization model chooses the best production portfolio to maximize profits in the case of detrimental price scenarios. Consequently, the decisions are based on historical records for sugar, ethanol and spot market electricity prices. Such information from past scenarios is used to robustify decisions against potential future short-falls, on account of historical market fluctuations. The validity of our results therefore relies on the assumption that future market conditions can be captured by such historical price records over several years.

As risk measure, we apply the Conditional-Value-at-Risk (CVaR), a coherent and convex, one-tailed measure. Following Rockafellar and Uryasev (2000), CVaR is amenable to a tractable, fully linear formulation, and optimizing CVaR has been shown to indirectly optimize other risk measures such as variance and Value-at-Risk (VaR) as well. Thus, given $q = 1 \ldots Q$ historical price observations, $p_{j,q}$ and production costs, c_j for each product $j \in J$, alongside investment costs, $\$_k$ for each technology $k \in K$, the proposed portfolio optimization model may be stated as:

$$\max_{\substack{x,r,z,\\P,u,\alpha}} \left\{ \underbrace{\frac{1}{Q}\sum_{q=1}^{Q} P_q}_{=:\text{ EP}}, \underbrace{\alpha - \frac{1}{Q(1-\beta)}\sum_{q=1}^{Q} u_q}_{=:\text{ CVaR}} \right\}$$

s.t. Model (1)–(8)

$\forall q = 1\ldots Q,$

$P_q = \sum_{j\in J}(p_{j,q} - c_j)x_j - \sum_{k\in K} \$_k z_k$

$P_q \geq \alpha - u_q$

$u_q \geq 0$
where P_q are auxiliary variables denoting the profit in each scenario $q = 1\ldots Q$; α is a decision variable corresponding to the VaR at confidence level β; and u_q, $q = 1\ldots Q$ are auxiliary variables introduced in the formulation in order to reduce it to a linear problem. Note that this is a bi-objective optimization problem, seeking a trade-off between expected profit (EP) and risk (CVaR). Also note that minimizing risk comes to maximizing the CVaR in our formulation. We apply the ε-constraint approach to construct the Pareto frontier here (Miettinen, 1999).

3. Case Study

A case study is defined based on a generic sugarcane plant in order to demonstrate the proposed portfolio optimization model for product mix and investments decisions in the sugarcane sector. This plant processes 3 million tonnes of sugarcane per year, an average-size plant in Brazil. The initial configuration of the cogeneration system is a traditional Rankine cycle running with a 67 bar boiler at 520°C and generating an average surplus electricity of 53 kWh per tonne of sugarcane processed. As the investment alternative, we consider the addition of a condensation turbine that increases surplus power generation to an average of 83 kWh per tonne.

The parameters used in the model are taken from the literature. Production and investment costs are from Grisi et al. (2012) and Dantas et al. (2013), respectively, while process yields and waste generation rates are derived from the Open Sugarcane Process Simulation Platform (Castro et al., 2018). The selling prices of sugar, ethanol and spot market electricity correspond to historical price records at a weekly frequency between 2002 and 2018. These prices are all expressed for the same base-year (2010 US$) by discounting the effect of inflation, before using them to estimate the expected profit and risk.

Since the regulated market does not present price variations within the contracted supply period, and since those prices are set during the energy auctions prior to making the investments, a sensitivity analysis is performed to assess how different price policies practiced by the government could affect investment and production decisions in the sugarcane sector. The range of regulated market prices used in this analysis is US$50-100 per MWh, based on the average prices practiced in Brazilian renewable energy auctions over the past 10 years. The results obtained are presented and discussed in the following section.

4. Results and Discussion

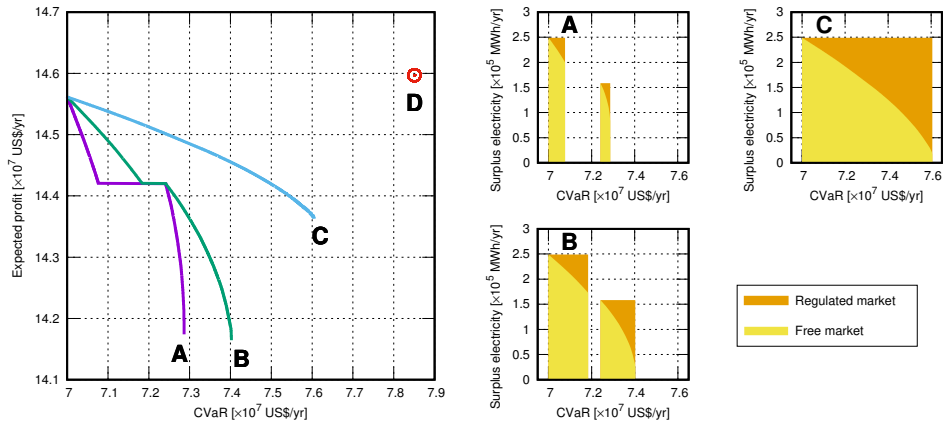
The model predicts two distinct investment behaviors within the range of regulated electricity prices investigated in the sensitivity analysis (US$50-100 per MWh): one when the price in the regulated market is lower than or equal to the expected price of the free market, and the other one when it is higher. This is expected since the regulated prices are not subject to variations and


Figure 1: Efficient frontiers and annual surplus electricity sales in the free and regulated markets for different regulated price scenarios. **A**: US$50/MWh; **B**: US$60/MWh; **C**: US$70/MWh; **D**: US$80/MWh.

are essentially risk-free. Consequently, when regulated prices are greater than the expected value of prices in the free market, a decision-maker will always choose to sell to the regulated market. Given the expected free market price of US$78 per MWh, this latter behavior is clearly seen in Fig. 1 (scenario **D**).

For lower prices practiced in the regulated market (scenarios **A–C**), there is a tendency for producers to prefer selling at spot market price. As price policies of renewable energy auctions in Brazil become more efficient, they attract sales to the regulated market and thereby generate more interest in investing towards surplus energy generation. Notice that for low regulated market prices, such as US$50-60 per MWh, only a risk-inclined investor would choose to invest in new bioelectricty projects, aiming most of their surplus electricity sales to the free market. This analysis corroborates the results of two auctions performed by the Brazilian government in 2011, with average prices of US$52 and US$57 per MWh, which led to significantly less contracted energy compared with the subsequent auctions in 2013, with average prices of US$65 and US$68 per MWh.

Another relevant aspect of this analysis is the disparity of portfolio choices for different risk levels. For lower prices in the regulated market in particular (scenarios **A–B**), a risk-inclined decision aiming to maximize the expected profit only, presents significant difference with a risk-averse decision. For instance, for the regulated market price of US$60 per MWh, a risk-inclined optimization model would recommend investing in a condensation turbine and selling all of the surplus electricity to the free market, a particularly risky strategy with regard to short-falls.

The efficient frontiers for all four price scenarios is shown on the left plot in Fig. 1. Recall that in our bi-objective optimization formulation, increasing the CVaR reduces risk. Therefore, the risk-neutral scenarios originate from the left and have the greatest expected profits, while risk-averse scenarios are on the right. The three frontiers for which regulated market prices are lower than the expected price in the free market (scenarios **A–C**) all originate from the same point, where a risk-inclined producer would sell all of its surplus electricity to the free market. For regulated price scenarios in the range of US$50-60 per MWh, the Pareto frontier presents a significant jump because the decision to invest is not made until the risk level is quite high. Below this threshold, the investment is not made, but surplus power is sold entirely to the free market. The sales decisions only change among prices in this range when risk starts playing a more important role than expected profit in the investor's decisions. Regulated prices of US$70 per MWh or

higher are sufficiently attractive to promote the investment, and we no longer observe a jump in the Pareto frontier. There is furthermore a clear tendency for risk-averse profiles to prefer the regulated market in all of the regulated price scenarios.

There is also a notable gain in efficiency as the prices in the regulated market increase. Although it is expected, this result is interesting as it shows a change in the trade-off between risk and profit among the scenarios. Clearly, raising the regulated market price reduces the gap between the expected profits in risk-averse and risk-inclined strategies. This shows how long-term electricity contracts may play a relevant role as a strategy to mitigate price risks of other products in the sugarcane business.

Finally, as far as assisting price policies to attract more bioelectricity investments is concerned, the sensitivity analysis of the portfolio decisions allows a better understanding of the regulated market prices that would be attractive to sugarcane producers. The results obtained with the cost conditions of the case study suggest that a price range between US$65-70 per MWh would raise the interest of risk-averse investors in implementing a condensation turbine to increase their surplus electricity generation. Naturally, there are other market aspects that may influence a producer's willingness to invest, such as economic and political uncertainties in Brazil. However, by evidencing the impact of long-term energy contracts on reducing the overall price risks of the sugarcane business and proposing economically attractive prices for the energy auctions, policymakers are more likely to succeed in increasing the share of bioelectricity in the national matrix.

5. Conclusions

This paper has presented a portfolio optimization model to address investment decisions in the Brazilian sugarcane sector. Price risks are accounted for by means of the Conditional-Value-at-Risk, in combination with historical price records of sugar, ethanol and spot market electricity, to enable risk-conscious decisions that are robust to potential shortfalls. A sensitivity analysis has been conducted for a variety of regulated market prices and risk-aversion profiles. Results obtained on a representative case study confirm that the decision to invest on bioenergy projects is highly sensitive to the price policies practiced in the regulated market, evidencing also the importance of bioelectricity sales on the economic performance of sugarcane mills. Typical optimal solutions also present a large sensitivity towards the level of risk, which confirms the need to account for market price variations in the analysis. The developed risk-conscious optimization framework therefore provides a more robust tool to assist policy-makers and to incentivize bioenergy projects in the Brazilian sugarcane industry.

Abstract

Ethanol may be produced from waste materials via a thermochemical-biochemical route employing gasification and syngas fermentation by acetogenic bacteria. This process is considered promising, but commercialization might be hindered by sub-optimal choices of design and operating conditions. In the present work, process systems engineering (PSE) techniques were applied for the optimization of a large-scale syngas fermentation bioreactor. Starting with the development of a dynamic model for a bubble column reactor with gas recycle, the multiple system outputs were studied with Principal Component Analysis to assist in the definition of relevant objective functions, and artificial neural networks were used to approximate the steady-state responses with fast and accurate functions. This framework was then used to conduct a multi-objective optimization aiming at maximizing the ethanol production rate, lower heating value efficiency and ethanol titer, while also minimizing acetic acid titer and reactor volume.

Keywords: bioethanol, syngas fermentation, multi-objective optimization, neural networks, principal component analysis

1. Introduction

Syngas fermentation is a biological process in which facultative autotrophic bacteria called acetogens convert CO, H_2 and CO_2 into cell mass, acids and alcohols. Most wild-type strains produce acetic acid and ethanol −and this is the focus of this work−, but other carboxylic acids and higher alcohols may also be obtained (Wainaina et al., 2018). Since syngas may be produced from the gasification of a diversity of feedstocks, including various waste materials, and syngas fermentation is conducted under mild conditions, this process has been gaining growing attention alongside other conversion pathways for waste to fuels and chemicals. Nonetheless, bench-scale experiments reported in the literature are often marked by difficulties with low productivity and unsatisfactory product selectivity. Moreover, modeling and optimization studies on this process are scarce in the literature, which makes it difficult to conduct appropriate economic and environmental assessments. This work therefore aims to fulfill part of this demand by presenting a bubble column model and a multi-objective optimization (MOO) framework using neural network surrogate models. The ultimate goal is to

provide insights into the process conditions and reactor design that enhance reactor performance and demonstrate how the proposed methods may be used for this purpose.

2. Syngas bioreactor model

2.1. Dynamic bubble column

The bubble column reactor (BCR) hydrodynamic model is based on the Axial Dispersion Model described by Deckwer (1992) and it considers the following main assumptions: (i) isothermal operation; (ii) axial dispersion is neglected in the gas phase; (iii) in the liquid phase substances are carried differentially by convective and dispersive flows; (iv) volumetric mass transfer coefficient (k_La), gas hold-up (ε_G) and liquid dispersion coefficient (D_L) are constant throughout the column; (v) atmospheric pressure at the top of the column. The system consists of 13 types of state variables distributed in space: the concentrations [mol/m^3] of 6 chemical species (i = CO, H$_2$, CO$_2$, ethanol or EtOH, acetic acid or HAc, and H$_2$O) distributed in the gas ($C_{G,i}$) and liquid ($C_{L,i}$) phases, and cell biomass ($C_{L,X}$) which is present in the liquid phase. It is therefore described by $13 \cdot N$ ordinary differential equations, where N is the number of discretization points considered. The general governing equations are formulated in Eqs. (1)-(3), where x is the spatial variable and u_G is the superficial gas velocity calculated at each point from a mole balance, as the gas expands due to reduced hydrostatic head or shrinks due to consumption by the cells. The hydrodynamic parameters k_La and ε_G are calculated using correlations by Heijnen and van't Riet (1984) and Deckwer et al. (1974), and a indicates the column operation mode: -1 if counter-current (present case), 1 otherwise. The saturation concentrations $C_{L,i}^*$ and $C_{G,i}^*$ are calculated using Henry's law constants and vapor pressures at 36 °C. In Eqs. (1)-(3), the boundary conditions ($x = 0$ and $x = L$) follow the model by Deckwer (1992), and the spatial derivatives are calculated using 1st and 2nd order finite differences.

$$\frac{\partial C_{G,i}}{\partial t} = -\frac{u_G}{\varepsilon_G} \cdot \frac{\partial C_{G,i}}{\partial x} - \frac{C_{G,i}}{\varepsilon_G} \cdot \frac{\partial u_G}{\partial x} - \frac{\dot{n}_{MT}}{\varepsilon_G} \tag{1}$$

$$\frac{\partial C_{L,i}}{\partial t} = -\frac{au_L}{(1-\varepsilon_G)} \cdot \frac{\partial C_{L,i}}{\partial x} + D_L \frac{\partial^2 C_{L,i}}{\partial x^2} + \frac{\dot{n}_{MT}}{(1-\varepsilon_G)} + v_i C_{L,X} \tag{2}$$

$$\frac{\partial C_{L,X}}{\partial t} = -\frac{au_L}{(1-\varepsilon_G)} \cdot \frac{\partial C_{L,i}}{\partial x} + D_L \frac{\partial^2 C_{L,i}}{\partial x^2} + \frac{\dot{n}_{MT}}{(1-\varepsilon_G)} + (\mu - k_d)C_{L,X} \tag{3}$$

$$\dot{n}_{MT} = k_L a_i (C_{L,i}^* - C_{L,i}), \, i = CO, H_2, CO_2 \tag{4a}$$

$$\dot{n}_{MT} = -k_L a_i (C_{G,i}^* - C_{G,i}), \, i = EtOH, HAc, H_2O \tag{4b}$$

The biokinetic variables v_i, μ and k_d refer to the specific secretion or production rate [mmol.g^{-1}.h^{-1}] of each component i, the specific biomass growth rate [h^{-1}] and the biomass decay rate [h^{-1}]. This kinetic model considers ethanol and acetic acid formation as well as cell growth, using CO/H$_2$ as energy sources and CO/CO$_2$ as carbon sources. The parameters that are used in the calculation of these variables were adjusted using experimental data obtained in a continuous stirred-tank reactor with high ethanol concentration, and the detailed modeling and statistical analysis are at the moment unpublished but under submission to a scientific journal (de Medeiros et al., Forthcoming).

2.2. Steady-state surrogate models

Steady-state solutions were generated by integrating the BCR ODE system over a sufficiently long time range using the MATLAB stiff solver *ode15s*. However, this procedure was proved very computationally expensive for some choices of process parameters, specifically when very low dilution rates were used in combination with high recycle ratios, with some case scenarios taking as long as three minutes to be solved. Since the multi-objective evolutionary algorithm requires a large number of objective function evaluations, the objectives were approximated with fast surrogate models. Similar strategies have been adopted before for a variety of chemical processes employing different types of models, such as artificial neural networks (ANNs) (Chambers and Mount-Campbell, 2002) and Kriging models (Quirante and Caballero, 2016). In the present work, multi-layer feedforward ANNs were trained with Bayesian regularization backpropagation to approximate responses that would be relevant for the optimization, namely: the concentrations of ethanol and acetic acid at the column outlet and the lower heating value (LHV) efficiency η_{fuel}, the latter being defined as the ratio between the total ethanol LHV and the total energy input considering syngas LHV and heat intake associated with the power consumed in the gas compressor. ANN architectures were selected after several tries, with the final ANNs containing two hidden layers with 10 to 20 neurons per hidden layer depending on the case. The data set used for ANN training and validation consisted of 2,780 points comprising random combinations of the operating and design parameters considered as model inputs (and optimization decision variables): dilution rate (D [h^{-1}]), fresh gas residence time (*GRT* [min]), gas recycle ratio (*RR*), column height (L [m]), and column aspect ratio (L/d_C). For the gas compressor, the power consumption was calculated in Aspen plus as function of the gas composition and flow rate at the top of the column, and the pressure at the bottom; Aspen Simulation Workbook was employed to facilitate the automatic execution of all considered scenarios. The output of the ANNs is depicted in Fig. 1 against the rigorous solutions (i.e. obtained with integration of the ODE system), where for each response the results are normalized with relation to the minimum and maximum values of the corresponding rigorous response.

3. Formulation of MOO problem

3.1. Decision variables and fixed conditions

The MOO problem aims at finding optimal combinations of the decision variables described in Sec. 2.2 within the following pre-defined ranges: *0.001 ≤ D ≤ 0.1 ; 5 ≤ GRT ≤ 50 ; 0 ≤ RR ≤ 0.8 ; 10 ≤ L ≤ 30 ; 3 ≤ L/d$_C$ ≤ 6*. Some variables are fixed in this study but should be analyzed in connection with other unit operations in future studies of the global process. These are: the fresh syngas composition (fixed at 60% CO, 35% H$_2$, 5% CO$_2$), which is affected by the choices of design and operating conditions in the gasifier; and liquid inlet composition (considered pure water), which could contain small amounts of acetic acid if distillation waste streams are recirculated within the process. Cell recycle is also considered with a fixed purge fraction of 10% of the cells.

3.2. Selection of objectives using Principal Component Analysis

Process performance often needs to be measured by multiple criteria which are conflicting, such that a decision must be made based on Pareto-optimal solutions. Nonetheless, a too large number of objectives might bring unnecessary complexity to the problem, both in terms of computational effort and interpretation of the results. With

that in mind, the multivariate technique of Principal Component Analysis (PCA) can be employed to uncover relationships among objectives and reduce the dimensionality of the problem (Sabio et al., 2012). In a nutshell, this is achieved by finding a new coordinate system that explains the variance in the original data set using a smaller dimensionality. In this study, PCA was applied to a set of 8 potential objectives calculated from the BCR model results at various conditions. Fig. 2 shows the coefficients (loadings) of the two first principal components (PC), which together explain nearly 87% of the data variance. These coefficients represent the contribution of the original variables to the PCs, thereby pointing out aligned or opposing tendencies. From this analysis, the gas conversions X_{CO} and X_{H2} were removed from the MOO since their tendencies are well captured by the LHV efficiency η_{fuel}. The other efficiency, η_{total}, considers the LHV of both ethanol and unconverted syngas. Since ethanol production is accompanied by CO_2 formation, this efficiency has an opposite trend to the conversions, eventually reaching 1 if no ethanol is formed; hence it was also removed from the analysis. The minimization objective functions were then defined with the 5 remaining metrics: (i) $OF_1 = -Prod$ (ethanol production rate); (ii) $OF_2 = -\eta_{fuel}$; (iii) $OF_3 = -C_{L,EtOH}$; (iv) $OF_4 = C_{L,HAc}$; (v) $OF_5 = V_R$ (reactor volume). Apart from the production rate and LHV efficiency that ideally would be maximized, the definition of objectives OF_3 and OF_4 takes into account possible energy expenses in downstream operations, and OF_5 is aimed at reducing CAPEX.
Figure 1. Validation of neural networks
Figure 2. Principal Component Coefficients

4. Generation and analysis of the Pareto front

The Pareto front was generated in MATLAB using a hybrid algorithm that starts with multi-objective genetic algorithm (MOGA) and shifts to a local goal attainment method once the solution is near the optimum front. The short evaluation times due to the adoption of neural networks made it possible to test the hybrid MOGA with different population sizes, with and without the hybrid search. Fig. 3 presents the pairwise projections of the Pareto front, specifically for the objective OF_1 (maximization of ethanol production rate) against the other four objectives. These plots can be used to delineate a range of desirable and feasible operation; for example, it is not convenient to aim at production rates higher than 2,700 kg/h, since this would require reactor vessels of at least 1,500 m³ which might be unpractical in real operation. It can also be noted that, for the current system, the highest LHV efficiencies are achieved at lower EtOH production rates, which makes sense since higher gas conversions are obtained when the

gas residence time is longer (lower gas velocity), thus leading to smaller mass transfer coefficients and reaction rates. The ethanol titer is bounded to a maximum 30 g/L for a large range of production rates, with increasing formation of undesirable acetic acid, while low production rates can lead to over 50 g/L ethanol with almost zero by-product. The normalized values of the parameters are shown in Fig. 4 for sub-sets selected from the boundary dashed lines depicted in Fig. 3, where it can be seen how the optimal parameters adapt to the objective functions. An ultimate decision would need to consider the relevance of these objectives on the outcome of the global process; for example, a lower production rate that is compensated by a more concentrated broth might in some cases be more advantageous than the other way around. Either way, the current results may be used to define an optimal region where the LHV efficiency is higher than 30%, the ethanol titer is higher than 20 g/L, the acetic acid titer is lower than 10 g/L, and the reactor volume is less than 1,500 m³; the decision variables in this region are in the range: *0.02 ≤ D ≤ 0.03 ; 32 ≤ GRT ≤ 50 ; 0.56 ≤ RR ≤ 0.8 ; 27.8 ≤ L ≤ 29.4 ; 3.8 ≤ L/dC ≤ 4.7.*
Figure 3. Pareto front 2-D Projections: (a)*OF₁ x OF₂*; (b)*OF₁ x OF₃*; (c)*OF₁ x OF₄*; (d)*OF₁ x OF₅*

5. Conclusions

In this study a modeling and optimization framework was built for syngas fermentation in bubble column reactors. First a spatial dynamic model was created to predict the concentrations of the chemical species and cells along the reactor in the gas and liquid phases; and the most relevant responses were approximated by artificial neural networks to reduce computational effort, so that objective functions could be evaluated efficiently during the multi-objective optimization search. We demonstrated how Principal Component Analysis can be used to reduce the complexity of the MOO problem

without losing significant information. Although further studies are needed connecting the bioreactor to other unit operations, the five-objective Pareto front generated in this study can be used to pre-define an optimal range of process conditions and reactor size.

Abstract

Syngas has traditionally been derived from fossil fuels, but alternative production routes have attracted significant interest recently, such as syngas from biomass gasification, electrolysis of water, or electrocatalytic reduction of CO_2. The composition of the produced syngas can vary drastically, in addition to presenting large price differences. The main contribution of this paper is a systematic, model-based comparison of three syngas conversion technologies, namely methanol, DME and Fisher-Tropsch syntheses, for a range of syngas compositions. The key performance indicators in this comparison are the break-even price of syngas, the carbon efficiency, and the energy return on energy investment. The results suggest that DME synthesis is the most promising technology both economically and in terms of carbon efficiency, while methanol synthesis presents the best energy efficiency.

Keywords: methanol, DME, Fisher-Tropsch, process simulation, techno-economic analysis, carbon efficiency, energy efficiency

1. Introduction

Syngas – a gas mixture made primarily of CO and H_2 – provides a flexible feedstock for a variety of chemical syntheses, including methanol (MeOH) and dimethyl ether (DME) production and higher hydrocarbons via Fischer-Tropsch (FT) synthesis. A majority of the syngas worldwide is currently produced from fossil hydrocarbon feedstock and carries a large environmental burden. In response to this, alternative routes to syngas generation have received significant attention, including biomass gasification, co-generation of CO and H_2 via electrochemical and solar routes, and catalytic reduction of CO_2 into CO (Foit et al., 2017). Many of these sustainable syngas production processes are at a much lower technological readiness level compared with syngas from fossil feedstock, and their integration within existing plants may not be so straightforward because the obtained syngas composition can vary drastically depending on the feedstock or selected route. There is also significant uncertainty about the projected price of sustainable syngas in a scaled-up production. This cursory analysis suggests that there exist significant opportunities for better integration and optimization across syngas production and conversion processes.

A number of research studies have been conducted on this topic in recent years. Trippe et al. (2013) compared direct DME synthesis and FT synthesis, using syngas from biomass gasification. They assumed that the syngas composition could be varied with-

out incurring a penalty, and therefore considered optimal $H_2:CO_x$ ratios of 1 for direct DME synthesis and of 2 for the FT synthesis. They furthermore used simplified models (Gibbs reactor) of the DME and FT reactors to conduct the assessment. Hankin and Shah (2017) compared methanol and DME syntheses (both direct and indirect) using CO_2 and H_2 as feedstock. They considered different layouts, including electrocatalytic cells (SOECs) and a separate water-gas-shift reactor prior to the reactor in order to adjust the $CO:CO_2:H_2$ ratio for each conversion technology, and they also used equilibrium models in their assessment.

The main objective of this paper is to conduct an assessment of alternative technologies for the production of fuels/chemicals from syngas, by accounting for different $H_2:CO_x$ ratios. Our focus is on three syngas conversion processes, namely FT, MeOH and indirect DME synthesis. Direct DME synthesis was not included in the analysis due to its much lower optimal syngas composition ($H_2:CO_x$ ratio close to 1; see Peng et al. (1999)) compared with the other three processes. A distinctive feature of our analysis is that it relies on detailed kinetic models of the various syntheses, which were calibrated against experimental data. We furthermore consider process flowsheets that are flexible enough to operate under different syngas compositions, not merely at the optimal syngas composition. Finally, the technologies are assessed in terms of their environmental and energy efficiency, alongside their economic performance.

2. Methodology

State-of-the-art process flowsheets for FT, MeOH, and DME syntheses are simulated using Aspen Plus® (FT, DME) and Aspen Hysys® (MeOH). Both simulation environments are also used to conduct the techno-economic analysis, using the information provided by the detailed models, which include mass and energy balances, thermodynamic properties and kinetics. Specifically, the kinetic rate expressions are taken from the works of Todic et al. (2013), Graaf et al. (1988) and Bercic and Levec (1993) for FT, MeOH and DME, respectively. All of these models have been calibrated against experimental data from dedicated measurement campaigns.

The influence of the syngas composition is analyzed by simulating each process with different $H_2:CO_x$ inlet ratios in the range of 1.6–2.4 and a fixed $CO:CO_2$ ratio of 10, as shown in Table 1. The molar flow rate, pressure and temperature are kept constant at 8000 mol.hour^{-1}, 24 bar and 80°C, as well the concentration of inerts (N_2, H_2O and CH_4) that are inherent to the syngas production process.

Three key performance indicators (KPIs) are used to assess and compare the syngas conversion processes. The *break-even price* (BEP) indicator represents the highest price we should be willing to pay for syngas in order for the conversion process to remain economically feasible, here considering a process life-time of 30 years and in the price scenario of Europe 2017. The *carbon efficiency* (CE) indicator accounts for the fraction of carbon from the syngas that ends up in the fuel products. Lastly, the *energy return on energy investment* (EROI) is the amount of energy in the products divided by the amount of energy provided to the process, considering chemical, thermal and electrical energy all together. An important difference between the MeOH, DME and FT processes is that the latter is a net producer of electricity, a saleable co-product that can improve both the BEP and EROI indicators.

Table 1: Molar composition of the different syngas streams used in the process simulation

x_i	$H_2:CO_x$				
[mol%]	1.6	1.8	2	2.2	2.4
H_2	59.7%	62.4%	64.7%	66.7%	68.5%
CO	33.9%	31.5%	29.4%	27.5%	25.9%
CO_2	3.4%	3.1%	2.9%	2.8%	2.6%
N_2, H_2O, CH_4	1.0%	1.0%	1.0%	1.0%	1.0%

Fischer-Tropsch liquids synthesis. The FT plant considered herein is based on the work of Graciano et al. (2018a,b), which comprises six main units: Fischer-Tropsch reacion, water-gas shift (WGS), upgrading, separation, Rankine cycle, and gas turbines (top row of Fig. 1). In the proposed arrangement, the syngas is mixed with H_2 surplus from the WGS unit to adjust the H_2:CO ratio to 2 (unless this ratio is already higher than 2). Then, the mixture feeds into the slurry bubble FT reactor filled with cobalt catalyst, producing the paraffin and olefin that compose the synthetic oil (synoil). This synoil is sent to the separation section to be fractionated into gasoline, kerosene, diesel, and wax products. The upgrading unit is responsible for converting both heavy synoil and recycled wax into lighter and more valuable fractions. The unconverted syngas from the FT unit passes through a WGS unit that converts part of the CO into H_2, before feeding into the FT reactor and the upgrading unit. The thermal energy produced by the exothermic FT reactions is recovered by the Rankine cycle unit and converted into electricity, while the gas turbine unit produces additional electricity by burning the tail gas from the WGS unit.

Methanol synthesis. The MeOH plant is simulated based on the process flowsheet developed by Van-Dal and Bouallou (2013) (middle row of Figure 1). This process comprises only two units: methanol reaction and separation. The former mainly consists of a compressor train and an adiabatic reactor filled with a fixed amount of copper-based catalyst and operating at 78 bar. The latter comprises a sequence of two flash drums and a distillation column, which separate the unconverted syngas and purify the methanol product to the product grade (AA grade), respectively. A heat integration analysis of the process reveals that the heat produced in the reactor is sufficient to cover the process needs, so no external heating utility is needed. By contrast, cooling water and electricity are still required and need to be supplied by external sources.

We consider two alternative copper-based catalysts with the objective to compare their effect on the methanol synthesis. The kinetic data of the first catalyst (Catalyst I) is taken from Van-Dal and Bouallou (2013), which relies on the model by Bussche and Froment (1996). The kinetic data for the second catalyst (catalyst II) is taken from Ng et al. (1999) work, which have been used to calibrate the model by Graaf et al. (1988). The amount of catalyst was adjusted in such a way that a conversion close to the equilibrium is obtained at the reactor outlet; the corresponding amounts of catalyst I and II are 44.7 and 26.6 tons, respectively.

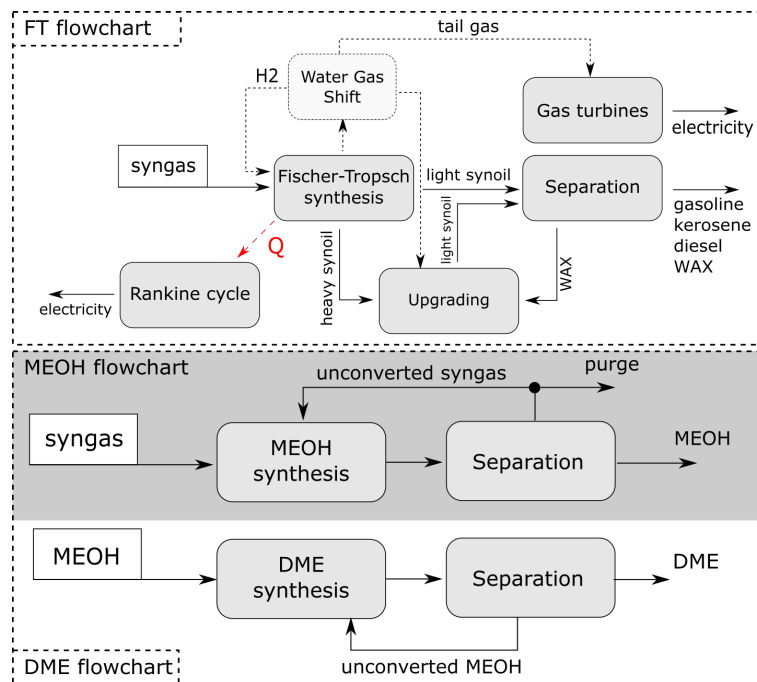
Dimethyl ether synthesis. The process flowsheet for indirect DME production comprises two steps, methanol synthesis and methanol dehydration (middle and bottom rows of Figure 1). The methanol produced from a given syngas composition is mixed with the recycle


Figure 1: Schematic diagrams for the FT process (top), MeOH process (middle), and DME process (bottom)

stream and heated up to 275°C in a furnace, before entering a jacketed tubular reactor to undergo DME synthesis. Then, the unreacted methanol is separated from the produced water and DME by a train of two distillation columns and recycled back to the reactor. Because water is the only impurity present in the recycle stream, a purge stream is not necessary here.

The kinetic model used in the simulation was initially calibrated against data from a double bed reactor fed with syngas and producing methanol and DME. The model was also tested against experimental data of DME synthesis from methanol, showing a good agreement with the experimental data (Bernardi et al., 2019).

3. Results and discussion

The process simulation results are summarized on Fig. 2. A first observation is that the $H_2:CO_x$ ratio of the syngas has a large effect on the three KPIs, which all pass through a maximum in the investigated range 1.6-2.4.

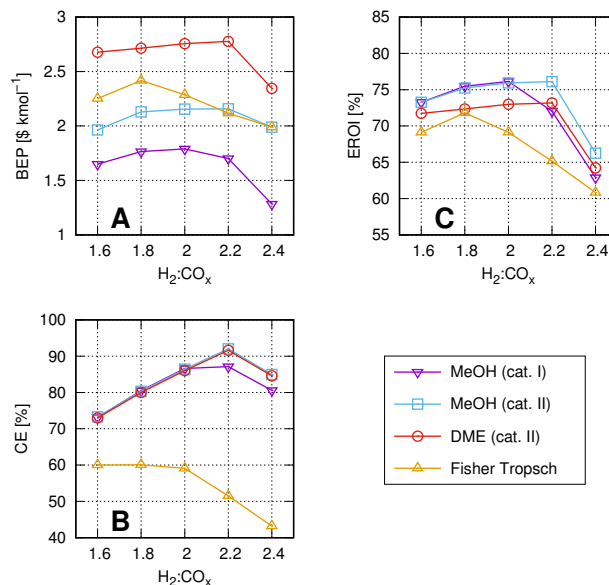
Economic performance. We start by noting that the catalyst choice has a great effect on the economic performance of the MeOH process, both in terms of capital and operating costs. The catalyst may also modify the optimal syngas composition. The FT process is found to be economically superior to the MeOH process for both catalysts, albeit the MeOH process with catalyst II becomes competitive with the FT process for $H_2:CO_x > 2$. Thereafter, catalyst II is selected to produce methanol in the first step of indirect DME production due to its superior economic performance compared to catalyst


Figure 2: Comparison between MeOH, DME and FT processes in terms of break-even price (**A**), carbon efficiency (**B**), and energy efficiency (**C**)

I. DME is found to be the most profitable product by a large margin, for all analyzed $H_2:CO_x$ ratios even considering a conservative price for the DME (e.g. Chinese market). These results are in agreement with Trippe et al. (2013), who predicted a slightly better economic performance for gasoline from DME compared with gasoline from FT.

Carbon conversion efficiency. The FT process presents the lowest carbon efficiency, around 60% for $H_2:CO_x \leq 2$ and decreasing to about 40% thereafter. This decline is attributed to the H_2 recycle needed for adjusting the $H_2:CO = 2$ at the FT reactor inlet. By contrast, the CE of the MeOH process is consistently over 70%, and it presents a maximum above 90% with catalyst II at the $H_2:CO_x$ ratio of 2. The effect of catalyst selection on the CE is rather low; the main difference being noticeable for $H_2:CO > 2$ due to catalyst I requiring a larger recycle stream. Lastly, there is hardly any difference in CE between the MeOH and DME processes, due to the near-100% conversion of the methanol dehydration in DME synthesis.

Energy efficiency. The most favorable EROI is consistently obtained for the MeOH process, and passes a maximum of about 75% for both catalysts around $H_2:CO_x = 2$. (Recall that the EROI calculation accounts for the chemical energy of the syngas feed, so the resulting EROI may not be greater than 100%.) A fast decline in the EROI is observed for larger $H_2:CO_x$ ratios, due to the increase in the recycle flowrate of unconverted syngas. Unlike CE, the EROI indicator is lower in the DME process than in its MeOH counterpart alone, a consequence of the extra process complexity and exergetic losses. Finally, the FT process presents the worst performance in terms of EROI. At its optimal syngas ratio $H_2:CO_x = 1.8$, it has a similar performance as the DME process nevertheless. This behavior is again explained by the higher complexity of the FT plant in comparison with the other two processes, which results in larger exergetic losses overall.

4. Conclusions

This paper has presents a systematic, model-based comparison between different syngas conversion technologies for the production of liquid transportation fuels. Our results show that the production of DME is the most attractive technology in both economic and carbon efficiency terms, while methanol synthesis has the best performance in terms of energy efficiency. It is also noteworthy that the techno-economic analysis provides quantitative price targets for novel syngas generation technologies. Our current investigations aim at completing the sustainability assessment by looking at additional environmental impacts and comparing different geographical locations (UK, US, South America and China).

Abstract

Acetic acid is an important bulk chemical, used as raw material in the production of vinyl acetate, terephtalic acid, acetate esters and acetic anhydride. All these processes include a step for separating the acetic acid from water, both high-purity and high-recovery of acetic acid being required. Although acetic acid and water do not form an azeotrope, the separation is difficult due to the tangent pinch present on the pure water end. A common industrial practice to overcome the tangent pinch is to add an entrainer and, therefore, to use heterogeneous azeotropic distillation. This work investigates the applicability of cyclic distillation to this difficult separation. A mathematical model is presented and used for sizing and optimization considering the total annual cost as objective function and the number of trays, feed tray location, and the duration of vapor-flow period as decision variables.

Keywords: Water, Acetic Acid, Cyclic distillation.

1. Introduction

Acetic acid is an important chemical, produced by methanol carbonylation, acetaldehyde oxidation and the oxidation of butane and/or naphtha fractions. All these processes contain a step for separating the acetic acid from water. Although acetic acid and water do not form an azeotrope, the separation is difficult due to the tangent pinch present on the pure water end. In this contribution, the applicability of cyclic distillation for separation of 10780 kg/h mixture of water (71%wt) and acetic acid (29%wt) is investigated. The required separation performance is given as purities of the acetic acid (99.3 %wt) and water (99.4 %wt) products.

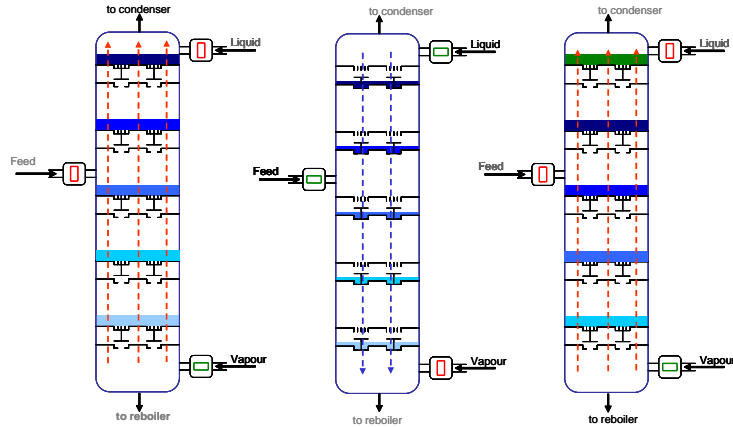
Cyclic operation of distillation columns is attractive for difficult separations, being already used for kerosene fractionation (petrochemical industry) and ethanol concentration (food industry). Cyclic operation of distillation columns (Patrut et al., 2014) consists of a vapour flow period and a liquid flow period, as shown in Figure 1. During the vapor flow period, the liquid remains stationary on the tray while the vapour is flowing upwards through the column. During the liquid flow period, the vapor flow is stopped, reflux and feed are supplied to the column, and the liquid holdup is dropped from each tray to the tray below. This mode of operation can be achieved by using perforated trays, without downcomers, combined with sluice chambers located under each tray.


Figure 1. Schematics illustrating the working principle of cyclic distillation: (a) vapor-flow period; (b) liquid flow-period; (c) beginning of a new vapor-flow period.

2. Mathematical model

The model of the cyclic distillation column (Patrut et al., 2014) is derived under the following assumptions: ideal stages (vapor-liquid equilibrium is reached); equal heat of vaporization; perfect mixing on each stage; negligible vapor holdup; saturated liquid feed. No assumptions are made here regarding the linearity of vapor-liquid equilibrium, negligible or constant pressure drop, infinite reboiler holdup or zero condenser holdup.

The vapor-flow period: For each component, $j = 1$, NC, the following equations describe the evolution of species holdup on each tray:

Condenser: $\dfrac{dM_{1,j}}{dt} = V \cdot y_{2,j}$ (1)

Trays: $\dfrac{dM_{k,j}}{dt} = V\left(y_{k+1,j} - y_{k,j}\right); \qquad k = 2, NT-1$ (2)

Reboiler: $\dfrac{dM_{NT,j}}{dt} = -V \cdot y_{NT,j}$ (3)

For each tray, $k = 1, NT$, the following relationships describe the liquid-vapor equilibrium:

$$P_k \cdot y_{k,j} - x_{k,j} \cdot \gamma_{k,j}\left(x_1, \ldots x_{NC}, T_k\right) \cdot P_j^{vap}\left(T_k\right) = 0 \tag{4}$$

$$x_{k,j} = \frac{M_{k,j}}{\displaystyle\sum_j M_{k,j}} \; ; \qquad\qquad \sum_j y_{k,j} - 1 = 0 \tag{5}$$

For each tray, $k = 3$, NT, the pressure is calculated based on the vapor flow rate and the amount of liquid on the tray above:

$$P_2 = P_{cond} + \Delta P_{cond} \; ; \qquad P_k = P_{k-1} + \Delta P\left(M_{k-1}, V\right) \tag{6}$$

The state of the system at the beginning of the vapor-flow period is the same as the state at the end of the liquid-flow period:

$$\mathbf{M}\left(t = 0\right) = \mathbf{M}^{(L)} \tag{7}$$

The state of the system at the end of the vapor flow period is found by integrating the equations (1)-(7)

$$\mathbf{M}^{(V)} = \mathbf{M}\left(t = t_{vap}\right) \tag{8}$$

The liquid-flow period: for each component, $j = 1, NC$, the following equations give the stage holdup at the end of the liquid-phase period:

Condenser: $$M_{1,j}^{(L)} = M_{1,j}^{(V)} - \left(D + L\right) \cdot x_{1,j}^{(V)} \tag{9}$$

Trays, rectifying section: $$M_{2,j}^{(L)} = L \cdot x_{1,j}^{(V)} \; ; \; M_{k,j}^{(L)} = M_{k-1,j}^{(V)} \; , k = 2, NF \tag{10}$$

Feed tray: $$M_{NF+1,j}^{(L)} = M_{NF,j}^{(V)} + F \cdot x_{F,j} \tag{11}$$

Trays, stripping section: $$M_{k,j}^{(L)} = M_{k-1,j}^{(V)} \; , \quad k = NF + 2, NT - 1 \tag{12}$$

Reboiler: $$M_{NT,j}^{(L)} = M_{NT,j}^{(V)} - B \cdot x_{NT,j}^{(V)} + M_{NT-1,j}^{(V)} \tag{13}$$

Equations (1) - (6) and (9) - (13) can be written in the following condensed form, where $\Phi^{(V)}$ and $\Phi^{(L)}$ are mappings relating the state at the start and the end of the vapor- and liquid-flow periods, respectively.

$$\left(M^{(V)}, x^{(V)}\right) = \Phi^{(V)}\left(M, x\right) \tag{14}$$

$$\left(M^{(L)}, x^{(L)}\right) = \Phi^{(L)}\left(M, x\right) \tag{15}$$

Periodicity condition requires:

$$\left(M^{(L)}, x^{(L)}\right) = \Phi^{(L)} \, \mathrm{o} \Phi^{(V)}\left(M^{(L)}, x^{(L)}\right) \tag{16}$$

A straightforward solution of equation (16) can be obtained by considering an initial state and applying relationships (14) and (15) until the difference between two iterations becomes small. However, the convergence can be accelerated by applying numerical methods suitable for algebraic equations (for example Newton).

The fugacity and activity coefficients have been calculated using the NRTL activity model for the vapor-liquid phase and Hayden O'Connell (HOC) fugacity coefficient model for the vapor phase. The parameters for the NRTL and HOC models have been regressed from the NIST TDE database using Aspen Plus.

3. Results and discussion

In order to size and to determine the most efficient column from an economical point of view, the operating characteristics of the cyclic distillation systems have been studied. It

is observed that, for a fixed number of trays, the required vapor flow-rate (which is directly related to the energy requirements) depends on the chosen feed tray. The variation of the required vapor flow-rate with the chosen feed tray for a column with 20 **trays is presented** in **Figure** 2.
Figure 2. Dependence of the vapor flow-rate with the feed tray for a 20 trays column (left); Variation of the vapor flow-rate with the number of trays (right)

The influence of the number of trays on the vapor flow-rate has been investigated by calculating the vapor flow-rate for columns with 20, 25, 30, 35 and 40 trays, fed at the optimal feed tray. The variation of the vapor flow-rate with the number of trays is represented in Figure 2 (right). The vapor flow-rate decreases with the increase of the number of trays, which indicates the existence of an optimum number of trays. The flow-rate decreases sharply between 20 and 25 trays, followed by a slower decrease between 25 and 40 trays. The variation of the total annual cost (calculated with well-known correlations) with the number of trays is shown in Figure 3.
Figure 3. Total annual cost for the water acetic acid through cyclic distillation column

The total annual cost decreases with the increase of the number of trays. However, the decrease between 35 and 40 trays is very small. For practical reasons, a column with 35 trays is further studied. The variation of the required vapor flow-rate with the bottoms product purity is shown in Figure 4.
Figure 4. Variation of the vapour-flow-rate with the bottoms stream purity (left); Equilibrium and operating curves for a 35 tray cyclic distillation column (right)

The equilibrium and operating curves for the 35 trays column are shown in Figure 4 (right). In the tangent pinch region, the equilibrium and operation curves are very close to each other, as in conventional distillation. The mass balance of the cyclic distillation column is shown in Table 1. The characteristics of the column are shown in Table 2.

Table 1. Mass balance of the water - acetic acid cyclic distillation column

Stream	Feed	Distillate	Bottoms
Flow-rate / [kmole/h]	477.31	424.76	52.55
Water mole fraction	0.8919	0.9982	0.0230
Acetic acid mole fraction	0.1081	0.0018	0.9770
Water mass fraction	0.7100	0.9940	0.0070
Acetic acid mass fraction	0.2900	0.0060	0.9930

Table 2. Characteristics of the water – acetic acid cyclic distillation column

Number of trays	35
Feed tray	25
Diameter / [m]	3.7
Height / [m]	22.2
Reboiler duty / [kW]	17037
Condenser duty / [kW]	12957

It should be noted that the water / acetic acid separation can be also performed by azeotropic distillation, using i-butyl acetate as entrainer. The acetic acid / water mixture and i-butyl acetate are fed to the first column. High-purity acetic acid is obtained as bottoms product, while the water – i-butyl acetate azeotrope is obtained in the distillate. The 2-phase azeotrope mixture is separated in a decanter. The organic phase is returned into the first column as reflux. The aqueous phase is fed into the second column, where high-purity pure water is produced as bottoms product and water – i-butyl acetate azeotrope is produced as distillate (Li et al., 2014).

Table 3 compares the economics of cyclic distillation, conventional distillation and azeotropic distillation alternatives, for an operating time of 8000 h/year and a payback period of 3 years.

Table 3. Cost summary for the water / acetic acid separation by different methods

	Cyclic distillation	Conventional distillation	Azeotropic distillation	
			Acetic acid column	Water column
Column / [k$]	806	1318	305	19.6
Trays / [k$]	142	280	45	1.2
Reboiler / [k$]	758	1129	515	64.7
Condenser / [k$]	397	521	605	10.1
CAPEX / [k$]	2102	3248	1470	95.6
Cooling water / [k$/y]	269	412	178	0.3
Steam / [k$/y]	3817	4527	1914	125.6
OPEX / [k$/y]	4087	4938	2092	125.9
Total annual cost / [k$/y]	4787	6021	2582	158

4. Conclusion

Separation of the acetic acid / water mixture in a distillation column operated in a cyclic manner appears to be economically competitive for the cases when impurification with a solvent is not acceptable. For comparison, when the separation is performed by conventional distillation, the optimal column has 70 trays, requires 6.03 kWh/kg acetic acid, for a total annual cost of 6200 k$/y. Azeotropic distillation (for example, using isobutyl acetate as entrainer) is cheaper (2.9 kWh/kg acetic acid, 2800 k$/y). Even though possible from a theoretical point of view, separation of water and acetic acid through binary distillation is unpractical. A very large number of trays is required in the rectifying section, to overcome the tangent pinch formed by the two components. Through cyclic operation, the number of trays is reduced to half and slightly lower energy consumption (therefore a lower total annual cost) is required for the same distillate purity and a higher purity of the bottoms product.

Abstract

This work addresses control issues of a batch reactive distillation for the production of methyl lactate via esterification reaction. The particular challenge of this classic process intensification case lies on that reactant is lighter than product and is easier to be taken away from the reaction, in such a way the conversion of loaded reactant is shrunk; to overcome this drawback, excess of reactant is typically added in the reactive zone. In order to guarantee a high conversion, a practical control approach is proposed: maintaining the maximum allowed temperature of the reaction through reboiler duty, and intermittently feeding the reactant excess, which is driven by maintaining a fixed amount of reactant in reboiler. The controllers for this two-point control configuration are conventional PI linear. The results in a simulation framework show that a reactant conversion greater than 90 % is reached with ease.

When the product is the lightest component in the mixture, the equilibrium reactions are favoured because the products are removed as the reaction proceeds; as a result, conversion is increased; however, when a reactant is the lightest component there are problems causing low conversion, and to overcome the problem, excess of such a reactant is fed in the reactive zone. Control strategy (one and two-point control) is proposed such a practical solution and novel conversion control is explored to ensure a 90% conversion. Also, the maximum temperature of the process is 393,15 K. The temperature in reboiler is satisfactorily controlled using the reboiler duty as the input control. The conversion set point (90 %) is reached with an intermittent fed of excess reactant, in this loop the control input is the feed.

Keywords: batch reactive distillation, batch distillation control, lactic acid.

1. Introduction

Reactive distillation is one of the most representative cases of process intensification (reaction and separation in one equipment), where equilibrium reactions are favoured because the products are removed as the reaction proceeds; as a result, conversions are increased and energy is saved. Nevertheless, in some reactions, certain reactants can be the lighter components, leading to low conversion because they are taken out from the reaction zone. In order to overcome this problem, it is necessary to use an excess of reactant to support the advance of the reaction; one example of this case come up in the

the esterification reaction between alcohols and carboxylic acids, such as methanol and lactic acid yielding methyl acetate and water.

A typical control structure of a continuous reactive distillation column uses the reactants feed to control the temperature in a selected stage. However, in a batch reactive distillation, the control strategy is different, one-point control can regulate temperature, but is not sufficient to guarantee conversion; then, using a two-points control configuration is resorted to (Sørensen and Skogestad, 1994). Moreover, the reactive system is another important factor due the physical properties.

Methyl acetate can be produced by reactive distillation. Figure 1 shows the reactive batch distillation with an inlet to allow intermittent reactant feed. The reaction is carried out in the reboiler, during which the methanol (MeOH) and water (W) are evaporated but condensed in the top accumulator, while the methyl acetate (ML) remain in the reboiler with the lactic acid (LA) and the methanol flow is fed into the reboiler, and the initial load of reactants as well. Aqar et al. (2016) studied the production of ML in a batch reactive distillation to optimize the LA conversion following an optimal control approach: When the column operates in total reflux, the maximum LA conversion achieved 62 %, and with the control system implemented, using the reflux ratio (RR) and the methanol flow as control inputs, the achieved conversion was greater than 90%. The result showed that the RR must be low to extract the water from the reboiler; however, the temperature profile was not shown in such study.

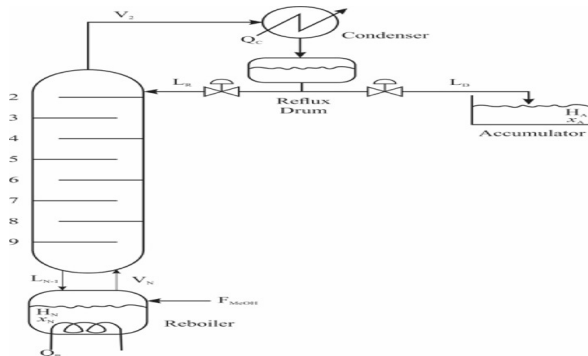
In the open literature there are a few works about control of batch reactive distillation: Sørensen and Skogestad (1994) demonstrated that one-point control strategy is enough to have a good control in the column for a typical case of reactive batch distillation where the products are the lighter components and reaction zone is in the reboiler. On this framework of designing a control system to guarantee a high conversion of reactant, controllability analysis in batch distillation is possible by linearized model, but if the model has high nonlinear behaviour large deviations could be presented and multiple points are necessary to know how controllability changes during the process (Biller and Sørensen, 2002). In this work, the nonlinear model of a batch reactive distillation column is rather used and the controllability is set by evaluating the performance of the proposed control system using one and two-points control strategy.


Figure 1. Batch reactive distillation with intermittent fed.

2. Method

Two control configuration are considered: (i) one-point control, and (ii) two-points control. In the one-point one, methanol inflow is manipulated to control the reboiler level; in this control scheme, the reboiler duty is kept constant at its maximum value. In the case of two-points control, two pairs were analysed. In the first structure, the reboiler duty was manipulated to control the reboiler temperature and the methanol feed was selected as input to control the bottom level. In the second structure, the heat duty supplied to the reboiler was used to control the reboiler temperature and the methanol feed flow was the input to control the LA conversion.

2.1. Reactive case study

In this work, the esterification of methanol with LA in a batch reactive distillation column was considered (Saenz et al. 2004). The initial load of LA and methanol was 100 mole (H_{N0}) in the reboiler, an equimolar mixture. Saenz et al. (2004) studied the kinetic of reaction LA and methanol to produce ML and water: they proposed different kinetics using Amberlyst 15 (Supelco) resin. The maximum temperature was 393,15 K to avoid desulfonization.

2.2. Model

An equilibrium model (total mass balances, component mass balances, equilibrium, summation, energy balances) is used for the distillation column and the condenser holdup is constant assuming a perfect control through flow distillate. The number of stages (NT) in the column was 10 including the condenser and reboiler ~~and accumulator~~ (Figure 1). The maximum reboiler duty was fixed at 7200 kJ h^{-1}, the maximum reboiler level was 157 moles (around 0,009 m^3). The process configuration and process features were recalled from Aqar et al. (2016), and the dynamic model followed Sørensen and Skogestad (1994) with a lineal tray hydraulic. The thermodynamically model UNIQUAC was used to calculate the Vapour–Liquid Equilibrium. A summary of column process conditions is shown in Table 1. The amount of catalyst used was 2% of the total grams of the mixture.

Table 1. Operation parameters in the column.

Maximum reboiler duty	7200 kJ h^{-1}
Maximum temperature in reboiler	373.15 K
Column pressure	100,325 N m^2
Hydraulic time constant	100(RR) s
Initial holdup on the trays	$[0.25(H_{N0})]/(NT-2)$
Initial liquid flow	10 % of initial charge (H_{N0})
Condenser holdup	$0.25(H_{N0})$

Hydraulic time constant was a function of RR and the condenser holdup was 2.5 % of the initial charge of the mixture. The vapour flow V2 is equal to the vapour flow VN.

2.3. Control strategies

To ensure reactant (methanol) in excess during the whole process, the initial reboiler level was kept constant and this will be the one-point control strategy. Control strategies summary are given in Table 2. Sørensen and Skogestad (1994) used the reboiler heat duty to control the reboiler temperature. So, it is possible to use the methanol reactant and the reboiler temperature in the next two-point control strategy.

Table 2. Control Strategies Summary.

Strategy	Control Input	Control Output
One-point Control	Methanol Flow	Reboiler Level
Two-point Control (a)	Reboiler Duty	Reboiler Temperature
	Methanol Flow	Reboiler Level
Two-point Control (b)	Reboiler Duty	Reboiler Temperature
	Methanol Flow	LA Conversion

In the first two-point control configuration (a), the level both and temperature in reboiler will be controlled. The temperature is the control output to avoid desulfonization of the resin and oligomerization of LA (Thotla and Mahajani, 2009). Another way to ensure the LA conversion is to control it directly with a SP equal or greater of 90 %. The two-point control strategy (b) used the methanol flow to control the LA conversion. In the two-point control strategies (a) and (b), the reboiler temperature is controlled with the reboiler duty. Proportional Integral (PI) controllers were used. A parametric tuning was employed through the equation (1), selecting the parameters that requires less control effort for the system. Where u_0 is the initial value of the control input at time zero.

$$effort = \int_{t_0}^{t_f} (u\text{-}u_0)^2 dt \tag{1}$$

3. Results

In this section, the simulation results will be presented. The control parameters for the PI-controllers used in the simulations are shown in the Table 3. The reboiler level is RL. For the one-point control, the reboiler duty was kept to its maximum value.

Table 3. Control parameters used in the PI controllers.

One-point Control	$K_p = 1\ kmol^{-1}$	$\tau_I = 10\ h$	$RL \rightarrow F_{MeOH}$
Two-point Control (a)	$K_p = 0.1\ kmol^{-1}$	$\tau_I = 10\ h$	$RL \rightarrow F_{MeOH}$
	$K_p = 100\ kmol^{-1}$	$\tau_I = 10\ h$	$T_{NT} \rightarrow Q_R$

Table 2. Control parameters used in the PI controllers.

Two-point Control (b)	$K_p = 100\ kmol^{-1}$	$\tau_I = 10\ h$	$X_{LA} \rightarrow F_{MeOH}$
	$K_p = 200\ kmol^{-1}$	$\tau_I = 10\ h$	$T_{NT} \rightarrow Q_R$

The reboiler level control presented a poor performance caused by the use of maximum value of reboiler duty in the whole operation; this is observed in Figure 2. Reboiler level SP was the initial charge of the mixture (100 mol).

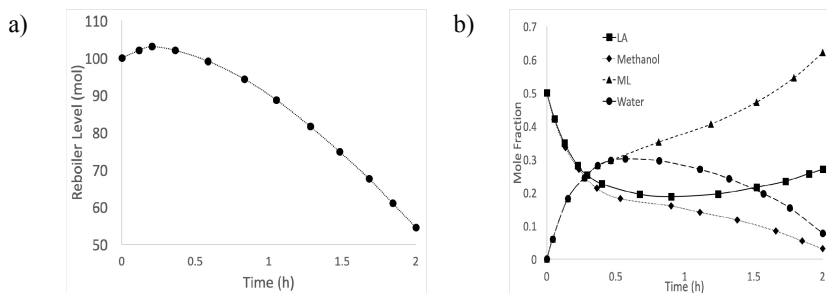
In the one-point control, the final LA conversion is 63 % because the system reached the equilibrium as in the reflux total operation; the RR was 0.3 for this case. In the two-point control strategy (a), the level and temperature in reboiler were controlled. The RR value was 0.3. The system has good control performance still the LA conversion is 65.2%. The control output response and reboiler composition profile are given in Figure 3.


Figure 2. a) control output response SP: 100 mol. b) Reboiler composition profiles for the one-point control strategy.
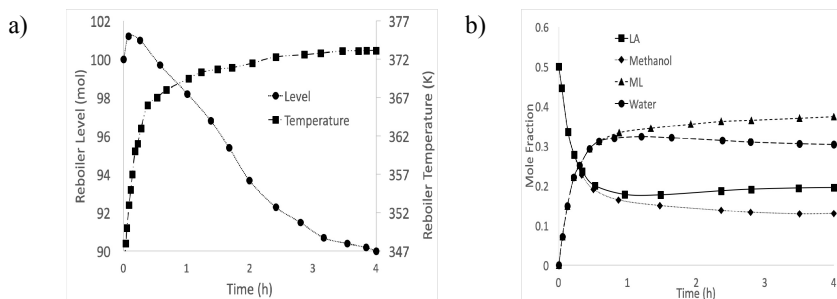

Figure 3. a) control output response; SP1= 100 mol, SP2= 373.15 K. b) Reboiler composition profiles for the two-point control (a) strategy.

In the two-point control strategy (b), the reboiler temperature was controlled satisfactorily while the LA conversion reaches the 96 % at the 6 h of operation with a RR = 0.1 and SP of 99 %. The ML mole composition at the final time (15 h) was 0.7,

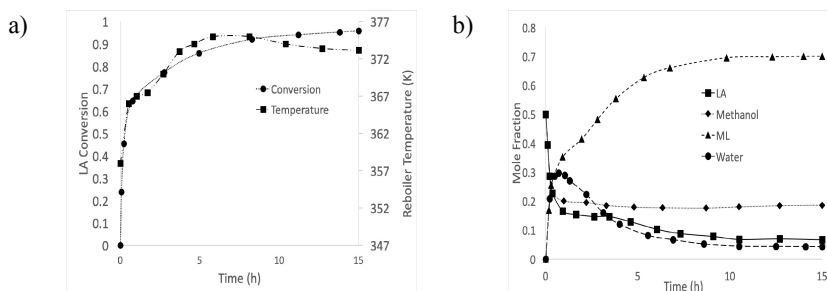
the methanol composition remains constant throughout the operation and the total amount of methanol flow was 397. 75 mol.


Figure 4. a) control output response b) Reboiler composition profiles for the two-point control (a) strategy.

4. Conclusions

The reboiler temperature in the reactive batch distillation was effectively controlled with two-point control (a), but it did not improve the LA conversion compared with the total reflux operation condition. Although considering temperature and reboiler level as control outputs did not raise LA conversion, reboiler temperature and LA conversion as control output did. The temperature specification was achieved using the two-point control strategy (b). Conversion control is a good option to improve the conversion in a batch reactive distillation. Even though the PI controller has shown good performance, in order to reduce the time operating a nonlinear controller is needed.

Abstract

This paper focuses on the data reconciliation technique (DR) in case of numerous biases. DR improves the degree of confidence in available information and generates consistent data. The inventory and analysis of the plant data (position and type of sensors …) enable an evaluation of the process redundancy. Classical Gross Error Detection and Identification (GEDI) techniques delete the biased variables, decreasing the redundancy. This leads to information loss and possibly an inability to apply DR. The methodology proposed here combines DR, based on a reduced model, and rigorous simulations to locate and estimate multiple biases and to make data consistent in case of inter-connected flows. This methodology is applied to the nuclear fuel recycling process within the scope of a state estimation tool built on a process simulation code.

Keywords: simulation, nuclear fuel treatment, data reconciliation, bias estimation.

1. Introduction

A measurement intrinsically possess uncertainty that prevents straightforward closure of mass and energy balances. In the data reconciliation (DR) methodology, accuracy is given to the measurements by exploiting redundancies in process data and physical constraints, from steady-state mass balances (Simpson et al., 1991) to nonlinear dynamic constraints (Liebman et al., 1992).

There are two main approaches to dealing with gross errors that impact DR. The first uses Gross Error Detection and Identification (GEDI) methods (Narasimhan and Jordache, 2000) and sequentially deletes the biased variables from the DR. The redundancy, which implies the ability of DR to correct the measurements in order to satisfy the process constraints, is reduced. However, performances of DR and GEDI are still limited in disrupted cases, such as multiple flows between two units, numerous gross errors, and the position and magnitude of gross errors (Corderio do Valle et al. 2018). The second

approach, not discussed in this study, modifies the objective function of DR to mitigate the effect of gross errors (Fuente, M.J. et al. 2015).

A new methodology for a nonlinear system is proposed here, combining the DR approach, based on a simplified model, and simulations, based on a first-principle model. It prevents the removal of the biased variables from the measurement set. The bias estimation is performed by the rigorous model, which enables the maximum redundancy to be kept. With a set of consistent input data generated by DR, the simulation can precisely estimate key indicators.

2. Methodology

Graph theory can be used to classify data in order to distinguish observable (measured or calculable) data from non-observable data. Among observable data, three categories can be defined: redundant data (deleting this measurement does not change the system observability), non-redundant and measured data, non-measured data. The redundant data are reconciled.

The n measurement vector X^B is linked to the true value of the measured variables X^T, the random error ε^B (assumed to be independent, with a zero mean and normally distributed), and the gross error B, here, the bias, by the following equation:

$$X^B = X^T + \varepsilon^B + B \tag{1}$$

Data reconciliation consists of minimizing an objective function constrained by a set of constraints f:

$$\underset{X^R, B}{Min}((X^B - B) - X^R)^T V^{-1}((X^B - B) - X^R)$$

$$s.t. f(X^R, \theta) = 0 \tag{2}$$

where X^R is the n reconciled values vector, V the (n,n) covariance matrix of the measured data, and θ the parameters of the system. X^R are the best estimates of process variables, in the sense of the maximum likelihood. A study of the redundant variables, depending on the process topology and the number of independent equations, enables the determination of the ability of the DR to calculate a consistent set of reconciled data.

A global approach is to solve the DR with the rigorous model as constraints and simultaneously estimates the reconciled values X^R and the biases B. In most industrial applications, the entire first-principle model of the process, named rigorous model thereafter, cannot be directly used as the constraints f for the DR. This is generally due to implementation difficulties, such as code interfaces, and complex numerical estimation of the gradient of the constraints. The methodology proposed performs bias estimation outside the DR by an iterative strategy. It divides the problem into two sub problems: the rigorous model estimates the biases while the DR solves Eq. (2), in regards of X^R only, with a reduced model as constraints. This simplified model is made up of a selection of linear and nonlinear equations specially chosen in order to exploit all information available from the measurements. In particular, it contains the total mass balance and, depending on the case study, some partial mass balances and equations for the calculation of physical properties and fluid phase equilibria.

Figure 1 displays the new methodology. First, a map of the process (list of fluxes, units, sensors, uncertainties etc.) is built offline to generate the redundancy graph. The second

step makes use of process expertise to identify bias locations, concerning measurements on internal or output fluxes. An initial simulation, based on the rigorous model, with input fluxes raw measurements X_{in}^B as input data, gives a first estimation for the biases $B^{C(0)}$. As regards the vector of the calculated bias B^C, each element is null except for the identified biased output variables. These elements are equal to the difference between the biased measurements X_{out}^B and the rigorous simulation calculated outputs X_{out}^C.

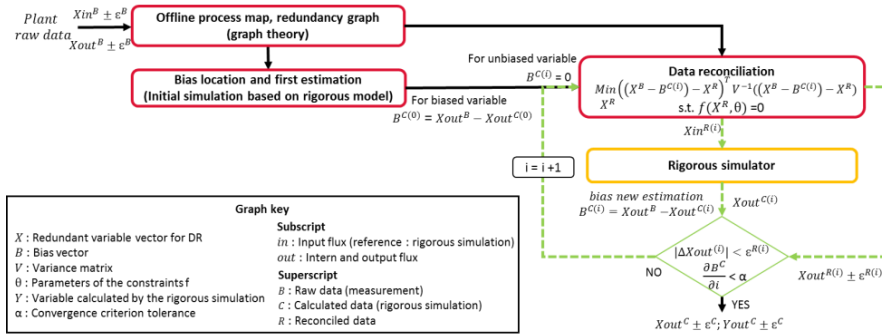
The DR is then solved iteratively with respect to X^R only, the values of biases $B^{C(i)}$ being considered fixed. Therefore, the process redundancy is unreduced by biases. To solve the nonlinear steady-state DR problem, this study uses the Fmincon function of Scilab software. The uncertainty for reconciled values is estimated at each DR solution by uncertainty propagation (Narasimhan and Jordache, 2000).


Figure 1: Bias identification and estimation methodology

At iteration i, the reconciled values of the input fluxes $X_{in}^{R(i)}$ are transferred to the rigorous simulator. The reconciled and calculated output flow information, $X_{out}^{R(i)}$ and $X_{out}^{C(i)}$ respectively, are compared. If the difference $|\Delta X_{out}^{C-R(i)}|$ between them is smaller than the uncertainties of reconciled data, the DR gives consistent values for rigorous model equations in the case of Lipschitz continuity around the solution. New bias values $B^{C(i)}$ are estimated with the last rigorous calculation. The best estimation of the bias values is reached when the biases between two iterations are constant. If these two criteria are not respected, bias information given to the DR is not satisfactory. The new bias values $B^{C(i)}$ are given to the DR for the next step. The iterations continue until the bias value estimation enables consistent data to be reached. The final DR is performed with fully known bias information, and has a minimal objective function value.

3. Case study

The methodology proposed in this paper is applied to the PUREX process and uses the PAREX simulation code developed and validated by the CEA (Dinh et al., 2008). This process carries out the treatment of spent nuclear fuel. Spent fuel contains the elements of interest, uranium and plutonium, and the waste, i.e. fission products. TBP (tributyl-phosphate) is the extractive molecule used to recover and purify uranium and plutonium through interconnected liquid-liquid extraction steps. For the final products, very specific features in terms of purity as well as extraction efficiency are required. In order to reach the necessary high performances, the metal loading of the solvent (metal mass flowrate in the solvent for a specific TBP mass flowrate) must be precisely controlled. This ratio is a sensitive parameter which deeply impacts the process state (Bisson et al., 2016). Therefore, DR aims to reduce uncertainty on this key process indicator by giving reliable

input data to the rigorous simulator PAREX. It is based on first-principle models notably taking into account the partitioning of the species, the transfer, and chemical kinetics.

This study deals with an extraction-stripping step of the PUREX process where many sensors are implemented, and can be separated into two categories. Major consideration is given to a specific set of sensors essential for operation, control, and to respect the safety regulations (multiple sensors, regular checking, preventive maintenance, etc.). They are listed as reference information for the industrial plant. The secondary sensors are not used for process control or for industrial safety. They give additional information, increasing redundancy, which can help process state estimation. Some of this additional data can have biases non-detectable with previously-acquired data. A scenario is defined in order to encounter identified causes of GEDI performance loss (Corderio do Valle et al., 2018): the biases concern flows connecting the same two units, and their suppression leads to the system being non-redundant.

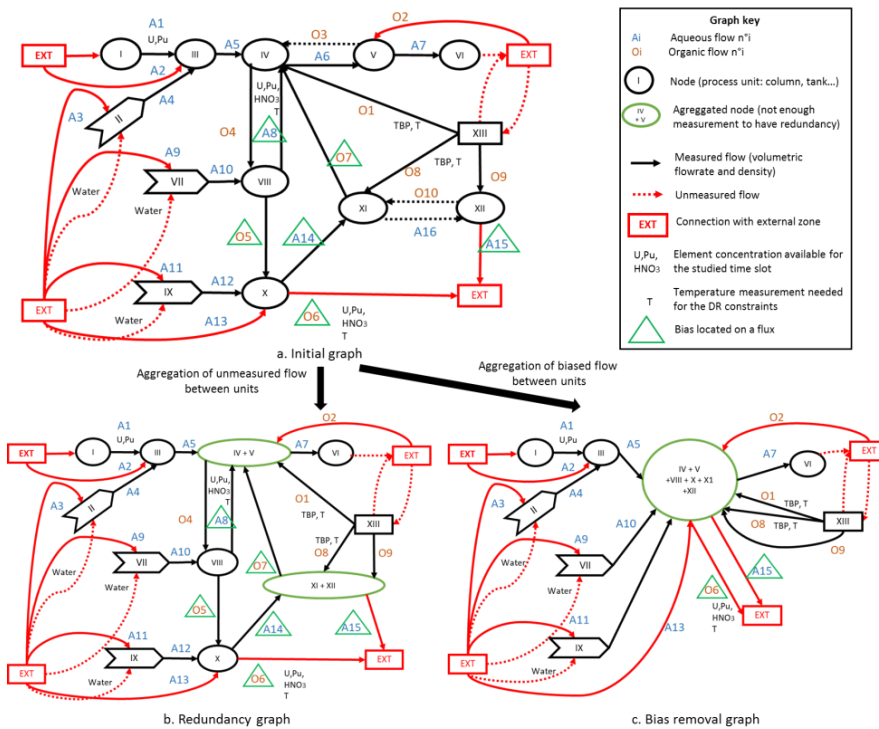
The initial graph of the PUREX process (Figure 2a) contains information about flows (directed arcs) and units (nodes). The redundancy graph (Figure 2b) is free of internal non-measured physical quantities: arcs depict constraints linking measurements of interest from one unit to the other. The measured variables used in the DR problem are volumetric flowrates, densities for each arc, temperature, and uranium, plutonium, nitric acid and TBP composition for specific arcs. The six identified biases are all located on internal and output flowrates measured by secondary sensors.


Figure 2: Graphs of an extraction-stripping step of the PUREX process.

For the classical GEDI methodology, each time a bias is detected, the redundancy decreases (Narasimhan and Jordache, 2000). The bias removal graph (Figure 2c) shows this loss of redundancy: DR cannot be applied on the aggregated node (IV+V+VIII+X+XI+XII), as only the calculation of the biases on output flowrates is possible in this scenario. In addition, classical GEDI techniques cannot locate a bias within two-way arcs between two units, such as between IV and VIII.

4. Results

The first bias estimation $B^{C(0)}$ was obtained by the comparison between measured internal and output flow-rates and the initial PAREX calculation. Four iterations were needed to obtain consistent bias estimations B^C and the minimum of the objective function. As soon as all biases can be considered constant, the iterations stop ($|B^{C(4)} - B^{C(3)}| < \alpha$, with $\alpha = 10^{-4}$ the tolerance of the convergence criterion). Note that the bias values are considerably higher than the measurement uncertainty in this scenario; therefore their contribution must be isolated.

All redundant data (80 variables), biased and unbiased, are reconciled. Figure 3 displays the differences ΔX_{out}^{B-R} between some of the measured X_{out}^B and reconciled X_{out}^R values and their corresponding uncertainties. The differences $\Delta X_{out}^{B-C(0)}$ and ΔX_{out}^{B-C} between the measured X_{out}^B and, respectively, initial $X_{out}^{C(0)}$ and final X_{out}^C PAREX values, are also laid out.

The differences $\Delta X_{out}^{B-C(0)}$ result from input measurement uncertainty. For flowrate A7, flowrate O4, and density A8, the reconciled values are closer to the PAREX calculations than the measured values, highlighting the consistency of the final data set. Moreover, the uncertainty of the reconciled values is smaller than the measurement uncertainty.
Figure 3: Comparison between measured, reconciled, and PAREX calculated outputs.

Concerning density A8 and density O6, the uncertainties of the reconciled values are very small and surround the reconciled and calculated values. These densities are linked to uranium and plutonium concentrations through a density equation. The analytical concentration measurement methods are more precise than the density sensors. Thus, the uncertainty propagation through the constraints enables the X_{out}^R to be more precise.

Concerning the other unbiased variables, mostly linked by mass balances, the reconciled X_{out}^R values are only slightly different from the measured X_{out}^B values. The two PAREX simulations give very similar results. This reflects the low sensitivity of these physical quantities to the change in the inputs from measured to reconciled values.

As PAREX input data are reconciled, accuracy is given to process indicators estimation. For instance, the uncertainty of the TBP mass flowrate is reduced by half (measurement uncertainty: 5.26 %, uncertainty of the reconciled value: 2.81 %). The uncertainties of uranium and plutonium mass flowrates are also reduced (from 2.8 % to 2.0 %), which leads to a better estimation of the metal loading in the solvent.

5. Conclusions

In classical GEDI methods, each bias decreases the redundancy of the system. The new methodology is based on nonlinear DR in which the biases are fixed and estimated by a rigorous model, with the reconciled values as input data. Therefore, the redundancy is not modified. For the bias estimation to be precise, the rigorous code and the DR iterate until the bias values offer a consistent set of reconciled data. This methodology enables explicit and inexplicit constraints for a DR problem to be addressed.

The proposed methodology was applied with success to a spent nuclear fuel treatment process. As a tool to reduce uncertainty in nuclear matter management within the plant, combining data reconciliation and the PAREX code could help in process monitoring and control.

Abstract

Bioprocesses have received great attention from the scientific community as an alternative to fossil-based products by microorganisms-synthesised counterparts. However, bioprocesses are generally operated at unsteady-state conditions and are stochastic from a macro-scale perspective, making their optimisation a challenging task. Furthermore, as biological systems are highly complex, plant-model mismatch is usually present. To address the aforementioned challenges, in this work, we propose a reinforcement learning based online optimisation strategy. We first use reinforcement learning to learn an optimal policy given a preliminary process model. This means that we compute diverse trajectories and feed them into a recurrent neural network, resulting in a policy network which takes the states as input and gives the next optimal control action as output. Through this procedure, we are able to capture the previously believed behaviour of the biosystem. Subsequently, we adopted this network as an initial policy for the "real" system (the plant) and apply a batch-to-batch reinforcement learning strategy to update the network's accuracy. This is computed by using a more complex process model (representing the real plant) embedded with adequate stochasticity to account for the perturbations in a real dynamic bioprocess. We demonstrate the effectiveness and advantages of the proposed approach in a case study by computing the optimal policy in a realistic number of batch runs.

Keywords: Reinforcement Learning, Batch Process, Recurrent Neural Networks, Bioprocesses

1. Introduction

There has been a global interest in using sustainable bio-production systems to produce a broad range of chemicals and substitute fossil derived synthetic routes (Harun et al., 2018). Bioprocesses exploit microorganisms to synthesise platform chemicals and high-value products by using different means of resources (Jing et al., 2018). Compared to a traditional chemical process, a biochemical process is highly complex due to the intricate relationships between metabolic reaction networks and culture fluid dynamics (del Rio-

Chanona et al., 2018). As a result, it is difficult to construct accurate dynamic models to simulate general large-scale biosystems, and plant-model mismatch is inevitable. Furthermore, bioprocess dynamics are often stochastic due to the underlying metabolic pathways which are sensitive to even mild changes in operating conditions (Zhang and Vassiliadis, 2015; Thierie, 2004). Therefore, developing control and optimisation strategies for bioprocesses remains an open challenge. Given these critical limitations in physical models, in this work we propose a data-driven approach to address this challenge.

We must seek a strategy that can handle both the system's stochasticity and plant-model mismatch. It is here that we have opted to use *reinforcement learning* and more specifically, *policy gradients*, the rationale behind this is next explained. Reinforcement learning (RL) addresses the problem of solving nonlinear and stochastic optimal control problems (Bertsekas, 2000). Two main branches have been established on how to solve dynamic optimisation problems via RL. The first one is based on *dynamic programming* (DP), hence termed approximate dynamic programming (ADP). DP relies on the Hamilton-Jacobi-Bellman equation (HJBE), the solution of which becomes intractable for small size problems with nonlinear dynamics and continuous state and control actions. Hence, past research has relied on using ADP techniques to find (approximate) solutions to this type of problem (Sutton and Barto, 2018). The second branch, is to use *policy gradients* which directly obtain a policy by maximising a desired performance index. This approach is well suited for problems where both the state and control space are continuous. We have therefore adopted this approach for this work. Policy gradient methods are further explained in Section 2.2.

Finally, to address plant-model mismatch, we have applied a data-driven approach. Although there are knowledge-based modelling strategies such as iterative learning (Moore et al., 2006), here we propose a fully data-driven method that can learn from the true dynamics of the system while incorporating previous knowledge.

2. Preliminaries

In this section we introduce important concepts for the proposed work.

2.1. Recurrent Neural Network

Recurrent neural networks, (RNNs) (Rumelhart et al., 1986), are tailored to address sequential data. RNNs produce an output at each time step and have recursive connections between hidden units. This allows them to have a "memory" of previous data and hence be well suited to model time-series. Thus, it could be said that RNNs are essentially simulating a dynamic system for a given set of parameters. In this work, RNNs are applied to parameterise the stochastic policy.

2.2. Policy Gradient Methods

A particular family of RL methods that do not require an explicit estimate of the value of state-action pairs are called *policy gradient methods*. These methods rely on a parametrised policy function $\pi_\theta(\cdot)$ that returns an action a given a state of the system s and a set of intrinsic parameters θ. In the case of stochastic policies, the policy function returns the defining parameters of a probability distribution over possible actions, from which the

actions are sampled:

$$a \sim \pi_\theta(a|s) = \pi(a|s, \theta) = p(a_t = a|s_t = s, \theta_t = \theta).$$ (1)

In this work, an RNN is used as the parametrised policy, which takes states and past controls as inputs and returns a mean and a variance from which a control is drawn. In this setting, the exploitation-exploration trade-off is represented explicitly as the variance of the underlying distribution of the policy. Deterministic policies may be approached as a limiting case where variance fades upon convergence. Let a sequence of H states and actions be called an *episode* τ. An episode τ is a secuence of states and actions generated by following the current policy, $\tau \sim p(\tau|\theta)$. The reward function $(R(\cdot))$ may be estimated over K episode samples:

$$\hat{R}(\theta) = \mathbb{E}_\theta[R(\tau)] = \int_\tau p(\tau|\theta)R(\tau)\mathrm{d}\tau \approx \frac{1}{K}\sum_{k=1}^{K} R(\tau^{(k)}).$$ (2)

The objective of policy gradient methods is to maximise a reward function $\hat{R}(\theta)$ by using gradient ascent techniques over a continuously differentiable policy. The evolution of the intrinsic parameters at each optimisation step m is given by

$$\theta_{m+1} = \theta_m + \alpha_m \nabla_\theta R|_{\theta=\theta_m}.$$ (3)

Differentiable policies guarantee smooth changes over sufficiently small variations of the parameters.

2.3. REINFORCE Algorithm

The REINFORCE (Williams, 1992) algorithm approximates the gradient of the policy to maximise the expected reward with respect to the parameters θ without the need of a dynamic model of the process. For this, it is necessary to take advantage of the gradient of a logarithm and a decomposition of the likelihood of an H step episode τ under a policy π_θ (Sutton and Barto, 2018; Peters and Schaal, 2008),

$$p(\tau|\theta) = p(s_0) \prod_{h=0}^{H} p(s_{h+1}|s_h, a_h) \cdot \pi_\theta(a_h|s_h),$$ (4)

to express approximate the desired gradient as

$$\nabla_\theta \hat{R}(\theta) = \int_\tau R(\tau)p(\tau|\theta)\nabla_\theta \log p(\tau|\theta)\mathrm{d}\tau \approx \frac{1}{K}\sum_{k=1}^{K} R(\tau^{(k)})\nabla_\theta \log p(\tau^{(k)}|\theta)$$
$$\approx \frac{1}{K}\sum_{k=1}^{K} R(\tau^{(k)}) \sum_{h=1}^{H} \nabla_\theta \log \pi_\theta\left(a_h^{(k)}|s_h^{(k)}\right).$$ (5)

The variance of this estimation can be reduced with the aid of an action-independent baseline b without introducing bias. A simple but effective baseline is the expectation of reward under the current policy, approximated by the mean over the sampled paths:

$$b = \hat{R}(\theta) \approx \frac{1}{K}\sum_{k=1}^{K} R(\tau^{(k)}),$$ (6)

$$\nabla_\theta \hat{R}(\theta) \approx \frac{1}{K} \sum_{k=1}^{K} \left(R(\tau^{(k)}) - b \right) \sum_{h=1}^{H} \nabla_\theta \log \pi_\theta \left(a_h^{(k)} | s_h^{(k)} \right). \tag{7}$$

This selection increases the log likelihood of an action by comparing it to the expected reward of the current policy.

3. Reinforcement Learning for Bioprocess Optimisation under Uncertainty

In this work, during Stage 1, we assume a preliminary model has been constructed to approximate the real system's dynamics. This approximate model can be used to generate a large size of episodes (different control actions subject to probability) for each training epoch (an epoch corresponds to a specific set of RNN parameter values) to *initially* design a control policy network that produces the model identified optimal policy. Hence the control policy is an RNN which takes states (including time to termination) and past controls as inputs and returns a mean and a variance from which a control action is drawn.

During Stage 2 (real plant optimal control), the policy network is directly updated using the real system (the plant) in a *batch-to-batch* framework. Accuracy of the control policy (*i.e.* the RNN) is therefore consolidated during an online implementation. The stochastic control policy is a RNN that represents a conditional probability distribution π_θ. The RNN predicts the mean and standard deviation of the next action through a deterministic map using the measurements (the previous states s_i, a sequences of previous actions (a_i) with $i \in \{-N, \ldots, -1\}$) and the time that is left for the end of the batch process. This proposed stochastic control policy is trained using the REINFORCE algorithm (see Section 2). This algorithm aims to maximise a given reward (*e.g.* concentration of target product at the final time), with the mean value of this reward being employed as a baseline during the update of RNN parameter values (see Eq. 6 & 7). The use of a baseline has been proven to be advantageous as long as it is independent of the control actions (Sutton and Barto, 2018).

Initially (Stage 1), the policy network is trained *off-line* using an available approximate model. The algorithm runs for several epochs and episodes until convergence. The network is then adopted to generate initial optimal policies for the real system (the plant, simulated by a model complex process model which is not available for RNN construction)(Stage 2). Methods used in the REINFORCE algorithm usually require a large number of episodes and epochs, therefore a good initial solution is paramount so that Stage 2 (which is assumed to be done in the actual plant) can be completed with few batch-to-batch runs. In order to keep the problem realistic, only a small number of batches is utilised in Stage 2 to refine the policy network.

4. Computational Case Studies

The proposed methodology is applied to a fed-batch bioreactor, where the objective is to maximise the concentration of target product (y_2) at the end of the batch time, using light and an inflow rate (u_1 and u_2) as control variables. The plant (real photo-production system) is simulated using the following equations:

$$\frac{dy_1}{dt} = -(u_1 + 0.5\, u_1^2)y_1 + 0.5\frac{u_2 y_2}{(y_1 + y_2)} \qquad \frac{dy_2}{dt} = u_1\, y_1 - 0.7 u_2\, y_1 \tag{8}$$

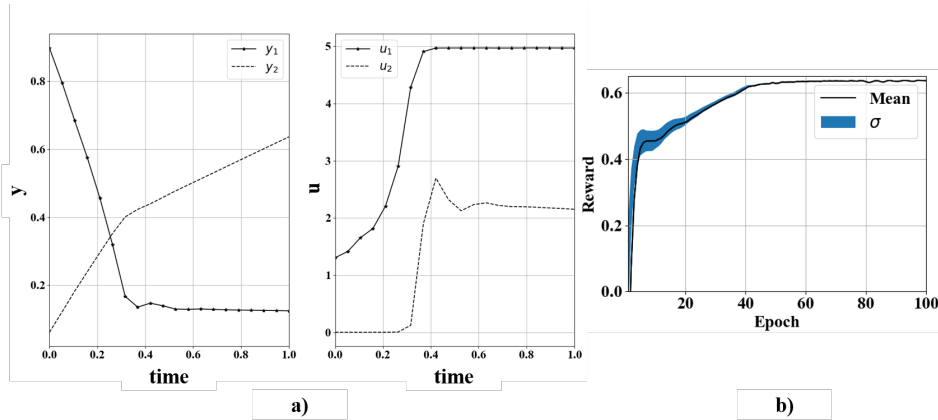
where u_1, u_2 and y_1, y_2 are the control variables and the outlet concentrations of the reactant and product, respectively. The batch operation time course is normalised to 1.


Figure 1: (a) The time trajectories produced by the trained policies. (b) The reward computed for the approximate model.

Additionally, a random disturbance is assumed, which is given by a Gaussian distribution with mean value 0 and standard deviation 0.02. It is assumed that only the following approximate model (simplified from the complex model) is known, and the preliminary training is performed based on this model to construct the control policy network, whilst the real system model is unknown due to the complexity of the process mechanisms.

$$\frac{dy_1}{dt} = -(u_1 + 0.5\, u_1^2)y_1 + u_2 \qquad\qquad \frac{dy_2}{dt} = u_1\, y_1 - u_2\, y_1 \qquad (9)$$

Initially, 100 epochs and 800 episodes are generated from the simplified model to search the optimal control policy that maximises the reward for Eq. 9. Control variables are constrained to be in $[0, 5]$. The control policy RNN is designed to contain 3 hidden layers, each of which comprising 15 neurons embedded by a hyperbolic tangent activation function. Adam (Kingma and Ba, 2014) is employed to compute the network parameter values. It should be mentioned that the reward computed after convergence is almost the same in comparison to the result given by the optimal control problem (OCP) at Stage 1. The maximum rewards for RL and OCP are 0.637 and 0.640, respectively. The reward for its epoch is depicted in Figure 2b) and the process trajectories after the final update of the policy network are shown in Figure 2a). This policy is then used to initialise the REINFORCE algorithm for the plant's RL (Stage 2), where 25 episodes are used (*i.e.* 25 real plant batches). The solution after only 4 epochs is 0.575 whilst the stochastic-free optimal solution identified using the *unknown* (complex) model of the plant is 0.583. The reward of this epoch is depicted in Figure 1b) and the process trajectories after the last epoch are depicted in Figure 1a).

5. Conclusions

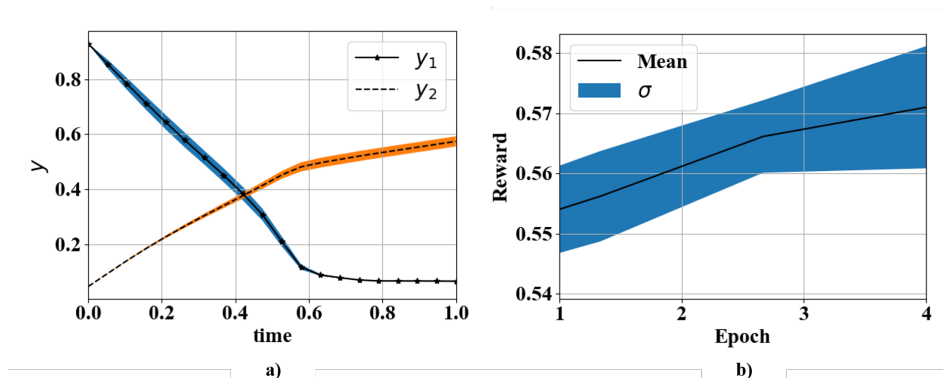
In this work we show that by adapting reinforcement learning techniques to uncertain and complex bioprocesses we are able to obtain a near optimal policy for a stochastic system where the true dynamics are unknown. Furthermore, we obtain this result in a realistic scenario where only a modest number of batch runs is used. We emphasise that


Figure 2: (a) The time trajectories produced by the real plant. (b) The reward computed by the updated training using the plant ("real" system) for each epoch.

we assume no process structure and embed both stochasticity and plant-model mismatch into the considered system, the optimisation of which is generally known to be intractable. Future work will focus on more complex case studies and exploring other RL methods, such as bias reduction and sample efficiency strategies.

Abstract

Safety and controllability are two important items that complement the economic analysis commonly done during a process design. Such factors are typically carried out once the process has been designed. Although some approaches have been proposed to include controllability properties from the design stage of the process, safety is still addressed after the design has been completed, so that safety devices are added to mitigate the consequences of potential accidents. Inherent safety is the most effective risk management approach, since actions can be taken to avoid accidents instead of mitigating their consequences. However, inherent safety is not a straightforward procedure, nor universal, and sometimes in conflict with other properties or parameters of the process. This manuscript describes a new index to account for inherent safety and controllability. The combination of a conditions number that accounts for controllability and a distance likely to cause death that emerges from the application of a quantitative risk analysis for the process was used as a basis. Three mathematical relationships were explored in the search for a suitable combination of such indices. The procedure was applied to a case study dealing with a distillation system design. Results show how the values obtained from the proposed index can give an initial assessment of the combined effect of risk and controllability as part of the design of a process.

Keywords: controllability, design, inherent safety, risk analysis.

1. Introduction

The concepts associated with inherent safety provide an effective tool for risk management. Inherent safety relies on the principles of elimination, minimization, moderation, substitution and simplification. The objective of inherent safety is to avoid risk instead of diminishing its consequences. The effectiveness of inherent safety depends on the stage of the plant life it is applied, being the design stage the most effective. The decisions based on inherent safety must be evaluated carefully, since inherent safety principles sometimes show conflicts among them. For instance, the minimization principle states that a process is safer when hazardous materials inventory is reduced, but dynamic performance might work against safety if inventory is reduced. Thus, it is important to assess safety in early stages of process design including this type of self-

conflicting behavior. Recently, a comprehensive review of process safety indices has been published (Roy et al., 2016). From this collection, some highlighted indexes are discussed here. Dow Fire & Explosion Index (DF&EI) was the first proposed index to account for safety in the mid-60's. There have been several works to assess inherent safety since it was defined in the 80's. The first index related to inherent safety was proposed by Heikkila et al (1996). This index is similar to DF&EI and considers two main parts of the process: chemicals properties and process conditions. Khan and Amyotte (2004) have published an integrated inherent safety index, named I2SI. This index is more complex and considers process control within inherent safety.

Most of the indices published so far are semi-quantitative, but many times weight factors are used to rank their importance. This semi-quantitative characteristic results in different processes with similar conditions so that material properties may get the same rating, which is not totally accurate. A quantitative risk analysis (QRA) has been shown as a proper tool to account for safety (Medina-Herrera et al., 2014). A QRA performs a more detailed study and provides a more exact risk measurement because probabilities and consequences are considered (AIChE, 2000).

The Morari resilience index (MRI) can be used to discriminate among process alternatives; the larger its value, the more controllable the process is. Another important index is the condition number (CN) related to system sensitivity against input disturbances. Small values are desired. Another important index is the relative gain array number (RGA$_{No}$) which gives information about the controlled and manipulated variables in the frequency domain; pairings with low RGA$_{No}$ values are preferred. All these indices provide a good basis to account for controllability, but a suitable approach to include both controllability and process safety is needed.

In this work, we propose a quantitative approach for process design that accounts for inherent safety considering both risk and controllability. In terms of risk, we use a QRA approach to obtain a distance likely to cause death, which relates to material inventory. For controllability, we test two indices, namely the condition number and the relative gain array. From a set of design candidates, the indices are normalized, and three mathematical relationships between risk and controllability are explored.

2. Safety Indices Calculation

2.1. Design approach

A set of initial designs (P) is considered to evaluate the performance of each design using the proposed indexes. Once the candidates are set, they are subjected to a combined controllability and QRA analysis. The approach is carried out using ASPEN Tech and MATLAB as software tools. In Aspen Plus steady state simulations are carried out, simulations are then exported to Aspen Dynamics, and the results are transferred to MATLAB, where indexes are computed.

2.2. Controllability analysis

In terms of controllability, a singular value decomposition procedure is carried out, from which the condition number CN_i is evaluated. Regularly, a matrix of gain is obtained for the process at zero frequency and a singular value decomposition analysis is carried out. In this work, we followed the methodology proposed by Gabor and Mizsey (2008) to

make calculations using a linearized state-space model system of every candidate i. The linearized state space model can be obtained with the Control Design Interface module. The methodology also computes MRI and RGA_{No}.

2.3. Quantitative risk analysis

QRA was implemented to assess the risk of a chemical inside process, following the methodology described in Medina-Herrera et al. (2014). The methodology is based on frequency and consequences analyses. First, catastrophic scenarios are identified from potential failures within the system using a bow tie procedure, and frequencies are calculated from literature data on failures. Then, a consequence analysis is performed for every catastrophic scenario previously identified. In brief, the consequences analysis implies quantification of the amount of material released, dispersion calculations, characterization of the scenario, and finally quantification of consequences. The models for consequence analysis were taken from CCPS Guidelines for Quantitative Risk Analysis in Chemical Process (AIChE, 2000). After the application of QRA, DD_i is obtained, which represents the distance of affectation such that there is a 50% chance of death in case of a catastrophic event. DD_i was selected because it can be calculated as measurement of risk even when layout is not yet defined, in an early design stage.

2.4. Normalization

After controllability and risk indices are individually evaluated, a normalization procedure is needed, since such indices have values with different orders of magnitude, and they also depend on the system of units.

When the set P was evaluated and controllability and risk indicators were obtained for each candidate i, a normalization procedure was used taking as a basis the highest value of each index, DD_i and CN_i, within the set P, that is,

$$\left. \begin{array}{l} DD_N^i = \dfrac{DD^i}{Maximum(DD^i)} \\[3mm] CN_N^i = \dfrac{CN^i}{Maximum(CN^i)} \end{array} \right\} \forall i \in P \tag{1}$$

As a result, the normalized indices are bound between zero and one, and they can be subject to numerical comparison on a consistent basis.

2.5. Basic mathematical relationships: Indices

After the indicators are obtained with similar orders of magnitude, they can be used to rank process alternatives from controllability and risk considerations. Even when the relationship between such items is complex, we can establish that they are related to the process safety. Facing the lack of knowledge about the relationship between controllability and risk to assess safety, we followed the methodology by Ni et al. (2010) to create indices with two different inputs, and derived three basic mathematical relationships. As a result, a proposed safety index, SI, was developed, and three versions of such an index were created. The objective of testing three different relationships is aiding in the analysis to understand whether risk and controllability are additive, factored or follow a balanced relationship.

The first version SI_1 is the addition of both criteria, distance likely to cause death (DD_N) and condition number (CN_N).

$$SI_1 = DD_N + CN_N \tag{2}$$

The second version, SI_2, is the product of both inputs,

$$SI_2 = DD_N * CN_N \tag{3}$$

For both additive and product relationships, the smaller the value of the index, the safer the process is.

The third version we explore is a fraction given by the distance likely to cause death divided by the condition number (see Eq. (4)). In this case, a value close to one means that the process is balanced from both controllability and safety considerations, which may not necessarily be desirable. A value higher than one would indicate that risk is a more important criterion than controllability, and vice versa.

$$SI_3 = DD_N / CN_N \tag{4}$$

These three versions arise from the lack of knowledge on the relationship between risk and controllability. It deemed convenient to calculate and evaluate all three alternatives for an initial insight into behavior of the proposed index.

3. Case Study and Results

The case study was taken from the CCPS Example of the guidelines for chemical process quantitative risk analysis (AIChE, 2000). The distillation system is a single column that separates n-hexane and n-heptane. The feed stream has 60,120 kg/h of a binary mixture with 58%wt of n-hexane. The purity specification for the top product is 0.9 on a weight basis, with a flowrate of 36,000 kg/h. The column has 16 equilibrium stages and the top pressure is 4.9 atm. The internal diameter calculated by ASPEN Plus was 2.7 meters. The residence time for sump was fixed at 6 minutes, and for reflux drum at 12 min using a 2D=L rule for tank dimensions. The QRA performed with the CCPS Guidelines has been used to analyze process risk. The objective of this example is to describe the methodology for the proposed index calculations along with the analysis of results. The hydraulic variables considered for this example were diameter and residence time for the reflux drum and sump. Such hydraulic variables affect both criteria, controllability and risk. In order to define the set of designs P, we took the CCPS design as the base case, which has a diameter of 2.71m and 12 and 6 min of residence time on the reflux drum and sump. Other designs were considered by varying the diameter from half the base diameter to three times that value, such that D = [0.5Dbase, 0.75Dbase, Dbase, 1.5Dbase, 2Dbase, 3Dbase] where Dbase=2.71m. As for the residence time, a range was fixed from 1 minute to 20 minutes, assuming equal values for both tanks. It should be noted that the base case assumes residence times of 12 and 6 minutes. When the diameter was varied, the designs were set with a residence time of 10 min for reflux drum and sump, and when residence time was varied, the diameter was kept fixed at 2.71m (in that case, the residence time was the same for reflux drum and sump).

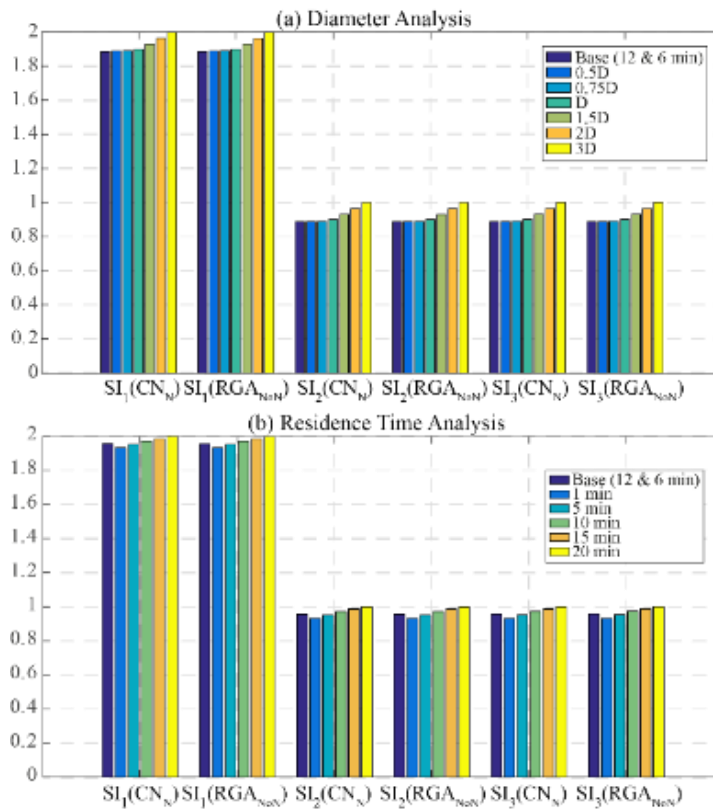
The results obtained are illustrated in Figure 1. We can observe that there is no significant difference using CN_N or RGA_{NoN} for the controllability component. We also observe that for the range analyzed, the trend seems not to be linear. The index presents almost the same value from 0.5 times diameter to the base diameter; after that point, increasing the diameter has a more pronounced effect on the three forms of the safety index, which means that increasing the diameter to improve controllability conflicts with the safety parameter. The safest design is the base case, according to SI_1 and SI_2. The design with three times diameter (3D) is more balanced between controllability and risk, as given from the results of SI_3, while for the base design controllability has a higher weight than risk ($SI_3 < 1$), which means that changing the diameter is not recommended for an inherently safer process. In part b, we observe that the contribution of the two controllability indicators used here is similar for the three safety indices. It is important to notice that for this variation range (1min -20 min) the trend seems to be linear. From SI_1 and SI_2, a residence time of 1 minute is the safest option. From the results of SI_3, the same trend is observed; decreasing residence time has a lower impact on risk with respect to the effect on controllability. Residence time has therefore an important effect on safety, as given from the risk evaluations conducted here.


Figure 1. CCPS case study Results of Proposed Indexes for analysis of (a) changes of diameter and (b) changes of residence times

Conclusion

A combined index that accounts for risk and controllability has been described. After normalizing the individual indices chosen for each item between zero and one, three types of relationships were explored. The results of the application to a case study taken from the CCPS publication showed that implementing the minimization principle of inherent safety can lead to a conflict with controllability properties, which calls for a careful consideration of risk and controllability during the design stage of a process. The approach given in this work attempts to contribute in that direction. It is worthy of mention that there is not a general guideline whether reducing inventory, which is called for from the minimization principle of inherent safety, is a correct policy when controllability is considered. The results of the application to the case study show this type of conflict. It is important to notice that this methodology has being implemented in case studies on steady state and it has not been implemented in an intrinsically dynamic system, such as a batch process. Further work is needed to consolidate these initial efforts towards the development of a useful index that combines risk and controllability and that can be used during the design stage of a chemical process.

A primal bounding approach for multistage stochastic programs of resource-constrained planning and scheduling with stochastic task success

Zuo Zeng, Selen Cremaschi*

Department of Chemical Engineering, Auburn University, Auburn, AL 36849, USA
selen-cremaschi@auburn.edu

Abstract

Resource-constrained planning and scheduling problems under stochastic task success, which are common in chemical industries, lend themselves well to being modelled using multistage stochastic programming (MSSP) because most projects involve a series of tasks that needs to be completed in stages and that may or may not be successful. However, these MSSP models rapidly grow and quickly become computationally intractable for real world problems. This paper presents three alternative ways to estimate objective function values in a general primal bounding framework for MSSP models of resource-constrained planning and scheduling with stochastic task success. The framework extends the concept of expected value solution. We apply the proposed framework with alternative objective function estimation approach to instances with varying project sizes (i.e., 3-, 4-, 5-, and 6- projects) with up to 4096 scenarios. The framework yields primal bounds within 1.01% of the true solutions for all tested cases with a reduction in solution times up to four orders of magnitude.

Keywords: multistage stochastic programming, primal bound, endogenous uncertainty, resource constrained planning, probabilistic task success

1. Introduction

This paper considers resource-constrained planning and scheduling problem with project selection and execution under uncertainties, where the development of projects will be extended or terminated depending on the results of success or failure of associated tasks (Honkomp, 1998). Each project requires a variety of the shared limited resources for completing the required tasks associated with it. If a project fails, it is abandoned, the resources that were originally assigned to that project become available and the return associated with that project is not realized. In these planning problems, the decisions are which projects to pursue and the best way to assign the resources to the chosen projects to maximize the returns. The uncertainties associated with the tasks are resolved once these tasks are in execution or are completed, which makes them endogenous. One approach for modeling and solving these problems is multistage stochastic programming.

Multistage stochastic programming (MSSP) is a scenario-based approach that considers recourse actions in multiple stages after observing uncertainties. Uncertainties are represented by scenarios, which usually are obtained as the Cartesian product of all possible outcomes of uncertain parameters. In explicit formulation, the decision variables are defined independently for each scenario, and non-anticipativity constraints (NAC) are added to prevent the current stage decisions from anticipating future realizations of

uncertain parameters. Size of a MSSP model, especially with endogenous uncertain parameters, grows rapidly with the number of uncertain parameters and their outcomes leading to both space and time complexities. In general, the solution approaches for these problems rely on heuristic or approximation approaches, and it has been shown that moderate-size problems can be solved to optimality. Example approaches are rolling-horizon heuristic approach (Colvin and Maravelias, 2009), sample average approximation (SAA) algorithm (Solak et al., 2010), decision-rules based approximation (Vayonos et al. 2011), improved Lagrangean decomposition framework (Gupta and Grossmann, 2014), sequential scenario decomposition approach (Apap and Grossmann, 2017), branch and bound algorithm (Brianna and Cremaschi, 2017), a generalized knapsack decomposition algorithm (Brianna and Cremaschi, 2015; Zeng et al., 2018), and absolute expected value solution (AEEV) framework (Zeng and Cremaschi, 2019).

In this paper, we investigate three approaches to estimate the expected objective function value to be used in the AEEV framework for generating tight primal bounds and implementable solutions for large-scale planning and scheduling problems under stochastic task success and. We present this approach using clinical-trial planning problem (Colvin and Maravelias, 2008), which is summarized in §2. AEEV framework and the proposed approaches to estimate the expected objective function value are presented in §3. The problem instances and the solutions obtained by three alternatives are given, compared and discussed in §4. Finally, we present concluding remarks in §5.

2. Clinical Trial Planning Problem

Under limited resources, the goal of clinical-trial planning is to maximize the expected net present value (ENPV) by determining which clinical trials of drugs to start and when to start them (Colvin and Maravelias, 2008). The endogenous uncertainty is in the outcomes of clinical trials. If a drug fails a clinical trial in a phase, it is abandoned. The observation of a clinical trial outcome depends on whether and when it has been started. There are three clinical trials, $J = \{PI, PII, PIII\}$, that must be completed for a drug under limited resources before the drug can generate revenue, rev_i^{max}. Drug $i \in I$ has known required resources ρ_{ijr}, cost C_{ij}, and fixed duration τ_{ij} associated with clinical trial j. There is a random variable, Ω_i, associated with each uncertain parameter for drug i, and its support is {PI-F, PII-F, PIII-F, and PIII-P}. Here, PI-F, PII-F, PIII-F correspond to drug i failing in clinical trials PI, PII, and PIII, and PIII-P indicates that drug i has successfully passed all clinical trials (Colvin and Maravelias, 2008). The scenario set, S, is constructed as the Cartesian product of uncertain parameter outcomes. The planning horizon is discretized $t = 1, 2, 3 \ldots T$ (period t starts at time $t - 1$ and ends at time t).

A slightly modified MSSP formulation (Colvin and Maravelias, 2008) for this problem is given in Eqns. (1) – (8). The MSSP model uses a binary variable $X_{i,j,p,s}$ which is equal to 1 if clinical trial (i, j) is started at time t in scenario s. Two continuous variables, $Y_{i,j,p,s}$ and $Z_{i,j,p,s}$, are bounded between 0 and 1, where $Y_{i,j,p,s}$ turns 1 if drug i completes clinical trial j by the beginning of time period t in scenario s, and $Z_{i,j,p,s}$ becomes 1 if drug i completes clinical trial $j - 1$ by time period p and has not started clinical trial j. Losses are represented by two penalty terms: γ_i^D (loss of market) and γ_i^L (loss of patent life).

$$max\ ENPV = \sum_s p_s(Rev_s + FRev_s - Cst_s) \tag{1}$$

$$Cst_s = \sum_{i,j,t} cd_t C_{i,j} X_{i,j,t,s} \quad \forall s \tag{2}$$

$$Rev_s = \sum_i success_{i,s} \left\{ \sum_t \left\{ rev_i^{max} X_{i,PII,t,s} - \gamma_i^D (Z_{i,PII,t,s} + Z_{i,PIII,t,s}) - \gamma_i^L (t \right. \right.$$
$$\left. \left. + \tau_{i,PIII}) X_{i,PIII,t,s} \right\} \right\} \quad \forall s \tag{3}$$

$$FRev_s = \sum_i success_{i,s} \left\{ \sum_j rev_{i,j}^{open} f_{i,j} Z_{i,j,|T|,s} \right\}$$
$$+ \sum_i success_{i,s} \left\{ \sum_{j \in \{PI,PII\}} \sum_{t > |T| - \tau_{i,j}} rev_{i,j,t}^{run} f_{i,j+1} X_{i,j,t,s} \right\} \quad \forall s \tag{4}$$

$$f(X_{i,j,t,s}, Y_{i,j,t,s}, Z_{i,j,t,s}) \leq 0 \qquad \forall i,j,t,s \tag{5}$$
$$h(X_{i,j,t,s}, Y_{i,j,t,s}, Z_{i,j,t,s}) = 0 \qquad \forall i,j,t,s \tag{6}$$
$$X_{i,1,1,s} = X_{i,1,1,1} \quad \forall i,s \tag{7}$$
$$-\sum_{t' \leq t} Z_{i^{s,s'},j^{s,s'},t',s} \leq Y_{i,j,t,s} - Y_{i,j,t,s'} \leq \sum_{t' \leq t} Z_{i^{s,s'},j^{s,s'},t',s} \quad \forall i,j, (s,s') \in \Psi, t > 1 \tag{8}$$

The objective function is represented by Eqns. (1) – (4), including the probability of scenario s (p_s), the costs Cst_s, current revenue Rev_s, and future revenue $FRev_s$. Current and future revenue depends on the outcome of uncertain parameter, $success_{i,s} \in \{0,1\}$, which is equal to 1 for drug i successfully passing all clinical trials in s, 0 otherwise. The total cost is discounted using the time discounting factor cd_t (Eq. (2)). The parameter $f_{i,j}$ (Eq. (4)) represents the fraction of the revenue that would be realized by completing all remaining trials at the end of the planning horizon. Inequalities, Eq. (5), and equalities, Eq. (6), are scenario specific constraints, which include resource and clinical trial sequencing constraints. Constraints (7) and (8) are NACs. The model grows rapidly due to the increases in number of candidate drugs, scenario size, which results in exponential growth in size of NACs (Eqns. (7) and (8)). It is important to note that for this type of planning problems that has uncertain task outcomes, the uncertain parameters are only incorporated in the objective function (Eqns. (3) and (4) in clinical trial planning model) because the outcomes of clinical trials only impact the ENPV in objective function.

3. Absolute Expected Value Solution (AEEV) framework

The framework generates and solves a series of deterministic sub-problems (DSPs) based on the observation of uncertainties and yields a feasible solution for the original MSSP model. Future unknown information is assumed to be at its expected value, and here-and-now decisions are made based on the current available information and expected values of future events. The uncertainties are observed after here-and-now decisions are made, and recourse actions are determined for each observed uncertain outcome. The AEEV framework repeats this process of making decisions with current and expected future information, observing uncertainties, and taking recourse actions until the end of the planning horizon. Details of the framework can be found in Zeng and Cremaschi (2019).

In resource-constrained planning and scheduling under stochastic task success, there are no recourse actions. The AEEV framework starts by making decision 1 by solving DSP$_{1,1}$, where indices (1,1) are the indices of sub-problems and time. In DSP$_{1,1}$, which is generated at the beginning of the planning horizon (Figure 1), all uncertain parameters take their expected values. After decision 1 is implemented, uncertainties associated with decision 1 are observed (observation 1). Based on observation 1, new sub-problems are

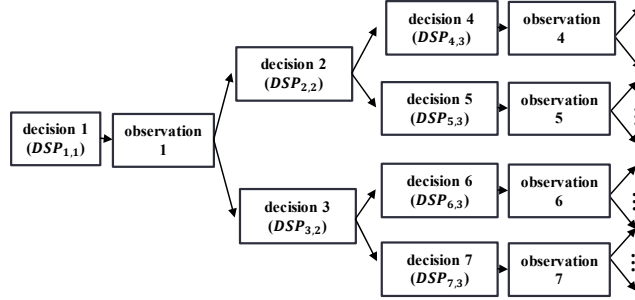
generated and solved to determine decisions, and associated uncertainties are observed. This process continues until the end of the planning horizon.


Figure 1. Traditional decision-making process under uncertainty for resource-constrained planning and scheduling under stochastic task success and the AEEV framework

Scenario tree observed for MSSP under endogenous uncertainty depends on decisions made, unlike the scenario tree for MSSP under exogenous uncertainty, which is fixed. AEEV framework works efficiently especially with endogenous uncertainties, where only partial scenarios and uncertainties can be observed in the planning horizon. The framework has a scenario-free structure and only generates and solves the necessary deterministic problems based on the realized outcomes, where the non-anticipativity is implicitly enforced. The objective function value obtained by AEEV framework is a valid primal bound for MSSP models with complete recourse.

3.1. The formulation of deterministic sub-problems (DSPs)

We use clinical trial planning model to illustrate the DSP formulation (Eqns. (9) – (15)) in AEEV framework. In DSPs, the scenario index and NACs are removed from the MSSP model, and the uncertain parameter values are set to their expected values ($E[success_i]$ in Eqns. (11) and (12)). The realizations of clinical trial outcomes until the current time period are incorporated in set F_n, where n is the sub-problem index. For failure outcomes, the values of the decision variables associated with subsequent trials are set to zero in F_n. Because the MSSP model contains uncertain parameters only in its objective function, scenario-specific constraints in DSPs are identical to the ones in the MSSP model.

$$max\ ENPV = Rev + FRev - Cst \tag{9}$$

$$Cst = \sum_{i,j,t} cd_t C_{i,j} X_{i,j,t} \tag{10}$$

$$Rev = \sum_i E[success_i] \left\{ \sum_t \{rev_i^{max} X_{i,PII,t} - \gamma_i^D (Z_{i,PII,t} + Z_{i,PIII,t}) - \gamma_i^L (t + \tau_{i,PIII}) X_{i,PIII,t} \} \right\} \tag{11}$$

$$FRev = \sum_i E[success_i] \left\{ \sum_j rev_{i,j}^{open} f_{i,j} Z_{i,j,|T|} \right\}$$
$$+ \sum_i E[success_i] \left\{ \sum_{j \in \{PI,PII\}} \sum_{t > |T| - \tau_{i,j}} rev_{i,j,t}^{run} f_{i,j+1} X_{i,j,t} \right\} \tag{12}$$

$$f(X_{i,j,t}, Y_{i,j,t}, Z_{i,j,t}) \le 0 \qquad \forall i, j, t \tag{13}$$
$$h(X_{i,j,t}, Y_{i,j,t}, Z_{i,j,t}) = 0 \qquad \forall i, j, t \tag{14}$$
$$X_{i,j,t} \in F_n \qquad \forall i, j, t \tag{15}$$

3.2. Three alternative ways to estimate objective function values in DSPs

In the MSSP model, $success_{i,s}$ is an uncertain parameter indicating if drug i passed all clinical trials in scenario s. The expected value of this parameter in MSSP model is $\sum_s^{s \in S} p_s success_{i,s}$, where p_s is the probability of scenario s. There is no scenario index in DSPs, and the uncertain parameter is replaced with an approximate expected value ($E[success_i]$, Eqns. (11) and (12)). Here, we propose three alternative ways to estimate this approximate expected value:

(1) A1: take $E[success_i] = \sum_s^{s \in S} p_s \cdot success_{i,s}$ at the initial time period, and it is fixed throughout the planning horizon.
(2) A2: take $E[success_i] = \sum_s^{s \in S} p_s \cdot success_{i,s}$ at the initial time period, and update $E[success_i]$ based on the realized outcomes of clinical trial for the drug.
(3) A3: update $E[success_i] = \sum_s^{s \in DSP} p_s \cdot success_{i,s}$, where $E[success_i]$ is calculated based on the scenario groups that belong to the sub-problem DSP.

The values of $E[success_i]$ in $DSP_{1,1}$ are equal to each other for all three approaches.

4. Case Study

We applied the AEEV framework to generate primal bounds for the clinical-trial planning problem with 3-, 4-, 5-, and 6-products, and three clinical trials with different planning horizon lengths. The complete parameters of the instances can be found in Brianna and Cremaschi (2017). We also solved the corresponding MSSP models to compare the objective function values obtained using A1, A2, and A3 by the AEEV framework. The models and algorithms were implemented in Pyomo and solved using CPLEX 12.6.3 to 0.1% optimality gap on a standard node of Auburn University Hopper Cluster. The MSSP and AEEV framework solution results are presented in Tables 1 and 2, respectively.

Table 1. Partial parameters of the clinical trial planning instances and the MSSP solution

Instance	Trials	Time Periods	Scenarios	ENPV	Soln. Time (CPUs)
3-prod	3	12	64	1193	12
4-prod	3	6	256	1700	20
5-prod	3	6	1,024	2087	1776
6-prod	3	6	4,096	2460	104,541

Table 2. The relative gap and solution times of AEEV framework using three alternative expected value estimation approaches (A1, A2, and A3)

	Relative Gap from MSSP solution			Solution Time (CPU s)		
Instance	A1	A2	A3	A1	A2	A3
3-prod	0.75%	0.08%	0.76%	6	6	6
4-prod	0.00%	0.00%	0.00%	4	5	4
5-prod	0.43%	1.01%	0.58%	8	7	6
6-prod	0.65%	0.81%	0.82%	55	54	52

Table 1 reveals the exponential growth in scenario size with the number of drugs and the corresponding growth in MSSP solution times. As can be seen from Table 2, the AEEV framework yields the optimum solution for 4-product instance and the largest relative gap is 1.01% for 5-product instance obtained by A2. The solution times seems to grow super-

linearly but not exponentially. A1 performs better among all except for 3-prod case with relative large 0.75% gap. Considering the fast solution time, we would recommend taking the best feasible solution from all three approaches, which we can summarize relative gaps as 0.08%, 0.00%, 0.43%, 0.65% for 3-, 4-, 5-, and 6-product instances.

5. Conclusion

This paper contributes three alternative objective function estimation approaches for AEEV framework to obtain primal bounds for MSSP of resource constrained planning and scheduling problems with stochastic task success. In such problems, the uncertain parameters are only incorporated in objective function, and scenario specific constraints can be readily transferred to deterministic models. Using all three approaches, the AEEV framework obtains the best feasible bounds within 0.65% of the true optimal for all instances of the clinical trial planning problem. The AEEV framework and the proposed objective function estimation approaches can be used to obtain feasible solutions and tight primal bounds for MSSPs under endogenous uncertainties where the model has complete recourse, and the AEEV framework do not suffer from space and time complexities. It should be noted that the AEEV framework may yield infeasible solutions if the MSSP model does not have complete recourse.

Abstract

This manuscript assesses the accuracy and computational efficiency offered by three different strategies for the estimation of probability distributions, applied to DAE systems. Specifically, two approximate PDF estimation techniques, named ODMCMC and PDFE&U, are compared to Bayesian Markov-chain Monte Carlo (BMCMC), using a simulation-based approach. The results of our analysis show that ODMCMC and PDFE&U offer a good trade-off between accuracy and computational efficiency, thus are excellent choices for time-critical PDF estimation tasks.

Keywords: Uncertainty quantification, Bayesian inference, optimization, drug delivery.

1. Introduction

The application of statistical techniques to the quantification of model uncertainty is a new paradigm, which has recently emerged due to the growing interest of industry and of the PSE community in stochastic optimization, robust design, real-time quality control and quantitative risk assessment. As an example, strategies for uncertainty quantification have been applied in areas such as robust process and product design (Mockus et al., 2011), drug delivery (Laínez et al., 2011) and stochastic dynamic optimization (Rossi et al., 2016).

Typically, model uncertainty quantification comes down to the estimation of the joint probability distribution (PDF) of some key uncertain parameters of the model, which often consists of a system of differential-algebraic equations (DAEs). To solve this type of PDF estimation problem, we usually rely on Bayesian inference methods such as Bayesian Markov-chain Monte Carlo (Green and Worden, 2015), which are well-established but also extremely computationally demanding. Therefore, it is important to investigate and develop new approximate PDF estimation strategies, which offer a good trade-off between accuracy and computational efficiency, and to validate them against state-of-the-art Bayesian inference approaches.

To that end, this contribution considers two approximate PDF estimation strategies plus a conventional one, and compares them to identify the most suitable method for solving PDF estimation problems, in which the underlying model is a DAE system. The approximate PDF estimation methods, analysed in this manuscript, include: (I) a novel Bayesian Markov-chain Monte Carlo algorithm, where sampling is performed by optimization (ODMCMC); and (II) a likelihood-free approach, recently proposed by

Rossi et al. (2018), which relies on a combination of parameter estimation, projection techniques and maximum likelihood estimation (PDFE&U). On the other hand, the conventional Bayesian inference strategy, included in this analysis, is standard Bayesian Markov-chain Monte Carlo (BMCMC). Note that we do not include Variational Inference (Beal, 2003) in our study because Yao et al. (2018) recently showed that this type of technique performs satisfactorily only for 28 % of all the problems they considered (over 200).

The comparison of approximate and conventional PDF estimation algorithms is performed by analysing both their computational efficiency and their outputs, i.e. their PDFs, using well-known statistical indicators (expectation, variance and quantiles) and the concept of confidence/credible region. The DAE model, selected for this study, is a pharmacokinetic (PB/PK) model for the administration of Gabapentin.

The rest of the paper is organized as follows: first, we introduce the rationale of PDFE&U and ODMCMC, with particular emphasis on the latter; then, we report the most significant results of our analysis on the accuracy and computational performance of PDFE&U, ODMCMC and BMCMC; finally, we discuss the most relevant consequences of these analyses.

2. Fundamental features of ODMCMC and PDFE&U

ODMCMC and PDFE&U are approximate strategies for estimation of the probability distribution of the uncertain parameters of a nonlinear system, using experimental data and (optionally) an existing PDF of the parameters (a so-called prior). These algorithms are designed for maximum computational efficiency, thus can easily handle DAE models, unlike conventional Bayesian inference frameworks. This section describes their features, novelties and implementation rationale.

ODMCMC is a novel type of Markov-chain Monte Carlo algorithm, in which sampling is performed by optimization. Specifically, this method does not make use of conventional random strategies to sample the posterior PDF (e.g. Metropolis-Hastings, Gibbs and No-U-Turn samplers), which only accept about 30 % of all the samples analysed. On the other hand, it selects optimal posterior samples by iterative solution of small-scale, multi-objective optimization problems, which measure the degree of optimality of every single sample based on two indices, namely, its linear and angular distances from all the other samples and its posterior probability density. This innovative sampling approach can efficiently identify samples, which uniformly span only those regions of the uncertainty space that are associated with high values of posterior probability density. Therefore, it allows us to approximate the posterior PDF with fewer samples and, consequently, to save computational resources. In addition, unlike conventional random samplers, it allows reliable and efficient approximation of complex, multi-modal posterior PDFs.

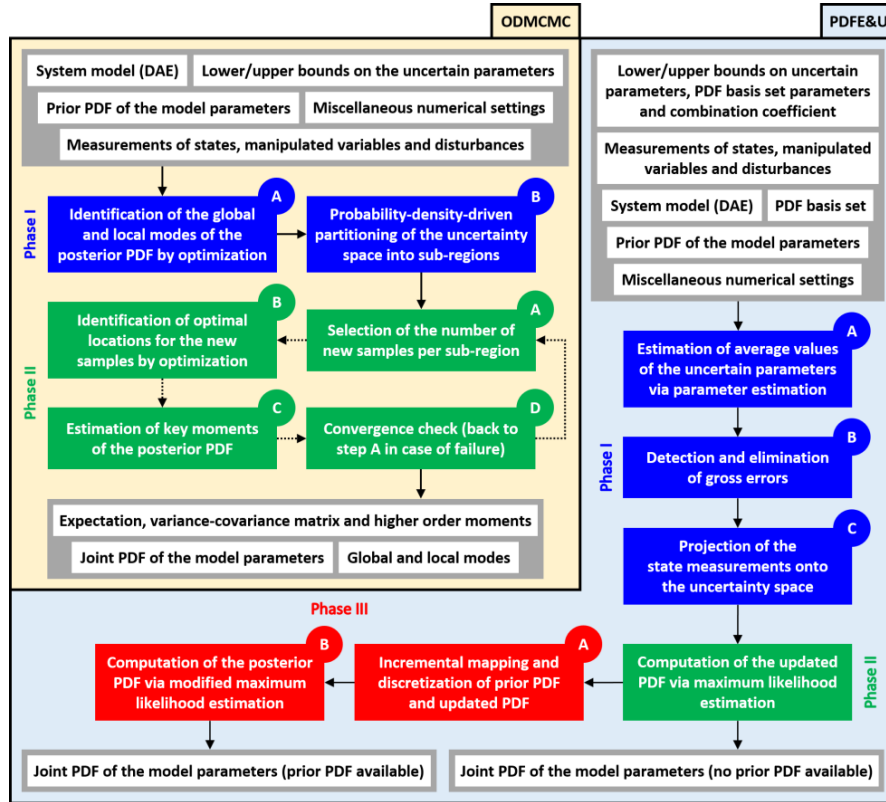
The rationale of ODMCMC is summarized in Figure 1. The algorithm is comprised of two phases, called Phase I and Phase II, of which the second is executed in an iterative fashion until convergence is reached. Phase I involves first computation of all the modes of the posterior PDF via multi-start optimization methods (step A), and then division of the uncertainty space into a user-supplied number of regions (step B), selected such that every one of them encompasses an appropriate interval of values of posterior probability density (further details cannot be reported due to space limitations).


Figure 1: Architecture of ODMCMC and PDFE&U.

Phase II involves iterative execution of steps A, B and C in series, until the variation in the first, second and third order moments of the posterior PDF over two consecutive iterations is smaller than some predefined error tolerance (step D). In step A, we compute the number of samples that must be added to every region of the uncertainty space in the current iteration, using an estimate of the algorithm convergence rate calculated by error extrapolation. Step B involves solution of several multi-objective optimization problems (one problem per region) via goal programming, which allow identification of the optimal locations of the new samples. All of these optimization problems are independent of each other, thus can be solved in parallel to improve the overall computational efficiency of the algorithm. Finally, in step C, we estimate the first, second and third order moments of the posterior PDF, using the samples selected up to the current iteration. These calculations rely on simple formulas, derived by discretization of well-known integral expressions, utilized to compute the moments of continuous probability distributions.

Before moving on, two final remarks are in order. First, note that ODMCMC technically requires identification of all the modes of the posterior PDF (Phase I – step A) via multi-start optimization. However, this requirement can be relaxed without affecting the accuracy of the algorithm, but at the cost of longer computation time. Second, note that the bottleneck for computational efficiency in ODMCMC is

represented by step A of Phase I and step B of Phase II, which are both parallelizable. Therefore, ODMCMC exhibits very good scalability features, unlike many conventional Bayesian inference strategies.

After introducing ODMCMC, we offer a brief description of the principal features of PDFE&U (the reader is invited to refer to Rossi et al. (2018) for further details). This is an innovative likelihood-free algorithm that relies neither on Bayes theorem nor on any sampling techniques to approximate the posterior PDF. In particular, it first projects the available experimental data (specifically the state measurements) onto the uncertainty space, by solving several small-scale, dynamic optimization problems. Then, it utilizes maximum likelihood estimation to convert the data projections into a new PDF, called the updated PDF. Finally, it combines updated and prior PDFs to compute a posterior. This sampling-free, two-stage strategy for estimating the posterior PDF offers a significant computational advantage over conventional Bayesian inference approaches. In addition, it allows PDFE&U to easily handle correlated/non-Gaussian measurement errors, features which make it difficult to apply standard Bayesian inference.

The rationale of PDFE&U is shown in Figure 1. The algorithm is composed of three phases, called Phase I, Phase II and Phase III, each of which involves one or more steps. However, due to space limitations, we only discuss step C of Phase I, which is the core of PDFE&U. In this step, we project every state measurement onto the uncertainty space by solving several small-scale, dynamic optimization problems, thus obtaining a set of "samples". This operation is conceptually the inverse of the problem of propagation of a probability distribution through a DAE system. It is the most computationally demanding task of PDFE&U but can be fully parallelized because all the dynamic optimization problems, previously mentioned, are independent of each other. As a consequence, the overall computational efficiency of PDFE&U is not negatively impacted.

Before moving on to our case study, it is important to comment on the implementation of both ODMCMC and PDFE&U. Both rely on the sequential approach, but the first has been implemented in a MATLAB® script while the second has been coded in C++, utilizing the BzzMath library as numerical engine (Buzzi-Ferraris and Manenti, 2012). In addition, the implementation of PDFE&U exploits parallel computing while that of ODMCMC currently allows only serial execution. All of this information will be useful for purposes of computational performance analysis (see the next section).

3. General assessment of ODMCMC, PDFE&U and BMCMC

The computational performance and accuracy offered by PDFE&U, ODMCMC and by a well-established implementation of BMCMC, i.e. Stan (Carpenter et al., 2017), have been analysed using a PB/PK model, which simulates the response of a patient to the administration of Gabapentin. Specifically, this case study involves estimation of the joint probability distribution of the 10 uncertain parameters of this PB/PK model, comprised of 34 nonlinear DAEs. The data set, used in this PDF estimation problem, includes about 150 data points, and consists of measurements of drug concentration in plasma and urine.

The results of the aforementioned PDF estimation problem are summarized in Figure 2 and Figure 3. Specifically, Figure 2 reports the most important statistical properties of the 10 uncertain model parameters, computed by PDFE&U, ODMCMC and Stan

(BMCMC + Random Effects). On the other hand, Figure 3 shows the 95 % credible regions of drug concentration in a patient's blood stream, predicted by both PDFE&U and ODMCMC.
Figure 2: Statistical analysis of the PDFs computed by PDFE&U, ODMCMC and Stan (some quantities are reported in log-scale to improve the chart readability; μ, σ and qX stand for expectations, standard deviations and X % quantiles).
Figure 3: Predicted enclosures of the profiles of drug concentration in a patient's blood stream at 95% confidence level (the black/blue dots are the experimental data; the black/blue curves represent the profiles of drug concentration in the blood stream of the average patient).

Both Figure 2 and Figure 3 confirm that PDFE&U tends to overestimate variance but provides decent estimates of the central tendency measures and of the qualitative properties of the PDF (specifically variance ratios), at a very attractive computational cost (Table 1).

Table 1: Computational performance of PDFE&U, ODMCMC and Stan.

Case study	Model size	Number of uncertain parameters	Time elapsed for solving a single PDF estimation problem [h]		
			PDFE&U	ODMCMC	Stan
Administration of Gabapentin	34 DAEs	10	$0.3 - 0.6$[a]	≈ 40[b]	≈ 120[a]

[a] Simulations performed with custom C++ codes; [b] Simulation performed with MATLAB® R2018a

On the other hand, ODMCMC proves to be more accurate than PDFE&U (Figure 2) in terms of both variance and central tendency measure estimates, but also demonstrates to be slightly less computationally efficient (since ODMCMC has been implemented in a MATLAB® script, its computational time, shown in Table 1, must be divided by at least a factor of 20). In addition, it tends to underestimate variance, as shown in Figure 3.

4. Conclusions

The results of the case study, discussed in the previous section, suggest that both ODMCMC and PDFE&U provide a favourable trade-off between accuracy and computational efficiency, by comparison to Bayesian Markov-chain Monte Carlo methods. This allows us to conclude that ODMCMC and PDFE&U are more suitable for time-critical applications, where the PDF estimation task must be completed as soon as possible (e.g., in stochastic dynamic optimization, robust data reconciliation and robust soft-sensor systems). Conversely, Bayesian Markov-chain Monte Carlo is more accurate and reliable, and is more suitable for offline, detailed PDF estimation studies.

In the near future, we are planning to improve and augment both ODMCMC and PDFE&U, with the aim of reducing the gap in accuracy between these two strategies and BMCMC without negatively affecting their computational efficiency.

Deterministic Global Process Optimization: Flash Calculations via Artificial Neural Networks

Artur M. Schweidtmann[a], Dominik Bongartz[a], Wolfgang R. Huster[a] and Alexander Mitsos[a*]

[a]*Process Systems Engineering (AVT.SVT), RWTH Aachen University, Aachen 52074, Germany*
amitsos@alum.mit.edu

Abstract

We recently demonstrated the potential of deterministic global optimization in a reduced-space formulation for flowsheet optimization. However, the consideration of implicit unit operations such as flash calculations is still challenging and the solution of complex flowsheets incorporating such operations can be intractable. We show that the solution of flash equations can be integrated in global optimization via artificial neural networks (ANNs). Thus, flash calculations are no longer performed within the flowsheet optimization. Instead, flash equations are solved offline and then learned using ANNs. ANNs have been used successfully in the literature to learn flash equilibria but have not yet been included in deterministic global optimization for this task. We embed the ANNs in a hybrid model and use deterministic global optimization to solve it. In addition, we utilize deterministic global optimization to calculate a guaranteed worst-case accuracy of ANNs compared to a rigorous model. We demonstrate the proposed approach on an illustrative five-component vapor-liquid equilibrium flash using our in-house solver MAiNGO.

Keywords: Reduced-space, McCormick relaxations, Guaranteed accuracy, Flowsheet

1. Introduction

The optimization of process flowsheets is still a major challenge after many years of important advances in process systems engineering. Flowsheet optimization problems typically result in nonlinear programs (NLPs) that exhibit nonconvexities and multiple local optima. In contrast to local and stochastic global solution methods, deterministic global optimization methods are guaranteed to identify global optima, making them a desirable solution method.

In the previous literature, deterministic global optimization of flowsheet problems has mostly been performed using general-purpose global solvers and an equation-oriented modeling approach (also known as full-space). However, when complex processes are considered, this leads to large-scale optimization problems. In addition, the equation-oriented modeling approach necessitates bounds on all modeling variables which can be difficult to determine. An alternative to this is a hybrid between the equation-oriented and a sequential modular approach where the branch-and-bound solver operates only in a subset of the model variables (also known as a reduced-space approach) (Byrne and Bogle (2000); Balendra and Bogle (2009)). Similar reduced-space approaches have long been used for simulation and local optimization (e.g., Tolsma et al. (2002); Poth et al. (2003)). We recently demonstrated the potential of reduced-space for deterministic global flowsheet optimization (Bongartz and Mitsos (2017)) and hybrid flowsheet problems with artificial neural networks (ANNs) embedded (Schweidtmann and Mitsos (2018); Rall et al. (2019)). Therein and herein, we use our in-house solver MAiNGO (Bongartz et al. (2018)) which in turn relies on propagation of McCormick relaxations (McCormick (1976)) through external functions (Mitsos et al.

(2009); Chachuat et al. (2015))

However, a particular challenge of realistic flowsheet optimization problems lies in the consideration of accurate thermodynamic calculations and complex unit operations because these often include implicit functions and complex calculations. In the reduced-space formulation, these can lead to additional variables, equality constraints, and weak McCormick relaxations (Stuber et al. (2015); Schweidtmann et al. (2019); Bongartz and Mitsos (2019)). A possible solution to this is to substitute complex model parts by surrogate models. This can essentially reduce the number of optimization variables and equality constraints that the B&B algorithm branches on because the surrogate models are called as external functions (Schweidtmann and Mitsos (2018)). In some cases, the McCormick relaxations of surrogate models are even tighter than the ones of the substituted model (Schweidtmann et al. (2019)).

Machine learning surrogate models have been used extensively in the previous process systems engineering literature (Lee et al. (2018)), e.g., for embedding them in hybrid process models (e.g., Caballero and Grossmann (2008); Mistry et al. (2018); Rall et al. (2019)) or black-box optimization of simulations (e.g., Wilson and Sahinidis (2017); Boukouvala et al. (2017)). In addition, multiple works have addressed the learning of single species thermodynamic properties (e.g., Chouai et al. (2002); Laugier and Richon (2003)) and vapor-liquid equilibrium compositions (e.g., Sharma et al. (1999); Sözen et al. (2004); Şencan et al. (2006); Nentwich and Engell (2016); Keßler et al. (2017)) demonstrating that ANNs are capable of learning those properties accurately. In our previous organic Rankine cycle case study, we have showed that substituting an implicit Helmholtz thermodynamic model for ethanol by ANNs leads to favorable solution times for the optimization because of a reduction in the number of optimization variables and equality constraints as well as tighter relaxations (Schweidtmann et al. (2019)). However, many chemical engineering applications include flash calculations which do not lend themselves as naturally to a reduced-space formulation and may require a number of variables and constraints to remain in the optimization problem (Bongartz and Mitsos (2019)). ANNs for thermodynamic equilibrium equations have not yet been included in deterministic global optimization. Further, the previous literature does not provide guarantees on the accuracy of trained ANNs but mostly indicates their performance on a finite test set.

We propose to learn thermodynamic equilibrium via ANNs in order to include them subsequently in deterministic global optimization problems. The method learns the solution of flash calculations retrieved from a nonsmooth model that describes not only the two-phase region, but also single-phase output streams (Sahlodin et al. (2016); Watson et al. (2017)). Furthermore, we compute a guarantee on the worst-case performance of ANNs compared to an analytical model using deterministic global optimization. The method is illustrated on a five-species nonideal mixture.

2. Flash calculations & illustrative case study

Many chemical flowsheets include flash separations that are assumed to be in equilibrium. Herein, we consider a vapor-liquid equilibrium (VLE) flash: Given an inlet stream flow rate (F) and its molar fractions ($\mathbf{z}$), the flash calculation determines the outgoing flow rates of the liquid stream (L) and vapor stream (V) with their corresponding molar fractions $\mathbf{x}$ and $\mathbf{y}$, respectively. The flash has two degrees of freedom that are either specified by design or are optimization variables. In this work, we use temperature (T) and pressure (p) as the degrees of freedom because intensive properties are advantageous for data-driven modeling (see Section 4).

The flash model consists of balance equations for overall molar flow rates Eqn. (1), component flow rates Eqn. (2), the isofugacity equation Eqn. (3), and the closure relation Eqn. (4) (c.f., Watson et al. (2017)):

$$F - L - V = 0 \tag{1}$$

$$F \cdot z_i - L \cdot x_i - V \cdot y_i = 0 \qquad\qquad\qquad i = 1,..,N \tag{2}$$

$$f_i^V(p,T,\mathbf{y}) - f_i^L(p,T,\mathbf{x}) = 0 \qquad\qquad\qquad i = 1,..,N \tag{3}$$

$$\text{mid}\left(V/F, \quad \sum_{i=1}^{N}(x_i - y_i), \quad V/F - 1\right) = 0 \tag{4}$$

where N is the number of components and f_i^V, f_i^L are the fugacities of component i in the vapor and liquid phase, respectively. Note that herein we use the nonsmooth closure relation proposed by Watson et al. (2017) which is based on the commonly used closure relation $\sum_{i=1}^{N}(x_i - y_i) = 0$ and which can model both two-phase and single-phase outlet streams. We use the flash model Eqns. (1) - (4) to generate data for training the ANNs (Section 3) and as a reference model for comparison to the data-driven approach (Sections 4 & 5). Note that we use the isofugacity equation Eqn. 3 and thus cannot guarantee stable states because we want to avoid a bilevel problem which arises when the Gibbs free energy is minimized as an embedded optimization problem. However, the proposed approach can in principle be applied to these as well.

For illustration, we consider a five-species mixture of hydrogen (H_2), carbon dioxide (CO_2), carbon monoxide (CO), methanol (MeOH), and water (H_2O). We assume ideal gas/liquid phases, use Henry's law for the supercritical species H_2, CO_2, and CO being dissolved in liquid methanol and water, and use model parameters and the solvent mixing rule from AspenPlus. The case study is described in more detail in Bongartz and Mitsos (2019) where rigorous, not hybrid, flash models with the common closure relation were optimized.

3. Training of the artificial neural networks

In order to generate the training data set, we create a Latin hypercube of 20,000 points on $z_i \in [0,1], T \in [300,512]$ K, $p \in [1,66.5]$ bar with $\sum_{i=1}^{N} z_i = 1$. Then, we simulate the fully specified flash model Eqns. (1) - (4) in MAiNGO. Herein, we use an inlet stream flow rate of 1 kmol/s without loss of generality. As we use the nonsmooth closure relation Eqn. 4, data on the complete box-constrained input domain is feasible.

For training, the input vector of the ANNs is set to $(z_{H_2}, z_{CO_2}, z_{CO}, z_{MeOH}, T, p)^T$ and the output vector is set to $(x_{H_2}, x_{CO_2}, x_{CO}, x_{MeOH}, \beta)^T$ with $\beta = V/F$. The training is conducted in MATLAB using Bayesian regularization backpropagation because we observed that regularization leads to tighter relaxations and favorable performance in subsequent optimization studies. However, the comparison of training algorithms is not within the scope of this work. All outputs are learned using individual ANNs with two hidden layers with ten nodes each. Furthermore, the hyperbolic tangent activation function is used in the hidden and output layers as we know from physical understanding that our outputs are bounded.

4. Optimization of hybrid flash model

In this section, the learned ANNs are embedded in an hybrid optimization problem that is solved using our deterministic global solver MAiNGO. In particular, the ANNs are used to compute $x_{H_2}, x_{CO_2}, x_{CO}, x_{MeOH}, \beta$ and the remaining mole fractions and flows are obtained by solving overall and component molar balances. This gives a hybrid flash model where the equilibrium is learned via ANNs and the balances are given by mechanistic equations. This allows for applying the hybrid model to any given input flow rate. All problems were solved on an Intel(R) Core(TM) i7-4790 CPU with 3.60 GHz, 16 GB RAM, and Windows 7 64 bit operating system.

For the illustrative case study, we consider an inlet stream of $F = 1$ kmol/s with the composition $\mathbf{z} = (0.644, 0.195, 0.025, 0.072, 0.064)^T$. The objective of the problem is to identify $T \in [300,512]$ K and $p \in [1,66.5]$ bar that maximize the amount of methanol recovered in the liquid phase, i.e., $\min -L \cdot x_{MeOH}/(F \cdot z_{MeOH})$, subject to the purity constraint $x_{CO_2} \le 0.01$.

As shown in Table 1, the solution point of the hybrid ANN model is close to the one of the rigorous model. The optimal point of the illustrative problem is at the lower temperature boundary, intermediate pressure, and results in a two-phase outlet stream. The solution time of the hybrid

Table 1: Problem size and solution statistics of the illustrative flash case study (relative optimality tolerance 10^{-3}). In the table we use the following abbreviations: Var.: number of optimization variables, Eq.: number of equality constraints, Ineq.: number of inequality constraints, CPU: computational time, Iter.: number of iterations, T: temperature, p: pressure, Obj.: objective value.

Formulation	Problem size			Performance		Solution point		
	Var.	Eq.	Ineq.	CPU [s]	Iter.	T [K]	p [bar]	Obj. [%]
Rigorous flash	6	4	1	3.74	2,195	300	16.7	93.2
Hybrid flash	2	0	1	0.59	347	300	16.5	93.7

model gives a considerable speedup as it takes less than 16% of the solution time of the rigorous model. One reason for the speedup is the smaller problem size of the hybrid model, i.e., the B&B algorithm has to branch only on the two degrees of freedom and requires less iterations. In contrast, the optimization problem including the rigorous flash model has four additional optimization variables and equality constraints because the model is not explicit in the degrees of freedom (c.f. *ideal flash formulation* in Bongartz and Mitsos (2019)).

5. Guaranteed accuracy of the artificial neural networks

When ANNs and other surrogate models are used in decision-making processes, trust in the accuracy of their predictions is a major concern. Typically, ANNs are trained on a large set of training data and subsequently validated on an independent test set. However, even in cases where accurate fits are obtained on both the training and test set, there is no guarantee that the model gives reasonably good predictions on the whole input or even out of the sampled training domain because of the universal approximator theorem (e.g., Hornik et al. (1989)). This means that an ANN of sufficient size can in principle represent any continuous function - also unphysical functions between training and test points. Previous works addressed this problem, e.g., Wilson and Sahinidis (2017) use an adaptive sampling technique where they iteratively select new training points by maximization of the error between the surrogate model and the underlying simulation used for data generation using a stochastic black-box solver. However, the stochastic solution approach does not provide a guaranteed worst-case accuracy.

In this section, we propose a method that computes a guaranteed accuracy of ANNs for cases where an algebraic formulation of the underlying model used for data generation is available. In particular, we maximize a norm of an error between the underlying model for data generation and our surrogate model on a compact input domain using deterministic global optimization. Any upper bound of this maximization problem provides a guarantee on the worst-case performance of the surrogate model.

For illustration, we maximize the squared distance of the component molar liquid streams of the rigorous flash model and the previously trained ANN. This problem is reformulated to an equivalent minimization problem as the optimization literature usually formulates minimization problems:

$$\min \quad -||(\mathbf{L}_{\text{ANN}} - \mathbf{L}_{\text{Rig flash}})||_2^2 \tag{5}$$

subject to the rigorous flash model Eqns. (1) - (4) and the hybrid flash model where $\mathbf{L}_{\text{Rig flash}} = L_{\text{Rig flash}} \cdot \mathbf{x}_{\text{Rig flash}}$ is the liquid molar flow rate vector from model Eqns. (1) - (4) and $\mathbf{L}_{\text{ANN}}$ is the vector of corresponding predictions computed by the hybrid flash model. Herein, we compare component molar flow rates and not mole fractions because they are a relevant measure for the error for both the two-phase and the single-phase case. Given inlet mole fractions of $\mathbf{z} = (0.644, 0.195, 0.025, 0.072, 0.064)^{\text{T}}$ and a total inlet stream of $F = 1$ kmol/s, the optimization problem Eqn. (5) is solved for the degrees of freedom $T \in [300, 512]$ K and $p \in [1, 66.5]$ bar.

The solution point with the largest squared distance that has been found in the B&B algorithm is $2.05 \cdot 10^{-4}$ kmol^2/s^2 at $T^* = 315$ K, $p^* = 1.1$ bar with $\mathbf{L}^*_{\text{Rig flash}} = (1.2 \cdot 10^{-7},\ 1.2 \cdot 10^{-6},\ 6.4 \cdot 10^{-9},\ 1.3 \cdot 10^{-3},\ 5.0 \cdot 10^{-3})^{\mathrm{T}}$ and $\mathbf{L}^*_{\text{ANN}} = (1.3 \cdot 10^{-6},\ 1.6 \cdot 10^{-5},\ 1.8 \cdot 10^{-7},\ 5.0 \cdot 10^{-3},\ 1.9 \cdot 10^{-2})^{\mathrm{T}}$ in kmol/s. This solution is near the phase boundary, i.e., $\beta = 0.994$, indicating that inaccuracies of the ANNs are higher near the phase boundary. Also, the solution point is near the box constraints of the training data indicating that it is sensible to extend the training set outside the actually used input domain. However, the result also shows the worst-case absolute inaccuracies are relatively small. The lower bound of the problem gives a guaranteed worst-case performance of $1.41 \cdot 10^{-3}$ kmol^2/s^2. Herein, an absolute optimality gap of $1.21 \cdot 10^{-3}$ kmol^2/s^2 remains after the maximum solution time of 43,200 CPU seconds showing that the guaranteed accuracy optimization problem is much harder to solve than the optimization of the hybrid flash model in Section 4.

6. Conclusion

We propose a hybrid modeling approach that learns thermodynamic equilibria of multicomponent mixtures via ANNs for subsequent deterministic global process optimization. The ANNs learn liquid equilibrium mole fractions and the vapor-to-feed ratio from a set of data covering both two-phase and single-phase regions. Then, we combine the ANNs with rigorous balance equations to form a hybrid flash model. An illustrative five-component flash case study shows that the hybrid flash model can be optimized in less than 16% of the CPU time necessary to optimize a rigorous flash model. Finally, deterministic global optimization is used to compute a guaranteed worst-case accuracy of the ANNs compared to a rigorous flash simulation.

The considerable speedup of the optimization does, however, come at the cost of offline data generation and training of the ANNs (on the order of minutes to hours). Thus, the hybrid modeling of a single flash calculation does not seem practical unless the optimization problem needs to be solved very quickly. However, it is expected that the substitution of several flash calculations in larger flowsheet problems will give much larger speedups due to the exponential worst-case runtime of B&B algorithms. Furthermore, this work presents a first step towards the learning and subsequent deterministic global optimization of complete separation columns. This is a promising future work because the reduced-space optimization of rigorous column models requires tear variables and flash calculation on every stage whereas an ANN could learn the column as a whole.

The computation of a guaranteed worst-case performance of ANNs is also a relevant contribution because it can be used as a rigorous tool to identify regions in the input domain with large errors, choose new training points accordingly, or select a suitable network architecture/complexity. In addition, the method allows us to use ANNs as a model reduction technique with guaranteed accuracy in the future.

Abstract

In this work, a mixed integer linear programming (MILP) model is presented to obtain the optimal layout of a multi-floor chemical process plant with minimum risk in fire and explosion scenarios. Layout decisions determine the spatial arrangement of process plant equipment on available land area considering the equipment interconnections, dimensions, costs, general operability, as well as associated structures and auxiliary units. Optimal decisions ought to strike a balance between risk and cost savings. Previous attempts to include safety considerations in the layout decision making process have been restricted to minimise connection and risk costs alone, with some unrealistic assumptions on safety distances for mostly single floor layout cases. The model presented adopts the Dow's Fire & Explosion system to quantify risk in order to determine the optimal multi-floor plot layout simultaneously with more realistic constraints for safety distance calculations. The optimal layout design obtained minimises costs attributed to the installation of connecting pipes, pumping, area-dependent construction of floors, land purchase, as well as the risk associated with fire and explosion events by inherent and passive strategies.

Keywords: multi-floor plant layout; safety; optimisation; MILP

1. Introduction

Right from conceptualisation to plant decommissioning, it is quite important that safety assessments be carried out for every aspect of a chemical process plant design project (Khan and Amyotte, 2004). Improper safety considerations at each stage of design or operation can result in fatalities, injuries, disruption of production activities within the plant and its neighbouring environment. Amidst a range of factors that contribute towards the overall safety levels, a study has shown that 79% of process plant accidents were attributed to design errors, the most critical being poor layout (Kidam and Hurme, 2012). Layout design determines the spatial arrangement of chemical process plant units considering their interconnections based on pre-defined criteria. These units may be process vessels in which unit operations are carried out, storage facilities, work centres or departments, and their spatial arrangement affect capital and operating costs, efficiency of plant activities, and of particular concern to this work, the overall safety levels within the plant and the immediate environment. From an optimisation point of view, safety considerations in layout designs have been considered in the past. While a great deal of research has

focused on the economic aspects alone - piping, construction and operating costs associated for a layout configuration, an ideal plant layout design ought to establish a balance between risks and costs. In a recent review, Roy et al. (2016) outlined available safety metrics for process design and their level of application. One of the key indices applicable to layout design with numerical quantification is the Dow Fire and Explosion Index (F&EI). The Dow F&EI was developed by American Dow Chemical Company (American Institute of Chemical Engineers, 1994) and is currently a widely applied method for hazard evaluation of chemical and industrial processes (Wang and Song, 2013). It estimates the hazards of a single unit based on the chemical properties of the material(s) within it, and the potential economic risk such equipment poses to itself and neighbouring structures with or without the installation of protection devices. A similar concept was adopted by Penteado and Ciric (1996) in a mixed integer non-linear programming (MINLP) model where financial risks associated with potential events from process units were modelled as cost functions with an overall objective to minimise the net present cost of a single floor layout. The choice of safety devices was also made available to reduce the associated risk levels. Patsiatzis et al. (2004) proposed a mixed integer linear programming (MILP) model solely based on the Dow F&EI to minimise the total cost associated with connecting process units by pipes, financial risks and the purchase and installation of protection devices. Other research activities have built on these to include multi-floor considerations (Park et al., 2018), human risk considerations, and in more recent times by employing the Domino Hazard Index (López-Molina et al., 2013).

In this work, an MILP model is proposed to address the multi-floor process plant layout problem with safety considerations, which are quantified using the Dow F&EI. Readers may consult the Dow's F&EI Hazard Identification guide (American Institute of Chemical Engineers, 1994) for detailed steps to calculate this metric. The proposed model will minimise the total cost attributed to pipe connections, pumping, floor construction, land purchase, installation of protection devices and financial losses in the event of an accident, which prior to this work has not been simultaneously addressed. Safety distances between equipment items are also modelled in a new way - from the opposing boundaries of equipment items as compared to the midpoints as previously done in order to better capture the actual distances between equipment for risk quantifications. Tall equipment items spanning through consecutive floors are also considered with the model determining the optimal number of floors and the equipment floor and spatial arrangements.

In the rest of the paper, the problem description is outlined in section 2. In section 3 the mathematical model is proposed and its computational performance is shown with a relevant case study in section 4. Final remarks are given in section 5.

2. Problem Description

The problem is as follows: *Given* a set of process plant units ($i \in I$), their dimensions - length (l_i), breadth (d_i) and height (h_i) - and connectivity network with space and unit allocation limitations, a set of potential floors for layout with respective floor height (FH), a set of pertinent equipment item ($i \in I^{pe}$), a set of protection device configurations available for each pertinent item ($p \in P_i$), with associated costs (C_{ip}^p) and loss control credit factor if installed on an equipment item; *determine* the total number (NF) and area of floors (FA), the protection device configuration, p, to be installed on each pertinent equipment item, and the plot layout *so as to* minimise the total plant layout and safety costs.

It is assumed that the geometries of all process plant equipment are rectangles, with horizontal connection distances taken as the rectilinear distance from the geometrical centres in the x-y plane. Vertical connection distances are taken from a design-specified height on each equipment. For safety considerations, all rectilinear distances are taken from the boundaries of equipment items to evaluate the probability, magnitude and impact of an incident. Equipment items are allowed to rotate by 90° and those with heights greater than the floor height can extend through consecutive floors but must start from the base of a floor.

3. Mathematical Formulation

The mathematical formulation constitutes an extension of model A.1 in Ejeh et al. (2018) for the multi-process plant layout problem and by Patsiatzis et al. (2004). All constraints in model A.1 (Ejeh et al., 2018) apply with the following modifications/additions. First of all, the distance constraints written for connected equipment items ($f_{ij} = 1$) (Patsiatzis et al., 2004), are further written for pairs of items (i, j) including a pertinent item, $i \in I^{pe}$, and any other item j, i.e., $\zeta = \{(i, j) : i \in I^{pe}, j \neq i\}$.

For safety considerations, the rectilinear distances between equipment items taken from the geometrical centres no longer seem to be a valid assumption. This is especially true for process plants having large and/or tall equipment items where rectilinear distances from the geometrical centres may have a high value but the equipment items are physically close to each other. A more valid assumption will be to calculate the separation distances from the equipment boundaries as illustrated in Figure 1, as an event on a pertinent item i can emanate at any point within the item up to its boundaries.
Figure 1: Vertical and horizontal safety distances between equipment items

For vertical separation distances between any two equipment items i and j (VD_{ij}), the distance is taken from the top of j to the bottom of i if i is on a higher floor than j, and if the reverse is the case, from the top of i to the bottom of j. However, if both i and j are on the same floor, i.e., $N_{ij} = 1$, the vertical separation distance is taken to be zero. The conditions stated above are modelled by Eqs. (1) - (3) where S_{ik}^s is a binary variable with a value of 1 if item i starts at floor k, and η_{ij}^u and η_{ij}^d are positive variables evaluated by Eqs. (4) - (6).

Horizontal separation distances are also calculated from the item boundaries in the x and y planes as XD_{ij} (Eqs. (7) - (11)) and YD_{ij} (Eqs. (12) - (16)) respectively (Figure 1). A value of zero is assigned to these distances if the opposing boundaries of an item i is not strictly to the right or left (in the x plane), or above or below (in the y plane) j. That is, items i and j overlap at any point on either the x or y plane. The binary variable W_{ij}^{xo} is

assigned a value of 1 if item i is strictly to the right or left of item j or 0 otherwise. The same applies for W_{ij}^{yo} if item i is strictly above or below j. The relative distances between items i and j in the x plane are represented by R_{ij} and L_{ij} if i is to the right of j, and if i is the left of j respectively. A_{ij} and B_{ij} represent the relative distances in the y plane if i is above j, and if i is below j respectively. $E2_{ij}$ is a non-overlapping binary variable and BM is a large number (Patsiatzis et al., 2004). Given these modifications, the total safety distance, TD_{ij}^s, between equipment items i and j is then calculated by Eq. (17).

$$VD_{ij} \leq FH\sum_k (k-1)(S_{jk}^s - S_{ik}^s) - h_i + \eta_{ij}^u + BM \cdot N_{ij} \qquad \forall (i,j) \in \zeta \qquad (1)$$

$$VD_{ij} \geq FH\sum_k (k-1)(S_{jk}^s - S_{ik}^s) - h_i + \eta_{ij}^u - BM \cdot N_{ij} \qquad \forall (i,j) \in \zeta \qquad (2)$$

$$VD_{ij} \leq BM \cdot (1 - N_{ij}) \qquad \forall (i,j) \in \zeta \qquad (3)$$

$$\eta_{ij}^u - \eta_{ij}^d = 2FH\sum_k (k-1)(S_{ik}^s - S_{jk}^s) + h_i - h_j \qquad \forall (i,j) \in \zeta \qquad (4)$$

$$\eta_{ij}^u \leq BM \cdot W_{ij}^z \qquad \forall (i,j) \in \zeta \qquad (5)$$

$$\eta_{ij}^d \leq BM \cdot (1 - W_{ij}^z) \qquad \forall (i,j) \in \zeta \qquad (6)$$

$$x_i - x_j + 2L_{ij} \geq \left(\frac{l_i + l_j}{2}\right) - BM(1 - W_{ij}^{xo}) \qquad \forall (i,j) \in \zeta \qquad (7)$$

$$XD_{ij} \leq R_{ij} + L_{ij} - \left(\frac{l_i + l_j}{2}\right) + BM(1 - W_{ij}^{xo}) \qquad \forall (i,j) \in \zeta \qquad (8)$$

$$XD_{ij} \geq R_{ij} + L_{ij} - \left(\frac{l_i + l_j}{2}\right) - BM(1 - W_{ij}^{xo}) \qquad \forall (i,j) \in \zeta \qquad (9)$$

$$XD_{ij} \leq BM \cdot W_{ij}^{xo} \qquad \forall (i,j) \in \zeta \qquad (10)$$

$$W_{ij}^{xo} \geq 1 - E2_{ij}\big|_{j>i} - E2_{ji}\big|_{i>j} \qquad \forall (i,j) \in \zeta \qquad (11)$$

$$y_i - y_j + 2B_{ij} \geq \left(\frac{d_i + d_j}{2}\right) - BM(1 - W_{ij}^{yo}) \qquad \forall (i,j) \in \zeta \qquad (12)$$

$$YD_{ij} \leq A_{ij} + B_{ij} - \left(\frac{d_i + d_j}{2}\right) + BM(1 - W_{ij}^{yo}) \qquad \forall (i,j) \in \zeta \qquad (13)$$

$$YD_{ij} \geq A_{ij} + B_{ij} - \left(\frac{d_i + d_j}{2}\right) - BM(1 - W_{ij}^{yo}) \qquad \forall (i,j) \in \zeta \qquad (14)$$

$$YD_{ij} \leq BM \cdot W_{ij}^{yo} \qquad \forall (i,j) \in \zeta \qquad (15)$$

$$W_{ij}^{yo} \geq E2_{ij}\big|_{j>i} + E2_{ji}\big|_{i>j} \qquad \forall (i,j) \in \zeta \qquad (16)$$

$$TD_{ij}^s = XD_{ij} + YD_{ij} + VD_{ij} \qquad \forall (i,j) \in \zeta \qquad (17)$$

The area of exposure and maximum probable property damage cost constraints are as described in Patsiatzis et al. (2004) using the modified total distance, TD_{ij}^s.

The objective function (Eq. (18)) is the minimisation of the total cost attributed to connection, pumping, land purchase, construction, financial risk and the installation of protective devices. The financial risk is evaluated from the actual maximum probable property damage cost (Ω_i) (Patsiatzis et al., 2004) and μ_{ip} is a binary variable with a value of 1 if protection device configuration p is to be purchased and installed on pertinent item $i \in I^{pe}$. C_{ij}^c, C_{ij}^v, C_{ij}^h, LC, $FC1$ and $FC2$ represent the connection cost, vertical pumping cost, horizontal pumping cost, area-dependent land purchase cost, fixed floor construction

cost and area-dependent floor construction cost respectively.

$$min\sum_i \sum_{j\neq i:f_{ij}=1} [C_{ij}^c TD_{ij} + C_{ij}^v D_{ij} + C_{ij}^h (R_{ij} + L_{ij} + A_{ij} + B_{ij})] + FC1 \cdot NF$$

$$+FC2\sum_s AR_s \cdot NQ_s + LC \cdot FA + \sum_i \Omega_i + \sum_{i,p \in P_i} C_{ip}^p \cdot \mu_{ip} \tag{18}$$

4. Case study

The model proposed was applied to an Ethylene oxide plant (Figure 2) (Patsiatzis et al., 2004). Six protection device configurations are made available for installation, with the first configuration having no protection device purchased or installed. Full details for the configurations, the characteristic protection devices in each, and the associated cost and loss control credit factor can be found in Patsiatzis et al. (2004). The model was solved to global optimality using GAMS modelling system v25.0.2 with the CPLEX v12.8 solver on an Intel® Xeon® E5-1650 CPU with 32GB RAM. It had 260 discrete and 386 continuous variables with 894 equations, and obtained a total cost value of 480,114.4 rmu in 33s.
Figure 2: Flow diagram of Ethylene Oxide plant

Figure 3 shows the optimal layout plot with safety considerations. With the inclusion of fire and explosion scenarios, an additional floor is required compared to the layout results without safety considerations (Ejeh et al., 2018). Out of the total cost of 480,114.4 rmu, 175,000 rmu was attributed to the installation of protection devices, 187,535.4 to financial risks and 117,579.0 rmu to connection, pumping and construction costs. The latter cost quota is much larger when compared to the case without safety considerations, 66,262 rmu (Ejeh et al., 2018), owing to additional separation distances between equipment items, a larger floor area (30m× 30m compared to 20m× 20m), as well as the cost of the additional floor constructed.

pertinent equipment items
Figure 3: Optimal layout results

For the case where safety was not considered and no protection device was installed, the financial risk was calculated, based on the layout results obtained in Ejeh et al. (2018), to

be 935,820.9 rmu. In the optimal solution with safety considerations, protection devices were installed on all the pertinent equipment items - 1, 3 and 5 - to reduce the probability and magnitude of an incident. The total cost of purchase and installation was 175,000 rmu, with a reduced financial risk of 187,535.4 rmu. Hence, the cost of protection devices, financial risk, and other layout costs combined is much less for the case where safety is considered and protection devices are installed than if they were not. This provides for a more informed balance between cost savings and financial risks.

5. Concluding remarks

An MILP model (extended from Ejeh et al., 2018 and Patsiatzis et al., 2004) was proposed for the multi-floor process plant layout problem considering connection, pumping, construction, financial risk and protection device installation costs in fire and explosion scenarios. The model successfully described tall equipment items spanning through multiple floors with more accurate safety distance calculations obtained from the boundaries of neighbouring equipment items within similar floors and on different floors. The proposed model was applied to a 7-unit case study having 3 pertinent equipment items and 6 protection device configurations. 3 floors were obtained for the optimal solution, with a larger floor area and total cost compared to the same case without safety considerations. Overall, the proposed model is proved to be able to optimise the installation of protection devices and significantly reduce the risk associated with fire and explosion, resulting in a substantial decrease in probable property damage cost, much higher than the required additional safety device purchase, installation, connection, pumping and construction costs. Future work will seek to apply the model to larger case studies with more complex connection networks.

A Generalized, Nonsmooth Operator for Process Integration

Caroline J. Nielsen[a,*] and Paul I. Barton[a]

[a]*Massachusetts Institute of Technology, 77 Massachusetts Ave., Cambridge, MA 02139, USA*
cjn1994@mit.edu

Abstract

This work presents a novel, generalized method for solving resource targeting problems for process integration. The approach uses nonsmooth systems of two equations per resource to simulate the process under optimal resource reuse. The resulting equation system, including process models, is solved using new advances in the automatic generation of LD-derivatives to supply generalized derivative elements to nonsmooth equation-solving methods. Therefore, this method can be used to solve for process variables in addition to resource targets and retains the same number of equations regardless of the number of resource sources and sinks in the problem. An illustrative example of combined mass and water integration is included to demonstrate the strengths and flexibility of this approach.

Keywords: Process integration, Targeting, Process design, Nonsmooth equations

1. Introduction

Process integration methods have been widely proposed and utilized to minimize resource use through optimal reuse. These approaches were initially considered for heat recovery in heat integration problems (Linnhoff and Flower, 1978) and were then extended to the recovery of materials in mass exchange networks (MENs) and water allocation problems (El-Halwagi and Manousiouthakis, 1989; Dhole et al., 1996). In recent years, integration methods have also been applied beyond these traditional areas to new problems, such as hydrogen allocation, carbon planning, and even inventory problems (Alves and Towler, 2002; Munir et al., 2012; Castillo and Mahalec, 2013). There is a significant body of work on solving these integration problems; however, although the underlying integration problem is the same for each application, the existing solution methods are specific to one resource type and not immediately generalizable.

Process integration problems consist of two stages, first, determining the minimum attainable fresh and waste resource flows, and second, designing a resource conservation network that can approach these targets. The focus of this work is the former resource targeting problem. By eliminating the network design step and avoiding simultaneous superstructure approaches that scale poorly with problem size, resource targeting is able to consider resource usage and constraints efficiently when screening and optimizing plant designs.

The simplest class of targeting approaches are graphical pinch analysis and cascade (also

referred to as transshipment) formulations. These approaches are easy to use and physically intuitive, but are applicable to only a limited number of scenarios and are usually unable to solve for process variables. Therefore, they cannot be used to simulate systems with known resource targets or for simultaneous process integration and optimization. To address these limitations for heat integration, Navarro-Amoros et al. (2013) proposed a cascade-type model that uses disjunctions to determine temperature intervals. Alternatively, Duran and Grossmann (1986) developed a "pinch location method," which avoids the construction of temperature intervals by using an optimization formulation with nonsmooth inequalities that is solved using smoothing approximations or as a disjunctive program (Grossmann et al., 1998). However, all of these approaches either require approximations or solving nonconvex MINLPs, and they scale either cubically or quadratically with the number of hot and cold streams in the problem.

To avoid approximations and improve scaling, Watson et al. (2015) reformulated the inequalities in the pinch location method to a create a simple system of nonsmooth equations to simulate heat integration systems. In this work, we extend the approach of Watson et al. to develop compact nonsmooth operators that can be applied beyond heat integration to the general integration problem. The result is a solution method that scales well with problem size, requires only equation-solving approaches, and can solve for process variables while simultaneously considering the integration of multiple resources.

2. Problem Statement

Consider a set of resources types under consideration for integration, T. Using the notation for general resource integration presented by Foo (2013), for each resource type $n \in T$, there exists a fresh resource supply, $R_{SR,n}$, and a waste resource flow, $r_{SK,n}$, a set of sources, SR_n, with constant states $S_{i,n}$ that change in quality from $Q_{i,n}^{in}$ to $Q_{i,n}^{out}$, and a set of sinks, SK_n, with states $s_{j,n}$ that change in quality from $q_{j,n}^{in}$ to $q_{j,n}^{out}$. The source and sink states determine the extent to which a resource transfer $R_{i,n}$ or $r_{j,n}$ will affect the quality according to $R_{i,n} = S_{i,n}\Delta Q_{i,n}$ or $r_{j,n} = s_{j,n}\Delta q_{j,n}$ respectively, and the quality is selected such that higher values indicate higher purity resources.

Table 1: State and qualities for common integration types.

Integration Type	Quantity	Quality	State
Heat	heat transfer rate	temperature	heat capacity flow rate
Mass	contaminant mass load flow rate	concentration in reference stream	scaled solvent mass flow rate
Water	water mass flow rate	negative cumulative contaminant mass load flow rate	inverse contaminant concentration, sorted by increasing concentration

The states and qualities for common integration problems are given in Table 1. Note that for mass integration problems, concentrations and flow rates are transformed to their corresponding values in a specified reference stream using equilibrium relations. Additionally, in water allocation problems, the sources and sinks must be sorted by increasing

concentration, and the qualities are the negative of the cumulative contaminant flow rates of the sources or sinks in this order to ensure that high purity water flows have higher quality values.

Given this system, we want to be able to solve the following problem for a selection of unknowns from the vector of process variables, $\mathbf{x}$, and the $|T|$ vectors of resource utilities, $\mathbf{y}_n = (R_{SR,n}, r_{SK,n})$:

$$\mathbf{0} = \mathbf{h}(\mathbf{x}, \mathbf{y}_1, \dots, \mathbf{y}_{|T|}),$$

$$\mathbf{y}_n = \underset{\mathbf{y}_n, R_{1,n}, \dots, R_{K_n-1,n}}{\arg\min} R_{SR,n}, \quad \forall n \in T,$$

$$\text{s.t.} \quad 0 = R_{SR,n} - R_{1,n} + \sum_{i \in SR_{1,n}} S_{i,n} \Delta Q_{1,n} - \sum_{j \in SK_{1,n}} s_{j,n} \Delta q_{1,n},$$

$$0 = R_{k-1,n} - R_{k,n} + \sum_{i \in SR_{k,n}} S_{i,n} \Delta Q_{k,n} - \sum_{j \in SK_{k,n}} s_{j,n} \Delta q_{k,n}, \quad \forall k \in \{2, \dots, K_n - 1\},$$

$$0 = R_{K_n-1,n} - r_{SK,n} + \sum_{i \in SR_{K_n,n}} S_{i,n} \Delta Q_{K_n,n} - \sum_{j \in SK_{K_n,n}} s_{j,n} \Delta q_{K_n,n},$$

$$0 \le R_{k,n}, \quad \forall k \in \{1, \dots, K_n - 1\}.$$

This problem consists of a process model, $\mathbf{h}$, dependent on resource utilities and process variables, and embedded resource minimization problems parametric in the process variables. These minimization problems are constrained by resource balances and feasibility constraints for resource transfer. While a number of formulations of these constraints have been presented in the literature, for the sake of example, here we use the transshipment formulation of Papoulias and Grossmann (1983), which ensures that resource flows, $R_{k,n}$, are positive from high to low quality between the K_n quality intervals that have quality changes $\Delta Q_{k,n} = \Delta q_{k,n}$.

3. Operator Formulation

Our approach to solving the general integration problem is using explicitly nonsmooth equations to express the solutions of the embedded minimization problems. This formulation results in two equations per resource n in addition to the process model. Neglecting the index n for clarity, these two equations can be written as

$$0 = \sum_{i \in SR} S_i (Q_i^{in} - Q_i^{out}) - \sum_{j \in SK} s_j (q_j^{out} - q_j^{in}) + R_{SR} - r_{SK}, \tag{1}$$

$$0 = \min_{p \in P} \{RBP_{SK}^p - RBP_{SR}^p\} + r_{SK}, \tag{2}$$

where P is the finite index set of pinch point candidates and

$$RBP_{SR}^p := \sum_{i \in SR} S_i [\max\{0, Q^p - Q_i^{out}\} - \max\{0, Q^p - Q_i^{in}\}$$

$$- \max\{0, Q^{min} - Q^p\} + \max\{0, Q^p - Q^{max}\}], \quad \forall p \in P,$$

$$RBP_{SK}^p := \sum_{j \in SK} s_j [\max\{0, (Q^p - \Delta Q_{min}) - q_j^{in}\}$$

$$- \max\{0, (Q^p - \Delta Q_{min}) - q_j^{out}\} + \max\{0, (Q^p - \Delta Q_{min}) - q^{max}\}$$

$$- \max\{0, q^{min} - (Q^p - \Delta Q_{min})\}], \quad \forall p \in P,$$

where $Q^{min,max}$ and $q^{min,max}$ are the minimum and maximum qualities across the sources or the sinks, respectively, ΔQ_{min} is the minimum feasible quality difference for resource transfer to occur, and the source qualities at the potential pinch points are

$$Q^p = \begin{cases} Q^{in}_i, & \forall p = i \in SR, \\ q^{in}_j + \Delta Q_{min}, & \forall p = j \in SK. \end{cases}$$

Here, Equation 1 is the overall resource balance, and Equation 2 is the resource balance below potential resource transfer pinch points. Equation 2 uses a simple nonsmooth expression to ensure that the resource balance is nonnegative below all potential pinch points and zero below at least one of these potential pinch points, i.e. resource transfer is always feasible and at least one pinch point exists to ensure optimality. The expressions for $RBP^p_{SR,SK}$ are the cumulative source and sink resources below the potential pinch point quality. The nonsmooth max terms capture the position of the inlet and outlet qualities of the source or sink in relation to the potential pinch point quality. Nonphysical extensions to the cumulative resource quantities are also included, which avoid additional singular regions or infinite solutions by ensuring the difference between the source and sink resource balances is always defined.

These two equations replace the embedded minimization problem for each resource and we solve the resulting system of equations with a nonsmooth equation solving method such as the semismooth or LP Newton methods (Facchinei et al., 2014). In the past, these methods have been limited by the ability to calculate useful generalized derivative elements automatically. However, using recent work by Khan and Barton (2015), we calculate LD-derivatives using a vector forward mode of automatic differentiation which computes elements of the B-subdifferential for piecewise differentiable functions. Therefore, we are able to automatically compute generalized derivative elements to achieve local quadratic convergence for these nonsmooth equation-solving methods.

4. Example: Dephenolization and recycling of aqueous wastes

Adapting the problem presented by El-Halwagi (2012), we consider an oil recycling facility that uses steam strippers to remove sulfur and other light compounds from the oil streams. The main contaminant of concern in the stripper condensates is phenol, which can be removed through transfer to the oil streams in a MEN. Here, we consider the possibility of reuse of the stripper condensate after dephenolization to reduce both fresh water consumption and wastewater production. We wish to determine the minimum attainable fresh and waste water flow rates as well as the phenol concentrations and water flow rates throughout the system. We require that no external utilities are used in the MEN and that the concentrations of the two stripper condensates are the same when they exit the MEN. We also assume that there are phenol concentration limits in the boilers that limit the inlet concentrations to the strippers and that the mass of phenol transferred in the strippers is constant. (This assumption can be replaced by more complex stripper models if desired.) The parameters for this system are given in Table 2.

To solve this problem, we used two integration operators, one for the allocation of water and one for the mass exchange of phenol. We obtained the sorted mass fractions required to determine the states and qualities for the water allocation problem using a simple bubble sort algorithm. Because this algorithm applies a fixed number of min

Table 2: System parameters for dephenolization example.

Stream	Flow rate (kg/h)	Inlet mass fraction	Outlet mass fraction
Lube Oil	5	0.005	0.015
Gas Oil	3	0.010	0.030
Stripper 1 steam	2.5	0.005	z_2
Stripper 2 steam	z_1	0.002	z_4
Stripper 1 wastewater	2.50	z_2	z_3
Stripper 2 wastewater	z_1	z_4	z_5
Fresh water	z_6	-	-
Wastewater	z_7	-	-

Stripper 1 mass load: 0.11 kg/h
Stripper 2 mass load: 0.03 kg/h

Equilibrium relation for lube oil: $y = 2.00x_1$
Equilibrium relation for gas oil: $y = 1.53x_2$
Minimum MEN concentration difference: $\varepsilon = 0.001$

and max functions for a given input size, it allows us to automatically calculate LD-derivatives for the sorting process that can be supplied to nonsmooth equation-solving methods (Watson et al., 2015). In addition to the integration operators, we also included process equations describing the constant mass transfer in the strippers and equating the MEN water outlet concentrations. The result was a nonsmooth system of 7 equations which we solved for 7 unknowns using a semismooth Newton method to give $z = (0.84, 0.049, 0.013, 0.038, 0.013, 2.27, 2.27)$. For a range of initial guesses, the semismooth Newton method quickly converged to the solution in 3 to 9 iterations. The mass and water composite curves for this solution are given in Figure 1 and demonstrate that our solution method produces the optimal pinch behavior.

(a) Water allocation network.

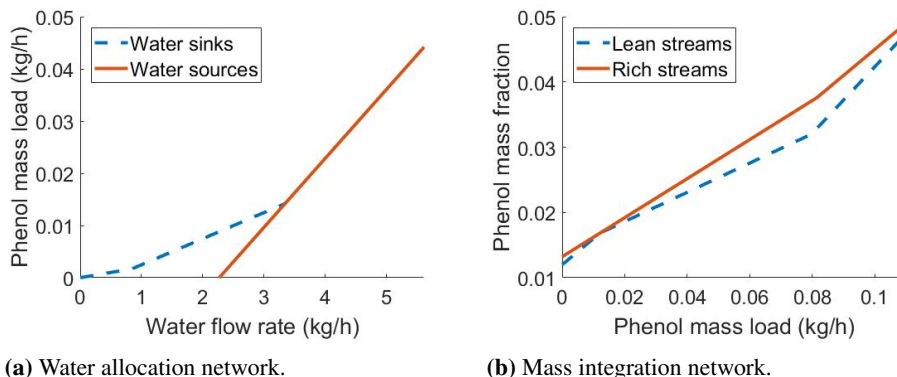
(b) Mass integration network.


Figure 1: Composite curves for the optimized dephonolization system.

5. Conclusions

We have developed an approach for solving process integration problems using compact, nonsmooth operators. These operators are generalizable to the integration of any resource and can be combined to simultaneously consider multiple resources coupled by a process model. These operators also only require equation-solving methods, can solve for process variables, and are only two equations per resource regardless of the number of sources and sinks in the problem. As a result, we have formulated a readily adaptable approach that significantly reduces problem complexity and can provide computationally tractable solutions to a wide variety of large-scale integration problems.

Abstract

This work addresses the production of gasohol using gasoline as a separation agent, an alternative approach to processes that recover and dehydrate ethanol before its blending with gasoline. Experimental data was used to build the thermodynamic model used to predict phase equilibrium and thermophysical properties. Two configurations for the direct manufacture of E10 gasohol were analyzed. Process I is extraction-based whereas Process II is extractive distillation-based. The processes were compared with each other in terms of energy needs as well as with a state-of-art process where ethanol dehydration is performed with molecular sieves (Process MS). The results show that Processes I and II are energetically favorable, and consume, after process optimization and heat integration, 30% less heat than Process MS, for ethanol concentrations in fermentation broths between 2 and 10 wt%. Furthermore, estimated ethanol separation costs are approximately \$0.19/kg·ethanol for a 5 wt% feed.

Keywords: Ethanol separation; Gasohol direct production; Process design; Heat integration; Techno-economic analysis

1. Introduction

The pursuit of alternative sources of energy prompted global research and industrial developments of biofuels. Ethanol (produced from diverse sources) falls into this class and is typically marketed in blends with gasoline (as gasohol) for road transport vehicles. The downstream processing of fuel-grade ethanol involves the removal of the solids fraction and secondary products from the broth, followed by concentration and dehydration to prevent phase separation in fuel systems. This step is energy-intensive because of the need of separating the water, and challenging by the existence of a binary azeotrope in the ethanol/water mixture which hinders the economic performance of the process.

Several separation systems are described in literature for the recovery and dehydration of ethanol, including pressure-swing distillation (Black, 1980), liquid-liquid extraction (Neves et al., 2011), salt-effect distillation (Zeng and Li, 2015), and azeotropic, extractive and dividing-wall distillation operations (Singh and Rangaiah, 2017). Kubička et al. (2013) describes an arrangement coupling a distillation pre-concentration step followed by molecular sieves, which adsorb the reminiscent water out of ethanol with great energy efficiency. Configurations including membrane separation units (e.g., pervaporation, vapor permeation) for water removal in the vicinity of azeotrope mixture after a previous ethanol concentration step were also successfully implemented (Vane, 2008).

All the aforementioned configurations have a common feature. They are designed to produce anhydrous ethanol. However, this approach may be economically sub-optimal if the product is to be marketed as a blend with gasoline rather a pure fuel or chemical. Another option is to consider hydrocarbon streams to be incorporated from diverse sources in ethanol separation systems, or simply pre-blending gasoline with ethanol on-site. Potential opportunities for heat and process integration could arise, besides the utilization of hydrocarbon cuts as solvents for water elimination.

Schemes for the direct production of gasohol were developed in previous contributions wherein gasoline fractions work as solvents in extraction columns where the final product is obtained from a concentrated aqueous solution of ethanol (Kyle, 1981; Stacey et al., 2016) or as entrainers in extractive distillation systems (Black, 1980; Chianese and Zinnamosca, 1990). Estimates indicate achievable energy savings of 17–68% for both methods compared with classical azeotropic distillation methods. Nevertheless, no rigorous process simulation is provided to quantify in detail the operating conditions, materials and energy requirements (Stacey et al., 2016); besides the process optimization and heat integration were not addressed (Black, 1980; Kyle, 1981; Chianese and Zinnamosca, 1990). Noticeably, a techno-economical analysis of processes that incorporate gasoline fractions in ethanol separation can benefit potential users and complement existing references.

Consequently, this work examines the production of gasohol using gasoline as a separating agent, focusing on techno-economic aspects involving different process designs and comparing their performance to the benchmark. We developed a modeling framework to describe accurately phase equilibria and thermophysical properties of mixtures (Section 2). Subsequently, two main configurations were simulated in Aspen Plus®, analyzed at base case conditions (i.e., close to the ones reported in the literature). Specifically, they are compared against each other and with a benchmark alternative – Process MS – regarding the energy consumption for achieving ethanol concentrations in broth in 2–10 wt% (Section 3). Next, process optimization and pinch analysis were carried out to estimate the minimum energy needs for both processes (Section 4). Moreover, heat exchanger networks (HENs) were also optimally designed for minimum total cost using systematic strategies, with the ethanol production cost estimated and compared with those reported in literature. Finally, the paper closes in Section 5 with a summary of the main findings.

2. Modeling framework

The scope of analysis is the separation of ethanol, where a simplified broth composition is assumed, i.e., the secondary products and solids were previously removed. Therefore, the components in the stream are water, ethanol, and gasoline. The latter may be modeled as an assay with different cuts of hypothetical components or as a single hypothetical component, with the pure and mixing thermophysical parameters estimated from petroleum distillation-curves. However, classical equations-of-state are usually inadequate to describe liquid phase non-idealities of mixtures containing polar components, like water and ethanol (Carlson, 1996). Consequently, gasoline was considered as a single pseudo-component, wherein pure thermophysical properties are estimated using a distillation-curve ASTM D86 presented in Andersen et al. (2010) and the API methods (Aspentech, Inc., 2016). Phase equilibrium is modeled considering the vapor as an ideal gas and non-ideality in liquid phase is modeled with NRTL model (Renon and Prausnitz, 1968).

2.1. Data regression

The binary interaction parameters of NRTL model were fitted to an experimental data set collected from several works containing 40 tie-lines of the ternary water-ethanol-gasoline system, plus 23 points of VLE and 9 of excess molar enthalpy for the binary ethanol-gasoline. The fitting strategy followed here is similar to that in Granjo et al. (2014), where data points were weighted uniformly and phase stability conditions were explicitly included in the mathematical formulation. Regression results show a good agreement between experiments and model predictions, since the global

average relative deviation (ARD) is 5.3% with an ARD of 0.7% in tie-line predictions (check Figure 1).

3. Process simulation & benchmark

Two processes described in literature are used for benchmark. In Process I, the broth stream is pre-concentrated up to the vicinity of the azeotropic concentration (∼90 wt% ethanol), and then fed to an extraction column, with the gasohol leaving the extract while raffinate goes to a gasoline recovery distillation column (Kyle, 1981). Process II is similar to Process I, but the extraction column is replaced by an extractive distillation arrangement where the product leaves in the bottoms and the distillate is decanted (Black, 1980). Processes I and II are represented in Figure 2 and Figure 3, respectively. To assess the thermal efficiency, energy requirements of Processes I and II were estimated for ethanol concentrations in feed within 2–10 wt%. It was considered a continuous processing plant with an hourly capacity of approximately 2 tonnes of ethanol (dry mass) and 8322 h/y of operation.

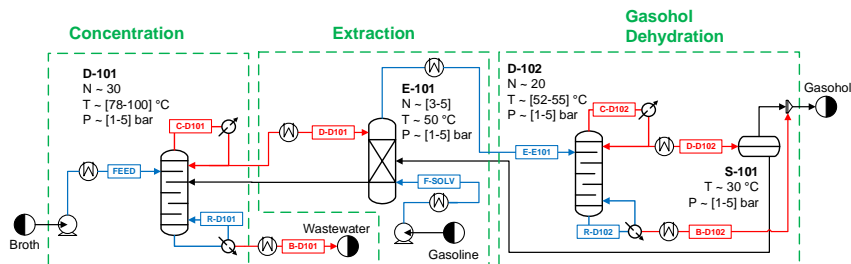
For a comparative analysis, energy needs were calculated for a liquid saturated feed with 2–10 wt% ethanol and (i) a *Single Column* system comprehending an ethanol/water distillation column operating at 1 atm, with total condenser and producing a distillate with 93.5 wt% ethanol; (ii) a *Double Column* system consisting on a stripping column followed by a concentration distillation column (with total condenser), both at 1 atm and producing a distillate with 93.5 wt% ethanol; and (iii) Process MS involving a dehydration step with molecular sieves preceded by a double-column distillation system. The total number of stages (NT) and the feed stage (NF) in D101 and D102 were estimated with the approximate methods of Fenske-Underwood-Gilliland, whereas the reboiler duties and reflux ratio were optimized to find the minimum energy consumption. NT_{D101} and NF_{D101} in Single Column/Process I are 30 and 12, respectively. NT_{D101}, NT_{D102}, and NF_{D102} in Double Column/Process II/Process MS are 26, 34, and 20, respectively. The operating conditions of D102 and the extraction column in Figure 2 are similar to the ones in Kyle


Figure 2: Process flowsheet diagram of Process I.
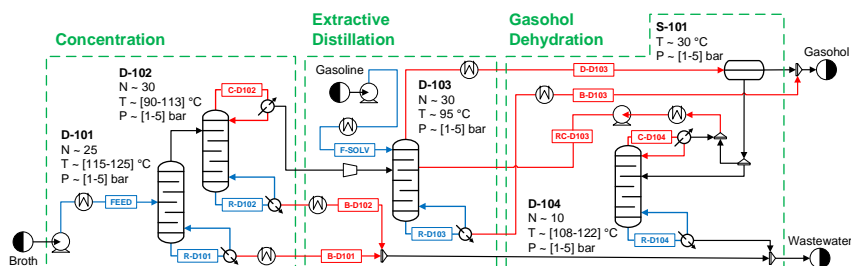

Figure 3: Process flowsheet diagram of Process II.

(1981), whereas the conditions D103 and D104 of Figure 3 are similar to the ones reported in Black (1980).

Figure 4 shows that Processes I and II are energy-efficient, since their heat duties to produce E10 gasohol at base case conditions are, respectively, within 5.1–14.1 MJ·heat/kg·ethanol and 4.8–13.8 MJ·heat/kg·ethanol for ethanol concentrations in feed between 10 wt% and 2 wt%. This means that Process I requires on average 0.9 MJ·heat/kg·ethanol of heat to produce E10 gasohol from near-azeotropic composition, while Process II needs about 1.6 MJ·heat/kg·ethanol. These figures are competitive with those reported in Singh and Rangaiah (2017) considering other technologies (0.7–5.1 MJ·heat/kg·ethanol). Both processes also compare well with Process MS, since molecular sieves are reported to spend 1–2 MJ·heat/kg·ethanol to produce 99.5 wt% ethanol from ethanol/water azeotropic distillates (Vane, 2008).

4. Process optimization and heat integration

Once the performance of Processes I and II at base case conditions were found, the goal is to determine the operating conditions that minimize the total hot utilities consumption. For such a purpose a mathematical program was formulated and then solved in Aspen Plus® V10 using BOBYQA (Powell, 2009), where reboiler duties and reflux ratios of all distillation columns in Processes I and II were optimized to minimize energy consumption. The total number of stages, feed stages and operating pressures remain fixed. Afterwards, pinch analysis was carried out with ASPEN Energy Analyzer to find the theoretical minimum energy usage for both processes with $\Delta T_{\min} = 10\,°C$. Dashed lines in Figure 4 show that modifications in operating conditions and heat integration can significantly reduce the energy needs of Processes I and II to 3.8–14.0 MJ·heat/kg·ethanol and 3.5–12.2 MJ·heat/kg·ethanol, respectively, for ethanol concentrations in broth between 10 wt% and 2 wt% which represent energy savings up to 30% compared to Process MS. Practically, the lower energy consumptions are due to (i) the reduction in heat requirements for solvent recovery; and (ii) the heat integration between the pre-concentration distillation columns and the gasoline
Figure 4: Energy duty vs. ethanol concentration in feed for the various process configurations. Dashed lines represent the Processes I and II optimized for minimum energy requirements.

recovery/extractive distillation columns.

4.1. HEN optimal design and ethanol production cost

Now we consider the plant capacity and the optimal operating conditions obtained before, and design optimal HENs for both processes. A concentration of 5 wt % of ethanol in the broth is used for demonstration. The optimal design of HENs for minimum total cost was determined with Aspen Energy Analyzer, which uses a sequential procedure where superstructures similar to those proposed by Yee et al. (1990) are built and solved as MILP problems to provide feasible HENs satisfying the heat load distributions. Finally, ethanol production cost was estimated from capital and manufacturing costs for a 15 years life plant. Figure 5 shows the optimal HEN found for Process I. It is observed that the overhead vapor and the bottom streams of D-101 (respectively, C-D101 and B-D101) are the main heat sinks and are used to heat the feeding stream, pre-heat the solvent and in the reboiler of D-102. Regarding the production costs, Processes I and II have similar figures (respectively, $0.17/kg·ethanol and $0.19/kg·ethanol) and they are in the lower decile of the costs range indicated by Singh and Rangaiah (2017), i.e. $0.03–3.65/kg·ethanol. However, a fair comparison in this case is hard due to the different concentrations of ethanol in the fermentation broths and the set of assumptions used in techno-economic analyzes.

5. Conclusions

This contribution addresses the direct production of gasohol where gasoline is employed as separating agent. It is demonstrated that Processes I and II are energetically favorable relatively to Process MS, especially after optimization and heat integration. Specifically, total energy savings can reach up to 30% for ethanol concentrations in feed within 2–10 wt %. The results show that these alternative processes can be very competitive (production costs ca. $0.19/kg·ethanol) when gasoline can blend on ethanol production site or the integration with a petrochemical plant is possible. The capital costs involved are potentially low as the retrofitting of existing distillation facilities would require a limited number of modifications. Future works may include the simultaneous optimization and heat integration of multi-effect and/or dividing-wall distillation systems seeking for further decrease of energy and capital costs.

Abstract

This paper presents a MILP-based decomposition algorithm for solving large-scale scheduling problems with assembly operations in flexible flow shop environments. First, a rigorous mixed-integer linear (MILP) formulation based on the general precedence notion is developed for the problem under study. Then, the MILP model is embedded within a decomposition algorithm in order to accelerate the resolution of large-size industrial problems. Finally, the proposed solution approach is tested on several examples derived from a real-world case study arising in a company that builds vessels for the offshore oil and gas industry.

Keywords: flexible flow shop, scheduling problem, assembly operations, MILP model, decomposition strategy.

1. Introduction

The flexible flow shop scheduling problem (FFSP) is a generalization of the classical flow shop problem (FSP), wherein all products follow the same flow processing line but all of them may not visit all processing stages. When some stage on the line performs an assembly operation, the problem is known as FFSP-A. Generally, the objective is to minimize the completion time of all products (makespan). This type of scheduling problem appears in many industrial applications such as automotive industry, paint companies, and shipbuilding industry, between others.

The FFSP-A is strongly NP-hard (Pinedo, 2016). Consequently, real-world industrial problems lead to intractable model sizes when rigorous mathematical formulations are used. To overcome this drawback, this works presents a decomposition algorithm that allows finding high quality solutions with low computational effort even for large-size instances. The decomposition approach first obtains a good schedule (constructive stage), by using an insertion method, and then improves it (improvement stage) by executing partial rescheduling actions. All decisions in the iterative procedure are taken by solving a MILP model featuring a reduced search space. Specifically, the mathematical formulation used in this paper was developed applying the general precedence notion, but other alternative approaches can be considered too. The applicability and efficiency of the solution strategy is tested by solving a challenging real-world problem dealing with the construction of a ship for the development of marine resources, specifically for the offshore oil and gas industry.

2. Mathematical formulation

The FFSP-A problem consists of a set of products $i \in I$ $(i = 1,2,\ldots,|I|)$ processed through several consecutive operation stages $s \in S$ $(s = 1,2,\ldots,|S|)$ with parallel identical units $k \in K_s$ working in parallel at each stage s. The subset S_i identifies all stages processing product i, while the parts $i' \in I$ that integrates a product i are defined by the subset SA_i. The subset $S^a \subseteq S$ contains all stages performing assembly operations. The final products obtained on the line are identified by subset I^f $(I^f \subset I)$. Either the non-intermediate storage (NIS) policy or the unlimited intermediate storage (UIS) policy between stages can be adopted. When a NIS strategy is used, each processing unit becomes intermediate storage if its processing has finished and the next step is not available yet.

The problem constraints can be mathematically modelled using any of the continuous-time formulations that have been published in the literature for the short-term scheduling of multistage batch plants (Méndez, Henning and Cerdá, 2001). Particularly, the MILP model developed in this work and presented follow is based on the general precedence notion. It is worth to remark that some changes have been incorporated to the original proposal in order to consider the assembly operations. As shown Eq. (1), the main goal is to minimize the total time required to obtain the final products.

$$minimize\ MK \tag{1}$$

$$\sum_{k \in K_s} Y_{ik} = 1 \qquad \forall\, i \in I, s \in S_i \tag{2}$$

$$Tf_{is} \geq Ts_{is} + tp_{is} \qquad \forall\, i \in I, s \in S_i \tag{3}$$

$$Ts_{is} = Tf_{i(s-1)} \qquad \forall\, i \in I, s \in S_i\,,(s-1) \in S_i, s > 1 \tag{4a}$$

$$Ts_{is} \geq Tf_{i(s-1)} \qquad \forall\, i \in I, s \in S_i\,,(s-1) \in S_i, s > 1 \tag{4b}$$

$$Ts_{is} \geq Tf_{i'(s-1)} \qquad \forall\, i \in I, i' \in SA_i, s \in S^a, s \in S_i, (s-1) \in S_{i'} \tag{5}$$

$$Ts_{i's} \geq Tf_{is} - M(1 - W_{ii's}) - M(2 - Y_{ik} - Y_{i'k})$$
$$\forall\, i \in I, i' \in I, s \in S_i, s \in S_{i'}, k \in K_s, i < i' \tag{6}$$

$$Ts_{is} \geq Tf_{i's} - MW_{ii's} - M(2 - Y_{ik} - Y_{i'k})$$
$$\forall\, i \in I, i' \in I, s \in S_i, s \in S_{i'}, k \in K_s, i < i' \tag{7}$$

$$MK \geq Tf_{is} \qquad \forall i \in I, s \in S_i : s = |S| \tag{8}$$

Eq. (2) defines the allocation constraint. Binary variable Y_{ik} takes 1 as value when product i is processed in unit k; otherwise, it is set to zero. Eq. (3) computes the ending

time Tf_{is} of product i at stage s as its starting time Ts_{is} plus the associated processing time pt_{is}. The storage police between two consecutive stages is represented by Eq. (4a) for NIS or Eq. (4b) for UIS. Constraint (5) determines that the assembly of a product i in stage $s \in S^a$, with $s \in S_i$, must begin after its associated sub-assemblies $i' \in SA_i$ have completed their processing in the previous stage. Eqs. (6) and (7) define the sequencing constraints on a same unit k. Binary variable $W_{ii's}$ is the general precedence variable in stage s. Finally, Eq. (8) states a lower bound for the variable MK to be minimized.

3. The MILP-based decomposition algorithm

The computational efficiency of the full space approach presented in the above section or any other rigorous formulation is rapidly deteriorated when increasing the problem size. For industrial applications, the solvers report solutions with a high GAP after several CPU hours. This weakness can be overcome by solving the mathematical model several times but considering a reduced search space at each iteration. Even though this solution strategy does not guarantee the optimality of the solution found, it allows reporting practical solutions with reasonable computational time.

The decomposition method presented here is based on the strategy of first obtaining an initial solution (*constructive stage*), to then gradually enhance it by applying several rescheduling iterations (*improvement stage*). Both algorithmic stages have as core the general precedence MILP model presented previously. At this point, it is worth mentioning that other alternative mathematical formulations (Méndez *et al.*, 2006) may also be easily adapted to the proposed decomposition strategy.

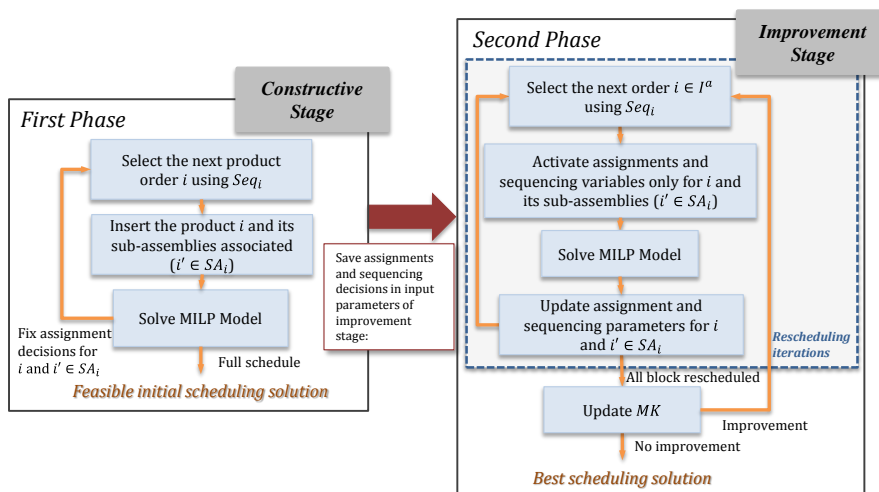
The general structure of the algorithm is given in Figure 1. Note that a feasible initial scheduling solution is obtained from inserting order by order in the constructive stage. Then, an iterative enhancement-based technique is used to improve the current solution. The assignment and sequencing decisions are left free only for the product that is being rescheduled in each improvement iteration, which significantly reduces the optimization search space. When no improvements are obtained for the objective function, the current solution is reported as the best solution for the problem under study.


Figure 1: Overview of the iterative MILP-based algorithm.

3.1. First phase: Constructive step

The first phase of decomposition algorithm aims at generating an initial full schedule with low computational effort. The constructive method is based on the insertion technique presented by Kopanos et al. (2010) for solving large-scale pharmaceutical scheduling problems. These authors propose to insert (schedule) the products one-by-one in an iterative mode. As the FFSP-A problem includes assembly operations, it is needed that a product $i \in I^f$ and its sub-assemblies $i' \in SA_i$ will be inserted and scheduled at each iteration. Every time the MILP model (1)-(8) is solved, the binary variables Y_{ik} and $W_{ii's}$ for the new products scheduled are fixed at their optimal values.

One key point to consider in the constructive stage is to define the order in which the products will be inserted. The insertion criterion should be determined according to the problem features (Roslöf et al., 2001, 2002), for example, it can follow the lexicographic order or is based on a specific sequence. The aim should always be to find a good initial scheduling solution in a short computational time.

The constructive stage procedure ends when all products have been scheduled. Next, the initial solution is sent to the next algorithmic phase (improvement stage) using the parameters sY_{ik} and $sW_{ii's}$, which indicate the assignment and sequencing decisions taken by the constructive stage.

3.2. Second phase: Improvement step

Taking as starting point the assignments sY_{ik} and sequencing decisions $sW_{ii's}$ obtained as initial solution in the constructive step, this second phase applies the strategy of rescheduling each product $i \in I$ in a sequential way to try to improve the current solution. In other words, reassignment and reordering decisions are iteratively taken for each product i and its sub-assemblies $i' \in SA_i$. The improvement stage is executed sequentially until no improvement can be achieved to the makespan.

A boolean parameter $active_i$ is used for determining the subset of products i that can be rescheduled at each iteration. Thus, the MILP formulation (1)-(8) will active only the binary variables Y_{ik} and $W_{ii's}$ for products i with $active_i = true$. For other products, only timing decisions can be made. Reassignment to other units is not allowed for products with parameter $active_i$ set to false. Furthermore, their relative position in the processing sequence remains unchanged. This decomposition strategy allows reducing the number of binary variables of the mathematical formulation with regards to the full space approach, reducing drastically the CPU time needed to solve the model. Note that solving the full space approach is equivalent to set $active_i = true \ \forall \ i \in I$.

Every time a rescheduling action is executed, the current solution is updated. Once the rescheduling step was applied for all products, the procedure checks the makespan achieved. If the solution found is better than the best solution obtained until that moment, the algorithm updates the makespan and goes to execute the improvement step for all products again. Otherwise, the algorithm ends and reports the current solution as the best solution found for the problem under study.

4. Computational results

The MILP-decomposition algorithm is applied for the solution of a complex case study arising in a shipbuilding company, which constructs ships for the development of

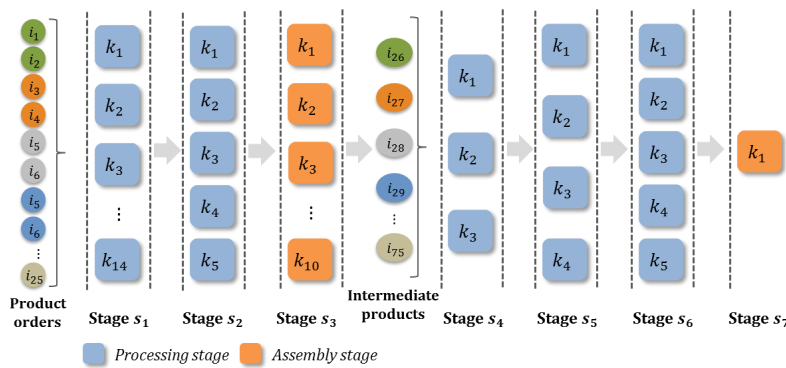
marine resources, specifically for the offshore oil and gas industry. This real-world FFSP-A problem involves 7 processing stages, each one with K_s processing units working in parallel, as is shown in Figure 2. A ship is built using dozens of blocks of specific size. A block is the largest construction unit of a ship. In turn, each block is assembled from one or more sub-blocks, which are composed of steel plates according to the design drawing for the ship. Both blocks and sub-blocks are considered intermediate products in the ship, which contains other components such as pipes, supports, and electronic equipment. From Figure 2, it follows that stage s_1-s_2 process sub-blocks, which are then assembled in stage s_3 to form the block. The last processing stages on the line (s_4-s_6) perform operations on the blocks, which are finally transported and positioned in a dry dock (*stage s_7*) for assembling the ship. Note that this manufacturing process includes two assembly stages: in the first one, each block is constructed by one or more sub-blocks while in the second one the mounting of these blocks is carried out to build the ship.


Figure 2: FFSP-A process – case study.

From the original case study, 10 problem instances were derived in order to test the computational performance of the decomposition algorithm when facing different problem sizes. Alternative storage policies, UIS and NIS, were considered for each problem size. Moreover, it is assumed that the blocks are formed by two sub-blocks. All experimental studies were implemented in GAMS 24.9.2 with CPLEX 12.6.3.0 as MIP solver and run on a PC with four-core Intel Xeon X5650 Processor (2.6 GHz). Besides, the termination criterion imposed for the solution of all problem instances has been either 0 % optimality gap or 3600 sec of CPU time.

Table 1 presents a comparison of both the results reported by MILP model and those reached by the decomposition algorithm. The expression $N \times M$ refers to a ship constructed with N blocks and M sub-blocks. The smallest problem addressed involves 10 sub-blocks and 5 blocks, while the biggest one deals with a ship built with 50 sub-blocks and 25 blocks. From Table 1, it follows that when the amount of blocks exceeds the number of 5, the full space approach does not find the optimal solution within the time limit specified, reporting a high integrality GAP for all examples. Instead, near-optimal solutions, sometimes the optimal one, are found by the solution strategy for all problem instances in few seconds of CPU time. For the more complex instance, P.10, the algorithm finds a solution of 270.5 days after 56.6 seconds, reaching an improvement of 16.5% with regards to the solution reported by the MILP model after 3600 seconds of CPU time.

Table 1: Comparison between exact MILP formulation and MILP-based algorithm statistic.

Problem	Size $N \times M$	Storage policy	MILP Model			MILP-based strategy			Enhanced solution (%)
			MILP solution	GAP (%)	CPU Time (s)	Initial solution	Best solution	Total CPU (s)

5. Conclusions

A MILP-based iterative solution algorithm for solving industrial-scale FFSP-A problems has been presented in this work. The procedure was based on a MILP scheduling formulation rely on the general precedence notion. The performance of the proposed methodology has been deeply evaluated by solving several instances derived from a real-world case of study. Computational results showed that high-quality solutions can be efficiently found by the algorithm in short computational time, outperforming the rigorous optimization approach.

Abstract

Global agricultural trade flows demonstrated a three-fold growth during the past decade particularly in emerging economies. At the same time, global food scandals in conjunction with the spillover effects in economy and society highlight the unreliability of existing food tracking systems and the inefficiency in monitoring food quality and fraud incidents across global food supply chains (SCs). Blockchain technology (BCT), which has already been successfully applied on the financial industry to validate critical transactions, seems to be a promising option. This research investigates a two-stage containerized food SC by implementing a demonstrator application at the Hyperledger Fabric framework. The study findings indicates that on one hand BCT has entered its maturity phase while on the other hand its adoption in food SC operations could add significant value by authenticating critical parameters and providing enhanced traceability . At the same time, BCT enabled by other digital technologies could allow for the optimization of global food SCs. Thus, BCT constitutes a promising digital technology that provides the capability to food SC stakeholders to securely share information, enhance process control and traceability and prevent potential risks.

Keywords: container handling, food supply chain, blockchain, traceability.

1. Introduction

Global agricultural trade flows are valued at about USD 1.7 trillion annually (FAO, 2017), demonstrating a three-fold growth during the past decade, particularly in emerging economies. At the same time, wastage/losses of perishable products along with global food scandals and in conjunction with associated spillover effects in economy and society, highlight the unreliability of existing food tracking systems and the inefficiency in monitoring food quality and fraud incidents across farm-to-fork food supply chains (SCs). To that end, blockchain constitutes a promising digital technology

that provides food SC stakeholders the capability to securely share information and prevent potential risks. To this effect, the financial technology (FinTech) industry provides solutions, such as the blockchain technology (BCT), that could (Christidis and Devetsikiotis, 2016): (i) provide a sustainable, robust and secure option for promoting synergies and reliable information sharing across SCs; (ii) minimize time consuming actions that comply with continuously changing legislation; (iii) reduce the need for trusted third parties; and (iv) introduce the use of smart contracts. Despite the prospects of BCT in end-to-end SC operations, a framework describing data requirements for containerized food SCs, particularly in case of maritime logistics, is still lacking.

In this regard, this research first provides a systematic literature review for mapping the blockchain landscape and proposes a blockchain framework for containerized food SCs. The framework contributes to the SC management research by establishing a blockchain infrastructure that employs smart interconnected devices across network echelons and further provides the capability to food SC stakeholders to securely share information, enhance process control and traceability, and prevent potential risks to containerized food SCs. A pilot case study in Greece is presented for the shipping container industry transporting perishable food products in refrigerated containers. The smart containers enable the uninterrupted communication with the blockchain backbone and allow the continuous and reliable storage of critical information. The case particularly focuses on critical maritime logistics processes involved in, namely: (i) preannouncement phase; (ii) port of origin storage yard; (iii) origin vessel; (iv) sea transport; (v) destination vessel; (vi) port of destination storage yard; and (vii) last mile logistics. To that end, our analysis captures key data requirements from key involved stakeholders, namely line shipping companies, terminal operators and port authorities (Lee and Song, 2017).

2. Blockchain Technology in Food Supply Networks

Global food trade has increased the total transportation time and distance from the farmer to the end consumer. In addition, fresh and processed food is vulnerable to hygiene and safety risks at all food SC echelons, thus rendering the farm-to-fork assessment of the products' quality very challenging. Aung and Chang (2013) stated that the transition of the food industry to a global value network necessitates traceability systems and faster response times to prevent food scandals. Wahyuni et al. (2018) identified risks across end-to-end food SCs by analyzing a case study for the fish industry. Across the entire spectrum of food SC operations, all stakeholders are responsible for preventing any biological and chemical contamination. Stakeholders are encouraged to use Information and Communication Technologies (ICTs) for advanced control, and monitor all 'source-make-deliver' processes to safeguard perishable products and eliminate quality variations from the stringent food safety requirements.

BCT could signal a digital transformation to the food SC landscape, affect key SC objectives (e.g. cost, quality, speed, risk reduction, flexibility) and increase transparency and accountability (Kshetri, 2018). Caro et al. (2018) presented AgriBlockIoT, a practical implementation of BCT using the Ethereum and the Hyperledger. Internet of Things (IoTs) devices capture and directly transmit data to the BCT ecosystem, while sensors ensure the automated execution of smart contracts. Tse et al. (2018) introduced BCT to the food industry in China to tackle food safety issues, as it provides a permanent record for each transaction and a replacement for traditional paper tracking systems. The authors also included an Administration and Regulator level at their

implementation in order to help government track, monitor and audit the food SC. Finally, Tian et al. (2017) identified the emerging role of ICTs to the SC ecosystem and focused on an innovative decentralized BCT for implementing a real-time food tracing system based on Hazard Analysis and Critical Control Points and the IoTs.

3. Business Processes in Containerized Food Supply Chains

In order to analyze the critical business processes in containerized food SCs, this research explores the illustrative real-world case study of an end-to-end food SC. In particular, we study a Greek Third-Party-Logistics provider, located in the city of Thessaloniki, offering services for containerized food. The investigated case study takes into consideration the following business processes – farming-processing-distribution – where all retrieved critical information is stored in a BCT structure to ensure the product quality. The main focus of the Third-Party-Logistics provider is on logistics processes involved in maritime containerized global transportation through using reefers.

The end-to-end perspective of the investigated case study enables integrated data gathering and ensures visibility and traceability across all food SC stages. We recognize that the gathered data across the food SC under investigation can be segmented in two categories: (i) critical data that are considered as input to a BCT framework; and (ii) supporting data that are considered as informative metadata. We claim that the identification of these data categories supports the viable development of BCT software as the required resources (e.g. storage capacity, energy consumption) are minimized.

3.1. Farming and Processing

In a typical food SC ecosystem, the agricultural commodities are being collected by the farmer and are then forwarded downstream the SC to the retailer and the final consumers. Every farmer is characterized by primary production focus (Farmer ID and metadata) at a specific geolocation of a field (Field ID and metadata) in the farm (Farm ID and metadata). Furthermore, the farming processes involved include sowing, cultivation and harvesting of agricultural commodities. At each process it is necessary to retain critical information and transactions, including: quality of the seeds (Seed ID and metadata); cultivation practices (Cultivation Type IDs and metadata); used fertilizers (Fertilizer ID and metadata); environmental conditions during the growth of the product (environmental metadata). IoTs devices are vital for the uninterrupted communication of the SC software and BCT with the farming infrastructure. At a second stage, food and beverages processing industry utilizes the inbound agricultural materials as input to manufacture processed foods and distribute the final products to wholesalers. Critical data include: industry's ID; food processing methods; ingredients and preservatives; processed food ID and all relevant metadata. Industry 4.0 technologies enable the direct communication of the manufacturing environment (equipment and machinery) with the infrastructure and BCT.

3.2. Distribution

Wholesalers are responsible for the distribution of the final products to retailers. At the distribution process transportation conditions are critical as they could tamper the quality of food products, particularly in the case of perishable goods. Refrigerated containers store agricultural products and with the use of smart sensors a 24/7 link for informing the ICTs and BCT of the SC is ensured. The distribution of agri-commodities from the wholesaler to retailers involves three major entities: (i) port of origin; (ii) shipping line for maritime freight; and (iii) port of destination.

3.3. Port of Origin

At the port of origin, the process begins with the preannouncement phase. The list of export containers to enter the Container Terminal is required for the communication between the shipping agent who handles the container and the port authority, and it must be submitted before the arrival of each container (48h in advance). Port authorities use this list to plan the transport of the container by examining the origin, content, port of destination, Verified Gross Mass as well as space availability at the port, and the required temperature limits for preserving the agricultural products. The port's handling equipment (e.g. forklift, and straddle carrier) is used for transferring the container boxes close to the dock in order to be positioned in the vessels by Gantry Cranes based on specific EDI messages (container loading list). Containers are categorized according to: (i) port of destination; (ii) agent responsible for transportation (i.e. primary or secondary); (iii) container's properties (i.e. Verified Gross Mass, container size – 20, 40, 45, high-cube); (iv) load (e.g. barrels, parcels, boxes); (v) container type (e.g. reefer); (vi) hazard type (e.g. non-flammable gas, organic peroxides, oxidizing substances, substances demonstrating fire hazard, mass explosion hazard); and (vii) payment responsible. Once the refrigerated container is at the storage yard it is plugged at the power supply in order to maintain appropriate temperature while at the same time it communicates its status to the information communication infrastructure. The final responsibility of the port of origin is the ship loading from the origin vessel with the use of straddle carriers. Port employees are equipped with personal digital assistant devices to confirm the execution of every individual task. It is critical to continuously monitor containers, in an automated manner, to track container flows.

3.3.1. Shipping Line for Maritime Freight

Once a container is correctly loaded at the ship, the port has no further obligations and the ship has to fulfil the consignment. Provided that a refrigerated container is safely loaded, it must be plugged in to the ship's power supply. The ship's operator manually establishes the correct temperature at the reefer and ensures that it properly operates during shipment. The Electronic Data Interchange message that presents the exact position of every container in the ship is generated in order to inform all stakeholders. The reverse process then takes place as the container arrives at the port of destination. The CORPAR order for unloading containers, along with the determination of the containers' exact position, is executed to complete the unloading process.

3.3.2. Port of Destination

At the destination port, and prior to the arrival of the ship, port authorities use the bill of lading in order to plan the handling of the inbound containers by examining their origin, content and destination as well as space availability at the port and temperature requirements for preserving the transported food products. Bills of lading are submitted in either Electronic Data Interchange or Extensible Markup Language formats and contain attributes such as: quantity; weight; type of hazards; type of container (e.g. size, reefer); state information (e.g. temperature tolerance limits). Port authorities review the bill of lading and proceed to the appropriate preparatory activities. In case a specific product is on the bill of lading, the port receives the container and temporarily stores it at the destination warehouse. Containers are stored according to their load, destination or transportation agent. In the case of reefer containers, a power supply is necessary for ensuring appropriate storage conditions. The port operator is responsible for the reefer and the temperature settings which should be clearly stated at the bill of lading. Selected containers could be moved for customs control where all the obligatory custom

declaration forms are checked and then the container is moved for a short-term storage to the destination storage yard. All transport information during last mile logistics must be monitored to safeguard the quality of the delivered products.

4. Digital Transformation: Blockchain Framework

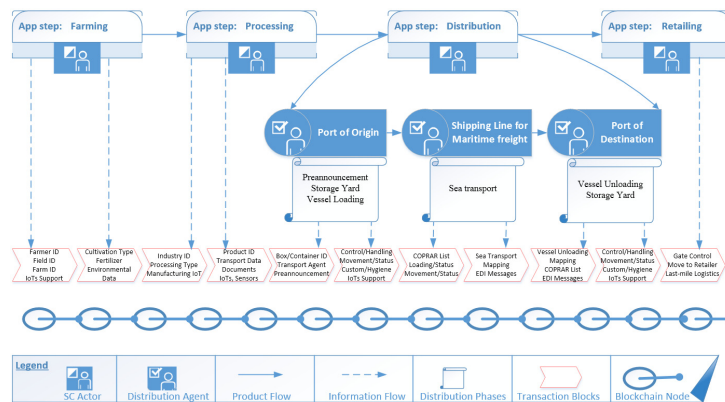
Modeling the containerized food SC processes enables the digital transformation of the shipping industry and provides added value to the SC (Scholliers, 2016). Food value networks are sensitive to time critical parameters and to the transportation and storage conditions of the agricultural commodities. Perishable products should be delivered to the consumers without losing their organoleptic and nutritional properties and this could be safeguarded by the use of innovative information technology-based solutions. The proposed framework enables the integration of BCT from a farm-to-fork perspective, with special focus on the business model of containerized food SCs. Every step of the process is designed in order to provide all the obligatory and critical data to the sequential blocks of the BCT framework. The blockchain architecture could follow a public (Ethereum) or a private (Hyperledger) scenario and blockchain nodes are responsible for safeguarding the information flow of the SC and ensure data integrity. In tandem with IoTs devices (e.g. radio-frequency identification) and autonomous vehicles in industrial environments that can operate on a 24/7 basis (Bechtsis et al., 2018), communication with the blockchain allows real-time information and data sharing among all stakeholders, hence increasing traceability and trust. Finally, a demonstrator working model is implemented at the Hyperledger Fabric framework. The use case scenario involves a two-stage Distributor and Retailer SC business model that includes Assets (Product, Driver, Container, Truck), Transactions (Product Transportation Steps) and Events (Distributor and Retailer Updates). The Business model for all entities was implemented at the Hyperledger Composer and was tested using the Hyperledger's Playground interface. Every participant could receive credentials for joining the network either by simply communicating with other peers or by creating a distinct node. The proof of concept scenario used the levelDB for the immutable transaction log and CouchDB for storing metadata. Further research is needed for developing a full scale SC tool that will implement the proposed containerized food SC framework (Figure 1).


Figure 1. Blockchain Framework for Containerized Food SCs

5. Conclusions

The study findings indicate that BCT is in its maturity phase as it has been successfully applied on the FinTech processes. Digital technologies and the blockchain framework focus on critical transactions provide added value to SC operations and promote optimization techniques to global organizational challenges. The proposed framework integrates operations of the various partners across a global containerized food supply chain on a single secure information sharing process implemented on a farm-to-fork blockchain platform. A working model of a two stage SC was implemented on Hyperledger Fabric as a proof of concept demonstrator. The cost of developing/operating or leasing this platform, which is closely related to the volume of exchanged data, as well as the additional costs (sensors, IoTs devices) for collecting the necessary information will be the key parameter for documenting the feasibility (under business terms) of this system for a supply network.

Abstract

Nations in the Gulf Cooperation Council (GCC) utilise their vast oil and natural gas resources in order to satisfy the demand for water and power, which continues to increase due to population and economic growth. The abundance in fossil fuels and relatively low O&M costs make fuel-based technologies a de-facto choice when planning new power or desalting facilities which are proven to have the lowest levelized cost compared to other alternatives. However, energy intensive desalination systems have contributed to high greenhouse gas (GHG) emissions and increased costs. Recently, several facilities have been designed to include renewable energy in order to mitigate GHG emissions and improve the overall environmental welfare. This study evaluates different power and desalting configurations using both fossil-based and renewable energy sources to determine an optimal configuration that minimises CO_2 emissions at a relatively low levelized cost. Using the current utilities infrastructure in Qatar as a basis, six configurations were devised where three of them mimic current configurations and three were proposed. The technologies selected were limited to existing configurations: open cycle gas turbine (OCGT), combined cycle gas turbine (CCGT), multi-stage flash (MSF), and seawater reverse osmosis (SWRO), and three renewable technologies concentrated solar power (CSP), solar PV, and biomass integrated gasification combined cycle (BIGCC). At a system-level, optimisation of levelized costs vs global warming potential (GWP) was conducted using a stochastic programming framework. The findings conclude that current configurations are suboptimal and the infusion of renewable energy sources (RES) into the combined power and desalting plant (CPDP) infrastructure significantly improves CO_2 emissions with a reduction ranging between 52% and 67% and overall system levelized cost decrease between 8% and 32%.

Keywords: Portfolio optimisation, renewable energy, stochastic processes, levelized costs, environmental impact.

1. Introduction

Economic and population growth in the Middle-East since the hydrocarbon boom has increased the industrial and urban demand for water and energy resources. By 2030, water demand globally is expected to rise by 25%, with a 50% increase in energy (Madani et al., 2015). Considering the demand for both, water and power, the countries in the GCC bordering the Arabian Gulf, are reliant on co-generation power desalting plants (CPDP) which produce two useful utilities: electricity and freshwater. In fact, 44% of the global desalination capacity is located in the Middle-East and North Africa

(Voutchkov, 2016). Desalination is an energy intensive process in which associated emissions are a function of the input energy, i.e. natural gas, oil, etc.

The State of Qatar, a peninsula located in the heart of the Arabian Gulf, suffers from freshwater scarcity as it is located in a hyper arid region with renewable groundwater rate equivalent to 58 million m^3 annually (Darwish, 2014). It exhibits a similar development profile to those witnessed by the rest of the region and in terms of its energy resources, Qatar possess approximately 25.4 trillion m^3 of gas reserves and its annual output of liquefied natural gas is 77 million tons per year (Qatargas, 2018). Technology advancements in the provision and supply of natural gas, in addition to the fact that it is considered the cleanest of fossil fuels has enhanced the position of natural gas as an energy resource. In fact, natural gas, it is the sole driver of power generation in Qatar and has witnessed increasing demand in the global market, therefore offering further opportunities for the export of natural gas and associated products. Several utility plants based on affordable and clean natural gas have been constructed in Qatar in order to satisfy water and electricity increasing needs as illustrated in Table 1. The State of Qatar aims to diversify the energy mix and reduce GHG emissions through the integration of alternative and renewable energy and desalination technologies. This study serves as a guideline for decision makers offering a comparative tool for identifying an optimal mix of power and water systems minimizing environmental and economic impacts.

Table 1. List of CPDP facilities in Qatar (Kahramaa, 2017).

Plant	OCGT (MW)	CCGT (MW)	MSF (MIGD)	SWRO (MIGD)
RAF A	497			
RAF A1			45	
RAF A2			36	
RAF A3				36

RGPC		2,730	63	
M Power		2,007		
UHPC		2,520	76.5	60
Total	2,049.5	9,038	383.5	96

In terms of portfolio optimisation, Bhattacharya and Kojima (2012) examined the increase of renewable energy contribution in the energy supply portfolio for Japan utilizing mean-variance portfolio (MVP) optimisation. Fuss et al. (2012) examined the adoption of renewable energy and carbon-saving technologies across different socioeconomic scenarios. Cucchiella et al. (2012) analysed the electricity market in Italy using MVP, and reviewed a set of optimal portfolios with different energy mixes. The study concluded that it is necessary to include renewable energy into the portfolio to mitigate the high investment risk in this market. Lucheroni and Mari (2014; 2015; 2016) used stochastic levelized cost of energy (LCOE) theory to determine the optimal power generation portfolio for different scenarios. Govindan et al. (2018) estimated the LCOE for CCGT using stochastic modelling and applied it into a portfolio optimisation of different energy and water technology mixes as part of energy, water and food

(EWF) Nexus studies. Namany et al. (2018) expanded on the work by Govindan et al. (2018) and Al-Ansari et. al (2015; 2017) by applying a game theoretic approach using a Stackelberg duopoly model to the EWF Nexus. The study considered a CCGT competing against bio-energy with carbon capture and storage (BECCS). Darwish et al. (2014, 2015) provided a techno-economic analysis of different CPDP to improve energy and water security in Qatar in a cost-effective manner. The aim of this paper is to evaluate the integration of RES, consisting of PV, BIGCC and CSP, into the existing utilities infrastructure in terms of CO_2 emissions and levelized costs by applying stochastic modelling and multi-objective genetic algorithm optimisation.

2. Methodology

Using a stochastic optimisation framework that considers fluctuation in natural gas prices, this study models diverse power and desalting scenarios using a combination of renewable and non-renewable energy sources to identify the optimal configuration with the lowest levelized and environmental impact. The utilities infrastructure is segregated by typical configurations of CPDP as illustrated in Table 2. There are 3 existing configurations observed based on 2 power technologies OCGT and CCGT and 2 water desalination technologies MSF and SWRO. Typically, configurations tend to improve over time transitioning to a more reliable and efficient technology as was obvious from the transition of legacy OCGT systems in favour of CCGT and from expensive and energy intensive MSF to SWRO. Three new technologies were selected based on suitability for the environment in the Middle-East, CSP, PV and BIGCC.

Table 2 List of Current CPDP Configurations.

Configuration	OCGT	CCGT	MSF	SWRO
1	1.0		1.0	
2		1.0	1.0	
3		1.0	0.63	0.37

Figure 1 illustrates a comparison of the 7 technologies together with the 3 existing configurations. The aforementioned technologies form the baseline and will be used for comparison with 3 additional scenarios that are based on a portfolio optimisation using stochastic modelling of natural gas prices, thus providing a representation for natural gas price volatility. The model was based a mean gas price and a standard deviation as predicted by Govindan et al. (2018).
Figure 1. Current Water and Power Technologies and CPDP Configurations.

A multi-objective genetic-algorithm (GA) model was developed for the 7 technologies representing 7 decision variables with the aim of minimizing both the overall levelized costs of the system and GWP. Levelized costs and GWP factors per technology were selected from literature as described in Table 3. Subsequently, two optimisation objectives are formulated for the levelized costs and GWP respectively:

$$Minimize \sum_i c_i x_i \tag{1}$$

$$Minimize \sum_i e_i x_i \tag{2}$$

Where, c represents the levelized cost factors, and e represents the emission factors per technology.

The optimisation was subject to a number of constraints:

$$x_{OCGT} + x_{CCGT} + x_{CSP} + x_{PV} + x_{BIGCC} = 1 \tag{3}$$

$$x_{MSF} + x_{SWRO} = 1 \tag{4}$$

$$0 \le x_i \le 0.5 \tag{5}$$

Several iterations will be run to ensure a representative sample is obtained and the median pareto front will be selected for comparison with the existing configurations.

Table 3 Levelized Costs and GWP Factors per Technology.

Technology	Levelized Cost ($/kWh, $/m³)	Source	GWP (gCO₂e/kWh, gCO₂e/m³)	Source
OCGT	0.17	NREL OpenEI	490	IPCC (2014)
CCGT	0.093	Govindan (2018)	341.56	Al-Ansari (2017)
MSF	2.43	Darwish (2015)	73.35	Darwish (2015)
SWRO	0.8	Darwish (2015)	14.67	Darwish (2015)
CSP	0.16	NREL OpenEI	27	IPCC (2014)
PV	0.215	Al-Ansari (2017)	33.79	Al-Ansari (2017)
BIGCC	0.1	NREL OpenEI	230	IPCC (2014)

3. Results and Discussion

Thirty iterations were run using the GA model and a representative sample was obtained as illustrated in Figure 2. The median pareto front (Figure 3) is selected for comparison with the different configurations. Figure 4 illustrates the three manually selected points from the pareto front in comparison to the existing configurations. It is evident that current configurations are suboptimal although the more recent installations following configuration 3 display significant improvement and do approach the optimal solution in the right direction. However, without the integration of RES, the configurations will continue to be suboptimal and increasing share in the portfolio should be assigned to

CSP, BIGCC, and PV. Using configuration 5 as a representative proposed configuration and the comparison to exiting configurations reveal that configuration 5 displayed an improvement in GWP of 67%, 55%, and 52% in relation to configurations 1, 2, and 3 respectively. A similar comparison using levelized costs showed an improvement of 32%, 30%, and 8%. All 3 proposed configurations exhibited a significant share of renewables and a large reduction of natural gas-driven technologies from 100% to a range between 10% and 20%. Water desalination technologies on the other hand had an equal share in the portfolio due to the given constraints in the optimisation problem formulation.
Figure 2. Pareto front for 30 iterations.
Figure 3. Median Pareto front.
Figure 4. Comparison between 3 optimal configurations with existing ones.

4. Conclusions

In this paper, current CPDP configurations in Qatar are compared to a set of proposed configurations using non-conventional RES such as CSP, PV and BIGCC. Using stochastic modelling of natural gas prices and a multi-objective GA optimisation, it is concluded that the 3 current configurations evaluated are suboptimal. The optimal configurations are represented by a significant share of RES technologies which decrease both CO_2 emissions and levelized costs. Considering, water desalination, since there are only two technologies and both are constrained not to exceed a 50% share, the load is distributed to both of them equally. In the event that the constraint is removed, SWRO would dominate due to its significantly low levelized cost and GWP factors. However, such a scenario is not possible due to the large installed base of MSF units in Qatar. Similarly, gas-driven power generation units with a huge installed base, are also somewhat difficult to upgrade to RES. Meanwhile, RES integration can be considered for future network expansions or upgrade projects. Future research can consist of the integration of additional RES technologies such as nuclear, wind and geothermal and further evaluation of less-common water desalination technologies such as multiple-effect distillation (MED), membrane distillation (MD) and mechanical vapor-compression (MVC).

Computer-aided Design of Solvent Blends for the Cooling and Anti-solvent Crystallisation of Ibuprofen

Oliver L. Watson[a], Amparo Galindo[a], George Jackson[a], Claire S. Adjiman[a,*]

Abstract

We present a general computer-aided mixture/blend design (CAM^{b}D) formulation for the design of optimal solvent mixtures for the crystallisation of pharmaceutical products. The proposed methodology enables the simultaneous identification of the optimal process temperature, solvent and anti-solvent molecules, and solvent mixture composition. The SAFT-γ Mie equation of state is used for the first time in the design of crystallisation solvents; based on an equilibrium model, the formulation considers both the crystal yield and solvent consumption. This design formulation is implemented in gPROMS and successfully applied to the crystallisation of ibuprofen, showing that this more general approach to crystallisation design can be used effectively to optimise the desired metrics.

Keywords: Crystallisation, CAM^{b}D, SAFT, solvent mixture design.

1. Introduction

The majority of pharmaceutical products are delivered to patients in solid form, such as tablets or aerosols. During their manufacture, crystallisation is particularly important in determining the properties of the crystalline form of the drug, which can impact downstream processing and ultimately the *in vivo* efficacy of the pharmaceutical product (Variankaval et al., 2008). Solvent-based crystallisation is commonly employed; as such, the effect of solvent choice is wide-reaching. Thermodynamically, the impact of this decision will manifest itself as changes to the solubility of the Active Pharmaceutical Ingredient (API), and thus as differences in two key performance indicators: the yield of API; and the mass of solvent required to complete the crystallisation. Currently, the selection of solvents for the crystallisation of newly discovered drug molecules is often performed via time-consuming and expensive experiments (Brown et al., 2018). Due to the material constraints inherent in early drug development, alongside the short timeframes required to maximise active patent life, the full range of solvent mixtures and process conditions cannot be completely explored.

With the aim of guiding experiments towards optimal candidate molecules, the application of Computer Aided Molecular Design (CAMD) in solvent selection and design has been explored (Achenie et al., 2003; Gani, 2004) over the last decades, thus facilitating faster development of crystallisation processes (Karunanithi et al., 2006). Karunanithi et al. (2005) proposed a decomposition-based approach, whereby smaller, successive subproblems are posed and solved to avoid being overwhelmed by the number of potential solutions. Most existing methodologies follow a similar approach; a specific

crystallisation technique is utilised, process operating conditions are fixed, and the problem is then focused on the selection of a single solvent. More integrated problems, in which cooling and anti-solvent effects are treated simultaneously and solvent mixtures are considered, have not yet received attention. This is likely due to the complexity of formulating and solving a mixed-integer optimisation problem to represent these design choices; such problems result in challenging non-convex feasible regions for the continuous variables, in addition to the combinatorial solution space. More recently, the use of Generalised Disjunctive Programming (GDP) within the CAM^{b}D framework has been proposed to design optimal solvent mixtures that maximise solubility (Jonuzaj et al., 2016; Jonuzaj and Adjiman, 2017); optimal mixtures were shown to outperform pure compounds.

In view of the potential limitations highlighted in the current CAMD framework for solvent selection, a more comprehensive CAM^{b}D formulation for the design of crystallisation solvent systems is proposed here. This is developed via a general methodology, whereby the identities of solvent and anti-solvent molecules are optimised, in conjunction with their compositions and the process operating conditions, to maximise the crystal yield. This design formulation is implemented in gPROMS and successfully applied to the design of the solvent-based crystallisation of ibuprofen.

2. Crystallisation design

2.1. Problem definition

The CAM^{b}D problem is based on a generic formulation for the design of a crystallisation solvent system, whereby optimal solvent and anti-solvent molecules (s_1 and s_2 respectively), their compositions and the process temperatures are identified to maximise the performance objective, taken here to be the API crystal yield. Hence, the design considers both the initial state, where all the API is dissolved in the solvent blend, and the final state, where the system has reached an equilibrium between the crystalline API product and the remaining API dissolved in the final solvent mixture. By using solvent blends in both the initial and final states, the anti-solvent can serve a dual purpose. The enhanced solubility often exhibited by solvent mixtures (Granberg and Rasmuson, 2000) can first be exploited in the initial state, followed by a large reduction in API solubility in the final state after further addition of anti-solvent. Moreover, the proposed formulation enables simultaneous cooling and anti-solvent crystallisation, allowing the design to incorporate the benefits of both techniques simultaneously.

2.2. Model formulation

The formulation is based on an equilibrium model, where the SAFT-γ Mie equation of state (EoS) (Papaioannou et al., 2014) is used to calculate the activity coefficients required to determine the solubility of the API molecule in the solvent mixture in the initial and final states; Hutacharoen et al. (2017) have shown recently that this thermodynamic platform can provide high quality predictions of solubility. Furthermore, because anti-solvent crystallisation is dependent on both solvent and anti-solvent remaining in a single liquid phase, a miscibility function is included in the formulation to ensure the solubility of the binary solvent pair at the initial and final stages. Whilst this only guarantees the phase stability of the binary solvent mixture, calculation of the stability of the ternary mixture would lead to a more challenging problem. The addition of the API is assumed

not to significantly affect the calculated phase stability – this is then validated after a solution to the design problem is found.

In addition, whilst the selected solvent and anti-solvent must remain in the liquid phase throughout the crystallisation process, how this requirement is implemented into the formulation can affect the optimisation outcome. It is often chosen to design a cooling crystallisation by fixing the initial and final temperatures, and thus to exclude any solvents with melting or boiling temperatures which lie within those operating limits (Karunanithi et al., 2006). Whilst this is likely chosen to reduce the complexity of the problem – operating temperature is no longer a manipulated variable of the CAM^{b}D problem, and consequently solvent candidates only need to be screened once – this method may also limit the results by screening out powerful yet volatile solvents or anti-solvents. With the approach proposed here, the optimal process temperature and solvent molecules are selected simultaneously, highlighting potentially interesting solvent mixtures regardless of volatility. A liquid range constraint is thus included for all solvent molecules.

The key model equations are provided in Table 1, where the crystal yield, Y_{API}, is defined as the difference in the number of moles of API dissolved in the liquid phase, n_{API}^L, between the initial state (subscript 0) and final state, relative to the number of moles dissolved in the initial state before crystallisation. The solubility of the API of equilibrium, x_{API}^*, is related to the activity coefficient of the API at equilibrium, γ_{API}^*, the enthalpy of melting of the API, ΔH_{API}^m, the melting temperature of the API, T_{API}^m, and the operating temperature of the system, T; R is the ideal gas constant. When determining the phase stability of the binary solvent mixture, the partial derivative of the chemical potential of the anti-solvent in the binary mixture, $\mu_{S_2}^{S_1,S_2}$, is calculated with respect to the mole fraction of the anti-solvent in the binary mixture, $x_{S_2}^{S_1,S_2}$, at fixed temperature and pressure, and must be non-negative for the solvents to be miscible.

Table 1: Key model equations.

Description	Equation
Objective function: Maximise crystal yield	$$\max Y_{API} = \frac{n_{API,0}^L - n_{API}^L}{n_{API,0}^L}$$
Solid-liquid equilibrium model	$$\ln x_{API,0}^* + \ln \gamma_{API,0}^* = \frac{\Delta H_{API}^m}{R}\left(\frac{1}{T_{API}^m} - \frac{1}{T_0}\right),$$ $$\ln x_{API}^* + \ln \gamma_{API}^* = \frac{\Delta H_{API}^m}{R}\left(\frac{1}{T_{API}^m} - \frac{1}{T}\right)$$
Miscibility constraint	$$\left(\frac{\partial \mu_{S_2,0}^{S_1,S_2}}{\partial x_{S_2,0}^{S_1,S_2}}\right)_{T_0,P} \geq 0, \qquad \left(\frac{\partial \mu_{S_2}^{S_1,S_2}}{\partial x_{S_2}^{S_1,S_2}}\right)_{T,P} \geq 0$$

3. Case study: maximising the crystal yield of ibuprofen

3.1. Problem description

Ibuprofen is a widely-used pharmaceutical compound known for its anti-inflammatory properties. The objective of the design problem examined here is to identify an optimal solvent mixture and corresponding process conditions required to maximise the crystal

yield of the API, ibuprofen. In addition to this, it is important to investigate how the choice of solvent and temperatures affects the overall solvent consumption for the crystallisation, whereby a lower consumption is preferable. Solvents are selected from a list of eight candidate molecules, compiled from low-toxicity solvents with parameters available in the SAFT-γ Mie framework (Dufal et al., 2014). To understand the effects of the process temperature on the design problem, six design scenarios are run; in each, the upper temperature limit is different, ranging from 290 K to 330 K, whilst the lower temperature limit is always fixed at 290 K and the solvent consumption was not constrained. These specifications are summarised in Table 2.

3.2. Results and discussion

The formulation is implemented in gPROMS version 5.1.1.55066, using gSAFT to perform calculations using the SAFT-γ Mie EoS. The results of the design problems pertaining to the integrated cooling and anti-solvent method are summarised in Figure 1, and the comparison between cooling, anti-solvent, and the integrated approach are given in Table 3. For all problem solutions, the stability of the ternary system is confirmed using gSAFT within gPROMS.

As can be seen in Figure 1, the combination of cooling and anti-solvent crystallisation, utilising solvent mixtures, leads to a high crystal yield, which is fractionally increased by relaxing the upper temperature limit. Furthermore, the solvent consumption improves simultaneously with the objective function as the upper temperature limit is increased, leading to increasingly environmentally benign design. This is largely due to an increase in the ratio of solvent to anti-solvent in the initial solvent mixture, meaning a smaller mass of anti-solvent is required to drive forward the crystallisation to the final state. Interestingly, the optimal process temperature of the initial state is not always equal to the upper temperature limit. When the maximum temperature is fixed at 320 K, the optimal initial temperature found is 319.15 K, as a solvent liquid range constraint becomes active near the boiling point of acetone. Additional optimisations confirm that this result remained optimal up to an upper temperature limit of 323 K. Maximising the temperature range, $T_{max} - T_{min}$, is thus not always optimal and this emphasises the importance of employing a general formulation.

In addition to the combined cooling and anti-solvent crystallisation approach, problems involving only cooling or anti-solvent crystallisation are solved, as summarised in Table 3. Although the solvent consumption decreases when using cooling crystallisation, a much lower crystal yield is obtained. Anti-solvent crystallisation allows one to achieve a similar result to the integrated approach, but the crystal yield is marginally lower and the solvent consumption is higher. Here, Y_{API} is the crystal yield of the ibuprofen, and χ_s is the solvent consumption of the crystallisation, defined as the total mass of solvent mixture used in the final state, normalised by the mass of crystalline API produced.

Table 2: Problem specifications.

Description	Model inputs
Components in the mixture	API, s_1, s_2
Candidate molecules	water, acetone, ethanol, 1-propanol, 1-butanol, 1-pentanol, n-pentane, n-heptane 28 potential binary solvent pairs
Temperature limits	T_{min} /K $= 290$, T_{max} /K $= \{290, 300, 310, 320, 325, 330\}$
Figure 1: Optimised crystal yield of ibuprofen for different initial operating temperatures. The final temperature for all crystallisations was 290 K, whilst the upper temperature limit is changed per design, which in turn affects the initial operating temperature. The × symbol indicates the percentage crystal yield (left axis), whilst the △ symbol refers to the solvent use, normalised by the mass of API crystal produced (right axis). For points below 320 K, the solvent mixture is formed with acetone and water, whereas above this temperature the mixtures comprise of ethanol and water. The data points are labelled with the mole fraction of anti-solvent in the initial binary solvent mixture.

Table 3: Comparison of the integrated methodology to standalone methods.

Case	Solvent selection	T_0 /K	T /K	$x_{s,0}^{s_1,s_2}$	$x_s^{s_1,s_2}$	Y_{API} %	χ_s /(g/g)
Integrated	s_1: Acetone s_2: Water	310	290	s_1: 0.5809 s_2: 0.4191	s_1: 0.0253 s_2: 0.9747	99.99	4.329
Anti-solvent	s_1: Acetone s_2: Water	310	310	s_1: 0.5814 s_2: 0.4186	s_1: 0.0264 s_2: 0.9736	99.97	4.506
Cooling	s_1: Acetone s_2: Water	310	290	s_1: 0.4249 s_2: 0.5751	s_1: 0.4249 s_2: 0.5751	95.28	0.705

4. Conclusions

A general formulation for the design of optimal solvent blends for the crystallisation of pharmaceuticals is presented, based on a (CAM^{b}D) framework. With this general approach the optimal solvent and anti-solvent molecules, their compositions and the process temperatures required to maximise the crystal yield of a given API can be identified simultaneously. The general formulation is successfully applied to the crystallisation of ibuprofen, where the optimal solvent mixture is determined for several operating temperatures. The simultaneous design of the solvent mixture and operating temperature lead to improved results compared to those achieved when the temperature range is fixed. Better results are also found for the integrated cooling and anti-solvent crystallisation technique compared to standalone methods. A ranked list of potential

solvent mixtures can be generated using the proposed methodology, with the overall aim to guide experiments rapidly towards high performance crystallisation systems.

Abstract

Desalination is one of the possible solutions to the world's potable water scarcity. In order to make the process feasible and sustainable, use of renewable energy is a very useful option. The multi-effect desalination (MED) process linked with solar energy is one of the most thermodynamically efficient and the one with lower cost by produced potable water. In this context, the present work focuses on modelling a MED process with thermosolar energy applied to the local conditions of northeastern Brazil. This region suffers from water scarcity but, on the other hand, shows the highest levels of solar radiation in Brazil. Despite that, the literature still lacks a study concerning the technical viability of operating a desalination process with solar energy in this semi-arid region. The steady-state model is based on mass and energy balances and empirical correlations from literature to calculate the enthalpy of water and brine as well as boiling point elevation and latent heat. The model is firstly validated against simulated results from the literature regarding the Plataforma Solar de Almeria. The results have shown that the implementation of a solar desalination plant in Northeast Brazil is technically feasible. The obtained model is useful for further process optimization towards minimization of investment and operational costs and to facilitate access to potable water in arid regions with high solar incidence.

Keywords: Desalination, MED, Solar, Brazil

1. Introduction

The need of potable water increases proportionally to the world's population growth; however, the planet's water sources are mostly salty water and the fresh water sources are scarce. According to Al-Rawajfeh et al. (2017), more than two billion people currently suffer from lack of water and until 2025 this number will rise to more than four billion people. One possible solution to increase the fresh water availability is the salty water desalination, since salty water is abundant through oceans and seas. Desalination is a process that aims to remove the excess of salt, microorganisms and some particles present on seawater or brackish water. According to Byrne et al (2015), this process may be accomplished in different ways, the most commercially used are: reverse osmosis (RO), multi stage flash desalination (MSF) and multi-effect desalination (MED).

Energy cost is one of the factors which has strong impact on desalination process total cost (Ghobeity and Mitsos, 2014; Shatat et al, 2013). The energy used by the main desalination industries comes predominantly from fossil fuels, which are responsible for increasing the release of carbon dioxide to the atmosphere, contributing to the greenhouse

effect (Siirola, 2012). Due to this energy cost and carbon dioxide emission, a renewable and abundant energy source, like solar energy, would offer some benefits. Solar energy can be used as electric or thermal energy source.

MED and RO are the cheapest desalination processes and their costs in large scale commercial plants are around 1 USD/m³ (Shatat et al, 2013). On the other hand, when comparing desalination costs using renewable energies, Alkaisi et al. (2017) report that MED process with solar thermal energy has the lowest cost by m³ (2.5-3 USD/m³) while RO process with solar electric energy has a cost of 12.5-16.8 USD/m³. RO process requires mainly electrical energy and MED mainly thermal energy. El-Dessouky et al. (1998) also affirm that MED process has more operation flexibility, being able to operate from 0 to 100% of plant capacity, and presents shorter start time and less specific investment cost.

Considerable efforts have been made for the research of MED desalination plants coupled with solar energy. Desalination plant of Plataforma Solar de Almeria (PSA), in Spain, for example is one of those plants. It is a desalination plant composed of 14 effects with a design capacity of 72 m³/day. This plant has been modeled by several authors. Hatzikioseyian et al. (2003) develop a stationary model aiming to evaluate plant performance regarding energy consumption. Roca et al. (2012) develop a dynamic model to optimize distillate production. De La Calle et al. (2014) focus on thermal transient behavior of a MED plant's first cell, which is main responsible for plant energy consumption. In Turkey, Yilmaz and Söylemez (2012) simulate a stationary MED plant in Turkey regions using wind and solar energy. It has 12 effects and capacity of 1m³/day. Simulation results show that, although both energies are intermittent, solar energy is more stable than wind. In Jordan, Bataineh (2016) analyzes a stationary MED desalination plant combined with thermo compressor coupled with solar energy. It has 12 effects, capacity of 43,000 m³/day, 1,080,000 m² of solar collectors and a gas boiler back up to continuos operation. In this scenario, results show that solar energy can suplly almost 70% of energy demanded for this plant. Bataineh (2016) also affirmes that MED desalination plants powered by solar energies are able to produce more than 35 L/m²/day in regions with solar radiation above 4.8 kWh/m²/day.

The Northeast of Brazil is a semi-arid region where 11 million people suffers from fresh water scarcity (Rocha and Soares, 2015), although brackish water on underground wells is available. According to Fichter et al. (2017), the Northeast of Brazil has great potential to use solar energy because it presents solar radiation above 6 kWh/m²/day. Despite the investments and studies on desalination process in Middle East and North Africa, Brazil is still giving it first steps. Up to author's knowledge, there is no technical feasibility study of MED processes coupled with solar energy applied to the irradiation and water demand of the Brazilian semi-arid region. This paper, therefore, analyzes the technical feasibility of a MED desalination plant coupled with solar energy in Bom Jesus da Lapa (BA), a city in Northeast of Brazil. The study is based on a stationary model, validated with data from literature, considering different scenarios of solar radiation during the year.

2. Methodology

The desalination process model is based on Hatzikioseyian et al. (2003), which represents the PSA. Figure 1 represents the process layout which comprises the solar collectors and the MED process. In order to maintain plant's operation during night hours, the

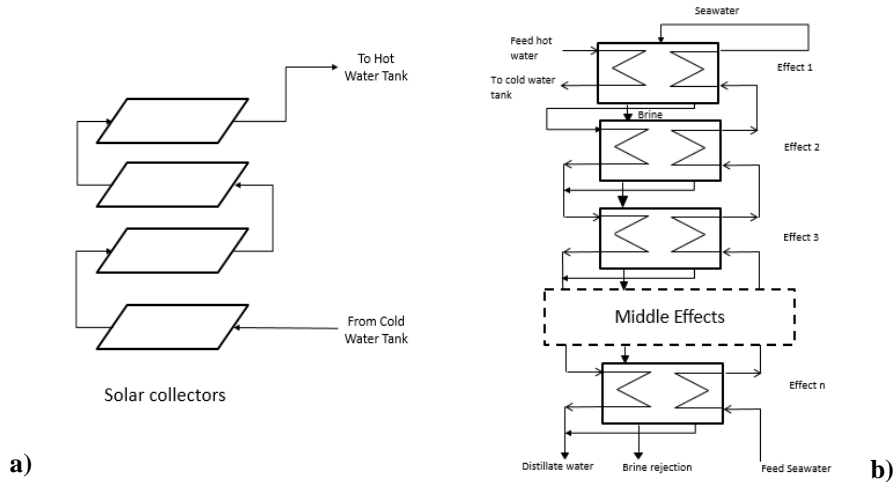
water heated by collectors feeds two tanks which are perfectly insulated and store the thermal energy. The hot water tank supplies the MED plant and the cold water returns to the cold-water tank.


Figure 1 – Schematic of process layout: a) Solar collectors b) MED desalination plant.

Additionally to the mass and energy balance presented by Hatzikioseyian et al. (2003), the following assumptions and equilibrium relations are considered in the present model:

- The temperature difference between saturated vapor and non-evaporated brine in equilibrium at an effect is obtained by the boiling point elevation (BPE), following Aly and El-Fiqi (2003);
- The mass production of saturated vapor at an effect is estimated by the latent heat of vaporization λ according to Roca et al. (2012);
- The enthalpy of brine and liquid water follows Sharqawy et al. (2010) model, which was validated here with experimental data from Chou (1968), presenting deviations up to 4 %;
- The vapor enthalpy follows Khademi et al. (2009), which was validated here with experimental data from Smith et al. (1996), presenting deviation up to 1 %;

Solar collectors' model was developed accordingly to Al-Ajlan et al. (2003), which focus on flat plate collectors to heat water. The water outlet temperature is computed based on the geometry of the collectors and on the following input variables: solar radiation, ambient temperature, water mass flow rate and inlet temperature. The stationary model was implemented in MOSAICmodeling (MOSAIC, 2018) and solved in MATLAB ®.

The base case for simulation has the same number of effects (14) and distillate production capacity (72 m³) as the PSA. The brackish water is fed at 30 °C and 0.3 bar with 7 g/L of salt, considering the average brackish water salinity in Brazilian semi-arid region (Menezes et al, 2011). According to Palenzuela et al. (2011), the hot water flow rate to the first stage (Figure 1b) is 12 L/s, whose inlet and outlet temperatures are 74 °C and 70 °C, respectively. Considering the average water consumption recommended by the World Health Organization guideline, that is 50-100 L per person per day (United Nations, 2018),

and the population from Bom Jesus da Lapa, which is around 60,000 people, the plant nominal capacity could supply approximately 2% of the population's fresh water need. The daily average solar radiation data from Bom Jesus da Lapa (BA) was collected by the RETScreen software (RETScreen, 2018) and is about 5.7 kWh/m²/day, while at Almeria this value is about 4.9 kWh/m²/day. The daily average solar radiation data considers a daily cycle with 24h but in Bom Jesus da Lapa (BA) the sun shines during 12h. Therefore, the average solar radiation considered for simulation is the double of the collected data.

3. Results and discussion

Figure 2a compares the model prediction with simulated data from Hatzikioseyian et al. (2003). Results show good fit of data as deviations up to 1% were obtained. Furthermore, the predicted total condensate water production is 5017.4 L and the predicted total brine production is 2982.6 L presenting deviations of 0.3% and 0.6%, respectively. Figure 2b shows the temperature and brine salinity profile along the desalination effects. The temperature decreases due to decreasing pressure in order to enable an efficient flash evaporation and brine salinity increases due to evaporation and production of fresh water.

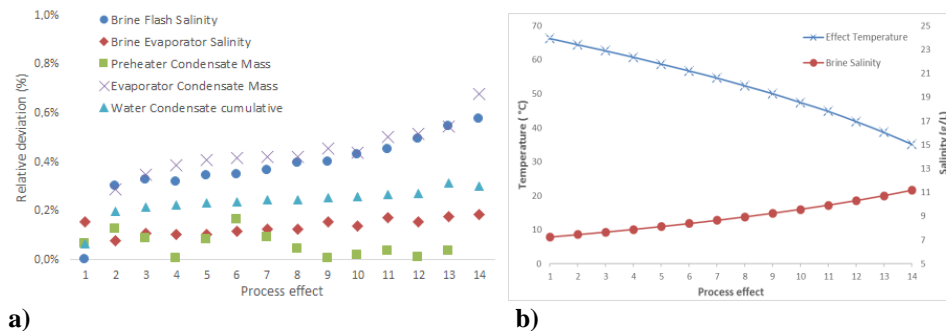
a)   b)


Figure 2: a) Validation of MED model: deviations of the model predictions against the data reported by Hatzikioseyian et al. (2003); b) Profile of temperature and brine salinity along process effects.

The solar collectors' model also presents good fit with Al-Ajlan et al. (2003), with deviations up to 0.7 %. The collectors' area needed to supply thermal energy to the MED base case is about 2929 m², which is 9.6% higher than the PSA. According to Bataineh (2016), though, the Almeria's plant has a gas boiler back-up system which can supply up to 30% of desalination thermal energy needs, what can explain the lower collectors' area in the PSA. Table 1 shows the required area for the solar collectors for MED plants with different capacities. It further shows the percentual of the population which would be benefited by the desalination plant.

The daily solar radiation at Bom Jesus da Lapa (BA) varies every month of the year according to Figure 3. Considering the solar area of the base case 2,929 m², the collectors' hot water temperature and the distillate production for the varying solar radiation are shown in Figure 3. The average distillate production is 24.5 L/m²/day for an average solar radiation of 5.7 kWh/m²/day Although Bataineh (2016) affirms that MED plants coupled with solar energies are able to produce more than 35 L/m²/day in regions with solar radiation above 4.8 kWh/m²/day, another source of energy, besides solar energy, is used. Furthermore, the plant studied by Bataineh (2016) is a large scale plant combined with thermo compressor system which may increase desalination energy efficiency.

Therefore, the distillate production obtained for Bom Jesus da Lapa is acceptable and cannot be directly compared with the value reported by Bataineh (2016).

Table 1 : Sensibility analysis of water production and solar collectors' area.

Water Production capacity(m³/day)	Solar Area(m²)	City's population supplied (%)
72	2,929	2 %
144	6,182	4 %
288	12,365	8 %
576	23,628	16 %
Figure 3 – Model Results and solar radiation data

4. Conclusions

This paper developed a model for a MED plant operated with thermosolar energy, which was successfully validated with data from literature. The model was used to evaluate the technical feasibility of the process in the northeastern Brazil, where the population suffers from water scarcity. The results show that is possible to produce fresh water using solar energy due to the high irradiation rates. Further studies might focus on the economic feasibility analysis to implement this MED desalination plant in Bom Jesus da Lapa (BA).

Abstract

In chemical laboratories there are always a permanent need to apply flexible, target oriented and efficient control solutions and data acquisition. Traditional equipment and methods utilized are however either time consuming or relatively expensive causing chemical laboratories often to be either not equipped with proper data acquisition and control systems or the installed setup is not easily reconfigured etc... Our aim is to show a simple and promising example that provides flexible and efficient control solution in chemical laboratories.

Keywords: distillation column control, fixed-, variable reflux

1. Introduction

Automation and process control is carried in increasing depth since the 50's. With such solution, operation of plants has become more precise, cost efficient and more safe. In smaller scales, such as chemical laboratories where various processes are investigated, reconfigured and developed, processes are regulated either manually or with high relative investment. Our choice for control as a demonstration is a distillation column that is particularly important since it is such a separation process that includes the common control problems and challenges that may occur in operation Luyben (1989). These common problems are found as a cause of high difference of time constants of process variables (PV), delay, process stiffness, interacting loops etc. studied by Morari et al. Grosdidier et al. (1985). Some of the mentioned problems and challenges occur only in MIMO (multiple input multiple output) control while others are also appear also in SISO systems. In our case we investigate a SISO (single input single output) case of column bottom and head temperature control that is in direct function of the product purity. With various control solutions and setup, cost-efficient and flexible operation can be carried out in laboratory sizes as well.

2. Methods and experimental Setup

In our work we define two cases:

- case A: purifying chlorobenzene from impurities

• case B: separating n-heptane and hexane

The column (see figure 1) for case A glass wall distillation column with the height of 30 cm height of Mellapak structured packing from Sulzer Chemtech and for case B it is built of two packed stages filled with random glass raschig ring type packings. In both cases the top of the column includes a gas vapor separator below the condenser. The condensed liquid is driven out of the column to a glass valve that is able vary the reflux ratio based on its on/off time ratio. The glass valve is driven by a 24 V solenoid valve and mosfet structure driven by the controller digital output. Preliminary tests showed, that the minimal time of stay/state should set to be at least 2 seconds. For normal operation we set the periodic time to be 10 seconds.

The reboiler of the distillation column is a 750 ml triple neck type round-bottom flask filled to with 500 ml of the initial liquid mixture.The heat is applied at the bottom by a heating basket by Bovimex MBO that is powered by 50 Hz 230 V AC and actuated with a solid state relay (SSR) that is regulated by the digital output of the Arduino board with the periodic time of 2 seconds. As the solid state relay is only capable of cutting power at 0 V crossings of the power source, 2 seconds is chosen as time period so the minimal resolution of the power adjustment is 1%.

In case of distillation, the temperature measurement should be particularly precise as in such case it is the process variable (PV) that gives the basis of the quality of control. In the investigated scenario, the temperature range is set to 0-200 $°C$ with a precision range of +/- 0.1 $°C$. In order to satisfy these, RTD PT100 temperature sensors are applied with two approaches. The measured signal is either applied to a MAX31865 temperature sensor amplifier DAC from Adafruit or is sent to a signal transmitter to form 4-20 mA analog signals. In case of the utilization of MAX31865, in order to receive the most accurate signals the measured resistance is

Figure 1: Distillation column and control scheme

continually compared to a lookup table including resistance and temperature value pairs of DIN 43760/IEC 751 standard. The thermometer verification is carried out by the boiling of penthane at atmospheric pressure (36.1 $°C$) and as the steady state is achieved, the thermometer oscillates within +/- 0.1 $°C$ range. In case of the analog signal processing two point temperature verification is carried out, by adjusting the range minimum and span of the transmitter.

The microcontrollers utilized are Arduino UNO and Due that are particularly popular for process control studies Rubio-Gomez et al. (2019). In case of analog signal input the transmitted signal is converted to 0-3 V to match the controller input range. These analog input reads are then refined with running average that takes 200 samples and gives two digital signals/second. Such frequency of data acquisition in such system is sufficient and will not cause stability problems. In case of digital input, SPI communication is utilized. Output signals are connected to the digital output pins with PWN. The Arduino is programmable by integrated development environment (IDE) with a PC by defining the variables of the different input and output pin-s, setpoints and generating the control algorithm etc. In other cases it is also possible to retransmit the Arduino's I/O and perform the data acquisition and control at a higher level.

As for controller tuning, different methods are available. In order to test the built system and closed loop a number of tuning methods and setups are investigated, these are:

- PID applying step response (open Z-N tuning) tuning
- PID applying Matlab PID tuner
- Cohen Coon method

2.1. Open Loop Ziegler-Nichols Method

The Ziegler-Nichols Method is one of the best known tuning methods, that is based an open loop step-response function of time (Ziegler (1942)). The produced response function is approached by a first order transfer function with dead time. Applying the extracted parameters (K, τ and D_s) heuristic tables are utilized for tuning.

2.2. Cohen Coon method

The Cohen Coon tuning method also approximates the process with a first order element with dead time, but it is calculated differently (Cohen and Coon (1953)). Some literature favor the Cohen Coon method as it is more flexible with dead time compared to the Z-N method. To determine the tuning parameters just like with Z-N method, tuning tables are used.

2.3. Matlab PID tuner

Matlab PID tuner is an application of Matlab software that allows the instant tuning of a processes. The tuner application includes process identification in which the One pole + delay model is used. The application automatically calculates the linear model of the process and it provides interactive tuning where performance and robustness can be balanced. In our case the control loop is tuned for both performance and robustness to have only a moderate overshoot and after damping to settle on the new setpoint.

2.4. Model based control

A model based composition control is carried out with the model mixture of n-heptane and hexane. The internal model is divided to a reflux plan and the reflux control part. In order to achieve the planed product purity the number of theoretical plate (NTP) for the column is measured. In order to keep the composition of the distillate constant, the slope of the distillation working line must change in time and thus the reflux ratio changes as

well. The reflux control part executes the process including startup, setting the correct reflux ratio to the corresponding reboiled temperature and the shut down procedure.

3. Results

In figure 2 the temperature response of the step change of 50% can be observed that is applyied to demonstrate a startup. The initial temperature is room temperature and the final value settled at ~120 $°C$. The tendency of the function shows dead time of ~5 minutes, while the rising time has an inflection at 26 minutes and the final value is reached at ~32 minutes.
Figure 2: Response of the open loop distillation column

Based on the step response, the different tuning method show different control qualities for the column bottom temperature control (see figure 3).

Table 1: Evaluation of different tuning methods

rating parameter	Open Z-N Method	Cohen-Coon method	MATLAB PID Tuner
rise time [min]	82	23	17,5
maximal overshoot [$°C$]	2.65	18.2	10,6
settling time [min]	183	61.5	90
steady state error [$°C$]	$(-0.1) - (+0.4)$	$(+0.2) - (+0.6)$	± 0.5
ISE	5041300	2956470	2187620
Figure 3: Column bottom temperature control with different tuning methods

The bang-bang control of the top product is shown on figure 4 for purifying chloroben-zene from impurities. In The figure the top temperature of the column to and the reboiler is shown in the function of time. A results show a typical startup and operation proce-dure, where the dead time of the column top temperature is roughly over 15 min. As the column reaches the steady state within the target temperature range the reflux valve starts it operation with a reflux ratio of 3. It can be observed, that as product is taken away from the system, the bottom temperature starts rising as the composition changes in the reboiler.
Figure 4: onoff control

The case of varying reflux composition control is shown in figure 5. The figure shows the case of separating n-hapten from hexane. The top and the bottom temperature and the reflux ratio in the function of time. After the steady state is established the reflux ratio is adjusted according to the calculated reflux plan to maintain the desired product purity. At the reflux ratio of 14 the product rate becomes so small, that the system shuts the reflux valve and the heating off, shutting the process down.
Figure 5: Variable reflux ratio control

4. Conclusions

There is permanent demand for target oriented and flexibly operated apparatus in chemical laboratories for efficient research activities. This challenge can be overcome by the utilization of microcontrollers. In many cases the additional knowledge for implementing such devices make such solution time consuming and effort intensive, while professional out of the box devices prices are high. Increasing popularity of microcontrollers these barriers are constantly stretched and by now user-friendly solutions are available. Applying such solution data acquisition and process control at laboratory scale is made practical and easy and cost efficient. As for demonstration in a chemical laboratory, batch distillation process is investigated with various cases of SISO control. In these cases The column bottom and head temperature is controlled either by the reboiler duty or the reflux ratio. Including on-line in-situ data acquisition, process analysis and controller tuning is carried out. The control structure is also investigated applying on-off, PID, and model based control strategies.

Abstract

Adopting reliable process models is one of the main requisites for wide spread use of process models in industry for design, control, operation and troubleshooting purposes. Validating a model against operational conditions is a plausible way to guarantee assurance and reproducibility of model outputs. Economic and sustainability analysis together with process intensification (PI) can provide feasible solutions for industrial hot-spot identification and removal. In this work, an industrial scale urea plant was modelled and simulated in a commercial process simulator. More than thirty different industrial process parameters were statistically analysed and used to perform the model validation. Economic and sustainability analyses were performed and the main hot-spots were identified. Process intensification at phenomena-level was employed to obtain more sustainable intensified process flowsheets. The results show that economic and environmental factors can be improved to reliable extent since the process model is closely replicating the reality in the base case and it fits well with industrial data.

Keywords: industrial data validation, process intensification, sustainable solutions.

1. Introduction

Modelling and simulation plays an important role in the development of chemical engineering systems. For laboratory, pilot or even industrial scale, computer aided solutions are one of the most cost effective tools available and, sometimes, the only option for engineering judgments. In order to guarantee the accuracy of these judgments it is necessary that the computational models correspond very well to the industrial data. Then, they can also be a good tool for real improvements trough analysis like economic, sustainability, Life Cycle Assessment (LCA) and even reaching Process Intensification in order to achieve a more sustainable process.

This paper is on demonstrating the importance of validating simulations against real industrial data to make development of more advanced modelling approaches and even intensified solutions for existing chemical process possible.

2. Process description and modelling

The base case studied in this paper is the production of urea through CO_2 stripping. This process is divided into five blocks: Synthesis, Evaporation, Desabsorption and Hydrolysis, Recirculation and Prilling, as it can be seen in Fig.1.

Figure 1: Simplified block diagram for the urea production process.

The principal section of this process is the Synthesis where reactions between NH_3 and CO_2 to produce ammonium carbamate and urea take place. The product of this section goes to Evaporation section to concentrate the urea and then it is sent to the Prilling. The remaining unconverted reactants are processed and recovered in the Hydrolysis and Desorption sections and, before they are sent again to Synthesis section, pressure and temperature need to be adjusted in the Recirculation step. The main equipment in each section are: Synthesis – pool condenser, reactor, stripper and scruuber; Evaporation – Pre-evaporator, 1st and 2st evaporator; Desabsorption and Hydrolysis – adsorber, dessorber I and II; Recirculation – rectifying column and condenser; Prilling – prilling tower. The reactions occurring at this process and considered in this paper are the well know ammonia and carbon dioxide producing ammonium and this one dehydrating in urea and, finally, the biuret formation, which presents a lack in literature of the area and it occurs from the condensation of two urea molecules resulting in biuret and ammonia. This process was modelled assuming steady state conditions, SR-POLAR for thermodynamic representation, production of biuret in the Pool Condenser, Reactor, Stripper and in all the Evaporators. Kinetics models were taken from Chinda et al. (2017).

3. Process validation

The experimental data used for validating the simulation was provided by an industrial urea plant in Brazil. A statistical analysis based on dispersion was performed with the plant capacity in order to exclude data that may have been taken in transient process conditions. For this, it was considered that coefficient of variation to be less than 1.5% would reflect stability in operation of the industrial plant. Statistical concepts such as arithmetic mean and standard deviation sample to calculate the variation coefficient were employed. Using this criteria it was found that the set of points at steady state available for validating the simulation was in range capacity from 86.45% to 98.21%. Validation of the simulation was performed by calculating the difference between industrial and simulated data and dividing it per industrial data.

A total of 37 different process parameters were evaluated following this criteria, among them stream temperature, steam generation, mass fraction composition for CO_2, NH_3, urea, H_2O and biuret, CO_2 conversion in the reactor and stripper efficiency. For all evaluated mass fractions, the deviation between the value predicted by the simulation

and the real value obtained from industrial data were less than 5%, while for steam generation and streams temperature the deviation was less than 8%. Fig. 2(a) shows the comparison between mass fraction for each component in the outlet of the reactor and the stripper. While in Fig 2(b) it is possible to see no deviation tendency for the 10 points evaluated in the steam generated in the Pool Condenser and in the outlet temperature of the Stripper liquid phase corresponding to the production capacity of the urea plant.
Figure 2 (a): Comparison between mass fraction composition in the outlet of the reactor and the liquid outlet of stripper. **(b)** Deviation analysis of the simulation data for the steam generation in the Pool Condenser and outlet temperature of the Stripper.

4. Process performance analysis & Hot-spots identification

Economic analysis was performed using ICAS-ECON. Sustainability analysis was carried out using the framework by Carvalho et al. (2008), Mansouri et al. (2013), and Tallis (2002); and for LCA analysis UK Government GHG conversion factors and IPCC emission factors were used.

4.1 Economic, life cycle assessment and sustainability analysis

The economic and life cycle assessment as a part of the performed analysis provide evidence that the main drivers for operating costs in urea production process are, heating (56.06 %), cooling (9.43 %) and electricity (34.51%). The analysis also showed that the rectifying column, the pre-evaporator, the 1st evaporator and the CO_2 compressor have the large utility cost, around 89.52% collectively. Furthermore, CO_2 compressor also has the largest carbon footprint because of its high-energy consumption, around 40.95 Wh.

The sustainability analysis performed in this study is a set of calculated closed- and open- paths. The method calculates and ranks as a set of mass and energy indicators, from the data obtained from steady-state simulation validated with industrial data. The main sustainability indicators are given in Table 1; and their corresponding paths are given in Fig. 2.

Table 1: Base case more expressive economic and sustainability indicators.

Path	Compound	MVA (10^3 $ /year)	TA (10^3 $ /year)	EWC (10^3 $ /year)	AF (10^3 $ /year)	MJ energy/kg product	kg product/kg raw material	Total kg CO_2 Equivalent
OP150	H_2O	-11	-177.204	166.427	-			
CP284	H_2O	-	-	47.220	0.030	2.18	0.75	0.20
CP1	NH_3	-	-	36.148	0.295			

Note: MVA – mass value added, TVA – total value added, EWC – energy to waste cost, CO2 equivalent, carbon footprint, OP – open path, CP – closed path.

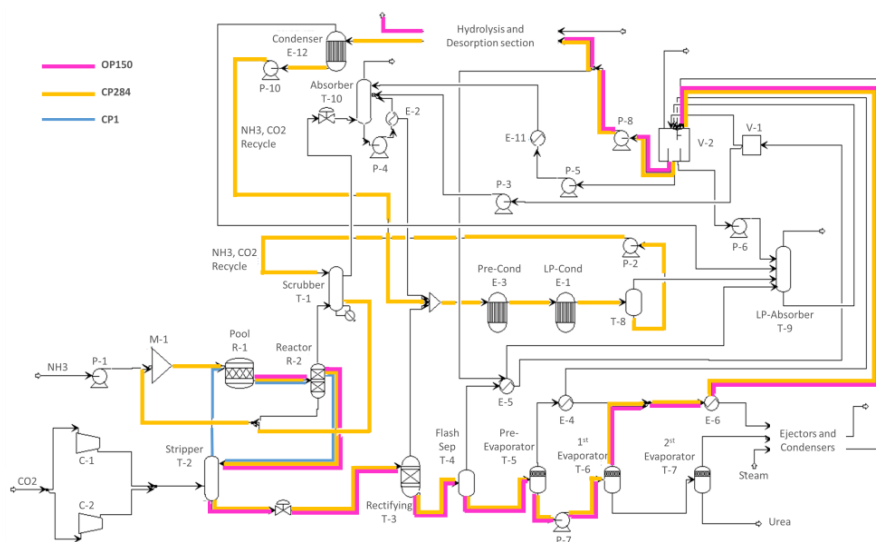
It can be seen in the Table 1, that water in the OP150 water is losing its value as it exits the process through this path. On the other hand, on the CP284 it is possible to see a high flow of water being recycled resulting in high loads of energy and waste/use of utilities for raw material recovery. The same also applies to ammonia in CP1 and water in the CP284. Fig. 3 shows a task-based flowsheet with the main closed- and open-paths.


Figure 3: Base-case design for Synthesis, Evaporation and Recirculation sections for the production of urea, including process bottlenecks, closed- and open- paths.

4.2   Process hot-spots identification

The hot-spots identified based on the results of the economic, LCA and sustainability analysis are present in Table 2 and indicates the necessity of reducing the utility consumption. Utility is highly demanded in Evaporation and Recirculation sections. Thus, the Process Intensification was focused just in these sections.

Table 2: Urea Process hot-spots.

Hot-Spots	Design targets	Improvement solution
Limiting equilibrium	Un-reacted raw materials	-Reduction in number of unit operations
High energy consumption and/or demand	products recovery	- Improvement in sustainability and LCA factors

5. Process Intensification

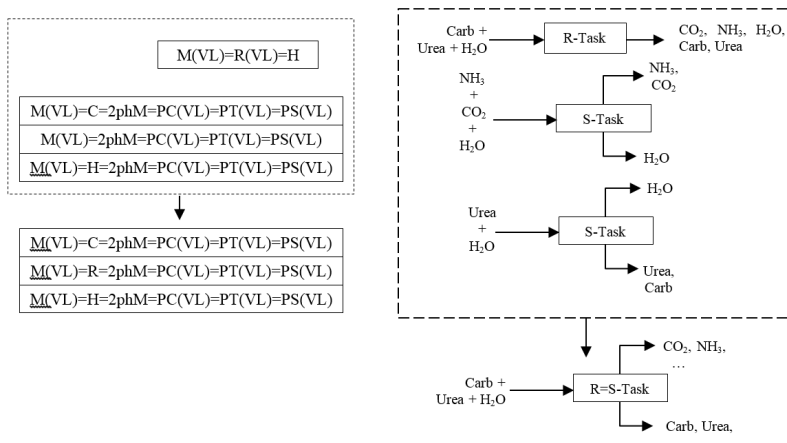
Process Intensification was performed using a multi-stage framework according to (Babi et al, 2015) and (Garg et al, 2018). The base case was translated in a task-based flowsheet in order to identify Phenomena Building Blocks (PBB's), and generate Simultaneous Phenomena Building Blocks (SPB's). The total number of SPB's calculated were 16278, for 11 PBB's. Since, not all of them are feasible, following connectivity rules, it was found possible only 70 SPB's. The identified feasible SPB's are combined to form basic structures and then they were translated into unit-operations, as reactive distillation as it can be seen in Fig. 4.


Figure 4: Basic structures combined into intensified unit operations: reactive distillation.

Finally, two intensified flowsheet alternatives are generated, as shown in Fig. 5 for Evaporation and Recirculation sections. Alternative 1 is the combined basic structure translated into Pervaporation membrane, while in Alternative 2 it is translated to Vapour permeation membrane.

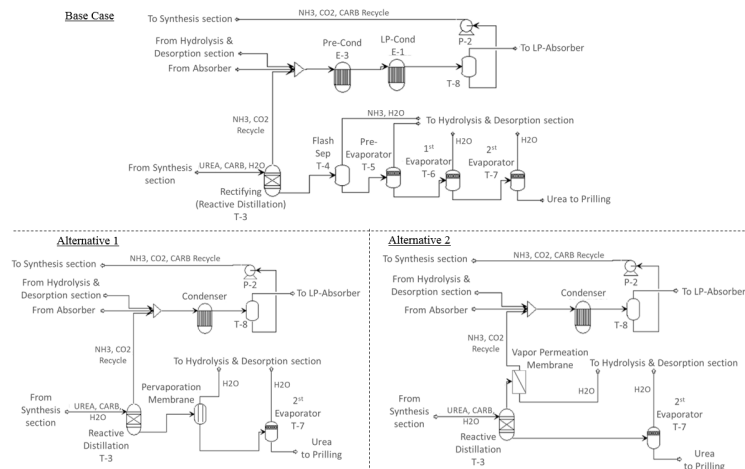
The two process alternatives offer superior performance in terms of all indicators to the base case process, given that the best process alternative is the pervaporation membrane option (alternative 1). The energy consumption per one unit of urea is significantly reduced (53.48%) as well as utility cost (42.27%). The hot utilities (steam/hot water) and cold utilities (cooling water) usage were reduced to 68.63% and 29.15%, respectively. In addition, the carbon footprint, HTPI and GWP were reduced to 41.63%, 1.51% and 1.39%, respectively.


Figure 5: Base case and intensified flowsheet analysis.

5. Conclusions

Modelling and simulation of a urea plant was performed and validated with industrial data. Hot-spots were identified through economic and sustainability analyses. For Evaporation and Recirculation sections two feasible intensified alternatives were proposed using membranes. The pervaporation membrane unit for the separation of H_2O/Urea shows itself as the most sustainable one. The validation step with industrial data was an essential factor to perform a reliable and realistic study in order to suggest improvements to the process.

Abstract

We present a systematic framework for the design and operability/safety optimization of process intensified systems, with specific focus on reactive distillation processes. This framework is based on a phenomenological process intensification/synthesis approach (i.e., Generalized Modular Representation Framework) which first identifies promising intensified tasks and then translates them to equipment-based flowsheet alternatives. Flexibility analysis is integrated with the synthesis model to ensure that resulting design configurations are operable under varying operating conditions. To systematically account for inherent safety performance, risk assessment criteria are included as process constraints involving failure frequency and consequence severity criteria. A case study on the production of methyl tertiary butyl ether is presented to highlight the potential of the proposed approach in deriving inherently operable and safe intensified reactive separation systems.

Keywords: Process intensification, Reactive distillation, Generalized Modular Representation Framework, Operability analysis, Risk assessment

1. Introduction

In recent years, process intensification (PI) has attracted burgeoning interest in the chemical engineering research community and the chemical/energy industry due to its potential for drastic improvements in process productivity, efficiency, and profitability (Tian et al., 2018). The integration of multiple processing tasks into a single unit (e.g., combined reaction/separation processes) is one of the major PI pathways towards the development of breakthrough technologies. Reactive distillation (RD), a classic intensified invention, is showing significant energy and cost savings over conventional reactor-distillation counterparts (between 15 and 80 %) (Harmsen, 2007). Recent works for the synthesis of reactive separation systems have been leveraging phenomenological representation methods to systematically generate intensified process options from a lower-aggregated level without the pre-postulation of plausible unit-operation-based flowsheets which may hinder the discovery of novel solutions (Tula et al., 2017; da Cruz and Manousiouthakis, 2017; Demirel et al., 2017). However, these efforts mainly focus on steady-state design

at nominal operating conditions. The operational performances in these units under uncertainty and disturbances are mostly neglected, whereas their highly integrated schemes often decrease the degrees of freedom of the online decision maker, adversely affecting the process safety and limiting the operability of the systems (Baldea, 2015). Therefore, a holistic synthesis approach is required for the delivery of reactive distillation systems with guaranteed operability and safety performances at the early design stage.

In this work, we introduce a systematic framework for intensified process synthesis, which is based on the phenomenological Generalized Modular Representation Framework (GMF) with embedded process operability and safety assessment criteria. The rest of the paper is organized as follows. In Section 2, the proposed framework is presented in detail. Section 3 showcases this approach on a distillation-based reactive separation process for methyl tertiary butyl ether (MTBE) production. Finally, conclusions and directions for future work are discussed in Section 4.

2. Synthesis framework for Process Intensification

To address the synthesis of operable PI systems, we propose an integrated framework as depicted in Figure 1, with its stepwise procedure described in what follows:

Step 1: Process Intensification/Synthesis Representation via Generalized Modular Representation Framework – GMF, originally introduced by Papalexandri and Pistikopoulos (1996), represents chemical processes with two sets of phenomenological building blocks, namely the pure heat exchange module and the multifunctional mass/heat exchange module. Utilizing Gibbs free energy-based driving force constraints to characterize mass/heat transfer feasibility, GMF characterizes various (intensified) tasks (e.g., separation, reaction, combined separation/reaction) by optimizing physical and chemical driving forces to exploit the "ultimate" thermodynamic design space. The synergistic integration of multiple phenomena are automatically explored via superstructure optimization (Ismail et al., 2001) without a pre-postulation of plausible (and possibly myriad) tasks.

Figure 1: Proposed framework for the synthesis of operable process intensification systems (adapted from Tian et al. (2018)).

Step 2: Process Operability/Safety Analysis – Flexibility test is applied to identify the critical operating conditions when the resulting design configuration is operated under an expected range of the uncertainty. As for the consideration of inherent safety, risk assessment criteria (Nemet et al., 2017), which account for equipment failure frequency and consequence severity at the release of entire intrinsic hazards existing in the process, are included as constraints in the synthesis model to enable systematic generation of inherently safer design options instead of iterative evaluation in a posterior manner.

Step 3: Process Synthesis/Optimization – In this step, an integrated GMF-operability-safety synthesis strategy is developed in the formulation of a mixed integer nonlinear

programming (MINLP) problem, as shown in Table 1. The Generalized Benders Decomposition (GBD) method (Geoffrion, 1972) is utilized for the solution of this optimization problem and is implemented in the General Algebraic Modeling System (GAMS) (Rosenthal, 2016). The primal NLP subproblem is solved with solver CONOPT and the master MIP problem with CPLEX. The optimization results will deliver optimal GMF-based design configurations with desired operability and safety performances.

Step 4: Operable Intensified Designs Verified via Steady-State & Dynamic Simulation – The resulting GMF configurations are translated to corresponding equipment-based flowsheet alternatives and validated with steady-state simulation. To integrate steady-state and dynamic operation, "high-fidelity" dynamic models are developed to fully capture and analyze the system dynamics. This allows for further design and control optimization studies (Pistikopoulos et al., 2015; Diangelakis et al., 2017). Closed-loop validation is finally performed, with necessary iterations between different steps to ensure the delivery of consistent and verifiable operable intensification systems throughout the framework.

Table 1: Mathematical model for GMF-flexibility-safety synthesis – an indicative list.

GMF Synthesis Model	
Mass balance	$f^{LI}x_i^{LI} + f^{VI}x_i^{VI} - f^{LO}x_i^{LO} - f^{VO}x_i^{VO} + \sum \nu_i \times r \times M_{cat} = 0$
Energy balance	$f^{LI}h_i^{LI} + f^{VI}h_i^{VI} - f^{LO}h_i^{LO} - f^{VO}h_i^{VO} + \sum \triangle H_{reac} \times r \times M_{cat} = 0$
Driving force constraints	$G2_i = \ln\left[\frac{\gamma_i^L x_i^L P_i^{\mathrm{sat},L}}{\phi_i^V x_i^V P_{tot}}\right] + \sum_i \sum_k \left[\frac{\nu_{ik}\Delta G_i^f}{RT} + \nu_{ik}\ln(\phi_i^V x_i^V P_{tot})\right]\frac{\partial \varepsilon_k}{\partial n_i^L}$

3. Case study: MTBE production

In this section, the proposed framework is tested on a reactive separation system for the production of methyl tertiary butyl ether (MTBE) (Ismail et al., 2001). The case study aims to demonstrate the integration of operability/safety criteria at the early synthesis level as well as the potential of systematically deriving multiple intensified design options with different operational and cost performances for decision-making.

3.1. Problem statement

MTBE can be produced via the catalytic reaction of methanol (MeOH) and isobutylene (IB4) in the liquid phase using an ion-exchange resin as catalyst (e.g., Amberlyst 15 (Rehfinger and Hoffmann, 1990)). The production task is to obtain liquid MTBE at a rate of at least 197 mol/s with a purity higher than 98 mol%. Raw material availability (i.e., methanol and butene feed streams with given composition, flowrate, and temperature) is taken from Hauan et al. (1995). Additionally, an uncertainty range of ± 10 mol/s is considered for the methanol feed flowrate. Given the hazardous properties of the substances in this process, manifold process risks (i.e., toxicity, flammability, explosiveness) need to be considered for a holistic evaluation of inherent safety performance. The synthesis objective is to identify a flowsheet alternative to meet the MTBE production specifications with minimum total annualized cost (TAC) and desired operability/safety performance.

3.2. Synthesis with operability and safety considerations

In this case study, a maximum of 10 GMF mass/heat exchange modules and 20 pure heat exchange modules are allowed for the representation/synthesis of this process. The separation and/or reaction task taking place in each mass/heat exchange module is not postulated *a priori*, but to be determined through the superstructure optimization driven by the minimization of total annualized cost.

A nominal GMF configuration without flexibility or safety considerations is first synthesized as a reference design. The resulting MINLP model has 14,594 constraints, 8,098 continuous variables, as well as 734 binary variables. The optimal solution, shown in Fig. 2, features reactive distillation column at a total annualized cost of 1.7×10^6/y. In this nominal design configuration, two pure heat exchange modules are selected as reboiler/condenser, while two reactive separation modules are used as reaction zone to produce MTBE, two separation modules as stripping section to separate unreacted methanol/isobutylene back to reaction zone, and another one as rectification section to transfer n-butene to distillate.
Figure 2: Nominal design.

Flexibility analysis is then applied to test if the nominal GMF configuration can be operated under the uncertainty of methanol feed flowrate, which identifies a critical point at the higher flowrate extreme value. On the other hand, inherent safety performance is improved by reducing the overall process risk by at least 20 % than that seen in the nominal design. The resulting design alternative, as shown in Fig. 3(a), utilizes four mass/heat exchange modules. Thus in this case, the enhancement of process safety is achieved by minimizing the unit size.

However, a comparatively more "risky" component is observed in Fig. 3(a) - i.e. the second reactive separation module (numbered from top to bottom) takes up more than 1/3 of overall process risk. To avoid the safety concerns resulting from a single module, the individual module risk is constrained to be less than 30 % of the overall process risk. The new optimal design configuration is illustrated in Fig. 3(b). The afore-mentioned module

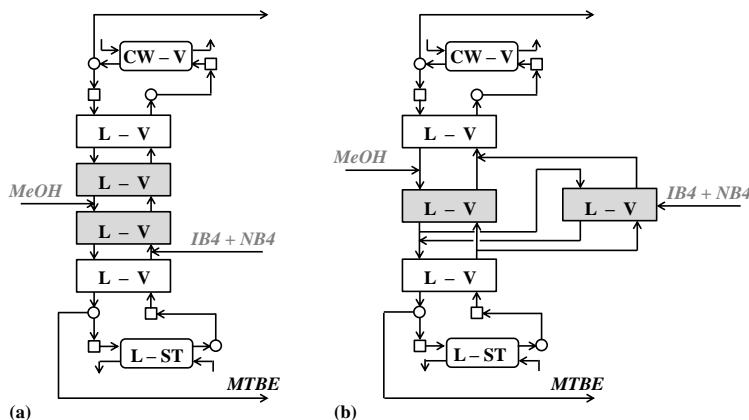
is bypassed to alleviate its mass/heat transfer burden, thus introducing more degrees of freedom to enhance the system's flexibility and operability performances. The detailed design and operating parameters can be found in Table 2.


Figure 3: Flexible & inherently safer design configurations.
(a) Operable design I, (b) Operable design II

3.3. Steady-state & dynamic simulation and validation

Having generated the optimal and operable GMF configurations for the MTBE production (Fig. 3), in this step we identify and validate the corresponding equipment-based flowsheet using steady-state simulation. Each GMF separation module is translated to two distillation trays in Aspen Plus® RADFRAC column (Aspen, 1981-2018), while each GMF reactive separation module to three reactive distillation trays. Therefore, the first operable design is verified as a 13-tray RD column, while the other one as a 10-tray RD column integrated with an additional 3-tray side-column. Table 2 provides a summary of quantitative validation between GMF and Aspen simulation on design/operating variables. "High-fidelity" dynamic models (Schenk et al., 1999) are also developed for the reactive distillation systems (Fig. 3) in gPROMS ModelBuilder® (PSE, 1997-2018), consisting of a system of differential and algebraic equations (DAE) for the description of component molar and energy balances for each tray, the partial reboiler and the total condenser, reaction kinetics, phase equilibrium, etc. The developed dynamic systems will be utilized for the derivation of receding horizon control policies (Pistikopoulos et al., 2015) to guarantee the optimal operation of the proposed designs.

Table 2: GMF quantitative validation with Aspen simulation.

	Nominal Design		Operable Design I		Operable Design II	
	GMF	Aspen	GMF	Aspen	GMF	Aspen
Column pressure (atm)	5.46	6.00	7.85	7.95	9.48	8.20
Reflux ratio	1.70	2.10	1.70	2.50	1.70	3.30
Reboiler duty (kW)	7.5×10^3	6.6×10^3	8.4×10^3	9.6×10^3	8.9×10^3	2×10^4
Condenser duty (kW)	2.3×10^4	2.2×10^4	2.3×10^4	2.4×10^4	2.3×10^4	3.4×10^4
Module/Tray Number	7	15	6	13	6	13
Bottom product flowrate (mol/s)	197.0	197.0	197.0	197.0	197.0	197.0
Product purity (MTBE mol/mol)	0.98	0.98	0.98	0.98	0.98	0.98
TAC ($\times 10^4$\$/y)	171.1		182.4		190.2	

4. Conclusion

In this paper, we have presented a systematic framework to efficiently address the combinatorial PI design space and to integrate steady-state synthesis, dynamic analysis, and operability assessment to deliver validated operable intensification designs. It is shown, through an MTBE reactive separation example, that operability considerations may result in significant structural and operating changes of the process optimal solutions. Ongoing work addresses simultaneous design and control studies on the resulting MTBE reactive distillation configurations to close the loop under dynamic operating conditions.

Abstract

Industrial emissions of CO_2 have observed a rapid increase since the industrial revolution and is accepted as a major contributor towards global warming. Despite the low market demand for the captured CO_2, carbon capture and storage has not seen commercial deployment due to questions regarding economic feasibility. As such, carbon capture and utilisation (CCU) is considered as an alternative and commercially viable CO_2 reduction approach, which can contribute effectively to the economy and environment. In CCU systems, captured CO_2 is utilised as a feedstock in other processes which require CO_2. This includes the synthesis of chemicals and materials such as Fischer-Tropsch Gas-to-liquid (GTL) production. The purpose of this paper is to evaluate the production of LPG, gasoline, diesel and wax using a Fischer-Tropsch (FT) GTL process model utilising mainly synthetic and captured CO_2 as a raw material. The aim is to assess the effects of reforming methods, recycle ratio of syngas mixture on the process efficiency. The reforming unit of this study includes both; auto-thermal reforming (ATR) and steam-methane reforming (SMR), to form synthesis gas (syngas). Moreover, the application of the Anderson–Schulz–Flory (ASF) equation on the product distribution of FT synthesis is studied to investigate the growth probability of hydrocarbons (α) affected by CO_2 utilisation. This GTL process is modelled using Aspen HYSYS software, and mainly includes a feeding unit, a reforming unit, an FT synthesis unit, upgrading and separation units and recycling units. The unreacted syngas mixture is recycled to the FT synthesis unit to enhance process efficiency and reduce the required amount of fresh feed. This work indicates that the optimal application of ASF with CO_2 captured can increase the production rates of paraffin's and olefins depending on the variation of α and H_2/CO. Initial results demonstrated promising results for an SMR case with around 27% and 4% increase in CO and H_2 production; respectively, when introducing CO_2 with around 38% mass flowrate of natural gas. The ATR case demonstrated less potential with only 9% increase in CO production when introducing the same flow rate of CO_2. The findings of this study include the effect of this increase on the production of fuel liquids such as gasoline and diesel and the optimization of ASF and H_2/CO ratio when introducing the captured CO_2. These results can have a positive impact on enhancing the overall process efficiency and reduce significantly the environmental impact.

Keywords: CO_2 Utilisation, ASF, Auto-Thermal Reforming, Steam-Methane Reforming, Gas-to-Liquid.

1. Introduction

Conversion of gas to liquids in what is known as (GTL) through the Fischer-Tropsch process has increased in production globally comparing to 2010 by 150% in 2015 and is expected to reach 500% by 2025 after commissioning of large scale plants in South Africa and Uzbekistan (EIA, 2017). The main purpose of the GTL process is to convert natural gas (NG) into synthesis products mainly hydrogen and carbon monoxide and subsequently to refined products such as LPG, gasoline, diesel and wax. GTL products contribute effectively to the environmental performance due to the low sulphur and aromatic fuels derived from the process as synthetic fuels. In addition, the process has low emissions of carbon monoxide, nitrogen oxides, hydrocarbons, and other components. Hence, synthetic fuels (GTL products) are considered green fuels, which have an added benefit of reducing the dependence on conventional fuels (Shell, 2018). Although the process is considered as environment-friendly, the GTL process with the Fischer Tropsch Synthesis (FTS) reaction has a very high cost breakeven value when compared to the conventional refinery product (Wood *et al.*, 2012). The GTL process consists of five main sections: pre-reforming, reforming, FT synthesis, upgrading and product fractionation. Upon conversion of the NG into syngas through different reforming technologies, the syngas is converted to liquid hydrocarbons in the FT reactor. These liquid hydrocarbons are then processed in the upgrading unit using hydrogen and separated as refined products in a fractionation column. There are different types of reformers used for syngas production. The main reformers include; Steam Methane Reforming (SMR) and Partial Oxidation Reformer (POX). However, some other reforming units can used, such as dry methane reforming (DMR) and Auto Thermal Reforming (ATR) (Baltrusaitis and Luyben, 2015). The cost and the efficiency of producing a stable molecule pair of CO and H_2 (syngas) form a challenge to these techniques. As part of the GTL process, CO_2 can be utilised as a raw material or as part of recycling process to shift the chemical equilibrium in the aforementioned reformers and upgrade syngas quality. As such, the process design parameters, which need to be considered include: reactor/process design, effect of operating conditions, and the amount of CO_2 where each element is affecting the overall efficiency of the hydrocarbon products distribution including H_2/CO ratio of syngas and catalyst selectivity. The economic feasibility for CO_2 utilisation in the GTL process was studied by Zhang et al. (2014) based on two models. The first model to feed fresh CO_2 to the reforming unit and the FT synthesis unit to produce the required hydrocarbons. The second model considered fresh CO_2 as a direct feed to the FT synthesis unit only. The study targeted the process CAPEX and OPEX, and it was concluded that the two processes are environmentally friendly and economically feasible at large-scales. Rafiee et al. (2017) explored feeding captured CO_2 into the GTL plants' SMR or ATR processes. The economic feasibility demonstrates a benefit for both the emitters and consumers considering low project costs. Applied a multi-objective optimization which considered minimising of CO_2 emissions, while maximising carbon efficiency and mass flow of wax was demonstrated (Panahi et al., 2018) . The results indicated a high wax production rate and carbon efficiency, albeit with higher CO_2 emission than the base case.

The objective of this work is to evaluate the production of LPG, gasoline, diesel and wax using a GTL process model utilizing mainly FT synthetic and captured CO_2 as raw materials. The aim is to assess the effects of reforming methods and recycle ratio of syngas mixture on the process efficiency. The reforming units considered in this study include both; ATR and SMR, to form syngas. Moreover, the application of the Anderson–

Schulz–Flory (ASF) equation on the product distribution has been studied to investigate the growth probability of hydrocarbons (α) affected by CO_2 utilisation.

2. Process model of GTL

In addition to the sinks considered by the authors in the previous study (Al-Yaeeshi, et al., 2018), the system considered is comprised a single CO_2 source and multiple GTL plants located in close proximity. The optimization model is developed for each GTL plant based on different reformer technologies, where the objective function is to maximise the total CO_2 utilised taking into consideration the highest production of LPG, gasoline, diesel and wax. This can ensure lower harmful emissions to the environment and increased economic benefits. Hence, it is important to assess the efficiency of integrating the CO_2 into SMR and ATR and compute the enhancements in the output production. The data are related to a specific CO_2 source; namely from Qatar Gas (QG), and multiple GTL sinks for CO_2 utilisation; namely Oryx GTL, and Pearl GTL in the Ras Laffan industrial zone.

2.1. GTL Process Technology

The feed consisting of NG and steam with O_2 in the case of ATR enters a Gibbs Reactor, where NG is reformed to mainly CO and H_2. The syngas produced is first purified from water and then sent to the FT section to produce the higher carbon molecules. The effluent from the FT reactor is purified in a 3-phase separator to remove water and recycle back the unreacted CO and H_2 for what's known as Tail gas. The high hydrocarbon content stream is send to the upgrading section, where the higher molecules are cracked with H_2 into smaller ones. The cracked effluent is finally sent to the fractionation unit where the unreacted H_2 is first recycled to the hydrocracking unit and the product is distilled into LPG, gasoline, diesel, and wax. Part of the wax is recycled back to the upgrading unit to increase the efficiency of the section (Figure 1).
Figure 1: Process flow diagram of GTL plant

2.2. CO₂ Source Data

Emissions of CO_2 from Qatar Gas is approximately 35.8 Mt/year (Sayeed, 2016). The capturing of CO_2 is processed by chemical absorption using amine solvents, with the maximum achievable capture removal efficiency of 90%. The captured CO_2 is transferred though a pipeline connected to Pearl GTL and Oryx GTL plants.

2.3. CO2 Sinks Data (Pearl GTL and Oryx GTL)

The Pearl GTL is the largest GTL plant on the global scale. Utilising ATR technology, it produces LPG, naphtha, kerosene, diesel and base oils. It is supplied with 1.6 billion cubic feet per day of lean methane-rich gas from the Qatar north gas field. The capacity of plant 260,000 bbl/day divided as 120,000 bbl/day upstream products and 140,000 bbl/day GTL

products (Shell, 2018). Oryx GTL utilizes ATR technology and is supplied with 330,000 cubic feet per day of lean methane-rich gas from the Qatar North gas field to produce 34,000 barrels per day of liquids with 24,000 barrels of GTL diesel, 9,000 barrels of naphtha and 1,000 barrels of liquefied petroleum gas (QP, 2018).

3. Methodology

This study develops a simulation model of a GTL plant which integrates CO_2 as raw feed to attain optimal production of hydrocarbon products based on integrated SMR and ATR reformers. The model assumes the captured CO_2 is pure and reaches the sinks at the required pressure of the GTL process at a given capacity which is not exceeded. The simulation is developed using Aspen HYSYS-V9 using the parameters listed in Table 1.

Table 1. Model parameters

Parameter	NG	Steam (ATR)	O$_2$ (ATR)	Steam (SMR)
Flow (T/d)	1.54×10^4	6.49×10^3	1.72×10^4	4.87×10^4
T (C)	25	500	144	500
P (bar)	1	25	25	25
	Reformer	**FT**	**Hydrocracking**	**Fractionator**
T (C)	1050	250	345	Top P: 1 bar
P (bar)	23	24	80	Bottom P :1.5 bar
	1st Purge (ATR)	**2^{ed} Purge (ATR)**	**1st Purge (ATR)**	**2^{ed} Purge (ATR)**
%	5	5	8	1

The scenarios considered vary depending on plant capacity, reformer types, and feed rate of CO_2 into Oryx GTL and Pearl GTL. It is considered that the plant capacity for the two trains is 34000 bbl/day with 15372 ton/d of NG feed flow rate with molar steam to carbon ratio (S/C) of 0.4, and oxygen to carbon ratio of 0.6 in the case of ATR. However, the steam to carbon ratio in the case of SMR will increase to a ratio of 3 with zero oxygen while the NG will remain the same. The CO_2 injection to the ATR/SMR reformer has been varied between 500-2500 ton/d to examine its effect on the production rates of the refined products compared to the ATR case with zero CO_2 feed. The target is for the H_2/CO ratio to be in the acceptable range and to maximise the production.The main constraint used in the model is the appropriate ratio of H_2: CO which does not exceed a ratio of 2 in the case of ATR (Aasberg-Petersen et al., 2003) and 3 in case of SMR (Rafiee et al., 2017) without CO_2 injection, to ensure optimal synthesis gas after the reformers. A carbon mass balance has been applied to estimate the FT products distribution according to the Anderson-Schulz-Flory model, illustrated in Eq. (1) (Krishna and Sie, 2000).

$$W_n = Cn (1 - \alpha)^2 \alpha^{n-1}$$ Eq. (1)

Where, W_n is weight fraction of a particular product characterized by the carbon number (Cn) and chain growth probability (α).

4. Results

The results demonstrated a higher rates of refined products with the addition of CO_2 for both cases. In the base case of the ATR reformer with zero injection of CO_2, an H_2/CO ratio of 2.15 is achieved after the ATR reformer, and a ratio of 3.1 is achieved before the

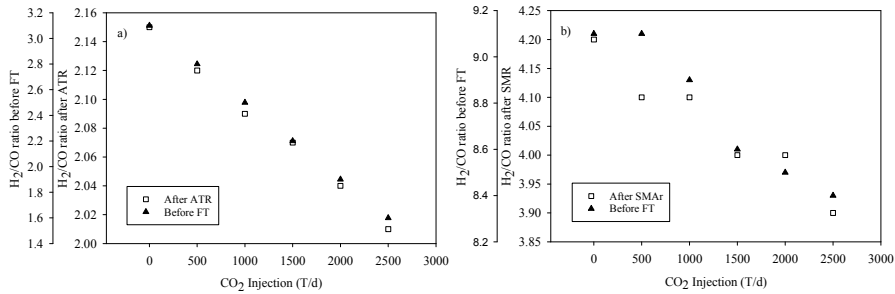
FT reactor. These ratios were reduced significantly with the addition of CO_2 to the system. As illustrated in Figures 2a and 3a, the H_2/CO ratio before the FT reactor performance declined. Furthermore, production rates of LPG, gasoline, diesel and wax demonstrated increasing trends. Moreover, the SMR reformer indicated a high production of LPG and wax in comparison with the base reference case of ATR and conversely to gasoline and diesel, where the results demonstrated a substantial decrease. Furthermore, it can be deduced that in case of the ATR the total production of the refined products is larger in comparison to the SMR. Furthermore, the CO_2 rate to the system has a significant impact on the H_2/CO ratio after the SMR and before the FT reactor as illustrated in Figure 2b. This contributes positively to the overall process as it will reduce the needed purge rate and increase the production rates of refined products.


Figure 2: Impact of CO_2 injection on H_2/CO ratio in a) ATR and b) SMR
Figure 3: Production trend of refined products in a) ATR and b) SMR with CO_2 injection rates
Figure 4: Impact of (α) in a) ATR and b) SMR on production trend of refined products

The study of varying growth probability of hydrocarbons is conducted to examine the effect on production rates and to identify the optimal location of α. The results of the ATR case, illustrated in Figure 4a, indicate an increasing trend for the wax with the increase in α, while the three remaining products illustrated a declining trend. The diesel production indicated a peak around 0.92α at approximately 3630 T/d. The SMR case demonstrated a

declining trend in the production of LPG and gasoline with the increase of α. Whereas, the production rates of diesel and wax demonstrated an increasing trend with a peak value of around 0.95α in the case of Diesel.

5. Conclusion

The study demonstrates the suitability of integrating CO_2 into GTL plants in order to increase production rates of finished products, reduce rogue CO_2 emissions and to generate economic benefits. The GTL plants considered in this study consist of two different reforming operations, ATR and SMR. The base reference considered is the ATR with zero CO_2, after which the injection of CO_2 is studied at varying rates between 500-2500 tonne per day to monitor the refined production rates. The results demonstrated a significant enhancement, however the LPG and wax in the case of the SMR are larger than the base reference case, although the purge and the H_2/CO is higher for the case after the reformer and before the FT reactor. Future studies should include the computation of net emissions of CO_2, and the economic viability considering process steam and heat energy requirements.

Consequential Life Cycle Analysis for Food-Water-Energy-Waste Nexus

Yanqiu Tao, Fengqi You

Cornell University, Ithaca, New York, 14853, USA

Abstract

Animal manure, as a type of unavoidable organic wet biomass waste, contains abundant nutrients, moisture and pathogen, therefore how to properly handle them has become an arising problem. Opposite to the severe challenge, dairy manure can be viewed as stably supplied feedstocks for biorefinery, which is invariant to seasonal and climate change and is of huge quantities. In this study, to thoroughly explore the potential to treat manure as biorefinery feedstocks, we select three promising thermo-chemical technologies, namely slow pyrolysis, fast pyrolysis and hydrothermal liquefaction and quantify their corresponding environmental impacts. We adopt a consequential life cycle assessment (LCA) approach, and successfully capture the environmental impact both attributed to the target process and consequential to the affected processes and markets. Lastly, we compare the consequential environmental impact with the attributional environmental impact and find consequential LCA advantageous to capture environmental impact without overestimation.

Keywords: wet biomass, dairy manure, pyrolysis, hydrothermal liquefaction, consequential life cycle assessment

1. Introduction

Organic wastes treatment is recognized as one of the most challenging issues in the systems engineering of food-water-energy nexus (FWEN) (Garcia et al., 2016). For example, animal manure, as one main type of unavoidable organic wastes, is rich in nutrients, bacteria and aerobic organics, hence it causes severe degradation of water and soil quality and makes contribution to greenhouse gas emission if being composted or landfilled (Yue et al., 2014). However, if handled properly, manure wastes can be converted to value-added products, for example biochar, biogas and bio-oil, which may bring both environmental and economic benefits (Garcia and You, 2017).

To address this issue, we specifically focus on the treatment of dairy manure wastes in this study. The environmental impact of three promising technologies for organic waste conversion, namely slow pyrolysis, fast pyrolysis and hydrothermal liquefaction, are evaluated and compared. To assess the environmental impacts, we adopted a cradle-to-grave analysis technique named life cycle assessment (LCA). The methodology of LCA involves four steps: goal and scope definition, life cycle inventory analysis (LCI), life cycle impact assessment (LCIA) and interpretation. The first step, goal and scope definition, includes the definition of the goal of LCA, the functional unit, system boundary, allocation procedures, type of methodology, life cycle impact category and assumptions. The second step LCI involves compilation and quantification of LCI data such as mass and energy flow rates. Next, LCI data is assigned to life cycle impact categories such as global warming potential (GWP) and multiplied by the

characterization factors of corresponding impact categories. Eventually the environmental impact indicators are obtained and interpreted during the final step. Notably, interpretation does not only happen in the end, but is conducted iteratively in every step of LCA.

LCA approach can be classified into two types: attributional LCA (ALCA) and consequential LCA (CLCA). The conventional ALCA takes a "snapshot" of existing conditions by only taking into account the environmental impacts of direct physical flows attributed to the life cycle of the products (Yang 2016). One underlying assumption of ALCA in which supply of inputs are unlimited implies the absence of both market effects and indirect environmental impacts. Therefore, ALCA is not suitable for situations where market effects and those indirect environmental impacts are not negligible, which accounts for the vast majority of the real world cases. Furthermore, another assumption, fixed input/output coefficients, eliminates possibilities for ALCA to capture any change in decision making to targeted processes.

In contrary to ALCA, by involving market constraints, CLCA is capable of capturing consequential environmental impacts in response to changes all through the targeted processes. CLCA systematically identifies the affected processes that change its production in response to the changes in both demand for inputs and supply for outputs, and sequentially expands its system boundary by including those indirectly affected processes. Several frequently-used methods to quantify the indirect environmental impacts are scenario analysis, simple partial equilibrium (PE) model, sophisticated PE model and computable general equilibrium (CGE) model (Garcia and You 2018). Considering model resolution, model maturity and the viability of the plan to incorporate CLCA into an optimization framework, it is the most appropriate to integrate the simple PE model in our CLCA study. Simple PE model replies on the microeconomic concepts of price elasticity of demand and supply, and it is confined to only one or a few economic sectors. While in reality, economic consequences can be passed on through multiple levels of markets, intuitively in this study, we aim to identify and analyze no more than two levels of markets and no more than one affected technology. Considering the inherently interrelated nature of FWEN, the CLCA approach is more reliable and may contribute to the improvement of systems engineering of more sustainable production, consumption, and distribution processes in the FWEN (Gong and You 2017).

2. System boundary, assumptions, and consequence identification

The goal of this consequential LCA is to assess the consequential life cycle environmental impacts of three thermo-chemical technologies: slow pyrolysis, fast pyrolysis and hydrothermal liquefaction (HTL), and make a comparison between the attributional and consequential environmental impacts. Pyrolysis is a thermo-chemical process that converts the waste biomass into a series of value-added products: product gas, bio-oil and biochar in the absence of oxygen (Zhang et al. 2014). Pyrolysis can be categorized as slow pyrolysis and fast pyrolysis, according to the heating rate and residence time (Gebreslassie et al., 2013). Particularly, the product yields vary with temperature, where the slow pyrolysis produces more product gas, biochar and less bio-oil, while the fast pyrolysis leads to more oil product (Goyal et al, 2008). Notably, by taking into account its capability of more than 100-year carbon sequestration and fertilizer use efficiency improvement, biochar is especially valuable from an

environmental point of view (Roberts 2010). Hydrothermal liquefaction converts biomass into bio-oil, product gas, hydro-char and aqueous phase product at moderate temperature in water (Gong et al. 2014). Therefore, this process does not need the energy-intense drying process and may serve as an ideal approach to handle wet biomass (Gollakota et al, 2018).

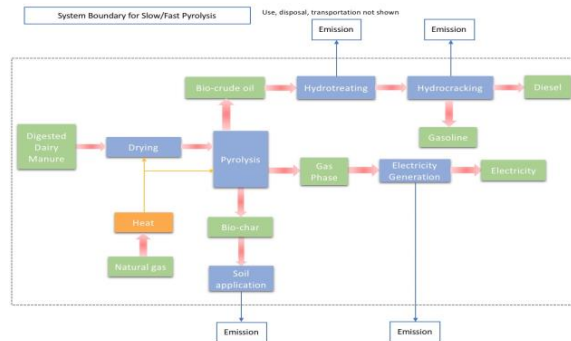
The functional unit is defined as treatment of 1 t fresh dairy manure. System boundary for the slow and fast pyrolysis is shown in Figure 1. In both processes, we start from collection of 1 t fresh dairy manure, transport it to anaerobic digestion (AD) and solid-liquid separation (SLS) (Aguirre-Villegas and Larson 2017). The avoided emission resulted from the AD-derived biogas is not included in the system boundary. Then, the pre-treated feedstock is transported to the biorefinery and undergone thermal-drying prior to being pyrolyzed. The heat is assumed to be supplied by high pressure steam, which is vaporized using natural gas (Gong et al., 2014). The resulting wastewater is sent to a wastewater plant for treatment and recycling. The biochar from pyrolysis is used as a soil amendment, which is then transported and applied to soil. Product gas will be used to generate electricity, and bio-oil will be converted to gasoline and diesel after being hydrotreated and hydrocracked. System boundary for the HTL is shown in Figure 2. After AD and SLS, the digested dairy manure is transported to the biorefinery and sent to the HTL reactor directly. The resulting bio-oil will be converted to gasoline and diesel, gas will be emitted directly, hydro-char will be applied to soil as P, K fertilizer. Additionally, the aqueous phase is treated by anaerobic digestion and used for algae cultivation (Zhou et al. 2015).


Figure 1. System boundary for slow and fast pyrolysis
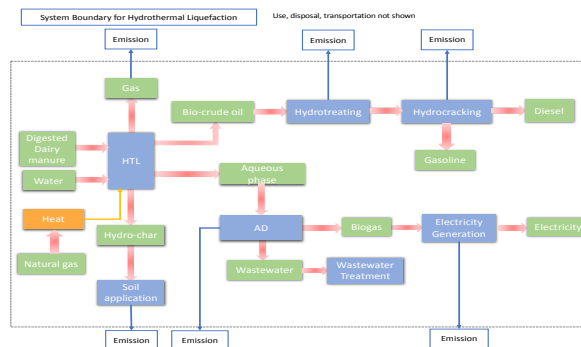

Figure 2. System boundary for hydrothermal liquefaction

While feedstocks are consumed, products are generated, the biorefinery interacts with the feedstock and product markets and breaks the current market equilibrium. The change in supply and demand in the feedstock and product market lead to change in the price and quantity, and eventually shifts to a new market equilibrium. This will also consequentially affect the market equilibrium in the downstream market. Therefore, it is important to identify the affected markets and capture the changes. There are five markets directly interacting with the target process: (1) Gasoline market. As an additional supply of gasoline is introduced into the market, the demand for fossil-based gasoline decreases, and the market reaches a new equilibrium. (2) Diesel market. The diesel market experiences the same trend as the gasoline market. (3) Electricity market. We assume that the price elasticity of demand is zero, and thus the increase in supply of electricity from the target process can be completely absorbed by other electricity suppliers. (4) Biochar market. The biochar market is very small and expanding, so we will not model the market behavior of biochar. Instead, we will only account for its improved fertilizer use efficiency and avoided soil emission during soil application. (5) Natural gas market. The natural gas will be consumed as a feedstock to generate heat for vaporization. The increased demand for natural gas will lead to increased price, and thus consequentially increased demand in other fossil-based fuels in the downstream market of heat generation. Two other modifications we made are: (1) Hydro-char. Because the hydro-char is sold as a substitute for P, K fertilizer, it will in fact avoid emissions during the use and disposal of the P and K fertilizers. (2) Dairy manure. Since the dairy manure market is absent, we will only calculate the avoided manure composting emissions.

3. Life cycle assessment results

Following the steps of consequential LCA, we obtain results as shown in Figure 3. The 100-year global warming potential (GWP) generated from consequential analysis for the treatment of fresh dairy manure using slow pyrolysis, fast pyrolysis and HTL are: 26.6, 34.7 and 15.7 kg CO_2 eq., respectively. HTL has the overall best performance with respect to the 100-year GWP. The energy-intensive process involved in the slow and fast pyrolysis process, thermal-drying, contributes to a large portion of the environmental burden. Moreover, the natural gas market accounts for a large part of the GWP, and this is mainly because the demand for natural gas consumed in our processes is fulfilled by the substitution of fossil-based fuel, which puts much consequential environmental burden on the target process. In contrary, the consequential GWP associated with the products are all negative, especially for the electricity. This result confirms that the products from these three technologies are truly environmental friendly. Attributional LCA is also conducted for comparison, the result is shown in Figure 4 and 5. The attributional LCA shows a similar trend that HTL has the best performance among the three technologies, except that the net GHG emissions are significantly higher. The 100-year GWP value of slow pyrolysis, fast pyrolysis and HTL are 85.9, 89.2 and 52.7 kg CO_2 eq., respectively. Since the attributional approach overlooks a series of consequences, it overestimates the overall environmental impacts of each target process.
Figure 3. CLCA environmental impacts evaluated by 100-year GWP
Figure 4. ALCA environmental impacts evaluated by 100-year GWP
Figure 5. Comparison of ALCA and CLCA using 100-year GWP

4. Conclusion

We conducted attributional and consequential life cycle analysis for three types of thermo-chemical conversion of dairy manure. In both ALCA and CLCA, HTL showed the best environmental performance with respect to the 100-year GWP. Moreover, by including consequential environmental impacts associated with the affected processes and downstream markets, CLCA leads to a much lower GWP than ALCA does. In the future, we will further extend our research to consequential life cycle optimization and broaden the scope of our study by integrating spatial analysis tools and uncertainty analysis.

Abstract

Life cycle assessment (LCA) is the most applied methodology to compare the environmental impacts of different products and processes. As uncertainty may be present in the first three steps of an LCA an uncertainty analysis should be considered allowing higher confidence in the results. However, few LCA studies include this analysis and when it is included is mostly applied to the LCI step of an LCA. Thus, the goal of this study is to develop a methodology to apply uncertainty analysis on the characterization factors used at the midpoint level in the LCIA step. The methodology employs Monte Carlo simulation as the stochastic modelling technique. A case study comparing the use of softwood and hardwood in the production of unbleached Kraft pulp is utilised to better explain the application of the developed methodology. As main results it can be concluded that the use of softwood as a raw material is overall worse for the environment than the use of hardwood when considering the production of unbleached Kraft pulp.

Keywords: Life Cycle Assessment, Uncertainty, Monte Carlo, ReCiPe, Pulp Production

1. Introduction

Life cycle assessment (LCA) is a four-step methodology for calculating the environmental impact of a product or service. The first step of this methodology, goal and scope definition, consists of defining the main objectives of the study, the functional unit (a representative element of the system being study), and system boundary. In the next step, life cycle inventory (LCI), all the flows that go in (e.g. raw materials and electricity) and out (e.g. emissions and solid waste) of the system are collected. The third step, life cycle impact assessment, consists in categorizing and characterizing the life cycle environmental impact of the system under study by converting the flows collected in the previous step into environmental impact using different parameters such as characterization factors. There are several LCIA methods that consider different categories and parameters. In the last step, results interpretation, the LCA study results are analysed and interpreted to identify the hotspots (areas to be prioritized for action) of the system and suggest possible improvements (ISO 14000 2006).

The aforementioned methodology is the most used to support environmental decision making and for this reason, the reliability of LCA results is of extreme importance. As uncertainty is always present in LCA (Björklund 2002), an adequate uncertainty analysis should accompany LCA studies to help decision makers having more confidence in the results. A literature review was conducted to understand how uncertainty in LCA has been addressed and it was concluded that uncertainty analysis has been increasingly included in LCA studies usually in the form of sensitivity analysis but also through Monte Carlo simulation and scenario analysis. Furthermore, uncertainty in the LCIA step is

rarely treated and there is no clear guidance on how to take uncertainty into account. For these reasons, the main goal of this work is to develop a methodology capable of addressing the uncertainty associated with the characterization factors applied in the LCIA step by exploring Monte Carlo simulation. The developed methodology is applied to a case-study to show its usability in the decision-making process.

2. Methodology

The methodology followed in this study comprises three main steps:

Step 1 – Case Study Description

The first step of the methodology consists in applying the first two steps of an LCA to the case study in analysis.

Step 2 – Environmental Impact Assessment

In this step, the third step of an LCA, Life Cycle Impact Assessment, is deterministically and stochastically applied to the case study under analysis. To deterministically apply the LCIA, a deterministic environmental assessment model was developed in Excel considering the LCIA method ReCiPe 2008 with Hierarchist perspective (Goedkoop, et al. 2013), which considers 18 midpoint categories that can be further aggregated into three endpoint categories. After being normalized and weighted, these endpoint categories are added to calculate a single score (SS) that reflects the overall environmental impact of the system under study. To stochastically apply the LCIA, Monte Carlo simulation is applied to the deterministic model using the @Risk software (Palisade Corporation 2016). Three main tasks were followed for the stochastic analysis:

- Uncertain Parameters Identification – The characterization factors of 14 out of the 18 midpoint categories have uncertainty associated. The other four midpoint categories, agricultural land occupation, urban land occupation, natural land occupation, and water depletion do not have uncertainty associated.
- Probability Distributions Assignment – From the 14 midpoint categories consider as having uncertain characterization factors, probability distributions should be assigned to the characterization factors of the most impactful midpoint categories (identified using a pareto analysis). The @Risk software was used to fit several probability distributions to the characterization factors available for each impactful midpoint categories. The Akaike Information Criteria statistics was used as a goodness-of-fit statistics to help determine the best fit.
- Simulation Settings Definition – Instead of defining the number of iterations at the beginning of the simulation, the @Risk software should be run in Auto-Stop mode until all results reach an established convergence tolerance (3% and a confidence level of 95% are the default settings). This means that the simulation will stop when the estimated mean of the results simulated is within 3% of its actual value and is accurate 95% of the time.

Step 3 – Results Analysis

The last step of the methodology followed in this study coincides with the last step of the LCA methodology and consists in analysing and comparing the deterministic and stochastic environmental impacts obtained in the prior step.

3. Case-Study

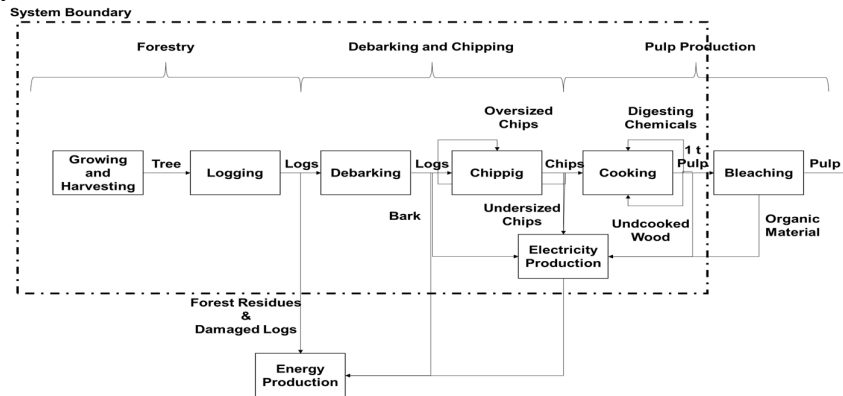
The first stage in wood pulp production (i.e. pulping) consists in growing and harvesting the trees. Then, the trunk of each tree is bucked into logs, which are delivered to mills where they are debarked (bark contains few cellulose fibres, the main component of paper products) and chipped. The next stage consists in separating the cellulose fibres from the other wood components such as lignin (the "glue" that cements the fibres together), extractives (e.g. fats, waxes and alcohols), minerals and other inorganics. This can be done through different processes but the most common is the Kraft (sulphate) process. In this process, the wood chips are pressure-cooked with water and chemicals, sodium hydroxide (NaOH) and sodium sulphide (Na2S), in a digester. The resulting pulp is screened to remove uncooked wood and washed to remove the spent cooking mixture. Depending on the final product, the pulp can be bleached after being produced due to the brown coloration of the raw pulp caused by the presence of lignin that was not removed during cooking (Bajpai 2012) (Teschke 2011). In Figure 1, the pulp life cycle is represented.


Figure 1 - Pulp life cycle including system boundary and functional unit

The species of the wood used as raw material is one of the characteristics that mostly influences the final properties of the pulp produced. Each tree species can be classified into one of two main families, the hardwoods and the softwoods.

In this paper, two different processes are compared – Case A (production of unbleached Kraft softwood pulp) and Case B (production of unbleached Kraft hardwood pulp). The system boundary considered is cradle-to-gate including the processes within the dashed rectangle in Figure 1 and the functional unit selected is 1 t of unbleached Kraft pulp produced in Europe.

The LCI of each system analysed was retrieved from the ecoinvent v3.3 database (ecoinvent 2018) with consequential system model which was assessed through the software SimaPro 8.4.0 (PRé Consultants 2018).

The results obtained through the deterministic and stochastic application of the LCIA to the case study presented are presented and discussed in the next section.

4. Results Analysis

4.1. Deterministic Results

After applying the deterministic environmental assessment model to the case study, it can be concluded that producing 1 t of unbleached Kraft softwood pulp (Case A) results in an

overall environmental impact of about 300 Pt while the same process using hardwood (Case B) results in an overall environmental impact of 238 Pt, which implies that the use of softwood as a raw material is worse for the environment than the use of hardwood. A pareto analysis was conducted considering the normalised results at the midpoint level of using softwood as a raw material to produce 1 t of unbleached pulp (Figure 2).
Agricultural Land Occupation (ALO), Particulate Matter Formation (PMF), Freshwater Eutrophication (FEut), Urban Land Occupation (ULO), Terrestrial Acidification (TA), Fossil Depletion (FD), Human Toxicity (HT), Marine Eutrophication (MEut), Marine Ecotoxicity (MEco), Photochemical Oxidant Formation (POF), Climate Change (CC), Natural Land Transformation (NLT), Freshwater Ecotoxicity (FEco), Terrestrial Ecotoxicity (TEco), Metal Depletion (MD), Ionising Radiation (IR), and Ozone Depletion (OD)

Figure 2 - Pareto analysis conducted considering the results at the midpoint level of Case A

By analyzing Figure 2, five midpoint categories (ALO, PMF, FEut, ULO, and TA) are responsible for about 80% of the overall environmental impact of producing 1 t of softwood unbleached Kraft pulp. Agricultural land occupation is the most contributing midpoint category because this process requires a continuous use of forestry land area. When comparing the results at the midpoint level of Case A and Case B, it can be concluded that the use of softwood as a raw material to produce 1 t of unbleached Kraft pulp has a higher result (worst for the environment) in 14 of the 18 midpoint categories considered in the ReCiPe 2008 method.

4.2. Stochastic Results

From the five midpoint categories identified in Figure 2 as being the most impactful in terms of environmental impact, three have uncertainty in the characterization factors (PMF, FEut, and TA) has previously explained. The simulation ran until the convergence of results previously stipulated was obtained which occurred after 2000 iterations.

Several stochastic results were obtained, and Figure 3 presents a summary of these results through box and whisker plots regarding the difference between Case A and Case B. Looking at the right side of Figure 3, it can be concluded that the difference between the single scores will be at least 61.90 Pt and at most 70.53 Pt. There is a 25 % chance that this difference will be lower than 62.05 Pt and higher than 62.35 Pt and a 50 % chance that it will be between these values. The inter-quartile range could be used as a measure of data variability and is calculated through the difference between the third quartile and the first quartile presented in Figure 3. Using this measure and looking at the left side of Figure 3, it can be concluded that the difference between terrestrial acidification shows the lowest variability while the difference between freshwater eutrophication shows the greatest variability.
Figure 3 - Box and whisker plots of the difference between the three most impactful midpoint categories (on the left) and single score (on the right) of Case A and Case B

The characterization factor assigned to nitrogen oxides in the PMF midpoint category is the one that most contributes to the variability of the difference between the single scores of Case A and Case B (right side of Figure 3). In the other two most impactful midpoint categories, the characterization factor assigned to the emission of phosphate to the water in the FEut midpoint category and ammonia to the air in the TA midpoint category are the ones that most contributes to the referred variability.

4.3. Results Comparison

The difference between the deterministic single score for Case A and Case B (black square in the right side of Figure 3) and the difference between the value of the three most impactful midpoint categories for Case A and Case B (black squares in the left side of Figure 3) are represented in Figure 3. The comparison of the deterministic and stochastic results allows the following conclusions to be drawn:

1. The deterministic difference between the single score of Case A and Case B is about 62.36 Pt (see square in the right side Figure 3). A positive difference means that Case A is overall worst for the environment than Case B.

2. The difference between the single score of Case A and Case B, in the stochastic scenario, is always positive and ranges from 61.90 Pt and 70.53 Pt (see right side Figure 3), which means that even with uncertainty Case B has always lower environmental impact. Therefore, the confidence in this conclusion is high.

3. The deterministic difference between the single score of Case A and Case B is close to the third quartile of the stochastic results (see right side of Figure 3). This reveals that the deterministic difference between the single score of both cases is overestimated – there is 75 % chance that this difference is actually lower and therefore the overall improvement from Case A to Case B is lower than the initial estimated (62.36 Pt).

4. The deterministic difference between Case A and Case B considering the two of the most impactful uncertain midpoint categories (PMF and FEut) is also close to the third quartile of the stochastic results (see left side of Figure 3), which also points out to an overestimation of the improvements obtained by switching from softwood to hardwood. In the case of terrestrial acidification the deterministic difference between Case A and Case B is closer to the median – the deterministic results obtained for this midpoint category are more robust.

5. These overestimations of results lead to the conclusion that there is a high chance that the environmental impact improvements obtained by switching from the use

of softwood to hardwood to produce unbleached Kraft pulp are smaller than expected.

5. Conclusions

A methodology to address uncertainty in the characterization factors used in the LCIA step of an LCA was proposed and applied to a case study where the use of softwood and hardwood in the production of 1 t unbleached Kraft pulp were compared. From this application it was concluded that the use of hardwood is, overall, better for the environment even when considering the uncertainty associated with the characterization factors at the midpoint level. However, the improvements obtained by switching from softwood to hardwood to produce unbleached Kraft pulp are expected to be smaller than the deterministic assessment revealed. This reinforces the problem with deterministic LCA – it leads to misleading perception regarding the differences between the environmental profile of different products or processes.

Future research should include the application of uncertainty analysis to other LCIA methods besides ReCiPe 2008 along with the study of other parameters such as the normalization and weighting factors.

Abstract

In this work, an end to end bio-pharmaceutical production process of the API lovastatin is developed through a systematic process synthesis and design approach, and then simulated. The developed simulation is intended to be used as benchmark process model as it captures the generic process dynamics of a bio-pharmaceutical process, and as such it is well-suited to use as a test problem to evaluate different processing scenarios in continuous fermentation processes. The synthesis and design of the simulation is realised through a methodology based on two complimentary steps, that can be applied individually or in conjunction, and is adopted to synthesize the upstream and downstream processing pathway. As such, the process model can be operated either as a whole, or as an individual upstream or downstream process. The open loop response of the whole benchmark simulation is presented here.

Keywords: upstream design, process development, benchmark process model, process modelling and simulation.

1. Introduction

Pharmaceutical manufacturing is a highly regulated field, where the regulations together with economics dictate that the process for production of an active pharmaceutical ingredient (API), which is generally synthesized in lab scale for clinical trials, must be quickly scaled up to full scale manufacturing once approval of the drug is granted. As a result, industry in general focuses on batch synthesis processes while downstream purification typically runs in a semi continuous manner, despite the inherent cost of inventory (Plumb, 2005). Due to this limited time for process development as well as the changing of operating regimes, there is a need for accurate benchmark process models. This work focuses on the field of fermentation as previous work in the domain of API continuous manufacturing through traditional organic synthesis has been carried out by Benyahia et al., whose work has then been exploited for control and other purposes (Ramin, Mansouri, Udugama, Benyahia, and Gernaey 2018), Mansouri, Udugama, Huusom, Gernaey, & Benyahia, 2018). In this work we will discuss the synthesis of an end to end benchmark process model for bio-pharmaceutical manufacturing with an emphasis on illustrating how process systems engineering

principles were used develop the benchmark, in particular the downstream unit operation selection and layout. The dynamic behavior of both upstream and downstream unit operations is illustrated with relevant step test and disturbances in the following sections. The intended uses for this benchmark include but are not limited to process control and proc optimization, while the benchmark is also designed so the process can be operated as an end to end model or as a separate downstream process model. The benchmark model is developed in Matlab Simulink environment and can be obtained by contacting the corresponding author; while a full manuscript detailing the modeling of each unit operation will be published in the near future.

2. Upstream design

The upstream process is designed through a three step hierarchical methodology as described below. The feed to the upstream is a liquid mixture with dissolved solid compounds which are lactose, adenine and cells, responsible for the production of the API lovastatin.

Level 1 (kinetic model selection)
The first step requires the selection of a kinetic model to describe the underlying physical and chemical phenomena occurring during the chemical reaction. Macro-kinetic unstructured models are preferred to micro-kinetic models since they are able to represent the system as a whole thus being suitable for the purpose of reactor modeling.

Level 2 (batch to continuous)
A subsequent step in the methodology would require the shifting of batch reactor model/operations to continuous reactor operations as the kinetic models are generally developed using batch operations.

Level 3 (choice of upstream design and simulation)
In this stage the upstream process is modelled and its operating parameters are optimized. One major issue common to many pharmaceutical processes is the dilution of the desired product in the reacting mixture, thus an efficient solution for the upstream design has to be chosen to achieve a tradeoff between the product final titer and productivity, in order to facilitate the downstream recovery and purification operations.
Figure 1: Upstream recirculation process design

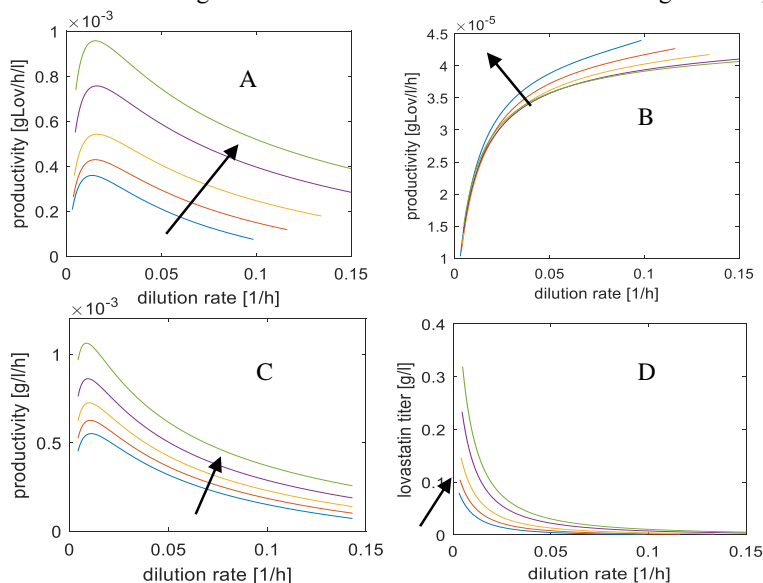
These issue are remedied by selecting an upstream process with cell recirculation, embedding a mixer, a continuous reactor and a cyclone for biomass recirculation. The upstream process model has been solved by means of steady state component and total material balance equations to test the effect of a couple of design parameters which are the recirculation factor, defined as the ratio between the recycle flowrate and the outflow from the reactor, and the cell recycle factor characterized as the ratio between biomass concentration in the recycle stream and reactor outlet stream. Figure 2 illustrates the effect of recycling on overall upstream productivity (subplots A and C) and reactor productivity (Subplot B), and is based on the implementation of the upstream process design illustrated in Figure 1 in the Matlab Simulink environment. The highest upstream productivity has been achieved with the largest recycle ratio whereas the opposite is true for the reactor productivity, as indicated by the arrow which points out the direction of increasing recirculation factor. Despite a trade-off between maximum and minimum recycle ratio, a higher recirculation factor is suggested to accomplish a higher final titer of the desired product directed downstream (Subplot D), where the recirculation factor is increasing in the direction of the arrow. It is important to note that the productivity of the overall upstream system (Subplots A and C), benefits from an increase in the amount of cells recycled, namely an increase in the β parameter. The evidence presented by this analysis thus far supports the idea that the upstream design benefits from a high volumetric flow recirculation rate and a large cell recycle.


Figure 2: Figure showing overall upstream productivity (Subplot A), reactor productivity (Subplot B), and final titer (Subplot D) upon increasing of the recirculation factor. Subplot C shows changes in the overall upstream productivity with increasing cell recirculation factor β.

3. Downstream process synthesis

The methodology currently adopted in the downstream process synthesis employs physicochemical properties and their relation to separation techniques to develop separation processing pathways. All separation techniques achieve their separation task

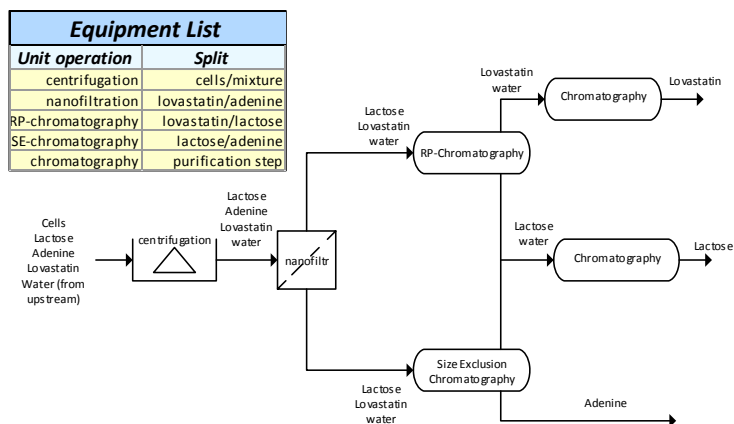
by exploiting physicochemical property differences between the separating components. The methodology has been extended, along with the inclusion of new physicochemical properties, including the most frequently used separation technologies in the bio-pharmaceutical field, which are centrifugation, electrophoresis, size exclusion and reversed phase chromatography, nanofiltration and reverse osmosis. The application of the methodology to the Lovastatin case study results in the processing route depicted in figure 3.


Figure 3: Downstream process synthesis result

4. Process simulation

In this section the upstream (Figure 1) and downstream process (figure 4) are connected and simulated as a continuous process by means of unit operation models either retrieved in the literature or derived from first principles.

The processing flowsheet illustrated in the figure accounts for the following hypotheses:

• A second centrifuge in series with the first one has been added to the process to discard the whole amount of cells
• A tank has been embedded to collect the fermentation broth thus offering the possibility to inject a limited amount of samples directed to membrane operation and chromatography.
• The separation step of adenine from lactose by means of size exclusion chromatography has been ruled out because nearly the whole amount of lovastatin goes in the retentate stream.
• The process simulation time adopted is 720 hours. The tank is emptying in the last 20 hours at a constant flowrate fixed by membrane specifications.
• The operating time of single filtration and chromatography is four hours each

Figure 4: Overview of the downstream benchmark process

Figure 5 highlights the behavior of the four components of interest in the cyclone outlet flow, which is directed downstream for final recovery and purification and is obtained by the benchmark process model (overall process illustrated in figure 1 and 2) developed in the Matlab Simulink environment. The increase of lovastatin (subplot A) and cells concentration (subplot B) comes along with a decreasing concentration of lactose (dashed line, right plot) and adenine (dotted line, right plot).

Subplot C of Figure 6 shows the separation of lovastatin from lactose and adenine. Subplots A and C of Figure 6 instead show how sample dilution in the processing mixture decreases as an effect of membrane filtration which contributes to achieving a final product which is more concentrated.
Figure 5: Cyclone concentration of lovastatin (subplot A), cells, lactose and adenine (subplot B)

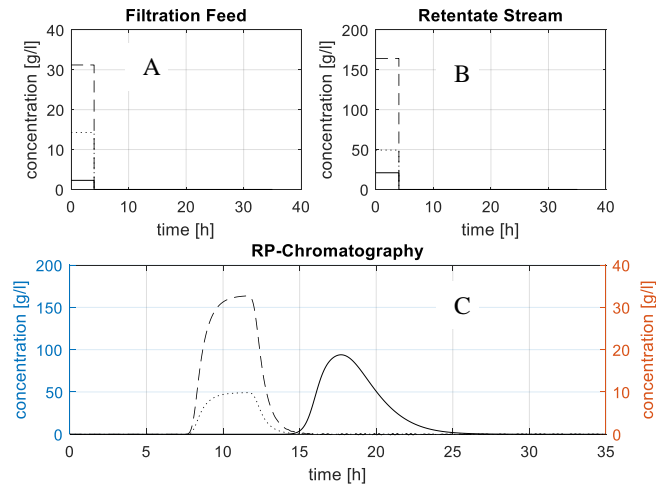
Please note that no energy integration has been included in the model in view of the fact that reactor temperature is not an issue for the present reaction as reported in the literature (Bizukojc & Ledakowicz, 2007). Besides, the downstream separation technologies employed in the process are isothermal.


Figure 6: Filtration feed concentration (subplot A), retentate stream concentration (subplot B) and the final chromatogram (Subplot C)

5. Conclusion

It has been successfully demonstrated that such a benchmark simulation has the ability to reproduce component behavior in a fermentation process, therefore representing an alternative to experimental evaluations, which could be time consuming and expensive. Furthermore the benchmark process allows evaluating different scenarios as its flexibility lies in the wide range of operational parameters that can be changed. We do believe the process represents a valid playground to test different control strategies, which would be a future work to be carried out on the presented process flowsheet.

Abstract

Facing uncertain situations and deciding a course of action is an opportunity to help students understand the practical implications of the theoretical knowledge and prepares them for the future challenges as engineers. However, allowing "failures and making wrong decisions" is becoming more and more challenging in industry due to safety and economic reasons and must be essentially allowed in academia. However, in academia it is also very challenging due to limitations in resources and safety concerns. Meanwhile, simulators are generally valuable tools for education that allow an intuitive learning based on action and offer the students an autonomy in their decision-making process. In spite of these advantages, the simulators commonly used in engineering education are meant for commercial purposes and incorporate a rigorous description of the process. Therefore, they are not inherently ready to be deployed in an educational program. This work presents a model-based pedagogical simulation tool, *FermProc*, having a clear objective for use in bio-manufacturing education. The in *FermProc* implemented computer-aided framework devises an active learning design based on the creation and analysis of different realistic and unrealistic scenarios such that students can safely confront common operational problems. Therefore, this model-based tool is intended to provide the users with the experience and the confidence to face and resolve uncomfortable situations encountered while operating a bioprocess.

Keywords: Learning by failure, Educational Simulator, Bioprocess simulator, Decision-making.

1. Introduction

A survey conducted by Nguyen (1998), stated that industry "requires an engineering graduate with an equivalent of a person with 10 years of experience" and "a person with motivation, who is creative, a good team member, risk-taking and decisive". Up-to-date, the current changing technological landscape makes it even more necessary to provide engineering graduates with these qualities. Most of these attributes are strongly connected to training. However, providing the opportunity for such training can be difficult considering the increasing number of students, the time restrictions, and the available resources. Simulators, with learning based on action and enhancing exploration, can help in fulfilling this need (Balamuralithara and Woods 2009). However, the question to answer is if "simulators can solve the problems we are

interested in?" Even so, the majority of the commercial simulators used in engineering education lack a pedagogical aim in the design; which entails limitations in the learning process. For example, in the case of infeasible operational conditions, commercial simulators are not prepared to provide information about the corresponding inappropriateness. On the other hand, the acquisition of knowledge and skills can be facilitated through an enjoyable experience and considering the new habits and interests of the students (Kiili 2005).

In this work, different approaches inside a model-based software that allows experiencing failure with the support of learning content for bioprocesses are presented. Furthermore, game-based elements are implemented inside the computational tool to encourage an enjoyable experience and the conceptualisation of complex knowledge. Therefore, the current version of the virtual software, *FermProc*, is explained, with its design requirements and advantages for allowing the learning by failure.

2. *FermProc*: A pedagogical model-based tool for bioprocesses

FermProc is a software designed with prime pedagogical objectives based on a previously developed methodology (Caño et al. 2018). Hence, it includes the simulation of mathematical models, as well as the possibility to modify them, learning-hints, questionnaires, mini-games, and the possibility to confront realistic technical problems. Furthermore, the process simulation is developed in an open-source platform, thus offering the possibility for students to access the mathematical models and gain a profound understanding about their complexity.

2.1 Design requirements of FermProc

This model-based tool is based on three pillars: 1) a careful learning design, 2) a motivational approach based on the use of gamification and, 3) the use of template-based models that can be displayed, reused and modified (Fedorova, Sin, and Gani 2015). Template-based modelling is an approach that requires the development of models on divisible pieces that compose a template. Through this approach, a model is decomposed into three sets of equations; i) balance equations, ii) constitutive equations and iii) connection and conditional equations (Cameron and Gani 2011). Each existing concept can be treated as a building block which can be combined with other suitable building blocks to create a new model. Meanwhile, the rational combination of equations to create a new model requires previous knowledge of the user or it can evolve to the creation of an additional process model. In both scenarios, the users can explore and learn about the construction of mathematical models. Furthermore, due to the educational aims, this software provides an organized and versatile learning experience in a user-friendly environment that engages the user in the learning process. This is promoted by the presence of rules and explanation across the tool.

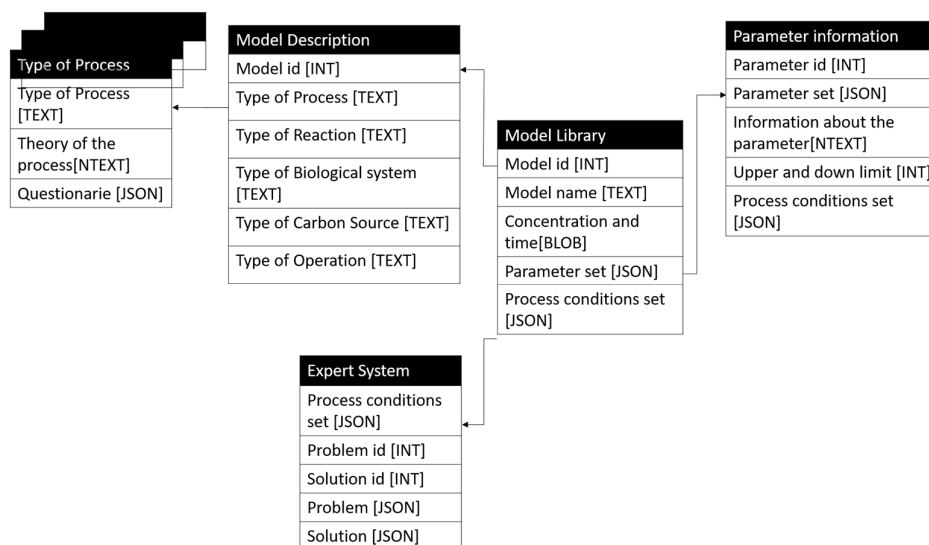
In order to fulfil the design requirements, a relational database is developed in SQLite. This database scheme with the corresponding data types can be seen in Figure 1. The database collects and reuses interrelated rules for a comprehensive modification of the kinetic models (shown in Figure 2). Moreover, it uses the process conditions to correlate an "expert system" with problem and solutions. The problem-solution feature in *FermProc* will be further explained in Section 2.2.


Figure 1. Database scheme with data types.

2.2 *Advantages of FermProc*

FermProc is a platform developed "*by* students *for* students" with the support of highly skilled teachers. This is done through involving the students in all the steps of the process as co-designer and co-developers of the computational tool. Therefore, in contrast with other commercial simulators, *FermProc* has clear learning goals. At its current stage, they are the acquisition of i) knowledge for the understanding of the mathematical model associated with a bioprocess, ii) skills in the evaluation of fictional and non-fictional scenarios in a bioconversion and iii) competences in meaningful decision-making across the design of the bioprocess. Moreover, this software has the objective to promote creativity and critical-thinking as it allows to make and take control of mistakes. This is done by the support of theory in every decision taken by the user, the need for applying their knowledge in different scenarios and a continuous assessment of the choices of the user. In the current stage of development, this is put into practice with the modification of the simulated model and other activities implemented as mini-games or multimedia content.

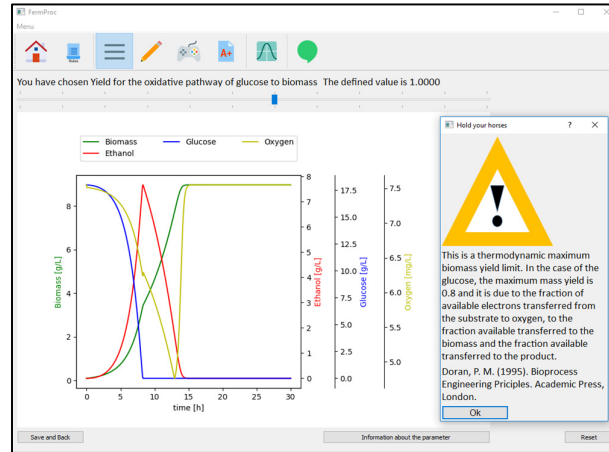
The feature for the modification of a chosen model can be seen in Figure 2. Initially, the model is selected based on a series of questions related to the bioprocess to be simulated. These choices are supported by theoretical content and the structure of the selected model is explained with a visual help or a video. Once the model is selected and solved inside the tool, the user can select a parameter or operational condition from the mathematical model and modify different values in a range depending on the parameter or selected conditions. If the modified value is out-of-range due to, for example, a thermodynamic restriction, the software will display a new window with the theoretical explanation and the corresponding literature reference. This allows enhanced awareness of the feasible range of values and provides a source of information that the users can rely on to intensify knowledge about the applied model.


Figure 2. Example of the screen for the modification of the model in FermProc with a popup window that will appear when an out-of-range value is selected.

In addition, other activities are implemented to engage the creativity of the user and to make complex knowledge more approachable with the inclusion of game elements. Some examples of the implemented mini-games inside *FermProc* are:

- A *memory game* for matching combinations of definitions, nomenclature and international units of the parameters involved in a complex fermentation model. With different levels of difficulty, the user starts connecting nomenclature and definition and advances to connect nomenclature and units.

- A "*what is what?*" for the analysis of graphs. The software solves the model, chosen by the user, with different initial model parameter values (1%, 25%, 50% and 100%) and generates a graph for each simulation. Then, the user is required to choose the graph with the highest value of the parameter. In the current state, the parameters are associated with the biomass growth and the choice is made based on the plot of the evolution of the biomass concentration against the time. This system can provide the user with the training for the critical thinking needed to associate the variation of parameters that are not directly represented in the graphs but have an effect in the process. In addition, the understanding of mechanistic models is strongly intensified using this approach.

- An *operational problem*. In this game, the user needs to recognize an operational issue and select a solution from a problem and solution data set. This can be seen in Figure 3 and Figure 4. The operational problem is randomly picked inside a database (in Figure 1) considering the process modelled. For example, in Figure 3, the user is facing a very low *Saccharomyces cerevisiae* growth rate and he/she needs to use the available information about glucose, ethanol, oxygen and the set value temperature and the measured temperature to identified possible problems in the operation

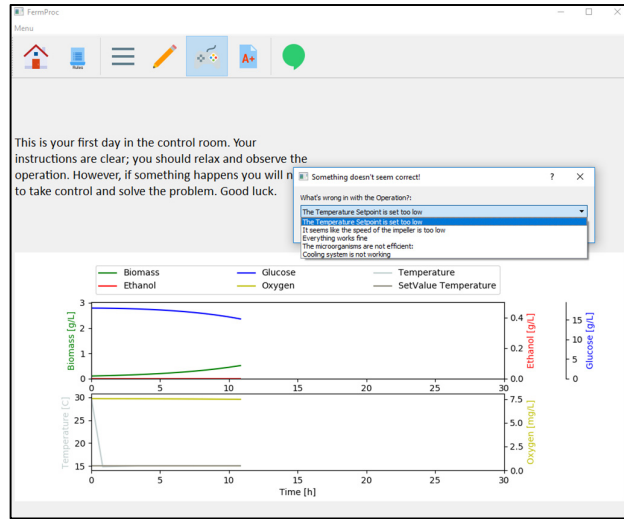
process. In this specific case, the low efficiency of the microorganisms is due to a low fixed temperature value (of 15ºC) when yeast has an optimal growth rate at 30ºC (Sonnleitner and Käppeli 1986).


Figure 3. The screen of the first step of the operational problem in which the problem needs to be categorized.
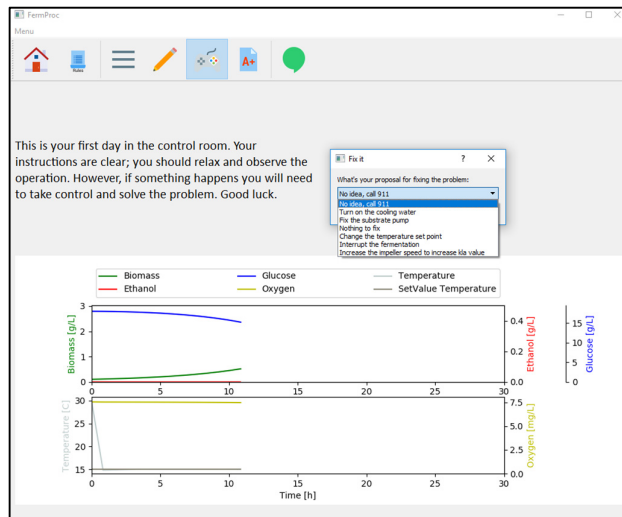

Figure 4. The second step of the operational process mini-game. A solution for the issue needs to be proposed based on the available solutions. Due to lack of space, the screen for the modification of the parameter (such as, like in this case, the change of the temperature setpoint and the choices based on the type of microorganism you are using) hasn't been included in this manuscript

The problem-solution database, that is part of the Figure 1, is created with the experiences gained by industry and academia, and therefore the users can confront real-life situations. It is expected that as the users are solving those operational issues, they are building confidence in its decision-making abilities and developing a skilled mind-set with awareness of the most common failures and the capability of solving hand-on problems.

Therefore, *FermProc* is designed considering how to allow meaningful failures and to make choices with the support of a learning design and content. Consequently, as the user goes through the software, he/she develops the abilities to analyse and confront problematic situations and make decisions about the process. It is important to highlight that *FermProc* is still in development and a user experience is planned for summer 2019 to corroborate the design and features of the software.

3. Conclusions

In order to allow students to gain experience without exposing themselves or put the installations at risk and with a limited consumption of time and resources, new and innovative model-based tools need to be developed. In the case of bioprocesses, several technical problems can happen during the operation that will require a fast analysis and critical response. Considering those issues, *FermProc,* which is a model-based tool for the simulation of bioprocesses, is developed. It integrates learning design and game elements. In its current state of development, *FermProc* is prepared to facilitate comprehension of kinetic parameters and their limits. *FermProc* also has implemented other activities such as problem-solution database that will help students to face technical problems while gaining theoretical knowledge in a safe environment.

Data-Based Robust Model Predictive Control Under Conditional Uncertainty

Chao Shang, Wei-Han Chen, Fengqi You

Cornell University, Ithaca, New York, 14853, USA

Abstract

In this work, a novel data-driven robust model predictive control (RMPC) framework is outlined for optimal operations and control of energy systems, where uncertainty in predictions of energy intensities enters into the process in an additive manner. However, the distribution of prediction errors may be time-varying and depend on other external variables. To appropriately describe the distribution of uncertainty, a novel concept of conditional uncertainty as well as the conditional uncertainty set is proposed, which disentangles the dependence of distribution on external variables and hence reduces the conservatism. In general, the conditional uncertainty set can be modelled by integrating domain-specific knowledge and data collected from previous experience. An example arising from agricultural irrigation control is presented to illustrate of the effectiveness of the proposed methodology.

Keywords: Model predictive control, robust optimization, data-based decision-making

1. Introduction

In the past two decades, model predictive control (MPC) has established itself as an enabling technology for optimal control and operation of dynamic complex systems, with uncountable applications in process industries (Morari and Lee, 1999). In the MPC framework, a dynamic process model is adopted to describe future system behaviour, based on which the input sequence is optimized by various MPC algorithms. Despite of its significant success, MPC technology commonly requires heavy manual workload for maintenance, mainly because of model mismatch and random disturbances that drive the system to deviate from its trajectory and affect the control performance (Chu et al. 2015).

To address this issue, robust MPC (RMPC) has been extensively investigated in both academia and industries (Saltık et al., 2018), with representative applications in building control (Zhang et al., 2017), operations of smart grid (Zong et al., 2012), and irrigation systems (Delgoda et al., 2016), where process systems are influenced by various weather and climatic factors in an additive manner, such as solar radiation, wind energy, rainfall, etc. Fortunately, thanks to the development of information technology, forecasts of many climatic factors have become more and more easy to attain nowadays. However, these forecasts themselves are not sufficiently accurate, thereby bringing uncertainties in forecast errors. Consequently, in the associated RMPC scheme, the external disturbance can be decomposed into a known deterministic input arising from forecasts, and the uncertainty representing forecast errors. In existing studies, norm-based uncertainty sets, as a basic ingredient in robust optimization and RMPC, have been adopted to characterize the distribution of uncertain forecast errors.

In this work, we point out the limitations of using traditional norm-based uncertainty sets to deal with forecast errors of energy intensities. In fact, their distributions can be heavily

dependent on some other external variables, e.g. forecast values, thereby showing significant time-varying characteristics. Motivated by this, we make clear such dependence with some concrete examples, and define a new conditional uncertainty set to disentangle the dependence of forecast error on external variables. In this way, primitive uncertainties independent from external variables can be effectively extracted, based on which the time-varying uncertainty distribution can be expressed in a unified manner, thereby significantly reducing the conservatism of RMPC. To determine the distribution of primitive uncertainties in a data-driven way, the use of support vector clustering (SVC)-based uncertainty set (Shang et al., 2017) is recommended. We adopt an example from irrigation control and carry out closed-loop simulations based on real weather prediction and measurement data. Case studies show that the proposed approach can help reducing conservatism of RMPC significantly and safely maintain soil moisture above a certain level with reduced water consumptions.

2. Robust Model Predictive Control under Conditional Uncertainty

2.1 Robust Model Predictive Control

We consider optimal control problems of the following linear system:

$$x_{t+1} = Ax_t + Bu_t + Ev_t + Hw_t ,\tag{1}$$

here x_t and u_t are the system state and control input, v_t and w_t are deterministic disturbance and random disturbance, and $\{A, B, E, H\}$ are system matrices of appropriate dimensions (Tatjewski, 2007; Seborg et al. 2010). Given the control horizon N, Compact expression of system dynamics given the control horizon N:

$$x = Ax_0 + Bu + Ev + Hw ,\tag{2}$$

where $x = [x_1^{\mathrm{T}}, \mathrm{L}, x_N^{\mathrm{T}}]^{\mathrm{T}}$ is the stacked sequence of future states, and $\{u, v, w\}$ can be defined in a similar way. System constraints can be generally expressed as $Cx + Du \le f$. In the presence of uncertainty, future control inputs u are essentially functions of past disturbance w, which can be approximately parameterized by affine disturbance feedback (ADF) policy (Ben-Tal et al., 2004; Goulart et al., 2006; Shang et al., 2018):

$$\pi(w) = Pw + q .\tag{3}$$

Here P has a lower-triangular structure to respect the causality of ADF policy. By optimizing over coefficient matrix P and vector q, the formulation of traditional RMPC reads as follows (Saltık et al., 2018):

$$\min_{\pi} J_H(x_0, \pi)$$
$$\text{s.t. } x = Ax_0 + B\pi(w) + Ev + Hw \tag{4}$$
$$Cx + D\pi(w) \le f, \ \forall w \in \Omega$$

where $J_H(x_0, \pi)$ denotes the loss function to be minimized, and Ω is the uncertainty set to describe the region of uncertainty. The most-used formulations of Ω are typically based on l_1, l_2 and l_∞ norms, e.g., $\Omega = \{w \mid \| w \|_1 \le \Gamma\}$ (polyhedral), $\{w \mid \| w \|_2 \le \Gamma\}$

(ellipsoidal), and $\{w \mid \| w \|_\infty \leq \Gamma\}$ (box), where Γ stands for the size parameter (Bertsimas and Sim, 2004). By adopting techniques from robust optimization, one can translate (4) into a tractable optimization problem by introducing auxiliary variables (Ben-Tal et al., 2004).

2.2 Description of Conditional Uncertainty

A potential limitation of (4) lies in that, unnecessarily conservative solutions may be attained because the structure of Ω cannot well describe the distribution of w. Specifically, in the optimal operations and control of energy systems, it is common that w and v represents future predictions and prediction errors of energy intensities. For example, in operations of micro-grid, predictions of wind and solar energies are typically available based on weather forecasts (Zong et al., 2012). In this case, the distribution of prediction errors may exhibit time-varying characteristics. Consider two different cases where predictions of solar energies are made in the daytime and at night. In the daytime, due to varying cloudiness, predictions tend to be uncertain, while at night predictions are much more accurate in the absence of sunlight. Hence, prediction errors in the day time will be more pronounced than those at night. It implies that one cannot use generic uncertainty sets to appropriately tackle such uncertainty, and hence research attentions are required in this vein.

We state that, such uncertainty can be understood as being dependent on some external variables, which can be prediction values in the case of solar energy predictions. This is because prediction values of solar energy will be high in the daytime and be low at night, which embody time-varying information themselves. Our idea is to disentangle the dependence the time-varying uncertainty on the external variables, thereby obtaining the underlying primitive uncertainty whose distribution tends to be time-invariant. Formally, such dependence can be described in the following generative manner:

$$w = g(\boldsymbol{\delta}, z), \tag{5}$$

where $\boldsymbol{\delta}$ and z denote external variables and the primitive uncertainty, respectively. $g(\cdot, \cdot)$ is a specific function to be determined. We further assume that with $\boldsymbol{\delta}$ given, there is a one-to-one mapping from w to z, which is denoted as:

$$z = g^{-1}(\boldsymbol{\delta}, w). \tag{6}$$

Because of the effect of decoupling $\boldsymbol{\delta}$ from z, which has a homogeneous distribution, a constant uncertainty set D can be adopted. Recently, a popular and efficient way to parameterize D is to utilize machine learning techniques (Ning and You, 2017, 2018), where SVC induced by the weighted generalized intersection kernel (WGIK) is an appealing one due to its compact representation capability, ease of implementation and robustness to outliers. The typical expression of the SVC-based uncertainty set is given by (Shang et al., 2017):

$$D = \left\{ z \mid \sum_i \alpha_i \| \mathbf{Q}(z - z^{(i)}) \|_1 \leq \theta \right\}, \tag{7}$$

where $\mathbf{Q}$ is a weighting matrix, and $\{z^{(i)}\}$ are historical samples of z. Parameters $\{\alpha_i\}$ and θ can be obtained by solving a dual quadratic program (Ben-Hur et al., 2001). With the distribution of z described by D, we can further arrive at the expression of Ω:

$$\Omega = \{ w \mid w = g(\boldsymbol{\delta}, z), \, z \in D \}. \tag{8}$$

We refer to (8) as *conditional uncertainty set*, which is established based on the data-driven uncertainty set D of primitive uncertainty z.

2.3 Robust Optimal Control with Conditional Uncertainty Set

Because w can be expressed in terms of z, the ADF policy can be defined directly on z, which is $\boldsymbol{\pi}(z) = \mathbf{P}z + \boldsymbol{q}$. Up to now, we can derive the following optimal control problem:

$$\min_{\boldsymbol{\pi}} \ J_H(x_0, \boldsymbol{\pi})$$

$$\text{s.t. } \boldsymbol{x} = \mathbf{A}x_0 + \mathbf{B}\boldsymbol{\pi}(z) + \mathbf{E}v + \mathbf{H}\boldsymbol{g}(\boldsymbol{\delta}, z) \tag{9}$$

$$\mathbf{C}\boldsymbol{x} + \mathbf{D}\boldsymbol{\pi}(z) \le \boldsymbol{f}, \ \forall z \in D$$

With $\boldsymbol{g}(\cdot, \cdot)$ appropriately defined, (9) can be regarded as a traditional robust optimization problem and is amenable to a dual reformulation (Shang and You, 2019). Next, an irrigation control example is presented to demonstrate its generality.

3. An Irrigation Control Example

In the context of irrigation control, the irrigation amount is manipulated to keep soil moisture level within a proper range. The water balance in the root zone soil can be mathematically expressed as $x_{t+1} = (1 - c) \cdot x_t + u_t + v_t + w_t$, where x_t is the soil moisture level, u_t is the irrigation amount, and $c \cdot x_t$ stands for the amount of runoff and water percolation ($0 < c < 1$) (Delgoda et al., 2016). We assume that $v_t = - e_t + y_t$, where e_t denotes the amount of crop evapotranspiration that is precisely known, and y_t is the predicted rainfall amount. w_t is the rainfall prediction error at stage t. The control goal is to minimize water usage subject to limited water supply $u_t \le 10$ mm while maintaining soil moisture above a safety level $x_t \ge 30$ mm, because the deficiency in soil moisture can probably lead to crop devastations. Such goal can be easily interpreted by choosing appropriate loss functions and constraints.

To devise a conditional uncertainty set for w, we first plot in Figure 1 the joint empirical distribution of w_t and y_t ($t = 1$) based on real weather data collected at Des Moines, Iowa. It can be observed that the distribution of w_t is apparently asymmetric and varies with the value of y_t. In particular, when the value of w_t is negative, the ground truth rainfall amount p_t is smaller than predicted, and hence we have $w_t = p_t - y_t \ge -y_t$. By the same token, when the value of w_t is non-negative, the ground truth rainfall amount p_t is larger than predicted but smaller than a maximum $p^{\max}$, and hence we have $w_t = p_t - y_t \le p^{\max} - y_t$. Therefore, the ranges of positive and negative parts of w_t rely on the predicted value y_t, which highlight the requirement of employing the conditional uncertainty set. Based on such an observation, we propose to parameterize Ω as follows:

$$\Omega = \left\{ \boldsymbol{w} \,\middle|\, \boldsymbol{w} = \mathbf{G}(\boldsymbol{y})^+ \boldsymbol{w}^+ - \mathbf{G}(\boldsymbol{y})^- \boldsymbol{w}^-, \ \boldsymbol{w}^+ - \boldsymbol{w}^- \in D, \ \mathbf{0} \le \boldsymbol{w}^+, \boldsymbol{w}^- \le \mathbf{1} \right\}. \tag{10}$$

Therefore, $z = \{\boldsymbol{w}^+, \boldsymbol{w}^-\}$ stands for the primitive uncertainty that explains variations within w. Diagonal coefficient matrices are given by:

$$\mathbf{G}(\boldsymbol{y})^{+} = \mathrm{diag}\left\{p^{\max} - y_1, \mathrm{L}\;, p^{\max} - y_N\right\}, \; \mathbf{G}(\boldsymbol{y})^{-} = \mathrm{diag}\left\{y_1, \mathrm{L}\;, y_N\right\}, \tag{11}$$

which help normalizing the primitive uncertainty. To construct D, historical prediction and measurement data have been collected at Des Moines, Iowa from Jun 2016 to Oct. 2016. Since D is essentially a polytope, the above problem is a typical robust optimization problem that allows for a tractable dual reformulation. Here the external variables $\boldsymbol{\delta}$ become future rainfall predictions $\boldsymbol{y}$. Finally, the optimal control problem (9) becomes:

$$\min_{\boldsymbol{\pi}} \; J_H(x_0, \boldsymbol{\pi})$$

$$\mathrm{s.t.}\; \boldsymbol{x} = \mathbf{A}x_0 + \mathbf{B}\boldsymbol{u} + \mathbf{E}\boldsymbol{v} + \mathbf{HG}(\boldsymbol{y})^{+}\boldsymbol{w}^{+} - \mathbf{HG}(\boldsymbol{y})^{-}\boldsymbol{w}^{-} \tag{12}$$

$$\mathbf{C}\boldsymbol{x} + \mathbf{D}\boldsymbol{\pi}(\boldsymbol{w}^{+}, \boldsymbol{w}^{-}) \le \boldsymbol{f}, \; \forall \boldsymbol{w}^{+} - \boldsymbol{w}^{-} \in D, \; 0 \le \boldsymbol{w}^{+}, \boldsymbol{w}^{-} \le 1$$

where $\boldsymbol{\pi}(\boldsymbol{w}^{+}, \boldsymbol{w}^{-}) = \mathbf{P}^{+}\boldsymbol{w}^{+} + \mathbf{P}^{-}\boldsymbol{w}^{-} + \boldsymbol{q}$ stands for the ADF policy. Closed-loop simulations have been executed from May 2017 to Oct. 2017 under open-loop control, certainty equivalent MPC (CEMPC), and the proposed method. The results with respect to monthly irrigation amounts and constraint violation probabilities have been summarized in Tables 1 and 2.

Table 1. Monthly Irrigation Amounts in 2017

	Jun.	Jul.	Aug.	Sep.	Oct.
Open-Loop Ctrl. (mm)	300.00	283.00	226.00	268.00	92.00
CEMPC (mm)	196.64	209.03	141.11	131.12	47.32
RMPC (mm)	198.87	209.55	142.39	132.87	50.11

Table 2. Monthly Violations Probabilities of Soil Moisture Levels in 2017

	Jun.	Jul.	Aug.	Sep.	Oct.
Open-Loop Ctrl. (%)	0.00	0.00	0.00	0.00	0.00
CEMPC (%)	21.67	23.38	15.32	17.50	5.98
RMPC (%)	0.00	0.00	0.00	0.00	0.00

It can be observed that, the open-loop control strategy that determines weekly irrigation schedule in advance, leads to zero probability of soil moisture deficiency along with the greatest water consumptions. In contrast, CEMPC yields the most aggressive control actions, since the least amount of water is used. However, the price is that state constraints are frequently violated, which may heavily compromise crop productivity. The proposed data-based RMPC achieves a satisfactory performance. On one hand, it reduces the water consumption by about 40% compared to open-loop control, which is the state-of-the-art technology. On the other hand, it successfully safeguards soil moisture level constraints. This owes to an appropriate characterization of the uncertainty distribution based on the proposed conditional uncertainty set constructed with historical data. The proposed method can achieve a desirable balance between saving water, and hedging against uncertainty in forecast errors with the aim to reliably avoid potential harm to crop.

4. Conclusions

This paper features a new framework for RMPC under additive conditional uncertainty, where the dependence of original uncertainty on primitive uncertainty is clearly described, based on which data-driven uncertainty sets are constructed to indirectly

characterize the distribution of original uncertainty. The proposed method applies to optimal operations and control of energy systems where predictions of energy intensities are available but inevitably induce uncertain prediction errors. By compactly describing the distribution of uncertainty with the proposed conditional uncertainty set, the conservatism of control actions can be efficiently reduced, which uncovers the value of leveraging big data. A real-world case study based on agricultural irrigation systems is performed to show the effectiveness and merits of the proposed method.

Abstract

The National Institute of Environmental Health Sciences (NIEHS) Superfund Research Program (SRP) aims to support university-based multidisciplinary research on human health and environmental issues related to hazardous substances and pollutants. The Texas A&M Superfund Research Program comprehensively evaluates the complexities of hazardous chemical mixtures and their potential adverse health impacts due to exposure through a number of multi-disciplinary projects and cores. One of the essential components of the Texas A&M Superfund Research Center is the Data Science Core, which serves as the basis for translating the data produced by the multi-disciplinary research projects into useful knowledge for the community via data collection, quality control, analysis, and model generation. In this work, we demonstrate the Texas A&M Superfund Research Program computational platform, which houses and integrates large-scale, diverse datasets generated across the Center, provides basic visualization service to facilitate interpretation, monitors data quality, and finally implements a variety of state-of-the-art statistical analysis for model/tool development. The platform is aimed to facilitate effective integration and collaboration across the Center and acts as an enabler for the dissemination of comprehensive ad-hoc tools and models developed to address the environmental and health effects of chemical mixture exposure during environmental emergency-related contamination events.

Keywords: Data analytics, data integration, statistical analysis, collaborative networks.

1. Introduction

The risk of chemical contamination and exposure to hazardous chemicals are elevated during and after natural catastrophic events (*i.e.,* hurricanes) due to the increased mobility of many chemical toxicants. In such situations, the rapid and precise examination of potential sources and pathways of chemical contamination becomes essential: (i) for identifying their adverse health impacts and (ii) for delivering solutions to mitigate such

adverse effects. To this end, Texas A&M Superfund Research Program (TAMU Superfund Research Center, 2018) aims to build both experimental and computational models, methods and tools through exposomics research and data analysis. The program extensively studies the health, economic and social impacts of hazardous complex chemical mixtures after environmental emergencies with Galveston Bay/Houston Ship Channel area being selected as a case study.

TAMU SRP is a cross-disciplinary program and has a tightly integrated structure which governs four main research projects (two environmental and two biomedical research projects). The two environmental projects, namely Project 1 and 2, focus on understanding dynamic exposure pathways under the conditions of environmental emergencies and designing novel broad-acting sorption materials for reducing bioavailability of contaminants. Project 3 and 4, being the two biomedical projects, are studying *in vitro* and *in vivo* hazard, kinetics and inter-individual variability of responses to chemical mixtures and developing *in vitro* multiplex single-cell assays to detect endocrine disruption potential of mixtures. Each of these projects utilizes various experimental methodologies for detecting, assessing, evaluating and characterizing the effects of complex chemical contaminants including Gas Chromatography-Mass Spectrometry (GC-MS), Ion Mobility-Mass Spectrometry (IM-MS), Inductively Coupled Plasma Mass Spectrometry (ICP-MS), Ultraviolet-Visible Spectroscopy (UV-Vis), high-throughput imaging and image analysis. Hence, these four projects generate large quantities of highly diverse datasets, where their maintenance and analysis require a systematic approach through the development of a computational platform.

In addition to the four main research projects, there are three research supporting cores within the TAMU SRP, one of which is the Data Science Core. The Data Science Core serves as the basis for translating the data produced by the four research projects into useful knowledge for the community via data collection, quality control, analysis, visualization and model generation. This Core functions as a hub that collects, processes and integrates the aforementioned diverse datasets over a computational platform to draw specific conclusions via supervised (*i.e.,* regression, classification) and unsupervised (*i.e.,* clustering) analysis. These techniques are widely used in process systems engineering (PSE) including process monitoring (Onel et al., 2018b) and grey-box optimization (Beykal et al., 2018). In this work, we present the TAMU SRP computational platform which aims to promote collaboration across the Center and facilitate dissemination of methods/data across all projects of the program as well as to the wider community. The computational platform is developed as an online tool that specifically uses a relational database for data storage as well as statistical and machine learning techniques to create decision support models, housing both novel computational methodologies and state-of-the-art data analytics techniques. It establishes an accessible front-end interface for the application of the high-performance models and tools developed during collaborations with individual research projects (Onel et al., 2018a). The details of the computational platform are provided in the following sections where its integration and connection with one of the biomedical projects is demonstrated as a motivating example.

2. Computational Platform

The online computational platform is developed in Python environment, whereas the backend functionalities utilize either R or Python environments. The relational database for storing and sharing data across the Center is based on SQLite. A flow diagram of the

platform is shown in Figure 1. The computational platform is developed and implemented in two stages. The first stage entails the dissemination of datasets and methodologies across the Center for supplying a convenient environment for collaboration among all projects. The second stage enables access to the extracted knowledge, models, and tools with the scientific community, government and commercial stakeholders. In this work we will only present the developments of the first stage.
Figure 1. Online computational platform flowchart.

The computational platform first requires a data upload by the user, which is further passed to an initial quality monitoring module. The quality monitoring module checks the dataset for any missing data and/or outliers. Missing data is handled two-fold: (i) Deletion of rows or columns that include missing data, (ii) imputation by k-nearest neighbor (k-NN) methodology (Ramaswamy et al., 2000). This pre-processed data is stored under the relational database for future reference. A summary of this first module is provided as a feedback to the user. Second, the user specifies a type of inquiry, namely visualization and analysis. Currently, four visualization techniques are implemented within the platform including, boxplots, heatmaps, pie charts and scatter plots. Guidelines for selecting the relevant visualization technique is provided online. The generated plots or maps are then displayed on the interface which can be downloaded by the user. Specifically, further interpretation of boxplots, containing the summary of statistics (*i.e.*, median, interquartile range etc.) is provided along with the visuals. Next, the datasets can be analyzed via unsupervised or supervised techniques depending on the purpose of the study. For untargeted analysis, clustering with hierarchical, k-means, and deep learning techniques are utilized. For targeted analysis, where the output of certain experiments is known and used for training models, supervised learning approaches are chosen. Specifically, for the datasets with discrete type of output (or label), classification techniques are used. Current classification techniques include Support Vector Machines (SVM), Random Forest (RF) Algorithm, and logistic regression. Whereas if the output of the dataset is continuous, regression techniques are employed. Here, in addition to SVM and RF Algorithm, interpolation (*i.e.*, Kriging, radial basis functions) and multivariate regression techniques (*i.e.*, linear, quadratic) are employed. The analysis selection is guided by the collaboration between the Data Science Core personnel and individual research projects. Once the data analysis methodology is established for a specific type of data, custom tools are generated and implemented within the platform. This automates the workflow across the Center, minimizes repetitive efforts, thus increasing the overall efficiency.

It is important to note that the large (*i.e.,* exposomics and imaging) datasets generated by the two biomedical research projects under TAMU SRP are in high dimensional space. This necessitates the use of dimensionality reduction techniques along with the aforementioned data analysis methodologies. To this end, numerous dimensionality reduction methodologies are implemented in the computational platform. These include

Principal Component Analysis, Chi-squared test, built-in feature ranking algorithms of RF and in-house developed SVM-based feature selection algorithms (Onel et al., 2018b).

3. Motivating Example

Here, we present a motivating example from TAMU SRP Project 4 to showcase the use of the developed computational platform. This project focuses on understanding the hazardous effects of environmental contaminants and mixtures that may interfere with proper function of the human endocrine system, causing several adverse health effects (*i.e.,* reproductive, developmental, metabolic etc.) due to modulations in hormone nuclear receptors' action. Hence, Project 4 personnel develop single-cell high throughput microscopy experiments with associated image analysis and informatics, thus producing high dimensional imaging data to fingerprint the endocrine disruptor potential of chemicals and environmental mixtures, whereas Data Science Core personnel use the generated data to build predictive models that classifies and quantifies the endocrine disruptor potential. Below, the development of data-driven models that predict potential activity of chemicals on a prototypical target, the estrogen receptor (ER), and their use through the computational platform are described in detail.

In order to establish a framework, 45 known chemical compounds (agonists, antagonists and inactive for the ER) used by the United States Environmental Protection Agency (US EPA) are utilized to determine the effectors of ER action (Judson et al., 2015). The GFP-ERα:PRL-HeLa cell line, and its derivatives, is an engineered model that allows multi-parametric simultaneous measurements of many important features, including, ligand binding, DNA binding, chromatin remodeling and transcriptional output, required for the activation of Estrogen Receptors (ER) (Szafran et al., 2017). This high throughput microscopy assay is used to test the responses to the EPA 45 reference compounds as well as to the control agonist 17β-estradiol (E2) and antagonist 4-hydroxytamoxifen (4OHT). The effect of these test chemicals can broadly be classified three-fold: (i) agonist (which elicits a positive response of the ER signaling pathway – akin to E2), (ii) antagonist (mimicking a response like 4OHT), or (iii) inactive. By treating the cells with a six-point dose-response of these compounds, high throughput imaging data is generated and analyzed. This yields a data matrix of 180 (4 measurements for each 45 compounds) by 70 descriptors (features). Each descriptor considers various aspects of the ER pathway (*i.e.,* Is the ER level changing? Does ER bind to DNA? How much chromatin remodeling happens? etc.). This dataset is later passed to the Data Science Core for further analysis and for modeling the ER disrupting potential of the tested compounds. The details on model generation and step-by-step use of the developed model within the computational platform are provided below.

Step 1 – Data Quality Monitoring: As an initial step, the quality of the received experimental data is inspected by identifying any potential missing data. In this case study, there are no missing data. The complete dataset is analyzed to detect any potential outliers via hierarchical clustering algorithm with complete linkage methodology and Euclidean distance metric. Identification and removal of outliers is essential in order to ensure accurate model development. The results reveal "Reserpine" as an outlier, which has been removed from further analysis (Figure 2).

Step 2 – Normalization: The goal is to classify the compounds based on agonist/antagonist activity. To achieve this, inactive compounds must be separated prior

to normalization and model building. This is done by using a threshold for the cell population with a visible nuclear spot, signifying ER-DNA binding. Less than 10% of the cell population, that has a visible nuclear spot, are considered to be inactive and removed from further analysis. Then, the dataset is normalized in order to attain a consistent range per feature. Specifically, the order of magnitude of intensity related measurements significantly differ from measurements derived from nucleus shape. Therefore, normalization is performed by using Equation 1.

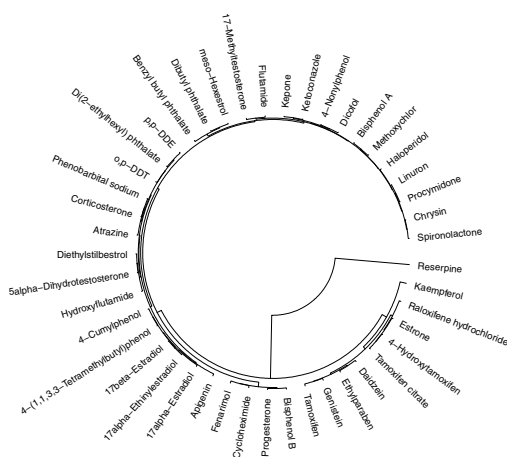
$$sample_{normalized} = \frac{sample - median(media)}{median(E2) - median(media)} \tag{1}$$


Figure 2. Outlier identification via hierarchical clustering. Reserpine is identified as outlier.

Step 3 – Predictive Modeling & Dimensionality Reduction: Once the data is pre-processed, cleaned from outliers and normalized, various classification algorithms are applied to build predictive models. In this study, RF algorithm is employed for the classification of agonist/antagonist activity and for identifying important descriptors through the built-in feature ranking property (Breiman, 2001). Tuning is performed and optimal number of trees is identified as 500. Final model is then built with the optimal number of trees by using 5-fold cross-validation. The top 10 informative features achieved during modeling are also reported in Table 1. The model accuracy before dimensionality reduction is achieved as 90%, whereas the end-model, the reduced model that use the top 10 informative features, has 92% accuracy.

Step 4 – Automation of Analysis: This end-model is then converted into an executable tool and implemented to the Python based environment of the computational platform.

4. Future directions

Development of the computational platform is an ongoing process. As new data are generated, corresponding tools and models are tailored, updated and incorporated in the platform. Current limitation of the platform is that the analysis only covers the Center projects and datasets. However, access to historical data provided by government agencies is crucial for comparative analysis in TAMU SRP (*e.g.,* ToxCast and Tox21 initiatives). Therefore, additional features will be provided for access to the relevant public data repositories through integration. Finally, one of the main goals of the Data Science Core is to serve as a basis to facilitate TAMU SRP data analysis and understanding. Therefore, training for the use of generated models and tools within the computational platform will be provided in collaboration with the Research Translation and Training Cores.

Table 1. Top 10 informative features for agonist/antagonist classification.

Rank	Measurement	Rank	Measurement
1	Nucleoplasm GFP Pixel Intensity Variance	6	Ratio of Nuclear Spot to Nucleoplasm GFP Intensity
2	Nuclear GFP Pixel Intensity Variance	7	Nuclear Spot GFP Pixel Intensity Variance
3	Nucleoplasm 90th Percentile GFP Pixel Intensity	8	Cytoplasm 75th Percentile GFP Pixel Intensity
4	Nuclear 90th Percentile GFP Pixel Intensity	9	Nuclear Spot 75th Percentile GFP Pixel Intensity
5	Nuclear Spot 90th Percentile GFP Pixel Intensity	10	Cytoplasm 90th Percentile GFP Pixel Intensity

5. Conclusions

In this study, development of a computational platform for the Texas A&M Superfund Research Center is presented. This platform provides on-demand, intuitive access to the custom-made data analysis tools and models developed for the environmental and biomedical projects within the Center. These analysis techniques are applicable to PSE problems. The ultimate goal is to establish an online data analytics services for rapid decision-making during environmental emergencies. This research is funded by U.S. National Institute of Health grant P42 ES027704 and Texas A&M Energy Institute.

Abstract

Atomic layer deposition (ALD) is a gas-phase coating technique that can be used to coat nanoparticles in a fluidized bed reactor. ALD is based on the alternating supply of two precursors, which makes it an inherent dynamic process. We discuss a multi-scale, multi-phase mass transfer-diffusion-reaction model capable of predicting the evolution of surface coverage of particles at different local operating conditions. The dynamic ALD-reactor model can be extended with operational scenarios. The reactor design combined with the scenarios has many degrees of freedom, yielding ample opportunities to optimize the process with efficient utilization of precursors.

Keywords: particle technology, nanotechnology, fluidization, ALD, nanoparticles

1. Introduction

Nanostructured particles (e.g., core-shell nanoparticles or nano-decorated micro-particles) have high a potential in applications such as catalysis and energy storage, but also in medicine and food. However, from designing products incorporating nanostructuring to produce them in large quantities is not trivial. Gas-phase coating using atomic layer deposition (ALD, a variant of chemical vapour deposition) can be used to provide the surface of a particle with either an ultrathin continuous coating or a decoration of nanoclusters. When carried out in a fluidized bed or a pneumatic reactor, ALD is an attractive way of producing nanostructured particles with excellent scale-up potential (Salameh et al., 2017). Even nanopowders can be treated with this process. This is facilitated by the fact that during fluidization they are not present as individual particles but as very dilute agglomerates of several hundreds of microns.

2. Atomic Layer Deposition in a Fluidized Bed

Atomic layer deposition (ALD) is a gas-phase coating technique that is being increasingly used in the semi-conductor industry to provide microchips with coatings on the order of 1-10 nm. It enables digital control over the amount of deposited material by relying on sequential self-limiting surface reactions. In ALD the compound to be deposited is synthesized directly on the substrate surface instead of being deposited from the vapour phase as in other thin film techniques such as chemical vapor deposition (CVD), from which ALD is derived. The synthesis of the desired compound is typically split into two

steps, each step follow by a purge. Each reaction step involves self-saturating chemisorption reactions between a precursor and the substrate surface. The precursor is provided for a certain period of time, which is typically called the pulse time. The purge step after the precursor pulse is crucial to preserve the self-limiting nature of ALD reactions, as it prevents the intermixing between different precursors, and between precursors and reaction by-products, which might result in uncontrolled deposition. By repeating these steps in a cyclic fashion one can grow the desired material with a resolution set by the amount of material deposited in each cycle referred to as growth per cycle (GPC), which is usually a fraction of a monolayer. This in principle translates into an atomic-level control over the material properties (Van Bui et al., 2017).

Since ALD is a surface-driven process, its use is not limited to wafers and other flat substrates, but it can also be used to obtain conformal coatings on substrates with complex geometries such as high-aspect-ratio structures for electronic devices, porous media and powders (Van Bui et al., 2017, Longrie et al., 2014, Puurunen, 2005). Especially its application to powders is interesting: 70% of the industrial processes involve powders, and there is an increasing demand for nanostructured powders. By applying ALD to a fluidized bed, we have a precise, versatile and scalable way of making such powders.

3. Modelling ALD in a Fluidized Bed Reactor

Fluidized bed ALD is an interesting process from a dynamics point of view, since the fluidized bed dynamics (gas residence time and particle mixing ~ seconds) is combined with very fast ALD reaction kinetics (<< 1s) and relatively slow precursor pulse times (~ minutes), in order to provide enough precursor molecules to cover all surface. In order to analyze the interplay between these phenomena, we developed a multiscale model to describe this process (Grillo et al., 2015), which will be briefly recapped here.

Our dynamical model captures the essential features of the coupling between the precursor transport, from the reactor- to the particle-scale, and the kinetics of the ALD surface reactions. During ALD in fluidized bed reactors, the precursor transport takes place on at least three different length scales: (1) from the inlet of the reactor throughout the bulk of the gas phase, (2) from the bulk of the gas phase to the outer surface of the particles, and (3) from the outer surface of the particles to their inner porous structure. We therefore describe the precursor transport via two sub-models: the one describing the transport across the length scales (1-2), which we refer to as the "reactor-scale", and the second describing the transport within the inner structure of the particles (3), which we refer to as the "particle-scale". Next to the precursor transport we also account for the precursor consumption arising from the gas-solid reactions taking place on the surface of the particles. In particular, to retrieve the self-limiting nature of ALD surface reactions our model also incorporates the detailed balance of the surface coverage of active sites prescribed by the stoichiometry of the chemistry of choice.

The reactor-scale model is based on the two-phase theory of bubbling fluidization. The latter accounts for the uneven distribution of gas within a fluidized bed of cohesive

powders such as many nanostructured particles. It assumes that the gas flow at the reactor inlet is distributed between two phases: the emulsions phase, characterized by a high density of particles, and the bubble phase, which instead contains only gas. The gas flow in the bubble phase is approximated to be plug flow; the emulsion phase is assumed to be fully mixed. Furthermore, the two phases exchange precursor through interphase mass transfer mediated by both diffusion and convection, and the precursor can reach the particles only in the emulsion phase through mass transfer. The reactor-scale precursor transport model therefore translates into the following system of differential equations:

$$\frac{\partial C_b}{\partial t} + u_b \frac{\partial C_b}{\partial z} = -K_{be}(C_b - C_e) \tag{1}$$

$$\varepsilon_e \frac{dC_e}{dt} = \frac{u_e}{H}(C_{in} - C_e) + \frac{K_{be}\delta}{H(1-\delta)}\int_0^H (C_b - C_e)dz - K_{ga}\frac{6(1-\varepsilon_e)}{d_p}\left(C_e - C_p|_{r=R_p}\right) \tag{2}$$

where $C_b, C_e, C_p|_{r=R_p}, C_{in}, u_b, u_e, \varepsilon_e, \delta, z, H, K_{be}, K_{ga}$ are the concentration of precursor in the bubble phase, in the emulsion, at the particles outer surface, at the reactor inlet; the gas velocity in the bubble, and in the emulsion; the gas volume fraction in the emulsion phase; the total volume fraction of the bubble phase; the vertical distance from the inlet of the reactor; the total height of the reactor; the bubble-to-emulsion mass transfer coefficient; and the gas-to-particle mass transfer coefficient, respectively.

The precursor transport at the particle-scale is modeled in terms of diffusion and reaction of dilute species within porous spheres. Nanostructured particles such as nanoparticle agglomerates may present a hierarchical porous structure: pores of different sizes at different length scales. This means that the transport model should take into account that the diffusion rates are a function of the position within the pore network. Nevertheless, if the transport through the pore network is limited along a preferential direction (e.g., the radius of the nanoparticle agglomerate), then its description can be reduced to a diffusion problem within mono-dispersed porous media in spherical coordinates:

$$\epsilon_p \frac{\partial C_p}{\partial t} = \frac{D_p}{r^2}\frac{\partial}{\partial r}\left(r^2 \frac{\partial C_p}{\partial r}\right) + g(C_p, \boldsymbol{\theta}) \tag{3}$$

$$D_p \frac{\partial C_p}{\partial r}\Big|_{r=R_p} = K_{ga}\left(C_e - C_p|_{r=R_p}\right) \tag{4}$$

where $C_p, D_p, r, R_P, \varepsilon_p, g, \boldsymbol{\theta}$ are the concentration within the particles, the diffusion coefficient, the radial distance, the radius of the particle, the particle porosity, the reaction term arising from the surface reaction kinetics, and the surface coverage of the active sites, respectively. As already argued in our previous work (Grillo et al., 2015), this treatment is suitable for describing the precursor transport through both nanoparticle agglomerates and nano-porous particles presenting mono-dispersed pores.

The precursor model at the particle scale is coupled to the kinetics of the ALD surface reactions via the evolution of the surface coverage of the active sites:

$$\frac{\partial \boldsymbol{\theta}(\mathbf{r})}{\partial t} = f(C_p(r), \boldsymbol{\theta}, \mathbf{v}) \tag{5}$$

where $\mathbf{v}$ are the reaction rates associated with the surface reactions. The latter balance can assume varying degree of complexity depending on the number and nature of the active sites and of the gas-solid reactions involved in the surface chemistry behind the ALD scheme of choice.

4. Operation

The ALD fluidized bed reactor is by nature operated in a non-stationary way: precursor pulses are alternated with purges by inert gas. Figure 1 gives a schematic of the operation: after loading the reactor with particles, a precursor pulse is given (e.g., a metal precursor), then a purge with inert gas (typically nitrogen) to remove byproducts and possible excess precursor, followed by a pulse of the second precursor (e.g., an oxidizer), and finally again a purge with inert gas. The length of the pulse and purge periods depends on parameters such as surface area of the substrate, concentration of the precursors, and reaction rate. The precursor pulse and purge periods typically last a few minutes.

The precursor pulse and the purge step are characterized by several processes that take place at different time scales. Analyzing the relative order of magnitude of such time scales offers a clue into the scalability and controllability of the process. With regard to the precursor pulse, we already shown through a time scale analysis that all the relevant chemical and physical processes are typically faster than the rate at which the precursor is supplied by as much as five orders of magnitude. This allows one to tailor the precursor pulsing time such that just enough precursor is being supplied to for saturating all the available surface. In other words, no precursor will be wasted.

A key aspect that our model currently does not take into account is the time scale associated with the purging of excess precursor and reaction by-products. In fact, as already pointed out elsewhere (Onn et al., 2018), the purging step in ALD on powders is particularly cumbersome compared to ALD on flat substrates. This is mainly due to two phenomena that slow down the purging process: (1) capillary condensation of precursor within small pores and (2) delayed desorption kinetics caused by the fact that, once desorbed, a molecule has a high probability of adsorbing on another location, either within the porous structure of the same particle or even on other particles within the fluidized bed, before leaving the reactor. The purging dynamics during ALD on powders certainly merits investigation because, on the one hand, the effective purging of unreacted precursor is essential to the self-limiting nature of ALD, and on the other hand excessively long purging times undermine the overall throughput of the process. The model presented here represents a starting point in this regard because it can be readily integrated with a set of equations describing the desorption kinetics of excess precursor.

The amount of precursor to be fed is determined by the surface area in the reactor. Often, it is not possible to exactly know this quantity. In that case, it can be attractive to monitor the outlet of the reactor for a breakthrough of the precursor, e.g. by a mass spectrometer. Since the precursor concentration in the outlet approaches a block wave (Grillo et al., 2015), it is possible to quickly respond to a decrease in precursor concentration.
Figure 1. Schematic of the operation of a fluidized bed reactor for ALD

5. Dynamic reactor model with operational scenarios

The reactor operation with its sequence of precursor additions and pulses can be modelled by including the species mass balances, the energy balance, and the transfer and reaction rate equations. The result is a mix of partial differential equations for the bubbly phase, ordinary differential equations for the emulsion phase with algebraic equation for rate laws. The resulting reactor model is written in a compact way, where $x(z,t)$ represents the internal physical state (concentrations, temperature, pressure and fluxes) of all matter (in gas & in solid particles) in the reactor at position z at time t:

$$\frac{\partial x}{\partial t} = f\left(\frac{\partial x}{\partial z}, x; p, d\right) \tag{6}$$

The physical parameters are denoted by p, while d is the set of the reactor design parameters.. The model equations are first-order in the spatial derivative of the states as shown in eq. (1). The radial coordinate (r) and the associated concentration dependency in eq. (3) and (4), are assumed to have been approximated by discretization or by orthogonal collocation, considerably extending the number of states at position z.

There is a boundary condition at entrance $z = 0$: $x(0, t) = g(t)$ (7)

as well as an initial condition for $t = 0$: $x(z, 0) = x_0$ (8)

Let this initial condition correspond to a fully fluidized bed in a steady state at the end of the loading, just before any precursor addition will start. The particles are supposed to be in a clean state at $t = 0$.

During the sequence of precursor additions and pulses the model equations remain invariant. It is the inlet boundary condition that changes per addition and pulse. Let the sequence of additions and pulses be denoted by j ($j = 1, 2, …N$), while the starting time of inlet operation j by T_j and it is running till time T_{j+1}. For inlet operation j one has:

Inlet condition: $x_j(o, \ t) = g_j(t)$ for $T_j < t \le T_{j+1}$ (9)

Initial condition: $x_j(z, \ T_j) = x_{j-1}(z, \ T_j)$ for $0 < z < H$ and $t = T_j$ (10)

The inlet condition reflects the feeding conditions during inlet operation j, while the initial condition for this operation j is equal to the final state at the end of the previous operation j -1. In pulsing intervals the inlet concentrations of precursors are zero.

The product quality at the end of the last operation, pulse $N(Q_N)$ can be related to the process state $x_N(H,T_N)$:

$$Q_N = h(X_N(H, T_N)) \tag{11}$$

Given the operational policies as the set $\{g_j(t), T_j \mid j = 1, .. ,N\}$ and the initial condition (8) one can simulate the evolution of states $x(z,t)$ over time t by means of (6), (9) & (10). Then it becomes possible to perform sensitivity analyses of the end state, $x_N(H,T_N)$ with respect to the:

- physical parameters (p);
- design parameters (d),
- the starting times of pulses $\{T_j; j=1, .. , N\}$ and
- piece-wise constant pulse inlet conditions $\{g_j(t) = g_j \ ; j=1, .. , N\}$.

Furthermore one can analyse operational features such as stability and system time constants by determining the eigenvalues of the Jacobian matrix of the differential equations at reactor exit $z = H$. The ultimate objective is, given a certain product specification (Q_N^*), to obtain an optimum operational policy $\{T_j^*, g_j^*, j = 1, .. , N\}$ and reactor design (d^*). I.e., an optimum is sought for an economic objective function, while making full use of the precursors. The many degrees of freedom process has, likely make it sustainizable (Jorat & Manousiouthakis, 2018): for the right set of parameters, it can be operated in a sustainable manner.

6 Conclusions

The typically fast kinetics of ALD surface reactions enable the complete uptake of the added precursor, even in the limit of high surface coverages. This has been shown by multi-scale modelling of physical phenomena in the reactor. The same multi-scale model used to analyze the precursor utilization is also amenable to the incorporation of the desorption kinetics of excess precursor. Such extended model can inform the choice of the optimal purging time. The alternation of precursor pulses and purging steps translates into many degrees of freedom. These can be used to optimize the process in line with a given economic objective function, while ensuring nearly full consumption of the supplied precursors. A mathematical model of the reactor with its operational scenarios is formulated as the starting point for such optimizations.

Abstract

In a solar power tower plant, solar radiation is reflected by the heliostat field and concentrated in the receiver at the top of the tower to provide energy for conventional thermodynamic cycle. For the heliostats composed of small facets, heliostat canting, which means applying specific rules for the orientation of single facets, can reduce the size of reflected energy spot and increase the concentration ratio and the optical efficiency of the heliostat filed. An optimization based on the paraboloid canting method is presented in this paper. The facets are aligned to fit the paraboloid to get a minimal spillage lost. A two-stage method combining Particle Swarm Optimization (PSO) and direct search method based on quadratic fitting model is designed to solve the optimization problem. The simulation results of two real plants demonstrate that the canting method with the optimal parameter can reduce the spillage lost significantly.

Keywords: Solar power tower plant, Heliostat canting, PSO, Direct searching optimization, Quadratic fitting model.

1. Introduction

Concentrated solar power (CSP) technologies offer promising options for high efficiency solar energy applications. Of all CSP technologies available, the solar power tower (SPT) can achieve higher temperature up to 1000ºC and hence higher efficiency (A.Boretti et al, 2017). In a SPT plant, the solar radiation is reflected and gathered by an array of mirrors called heliostat field to the aperture of receivers to form high-temperature steam.

A large heliostat is usually composed of several small flat facets and the power reflected by a flat mirror creates a large energy spot on the receiver plane due to the sun shape and various errors, such as optical, tracking, and positioning. This usually causes spillage lost, that part of the energy spot is out of the receiver area, and reduces the heliostat field efficiency. Therefore, the alignment of facets in a specific orientation on the heliostat frame, usually called heliostat canting, influences the focusing performance of the heliostat significantly. Applying specific rules for the orientation of single facets does not necessarily mean additional cost, since also standard canting methods require precise and controlled orientation of the facets (Buck and Teufel, 2009). On the other hand, the reduction of the spot size can decrease the spillage lost and provide heliostat aiming strategy more operating choices, thus a higher optical efficiency of the heliostat field and a better power distribution on the receiver can be achieved.

For the heliostat with azimuth-elevation tracking, traditional canting methods include on-axis canting and off-axis canting. Jones (1996) investigated the difference of the two strategies and concluded that off-axis canting can achieve slightly higher efficiency but it depends on the appropriate canting date and time. Moreover, dynamic off-axis canting, in which the facets are actively controlled such that the center of each facet is always perfectly focusing, is concerned in simulation and shows a remarkable reduction of spot size (Bonanos and Noone, 2012), but it's complex and costly in practical applications. Another canting method is aligning the facet normals parallel to the corresponding surface normals of a paraboloid. Buck and Teufel (2009) compared the three methods above and paraboloid canting gets the best result. However, no optimization method is employed to ensure the optimal alignment for the entire year in these methods.

An optimization of heliostat canting based on paraboloid pattern is presented to find the minimum annual spillage. In section 2, the Monte Carlo raytracing method is introduced and the optimization model is built. A two-stage method combining PSO and direct search method based on quadratic fitting model is designed to solve the optimization problem in section 3. Section 4 explores the practical applications of the proposed method in two heliostat fields, namely a test small heliostat in Hangzhou, China, and the large heliostat of PS10. Finally, conclusions are drawn and future research is indicated in Section 5.

2. Optimization model

2.1. Flux distribution on the receiver

The calculation of the flux distribution on the receiver surface is fundamental for the design and operation of a solar power tower plant. The sun is a disk rather than a point observed from any place on the earth. Therefore, the incident rays can't be considered parallel but a group of light described by the sun shape. The common way to calculate the flux distribution on the receiver can be divided into two classes, raytracing approaches and analytical approaches. Considering the high accuracy, a raytracing process using Monte Carlo method to address the sun shape is employed in this paper. An empirical sun shape model proposed by Walzel et al (1977) is adopted to evaluate the solar energy flux density $S(\alpha)$ for different values of the solar angle α:

$$S(\alpha) = \begin{cases} S_0 \left[1 - \lambda (\dfrac{\alpha}{\alpha_s})^4 \right], & \alpha \leq \alpha_s \\ \qquad 0 \qquad , & \alpha > \alpha_s \end{cases} \tag{1}$$

where S_0 is a parameter related with the direct normal irradiance, λ=0.5138 is a constant, α_s=4.6 mrad is half the angle of the light cone and the solar angle α is the angle between the vector QP and QO as shown in Figure 1 and P is a point on the solar disk.

Consequently, a large number of rays are produced depending on the probability of the energy flux density by Roulette Wheel Selection Principle. Figure 2 illustrates the flux distribution of the solar disk by random points, where the closer the points appear to the center of the sun, the greater the number of the points is. In the raytracing process, a set of random points are generated on the heliostats and each point reflected a group of sun light illustrated in Figure 2.
Figure 1 solar disk and solar angle
Figure 2 solar flux density

The raytracing method, however, needs huge amount of sun light be traced to get the accurate result and it is a time-costing process. Therefore, a parallel implementation of this process is utilized based on CUDA platform to speed up the simulation.

2.2. Paraboloid canting optimization

As mentioned above, the large reflected flux spot will cause spillage lost. A paraboloid canting method can be applied to improve the situation. The objective of the optimization problem is described as:

$$\min_{a,b} \ f(a,b) = \sum_{t=1}^{n_s} \sum_{i=1}^{n_f} \left[1 - \frac{E_{t,i}^{in}(a,b)}{E_{t,i}(a,b)} \right] \tag{2}$$

where n_s and n_f are respectively the sample number in a year and the facet number, $E_{t,i}(a,b)$ is the total power reflected by the facet i at sample time t when aligned to fit the paraboloid determined by the parameters (a, b), and $E_{t,i}^{in}(a,b)$ is the part in the receiver area. The objection function represents the spillage lost of the specific heliostat for an entire year. The facets normal vectors are determined in the way showed in Figure 3. For the facet center at position (x, y, z) in the heliostat coordinate, x and y are predetermined by heliostat size and facet numbers, and z is calculated through the standard paraboloid equation and then the facet normal vector is set to the surface normal vector at this point. There are gaps between adjacent facets to ensure that no collision occurs when applying different canting angles.
Figure 3 paraboloid canting

More than 500 samples are calculated to ensure the result behave well in the entire year. The sampling interval is three days and five or six uniformly spaced times are chosen in each sampled day according to the day length. The reflected spot at each sample time is obtained by Monte Carlo ray tracing method based on GPU. As the objective function is calculated through raytracing, the derivatives are not available. Also the high time cost of objective function evaluation and the noise of Monte Carlo method bring difficulties to the solving process.

3. Optimization algorithm

A two-stage method combining PSO and direct search method based on quadratic fitting model is designed to solve above optimization problem.

PSO is a metaheuristic as it makes few or no assumptions about the problem being optimized and can search very large spaces of candidate solutions. The output of this algorithm, with parameters selected appropriately can converge to the neighbourhood of the optimum after several iterations. More details about PSO can be found in Bonyadi and Michalewicz (2017). The fitness of swam is evaluated in each iteration and the rate of convergence falls down as the particles move to the neighbourhood of the optimum.

A direct search method with trust region is combined to find the optimal result in the neighbourhood of the preliminary result offered by PSO. The trust region method behaves well in the search of small scale so that the times of objective function evaluation to find the final optimal result can be reduced significantly.

During the iteration, a cheaper model is built around the current optimal point in place of the real expensive one. There are several research and optimization solver (Powell, 2007) using quadratic interpolation model. In this problem, however, due to the noise in the objective function evaluation, the interpolation may not represent the real model well, which leads to a slow convergence process or even to a failure. Thus, the quadratic approximation model, which is more robust to the noise, is used in the trust region. The algorithm procedure is as follows:

Step 1. Initialization: Choose an initial trust region radius $\Delta_0>0$ and an approximation set Y with L points derived from PSO. Determine $x_0 \in Y$ such that $f(x_0)=\min_{y \in Y} f(y)$.

Set values for parameters $\eta \in (0,1)$, $\theta_0 \in (0,1)$, $\theta_1 \in (1,2)$, maximal number of iterations k_{max}, error tolerance ε , maximal fitting error E_{max} and upper limit of the cardinality of the approximation set L_{max}. Set $k=0$.

Step 2. Using the current approximation set Y, build the quadratic fitting model $m_k(x)$ and compute the minimal point x_k^+ within the trust region $B_k = \{x_k + s \mid s \in R^n, \|s\| < \Delta_k\}$ such that $m_k(x_k^+)=\min_{x \in B_k} m_k(x)$. Compute $f(x_k^+)$ and the ratio:

$$\rho_k = \frac{f(x_k)-f(x_k^+)}{m_k(x_k)-m_k(x_k^+)} \tag{3}$$

Step 3. Update the approximation set and the trust region radius. For the successful step that $\rho_k > \eta$, include x_k^+ in Y and check the existing points to drop the ones far away from x_k^+ . Set $\Delta_{k+1} = \theta_1\Delta_k$. For the unsuccessful step that $\rho_k \leq \eta$, add more sample points to Y and set $\Delta_{k+1} = \theta_0\Delta_k$. The point that maximizes the qualitative index $\delta(x)$ is added to Y until the fitting error is less than E_{max} or the cardinality of the approximation set $L> L_{max}$. $\delta(x)$ is described in Eq. (4).

$$\delta(x) = \sum_{j=1}^{L} \lambda \|x - x_j\| + (1-\lambda)(S(x) - S_j(x))^2 \tag{4}$$

where x_j represents existing point in *Y*, and $\left\| x - x_j \right\|$ is the Euclidean norm, which is used to place new points in relatively unexplored region and as far away from the existing points as possible. $S(x)$ is the fitting model built using all points in set *Y*, $S_j(x)$ is the fitting model built using all points except point x_j. The impact of locating a sample point in the neighbourhood of x_j on $S(x)$ is measured in this way. With the weighting factor $\lambda \in (0,1)$, a new point can be placed to achieve space filling and high impact on the current model, without evaluation of the real objective function.

Step 4. Update the current iteration and check for convergence. For the successful step, set $x_{k+1} = x_k{}^+$, else $x_{k+1} = x_k$. Increase *k* by one and go to step 2 until the termination criterion, $k > k_{\max}$ or $\left\| x_{k+1} - x_k \right\| < \varepsilon$ is satisfied.

The minimal annual spillage lost can be achieved using the optimization method above.

4. Case studies

The optimization is applied to get the canting paraboloid parameter for a test heliostat in Hangzhou, China and different heliostats in PS10, Spain. The two cases represent the small size and large size heliostats respectively, both of which are serving in the existing SPT plant and are two different technologies with their own advantages and disadvantages. Three typical heliostats positions in the PS10 field are considered, the two exactly in the northern direction of the receiver with different distance and the other one located in the northwest.

The optimization results are listed in Table1. The position of heliostat is represented in the coordinates system that x-coordinate points to the east, y-coordinate to north and z-coordinate to the zenith. In order to reveal the influence by the heliostat canting, a receiver size smaller than the actual receiver in the plant is used. It should be noted that the receiver size is also adjusted to get the optimal canting angles in the optimization process though it's fixed in an established plant. Since the spot size of heliostat far away from the receiver and the one in the northwest side is much larger than that of the nearer one and the one exactly in the north, the formers need larger receiver size to obtain acceptable spillage lost. The objective function calculation times in the trust region process and time consumption of the programme running on the computer equipped with NVIDIA GeForce GTX 1080 are also shown in Table 1. The optimal result can be obtained in less than an hour for various heliostats.

Table 1 heliostats parameters and optimization results

Heliostat No.	location	size (m²)	facets number	receiver size	position	optimal (a, b)	minimal lost	objective evaluation times	time consumption
1	Hangzhou	2	3×3	1.69 m²	(12, -107, 1.2)	(28, 32)	7.17 %	17	2461 s
2				16 m²	(0.84, 110, 11)	(25, 23)	14.63 %	18	3018 s
3	PS10	121	7×4	36 m²	(0.84, 698, 52)	(55, 52)	15.19 %	15	2846 s
4				28 m²	(139, 138, 15)	(30, 26)	14.22 %	20	2961 s

The reflected spots of the heliostats at 8:00, 12:00 and 16:00 in 26th, April under the circumstances that the facets are aligned in on-axis canting, dynamic off-axis canting and in the paraboloid determined by the optimization result separately are illustrated in Figure 4. Compared with the on-axis canting, the optimal paraboloid canting method

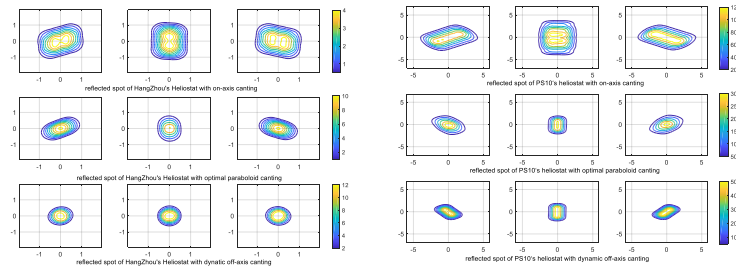
reduces the spot size remarkably. The spot sizes of the optimal paraboloid canting are slightly larger than that of the dynamic off-axis canting which nearly represents an ideal situation. More significant reduction of the spot size can be achieved for the larger heliostat with more facets. Actually, the spillage lost in PS10's origin receiver (168 m^2) can be decreased to zero using the optimal canting angle.


Figure 4 reflected spot of small heliostat (left) and large heliostat (right)

5. Conclusions

An optimization based on the paraboloid canting method is developed in this paper to reduce the reflected spot of the heliostats and improve the annual optical efficiency of the SPT plant. With the combined optimization method, the optimal result can be got at a low time cost, which is helpful when a large number of heliostats are designed in a SPT plant. The further research will be focused on the integrated optimization of the heliostat field and the receiver.

Effect of Non-Ideal Kinetics on Hybrid Reactive Distillation Models for Selectivity Engineering

Deepshikha Singh, Antarim Dutta, Ankur Gaur, Shabih Ul Hasan*

Department of Chemical Engineering, Motilal Nehru National Institute of Technology, Allahabad 211004, India

shasan@mnnit.ac.in

Abstract

Multi-reaction schemes comprise of highly non-ideal mixtures (such as alcohols, esters, aldehydes, ethers, water, etc.) can be quite often found in fine chemical industries. Previous work [Hasan et al., 2014] has looked at finding the designs for simple and complex hybrid RD columns targeting to obtain the desired selectivity for ideal kinetics and in the present work we extend it to cover non-ideal kinetics. In particular, it is found that in case of non-ideal kinetics the single feed hybrid RD models to be used are strongly dependent on the number of components involved in a multireaction scheme, contrary to our earlier work for ideal kinetics in which the hybrid RD models used were depends on the number of products that undergo further side reactions and is applicable for any number of components. The developed method is applicable to single reactant as well as multi-reactants single-feed hybrid RD columns, provided all the reactants should be saddle in the residue curve map and is limited to four components.

 Keywords: Hybrid Reactive Distillation, Non-ideal kinetics, Design, Selectivity

1. Introduction

Reactive Distillation (RD) which is a combination of reaction and distillation in a single functional unit can also be effectively used to obtain desired selectivity in multi-reaction schemes comprises of highly non-ideal mixtures. The present work concerns the design and selection of type of single feed hybrid RD models depending upon whether the given reaction kinetics is ideal or non-ideal. A van de Vusse type hypothetical reaction scheme having ideal and non-ideal kinetics is used as an example, with the capability of the new approach demonstrated in terms of its ability to provide promising designs of hybrid RD models to obtain desired selectivity in multireaction schemes.

2. Design Methodology

The methodology starts with non-reactive distillation column (non-RD) and then introduces the reaction related attributes. For non-RD, we use the concept of visualization of the locus of feed stage compositions (LFSCs) in 3D composition space. For reaction related attributes we view the column as a reactor and relate it to the conventional reactors for which geometric interpretation is well studied through the attainable region approach. Glasser et al. (1987) presented geometrical interpretation of CSTR in terms of process vectors viz. reaction and mixing. In order to know whether a point in the composition space is attainable or not, they derived a condition that the rate vector at that point is collinear with the mixing vector of feed and product stream. The component material balance of CSTR gives the required condition. It must be noted that the reaction takes place at the product composition in the case of CSTR. On the other hand, in an arbitrary reactor (R), if the composition at which reaction takes place is

different than the product composition, then the collinearity condition is no longer valid. The composition at which reaction takes place is dependent on the type of reactor. One can control this composition by introducing separation attributes as is done the case of reactive distillation.
Fig. 1. Analogy between Arbitrary reactor (R) and hybrid RD Column (HRD) with side draw

Now, as shown in Fig.1, let us consider a side draw hybrid column with single reactive stage. It may be noted that the reaction in the column does not take place at a composition corresponding to that of the product (P). The overall product composition is the one obtained by virtually mixing the distillate and bottom streams. The composition of the reactive stage depends on the distillation attributes such as reflux ratio, feed location, number of stages, etc. Therefore, the next exercise is to know – which are the points in the composition space that can be the potential reactive stage composition(s) giving the desired selectivity corresponding to the point of desired product composition. The following section determines the surface of such feasible reactive stage compositions.

2.1. Surface of Reactive Stage Compositions (SRSCs)

Consider an equimolar van de Vusse type reaction scheme Eq. (1) with one reacting component A having all the reactions irreversible, except B to A, with first, second and third reactions are of 1st order while the fourth reaction A to D is of 2nd order. The feed is pure reactant A and the kinetic rate constants are given by [$k1$ $k2$ $k3$ $k4$] = [2 1 1 3]. The non-ideal kinetics is given by Eq. (2) and for ideal kinetics (Table 1) the value of activity coefficients of all components is taken as unity.

$$A \underset{undesired\,(k_2)}{\overset{desired\,(k_1)}{\rightleftharpoons}} B \xrightarrow{undesired\,(k_3)} C$$
$$A \xrightarrow{undesired\,(k_4)} D \tag{1}$$

$$[r_A\ r_B\ r_C\ r_D] = [\ -k_1\gamma_A x_A^* - k_4\gamma_A^2 x_A^{*2} + k_2\gamma_B x_B^*,\ k_1\gamma_A x_A^* - k_2\gamma_B x_B^* - k_3\gamma_B x_B^*,\ k_3\gamma_B x_B^*,\ k_4\gamma_A^2 x_A^{*2}] \tag{2}$$

The material balances for components A and B on any arbitrary reactor are given by

$$x_{A,P} - x_{A,0} = \tau.\sum_{k=1}^{nR} r_{k,A}(x^*) \tag{3}$$

$$x_{B,P} - x_{B,0} = \tau.\sum_{k=1}^{nR} r_{k,B}(x^*) \tag{4}$$

where τ is the residence time and nR represents number of reactions

Divide (3) by (2) we get,

$$\frac{x_{B,P} - x_{B,0}}{x_{A,P} - x_{A,0}} = \frac{r_B}{r_A} = \frac{k_1\gamma_A x_A^* - k_2\gamma_B x_B^* + k_3\gamma_B x_B^*}{-k_1\gamma_A x_A^* - k_4\gamma_A^2 x_A^{*2} + k_2\gamma_B x_B^*} \tag{5}$$

where $x_{i,p}$ is the product composition of component i, $x_{i,0}$ is the inlet composition of component i and x^* denotes the compositions at which the reaction takes place in the reactor. The LHS of Eq. (5) is the slope of line joining points A (x_{A0}, x_{B0}) and P (x_{AP}, x_{BP}) as shown in Fig. 2. It should be noted that point P is on ABD plane in Fig. 2 and since Eq. (5) is independent of x_{CP}, its value is not required for plotting the SRSCs.
Fig. 2. Surface of reactive stage compositions (SRSCs).
Fig. 3. Shifting of SRSCs with variation in desired selectivity

Hence, for any desired point P in the composition space, Eq. (5) gives a relation between x_A^* and x_B^*. One can plot the SRSCs for the quaternary mixture by taking a meshgrid of [x_A^*, x_C^*] and plot x_B^* compositions [by solving a non-linear equation (Eq. 5) at each point of meshgrid; with γ being calculated by *WILSON* model] as shown in Fig. 2. Figure 3 indicates that with increase in the desired selectivity keeping conversion fixed, the feasible reactive stage compositions get reduced.

2.2. Effect of non-ideal kinetics and thermodynamic models on SRSCs
Fig. 4. Effect of non-ideal kinetics on SRSCs for ZEO and AZEO mixtures.
Fig. 5. Effect of thermodynamic models on SRSCs for ZEO and AZEO mixtures.

In case of azeotropic systems, non-ideal vapor-liquid equilibrium and distillation boundaries [for multicomponent azeotropic mixture in Fig.4, see Hasan et al., 2014; Section 4 (Example 3)] are responsible for the contraction of the feasible reactive stage compositions required for the design of hybrid RD column. Figure 4 shows that if non-ideality is present in kinetics as well then these feasible reactive stage compositions reduces further and thereby increase the design complexity for RD systems. Figure 5 indicates that there is no effect of thermodynamic models (WILSON & NRTL) on the surface of reactive stage compositions both for zeotropic as well as azeotropic mixtures.

2.3. Selection of Single Feed Hybrid RD Models

Hasan et al. (2014) proposed a design algorithm for ideal kinetics in which the type of hybrid RD models to be used in order to obtain the feasible design of desired selectivity is strongly dependent on the nature of reaction schemes i.e. whether in a complex reaction scheme one, two or more products undergo further side reaction(s). If one product undergoes further side reaction, then simple hybrid RD column (SHRD) is capable to give desired selectivity and if two product undergoes further side reaction then hybrid RD column with side draw is to be used. In the present example (Eq.1) although only one product undergoes further side reaction, due to the presence of non-ideal kinetics it is found that the desired selectivity is achievable by using simple hybrid RD model in a three component multi-reaction scheme while for four components multi-reaction scheme hybrid side-draw RD model is needed. The design procedure of which is explained in the next section.

2.4. Design Procedure

Consider a simple hybrid side-draw RD column with one reactive stage (Fig. 6a) and a reactor-separator system (Fig. 6b). A systematic methodology that uses intersection of LFSCs with the selected reactive stage composition (X^*) to obtain feasible designs of desired selectivity using hybrid RD column for the reaction scheme given by Eq. (1) is described. The approach presented here exploits the fact that if we split the reaction and distillation attributes of the hybrid RD column (Fig. 6a), then the new configuration (Fig. 6b) gives the same performance as that of a hybrid RD column. If the feed stage in the RD column is the reactive stage, then the column profiles of non-RD and RD column coincide for the same distillation attributes. This would be made clear with the following example.
Fig. 6. (a) Hybrid (RD) column. (b) Reactor separator system (Non-RD).

A simplified equimolar van de Vusse type reaction scheme with only one reacting component with rate constants, [k1 k2 k3 k4] = [2 1 1 3] is chosen as an illustrative example (see Eq. 1). The reaction takes place in the liquid phase and the assumption of constant molar overflow is valid. Following are the proposed step-by-step design procedure to obtain desired selectivity using hybrid RD column with side draw:

Step 1: Select any point P (Fig. 2) according to the desired selectivity of intermediate product, B in the composition space. This point represents the overall output composition of hybrid RD column with side draw (Fig. 6b), obtained by virtually mixing distillate, side draw and bottoms streams. Hence, it can be considered as the feed to Non-RD column in Fig. 6a.

Step 2: Join point P (0.3, 0.275) with A (1, 0) to calculate the slope of line AP, and hence obtain the SRSCs using Eq. (5) as shown in Fig. 2.

Step 3: Select any X^* on the curve of SRSCs as shown in Fig. 2. For the present example we have selected $X^* = [x_A^* \ x_B^* \ x_C^*] = [0.52, 0.1934, 0.12]$.

Step 4: Find the composition of all the components in the hypothetical feed that is sent to the non-RD distillation column (Fig. 6b) by using the material balances given by Eq.

(7), Eq. (8) and Eq. (9). The composition of C is related to the extent to which individual reactions take place, which in turn depends on the Damkohler number (Da) number i.e. the ratio of characteristic liquid residence time to the characteristic reaction time (Eq. 6).

$$Da = \left(\frac{W_{cat} * k_{ref}}{F} \right) \tag{6}$$

We determine Da by applying material balance for either component A (Eq. 7) or component B (Eq. 8) for any arbitrary reactor in which reaction takes place at the selected composition, X^*. Further, by using material balance for component C (Eq. 9), one can find the composition of C in the feed to the distillation column. Composition of D can be obtained by summation equation.

$$x_{A,0} - x_{A,P} + Da\left(\frac{-k_1\gamma_A x_A^* - k_4\gamma_A^2 x_A^{*2} + k_2\gamma_B x_B^*}{k_{ref}} \right) = 0 \tag{7}$$

$$x_{B,0} - x_{B,P} + Da\left(\frac{k_1\gamma_A x_A^* - k_2\gamma_B x_B^* + k_3\gamma_B x_B^*}{k_{ref}} \right) = 0 \tag{8}$$

$$x_{C,0} - x_{C,P} + Da\left(\frac{k_3\gamma_B x_B^*}{k_{ref}} \right) = 0 \tag{9}$$

Step 5: Specify the number of stages and feed location (say N=12, Nfl=7th stage) with Reboiler as first stage. Side draw location depends on the volatility of that product whose composition is required to be adjusted through side draw to obtain the desired selectivity; in the present case it is component C. Hence, if the volatility of component C is less than the volatility of the reactant A then the side draw location is below the feed location (Sd= 6th stage).

Step 6: Find the operating parameters such that the feed stage of Non-RD column coincides with the selected reactive stage composition, X^*. To obtain this intersection draw the family of curves (FOC) representing LFSCs obtained for a range of distillate to feed ratio (D:F) and boil-up to feed ratio (V:F) ratios by choosing initially some arbitrary value of side draw to feed ratio (say SD=0.1) as shown in Fig. 7.
Fig. 7. FOC for a range of D:F at different values of V:F and S:F representing LFSCs.
Fig. 8. Identical column profiles in triangular diagram

Range of D:F can be decided based on whether or not one of the LFSCs crosses the curve of SRSCs containing selected reactive stage composition, X^*, while the V:F ratio can start from any small value till the performance becomes insensitive at higher values.

It should be noted that there is one curve that corresponds to the range of *D:F* at a given value of *SD* and *V:F*. Now if one considers the range of *V:F* too then a family of curves can be plotted. Fig. 7 shows three such families for a range of distillate to feed ratio (*0.1-0.5*) and boil-up to Feed ratio (*1-10*) at three different values of *SD*. It can be clearly seen in Fig. 7 that the reactive composition, *X** of interest lies in the vicinity of curves obtained for *SD*=0.2.

Step 7: Next step is to consider the range of side draw to feed ratio, near the value SD=0.2 and narrow down the ranges of *D:F* and *V:F* ratios based on the results shown in Fig. 7. The values of three operating parameters viz. *SD*, *V:F*, and *D:F* at which the exact intersection of feed stage of Non-RD column with the selected reactive stage composition, *X** is found are 0.22, 3.225 and 0.321, respectively. The column profile for Non-RD side draw column in 3D composition space (Fig. 8) is then plotted.

Step8: Obtain the column profile for RD, with the feed as pure A and the feed stage as the reactive stage, using the same design and operating parameters as used for the Non-RD case. The profiles coincide (Fig. 8) to indicate that the design is feasible. Hence, the desired selectivity for the given reaction scheme with non-ideal kinetics is attainable through hybrid side-draw RD column with design specifications given in Table 1.

Table 1. Design specifications for hybrid RD Models for ideal and non-ideal reaction kinetics

Kinetics Type	Ideal Kinetics [Hasan et al., 2014]		Nonideal Kinetics [Present work]	
Reaction Scheme	Eq. (1)		Eq. (1)	
Rate Constants	*[k1 k2 k3 k4] = [2 1 1 3]*		*[k1 k2 k3 k4] = [2 1 1 3]*	
Column configuration	Non-RD SHRD Model	RD SHRD Model	Non-RD Side Draw Model	RD Side Draw Model
Number of components, *NC*	4	4	4	4
Volatility Order	B > A > C > D	B > A > C > D	B > A > C > D	B > A > C > D
Number of stages, *N*	12	12	12	12
Feed location, *Nfl*	6th Stage	6th Stage	7th Stage	7th Stage
Feed flow rate, F	1	1	1	1
Side draw location, *Sdl*	-	-	6th Stage	6th Stage
Feed composition, *Xf*	(0.30, 0.275, 0.0701, 0.3549)	(1, 0, 0, 0)	(0.3, 0.275, 0.0816, 0.3434)	(1, 0, 0, 0)
Number of reactive stages, *Nr*	-	1	-	1
Location of Reactive stage, *Nrl*	-	6th Stage	-	7th Stage
Damkohler Number, *Da*	-	0.3641	-	0.4741
Distillate to feed ratio, *D:F*	0.3775	0.3775	0.321	0.321
Vapor to feed ratio, *V:F*	2.315	2.315	3.225	3.225
Side draw to feed ratio, *S:F*	-	-	0.22	0.22
End Compositions after mixing the distillate and bottom streams	(0.3, 0.275, 0.0701, 0.3549)	(0.30, 0.275, 0.0701, 0.3549)	(0.3, 0.275, 0.0816, 0.3434)	(0.3, 0.275, 0.0816, 0.3434)

3. Conclusions

A combined graphical-simulation algorithm for the design and selection of type of hybrid RD models is developed considering both ideal and non-ideal kinetics. For same reaction scheme, volatility order, and number of components it is found that for ideal kinetics SHRD and for non-ideal kinetics hybrid RD side draw model is capable to obtain the desired selectivity. The next step of the algorithm is to extend its applicability for mixtures (including multiazeotropic) containing more than four components.

Abstract

Wax deposition problems are an increasingly important research topic in the oil industry, as wells and pipelines become longer and heavier crude oils are explored. Much has been published within pipelines domain but information about such challenge in wells is much scarcer. Wax deposition is due to the cooling process, which occurs when oil flows from the high-pressure reservoir to the surface. Heat loss, with temperature reduction, induces wax crystallization and the subsequent well plugging. This leads to the decrease of well flowrates, and eventually causes the total blockage.

One of the goals of this work was to determine wax deposition by applying Aspen HYSYS, as a modelling tool and developing a numerical model in Matlab to face some limitations encountered in Aspen HYSYS.

One major accomplishment of the conceived Matlab model was being able to accurately consider internal pipe insulation, the effect of pipe-in-pipe, as well as the underlying geological conditions. Also, two comprehensive engineering solutions, including heating and insulation, were assessed for one oil well with proven wax deposition problems.

In conclusion, Aspen HYSYS is highly recommended for most applications since, beyond showing reliable results, is very versatile, user-friendly and has a vast database of worldwide oils' common properties. However, Aspen HYSYS does not accurately allow esteeming wax precipitation curve, nor the Wax Appearance Temperature, given the oil properties. This is quite a hindrance for wax deposition simulations and leads to the need for experimental data.

Keywords: Wax deposition, Paraffinic oil crudes, Flow Assurance.

1. Introduction

Among the naturally occurring hydrocarbons that compose crude oils are the alkanes, or paraffin hydrocarbons, with the chemical formula C_nH_{2n+2}. Groups of normal paraffins, with 16 or more carbon atoms, form crystalline solid substances (designated wax), when the fluid temperature decreases below the wax appearance temperature (WAT). As cooling proceeds, the dissolved paraffins align together and bind a solid crystalline wax structure. Such wax deposits reduce the net internal diameter and consequently affect the crude oil production (Averbuch, 2006).
Developing improved computational models can help to predict upcoming operational problems, by allowing to take preventive measures so that the losses caused by the well shutting down can be avoided (Coutinho et al., 2004).
This article will focus on the prediction of the wax precipitation from crude oils.

2. Methodology

Modelling wax deposition is a complex endeavour because it involves several disciplines, such as: chemistry, thermodynamics and fluid mechanics. In this case, Aspen HYSYS and Matlab were applied to perform the simulations. The modelling approach encompassed the following steps:

i. Experimental data was collected, so that a broad database of wax deposition measurements was synthesized. Then, using Aspen HYSYS, the experimental conditions were simulated;

ii. The results were compared with the gathered experimental data. A critical evaluation was performed, validating Aspen HYSYS models;

iii. Once observing Aspen HYSYS software limitations for the analysis purpose, a Matlab model was considered to overcome them;

iv. Matlab model was applied to a real case of a well. Finally, the model was used to assess a wide range of possible engineering strategies for avoiding or controlling wax deposition.

3. Aspen HYSYS simulation

3.1. Fluid characterization

Aspen HYSYS was used to simulate 8 published experimental data sets, presented in Rosvold's work (2008). The pipeline system, tested in this experiment, was composed by a horizontal pipe, with 5.31 m of length and an inner diameter of 51.70 mm. The temperature around this pipeline was kept constant and equals to 10 ºC. In these experiments, a condensate from the North Sea was used and its wax appearance temperature was 45 °C. The characteristics of each experiment and the wax precipitation curve are referred in the Table 1.

Table 1 – Rosvold's experiments data (Rosvold, 2008)

Lab. tests	Flow rate (m^2/h)	Inlet temp. (ºC)	Wax precipitation curve
A	5	20	
B	10	20	
C	15	20	
D	21	20	
E	25	20	
F	21	15	
G	21	30	
H	21	40	

To evaluate the wax deposition behaviour in time, as function of the flow rate and the oil inlet temperature, the graphs shown below were drawn considering the experimental data (Rosvold, 2008).
Figure 1 – Temporal evolution of wax deposition thickness for different flow rates and inlet temperatures.

For the same oil inlet temperature, the higher the flow rates are, the lower the wax deposition thickness will be. Maintaining the flow rate constant, the general tendency is to have fewer wax deposits as the temperature is higher.

3.2. Process flowsheet diagram

For this case, the steady-state model was performed in Aspen HYSYS, using the process flowsheet presented in Figure 2.
Figure 2 – Process flowsheet to simulate the wax deposition inside a pipe, using Aspen HYSYS

HYSYS contains a tool called pipe segment model, in which two of the following variables are required: inlet pressure, outlet pressure, or flow rate. Once two of these parameters are specified, the third will be computed. Furthermore, geometrical inputs need to be included, such as: length, elevation change, pipe diameter and material.

To calculate pressure and temperature, HYSYS uses an iterative routine to estimate these parameters. Once the inner pressure loop has converged, the outlet temperature is calculated, using the Eq. (1):

$$Q = U \times A \times \Delta T \tag{1}$$

Where, Q is the amount of heat transferred (W), U is the overall heat transfer coefficient ($W/(m^2 \cdot K)$), A is the outer heat transfer (m^2) and ΔT is the log mean temperature difference (K).

The wax equilibrium calculations were performed using the AEA model, given by the Eq. (2):

$$\ln K_i = \frac{\Delta h_i^f}{RT}\left(1 - \frac{T}{T_i^f}\right) + \frac{\Delta C_p}{R}\left[1 - \frac{T_i^f}{T} + \ln\frac{T_i^f}{T}\right] + \int_0^P \frac{V_i^L - V_i}{RT} \partial P \tag{2}$$

Where, K_i is the equilibrium constant, which is the ratio of concentrations of a particular component in the solid and liquid phase, Δh_i^f is the enthalpy of melting, R is the gas constant, T is the temperature, T_i^f is the melting temperature, ΔC_p is the heat capacity difference between solid and liquid, V_i^L is the molar volume, and P is the pressure.

Peng and Robinson Equation of State has been selected for its accuracy and the simplicity (Luo et al., 2014).

3.3. Analyses and Simulation Results

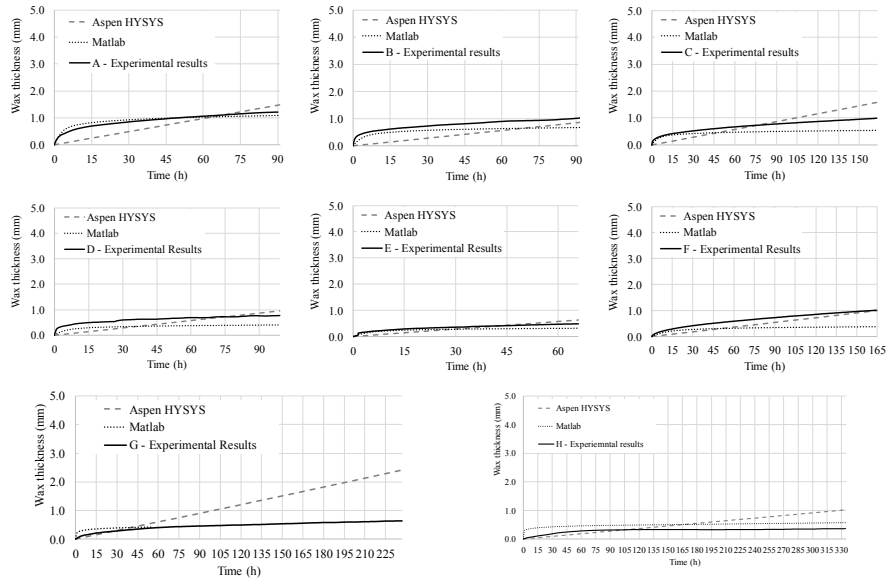
These eight experiments were simulated in Aspen HYSYS to understand the software ability to forecast the wax deposition in real scenarios. The results obtained were synthetized in the Figure 3.


Figure 3 – Aspen HYSYS and MATLAB simulation results and the Rosvold's experimental data

The maximum deviation between the experimental data and the simulated results happened in the experiment G. In this case, the relation between the wax deposition thickness and the inner radius obtained in laboratory experiments was 2.5%, while for the simulated results this relation was 9.3%.

A sensibility test was performed to understand the influence of the overall heat transfer coefficient (OHTC) on the wax deposition thickness. As it was expected for higher OHTC, the estimated wax deposition will be higher. Using the OHTC automatically determined by the software, the results from the simulations and the experimental differed no more than 6 mm.

Doing this sensibility test, it was possible to perceive that Aspen HYSYS has some limitations, namely, the impossibility to include the effect of internal pipe insulation, since only an external one is allowed.

The influence of pressure on the paraffin deposition is negligence when modelling this system, because the fluid pressure was not substantial. Nevertheless, this parameter can be relevant in other cases (Coutinho et al., 2004).

4. MATLAB simulation

4.1. Description and Methodology

MATLAB model most significant accomplishments are the ability to accurately consider internal pipe insulation, the effect of pipe-in-pipe (tubing plus casing), as well as the heat transfer for different geological layers around the well. These are some of the aspects that HYSYS does not allow simulating, yet. The procedure developed in MATLAB to determine the wax deposition inside the well is presented in Figure 4.
Figure 4 – Methodology to determine the wax deposition

Molecular diffusion, given by Eq. (3), was the chosen mechanism to model wax deposition, due to its most wide acceptance in the bibliography (Huang et al., 2015).

$$\frac{dm_i}{dt} = -\rho \times D_i \times A \times \frac{dw_i}{dT}\frac{dT}{dr} \tag{3}$$

Where, m_i is the mass, D_i is the effective diffusion coefficient, A is the deposition area, w_i is the weight fraction, r is the radial distance and i is the component i.

In order to consider the effect of insulation provided by the wax deposit layer, Eq. (4) was used for computing the overall heat transfer coefficient, U_{in} (W/(m². °C)):

$$\frac{1}{U_{in}} = \frac{r_{in}}{r_{deposit}}\frac{1}{h_{in}} + \frac{r_{in}}{k_{deposit}}ln\left(\frac{r_{in}}{r_{deposit}}\right) + \frac{r_{in}}{k_{pipe}}ln\left(\frac{r_{out}}{r_{in}}\right) + \frac{r_{in}}{r_{out}}\frac{1}{h_{out}} \tag{4}$$

In this equation, h_{in} is the inside convective heat transfer coefficient (W/(m². °C)), k_{pipe} is the thermal conductivity of the steel pipe, $k_{deposit}$ is thermal conductivity of waxes deposit (W/(m. °C)), h_{out} is the outside convective heat transfer coefficient (W/(m². °C)), $r_{deposit}$ is the distance between the centre and the deposit (m), r_{in} and r_{out} are the inner and outer pipe radius, respectively (m).

4.2. Fluid characteristics

This model considers fluid properties provided by Aspen HYSYS, which were determined by the pseudo-compounds estimated through the TBP curves (Cuadros et al., 2009). Viscosity laboratorial tests were also used to further tune the fluid model.

4.3. Analysis and Simulation results

Firstly, the results from MATLAB model were validated trough the comparison with Rosvold's experimental data. Estimated thicknesses are quite similar to those obtained experimentally, as presented in the Figure 3. There is, however, a slight tendency (of 0.6 mm, in maximum) to underestimate the thickness at the beginning and to overestimate (by no more than 0.3 mm, in maximum) as time progresses. The same MATLAB model was used to simulate one productive well. Also, two comprehensive engineering solutions, including heating and insulation, were assessed for one oil well with proven wax deposition problems. The geometric characteristics of the oil well and the simulated profiles are shown in the Figure 5.
Figure 5 – Well cross section characteristics and MATLAB simulation results for two scenarios

Assessing both scenarios, it is possible to conclude that the only one capable of maintaining crude oil temperature above the WAT is the heating solution. However, this technique can eventually damage the geologic formation (Newberry and Barker, 2013).

5. Conclusions

In conclusion, Aspen HYSYS is highly recommended for most applications since, beyond showing reliable results, is very versatile, user-friendly and has a vast database of worldwide oils' common properties. However, Aspen HYSYS does not allow esteeming wax precipitation curve, nor the wax appearance temperature, given the oil properties. This is quite a hindrance for wax deposition simulations and leads to the need for experimental data. The proposed methodology combines accurate and highly reliable Aspen HYSYS modelling with versatile Matlab programming to provide a novel approach for wax deposition estimation in wells. Allowing the consideration of internal pipe insulation, pipe-in-pipe and the different geological layers around the well effects into the numerical simulations is regarded as a major advantage for this proposal.

On the drawbacks side, both the Aspen HYSYS and the conceived Matlab model do not account for the effect of pressure on the wax precipitation curve nor the inside well pumping system effect onto the wax deposition dynamics. Thus, those are the model current restrictions. While conceived models' reliability and truthfulness has been observed against experimental data where the aforementioned restrictions do not play a major role, further developments on such matters are required for increasing the model applicability towards cases where pumping systems are used and significant pressure in the well lower length is observed. Such developments are ongoing.

Abstract

The choice of the employed solvent often strongly influences the performance of chemical processes. To obtain optimal process designs, we propose a method for the integrated in silico design of solvents and reaction-based processes. The search space of possible solvent molecules is explored by a genetic optimization algorithm which is directly linked to gradient-based process optimization. Thereby, the process performance of the designed solvent is evaluated. While most approaches for such integrated design problems are based on group contribution methods and limited to equilibrium properties, we here propose a quantum mechanics-based approach to capture reaction kinetics. The integrated design method is successfully applied to the design of solvent and process for a carbamate cleavage reaction. The presented method allows for efficient design of a large number of promising solvents within the integrated reaction solvent and process design.

Keywords: computer-aided molecular design, process design, quantum mechanics

1. Introduction

The performance of chemical processes largely depends on the occurring chemical reactions, which are in turn influenced by the choice of solvent (Reichardt, 1990). Thus, the selection of optimal solvents is essential in the design of reaction-based processes. As the number of potential solvents is theoretically unlimited, systematic solvent design methods have been developed. The success of such methods depends on the evaluation of candidate solvents. For a reliable evaluation, first, a sound prediction of solvent impacts on the reactions is essential and second, the objective used for the evaluation should reflect the performance of candidate solvents in the process.

The sound prediction of solvent impacts on reactions has been addressed by several solvent design methods (Papadopoulos et al., 2018). Struebing et al. (2013) calculate reaction kinetics from surrogate models fitted to few data points derived from quantum chemical calculations. Austin et al. (2018) propose a design method where reaction kinetics are predicted for every candidate solvent based on transition state theory and a correction term fitted to experiments. However, in these approaches, solvents are assessed based on reaction rate constants as design objective and the designed solvents are likely different

from those showing optimal performance in the chemical process. The approach proposed by Zhou et al. (2015) overcomes this disadvantage by employing a process model allowing for the process-based assessment of the designed solvents. However, the solvent impact on reaction kinetics is predicted with a simplified model fitted to few available experimental data points, which does not guarantee good extrapolation.

To overcome the limitations of previous approaches, we here propose an integrated reaction solvent and process design approach using a sound prediction of reaction kinetics combined with a process-based assessment of solvents. The required reaction rates are determined by fully predictive, quantum chemistry-based computations. Experimental data is not needed and only used for validation. To reduce the computational effort such that large molecular design spaces can be explored, we separate the computation of solvent-independent and solvent-dependent quantities required for calculating reaction rates. Detailed process optimizations are employed for the process-based solvent assessment. To demonstrate the proposed approach for integrated reaction solvent and process design, we apply it to the case study of a carbamate cleavage process.

2. Approach for the Integrated Reaction Solvent and Process Design

The integrated solvent and process design problem is formulated based on the general computer-aided molecular and process design (CAMPD) problem by Gani (2004):

$$
\begin{aligned}

\end{aligned}
\tag{1}
$$

The process-based objective $f(x,y)$ (e.g., a product yield) depends on n continuous process variables x (e.g., temperatures) contained in the operation range X and on the molecular structure of the inert solvent y contained in the molecular design space Y. The equality constraints $g_1(x,y)$ correspond to the process model (see section 2.2) and the equality constraints $g_2(x,y)$ to models for kinetic and thermodynamic properties (see section 2.1). Constraints $g_3(y)$ ensure feasibility of the molecular structures y, e.g., by ensuring correct valency of all atoms in a molecule. Inequality constraints $c_1(y)$ limit molecular properties like the number of atoms in the molecule as well as thermodynamic properties like boiling points. The solution of the integrated design problem is the combination of the optimal solvent with its optimal process conditions.

2.1. Prediction of Reaction Kinetics and Thermodynamic Properties

Reaction rate constants are predicted based on transition state theory (Eyring, 1935) from the activation barrier $\Delta G^{\ddagger}$ between the reactants and the transition state. The activation barrier $\Delta G^{\ddagger}$ is computed in two steps for a reaction in an inert solvent (Kröger et al., 2017):

1. Geometries of reactants and transition states are optimized and vibrational frequencies are determined with b3lyp and TZVP basis set using the software Gaussian

    09 (Frisch et al., 2009). Electronic energies are calculated with DLPNO-CCSD(T) and aug-cc-pVTZ basis set using the software ORCA (Neese, 2018). Next, the activation barrier $\Delta G^{\ddagger}$ in an ideal gas state is computed with the statistical thermodynamics package TAMkin (Ghysels et al., 2010).

2. Solvation effects are accounted for based on Gibbs free energies of solvation G^{solv} of reactants and transition states. We predict G^{solv} using the COSMO-RS method (Eckert and Klamt, 2002) implemented in the COSMOtherm software (Eckert and Klamt, 2017).

Step 1 is the computationally most demanding step, but is independent of the solvent and thus needed only once per reaction. COSMO-RS is also used for predicting normal boiling points and vapor pressures as well as activity coefficients used to fit parameters for the NRTL model (Renon and Prausnitz, 1968). NRTL is used to efficiently compute activity coefficients in process optimization.

2.2. Process Modeling

Process models are formulated as differential-algebraic systems of equations (DAE) based on balance equations. Further, the models contain algebraic equations describing phase equilibria and the NRTL equations. Process models are implemented in MatLab (The MathWorks, Inc., 2015) and solved with the DAE solver ode15s.

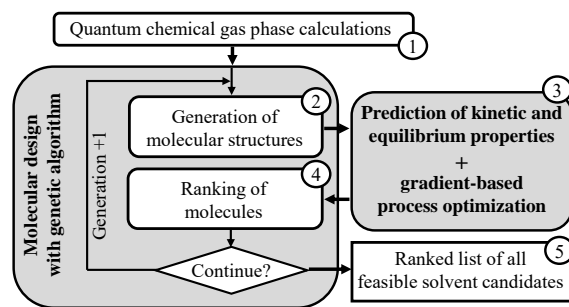
2.3. Solution of the Integrated Design Problem


Figure 1: Flowsheet of the solution approach to the integrated design problem.

To solve Problem 1, first, the quantum-chemical gas phase calculations are performed (step 1 in Figure 1). Next, the actual integrated design problem is solved with a hybrid optimization scheme. The molecular structure of the solvent is optimized with the genetic optimization algorithm LEA3D as proposed for non-reactive systems by Scheffczyk et al. (2017). For this purpose, candidate solvent molecules are generated by connecting 3D molecule fragments from a given library (step 2). Full 3D structural information is maintained in this step. Next, the 3D molecular structures are used to predict kinetic and thermodynamic properties of the resulting reaction systems based on quantum chemistry and to optimize processes with the candidate solvents (step 3). For this purpose, we use gradient-based optimization with fmincon in MatLab (The MathWorks, Inc., 2015). Based on the final objective function values of the process optimizations, the candidate solvents are ranked (step 4) and refined (step 2). Steps 2 to 4 are repeated for a predefined number of iterations before a ranked list of all feasible solvents is returned (step 5).

3. Case Study: Thermal Cleavage of Cyclohexyl Carbamate

The thermal cleavage of methyl carbamates to isocyanates and methanol is part of a production route of industrially important isocyanates (Six and Richter, 2000). Carbamate cleavage reactions are strongly endothermic (Leitner et al., 2018) with an unfavorable reaction equilibrium almost completely on the reactants' side. To avoid the fast back-reaction, methanol has to be continuously removed from the reactor. As methanol is volatile at typical reaction temperatures around 200 °C, it can be removed by stripping with an inert gas like nitrogen (Cao et al., 2015). In this work, we consider the cleavage of cyclohexyl carbamate (CHC) in a batch reactor with nitrogen stripping and a flash for recycling flushed out isocyanate and solvent (Figure 2).
Figure 2: Batch process for CHC cleavage.

3.1. Prediction of Reaction Rate Constants
Figure 3: Log-log plot of experimental vs. predicted rate constants.

Alcohols and carbamates have an autocatalytic effect on carbamate cleavage reactions (see e.g., Thiele (1979)). Therefore, we consider the completely non-catalytic cleavage reaction as well as autocatalysis by carbamate and methanol molecules. Suitable experimental data for direct validation of the predictions for the autocatalytic carbamate cleavage is not available in the literature. However, the carbamate cleavage can be considered as reverse reaction of the isocyanate-alcohol reaction (Thiele, 1979). Moreover, different aliphatic isocyanates (Lorenz et al., 1984) and different alcohols (Sardon et al., 2013) have been shown to react with similar rate in isocyanate-alcohol reactions. Thus, we use rate constants determined experimentally by Lorenz et al. (1984) for the reaction of the cycloaliphatic isocyanate group in isophorone diisocyanate with butanol for comparison (Figure 3). The deviation of our predictions from the experimental values is much less than one order of magnitude, which can be considered a very good agreement (Kröger et al., 2017). Moreover, we aim at comparisons of solvents such that several errors cancel. Thus, the chosen prediction methods for rate constants are regarded as suitable for the reactions under consideration in this work.

3.2. Specifications for the Integrated Solvent and Process Design

As process objective $f(x, y)$, the yield of isocyanate is chosen and defined as the final amount of isocyanate devided by the initial amount of carbamate in the reactor. The free process variables x are the temperature T^{flash} in the flash (cf. Figure 2) and the volume flow of nitrogen $\dot{V}_{N_2}$. We set a constant reactor temperature of $T^R = 200\,°C$, a pressure of $p = 4\,\text{bar}$, a reactor volume $V^R = 1\,\text{m}^3$ and a reaction time of $t^R = 10\,\text{h}$. A library of 3D fragments is used for the genetic optimization of solvent structures y in 25 generations with a maximum of 40 molecules per generation. Alkanes, aromates, ketones, ethers, esters, nitro- and nitrile compounds are suitable solvents for carbamate cleavage (see

Ephraim et al. (1958) and Merger et al. (1983)) and according fragments are provided. As only inert solvents are desired, protic substances are not considered because they may react with the produced isocyanate. As inequality constraints $c_1(y)$, the number of non-hydrogen atoms in solvent structures y is limited to a maximum of 20 and a minimal normal boiling point of the solvents of 176 °C, which is 10 °C higher than the normal boiling point of the produced isocyanate, is required to prevent solvent evaporation.

3.3. Results of the Integrated Solvent and Process Design

The solution of the integrated solvent and process design problem takes about 6 days using an Intel Xeon CPU E5-1660 v3 @ 3.00 GHz with 16 virtual processor cores. The design results in an optimal process with the inert solvent n-undecane and an isocyanate yield of 68%. The temperature in the flash is $T^{\text{flash}} = 20.5\,°C$ and the nitrogen flow rate is $\dot{V}_{N_2} = 0.72\,m^3\,min^{-1}$, which is in a similar range as the experimental conditions used by Cao et al. (2015). 176 designed solvents meet all constraints (Figure 4). Interestingly, solvent selection based

Figure 4: Yields of optimized carbamate cleavage processes for 176 designed feasible solvents.

on equilibrium constants of the cleavage reaction fails (solvent benzaldehyde, 43% yield). The reason is that methanol removal prevents the control of the process by reaction equilibrium. A selection based on the rate constant of carbamate cleavage results in a good solvent (i-icosane, 62% yield), but not in the best solvent. The reason is that a tradeoff between high rate constants and favorable vapor-liquid equilibrium properties is important to achieve maximum product yield. This tradeoff is only captured by integrated solvent and process design, which clearly shows the strength of the proposed approach.

4. Conclusion

An approach is presented for the integrated design of reaction solvents and processes which overcomes the limits of previous approaches. Our approach uses quantum chemistry-based predictions of reaction kinetics and thermodynamic properties and thus avoids simplified models. The integrated solvent and process design problem is solved with a hybrid optimization scheme combining genetic optimization of solvent structures and gradient-based process optimization. In a case study of a carbamate cleavage process, the strength of the integrated design compared to a solvent selection by equilibrium or rate constants is demonstrated.

Abstract

Nowadays the growing concerns about the environment and society in general led companies to invest in a sustainable development. In this way, companies' design and planning decisions need to encompass simultaneously economic, environmental and social concerns. In addition, considering the complexity associated with market uncertainties, there is the need to consider risk management. This work is developed along this line and proposes a mixed integer linear programming model (MILP) that accounts for the economic and environmental performances in the same objective function by monetizing environmental impacts and simultaneously considering the most popular risk measures in the literature, CVaR. The goal is to maximize the difference between the expected net present value and the environmental impact while minimizing the associated risk. The augmented ε-constraint method is used to generate a Pareto-optimal curve in order to determine the trade-off between the objective functions. Conclusions can be drawn based on decision makers' risk profile as well as how monetization can support the decision maker's decision. A European supply chain case study is explored.

Keywords: supply chain, sustainability, risk management, monetization, uncertainty

1. Introduction

The importance of supply chain (SC) has been well-known for years in both scientific and industrial communities. As supply chain is a complex logistic system that covers the set of all activities from raw materials to final products' sales, it involves a careful and efficient management so that it is possible to obtain satisfactory results for the company. In fact, supply chain management intends to optimize customer value and to achieve a competitive advantage in the market. However, in the past, this optimization only included the economic performance of the supply chain. Taking into account the increasing companies' competitiveness and governmental pressures, SC has extended its goals to consider environmental and social concerns as well (Barbosa-Póvoa et al., 2017). The management of those economic, environmental and social concerns resulted in the appearance of sustainable supply chain (SSC) concept, which is a recognized area by the World Commission on Environment and Development. If managing a supply chain was a difficult task due to the higher number of variables, entities and products that can be included, then including environmental and social concerns makes this difficulty and complexity even greater. Thus, managing sustainable supply chains towards efficient and sustainable objectives is a challenge, especially if this encompasses the design and planning of the chain. Besides sustainability and responsiveness that supply chain management has to obey, risk management is also a current reality that needs to be

accounted when considering the supply chain design and planning problems (Barbosa-Póvoa, 2017). In this way, the typical design and planning models for minimization of supply chain costs need to become more holistic. In fact, the majority of real-world supply chain problems are dynamic, because there are several uncertain factors, like raw material prices, demand, labour costs, among others (Cristonal et al., 2009). For this reason, there is the need to develop risk management tools that efficiently address the uncertainty involved. In the literature, there are several examples of the application of risk measures in supply chain design and/or planning. However, this application is mainly done in the financial area, which means that only the economic performance of the supply chain is assessed. Nevertheless, risk can have impact in multiple dimensions, such as financial, environmental and social aspects and, therefore, that should be accounted when analysing risk in supply chains, particularly in sustainable supply chains. This paper presents a mixed integer linear programming model (MILP) that accounts for the economic and environmental concerns in the same objective function by monetizing environmental impacts and considering a risk measure. The goal is to maximize the difference between economic and environmental performances while minimizing the associated risk.

2. Environmental monetization methodologies

There are several methods to assess environmental impacts. The most used methodology is life cycle assessment (LCA). One of the most controversial phases of LCA is the life cycle impact assessment (LCIA), as it encompasses the assignment of weighting factors by decision-makers and it may be difficult to choose the best method to use. On the LCIA phase, there are methods that assess environmental impacts with scores and others that monetize. According to the European Commission, EPS 2000 is a quite complete method and it has the uncertainties fully specified when compared to other LCIA methods. For this reason, in this study, monetization is performed by using EPS. The environmental impacts are quantified in a monetary unit through EPS, which is mainly derived from future costs (raw material depletion), direct losses (production) and willingness-to-pay WTP (health, biodiversity, and aesthetic values). The WTP values resulted from academic knowledge to proactively reduce environmental impacts (Steen, 1999).

3. Problem description and model characterization

The problem intends to study the design of a generic SC, where raw materials flow from suppliers to factories and final products are obtained. These final products move to warehouses or directly to markets. In addition, at the markets, end-of-life products can be recovered and sent to warehouses or directly to factories to be remanufactured. Taking into account the possible set of locations of SC entities, production and remanufacturing technologies, possible transportation modes between entities, and products within the SC, the main objective is to obtain the SC network structure, supply and purchase levels, entities' capacities, transportation network, production, remanufacturing and storage levels, supply flow amounts, and product recovery levels, in order to maximize profit, minimize environmental impacts, and minimize financial risk. The mixed integer linear programming (MILP) model used to solve this problem is based on da Silva et al. (2018). This model was extended to consider simultaneously two objective functions through the augmented ε-constraint method (Mavrotas, 2009), namely the maximization of the difference between economic and environmental performances, and the minimization of

the financial risk, considering demand uncertainty. The first objective function is represented by Eq. (1), which is the maximization of the difference between the expected net present value (eNPV) and expected environmental impact (eEnvImpact). The economic performance is assessed through the eNPV (represented by Eq (2)), which is obtained through the sum of each node's probability multiplied by the discounted cash flows (CF_{Nt}) in each period t and for each node N at a given interest rate (ir). These CF_{Nt} are obtained from de net earnings (difference between incomes and costs). The costs include raw material costs, product recovery costs, production/remanufacturing operating costs, transportation costs, contracted costs with airline or freight, handling costs at the hub terminal, inventory costs, and labour costs. In addition, for the last time period, it is considered the salvage values of the SC (FCIγ). The environmental performance is assessed through the eEnvImpact (represented by Eq. (3)), LCA is performed on the transportation modes, in the technology involved, and on entities installed in the SC boundaries, using EPS 2015 (updated version of EPS 2000). The Life Cycle Inventory is retrieved from the Ecoinvent database (assessed through SimaPro 8.4.0 software). The LCA results are expressed in Environmental Load Units (ELU) and used as input data (*ei*) in Eq. (3), particularly in the environmental impact of transportation (first term), in the environmental impact of entity (second term), and in the environmental impact of technology (third term). The second objective function is represented by Eq. (4), where it is intended to minimize the financial risk, which is modelled through the adoption of conditional value at risk (CVaR). CVaR evaluates the likelihood of obtaining the difference between eNPV and eEnvImpact lower than value-at-risk (VaR). VaR is the minimum difference between NPV and EnvImpact for a given confidence level (α).

$$\max (e\text{NPV}_N - e\text{EnvImpact}_N) \tag{1}$$

$$\text{eNPV}_N = \sum_N pb_N \left(\sum_{t \in T} \frac{CF_{Nt}}{(1+ir)^t} - \sum_\gamma FCI_\gamma \right) \tag{2}$$

$$\text{eEnvImpact}_N = \sum_N pb_N \left(\sum_{\substack{t \in T \\ (a,m,i,j) \in NetP}} ei_{ac} pw_m d_{ij} X_{maijtN} + \sum_{i \in I_f \cup I_w} ei_{ic} YC_i \right.$$
$$\left. + \sum_{\substack{t \in T, i \in I_f \\ (m,g) \in H}} ei_{mgc} pw_m (P_{mgitN} + R_{mgitN}) \right) \tag{3}$$

$$\min Risk = \max CVaR_\alpha = \max \left(VaR - \frac{1}{1-\alpha} \sum_N (pb_N \cdot \delta_N) \right) ; \ \delta_N \geq VaR - NPV_N \tag{4}$$

4. Case study

The model is applied to an electronic components' producer located in Italy (Silva et.al., 2018). The company's suppliers are located in Verona. Currently, this company owns a factory and a warehouse with enough capacity to meet the demand of their existing clients. These clients are located in three main European markets, namely in Spain, Italy, and Germany. The SC capacity cannot meet a demand increase and four new potential clients induce the company's decision-makers to study different SC possibilities of expansion. Given the locations of the clients, Leeds and Hannover are possible locations for installing new factories, which may lead to significant changes in the transportation modes, particularly for clients that are located outside Europe. Also, other possible warehouse locations close to the markets have to be considered. There are two types of products (fp1 and fp2) that are currently being produced through two technology types.

There are two new technologies available to produce those products. Furthermore, end-of-life products can be recovered and remanufactured into final products. In addition, transportation can be performed only by road or through a combination of road, air and sea transportation modes. There are two types of road transportation available (Truck1 and Truck2) that vary in terms of capacity, investment costs, depreciation rate, variable costs, and vehicle consumption. This work accounts for product's demand uncertainty through a scenario tree approach, due to the fact that this is a method that allows the discretization of stochastic data over the time horizon and can be adjusted during the planning horizon. In this scenario tree (Figure 2), a node N characterizes a possible state and the arcs represent the evolutions it may have. Each node has a specific probability and a path from the root to a leaf node represents a scenario.
Figure 1 . Scenario tree - values for probability and demand (D) variation are represented

5. Results

Based on the SC reality, two cases are studied to understand the different decisions that can be made, considering the design and planning of the SC. Case A considers a stochastic approach since products demand is uncertain and does not considers a risk measure (risk neutral); while case B considers uncertainty in products' demand and studies the trade-offs between the expected value of (eNPV-eEnvImpact) and the associated financial risk, assessed through CVaR. Case B is analysed for the extreme values, namely the highest and lowest associated risk. Table 1 shows the eNPV and the eEnvImpact obtained in both cases (A and B). For case B, assuming a confidence level of 95%, it is necessary to compute all the scenarios and assess the cumulative distribution function (Figure 2). Thus, VaR is equal to -40043x10^4€., meaning that, at the end of the time horizon, the difference between eNPV and eEnvImpact for the design and planning of this supply chain is going to be, at least, this value. Thus, it is possible to obtain the Pareto curve assessed through CVaR (Figure 3).

Comparing the different cases, it can be seen that the risk neutral case has an eNPV of 97729x10^4 € and a correspondent eEnvImpact of 218570x10^4€. Regarding case B, the results show that when the difference between eNPV and eEnvImpact increases the related risk also increases. Analysing in detail the extreme points of the Pareto curve, it is visible that the lowest risk decision is associated with the lowest eNPV and the highest eEnvImpact. In contrast, the highest risk decision offers better results for eNPV comparing with the risk neutral case, showing the relevance of considering risk measures.
Figure 2. Cumulative distribution function to determine VaR
Figure 3. Pareto curve using CVaR risk measure

Table 1. Results for the economic (eNPV) and environmental (eEnvImpact) performances.

	Case A	Case B	
	Risk-neutral	High-risk	Low-risk
	Stochastic	*CVaR*	
eNPV (x10⁴)	97729 €	97745 €	97675 €
eEnvironmental impact (x10⁴)	218570 €	218600 €	220940 €

Table 2 shows SC structure decisions considering the results depicted in Table 1. It can be seen that there are some changes across the cases A and B. Additionally to the already existent factory, all cases are going to have the same new factories installed. The results also show that in all cases there is the need to expand the existing capacity by opening new warehouses. Regarding suppliers' allocation, it can be seen that in risk neutral and high-risk cases, where environmental impacts are lower, the results show that most factories are supplied by the closest suppliers. This can be explained by the lower environmental impact of transportation. On the other hand, in the low-risk case, all factories are supplied by all suppliers, which results from the balance between the lower costs of raw materials and fewer transportation costs. Regarding transportation, the truck with more capacity (Truck2) is preferred in all cases, since this has a lower environmental impact. In terms of intermodal transportation, sea option is preferred in all scenarios, while air transportation is not used. Going deeper into the results, it can be seen that the network structure of the risk-neutral case is similar to the high-risk case, due to the fact

that both SC entities and transportation modes are the same, with some differences in capacities involved and in the product flows between entities.

Table 2. Summary of the SC decisions considering the different cases

		Case A		Case B
		Risk-neutral	High-risk	Low-risk
Factories		The same in all cases		
Warehouses		The same in all cases		
Suppliers allocation		Factories are supplied in totally by the closest supplier		All factories are supplied by all suppliers
Production		Most production of fp1 is in the existing warehouse		
		Most production of fp2 is divided between two new warehouses		
Inventory		fp1 and fp2 divided between Verona and Sofia; and most inventory of fp2 kept in Verona		fp1 and fp2 divided between Verona and Sofia
Transportation	Road	4 Truck1 and 17 Truck2	5 Truck1 and 17 Truck2	5 Truck1 and 18 Truck2
	Air	Not used		
	Sea	Used in all cases		

6. Conclusion

This study aimed to develop an optimization model for the design and planning of a generic SC, where the maximization of the difference between the expected economic and environmental performances was considered against the minimization of financial risk under uncertainty on the products demand. Considering the assessment of risk, CVaR was used. To show the trade-offs between (eNPV – eEnvImpact) and risk, a Pareto optimal curve was developed through the application of the augmented ε-constraint method. It is important to notice that this analysis was only possible, due to the monetization, which was able to quantify the environmental impacts in a monetary unit. This allowed to include in the same objective function both economic and environmental impacts. Furthermore, from the analysis made, it was clear that results are influenced by differences in risk strategies and this proves the importance of risk management in solving real-life problems. For future work, further research should be done on this topic to evolve monetization approaches in order to be a reliable alternative to evaluate environmental impacts. Also, an extension of this work should consider different risk measures and a more comprehensive study of uncertainty so as to even better conclude on its adequacy.

Abstract

This work aims to optimise the operation of an evaporation network with shared resources in real time. The goal is minimising the resource utilisation (live steam and cooling water) while satisfying a set of operational constrains. Hence, problems of optimal load allocation of feeds to plants and cooling-water distribution among them arise. The work bases on plants surrogate models, experimentally obtained, and analyses different formulation alternatives of the optimisation from the practical point of view: centralised vs distributed approaches. In particular for the distributed approach, we propose a problem decomposition which allows us to solve the problem in two iterative ways: 1) as two independent optimisations or 2) via price-coordination schemes.

Keywords: decomposition methods, RTO, evaporation network, resource efficiency

1. Description of the case study

Manufacture of viscose fibers in Lenzing AG bases on a continuous spinning process where cellulose pulp transforms into very thin threads. This process performs in an acid bath ("spinbath" from now on) which is progressively degraded. Consequently, it must be continuously recovered. Therefore, a side evaporation process is performed in parallel to remove part of water. For this task, an evaporation network of 15 plants is available to serve in 5 different types of spinbath, where a single plant is formed by several equipment. See Pitarch et al. (2017b) for a deeper description.

Plants efficiency depends on several factors: the evaporation flow removed from the spinbath (plant load) EC, the spinbath temperature T and circulating flow F_s, the fouling state in the heat exchangers and the performance of the cooling system (see Figure 1a). In particular, the more cooling water (shared resource) is provided to the surface condenser, the less live steam consumption (utility) is needed to achieve the evaporation setpoint.

Denote the *specific steam consumption* (*SSC*) by the live steam usage per unit of evaporated water (Pitarch et al., 2017a). Then, the *absolute steam consumption* (*ASC*) in each plant is computed by $ASC = SSC \cdot EC$.

(a) Evaporation plant   (b) Evaporation network
Figure 1: Systems simplified schemes.

Plant surrogate models were developed to estimate the *SSC* in Kalliski et al. (2019), which, after straightforward manipulations, is found to depend on *EC* and on the cooling capacity of the surface condenser C_{pow}, as shown in (1). The cooling system performance is also modelled experimentally: the outlet cooling-water temperature of the condensers T_{out} is estimated by a polynomial function up to degree 3 on the cooling-water flow F_{w} and affine in its inlet temperature T_{in}, as proposed in (Marcos et al., 2018):

$$SSC = \beta_2 \cdot EC + \beta_1 \cdot C_{\text{pow}} + \beta_0; \qquad C_{\text{pow}} = 4.18 \cdot F_{\text{w}}(T_{\text{out}} - T_{\text{in}})/3600 \tag{1}$$

$$T_{\text{out}} = \alpha_0 + \alpha_1 F_{\text{w}} + \alpha_2 F_{\text{w}}^2 + \alpha_3 F_{\text{w}}^3 + T_{\text{in}} \tag{2}$$

Here, $\theta = \{\beta_0, \beta_1, \beta_2, \alpha_0, \alpha_1, \alpha_2, \alpha_3\}$ are experimental regression parameters.

According to the physical layout of the evaporation network, the plants can be grouped in two subnets, each one directly supplied by an independent water source. The water distribution among plants is done in parallel and, additionally, the exceeding water in Subnet 1 (F_{c}) can go to Subnet 2 but not backwards (see Figure 1b). Further details on the evaporation network can be found in Palacín et al. (2018); Marcos et al. (2018).

2. Problem formulation

The objective is to allocate feeds to plants and distribute the cooling-water in the network at minimum cost. This cost is a trade-off between the usage of resources: live steam and cooling water, times their respective "prices" (P_s and P_w). Three sets of decision variables are defined: $X_{e,p} \in \{0,1\}$ to link product p to plant e, $EC_{e,p} \in \mathbb{R}$ defining the evaporation flow of p to be achieved in plant e, and $F_{\text{w} \, e} \in \mathbb{R}$ defining the water sent to plant e. Further, an additional variable $F_{\text{c}} \in \mathbb{R}$ indicates the flow of water sent from Subnet 1 (SN1) to Subnet 2 (SN2). Hence, for a given set of $e \in \mathscr{E}$ evaporation plants that have to process $p \in \mathscr{P}$ spinbaths, the centralised formulation of the optimisation problem is:

$$\min_{X_{e,p}, EC_{e,p}, F_{\text{w} \, e}, F_{\text{c}}} \quad J = \sum_e^{\mathscr{E}} \left(\sum_p^{\mathscr{P}} ASC_{e,p} \cdot P_s + F_{\text{w} \, e} \cdot P_w \right) \tag{3a}$$

$$\text{s.t.:} \quad \sum_p^{\mathscr{P}} X_{e,p} \leq 1 \quad \forall e \in \mathscr{E}; \qquad X_{e,p} = 0 \quad (e,p) \in \mathscr{N} \tag{3b}$$

$$\sum_{e}^{\mathscr{E}} EC_{e,p} \geq \mathrm{SP}_p \quad \forall p \in \mathscr{P} \tag{3c}$$

$$\sum_{e}^{\mathscr{E}_{SN1}} F_{\mathrm{w}\ ee} + F_{\mathrm{c}} \leq \mathrm{F}_{\mathrm{S}1}; \quad \sum_{e}^{\mathscr{E}_{SN2}} F_{\mathrm{w}\ e} - F_{\mathrm{c}} \leq \mathrm{F}_{\mathrm{S}2}; \quad F_{\mathrm{c}} \geq 0 \tag{3d}$$

$$\underline{\mathrm{EC}}_{e,p} \cdot X_{e,p} \leq EC_{e,p} \leq \overline{\mathrm{EC}}_{e,p} \cdot X_{e,p} \quad \forall e \in \mathscr{E},\ \forall p \in \mathscr{P} \tag{3e}$$

$$\sum_{p}^{\mathscr{P}} X_{e,p} \cdot \underline{\mathrm{F}}_{\mathrm{w}\ e} \leq F_{\mathrm{w}\ e} \leq \overline{\mathrm{F}}_{\mathrm{w}\ e} \cdot \sum_{p}^{\mathscr{P}} X_{e,p} \quad \forall e \in \mathscr{E} \tag{3f}$$

$$T_{\mathrm{out}\ e} \leq \mathrm{T}_{\max} + \left(1 - \sum_{p}^{\mathscr{P}} X_{e,p}\right) \cdot \mathrm{M} \quad \forall e \in \mathscr{E} \tag{3g}$$

Where the sets $\mathscr{E}_{SN1}$ and $\mathscr{E}_{SN2}$ ($\mathscr{E} = \mathscr{E}_{SN1} \cup \mathscr{E}_{SN2}$) include the plants belonging to SN1 and SN2 respectively, the set $\mathscr{N}$ represents connections between some plants and spinbaths that are forbidden due to the factory layout, and M is a big enough number.

The problem constraints are: (3b) each plant can only serve in one spinbath loop at a time; (3c) total evaporation demands per spinbath (SP_p) have to be fulfilled; (3d) total water consumption in each subnet has to be lower than the available at the sources (F_{s}), considering that exceeding water can go from SN1 to SN2 but not backwards; (3e)-(3f) evaporation and water flows are bounded and; (3g) outlet water temperatures have to be lower than a limit ($\mathrm{T}_{\max}$), stated by the environmental regulation.

The presence of discrete and continuous variables as well as the nonlinear dependency of (3a) and (2) on them, makes (3) become an MINLP problem.

3. Problem decomposition

In order to avoid the issues that commonly arise with MINLP (slow convergence, high computational demands, etc.), we propose a suitable decomposition of (3) in two local optimisation subproblems, according to the physical layout of the evaporation network. In fact, the overall equipment can be grouped in two sets or networks: 1) the spinbath allocation one, composed by the evaporation plants and the spinbath loops themselves, and 2) the water distribution from the sources to the respective plant surface condensers. Hence, a first local problem can handle the plants load allocation whereas a second one optimises the water distribution. By this decomposition, only the magnitudes EC and C_{pow} are shared between problems 1) and 2).

1. Load-allocation problem:

$$\min_{X_{e,p}, EC_{e,p}} \quad J_1 = \sum_{e}^{\mathscr{E}} \sum_{p}^{\mathscr{P}} SSC_{e,p} \cdot EC_{e,p} \cdot \mathrm{P}_s \quad \mathrm{s.\,t.:} \quad (3b), (3c), (3e) \tag{4}$$

In this way, (4) is a mixed integer quadratic programming (MIQP) problem, provided that C_{pow} in (1) is assumed known.

2. Cooling-water distribution problem:

$$\min_{F_{\mathrm{w}\ e}, F_{\mathrm{c}}} \quad J_2 = \sum_{e}^{\mathscr{E}} \left(SSC_e \cdot \sum_{p}^{\mathscr{P}} EC_{e,p} \cdot \mathrm{P}_{\mathrm{s}} + F_{\mathrm{w}\ e} \cdot \mathrm{P}_{\mathrm{w}} \right) \quad \mathrm{s.\,t.:} \quad (3d), (3f), (3g) \tag{5}$$

Thus, assuming that the load allocation ($EC_{e,p}$) is known, (5) is an non linear programming (NLP) problem.

Now, we can solve the original problem in two iterative ways: sequentially as two fully independent optimisations, or in a price-coordination fashion. See next section.

4. Implementation

The above formulated optimisation problems (3), (4) and (5) are coded in Pyomo (Hart et al., 2017). The centralised version (3) uses Bonmin as MINLP solver (Bonami et al., 2008), whereas Gurobi Optimization (2018) is used to solve the MIQP (4) and Ipopt (Wächter and Biegler, 2006) to solve the NLP (5). In order to implement the decomposition approach in an iterative fashion, we propose the following.

4.1. Sequential approach

Take $C_{\text{pow } e}$ as known (computed by (1)-(2) and from given flows $F_{\text{w } e}$) and solve (4). Then, from the obtained solution, take the values of $EC_{e,p}$ and solve (5), getting a new set of values $F_{\text{w } e}$ to compute the $C_{\text{pow } e}$ and so on. The procedure is formalised in:

Algorithm 1 Sequential optimisation

1: Compute the $C_{\text{pow } e}$ from current (measured) $F_{\text{w } e}, T_{\text{out } e}, T_{\text{in}}$ and set $\varepsilon = 1$
2: **while** $\varepsilon > 0.001$ **do**
3:      Solve (4) and save the computed allocation $EC_{e,p}$
4:      Solve (5) using the $EC_{e,p}$ from Step 3 and get a water distribution $F_{\text{w } e}, T_{\text{out } e}$
5:      Compute $\varepsilon = \sum_e^{\mathscr{E}} \left\| C_{\text{pow } e} - 4.18 F_{\text{w } e} \cdot (T_{\text{out } e} - T_{\text{in}})/3600 \right\|_2^2$
6:      Update $C_{\text{pow } e} = 4.18 F_{\text{w } e} \cdot (T_{\text{out } e} - T_{\text{in}})/3600$ with values from Step 4

4.2. Distributed approach

In a distributed fashion, we need to decouple problems (4) and (5) to allow a "true" parallel implementation. Thus, we make use of the well-known Lagrangean or price-driven decomposition approaches (Cheng et al., 2007).

Indeed, now $C_{\text{pow } e}$ will be also *local* decision variables in (4) and EC_e will be so in (5) as well[1]. Then, we have to add a *coordination* layer to progressively force both sets of magnitudes to be equal in both local optimisations (shared constraints). As usual in Lagrangean decomposition, these constraints will be added as a penalty in the respective objective functions:

$$J_1 = \sum_e^{\mathscr{E}} \left(\sum_p^{\mathscr{P}} SSC_{e,p} \cdot EC_{e,p} \cdot P_s + \frac{1}{2} \left(p_{11e}(C_{\text{pow } e} - \mathbf{C}^*_{\textbf{pow } e})^2 + p_{12e}(\sum_p^{\mathscr{P}} EC_{e,p} - \mathbf{EC}^*_e)^2 \right) \right) \quad (6)$$

$$J_2 = \sum_e^{\mathscr{E}} \left(SSC_e \cdot EC_e \cdot P_s + F_{\text{w } e} \cdot P_w + \frac{1}{2} \left(p_{21e}(C_{\text{pow } e} - \mathbf{C}^*_{\textbf{pow } e})^2 + p_{22e}(EC_e - \mathbf{EC}^*_e)^2 \right) \right) \quad (7)$$

---
[1] Note that variables EC_e equivalently replace $\sum_p^{\mathscr{P}} EC_{e,p}$ in (5) to reduce the problem size.

Where $p_{ije} \in \mathbb{R}^+$ are the *shadow prices* for "resource" utilisation and $\mathbf{R}^* := \{\mathbf{C}^*_{\text{pow } e}, \mathbf{EC}^*_e\}$ are the reference values, computed somehow from the local solutions of both optimisations in in the previous iteration. In this way, both problems will be managed by a co-ordinator which, in each iteration k, will receive the values got for the shared variables $R_e := \{C_{\text{pow } e}, EC_e\}$, and it will update the prices as well as the reference values for the next iteration $k+1$ according to the following rules:

$$p_{ije}^{[k+1]} = p_{ije}^{[k]} + (R_{ije}^{[k]} - \mathbf{R}^{*[k]})^2 \cdot \mu^{[k]}; \quad R_{ije} \in R, \ \mathbf{R}^* \in R \qquad (8)$$

$$\mu^{[k+1]} = \mu^{[k]} \cdot \lambda; \qquad \lambda > 1 \qquad (9)$$

$$\mathbf{C}_{\text{pow } e}^{*[k+1]} = C_{\text{pow } e}^{[k]}(2); \qquad \mathbf{EC}_e^{*[k+1]} = EC_e^{[k]}(1) \qquad (10)$$

Where notation $R_e^{[k]}(i)$ denotes the values of variables R_e, solution of subproblem i at iteration k. Progressive hedging (Rockafellar and Wets, 1991) is used in (9) to update the factor μ in each iteration, via the user-defined parameter λ. The procedure to solve the distributed optimisation is summarized below.

Algorithm 2 Distributed optimisation

1: Set $\mathbf{R}^*$ to the current values measured from the plants and $p_{ije} = \varepsilon = 0.1$
2: **while** $\varepsilon > 0.001$ **do**
3:      Solve subproblems (4) and (5), and get new values for R_{ije}
4:      Compute $\varepsilon = \left\| R_{ije} - \mathbf{R}^* \right\|_2^2$
5:      Update prices p_{ije} and references $\mathbf{R}^*$ with (8)-(10)

Of course, due to the non-convex nature of the problem, global optimality is not guaranteed in either of the implementations, centralised or distributed.

5. Results and discussion

For the sake of comparison/analysis, we have solved the problem from a particular network situation following the three presented ways. Table 1 shows a brief summary.

Table 1: Optimised cost and computational effort for the 3 approaches.

	Total CPU Time (s)	Optimal cost (€/h)	Iterations
Centralised	29.64	962.82	-
Sequential	0.89	964.81	3
Distributed	1.73	964.33	6

We can conclude that the three approaches are able to reach nearly the same (local) optimal solution[2]. However, as expected, the centralised problem elapses more time to reach the solution. This is not a major issue in this application (the execution period for real-time optimisation is about 30 min.) but, it will be so if the problem grows by considering fouling predictions over time or by including more parts of the factory (the water network is larger and also serves to other processes, and there is a heat-recovery network which also interacts with the evaporation one).

---

[2]Values $p_{ije}^{[0]} = 0.1$, $\mu^{[0]} = 1$ and $\lambda = 1000$ were set for the distributed approach.

6. Conclusions

In this work we addressed a medium-scale real-time optimisation problem ($\sim$200 variables, it depends on the approach) on resource efficiency in an industrial evaporation network with shared resources. The proposed approaches will support the operators to take better decisions in real time, thus, improving the operation of the overall network: product-plant allocation and water distribution to the cooling systems.

The plant models are incorporated in three different optimisation schemes, analysing the convenience of the decomposition approaches vs the centralised one. In this case study, the three approaches solve the problem in acceptable CPU time for real-time purposes, although the iterative sequential approach has arisen as the most efficient one. The key is the proposed decomposition for the original centralised problem, which allows us to formulate two effortless independent problems (MIQP and NLP), solved efficiently by modern optimisation algorithms.

Apparently, the price-coordination approach does not have any advantage here: the optimal cost is slightly higher than the one reached by the centralised and it elapses double time than the sequential. This is because the centralised problem is not so large-scale, many constraints are affine in the decision variables, and the advantages of parallel computation cannot be exploited with just two local optimisation subproblems. Nevertheless, this approach will clearly beat the other two if the problem is extended to consider uncertainty in an explicitly way via, for instance, two-stage stochastic optimisation.

Abstract

This work investigates the use of variable pricing to control electricity imported and exported to and from both fixed and unfixed distributed energy resource network designs within the UK residential sector. It was proven that networks which utilise much of their own energy and import little from the national grid are barely affected by variable import pricing, but are encouraged to export more energy to the grid by dynamic export pricing. Dynamic import and export pricing increased CO_2 emissions due to feed-in tariffs which encourages CHP generation over lower-carbon technologies such as solar panels or wind turbines.

Keywords: Internet-of-Things, Distribution Energy Resource, Mixed-Integer Linear Programming.

1. Introduction

Most electricity on the UK grid comes from large producers based far from customers, e.g. large offshore wind farms or isolated nuclear plans, leading to enormous volumes of electricity being wasted through transmission losses and step-up/step-down transformers [1]. Distributed Energy Resource (DER) networks have the potential to provide buildings capabilities for self-generation from renewable or low carbon assets and reduce both emissions and energy bills through mitigation of much of these losses [2]. Government incentives make a good case for investing in DER technologies, however large-scale investment into domestic DERs without sensible controls would destabilize the national grid [3]. Internet of Things (IoT) technologies have the potential to better control and optimize DERs, in conjunction with the needs of national electricity grids. This can be done through internet connected controllers which utilize live data on energy prices, generation, consumption, and asset failures, in a way which is aligned with national grid strategies. It also presents the capability to optimize the design and operation of local renewable resources, to cope with predicted changes in weather or disruptive events. The work presented in the following sections focuses on the use of IoT-type integration and communication strategies for the control of residential DERs, as opposed to the control of entire grids, as presented by [4]. With

respect to dynamic pricing, the paper is unique from [5] in that it investigates both demand- and supply-side control. Finally the model builds on the models presented in [6] and [7]. The novelty is in the investigation of the effect of dynamic pricing on the demand- and supply-side control in residential housing scenarios. Section 2 presents the methodology, Section 3 the mathematical formulation, while Section 4 the results and discussion.

2. Methodology

A case study is used to illustrate the approach: a residential house arrangement based on streets in Guildford, Surrey, UK, with 5 houses (Fig.1). The demand profiles for this arrangement are presented in Fig.2
Fig 1. Design of the baseline scenario network

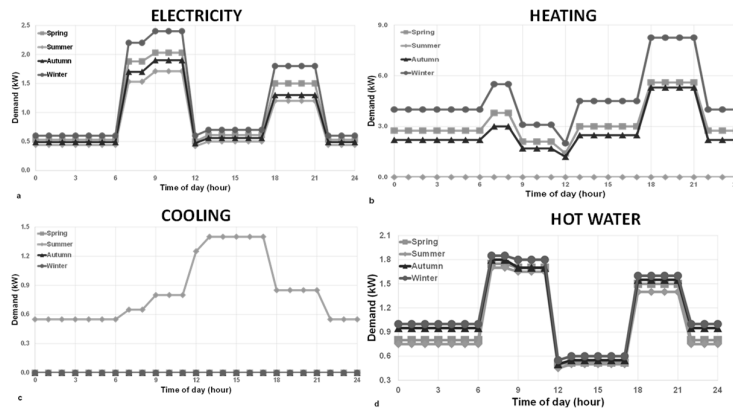
A baseline scenario with a set, pre-designed DER network is used to investigate the effect of dynamic pricing. A simulation is run to optimize the design of the network without IoT control, based on a number of available renewable technologies. The set of technologies installed in the network (*Tech*) could include: absorption chillers (*Abs*), air conditioning units (*AC*), biomass boilers (*BB*), gas boilers (*GB*), combined heat and power generators (*CHPs*), which are fuel cells, internal combustion engines or Sterling engines, gas heaters (*GH*), heating/cooling pipelines, microgrid controllers (*MGCC*), photovoltaic cells (*PV*), thermal storage (*TS*) and wind turbines (*WT*). A second scenario is investigated, where the design of the network is completed with IoT dynamic pricing control strategies. This is done to compare the design and operation of DER networks which have been designed and are yet to be designed.


Fig 2. Demand profiles for the network for electricity, heating, cooling and hot water

Real seasonal and hourly variations in supply and demand of the various energy requirements and renewable generating assets are considered for the models. Weather and demand data is split into four seasons (*m1* – spring, *m2* – summer, *m3* – autumn and

m4 – winter), which each lasts for three months (Mar-May, Jun-Aug, Sep-Nov, Dec-Feb). Every day is split into six periods (*p1 – p6*) in which demand, weather operation and thus energy supply are constant. The concept of dynamic pricing is investigated through the use of Equations (1) and (2), which calculate the price (in British pence per kWh) of electricity from the DER network purchased $(P_{Elec,mp})$ and sold $(P_{SalElec,mp})$ to the grid, respectively. The price is scaled against the average electricity price $(P_{Elec,Avg}$ and $P_{SalElec,Avg}$, for the purchased and sold price, respectively) for the UK residential sector, by dividing the national demand $(NatDemand_{m,p})$ at time of day, *p*, and season, *m*, by the yearly average national demand $(NatDemand_{Avg})$.

$$P_{Elec,mp} = P_{Elec,Avg} \cdot NatDemand_{m,p}/NatDemand_{Avg} \qquad (1)$$

$$P_{SalElec,mp} = P_{SalElec,Avg} \cdot NatDemand_{m,p}/NatDemand_{Avg} \qquad (2)$$

Table1. Cost of imported and exported electricity, per time of day and year

Time period (*p*)	*p1*	*p2*	*p3*	*p4*	*p5*	*p6*
Time of day	07:00-09:00	09:00-12:00	12:00-13:00	13:00-18:00	18:00-22:00	22:00-07:00
Season, *m*	Price purchased electricity, $P_{Elec,m,p}$ (pence/KWh)					
Spring, *m1*	31.120	33.660	8.290	10.110	24.870	8.787
Summer, *m2*	25.370	28.350	6.964	8.290	19.900	7.295
Autumn, *m3*	28.190	31.500	7.793	9.285	21.550	8.124
Winter, *m4*	36.480	39.790	9.948	11.610	29.840	9.948
Season, *m*	Price exported electricity, $P_{SalElec,m,p}$ (pence/KWh)					
Spring, *m1*	9.625	10.390	2.560	3.123	7.680	2.713
Summer, *m2*	7.833	8.755	2.150	2.560	6.144	2.253
Autumn, *m3*	8.703	9.727	2.406	2.867	6.655	2.509
Winter, *m4*	11.260	12.290	3.072	3.584	9.215	3.072

Overall the price of purchased electricity, taken as a time average, is $P_{Elec,Avg} = 16.29$ pence/kWh, while the price of exported electricity is that given by the government incentives, $P_{SalElec,Avg} = 5.03$ pence/kWh. Table 1 shows the calculated values for the imported and exported electricity, for each time period throughout the year.

3. Mathematical model

The model's objective function minimises the total cost of the network, C_{Total}, which is calculated as the sum, for all technologies, of the investment costs, C_{Inv}, annualised over the project lifetime, n (years), and the annual operating and maintenance costs, $C_{O\&M}$, the annual cost of carbon emission taxation, C_{Tax}, the annual cost of imported energy and fuel, C_{Fuel}, minus the annual income, C_{Inc} made from exporting the electricity to the grid, feed in tariffs (FITs) and renewable energy heat incentives (RHIs):

$$C_{Total} = \sum_{Tech}(C_{Inv} + C_{O\&M}) + C_{Tax} + C_{Fuel} - C_{Inc} \qquad (3)$$

The annualized investment costs are calculated using a capital recovery factor, *CRF* based on an interest rate, *r* (%), and project lifetime, *n*:

$$CRF = r(1+r)^n/[(1+r)^n - 1] \qquad (4)$$

A cost per kW of installed capacity, or cost per meter of piping and wiring was found, for each technology, from literature based on UK case studies and industrial sources, and used to calculate the annualised cost for each technology:

$$C_{Inv,tech} = \sum_i (CRF \times C_{InvTech} \times Max_{Tech,i}) \tag{5}$$

Here, the $Max_{Tech,I}$ is the maximum power generated by the technology in a house i, in a year, and represents the required capacity. The installed capacity must also fall between upper and lower bounds of available technology units. Binary variables are used to decide whether or not a technology is installed in a home.

O&M costs of the technologies are calculated using fixed costs, C_{Fixed} and variable costs, C_{Var}. The costs are defined in £/kWh.

$$C_{O\&M,tech} = \sum_i \left[\left(C_{Fixed} \times Max_{Tech,i} \right) + \left(C_{Var} \times \sum_{m,p} Gen_{Tech,i,m,p} \right) \right] \tag{6}$$

C_{Tax} is calculated from the government tax per kg of CO_2 emitted, P_{CO2}, the carbon intensity of electricity purchased from the grid, CI_{grid}, and carbon intensities of emitting technologies, namely: *GB*, *CHP* and *CH*. All these units consume natural gas, so their intensities are calculated as the carbon intensity of grid gas CI_{Gas} divided by the technology efficiency, η_{Tech}. The intensities are defined in kg CO_2/kWh. The cost of fuel, C_{Fuel} is equal to the volume of gas and electricity purchased multiplied by the respective cost of each technology. The income, C_{Inc} is calculated from FITs per kWh of low carbon heat or electricity generated, $P_{FIT,Tech}$, electricity sales to the grid, $ESal_{Tech,i,m,p}$, and the annual payment for the utilization of a *BB* under the RHI, P_{RHI}. For pipelines and microgrid (*MG*) cables, binary variables are used to indicate connections between homes. An *MG* controller binary, Z_i, is introduced and its existence is decided by the *MG* cable existence. The demands for the house are met with balance equations that match demand with appropriate technologies:

$$Load_{i,m,p} + Additional\ Demand - \sum_j(\beta_{i,j}Q_{j,i,m,p} - Q_{i,j,m,p}) = E_{Grid,i,m,p} + \sum_{tech} Self_{i,m,p} + StorOut_{i,m,p} \tag{7}$$

$Load_{i,m,p}$ represents a generic demand, while *Additional Demand* can come from a unit (e.g., *AC* electricity) which, when installed, adds extra demand. $E_{Grid,i,m,p}$ represents electrical energy imported from the grid, while $Self_{i,m,p}$ is energy generated for self-use by the installed units. *StorOut* is the power available from storage facilities. *Q* is the power transferred via the *MG* or pipelines from house *j* to *i*. This value is subtracted from the demand and vice versa for *QE*. The left side of the equation is the net demand, met by technologies and imports on the right side. β is a loss coefficient, dependent on the cable or pipe lengths between 2 homes. Looped networks are mitigated by the following equation where *E* is a numerical position of a connected home. A higher order home cannot give energy to lower order homes, only import it from them, while *card* is the value of *i*.

$$E_j \geq E_i + 1 - \left[card_i \times \left(1 - YMG_{i,j} \right) \right] \tag{8}$$

Moreover, energy flows in one direction along connections, and the energy transferred must be equal to the sum of energies from contributing technologies within the house *i*. Finally, the *MG* controller itself uses electricity and therefore has an *O&M* cost.

The electricity generated in the network which exceeds demand can be sold to the national grid. *CSalGRID* represents the annual income from electricity sales for the network and is calculated as the volume of electricity sold for a given technology and time period multiplied by the length of that time period, the number of days in which in that time period appears, and the number of months in which those days appear. This is summed for all time periods, houses and technologies. To ensure that homes do not become power plants, and are only selling electricity and not generating it for profit, a rule is put in place that states that the total energy sold from all technologies cannot

exceed that generated by all units, minus the demand of the home. The annual electricity cost for energy purchase from the grid, *CPurGrid*, is calculated as the sum for all houses and time periods, of the volume purchased in any given period multiplied by the length of time period and the number of days and months. At any time, a house either buys or sells electricity, not both.

$$PurGRID = \sum_{i,m,p} EGRID_{i,m,p} \times PElec \times day(m) \times hours(p) \times season(m) \qquad (9)$$

According to legislation, *BB* units are not allowed to provide heat to more than one home, and there is also a limitation on the annual heat produced from *BB* which receive RHI payments. The capacity of the generating units is based on the demands which can come from self-provisions, sales to the grid, storage and transfer to other homes:

$$Self_{tech,i,m,p} + Sal_{tech,i,m,p} + Stor_{tech,i,m,p} + \sum_j Q_{tech,i,j,m,p} = Gen_{tech,i,m,p} \qquad (10)$$

Power generation from a unit cannot occur in a house unless the unit is installed.

The money earned through FITs is calculated from the FIT price or electricity generated, *PFIT_Tech*.

$$FITPay = \sum_{i,m,p,tech} (EGen_{tech,i,m,p} \times PFITCHP \times day(m) \times hours(p) \times season(m))$$

For the sake of space, only one *CHP* is permitted in which dwelling. Electricity generation from *PV* cells is a function of solar irradiance, which varies with the time of day and seasons, the surface area installed (a variable which the model optimizes) and the panel efficiency, a set parameter. The volume of energy in the *TS* is a function of the volume in the unit in the previous time period, what is sent to the unit, what is withdrawn from the unit for heating and *DHW* demand, as well as the static loss. A balance is needed to calculate how much energy can be withdrawn and is based on energy provided in the previous time period. It is impractical to have *WT* in adjacent houses, hence a rule is put in place that there must be at least one house gap between *WT* installations. Power generated by *WTs* is not a continuous function of the available wind resource but is instead, a piecewise function dependent on the "rated", "cut in" and "cut-out" speed for the units available. Finally, a tax is imposed for electricity taken from the grid, which has its own carbon intensity.

4. Results and conclusions

The model is formulated as a MILP and solved using the GAMS CPLEX solver [8]. A summary of models' statistics and solution times is shown in Table 2. The combined variable import and export pricing increase charges both from and to the grid but, overall, profitability is increased. This is due to the extreme differences in volumes of imported and exported energy. While the relative increase in charges from purchased electricity is much higher than the relative increase in sales, the absolute increase in charges is slightly smaller than absolute increase in sales. This is due to the network generating much of its own energy. Carbon emissions per kWh are increased due to increased sales from *CHP* units which are more economically incentivised by the FIT payments than generation from *WT*. In the variable network design case study, variable pricing greatly affects the installations made and the operation of the DER network. The network becomes much less dependent on thermal storage (*TS*) capabilities and a pipeline connection is installed between houses *i4* and *i5*. The network also becomes less dependent on *AC* units for cooling demands and the number of absorption chillers (*Abs*) is increased. This is due to increased *CHP* sizes which allow *Abs* to be added and

also the ability to share cold loads through the pipelines. Fig. 3 shows the layout of the newly designed network. In terms of operational effects, dynamic pricing increases environmental impacts, as for the fixed network, due to UK FIT payments encouraging electricity generation from *CHPs* over other renewable assets. Profitability increases more than for the fixed network because the model is able to adjust to the changes in pricing and take advantage of a more economical trading scenario.

Table2. Economic and environmental results of the different case studies

Pricing	Constant	Dynamic	Dynamic
Scenario	Baseline	Fixed	Unfixed
CO_2 emissions (kg / kWh)	0.0856	+ 1.17 %	+ 25.00 %
Profitability (£ / year)	1,535.81	1,550.80	1,620.83
Investment cost (£)	51,178.72	+ 0.00 %	+ 12.30 %
Sales to grid (£ / year)	1,106.57	+ 2.00 %	+ 47.30 %
Grid purchases (£ / year)	9.85	+ 143 %	- 100 %
Equations	3,810	3,810	10,397
Variables	4,475	4,475	14,983
Binaries	120	120	226
CPU Time (s)	0.14	0.11	160.22
Fig 3. Layout of the newly designed DER network for dynamic import and export pricing

Furthermore, the short times for solving the models is encouraging as it demonstrates that optimization using dynamic pricing control is achievable and the network should be able to respond rapidly and reliably to incoming demand and pricing data, even for time periods in the distant future.

Abstract

Traditional food supply chains are often centralised and global in nature. Moreover they require a large amount of resource which is an issue in a time with increasing need for more sustainable food supply chains. A solution is to use localised food supply chains, an option theorised to be more sustainable, yet not proven. Therefore, this paper compares the two systems to investigate which one is more environmentally friendly, cost efficient and resilient to disruption risks. This comparison between the two types of supply chains, is performed using MILP models for an ice cream supply chain for the whole of England over the period of a year. The results obtained from the models show that the localised model performs best environmentally and economically, whilst the traditional, centralised supply chain performs best for resilience.
Keywords: supply chain management, flow configuration model, ice cream, centralised versus localised, MILP.

1. Introduction

Food supply chains (FSCs) are complex due to the large amount of actors, but are also unique amongst the supply chains (SCs) due to seasonal production and demand, as well as requiring to operate at refrigerated temperatures to ensure food safety and quality. The traditional FSC require a large amount of resources, which is an issue in a time with increasing need for more sustainable food supply [1, 2]. The majority of the FSC are very global and centralised, a solution designed to minimise the cost of the whole chain and therefore to increase the profits of a company. However, these are not considered sustainable due to the large amount of resource they consume [3]. A theoretical approach has been proposed to make the FSC more sustainable by having it localised [4, 5], a solution where all actors function within the same area. These FSC are seen to be more sustainable since the local customers are using local ingredients and a decrease in CO_2 emissions and resource demand can be achieved [6]. Thus there are significant business trade-offs to consider in deciding on an operational strategy – and some of these trade-offs may be entirely valid between food chains and food transport. Although the localised FSC has been theorised to be more sustainable in environmental terms, this has not been proven through a model, as most existing studies optimise without considering all the chain stages [7, 8]. For comparison of centralised and localised SCs, MILP models have

been developed. To perform this comparison, an ice cream SC model is developed for England, incorporating the use of the 8N configuration neighborhood flow approach [9].

2. The neighbourhood flow approach and the FSC

The model is built for the ice cream SC over a period of one year and consists of 4 different actors. The first set of actors are represented by a total of 16 different suppliers, all with different supply capacities, providing two ingredients. Half of the suppliers will simulate dairy farms, supplying only milk, while the other half will simulate sugar factories, providing the sugar. The second set of actors are the factories where both milk and sugar from the suppliers will use. The milk is transported from suppliers to each factory, where ingredient storage is available, before manufacturing. In the centralised model there is 1 large factory while the localised model considers 8 small factories. All factories make 4 different types of ice cream (SKUs). The third set of actors is represented by the SKU warehouses, which is the location where products are stored during the time the factories are producing more than the demand. In the localised model there will be 8 small warehouses, while the centralised model assumes 3 large ones. Only the product that leaves the factory and needs to be stored will be transported to the warehouse, while the rest is sent directly to the demand centre. The demand centre is the final actor and the customer of the FSC. There is a total of 8 different demand centres where the demand and locations are the same for both the localised and the centralised model. The demand at the centres varies for each type of SKU and across the individual 52 weeks of a year. The movement between the actors of the FSC is summarised in Fig.1.
Figure 1: The flow between the actors of the ice cream supply chain

To simulate the locations, the transport of ingredients and ice cream between the actors all the models will use a neighbourhood flow approach with the use of the 8N configuration as set out by [9]. The neighbourhood flow approach requires the use of a grid system which consists of multiple different regions. A region is specified to contain an actor and the ice cream or the ingredients can be transported from one actor to another through flow from one region to another neighbouring region through 4N or 8N flows. If the corresponding actors that send and receive the transported goods are not in neighbouring regions the simulation model will move the goods from one neighbouring region to another and repeat this process until the goods are delivered to the required actors. The size of each region is taken as being 50x50 km, the distance travelled by the goods through 4N neighbourhood flow is 50 km, while for the 8N flow is 70.7 km. the grid system that the neighbourhood flow approach uses has been set up to simulate the whole England in both models, which resulted in a total of 69 different regions of 50x50 km size (Fig.2). In the centralised model all actors required for the SC can be in any region, and the ingredients and products can be transported through any region shown in Fig.2. For the localised models, different local area sizes and location are selected where the different regions of England are designated by double lines in Fig.2. Moreover, in the localised models London and the SE of England are considered to be the same region due

to Greater London's small size, and the practical assumption that some actors may not be present here, such as the farm, the warehouse or the factory.
Figure2: Grid system for England, used to simulate the FSC models

3. Mathematical formulation

In all the MILP models developed, the constraints remain the same and only the objective equations differ.

3.1. Model constraints

The amount of ingredients h, being taken from the supplier in region g in week t, cannot exceed the amount of ingredients that are available weekly from the supplier:

$$SupplyUse_{h,g,t} \leq MaxSupply_{h,g} \qquad \forall\, h, g, t \tag{1}$$

The total amount of ingredients h, stored in the factory in region g in week t cannot exceed the factory maximum ingredient storage.

$$INVIng_{h,g,t} \leq INVIngCap_{h,g} \qquad \forall h, g, t \tag{2}$$

The amount of ingredients h in the factory storage in region g in week t is equal to the amount of ingredients h that is in the factory storage in the previous week, plus the ingredient delivered from the suppliers minus the amount of ingredients used to produce the SKU in the factory in week t. The set up time and the production time of every SKU

in a factory in region *g* in week *t* cannot exceed the maximum weekly production time allowed for each SKU. The ingredients and the SKU should satisfy mass balances for each region g and week *t*.

3.2. Economic objective equation

The objective of the centralised and localised economic models is to minimise the total economic cost of the whole SC. The costs consists of the factory production costs, *ProdC*, the ingredients purchase, transport, *IngTransC* and storage, *ISC, WHC* costs, the SKU storage and transport, *SKUTransC* costs and a penalty if demand is not met at the demand centres, *DNMPen*:

$$TEC=ISC+ProdC+WHC+IngTransC+SKUTransC+DNMPen \qquad (3)$$

3.3. Resilience objective equation

In the resilience model, localised and the centralised SC are tested under disruptive scenario of the supplier not being able to provide ingredients over an 8 week period of high demand. The objective is to minimise the total demand that is not met at the demand centres.

$$DNM = \sum_i \sum_g \sum_t \left(Demand_{i,g,t} - Retailer_{i,g,t}\right) \qquad (4)$$

To this end, an extra equation is added to the model to calculate the rate of fulfilment for every SKU in every week *t* for all the demand centres.

3.4. Model parameters

The value of the parameters is chosen to closely match realistic values of an ice cream SC. The total yearly demand is split into weekly demands that match the typical seasonal demand (Fig.3). The weekly demand split into the 4 SKUs, and split between the 8 different demand centres across England. The selection of the regions is based on the population for the localised area. The demand centres and their proportion are localised in regions 6 (10%), 23 (32%), 34 (10%), 37 (11%), 43 (8%), 53 (13%), 55 (10%), 67 (5%). The location and maximum supply available from each supplier is the same for both the localised and centralised models. The availability of supply is assumed constant over the year. Each localised region must have a milk and a sugar supplier. The region with milk suppliers are assumed in locations where the density of dairy farms is high. The milk suppliers are in regions 5 (600 t/wk), 16 (1,550 t/wk), 39 (600 t/wk), 41 (600 t/wk), 49 (500 t/wk), 60 (600 t/wk), 61 (700 t/wk), 63 (300 t/wk), while the sugar supplier are in regions 3 (450 t/wk), 9 (800 t/wk), 31 (350 t/wk), 40 (350 t/wk), 43 (300 t/wk), 56 (300 t/wk), 57 (350 t/wk), 67 (150 t/wk). For the centralised model there will be only one large factory located in region 42, the most central region.

For the localised model there are 8 small factories in regions 25, 52, 44, 35, 13, 54, 51, 62. It is assumed that ice cream consists of 75% of milk and 25% of sugar. The factory maximum ingredients capacity differs for all the 8 different factories in the localised model, and the factory maximum ingredients capacity for the single centralised factory in the centralised model is the sum of all the 8 different localised factories maximum ingredients capacities. The warehouses are located in regions 21 (4,000 t), 34 (2,000 t), and 54 (1,170 t) for the centralised model, and in regions 17 (3,000 t), 57 (1,100 t), 45 (620 t), 26 (590 t), 7 (560 t), 56 (560 t), 50 (475 t), 50 (475 t) and 64 (260 t).
Figure3: The weekly demand profile

Moreover, all the cost parameters (ingredients, transport, manufacturing, storage) are expressed according to the values for the UK. If the SC does not meet the demand there is a penalty defined as the price the ice cream would sell at the demand centre.

4. Results

4.1. Economic results

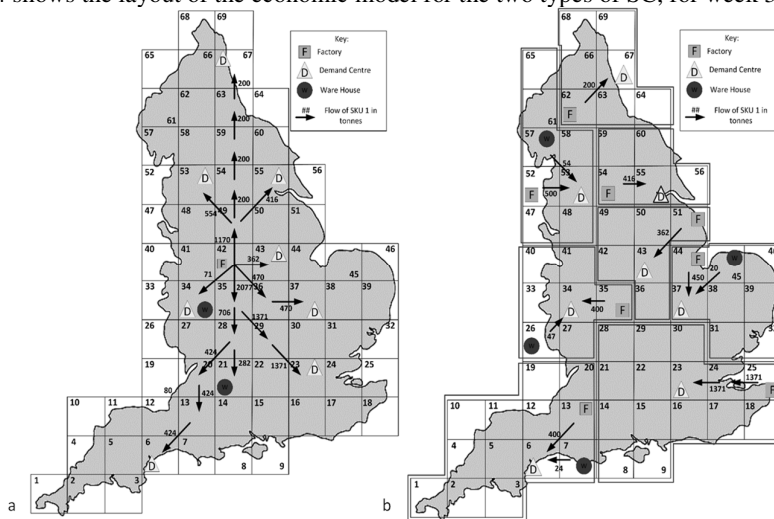
When the centralised economic model is optimised to minimise the total SC cost, the results was that it would cost a total of £214.3 million over all of the 52 weeks. Since over the 52 weeks the SC handles 231,600 tonnes of ice cream, the cost in terms of every unit of ice cream is £925.25 per tonne of ice cream. When the localised economic model is optimised to minimise the total SC costs, it would cost £213 million over the 52 week period. Since the localised SC handles overall the same amount of ice cream as the centralised one, the cost in terms of unit of ice cream is £919.50 per tonne of ice cream. Fig.4 shows the layout of the economic model for the two types of SC, for week 33.


Figure4: Flow of SKU1 in week 33 for the a) centralised SC and b) localised SC

4.2. Resilience results

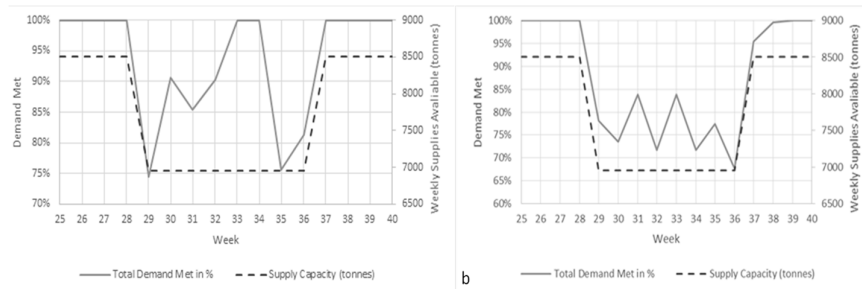
The disruption scenario assumes that the milk supplier in region 16 is not able to provide any milk over an 8 week period in the high season. In the centralised SC the minimum of the demand not being met achieved is 8,582 tonne of ice cream, with the model specifying the overall weekly fulfilment rate. The resilience index for the centralised SC is 0.932. For the localised SC the minimum demand not being met achieved from the optimised model is 16,485 tonnes of ice cream, with the optimised model specifying the overall weekly fulfilment rates. The resilience index in this case is 0.869. Fig.5 shows the demand profile fulfilment during the SC disruption scenario.


Figure5: Demand profile fulfilment during the SC disruption scenario for the a) centralised and b) localised model;

5. Conclusions

This work describes the development of two MILP models to simulate a centralised and a localised ice cream SC in England over 52 weeks, using the 8N neighbourhood flow configuration. The two SC are compared at economical and resilience level. The localised SC is £1.377 million cheaper than the centralised one due to the shorter transportation distances between the various actors. At resilience level, the centralised SC has a higher resilience index, due to the possibility to being supplied from other regions when one of the suppliers fails to fulfil the demand. Although centralised distribution shows efficiency benefits, the distributed system may have the ability to reduce temporal, geographical and administrative gap between decision makers and the impact of their decisions, reduce the possibility of widespread impacts if production systems fail and avoid the need for long-distance transport infrastructure. Rather than considering the two configurations as alternatives to each other, a sustainability assessment considering economic, environmental and societal situations where complementarities and synergies between centralised and localised FSC occur should be investigated.

Novel refrigeration cycle configurations for performance improvements in LNG processes at small scale

Fernando Almeida-Trasvina* and Robin Smith

Centre for Process Integration, School of Chemical Engineering and Analytical Science, The University of Manchester, Manchester M13 9PL, UK

hector.almeidatrasvina@manchester.ac.uk

Abstract

The refrigeration cycles employed in the LNG industry are highly energy-intensive. The costs associated to the shaft work energy required for refrigerant compression usually dominates the overall operating costs of the LNG plant. In this work, four different single mixed refrigerant (SMR) cycle configurations, including the commercial PRICO cycle and the CryoMan cycle, are studied for energy-efficiency improvements in the production of LNG at small scale (i.e. up to 1 million tonnes per annum, MTPA). The cycle configurations are based on structural modifications applied to the PRICO cycle. The four configurations are first optimised to minimise shaft work demand, so analysis is carried out in the scenario in which each cycle fully exploits their corresponding configuration. Additionally, the complexity of the SMR cycles, in terms of number of compression stages is kept similar, so the energy savings can be associated to the structural modifications only. From the four SMR cycles, the CryoMan cycle is the most energy-efficient, achieving saving of around 8.5% compared to the commercial PRICO cycle. The exergy analysis applied to their multi-stream heat exchangers (MSHE) suggests that the structural modifications allow reducing the refrigeration duty at the lowest temperature level to bring energy savings.

Keywords: LNG, small scale, refrigeration cycle, SMR cycles.

1. Introduction

Small scale production of liquefied natural gas (LNG), i.e. up to 1 MTPA, is becoming commercially attractive. To liquefy a natural gas stream (to around –160 °C), energy-intensive refrigeration cycles are usually employed. The shaft work energy required for refrigerant compression strongly dominates the overall operating costs of the LNG plant. Thus, minimising shaft work energy demand of a given cycle configuration leads to minimising operating costs. The PRICO single mixed refrigerant (SMR) cycle is the commercial benchmark SMR cycle for small scale production of LNG.

The energy-efficiency of mixed refrigerant cycles can be improved by structurally modifying its configuration, as shown by Almeida-Trasvina and Smith (2018) for cascade cycles in large scale production of LNG. However, little research has been done in structural modifications to mixed refrigerant cycles for LNG processes at small scale. He et al. (2019) optimised the energy-efficiency of an SMR cycle consisting of two MSHE stages but with a flash unit before the first MSHE unit. Aslambakhsh et al. (2018) optimised the PRICO cycle considering both operating and capital costs. Nguyen et al. (2018) optimised the energy-efficiency of the PRICO cycle for five different

natural gas feeds. Morosuk et al. (2015) analysed the PRICO cycle using exergy analysis for improving its energy-efficiency. Mehrpooya and Ansarinasab (2015) assessed two SMR cycles using an exergoeconomic analysis.

In this paper, the energy-efficiency performance of four different SMR cycles is studied. The SMR cycle configurations are based on structural modifications applied to the PRICO cycle, and are taken from Zheng (2009). The SMR cycles are first optimised in a case study for small scale production of LNG. The complexity of the SMR cycles (in terms of number of compression stages) is kept similar, so differences in energy performance can be associated to their structural modification only. Exergy analysis is applied to each configuration so as to bring insights of how each structural modification allows achieving energy savings.

2. Configuration of the single mixed refrigerant (SMR) cycles

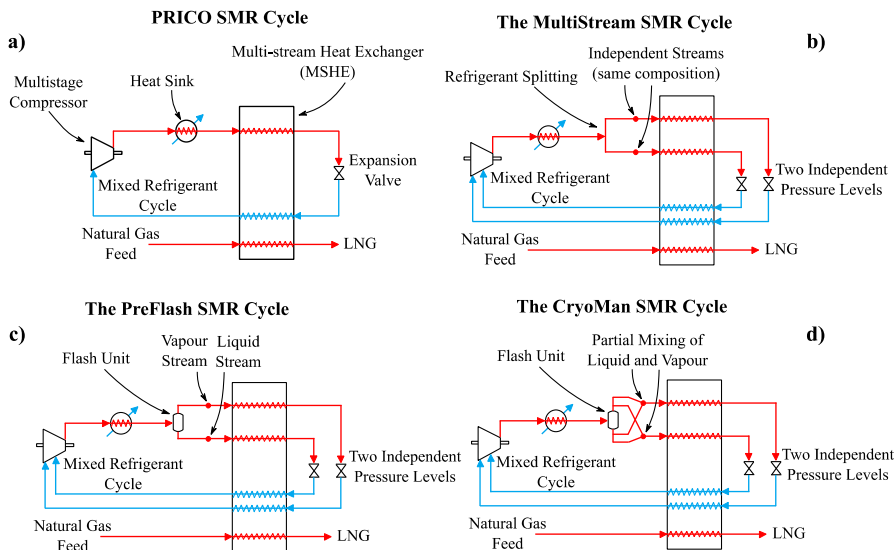
Figure 1 shows the four SMR cycles studied in this paper. The PRICO cycle is shown in Figure 1a. In the MultiStream cycle (Figure 1b), the structural modification consists in splitting the refrigerant stream flow rate into two streams before entering the MSHE, each with an independent evaporating pressure. In the PreFlash cycle (Figure 1c), the structural modification consists in using a flash unit; the resulting refrigerant streams would then have different compositions between each other. In the CryoMan cycle (Figure 1d), the main refrigerant stream is also split into two streams using a flash unit, and the resulting flash outlet streams are partially mixed to create the two refrigerant streams that provide cooling in the MSHE.


Figure 1. SMR configurations: a) PRICO; b) MultiStream; c) PreFlash; d) CryoMan.

The configurations of the SMR cycles are defined to have a total of three compression stages for refrigerant compression, in order to have similar complexity across the SMR cycles since compressors are major contributors to capital costs and also impact on energy performance (Mokhatab et al., 2014, Ch. 3.2).

3. Optimisation of the SMR cycle configurations

The operating variables of the four SMR cycles are optimised in order to analyse their best performance, i.e. the scenario in which the SMR cycles are fully exploiting their corresponding structural modifications to reduce the energy demand.

All the four SMR cycle configurations are optimised to minimise the specific shaft work energy demand (Equation 1) in a case study to produce LNG at small scale. The data of the natural gas is taken from Fahmy et al. (2016), and is given in Table 1. The natural gas feed flow rate is equivalent to LNG production of 1.0 MTPA. It is assumed that the minimum temperature approach for heat exchange in the MSHE is 2 °C; a maximum pressure ratio of 3.5 has been defined for any compression stage.

$$\frac{W^{Total}}{\dot{m}_{LNG}} = \frac{\sum_{i=1}^{n} W_i^{Stg}(\phi)}{\dot{m}_{LNG}} \tag{1}$$

The optimisation strategy followed in this work is similar to that employed by Almeida-Trasvina and Smith (2018) for the optimisation of cascade refrigeration cycles for large scale production of LNG. The strategy consists in applying a stochastic algorithm to search the solution space (using Genetic Algorithm) and avoid local optima, and the best solution found is fed to an SQP solver to refine the solution.

Table 1. Natural gas specifications for the case study.

Flow rate [kg·s^{-1}]	31.71
Inlet pressure [bar]	63.0
Inlet temperature [°C]	25.0
Outlet temperature [°C]	−161.0
Composition [mole fraction]	
Methane	0.98385
Ethane	0.01070
Propane	0.00090
n-Butane	0.00020
CO_2	0.00005

The results from the optimisation are presented in Table 2. The CryoMan cycle is the most energy-efficient of the four SMR cycles. The CryoMan cycle performance is equivalent to a specific shaft work demand of 28.67 MW·MTPA LNG^{-1}, whereas that of the PRICO cycle is 31.32 MW·MTPA LNG^{-1}. That is, the CryoMan cycle achieved energy savings of around 8.5% compared to the PRICO cycle.

The results in Table 2 suggest that manipulating the refrigerant composition brings energy savings. The modification applied to the PreFlash cycle (i.e. the flash unit) implies splitting the refrigerant stream into two streams that have different composition with respect to each other (unlike with the MultiStream cycle). Energy savings of 3.22% are achieved by the PreFlash cycle compared to the MultiStream cycle.

Table 2. Energy-efficiency comparison between the SMR cycles (relative to PRICO cycle).

	PRICO SMR Cycle	MultiStream SMR Cycle	PreFlash SMR Cycle	CryoMan SMR Cycle
Compression Stages	3	3	3	3
LNG production [MTPA]	1.00	1.00	1.00	1.00
Specific shaft work [MW·MTPA^{-1} LNG]	31.32	30.47	29.38	28.67
Energy savings [%]	——	+ 2.71%	+ 6.19%	+ 8.46%

The CryoMan SMR cycle allows manipulating further the refrigerant composition by partially mixing the flash unit outlet streams. Energy savings of around 2.78% are achieved by the CryoMan SMR cycle relative to the PreFlash SMR cycle.

4. Exergy analysis of the SMR cycles

In refrigeration cycles, exergy is defined as the minimum shaft work input (Equation 2) needed to provide refrigeration at a given temperature, assuming a thermodynamically reversible process (Venkatarathnam, 2008, Ch. 1.4). Equation 2 suggests that the exergy increases either as the refrigeration temperature (T_{Evap}) decreases, or as the refrigeration duty (Q_{Evap}) increases. The term in brackets on the right-hand side of the equation is widely known as the Carnot factor. Alternatively, exergy can be expressed as in Equation 3, which implies that the exergy demand is also dependent on the nature of the refrigerant mixture employed (values of enthalpies and entropies).

$$Ex = -W_{rev} = Q_{Evap}\left(\frac{T_{Cond}}{T_{Evap}} - 1\right) \tag{2}$$

$$Ex = n\left[\left(h_{out} - h_{in}\right)_{Evap} - T_{Cond}\left(s_{out} - s_{in}\right)_{Evap}\right] \tag{3}$$

Exergy analysis is applied to the SMR cycles, by plotting the exergy composite curves (from Equation 2) of the MSHE for each SMR cycle. The exergy composite curves are the analogue of the conventional composite curves, but the temperature axis in the latter is replaced by the Carnot factor. The area between the exergy composite curves represents exergy loss, associated to the temperature difference needed for heat transfer.

Figure 2 shows the exergy composite curves for each optimised SMR cycle. As can be implied from Equation 2, the area between the exergy composite curves is minimised at the cold end of the process across the four SMR cycles. Moreover, the overall exergy losses are gradually reduced with each of the structural modifications applied. The exergy losses in the MSHE for the PRICO cycle are equivalent to 2.71 MW, whereas in the CryoMan cycle the exergy losses are equivalent to only 1.13 MW, i.e. the losses are reduced by around 58%.
Figure 2. Exergy composite curves of MSHE for each SMR cycle.

The main results from the exergy analysis over the MSHE unit for each SMR cycle are shown in Table 3. The exergy efficiency in Table 3 is defined as the ratio of overall exergy change of the natural gas stream (15.72 MW) to the total shaft work demand for refrigerant compression. The exergy duty in the MSHE is calculated for both composite curves at intermediate temperatures using Equation 3.

Table 3. Summary of exergy performance results for each SMR cycle.

	PRICO SMR cycle	MultiStream SMR cycle	PreFlash SMR cycle	CryoMan SMR cycle
Shaft work demand [MW·MTPA LNG^{-1}]	31.32	30.47	29.38	28.67
Exergy Duty MSHE [MW]	54.79	53.12	44.06	43.17
Exergy Losses MSHE [MW]	2.71	2.22	1.18	1.13
Exergy Efficiency [%]	50.19	51.59	53.50	54.83

As shown in Table 3, the exergy duty in the MSHE is decreased by around 9.1 MW when the flash unit is introduced, since the refrigerant flow rate in the low pressure stream (at the lowest temperature level) is significantly reduced. Also, the flash unit helps reducing the exergy losses by creating two different refrigerant compositions that yield a reduced area between the composite curves (see Figure 2).

In the CryoMan cycle, partial mixing of the streams leaving the flash unit allows to reduce further the flow rate of the stream at the lowest temperature level, and also to reduce the exergy losses by manipulating the refrigerant composition of each resulting stream. Thus, the exergy demand further reduced, bringing the corresponding savings in shaft work demand.

5. Conclusions

The structural modifications applied to the PRICO cycle were demonstrated to bring significant energy savings – up to 8.46 % with the CryoMan cycle – for configurations with similar level of complexity in terms of number of compression stages, and for the same liquefaction duty. The results from the exergy analysis suggest that structural modifications should be applied with the aim to reduce the refrigeration load at the lowest temperature level. Additionally, creating different refrigerant compositions and manipulating refrigerant flow rates allow minimising the exergy losses in the MSHE.

Further study is still needed on the implications of structural modifications in the configuration of LNG mixed refrigerant cycles. More insights would be useful to further develop and optimise novel LNG refrigeration cycles more systematically.

Abstract

Current industrial trends promote reduction of material and energy consumption of fossil fuel burning, and energy-intensive process equipment. It is estimated that approximately 75% of the energy consumption in hydrocarbon processing facilities is used by such equipment as fired heater, hence even small improvements in the energy conservation may lead to significant savings [1, 2]. In this work, a mathematical modelling and optimisation study is undertaken using gPROMS® ProcessBuilder® to determine the optimal operating conditions of an existing API 560 Type-E vertical-cylindrical type natural draft fired heater, in operation at the Atuabo Gas Processing Plant (GPP), in the Western Region of Ghana. It is demonstrated that the optimisation results in significant reduction of fuel gas consumption and operational costs.

Keywords: fired heater, tubular heater, mathematical modelling, optimisation, gPROMS.

1. Introduction

Fired heaters, also commonly called furnaces, are a primary source of thermal energy for process heating operations in petroleum refining and chemical plants. They have been studied extensively, both experimentally and theoretically, and previous work [1-3] draws attention to the need of conserve energy, improve energy efficiency and reduce carbon emissions. Notably, most fired heaters models from literature are lumped parameter models with steady-state assumptions, mainly due to the complex thermodynamic mechanisms making the problem computationally expensive to solve [1-3]. For instance, longitudinal and radial variations or temperature gradients of the hot flue gases along the vertical height of the fired heater are normally ignored. The novel approach adopted for this work involves the distributed parameter system modelling of the temperature profiles in the tubular coils and the heat transfer fluid (HTF). The resulting 'white-box' model may serve as basis for conducting simulation studies to aid decision-making and to identify the best operating conditions within the specified constraints that minimise the operational costs. The model is applied to a 15.8 MW fired heater (H600) in operation at the GPP. The total heat input is supplied by the combustion reaction of fuel gas and combustion air occurring in 8 sets of floor mounted, upwards firing, gas only pre-mix

main burners. A fuel gas-fired pilot is also supplied to each set of main burners. Aside the need to improve efficiency, significant deviations from the desired HTF supply temperature have on many occasions hampered smooth operation. Currently, there is no validated model of H600 to aid monitoring of thermal efficiency, to identify areas for process improvements and to aid trouble-shooting of process deviations. Furthermore, the current temperature control scheme has been ineffective at rejecting disturbances such as changes in fuel gas pressure.

2. Mathematical model

The mathematical model is applied for each section of H600 (Fig.1), namely convection (CS), shield (SS) and radiant section (RS). A 1D tube coil running through the RS, SS and CS is considered. The axial variation is related to the tube wall and the HTF temperatures, while the flue gas temperature along the sectionalised vertical height of the heater is lumped. The tubes in the SS are assumed isolated from the RS. All tube coils are uniformly heated. The combustion process is assumed to be steady-flow and the CO_2, N_2 and other non-hydrocarbon components of the fuel are ignored in combustion reaction calculations. Key geometrical characteristics of H600 are summarised in Table1.

Fig.1: The distinct sections in a box-type style fired heater

Table1: Geometry of the fired heater

Parameter	Radiant section	Shield section	Convection section
Number of tubes	88	24	72
Overall length [m]	138.69	21.8	62.94
Outside tube diameter [mm]	114.3	114.3	114.3
Effective tube length [m]	12.192	6.245	6.245
Cold plane surface area [m^2]	217.8	33.27	-
Total heating area (bare) [m^2]	398.46	53.86	-
Total heating area [m^2]	-	-	1946
Orientation of tubes	Vertical	Horizontal	Horizontal
Tube material of construction	ASTM A106 Gr.B	ASTM A106 Gr.B	ASTM A106 Gr.B

2.1. Radiant section/firebox

On a rate basis, the conservation of energy in the fired heater is given by:

$$Q_F + Q_{air} = Q_R + Q_{WL} + Q_G \tag{1}$$

Where Q_F=the total rate of heat released by the combustion of the fuel gas [W]; Q_{air}=the rate of heat flow into the burners in the combustion of air [W]; Q_R=the heat duty of the RS [W]; Q_{WL}=total rate of heat loss through the fired heater walls [W]; Q_G=rate of heat flow out of the RS in the flue gases [W].

$$Q_F = N_B \cdot \left(min\left(\eta_{MB} \cdot \left(\frac{\dot{m}_{F-MB} \cdot LHV_F}{N_B}\right), Q_{MaxHR-MB}\right) + min\left(\eta_{PB} \cdot \left(\frac{\dot{m}_{F-PB} \cdot LHV_F}{N_B}\right), Q_{MaxHR-PB}\right) \right) \tag{2}$$

With N_B=number of burner in use; η_{MB}, η_{PB}=efficiency of the main/pilot burners; LHV_F=lower heating value of the fuel gas [J/kg]; $Q_{MaxHR-MB}$, $Q_{MaxHR-PB}$=design maximum rate of heat released per main/pilot burner [W]; $\dot{m}_{F-MB}$, $\dot{m}_{F-PB}$=total mass flowrate of fuel gas supplied to main/pilot burners [kg/s]. Based on the ratios of the maximum heat released per pilot burner to the main burner, $\dot{m}_{F-PB}$ is assumed to be 0.0133% of $\dot{m}_{F-MB}$.

$$Q_{air} = \dot{m}_{act-air} \cdot c_{air} \cdot (T_{air} - T_{ref}) \tag{3}$$

Where $\dot{m}_{act-air}$=actual mass flowrate of air supplied to burners [kg/s]; c_{air}=mass specific heat capacity of air [J/kgK]; T_{ref}=reference temperature [K]; T_{air}=temperature of air [K].

$$Q_R = F \cdot \sigma \cdot \alpha \cdot A_{cp,r} \cdot (T_{Gr}^4 - T_{w,avg,r}^4) + h_{Gr} \cdot A_{Sr} \cdot (T_{Gr} - T_{w,avg,r}) \tag{4}$$

With F=overall heat exchange factor to allow for both geometry and non-blackbody emissivities of cold and hot bodies; σ=the Stefan-Boltzmann constant [W/m²K⁴]; $A_{cp,r}$=area of cold plane replacing a bank of RS tubes [m²]; $A_{S,r}$=total outside area of the RS tubes [m²]; h_{Gr}=convection heat transfer coefficient flue gas-outside of the tube wall [W/m²K]; T_{Gr}=temperature of flue gases leaving RS [K]; $T_{w,avg,r}$=average temperature of the wall in the RS, calculated as the mean between the temperature at the entrance and the temperature at the exit of the section [K].

$$Q_{WL} = f_{WL} \cdot Q_{in} \tag{5}$$

With f_{WL}=factor of fired heater wall losses; Q_{in}=total rate of heat into the fired heater [W]. The overall enthalpy of the flue gases is expressed as the sum of the product of the molar flow rates and the specific heat capacities of each component gas. Thus:

$$Q_G = \sum n_i \cdot \Delta H_{m,i} \tag{6}$$

With n_i=molar flowrate of component i released by the combustion reaction [kmole/s]; $\Delta H_{m,i}$=the molar enthalpy change of component i [J/kmole].

The rate of change and axial variation of the thermal energy per unit length of tube wall and the HTF are given as:

$$\frac{\partial H_{wr}(t,z)}{\partial t} = F \cdot \sigma \cdot \pi \cdot D_o \cdot (T_{Gre}^4 - T_{wr}^4(t,z)) + h_{Gr} \cdot \pi \cdot D_o \cdot (T_{Gre} - T_{wr}(t,z)) - h_{Lr} \cdot \pi \cdot D_i \cdot (T_{wr}(t,z) - T_{Lr}(z,t)) \tag{7}$$

$$\frac{\partial H_{Lr}(t,z)}{\partial t} = -u_{Lr} \cdot \frac{\pi \cdot D_i^2}{4} \cdot H_{Lr}(t,z) + h_{Lr} \cdot \pi \cdot D_i \cdot (T_{wr}(t,z) - T_{Lr}(z,t)) \tag{8}$$

Where H_{Lr}=the enthalpy of the wall in the RS; D_o, D_i=the outer/inner tube diameter [m]; T_{Gre}=the effective radiating gas temperature [K]; T_{wr}=temperature of the wall in the RS [K]; h_{Lr}=convection heat transfer coefficient wall-HTF [W/m²K]; T_{Lr}=temperature of the HTF in the RS [K].

A general balance equation for the combustion of gaseous hydrocarbon fuels with dry excess air is published by [2] in the form:

$$C_A H_B + \varepsilon \left(A + \frac{B}{4}\right)(O_2 + 3.762N_2) \to A \cdot CO_2 + \frac{B}{2}H_2O + (\varepsilon - 1)\left(A + \frac{B}{4}\right)O_2 + \varepsilon\left(A + \frac{B}{4}\right)3.762N_2 \tag{9}$$
Where ε = excess air.

While the conservation of mass for the flue gases is expressed as: $\dot{m}_F + \dot{m}_{Air} = \sum \dot{m}_i (10)$.

The composition of the fuel gas is assumed as: 65.59% C1; 17.8032% C2; 12.2454C3; 0.8817% i-C4; 1.5703 n-C4; 0.1766% i-C5; 0.1303 n-C5; 0.0515% C6+; 0.0231% N_2 and 1.4976% CO_2.

With $\dot{m}_F$=total mass flowrate of fuel gas [kg/s]; $\dot{m}Air$=total mass flowrate of air [kg/s]; i=CO_2; H_2O; $O2$; $N2$. The temperature control valve is modelled as in [8].

For the SS and CS, the heat transfer equations are written as:

$$Q_{Section} = Q_{Section,in} - Q_{Section,out} \tag{11}$$

The rates of heat for the flue gases in and out of the sections are calculated using a third-degree polynomial function for the specific heat in the form: $\bar{C}_p = \alpha + \beta T + \gamma T^2 + \delta T^3$.

For the wall and the HTF, equations like (7) and (8) are used and adapted to the geometries and operating conditions of the CS and SS, respectively.

For each section of the fired heater, the general form of the initial and boundary conditions for the temperature of the wall, T_w and the fluid, T_F are expressed as:

$$T_{L,Section}(0,z) = T_{Lout,Section-1}; \qquad T_{w,Section}(0,z) = T_{wout,Section-1}; \qquad T_{L,Section}(t,0) =$$
$$T_{Lout,Section-1}, \forall t; \; T_{w,Section}(t,0) = T_{wout,Section-1}, \qquad \forall t \qquad (12)$$

The Berman equation [1] is used to determine the convection heat transfer coefficient, h_{Gs} in the CS: $h_{Gs}=1.1(h_{Cs}+h_{Rs})$. The radiant heat transfer coefficient is not considered for the finned tube bank of the CS.

$$h_{Cs} = \left(1.273 T_{f,s}^{0.28} \cdot G_{max,s}^{0.6}\right)/D_0^{0.4} \qquad (13)$$

With $\quad G_{max,s} = \dot{m}_G/A_{min,s}$ = flue gas max flux [m/s]; $A_{min,s}$=the minimum cross-section flow area [m²]; $T_{f,s}$=the film temperature [K].

The film temperature, $T_{f,s}$ and the radiant heat transfer coefficient, h_{Rs} are calculated from:

$$T_{f,s} = 0.5\left(T_{w,avg} + T_{Gr}\right) \qquad (14)$$
$$h_{Rs} = 0.2565 T_{Gr} - 2.84 \qquad (15)$$

For each section of the heater, the convection heat transfer coefficients for the inside tube wall and the HTF, varying with the axial position, are calculated from the relation:

$$h_L(z) = Nu(z) \cdot k_L(z)/D_i \qquad (16)$$

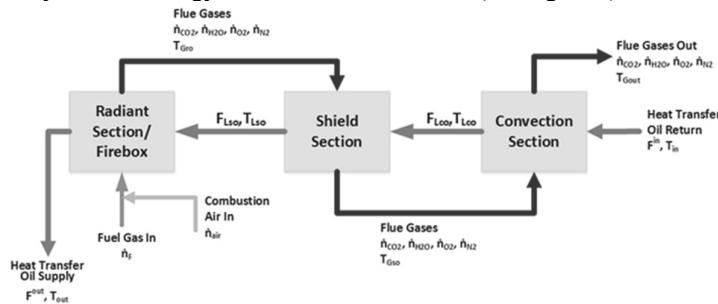
While, within the application ranges, the local Nusselt number is calculated from the Gnielinski correlation [5] and the local Darcy friction factor using Petukhov's correlation [6]. The heat transfer coefficient for the RS, h_{Gr} is specified as 11.36 W/m²K as reported by [7]. The thermophysical properties (density, specific heat capacity, thermal conductivity, and kinematic viscosity) of the tube coil material and the HTF, all of which vary with temperature are expressed in polynomial regression forms obtained using curve fitting techniques of the manufacturer's thermal data. The heat capacity relation of ASTM A106 Grade B as a function of temperature could not be obtained from literature and Type 304 stainless steel was used instead [4]. The different sections, RS, SS, CS of H600 are connected by mass an energy flows at their boundaries (see Figure 2).


Figure 2: Connectivity between the distinct zones of the fired heater

The parameters for H600, mostly consisting of geometrical quantities are specified in Table 2.

3. Optimisation

Energy consumption in the fired heater is to be optimised to identify the best process operating conditions within the specified constraint that minimise fired heater operational costs. The objective function is formulated as an economic model describing the sum of two key daily operating costs: the fuel gas burned, and the electrical power consumed in pumping the HTF:

$$\min \; f = (86400 \cdot c_F \cdot \dot{m}_F \cdot LHV_F) + \left(c_E \cdot \frac{F_L^{in} \cdot \rho \cdot g \cdot H_P}{3.6 \cdot 10^6 \cdot \eta_P \cdot \eta_M}\right) \cdot t_r \quad (17)$$

Subject to
$$25 \leq VT \leq 75$$
$$1.0 \leq \varepsilon \leq 1.5$$
$$130 \leq F_L^{in} \leq 340$$
$$523.15 \leq T_{out} \leq 548.15$$

With VT=valve travel [%]; F_L^{in}=total return volumetric flowrate of HTF to fired heater [m³/h]; T_{out}=HTF supply temperature [K]; η_P=pump efficiency=0.75; η_M=motor efficiency=0.85; c_F=fuel cost=$6.161 \cdot 10^{-9}$ [\$/J]; c_E=cost of electric power=0.32 [\$/kWh]; g=acceleration due to gravity [m/s²]; H_P=pump head=51 [m]; t_r=pump runtime per day [h]; ρ=average density of the fluid=735.16 [kg/m³]. The lower heating value of the flue gas, LHV_F was considered equal to 46,890 kJ/kg.

Table 2: Parameters for the sections of the heater.

Parameter	Radiant section	Shield section	Convection section
σ, [W/m²K⁴]	$5.7604 \cdot 10^{-8}$	$5.7604 \cdot 10^{-8}$	-
D$_i$, [m]	0.1023	0.1023	0.1023
D$_o$, [m]	0.1143	0.1143	-
Equivalent cold plane area, [m²]	217.88	33.27	-
Overall exchange factor, F	0.590	0.559	-
Reference temperature, T$_{ref}$ [K]	298.15	298.15	298.15
$Q_{MaxHR-MB}$, [W]	1,472,682	-	-
$Q_{MaxHR-PB}$, [W]	29,307	-	-
Mass per unit length of radiant tube coil, [kg/m]	16.07	16.07	20.5

4. Results and discussion

A plot of HTF temperature versus the axial position and time in the CS, SS, and RS, are illustrated in Figures 3-5, respectively. An overall temperature profile for the HTF is shown in Figure 6.
Figure 3: HTF temperature in the CS
Figure 4: HTF temperature in the

Table 3 shows a summary of the simulation results compared with measured data from the plant. A base case scenario is considered where the daily operating cost is 1,599.81 \$/day, based on a flow of fuel gas of 0.632 kg/s, a HTF return volumetric flow rate of 139.5 m3/h, and a total operating number of burners of 8. The optimisation using the model in gPROMS® resulted in an operating cost of \$776.18 \$/day, which equals to

283,305.70 \$/year. Overall, this translates into savings of about \$360,625 \$/year compared with the base case scenario. In percentage terms, savings of about 51.48% could be achieved.
Figure 5: HTF temperature in the RS
Figure 6: HTF temperature in H600

Table 3: Simulation results at 380 seconds.

Parameter	Predicted	Measured	%Error
Valve travel, VT [%]	50	37.45	-33.51
HTF Supply temperature, T_{out} [K]	505.58	523.95	3.51
Flue gas temperature, T_{Gr} [K]	647.19	758.7	14.7
Average radiant tube wall temperature, [K]	511.84	544.47	5.99
Flue gas temperature at exit of CS, [K]	546.13	520.50	-4.92

For a simulation time of 786 seconds, the optimum supply temperature is identified at 548.4 K. These results demonstrate how a model-based process systems approach can be deployed to achieve optimal operation of the fired heater. However, a more comprehensive study, with a validated model must be carried out before optimal operating conditions can be clearly identified.

5. Conclusions

The simulation results of the heater model indicate that the distributed parameter dynamic model proposed in this work closely approximates the actual process behaviour under varied operating conditions. Potential for significant annual savings have been identified. Furthermore, a parameter estimation and model validation should be performed to ensure good agreement between the model predictions and the actual behaviour of H600.

Molecular Modelling of Co-processing Biomass Pyrolysis Oil with Vacuum Gasoil in an Oil Refinery Fluid Catalytic Cracking Unit

Mohamed Al Jamri, Robin Smith, Jie Li [*]

Centre for Process Integration, School of Chemical Engineering and Analytical Science, The University of Manchester, Manchester M13 9PL, UK

Jie.li-2@manchester.ac.uk

Abstract

Integration of biomass resources in petroleum refining for sustainable production of transportation fuels has gained increased attention in the last few decades (IEA, 2013). One potential integration option is to mix biomass-based pyrolysis oil (BPO) with petroleum gas oil (VGO) and then co-process the blend in oil refinery fluidised catalytic cracking (FCC) units (Naik *et al.*, 2017). It is important to establish the prediction model of product yield and quality with such coprocessing in FCC units. In this work, a novel molecular-level modelling approach is proposed for kinetic modelling of co-processing BPO with VGO in an oil refinery FCC unit. Molecular-level characterisation of BPO and VGO blends using Molecular Type and Homologous Series matrix is first conducted. Then, a novel reaction network is synthesized and a reaction model is developed for the proposed reaction network which considers not only the complex intermolecular interactions between various types of molecular attributes in the feed, but also the interactions between individual molecules and catalyst surface. A hybrid optimisation strategy combining genetic algorithm with deterministic optimisation algorithm is developed to obtain the optimal parameters in the reaction model. The results demonstrate an overall good agreement between measured and predicted yields using the developed kinetic model for VGO: BPO blending ratio of 90:10, C/O ratio between 5 and 8, and reaction temperature of 525°C. PONA composition, oxygen compounds compositions and oxygen content in each product fraction such as gasoline, diesel and gas oil can also be predicted. The effect of different blending ratios of BPO and VGO on oxygenates compositions is demonstrated.

Keywords: Catalytic cracking, Fast pyrolysis oil, biomass, refinery, MTHS matrix.

1. Introduction

Integration of renewable biofuels into transportation sector is gaining increased attention. Several integration options (pyrolysis oil upgrading, fermentation, and gasification/F-T synthesis) have been proposed and investigated for biofuels production (Huber *et al.*, 2006; Petrus and Noordermeer, 2006; Vispute *et al.*, 2010; Serrano-Ruiz and Dumesic, 2011). Among these options, co-processing biomass pyrolysis oil (BPO) with heavy petroleum fractions such as vacuum gasoil (VGO) in the refinery fluid catalytic cracking (FCC) unit arises as a promising option. This is mainly due to the efficiency of pyrolysis processes in phase transformation (up to 70% liquid yield), as well as the low capital investment required as a result of using refinery's economy of scale (Wang *et al.*, 2016).

To evaluate and optimise this co-processing option, it is important to develop mathematical models for product yields and properties prediction in the FCC unit with

such co-processing of BPO and VGO. Although several approaches have been proposed for modelling of conventional FCC units (Feng *et al.*, 1993; Xu *et al.*, 2005; Gomez-Prado, 2009), only limited efforts have been reported for modelling of co-processing BPO with VGO in FCC units (Naik *et al.*, 2017). Conventional modelling approaches cannot be directly applied for modelling of co-processing option due to their inability to accurately characterise oxygenated molecules in the feedstock. Molecular-level characterisation and molecular-level reaction models can be used to overcome the limitations of the previously mentioned approaches. Such techniques are based on detailed description of the sizes and types of the various molecules present in process streams. A detailed molecular-level reaction network that takes into account the various interactions between the molecules themselves and the catalyst (if any) surface is employed to describe the chemical and physical changes that occur inside process units.

In this work, a novel molecular-level modelling approach is proposed for the modelling of co-processing BPO with VGO in an FCC unit. The proposed approach comprises molecular-level characterisation of blended feedstock using Molecular Type and Homologous Series (MTHS) matrix method, as well as molecular-level reaction network for catalytic cracking of hydrocarbons and oxygenated species found in blended feedstock. The proposed reaction network is tuned using a hybrid optimisation strategy combining Genetic Algorithm (GA) and Successive Quadratic Programming (SQP) to guarantee obtaining a reproducible solution in the vicinity of global optimum using a robust search method. The proposed approached is applied for the modelling of a pilot-scale FCC riser used for co-processing catalytic-pyrolysis-derived bio oil with VGO at a blending ratio of 10 wt.%. The results demonstrate an overall good agreement between measured and predicted yields using the developed kinetic model for VGO: BPO blending ratio of 90:10, C/O ratio between 5 and 8, and reaction temperature of 525°C. PONA composition, oxygen compounds compositions and oxygen content in each product fraction such as gasoline, diesel and gas oil can also be predicted. The effect of different blending ratios of BPO and VGO on oxygenates compositions is demonstrated.

2. Methodology

2.1 Process Stream Characterisation

The developed characterisation approach in this work provides detailed molecular-level information compatible with reaction models, efficiently and at low cost. In particular, the proposed method is based on Molecular Type and Homologous Series (MTHS) matrix which uses a 2-D matrix to capture the size and the type of the various molecules present in the stream, simultaneously (see Figure 1). The characterisation methodology used in this work is similar to the methodology presented in a previous work (Al Jamri *et al.*, 2018). The only difference is that in this work VGO and BPO are characterised independent from each other using two matrices. The two matrices are then blended according to the required blending ratio used in the feed stream to the process. In addition, the degrees of freedom (DOF) in the characterisation problem is reduced via introducing Volume Average Boiling Point (VABP) concept. This allowed to reduce the number of DOF from 3 to 2 for each hydrocarbon homologous series, which resulted in total reduction of DOF from 21 to 17 in the characterisation problem of VGO.

2.2 Reaction Network Modelling Methodology

Modelling of conventional catalytic cracking reaction network is a complex task. The complexity of this problem increases significantly when BPO oxygenated molecules are considered. This is mainly due to the limited information available in literature on bio oil molecules catalytic cracking pathways and kinetics compared to conventional hydrocarbon molecules usually found in petroleum streams. In addition, the already known kinetic behaviour of conventional petroleum fractions maybe affected when BPO is co-processed with VGO in a refinery FCC unit. Therefore, molecular-level reaction network is devised to quantify the effects of introducing oxygenated molecules on the kinetic behaviour of catalytic cracking reactions. The reaction network is synthesised by considering two different categories of molecules: hydrocarbons and oxygenates. Reaction pathways and kinetics for hydrocarbon molecules are deduced from previous work of Gómez-Prado (2009). Model compound studies for catalytic conversion of bio oil oxygenated molecules (Adjaye and Bakhshi, 1995a) are used for the synthesis of bio oil molecules catalytic cracking reaction network. The kinetic expressions and kinetic parameters values used to populate the kinetic network are taken from previous work (Adjaye and Bakhshi, 1995b).

The developed reaction network comprises 328 reaction terms, 299 of which are used for the description of hydrocarbons catalytic cracking reactions. The remining 29 reactions are used for the representation of catalytic conversion of bio oil oxygenated molecules. The main feature of the proposed reaction network is its ability in predicting the composition of various hydrocarbons (PONA) and oxygenates (Phenolics, aldehydes and ketones, acids and esters, and alcohols) in each liquid product fraction, which can be used to satisfy industrial requirements in monitoring and controlling product quality. In addition, the proposed methodology avoids the need for kinetic parameters re-fitting when feedstock composition and/or blending ratio changes as a result of using molecular-level reaction network.

Kinetic parameters tuning problem is formulated as a non-linear optimisation problem. The objective function considers the absolute difference between measured ($Y_{L,OP}^{msd}$) and model-predicted ($Y_{L,OP}^{PRE}$) products' yields of each lump (L) and operating condition (OP) (see Eq. 1). Different weights (W_L) are used to give similar sizes for each difference between the different product yields.

$$Obj = \sum_{L,OP} W_L \sqrt{\left(Y_{L,OP}^{msd} - Y_{L,OP}^{PRE}\right)^2} \qquad \text{Eq. 1}$$

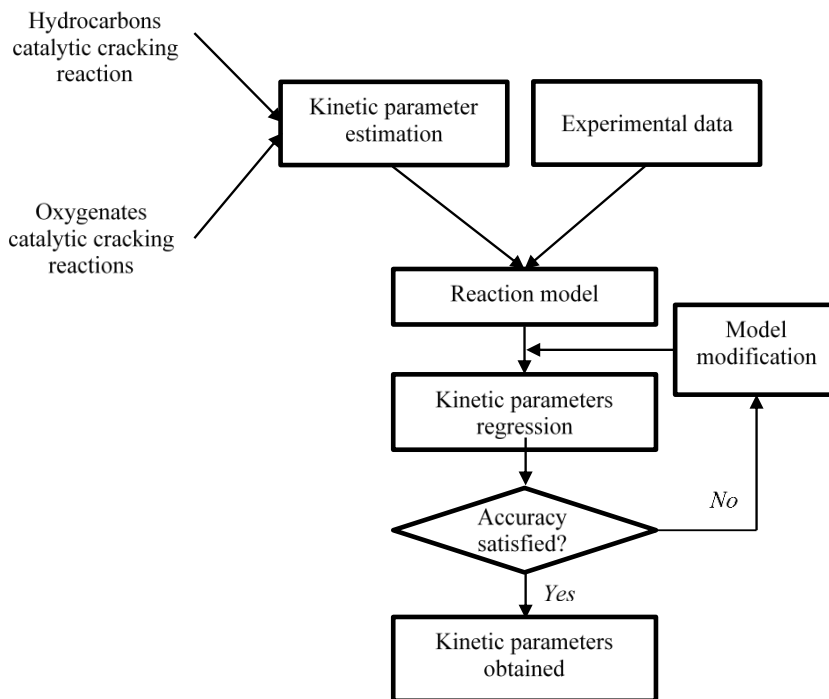
Kinetic parameters regression problem is solved using hybrid optimisation framework. Both stochastic and deterministic optimisation algorithm are employed in a unified framework (Figure 2). Initially, stochastic search methods (GA) is used to increase the chance of obtaining a solution in the vicinity of global optimum. The solution obtained from GA is fed to the deterministic algorithm (SQP) to improve the quality of the solution. This increases the chance of obtaining a reproducible solution in the vicinity of global optimum. The results obtained using this hybrid optimisation framework show good agreement between predicted and measured products' yields.


Figure 2 Kinetic Parameters Tuning Problem Solution Algorithm

3. Results and Discussion

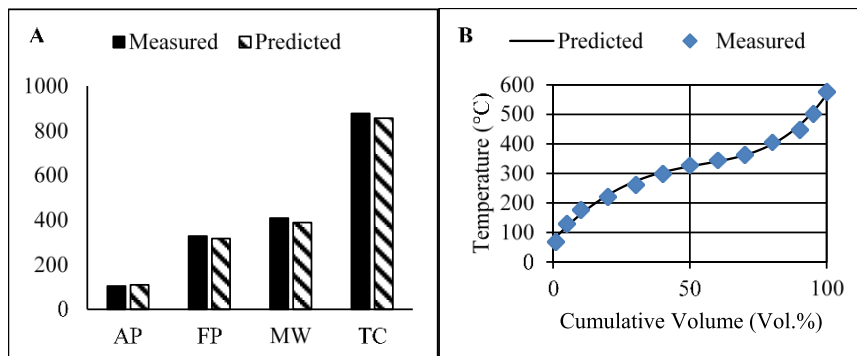
The proposed characterisation approach has been tested in the characterisation of a blend of 90:10 VGO:BPO. This blend is used as a feedstock for pilot-plant scale FCC riser (Wang *et al.*, 2016). In this work, BPO stream is characterised independently from VGO. The two characterisation matrices obtained are combined together according to the specified blending ratio and fed to the reaction model. This way, blending ratio in the reaction model can be varied without the need to re-characterise the blended stream. Figure 3A shows the values of relative error when measured bulk properties of VGO are compared to model-predicted values. A maximum error of 5% was found in the prediction of molecular weight (MW) and aniline point (AP). Figure 3B shows a comparison between measured and predicted boiling curve of BPO.


Figure 3 VGO and BPO characterisation results

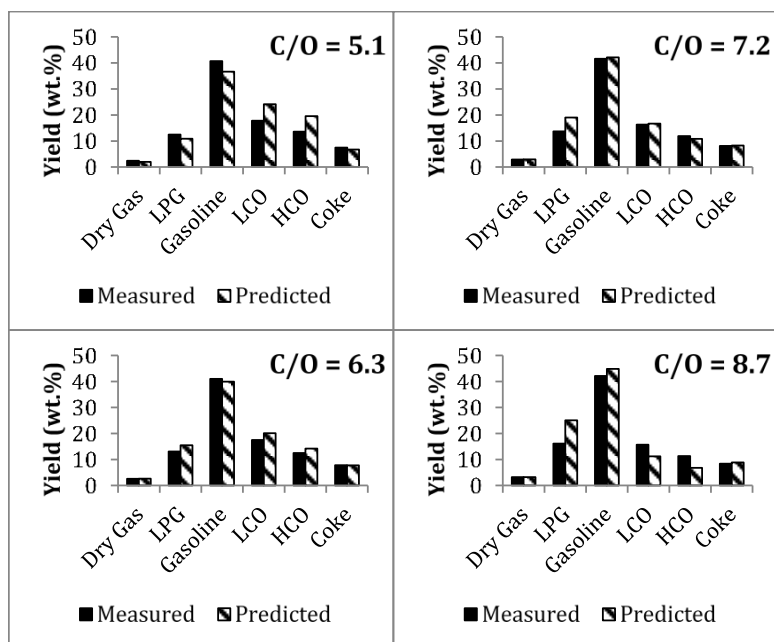
The compositional matrix obtained is fed to the reaction model, and kinetic parameters tuning is carried out using the proposed hybrid optimisation framework. The results obtained are shown in Figure 4. The value of index of correlation (R^2) for this fitting is found to be 0.933, which indicates good correlation with measured data.


Figure 4 Comparison between Measured and Predicted Yields at different C/O ratio

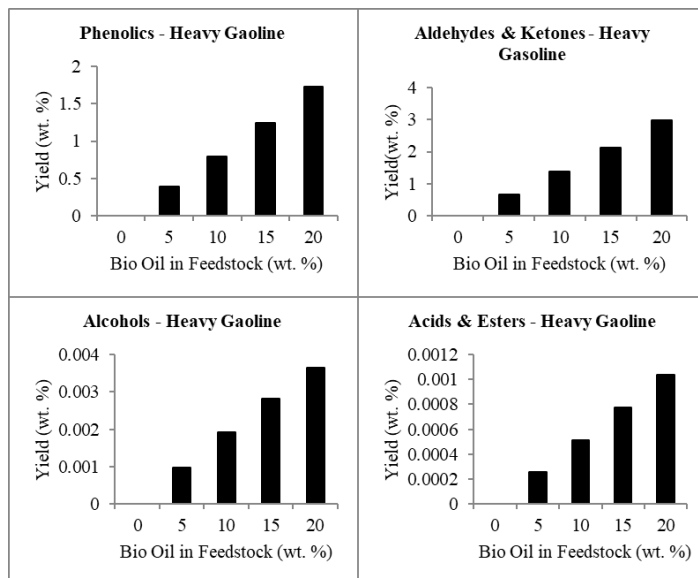
The novelty of the proposed modelling approach lies in the ability of the developed modelling framework in predicting PONA and oxygenates yields at different blending ratios. Figure 5 shows oxygenates yields in heavy gasoline fractions as a function of blending ratio.


Figure 5 Oxygenates Yields in Heavy Gasoline Fraction at different Blending Ratio

4. Conclusions

A novel approach for molecular-level modelling of co-processing BPO with VGO in an FCC unit is proposed. The methodology comprises a novel characterisation framework in which bulk properties are converted to molecular information using optimisation-based modelling approach. A novel molecular-level reaction network comprising 328 reactions is proposed and used for the modelling of pilot-plant scale FCC riser. The results obtained showed good accuracy when compared to experimentally measured data. The model exhibits ability in predicting the various molecular attributes (hydrocarbons and oxygenates) at different blending ratios.

Abstract

In this work there are shown different strategies to cope uncertainty in large-scale chance-constrained nonlinear programs. We present the design of a flare system as a case study. The design of this system is influenced by several uncertain factors, such as the volume and composition of the waste flow stream to be combusted and the ambient conditions. These systems are currently designed based on typical historical values for waste fuel gases and ambient conditions. Consequently, an improperly designed flare can be susceptible to extreme events previously not experienced. Particularly, we use moment matching (MM) when the algebraic form of the moments and the quantile function of the chance constrained (CC) distribution is known, and for more general settings when the distribution cannot be predicted we use the scenario approach (AS), the popular conditional value at risk (CVaR) and the recently proposed sigmoid value at risk (SigVaR). We demonstrate that the SigVaR approximation offers the best results and this approach overcome the conservative results of the AS and CVaR.

Keywords: Uncertainty, design, sigmoid conditional value at risk, flares.

1. Introduction

We study the chance-constrained nonlinear program:

$$\min_{d \in D} \varphi(d) \tag{1a}$$

Subject to

$$\mathbb{P}\left(f\left(d, \Xi\right) \le \bar{f} \right) \ge 1 - \alpha \tag{1b}$$

We review exact approaches to handle chance constrained problems (CC-P). We consider the special case in which the algebraic form of the quantile function is known or approximately known, and we propose to use moment matching to compute its parameters. However, there are some cases where the nonlinear chance constrained problems are particularly difficult to solve because nonlinear propagation makes it hard to obtain the distribution of output variables (this case will be analysed in a future work).

To handle more general settings, we consider the use of three different approximations. The first one is the scenario approximation, in this approach we approximate the chance constrain ensuring that the constrain is satisfied for each scenario or with probability of 1, and this implies that the constraint is satisfied for any probability different to one. This is extremely conservative; nevertheless, it let us express the chance constrain using the standard scenario-based stochastic programming formulation. The second approximation is the conditional value at risk, this approximation enables expressing our problem as a common nonlinear optimization problem, but CVaR can be slightly conservative. Moreover, the CVaR approximation does not offer a mechanism to enforce convergence to a solution of CC. The third approximation is the sigmoid value at risk approximation (Cao and Zavala, 2018), which provides a mechanism to determine exact solutions for CC-P.

2. Flare systems

Gas flares are used as safety (relief) devices that are used all over the world to manage abnormal situations in infrastructure systems (natural gas and oil processing plants and pipelines), manufacturing facilities (chemical plants, offshore rigs), and power generation facilities. Abnormal situations include equipment failures, off-specification products, and excess materials in start-up/shutdown procedures. In particular, flares prevent over pressurization of equipment and use combustion to convert flammable, toxic or corrosive vapors to less-dangerous compounds (Sorrels et al., 2017). A proper design of flare systems is vitally important due to it is influenced by several uncertain factors, such as the amount and composition of the waste fuel gases to be combusted and the ambient conditions like wind velocity. An improperly designed flare can be susceptible to extreme events previously not experienced or have as a result an oversized and expensive equipment. Here, it is proposed to use stochastic programming formulations to systematically capture uncertain conditions in the design procedure.
Figure 1. Flare system generic diagram.

3. Physical model

It was formulated a mathematical model for sizing a flare system (see Figure 1). The design goals are to minimize the equipment cost while controlling the thermal radiation level at ground level. It was based on the American Petroleum Institute standard 521 as follows:

The heat released by combustion H (BTU/h) is a function of the random input waste flow Q (lb/h) and the heat of combustion h_c (BTU/lb):

$$H = h_c Q \tag{1}$$

The flame length L (ft) can be calculated as a function of the released heat using an approximation of the form:

$$\log L = a_1 \log H - a_2 \tag{2}$$

The wind speed w (ft/s) is an important environmental factor that affects the tilting of the flame and the distance from the center of the flame. The following correlations capture the flame distortion as a result of the wind speed and the exit velocity:

$$\log \Delta X = \log\left(a_5 L\right) + a_6 \left(\log w - \log U\right) \tag{3}$$

$$\log \Delta Y = \log\left(a_7 L\right) - a_8 \left(\log w - \log U\right) \tag{4}$$

The flare stack diameter t (ft) is sized on a velocity basis. This is done by relating this to the Mach number M and the waste flow as:

$$M^2 = \left(\frac{a_3}{t^2}\right) Q^2 \tag{5}$$

The flare tip exit velocity U (ft/s) is function of the flow and the diameter:

$$U = a_4 \frac{Q}{t^2} \tag{6}$$

Here, ΔX and ΔY (ft) are the horizontal and vertical distortions. The distortions are used to compute the horizontal X, vertical Y, and total distance D (ft) to a given ground-level safe point (r,0) as:

$$X = r - \left(\frac{1}{2}\right)\Delta X \tag{7}$$

$$Y = h + \left(\frac{1}{2}\right)\Delta Y \tag{8}$$

$$D^2 = X^2 + Y^2 \tag{9}$$

Here, h (ft) is the flare height. The flame radiation K (BTU/h ft^2) is a function of the heat released and the total distance:

$$K = a_9 \left(\frac{H}{D^2}\right) \tag{10}$$

A primary safety goal in the flare stack design problem is to control the risk that the radiation exceeds a certain threshold value $\bar{k}$ (BTU/h ft^2) at the ground-level reference point (r,0). This is modelled using the CC:

$$\mathbb{P}\left(K \leq \bar{k}\right) \geq 1 - \alpha \tag{11}$$

The objective function is the cost (USD), which is a function of height and diameter:

$$\varphi(t,h) = \left(a_{10} + a_{11}\, t + a_{12}\, h\right)^2 \tag{12}$$

The height and the diameter play a key role in controlling the radiation at the reference point (i.e., a higher and wider flare reduces the radiation intensity). As a result, there is an inherent trade-off between capital cost and safety that must be carefully handled.

4. Case study

The design was considered of a flare stack that combusts a waste fuel gas flow, Q (see Figure 1). The goal is to design a flare system that minimizes cost and satisfies CC on the thermal radiation using the AS, CVaR, SigVaR, and MM approaches. In this work, the case is presented in which the input flow to the flare stack follows a log-normal distribution (with mean a = 10,000 lb/h and standard deviation b = 3,000 lb/h to exemplify a distribution with isolated events). All formulations were solved using 1000 random samples for the inlet flow (see Figure 2). The flare design must satisfy a CC on the radiation with a maximum threshold ($\bar{k}$) of 2,000 BTU/h ft^2 and with a probability $1 - \alpha = 0.95$. The optimization formulation is an NLP with 9,005 variables that was implemented using the open-source modelling language JuMP (Bezanson et al., 2017) and solved with Ipopt (Wächter and Biegler, 2006).

5. Results

Table 1 presents the optimal cost, diameter, and height for the flare system under the used approaches. The results show that the design of the AS approximation is the most conservative. The design is 64% more expensive than the MM design. This is since the

AS approach does not allow for explicit control of the probability of constraint satisfaction. The CVaR approximation reduces this highly conservatism, but it considerably overdesigns the flare stack. The optimal height obtained with CVaR is 67.70% larger and 20% more expensive than those obtained with MM; therefore, CVaR approximation reduces the extreme conservatism of the AS, but it still overdesigned. Table 1 also presents that the optimal solution of SigVaR ad MM are very close. The SigVaR design is only 1% more expensive than the MM approach, and that let to highlight the fact that the SigVaR solution is rightly conservative.

Table 1. Optimal Values for Design Variables

	AS	CVaR	SigVaR	MM
Cost (USD)	233,179	172,329	143,609	142,128
Diameter (ft)	1.70	1.70	1.70	1.70
Height (ft)	179.87	105.08	65.16	63.00

Figure 2 shows the empirical PDFs for the input flow and for the radiation at the optimal solution of the CVaR, SigVaR, and MM approaches. First, it is observed that, for the MM approach, the distribution of the radiation is indeed log-normal. This indicates that the structure of the flare model preserves the log-normal shape of the input flow. It is also observed that the histograms of SigVaR and MM are quite similar, with SigVaR being slightly more conservative. In particular, the tail of the SigVaR distribution is very similar to that of MM (the tail reaches values of 6,000 BTU/h ft^2 for SigVaR, compared to 6,100 BTU/h ft^2 with MM). The histogram of CVaR further validates the observation that this approach is very conservative (the tail reaches values of 4,000 BTU/h ft^2)
Figure 2. (Top-left) Inlet flow PDF, (top-right) radiation PDF using MM, (bottom-left) radiation PDF using CVaR, and (bottom-right) radiation PDF using SigVaR.
Figure 3. Radiation CDFs using MM, CVaR and SigVaR.

Figure 3 compares the optimal radiation CDFs obtained with CVaR, SigVaR, and MM. It can be seen again that CVaR is very conservative, achieving probability levels for the chance constraint of 98−99% (when 95% is only required). Also, the CDFs for SigVaR and MM overlap for the log-normal case, reinforcing that SigVaR provides good quality approximations and that the distribution of the radiation is indeed log-normal and thus MM is a good approach to solve the problem.

6. Conclusions

An application of moment matching techniques was presented to reformulate chance constraints when the shape of the underlying density function is known. It was also demonstrated the use of conservative approximations, that can be applied to more general setting in which the shape of the density function in unknown. A flare system design study showed that a sigmoid approximation overcomes the conservativeness of the popular conditional value-at-risk and scenario approaches, and it can be an excellent alternative when moment matching is not applicable. The proposed approaches enable the solution of large-scale NLPs with chance constraints.

Abstract

This work presents a general mathematical programming model for satisfying water, energy and food needs in isolated and low-income communities involving different process integration approaches. The problem consists in determining the optimal and sustainable configuration to satisfy the energy, water and food demands. Also, the use of waste-to-energy technologies is proposed aiming to obtain valuated products from wastes to reduce the environmental impact. A multi-objective analysis is presented considering the consumption of fresh water, the greenhouse gas emissions and the cost of the integrated system as objective functions. As case study, the community with the lowest index of poverty and marginalization from the State of Guerrero in Mexico is presented. The results show that it is possible to satisfy the water, energy and food needs in isolated communities accounting for integrated processes.

Keywords: Water-Energy-Food Nexus, Isolated community, Polygeneration, Optimization, Process integration.

1. Introduction

Water, energy and food are critical resources for meeting the social demands and socioeconomic development of communities and societies around the world (Fuentes-Cortés and Ponce Ortega, 2017). Nevertheless, there are communities that do not have access to energy and, consequently, there is a lack of access to water and food. Many rural communities or small towns still do not have access to these resources mainly due to their geographic location that makes difficult the interconnection with the electrical grid (Sánchez et al., 2015). Moreover, the provision of water from the public network is a big problem. Satisfying the basic needs of inhabitants in isolated communities is a problem that is closely related to the water-energy-food nexus due to the inhabitants consume considerable amounts of resources to meet their demands (Martínez-Guido et al., 2017). Water, energy and food are inextricably interrelated and each of them depends on others (Zhang and Vesselinov, 2017). The water-energy-food nexus is considered to achieve a sustainable development that allows maintaining the security of these resources and promote economic growth without affecting the environment considerably. However, the inadequate management of these resources may also

produce significant environmental impacts. Currently, alternative energy sources have been used to decrease the environmental impact. Also, there have been reported several studies related to the use of renewable energies implemented in isolated communities to generate electric energy (Ahadi et al., 2016). Furthermore, other researches have focused on distributed generation to produce electricity in remote places by isolated systems due to the generation units are close to the consumers and the transmission energy losses are negligible; examples of this type of generation are polygeneration systems, which can be defined as the simultaneous production of two or more energy utilities and products, seeking to take advantage of the maximum potential of the consumed resources. It has been demonstrated that polygeneration systems reduce fuel consumption, operational costs and consequently reduce the environmental impact, which is associated to the greenhouse gas emissions. There are many studies that propose the use of different schemes of distributed generation to meet the energy demands at a household level. Other researches have been focused on integrating different processes to take advantage of the available resources in residential complexes (Nuñez-López et al., 2018). Nevertheless, none of the previous mentioned works have considered the water-energy-food nexus involving a polygeneration system that allows to decrease the use of fresh resources and the environmental impact in an isolated community.

Another important challenge to decrease the environmental impact is planning a sustainable waste management system. In this context, Diaz-Barriga-Fernandez et al. (2017) proposed a multi-objective optimization approach for the strategic planning of a municipal solid waste management system considering recycle, reuse, transportation, separation and distribution of solid wastes. The management of municipal solid waste has been identified as one of the global challenges that must be carefully faced to achieve sustainable goals, recent researches have focused on proposing processes that convert waste-to-energy or valuated products. Matsakas et al. (2018) investigated the conversion of municipal solid waste to energy and chemicals by biological and thermochemical treatments that are among the most used technologies.

However, none of the previous researches has focused on studying different types of solid waste treatments in a low-income municipality to be a community in which their needs can be met through the proper management of their resources and recycled wastes. In addition, no research has been conducted to address the integration of water-energy-food nexus and the management of solid wastes in isolated communities, which can help to reduce the environmental impact and improve the living conditions of the inhabitants. Faced with this problem, it is needed to implement a system capable of integrating the energy-water-food nexus so that the needs of the inhabitants of the isolated community can be met. In this context, a polygeneration system is an attractive option to provide electricity, heating and cooling to the community, satisfying the energy demands making proper management of water and the resources which in turn will facilitate the food production and consequently the access to food.

2. Problem Statement

This work presents a mathematical programming model for the design of a residential polygeneration system in an isolated community considering the water-energy-food nexus (Figure 1). The problem consists in determining the optimal and sustainable configuration to satisfy the energy, water and food demands of the inhabitants. To meet energy demands, the existence of different cogeneration units such as Internal

Combustion Engines, Fuel Cells, Microturbines and Stirling Engines were contemplated. In addition, there was considered the use of of renewable energies such as solar collectors, aerogenerators and solar panels to help to satisfy the energy demands of the community. Water demand was satisfied by rainwater collection systems and wells, it was proposed the use of rainwater collection systems for provide water in the community, agriculture activities, cattle activities and gardening. Wastewater generated in the community was sent to blackwater and greywater treatment plants. The treated greywater was used in gardening, cattle and agriculture. Different types of crops and animal production were considered to satisfy the food demands of the inhabitants. The agriculture activities involve the production of peanut, jicama, corn, lemon, mango, papaya, and sorghum, and the livestock activities are related to the bovine, porcine, ovine, goat and bird production. On the other hand, the generated municipal solid wastes are separated in plastic, metal, paper, glass and non-recyclables, the latter can be treated in process plants such as pelletization, incineration, gasification, pyrolysis and anaerobic digestion to obtain pellets, steam, natural gas and pyrolysis oil that can be used as an energy source or can be sold.

The objective functions of the problem are to minimize the consumption of fresh water, the greenhouse gas emissions and the cost (Eq. (1)).

$$OF = \{ \min Cost; \ \min Water; \ \min GHGE \} \tag{1}$$

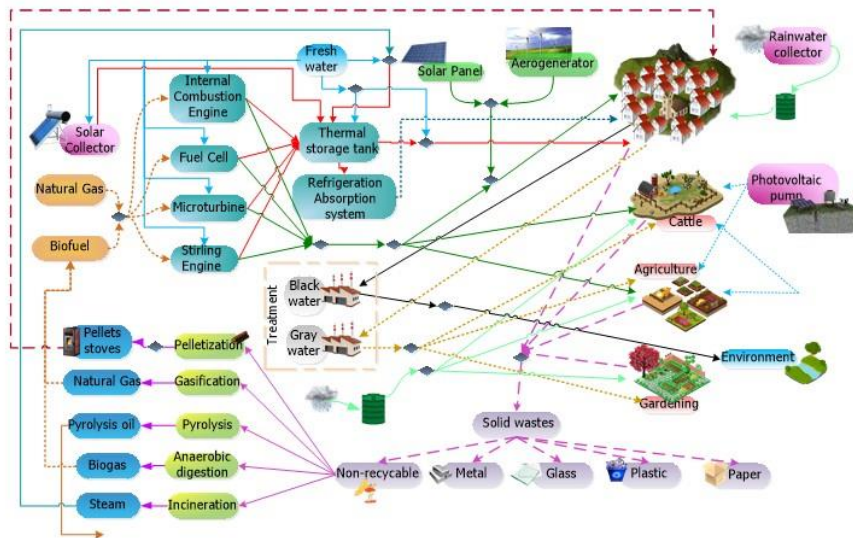
The economic objective function (*Cost*) considers the minimization of the total annual cost associated to satisfy the needs of the community, which includes operating and capital costs for each needed unit and the sales associated with animals, crops, pyrolysis oil, natural gas, biogas, pellets and recyclable products. Additionally, the environmental objective function involves the minimization of fresh water consumption (*Water*) and the minimization of greenhouse gas emissions (*GHGE*) produced by the cogeneration units and the process plants for non-recyclable wastes. To solve this problem, in this paper is proposed the superstructure shown in Figure 1 to satisfy the demand.


Figure 1. Proposed superstructure.

3. Case Study

There is considered the community of "Cochoapa el Grande", located in the State of Guerrero in Mexico with coordinates 17° 12′ N 98° 27′ O as case study, this community has been listed as the municipality with the highest index of poverty and marginalization in the country, mainly due to its geographical location which coincides with a mountainous zone called "Sierra Madre del Sur". The difficult access to the community as well as the irregular distribution of their localities causes that the water supply of the public network represents a severe problem and consequently agricultural and livestock activities are affected. Therefore, there is difficult access to food. Likewise, there is a lack of electric power, affecting the provision of services that are essential for human, social and economic development. Faced with this problem, there is proposed a polygeneration system capable of integrate energy, water and food demands of this isolated community.

4. Results

The proposed model corresponds to a Mixed-Integer Linear Programming problem and it was implemented in the software GAMS. The mathematical model consists of 3,138 continuous variables, 21 binary variables and 1,561 equations.
The points obtained from the functions to minimize water consumption, greenhouse gas emissions and cost are shown in Table 1.

Table 1. Results obtained for each scenario evaluated.

	Min Water	Min GHGE	Min Cost
Cost ($)	161,000,000	161,000,000	-27,903,000
Water (m³/y)	3,060,000	3,088,500	3,178,700
GHGE (t CO₂/y)	147,400,000	12,790,000	900,200,000

For the evaluated scenarios, water consumption does not vary significantly between the different solutions. If we compare the minimum consumption of fresh water scenario and the minimum cost scenario, which represents the highest consumption of fresh water, this only increase approximately 4 %. The selected cogeneration technologies for the case of minimizing the consumption of fresh water are represented by a Microturbine, a Fuel Cell and a Stirling Engine, while in the case of minimizing emissions a Fuel Cell is proposed, and in the case of minimizing costs the selected technology was the Microturbine. The case for minimizing the emissions selects the Fuel Cell for power generation. In the case of minimum consumption of fresh water, fuel requirements increase by 28 %. On the other hand, in the case of minimizing costs, 46 % more fuel is required than in the case of minimizing emissions, which causes a greater generation of greenhouse gases. For solid waste management, the processing plants selected in the scenario of minimizing emissions are the pelletization and pyrolysis plants. In the case of minimum consumption of fresh water, the pelletization, pyrolysis and incineration plants are selected, which represents a considerably increase in the GHGE and, in the case of minimizing costs, gasification, incineration and pelletization plants are selected.

Table 2. Results for the multi-stakeholder analysis.

	Stakeholder weights			Objectives			% Dis
Case	**COST**	**WATER**	**GHGE**	**COST**	**WATER**	**GHGE**	**% Dis**
	($U.S./y)	(m³/y)	(t CO_2/y)	($U.S./y)	(m³/y)	(t CO_2/y)

4	2	7	1	-15,080,000	3,060,000	96,820,000	5.42
5	1	2	7	-14,950,000	3,084,100	21,580,000	9.38
6	7	1	2	-26,990,000	3,070,400	96,820,000	6.24
7	8	1	1	-26,990,000	3,070,400	96,820,000	6.24
8	1	8	1	-15,080,000	3,060,000	96,820,000	5.42
9	1	1	8	-24,660,000	3,094,200	12,790,000	10.18

Due to the conditions of the community and because of the lack of processes to generate energy and manage the resources, very high costs are presented, which lead to an exponential increase in greenhouse gas emissions, as well as an increase in the use of water. This can be attributed to the fact that in the case of minimizing costs, it is sought to obtain the maximum production of animals and crops for sale. In the same way, the gasification and pyrolysis plants are selected to make use of the natural gas generated in the gasification plant and thereby reduce the cost associated with the purchase of natural gas and obtain profits from the sale of pyrolysis oil.

Because the objectives are in conflict, the methodology of Multi-stakeholder Optimization is used in this work with the purpose of finding a balance between the objective functions and giving feasible solutions to the problem. In addition, a dissatisfaction analysis is included in each of the proposed feasible solutions. The dissatisfaction of each of the objective functions, as well as the total dissatisfaction for each of the scenarios is presented in Table 2. There were randomly generated weights and it was calculated the percentage of dissatisfaction.

The results obtained in general show that in cases were the objective has a greater weight in the GHGE objective present a greater percentage of dissatisfaction. Moreover, it is possible to obtain better results in cases were the weights are distributed between the three objectives, as Cases 1, 2 and 3, with 4.5% of dissatisfaction, which is the lowest percentage of dissatisfaction of all the evaluated feasible solutions.

5. Conclusions

This paper has presented a multi-objective optimization approach for the optimal design of a polygeneration system applied in a low-income and isolated community. The proposed model is capable to determine the optimal configuration of technologies that meet the demands of water, energy and food of the community accounting for economic and environmental objectives. There were evaluated different scenarios for the

minimum cost of the integrated system, the minimum fresh water consumption and the minimum greenhouse gas emissions generated. To trade-off the proposed objectives, it is presented a multi-stakeholder approach which is capable to find the compromise solution which is the point where the objectives are minimized simultaneously. As case study, it was considered the community of Cochoapa el Grande, which is the community with the lowest human development index of Mexico. There were generated different feasible solutions and it was evaluated the dissatisfaction percentage of each one. The results show that the compromise solution is very close of the Utopian Point, which indicates that is possible to obtain a solution that satisfies almost entirely the minimum of the objectives. It should be noticed that in the generated feasible solutions the dissatisfaction increases when it is assigned a major priority to the GHGE objective. On the other hand, the lowest percentage of dissatisfaction corresponds to the cases in which the priorities are distributed between the three objectives.

Abstract

This work presents an optimization model for the strategic planning to satisfy the national demands of natural gas considering unconventional extraction such as shale gas and offshore extraction and conventional ways to produce associated and non-associated natural gas using enhanced gas recovery systems, as well as importation. The model incorporates a multi-objective optimization strategy to obtain trade-offs between economic, environmental and health issues.

A case study from Mexico is presented to show the applicability of the proposed approach to satisfy the increasing national demand of natural gas through different extraction ways. Furthermore, in the presented study, economic, environmental and health factors were evaluated to select the best option. The economic factors consider costs associated with the production and treatment of natural gas, the used fresh water and the costs that involve the transportation of natural gas from its point of extraction to final markets. Regarding to the environmental impact, the fresh water consumption and CO_2 emissions are considered. The occupational health of the involved processes in the production of natural gas is also evaluated, this because workers are continuously exposed to hazardous substances that can cause long-term damage. Results show that it is possible to decrease imports to satisfy the national demands for natural gas only with their own resources, and taking care for the economic, environmental and health issues.

Keywords: Strategic planning, Natural gas, Fresh water, CO_2 emissions, Occupational health.

1. Introduction

Several works have analysed the strategic planning of shale gas to satisfy diverse demands; in this sense, Gao and You (2015) proposed a model for designing a shale gas supply chain accounting for the involved water supply, as well as the economic and environmental impacts.

It should be noticed that a large part of the oil reserves is below the sea. In Mexico, more than 80% of total oil production is provided from the sea. This zone is in the states of Campeche, Yucatán and Quintana Roo, and includes approximately 189,056 square kilometres (PEMEX, 2017). However, this method is very challenging, since it does not

only must deal with extracting oil to the surface by drilling in the sea, without having visibility, but also avoiding the sea contamination with hydrocarbons.

Once the oil is not extracted from the well, means that this is exhausted. However, there are several improved recovery techniques that stimulate the subsoil, these are known as Enhanced Oil/Gas recovery (EOR/EGR), causing the release of oil that is currently contained in the deposit. Li et al. (2018) investigated the natural gas production from fracture-filled methane hydrate reservoirs by the CO_2 replacement method.

Moreover, occupational health deals with all aspects of health and safety in the workplace and it has a strong focus on primary prevention of hazards. The health of the workers has several determinants, including risk factors at the workplace leading to cancers, accidents, musculoskeletal diseases, respiratory diseases, hearing loss, circulatory diseases, stress related disorders and communicable diseases and others (WHO, 2018).

However, it is important to note that the reported approaches for the strategic planning for satisfying the national demands of natural gas have not considered simultaneously conventional and unconventional resources with economic, environmental (associated to emissions and used water) and health implications for the proper analysis. These are important points that must be studied for the correct planning to satisfy the national demands of natural gas for any country, because these are intrinsically related. Therefore, this paper presents a general mathematical model to obtain energy independence from a country to take advantage of its own reserves of fossil fuels through using unconventional extraction methods such as shale gas, offshore extraction, and considering conventional ways to obtain natural gas that the country already has. In addition, in this paper the nexus between environment and health damages together with the economic implications is involved; also, the model considers reducing the consumption of fresh water and generation of CO_2 emissions, considering the configuration that represents the least damage for the workers that dangerous substances present in the extraction and production processes.

2. Problem Statement

Throughout the years, the conventional extraction of fossil fuels has been decreasing but the energy needs have increased; this way, different unconventional forms for the extraction of natural gas have been explored. However, these new ways of extraction have considered the costs and environmental damage mainly associated to emissions of CO_2, but the chronic diseases caused in workers and the implications in the use of fresh water have not been properly addressed since the planning stage.
The objective is to satisfy the national demands of natural gas for a given country.

3. Optimization Model

The proposed mathematical programming model is general, it is based on the superstructure presented in Figure 1, and it involves different forms of unconventional extraction such as shale gas, offshore extraction, and conventional forms; for example, the extraction of associated reservoirs using improved recovery techniques, the conventional extraction of non-associated deposits and even the importation of natural gas. Fresh water and seawater are used for producing natural gas through different

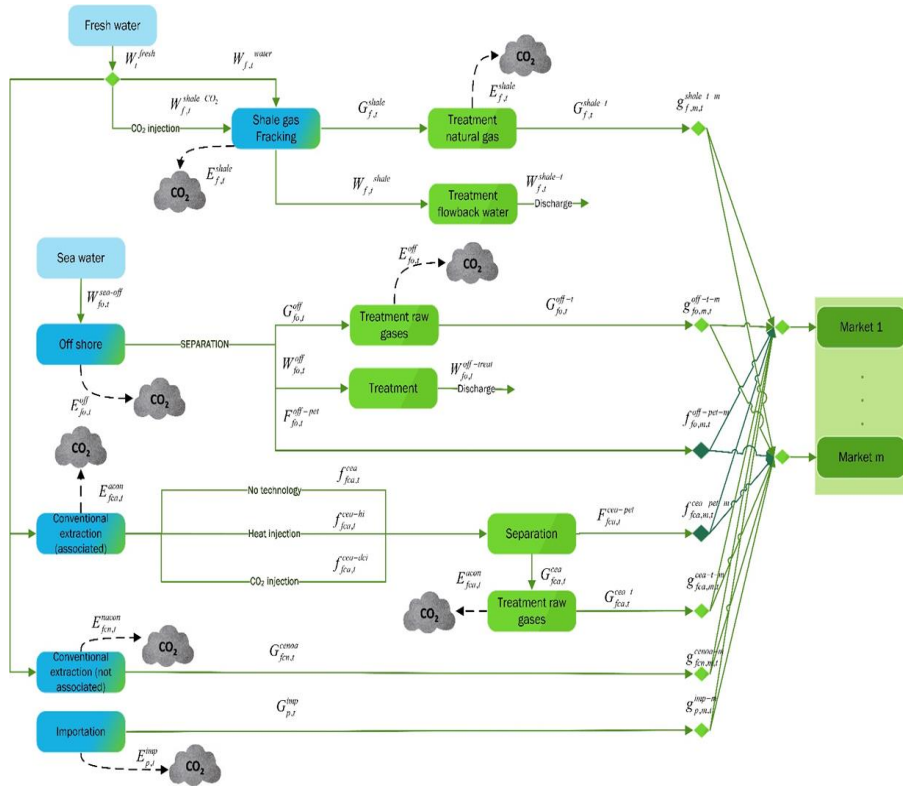
extraction methods. According to the type of extraction, the produced natural gas is separated, and it can be treated to eliminate dangerous substances to health. The natural gas obtained by each extraction method is distributed to the different markets. The model includes costs for producing natural gas, fresh water, treatment and transportation. In addition, the sale of oil obtained in offshore extraction and associated conventional extraction is considered.


Figure 1. Proposed superstructure

3.1. Profit

The profit is obtained by the sum of the sale of oil and natural gas, minus all the involved expenses:

$$Profit = Sale^{PET} + Sale^{NG} - Cost^{shale\text{-}prod} - Cost^{fresh\text{-}shale} - Cost^{treatment\text{-}shale} - Cost^{off\text{-}prod}$$
$$-Cost^{seawater} - Cost^{treatment\text{-}off} - Cost^{cea\text{-}prod} - Cost^{fresh\text{-}acon} - Cost^{treatment\text{-}cea} - Cost^{cenoa\text{-}prod} \quad (1)$$
$$-Cost^{fresh\text{-}nacon} - Cost^{imp} - Cost^{pet} - Cost^{transp-pet} - Cost^{transp-ng}$$

3.2. Total fresh water

The total used fresh water is the sum of each flow needed of water in shale, conventional associated and non-associated production:

$$TFW = \sum_{f}\sum_{t} W_{f,t}^{shale} + \sum_{fca}\sum_{t} w_{fca,t}^{fresh-acon} + \sum_{fcn}\sum_{t} w_{fcn,t}^{fresh-nacon} \tag{2}$$

3.3. Total emissions

The total emissions are the sum of the generated emissions in each process as it follows:

$$TE = \sum_{f}\sum_{t} E_{f,t}^{shale} + \sum_{wo}\sum_{t} E_{wo,t}^{off} + \sum_{wca}\sum_{t} E_{wca,t}^{acon} + \sum_{wcn}\sum_{t} E_{wcn,t}^{nacon} + \sum_{p}\sum_{t} E_{p,t}^{imp} \tag{3}$$

3.4. Occupational health

Occupational health has been evaluated in each of the options to produce natural gas that are considered in the superstructure. Equation 4 relates natural gas flows for each case multiplied by a factor that shows the relationship of damage between each of the options with respect to the most damaging. It is worth mentioning that shale gas is the one that generates the most health damage for workers who are exposed continuously to the substances present in the process.

$$HD = I^{shale}\cdot\sum_{f,t} G_{f,t}^{shale-t} + I^{off}\cdot\sum_{fo,t} G_{fo,t}^{off-t} + I^{cea}\cdot\sum_{fca,t} G_{fca,t}^{cea-t} + I^{cenoa}\cdot\sum_{fcn,t} G_{fcn,t}^{cenoa} + I^{imp}\cdot\sum_{p,t} G_{p,t}^{imp} \tag{4}$$

3.5. Objective functions

The formulation of the mathematical programming model is a multi-objective problem, where the objectives are to maximize the profit, minimize the consumption of fresh water, the total emissions and the health damage, subject to relationships (1-4).

$$ObjectiveFunction = MaxProfit; MinTFW; MinTE; MinHD \tag{5}$$

The model is a mixed integer linear programming model, and this was coded in the software GAMS.

4. Case Study

The consumption of natural gas in any country is of special interest to ensure independence on foreign countries to meet fuel needs. In this context, Mexico was selected as a case study, since this country has natural gas reserves by 31,904.7 billion cubic feet, of which 70.3% is associated natural gas and the rest is not associated. The associated natural gas is the one that is in presence with oil and other compounds in the reservoir and non-associated is because there is only natural gas in the reservoir. In addition, it is important to note that Mexico is in 6th place worldwide with a reserve of unproven but technically recoverable resources of shale gas with 545,000 billion cubic feet (EIA, 2018).

5. Results

The results for optimizing each objective separately are shown in Table 1. It should be noticed that by maximizing the PROFIT, there is a profit of 1.58×10^{10} \$/y, which is 186% higher than the case of minimizing the TFW (fresh water consumption), 2.1% greater than minimizing TE (total emissions) and 2,119% higher with respect to minimizing HD (damage to health).

Table 1. Results for optimizing different objectives separately

	Max PROFIT	Min TFW	Min TE	Min HD
PROFIT ($/y)	1.58×10^{10}	5.51×10^9	7.11×10^8	7.12×10^8
HEALTH DAMAGE	1,509,500	105,820	0.137	0.137
(MMmetric ton CO_2e/y)	22.774	1.091	0.690	0.690
Importation	0	0.273	0.273	0.272
Offshore	1.977	0.818	0	0
Shale	19.389	0	0	0
Associated	0.844	0	0	0
Non-associated	0.564	0	0.417	0.418
TOTAL FRESH WATER	36.576	0	14.333	14.333
(MMm³/ y)				
Importation	0	0	0	0
Offshore	0	0	0	0
Shale	2.729	0	0	0
Associated	14.464	0	0	0
Non-associated	19.386	0	14.333	14.333
Natural gas produced	1,901,853	1,901,847	1,901,853	1,901,843
(MMcfy)				
Importation	0	1,773,910	1,770,660	1,770,650
Offshore	309,142	127,937	0	0
Shale	1,252,970	0	0	0
Associated	162,304	0	0	0
Non-associated	177,437	0	131,193	131,193

On the other hand, health damage provides different scenarios, where this value helps to determine the harmful level of an option; where the higher the value, the greater the damage. In this case, the HD values are quite different. Minimizing TE and HD, there is less damage (0.137), in addition, when TFW is minimized, there is a decrease of 92.9% compared with the case when PROFIT is maximized, which represents the scenario with the greatest damage to health.

The total demand of natural gas in the country is 1,901,888.77 MMcfy; by maximizing PROFIT, 65.9% is satisfied through the production of shale gas, 16.2% with offshore production, 9.3% by associated conventional extraction and 8.5% by non-associated conventional extraction. It is important to highlight that in this scenario, importation is not used and despite having the greatest health damage, emissions and water consumption, it would be no dependence on another country to satisfy the demand for natural gas. When TFW is minimized, 93.3% is satisfied through importation and the rest through offshore production. In the cases when TE and HD are minimized, the results are very similar, 93.1% is imported natural gas and the rest is from the conventional production of non-associated natural gas.

The fresh water required to maximize PROFIT is used to produce shale gas, associated and non-associated natural gas. When TFW is minimized there is no water consumption since everything was satisfied through importation and offshore extraction. On the other hand, for the minimum TE and HD, there is only fresh water consumption due to the production of non-associated natural gas.

The greatest amount of total emissions (millions of tons of CO_2 equivalent per year) occurs when the PROFIT is maximized (22,774), where 85.1% is generated due to shale gas. In the case of minimum TFW (1.091), there is a decrease of 95.2% with respect to the maximum PROFIT scenario; for the minimum TE and HD, the decrease in emissions is 96.9%.

6. Conclusions

This paper has presented a mathematical programming model for the strategic planning to satisfy the national demands of natural gas. The proposed model incorporates non-conventional options, particularly shale gas, which can be used to decrease the imports. Furthermore, in the proposed model, in addition to economic objectives, the minimization for the fresh water consumption, CO_2 emissions and the health damage to the involved workers were considered.

Throughout the presented analysis for the case of satisfying the national demands of natural gas in Mexico, there was determined that is possible to satisfy these demands with a greater profit, less damage, fresh water consumption and emissions of CO_2. Also, occupational health was evaluated showing that when the profit increases, the higher the damage, but the less the damage, the more the dependence with another country because the needed imports. However, it can be noted that the dependence of Mexico (maximizing profit) with another country is reduced because the demand of natural gas can be satisfied with the national production, only by substituting importation with shale gas production and using the conventional reservoirs that already exist.

Finally, the proposed model is general, and it can be applied to different cases with different conditions.

Engineering success: What does it take to get PSE technologies used?

Sandro Macchietto*

aImperial College London, South Kensingto Campus, London SW72AZ, UK

s.macchietto@imperial.ac.uk

Abstract

Over the years there have been many excellent contributions in the ESCAPE conferences to the R component of R&D, but less emphasis on the D element, and even less on the steps required for taking a piece of research to the final users in industry, that is, the technology transfer process itself.

These days, initiatives in tech transfer (variously called "third mission" or "translation" activities) are everywhere. A variety of supporting structures (Enterprise Launch Pads, Spinout Clinics, Tech Launch Prizes, Venture Competitions, Technology Parks, etc.) are implemented in most academic and research establishments. The enterprise climate is possibly at its hottest for many years, the message has been spreading widely, and there are a number of notable successes. However, in my experience, there is still a big gap between theory and practice, only a very small fraction of researchers are involved and there is an enormous untapped potential. Based on 30-year experience of "translation" activities, some more successful than others, a personal overview is presented of what it takes to go from novel research to final use of a technology. It briefly touches on things found working and not, essential and unnecessary (or counter-productive), drawing on the experience of launching and managing two companies in the PSE area (including Process Systems Limited), various interdisciplinary consortia and two applied research centres. Some final comments address how to tweak the odds towards "engineering success by design".

Keywords: technology transfer, R&D translation, industrial uptake.

1. The numbers

The ESCAPE Conference Series is 29 years old. Assuming ~350-400 papers accepted in each one, altogether over 10,000 papers have been produced and passed a peer review quality test, representing a huge collective investment in research time and resources. No doubt they include a good number of seminal papers presenting highly innovative ideas, results and applications. A quick scan indicates that most contributions address the R component of R&D (not surprisingly, given the nature of the conference), with less emphasis on the D element and even less on the steps required for taking a piece of research to the final users in industry, that is, the technology transfer process itself.

The longevity of the conference is a good indicator of its perceived usefulness to the community. It is however a legitimate question to ask how many of these ideas have actually found their way into industry and are productively used as methods, tools, or embedded in products. Some relevant related questions are: Does good research actually produce good impact? How many good ideas result in eventual industrial uptake and

impact? Is academic recognition (e.g. publication in peer reviewed journals, number of citations) a good indicator of uptake and impact? How long does it take? And the more operative question, are there better mechanisms for "engineering" such success? These questions are complex and the subject of much research in the academic entrepreneurship community. Without pretence to provide a formal answer, some figures and considerations from personal experience are presented in the following.

The *inventive output* of an organisation is typically measured in terms of number of Disclosures (being considered for commercialisation) and Patents (filed and awarded), *technology transfer* performance in terms of Licensing and company Spinoff (formation plus various progress metrics e.g. survival rate, investment capital attracted, employment generated, turnover, growth, acquisition value, etc.). Other mechanism for transferring technology from academia include Consultancy, industrial projects and (in my experience, the main channel) "brain walks" (hiring of students and researchers).

Technology transfer is hard. US Venture capital funds invested $175bn in the two year technology boom period 1998-2000. Out the myriad companies started, Google, and Amazon are outstanding survivors, but most of the $175bn was wasted. The average rate of return of VC funds invested in the 2000-2004 period following the Dot.com bust was less than 2% (marginally less than ordinary bank savings). The concept of supporting the transfer of intellectual property (IP) and technologies from academic research into practical use was introduced in the UK in the 1980's Thatcher years. These days, initiatives in tech transfer (variously called "third mission" or "translation" activities) are everywhere. A variety of supporting structures (Enterprise Launch Pads, Spinout Clinics, Tech Launch Prizes, Venture Competitions, Technology Parks, etc.) are implemented in most academic and research establishments. The enterprise climate is possibly at its hottest for many years.

In the UK, Imperial College has a good reputation for being one of the most active and successful in technology transfer, and has created a quite variegated eco-system to nurture and support enterprise by student and staff along the long path from idea to Exit/IPO (Imperial College London, 2018, p.19). A summary of Imperial's tech transfer results for the 5 years to 2016-17 is given in Figure 1. A few things are worth noting. The number of yearly start-ups (5-9 per year) is relatively modest (those in the technology and industrial sectors based on IP produced by R&D are even fewer, 1-3 per year, most others being in health and medicine). Only about 20% of Disclosures results in a patent filing, with a conversion rate of ~50% to Patents granted. While a double digit number of new licences were signed each year and over 200 active ones are held, less than half of them (42% in 2016-17) actually generate income, on average of £33K each. Even a cursory thought to patenting, legal, commercial and administrative costs indicated there are no great returns here! Some data on generation rate and cost efficiency are also given in Fig. 1 in the form of ratios. On this basis, in 2016-17 £100m of research generated 92 Disclosures, 19 Patent filed and 11 granted, 2.5 IP based start-up and 4.4 student start-ups. The income from licensing and realisation of participated companies is 2.6% of the research income, a rate of return comparable to keeping the money in the bank. Actually, this performance is pretty good, as most societal and commercial gains do not accrue to the universities. A comparative analysis (Autio and Webb, 2015) of the ability of universities to spin out new ventures and their subsequent growth, found that while the UK entrepreneurial culture is weaker than in the US, after adjusting for population size and economic activity, UK universities are more efficient

Figure 1. Imperial College Inventive Output Scorecard YE 2016-2017 (extracts from Imperial College London, 2018, p. 20)

Metric	2012-13	2013-14	2014-15	2015-16	2016-17

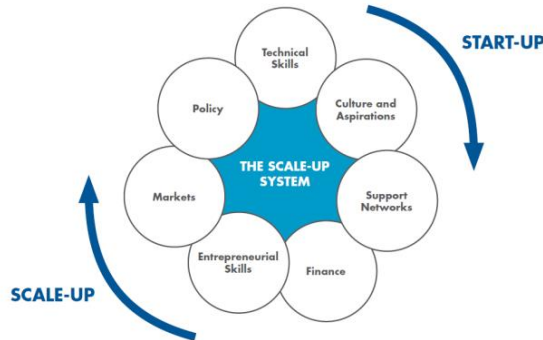
than German and US ones in generating new ventures (576 spinouts in UK vs. 428 in US per $ trillion GDP, and 48 vs.16 per $ billion of tertiary education spending). The UK however was found to lag the US in scale-up performance, due to lower funding (US spinout raised on average 50% more equity) and lower entrepreneurial aspirations, including a number which are good indicators of scalability (Risc Capital, Internationalisation, High Growth and Product and Process Innovation aspirations). Their analysis focused on low-carbon technologies, but also gives useful general data. They identify the ecosystem in Figure 2 as enabling enterprise.

The fraction of academics involved in impact-related activities even in a relatively enterprising place like Imperial is small, with 26%, of total academic staff involved in collaboration with industry, 41% in consulting, 13% in patent ownership and just 4% in IP commercialization (Gann et al, 2016). Patents and IP commercialisation are the least preferred ways by academics to generate impact. Recent emphasis has been more on unleashing students' enterprise juices, with excellent response and good success. This is particularly important. While universities still largely train students for big company employment, they increasingly like to start their own. It is useful to remember that Apple, Facebook, Microsoft, Uber, Spotify and Tesla were all started by university dropouts. Perversely, some universities that have encouraged student enterprise activities in the early years have found that significant numbers do not return to their books, and (in the UK) risk being penalised due to high drop-out rate (e.g. Sheffield University, article in The Times, 14 Nov 2018). Data on UK university technology transfer is provided by the Higher Education Statistical Agency (HESA, 2018), while R&D data by OECD countries are in (OECD, 2018).

Figure 2. Structures and ecosystem which enable enterprise in the UK (Autio and Webb, 2018, p. 4)


2. The practical experience

So much for statistics. If one follows the recommended path, first carries out fundamental research, then does a first prototype and product development, followed by trials, market research and business development. If/when this works, one may address commercialisation. This is often formalised into several sequential "technology readiness levels" (TRLs). In my experience, this has two main pitfalls. First, it may take years. Second, the best people at each stage are often not available for or interested in the next. A Phd or Post-doc who has demonstrated the superior convergence of a new algorithm is usually not interested in (or does not have the skills for) re-implementing it in professional code, with documentation, interfaces, testing, validation, versioning, customisation, applications support, etc. While continuity of funding across the TRLs is always a problem (some agencies fund research, other commercialisation, few the hard bit in between), in my experience a bigger challenge is ensuring continuity in technical expertise and injecting management, financial, commercial expertise at the right time.

Solving many problems: One way to address this is to pursue many related ideas in parallel, in larger projects with a broad research programme, with people of different competences, all at the same time. A multidisciplinary team ensures that each idea is explored from multiple angles and that many other unexpected ideas are generated, especially when industry is also closely involved. An example is represented by the Centre for Process Systems Engineering at Imperial, where from the inception PhDs and MSc researchers worked alongside "development" teams (full time programmers, project managers and industry visitors) on so-called "major projects", tasked with implementation, consolidation and early validation of the research. Notable outcomes of two of these projects were several "industry-tested" technologies that went into the Process System Enterprise spinoff, and the company formation itself.

Solving the right problem: In the PSE approach, a problem is conceptualised, formulated, analysed and solved. We typically seek an exact (rigorous) solution, using the best solvers, for a complete formulation. However, we often need to make simplifying formulation assumptions (e.g. on size, detail, constraints, nonlinearities) in order to use a solution technique. An alternative approach is to use an approximate solution of a more complete problem formulation. Failure to consider all relevant

problem features is in my experience a key reason limiting the credibility and acceptability of a new method in industry, where "better but feasible" always trumps "optimal but not quite feasible". Understanding the problems in their full detail and complexity, ideally in the plant or design office, can be a humbling experience! An example from my own research include Batch Processing (Crooks et al., 1992) in the food industry. Key features include multipurpose recipes, multiples sources for the same material that must remain segregated, vessels coupling through shared piping, condition-based cleaning, multi-layered product packaging, and a myriad of other subtle but essential elements. Much of the published work in this area considers such simplified views of the process that make the methods not applicable, whatever the elegance of the combinatorial solution. A more heuristic solution which however captured all required features was successfully applied industrially to scheduling and design of very complex, large scale food productions (e.g. Figure 3, Macchietto, 2005). Similarly, much elegant heat exchanger network (HEN) optimisation work in the literature cannot deal with fouling, very often present. This requires much more detailed, representative models and sophisticated solutions (e.g. Diaz et al., 2016).

Figure 3. Scheduling of beer production in one of the largest UK breweries (26 beer families, 140 pieces of equipment) (Macchietto, 2005)

Solving the problem right: A 90% success rate for a new optimisation method is a very good improvement over methods that only solve 80% of the problems. However, it is not good enough for practical everyday use in industry, as users will spend 90% of their time in dealing with the 10% of failures, and will soon give up. Achieving a 100% rate is not easy, maybe impossible, so should we park the method? A common R&D failure is that too much emphasis is put on performance, and too little on usability. To address this requires analysing, understanding and facilitating user's workflows, and where benefits and losses (for them) really lie. Not easy without close contact with target users in their environment. For example, Dr. Chen, a brilliant student of mine produced a new, 90% good, nonlinear optimisation algorithm (SRQP, for successive reduced quadratic programming) for his PhD thesis. We spent the next 18 months with BP to make it industry-usable, including adding some obvious (but not easy) items such as meaningful error messages, a range of fail-safe, gently-degrading features, a guide to options and reverse communication for ease of embedding in third party software. As a result, the now robust software was licensed to and used in 4 different commercial simulators, in various on-line control applications, and has been for 20 years, with hardly any modifications, the optimisation workhorse within gPROMS.

Changing the odds: An example combining many of the above features is the UNIHEAT project, a £9.3m collaboration between Imperial College, the Boreskov

Institute of Catalysis in Novosibirsk, Russia, BP, the University of Novosibirsk, UNICAT, a Russian company, and the Russian Skolkovo Foundation (Macchietto and Coletti, 2015). It featured large multidisciplinary research teams with adjacent expertise; a dedicated knowledge and technology transfer team; several related projects in parallel; concurrent research, demonstration/prototype development and proof of concept; significant, integrated industrial involvement; very early IP identification and development alongside the research. This turbocharged the whole process. Results obtained in three years, described in the reference, include, in addition to the expected large number of publications in scientific journals, 3 spinoffs and 22 patents filed, Expectations based on the ratios in Fig. 1 would be 0.23 spinoffs (at 2.5/£100m), and 1.9 patent filed (at 20/£100m). Results achieved represents a x10 improvement in R&D productivity, even for a difficult multi-partner project across 7 time zones.

3. Conclusions

Technology transfer is not easy, but a few mechanisms have proved useful to boost it. These include shortening the timescales by working on multiple related developments in multidisciplinary teams, industrial involvement from the beginning, making sure we address the right problems by understanding the solution end use and users, addressing usability as well as performance from the outset, and integrating knowledge and technology transfer professionals and activities with the R&D team. Results on a recent project thus configured show that a large increase in R&D productivity can be achieved.

Abstract

In this work, an optimization-based methodology to design formulated products, incorporating heuristic rules, property models and also quantified customer preferences, is proposed and applied to a skin moisturizer. The relative importance of each product attribute valued by customers is first quantified and then related parameters progressively incorporated in an optimization-based method that generates plausible alternative formulations. The proposed method can be useful to accelerate the selection among alternative formulations, moreover in a benchmarking process.

Keywords: Product design, Consumer assessment, Heuristics, Emulsions, Skin moisturizer

1. Introduction

In the highly competitive market, consumer acceptance has become an important factor in the formulated product design process. Besides key physicochemical properties of the final product, it is of paramount importance to account for the performance of the product as perceived by the final consumer. Therefore, the prediction of acceptability is essential in product development, especially in the domain of cosmetic products, whose performance assessment integrates not only functional but also sensorial characteristics (Wortel and Wiechers, 2000).

Here, a recently proposed methodology (Arrieta-Escobar et al., 2018, 2017) to find a set of plausible product formulations, based on mixed-integer programming and incorporating heuristic rules (modelled as algebraic restrictions), is extended to include the consumer assessment. Starting with a list of attributes directly valued by consumers, the importance level of each of them as well as their interactions are determined from data of usability tests made on an on-market product, by using fuzzy measures (Grabisch, 1995). These consumer parameters can then be incorporated into the optimal design problem formulation, progressively and accordingly to their level of importance but also

depending on the availability of models or heuristics correlating them with product composition. This stepwise procedure may result in a reduction in the number of lab scale tests and alternatives preceding to consumer testing. Our main objective is to illustrate the application of this methodology using a skin moisturizer as a case study.

2. Consumer assessment methodology

In "Affective Engineering" or "Kansei Engineering" approaches, usability tests are made to unveil the subjective and even unconscious perception of the user (Nagamachi, 1995). Recently a methodology to integrate the user's perception and identify the importance and interaction of consumer attributes, based on fuzzy measures was proposed by Camargo et al. (2014). This methodology combines a Hybrid Kansei Engineering approach (Matsubara and Nagamachi, 1997), which uses a prototype or mock-up to elicit the product attributes, with a fuzzy integral analysis, namely the Choquet integral (Choquet, 1954). The main advantage of this approach is the possibility to consider the attributes relevance, based on the user's preferences, and the interactions among them. Here, the aforementioned methodology was adapted for cosmetic emulsions in order to understand the importance level (Shapley index) along with the interactions among the attributes (Murofushi and Soneda indices) using a composite index. The main stages of this methodology are described in detail in the original paper, and here only some aspects will be mentioned in the context of a skin moisturizer example (see Figure 1).
Figure 1: Consumer assessment methodology. Adapted from (Camargo et al., 2014)

Consumer attributes reported in the literature (Parente et al., 2010) are classified in 8 groups (thickness, ease of spreading, stickiness, easy of absorption, freshness, residues, greasiness/oiliness and moisturization) and an on-the-market product (Bioderma® Atoderm Ultra-nourishing Cream) is chosen for the usability test. For that, a questionnaire was prepared, in which the participants were told to apply the product on their arms, and to answer two questions corresponding to each one of the 8 groups of attributes, using a 5-level ordinal scale from "not at all" to "very much" (Osgood, 1959). Two additional questions about product's acceptability allow the algorithm in the fuzzy integral analysis to "learn" how important the attributes were to the overall performance.

3. Skin moisturizer case study

A skin moisturizer can be described as a cosmetic product that provides a healthy skin feeling thanks to the use of moisturizing agents (humectants and emollients), typically delivered in the form of an oil in water (O/W) emulsion, stabilized with a combination of emulsifiers (mostly nonionic surfactants) and thickeners (Barel et al., 2001).

3.1. Ingredients, property models and heuristics

Skin moisturizer emulsifiers are usually a suitable combination of at least two nonionic surfactants (Rieger and Rhein, 1997) used at a minimum level of 2% and up to 5% (Rähse, 2013). The final HLB value of the combination – 1 part of medium HLB (9-15), 3 to 6 parts of high HLB (>16) and 2 to 6 parts of low HLB (<8) – should be between 8 and 15

to assure O/W emulsions. Also, a total surfactants/oil ratio of 1:4 to 1:6 should be kept to stabilize the resulting emulsion (Iwata and Shimada, 2013). The classical empirical HLB model is here adopted: HLB of the surfactant mixture should approximately match the HLB required by the oil mixture: HLB = RHLB.

Water-soluble polymers are added as thickeners to provide consistency and stability to the emulsion (Iwata and Shimada, 2013). The primary feeling (consistency at first contact) is correlated to the high viscosity η_1, perceived on the onset of flow of the product, under low applied stresses. In contrast, the secondary feeling (consistency during spreading) corresponds to a much lower final viscosity η_2, when the product is being applied under higher stresses (the emulsion has a strong shear-thinning behavior). Composition-viscosity data for polymer thickened aqueous solutions are available, based on which one has constructed linear models of $\log(\eta_1)$ and $\log(\eta_2)$ as a function of polymer concentration and also total content in oils.

Emollients are the main moisturizing agents and improve the spreadability of the product. A proper combination of at least one emollient of high, one of medium, and one of low spreading types, provides the complete profile for a well-performing product (Ansmann et al., 2005). The after-feel provided by the emollients is related to their greasiness value (γ), which can be calculated as a weighted average from individual values (scale from 1 to 5), available for a wide range of products (Mentel et al., 2014). Similarly, the RHLB value of the emollients mixture is estimated from individual values obtained directly from the providers or from other sources (Pensé-Lhéritier, 2016).

All formulations consider a fixed amount of mandatory ingredients, i.e. the humectant (3% Glycerol) and the preservative (0.7% Cosgard®).

3.2. Optimization of the formulation

Table 1 shows the most relevant design variables and a short formulation of the optimization problem. Thirty-six possible ingredients were considered (vector $\boldsymbol{y}$ and $\boldsymbol{x}$ have dimension 36): Six emulsifiers, three polymer thickeners, three fatty alcohols and twenty-four emollients. The complete list of adopted heuristics is not here reported. The resulting model is a small MINLP problem, easily solved in less than 1 s using GAMS/BARON.

Table 1. Product design variables and problem formulation.

Binary variables y (choice of ingredients) and continuous variables x (wt %)	Problem formulation
Emulsifiers: y_r, x_r Thickening polymers: y_n, x_n Fatty alcohols: y_m, x_m High spreading emollients: y_i, x_i Medium spreading emollients: y_j, x_j Low spreading emollients: y_k, x_k	Find vectors $\boldsymbol{y}$ and $\boldsymbol{x}$ that minimize cost, subject to: Heuristics of typical amounts and combinations of ingredients $2.0 \leq \gamma \leq 2.4$ $120 \leq \eta_1 \leq 500$ Pa.s, $0.023 \leq \eta_2 \leq 0.500$ Pa. s HLB = RHLB

4. Results and discussion

Thirty-two female users of moisturizers (average age 31 years old) tested the commercial product and completed the questionnaire. Table 2 contains the resulting average scores of each attribute, along with the normalized Shapley, Murofushi and Soneda and composite

indices. Under the latter metric, "ease of absorption" (0.29), "freshness" (0.25) and "residues" (0.20), are the most important attributes. Noteworthy is that these attributes also have the highest values of mutual interactions (Table 2 only shows the sums of the total interactions as normalized interactions).

Table 2. Scores, normalized values of Shapley (relative weights), Murofushi and Soneda (interactions), and composite indices.

Attribute	Symbol	Score	Normalized relative weights	Normalized interactions	Normalized composite index
Thickness	V	0.46	0.13	0.08	0.07
Spreadability	S	0.75	0.04	0.07	0.02
Stickiness	P	0.45	0.15	0.11	0.11
Ease of absorption	A	0.35	0.20	0.22	0.29
Freshness	F	0.31	0.21	0.18	0.25
Residues	R	0.30	0.15	0.20	0.20
Greasiness	G	0.74	0.05	0.06	0.02
Moisturization	H	0.61	0.07	0.08	0.04
Overall performance	C	0.43			1.00

A first basic formulation (Formulation 0) was generated solving the problem specified in Table 1. In this case, 3 of the 8 attributes of Table 2 are already addressed (at least partially): "Thickness" and "Spreadability" (through the imposed viscosity limits, which were determined from sensorial tests on general purpose creams), and also "Greasiness" (through the limits imposed on the greasiness value γ). In a second stage, the "residues" attribute (R) was then chosen as the next attribute to be considered, since, among the remaining 5 attributes, it is the most informative one and the easiest to evaluate (it has by itself a composite index of 0.20 and the highly correlated trio (A+F+R) adds up to 0.74). Formulation 0 and the commercial reference sample were then evaluated in this attribute, with results shown in Figure 2 (left side). The poor performance of Formulation 0 is clear.

Figure 2. "Residues" of the analyzed formulations compared with the commercial sample.

In a third stage, the optimization of product formulation was readdressed, now including an additional heuristic to correct residues excess: add up to 2% of low HLB emulsifier so as to reduce the micro-foam formation (Institute of Personal Care Science, 2016). With this extra restriction (and allowing RHLB to deviate up to one unit from HLB), the optimization resulted in Formulation 1 (also shown in Figure 2 – right side). Both Formulations 0 and 1 are presented in Table 3 and their rheological profiles in Figure 3.

Figure 2 clearly shows that the additional heuristic worked very well, with Formulation 1 presenting a level of white residues very similar to that of the commercial sample.

Integration of Consumer Preferences and Heuristic Knowledge in the
Design of Formulated Products: Application to a Cosmetic Emulsion

1343

Regarding rheology, both Formulations 0 and 1 have profiles similar to that of the commercial reference and in agreement with the simple viscosity models adopted in the optimization. Formulation 1 is thus a good candidate to customer satisfaction regarding attributes V, S, R and G (attributes A and F to the extent of their correlation with R too).

Table 3. Computer-generated alternative formulations for skin moisturizers.

| Ingredient	Cost (USD/kg)	Formulation 0	Formulation 1
Water A		60.00%	60.00%
Xanthan gum	35	1.10%	1.10%
Cetyl Alcohol	7.4	4.00%	4.00%
Polysorbate 60	15.5	0.50%	0.50%
PEG-100 Stearate	9.8	1.50%	1.50%
Glyceryl Stearate SE	8.9		1.00%
Sorbitan Stearate	12.5	1.30%	0.70%
Isopropyl Myristate	16.7	5.60%	6.80%
Paraffinum Liquidum	12.2	2.70%	3.20%
Persea Grattisima Oil	16.7	1.00%	1.00%
Water B		18.60%	16.50%
Glycerol		3.00%	3.00%
Preservative (Cosgard)		0.70%	0.70%
	Total	100%	100%
	Cost (USD/kg)	2.50	2.77
Figure 3. Rheological profile of the two formulations studied and of the commercial sample.

5. Conclusions

We have proposed an optimization-based methodology for the design of formulated products, which incorporates consumer assessment data along with available heuristic rules, and presented a case study of a skin moisturizer. Although not all product attributes were here addressed, the example provided illustrates how the proposed method can guide the selection among alternatives, according to the relative importance given by consumers to different product attributes and available information correlating product performance and acceptance with its composition.

An improved approach to scheduling multipurpose batch processes with conditional sequencing

Nikolaos Rakovitis, Jie Li,* Nan Zhang

School of Chemical Enginneering and Analytical Science,University of Manchester, Manchester M13 9PL,UK

Jie.li-2@manchester.ac.uk

Abstract

Scheduling of multipurpose batch processes has gained much attention in the past decades. Numerous models using different mathematical modelling approaches have been proposed. The model size and computational performance largely depend on the number of time points, slots or event points required. Most existing models still require a great number of time points, slots or event points mainly because a consumption task always takes place after its related production tasks regardless of whether it consumes materials from the related production tasks. Although two existing models have been developed to overcome this limitation, they can either lead to real time violation or generate suboptimal solutions in some cases. In this work, we develop an improved unit-specific event-based model in which a consumption task takes place after its related production task only if it consumes materials from the production task. A consumption task starts immediately after its related production task completes only if there is no enough storage for materials produced from the producing task. We also allow production and consumption tasks related to the same state to take place at the same event points. The results show that the proposed model generates same or better solutions than existing models with less number of event points and less computational time.

Keywords: Scheduling, Multipurpose batch process, Mixed-integer linear programming.

1. Introduction

Scheduling of multipurpose batch processes has received much attention during the past three decades (Harjunkoski et. al. 2014). A number of mathematical models have been developed using discrete-time and continuous-time modelling approaches. The continuous-time modelling approaches include slot-based, global event-based, sequence based, and unit-specific event-based approaches. The model size and the computational performance largely depend on the number of time points, slots or event points required. Most existing models still require a great number of time points, slots, or event points to generate the optimal solution since a consuming task must start after the related producing tasks even if it does not consume materials from the producing tasks. In addition, production and consumption tasks related to the same state are not allowed to take place at the same time points, slots, or event points. To tackle these issues, Seid and Majozi (2012) imposed consuming tasks to take place after related production tasks if materials produced from the production units are used by any related consuming task. However, their model could lead to storage violations in real time. Vooradi and Shaik

(2013) enforced a consuming task to take place after a related production task only if this consuming task uses materials from the specific production task with introduction of a high number of additional binary variables, leading to an intractable model size. Furthermore, materials are not allowed to be stored in a processing unit if it is idle, leading to suboptimality in some cases. These two efforts do not allow production and consumption tasks related to the same state to take place at the same time points, slots, or event points yet. Recently, Shaik and Vooradi (2017) and Rakovitis et al. (2018) did allow related production and consumption tasks to take place at the same event points. They still impose a consuming task must always start after the related producing tasks.

In this work, we develop an improved unit-specific event-based approach for this scheduling problem, which requires less number of event points than existing formulations. We use the definition of recycling tasks from Rakovitis et al. (2018) and allow related non-recycling producing and consumption tasks to take place at the same event points. Furthermore, the proposed model sequence a processing unit which process a consumption task with its related production task, only if it consumes materials from the unit that process that task, and it force the finish time of a consuming task to be equal to the start time of the production task, if materials produced by the producing task are not able to be stored. Finally, we allow processing units to store the materials that were produced during the events that the unit is inactive. The computational results demonstrate that the proposed model generates same or better solutions using less number of event points and less computational time.

2. Problem description

Figure 1 illustrates a multipurpose batch process facility involving S ($s = 1, 2, …, S$) states, J ($j = 1, 2, …, J$) processing units and I ($i = 1, 2, …, I$) tasks. The states include feed materials S^{feed}, intermediates S^{IN} and final products S^{FP}. Each processing unit can process I_j tasks, but process at most one task at a time. Two storage policies including unlimited or finite intermediate storage (UIS or FIS) for intermediate states are considered, while unlimited storage is available for feed materials and products. Unlimited amount of feed materials is assumed during the scheduling horizon. Finally, unlimited wait policy (UW) is considered for all batches. Given production recipes, minimum/maximum unit capacities, processing times, storage policy for each intermediate and the scheduling horizon, the scheduling problem is to determine the optimal allocation of tasks to units, the start and end times of each task, task sequences in a processing unit as well as the inventory profiles in order to maximize productivity.

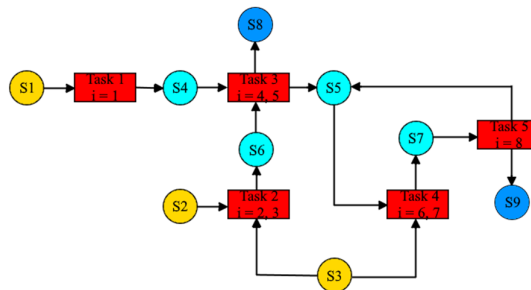

Figure 1 STN representation of a multipurpose batch process facility

3. Mathematical formulation

The mathematical formulation is developed using unit-specific event-based modelling approach because the advantages of this modelling approach have been well established in the literature. In the model, we have similar allocation constraints, capacity constraints, material balance constraints, and duration constraints to those of Rakovitis et al. (2018), which are not presented here. Next, we introduce new features of the proposed model.

3.1. Different tasks in different units

We define continuous variables $bc_{i,i',s,n}$ as material s produced from task i consumed by task i' at event n. Thus, the material consumed should not exceed total available materials.

$$-\sum_{j'}\sum_{i'\in \mathbf{I}_s^C, i\in \mathbf{I}_{j'}}\left(\rho_{s,i'}\cdot \sum_{n\leq n'\leq n+\Delta n} b_{i',j',n,n'}\right)\leq ST_{s,n-1}+\sum_{i\in \mathbf{I}_s^P}\sum_{i'\in \mathbf{I}_s^C} bc_{i,i',s,n} \qquad \forall s\in \mathbf{S}^{IN},n \qquad (1)$$

The amount of materials from i to i' (i.e., $bc_{i,i',s,n}$) should not exceed the production amount of task i or consumption amount of task i'.

$$\sum_{i'\in \mathbf{I}_s^C} bc_{i,i',s,n}\leq \rho_{s,i}\cdot \sum_{n-\Delta n\leq n'\leq n} b_{i,j,n',n} \qquad \forall s\in \mathbf{S}^{IN}, i\in \mathbf{I}_s^P, i\notin \mathbf{I}^{Re}, j,n \qquad (2)$$

$$\sum_{i\in \mathbf{I}_s^P} bc_{i,i',s,n}\leq -\rho_{s,i'}\cdot \sum_{n\leq n'\leq n+\Delta n} b_{i',j',n,n'} \qquad \forall s\in \mathbf{S}^{IN}, i'\in \mathbf{I}_s^C, j,n \qquad (3)$$

$$bc_{i,i',s,n}\leq z_{j,j',s,n}\cdot \rho_{s,i}\cdot B_{i,j}^{max} \qquad \forall s\in \mathbf{S}^{IN}, i\in \mathbf{I}_s^P, i\in \mathbf{I}_j, i'\in \mathbf{I}_s^C, i'\in \mathbf{I}_{j'}, j,j', j\neq j',n \qquad (4)$$

$$T_{s,j,n}\geq Tf_{j,n}-M\cdot\left(1-\sum_{i\in \mathbf{I}_s^P, i\in \mathbf{I}_j}\sum_{n-\Delta n\leq n'\leq n} w_{i,j,n',n}\right) \qquad \forall s\in \mathbf{S}^{IN}, j,n \qquad (5)$$

$$T_{s,j,n}\leq Ts_{j',n}+M\cdot\left(2-\sum_{i'\in \mathbf{I}_s^C, i\in \mathbf{I}_j}\sum_{n\leq n'\leq n+\Delta n} w_{i',j',n,n'}-z_{j',j,s,n}\right)$$
$$\forall s\in \mathbf{S}^{IN}, j, j', i\in \mathbf{I}_j, i\in \mathbf{I}_s^P, i\notin \mathbf{I}^{Re},n \qquad (6)$$

An active consumption task i' should be processed in a unit after the time that state s is available at the previous event n.

$$T_{s,j,n}\leq Tf_{j',n+1}+M\cdot\left(1-\sum_{i'\in \mathbf{I}_s^C, i'\in \mathbf{I}_{j'}}\sum_{n+1\leq n'\leq n+1+\Delta n} w_{i',j',n+1,n'}\right)$$
$$\forall s\in \mathbf{S}^{IN}, j, j', i\in \mathbf{I}_s^P, i\in \mathbf{I}_j, i\notin \mathbf{I}^{Re}, n<N \qquad (7)$$

3.2. Sequencing constraints for limited intermediate storage policies

For FIS states, it should be examined whether the materials produced can be stored.

$$\sum_{i\in \mathbf{I}_s^P, i\in \mathbf{I}_j, i\notin \mathbf{I}^{Re}}\sum_j \rho_{i,s}\sum_{n-\Delta n\leq n'\leq n} b_{i,j,n',n}+ST_{s,n}\leq ST_s^{max}+\sum_{i\in \mathbf{I}_s^P}\sum_{i'\in \mathbf{I}_s^C} bs_{i,i',s,n} \qquad \forall s\in \mathbf{S}^{FIS},n \qquad (8)$$

If they cannot be stored then they either have to be consumed immediately or stored in the unit, processing consuming task i' at event n, must take a non-zero value.

$$bs_{i,i',s,n} \leq B_{i,j}^{\max}\left(x_{i,i',s,n} + u_{i,i',s,n}\right) \qquad\qquad \forall s \in \mathbf{S}^{FIS}, j, j', i \in \mathbf{I}_s^P, i' \in \mathbf{I}_s^C, n \tag{9}$$

$$x_{i,i',s,n} + u_{i,i',s,n} \leq 1 \qquad\qquad \forall s \in \mathbf{S}^{FIS}, j, j', i \in \mathbf{I}_s^P, i' \in \mathbf{I}_s^C, n \tag{10}$$

$$\rho_{s,i} \cdot \sum_{n-\Delta n \leq n' \leq n} b_{i,j,n',n} \geq \sum_{i' \in \mathbf{I}_s^C} bs_{i,i',s,n} \qquad\qquad \forall s \in \mathbf{S}^{FIS}, j, i \in \mathbf{I}_s^P, i \in I_j, i \notin I^{\mathrm{Re}}, n \tag{11}$$

$$-\rho_{s,i'} \cdot \sum_{n \leq n' \leq n+\Delta n} b_{i',j',n,n'} \geq \sum_{i \in \mathbf{I}_s^P} bs_{i,i',s,n} \qquad\qquad \forall s \in \mathbf{S}^{FIS}, i' \in \mathbf{I}_s^C, j', n \tag{12}$$

If $bs_{i,i',s,n}$ takes a non-zero value, then the start time of consuming task as well as the finish time of the producing task are enforced to be equal.

$$T_{s,j,n} \leq Tf_{j,n} + M \cdot \left(1 - \sum_{i \in \mathbf{I}_s^P, i \in \mathbf{I}_j, i \notin \mathbf{I}^{\mathrm{Re}}} x_{i,i',s,n}\right) \qquad \forall s \in \mathbf{S}^{FIS}, j, n \tag{13}$$

$$T_{s,j,n} \geq Ts_{j',n} - M \cdot \left(1 - \sum_{i' \in \mathbf{I}_s^C} x_{i,i',s,n}\right) \qquad \forall s \in \mathbf{S}^{FIS}, j, j', i \in \mathbf{I}_s^P, i \in \mathbf{I}_j, i \notin \mathbf{I}^{\mathrm{Re}}, n \tag{14}$$

In order to avoid real time storage violations, between producing and consumption tasks occurring at the previous event the following constraint is introduced.

$$Tf_{j',n+1} \geq Ts_{j,n} - M \cdot \left(1 - \sum_{n+1-\Delta n \leq n' \leq n+1} w_{i',j',n',n+1}\right) \forall s \in \mathbf{S}^{FIS}, j, j', i' \in \mathbf{I}_s^C, i' \in \mathbf{I}_j, n < N \tag{15}$$

3.3. Allow production units to hold materials

We define $us_{j,n}$ as the extra amount of materials stored in a processing unit j at n.

$$ST_{s,n} \leq ST_s^{\max} + \sum_j \sum_{i \in \mathbf{I}_s^P, i \in \mathbf{I}_j} us_{j,n} \qquad\qquad \forall s \in \mathbf{S}^{FIS}, n \tag{16}$$

The amount of materials stored in a unit at n cannot exceed the amount produced at $n-1$.

$$us_{j,n} \leq \sum_{s \in \mathbf{S}^{FIS}} \sum_{i \in \mathbf{I}_j, i \in \mathbf{I}_s^P} \sum_{n-1-\Delta n \leq n' \leq n} \rho_{i,s} b_{i,j,n',n-1} + us_{j,n-1} \qquad \forall j, n > 1 \tag{17}$$

If a unit j holds some material at n, then it cannot process any task at this event.

$$us_{j,n} \leq \left[\max_{i \in \mathbf{I}_j}\left(B_{i,j}^{\max}\right)\right] \cdot \left(1 - \sum_{i \in \mathbf{I}_j} \sum_{n-\Delta n \leq n' \leq n} \sum_{n \leq n'' \leq n'+\Delta n} w_{i,j,n',n''}\right) \qquad \forall j, n \tag{18}$$

We define binary variables $xs_{j,n}$ to denote if a unit j holds materials.

$$us_{j,n} \leq \left[\max_{i \in \mathbf{I}_j}\left(B_{i,j}^{\max}\right)\right] \cdot xs_{j,n} \qquad\qquad \forall j, n \tag{19}$$

Finally, if a unit holds some material at n, the finish time of all consuming tasks must be equal to the start time of that unit.

$$T_{s,j,n} \leq Tf_{j,n} + M \cdot \left(1 - xs_{j,n}\right) \qquad\qquad \forall s \in \mathbf{S}^{FIS}, j, i \in \mathbf{I}_s^P, i \in \mathbf{I}_j, n \tag{20}$$

$$T_{s,j,n} \geq Ts_{j',n} - M \cdot \left(2 - xs_{j,n} - \sum_{n \leq n' \leq n+\Delta n} w_{i',j',n,n'} \right)$$
$$\forall s \in \mathbf{S}^{FIS}, j, j', i \in \mathbf{I}_s^P, i \in I_j, i \notin \mathbf{I}^{Re}, i' \in \mathbf{I}_s^C, i' \in I_{j'}, n \quad (21)$$

4. Computational results

We solve five examples including four well-established examples in the literature (Shaik and Floudas, 2009; Li and Floudas, 2010) to illustrate the capability of the proposed model. Both UIS and FIS policies are considered. We also compare the performance of the proposed model with the models of Li and Floudas (2010) (denoted as LF) and Vooradi and Shaik (2013) (denoted as VS). The computational results are given in Tables 1-2. From Tables 1-2, it can be observed that the proposed model reduces the total number of event points required for all examples compared to the LF model. This is because as it is depicted in figure 2 unit J1 is able to process 100 units of intermediate state using the proposed formulation since 50 of them can be temporary stored in the processing unit before being processed by J2, while by using existing formulations only 60 units can be processed since they cannot be stored in the processing unit and the storage capacity is 10. Compared to the VS model, the proposed model reduces the number of event points required for most examples except Examples 2 and 3 because all tasks in these two examples have to be treated as recycling task. The proposed model required less computational time for all examples compared to the LF and VS models especially for Example 3 which is reduced by 55% with UIS policy and 15% with FIS policy. More significantly, the proposed model generates a better solution than LF and VS models for Example 5. This is because a production unit is allowed to store materials produced. Therefore, the amount of materials produced can exceed the storage capacity. The optimal schedule for the proposed model is illustrated in Figure 2.
Figure 2 STN representation of a multipurpose batch process facility

5. Conclusions

In this work, an improved unit-specific event-based formulation for multipurpose batch processes has been presented. The proposed model allows related non-recycling production and consumption units to take place at the same event. Furthermore, a unit processing a consuming task is sequenced with a related production task, only if the unit processing the consuming task consumes materials from the unit processing the producing task. Additionally, a consumption task is allowed not to start immediately

after the finish of the related production task if storage is available. Finally, a processing unit is allowed to store materials if it is idle. The results demonstrate that the proposed model is able to generate same or better solutions, using less events, which can significantly reduce the computational time, especially in computationally expensive problems.

Abstract

Eco-Industrial Parks (EIP) aim to preserve environment while increasing competitiveness of companies. This paper presents a mathematical Mixed Integer Linear Programming (MILP) model to optimally grassroots design an EIP energy network comprising heat and electricity. In the utility system, heated steam is produced, network is designed by selecting boilers and turbines technologies and interconnection pipes between companies. Simultaneously in the on-grid Hybrid Power System (HPS) composed of wind turbines, solar Photovoltaic (PV) panels, steam turbines and external grid, the model can select which source to use to meet the power demand.
A case study of 10 industries from Yeosu real industrial park with seasonal data is provided to assess the model, first on economic comparison between stand-alone and EIP situation of companies, and secondly to determine which power source is profitable for HPS based on the sale price of electricity on the external power grid.
In conclusion, this model allows the optimal design of the energy network of an EIP with dynamic data and with the objective of minimizing the net present cost.

Keywords: Industrial Ecology, Eco-Industrial Parks, Utility Network, Hybrid Power System, Mathematical Optimization, Renewable Energies.

1. Introduction

Nowadays the risks of human-induced climate change are increasingly pointed out by scientific reports. These reports conclude that limiting global warming would require ambitious mitigation actions while achieving sustainable development which means a development leading to economic, environmental and social benefits (Brundtland et al., 1987). To these objectives, industry has an important role to play because classical linear model (extract, produce, consume, throw) is responsible for overwhelming extraction of natural resources and waste rejection.

Facing these environmental issues, Industrial Ecology (IE) provides an innovative way to produce goods and services based on a circular model (share, reuse, mutualize). Indeed, in these industrial ecosystems, energy and resources consumption are optimized, waste generation is minimized and effluents from one production process are used as raw materials for another (Frosch & Gallopoulos, 1989). An application to this concept are EIP, in which industries gather on a same site and thanks to their vicinity they share and exchange efficiently different flows (material, energy, utilities). Furthermore, while

reducing their environmental impacts they can also achieve greater economic competitiveness. To implement EIP in a sustainable way, companies need methods and optimization tools to design appropriate inter-enterprises exchanges. While an increased number of research projects have been carried out in recent years, Boix et al. (2015) pointed out that only a few deal with energy flow management neither with coupled networks. However, a systemic approach studying interactions between the different flows and optimizing them simultaneously would allow a better synergy between companies.

In the great majority of industrial parks, the facilities to meet energy demand are utility systems producing utilities for processes (i.e. mainly heat, cold streams and compressed air) and HPS that produce electricity using several power sources.

In utility systems, main energy consumption concerns heat, due to its high calorific value and its ability to generate power by rotating turbine. Moreover, in these utility systems, Combined Heat and Power (CHP) is an energy-efficient way to produce simultaneously electricity and thermal energy. Indeed, compared to the separate generation of heat and power, cogeneration can improve energy efficiency between 10 and 40% (Madlener & Schmid, 2003) and thereby reduces CO2 emissions. Through combined production raises other constraints such as operational planning of production. Yet a large number of publications are dedicated to optimizing the operational management of existing CHP, (Aguilar, 2007; Mitra, 2013) but only a few to design such facilities even less so adapted to EIP context with heat utility exchanges between companies. Afterwards, HPS, as a coupled system, is an efficient way to harness RE sources, relying on complementarity between sources. When it is connected to the external grid it is possible to compensate for the lack of production from other sources purchasing power, it is then called on-grid HPS. In addition, a decentralized production means to reduce reliance on external grid and reinforces the robustness of the power system.

In a previous publication, a study on on-grid HPS to supply electricity in an EIP was carried out using a mathematical LP model for the optimal design of this HPS with dynamic demand, on an hourly basis (Mousqué et al., 2018). This model has the possibility to select power sources to install between wind turbines, solar PV panels, biomass by combustion or also buy electricity from the grid.

To go further, this work extends the previous HPS model by presenting a generic optimization model to the grassroots design of both the utility network and the HPS of an EIP. The first purpose of this article is to assess economic interest that companies can encounter by sharing their heat and power facilities in comparison to their stand-alone situation. Another objective is to discuss which RE or energy-efficient electricity source can be profitable to supply EIP demand. Two optimal solutions are finally discussed depending on the sale price of electricity fixed by politic regulation. These results are obtained on a complex real problem using the proposed approach involving 10 companies in an EIP with real demands taken from Yeosu industrial park (Kim et al., 2010).

2. Problem statement

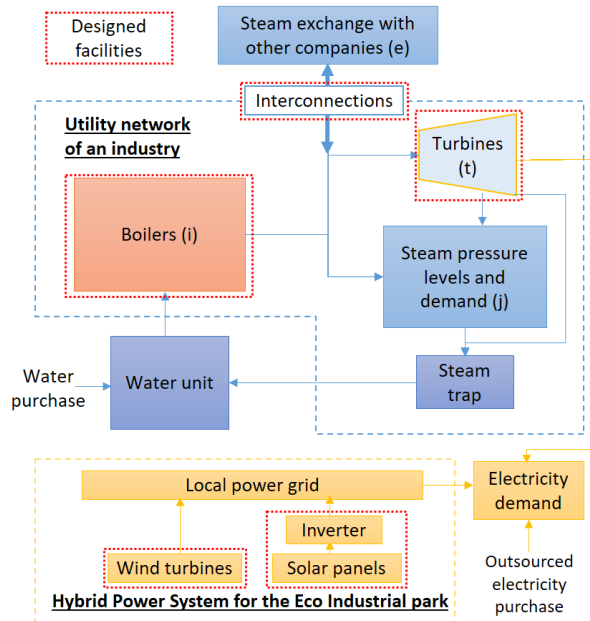
The aim is to design the exchanges of water, steam and electricity between processes inside a single company as well as exchanges between different companies, during several time steps. A generic superstructure (Figure 1) has been developed in order to show the different components taken into account in the model.


Fig 1. Superstructure of the utility system of an industry and HPS of the EIP.

In a company, steam flows through steam headers, different levels of steam pressure are taken into consideration. Pressure release valves are used to convert higher pressure steam into lower pressure steam by dropping its pressure. Steam is produced by boilers installed in companies. In the case studied in this publication, they are natural gas boilers. Different types of boilers can be installed depending on the maximum production capacity and the level of steam pressure produced. Boiler capacity range is between 50 and 100 % of its maximum power, because in this range boiler has a relatively constant efficiency (Aguilar et al., 2007) and also in seasonal operation it would be a big loss to operate the boiler at a low capacity, which means at a low efficiency level.

These power sources are selected to be RE technologies, i.e. wind turbines and photovoltaic panels, or energy-efficient such as cogeneration by mean of turbines. Data are dynamic with a seasonal variation (one-step for each season). In an EIP configuration, the power production is shared between companies and used to supply their demand. By connecting to external power grid, power can be bought and excess production can be sold. Finally, multi-stage extraction turbines can be selected between three technologies (i.e. 500 kW, 3 MW, and 15 MW). These turbines convert energy contained in high-pressure steam to a lower level of pressure or to condensed water. Higher is the pressure difference, higher the power production.

In this case, the production of renewable energy is considered as an average over a season. This estimate is only possible thanks to the external grid connection. Indeed, periods when production is higher or lower than the average production are supposed to be offset by the purchase or sale of electricity.

Water flow is a closed loop, after consumption from the process, water returns to the water unit, reducing water consumption. Each company has the possibility to buy water at every time step if necessary. Indeed, water losses by evaporating in water unit and steam losses by condensing trap or vent to evacuate overload are included.

3. Generic optimization model

Regarding the superstructure previously shown and the complexity of this model, due to the important numbers of continuous and binary design variables, a large-scale MILP model is developed. Due to its genericity, it is intended to be adaptable to the initial design of new EIP or to the retrofit of existing industrial parks, this last case by setting the initial structure.

The selected objective function is to minimize NPV of the designed utility network and HPS for a project duration considered of 20 years, with a discount factor of 7%. Constraints to model units are based on thermodynamic principles, mass and energy balances. Decisions variables are the different possible connexions between units and enterprises characterized by their type (VHS, HS, MS, LS, water…) and their flow and the decision to install or not a boiler and if it is installed which one is chosen? Capital and operational cost for installed boilers, turbines, pipes and the consumption of raw material are thus determined by the decision variables. Raw materials are fuel i.e. natural gas, treated water and electricity, which can be purchased or sold. Binary variables are used to select installed pipes between companies, installed technologies for boilers and turbines and operational state of boilers (i.e. switched on or off).

Given the high capacity of the superheated steam to be transported, losses in the interconnection pipes between the companies are considered negligible. Implemented data for boiler cost and steam pipes comes from economic evaluation manual (Chauvel et al., 2001) and are actualized using OECD Industrial Production Index. Renewable production is supposed to take place in France, with RTE report seasonal production (RTE, 2018) for these sources complete cost are those from ADEME (2016). Price for natural gas is set at 280 €/ton.

This model has 4101 constraints, 5103 variables including 540 binaries and it was solved with IBM ILOG CPLEX Optimizer.

4. Results and discussion

Two studies are conducted: an economic analysis of the case study to determine the interest of a company to take part of an EIP while the second one deals with the design of HPS power sources considering a different price for sale electricity.

This first study will compare Stand-alone and EIP solutions, both with a sale price of 0.05€/kWh which reflects the average price for electricity producer in France. While the second analyse will be a comparison between EIP (0.05) and EIP (0.10), latter case with a price of 0.10 €/kWh, considering politic aids to enhance creation of a local power grid. Detailed costs for these discussed optimal solutions are presented in Table 1.

Table 1

Overall economic comparison between Stand-alone and EIP situation.

Overall cost	Net Present Cost	Boilers cost	Power sources cost			Raw Materials cost				Pipes cost
			Turbines	Solar PV panels	Wind Turbines	Fuel	Water	Electricity purchased	Electricity sold	
Stand-alone	1,097,762 k€	56,294 k€	4,181 k€	- €	- €	1,040,671 k€	3,781 k€	4,311 k€	-11,478 k€	- €
EIP (0.05)	1,048,715 k€	36,186 k€	- €	- €	- €	1,001,113 k€	3,416 k€	4,430 k€	- €	3,569 k€
EIP (0.10)	982,324 k€	55,638 k€	56,647 k€	- €	38,594 k€	1,184,730 k€	3,923 k€	4,431 k€	-366,036 k€	4,396 k€

4.1. Stand alone and EIP (0.05) comparison

Observations show that while cost is slightly different for NPV of the EIP (0.05) (i.e. -4.7 %), for water (i.e. -10.7 %) and for fuel (i.e. -4.0 %), main reduction observed is for the cost of installed boilers (i.e. a reduction of 55.6 %). Additionally in stand-alone situation, the model proposes to invest in turbines, produce electricity and sale it.

This is because single companies have oversized boilers during seasons with lower demand, and this overproduction cannot be valorised. To avoid dumping it, it is profitable to install turbines to value this overproduction. In EIP configuration, cost for installed boilers is significantly reduced. In fact, pipe cost being less expensive than gain resulting from creating interconnections, companies share their production and their demand. This share allows a better size and management of installed boilers. This is observable by an average production ratio of installed boiler at 77% of their maximal production in EIP against 60% in stand-alone. However, on project life span, fuel is the most important cost, and in comparison between cases, only a few difference is observed. More accurate fuel consumption results should be obtained by including boiler inertia on a daily basis.

4.2. Impact of the electricity sale price on the design

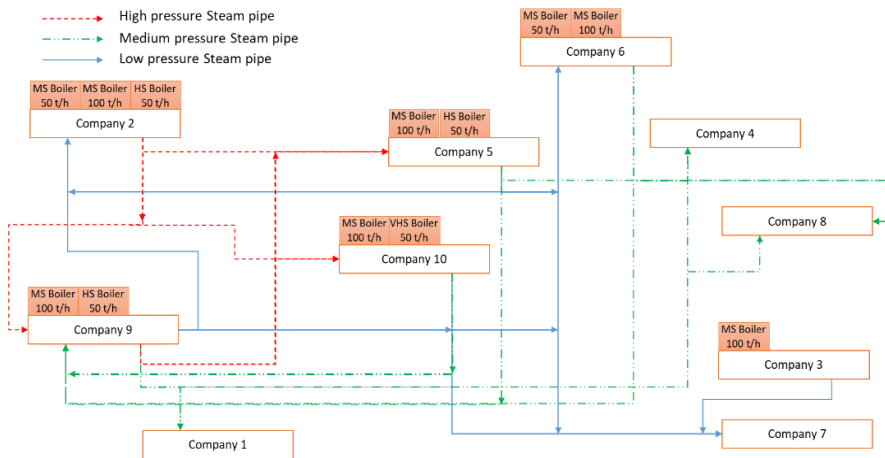
Figure 2 shows the optimal solution of the utility network for EIP (0.05) case, with boiler for each company and different pressure level exchanges, highlighting results that this model achieves and its complexity.


Fig 2. Designed boilers and utility steam exchange network for EIP (0.05).

With a sale price of 0.05 €/kWh neither turbines nor RE are selected, whereas when the sale price increases at 0.10 €/kWh both wind turbines and turbines are selected with three turbines of 15 MW. These choices can be justified with wind turbines and PV panels break-even point, which is calculated as respectively 0.094 €/kWh and 0.125 €/kWh, depending on discount factor and overall production and complete cost of each technology. For turbines, it is also dependent on utility system criteria, such as turbines and boilers technology (i.e. investment cost and efficiency), output pressure steam and if extra steam production is available to value it. However, over the lifespan of the project, the complete discounted cost for the installation of the turbines represents only a relatively

small part. For example, for a 500 kW system operating at nominal power, the cost of the installation is calculated at 0.019 €/kWh. Only based on an economic criterion, external electricity price has been identified as a main parameter to decide which technology to use. Turbines can be considered as an efficient way to value overproduction or overheated steam. Currently, wind turbines are cheaper than PV panels, although the difference is small, the design will depend mainly on the renewable resource available on the site.

5. Conclusion

A model of grass-root design of an EIP utility system and HPS with an economic criterion has been developed to determine the facility to invest in and the exchanges between companies. In this model, the implementation of this EIP represents a slight NPV gain, but a significant reduction in the investment cost of boilers. For HPS, a too low price of outsourced electricity does not foster to create a local grid with cogeneration, wind turbines or PV panels. However, other criteria could be taken into account, such as public subsidies on investment or on sale price to incite such technologies. This mathematical model has validated a first frame to assess capability of MILP to be solved on a real case of 10 companies taken from Yeosu industrial park with dynamic seasonal data. Further improves could be achieved, using this model on a case study with dynamic data on a daily basis (day and night) allowing more accurate results for boiler management, more detailed analyse on RE sources variation production depending on weather conditions. Another interesting point is that due to fuel cost importance, other fuels and boilers technology could be added. Finally using a multi-objective optimization, including environmental objective is another way to explore.

Abstract

In this work, we study the techno-economic feasibility of the urea alcoholysis process for the continuous manufacture of dimethyl carbonate. We propose a superstructure for the urea alcoholysis process based on patents and research articles found in literature. In this superstructure, different reaction and separation alternatives have been considered leading to 54 feasible flowsheets. Due to the complexity of some unit operations (reactive distillation columns, azeotropic distillation columns) and the reduce number of alternatives (or at least not prohibitive), we performed an exhaustive search to determine the most profitable flowsheet using Aspen Plus. Results prove the feasibility of this process, as long as a good catalyst is employed in the process.

Keywords: dimethyl carbonate, urea alcoholysis, process simulator, Aspen Plus.

1. Introduction

Dimethyl carbonate (DMC) is a non-toxic chemical that stands out thanks to its versatile use as reagent and solvent. DMC is employed as a substitute of dimethyl sulfate and methyl halides in methylation reactions, and as carbonylation agent to replace phosgene in the production of polycarbonates. DMC could also be used as a fuel additive since it has a higher oxygen content (53%) than the MTBE or TAME. However, the current price of DMC still prohibitively expensive to use as fuel additive (Ryu and Gelbein, 2006).

Different technologies to produce DMC have been studied, although a few of them are industrially exploited (Pacheco and Marshall, 1997). The commercial routes to make DMC that are currently in operation are: the older commercial process based on the phosgenation of methanol; and the greenest processes: liquid phase oxidative carbonylation of methanol (ENIChem), vapor phase oxidative carbonylation of methanol (Covestro and Ube), and transesterification of ethylene carbonate with methanol (Asahi Kasei). In addition, there is a developing process with some promise: the urea alcoholysis.

The urea route allows the production of DMC using urea and methanol as raw materials, which are abundant and not especially expensive. It also avoids the use of phosgene, carbon monoxide, nitric oxide and ethylene oxide, which are present in the commercial routes aforementioned. The most promising chemical scheme to obtain DMC form urea and methanol is based on a two-step reaction.

First, urea is converted to the intermediate methyl carbamate (MC) by reaction with methanol (Reaction 1a). Then, the carbamate is further reacted with methanol in the presence of a catalyst to produce DMC (Reaction 1b). The first reaction is thermodynamically favorable. In the work of Wang et al. (2007) it is also noted that a

high conversion of urea to MC can be reached quickly. However, the critical aspect associated with this route is the highly unfavorable equilibrium of the second step reactions, whose equilibrium constant is about $2.08 \cdot 10^{-3}$ at 300 K. This reaction is endothermic, therefore, a positive effect on the equilibrium is observed rising the temperature. Nevertheless, the gain on the equilibrium constant value is not so pronounces as to overcome the problems raised by the reaction thermodynamics, as it is shown in Table 1 (Wang et al., 2007). In addition, the component N-methyl methyl carbonate (NMMC) has been detected as the main byproduct, which is formed from the reaction of DMC with MC.

Beside the unfavorable thermodynamics of Reaction 1b, the synthesis of DMC from urea alcoholysis is a very attractive route since it avoids the hazards of using dangerous compounds, and would allow the synthesis of DMC starting from carbon dioxide, since the co-product ammonia can be recycled to the synthesis of urea ($NH_3 + CO_2 \rightarrow$ urea + water). The commercial success of this route basically depends on the development of an appropriate catalyst to the second reaction step, and the design of suitable reaction arrangements in order to carry out the second step reaction on a large industrial scale.

Remark that a large amount of works in academia and industrial literature can be found about this topic. However, as far as the authors are aware, the academia papers are mainly focus on the study of the reaction mechanisms and catalyst. And the patents, even though they describe the process for large scale production, all the examples that they provide are laboratory scale. Thus, the main aim of this work is to provide a preliminary techno-economic assessment for the urea alcoholysis process, based on the rigorous simulation of possible large industrial scale flowsheets.

$$NH_2CONH_2 + CH_3OH \rightleftharpoons NH_2COOCH_3 + NH_3 \qquad a)$$

$$NH_2COOCH_3 + CH_3OH \rightleftharpoons CH_3COOCH_3 + NH_3 \qquad b)$$

$$\text{-----------------------------}$$

$$NH_2CONH_2 + 2\,CH_3OH \rightleftharpoons CH_3COOCH_3 + 2\,NH_3 \quad c)$$
Reaction 1. a) Methyl carbamate (MC) formation. b) DMC formation. c) Global reaction.

Table 1. Temperature dependence of the equilibrium constant for reactions 1a and 1b.

T (K)	K – Reaction 1a	K – Reaction 1b
300	203.88	$2.08 \cdot 10^{-3}$
350	120.88	$4.30 \cdot 10^{-3}$
400	86.07	$7.20 \cdot 10^{-3}$
450	70.27	$1.04 \cdot 10^{-3}$
500	62.74	$1.37 \cdot 10^{-3}$
550	58.40	$1.66 \cdot 10^{-3}$
600	57.65	$1.92 \cdot 10^{-3}$

2. Superstructure for the DMC production process from Urea

The superstructure for the DMC production process form urea and methanol given in Figure 1 is considered. This superstructure consists of the following three main sections:

2.1. Reaction and ammonia recovery section

As discussed in the previous section, DMC is produced form the reaction of methanol with urea in a two-step reaction. The first reaction is thermodynamically favorable. However, the second one has a low equilibrium constant. Thus, as other equilibrium reactions (such as the production of diphenyl carbonate from phenol and DMC), Reaction 1b is best carried out in a reactive distillation column (Ryu and Gelbein, 2002). Under these conditions, the following alternatives have been considered. On the one hand, a continuous stirred-tank reactor (R-101) can be used for the production of MC without catalyst. Then the byproduct NH_3 is removed be means of a distillation column (C-101). This column can operate at lower or higher pressure than R-101. Depending on the operating pressure, around 7 or 14 bar respectively, refrigerated water or cooling water will be use in the column condenser as cold utility. C-101 bottoms product is fed to the reactive distillation column C-102, where MC is converted to DMC. This column strips the product DMC and co-product NH_3 form the reaction mixture, shifting the equilibrium to the product side. C-102 can operate with a total or partial condenser. The C-102 overhead stream, containing most of the unreacted MeOH, NH_3, CO_2 and some DMC is mixed with a stream coming from the distillation section with similar composition, and fed to the C-103 column. In this column, NH_3 is recovered as top product, and the bottom product, containing MeOH and some DMC, is recycled back to the reaction section.

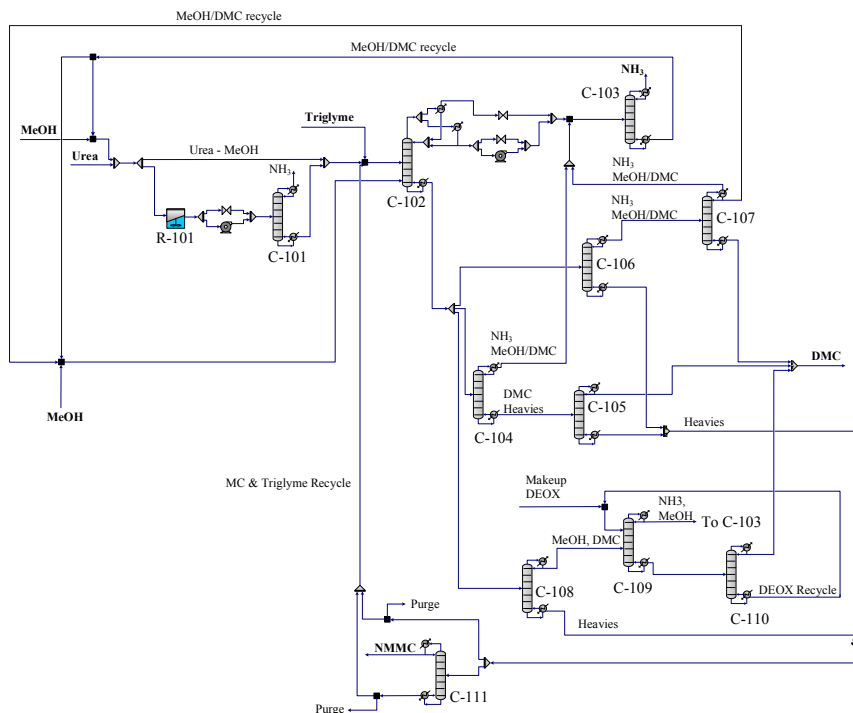

Figure 1. Superstructure for the production of DMC from urea and methanol.

As in the previous ammonia recovery column (C-101), the refrigerant fluid in the condenser of C-103 can be refrigerated water or cooling water depending on the column

operating pressure. On the other hand, reactive distillation column R-102 can be used as the single reactor to carry out the two-step reaction.

The reaction of MC with methanol to DMC takes place in the presence of a catalyst. Different heterogeneous and homogeneous catalyst have been studied so far. In the present work, the homogeneous catalyst triglyme is used according to the US patent 6,392,078(Ryu and Gelbein, 2002).

2.2. Distillation section

The crude DMC from the bottom product of C-102 is diverted to the distillation section. This stream, containing NH3, unreacted MeOH, DMC product and heavier compounds (NMMC, unreacted MC and triglyme) has to be separated into three main streams: high purity DMC product stream, a MeOH recycle stream (which will contain DMC and NH3), and a stream containing the heavy compounds (NMMC, MC and triglyme).

The binary system MeOH-DMC has a homogeneous azeotrope which makes the separation somewhat more complex. Fortunately, this azeotrope is pressure dependent, increasing the percentage of MeOH with pressure (Romano, 1976). For instance, at one bar the azeotrope composition of MeOH is around to 85 mol%, and at 15 bar around to 96 mol% (Yunhai et al., 2005). This allows for using pressure distillation to improve the MeOH-DMC separation.

Two different sequences are considered in the superstructure shown in Figure 1 based on exploiting this change in the azeotropic composition with pressure. The direct sequence (C-104 and C-105 columns), and the indirect sequence (C-106 and C-107 columns).

In the direct sequence, C-104 column operates at around 12 bars. At higher pressures, the temperature in the reboiler overcomes 240ºC, which prevent from using high pressure steam (41 barg, 254 ºC) as hot utility. The overhead product from C-104 is a mixture of MeOH-DMC close to the azeotrope composition and all the NH_3 in C-102 bottom product, while the bottom product contains DMC and the heavier compounds. The C-104 column bottoms are fed to C-105 distillation column where high purity DMC is obtained as top product. The column bottoms, containing NMMC, MC and triglyme are sent to the catalyst and MC recovery section. C-105 column operates close to atmospheric pressure. In the indirect sequence, the C-106 column splits the bottom product of the reactive distillation column into a stream containing all the NH_3, MeOH and DMC as top product, and a stream containing the heavier compounds (NMMC, MC and triglyme) as bottom product. The C-106 bottoms are diverted to the catalyst and MC recovery section. The overhead product is fed into the high-pressure C-107 column. In this column (C-107), high purity DMC is obtained from the bottoms, and a mixture of MeOH-DMC close to the azeotrope composition with the NH_3 as top product. The C-106 column operates at atmospheric pressure, and C-107 at 12-16 bar. A third alternative has been considered in the superstructure based on extractive distillation (C-108, C-109 and C-110). For instance, the US Patent No. 5,214,185 (Nishihira et al., 1993) disclosed the separation of the DMC-MeOH mixture by using dimethyl oxalate (DMOX) as solvent, and US Patent No. 6,392,078 (Ryu and Gelbein, 2002) assert that diethyl oxalate (DEOX) has more desirable properties than DMOX. The extractive distillation sequence proposed in Figure 1 can be used either with DMOX and DEOX. Preliminary simulations have shown that both solvents are effective, and in or work we selected DMOX.

2.3. Catalyst and methyl carbamate recovery section

The bottom product of C-105, C-106 or C-108 depending on whether the direct sequence, indirect sequence or extractive sequence is selected respectively, is sent to the catalyst and MC recovery section. In this section, part the undesired product NMMC is removed by means of C-111 column or a purge, in order to control the build-up of this component in the system. If the purge is selected, a bleed of 3-5% is performed in the stream. If the distillation column is selected, most of the NMMC is removed from the system and the performance of the process improves, at the expense of using an additional column.

3. Results

An exhaustive search is performed using the flowsheeting program Aspen Plus to determine the most profitable flowsheet based on raw material, products, and utility costs. Actually, the existence of dominated solutions avoids the need of simulation all 54 alternatives. For instance. The composition specifications of the effluent heavy stream from the distillation section is the same independently of the selected distillation arrangement. If we compare all the alternatives resulting from fixing the direct distillation sequence followed by C-111 column (9 alternatives), with the alternatives resulting from fixing the direct distillation sequence followed by the purge in order to control the build-up of byproduct NMMC (9 alternatives), it is possible to determine that the use of C-111 column gives the best results. Thus, the remaining branches of the decision tree that uses purges to control the amount of NMMC can be cut-off (18 alternatives).

The main results for the best flowsheet are summarized in Table 1. The best flowsheet consists of the following columns: C-102 with partial condenser, C-103 at low temperature, C-104, C-105 and C-111 (Figure 2). The yearly DMC plant production rate was fixed to 52 Kton/y, based on 8,000 operating hours per year. The price for the raw materials and products were taken from different webs (www.icis.com, www.mathanex.com, and www.alibaba.com), and the prices for the utility services from Turton et al. (2008).

Table 1. Results for the best flowsheet simulation

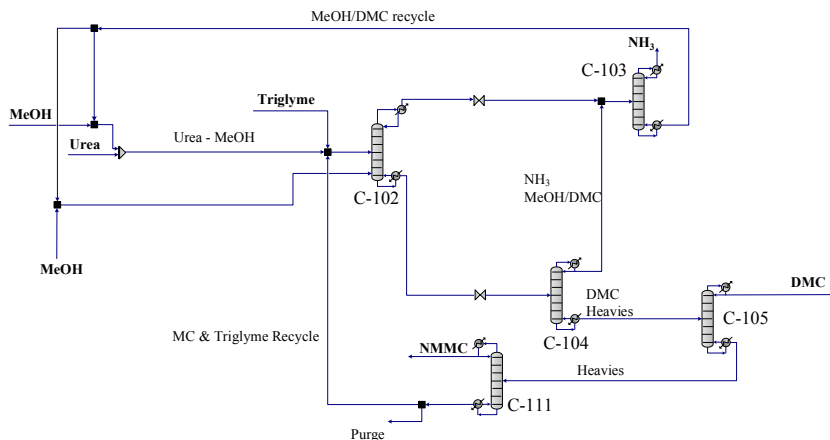
| Materials	ton/h	$/ton	$MM/y	Utilities	MW	$/MWh	$MM/y
Feed stock			**22.40**	**Hot utility**			**9.30**
MeOH	4.97	340.0	13.53	LPS (5 barg)	9.35	50.6	3.78
Urea	4.98	221.5	8.82	MPS (10 barg)	0.05	53.4	0.02
Triglyme	0.01	830.0	0.05	HPS (41 barg)	10.77	63.7	5.49
Products			**48.33**	**Cold utility**			**0.63**
DMC	6.50	830.0	43.16	CW (30ºC)	13.17	1.3	0.14
NH3	2.69	240.0	5.17	RW (5ºC)	3.91	15.9	0.50
Operating Costs ($MM/y)							32.32
Product Sales – Feed Costs ($MM/y)							25.93
Profit Value ($MM/y)							**16.00**


Figure 2. Best flowsheet for the production of DMC from urea and methanol

4. Conclusions

The urea process for making DMC is a promising alternative to the current processes, since it avoids the hazards of using dangerous compounds, and also would allow the synthesis of DMC starting from carbon dioxide. The results of this preliminary techno-economic study show that, if a catalyst that permit overcome the kinetic barriers of the second step reaction is developed in the future, DMC could be synthesized with considerable annual positive cash flows.

Acknowledgments.

Abstract

Natural gas (NG) is liquefied for shipping and storage purposes, this gas in liquid state is known as liquefied natural gas (LNG). The trade of LNG is usually regulated by contracts between suppliers and buyers. Historically long term contracts covering 20-25 years have been used; but more recently, due to emergence of new suppliers and consumers spot market purchases of LNG has also become possible. Nowadays, a consumer can opt to procure LNG via long term contracts or from spot market purchase or a combination of the two. We seek to evaluate the relative benefits of long term versus spot purchases. As a first step, in this paper, we report a mixed-integer linear programming (MILP) model to compare the cost of transportation through long term contracts as against spot market purchase. Several examples are solved; the results show that, in every case, spot market purchase is better compared to long term contracts.

Keywords: LNG, mixed integer linear programming, Long term contracts.

1. Introduction

Consumption of natural gas (NG) has grown steadily in recent years all over the world. Major factors that have contributed to this growth are environmental impact of conventional fossil fuels, abundant availability, and local market liberalization (Pospíšil et al., 2019). Despite NG being the most favored fossil fuel, its transportation to distant markets constitutes a challenge due to its gaseous state. Its liquefied form, liquefied natural gas (LNG), with its 600 time reduction in volume over NG, can be more easily transported using specially designed LNG carriers (Kumar et al., 2011).

Trade of LNG is usually regulated by contracts between suppliers and buyers. Historically, there were only a few buyers and suppliers of LNG. So contracts were generally 20-25 years long and thus provided security of demand and supply to sellers and buyers, respectively. In recent years, new suppliers have emerged, and LNG trade is increasing rapidly. Further, local NG market liberalization in many countries has also triggered many small companies to become LNG consumers. The emergence of these new players, especially small companies in the power sector and fertilizer manufacturers which use the regasified LNG as a feedstock has led to competitive LNG markets, but one characterized by high demand variability. Consequently, there is an increased need felt by regasification terminals to increasingly purchase LNG through short term (i.e., spot) contracts. In this paper, we seek to evaluate the relative benefits of

long term versus spot purchases. Specifically, we develop a mathematical programming to quantify the transportation cost of LNG purchase for a given demand via spot market and long-term contracts.

1.1. Literature Review

In literature, procurement of LNG is considered as a contract (vendor) selection problem, mainly from a buyer's perspective. The problem is formulated from the point of a focal company that needs to procure a certain amount of LNG over a planning horizon. The company can buy LNG from suppliers distributed all over the world. A supplier may offer one or more contract options. Typically, a mathematical model can be used to choose a set of contracts (vendors), which allows the buyer to minimize the procurement cost. Till the 1970's, vendor selection was done using linear weighting model where each vendor was scored on multiple decision criteria and the vendor with maximum score selected. Later on, researchers started using linear programming (LP) for vendor selection (Khalilpour and Karimi, 2011).

Contract selection problems reported in literature are usually from single buyer's perspective. See for examples (Khalilpour and Karimi, 2011) and (Jang et al., 2017). No model has been proposed to make a comparative study between spot market purchase and long term contracts for a set of buyers. In this paper, we therefore develop separate models for the long term and spot purchase of LNG and compare the optimal transportation costs.

2. Problem Statement

Consider a set of buyers and producers of LNG distributed all over the world. Each consumer and producer has its own specific production and consumption profile. Let P (p=1, 2, ...P) be the total number of producer and C (c=1,2, ...C) be the total number of consumers such that I= P $\cup$ I. Each site has a storage tank. A heterogeneous fleet of V ships (v=1,2, ...V) is used to transport LNG and manage the inventory level at all sites. A site i has J_i identical jetties. Thus, at most J_i number of ships may load/unload at a site. For spot market purchase, ship moves among all sites to maintain inventory level at each site, while for long term contract, ships move only between sites that have contracts with each other.

Initial positions of ships, capacity, loading/unloading rate, material onboard are known. Site to site travel costs, number of sites, production, and consumption profile are also known along with duration of the planning horizon. Sites having long term contracts with each other are known. The aim is to administer the ship movements over the planning horizon so that inventory levels are maintained at all the sites for both spot market purchase as well as for long term contracts.

2.1. Example 1

This example consists of two ships; five ports in which two of them are production sites (Site 1 and Site 2) while three of them are consumption sites (Site 3, 4 and 5). Every port has one jetty at each site. Each port has storage tank with limited capacity. Planning horizon is of 10 days. At time zero both ships are empty. Initially, ship 1 is at Site 1 while ship 2 is at Site 2. Loading/Unloading rate of both the ships at every site is 12t/day. Complete data for this example is shown in Tables 1 and 2. Producer 1 has contract with Consumer 3 while Producer 2 have contract with Consumers 4 and 5.

Table 1: Supply and demand data for Example 1

Site	Type	Initial material (t)	Capacity (t)	Production / Consumption rate (t/day)
1	Producer	2	80	2
2	Producer	6	100	1.25
3	Consumer	3	25	0.5
4	Consumer	2	40	0.5
5	Consumer	5	60	1

Table 2: Travel time and travel cost for ships in Example 1

i→j	Travel time	Travel cost
i1→i2	1.62	38.90
i1→i3	1.75	42.07
i1→i4	2.05	49.21
i1→i5	1.99	47.72
i2→i3	0.16	3.95
i2→i4	0.82	19.76
i2→i5	0.73	17.50
i3→i4	0.95	22.89
i3→i5	0.86	20.64
i4→i5	0.33	7.80

3. Mathematical Model

The proposed model for spot market purchase is based on the model for bulk maritime logistics for the supply and delivery of multiple chemicals reported by (Li et al., 2010). They developed a model for a multinational company (MNC) which has sites distributed globally. The model considers multiple materials such that the product of one site is a raw material for another. The goal of the model was to develop routing and scheduling for a fleet of ships while ensuring the continuity of operation at all sites at minimum transportation costs. (Li et al., 2010)'s model has been simplified for the transportation of LNG by reducing the dimensions of all variables which explicitly considered the multiple materials to one (LNG). These variables denoted storage tank capacity, material unloading, material onboard etc. For long term contracts, this model is modified with additional constraints to model the stipulated contract terms.

3.1. Modeling long term contracts for procuring LNG

Long term contracts are between suppliers and buyers and specify the quality, quantity, payment terms, etc of the product to be delivered to the buyer over a specified period of

time. For modelling long term contracts we consider a set of producers P (p=1,2,…P) with each producer having supply contracts with a set of customers L_{cp} ($L_{cp} \subseteq C$) . Since producer p has contracted only with customers L_{cp}, ships from p can only move to L_{cp}. Hence we write

$$\sum_{i=1}^{P} \sum_{j \notin L_{cp}} z_{vijk} = 0 \qquad 1 \le v \le V, 1 \le k \le K \tag{1a}$$

$$\sum_{i \in L_{cp}} \sum_{j \notin L_{cp}, j \ne i} z_{vijk} = 0 \qquad 1 \le v \le V, 1 \le k \le K \tag{1b}$$

where z_{vijk} is equal to 1 when ship v is at site i in slot k and at site j in slot $k+1$, otherwise it is zero.

3.2. Objective Function

The objective is to minimize total transportation cost over the planning horizon. Let Cv_{vij} be the cost of travelling from site i to site j via ship v. Then the objective function can be written as:

$$\sum_{v=1}^{V} \sum_{i=0}^{I+1} \sum_{j=0, j \ne i}^{I+1} \sum_{k=1}^{K} Cv_{vij} * z_{vijk} \tag{2}$$

Eq.(1a) and Eq.(1b) are specific to the long term contract model; all other equations are common to both the models.

4. Case Studies

We have solved three examples to assess our model. These examples vary in planning horizon, distances between the sites and production and consumption rates. We used Cplex 12.8.0 on a Lenovo idea pad 510 workstation (core i5-7200U, 8GBmemory) for solving these examples running on windows 10. Results of these examples are summarized in Table 3.

4.1. Case Study 1

In this example, Site 2 has contracts with Sites 4 and 5 while Site 1 has a contract with Site 3. Results shows that Ship 1 loads 5.58 t of LNG during [0,0.465] from Site 2 then moves to Site 4 and Site 5 to deliver 4.0 and 1.58 t of LNG at time (in days) 1.28 and 3.53 respectively. Then, it moves to Site 2 again to load 5.48 t of LNG and delivers it to Site 5 from time [5.581, 6.038]. Ship 2 loads 0.78 t of LNG from Site 1 during [0, 0.065] and delivers it to Site 3. Then it moves back to Site 1 to load 2.21 t of LNG which is delivered to Site 3. Fig 1 shows the resulting inventory profile of the sites over the planning horizon.

When the same example is solved as a spot market purchase problem, there is a significant reduction in the transportation cost. Here Ship 1 loads 5 t of LNG from Site 2 and delivers it to Sites 4 and 5. Ship 2 loads 1.2 t of LNG from Site 1 during [0,0.1] and delivers it to Site 3 and then moves to Site 2 to load 5 t of LNG which is delivered at Site 5 in between [4.56,4.97]. It then returns to Site 2 to load 2.8 t which is delivered at Site 3 during [5.99, 6.22]. The total transportation cost is therefore reduced by 46.64%. Fig 2 shows the inventory profile of the sites over the planning horizon with spot purchases.

Table 3: Results for examples

Example	Planning Horizon	No. of Voyages Spot / Long Term	No of Iterations Spot / Long Term	Time (min: sec: ms) Spot / Long Term	Optimal Cost Spot / Long Term
1	10	7/9	5435k/211k	00:50:40/02:43:29	88.82/146.7
2	15	10/11	8264k/1632k	03:56:82/00:43:26	134.11/136.77
3	25	3/6	10k/13k	00:00:90/00:01:48	127.03/220.76

5. Discussion

We solved two other examples with different parameters (see Table 3). In these examples also, the transportation cost with spot market purchase is less than with the long-term contract. The difference in the transportation costs between the long term and spot purchases increases significantly when the producer and consumer sites are at large distances. These clearly indicate that spot purchases lead to a more optimal usage of the ships – i.e., the same demands can be more effectively met in the absence of long-term contracts. The current model relies on a number of simplifying assumptions. Here, the price of the LNG cargo has not been taken into account. In practice, purchases through long term contracts may have price advantage. The net effect of lower cargo price and a higher transportation cost therefore needs to be evaluated. Also, the current model assumes deterministic values for all parameters; in reality, these would vary based on demand. In future, we aim to develop a model that can incorporate effect of demand variability.

Abstract

Liquefied natural gas has started to establish itself as the fuel of choice across the globe, evident from its sustained growth over the last three decades. As a result, more regasification terminals are coming up every year. Hence, it is critical to develop technologies which make sure the plants are operated efficiently. This paper studies the generation and management of Boil Off Gases (BOG) in LNG regasification terminals. The effect of time varying ambient temperature on the BOG generation is studied, and ways to improve the operational efficiency of BOG compressors are suggested.

Keywords: LNG, Ambient temperature, Regasification, BOG compressor

1. Introduction

As the global population increases, world's energy demand stands to double by the year 2050. Natural gas is believed to have a significant role in driving this rising demand. Gas is the fastest growing hydrocarbon market today. Natural Gas (NG), being the cleanest fossil fuel, has become the fuel of choice in many of the developed and emerging economies. NG demand is expected to grow at an average of 2% per year which is twice the rate of total worldwide energy demand. Natural gas is transported to India as Liquefied Natural Gas (LNG) through specially designed ships known as LNG carriers. Natural gas is converted to liquefied natural gas (LNG) by refrigeration below -162°C; this reduces its volume by 600 times. LNG is imported to the regasification terminal, where it is stored, vaporized and distributed to the customers.

Processes involved in the regasification are energy intensive. Vaporizers, used for conversion of LNG to natural gas uses major share of energy consumption in the plant. Although the storage tanks are provided with extensive insulation, the heat ingress into them cannot be avoided. This leads to the vaporization of LNG producing Boil off Gases (BOG). Excessive buildup of BOG causes surge in the storage tank pressure. For the safe operation of the plant, the tank pressure must be kept much below the designed level of the pressure. Hence, it is imperative that the BOG is timely taken out and either liquefied or sent to distribution line. The pressure in the distribution line is over the range of 75bar which is significantly higher when compared to pressure of the BOG which is nearly 1.17 bar. So, the warm BOG produced are liquefied in the recondenser and sent back into the storage tank, causing the temperature to rise. BOG is transported to the recondenser through BOG compressor. The composition of BOG and LNG is quite different, with the former having more methane and latter having relatively heavier hydrocarbons. The BOG management process is also an energy intensive one.

BOG management is one of the most challenging tasks in the operation of a regasification terminal. Most studies assume a constant BOG rate while devising energy efficient ways to condense BOG and transport them back to the storage tank. In reality, BOG generation is not constant and it fluctuates in the course of a day. For estimating the BOG generation rate, modeling of the storage tank is cardinal and it also enables us to study the dynamics of the regasification terminal, closer to the reality. In the paper, we studied the effect of ambient conditions on the variation in the BOG generation. Further, we also propose methodologies to reduce to energy consumption in the operation of BOG compressors.

2. Various Models of BOG in Literature

BOG management holds a major role in reducing the energy consumption in the plant. Effects of BOG generation often cause ripple effects in other operations in the plant. Different studies have incorporated these effects in their models. The fluctuation in the BOG generation causes change in the level of LNG in the recondenser.(Shin et al., 2008) studied the effect the above occurrence can have on the high pressure LNG pump (which pumps LNG from the recondenser to the vaporizer) e.g. cavitation of the pump and equipment vibration.(Park et al., 2012) proposed a retrofit design the form of intermittent cooling of the BOG before its compression, saving compression costs. But many of those studies like above, were done on the underlying assumption of constant BOG generation. Studies by (Saleem et al., 2018) brought better insights into factors affecting BOG generation, by studying the heat ingress magnitude and convective heat transfer in the LNG storage tank. Most models also assumed that the vapor and liquid phases in the LNG tank are at same temperature and composition. (Effendy et al., 2017) studied the BOG generation in the storage tank by taking into account the temperature and composition variation which exists in the different phases. In their model, the storage tank is considered to be composed of four subsystems, namely, vapor, liquid, flash, recirculation subsystems. Also, the heat leaks from the surroundings to the liquid and vapor subsystems are accounted for separately.

The temperature of the liquid subsystem is governed by the following energy balance:

$$\frac{dT_L}{dt} = \frac{4}{\pi D_T^2 \rho_L h}\left[-\frac{\lambda \dot{m}_e}{C_{p,L}} + \left(1 - \overline{f}_F\right)\dot{m}_r\left(T_v - T_L\right) + \frac{\dot{Q}_L}{C_{p,L}}\right] \tag{1}$$

$$\dot{Q}_L = U_{side}\left(\pi D_T h\right)\left(T_a - T_L\right) + U_{bottom}\frac{\pi D_T^2}{4}\left(T_{bottom} - T_L\right) + U^*\frac{\pi D_T^2}{4}\left(T_V - T_L\right) \tag{2}$$

where T_L is the temperature of liquid phase, D_T is diameter of the storage tank, ρ_L is the density of liquid phase, h is the height of liquid in storage tank, λ is the latent heat of vaporization, $\dot{m}_e$ is the LNG evaporation rate, $C_{p,L}$ .specific heat capacity of liquid subsystem, $\overline{f}_F$ is the fraction of liquid phase in the flash subsystem, $\dot{m}_r$ is the rate of recirculation liquid returning back to the tank, T_V is the temperature of the vapor

phase, $\dot{Q}_L$ is rate of heat leak into the liquid subsystem, T_{bottom} is the temperature of bottom of the storage tank, U_{side}, U_{bottom}, U^* are the overall heat transfer coefficients at storage tank shell, bottom and the vapor-liquid interface respectively

The temperature of the vapor subsystem is governed by the following energy balance:

$$\frac{dT_V}{dt} = \frac{\left[\dot{m}_E \left(T_L - T_V \right) + \left(T_F - T_V \right)\left(1 - \overline{f}_B \right) \overline{f}_F \dot{m}_R + \dfrac{\dot{Q}_V}{C_{p,V}} \right]}{m_V} \tag{3}$$

$$\dot{Q}_V = U_{top} A_{top} \left(T_a - T_V \right) + U_{side} \left(\pi D_T \left(H - h \right) \right) \left(T_a - T_V \right) + U^* \frac{\pi D_T^2}{4} \left(T_L - T_V \right) \tag{4}$$

where, U_{top} is the overall heat transfer coefficient at top of the storage tank, T_F is the temperature of the flash subsystem, $\overline{f}_B$ is the fraction of boil off stream, $\dot{Q}_V$ is the total heat transfer into vapor phase, $C_{p,V}$ is the specific heat capacity of vapor phase.

Rate of change of mass in the vapor subsystem is governed by the follow equation:

$$\frac{dm_V}{dt} = -\frac{\pi D_T^2}{4} \rho_V \left[\frac{dh}{dt} + \frac{\left(H - h \right)}{T_V} \frac{dT_V}{dt} \right] \tag{5}$$

Total amount of BOG generated is given by:

$$\dot{m}_B = \dot{m}_E + \overline{f}_F \dot{m}_R - \frac{dm_V}{dt} \tag{6}$$

where $\dot{m}_B$ is the rate of BOG generation.

As heat leaks into the tank, the LNG boils and the BOG generated has to be managed so that the pressure of the tank remains within the safety limits. This is typically done by a BOG compressor as it transports the vapor into the liquefaction system. BOG compression being energy intensive, it is critical to optimize the operation of the process.

3. Effect of Ambient Conditions on Boil Off Gas Generation

We consider a regasification terminal operated in the holding mode i.e. LNG is not transferred from the carrier ship to the storage tank.

The objective of this paper is to demonstrate the effect of ambient weather conditions on the generation of Boil off Gas (BOG) and optimal operation of BOG compressor in a LNG regasification terminal. The LNG storage tank and recirculation pipeline are modeled by utilizing the model proposed by (Effendy et al., 2017). The regasification

plant modeled has eight storage tanks, and ten cooling lines connecting the jetties to the storage tanks. The storage tank is assumed to be operated in an isobaric regime so that any BOG generated will be evacuated from the tank. The simulation is run for a span of 16 days.

Figure 1: Ambient temperature profile in Hazira, India

In order to understand the effect of ambient temperature, the temperature profile in Dahej, where India's largest regasification terminal is situated was considered. On a typical day in November, the temperature was observed to be rising quickly after sunrise from 26 ℃ to 35 ℃ in six hours, then remaining fairly constant at 35 ℃ for five hours and slowly cooling to 26 ℃ over twelve hours. The first and last temperature regime fitted for a quadratic and linear fit respectively. It is assumed here that a given day starts at 6 a.m. in the morning (around sunrise).

$$Ambient\,Temperature\,(K) = \begin{cases} 1 < t_k < 7 \rightarrow 0.107*x^2 + 0.536*x + 298 \\ \qquad 8 < t_k < 12 \rightarrow 308 \\ 13 < t_k < 24 \rightarrow -0.601*x + 313.46 \end{cases} \qquad (7)$$

The above ambient temperature function was incorporated into the model proposed by Effendy et al. (2017) and the BOG generated thereof was calculated. The variation of BOG generation rate on a given day due to the change in ambient conditions is shown in Figure 2.

Figure 3 shows the BOG generation over a 16-day period for three different conditions – ambient conditions constant at 25 ℃, ambient conditions constant at 30.5 ℃ (median temperature of the profile in Figure 1) and ambient temperature varying as per Figure 1. From this, it can be readily inferred that there is significant fluctuation in the BOG generation over the course of a day, and this fluctuation also depends with the inventory level of the LNG in the tank. The BOG generated is recompressed back to liquid using

compressors – the substantial variation in BOG generation rates described above, therefore, motivate a study of suitable operations regimes for the compressor network.
Figure 2: Variation of BOG generation resulting from the ambient conditions in Figure 1
Figure 3:Comparison of BOG generation rate for various ambient models

4. Effect on Compressor Operations

The compression cost can be significantly reduced by improving the operation of the compressor network for processing a specified amount of BOG. (Shin et al., 2007) proposed a method to minimize the power consumption using mixed integer linear problem (MILP) formulation, which improved the operational policies based on safety analysis on the dynamics of the tank pressure. Hence, for reducing the energy

consumption in a regasification terminal, it is important to optimize the operation of the BOG compressors.

In our study of compressor operations, following Shin et al. (2007) we assume that at load levels of 0, 50%, 75%, and 100%, the current requirement by the compressor is 65 A, 115 A, 127 A, and 145 A, respectively. Given the voltage of 6900 V, the corresponding amount of energy consumed is 449 kW, 794 kW, 876 kW, and 1000 kW. Table 1 shows the energy consumed by BOG compressors when operated at different loads. The quantity and quality i.e. the flow rate and enthalpy, of the BOG generated by the LNG train vary depending upon the operating conditions in the plant, as well as on the mode of operation.

As the BOG generation rate changes significantly over time, optimizing the compressors could save significant amounts of energy. A simple analysis reveals a reduction of over 13% on a given day in compressor energy consumption when BOG compressors are operated differently over the course of the day. Further, as evident from Figure 3, the BOG generation profiles are different from day to day depending on the inventory, so the energy optimal mode and the savings potential would also vary on a daily basis and motivates real-time optimization.

5. Conclusions

As the size of LNG regasification plants grow, and multiple LNG trains are connected, the complexity of BOG management also increases. BOG management is a multi-faceted problem requiring study of hydraulics, transient behavior and compressoroperations. This paper has demonstrated that the effects of ambient temperature on the rate of BOG generation is significant and motivates daily optimization of compressors' operation modes. Further, we believe such studies would educate new designs of regasification terminals in tropical regions.

Abstract

Human errors are a root cause of majority of accidents occurring in the process industry. These errors are often a result of excessive workload on operators, especially during abnormal situations. Understanding and measurement of cognitive workload (overload), experienced by human operators while performing key safety critical tasks, is thus important to the understanding of human errors. Subjective measurements of workload are often not reliable and there is a need for physiological based parameters of workload. In this work, we propose a methodology to measure cognitive load of a control room operator in terms of a biomarker, specifically theta/alpha ratio, obtained from a single electrode EEG signal. Real-time detection of the biomarker can enable minimize errors and improve safety.

Keywords: EEG, human errors, cognitive workload, safety

1. Introduction

With the advancement of technology and enhanced automation, the role of human operators has been shifting more towards monitoring the process operations. However, the disturbances in the process often call for human intervention. It often happens that humans commit errors in either planning or execution of actions; human errors have been a root cause of over 70% of accidents in process industries (Mannan, 2005). This situation is similar in other safety critical domains like aviation, health and nuclear industries. The reason for such errors is often attributed to the high cognitive workload experienced by the operator(s) during abnormal process events (Bhavsar et al., 2015). During these events, the operator uses their mental model of the process (developed during training, prior knowledge about the process, heuristic rules learnt from experience with the process, etc.,) to initiate and execute a sequence of steps that would bring the process back to normal operating conditions. However, any mismatch between the plant behaviour and the mental model would result in higher cognitive workload, a common cause for human errors. Therefore, it is imperative to understand the nature and evolution of the mental model of the operators.

Mental models of an operator can be broadly divided into three categories: skill based, rule based and knowledge-based (Reason, 1990). Operators use skill-based models to perform repetitive tasks which do not require any mental effort. For instance, an experienced driver on a traffic free road subconsciously performs driving related

actions. An if-then rule-based mode would be used to tackle some abnormal situations in the process, specifically those that they are well-versed with a priori. Operators resort to a knowledge-based mode when they face a new situation where skill-based and rule-based modes are not available; they therefore need to apply their knowledge to identify suitable actions. However, operators traverse between the three mental modes (Reason, 1990) in the course of handling an abnormal situation. The resulting cognitive workload is different in each of the mental states. Therefore, it is essential to understand, explain and predict the transition among the various mental modes based on cognitive load so that the nature of the human errors can be uncovered and interventions taken to minimize the same. This is the ultimate objective of the research described here.

2. Literature Survey

Cognitive workload is experienced because of the limited working memory capacity of humans (Parasuraman, 2008). A mismatch between this capacity and demands of the process leads to errors which may transform into catastrophic accidents. To understand the underlying cognitive constructs during such mismatch, the nature and extent of cognitive workload needs to be quantified. Physiological parameters offer a potent approach to understand the underpinnings of human behaviour and provide information about the internal state of an individual. One such is Electroencephalogram (EEG) which has been used in diverse fields to understand the mental states of humans and predict stress levels and cognitive load.

EEG involves measurement of electrical activity of the brain using electrodes which are placed on skin. The electrical activity is the result of neural-oscillations occurring in brain due to fluctuations in excitability of neurons in response to stimuli. A raw EEG signal is comprised of various frequency components which are often clubbed into different frequency bands for the purpose of drawing meaningful observations. The commonly used frequency bands are delta (1-4 Hz), theta (4-7 Hz), alpha (8-12 Hz), beta (12-30 Hz), and gamma (30-80 Hz). Alpha and theta band activity have been extensively used for cognitive load measurement. Specifically, alpha activity is associated with idling, arousal and workload. A decrease in alpha activity is associated with increase in arousal, mental load, stress and anxiety (Neurosky, 2015). Conversely, an increase in alpha activity signifies idling or calmness (Pfurtscheller et al., 1996). Lim et. al, (2014) showed a significant increase in alpha activity when the eyes were closed, reflecting relative calm. Theta activity is also associated with attention and internal mental processing (Harmony et al., 1996); hence, an increase in theta activity means more mental effort. The power spectral density of delta waves has been reported to show a positive correlation with mental stress (Awang et al., 2011). Other frequency bands also have some significance e.g. beta waves in optimum condition can help with memory, conscious focus and problem solving (Abhang, 2016); delta waves are associated with adult sleep; and gamma waves with hypertension and high mental activity.

The potential of EEG to predict cognitive workload for dynamic processes has, however, been limited. Nevertheless, these frequency bands in the EEG signal have been used as biomarkers, for instance in the aviation sector involving dynamic tasks. A study by Gentili et. al, (2014) highlight the potential of theta by alpha ratio to measure cognitive workload and degradation of pilot performance when carrying out complex

tasks involving manoeuvring. Theta by alpha ratio is reported to increase with task complexity. A study by Wilson (2002) revealed that the alpha band relative power decreased while delta band relative power increased for pilots, when compared at the same electrode locations in comparison to their pre-flight baseline values, for the majority of cases. These studies highlight the potential of EEG to offer insight into task difficulty and workload. There is, hence, a need to carry out cognitive workload studies in chemical process industries which like aviation offer highly dynamic situations involving high-risk and potential for disasters. The cognitive workload of the plant operators, in the process industry domain, depends on their ability to develop a mental model in a given situation, which is distinctly different from the time space representation of airplane pilots and drivers. Previously, the authors have explored eye-tracking based approaches to understand the cognitive behaviour of control room operators in process plants (Bhavsar et al., 2015). However, to the best of authors' knowledge, there is hardly any work, in this domain, to understand the cognitive workload of operators using EEG. In this paper, we seek to evaluate the potential of EEG biomarkers to discriminate between levels of cognitive load (mental states) and task difficulty.

3. Experimental Methodology

The experiment consists of monitoring a simulated ethanol production plant via a Human Machine Interface (HMI). The process involves an exothermic reaction between ethene and water taking place in a jacketed Continuous Stirred Tank Reactor (CSTR) whose output goes to a distillation column for separation of ethanol product. In case of any disturbance in the plant, the operator needs to take action(s) to bring the process variables to within acceptable limits, using various flow control sliders operable from HMI, as deemed appropriate by the participant. The reader is referred to Iqbal and Srinivasan (2017) for a detailed description of the process.

The study involved 6 post graduate chemical engineering students who performed 8 disturbance rejection tasks after receiving proper training (reading handouts and video training). During the course of the experiment the EEG data was recorded using Neurosky Mindwave+ single electrode headset. Different tasks involved dealing with different abnormalities. Tasks 1 and 2 involved a disturbance in coolant flow rate which resulted in the coolant flow rate crossing the upper alarm limit. Tasks 3 and 4 involved tackling the disturbance in coolant flow rate going outside the lower shutdown limits. Tasks 5 and 6 demanded bringing back the process to within alarm/acceptable limits in response to feed flow rate to CSTR breaching the upper alarm limit. The tasks differed by the magnitude of disturbance which in turn accordingly affected other process variables. Task 7 and 8 involved a disturbance in the feed flowrate going outside the lower alarm limits.

4. Results

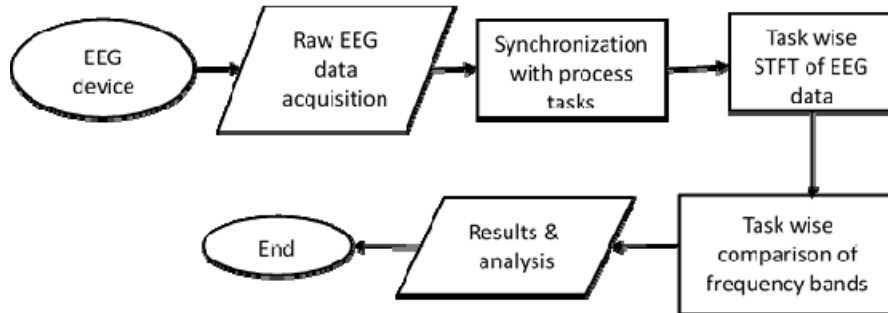
An overview of the methodology employed to study the cognitive workload and related constructs is shown in Figure 1. We recorded the operators' EEG during the course of different tasks using an EEG headset and then carried out task-wise Short Time Fourier Transform (STFT) of the recorded raw EEG signal to obtain information in frequency domain. Among various possible biomarkers that have been reported in literature, theta (4-7 Hz) and alpha activity (8-12 Hz) showed promising results, which


Figure 1: Overview of the methodology

are reported after the detailed description of a typical task in the following paragraph.

A typical task involves a disturbance resulting in a process variable(s) going outside its acceptable limits designated by upper and lower alarm limits. The operator is notified about the disturbance by an alarm entry in the alarm log and by change in colour of the tag(s), representing that variable(s) in the process schematic to red. The operator needs to assess the situation, decide on the appropriate recovery action and then take the action by moving appropriate slider(s) to bring the process variable(s) back to within acceptable limits. If the operator is unsuccessful to bring the process within normal bounds within a short time, the disturbance will result in the process variables crossing the shutdown limits (which is considered as a failure). The operator can see the trend of any process variable on HMI by clicking on the tag corresponding to that variable. The tasks have been designed in such a way that different aspects of cognitive behaviour and workload of operators could be studied; the tasks involve abnormal events (depending on the nature and magnitude of initial disturbance) with single alarm triggered, multiple alarms triggered in slow/quick succession and similar tasks i.e. tasks of varied difficulty as well as tasks of similar difficulty are included in the study.

Consider tasks 1 and 8, the simplest and the most difficult tasks, respectively; Task 1 involves an abnormality in coolant flow rate (through jacket) which does not affect other process variables immediately whereas during Task 8 an initial disturbance in the feed flowrate results in triggering of other alarms (temperature and concentration of CSTR) in quick succession. The comparison of theta/alpha activity of participants for these tasks reveals that the ratio is lower for a majority of simple tasks compared to Task 8, as shown in Figure 2. Out of 6 participants, 4 participants showed higher theta/alpha ratio for Task 8. For those 4 participants the average value is 1.05 for Task 8 compared to 1.03 for Task 1. Only one showed a lower score for Task 8 and for 1 participant it showed a negligible change. We therefore evaluated if this ratio has the potential to differentiate task difficulty and the consequent mental workload.

A comparison of two tasks - 7 and 8 – was therefore performed. Task 8 is a more difficult task compared to Task 7 as it involves a larger disturbance in the feed flowrate. This larger disturbance in feed flowrate in turn results in triggering of multiple alarms (temperature and concentration of CSTR) in quick succession compared to Task 7 (where the deviations are relatively slow), and also involves rapid evolution of process variables to outside shutdown limits. A relative comparison of these two tasks, for all
Figure 2 Theta by alpha ratio comparison of Task 1 vs Task 8

Figure 3 Theta by alpha ratio comparison of Task 7 vs Task 8

the 6 participants revealed that out of the 6 participants, 4 participants showed a higher theta by alpha ratio for task 8. For those 4 participants the average value was 1.05 for Task 8 compared to 1.04 for Task 7. One participant showing negligible change. Thus, theta by alpha ratio can act as a marker to predict the cognitive load as imposed by the task difficulty and as perceived by the participant.

The trend shown by the theta by alpha ratio in our study is in line with the results reported by Gentili et. al, (2014) during their pilot cognitive workload assessment studies. The alpha by theta ratio changes between easy and medium difficulty tasks and between medium & highest difficulty tasks in their study was around 0.05 and 0.08, respectively. The reason for the smaller difference in the values observed in our study can be attributed to the different nature and level of the complexity of the tasks in our study compared to theirs; the nature of the EEG device especially the electrode employed is also known to lead to differences. Our tasks involved control room tasks which would last 2-3 minutes while in their case the operator would carry out each task for 10 minutes. The persistent workload for longer duration experienced by pilots in their study might have invoked different levels of theta and alpha activity compared to our study. Our study is also consistent with the pilot-workload study by Wilson (2002) in terms of alpha activity; the study revealed that alpha activity corresponding to the different electrodes decreases for majority of the electrode positions in comparison to pre-flight base line values, though the differences were not always significant for all the electrodes; alpha activity alters the theta by alpha ratio. Nevertheless, in real control room settings where the disturbances and the remedial procedures can persist for longer time, our biomarker can show more significant differences. Further, more studies need to be carried out to identify the regions of brain which are more important for the cognitive workload determination involving different nature of dynamic tasks involved in process industries. This will help in a holistic understanding of cognitive workload determined using EEG based bio-markers. The tracing of the workload of the operators using biomarkers can help us minimize human errors due to high cognitive workload. If the workload during an unknown disturbance crosses a particular threshold/limit, automatic cues (may be in the form of additional information about the disturbed segment of the process) can be provide to the operator accordingly to minimize the likelihood of error.

5. Conclusions

In this work, we have found that EEG based bio-markers have the potential to help quantify the task difficulty and the consequent cognitive workload on the participants. Our results show that theta by alpha ratio is higher for tasks which are more difficult and impose higher cognitive workload on the participants. This marker can be used to assess training level of the operators before they are asked to monitor a plant. These will ensure their preparedness and feasibility for tasks involving monitoring and control of the processes in highly hazardous chemical process industries. In the future, we plan to measure the cognitive workload using EEG in real-time and also correlate them with markers obtained from our eye-tracking studies. Real time gauging of cognitive workload can help create systems which provide relevant cues to check the workload of operators by providing appropriate support in the form of certain information or otherwise. Multivariate analysis, involving various physiological parameters obtained from EEG and eye-tracking will help arrive at robust indices of cognitive load which will go a long way in understanding and obviating human errors.

Optimal design of biomass supply chains with integrated process design

Theodoros Damartzis[*], François Maréchal

Industrial Process and Energy Systems Engineering (IPESE), Ecole Polytechnique Fedérale de Lausanne (EPFL) Valais, 1951, Sion, Switzerland

theodoros.damartzis@epfl.ch

Abstract

The current work focuses on the optimal design of biomass supply chains, addressing the conversion of raw materials into useful services. The latter include not only heat and power but also synthetic bio-based fuels (e.g. bio-SNG). Optimally pre-designed processing units representing the conversion facilities responsible for the transformation of biomass are employed. This permits the use of standardized units that act as building blocks within a MILP optimization problem, significantly simplifying the formulation and solution of the problem. These building blocks encompass a variety of transformation options and carry specific information regarding their capacity, total processing cost, overall efficiency and energetic performance. Then, the supply chain design optimization problem aims not only to identify the most suitable conversion plant type but also to determine their location by minimizing the overall cost, expressed as the capital and operating expenses of the processing units as well as the transport costs between the points of operation. The above formulation is applied for the conversion of animal manure to different end products in the district of Brig in southern Switzerland. Results reveal the predominance of large centralized bio-SNG producing units as a consequence of their higher conversion efficiency.

Keywords: supply chain design, bio-SNG, biomass conversion, animal manure.

1. Introduction

The increasing depletion of the fossil-based energy resources as well as the new mandates for the insertion of renewables in the global energy mix are continuously shaping the background for the energy transition. As renewable energy sources are presented to be promising alternatives to the traditional fossil resources, an intensification of the efforts to deploy sustainable biomass-based energy systems is ongoing not only from a strategic decision point of view, but also from an environmental perspective (d'Amore and Bezzo, 2016).

However, the introduction of bioenergy into the existing energy market necessitates not only the efficient design of the processing of raw materials but also the consideration of the spatial interactions of the conversion plants with the supply and demand points (Chomette et al., 2018). A number of recent studies address the issue of the biomass supply chain design. Costa Melo et al. (2018) present a data envelopment analysis approach (DEA) to identify the most suitable transport pathway of wood from Africa to Europe. How and Lam (2017) proposed a novel optimization approach that incorporating principal component analysis (PCA) and analytical hierarchy process

(AHP) to determine the optimal transportation design and processing hub location in an integrated biomass supply chain. The work of Ghaderi et al. (2016) provides a comprehensive review regarding the design of biomass supply chains. In this paper, a large number of published works are compared and a large diversity on modeling approaches is revealed. Focusing more on manure as a source material and the production of bio-SNG, Calderón et al. (2017) provide a framework for the design and optimization of bio-SNG supply chain using av explicit MILP multi-period scheme.

However, one should not forget that the role of process design within the definition of the supply chain is crucial. Thus, a bigger approach is needed that accounts for the integration of process design with the supply chain, highlighting the benefits and revealing potential synergies between the various steps of the conversion path from raw materials to services. Moreover, such a formulation will set the transition from the well-established process design level to the larger scale market level. To account for the role of the design of the processing units in the supply chain, expressed both as the type of conversion plant but also in relation to the output capacity, the current work presents a holistic approach based on the model presented by Chomette et al. (2018) for the design of wet biomass supply chains. To this end, the type and size of the conversion plants will play a decisive role in the formulation of the supply chain. The type of the plant refers to the various sub-processes that are used to convert the raw material to useful products as well as the formulation of the entire process flowsheet, while the size represents the output capacity in energy units. Using optimally designed conversion plants as predefined building blocks permits the synthesis of the entire supply chain through a MILP optimization problem that aims to minimize the total cost, expressed as the sum of the processing and transport expenses. The above formulation is then presented in an illustrative example for Brig, one of the highest manure producing districts of the canton of Valais in Switzerland.

2. Methodology

2.1. Manure conversion and design of the building blocks

The use of animal manure as the raw biomass material offers the possibility of using a plethora of conversion options of variable efficiencies depending on the desired end use as well as the conversion pathway that is followed. The common conversion process is anaerobic digestion, in which manure is converted to biogas through a series of complex (bio-)chemical reactions. The employment of pretreatment options of the raw biomass offers the chance to increase the biogas yield from the digester, inducing however an extra processing cost. Especially in cases where thermal pretreatment is used, extra degrees of freedom appear in the design process, related to the heat exchange between the pretreatment unit and the rest of the process. Biogas, being a mixture of CH_4 and CO_2 in a molar ratio of roughly 60:40 has to undergo through a cleaning and upgrading process to remove traces of impurities like H_2S, NH_3, siloxanes etc. and increase its methane content, respectively. The final stream of upgraded biogas consists mainly of CH_4 and can be used as bio-SNG for grid insertion or power production in engines or fuel cells. On the other hand, anaerobic digestion leaves an undigested stream that still contains a large portion of the initial carbon content. It is therefore of great interest to extract the latter in order to maximize the efficiency of the overall process. Hydrothermal gasification (HTG) offers the possibility of converting wet organic

streams into methane using high pressure in a complex reactor scheme. The supercritical conditions that prevail within the HTG reactor ensure that the nitrous and phosphoric minerals are released unharmed in the residual output stream. Moreover, the use of catalytic methanation to convert the separated stream of CO_2 from the biogas is another option of further increasing the final bio-SNG yield. The methanation reactor can be fed with hydrogen produced through the electrolysis of water using renewables (e.g. solar power).

Using the MILP optimization framework described in Vigot et al. (2018), a number of possible configurations have been designed, each emphasizing in different process schemes and end products. Figure 1 shows the pareto front correlating the annualized process cost (in Swiss francs) with the overall energy efficiency of the process for a 100 kW unit.

Figure 1. Pareto front of various process designs for manure conversion.

2.2. Employed flowsheets and typical sizes

Three different indicative flowsheets have been chosen to be used in the design of the supply chain, each focusing in a different end product. The employed flowsheets are depicted in Figure 2.

Figure 2. Employed flowsheets for the conversion of manure to different end products.

As already mentioned, the size of the conversion units plays an important part in the supply chain design. The specific costs of each flowsheet expressed as Swiss francs per kW produced is shown in Table 1. The typical sizes are selected with a reference on the raw material supply as well as the existing plants in the application area. The nonlinear dependence of the specific cost with the output capacity of each plant stems from the nonlinear dependence of the process efficiency with the plant dimensions.

Table 1. Specific costs (cost per kW) in Swiss Francs (CHF) of the employed flowsheets

	50 kW	100 kW	250 kW
Bio-SNG	2945.90	2292.54	1830.96
Power	2188.55	1821.40	1605.95
CHP	866.28	709.39	594.17

3. Application - Results

The three types of conversion plants presented in Section 2 together with the three typical sizes are used for the design of a supply chain for manure conversion in the commune of Brig in southern Switzerland. Six source sites have been identified and the corresponding manure potentials are taken from Thees et al. (2017). Using the design framework presented by Chomette et al. (2018), the results are illustrated in Figure 3.

Figure 3. Supply chain results for manure conversion in the district of Brig, Switzerland

The horizontal length of the bars representing the processing units corresponds to the energetic output and specifically, 50 kW for small bars, 100 kW for medium bars and 250 kW for large bars. Similarly, the colors of the units correspond to the type of the plant, namely red for bio-SNG producing plants, blue for power production and green for CHP (also see Figure 2). It is seen that large centralized bio-SNG units are favored over the rest of the options due to the much larger energy efficiency of the process. In other words, these plants are able to convert more effectively a larger capacity of raw materials into bio-SNG. The centralized fashion in the placement is a direct consequence of the larger capital expenses that correspond to this type of conversion (Table 2). On the other hand, one can see that one biomass source is not limited to feeding a single conversion unit as shown in the northern part of the commune. According to the results, heat and power producing plants act as a supplement to the residual manure that is more expensive to be converted to bio-SNG. It has to be noted that this of course depends also on the initial choice of the building blocks. In other words, if an exhaustive investigation was made using all the available conversion options, it would be apparent that the highly efficient designs would be preferentially used over the other options. This of course, will increase the accuracy of the results but also drastically raise the computational effort and is the next step of this research.

4. Conclusions

A study for the design of manure supply chains was presented here. Based on a previous work, the approach involves the use of pre-designed processing plants representing the main steps of the biomass-to-services conversion chain. Such plants come equipped with information on their assigned capacity and type, the first being expressed as the energetic output of the conversion process while the second as the pathway from raw materials to products and are then used within a MILP design optimization framework. The latter is able to perform the spatial allocation by selecting the most suitable conversion type and size of each plant with regard to the supply of raw biomass by minimizing the total cost of the supply chain represented by the sum of the processing and transport costs. Three pre-defined process flowsheets, each accounting for the conversion of manure to different end products and with a different energetic efficiency, as well as three typical plant sizes selected by considering the domain of application are used for the design of the manure supply chain for the district of Brig in Switzerland. According to the model outputs, the conversion to bio-SNG in large plants of centralized fashion seems to be the most economically viable option.

Abstract

This work is part of a study to develop a multi-scale model of a Ca-looping (CaL) post-combustion process for CO_2 capture that relies on the carbonation reaction of CaO (s) and on the calcination of the resulting $CaCO_3$ (s) to generate a stream of highly concentrated CO_2 (g).

The literature lacks models that combine the modelling of both reactions with a cyclic structure that accounts for sorbent deactivation and allows for a realistic estimation in the case of incomplete reactions or different reaction media. Therefore, in this work two sub-models are combined to form this novel modelling approach for the simulation of complete carbonation-calcination cycles of the CaL process: The overlapping grain model for the carbonation reaction, and a proposed modified version (mRThPSD) of the rate equation theory for the pore size distribution (PSD) of calcined $CaCO_3$ (RThPSD) for the calcination.

The cyclic structure accounting for sorbent deactivation present in the proposed model was justified using data from fixed bed reactor experiments which highlights the relationship between loss of superficial area of CaO sorbents and loss of reactivity.

The model was implemented in gPROMS ModelBuilder® software and was validated with data from fixed bed reactor experiments for different CaL sorbents. One full CaL cycle was simulated successfully for dolomite, with the model estimating both reactions profiles and changes to the calcinated particle PSD with errors below 3%.

Keywords: Calcium-looping, CO_2 capture, modelling, carbonation, calcination.

1. Introduction

Calcium-looping (CaL) is a post-combustion technique for carbon capture and storage, where the carbonation of CaO (s) is used to capture CO_2 (g) and form $CaCO_3$ (s), the calcination of which yields a stream of highly concentrated CO_2 (g). CaL is a very

promising candidate for industrial post-combustion CO_2 capture due to the fact that widely available and low-cost natural limestone can be used as a sorbent.

Several carbonation and calcination reaction models can be found in literature, but one complete model that includes both reactions and a cyclic structure accounting for sorbent deactivation during reaction cycling does not exist. An existing model by Zhou et al. (2013) attempts a similar concept by combining the Overlapping Grain Model (OGM) by Liu and Dennis (2012) with an empirical equation that correlates sorbent deactivation with the cycle number. However, the lack of a detailed calcination model restricts it to the experimental conversion loss profile that originated the correlation, and respective temperatures and atmosphere compositions.

This work is part of a study aiming to techno-economically evaluate the implementation of a CaL CO_2 capture process in a Portuguese cement producer's industrial plant based on a multi-scale model of a CaL reactor. Hence there is an urgent need for a model of carbonation and calcination reaction cycles to be used for different reaction temperatures and reaction media, and thus different extents of reaction. By modeling the changes of the sorbent particle's porous structure during calcination using a modified version of the model originally proposed by Li et al. (2016), it is possible to estimate the changes on the sorbent particle's surface area during this reaction, which can be experimentally correlated to the loss of carbonation conversion. By estimating the post-calcination sorbent surface area, one can simulate the loss of carbonation conversion along multiple carbonation-calcination cycles for different extents of both reactions, as well as different temperatures and CO_2 partial pressures.

The objective of this work is to model the complete cycle: the carbonation reaction, the calcination reaction and the subsequent changes on the sorbent porous structure. The model was then implemented and validated in the gPROMS ModelBuilder® software. In this work, data from fixed bed reactor experiments are used to validate both sub-models. Experimental data are used to justify the relationship between the loss of superficial area of CaO sorbents and the loss of carbonation conversion, which allows to extend the simulation to multiple reaction cycles.

2. Model Development

To simulate a complete CaL cycle, two different models were combined as sub-models: the OGM by Liu and Dennis (2012) for the carbonation reaction, and a proposed modified version (mRThPSD) of the rate equation theory for the pore size distribution (PSD) of calcined $CaCO_3$ (RThPSD) by Li et al. (2016) for the calcination reaction.

2.1. Carbonation – Overlapping Grain Model - OGM

The OGM grain model considers that each CaO particle is composed of solid and randomly distributed spherical grains with different sizes. The formation of $CaCO_3$ during carbonation reaction is assumed to happen at the grain surface, causing the grain's volume to expand concentrically, increasing its radius, and shrinking the radius of the CaO core.

The known two main reaction regimes of carbonation are considered: a kinetic controlled profile for small reaction times and a diffusional regime for longer reaction times. By modelling the particle as an aggregate of dynamic grains with shells of $CaCO_3$ and allowing for particle porosity, two mechanisms can control the rate of reaction. The

particle porosity allows the inclusion of the diffusion of CO_2 in the porous network, and the layer of $CaCO_3$ around the grain adds an additional resistance to the transport of CO_2 between the pore and the front of reaction. In addition to the intrinsic reaction rate, these mechanisms contribute to more accurate carbonation simulations.

However, the OGM cannot estimate the maximum conversion for a given cycle and uses the deactivated fraction V_d as an input parameter, calculated as the difference between the theoretical maximum conversion and the experimentally observed conversion, that scales down the conversion estimated by the OGM to achieve the desired maximum conversion. The theoretical maximum conversion X_{Max} is a function of porosity of the initial CaO particle ε_0 and of the volumetric expansion coefficient between product and reactant α and can be calculated using Eq. (1).

$$X_{Max} = \frac{\varepsilon_0}{(1-\varepsilon_0)(\alpha-1)} \tag{1}$$

The OGM allows for CaO particles with non-reacting impurities by considering their molar volume in the calculation of α, as defined by Liu and Dennis (2012), thus this value varies between particles – e.g. 2.18 for pure CaO and 1.82 for dolomite. Due to this theorical maximum conversion, there is an experimental limitation that should be accounted for when attempting to fit the OGM to data from carbonation experiments.

Figure 1 displays a plot of X_{Max}, with values larger than 1 computed as 1; and shows that X_{Max} is increasingly sensitive to the value of ε_0 as α decreases. Generically, the porous characteristics of a sample of sorbent particles are not homogeneous, so it might occur that the porosity considered to be characteristic of a given sorbent sample of particles results in lower values of X_{Max} than the experimentally observed maximum conversion, which is of course impossible. As such, when fitting the model to the experimental results, and especially for the samples rich in CaO (e.g. commercial $CaCO_3$), one should verify that this is not the case. If this condition is not verified, the variability of the sorbent sample porosity should be known and used to increase the value of ε_0 in the OGM to ensure that X_{Max} will at least equal the experimental maximum conversion, and only then should the parameter estimation be performed. With the maximum possible ε_0 being 1, the difference in sensitivity means samples less pure in CaO (e.g. dolomite) have more possible ε_0 values for which $X_{Max} > 1$, and thus it is less likely that the condition is not verified. Nonetheless, it can still happen, since ultimately it is the variability of sample's porosity that is more indicative of the likeliness of the condition not being verified – more likely for batches with high variability and less likely if otherwise.

Figure 1 – Plot of the OGM's Theoretical Maximum Conversion (Eq. 1) for Initial Porosity between 0% and 60% and Alpha between 1.01 and 2.20.

2.2. Calcination – A rate equation theory for the PSD of calcined CaCO₃ - RThPSD
